Abstract □ Subjective spreadability, viscosity, and stickiness perceived with the fingers were predicted from fluid mechanics. The correlation coefficients of these predictions were 0.95 for spreadability, 0.95 for viscosity, and 0.90 for stickiness. The two important assumptions in the predictions were that spreadability and viscosity were perceived as shear stress and that stickiness was perceived as time. When the finger geometry was approximated as two parallel plates, the predictions only required rheological data for the Newtonian and non-Newtonian liquids used. While these liquids covered a range of 10^6 in apparent viscosity, large variations in other fluid properties such as density and surface tension were not studied.

Keyphrases □ Spreadability, subjective—predicted from fluid mechanics, equations □ Viscosity, subjective—predicted from fluid mechanics, equations □ Stickiness, subjective—predicted from fluid mechanics, equations □ Liquid texture—predicting subjective spreadability, viscosity, and stickiness

Previous papers on liquid texture presented interesting empirical relationships between subjective attributes and rheological parameters (1–7). For example, Stevens and Guirao (2) found for Newtonian liquids that:

$$\begin{pmatrix}\text{subjective}\\ \text{viscosity}\end{pmatrix} \propto \begin{pmatrix}\text{objective}\\ \text{viscosity}\end{pmatrix}^{0.44} \qquad \text{(Eq. 1)}$$

where the exponent of 0.44 is found empirically. As a second example, empirical curves were found (4, 6, 7) giving the conditions under which fluids of different rheological properties have the same subjective texture. Why these curves have their peculiar shape remained uncertain.

This paper predicts some attributes of liquid texture without introducing empiricism. It depends on two key assumptions: *(a)* that subjective stickiness is perceived as the time during which the finger is pulled away from the sticky surface, and *(b)* that subjective spreadability and viscosity are perceived as the shear stress on the fingers. That these assumptions are sensible is easily tested. For example, when water and honey are rubbed between the fingers, the

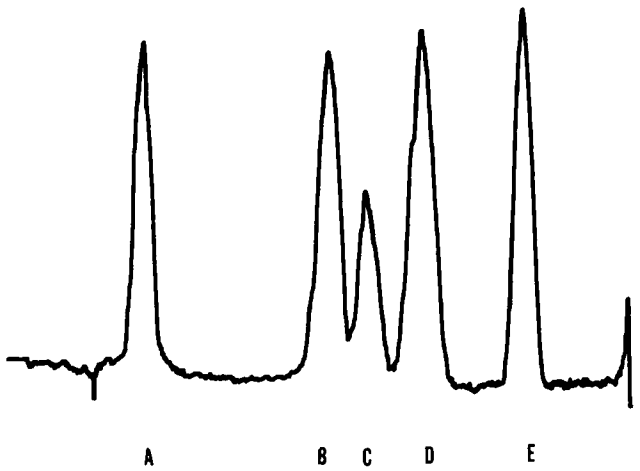

Figure 4—*Scan of derivatized sulfonamides separated on a silica gel TLC plate by development twice in diethyl ether (11 cm). Sulfonamides are: A, sulfathiazole; B, sulfadiazine; C, sulfamerazine; D, sulfadimidine; and E, sulfamethoxazole.*

sensitive and specific method utilizing these principles for the development of a tissue residue assay for sulfadiazine is described.

Fluorescamine was used previously as a means for detection of amino acids on TLC plates, but the quantitative aspects were not pursued (4). This report emphasizes the utility of this reagent as a useful analytical tool, especially for residue level determinations of sulfonamides. Undoubtedly, numerous extensions of this approach to include a broad range of drugs and pesticides can be made.

Predicting Subjective Spreadability, Viscosity, and Stickiness

MARIA L. DeMARTINE and E. L. CUSSLER [x]

Abstract □ Subjective spreadability, viscosity, and stickiness perceived with the fingers were predicted from fluid mechanics. The correlation coefficients of these predictions were 0.95 for spreadability, 0.95 for viscosity, and 0.90 for stickiness. The two important assumptions in the predictions were that spreadability and viscosity were perceived as shear stress and that stickiness was perceived as time. When the finger geometry was approximated as two parallel plates, the predictions only required rheological data for the Newtonian and non-Newtonian liquids used. While these liquids covered a range of 10^6 in apparent viscosity, large variations in other fluid properties such as density and surface tension were not studied.

Keyphrases □ Spreadability, subjective—predicted from fluid mechanics, equations □ Viscosity, subjective—predicted from fluid mechanics, equations □ Stickiness, subjective—predicted from fluid mechanics, equations □ Liquid texture—predicting subjective spreadability, viscosity, and stickiness

Previous papers on liquid texture presented interesting empirical relationships between subjective attributes and rheological parameters (1–7). For example, Stevens and Guirao (2) found for Newtonian liquids that:

$$\begin{pmatrix}\text{subjective}\\ \text{viscosity}\end{pmatrix} \propto \begin{pmatrix}\text{objective}\\ \text{viscosity}\end{pmatrix}^{0.44} \qquad \text{(Eq. 1)}$$

where the exponent of 0.44 is found empirically. As a second example, empirical curves were found (4, 6, 7) giving the conditions under which fluids of different rheological properties have the same subjective texture. Why these curves have their peculiar shape remained uncertain.

This paper predicts some attributes of liquid texture without introducing empiricism. It depends on two key assumptions: *(a)* that subjective stickiness is perceived as the time during which the finger is pulled away from the sticky surface, and *(b)* that subjective spreadability and viscosity are perceived as the shear stress on the fingers. That these assumptions are sensible is easily tested. For example, when water and honey are rubbed between the fingers, the

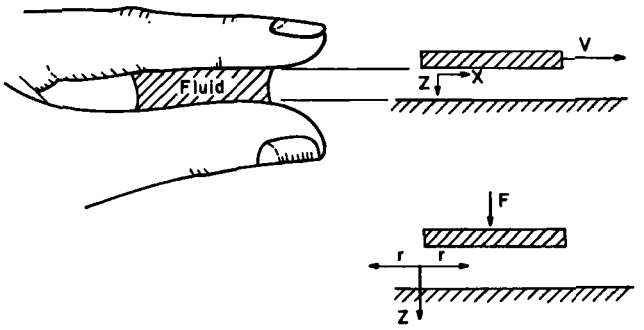

Figure 1—*Schematic representation of finger geometry as two parallel plates.*

fingers move in an oscillating motion with a constant period and amplitude; the finger velocity varies little with changes in objective liquid viscosity. Since the subjective viscosities of honey and water are very different, the subjective viscosity must be perceived not as velocity but as another quantity such as shear stress. This type of observation will be shown to lead to the successful prediction of liquid texture.

THEORETICAL

Finger Geometry and Fluid Rheology—There were three basic steps in developing predictions of spreadability, viscosity, and stickiness:

1. The finger geometry and fluid rheology were specified.
2. Equations for the thickness of the fluid film on the fingers as a function of time were developed.
3. How this fluid thickness leads to equations for predicting spreadability, viscosity, and stickiness was demonstrated.

In the first step, the actual geometry of the fingers was approximated by two parallel plates (Fig. 1). This approximation is reasonable only when the thickness of the sample is small relative to the radius of the finger. As suggested in Fig. 1, the shear force between the fingers is most easily found using Cartesian coordinates with the origin on one moving finger, but the thickness is most easily calculated in terms of cylindrical coordinates with the origin at the center of the film.

Just as parallel plates were used to approximate the finger geometry, the empirical power law model was assumed to approximate the fluid rheology (8):

$$\tau_{zx} = -m\left(\frac{\partial v_x}{\partial z}\right)^n \qquad \text{(Eq. 2)}$$

where τ_{zx} is the shear stress on a plane normal to the z direction and caused by motion in the x direction, v_x is the fluid velocity in the x direction, and m and n are rheological constants of this model. For a Newtonian fluid, n is unity and m is the viscosity; for the non-Newtonian fluids used in this work, n was always less than 1. The use of this equation required that the coordinate system be defined so that $(\partial v_x/\partial z)$ was always positive and τ_{zx} was not imaginary. Therefore, the coordinate system had to be redefined every time the velocity was reversed.

Thickness of Fluid Film—The second basic step in developing the desired predictions was to calculate fluid thickness for the approximate geometry and rheology. This problem was solved for Newtonian fluids by Stefan (9), yielding results frequently used in lubrication theory (10). For the power law fluids considered here, the equation of motion in cylindrical coordinates is:

$$\frac{\partial p}{\partial r} = -\frac{\partial \tau_{zr}}{\partial z} = m\frac{\partial}{\partial z}\left(\frac{\partial v_r}{\partial z}\right)^n \qquad \text{(Eq. 3)}$$

where p is the pressure and τ_{zr} is the stress on a plane normal to the z direction caused by motion in the r direction. The first boundary condition used with Eq. 3 was that the shear stress is zero in the exact center of the film; *i.e.*, that $\partial v_r/\partial z = 0$ when $z = 0$. The second boundary condition was that the velocity at the plates is zero; *i.e.*, that $v_r = 0$ when $z = \pm h/2$, where h is the film thickness between the fingers. Equation 3 was integrated using these conditions:

$$v_r = \left[\frac{1}{m}\frac{\partial p}{\partial r}\right]^{1/n}\frac{n}{n+1}\left[z^{(1/n)+1} - \left(\frac{h}{2}\right)^{(1/n)+1}\right] \qquad \text{(Eq. 4)}$$

The volumetric flow per unit arc, Q, was defined across a fluid element shaped like a piece of pie:

$$Q = \frac{2\int_0^{h/2}\int_0^{2\pi} v_r r\, d\theta\, dz}{\int_0^{2\pi} r\, d\theta} = 2\int_0^{h/2} v_r\, dz \qquad \text{(Eq. 5)}$$

Therefore, from Eqs. 4 and 5, Q was:

$$Q = 2\left[\frac{1}{m}\frac{\partial p}{\partial r}\right]^{1/n}\frac{n}{n+1}\int_0^{h/2}\left[z^{(1/n)+1} - \left(\frac{h}{2}\right)^{(1/n)+1}\right]dz \qquad \text{(Eq. 6)}$$

Then Q was related to the decrease of the fluid thickness by means of a mass balance on the same pie-shaped element already used:

$$-\frac{dh}{dt} = \frac{1}{r}\frac{\partial}{\partial r}(Qr) \qquad \text{(Eq. 7)}$$

Equations 6 and 7 were next combined and integrated using two more boundary conditions. The first of these was that the pressure is always finite or, in other words, that $p \neq \infty$ when $r = 0$. The second condition was that the pressure must be the atmospheric value p_0 at the edge of the fingers; *i.e.*, $p = p_0$ at $z = \pm h/2$ and $r = R$, where R is the effective radius of the fingers. The result of this integration was:

$$p = p_0 + \frac{m}{n+1}\left(\frac{2n+1}{4n}\right)^n\left(\frac{2}{h}\right)^{2n+1}\left(\frac{dh}{dt}\right)^n[R^{n+1} - r^{n+1}] \qquad \text{(Eq. 8)}$$

In this integration, dh/dt was assumed to be approximately constant. This pseudo-steady-state approximation took advantage of the fact that steady-state pressure gradients are approached rapidly.

Before Eq. 8 was finally integrated, it was rewritten in terms of the total normal force, F_0, acting on the plates:

$$F_0 + \pi R^2 p_0 = 2\pi\int_0^R pr\, dr \qquad \text{(Eq. 9)}$$

Combination of Eqs. 8 and 9 and integration over r yielded:

$$\frac{F_0}{R^{n+3}}\left(\frac{n+3}{2\pi m}\right)\left(\frac{n}{2n+1}\right)^n = \left(\frac{1}{h}\right)^{2n+1}\left(\frac{dh}{dt}\right)^n \qquad \text{(Eq. 10)}$$

a result similar to that of Parlato (11). Since the total normal force by the fingers was assumed a constant, the nth root of this equation could be integrated over time:

$$h = \frac{1}{\left[\frac{1}{h_0^{(n+1)/n}} + \left(\frac{F_0}{R^{n+3}}\frac{n+3}{2\pi m}\right)^{1/n}\frac{n+1}{2n+1}t\right]^{n/(n+1)}} \qquad \text{(Eq. 11)}$$

where h_0 is the initial film thickness at zero time. This equation shows how the thickness of the fluid film varies with time, finger geometry, and fluid rheology. It formed the basis for the predictions of subjective properties given in the next section.

Subjective Predictions—*Spreadability*—The third step in this development was the prediction of the subjective attributes. First, spreadability was assumed to be proportional to the reciprocal of the shear stress:

$$\begin{pmatrix}\text{subjective}\\ \text{spreadability}\end{pmatrix} \propto \frac{1}{\tau_{\text{spread}}} \qquad \text{(Eq. 12)}$$

For a thin film, combination of Eqs. 2 and 12 gave:

$$\begin{pmatrix}\text{subjective}\\ \text{spreadability}\end{pmatrix} \propto \frac{1}{m}\left(\frac{h}{V_{\text{spread}}}\right)^n \qquad \text{(Eq. 13)}$$

where V_{spread} is the steady velocity of the finger used in assessing

spreadability. This result was combined with Eq. 11 to give:

$$\begin{pmatrix}\text{subjective}\\ \text{spreadability}\end{pmatrix} \propto \frac{1}{mV_{\text{spread}}^{n}}\left[\frac{1}{h_0^{(n+1)/n}} + \left(\frac{F_0}{R^{(n+3)}}\frac{n+3}{2\pi m}\right)^{1/n} \times \frac{n+1}{2n+1}t_{\text{spread}}\right]^{-n^2/(n+1)} \quad \text{(Eq. 14)}$$

where t_{spread} is the average assessment time for spreading. Since all quantities on the right-hand side of this equation were measured by independent experiments, Eq. 14 provided a means of calculating spreadability. A plot of experimentally measured subjective spreadability *versus* the right-hand side of Eq. 14 should be linear.

Viscosity—Viscosity was assumed to be perceived as the shear stress, τ_{visco}, exerted on the finger:

$$\begin{pmatrix}\text{subjective}\\ \text{viscosity}\end{pmatrix} \propto \tau_{\text{visco}} = m\left(\frac{V_{\text{visco}}}{h}\right)^{n} \quad \text{(Eq. 15)}$$

where V_{visco} is the average finger velocity used on the thin fluid film. In fact, viscosity is assessed by rubbing the fingers with an oscillating motion, but the exact analysis of this motion is very elaborate (12). Combination of Eqs. 11 and 15 gave:

$$\begin{pmatrix}\text{subjective}\\ \text{viscosity}\end{pmatrix} \propto m(V_{\text{visco}})^{n}\left[\frac{1}{h_0^{(n+1)/n}} + \left(\frac{F_0}{R^{(n+3)}}\frac{n+3}{2\pi m}\right)^{1/n} \times \frac{n+1}{2n+1}t_{\text{visco}}\right]^{n^2/(n+1)} \quad \text{(Eq. 16)}$$

where t_{visco} is the assessment time for viscosity. All quantities on the right-hand side of Eq. 16 were determined experimentally. As a result, a plot of experimentally determined subjective viscosity *versus* the right-hand side of Eq. 16 should be linear.

For two special cases, the subjective viscosity could be predicted in simpler ways. First, for Newtonian fluids for which the initial thickness was large, $n = 1$, $m = \mu$, and $h \ll h_0$. Under these conditions, Eq. 16 is reduced to:

$$\begin{pmatrix}\text{subjective}\\ \text{viscosity}\end{pmatrix} \propto \mu^{1/2}\left[V_{\text{visco}}\left(\frac{4F_0 t_{\text{visco}}}{3\pi R^4}\right)^{1/2}\right] \quad \text{(Eq. 17)}$$

All quantities in brackets are characteristic of the assessment but experimentally independent of the fluid being judged. Thus, if subjective viscosity was, in fact, perceived as shear stress, a plot of the logarithm of subjective spreadability *versus* the logarithm of objective viscosity should have a slope of one-half.

The second special case for predicting subjective viscosity occurred when the film was mechanically prevented from thinning by means of a small sled holding the finger a constant distance from the surface (13). In this case, Eq. 15 assumed a very simple form for Newtonian fluids:

$$\begin{pmatrix}\text{subjective}\\ \text{viscosity}\end{pmatrix} \propto \tau_{\text{visco}} = \mu\left[\frac{V_{\text{visco}}}{h}\right] \quad \text{(Eq. 18)}$$

where h is now a constant of the small sled. The quantity in brackets is again characteristic of the assessment but independent of the fluid being judged. If subjective viscosity was truly perceived as shear stress, a plot of the logarithm of subjective viscosity assessed at constant film thickness *versus* the logarithm of objective viscosity should have a slope of unity.

Stickiness—Unlike spreadability and viscosity, which were assessed with a shearing motion, stickiness was assessed by a motion normal to the surface. First the finger was pressed against the sample being judged, and then the finger was pulled away. While the fluid mechanics in this situation were less well defined than for the previous two cases, the thickness of the film during this assessment can be approximately calculated from Eq. 11.

Stickiness was assumed to be perceived as the time during which the finger is pulled away from the sticky surface. This time varied inversely with the average velocity normal to the surface of the moving finger, dh/dt:

$$\begin{pmatrix}\text{predicted}\\ \text{stickiness}\end{pmatrix} \propto \frac{H}{dh/dt} \quad \text{(Eq. 19)}$$

where H is the distance at which the finger separates from the fluid. In general, H was a function of the fluid being tested. However, because the surface tension had approximately the same value for all of the fluids used, H was approximately a constant here.

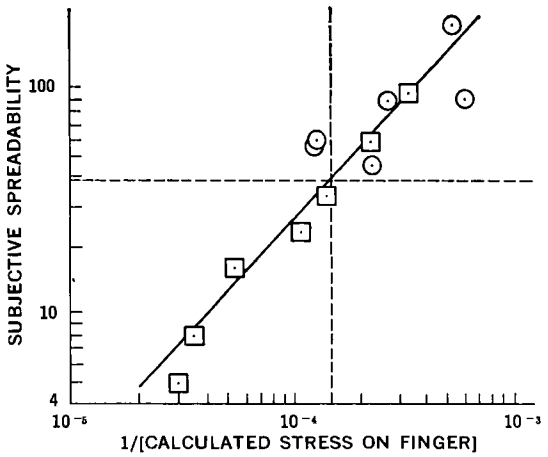

Figure 2—*Subjective spreadability* versus *[shear stress]*$^{-1}$. *The best line through the data has a slope of 1.05 ± 0.05, compared with a predicted value of 1.00. The circles and squares are Newtonian and non-Newtonian fluids, respectively.*

The velocity dh/dt can be calculated from Eq. 11 and combined with Eq. 19 to yield:

$$\begin{pmatrix}\text{subjective}\\ \text{stickiness}\end{pmatrix} \propto \frac{H(2n+1)}{n} \times \frac{\left[\frac{1}{h_1^{(n+1)/n}} - \frac{n+1}{2n+1}\left(\frac{F_1}{R^{n+3}}\frac{n+3}{2\pi m}\right)^{1/n} t_{\text{stick}}\right]^{(1+2n)/(1+n)}}{\left(\frac{F_3}{R^{n+3}}\frac{n+3}{2\pi m}\right)^{1/n}} \quad \text{(Eq. 20)}$$

where h_1 is the minimum film thickness after squeezing the film, F_1 is the normal force developed in pulling the finger upward, and t_{stick} is an average reference time. All quantities on the right-hand side of Eq. 20 were determined experimentally except for h_1, which was calculated from Eq. 11. Thus, a plot of experimentally measured subjective stickiness *versus* the right-hand side of Eq. 20 should be a straight line.

EXPERIMENTAL

Objective Measurements—The Newtonian fluids used in this work were silicone oils[1] ranging in viscosity from 2.6 to 85,000 cps. The non-Newtonian fluids included aqueous solutions of hydroxypropyl methylcellulose and aqueous solutions of polyacrylamide. Three grades of hydroxypropyl methylcellulose[2] were used as 2 wt. % solutions in water. The polyacrylamide solutions were prepared by polymerization of 2, 4, and 8% monomer in water. Polymerization was initiated with persulfate–bisulfite and continued at 60° for about 1 hr. Viscosities of the Newtonian fluids were measured with capillary viscometers[3], calibrated with Newtonian viscosity standards[4]. Rheological parameters of the non-Newtonian fluids were measured with a cone-and-plate viscometer[5].

In addition to these rheological properties, the predictions of spreadability, viscosity, and stickiness depended on various characteristics of the finger and its motion. Three of these characteristics were similar for all three subjective attributes: the average radius of the finger, R; the force used in thinning the film, F_0; and the initial film thickness, h_0. The average radius of the finger for 20 people was 0.75 cm, consistent with the measurements of Schaeffer and Chakravarti (14) who used a plate of 0.73 cm as a model of the second fingertip in the design of a commercial instru-

[a] Units used here are as follows: m, dynes sec^n cm^{-2}; h_0, cm; V, cm sec^{-1}; and calculated spreadability, 10^{-4} cm^2 dyne^{-1}. Other quantities are dimensionless. [b] These calculations involve three additional experimentally measured quantities: the average normal force, F_0, of 89,000 dynes; the average finger radius, R, of 0.75 cm; and the average assessment time, t_{spread}, of 10 sec. [c] Not included in the regression analysis.

ment. The normal force for thinning the film was found by placing different samples on the pan of a magnetic balance and then by touching the fluids in an imitation of the subjective assessments. Each of 20 people used the same force for all fluids, independent of the fluid's viscosity. This force was about 89,000 ± 5000 dynes.

The initial thickness of the sample, h_0, was measured directly in the case of spreadability as the mass of fluid adhering to the finger divided by the finger area. These values did vary with viscosity and are reported in the *Results* section. The same values were also used in calculations of viscosity and stickiness but had little effect on the calculations. Indeed, assuming that h_0 always equaled 0.1 cm gave equivalent results in these two cases.

The basic equations for predicting spreadability, viscosity, and stickiness also contained characteristics of finger motion, which were specific for the attribute being studied. For spreadability, these characteristics were the velocity of the finger, V_{spread}, and the time of spreading, t_{spread}, both of which were measured with a stopwatch during the subjective experiments. The velocity varied with viscosity and is reported below, but the time of spreading was a constant for each subject and had an average value of 10 sec. For viscosity, the specific characteristics were the average velocity of finger motion, V_{visco}, and the time of assessment, t_{visco}. These quantities, also measured during the subjective experiments, were both constant, independent of viscosity. The velocity had a period of 1.0 ± 0.2 sec and an amplitude of 0.5 ± 0.1 cm. The time for the assessment of viscosity was found to be 5 ± 1 sec.

For stickiness, the specific characteristics necessary for the calculations were the force used in pulling up the finger, the time of squeezing the fluid, and the time of pulling the finger. The pulling force was measured with a balance (14). The time for squeezing, measured with a balance and a stopwatch during some of the subjective experiments, was a constant 3.0 ± 0.2 sec. The time of pulling was measured as 0.1 sec, but this measurement was approximate.

Subjective Measurements—For each textural characteristic, panels of between 15 and 24 members of both sexes, ranging in age from 20 to 50 years and not trained prior to the present work, were asked in written instructions (14) to assess the different fluid samples relative to the first sample. These samples were presented in random order on a plastic plate at room temperature. For spreadability, observers spread the samples along the plate with their index finger; for viscosity, observers often preferred to rub the samples between their fingers and were permitted to do so; for stickiness, observers touched the sample and then pulled their fingers away.

Whenever necessary, observers were allowed to go back to the standard for comparison. A judgment of zero was not accepted for any property; in that case, the concept of ratio scaling was clarified, and use of fractional numbers (1/10, 1/100, *etc.*) was encouraged. The subjective data were analyzed with linear regression analysis after a logarithmic transformation (15).

RESULTS

Spreadability—The agreement of the experimental and predicted values of the subjective assessments is clearest if the three attributes of spreadability, viscosity, and stickiness are discussed sequentially. The raw data for spreadability are shown in Table I. The first three columns give the fluid and its rheological parameters in terms of the power law model in Eq. 2. The next two columns give the initial thickness, h_0, and the spreading velocity, V_{spread}, both measured during the subjective assessments. The sixth column gives the reciprocal of the stress calculated from Eq. 14, using experimental quantities shown in the table. The final column gives the subjective spreadability measured by ratio scaling. The value for water deviates considerably from the trend shown by the other fluids; it probably lies outside the range of perception and was discarded when estimating the regression line.

The theory for spreadability predicts that a plot of the logarithm of subjective spreadability *versus* the logarithm of the right-hand side of Eq. 14 should be a straight line of slope unity. This prediction is in excellent agreement with the experimental slope of 1.05 ± 0.05 (Fig. 2). Phrased in other terms, the correlation coefficient between subjective spreadability and the reciprocal of the shear stress is 0.95. This correlation is impressive.

Equation 14 also predicts that two Newtonian fluids of different viscosities will never have the same subjective spreadability. In this case, n is always unity, so different values of $m = \mu$ imply dif-

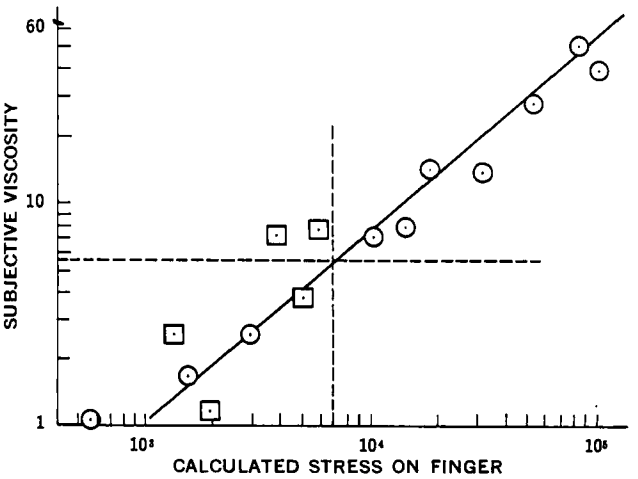

Figure 3—*Subjective viscosity* versus *shear stress. The best line through the data has a slope of 0.86 ● 0.02, compared with a predicted value of 1.00. The circles and squares are Newtonian and non-Newtonian fluids, respectively.*

[a] Units used here are as follows: m, dynes sec^n cm^{-2}; predicted viscosities, 10^{-3} dynes cm^{-2}; and h_0, cm. Other quantities are dimensionless. [b] These predictions use four additional experimentally measured quantities: the average finger radius, R, of 0.75 cm; the average normal force, F_0, of 89,000 dynes; the average velocity, V_{visco}, of 3.1 cm sec^{-1}; and the average assessment time of 5 sec.

ferent spreadabilities. On the other hand, groups of non-Newtonian fluids can have the same spreadability when m and n differ. The only requirement is that the combination of m and n given by Eq. 14 results in the same predicted spreadability.

The results in Table I and Fig. 2 support this prediction. For example, silicone oil (936 cps) and silicone oil (1770 cps) are perceived subjectively as 33.0 and 23.0, respectively. However, the data confirm that a Newtonian fluid can show the same spreadability as a variety of non-Newtonian fluids with very different values of m and n. For example, silicone oil (70 cps), polyacrylamide (8%), and hydroxypropyl methylcellulose (8000 cps, 2%) all have about the same spreadability (58.0, 55.0, and 58.0, respectively), even though their rheological parameters are very different.

Viscosity—The data for subjective and predicted viscosity are shown in Table II. The first three columns give the rheological properties of the fluids in terms of Eq. 2. The initial film thickness, h_0, in the fourth column is not critical in the calculations; changes in these values by a factor of 2 have little effect on the results. The fifth column gives the predicted viscosity calculated from Eq. 16, using the values given in this table. The final column reports the subjective viscosity.

The theory predicts that a plot of the logarithm of subjective viscosity *versus* the logarithm of the right-hand side of Eq. 16 should be linear with a slope of 1. This predicted slope is in good agreement with the experimental value of 0.86 ± 0.02 (Fig. 3). The correlation coefficient between subjective viscosity and the calculated stress on the finger is 0.95. The agreement is not quite as close as that found for spreadability. However, in the derivation of the theory for viscosity, the major assumption was made that the periodic motion of the fingers can be approximated as a steady motion between parallel plates. In view of this approximation, the predictions of the theory are very good.

Other theoretical predictions for Newtonian fluids are tested in Fig. 4. The circles in this plot represent the logarithm of subjective viscosity plotted *versus* the logarithm of objective viscosity of the Newtonian fluid. The slope of the line drawn through these data is 0.40 ± 0.01, in good agreement both with other experimental studies of subjective viscosity (3) and with the value of 0.50 predicted by Eq. 17. Since the prediction requires only a measurement of Newtonian viscosity, additional properties like finger area and assessment time are constant and need not be measured experimentally.

These results and the others in this paper were unaffected by the temperature of the samples. For example, subjective Newtonian viscosity evaluated at skin temperature of 32° leads to an exponent of 0.41. This insensitivity is a consequence of ratio scaling. While viscosity changes significantly with temperature, the changes are similar percentages for all fluids used. Thus, the relative subjective viscosity measured by ratio scaling does not depend strongly on temperature.

The triangles in Fig. 4 represent the logarithm of subjective viscosity assessed at constant film thickness and plotted *versus* the

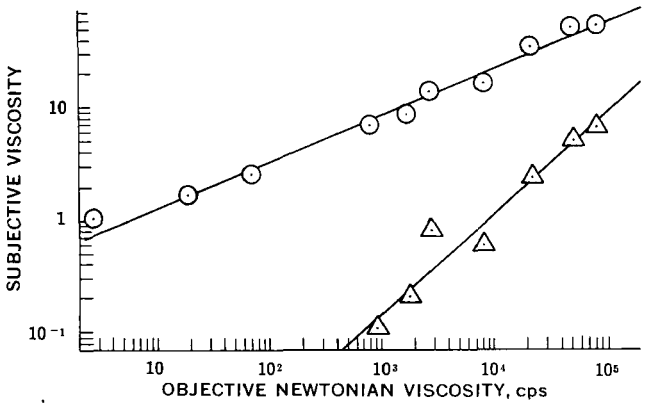

Figure 4—*Subjective viscosity* versus *objective Newtonian viscosity. The circles are values obtained when the thickness of fluid on the fingers varies during the assessments. The best line through these data has a slope of 0.40 ± 0.01, compared with 0.50 predicted by Eq. 17. The triangles represent assessments at constant fluid thickness; the best line through these values has a slope of 0.89 ± 0.06, compared with 1.00 predicted by Eq. 18.*

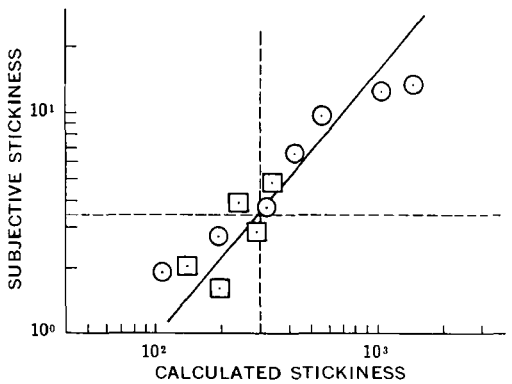

Figure 5—*Subjective stickiness* versus *stickiness calculated from Eq. 20. The best line through the data has a slope of 1.12 ± 0.08, compared with a predicted value of 1.00. The circles and squares are Newtonian and non-Newtonian fluids, respectively.*

Table III—Stickiness for Six Newtonian and Six Non-Newtonian Fluids[a]

Fluid	m	n	F_1	Calculated h_1[b]	Stickiness from Eq. 20[c]	Subjective Stickiness
Silicone oil, 936 cps	9.36	1.0	1.3	0.94	1.0_7	1.8_7
Silicone oil, 1770 cps	17.70	1.0	1.7	0.68	1.9_2	2.7
Silicone oil, 2805 cps	28.05	1.0	1.9	0.86	3.2	3.8
Silicone oil, 8450 cps	84.50	1.0	2.1	1.09	4.2	6.6
Silicone oil, 23,300 cps	233.0	1.0	2.7	1.29	5.7	9.8
Silicone oil, 51,500 cps	515.0	1.0	2.8	1.35	10.7	12.5
Silicone oil, 85,000 cps	850.0	1.0	3.4	1.35	15.0	13.2
Polyacrylamide, 2%	0.13	0.93	1.2	0.15	0.85	0.2_7
Polyacrylamide, 5%	28.	0.52	1.6	0.42	1.3_9	2.0
Polyacrylamide, 8%	390.	0.47	1.4	1.30	3.4	4.7
Hydroxypropyl methylcellulose, 400 cps, 1.5%	3.4	0.79	1.7	0.30	1.9_5	1.62

Hydroxypropyl methylcellulose, 15,000 cps, 2%	630.	0.32	2.1	1.30	2.4	3.9

[a] Units used here are as follows: m, dynes sec^n cm^{-2}; pulling force, F_2, 10^5 dynes; calculated h_1, 10^{-2} cm; and calculated stickiness, 10^2 sec cm^{-1}. Other quantities are dimensionless. [b] These predictions use four additional experimentally determined quantities: the average finger radius, R, of 0.75 cm; the average force thinning the film, F_0, of 89,000 dynes; the initial film thickness, h_0, given in Tables I and II; and the average time thinning the film of 3 sec. [c] These calculations use one additional experimentally estimated quantity: the average time for pulling up the finger, t_{stick}, of 0.1 sec.

logarithm of objective viscosity. These data were obtained by attaching to the finger a small sled with 0.06-cm runners, so that the finger touched the fluid but did not thin the fluid film. The best line through these data has a slope of 0.89 ± 0.06, in good agreement with the value of 1.00 predicted from Eq. 18. This slope is also consistent with earlier experiments showing that perceived force varies linearly with objective applied force (1). Both this result and the previous one illustrate how fluid mechanics, exemplified here by film thinning, influences the subjective perceptions.

Stickiness—The data for subjective and predicted stickiness are shown in Table III. The first three columns again give the fluid and its rheological properties. The final column gives the subjective stickiness as determined by ratio scaling.

The remaining data are connected with the calculations, which are more involved in this case than in spreadability and viscosity. The calculation has two main steps. First, one must find the film thickness, h_1, at which the film is thinnest. Because h_1 was not accurately measured experimentally, it must be calculated from Eq. 11. The key variable in this calculation is the time that the film is thinned by squeezing, which was found by experiment to be 3 sec. The second step is the calculation in Eq. 20, which depends on the minimum film thickness, h_1, calculated in the first step; the pulling force, F_1, measured experimentally; and the average time, t_{stick}, for pulling the finger upward. This time was estimated as 0.1 sec, but this estimation is not definitive.

The theory culminating in Eq. 20 predicts that a plot of the logarithm of subjective stickiness *versus* the logarithm of the right-hand side of Eq. 20 should have a slope of 1. This predicted slope is in good agreement with the experimentally determined slope of 1.12 ± 0.08 (Fig. 5). However, the agreement is not as good as that found in the two previous cases: the correlation coefficient between subjective and predicted stickiness is only 0.90. This poorer agreement is probably a consequence of the much more involved calculations.

Conclusions and Limitations—The picture emerging from this study has a beguiling symmetry. For attributes assessed by a shearing motion, such as spreadability and viscosity, the perception is of shear force with (approximately) constant velocity. For attributes assessed by a normal motion, like stickiness, the perception is proportional to time or velocity with (approximately) constant force. Calculations based on this picture give correlation coefficients of 0.90 or better between subjective and predicted assessments. These calculations are most definitive for Newtonian liquids, where no additional properties need be measured. They are also successful for spreadability, where the additional parameters involved are easily measured. The calculations are least successful for stickiness, where they are most complex.

However, the results given in this paper are limited by the fact that only the apparent viscosity of the fluids varies widely. This single variable is doubtless partially responsible for the well-defined conclusions that were reached. The effect of large changes in other physical properties may not be minor. For example, three physical properties that would alter the results are fluid elasticity, fluid finger wetting, and fluid thermal conductivity. The first of these properties, which requires a more complex rheological model than that in Eq. 3, is probably more important for subjective "slipperiness" than for the three attributes involved here (15). When studying elastic fluids, observers using ratio scaling frequently gave a value of zero to any nonelastic fluid, regardless of its viscosity.

Wetting between the fluid and the finger will strongly affect the total amount of fluid adhering to the finger and will change h_0 used in calculating both spreadability and viscosity. It also will affect H, the distance at which the finger separates from the fluid in the assessment of stickiness. Changes in fluid thermal conductivity are probably most important in the colloidal systems used in cosmetics, where the oil-in-water emulsion changes rapidly into a water-in-oil emulsion. This emulsion "break" causes a sudden 300% change in the heat lost by the finger. These effects should be much easier to predict than those of elasticity.

Because of these limitations, the results in this paper are a first step rather than an exhaustive picture. They allow the *a priori* prediction of some empirical exponents in Stevens' law. They give a firmer basis to the universal curves of equivalent texture (5–7). They suggest a rationale for ingredient substitutions and may aid in planning test panels, but they are certainly no substitute for these panels. Nevertheless, the results provide an intriguing indication that consumer reactions may be strongly influenced by physical restraints such as fluid mechanics.

NOMENCLATURE

F_0 = force used in thinning the film
F_1 = normal force developed in pulling the finger upward during assessment of stickness
h = thickness of the fluid sample at any time t
h_0 = initial thickness of the fluid sample
h_1 = minimum film thickness after squeezing during assessment of stickness
H = distance at which the finger separates from the fluid in assessment of stickiness
m,n = consistency and flow index in the power law model for non-Newtonian fluids
p = pressure
p_0 = atmospheric pressure
Q = volumetric flow per unit arc
R = radius of the finger
t = time
t_{spread}, t_{visco}, t_{stick} = times of assessments of spreadability, viscosity, and stickiness, respectively
v_x = velocity of flow in the x direction (Cartesian coordinates)

v_r = velocity of flow in the r direction (cylindrical coordinates)
V_{spread}, V_{visco} = average velocity with which the finger moves in assessment of spreadability and viscosity
μ = viscosity of Newtonian fluids
τ_{zx}, τ_{zr} = components of shear stress
τ_{spread}, τ_{visco} = stress exerted by the fluid on the finger during assessment of spreadability and apparent viscosity, respectively

Electronic Spectra and Electronic Structures of Some Antimicrobials Derived from Proflavine

STEPHEN G. SCHULMAN [x], DATTA V. NAIK, ANTHONY C. CAPOMACCHIA, and TIMOTHY ROY

Abstract □ The shifts in the absorption and fluorescence spectra of 3-aminoacridine, proflavine, acridine orange, and acridine yellow were employed to show that the singly charged cations, the predominant species at biological pH, exist in the ground state in the amino form. In the lowest excited singlet state, however, the monocations of the diaminoacridines have the imino structure, a conclusion supported by the relative ground- and excited-state pKa values of the reactions of the monocation with H^+. The ground-state amino structure has its positive charge concentrated at the heterocyclic nitrogen atom, a fact that is of primary importance in determining the geometry of binding to DNA.

Keyphrases □ 3,6-Diaminoacridine derivatives—electronic spectra and electronic structures □ Proflavine derivatives—electronic spectra and electronic structures □ Antimicrobials—3,6-diaminoacridine derivatives, electronic spectra and electronic structures □ Electronic spectra and structure—diaminoacridine dyes, dependence upon solvent properties and state of protonation □ DNA—interaction with diaminoacridine dyes, electronic spectra and structure of dyes

Several dyes (acridine orange and acridine yellow) derived from proflavine (3,6-diaminoacridine) are employed as bacteriostatic agents, biological stains, and spectroscopic probes of the interactions of nucleic acids with small molecules (1). These substances are well known for their mutagenic effects arising from their interactions with nucleic acids (2). The singly charged cations, which are the prevalent prototropic species, at biological pH derived from proflavine (3,6-diaminoacridine), acridine orange [3,6-bis(dimethylamino)acridine], and acridine yellow (2,7-dimethyl-3,6-diaminoacridine) have been employed extensively in binding studies with nucleic acids (3). These dyes exhibit electronic absorption and fluorescence spectral changes upon binding to DNA.

The interactions of the diaminoacridines with DNA are generally believed to entail electrostatic association of the site of positive charge, in the singly protonated dye molecule, with a negatively charged phosphate ester linkage of the nucleic acid "backbone." In the case of proflavine, it has been shown that the remainder of the dye molecule is inserted between two base pairs of the double helix (or between individual bases in single-stranded nucleic acids), oriented toward the center of the helix and stabilized by hydrophobic interaction with the helix (2). There is, however, some disagreement as to whether the positive charge of the singly protonated diaminoacridine cations is predominately concentrated at the heterocyclic nitrogen atom of the acridine ring (the site of protonation) or at one of the amino nitrogen atoms. This argument arises from the possibility of writing the valence bond structures of the singly protonated cations of proflavine in either of two ways (I and II).

v_r = velocity of flow in the r direction (cylindrical coordinates)
V_{spread}, V_{visco} = average velocity with which the finger moves in assessment of spreadability and viscosity
μ = viscosity of Newtonian fluids
τ_{zx}, τ_{zr} = components of shear stress
τ_{spread}, τ_{visco} = stress exerted by the fluid on the finger during assessment of spreadability and apparent viscosity, respectively

Electronic Spectra and Electronic Structures of Some Antimicrobials Derived from Proflavine

STEPHEN G. SCHULMAN [x], DATTA V. NAIK, ANTHONY C. CAPOMACCHIA, and TIMOTHY ROY

Abstract □ The shifts in the absorption and fluorescence spectra of 3-aminoacridine, proflavine, acridine orange, and acridine yellow were employed to show that the singly charged cations, the predominant species at biological pH, exist in the ground state in the amino form. In the lowest excited singlet state, however, the monocations of the diaminoacridines have the imino structure, a conclusion supported by the relative ground- and excited-state pKa values of the reactions of the monocation with H^+. The ground-state amino structure has its positive charge concentrated at the heterocyclic nitrogen atom, a fact that is of primary importance in determining the geometry of binding to DNA.

Keyphrases □ 3,6-Diaminoacridine derivatives—electronic spectra and electronic structures □ Proflavine derivatives—electronic spectra and electronic structures □ Antimicrobials—3,6-diaminoacridine derivatives, electronic spectra and electronic structures □ Electronic spectra and structure—diaminoacridine dyes, dependence upon solvent properties and state of protonation □ DNA—interaction with diaminoacridine dyes, electronic spectra and structure of dyes

Several dyes (acridine orange and acridine yellow) derived from proflavine (3,6-diaminoacridine) are employed as bacteriostatic agents, biological stains, and spectroscopic probes of the interactions of nucleic acids with small molecules (1). These substances are well known for their mutagenic effects arising from their interactions with nucleic acids (2). The singly charged cations, which are the prevalent prototropic species, at biological pH derived from proflavine (3,6-diaminoacridine), acridine orange [3,6-bis(dimethylamino)acridine], and acridine yellow (2,7-dimethyl-3,6-diaminoacridine) have been employed extensively in binding studies with nucleic acids (3). These dyes exhibit electronic absorption and fluorescence spectral changes upon binding to DNA.

The interactions of the diaminoacridines with DNA are generally believed to entail electrostatic association of the site of positive charge, in the singly protonated dye molecule, with a negatively charged phosphate ester linkage of the nucleic acid "backbone." In the case of proflavine, it has been shown that the remainder of the dye molecule is inserted between two base pairs of the double helix (or between individual bases in single-stranded nucleic acids), oriented toward the center of the helix and stabilized by hydrophobic interaction with the helix (2). There is, however, some disagreement as to whether the positive charge of the singly protonated diaminoacridine cations is predominately concentrated at the heterocyclic nitrogen atom of the acridine ring (the site of protonation) or at one of the amino nitrogen atoms. This argument arises from the possibility of writing the valence bond structures of the singly protonated cations of proflavine in either of two ways (I and II).

[a] T = triply charged cation, D = dication, M = monocation, and N = neutral species.

Consequently, two models for the geometry of the intercalative binding of proflavine-like dyes have been proposed: one with the heterocyclic nitrogen atom directed toward a phosphate ester group, leaving both exocyclic amino groups outside the helix, and one with an exocyclic nitrogen atom directed toward a phosphate ester group, having the other exocyclic group directed very nearly toward the center of the helix (3, 4). Löber (5) noted the similarity between the absorption and fluorescence spectra of singly protonated acridine orange and pyronine G, the xanthene analog of acridine orange, and suggested this similarity as evidence for the latter intercalation model. In pyronine G, the unprotonated molecule is singly charged and, because of the greater electronegativity of oxygen relative to nitrogen, Structure III is favored over Structure IV. Consequently, Structure V would, by spectral analogy, be favored over Structure VI for singly protonated acridine orange.

To elucidate the electronic structures of the diaminoacridine dyes and, ultimately, their interactions with DNA, the present study of the dependence of their electronic spectra upon solvent properties and state of protonation was undertaken.

EXPERIMENTAL

The pH measurements were made on a pH meter[1] with a combination silver–silver chloride glass electrode. Electronic absorption spectra were taken in 1-cm silica cells on a grating-type spectrophotometer[2]. Fluorescence measurements were taken on a fluorescence spectrophotometer[3] whose monochromators were calibrated against the line emission spectrum of xenon. Emission spectra were corrected for the wavelength response of the monochromators and phototube by means of a corrected spectra accessory employing a rhodamine-B quantum counter.

[a] M = monocation, and N = neutral species.

3-Aminoacridine was prepared by the deamination of proflavine according to the method of Martin and Tong (6). Proflavine[4], acridine orange[4], and acridine yellow[4] were purified by several recrystallizations of each from absolute ethanol.

Absorption and fluorescence spectra were taken on 1×10^{-5} *M* solutions of 3-aminoacridine, proflavine, and acridine yellow. However, because of the aggregation of acridine orange, which is appreciable at $\sim 10^{-5}$ *M*, the spectra of this compound were taken on 1×10^{-6} *M* solutions. The spectrophotometric titration procedures employed were described previously (7).

RESULTS

The electronic spectral maxima of 3-aminoacridine and of the diaminoacridines in various states of protonation, in aqueous and sulfuric acid media, are presented in Table I. The spectra of 3-aminoacridine are shown in Fig. 1. The spectral maxima of the neutral species and monocation derived from each compound, in chloroform, are presented in Table II. The pKa values (determined absorptiometrically) for the various prototropic reactions are listed in Table II. Also presented in Table II are the inflection points (pKa*) in the fluorometric titration curves corresponding to each measurable excited-state reaction.

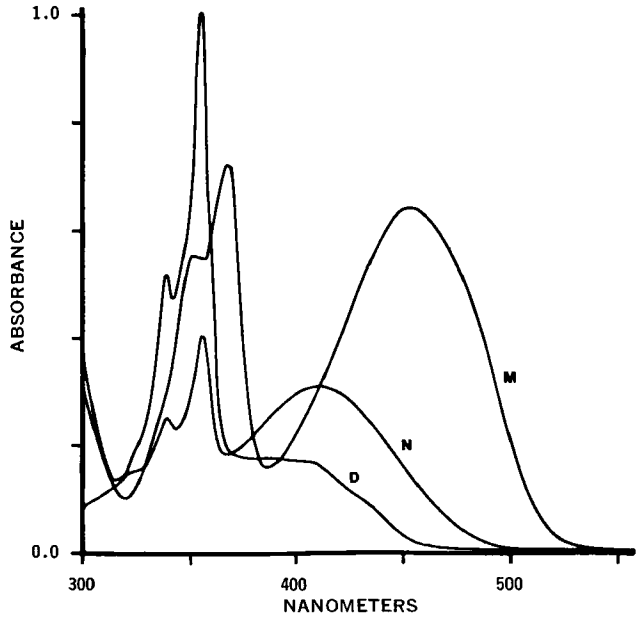

Figure 1—*Absorption spectra of 3-aminoacridine* ($\sim 5 \times 10^{-5}$ M). *Key: N, neutral; M, monocation; and D, dication.*

In each compound studied, only the neutral species ⇌ monocation interchange did not measurably occur during the lifetime of the excited state. The pKa* values for the trication ⇌ dication and dication ⇌ monocation excited-state reactions are believed to correspond very closely to the excited-state dissociation constants for these reactions.

DISCUSSION

The longest wavelength absorption bands of arylamines may be thought to originate from the transfer of electronic charge from the amino group to the vacant π^*-orbitals of the aromatic ring as a result of the interaction of the ground-state molecular electronic distribution with the electric vector of the exciting light (8). In the ground state, the aromatic ring is weakly conjugated with the amino group; but in the excited state the amino group is more extensively conjugated with the aromatic ring, resulting in stabilization of the excited state relative to the ground state. As a result, the longest wavelength absorption band of the aminoaromatic lies at a lower energy or longer wavelength than the longest wavelength absorption band of the parent hydrocarbon.

Protonation of the amino group removes the lone pair from conjugation with the aromatic ring in ground and excited states, resulting in an absorption spectrum very similar to that of the parent aromatic hydrocarbon but slightly displaced due to the polarizing influence of the protonated amino group. The second longest wavelength band of an arylamine originates from an essentially ring-localized transition and is relatively unaffected by protonation of the amino group (8). The fluorescence of an arylamine, which entails the spontaneous transfer of charge from the aromatic ring back to the amino group, lies at longer wavelengths than that of the parent hydrocarbon. However, the excited state from which fluorescence occurs and the ground state to which it occurs are somewhat different than the corresponding states involved in the longest wavelength absorption process.

The weakly conjugated amino group in the thermally equilibrated ground-state molecule is essentially tetrahedral in geometry. Because electronic transitions are somewhat faster than nuclear motions, the amino group in the electronically excited state, produced by absorption (the Franck–Condon excited state), is still predominately tetrahedral. However, subsequent to light absorption and prior to fluorescence, the amino group becomes planar (or nearly so) with respect to the aromatic ring to give the molecular configuration of lowest energy in accord with the highly conjugated excited amine. When fluorescence occurs, the light emission process is so rapid that the ground state in which the molecule initially arrives is thermally excited, retaining the planar amino group of the excited-state equilibrium geometry. Because the excited state involved in fluorescence is lower in energy than that involved in absorption and the ground state involved in fluorescence is higher than that involved in absorption, the fluorescence lies at longer wavelength than the longest wavelength absorption band. It can be concluded that, although both the absorption and fluorescence processes in question involve transition between the ground and first excited singlet states, the absorption process reflects the ground-state molecular structure while the fluorescence process reflects the excited-state atomic configuration.

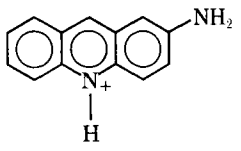
In nitrogen heterocycles such as acridine, the introduction of amino groups produces spectral effects similar to those just discussed but with some qualitative differences. The nitrogen atom is more electronegative than carbon and, therefore, exerts an attractive influence on the π-electron system of the aromatic ring as well as on the lone pair of an amino substituent (9). Because the excited states of aromatic rings and arylamines are generally more polar than their ground states, the attractive or stabilizing influence of the nitrogen atom is generally greater upon the excited state than upon the ground state. The result is that the longest wavelength absorption and fluorescence bands of *N*-heterocyclic amines lie at longer wavelengths than in the corresponding carbocyclic systems. This effect is much more pronounced in ring-protonated *N*-heterocyclic amines, in which the ring-protonated nitrogen is even more electronegative.

In aminoacridines, the longest wavelength absorption and fluorescence bands [the ^1L_a bands in the Klevens and Platt (10) nomenclature system] are extremely sensitive in position to the state of protonation of the heterocyclic nitrogen atom. The second absorption band (^1L_b) of an aminoacridine, however, is much less sensitive to protonation of the heterocyclic nitrogen atom and is indicative of the acridine ring system, lying at ~350–370 nm in monosubstituted acridines.

At this point, it is desirable to distinguish between two types of ring-protonated amino *N*-heterocycles: Type 1, those for which conjugation of the amino group with the aromatic ring cannot be represented by low energy canonical structures, *e.g.*, 2-aminoacridinium ion (VII); and Type 2, those for which conjugation of the amino group with the aromatic ring can be depicted by a formal low energy valence-bond representation, *e.g.*, 9-aminoacridinium ion (VIII and IX).

Protonated *N*-heterocyclic amines of the first type are weakly conjugated in the ground state because of orbital occupancy restrictions. However, they are substantially conjugated in the lowest excited state because the π^*-orbitals, which become occupied in the excited state, provide an electronic pathway between the amino group and the aromatic ring (7). Therefore, these compounds are characterized by spectroscopic behavior of the kind discussed up to this point. Moreover, the dissociation constants of these species are typical of the class, having pKa ~5–6 and pKa ~0–1 for dissociation from the ring nitrogen atom and for protonation of the amino group, respectively (7).

The second type of protonated *N*-heterocyclic amines may be extensively conjugated in the ground state because the canonical structure alternative to the protonated *N*-heterocyclic amine (the iminium ion) provides a low energy electronic distribution, which does not violate the restrictions imposed by the Pauli exclusion principle (7). The iminium structure may be regarded as the ex-



VII

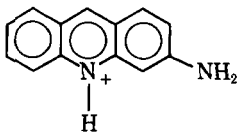
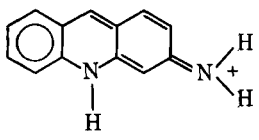
IX



X



XI

treme limit of conjugation of the amino group with the protonated heterocyclic ring. However, in such a structure, it is clearly impossible for light absorption to transfer charge from the exocyclic group to the ring. Rather, because of the positive charge on the exocyclic group, the low energy π^*-orbital associated with this group (similar to a carbonyl group), and the lone pair localized on the heterocyclic nitrogen atom, absorption entails transfer of charge from the ring to the exocyclic group so that conjugation of the exocyclic group is actually less extensive in the lowest excited singlet state than in the ground state.

In this extreme situation, the ground state would be relatively more stabilized by the presence of the amino group and, as in the case of the 9-aminoacridinium ion, the ^1L_a absorption and fluorescence spectra would be expected to lie at shorter wavelengths than those of the acridinium cation (7). Moreover, the loss of aromaticity in the ground state should, as in the case of the 9-aminoacridinium monocation, shift the ^1L_b band (characteristic of aromatic ring size) to shorter wavelengths.

Dissociation or protonation of the monocation restores the aminoacridine or ammonium acridine structure, and either process thus shifts the spectra to longer wavelengths. The pKa values of these compounds also reflect the loss of positive charge at the ring nitrogen atom and the gain of positive charge at the exocyclic nitrogen atom in the ground state. For example, in 9-aminoacridinium monocation, pKa = 10.0 for the heterocyclic nitrogen atom and −8.5 (7) for the exocyclic nitrogen atom. Moreover, the dissociation constants of the excited species of the Type I ring-protonated heterocyclic amines are more basic at the ring nitrogen atom and less basic at the exocyclic nitrogen atom while those of the Type 2 compounds are in the opposite order, in accord with the opposite directions of flow of electronic charge in either type of ring-protonated heterocyclic amine (7).

As previously mentioned, the 9-aminoacridinium ion and the 2-aminoacridinium ion represent two extremes of conjugative behavior in ring-protonated *N*-heterocyclic arylamines. In the 9-aminoacridinium cation, the 9-iminoacridan cation form predominates because it is not only allowed electronically but also is electrostatically favored by the proximity between the heterocyclic and exocyclic nitrogen atoms as well as by the inherently low aromatic stability of the central ring of anthracene and acridine derivatives. However, in certain ring-protonated aminoacridines, such as 3-aminoacridine, the amino group is considerably more separated from the heterocyclic function so that the polarization of the amino lone pair of X to form XI is a weaker interaction than in the 9-aminoacridinium cation.

Moreover, the formation of XI from X entails the disruption of two aromatic rings, including one that is normally stabilized by an aromatic sextet, and is, therefore, less favorable electronically than the corresponding process in the 9-aminoacridinium cation. Under such circumstances, it is to be expected that the electronic distribution in the 3-aminoacridinium ion would be intermediate between Structures X and XI. In this case, the long wavelength electronic absorption band of the 3-aminoacridinium ion could entail transfer of electronic charge away from the amino group and toward the heterocyclic function if the actual structure is closer to the amino form (X), in the ground state, or transfer of electronic charge toward the imino group and away from the heterocyclic function if the structure is closer to that of the imino form (XI). If X more accurately represents the structure of the 3-aminoacridinium monocation, the long wavelength absorption band should shift to shorter wavelengths upon dissociation from the heterocyclic group or protonation of the amino group while the corresponding prototropic processes should result in absorption spectral shifts to longer wavelengths if XI is closest to the actual structure.

Similar arguments are applicable to the shifting of the fluorescence spectra of the 3-aminoacridinium monocation upon protonation or dissociation. However, because of the conformational relaxation that takes place in the excited state subsequent to absorption and prior to emission, it is possible that the electronic charge

redistribution produced by going from the ground state to the lowest excited singlet state would convert the predominately amino-type ground-state monocation X into the predominately imino-type excited-state monocation (XI) or vice versa. The result of such an interaction would be that protonation and dissociation of the monocation would produce absorption and fluorescence shifts in opposite directions.

In 3-aminoacridine, the shifts of the ^1L_a absorption and fluorescence bands of the monocation upon dissociation to the neutral species or protonation to the dication, the presence of a well-defined ^1L_b band (between 350 and 370 nm) in all species, and the greater acidity of the dication in the lowest excited singlet state relative to the ground state all indicate that the monocation of 3-aminoacridine is predominately aminoacridine-like in ground and lowest excited singlet states (X).

In proflavine, the presence of the second amino group in the monocation results in a somewhat more complicated picture. The triply and doubly charged cations derived from proflavine are similar in electronic structure to the dication and monocation, respectively, derived from 3-aminoacridine. Because of the absence of lone pairs on both amino groups, the spectra of the trication of proflavine are similar to those of an unsubstituted acridinium ion (the iminium structure is impossible in the trication). Dissociation of one amino group to form the dication frees one lone pair for the interaction with the aromatic system. Because of the positive influence of the remaining protonated amino group, the charge-transfer interaction between the free amino group and the heterocyclic ring is enhanced, with the greatest stabilization effected on the excited state because of its great charge-transfer character. As a result, the ^1L_a and fluorescence bands of the dication lie at slightly longer wavelengths than those of the monocation of 3-aminoacridine (because of the lack of the $-NH_3^+$ group in the latter) as well as at much longer wavelengths than the corresponding spectra of the trication.

This behavior is anticipated for the spectrum of the amino form of the dication and is supported by the occurrence of the ^1L_b band typical of an acridine ring as well as by the fact that the free amino group is less basic in the first excited singlet state than in the ground state. If the imino form predominated, the loss of aromaticity in the acridine ring should have shifted the ^1L_b, ^1L_a, and fluorescence bands to shorter wavelengths while the imino structure of the exocyclic group should have resulted in enhanced basicity in the lowest excited singlet state.

In the monocation derived from proflavine, the ^1L_a absorption and fluorescence bands lie at wavelengths shorter than those of the corresponding spectral bands in both the monocation of 3-aminoacridine and the dication of proflavine. Moreover, the ^1L_b band in the proflavine monocation is not visible. The lack of appearance of the ^1L_b band is not in itself indicative, because this band could be extremely weak in intensity and buried under the tailing of the extremely intense ^1L_a band in the monocation of proflavine. However, the shifting of the ^1L_a absorption and fluorescence bands and the fact that pKa* > pKa for the dication–monocation intercon-

version suggest that at least the excited monocation is in the imino form (II).

Upon dissociation of the monocation of proflavine (from the heterocyclic nitrogen atom) to form the neutral species, the ^1L_a absorption band shifts to a shorter wavelength by an amount comparable to the corresponding shift in 3-aminoacridine. However, the fluorescence band of the monocation moves to a slightly longer wavelength upon dissociation from the heterocyclic nitrogen atom. These results indicate that, in the ground state, the monocation is predominately in the amino form (as 3-aminoacridine) and support the conclusion that in the lowest excited singlet state the monocation fluoresces as the imino valence tautomer. The neutral molecule is, of course, amine-like in ground and excited states, since an imino form in this species would be an inherently unstable zwitterion with positive and negative charges both borne by nitrogen atoms (*i.e.*, atoms of comparable electronegativity).

The small shift of the ^1L_a band of the dication to shorter wavelengths upon dissociation to the monocation can be rationalized in terms of the ground-state amino structures of both the dication and monocation as follows. Since the ^1L_a band arises from the promotion of an amino group lone pair electron to a π^*-orbital of the acridinium ring, the release of an additional lone pair of comparable energy, by dissociating the dication to the monocation, does not have much effect upon the orbital aspect of the transition. However, while the positive charge of the ammonium group of the dication enhances charge transfer in the excited state and thereby lowers the energy of the transition relative to that in the 3-aminoacridine monocation, the extra lone pair in the proflavine monocation causes greater electron repulsion in the charge-transfer excited state and thereby destabilizes the excited state with respect to the ground state. Hence, the ^1L_a band of the proflavine monocation lies at a shorter wavelength than that of the proflavine dication or the monocation of 3-aminoacridine, while the ^1L_a band of the neutral proflavine lies at a shorter wavelength than that of neutral 3-aminoacridine.

The spectroscopic and prototropic behavior of acridine orange is comparable to that of proflavine. However, the 2,7-dimethyl-substituted proflavine, acridine yellow, behaves differently in one way. The fluorescence of the neutral molecule is at slightly shorter wavelength than that of the monocation. However, the excited-state pKa* of the dication–monocation interconversion is more basic than the corresponding ground-state pKa, indicating that the imino structure of the monocation is in the excited state. The anomalous fluorescence shift observed upon going from the monocation to the neutral molecule in acridine yellow appears to be due to greater steric inhibition, by the methyl groups in the 2- and 7-positions, of conjugation in the excited state of the neutral species, resulting in an anomalously short fluorescence wavelength in this species. The apparently greater sensitivity to solvent polarity or hydrogen-bonding capacity of the fluorescences of the neutral proflavine and acridine orange molecules relative to that of the corresponding monocations also reverses the order of the fluorescence maxima of proflavine and acridine orange, although the amino and imino structures of the neutral molecules and monocations are, presumably, preserved in chloroform (Table II).

In light of the results of these experiments, it may be predicted that proflavine, acridine orange, and acridine yellow bind in their monocation forms to DNA in such a way that the positively charged heterocyclic nitrogen atom is oriented toward a phosphate ester group. However, upon excitation, the sites of predominant positive charge in the monocations shift to the exocyclic nitrogen atoms. Thus, the excited dye molecules bound to DNA will generally not be in the binding configuration of lowest electrostatic energy. They will tend to reorient themselves as best they can, before fluorescing, to achieve the lowest energy configuration. Although translational motions of the bound entities are severely restricted, the lifetime of a typical fluorescent excited state is more than adequate to allow for rotational and vibrational rearrangements. Consequently, electronic absorption spectroscopy appears to be a very powerful and readily available tool for the probing of drug–receptor interactions. However, much more work remains to be done before fluorescence spectroscopy can enjoy the same interpretive versatility.

Effect of Surfactants on Absorption through Membranes III: Effects of Dioctyl Sodium Sulfosuccinate and Poloxalene on Absorption of a Poorly Absorbable Drug, Phenolsulfonphthalein, in Rats

SHAH N. MALIK, DONALD H. CANAHAM, and M. WAFIK GOUDA ˣ

Abstract □ The influence of dioctyl sodium sulfosuccinate and poloxalene on the GI absorption of phenolsulfonphthalein in the rat was studied. Urinary excretion data after oral administration of the drug to intact rats and loss of the drug from the whole small intestine as a loop were both utilized to assess the effect of the surfactants on absorption. Dioctyl sodium sulfosuccinate markedly increased the absorption of the drug, and the extent was dependent on the surfactant concentration. Maximum effect was observed at the reported ED_{50}, in rats, of the surfactant as a fecal softener. The mechanism responsible for absorption enhancement seems to be an alteration of the permeability of the intestinal membrane. Micellar complexation between the drug and the surfactant resulted in a lesser increase in absorption at the higher surfactant concentrations. Poloxalene did not increase drug absorption, but higher concentrations caused a decrease in absorption due to micellar entrapments of the drug molecules. The influence of dioctyl sodium sulfosuccinate on the peritoneal absorption of the drug was also investigated. Lower doses of the surfactant increased absorption of the drug by altering the membrane permeability. Higher doses decreased absorption due to unavailability of the drug molecules entrapped in the micelles.

Keyphrases □ Surfactants—effects of dioctyl sodium sulfosuccinate and poloxalene on absorption of phenolsulfonphthalein in rat □ Dioctyl sodium sulfosuccinate—effect on absorption of phenolsulfonphthalein in rat, urinary excretion and *in situ* intestinal loop data □ Poloxalene—effect on absorption of phenolsulfonphthalein in rat, urinary excretion and *in situ* intestinal loop data □ Absorption—effects of dioctyl sodium sulfosuccinate and poloxalene, rats

Dioctyl sodium sulfosuccinate USP (I) and poloxalene[1] are two surfactants used medicinally as fecal softeners. It was suspected that the presence of I in combination with oxyphenisatin acetate, a nonabsorbable peristaltic stimulant, resulted in promotion of intestinal absorption of oxyphenisatin and, therefore, caused jaundice in several patients (1, 2). A systematic study of the effect of these surfactants on the absorption of various drugs was undertaken. A previous report (3) showed that both surfactants enhanced the absorption of pentobarbital, a readily absorbable drug, through the goldfish membrane. Dioctyl sodium sulfosuccinate was also found to change the rate of absorption of pentobarbital from the rat intestine (4).

The purpose of the present investigation was to study the effect of both surfactants on the GI absorption of a poorly absorbable drug, phenolsulfonphthalein (phenol red), in the rat.

Although Lish and Weikel (5) reported that I enhances the absorption of phenolsulfonphthalein from the rat colon while poloxalene does not, these investigators used only one concentration of the surfactants. Since the action of surfactants on drug absorption is known to be concentration dependent, and since more recent reports (6) have shown that phenolsulfonphthalein, like most other drugs, is absorbed mainly from the upper GI tract, a more detailed study of the effect of various concentrations of the surfactants on the absorption of phenolsulfonphthalein from the intact rat and from *in situ* intestinal loops was deemed appropriate. The effect of I on the peritoneal absorption of phenolsulfonphthalein was also examined.

EXPERIMENTAL

Poloxalene, dioctyl sodium sulfosuccinate[2], and phenolsulfonphthalein[3] were all used as received. All other chemicals were either USP or reagent grade.

Absorption Studies in Intact Rats—Male Sprague–Dawley rats, 200–380 g, were starved for 18–20 hr with water allowed *ad libitum*. The experiments were performed in a crossover fashion with each rat serving as its own control. About half the number of animals received a control dose of 2 ml of phenolsulfonphthalein solution (0.75 mg/ml) in distilled water by gastric intubation. The other half received an equal volume of the same solution in distilled water containing one concentration of the surfactants studied. After a recovery period of 3 days, the procedure was reversed.

Urine was collected for 24 hr, and the amount of phenolsulfonphthalein excreted was determined spectrophotometrically at 560 nm following the method of Feldman and Gibaldi (7). The percent of the drug absorbed was calculated by means of a standard curve.

In a second set of experiments, the test animals were injected intraperitoneally in a crossover fashion with 0.5 ml of phenolsulfonphthalein solution (0.75 mg/ml) in distilled water or an equal volume of the same solution in distilled water containing one concentration of dioctyl sodium sulfosuccinate. The amount of the drug excreted in the urine was determined as already described, and the percent absorbed in the presence of various concentrations of the surfactant was calculated.

Absorption Studies from *In Situ* Intestinal Loops—Fasted Sprague–Dawley rats, 200–300 g, were used. The degree of intestinal absorption was measured using *in situ* single loop preparations (8, 9). The loop used was whole small intestine. The animals were anesthetized with ether, and a midline incision was made to expose the small intestine. Ligatures were placed about 1 cm distal to the pyloric junction and 1 cm proximal to the ileocecal junction. Care was taken not to occlude major blood vessels. Physiological saline was injected into the loop until the washings became clear.

The rats were kept under light anesthesia for 20–25 min, before closing the ileocecal end, to allow for absorption of any residual solution. Five milliliters of phenolsulfonphthalein solution (0.75 mg/ml) in distilled water or in various solutions of the surfactants was introduced into the intestines through the pyloric ligature by means of a syringe and a blunt needle. The midline incision was then closed and the animals were allowed to recover. The animals

[a] Values represent mean of nine animals.

were sacrificed after 3 hr; the whole small intestine was removed, washed with saline to remove any blood adhering to its surface, homogenized, and assayed for drug content according to Lish and Weikel (5).

The percent of phenolsulfonphthalein absorbed was calculated by measuring the difference between the amount introduced into the loop and the amount recovered from the intestinal homogenate.

Solubility Studies—Equilibrium solubility was employed to determine the extent and the nature of possible interactions between the drug and the surfactants. Excess amounts of powdered phenolsulfonphthalein were placed in 25-ml ampuls with 10-ml solutions containing various surfactant concentrations. The ampuls were sealed and then rotated in a constant-temperature water bath at 37 ± 0.1°. After equilibrium was achieved, an aliquot was filtered through 0.45-μm filters[4]; the amount of the drug in solution (adjusted to pH 10 with sodium hydroxide) was determined spectrophotometrically at 560 nm.

Partition Studies—Solutions of phenolsulfonphthalein (0.05%) were prepared in a phosphate buffer (0.01 *M*, pH 6.0) or in the same buffer containing various concentrations of I. Ten milliliters of these solutions was added to an equal volume of *n*-octanol, previously saturated with the buffer solution, in a 50-ml erlenmeyer flask. The contents were equilibrated at 37 ± 0.1° for 2 days. After separation by centrifugation (at 37°), an aliquot of the aqueous phase was assayed spectrophotometrically for its drug content. The partition coefficient was calculated by difference. The organic phase, *n*-octanol, was chosen on the basis of its favorable nonpolar lipid character (10, 11). The pH of the solutions simulates the average pH of the small intestine.

RESULTS AND DISCUSSION

Phenolsulfonphthalein is a poorly absorbable, weak acid (pKa 7.9). The poor absorption of the drug from the small intestine is attributed to the low lipid–water partition coefficient of the unionized form, while the poor absorption from the stomach can be attributed to the opening of the sulfolactone ring at low pH (≤2) and the generation of the benzenesulfonic acid group that becomes ionized at the stomach pH (11). Intestinal perfusion studies in rats have shown that phenolsulfonphthalein is equally absorbed in the proximal and distal regions of the small intestine (12). At the concentration employed in this study (0.75 mg/ml), phenolsulfonphthalein absorption from the rat intestinal tract occurs mainly by passive diffusion (13).

Effect of Dioctyl Sodium Sulfosuccinate on GI Absorption of Phenolsulfonphthalein—Table I shows the urinary recovery of phenolsulfonphthalein as the percent of dose after oral administration of 2 ml of a 0.75-mg/ml solution in the presence or absence of various concentrations of I. The percent of the drug absorbed in control animals was, on the average, about 5% of the dose administered. All doses of the surfactant significantly increased drug absorption. Differences between absorption from solutions containing I and control solutions are significant at $p < 0.001$ as determined by the Student *t* test for paired data.

The effect of I on the absorption of phenolsulfonphthalein from the intact rat was dependent on the amount of the surfactant administered. Maximum effect was observed at the dose level of 20–30 mg, corresponding to a 1–1.5% surfactant concentration in the administered solution. The dose that caused the maximum increase in drug absorption was approximately equal to 100 mg/kg, the ED_{50} reported for the fecal-hydrating effect of the surfactant (14).

The enhancement of phenolsulfonphthalein absorption in the intact rat due to coadministration of the surfactant could be the result of one or more mechanisms. For example, dioctyl sodium sulfosuccinate was reported to retard gastric emptying when administered intraduodenally (15). Such a delay in the GI transit rate could conceivably result in increased absorption of phenolsulfonphthalein when the two drugs are administered together. Other possible mechanisms include a possible interaction between the surfactant and the drug and/or a direct effect of the surfactant on the GI membrane with a resultant change in drug absorption.

Therefore, it was of interest to consider the absorption of the drug from a well-defined segment of the GI tract. The whole intestine as a loop is well suited for this purpose. This technique allows the study of the surfactant effect without the complicating problem of gastric emptying and permits a better control of the concentration of the surfactant at the absorption site. In addition, it was of interest to determine if *in situ* techniques correlate with absorption studies from intact animals.

The results obtained from intestinal loop experiments are presented in Table II. A significant increase in the absorption of phenolsulfonphthalein in the presence of the surfactant was observed. Differences between absorption from solutions containing I and control solutions were significant at $p < 0.001$ as determined by the Student *t* test for unpaired data. The intestinal loop experiments also indicated a dose-dependent effect of the surfactant on the intestinal absorption of phenolsulfonphthalein. Although there were quantitative differences in the extent of absorption between intestinal loops and intact rat experiments, the activity of the surfactant followed more or less the same pattern. These quantitative

Table III—Apparent Partition Coefficients for Phenolsulfonphthalein (0.05%) in the Presence of Various Concentrations of Dioctyl Sodium Sulfosuccinate

0.01	0.08
0.1	0.08
0.25	0.07
0.5	0.08
1.0	0.07
1.5	0.08

differences are to be expected in view of the differences in the effective concentration of both the drug and the surfactant at the absorption site and the differences in techniques. Nevertheless, the intestinal loop experiments proved to be in good qualitative correlation with intact animal absorption studies.

The results of the absorption studies from intestinal loops suggest that other factors besides delay in gastric emptying are mainly responsible for absorption enhancement. A significant change in the ability of the drug to permeate the GI membrane may result from an interaction between phenolsulfonphthalein and the surfactant to form a complex with a higher affinity for the membrane. The magnitude of interaction of the drug with the surfactant was determined by equilibrium solubility studies. Figure 1 shows that the solubility of the drug increases above the critical micelle concentration (CMC) of the surfactant, indicating micellar complexation.

The possibility that a complex of the drug and the surfactant has better affinity for lipoidal membranes was investigated by partition studies (Table III). Both premicellar and postmicellar concentrations of the surfactant did not increase the partitioning of phenolsulfonphthalein between *n*-octanol and water.

On the basis of the absorption, solubility, and partition studies, it is suggested that the enhancement of phenolsulfonphthalein absorption represents the sum of two main effects: modification of the permeability of the membrane and micellar complexation of the drug. The membrane effect of the surfactant is believed to increase absorption, while the micellar entrapment of the drug molecules usually decreases absorption. The results of the absorption studies indicate that the membrane effect is predominant. However, at higher concentrations of the surfactant (higher doses), the micellar entrapment results in a lesser increase in absorption. Several reports (4, 8, 16–20) attributed the absorption enhancement effect of various surfactants to a direct effect on the biological membrane.

The absorption studies in intact rats indicated that any effect of the surfactant on membrane permeability was reversible. Urinary excretion data obtained from control studies in rats, 3 days after each had received the surfactant, were essentially identical to those obtained from control studies in rats with no previous exposure to the surfactant.

Effect of Dioctyl Sodium Sulfosuccinate on Peritoneal Absorption of Phenolsulfonphthalein—In view of the finding that the surfactant could change the permeability of the GI membrane, it was of interest to determine whether it has a similar effect on the peritoneal membrane. The results are shown in Table IV. The concomitant administration of the surfactant with the drug resulted in a small but significant ($p < 0.01$ as determined by the Student *t* test for paired data) increase in the drug absorption up to a 0.5-mg dose (corresponding to a 0.1% surfactant concentration). Above this dose, the drug absorption was significantly decreased. The effect of the surfactant on the peritoneal absorption of the drug was qualitatively similar to its effect on the GI absorption. The extent in increase in absorption, however, was less in the case of peritoneal absorption, and a decrease in absorption was observed at higher surfactant concentrations.

The mechanism by which the surfactant changes the peritoneal absorption of the drug seems to be basically similar to the one observed in the GI absorption studies. At lower surfactant concentration (lower dose), there was a potentiation of absorption through a direct effect on the membrane. At higher concentrations, the drug was entrapped in the micelles and was not readily available so a decrease in absorption was observed. The effect of dioctyl sodium sulfosuccinate on the peritoneal membrane and the resultant change in permeability reported in this study are in agreement with the findings of Mattocks and Penzotti (21). These investigators reported that the same surfactant accelerated peritoneal dialysis of both urea and sodium phosphate, and they attributed its effect to direct action on the structure of the mesentary membrane by removal of phospholipids.

Effect of Poloxalene on GI Absorption of Phenolsulfonphthalein—The total urinary excretion of the drug in the presence and absence of the surfactant is shown in Table V. No increase in absorption was noticed with the lower doses of the surfactant, while a significant decrease ($p < 0.05$) was observed at higher doses. The results of the intestinal loop experiments are presented in Table VI. Again, the same pattern of surfactant activity was observed. There was no significant change at lower concentrations, but a significant decrease in absorption ($p < 0.001$) was observed at higher concentrations.

The failure of poloxalene to increase drug absorption from the GI tract of the rat is in contrast to the absorption-enhancing effect of similar concentrations of the surfactant of pentobarbital in the goldfish (3). This nonionic surfactant apparently can change the

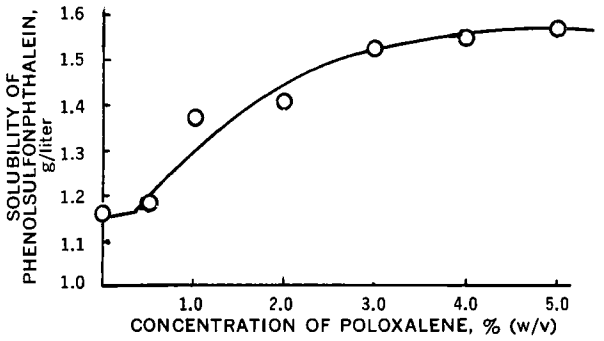

Figure 2—*Effect of poloxalene on the equilibrium solubility of phenolsulfonphthalein at 37°.*

permeability of the goldfish membrane but is unable to cause a significant change in the rat GI membrane. A similar nonionic surfactant, polysorbate 80, was also found to promote drug absorption in the goldfish but not in the rat (22). The lack of promotion of phenolsulfonphthalein absorption by poloxalene observed in this study is in agreement with the findings of Lish and Weikel (5) and the reported lower toxicity of nonionic surfactants toward biological membranes (23).

The decrease in absorption observed at higher concentrations of the surfactant is attributed to micellar entrapment of the drug molecules, as evidenced by the solubility curve shown in Fig. 2. It is suggested that the drug in the micellar phase is unavailable for absorption. Therefore, the effective concentration at the absorption site is less than the apparent concentration, resulting in a decrease in absorption. Higher concentrations of other nonionic surfactants were found by many investigators (24–27) to cause a similar decrease in drug absorption.

SUMMARY

Dioctyl sodium sulfosuccinate, an anionic medicinal surfactant, increased the absorption of phenolsulfonphthalein, a poorly absorbable drug, in the rat. Poloxalene, a nonionic medicinal surfactant, did not increase absorption of the drug; however, higher doses resulted in a decrease in absorption. The possibility that dioctyl sodium sulfosuccinate, a widely used fecal softener, causes a similar enhancement of drug absorption in humans is currently under investigation.

Effect of Surfactants on Absorption through Membranes IV: Effects of Dioctyl Sodium Sulfosuccinate on Absorption of a Poorly Absorbable Drug, Phenolsulfonphthalein, in Humans

NAWAL KHALAFALLAH *, M. WAFIK GOUDA ‡x, and SAID A. KHALIL *

Abstract □ To explore the effect of dioctyl sodium sulfosuccinate on drug absorption in humans, the urinary excretion of a poorly absorbable drug, phenolsulfonphthalein, administered in solution with and without the surfactant was determined. Coadministration of a therapeutic dose of the surfactant with the drug solution resulted in a significant increase in the initial rate of absorption. A small increase in the extent of absorption was also observed. Pretreatment with the surfactant for 6 nights, followed by administration of the drug on the 7th day, did not significantly change the rate or extent of absorption. The surfactant is thought to have a direct effect on the GI membrane, resulting in a temporary change in its permeability. This effect appears to be reversible after a few hours.

Keyphrases □ Dioctyl sodium sulfosuccinate—effect on phenolsulfonphthalein absorption, humans □ Phenolsulfonphthalein absorption—dioctyl sodium sulfosuccinate effect, humans □ Surfactant effect—dioctyl sodium sulfosuccinate on phenolsulfonphthalein absorption, humans □ Absorption, drug—effect of surfactant (dioctyl sodium sulfosuccinate) on phenolsulfonphthalein, humans

Hepatic drug reactions are not uncommon. Various drugs were reported to cause such reactions, yet involvement of a laxative preparation in jaundice manifestations is a novelty (1). Recently, clinical observations describing hepatitis with jaundice manifestations in humans, during long-term administration of a widely used and generally assumed innocent laxative combination, were reported (1–3). This laxative product incorporates dioctyl sodium sulfosuccinate (I) as a wetting agent and a stool softener together with sodium carboxymethylcellulose and the cathartic oxyphenisatin acetate. A hypersensitivity to oxyphenisatin was suggested as the probable cause of hepatitis (3). These reports have drawn attention to the possibility of I being indirectly responsible for causing jaundice. The surfactant was suspected of producing a hyperabsorptive state by a direct action on the biological membrane, resulting in the absorption of toxic amounts of oxyphenisatin (4). Similarly, toxicity in rats (5) after oral administration of subtoxic doses of danthron (1,8-dihydroxyanthraquinone) with I was attributed to increased absorption of the former in the presence of the surfactant. Clinical data in humans (6) also support the observed toxicity in rats. Consequently, warning notes have appeared in the literature concerning the hazards of drug combinations containing I (4, 7).

A systematic study of the effect of I on drug absorption through biological membranes of varying complexities was undertaken. The purpose of such a study is to determine whether this seemingly inert surfactant (8) changes the absorption profile of representative drugs when both are given concomitantly. A previous report (9) showed that I enhances the absorption of pentobarbital, a readily absorbable drug, in the goldfish. Dioctyl sodium sulfosuccinate also enhanced the absorption of a poorly absorbable drug, phenolsulfonphthalein, in the rat (10). Since animal studies may only indicate similar effects in humans, a study of the effect of this surfactant on drug absorption in human volunteers was deemed appropriate. The effect of coadministration of the drug and the surfactant in solution on drug absorption under experimentally controlled conditions was examined. In addition, the effect of I on the absorption of the drug under clinically oriented conditions was determined.

EXPERIMENTAL

Twelve healthy male volunteers participated in the present study (Table I). The study was designed in a crossover fashion. The urinary excretion of orally administered phenolsulfonphthalein was determined subsequent to the administration of each of the following treatments:

A. 20 mg of phenolsulfonphthalein[1] (12 subjects).

B. 20 mg of phenolsulfonphthalein and 250 mg of dioctyl sodium sulfosuccinate[2] (11 subjects).

C. 20 mg of phenolsulfonphthalein and 500 mg of I (four subjects).

D. 20 mg of phenolsulfonphthalein alone on the morning of the 7th day following the daily administration of 200 mg of I, in the form of 50-mg capsules[3], taken after supper for 6 successive days (six subjects).

At least 1 week elapsed between two successive treatments in any one subject. Each dose was dissolved in 50 ml of water, and 20 mg of sodium bicarbonate was added to aid the solubility of phenolsulfonphthalein. Solutions containing the doses were administered to subjects in the morning on an empty stomach. No food was allowed for the next 4 hr. Fluid intake was regulated to permit hourly collection of urine, and no other drug was permitted throughout the experimental period. Doses containing the surfactant, when administered, produced temporary throat irritation, which explains the reduced number of volunteers in Treatment C.

Subsequent to dose administration, urine was collected hourly for 7–9 hr and then every 2–3 hr until the drug could no longer be detected in the urine. All urine samples were stored in a refrigerator and assayed within 24 hr according to McLeod *et al.* (11). The buffer solution, suggested by Ashley and Levy (12) to avoid underestimation of phenolsulfonphthalein particularly in acidic urine, was used to dilute the urine samples. Diluted urine was centrifuged, and the supernate absorbance was determined at 560 nm spectrophotometrically[4]. Necessary blanks were prepared using urine diluted with 0.1 *N* acetic acid.

RESULTS AND DISCUSSION

The amounts of phenolsulfonphthalein excreted 1 and 24 hr following Treatments A–D are given in Table I. The two excretion parameters reported were chosen to reflect the rate and extent of phenolsulfonphthalein absorption. Plots of the time course of drug excretion following the treatments are shown in Fig. 1.

The average amounts of phenolsulfonphthalein excreted in 1 and 24 hr in the control treatment (Treatment A) were 1.4 and 11.3% of the dose, respectively. These values are in close agreement with those reported by other investigators (12). The urinary excretion pattern observed with the majority of subjects in the control study exhibited two excretion peaks at approximately 2 and 5 hr. Ashley and Levy (12) reported similar excretion patterns in humans following the same dose of phenolsulfonphthalein as a solution. The secondary excretion rate peak, after food ingestion, was attributed to transfer of residual drug from the stomach to the intestine or enhanced absorption due to discharge of bile into the intestinal lumen.

The urinary excretion data reported in Table I were statistically analyzed. Each set of data was compared with the control data from the same subjects using a paired *t* test (Table I). It can be observed from the 1-hr urinary excretion data that coadministration of 250 mg of the surfactant and the drug (Treatment B) resulted in a significant increase in the rate of phenolsulfonphthalein absorption. In the presence of the surfactant, 3% of the administered dose was excreted within 1 hr (Treatment B, average of 11 subjects) compared to a value of 1.4% of the dose in the absence of the surfactant (Treatment A, average of the same subjects). The dose of I administered in Treatment B, which resulted in the hyperabsorptive state, was within the usual prescribed oral dose [100–400 mg daily (13)]. Criticism has been raised against *in situ* data reporting surfactant effects on drug absorption. Such data are sometimes obtained under nonphysiological conditions, such as using high surfactant concentration (14), which prevents extrapolation of results to human therapy.

Coadministration of the drug and 500 mg of the surfactant resulted in a similar significant increase in the rate of absorption. Inspection of the 1-hr urinary excretion data following Treatment C suggests that doubling the dose of the surfactant did not increase the rate of drug absorption over what was observed following Treatment B. On the contrary, there seemed to be a lesser increase in the absorption rate at the higher surfactant dose. This concentration-dependent effect of the surfactant was also observed in similar studies in the rat (10). The 500-mg dose of the surfactant corresponds to an approximately 1% concentration in the administered solution. Previous studies (10) showed that such a concentration results in micellar entrapment of the drug molecules and, hence, the observed smaller increase in the absorption rate. The number of volunteers participating in both Treatments B and C was too small to permit statistical analysis of the difference between the two sets of data.

In Treatment D, where there was premedication with capsules containing 200 mg of the surfactant for 1 week, experimental conditions were selected to simulate a possible clinical situation where this stool softener surfactant is administered for some time and a poorly absorbable drug is administered during the same period. Such a clinical situation is very likely. Treatments B and C simulate another possible situation where patients may take the two drugs at the same time or where patients receive a combination dosage form containing the two drugs. It was a combination dosage form of I and the nonabsorbable oxyphenisatin acetate that resulted in hepatic toxicity (1–3).

The 1-hr urinary excretion data obtained following Treatment D indicates a small increase in the rate of absorption. The amount of phenolsulfonphthalein excreted increased from 1.3% (average of six subjects) to 1.8% of the dose (average of the same subjects). Statistical analysis of the data indicates that the difference between the two means is not significant. This result could be due to a decline in the surfactant effect during the time (overnight) that elapsed before drug administration. The effect of this surfactant (9, 10) and others (15, 16) on animal membranes was found to be reversible; membranes regained normal behavior after some time.

In the present study, the hyperabsorptive state described by the 1-hr urinary excretion data following Treatments B and C was most probably due to a direct action of the surfactant on the membrane. A similar mode of action was suggested in animal studies using phenolsulfonphthalein with I (10). The latter was also shown to accelerate peritoneal dialysis of urea and phosphates in rabbits (17). Various investigators attributed promotion of drug absorption in the presence of surfactants to a similar mechanism (15, 16, 18–20).

The exact mechanism of the surfactant-induced change in the membrane permeability is still unknown. The possibility of removal of phospholipids from the membrane by surfactants was suggested (17), as was alteration of the highly ordered barrier by such agents (21). Recently, Dujvone and Shoeman (22) reported that patients given therapeutic doses of dioctyl sodium sulfosuccinate excreted considerable amounts in the bile; therefore, the previous belief that this surfactant is not absorbed from the GI tract was invalidated.

It is likely that some of the surfactant molecules, in passing through the biomembrane, remain dissolved in the lipoidal cell wall. Plasticization results from the dissolution of low molecular weight compounds in high molecular weight materials. Physical properties, including permeability, undergo substantial changes. In the present study, dissolution of I in the lipoidal cell wall and a resultant permeability increase due to plasticization of the membrane was probably responsible for the observed increase in the rate of absorption of phenolsulfonphthalein. Lovering and Black (23) suggested a similar mechanism to explain the enhancement of permeation of phenylbutazone through everted rat intestines.

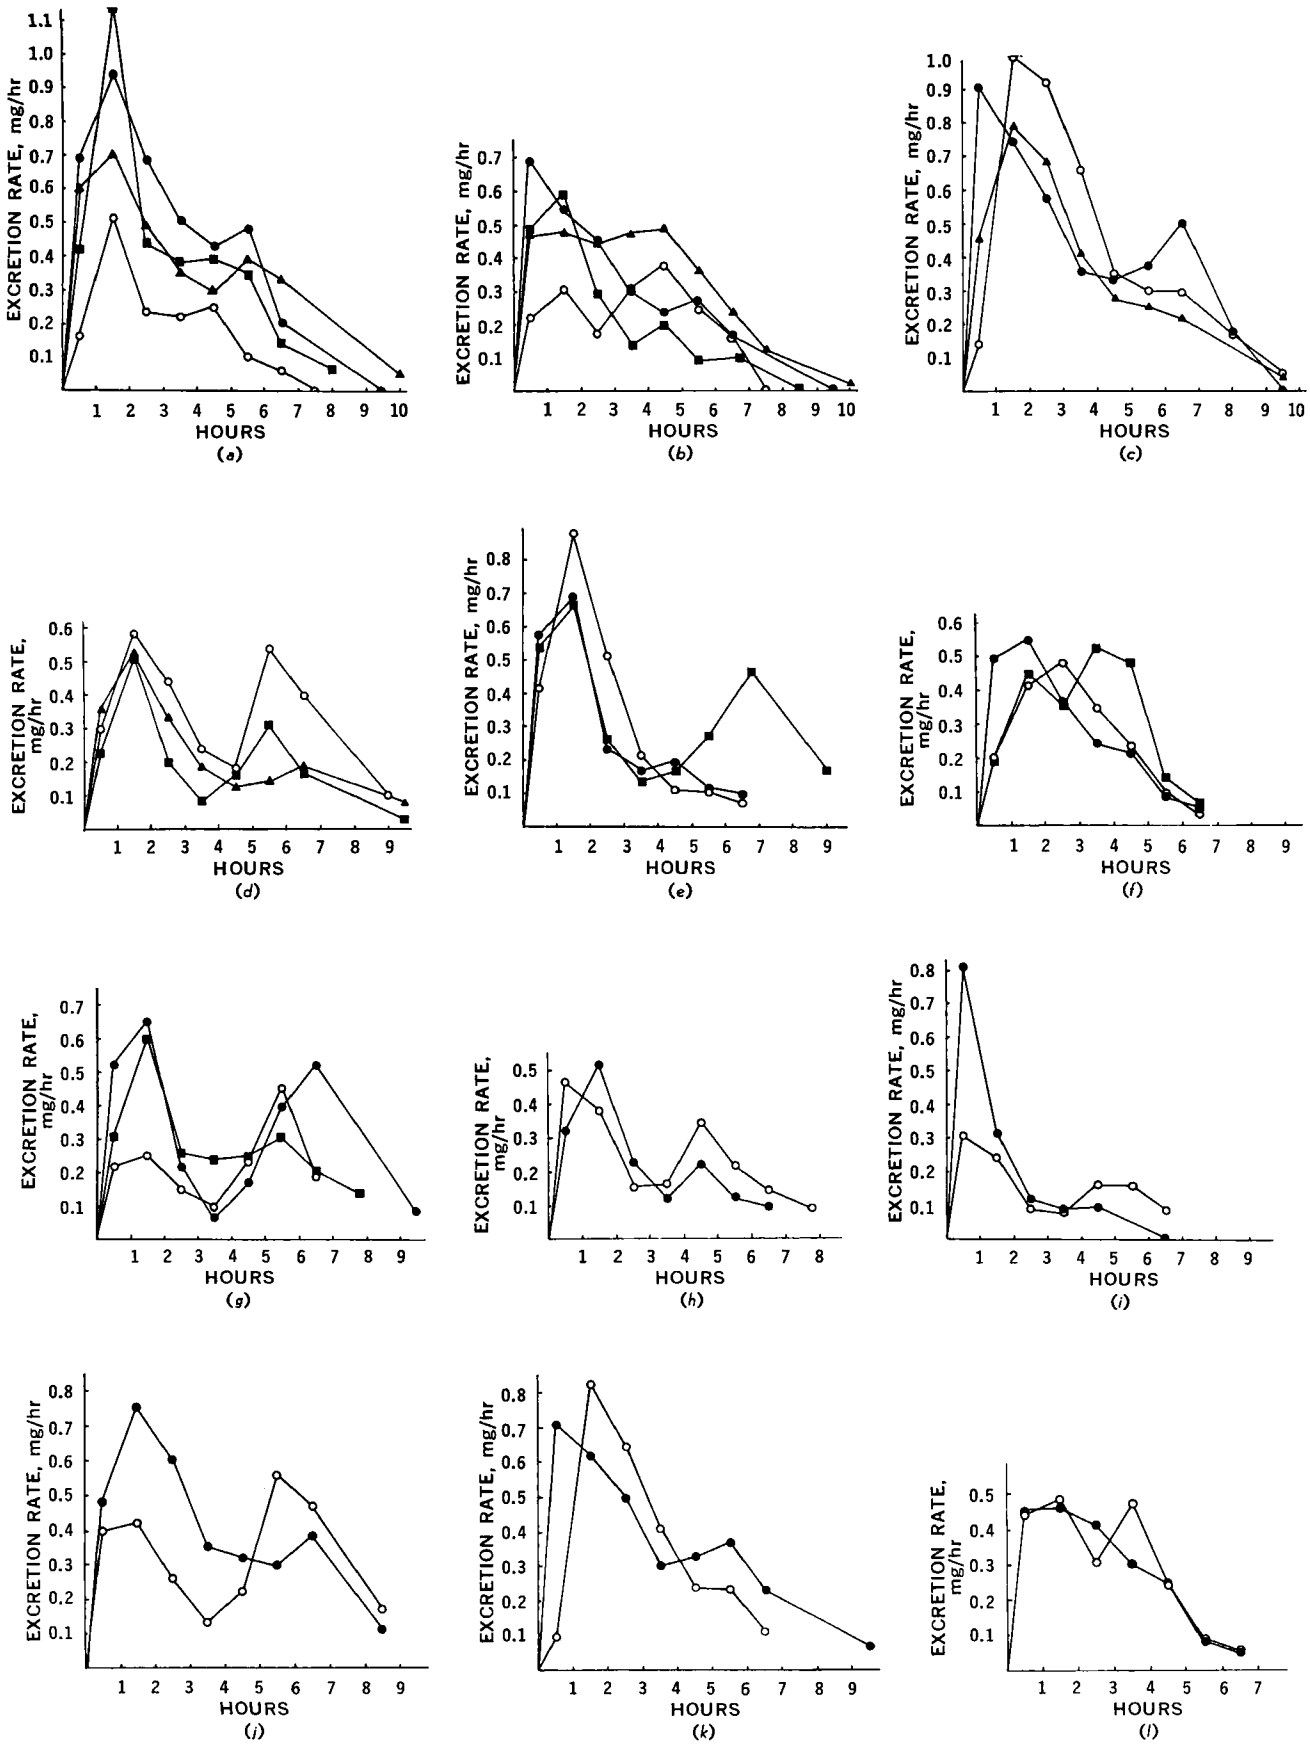

Figure 1—*Urinary excretion rates of orally administered phenolsulfonphthalein in human volunteers:* (a) *Subject GM,* (b) *Subject NK,* (c) *Subject SK,* (d) *Subject OA,* (e) *Subject SA,* (f) *Subject AE,* (g) *Subject AR,* (h) *Subject AN,* (i) *Subject AA,* (j) *Subject MM,* (k) *Subject WG, and* (l), *Subject HE. Key:* ○, *Treatment A;* ●, *Treatment B;* ▲, *Treatment C; and* ■, *Treatment D.*

Whatever the exact nature of this hyperabsorptiveness may be, it is generally agreed that it is reversible (9, 10, 15, 16). The membrane regains normal behavior toward drug permeation after some time, in contrast to the persistent hyperpermeability caused by fatty acids and aspirin (24).

Administration of 250 mg of the surfactant in phenolsulfonphthalein solution increased the total recovery of phenolsulfonphthalein from 10.9 to 13.5% (average of 11 subjects that participated in both Treatments A and B). This small increase was of borderline significance ($0.05 < p < 0.1$). Coadministration of 500 mg of the surfactant and premedication with capsules containing 200 mg of I did not significantly change the extent of absorption of phenolsulfonphthalein (Treatments C and D, Table I). Unavailability of the drug molecules for absorption due to micellar entrapment (10) could be the reason why a 500-mg dose of the surfactant did not increase the extent of absorption. The regaining of normal permeability characteristics by the membrane is probably responsible for the lack of increase in the extent of absorption following premedication with the surfactant capsules.

Two other factors should be considered for their possible implications on the results obtained in this study. The first factor is the mechanism of absorption of phenolsulfonphthalein. The drug is reported to be absorbed in animals and humans by both passive and specialized mechanisms (11, 25, 26). The latter has been described as a low capacity active transport process. Surfactants *have sometimes* been shown to retard the net absorption of drugs absorbed mainly by active mechanisms, in spite of the absence of drug micelle interactions (27–29). In the present investigation, although the coadministration of 250 mg of the surfactant and phenolsulfonphthalein resulted in an increase in net absorption, the increase was not as high as anticipated. Therefore, the mechanism of absorption of phenolsulfonphthalein could have exerted a damping effect on the increase in net absorption.

The second factor is that I has been reported to exert a pharmacological effect in animals that is not shared by other surfactants. It retards gastric emptying rate and inhibits gastric secretion in rats (30). These effects were only demonstrated at relatively high doses of the surfactant. Lish (30) reported retardation of gastric and intestinal motility using 100–1600 mg of I/kg in rats, while effects on gastric secretion were observed with 20–100 mg/kg in rats. In the present study, the hyperabsorptiveness was achieved with an average dose as low as 4 mg/kg in humans. Furthermore, the excretion pattern observed in Treatment B (Fig. 1) strongly suggests a direct action of I on the biomembrane and does not favor any of the previously discussed pharmacological effects of the surfactant. The sudden rise in urinary excretion rate of phenolsulfonphthalein during the 1st hr, with no apparent delay in peak excretion rate and no significant prolongation of absorption time, support the suggestion that the observed increase in absorption is due to a temporary change in membrane permeability.

In conclusion, the results of this study show that the initial rate of absorption of a poorly absorbable drug, phenolsulfonphthalein, from solution can be increased by the coadministration of a widely used medicinal surfactant, dioctyl sodium sulfosuccinate. The extent of absorption was only slightly increased. The results obtained also indicate that inclusion of this surfactant with the nonabsorbable laxative, oxyphenisatin acetate, could be one reason for the observed hepatic toxicity of the combination dosage form (4).

Therefore, it is imperative, as suggested by Tucker (31), that the possible effects of this and other surfactants on the absorption of each drug with which they are to be used be fully assessed. The drastic rise in excretion rate of phenolsulfonphthalein during the 1st hr (Subject WG, Treatment B, Table I) is strong proof of the possible hazards that may result from a sudden unintentional rise of the blood level of a potentially dangerous drug.

Antimicrobial Evaluation of Diastereoisomeric 2-Dimethylaminomethyl-6-phenylcyclohexanols and Related Esters

J. R. DIMMOCK *x, W. A. TURNER *, and H. A. BAKER ‡

Abstract □ 2-Dimethylaminomethyl-6-phenylcyclohexanone was reduced to give the isomeric 2-dimethylaminomethyl-6-phenylcyclohexanols, which were then converted to a number of novel esters. These derivatives were screened against a wide range of microorganisms. The alcohol possessing an axial hydroxy group had high activity against *Candida albicans*, in contradistinction to the isomer having an equatorial hydroxy function, which was approximately 30 times less active. The esters from the isomeric alcohols demonstrated a low level of antimicrobial activity with the exception of the 10-undecenoyl ester of 2-dimethylaminomethyl-6-phenylcyclohexanol (possessing the equatorial hydroxy group), which showed significant activity against three pathogenic fungi.

Keyphrases □ 2-Dimethylaminomethyl-6-phenylcyclohexanone—conversion to isomeric alcohols and esters, screened for antimicrobial activity □ 2-Dimethylaminomethyl-6-phenylcyclohexanols and esters—screened for antimicrobial activity □ Antimicrobial activity—screening of diastereoisomeric 2-dimethylaminomethyl-6-phenylcyclohexanols and esters

It is well established that β-aminoketones (Mannich bases) have a wide range of chemotherapeutic properties (1–5) including antimicrobial activity (6–10). In addition, reduction of the keto group of Mannich bases has led to compounds with increased pharmacological activity (4). It was decided to prepare the Mannich base from 2-phenylcyclohexanone to compare the activity of this β-aminoketone (I) and related compounds with the corresponding acyclic derivative, 4-dimethylamino-1-phenyl-2-butanone, and its analogous derivatives.

Reduction of I should lead to the formation of isomeric alcohols (II*a* and II*b*), the differences in stereochemistry of which may reflect different potencies against microorganisms. Furthermore, it was hoped to use the concept of latentiation (11) by preparing esters (III and IV) that would be predicted to undergo *in vivo* hydrolysis to the parent alcohols (II*a* and II*b*). The rate of hydrolysis in the series of benzoyl esters would be dependent on several factors, including the Hammett value of the nuclear substituents. In addition, steric impedance of the esters IV containing an axial ester group would be expected to be greater than in the series containing an equatorial ester configuration (III). The rate of hydrolysis of the esters, if carried out enzymatically, also may be dependent on the stereochemical requirements at a receptor site of the enzyme. Thus, a correlation between the rate of release of the alcohols and antimicrobial potency may emerge in this series of compounds.

Finally, it was proposed to synthesize the phenoxyacetyl and 10-undecenoyl esters of II*a* and II*b*, which may lead to the release of phenoxyacetic and 10-undecenoic acids *in vivo;* both of these compounds are known to possess antifungal activity.

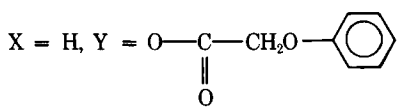
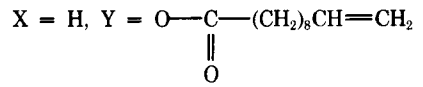
$R_1 = R_2$ = H, Cl, NO_2, OCH_3





EXPERIMENTAL[1]

The preparation of the compounds described in this work was reported previously (12). The compounds in Table I were evaluated using an agar dilution method. In each case a stock solution of the compound was prepared by dissolving 20 mg of the sample in 1 ml of dimethyl sulfoxide, followed by the addition of 3 ml of water. Aliquots of the stock solution were pipetted into melted trypticase soy agar (BBL) to give final concentrations of the compound of 200, 50, 12.5, and 3.1 μg/ml. After hardening, the agar surface was inoculated with appropriately diluted suspensions of the test organisms using a multiple inocula replicating device[2]. The seeded plates were incubated (18 hr at 30° followed by 18 hr at 37°), and the plates were then observed for microbial growth.

The screening techniques for the compounds listed in Table II were as follows. In the antibacterial screen, 1 ml of stock solution (1000 μg/ml) was added to 9 ml of nutrient broth to give an initial concentration of 100 μg/ml and 1:1 dilutions were then added to nutrient broth. All tubes were inoculated with 0.1 ml of a 1:10 dilution of an 18-hr culture of the test organism. All tubes were incubated for 24 hr at 37° and then examined for growth.

The antifungal screen involved the addition of 1 ml of the stock solution (1000 μg/ml) to 9 ml of Sabouraud broth to give an initial concentration of 100 μg/ml and 1:1 dilutions were added to Sabouraud broth. A spore suspension (0.1 ml) of *Trichophyton granulosum* and *Microsporum gypseum* and 0.1 ml of a 1:100 dilution of a broth culture of *Candida albicans* were added to the test tubes containing the various concentrations of the test substances. Tubes containing *C. albicans* were incubated at 37° and tubes containing *M. gypseum* and *Tr. granulosum* were incubated at 28°. Tubes were examined for growth after 4 and 9 days of incubation.

In the antitrichomonal screen, 1 ml of the stock solution (1000 μg/ml) was added to 9 ml of Diamond medium to give an initial

[a] Figures in table are the minimum inhibitory concentrations of the compounds in micrograms per milliliter. [b] The strains of microorganisms in this table are identified by the following numbers: ATCC 9790, SK&F 24390, SK&F 23390, SK&F 4200, SK&F 11320, SK&F 12140, SK&F 11350, SK&F 17410, ATCC 101, SK&F 3470, ATCC 6633, ATCC 9848, ATCC 16040, SK&F 330, EK1, EK2, ATCC 11551, ATCC 8668, and ATCC 9341, respectively. [c] Strain resistant to penicillin G. [d] Strain sensitive to penicillin G.

concentration of 100 μg/ml and 1:1 dilutions were made. Tubes were inoculated with approximately 2.5×10^5 organisms/ml and examined microscopically for growth after 48 hr of incubation.

RESULTS AND DISCUSSION

The preparation and chemical properties of Compounds I–IV were described previously (12). Table I indicates that the β-aminoketone (I) had a good level of activity against the fungus *Trichophyton mentagrophytes* and low levels of activity against seven other microorganisms. Compound I was screened in the plaque inhibition test against rhinoviruses HGP, 28, 1059, and 33342 and was inactive at a concentration of 100 μg. In another screen, I was shown to reduce *Trichinella spiralis* parasites in mice by 24% at a dose of 50 mg/kg (25 mg/kg po and 25 mg/kg sc).

Reduction of I with lithium aluminum hydride gave a 3:1 mixture of isomeric alcohols (IIa and IIb), which was separated by column chromatography. Physicochemical determinations, principally PMR spectroscopy, provided evidence of the stereochemistry of IIa and IIb (Scheme I).

As can be seen from Tables I and II, IIa was virtually devoid of antimicrobial activity. However, alcohol IIb, while failing to show significant activity against most of the microorganisms listed in Table II, showed excellent activity against *C. albicans*. The large potency differences between IIa and IIb against this important pathogenic fungus are noteworthy, illustrating the potency variations between geometrical isomers (13). The lack of activity in IIa may possibly be due to its accessible equatorial hydroxy group, which may allow facile metabolism and detoxification to occur. In addition, the equatorial hydroxy group may form hydrogen bonds readily prior to reaching a site of action. In comparing the bioactivity of I, IIa, and IIb, the broader spectrum of activity of I is noteworthy. It is possible that I, being a Mannich base, can undergo deamination to the corresponding α,β-unsaturated ketone, which may be the active derivative (14). Neither IIa nor IIb would be expected to undergo such a biotransformation.

The masking of the polar hydroxy group by forming the benzoate esters of IIa was accomplished. However, the unsubstituted compound (IIIa) was virtually devoid of antimicrobial activity in the screens chosen. Substitution of the aromatic ester function by electron-withdrawing influences, to increase the predicted *in vivo* hydrolysis, yielded virtually inactive compounds (IIIb, IIIc, IIIe, and IIIf). The ester IIId, containing the electron-repelling methoxy group, would be expected to undergo slower hydrolysis than the other esters, but it failed to demonstrate a significant level of activity. The phenoxyacetyl ester (IIIg) showed virtually no activi-

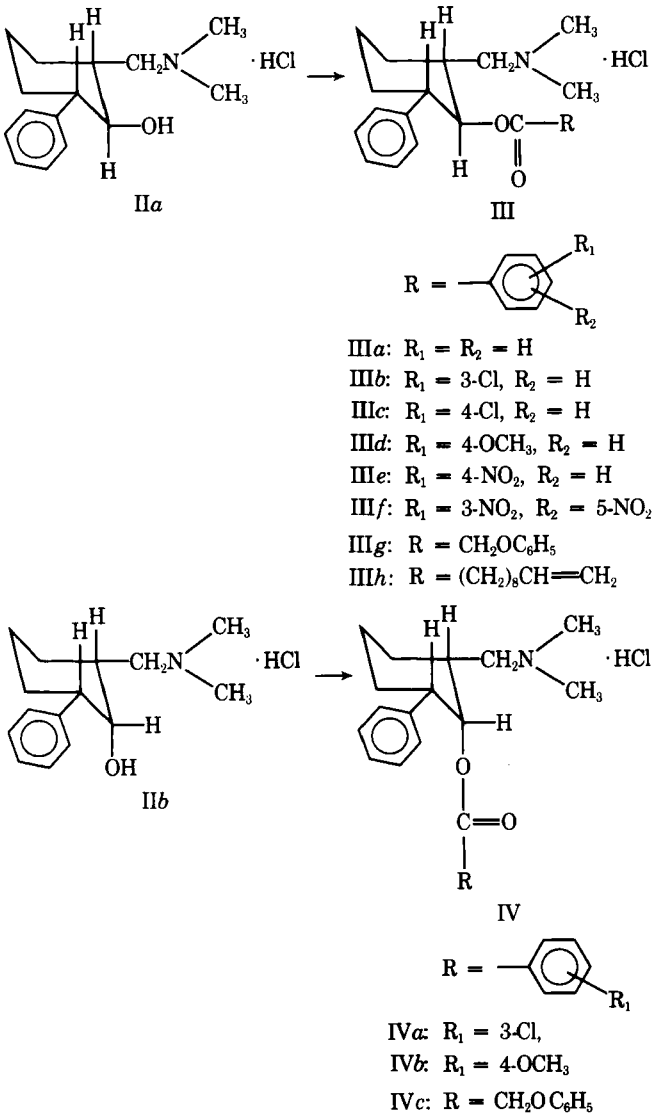
[a] Figures in table are the minimum inhibitory concentrations of the compounds in micrograms per milliliter. [b] The strains of microorganisms in this table are identified by the following numbers: AY-F-598, AY-F-605, AY-F-604, AY-B-353, AY-B-352, AY-B-355, ATCC 11229, AY-B-357, AY-B-358, AY-B-359, AY-B-360, AY-B-361, ATCC 10081, ATCC 9103, ATCC 30001, and ATCC 30003, respectively. [c] Activity values against resistant strains of *C. albicans* AY-F-610–619 were 20, 16, 32, 62.5, 32, 62.5, 62.5, 32, 32, and 32 μg/ml, respectively. [d] Strain resistant to penicillin G potassium. [e] Strain sensitive to penicillin G potassium.



Scheme I

ty at high doses, suggesting that the ester was not breaking down to yield the established antifungal agent, phenoxyacetic acid.

Attempts to prepare the analogous series of esters from II*b* were not completely successful. Only in the case of the phenoxyacetyl ester (IV*c*) was a crystalline ester obtained uncontaminated with unreacted alcohol. In other cases, a mixture of alcohol and ester was obtained; this mixture proved difficult to separate, although IV*a* and IV*b* were obtained in very low yields. By the time II*b* and its related esters were available for assessment as antimicrobial agents, the screen used to evaluate the previous compounds (Table I) became unavailable. However, the novel esters IV*a*, IV*b*, and IV*c* were evaluated elsewhere and compared to the analogous esters III*b*, III*d*, and III*g* along with the isomeric alcohols II*a* and II*b* (Table II). Esters IV*a*, IV*b*, and IV*c* did not show promising levels of activity, which may indicate failure for hydrolysis to occur under biological conditions.

Finally, attempts to prepare the undecenoyl esters of II*a* and II*b* were undertaken. While an attempt to form the ester from the sterically hindered alcohol II*b* was unsuccessful, II*a* reacted with undecenoyl chloride to give III*h* in good yield. Table II indicates that III*h* possesses high activity against three species of pathogenic fungi. Further studies of III*h* against 10 resistant strains of *C. albicans* showed activity between 16 and 62.5 μg/ml (Table II), considered to be too low a level to warrant further investigation. However, the fact that the undecenoyl ester (III*h*) showed far greater antifungal activity than the corresponding phenoxyacetyl derivative (III*g*) may indicate steric restraints of the aryloxyalkyl ester imposed by the bulky aromatic ring. The olefinic derivative (III*h*) may be able to undergo *in vivo* hydrolysis to undecylenic acid.

In summary, the work demonstrates that another Mannich base (I) shows antimicrobial potency as well as stereospecificity of the isomeric 2-dimethylaminomethyl-6-phenylcyclohexanols (II*a* and II*b*) toward *C. albicans*. Esters of II*a*, with one exception, prepared from II*a* failed to enhance the antimicrobial potency and all of the esters of IV failed to retain the activity against *C. albicans* shown by the precursor alcohol II*b*. The high activity of the undecylenic ester of II*a* may be due to its ability for facile hydrolysis to undecylenic acid, in which case the substituted cyclohexanol can be considered a novel carrier group for the active antifungal agent.

Determination of (±)-1,2-Bis(3,5-dioxopiperazinyl)propane Plasma Levels in Rats, Rabbits, and Humans by GLC and Mass Fragmentography

W. SADÉE ˣ, J. STAROSCIK, C. FINN, and J. COHEN

Abstract □ Specific assay procedures were developed to measure plasma concentrations of (±)-1,2-bis(3,5-dioxopiperazinyl)propane (I) by GLC using flame-ionization detection with a sensitivity limit of 5 μg/ml and by GLC–mass fragmentography with a sensitivity limit of 0.2 μg/ml. Applicability of the assay procedures was demonstrated in rats, rabbits, and humans. Plasma concentration–time curves of total ^{14}C activity and intact I were obtained in rats and rabbits following oral and intravenous administration of ^{14}C-I. Plasma elimination half-lives of I in the first 2 hr following intravenous doses in rats were 40 and 45 min in two rats. Plasma levels of I were measured over 6 hr after an intravenous dose in rabbits and followed a two-compartment open model with a terminal log-linear plasma half-life of 85 min. Significantly higher total ^{14}C levels compared to intact I plasma concentrations indicated rapid biotransformation in both rats and rabbits to unknown metabolites. The oral bioavailability appeared to be limited in both species relative to intravenous administration. Two patients receiving 3 g of I/m^2 in tablets orally showed plasma levels of I similar to those obtained after oral doses in rats and rabbits, with peak concentrations at 2 hr after the dose (3.8 μg/ml) and with still measurable levels 12 hr after the dose (0.4 μg/ml).

Keyphrases □ (±)-1,2-Bis(3,5-dioxopiperazinyl)propane—determination of plasma levels, rats, rabbits, and humans, GLC and mass fragmentography □ Dioxopiperazines—determination of (±)-1,2-bis(3,5-dioxopiperazinyl)propane plasma level, rats, rabbits, and humans, GLC and mass fragmentography □ GLC—determination, plasma levels of (±)-1,2-bis(3,5-dioxopiperazinyl)-propane, rats, rabbits, and humans □ Mass fragmentography—determination, plasma levels of (±)-1,2-bis(3,5-dioxopiperazinyl)-propane, rats, rabbits, and humans

The dioxopiperazine, (±)-1,2-bis(3,5-dioxopiperazinyl)propane[1] (I, Scheme I) (1), is under clinical investigation as a chemotherapeutic agent against various neoplasms (2, 3). Its interesting pharmacological properties include normalization of tumor vasculature and the prevention of metastases of Lewis lung tumor in mice (4–6). The plasma disappearance half-life of I, following intravenous injections of ^{14}C-I in rats, was found to be about 30 min when measured by a bioassay using cultured Chinese hamster cells; total ^{14}C activity declined less rapidly, indicative of the presence of metabolites (7). The bioavailability of oral ^{14}C-I doses in humans appeared to be inversely related to the amount administered as judged by ^{14}C urinary excretion (8).

This article reports a specific chemical assay using GLC with flame-ionization detection and, for low concentrations of I, GLC–mass fragmentography. These methods were previously applied in other pharmacokinetic studies, *e.g.*, plasma levels of fluorouracil[2].

Rats and rabbits were utilized as experimental animals to demonstrate the applicability of the assay procedures, since pharmacokinetic data using the bioassay were available in rats (7) and evaluation of the effect of combination therapy with adriamycin and I on adriamycin cardiac toxicity is being investigated in rabbits. No intravenous preparation of I is yet available for human use due to limited solubility of the racemic mixture. The isolated optical isomers are considerably more soluble (9) and may provide an intravenous preparation in the future.

EXPERIMENTAL

Instrumentation and Apparatus—The assay was carried out on a gas chromatograph[3] equipped with a flame-ionization detector and a 1.8-m (6-ft) × 2-mm (i.d.) glass column packed with 3% polymethylsiloxane[4] on 100–120-mesh silanized diatomaceous earth[5]. Flow rates were approximately 35 ml/min for nitrogen, 30 ml/min for hydrogen, and 300 ml/min for air. The injector, column, and detector were operated at 210, 210, and 250°, respectively.

The GLC–mass fragmentography assay was performed on a gas chromatograph[6] equipped with an identical glass column and interfaced with a mass spectrometer[7] by a separator[8]. Helium, at a flow rate of 20 ml/min, was used as the carrier gas. The ionizing voltage was 70 ev.

Reagents—Chemicals were of analytical grade with the exceptions noted[9].

An ethereal alcoholic solution of diazomethane was prepared by the reaction of potassium hydroxide with *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide[10] and stored at −10°. Because of its toxicity and explosiveness, all manipulations involving the generation or use of diazomethane were carried out in a well-ventilated hood behind a safety shield.

GLC—To 0.5 ml of plasma containing 5–50 μg of I were added 0.5 ml of saturated aqueous ammonium sulfate, 6.0 ml of ether–isopropyl alcohol (4:1 v/v), and 0.05 ml of a solution of 5 μg of methyl arachidate in methanol as an internal standard. Samples were mixed on a vortex-action high-speed mixer in stoppered test tubes for 4 min and centrifuged. The ethereal phase was pipetted into another test tube and evaporated to dryness with a stream of nitrogen at 40°. The residue was transferred to a 3.0-ml vial[11] with

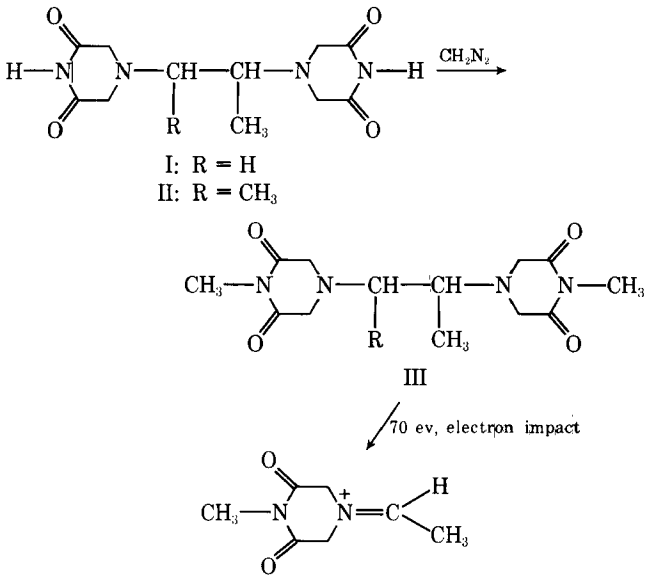

Scheme I

3 × 0.5 ml of methanol, and the solution was again evaporated with a stream of nitrogen at 65°.

The residue was dissolved in 0.2 ml of methanol, and about 1.5 ml of diazomethane solution was added. The sealed vial was kept at room temperature for 4 hr, and then excess diazomethane was evaporated by allowing the opened vial to stand in the hood for several minutes. The remaining solution was evaporated to dryness with a stream of nitrogen at 65°. Care should be taken to thoroughly dry the residue at this point. The residue was dissolved in 0.1 ml of methylene chloride, and a 2–3-μl aliquot of this solution was injected into the chromatograph.

At a column temperature of 210°, methyl arachidate and the dimethylated derivative of I had retention times of 6.5 and 8.0 min, respectively. Both chromatographic peaks were sufficiently separated from each other and from interfering peaks in the methylated plasma extract to allow the determination of their relative heights. A plot of peak height of I/peak height of methyl arachidate *versus* concentration of I was linear over the 5–50-μg/ml range of plasma. The column must be reconditioned at about 260° for 15 min after each injection to elute less volatile plasma components.

GLC–Mass Fragmentography Assay—Extraction and derivatizing procedures were identical to those in the GLC assay using flame ionization. In place of methyl arachidate, 0.1 ml of a solution containing 1 μg of II in methanol was added as the internal standard[12]. Aliquots of 2–3 μl were injected on the column. The fragment ion at *m/e* 155 was used to monitor both methylated I and II (Scheme I). At a column temperature of 230°, the dimethylated derivatives of I and II had retention times of 4.0 and 5.0 min, respectively. A standard curve was again constructed from peak height ratios by assaying plasma samples containing known amounts of I in the 0.2–2.0-μg/ml range. A plot of peak height of I/peak height of II *versus* concentration of I was linear in this range.

Radioactivity Analysis—Plasma samples (0.1 ml) were counted for ^{14}C activity in 10 ml of scintillation fluid[13] in polyethylene vials. The counter[14] had a ^{14}C efficiency of 75–85%, and counts were corrected by the channels ratio method. The ^{14}C activity was expressed as equivalents of ^{14}C-I.

Animal Procedures—Female Sprague–Dawley rats, 250–300 g, were used. Blood samples were collected from a carotid cannula, spun in a microcentrifuge[15], and frozen for subsequent analysis.

[12] Compound II could not be used as the internal standard for the flame-ionization GLC assay because it could not be adequately resolved from interfering plasma components.

296 (M^+)	4.4	—	—

Compound I was stable in frozen plasma samples over several weeks. New Zealand white rabbits, ~2 kg, were also used and blood specimens were obtained from an ear artery.

Doses of I were prepared in water, and sufficient 1.0 *N* HCl was added to dissolve all crystals completely. ^{14}C-I was added to obtain a specific activity of 100 dpm/μg. All doses were administered orally by stomach intubation or intravenously by injection over 1 min at a level of 120 mg/kg in rats and 50 mg/kg in rabbits.

Clinical Protocols—Human subjects received oral doses of I (3 g/m^2) in tablets as part of their medical treatment in the Western Cancer Study Group. Blood samples were obtained by venipuncture into containers[16] containing ethylenediaminetetraacetate and centrifuged, and the plasma was frozen for subsequent analysis. The use of this container resulted in an interfering peak with the same retention time as I, invalidating the flame-ionization GLC assay data. Plasticizers and similar compounds may have been possible contaminants. No interference by this contaminant was noted when utilizing single ion detection at *m/e* 155 in the GLC–mass fragmentography assay.

RESULTS

Assay Procedures—Chemical analysis of I imposed several analytical problems due to its polarity, amphoteric character, and lack of UV absorbance. The aqueous lipid extraction procedure, using saturated ammonium sulfate, yielded about 70% recovery of the drug from plasma samples. Suitable GLC characteristics were obtained by derivatization with diazomethane to give the *N,N'*-dimethylated derivative (III, Scheme I). The sensitivity of the flame-ionization GLC procedure was limited to 5 μg of I/ml of plasma due to interfering endogenous substances. Thus, single ion detection by mass spectrometry was employed to increase both specificity and sensitivity. Due to its close chemical similarity, Compound II was selected as the internal standard to compensate for extraction losses and irreversible adsorption processes during analysis at low concentrations.

The dimethylated derivatives of I and II are separated by GLC; both give rise to one major fragment ion at *m/e* 155 (Table I), which can be used to quantitate I and II. It is difficult to prove specificity of the assay for I in the presence of its metabolites since their structures remain unknown. The following criteria for assay interference by metabolites have to be met: extractability into the organic phase, identical GLC retention time, and fragment ion at *m/e* 155 representing a major peak in the mass spectrum. These criteria do not apply to possible hydrolytic polar metabolites. Therefore, the described assay is specific for I commensurate with current standards of plasma drug analysis.

The detection limit of pure samples of I by monitoring the fragment ion at *m/e* 155 was in the low picogram range. The detection of I in plasma samples after extraction was limited to approximately 0.2 μg/ml due to endogenous compounds with a high interference probability at the relatively low mass setting of *m/e* 155. However, this sensitivity limit was sufficient to measure I in rat, rabbit, and human plasma following therapeutic doses.

Plasma Levels in Rats—The plasma concentration–time

[16] Vacutainers.

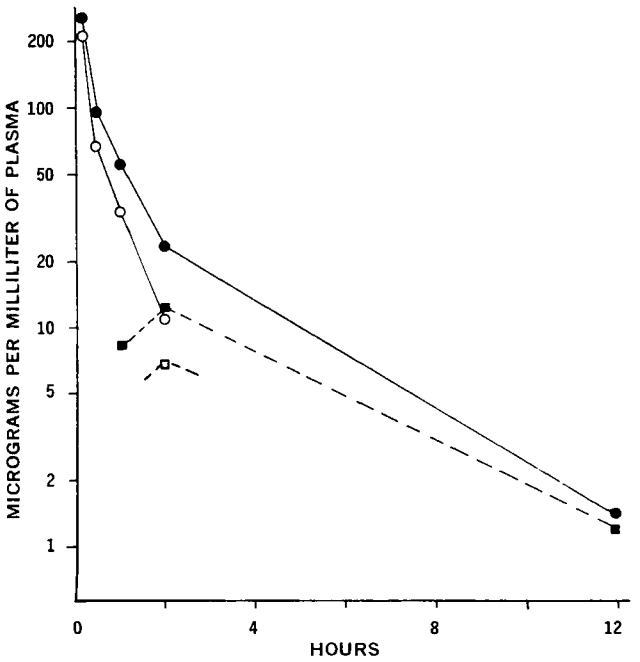

Figure 1—*^{14}C plasma activity and intact I plasma levels following a dose of 120 mg of I/kg in two rats. Key: ●, ^{14}C activity following intravenous dose; ■, ^{14}C activity following oral dose; ○, intact I levels following intravenous dose; and □, intact I levels following oral dose.*

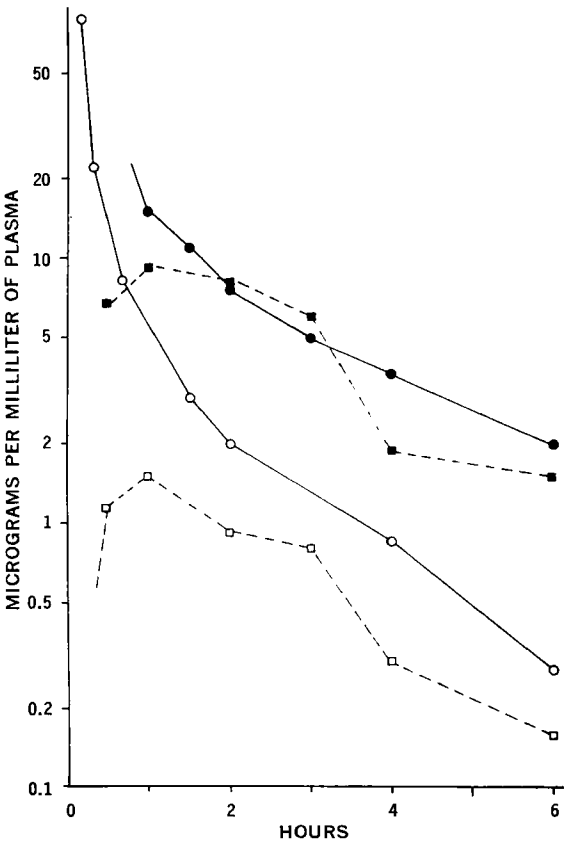

Figure 2—*^{14}C plasma activity and intact I plasma levels following a dose of 50 mg of I/kg in two rabbits. Key: ●, ^{14}C activity following intravenous dose; ■, ^{14}C activity following oral dose; ○, intact I levels following intravenous dose; and □, intact I levels following oral dose.*

curves measured by flame-ionization GLC and total ^{14}C activity resulting from an oral and intravenous dose of 120 mg of I/kg in two different rats are depicted in Fig. 1. Following intravenous administration, plasma levels of I rapidly disappeared during the initial distribution phase between 0 and 20 min and then declined with a half-life of about 40 min. A second rat showed a half-life of 45 min under identical conditions. The volume of distribution was obtained by extrapolating the apparent log-linear elimination phase to zero time and amounted to 120% of body weight in both rats. Total ^{14}C activity decreased less rapidly due to the formation of ^{14}C-labeled metabolites.

Following oral doses, peak plasma levels of 7 μg of I/ml were obtained after 2–4 hr, as measured by flame-ionization GLC (Fig. 1). Plasma levels of I were below the detection limit of this assay in all other samples.

Plasma Levels in Rabbits—^{14}C-I was orally and intravenously administered at a dosage of 50 mg/kg in two different rabbits (Fig. 2). Total ^{14}C plasma activity was again higher than the concentration of intact I, which was followed by GLC–mass fragmentation over 6 hr. The intravenous plasma concentration *versus* time curve of I could adequately be described by a two-compartment open model with a rapid α-phase ($\alpha = 4.15\ hr^{-1}$) and a slower β-phase ($\beta = 0.49\ hr^{-1}$, $T_{1/2} = 85$ min). The zero time intercepts were $A = 52$ μg/ml and $B = 5.5$ μg/ml.

Peak plasma concentrations of 1.5 μg/ml were obtained about 1 hr following oral administration and then declined parallel to the intravenous I concentration–time curve (Fig. 2), dropping below measurable levels 6 hr after administration. Total ^{14}C plasma activity remained as high as 0.6 and 0.5 μg/ml 24 hr after oral and intravenous administration, respectively, in these two rabbits.

Plasma Levels in Humans—The plasma concentration–time curve of I resulting from an oral dose of 3 g/m^2 (4.5 g) was measured by GLC–mass fragmentation (Fig. 3). Peak plasma levels of 3.8 μg of I/ml were obtained 2 hr following administration. Similar plasma concentrations were achieved in another patient under identical conditions. Twelve hours following administration of I, the plasma concentration in this patient had declined to 0.4 μg/ml and was below the detection limit (0.1 μg/ml) 24 hr after administration.

DISCUSSION

The specific assay for the determination of I in plasma samples was developed to evaluate the pharmacokinetics of this antineoplastic agent. The preliminary results are reported here.

Rat Studies—The plasma half-life of I measured by bioassay was about 30 min following an intravenous dose of 120 mg of I/kg (7). A plasma half-life of 40–45 min was found by the flame-ionization GLC assay under equivalent experimental conditions. Therefore, it is likely that no significant amounts of pharmacologically active metabolites were formed if one assumes that the bioassay is correlated with antineoplastic activity. Studies on the structure–activity relationships indeed demonstrate that pharmacological activity is very structure specific, and slight modifications of the chemical moiety of I usually abolish its antineoplastic activity (1, 10). However, it is difficult to assess pharmacological properties of I such as normalization of tumor vasculature, and formation of pharmacologically active metabolites cannot be ruled out.

The plasma half-life of 40–45 min for I may not represent the terminal log-linear elimination phase, since plasma levels were only followed over 2 hr by flame-ionization GLC.

Rabbit Studies—Plasma concentrations of I were measured by GLC–mass fragmentography over several half-lives. A log-linear β-phase for the elimination of I from plasma with a half-life of 85 min was reached 2 hr following intravenous administration. Initial plasma concentrations of I after intravenous injection were comparable to those obtained in rats when correcting for the lower dose in rabbits.

Plasma concentrations following oral doses were significantly lower than following intravenous doses in both species, indicating a limited oral bioavailability of I.

Human Studies—Only two patients were evaluated, each giving plasma concentration–time curves for I similar in order of magnitude to those obtained after oral doses in rats and rabbits. Therefore, it appears that both animal species may be useful as models for human pharmacological studies of I.

It cannot be determined at this point whether the limited bioavailability of I from oral preparations is due to low solubility or to

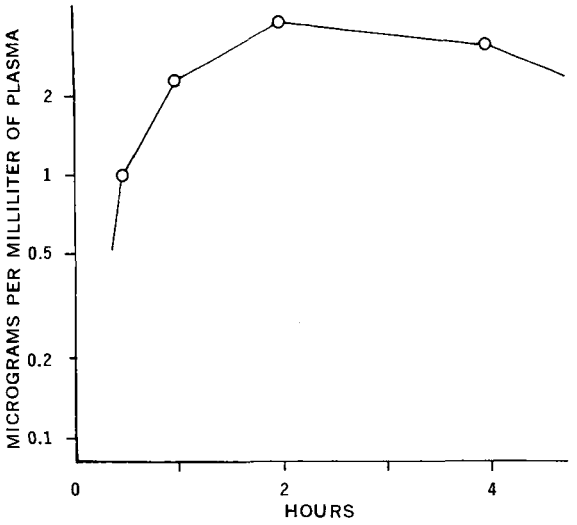

Figure 3—*Plasma concentrations of I in human subject following an oral dose of 3 g of I/m^2 in tablets.*

slow absorption through the GI mucosa. When given orally, I was slowly absorbed in all experiments, although an aqueous solution was used in rats and rabbits. The bioavailability of I is being studied.

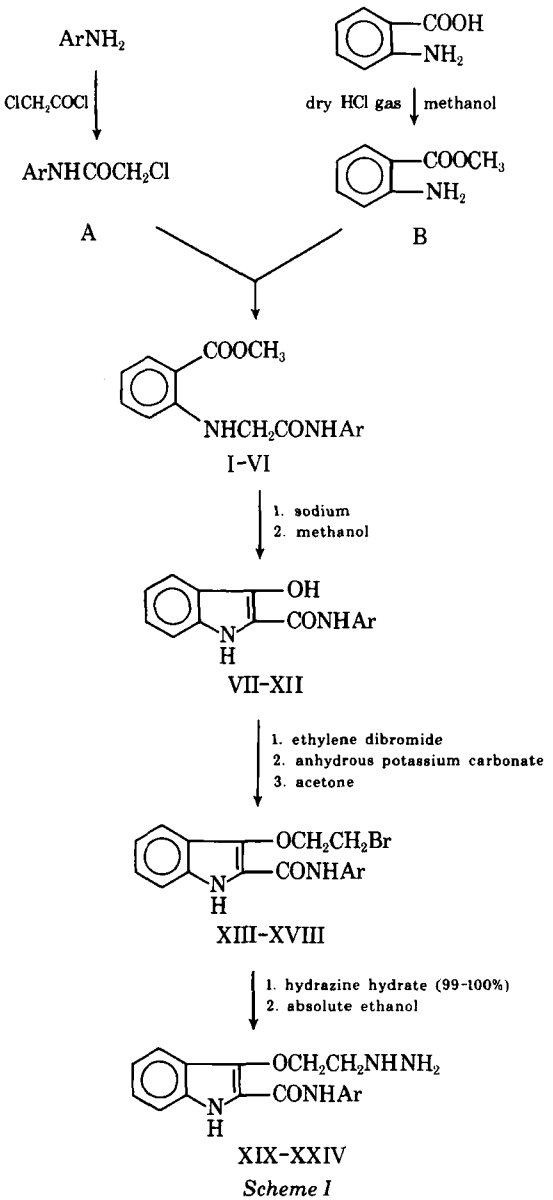

Scheme I

In the present investigation, these indole derivatives were tested for their *in vitro* monoamine oxidase inhibitory property using kynuramine as a substrate and for their *in vivo* monoamine oxidase inhibitory property as evidenced by the reserpine reversal tests. Their anticonvulsant activity against pentylenetetrazol-induced seizures was also determined so that it could be correlated with their monoamine oxidase inhibitory property. These 2-(*N*-arylcarboxamide)-3-substituted ethoxyindoles were synthesized following the steps outlined in Scheme I.

EXPERIMENTAL

Chemistry—Arylamines, on treatment with chloroacetyl chloride, gave *N*-chloroacetyl derivatives (B) which, on reaction with methyl anthranilate (A), gave 2-carbomethoxyphenylglycine-substituted anilides (I–VI). These anilides were cyclized in the presence of sodium and methanol to the corresponding 2-(*N*-arylcarboxamide)-3-hydroxyindoles (VII–XII). These 3-hydroxyindoles were refluxed with ethylene dibromide in the presence of anhydrous potassium carbonate in acetone. This reaction gave 2-(*N*-arylcarboxamide)-3α-bromoethoxyindoles (XIII–XVIII) which, on treatment with hydrazine hydrate, yielded 2-(*N*-arylcarboxamide)- 3α-hydrazinoethoxyindoles (XIX–XXIV).

Analyses for carbon, hydrogen, and nitrogen were performed; melting points were taken in open capillary tubes.

***N*-Chloroacetyl Arylamines (A)**—A mixture of suitable arylamine (0.1 mole) and chloroacetyl chloride (0.11 mole) in dry benzene was refluxed on a steam bath for 4–5 hr. On cooling, the solid mass which separated was filtered, washed with water, dried, and recrystallized (8).

Methyl Anthranilate (B)—Anthranilic acid (0.20 mole) was introduced into absolute ethanol (100 ml) saturated with dry hydrogen chloride gas. The contents were refluxed for 2 hr, and the hot solution was poured into an excess of water. The pH of this solution was adjusted to 7.0 with sodium carbonate solution, and the solution was extracted with ether. The ether extract was dried, and removal of ether yielded methyl anthranilate, mp 23° (9).

2-Carbomethoxyphenylglycine-substituted Anilides (I–VI)—*N*-Chloroacetyl arylamine (0.03 mole) and methyl anthranilate (0.12 mole) were mixed and heated on a steam bath under anhydrous conditions. After 10 hr, 100 ml of dry benzene was added and the separated methyl anthranilate hydrochloride was removed by filtration. Benzene was removed by distillation from the filtrate. The residue was further heated for 8 hr, and the formed hydrochloride was again removed by filtration. The clear benzene solution was washed with 10% H_2SO_4, 10% Na_2CO_3, and water to re-

move excess methyl anthranilate and dried. Excess benzene was removed by distillation; solid anilide, which separated on cooling, was collected by filtration, dried, and recrystallized. Crystals were characterized by their sharp melting points and elemental analyses (Table I).

2-(*N*-Arylcarboxamide)-3-hydroxyindoles (VII–XII)—To a solution of 2-carbomethoxyphenylglycine-substituted anilides (I–VI) (0.015 mole) in 15 ml of dry benzene with a few drops of methanol was added dry sodium (0.017 g-atom). This reaction mixture was refluxed on a steam bath for 2 hr under anhydrous conditions. The reaction mixture was allowed to cool, dry ether was added, and the residue was filtered and dissolved in cold water. The resulting solution was acidified with cold hydrochloric acid (50%), and the separated solid was filtered, dried, and recrystallized from suitable solvents. These crystals were characterized by their sharp melting points and elemental analyses (Table II).

XXIII	>1000	0	100	26.19 ± 0.58
XXIV	>1000	0	100	33.28 ± 0.49

[a] No reserpine reversal response was noted. [b] Compound numbers as given in Table III. [c] Compounds were administered at a dose of 100 mg/kg ip. [d] All values represent the mean with standard error calculated from three separate experiments done in duplicate. All compounds were dissolved in propylene glycol. An equivalent amount of propylene glycol was added to control tubes. Final concentrations of compounds and kynuramine were 2×10^{-4} and 1×10^{-4} *M*, respectively.

hydroxyindoles (VII–XII) in dry acetone was added 0.011 mole of ethylene dibromide and 0.011 mole of anhydrous potassium carbonate. This reaction mixture was refluxed on a steam bath for 15–20 hr. The reaction mixture was filtered, and excess acetone was removed by distillation. The crude product, which separated on cooling, was filtered, dried, and recrystallized from suitable solvents. These compounds were characterized by their sharp melting points and elemental analyses (Table III).

2-(*N*-Arylcarboxamide)-3α-hydrazinoethoxyindoles (XIX–XXIV)—A mixture of 0.004 mole of 2-(*N*-arylcarboxamide)-3α-bromoethoxyindole and 99–100% hydrazine hydrate (0.004 mole) in absolute ethanol was refluxed on a steam bath for 12–15 hr. Excess ethanol was removed by distillation. The crude product, which separated on cooling, was filtered, dried, and recrystallized from suitable solvents. These compounds were characterized by their sharp melting points and elemental analyses (Table III).

Determination of *In Vitro* Monoamine Oxidase Activity—Monoamine oxidase activity of rat brain homogenates, using kynuramine as the substrate, was determined by the spectrophotofluorometric method described by Dwivedi *et al.* (10). The 4-hydroxyquinoline formed during oxidative deamination of kynuramine was measured fluorometrically[1], using activating light of 315 nm and measuring fluorescence at the maximum of 380 nm. The percent inhibition was calculated from the decrease observed in absorbance.

Determination of *In Vivo* Monoamine Oxidase Inhibition by Reserpine Reversal Test—Male healthy mice, 20–25 g, were divided into groups of five and kept in separate cages. A group of five mice was used for each compound. The compounds were administered in a 5% suspension of gum acacia in a dosage of 200 mg/kg ip. Reserpine was administered (5 mg/kg ip) 4 hr after the administration of the compounds.

In the control group of mice, reserpine produced sedation, ptosis, and miosis; in animals pretreated with phenelzine and pargyline, known monoamine oxidase inhibitors, reserpine administration caused excitation, piloerection, mydriasis, and increased motor activity. Animals treated with test compounds were observed for these effects.

Determination of Anticonvulsant Activity—Groups of 10 male mice, 20–25 g, were used. Aqueous suspensions (5% gum acacia) of the test compounds were injected intraperitoneally at a dosage of 100 mg/kg. Pentylenetetrazol (80 mg/kg sc) was administered 4 hr after administration of the test compounds. Animals were observed 60 min for occurrence of seizures (10). The number of animals protected in each group was recorded and the percent protection was calculated. Mortality was recorded 24 hr after pentylenetetrazol treatment.

Determination of Approximate LD_{50}—The approximate LD_{50} was determined by the method of Verma *et al.* (11). All compounds were suspended in 5% aqueous gum acacia and administered intraperitoneally.

[1] Aminco Bowman spectrophotofluorometer.

RESULTS AND DISCUSSION

2-(*N*-Arylcarboxamide)-3-substituted ethoxyindoles inhibit brain monoamine oxidase activity (Table IV). All indole derivatives tested were found to inhibit rat brain monoamine oxidase at a concentration of 2×10^{-4} *M*. The various aryl substituents linked to a carboxamide moiety at position 2 of the indole nucleus have no significant effect on the degree of inhibition, except 2-(*N*-α-naphthylcarboxamide)-3α-hydrazinoethoxyindole (XIX) which produces a relatively higher degree of inhibition. The presence of α-bromoethoxy (XIII–XVIII) and α-hydrazinoethoxy (XIX–XXIV) groups at position 3 of the indole nucleus also had no significant effect on the degree of inhibition.

In vivo monoamine oxidase inhibitory activity of these compounds, as evidenced by the reserpine reversal test, is recorded in Table IV. These indole derivatives (XIII–XXIV) failed to produce a reserpine reversal response as observed with phenelzine and pargyline. These observations revealed that these compounds were inactive in producing *in vivo* monoamine oxidase inhibition.

The anticonvulsant activity of the indole derivatives ranged from 10 to 30% (Table IV). Compounds XIV, XXI, XXIII, and XXIV were completely devoid of anticonvulsant activity. These compounds also had lower protective ability against pentylenetetrazol-induced death. All indole derivatives had an approximate LD_{50} of either 1000 or >1000 mg/kg (Table IV). These data demonstrate the relatively low toxicity of these indole derivatives. No structure–activity relationships were noted.

PHARMACEUTICAL ANALYSIS

GLC Trace Analysis of Dextromethorphan and Bromhexine Salts in Pharmaceutical Preparations

J. L. FABREGAS and A. MARGALET *

Abstract □ GLC proved to be particularly well suited for trace analysis of dextromethorphan and bromhexine salts in different pharmaceutical preparations, using diphenhydramine as the internal standard.

Keyphrases □ Dextromethorphan salts—GLC analysis in pharmaceutical preparations □ Bromhexine salts—GLC analysis in pharmaceutical preparations □ GLC—analysis, dextromethorphan and bromhexine salts in pharmaceutical preparations

Due to its bronchial mucolytic action, bromhexine has been incorporated in pharmaceutical preparations, especially since the preparation of *N*-(2-amino-3,5-dibromobenzyl)-*N*-cyclohexylmethylamine hydrochloride (1). Other studies reported its pharmacology (2), antitussive (3) and bronchosecretolytic activities (4), and metabolism (5, 6).

However, analytical procedures have been inadequate to determine bromhexine and dextromethorphan quantitatively in a pharmaceutical mixture, because of their similar solubilities, analogous UV absorptions (7, 8), and similar colorimetric reactions (9). Methods utilizing GLC analysis of dextromethorphan have been reported (10). None of these methods has been used for the quantitative determination of bromhexine. Under the conditions described here, GLC was particularly well suited for the analysis of dextromethorphan and bromhexine in pharmaceutical formulations containing antibiotics and essential oils.

Table I—Determination of Bromhexine and Dextromethorphan in Pharmaceutical Formulations

Formulation	Label Claim, mg	Range Found, mg	*SD*, mg	*CV*, %
Syrup				
Bromhexine	1.80	1.770–1.801	0.033	1.83
Dextromethorphan	2.90	2.904–2.940	0.037	1.28
Granulation				
Bromhexine	1.80	1.770–1.800	0.033	1.83
Dextromethorphan	2.90	2.860–2.901	0.042	1.45

EXPERIMENTAL

Chromatographic Conditions—A gas chromatograph[1] equipped with a −0.2–1.0-mv recorder[2] was used. A 1.5-m × 0.3-cm (5-ft × 0.125-in.) stainless steel column packed with 3% SE-30 (silicone rubber) on 100–120-mesh Varaport 30 was used. The column temperature was 180°, and the detector and injection port temperatures were 255 and 200°, respectively. The nitrogen carrier gas flow rate was 30 ml/min at 37 psi. A flame-ionization detector was used with a hydrogen flow rate of 30 ml/min and an air flow rate of 300 ml/min. The optimal working attenuation was 8×10^{-10} amp/mv.

Reagents—Carbon tetrachloride and chloroform[3], spectroscopic grade, were used.

Internal Standard—After a number of trials with other materials (codeine, ephedrine, chlorpromazine, and papaverine), diphenhydramine was chosen as the internal standard because of its commercial availability as a pure reagent[4] and its adequate separation from the other compounds, resulting in a symmetrical peak of low retention time (≃2.5 min).

For the internal standard solution, 30 mg of diphenhydramine hydrochloride was extracted with carbon tetrachloride, in alkaline media, following the procedure described for the sample preparation. The combined extracts were dried over anhydrous sodium sulfate and evaporated to dryness, and the residue was dissolved and diluted to 100 ml with carbon tetrachloride.

Preparation of Samples—An accurately weighed sample, containing dextromethorphan and bromhexine salts equivalent to

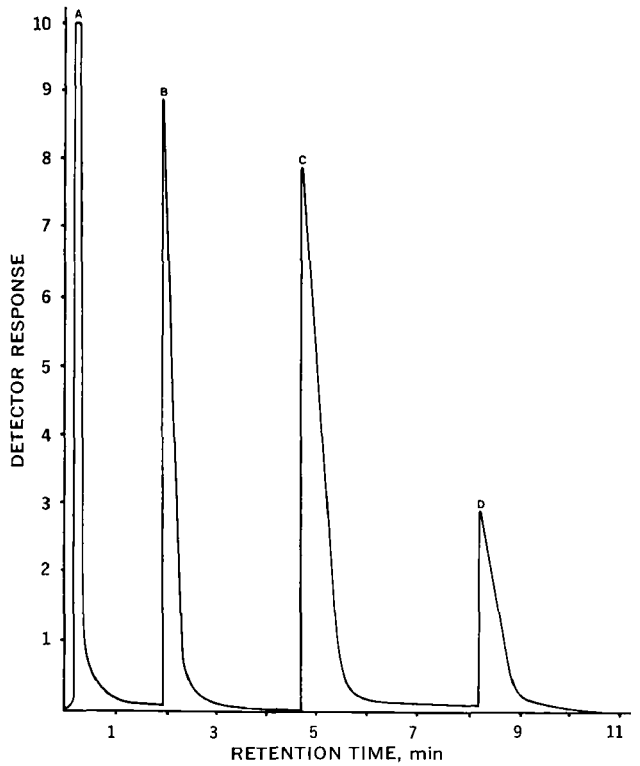

Figure 1—*Typical gas chromatogram. Key: A, chloroform; B, diphenhydramine; C, dextromethorphan; and D, bromhexine.*

2.3–3.2 and 1.4–2.5 mg of the respective bases, was extracted with five 35-ml portions of carbon tetrachloride in alkaline media. To the combined extracts, dried over anhydrous sodium sulfate, was added 5.0 ml of the internal standard solution. After evaporating to dryness, the residue was dissolved in 1.0 ml of chloroform (Solution A).

Preparation of Standards—For the working standard solution, a mixture was prepared of the same dextromethorphan and bromhexine salts[5] that were subjected to analysis and of known content as free bases. Four portions, equivalent to 110, 100, 90, and 80% of the formulation label claim, were accurately weighed and extracted following the procedure described for the sample preparation. To the extracts, dried over anhydrous sodium sulfate, 5.0 ml of the internal standard solution was also added. The resulting solutions were evaporated to dryness, and the four residues were dissolved in 1.0 ml of chloroform.

Assay Procedure—One microliter of the sample (Solution A) and standard solutions was injected into the gas chromatograph. The chromatograph was operated isothermally for the first 2 min, temperature-programmed at 2°/min, and switched to 12°/min just when the dextromethorphan peak reaches its maximum height. Under these conditions, the retention times relative to the internal standard were approximately 2.3 and 3.7 for dextromethorphan and bromhexine, respectively.

[5] The salts used in this study were prepared by the Research Division of Laboratorios Almirall, S.A., Barcelona, Spain.

Calculations—The peak areas were measured by multiplying their peak height times their width at half-height. Two standard curves were then established from the four standard tests by plotting the ratio of peak areas of dextromethorphan base to the internal standard against the weight of dextromethorphan base and the ratio of peak areas of bromhexine base to the internal standard against the weight of bromhexine base.

The concentrations of dextromethorphan and bromhexine bases in the sample were determined by computing the dextromethorphan–internal standard and bromhexine–internal standard peak area ratios, respectively, from the chromatogram and obtaining the corresponding weights from the standard curves. The values so obtained were then converted to percents of these two active ingredients in the original pharmaceutical formulation sample.

RESULTS AND DISCUSSION

To determine the recovery of bromhexine, samples were prepared containing eight different levels of known amounts of bromhexine base (1.55–2.55 mg); the precision of the chromatographic analysis was satisfactory. It was found that a linear relationship existed between the ratios of the observed peak areas of bromhexine base to the internal standard and the actual weight of bromhexine.

The results of this study led to the quantitative analysis of standard mixtures of bromhexine and dextromethorphan salts, with good agreement in the working ranges of 1.40–2.00 and 2.30–3.20 mg of the respective bases for 15 samples.

The results obtained under the experimental conditions and the good performance of the column during several months of continued use clearly indicate the column suitability for the proposed analytical system for conducting quality control assays of dextromethorphan and bromhexine in pharmaceutical preparations. The results are shown in Table I. A typical gas chromatogram is shown in Fig. 1.

Quantitative GLC Determination of Conjugated Estrogens in Raw Materials and Finished Dosage Forms

R. JOHNSON ˣ, R. MASSERANO, R. HARING, B. KHO, and G. SCHILLING

Abstract □ A GLC method is described for the quantitative analysis of conjugated estrogens. The procedure was used for the analysis of various estrogen mixtures obtained from formulations containing estrogen sodium sulfate salts. The method involves slurrying or dissolving a portion of the formulation in pH 5.2 buffer, hydrolysis with sulfatase enzyme, extraction with ethylene dichloride, and, finally, GLC separation and quantitation of the corresponding trimethylsilyl ethers on a 2.5% diethylene glycol succinate column.

Keyphrases □ Estrogen sodium sulfate salt formulations—enzymatic hydrolysis, GLC separation and analysis of conjugated estrogens □ Conjugated estrogen mixtures—enzymatic hydrolysis of estrogen sodium sulfate salt formulations, GLC separation and analysis □ GLC—separation, analysis, conjugated estrogens in estrogen sodium sulfate salt formulations

The analysis of conjugated estrogen mixtures has been the object of many studies. Various techniques such as TLC (1–3), liquid partition chromatography (4), colorimetric analysis (5), and GLC (6–9) have been used to separate and, in some cases, quantitate hydrolyzed estrogen mixtures of varying complexity. Gel permeation chromatography (10) also has been used in the partial resolution of some estrogen mixtures in conjugated form.

However, most reported methods are of limited use in completely separating and quantitating equine estrogen mixtures containing nine or more structurally similar estrogens. In many cases, these methods are not suitable for routine use because they may involve harsh hydrolysis techniques, lengthy extraction and purification steps, long elution times, and/or complex chemistry in the development of characteristic colors prior to quantitation.

These problems initiated the development of an assay method that would conveniently and completely hydrolyze the conjugated estrogens without creating artifacts and that would separate and quantitate the individual free estrogens. GLC appeared to offer the most promising method for separating and quantitating free estrogen mixtures. To accomplish this goal, it was necessary to develop a quantitative procedure for the complete conversion of the steroid conjugates to the free estrogens. After extensive investigation involving hot acid, solvolysis, and enzyme hydrolysis, the enzyme procedure was selected because it provided complete hydrolysis in the presence of tablet and other excipients without causing degradation.

Other criteria imposed and satisfied by this method are that it be relatively rapid, involve a limited number of steps, and offer a high degree of precision and accuracy. The method developed involves enzyme hydrolysis of the estrogen conjugates, a single extraction step, formation of the trimethylsilyl ether derivatives, and, finally, GLC separation on a very polar, selective column. The major estrogen peaks (up to 11) are then quantitated with disk or digital integration, using testosterone as the internal standard.

EXPERIMENTAL

Instrumentation—A research grade gas chromatograph[1] equipped with a U-shaped column and flame-ionization detector, together with a recorder[2] fitted with a disk integrator or equivalent, was used. A silanized (11) 1.8-m (6-ft) U-shaped glass column, 4 mm i.d., was packed with 2.5% diethylene glycol succinate[3] on 100–120 Gas Chrom Q[3]. This packing is prepared by using a 2.0–2.5% solution of the polyester in acetone and by making use of the absorptive properties of the solid support as described previously (12, 13).

Thorough degassing of the solid support under vacuum is also required to get a uniform liquid phase coating and to minimize tailing. The fluidized packing (14) is carefully packed into a column and conditioned with oxygen-free[4] nitrogen carrier gas at 200° overnight at 45 ml/min. Several injections of a silylating reagent[5] are made to achieve a stable baseline. After conditioning and when the column is not in use, the column oven temperature should be lowered to 175°.

Chromatographic Conditions—The following were utilized: column oven temperature, 195 ± 5°; detector temperature, 240°; injection port temperature, 225°; nitrogen flow rate, 45 ml/min; hydrogen flow rate, 40 ml/min; air flow rate, 1.8 S.C.F.H.; and range and attenuation, 100-10-1K (1×10^{-9} amp).

Reagents and Standards—The following required reagents and solvents were all of reagent grade quality or equivalent: 3A ethanol, ethylene dichloride, acetic acid, redistilled dry pyridine, anhydrous sodium sulfate, and anhydrous sodium acetate. The nine free estrogens used to determine chromatographic response factors relative to testosterone[6] were of reference standard quality[7].

Working Enzyme Solution—Sufficient enzyme concentrate[8] is taken and diluted to 50 ml with distilled water to give a working solution containing about 1000 ± 100 units of sulfatase enzyme/ml. All enzyme solutions should be stored at 4° until use.

Buffer Solution—The pH 5.2 buffer is prepared by combining 21.0 ml of 0.2 *M* acetic acid solution and 79.0 ml of 0.2 *M* sodium acetate solution. The solution should be checked on a pH meter and adjusted, if necessary, to pH 5.2 ± 0.1 unit.

Standard Steroid Solutions—Standard solutions of the steroids are prepared in 3A ethanol with the approximate desired concentrations (±10%) as follows: 17α-estradiol, 15 μg/ml; 17β-estradiol, 2 μg/ml; 17α-dihydroequilin, 45 μg/ml; 17β-dihydroequilin, 6 μg/ml; 17α-dihydroequilenin, 6 μg/ml; 17β-dihydroequilenin, 6 μg/ml; estrone, 180 μg/ml; equilin, 90 μg/ml; equilenin, 18 μg/ml; and testosterone, 100 μg/ml.

Standard Solution—One milliliter of each of the ten standards

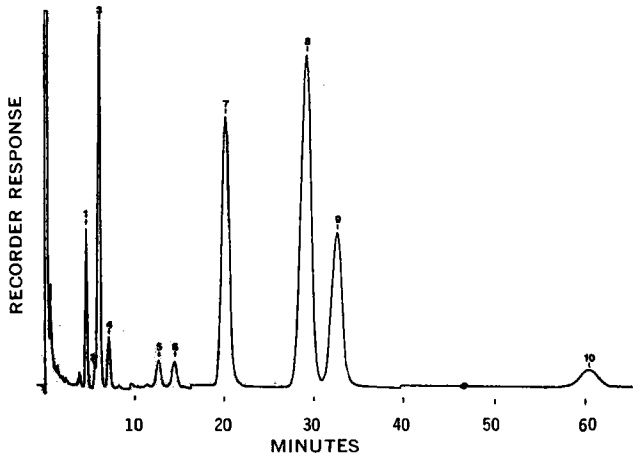

Figure 1—*Separation of the components of a nine-estrogen standard with testosterone as the trimethylsilyl ethers. The peaks with their relative retention times are: 1, 17α-estradiol (0.230); 2, 17β-estradiol (0.272); 3, 17α-dihydroequilin (0.299); 4, 17β-dihydroequilin (0.353); 5, 17α-dihydroequilenin (0.627); 6, 17β-dihydroequilenin (0.714); 7, testosterone (1.00); 8, estrone (1.452); 9, equilin (1.615); and 10, equilenin (2.988).*

is pipetted into a 12-ml centrifuge tube equipped with a Teflon-lined screw cap. Just prior to use, the solutions are evaporated to dryness at 40° in a water bath. The residue is dissolved in 15 μl of pyridine and 65 μl of silylating reagent[5], mixed well, and allowed to stand 15 min prior to injection. (The solution should be refrigerated when not in use and discarded after 24 hr.)

Preparation of Sample Extracts—*Tablets*—Randomly select 10 tablets from the sample and weigh to the nearest 0.1 mg. Place them in a mill[9] with one large and one small steel ball and mill them for 3 min. Collect the powder in an amber bottle and weigh a portion to the nearest 0.1 mg into a 60-ml (2-oz) extraction bottle fitted with a Teflon-lined screw cap. The sample weight should be approximately equivalent to one tablet so that from 0.3 to 2.5 mg of conjugated estrogens is taken for assay.

Add 15 ml of pH 5.2 buffer to the bottle and cap tightly. Shake mechanically for 0.5 hr, sonify for 30 sec in a sonic bath, and shake for an additional 0.5 hr. Add approximately 1000 units of sulfatase enzyme to the bottle and incubate for 20 min with shaking in a 50 ± 2° water bath. Immediately, without cooling the enzyme hydrolysate, pipet 15 ml of ethylene dichloride into the bottle, cap tightly, and shake mechanically for 15 min. Centrifuge the bottle at ~2000 rpm for 10 min and repeat if necessary to obtain a clear lower layer. Remove as much of this ethylene dichloride layer as possible and filter through a small amount of sodium sulfate (~5 g) in a 3.5-cm plastic funnel, containing a glass wool plug, into a 12-ml centrifuge tube.

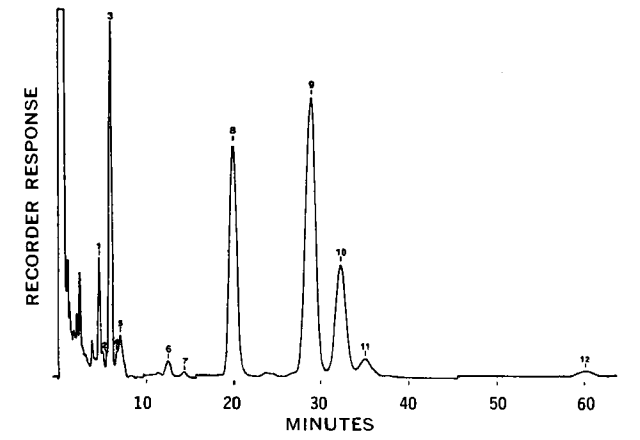

Figure 2—*Separation of a mixture of estrogen trimethylsilyl ethers derived from Sample A (see Table II). The peaks with their relative retention times are: 1, 17α-estradiol (0.235); 2, 17β-estradiol (0.280); 3, 17α-dihydroequilin (0.304); 4, iso-17α-dihydroequilin (0.337); 5, 17β-dihydroequilin (0.356); 6, 17α-dihydroequilenin (0.624); 7, 17β-dihydroequilenin (0.715); 8, testosterone (1.00); 9, estrone (1.443); 10, equilin (1.604); 11, Δ[8,9]-dehydroestrone (1.743); and 12, equilenin (2.980).*

Table I—Characteristics of Different Batches of Diethylene Glycol Succinate Liquid Phase

Measurement	Batch 1922	Batch 1989
IR, cm^{-1}	3530, 3460, 3260, 2960, 2880	3550, 3470, 2970, 2900
TGA	Two-step weight loss curve	Single-step weight loss curve
Viscosity[a], centistokes	0.646	0.739
Titration[b], mEq H^+/g	1.00	0.143
Water[c], %	1.03	0.86

[a] These are relative measurements obtained on a 5% solution of polymer in acetone at 25° using a Ubbelohde viscometer, model 1B-290. [b] The polymer was dissolved in dimethylformamide and titrated with tetrabutylammonium hydroxide in benzene–methanol (8:1). [c] The Karl Fischer method was used.

Injectable Vials—Carefully remove the caps from five lyophilized vials and add 5 ml of water to each vial. Recap, shake to dissolve the cake, pipet 2 ml from each vial into a 25-ml volumetric flask, and then dilute to volume. Pipet 1 ml into a 60-ml (2-oz) extraction bottle fitted with a Teflon-lined screw cap and add 15 ml of pH 5.2 buffer and 1000 units of sulfatase enzyme. Proceed with the hydrolysis and remaining steps described under *Tablets*.

Raw Materials—Given an approximate potency for the powdered sample, weigh one sample containing about 7.5 mg of conjugated estrogens into a 120-ml (4-oz) extraction bottle fitted with a Teflon-lined screw cap. Pipet 75 ml of pH 5.2 buffer into the bottle and shake mechanically for 10 min. Sonify the sample for 0.5 min in a sonic bath and then shake for an additional 5 min. Immediately pipet 15 ml of uniform suspension into a 60-ml (2-oz) extraction bottle. Add 1000 units of sulfatase enzyme and proceed with the hydrolysis and remaining steps under *Tablets*.

Instrument Standardization—Once the instrument has reached its operating temperature, the column should be conditioned with several injections of silylating reagent until a stable baseline is obtained. Inject about 2–4 μl of silylated standard and adjust the sample size and/or instrument attenuation so the major peaks (17α-dihydroequilin, testosterone, and estrone) are greater than 70% of full-scale deflection. To establish the identity of the standard estrogen peaks, compare their relative retention times (RRT) *versus* testosterone with those indicated in Fig. 1.

Measure accurately the areas of the estrogen and testosterone peaks using disk integration. Assume an exponential decay of the solvent peak and draw in this curve to meet the observed baseline points after 17α-estradiol and after 17β-dihydroequilin. Drop perpendiculars from each valley between the pertinent peaks to the projected baseline. This procedure will allow proper allocation of the peak areas to the estrogens involved.

Using the measured peak areas and known concentrations, calculate a response factor (RF) for each of the nine estrogens as follows:

$$RF = \left(\frac{A_t}{C_t}\right)\left(\frac{C_e}{A_e}\right) \qquad \text{(Eq. 1)}$$

where A_t = area of testosterone peak, C_t = micrograms of internal standard (testosterone) in standard, C_e = micrograms of estrogen in standard, and A_e = area of estrogen peak.

The standard is injected again following the last sample scan of

Table II—Compositions of Various Commercial Samples Containing Mixtures of Estrogen Sodium Sulfate Salts[a]

[a] These numbers represent an average of two separate determinations. [b] All components are expressed as the estrogen sodium sulfate salts. [c] Values are reported as milligrams per tablet, and samples have a label claim of 1.25 mg of conjugated estrogens/tablet. [d] Samples have a label claim of 0.625 mg of conjugated estrogens/tablet, and all values are reported as milligrams per tablet. [e] Sample of international origin has a label claim of 1.00 mg of conjugated estrogens/tablet with values as milligrams per tablet. [f] An international sample with a label claim of 20 mg/vial with all values reported as milligrams per vial. [g] A sample of international origin with a label claim of 25 mg/vial with values reported as milligrams per vial. [h] Powdered raw material samples with values reported as milligrams per gram.

the day, and the RF's are calculated and averaged with the first run. The average RF's are then used in subsequent sample calculations.

Chromatographic Analysis—Inject a portion of silylated sample. The injection size and/or instrument attenuation should again be adjusted to keep the major peaks greater than 70% of full scale. The sample estrogen peaks can be identified by comparing their RRT's *versus* testosterone with those indicated on the sample GLC scans (Figs. 2–4). Accurately measure the areas of the estrogen and testosterone peaks using disk integration.

For the peak clusters that are not completely resolved, the areas are allocated by dropping a perpendicular from the minimum to a baseline projected across the base of the peak group. For the quantitation of two naturally occurring double bond isomers, iso-17α-dihydroequilin and $\Delta^{8,9}$-dehydroestrone, two approaches can be taken. They can be listed separately and quantitative values can be reported for each, or their areas can be added to the areas of 17α-dihydroequilin and equilin, respectively, since they are structurally closely related. For this study the second approach is used since it allows a more direct comparison of the GLC values obtained here with those values obtained using an official method (17). With this procedure, a single injection from each of four samples can be assayed in between two injections of the standard on a single column in 1 day.

The weight of the individual conjugated estrogens present in the samples is calculated from the response factors, the sample peak areas, and the constant; the weights of the individual species are then summed to get the total weight of conjugated estrogens present in the sample as follows:

$$\text{weight conjugated estrogens} = \text{constant } (RF_e)(A_e) = \frac{\text{mg conjugated estrogens}}{\text{unit dosage form (tablet, vial, grams)}} \quad \text{(Eq. 2)}$$

and:

$$\text{constant} = \frac{15 \text{ ml } (1.38)(10^{-3} \text{ mg}/\mu\text{g})(C_t)}{x \text{ ml } (y)(A_t)} \text{ (dilution factor)} \quad \text{(Eq. 3)}$$

where:

15 ml = extract volume of ethylene dichloride
1.38 = factor for converting "free" estrogens into their corresponding estrogen sodium sulfate salts
10^{-3} mg/μg = conversion factor for micrograms to milligrams
C_t = micrograms of testosterone in sample
dilution factor = inverse of any additional dilution of any sample
x ml = number of milliliters of ethylene dichloride extract taken for assay
y = equivalent number of dosage form units taken into the assay (tablets, vials, grams)
A_t = area of testosterone peak in sample

RESULTS AND DISCUSSION

Sample Preparation—During the early phases of this development work, attempts were made to extract the estrogen conjugates from tablet or formulation excipients. Initial results from recovery studies of estrone sodium sulfate from placebo tablets showed some small and unreproducible losses. Also, the multiple extractions required proved tedious and time consuming. Therefore, the technique of suspending a portion of the powdered formulation in buffer, in the presence of sulfatase enzyme, was tried. This straightforward simple procedure was found to give consistent, quantitative recoveries.

Various studies with mineral acid hydrolysis of estrogen conjugates (15, 16) have shown that side reactions and steroidal transformations frequently occur. Since interest was in measuring the original components of the mixture without creating artifacts during workup, acid hydrolysis was not used.

The level of enzyme necessary to achieve complete hydrolysis in the presence of excipients was also studied. Earlier work with very high levels of enzyme indicated that protein binding of the estrogens and thick emulsions would be problems. The lower levels of enzyme used in this method (~1000 units of arylsulfatase/0.3–2.5 mg of conjugated estrogens) give complete hydrolysis of the conjugated estrogens within a short time without causing sample preparation problems. A more detailed study of the enzyme procedure will appear elsewhere.

Approximately 45 tablet samples from almost as many different manufacturers were assayed with this method. For two samples, the enzyme levels specified here were not high enough to achieve

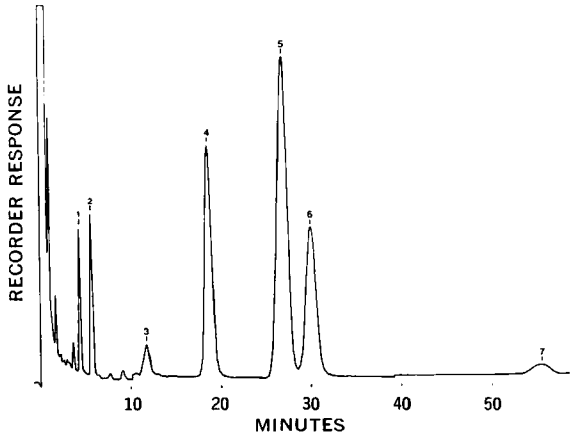

Figure 3—*Separation of a mixture of estrogen trimethylsilyl ethers derived from Sample D (see Table II). The peaks with their relative retention times are: 1, 17α-estradiol (0.233); 2, 17α-dihydroequilin (0.299); 3, 17α-dihydroequilenin (0.626); 4, testosterone (1.00); 5, estrone (1.441); 6, equilin (1.604); and 7, equilenin (2.957).*

where R = 
complete hydrolysis, because of the presence of certain tablet excipients that inhibited enzyme activity. A 5–20-fold increase in enzyme activity was necessary to get complete hydrolysis and consistent recoveries in these two instances. Phosphate, a known inhibitor of sulfatase activity, was found in these two samples.

Chromatography—A systematic study of a large number of liquid phases was carried out in an attempt to resolve complex estrogen mixtures of the type obtained from pregnant mare's urine. These mixtures are known to contain estrone, equilin, equilenin, 17α- and 17β-estradiols, 17α- and 17β-dihydroequilins, and 17α- and 17β-dihydroequilenins (1); the structures of these steroids as the sodium sulfate salts are as shown (I–IX).

Only two commercial liquid phases were found, both of which were polyesters (ethylene glycol succinate and diethylene glycol succinate), that did separate the major components of the estrogen mixture. The diethylene glycol succinate, however, offered the most promise because of its slightly improved thermal stability and its ability to perform the separation of the estrogen trimethylsilyl ethers in a reasonable time. Two major estrogens, estrone and equilin, from urinary equine extracts are almost completely resolved on this column, and excellent quantitative results can be obtained. To the knowledge of the authors, a quantitative GLC method that allows the direct determination of estrone and equilin simultaneously has not been reported previously.

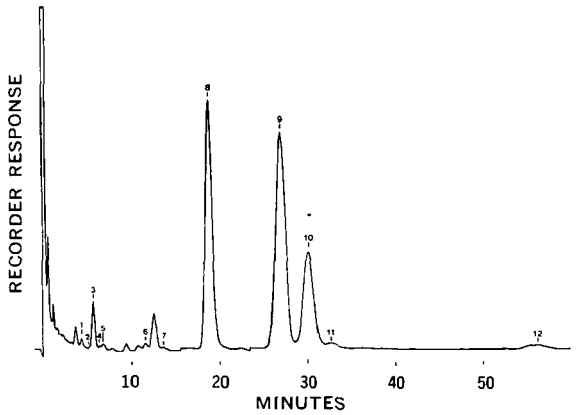

Figure 4—*Separation of a mixture of estrogen trimethylsilyl ethers derived from Sample I (see Table II). The peaks with their relative retention times are: 1, 17α-estradiol (0.232); 2, 17β-estradiol (0.281); 3, 17α-dihydroequilin (0.300); 4, iso-17α-dihydroequilin (0.333); 5, 17β-dihydroequilin (0.355); 6, 17α-dihydroequilenin (0.609); 7, 17β-dihydroequilenin (0.721); 8, testosterone (1.00); 9, estrone (1.427); 10, equilin (1.592); 11, $\Delta^{8,9}$-dehydroestrone (1.734); and 12, equilenin (2.969).*

The repeated preparation of diethylene glycol succinate columns showed that not all columns gave the same degree of peak resolution and peak symmetry. Some difference existed between the batches of liquid phase obtained from the same source. Therefore, IR, viscosity, thermogravimetric analysis (TGA), titration, and water measurements were made in an attempt to pinpoint the factors accounting for variations in the quality of the batches of polymer tested. The results are summarized in Table I for two batches of diethylene glycol succinate, one of which gave an excellent column packing (Batch 1922) and the other a poor packing (Batch 1989).

Interpretation of the data in Table I allows several conclusions to be made about the relative differences between the two batches of liquid phase tested. The batch of diethylene glycol succinate giving a high quality packing is more acidic (by both IR and titration) and has a lower viscosity; furthermore, the two-step TGA curve suggests that a wide range of molecular weight polymer units is present since a weight loss occurs at a temperature believed to be below the degradation temperature (~225°). These techniques and relative values are now being used on a routine basis to evaluate new batches of liquid phase prior to use.

In an attempt to control operator performance in reproducibly preparing the packings, TGA is used to monitor all new column packings. An acceptable weight range for the liquid phase loading varies from about 2.0 to 2.5%.

Quantitation—The quantitative composition of 12 different commercial samples containing conjugated estrogens is found in Table II. The table includes results for tablets of varying strengths together with raw material samples; the numbers represent an average of two individual determinations. The data clearly show the gravimetric quantities of all individual estrogenic components present in the samples for the first time. By summing these values, a total potency value is obtained which may differ significantly and is usually higher than the potency value obtained using an official method (17).

SUMMARY

A GLC method was developed for the quantitative analysis of complex mixtures containing conjugated estrogens. The method was used on both raw materials and finished dosage forms. It allows, for the first time, a complete delineation and quantitation of the conjugated estrogens present in extracts derived from preg-

nant mare's urine. Since the quality of the diethylene glycol succinate liquid phase and packed column is critical to the success of the method, details are provided relating to their use and conditioning.

Preliminary collaborative testing is underway to evaluate the use of this procedure as a routine control method. This method has also been used for the analysis of free estrogens, which might be present in formulations containing conjugated estrogens, by simply omitting the hydrolysis step and carrying out the balance of the procedure.

Analysis of Pholcodine in Cough Preparations

JACOB S. SHOHET

Abstract □ A rapid and simple method for the assay of pholcodine in various syrup and linctus formulations, based on color reaction with *p*-dimethylaminobenzaldehyde, is suggested. At specified conditions, the results obtained show good reproducibility.

Keyphrases □ Pholcodine—analysis in cough preparations □ Antitussives—analysis of pholcodine in cough preparations □ *p*-Dimethylaminobenzaldehyde—reagent, analysis of pholcodine in cough preparations

Pholcodine resembles codeine in its action as a cough suppressant for the relief of unproductive cough. It has some pharmacological advantages over codeine including the absence of side effects such as constipation and other withdrawal symptoms (1).

Although pholcodine, like codeine, is a common component in syrups and linctus formulations, little has been written concerning the assay methods of pholcodine in pharmaceutical preparations. It is often the sole active component in a preparation[1] but may be combined with ephedrine hydrochloride, papaverine hydrochloride, promethazine, *etc.*

[1] Examples for such preparations are Copholco (Wade Co.), Falcodyl (Norton), Sancos (Sandoz), *etc.*

DISCUSSION

Pholcodine linctus formulations have appeared in the BPC (2). The official assay procedure involves extraction with chloroform from an alkaline solution followed by nonaqueous titration. The accuracy of the method depends on the purity of inactive components, such as sucrose, sorbitol, glycerol, citric acid, and chloroform spirit, used in the formulation. Since these components constitute the majority of the linctus weight, any impurity may introduce error. Theoretically, this difficulty would be overcome by running a blank linctus containing all components except pholcodine. However, since there are so many formulations and variations, running a blank cannot be considered a practical solution. This method also suffers from the use of a relatively dilute titrant (0.02 *N* $HClO_4$) which affects the sharpness of the end-point.

No method or modification has been proposed (2) for the assay of pholcodine combined with other drugs. The nonaqueous titration cannot be applied, since the free bases of most drugs commonly formulated with pholcodine are miscible in chloroform and would be titrated simultaneously with the pholcodine. This is the case with ephedrine, pseudoephedrine, oxomemazine, promethazine, codeine, promazine, papaverine, chlorpheniramine, trimeprazine, *etc.* Other methods of analysis of pholcodine in syrups are the reaction with hexamethylenetetramine–lactose reagent (3) (ephedrine interferes) and TLC (4, 5).

The method proposed in this paper utilizes the reaction of pholcodine with *p*-dimethylaminobenzaldehyde in strong acidic medium. Under the specified conditions, reproducible results are obtained in the assay of pholcodine when formulated alone or in combination with other drugs. The present method also has the

advantage of determining pholcodine without preliminary separation from other combined drugs.

EXPERIMENTAL

Reagents and Chemicals—The following were used: dilute sulfuric acid, 10% (w/v); dilute ammonium hydroxide, 10% (w/v); chloroform (analytical reagent) and ether (analytical reagent); and pholcodine standard BP.

p-Dimethylaminobenzaldehyde reagent was prepared just prior to use by dissolving 1 g of *p*-dimethylaminobenzaldehyde (analytical reagent) in 100 ml of sulfuric acid, 70% (w/v).

Standard Solution—A solution of pholcodine standard, 0.4 mg/ml, was prepared by dissolving the solid in dilute sulfuric acid.

Sample Solution—An accurately weighed portion of syrup or linctus, equivalent to about 20 mg of pholcodine, was transferred into a 125-ml separator. The sample was made alkaline by addition of dilute ammonium hydroxide solution. The mixture was extracted successively with four 30-ml portions of chloroform. The chloroform extracts were combined, washed with 10 ml of distilled water, and evaporated to dryness. The residue obtained was dissolved in dilute sulfuric acid and diluted to a volume of 100 ml.

Procedure—Volumes of 0.5 ml of sample and standard solutions were separately transferred, in triplicate, into a series of test tubes. Dilute sulfuric acid (0.5 ml) was pipetted into another test tube to serve as a blank. *p*-Dimethylaminobenzaldehyde reagent (10 ml) was added; after vigorous shaking, the tubes were transferred into a water bath maintained at 60°. After 10 min, the tubes were removed and quickly cooled to room temperature. At 0.5 hr after removal from the bath and cooling to room temperature, the absorbance was read at a wavelength of 450 nm against blank reagents.

If the syrup contains orange extract, two preliminary extractions are necessary using a mixture of 15 ml of ether and 1 ml of dilute sulfuric acid. Then the procedure is followed beginning with "The sample was made alkaline . . ." under *Sample Solution*.

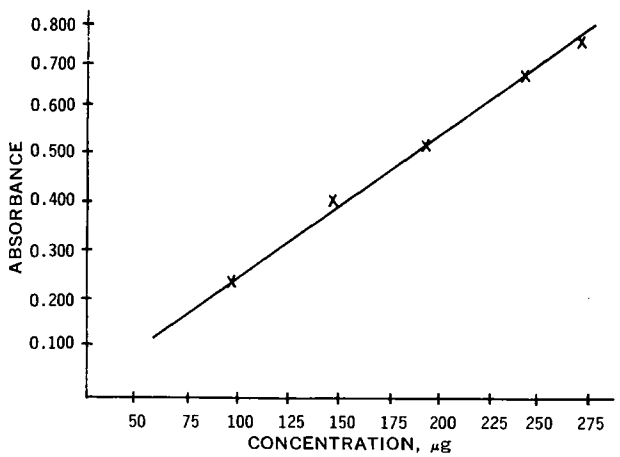

Figure 1—*Standard curve for pholcodine.*

RESULTS

When this method was tested on pholcodine samples containing various amounts of the drug, strict obedience to the Beer–Lambert law was achieved over the range of 50–250 μg of pholcodine (Fig. 1).

Both the accuracy and precision of the proposed method were checked on drug mixtures simulating existing commercial pharmaceuticals. Table I represents the composition of the pharmaceuticals, the labeled amounts of the active components, the amounts of pholcodine found by triplicate analysis, and the related interpretation of data. As shown, high accuracy and a small acceptable coefficient of variation were obtained. Table I also shows that the reaction of pholcodine with *p*-dimethylaminobenzaldehyde is specific as far as combination with common drugs is concerned.

The dependence of the absorbance on time, measured on samples just cooled to room temperature, is summarized in Table II. According to Table II, the color of the reaction product is sufficiently stable. The color reaction of pholcodine with *p*-dimethylaminobenzaldehyde is as sensitive as that of codeine with the same reagent (6, 7). The reaction mixture of codeine is not stable in light, but the reaction of pholcodine is not affected by such limitations.

Table II—Dependence of Absorbance on Time

Minutes	Absorbance	Change in Absorbance, %
0	0.485	—
5	0.485	—
10	0.488	0.62
20	0.492	1.44
30	0.496	2.27
60	0.505	4.13

Determination of Iodochlorhydroxyquin and Corticosteroids in Pharmaceutical Formulations

ROBERT E. GRAHAM *x, CHARLES T. KENNER ‡, and E. R. BIEHL ‡

Abstract □ Iodochlorhydroxyquin was separated from various corticosteroids using an acetonitrile–diatomaceous earth column. Iodochlorhydroxyquin was eluted with cyclohexane, and the corticosteroid was eluted with chloroform. Iodochlorhydroxyquin was determined by both a UV absorbance method and a new complexiметric method using the nickel chelate of iodochlorhydroxyquin. The corticosteroid was determined by the blue tetrazolium and isoniazid procedures. The average percent recovery for these four methods was 100.8, 99.4, 100.7, and 99.9, respectively, for 10 known mixtures. The standard deviation for the absorbance for 10 determinations of the nickel complex was 0.002 absorbance unit (0.31%). Various characteristics of the nickel and other complexes were evaluated, including the sensitivity, solubility, and wavelength of maximum absorbance in 14 different solvents. The analyses of 23 typical products are reported, for which the standard deviation, expressed as a percentage of the amount declared, was 1.31% for the UV, 1.34% for the complexiметric, 1.49% for the blue tetrazolium, and 1.22% for the isoniazid procedures. Methods of determination in the presence of interferences are discussed.

Keyphrases □ Iodochlorhydroxyquin and corticosteroid formulations—partition chromatographic separation, complexiметric analysis of iodochlorhydroxyquin, blue tetrazolium analysis of corticosteroid □ Corticosteroid and iodochlorhydroxyquin formulations—partition chromatographic separation, complexiметric analysis of iodochlorhydroxyquin, blue tetrazolium analysis of corticosteroid □ Partition chromatography—separation, iodochlorhydroxyquin and corticosteroid formulations □ Nickel complex formation—analysis, iodochlorhydroxyquin after separation from iodochlorhydroxyquin and corticosteroid formulations

The "American Drug Index 1973" (1) lists 36 manufacturers of pharmaceutical formulations that contain iodochlorhydroxyquin (5-chloro-7-iodo-8-quinolinol) (I). Five of these manufacturers prepare products containing only I, while 33 manufacture products containing I plus a corticosteroid such as hydrocortisone, hydrocortisone acetate, or prednisolone.

USP XVIII (2) specifies an IR procedure that is specific for I in creams, ointments, and suppositories. NF XIII (3) requires the same IR technique to determine I in creams, lotions, and ointments containing I plus hydrocortisone and uses the blue tetrazolium method for the corticosteroid. IR methods specific for I in pharmaceutical products were described (4, 5), but these procedures are difficult to use due to the volatility and odor of the carbon disulfide and the small volumes required in the extraction step.

Other reported methods include UV absorption (3), gravimetry (3), combustion in an oxygen flask followed by titration (6), polarography (7), fluorescence (8), GLC (9), and spectrophotometry (10–12). Spectrophotometric methods depend upon the formation of a colored metallic complex with I. The iron (III) complex (10, 11) and the copper (II) complex (12) have been utilized for the determination of I in certain pharmaceutical products.

This paper reports a simple, rapid, quantitative method for the separation of I from corticosteroids by partition chromatography using the diatomaceous earth–acetonitrile column described previously (13, 14). After separation, I is determined by conversion to the nickel complex and measurement of the absorption at 406 nm while the corticosteroid is analyzed by the blue tetrazolium procedure of USP XVIII (15). Twenty-one different pharmaceutical formulations of creams, lotions, ointments, and suspensions were analyzed by the proposed method. When necessary, the method may be supplemented by the use of IR (3), GLC (9), or TLC (16) to detect the presence of impurities such as 8-hydroxyquinoline, 5-chloro-8-hydroxyquinoline, 5-iodo-8-hydroxyquinoline, 5,7-diiodo-8-hydroxyquinoline, and 5,7-dichloro-8-hydroxyquinoline.

EXPERIMENTAL

Equipment—The following were used: a UV–visible recording

9	99.6	100.6	101.6	100.8
10	99.4	101.1	99.3	98.6
Average	99.4	100.8	100.5	99.9
SD[b]	0.3	0.3	1.0	0.7

[a] Each standard mixture contained approximately 6 mg of iodochlorhydroxyquin and 1 mg of hydrocortisone. [b] Calculated from the range by the method of Dean and Dixon (18).

spectrophotometer[1] with 1-cm quartz cells, a glass chromatographic column (2.2 × 25 cm constricted at one end to 0.4 × 5 cm) plus aluminum tamping rod, and an electrobalance[2].

Reagents—*Solvents*—All solvents were spectrograde, analytical reagent grade, pesticide grade, USP, distilled-in-glass, or nanograde. Absolute ethanol, acetone, acetonitrile, alcohol USP, carbon tetrachloride, chloroform, cyclohexane, dimethyl sulfoxide, dioxane, acetic acid, *n*-heptane, *n*-hexane, methanol, methylene chloride, and 2,2,4-trimethylpentane were used.

Acetonitrile–Cyclohexane (Mutually Saturated)—Mix 20 ml of acetonitrile and 270 ml of cyclohexane (sufficient for two determinations plus a reagent blank) in a separator, agitate vigorously for 2 min, and allow to stand with occasional swirling until both layers are clear. These mutually saturated solutions must be used whenever acetonitrile or cyclohexane is called for in these directions.

Chloroform (Water Saturated)—Add 50 ml of water to 250 ml of chloroform in a separator, agitate for 2 min, and allow both layers to clarify. This water-saturated reagent is required when aqueous trap layers are inserted but should not be used otherwise.

Diatomaceous Earth[3]—Acid washed was used.

Nickel Reagent (0.010 M)—Dissolve 248.8 mg of nickel (II) acetate tetrahydrate in absolute ethanol with heating on a steam bath. Cool and dilute to 100.0 ml with absolute ethanol. This solution is stable for at least 6 months. Other metal-ion reagents (0.050 *M*) were prepared for method development studies using the acetates in ethanol or methanol.

Standards—All solid standards were USP or NF reference standards. Prepare corticosteroid standards (0.0100 mg/ml) in alcohol USP and I standards (0.0600 mg/ml) in cyclohexane. Individually weighed samples of the standards were used in some studies.

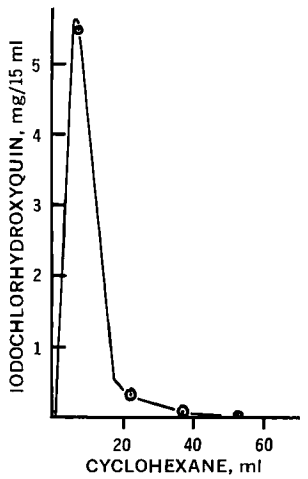

Figure 1—*Elution curve for iodochlorhydroxyquin.*

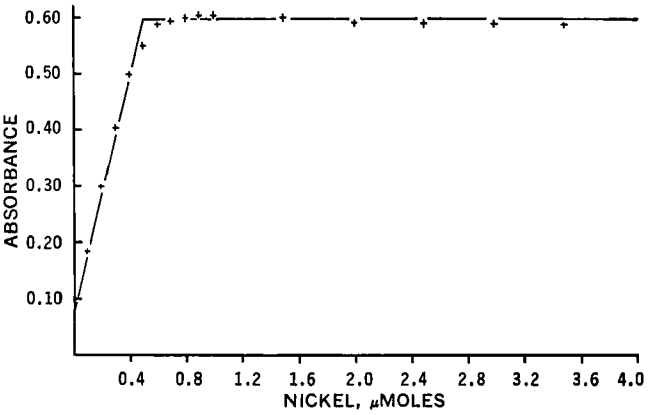

Figure 2—*Mole ratio study for nickel–iodochlorhydroxyquin complex.*

Sample Preparation—*Creams, Ointments, Lotions, Jellies, and Suspensions*—Prepare a composite sample by mixing thoroughly the contents of several containers and accurately weigh a sample equivalent to about 6 mg of I into a 100-ml beaker. Dissolve in 1.5 ml of acetonitrile plus 1.5 ml of cyclohexane with slight warming on a steam bath (1.5 ml of methanol plus 1.5 ml of water may be substituted for these solvents when necessary for complete solution of the formulation). Continue as directed under *Sample Layer*.

Standards—Accurately weigh (or pipet volumes that contain) about 1 mg of corticosteroid and 6 mg of I into a 100-ml beaker. Proceed as directed in *Creams, Ointments, Lotions, Jellies, and Suspensions*, beginning with "Dissolve in 1.5 ml of acetonitrile plus . . . ."

Column Preparation—*Acetonitrile Layer*—Insert a glass wool plug in the bottom of a chromatographic column. Thoroughly mix 4.0 g of diatomaceous earth with 4.0 ml of acetonitrile, transfer to the column, and pack firmly.

Trap Layer—Prepare and insert a neutral aqueous trap layer, as needed, according to Graham *et al.* (14).

Sample Layer—Thoroughly mix the dissolved sample or standard, prepared as directed under *Sample Preparation*, with 3.0 g of diatomaceous earth. Transfer to the column above the acetonitrile or trap layer and pack firmly. Dry wash the sample beaker, tamping rod, spatula, and funnel with 1 g of diatomaceous earth and transfer to the column. Dry wash the same equipment with

Table II—Characteristics of Complexes in Various Solvents

SD[d]		1.31	1.34	1.49	1.22

[a] Components present in each sample are listed in Table IV. [b] Number in parentheses indicates number of determinations. [c] Not determined due to interference in UV spectra caused by a cyclohexane-soluble complex or an ingredient other than I. [d] Expressed as percent of amount declared calculated from the difference in duplicates (20).

glass wool, transfer to the column, and pack firmly. Retain the beaker for washing with cyclohexane and chloroform during the *Column Elution* step.

Column Elution—*Compound I*—Wash the beaker successively with six 20-ml portions of cyclohexane and pour into the column, maintaining the liquid head between 8 and 12 cm above the column bed and catching the effluent in a 100-ml volumetric flask since the column holds up approximately 23 ml. Allow the last wash to drain completely, wash the tip of the column with cyclohexane, make the effluent to volume, and retain for determination as described under *Determinative Procedures*.

Corticosteroids—Rinse the sample beaker with 125 ml of chloroform in several portions and pour each through the column, maintaining the liquid head as close to the top of the column as possible and catching the effluent in a 150-ml beaker. Allow the last portion to drain completely from the column and rinse the tip with alcohol USP. Carefully evaporate the effluent just to dryness on a steam bath in a hood with a current of air to ensure complete removal of the acetonitrile. Dissolve in alcohol USP and dilute accurately to a volume containing approximately 10 μg/ml of corticosteroid. Retain for determination as directed under *Determinative Procedures*.

Determinative Procedures for I—*Ultraviolet Method*—Mix the cyclohexane effluent thoroughly and scan from 500 to 280 nm *versus* cyclohexane as the reference. Measure net absorbance from the baseline to the absorbance maximum at 326 nm. Calculate by comparison with standards run concurrently.

Complexiметric Method—Pipet 5.00-ml aliquots of the cyclohexane effluents for each sample and standard into small glass-stoppered flasks. Prepare a reagent blank using 5.00 ml of cyclohexane. To each flask, add 0.1 ml of nickel reagent, swirl, let stand for at least 1 min, and then scan from 500 to 340 nm *versus* the reagent blank. Measure the net absorbance of the maximum at 406 nm and calculate by comparison with the standards run concurrently.

Determination Procedures for Corticosteroids—*Isoniazid Method*—The procedure of Umberger (17) was used, except that the concentration of hydrochloric acid was doubled to increase the sensitivity.

Blue Tetrazolium Method—The procedure given in USP XVIII (15) was followed without modification.

METHOD DEVELOPMENT

Column Characteristics—*Elution*—A column was prepared as directed under *Column Preparation*, using 6.050 mg of standard I and fitting the column with a separator to allow the maintenance of a 12-cm liquid head which ensured a constant flow rate of 7 ml/min. A total of 285 ml of cyclohexane was collected in 15-ml fractions. Each fraction was taken to dryness carefully under air on a steam bath, dissolved in and diluted to an appropriate volume with acetic acid, and scanned from 500 to 280 nm.

The elution curve shown in Fig. 1 indicates that all of I is completely eluted in the first 60 ml of cyclohexane. In the proposed procedure, the column holds up approximately 23 ml of the 120 ml of cyclohexane used so that the retention of 97 ml provides an adequate safety factor. In several cases, a second 100 ml of cyclohexane was poured through the column. No I was found in any of these effluents. Tests on several alcoholic extracts remaining from the corticosteroid determinations also were negative for I.

Separation and Recovery—Ten separate standard mixtures containing approximately 6 mg of I and 1 mg of hydrocortisone were analyzed by the proposed procedure using all four determinative methods (Table I). The overall average recovery was 100.2%, and the overall average standard deviation was less than 0.6%. Portions of each sample effluent were evaporated, dissolved in small volumes, spotted on TLC plates, and chromatographed. In each case, a single spot appeared, showing complete separation.

Characteristics of the Nickel–I Complex—*Beer's Law*—During the investigation, samples containing 0.030–0.83 mg of I/5.1 ml showed a linear relationship between absorbance and concentration.

Mole Ratio—The mole ratio study (Fig. 2) showed that the complex contained 2 moles of I for each mole of nickel.

Absorbance Replication—Ten separate 5.00-ml aliquots of standard I in cyclohexane were pipetted into small glass-stoppered flasks, 0.1 ml of nickel reagent was added, and the resulting solutions were scanned from 500 to 340 nm. The average net maximum absorbance at 406 nm was 0.645 with a standard deviation calculated from the range (18) of 0.002.

Stability—The absorbance of a sample of I in cyclohexane was measured at 1-min intervals after the addition of the nickel reagent until the absorbance became constant and was then monitored periodically for 24 hr. The procedure was repeated several times and was also repeated using I in acetic acid. In all cases, the absorbance reached a maximum within 1 min and remained constant for 24 hr.

Volatility—Samples of the nickel complex with I were prepared in methanol and carefully evaporated under air on the steam bath just to dryness. Two of the dry samples were left on the bath for 40 min and two were left for 90 min, after which they were dissolved and the absorbance was measured. There was no loss due to volatility in either case.

Volatility of I—Twelve separate 5.00-ml aliquots of standard I were pipetted into small glass-stoppered flasks and placed under air on the steam bath. Eight aliquots were removed as soon as they reached dryness, two remained on the bath 30 min after dryness, and the last two remained on the bath 60 min after dryness. Each sample was dissolved in 5.00 ml of acetic acid, 0.10 ml of nickel reagent was added, and the solution was scanned from 500 to 280 nm *versus* a reagent bank. The recoveries for the first eight samples averaged 100.1% (range 98.6–101.2%) while the second two averaged 64% and the last two 49%. As a consequence, the cyclohexane effluent from the column should not be evaporated to dryness before the determination of I.

Metal Complexes with I (Solvent Effect)—Standard solutions of I were prepared in 14 different solvents. Separate 5.00-ml aliquots were treated with 0.1 ml of nickel reagent and scanned as in the proposed procedure against the reagent blank. The study was repeated with an iron (III) reagent (0.050 *M* in ethanol) and with a zinc (II) reagent (0.050 *M* in ethanol). The nickel and zinc solutions were scanned from 500 to 340 nm, and the iron solutions were scanned from 720 to 380 nm.

The net absorbance and the wavelength of maximum absorbance of each complex in each solvent are shown in Table II. The nickel complex with I was the most sensitive in all solvents, and the iron (III) complex was the least sensitive. The net absorbances for the nickel and the zinc complexes were at a maximum in dimethyl sulfoxide, but the iron complex showed minimum absorbance in this solvent and maximum absorbance in absolute ethanol. Cyclohexane appears to be a satisfactory solvent for all three complexes. The wavelength of maximum absorbance depended in part upon the solvent and varied from 378 to 418 nm for the nickel complex, from 395 to 407 nm for the zinc, and from 605 to 670 nm for the iron.

This experiment was repeated using only acetic acid as the solvent but using different metal reagents (0.050 *M* in ethanol or methanol). Of the metal ions tested, magnesium (II) and manganese (II) did not react, zinc (II) reacted partially, and copper (II), cobalt (II), and nickel (II) reacted completely. The reagent blanks were then scanned against acetic acid. There was a significant absorbance at the wavelength of maximum absorbance only in the case of the copper reagent blank.

RESULTS AND DISCUSSION

The analyses of 23 typical formulations containing both I and corticosteroids are shown in Table III. The standard deviation, expressed as the percentage of the amount declared, was 1.31% for the UV, 1.34% for the complexiметric, 1.49% for the blue tetrazolium, and 1.22% for the isoniazid procedures. Samples 6 and 22 were low in hydrocortisone while Samples 1, 19, and 23 were above the recommended limits set by USP. Samples 6 and 8 were low in I while Samples 4, 10, 13, 17, 19, and 23 were high. For Samples 3, 5, 6, 8, 18, 19, 21, and 22, comparison of the corticosteroid values by the blue tetrazolium and isoniazid methods indicates from 4 to 34% decomposition of the corticosteroid according to the test of Graham *et al.* (19). Application of the variation of absorbance with time test suggested in the same reference indicates interferences in the blue tetrazolium procedure with Samples 1, 4, and 5.

Samples 3, 4, 5, 7, 8, 10, 13, 14, 15, 17, 19, and 23 were varying shades of yellow, which was taken to indicate varying amounts of decomposition of I caused by the reaction with metal ions present in the ingredients or containers to form metal chelates. The presence of metal chelates of I in samples containing I often can be determined quantitatively by slight modifications of the proposed complexiметric procedure since all of the metal chelates studied are converted to the nickel complex upon addition of the nickel reagent. Two possibilities exist: *(a)* the metal chelate is not removed from the column with cyclohexane but is removed by the chloroform and *(b)* the metal chelate is removed from the column with the cyclohexane.

Sample 8, which contains aluminum acetate, is an example of the first type. When a sample from one tube was run by the proposed procedure, only 91.0% of the amount declared was found to be present. A portion of the chloroform eluate was concentrated by evaporation, the nickel reagent was added, and the solution was scanned against a blank of the nickel reagent in chloroform. Calculations showed that 16.0% of the amount of I declared was present in the chloroform eluate. A second sample from the same tube composite was dissolved directly in chloroform; total I was determined by adding the nickel reagent and was found to be 105.9%,

which agrees satisfactorily with the sum of 107.0% found separately. The presence of a metal–I complex of this type is indicated whenever the residue resulting from the evaporation of the chloroform fraction does not completely dissolve in the alcohol solvent used for the determination of the corticosteroid.

The presence of a cyclohexane-soluble metal complex of I is indicated when the amount of I cannot be determined by the UV procedure due to interference in the absorbance at 326 nm and when there is an absorbance peak close to 406 nm in the UV spectra. Sample 19 is an example of a formulation that contains both types of metal–I complexes. Analysis of a single tube composite by the proposed procedure indicated the presence of 88.1% by the UV method and 98.1% by the complexiметric method. The chloroform fraction was treated in the same manner as described for Sample 8 and was found to contain 46.1% of the amount of I declared. The total complexed and free I was determined by dissolving a second sample of the composite in chloroform, adding the nickel reagent, and scanning against a blank of the nickel reagent in chloroform. Total I was determined to be 149.8%, which compares satisfactorily with the 144.2% found by summing the values obtained separately.

Chloroform is not the solvent of choice for the determination of I by the complexiметric method since the nickel complex can exist in two different forms in chloroform; one absorbs at 402 nm and one absorbs at 470 nm. The equilibrium between these forms is affected greatly by the water concentration and causes the measurement at 402 nm to be lower than it should be whenever any water is present. The chloroform fraction is used to estimate the amount of the cyclohexane–insoluble metal–I complex since the solid metal–I complex remaining from the evaporation of the chloroform eluate was not sufficiently soluble in the 13 solvents listed in Table II. In the early phases of the investigation, the cyclohexane fraction was evaporated on a steam bath and the residue was dissolved in chloroform for the complexiметric determination. The trouble with the equilibrium between the two complex forms and the volatility of I led to the development of the direct measurement in the cyclohexane eluate.

The results for Samples 4, 7, 8, 19, 22, and 23 that were run on different days and/or from different containers did not agree satisfactorily, even though duplicates run at the same time were in close agreement for both I and the corticosteroid. This finding indicates nonuniformity in mixing during preparation and/or packaging.

Several products tested contained other pharmaceutically active ingredients such as lidocaine, neomycin sulfate, and pramoxine hydrochloride. No attempt was made to determine these components quantitatively.

Sample preparations and column elution for two samples require approximately 1.5 hr, and complete determination by all four determinative procedures can be completed in approximately 6 hr.

Assay of Sulfacetamide Sodium Ophthalmic Solutions by High-Pressure Liquid Chromatography

MELVIN H. PENNER

Abstract □ A high-pressure liquid chromatographic method, using an adsorption column and sulfabenzamide as the internal standard, is proposed for the determination of sulfacetamide sodium and its principal hydrolysis product, sulfanilamide, in eye drops. It affords an average recovery of 100.9% of added sodium sulfacetamide with a relative standard deviation of 1.9%.

Keyphrases □ Sulfacetamide sodium—ophthalmic solutions, assay, high-pressure liquid chromatography □ Sulfanilamide—assay as hydrolysis product of sulfacetamide sodium in ophthalmic solutions, high-pressure liquid chromatography □ High-pressure liquid chromatography—assay of sulfacetamide ophthalmic solutions

Sulfacetamide sodium solutions have been shown to undergo hydrolysis to sulfanilamide and sodium acetate and oxidative discoloration (1–5). The nitrite titration method used for sulfacetamide sodium ophthalmic solution in USP XVIII (6) does not distinguish between sulfacetamide and sulfanilamide

which agrees satisfactorily with the sum of 107.0% found separately. The presence of a metal–I complex of this type is indicated whenever the residue resulting from the evaporation of the chloroform fraction does not completely dissolve in the alcohol solvent used for the determination of the corticosteroid.

The presence of a cyclohexane-soluble metal complex of I is indicated when the amount of I cannot be determined by the UV procedure due to interference in the absorbance at 326 nm and when there is an absorbance peak close to 406 nm in the UV spectra. Sample 19 is an example of a formulation that contains both types of metal–I complexes. Analysis of a single tube composite by the proposed procedure indicated the presence of 88.1% by the UV method and 98.1% by the complexiметric method. The chloroform fraction was treated in the same manner as described for Sample 8 and was found to contain 46.1% of the amount of I declared. The total complexed and free I was determined by dissolving a second sample of the composite in chloroform, adding the nickel reagent, and scanning against a blank of the nickel reagent in chloroform. Total I was determined to be 149.8%, which compares satisfactorily with the 144.2% found by summing the values obtained separately.

Chloroform is not the solvent of choice for the determination of I by the complexiметric method since the nickel complex can exist in two different forms in chloroform; one absorbs at 402 nm and one absorbs at 470 nm. The equilibrium between these forms is affected greatly by the water concentration and causes the measurement at 402 nm to be lower than it should be whenever any water is present. The chloroform fraction is used to estimate the amount of the cyclohexane–insoluble metal–I complex since the solid metal–I complex remaining from the evaporation of the chloroform eluate was not sufficiently soluble in the 13 solvents listed in Table II. In the early phases of the investigation, the cyclohexane fraction was evaporated on a steam bath and the residue was dissolved in chloroform for the complexiметric determination. Assay of Sulfacetamide Sodium Ophthalmic Solutions by High-Pressure Liquid Chromatography

MELVIN H. PENNER

Abstract □ A high-pressure liquid chromatographic method, using an adsorption column and sulfabenzamide as the internal standard, is proposed for the determination of sulfacetamide sodium and its principal hydrolysis product, sulfanilamide, in eye drops. It affords an average recovery of 100.9% of added sodium sulfacetamide with a relative standard deviation of 1.9%.

Keyphrases □ Sulfacetamide sodium—ophthalmic solutions, assay, high-pressure liquid chromatography □ Sulfanilamide—assay as hydrolysis product of sulfacetamide sodium in ophthalmic solutions, high-pressure liquid chromatography □ High-pressure liquid chromatography—assay of sulfacetamide ophthalmic solutions

Sulfacetamide sodium solutions have been shown to undergo hydrolysis to sulfanilamide and sodium acetate and oxidative discoloration (1–5). The nitrite titration method used for sulfacetamide sodium ophthalmic solution in USP XVIII (6) does not distinguish between sulfacetamide and sulfanilamide

Table I—Response Factors for Standard Solutions[a]

Sulfonamide	Average Response Factor	*SD*	Variance	Coefficient of Variation, %
Sulfanilamide	6.4939	±0.2575	0.0663	±4.0
Sulfacetamide	0.8474	±0.0123	0.0001	±1.5

[a] Data calculated from three to five injections of each of four standard solutions.

Table II—Recovery of Sulfacetamide Sodium Added in Ophthalmic Preparations

Formulation	Recovery, %	Average Recovery, %	*RSD*, %
A	102.0, 100.3, 102.7, 102.3, 101.7, 100.0, 102.3, 102.0, 102.0, 102.0	101.7	±0.9
B	101.0, 101.3, 102.3, 104.3, 102.0, 102.7, 104.3, 100.0	102.2	±1.4
C	98.3, 96.7, 97.3, 99.3, 99.3, 99.0, 99.3, 100.3	98.7	±1.1

and is thus not stability indicating with respect to hydrolytic decomposition. A colorimetric assay was suggested based on the reaction of sulfacetamide sodium, an imide, with hydroxylamine and ferric chloride to form the ferric acethydroxamate complex (7). A quantitative TLC method was proposed in which sulfacetamide was separated from its degradation products with butanol–ammonia–water (9:1:8) followed by quantitation of the eluted zones *via* the Bratton–Marshall reaction (8). An alumina adsorption column and UV spectrophotometry were utilized for the separation and determination of sulfanilamide in ophthalmic solutions and tablets containing sulfacetamide (9); sulfacetamide is retained on the column.

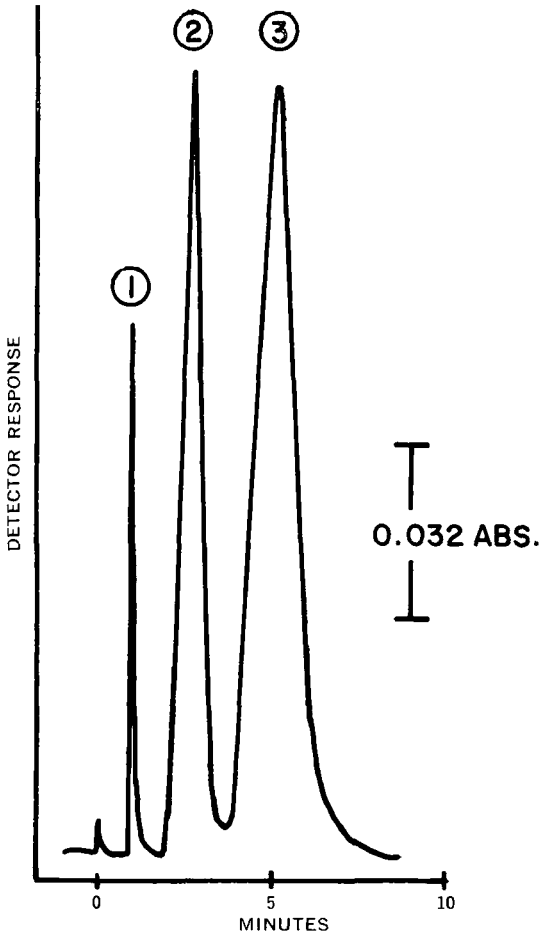

Figure 1—*Liquid chromatographic separation of the three sulfonamides. Key: 1, sulfanilamide; 2, sulfabenzamide (internal standard); and 3, sulfacetamide sodium.*

The recent availability of instrumentation for high-pressure liquid chromatography and reports (10, 11) on separations of sulfa drug mixtures using this technique with ion-exchange resins stimulated the work described here. A simple method was developed which requires only dilution of the sample to incorporate the internal standard and provides complete separation and quantitation of sulfacetamide and sulfanilamide within 10 min on an adsorption column. The method was used in a survey of the stability of several commercial sulfacetamide sodium formulations.

EXPERIMENTAL

Apparatus—A liquid chromatograph composed of a pump[1] (3000 psi maximum) with a pulse dampener and a UV monitor[2] (254 nm), a septumless injector[3], and a strip-chart recorder[4] outfitted with a potentiometric amplifier was used. A 70-cm × 2-mm i.d. stainless steel column packed with Corasil II, 37–50-μm particle size, was operated at 400 psi, with a 65% pump stroke resulting in a flow rate of about 2 ml/min. The mobile phase employed consisted of methylene chloride–isopropanol–concentrated ammonia (130:65:2.5), which was degassed by gentle heating prior to use. All injections were made with a 25-μl syringe[5].

Standard Preparation—Prepare individual stock solutions of sulfanilamide and sulfabenzamide internal standard at concentrations of 0.3 and 1.5 mg/ml of isopropanol, respectively. Accurately prepare a series of standard curve solutions to contain 0.9–1.65 mg of sulfacetamide sodium plus 0.15–1.5 mg of sulfanilamide/ml in 90% isopropanol. Each standard solution should contain 6.0 mg of internal standard/ml. The concentrations of sulfonamides represent a range of 60–110% sulfacetamide sodium and 1–10% sulfanilamide.

Sample Preparation—Dilute the sample solutions with isopropanol to obtain a concentration of 15 mg/ml. Pipet 1 ml of each sample into a 10-ml volumetric flask, add 4.0 ml of internal standard solution, and dilute to volume with isopropanol.

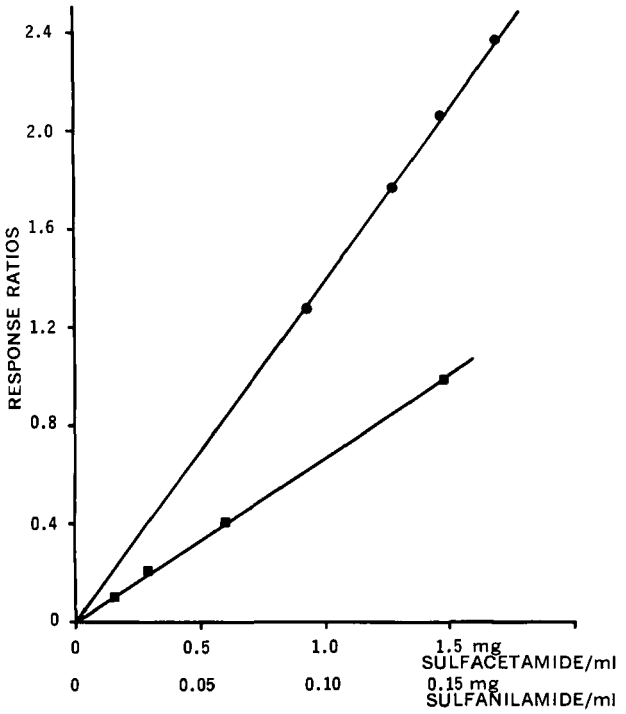

Figure 2—*Calibration curves indicating linearity of response of UV detector to sulfanilamide* (■) *and sulfacetamide sodium* (●).

Chromatographic Separation—With the UV monitor set at a suitable sensitivity range, inject 10 μl of each standard solution in duplicate. Sulfanilamide, sulfabenzamide, and sulfacetamide sodium appear as peaks after 1.0, 2.5, and 5.0 min, respectively. Compute the area of the sulfabenzamide and sulfacetamide sodium peaks arising from each standard injection, and determine the peak height of the sulfabenzamide and sulfanilamide peaks in each standard injection. Calculate the response factor, R, for sulfanilamide and sulfacetamide.

Inject each sample solution in duplicate, and calculate the concentrations of sulfacetamide sodium and sulfanilamide, if present, using the average response factors determined from the standards.

RESULTS AND DISCUSSION

All chromatographic runs were made employing a UV detector sensitivity of 0.32 absorbance unit full scale. A typical chromatogram is presented in Fig. 1. An internal standard was used to minimize the effects of small procedural variations. Sulfabenzamide was chosen as the internal standard since it eluted between the two sulfonamides of interest and, therefore, would not increase the analysis time.

The output of the UV detector was fed *via* an interface to a computer[6] programmed to determine peak heights and areas. Since sulfanilamide eluted as a rather narrow sharp peak, peak height rather than area was chosen as a more accurate measure of the concentration of this component. For the quantitation of intact sulfacetamide sodium, peak areas were employed. A linear response was obtained for the undegraded drug and its decomposition product over concentration ranges of 0–1.7 and 0–0.15 mg/ml, respectively (Fig. 2).

To compensate for day-to-day variations in any operating parameter, response factors for each sulfonamide were determined from a limited number of standard solutions each day the samples were analyzed. Since the response factors were linearly related to concentration, average response factors for sulfanilamide and sulfacetamide were calculated (Table I).

The results of adding known amounts of sulfacetamide sodium to each of three analytically prepared test formulations are shown in Table II. The data were obtained with replicate aliquots of each formulation injected in duplicate. Pooling the results of all 26 assays resulted in an average recovery of 100.9% with a relative standard deviation of 1.9%.

Sulfacetamide sodium ophthalmic preparations are usually available at solution concentrations of 30, 15, and 10%. Three different formulations[7] were assayed for each concentration, and two different lots of the same preparation were tested in one instance. The average results obtained for replicate aliquots of each formulation are presented in Table III. The only degradation product detected was sulfanilamide.

GLC Analysis of Griseofulvin: A Collaborative Study

MICHEL MARGOSIS

Abstract □ A GLC method for the assay of griseofulvin in bulk and dosage forms was subjected to a wide and rigorous collaborative study. An overall recovery of 99.52 ± 2.33% for three samples from 19 participating laboratories was obtained. The success of this study is ascribed to the fact that strict performance requirements are specified for the operating system.

Keyphrases □ Griseofulvin—GLC analysis, collaborative study □ GLC—analysis, griseofulvin, collaborative study

The GLC method for the assay of griseofulvin in pharmaceutical preparations reported previously (1) was shown to be useful in characterizing the drug and has proved to be more specific, accurate, and reliable than the current official UV and microbial assay methods (2). As in the preceding study of chloramphenicol (3), it appeared advisable to subject this method to a wide collaborative study encompassing industry and academia, as well as national and supranational organizations, to demonstrate its merits and validate its practical applicability.

EXPERIMENTAL

Separate vials containing three "unknown" samples and one internal standard were sent to 24 laboratories[1]. The first unknown sample, Sample 1, was a commercial bulk, nominally pure; unknown Sample 2 was a commercial tablet; unknown Sample 3 was a tablet specifically prepared with known excipients for this study. The nominal values of the griseofulvin concentration in these samples were obtained from the manufacturers when applicable and were verified independently by the official UV procedure and this GLC procedure. These concentration values were then established at 100.00, 75.58, and 45.99% for Samples 1, 2, and 3, respectively.

Additional bulk materials were provided as working reference material and to allow the analyst to become familiar with the method and to optimize the instrumental conditions.

9	4	95.65	1.05
10	4	100.09	0.40
11	2	98.79	1.45
12	4	100.97	0.81
13	10	99.74	0.65
14	4	99.49	1.14
15	4	98.93	1.33
16	6	99.23	2.29
17	4	96.96	1.42
18	12	99.33	2.29
19	4	99.41	1.22
Mean		99.01	1.50

The protocol of analysis was basically similar to that cited previously (1) and employed the identical curing and conditioning treatment recommended for practically all silicone columns. The calculations for potency (assay of griseofulvin), efficiency, resolution factor, and tailing factor were identical to those used in the collaborative study of chloramphenicol (3).

The analyst was requested to run duplicate injections of two separate weighings of each test sample and to compare the factor calculated from each to the average value obtained from the standard. When the coefficient of variation for five replicate injections of a standard solution exceeded a 2% limit, the entire system was to be tuned-up.

RESULTS[2]

Calculations and results from each collaborator were verified when sufficient data were available. These results include those submitted by the participants of this study and those calculated by the author from available chromatograms. Several sets of results were rejected outright. In two cases, precision values exceeding 5% in the replications of the standard were obtained. All results from another collaborator exceeded an acceptable sum rank limit by the Youden test (4), indicating a gross systematic error.

The final results were normalized to the nominal "labeled" concentration of the sample and are summarized in Tables I–IV for each sample and for the sum of the three samples. In Table V, "WD mean" is the result obtained through the weighted analysis of all observations from each collaborator, inclusive of "within sample" errors. "Mean" in Tables I–IV is the result obtained from the calculated mean from each collaborator; thus equal weight was attributed to each collaborator. The mean percent recoveries for Samples 1, 2, and 3 were 99.01 ± 1.50, 100.17 ± 2.05, and 99.37 ± 3.10, respectively, with an overall mean recovery of 99.52 ± 2.33% from 57 calculated means.

In Table V, results obtained from measurements by electronic integration are shown for comparison as well as to demonstrate the difference between the digital *versus* the combined digital and manual techniques. As expected, results derived from electronic

[2] All calculations, data processing, and statistical analyses were performed through the APL time-sharing system of an IBM 370/155 computer.

Mean		99.37	3.10

measurements were noticeably more precise, as indicated by the values of the range, variances, and standard deviations. All quantitative measurements were accomplished by one or more of six different procedures: electronic digital integration (11 sets), triangulation (six sets), peak height (four sets), disk integration (two sets), planimetry (one set), and cut and weigh (one set). These 25 sets of measurements were partitioned among the appropriate 19 participating laboratories as tabulated.

A computer plot of the results *versus* the frequency of results for each sample group numbering about 100, as well as for the combined groups of values totaling 303, yielded the typical S-shaped curve. A good fit to a normal distribution was indicated by the χ-square test for the results for each and for the combined samples. Because of its simplicity, a nonparametric sign test was performed; this indicated no detectable differences between the three samples at any confidence level.

The variances within each sample were found to be homogeneous by Bartlett's test, indicating similar reliability or precision from each collaborator at the 95% confidence level. Athough this test was not considered to be overly reliable within several sets of results because of the scarcity of observations, it may serve to attest that precision was more adversely affected by the manual techniques of peak measurements. A one-way analysis of variance was performed on all results calculated from each sample, and collaborator means were significantly different at $p < 0.05$ for all samples. However, when this analysis was performed on the means from each sample from each collaborator, no significant difference was noted between the laboratories ($F = 1.17$). This result was further verified in a two-way analysis of variance of the means, which indicated no significant differences between sample means ($F = 1.38$) and between laboratory means ($F = 1.26$).

A paired t-test was also employed to ascertain whether a statistically significant difference existed between the three samples. It was used to compare Samples 1 to 2, 2 to 3, and 1 to 3, but no such difference was detected at the 95% confidence level. A similar test comparing multiple groups of values (the Hotelling T square test) did indicate that the difference was not significant at the $p < 0.05$ level, but the calculation of this probability showed it to be near borderline (F of probability = 0.055, significant <0.05).

As mentioned before, Sample 3, made especially for this study, was formulated to contain 110 mg of griseofulvin in a 240-mg tablet containing lactose, starch, and magnesium stearate. The tablet weight varied somewhat (coefficient of variation = 1.25%), and the assay results on a per tablet basis gave a corresponding variation. To minimize this source of variation, the assay results in this study are reported on the basis of weight percent of granulation, which is indeed shown to be quite uniform.

Dechlorogriseofulvin was detected in the chromatograms by each collaborator but, because of its low concentration, it could be quantitated only by those 11 participants employing an electronic digital integrator. A 95% confidence limit of the mean for this component was calculated at 0.51–0.76% for the standard, 0.73–0.97% for Sample 1, 0.81–1.20% for Sample 2, 0.47–0.85% for Sample 3, or 0.70–0.87% for the combined total. The coefficient of variation for this measurement was estimated at about 30%, which may be acceptable for substances at this low concentration level and should also prove useful as an identity test for the product.

DISCUSSION

As in the earlier collaborative study, characteristics of column and operating conditions varied substantially from one laboratory to the next. Fifteen different models of GLC instruments from eight manufacturers were used; coiled or U-shaped columns ranged from 0.6 to 2 m in length and from 2 to 6 mm in diameter. Various supports were used with loading of 1–3% OV-17 in all but one case where 5% SE-30 was used. Except in one instance where argon was used, helium and nitrogen were used by about the same number of laboratories, with flow rates from 20 to 100 ml/min at column temperatures ranging from 245 to 280°.

Although wide flexibility was allowed in the selection of the analytical system, control of the method was attained by demanding that it meet certain performance requirements after subjecting the column to the proper temperature curing, sample conditioning, and suitability test as outlined in the protocol of analysis. These requirements included a measure of efficiency, resolution, a symmetry factor, and a maximum coefficient of variation of a number of replicate injections.

Variance	4.47	7.51	17.45	9.86	2.29	4.75	12.43	6.45
SD	2.11	2.74	4.18	3.14	1.51	2.18	3.53	2.54

[a] Labels A, B, and C are Samples 1, 2, and 3, respectively, and D is the combined value of all three, calculated by all methods of integration; those labeled with E are the corresponding results derived from electronic integration.

The efficiencies of the columns used in this study ranged from a minimum of about 300 to a maximum of 2000 theoretical plates/m with a mean of 993 ± 37 plates/m. The symmetry factor on the OV-17 phase was calculated to be from 0.7 to 1.3 with most from 0.9 to 1.15; with the SE-30 phase, a factor of 1.6 was obtained. Although the retention volume is a more characteristic qualitative property of the solute, the operating conditions in the different systems used were too variable and almost impossible to replicate for accurate measurement. In all cases but one, the resolution factor exceeded a value of 4 with most factors lying between 6 and 8.

The internal standard may be used quite effectively in lieu of the retention volume for identification of the drug, particularly when compared to the behavior of an authentic sample. In this study, the retention time of griseofulvin relative to tetraphenylcyclopentadienone ranged from 1.87 to 2.12 with a mean of 2.01 ± 0.06 (2.9%) (95% confidence interval: 1.98–2.04) in 19 cases where OV-17 was used; with SE-30, the relative retention time was 2.95.

The statistical difference noted in the one-way analysis of variance of all observations was likely due to the overloading of the chromatographic column, which was noted by some analysts during the study. This overloading may be avoided by injecting about 1 μg of solute either by using a reduced volume or by diluting the final solution about 10-fold. This decrease in the amount of injected solute improves the overall performance characteristics of the column, as typically demonstrated by one collaborator who increased the efficiency of the column threefold and greatly improved the symmetry of the peaks.

One participant had great difficulty in the elution of the internal standard because of condensation in the exit line. However, another participant employing an identical chromatograph, which does not normally possess the capability of separate heating of the exit port, obtained adequate and reproducible data. It is presumed that this result was achieved through a combination of higher temperatures and higher carrier gas flow rates. This was the only major handicap reported.

CONCLUSION

The participants in this collaborative study proved this GLC method for griseofulvin to be reliable and efficient. The results reported, analyzed, and discussed amply validate the method. Therefore, because of its demonstrated superiority, this method has been proposed for inclusion in the "Code of Federal Regulations" and is recommended for primary compendial and regulatory usage.

Drying Rates of Tablet Granulations II: Effect of Particle Size and Granular Densities

WILFRED O. OPANKUNLE *, BALDEV R. BHUTANI ×, and VISHNU N. BHATIA

Abstract □ The effects of the granule size and density on the drying rate kinetics of tablet granulations were studied using lactose and sulfathiazole granules prepared with acacia mucilage and povidone solution. The drying rate kinetics consisted of three distinct phases of drying when the drying rate was plotted against remaining moisture content: constant rate, first falling rate, and second falling rate periods. The effect of various statistical diameters and granular density on the drying rate during the first falling rate period was analyzed, and the mechanism of moisture migration during this phase of drying was identified.

Keyphrases □ Tablets—granulations, drying rates, effect of particle size and granular densities □ Granulations, tablet—drying rates, effect of particle size and granular densities □ Drying rates—tablet granulations, effect of particle size and granular densities, lactose and sulfathiazole granules prepared with acacia mucilage and povidone □ Particle size—effect on drying rates of tablet granulations □ Densities, granular—effect on drying rates of tablet granulations

In a preliminary investigation (1), a satisfactory technique was developed to study the kinetic rates of drying and to evaluate the effect of certain granulating adjuvants and fillers on the drying rates of tablet granulations.

It was observed that drying of granulation occurs through three distinct phases, as has been reported (2–6) for various materials in the chemical industry. The drying rate kinetic data vividly showed this drying as three straight lines when the drying rate (grams of moisture evaporated per hour per gram of dry solid) was plotted *versus* moisture content based upon dry solid. The first phase, generally termed the constant rate period, corresponded to the phase of drying during which the drying rate remained unchanged.

As long as the drying surface remained saturated with liquid moisture, the constant rate period existed. However, when the rate of drying exceeded the rate of moisture migration to the drying surface, the drying rate started falling, which initiated the first falling rate period. During this period, the drying rate depended more upon the physicochemical nature of the granulation and less on the external drying conditions such as temperature and air flow rate. During the second falling rate period, drying occurred by moisture evaporation within the granulation, followed by diffusion of water vapor from the interior of the granules to the drying air.

A major portion of the granulation drying takes place during the first falling rate period, so the drying rate during this phase has significant influence on the total drying time. Drying during the second falling rate period is usually extremely slow and utilizes proportionally larger amounts of energy. Thus drying during both falling rate periods can be significant in terms of the cost of the drying operation and the prolonged exposure of the active ingredients to heat.

This investigation is a detailed study of the effect of granule size on the drying rate. This parameter is related to other physical characteristics of granules such as density and porosity. An attempt was made to establish a relationship between the size and the density of granules and the drying rate during the first falling rate period. The first falling rate period was selected since the drying rate during this period is most affected by granulation properties and least by drying conditions. The effect of granules size and density has never been studied quantitatively for this phase of drying.

Lactose and sulfathiazole granules, prepared with acacia mucilage and povidone solutions as granulating agents, were selected as test substances.

EXPERIMENTAL

Equipment Design—The rates of drying of prepared granules were studied under standardized conditions. For each type of material, the temperature of inlet air, the velocity of air flow, and the method of granulation were kept constant. The apparatus developed by Bhutani and Bhatia (1) was used, but some modifications were made to enhance the reproducibility of the results obtained. The insulation of the heating chamber was improved by initially lining the outside of the chamber with glass wool followed by two layers of foam padding. This insulation kept the inlet air temperature more stable by eliminating heat loss. The second modification was related to the placement of the wet granulations in the drying tray. The bed thickness was reduced from 1.27 to 0.64 cm, and the granules were placed in the middle of the tray in the form of a square, 20 × 20 cm. This modification provided more direct and uniform contact between the granules and the drying air.

Granulating Process—On the basis of preliminary experiments, a standard granulating procedure was selected such that the variations in particle-size distribution due to variations in wet mixing time during granulation were completely avoided. A standard batch of granulation was prepared by granulating the test substance in a Glen mixer, using a definite quantity of concentrated solution of the binder and adding sufficient quantities of distilled water to obtain the wet mass. By keeping the amount of binder (dry weight) constant for a test substance, the particle-size distribution could be varied for a batch of granules by varying the amount of distilled water. The wet mass was then forced through a standard No. 8 mesh screen. Each granulation was prepared in quadruplicate, and the average results of the four batches were considered.

Lactose Granulation Studies—The drying chamber was preheated to about 42° with an inlet air temperature of 65° and the heating coil placed inside the dryer appropriately set to give the

[a] d_{geo} = geometrical mean diameter = 50% size from the logarithmic probability plot, d_v = mean volume diameter, d_s = mean surface diameter, and d_{vs} = mean volume surface diameter. [b] Densities represent average of three determinations. [c] Slopes of the first falling rate period calculated as g of moisture lost, g of dry solid × 100/hr, kg of dry solid, g of moisture still present. [d] σ_s = standard deviation for the slope of the first falling rate period obtained with 90% confidence limit.

desired temperature. The chamber was equilibrated at this temperature for 15 min prior to the introduction of granules. The initial moisture content of the granules was determined using a moisture balance[1] at 80° for 15 min. Sufficient sample of the wet granules was then spread uniformly to provide a 20 × 20-cm square bed of 0.64-cm thickness in a sample tray.

The tray was suspended inside the dryer from the weighing device and a thermocouple placed on the surface of the granules bed. The placement of the tray in the drying chamber requires the opening of the chamber door, which usually led to a slight drop in the drying chamber temperature. However, placement of the tray was done very quickly so that the drop in temperature was about 2° and the test granulations were immediately exposed to a temperature of 40 ± 1°.

The initial weight of the suspended system, *i.e.*, the weighing assembly and granules, was recorded along with the inlet air, granule surface, and outlet air temperatures every 30 min until the weight of the granulations became constant. At this point, the dryer was opened and the final moisture content of the granules was determined using the moisture balance.

Sulfathiazole Granulation Studies—The same procedure as described for lactose was used, except that the drying chamber was initially heated to about 53° with an inlet air temperature of 85°. The drying chamber was then equilibrated at 53° for 15 min. When placed in the dryer, the sulfathiazole granules were immediately exposed to a temperature of 50 ± 1°.

Determination of Mean Volume Diameter, d_v, Mean Surface Diameter, d_s, and Mean Volume-Surface Diameter, d_{vs}, of Granules—The statistical diameters were determined because of their physical significance and close relationship to the process of drying. Sieve analyses were performed on each of five batches of granules using standard U.S. sieve numbers 8, 10, 20, 40, and 60. Plots of the logarithm of sieve size against cumulative percent less than stated size (percent undersize) on a probability scale were obtained for each batch from sieve analysis data.

From log-probability plots, the geometric mean diameter, d_{geo}, and standard deviation, σ_{geo}, were calculated. Since a weight distribution was involved in this plot, the definitions of the statistical diameters in terms of weight distribution as derived by Hatch (7) were used for their determination:

$$\log d_v = \log d_{geo} - 3.4539 \log^2 \sigma_{geo} \quad \text{(Eq. 1)}$$

$$\log d_s = \log d_{geo} - 4.6052 \log^2 \sigma_{geo} \quad \text{(Eq. 2)}$$

$$\log d_{vs} = \log d_{geo} - 1.1513 \log^2 \sigma_{geo} \quad \text{(Eq. 3)}$$

Determination of Granular Densities—Accurately weighed samples of dried granules (about 5 g) were placed in a known volume of xylene, and the volume of xylene displaced was carefully determined. The granular density was then calculated from the weight of the sample and the granular volume.

Determination of Slopes of First Falling Rate Period—The drying rate (grams hour^{-1} kilogram^{-1} of dry solid) was plotted against the percent moisture content of granules on a dry basis for each drying run. The drying rate curves followed three distinct linear drying phases, as previously reported for tablet granulation (1). For the present investigation, the slopes of the first falling rate period were of particular interest and were determined by linear regression (3). Four runs were made for each formulation, and four slopes were determined from them. The averages of the slopes were calculated and used in this study. The standard deviations for the slopes were determined with a 90% confidence limit for each batch of granulations.

RESULTS AND DISCUSSION

The various physical parameters for lactose and sulfathiazole granules, prepared using acacia mucilage and povidone solutions, are presented in Table I along with their corresponding values for the slopes of the first falling rate period and the moisture contents at which the first falling rate period started (first critical point). The statistical diameters of the granules affected the first critical points for these batches (Fig. 1). As the mean volume–surface diameters of the granules increased, the first critical point occurred at a higher moisture content. Since the moisture movement within a larger size granule would be more restricted, whether by diffusion or capillary flow, unsaturation of the granulation surface occurs at higher moisture content. Therefore, for larger granulations, more drying occurs during the falling rate periods and more time is needed to dry them to a given final moisture content.

There was a marked difference in the shape of the curves for lactose and sulfathiazole granules. For sulfathiazole granules, which are mostly porous and the moisture present is unbound since the material is water insoluble, the relationship was linear; for lactose granules, the curve indicated an apparent logarithmic relationship. This observation suggests that the moisture movement during this phase of the drying rate is directly proportional to the moisture content of the sulfathiazole granules and thus basically due to a

capillary flow mechanism as reported for sand beds (6) and porous ceramic plates (5). For lactose granules, the moisture movement is due to a diffusion mechanism or to diffusion and a capillary flow mechanism, both occurring simultaneously as in the drying of clays and paper pulp (2).

Pitkin and Carstensen (9), while studying the final moisture content of sucrose granulations as a function of granule size, concluded that granules dry by a diffusional process. This conclusion is probably true for sucrose granules. However, in the present study, the mechanism of drying differed depending upon the nature of the ingredients present in the granulations.

The curves for the percent moisture content at the first critical point *versus* the mean volume diameter and the mean surface diameter were observed to be similar, and it was difficult to conclude if one statistical diameter gave a better correlation than the other two studied.

The density of the dried granules varied inversely with the granular size. Thus, opposite relationships were observed with densities of the granules compared with those observed with various statistical diameters. The curves for the percent moisture content at the first critical point *versus* densities of the granulations are shown in Fig. 2. As the granular density increased, the first critical point occurred at lower moisture contents. This relationship was linear for sulfathiazole granules; for lactose granules, an apparent logarith-

mic-type relationship existed. This phenomenon could be easily explained based upon mechanism of moisture movement within the granules during this phase of drying.

Linear relationships were also observed between the slopes of the falling rate period and the statistical diameters of granulations prepared using the same binding agent (Figs. 3–5). A reduction in the size of the granules led to an increase in the slope because for smaller granules the first falling rate period starts at a lower moisture content so moisture is depleted at a faster rate and, furthermore, the moisture movement to the surface of the granules occurs faster.

A logarithmic linear relationship was observed between the slopes of the first falling rate period and the granular density for both lactose and sulfathiazole granules (Fig. 6). As the granular density decreased, the moisture movement within the granules became more restricted and the rate of moisture depletion from the surface increased. The granular density affects the first critical points as well as the slope of the first falling rate period and, therefore, the drying rate curve of the granulations. Having established the effect of physical parameters upon the drying rate during the constant rate period, falling rate periods, and critical points, one could draw a drying rate curve for a given formulation and determine the drying time from the initial to a desired final moisture content.

Automated Method for Determining Calcium Disodium Edetate in Iodinated Contrast Media Parenterals

HOWARD W. ZIEGLER [x], WILMA L. ANDERSON, and JOHN T. SHADE

Abstract □ An automated method, based on the chelating reaction of calcium disodium edetate with zirconium and the subsequent determination of excess zirconium reacted with xylenol orange, was developed. The procedure is applicable to parenterals consisting of iodinated contrast media. Familiar modules of an automated analyzer were used, but the method can be performed manually if the sample load does not warrant automation. The pH should be controlled between 0.3 and 0.5. No interferences were encountered. Twenty samples per hour can be run on prepared sample solutions. The precision of a single determination, at the 95% confidence level, was ±0.008 mg/ml with a limit of detection near 0.40 mg/ml.

Calcium disodium edetate USP (I) is commonly added to iodinated contrast media parenterals (*e.g.*, sodium and meglumine iothalamates USP) as a sequestering–stabilizing agent. It is also used as an antioxidant in some foods and beverages such as salad dressings, margarine, barbecue sauce, beer, and wine. As a sequestering agent, it is added to complex traces of metals, thus preventing oxidation (catalyzed by trace metals) or possible discoloration.

Several colorimetric methods have been reported

Calcium disodium edetate USP (I) is commonly added to iodinated contrast media parenterals (*e.g.*, sodium and meglumine iothalamates USP) as a sequestering–stabilizing agent. It is also used as an antioxidant in some foods and beverages such as salad dressings, margarine, barbecue sauce, beer, and wine. As a sequestering agent, it is added to complex traces of metals, thus preventing oxidation (catalyzed by trace metals) or possible discoloration.

Several colorimetric methods have been reported

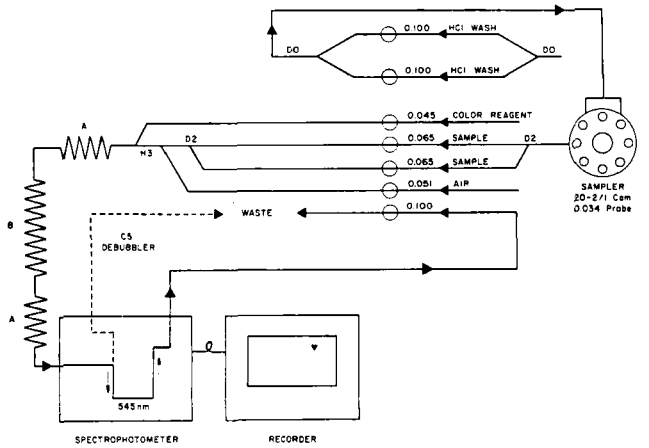

Figure 1—*Flow diagram of automated system for determining calcium disodium edetate. All tubing is standard. Key: A, 14-turn mixing coil, 2 mm i.d.; and B, 28-turn mixing coil, 2 mm i.d.*

for the determination of ethylenediaminetetraacetic acid (II). A method was reported that measures excess nickel with dimethylglyoxime after reaction with II (1). A procedure also was described using iron; the excess was reacted with thiocyanate (2). The use of a copper complex was reported (3), as was a procedure using chromium (4). The FDA "Food Additives Analytical Manual" (5) lists a method based on the chelating reaction of I on zirconium and subsequent determination of excess zirconium with xylenol orange. In the present study, this zirconium–xylenol orange (III) method, originally applied to the analysis of foods, was evaluated, adapted, and automated to analyze iodinated contrast media parenterals.

EXPERIMENTAL

Apparatus—A standard automated analyzer system[1] consisting of the following modules was used (Fig. 1): *(a)* a liquid sampler II[1] with 0.034 probe and 20-2/1 cam, *(b)* a proportioning pump II[1], *(c)* a spectrophotometer[2] modified with a 1-cm flowthrough cell, and *(d)* a strip-chart recorder[3].

Reagents and Solutions—*Zirconium Stock Solution*—Prepare by dissolving 1.77 g of zirconium oxychloride octahydrate in 100 ml of hydrochloric acid and dilute to 1000 ml with water in a volumetric flask.

Zirconium–Xylenol Orange (III) Color Reagent—Dissolve 50 mg of xylenol orange tetrasodium salt in 75 ml of water in a 500-ml volumetric flask. Add 5.0 ml of zirconium stock solution and 225 ml of 1 *N* HCl and dilute to volume with water. Age 24 hr and filter through a medium-porosity paper prior to use.

Hydrochloric Acid Wash Solution—Dilute 70 ml of concentrated hydrochloric acid to 2000 ml with water.

Calcium Disodium Edetate Stock Solution A—Prepare by dissolving 2.00 g of anhydrous (dried at 105° for 4 hr) calcium disodium edetate USP in water, adjust the pH to 7.0–7.5 with diluted sodium hydroxide or hydrochloric acid solution, and dilute to volume in a 100-ml volumetric flask with water.

Standard Solution B—Prepare by diluting 25.0 ml of Stock Solution A to 1000 ml with water

Diluted Standard Solution C (0.025 mg/ml of I)—Prepare by diluting 25.0 ml of Standard Solution B to 500 ml with water.

Transfer aliquots (usually five) of diluted Standard Solution C, ranging from 0.050 to 0.350 mg/100 ml, to 100-ml volumetric flasks; add 36 ml of 1 *N* HCl to each flask and dilute to 100 ml with water. Carry the standard solutions through the entire procedure with prepared sample solutions.

Procedure—Transfer a 2.0-ml aliquot of parenteral sample solution to a 100-ml volumetric flask. Add 20 ml of water and 40 ml of 1 *N* HCl, dilute to 100 ml with water, and mix. Let stand for at least 15 min with occasional swirling and allow the precipitate to settle. Filter a portion of the clear supernate through a dry, medium-porosity paper, discarding the first 10 ml. Fill an 8.5-ml turntable sample cup with filtrate and place in the sampler turntable.

Position the series of standard solutions in 8.5-ml sample cups ahead of the sample solutions and place one between every sixth sample. Insert the color reagent tube into the hydrochloric acid wash reservoir. Establish a baseline at zero absorbance by pumping hydrochloric acid wash through the system. Remove the color reagent tube and place it in the color reagent reservoir. Establish a steady "reagent blank" baseline, which will occur at about 0.3 absorbance unit.

[3] Technicon Corp., Ardsley, N.Y.

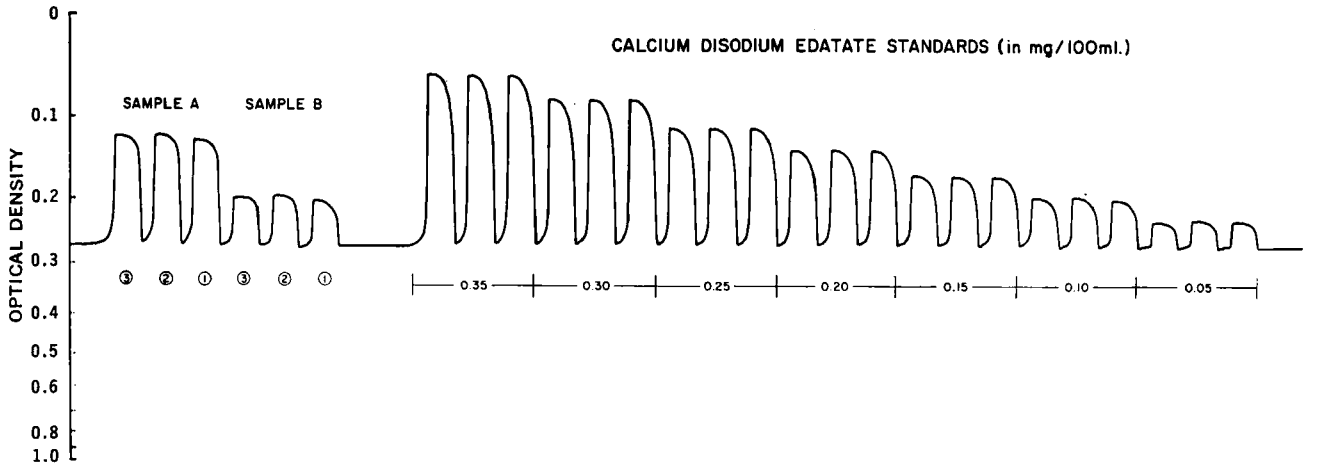

Figure 2—*Typical curves for the automated determination of calcium disodium edetate showing reproducibility of standards and actual readings of two different commercial parenterals on triplicate samples, individually prepared.*

Run the standards and sample solutions through the automated apparatus. Subtract the absorbances of the standards readings from the absorbance of the reagent blank baseline from the recorded peaks. Prepare a standard calibration curve by plotting the calculated absorbances *versus* the mg/100 ml of I taken for each standard. Calculate the milligrams per milliliter of I contained in a sample by dividing the milligrams read from a standard calibration curve by 2.

RESULTS AND DISCUSSION

Figure 2 shows a typical recording of a repeated series of standards. Typical curves for two commercial contrast media containing different levels of I are also shown in Fig. 2; triplicate samples, individually prepared, were used. Results of day-to-day reproducibility analyses are shown in Table I. A statistical evaluation of the results, from five replicates run on different days using four commercial products, indicates that the reproducibility at the 95% confidence level for a single determination is 0.008 mg/ml I (at the 0.1-mg/ml level).

The method is useful on formulations consisting of differing matrixes (*e.g.*, prepared with meglumine, sodium hydroxide, or saline). Several parameters were evaluated to ascertain if there were any interferences with the test. The experiments revealed the following:

1. The pH has an effect on optimum color development and should be controlled between 0.3 and 0.5. Alternatively, pH can be between 0.2 and 1.0 provided the pH of the sample and that of the standard solutions are identical. There is little or no color developed at pH <0.2. Investigations above pH 1.0 were not made.

2. The I level cannot be greater than 0.4 mg/100 ml, where full bleaching is achieved. This amount is equivalent to about 0.2 mg/ml in a typical iodinated contrast media parenteral solution or about double the level customarily added.

3. The wavelengths of the absorbance maximum shift slightly with concentration. The optimum wavelength was 545 nm, where a linear plot for all concentrations was obtained. The curve does not generally pass through the origin.

4. A phosphate salt is often added to parenterals as a buffer. No interference was found with as much as 0.2 mg/100 ml of sodium phosphate added to standard solutions.

5. Meglumine has no noticeable effect or interference on color development or other parameters of the test.

6. Fluoride ion interferes by bleaching and color complexation. If fluoride is suspected to be present, it can be masked by reaction with magnesium chloride (10 ml of a 25% solution) at pH 9 and then acidification with phosphoric acid (5 ml) (5) prior to color reaction.

7. Recovery studies using the manual procedure show an overall recovery of 96% (Table II).

The FDA procedure (5) calls for the preparation of separate xylenol orange and zirconium solutions to be used separately just prior to color measurement in standard and sample solutions. In this investigation, it was found that the reagents can be mixed and used as a single reagent. The mixed reagent should age about 24 hr and then be filtered. The solution is stable for several weeks. The mixed reagent is used essentially as a reagent blank to establish a working baseline in the automated procedure. This method is convenient since the reaction in the test is a bleaching of the highly colored solution. When using the technique, a positive slope can be obtained.

The method is fast, simple, and reproducible. Twenty prepared samples per hour can be run. The procedure can be performed manually as well. The method has been applied to other types of samples (*e.g.*, saline and plasma) with adaptations to remove or mask interferences. Meglumine iothalamate USP, sodium iothalamate USP, and combination formulas containing meglumine and sodium iothalamates and sodium acetrizoate have been run.

Automated High-Pressure Liquid Chromatographic Analysis of Aspirin, Phenacetin, and Caffeine

PETER P. ASCIONE ˣ and GEORGE P. CHREKIAN

Abstract □ An automated high-pressure liquid chromatographic (HPLC) method for the separation and determination of aspirin, phenacetin, and caffeine in pharmaceutical dosage forms is described. Separation of these compounds for quantitation is achieved on a controlled pore glass support, utilizing a mixture of acetic acid and chloroform as the mobile phase. The method is specific, accurate, and simple and provides for the quantitation of each chromatogram in a continuous fashion every 7 min. HPLC separation of other analgesics was studied on a spherical siliceous support. The feasibility of determining free salicylic acid in analgesics also was established.

Keyphrases □ Aspirin, phenacetin, and caffeine—automated high-pressure liquid chromatographic analysis □ Phenacetin, aspirin, and caffeine—automated high-pressure liquid chromatographic analysis □ Caffeine, aspirin, and phenacetin—automated high-pressure liquid chromatographic analysis □ High-pressure liquid chromatography—automated analysis, aspirin, phenacetin, and caffeine

The separation and determination of analgesics in pharmaceutical dosage forms have been difficult and time consuming. Column chromatography has been used as an official method for determining aspirin, phenacetin, and caffeine (1, 2), and numerous other methods including solvent extraction techniques for separation of components were reported (3, 4). Other methods for determining the various analgesics involve UV spectrophotometry (5, 6), IR spectrophotometry (7, 8), titration (2), and NMR spectroscopy (9).

The utilization of high-pressure liquid chromatography (HPLC) in pharmaceutical analysis of analgesics was first reported by Henry and Schmidt (10). A recent paper (11) reported conditions for the routine separation of common components of analgesic tablets. The determination of analgesics by HPLC overcomes many shortcomings of the previously reported methods (1–9).

The present work describes the automation of HPLC as applied to the separation and determination of aspirin, phenacetin, and caffeine. It also includes the chromatography of other analgesics and/or combinations amenable to separation and analysis by automated HPLC. By modifying the chromatographic conditions, a rapid quantitative analysis of free salicylic acid can be made.

EXPERIMENTAL

Instrumentation and Reagents—*Apparatus*—The apparatus used in the automated HPLC was acquired from commercial sources and modified as required. The following were used: a solvent delivery pump[1]; a modified sample injection valve[2]; a UV detector equipped with optical path at 254 and 280 nm[3]; a modified liquid sampler II, proportioning pump, and assorted tubing and fittings[4]; a multiple-program timer to control the operation of both the sample injection valve and the liquid sampler[5]; pneumatic air valves, 90 psi capacity[6]; pneumatic piston[7]; a digital integrator[8]; and a recorder equipped with a multirange input and variable chart speed[9].

Columns—Columns are commercially available. They are 600 × 2.1-mm i.d. × 0.6-cm (0.25-in.) o.d. stainless steel tubing with end fitting containing a 2-μm filter bed support with the following packings: Column 1, controlled pore glass CPG-10-240 A, 200–400 mesh[10]; and Column 2, Corasil II[11], consisting of solid glass cores with a porous silica surface. Each column was dry packed with the support by feeding small increments slowly into the empty column while subjecting it to vibration and sharp vertical raps on a hard surface. The addition, vibration, and tapping were continued until the column was completely packed.

Solvents—Spectral grade and/or analytical reagent grade chloroform, methylene chloride, and acetic acid were used.

Mobile Phase—The mobile phase is acetic acid (up to about 10% v/v) in chloroform of such composition that the retention times, when the chromatograph is operated at a flow rate of 1.0 ml/min at ambient temperature, are: aspirin, 135–145 sec; phenacetin, 220–230 sec; and caffeine, 370–390 sec. The recommended mobile phase is 8% acetic acid in chloroform (v/v).

Aspirin, Phenacetin, and Caffeine Working Standard—Use reference standards of known purity. Weigh accurately about 58 mg of aspirin, 43 mg of phenacetin, and 8 mg of caffeine, and dissolve in 100 ml of mobile phase.

Preparation of Sample (Capsules)—Accurately weigh an amount of sample containing the equivalent of the working standard. Transfer to a 100-ml volumetric flask with the aid of 50 ml of mobile phase. Shake for 10 min and dilute to volume with mobile phase. Then filter a portion through fast flow paper.

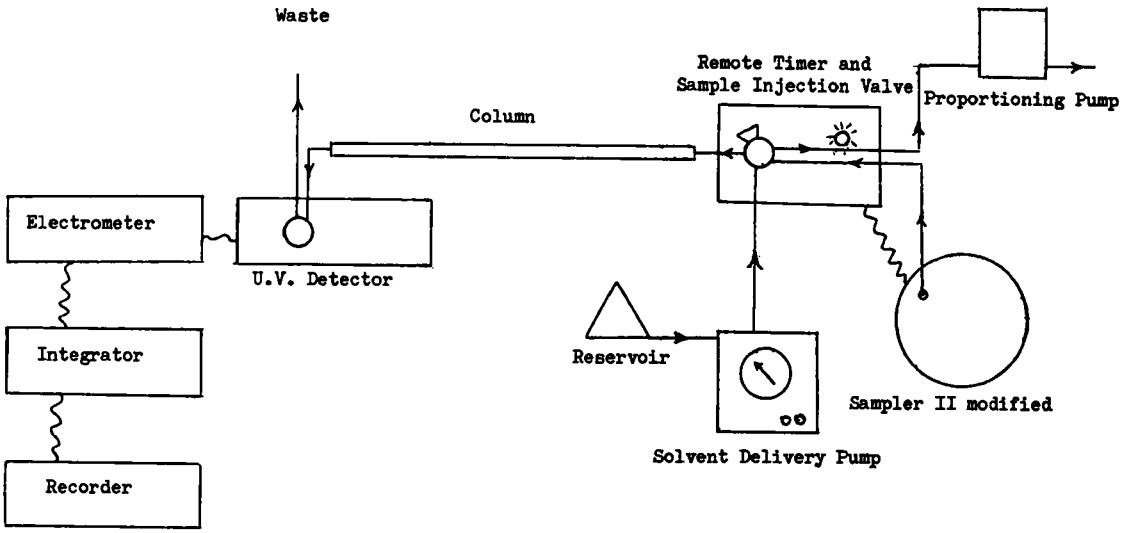

Figure 1—*Schematic diagram of the automated high-speed liquid chromatograph.*

Automated Liquid Chromatographic Procedure—*Chromatographic Conditions*—A steady baseline is established with the following in operation: solvent delivery pump at a flow rate of 1 ml/min, Column 1, UV detector set at 280 nm and a range of 0.32 absorbance unit full scale, integrator settings, slope sensitivity up at 0.1 mv/min, slope down at 0.1 mv/min, peak level at 10 mv, shoulder control at front "on," shoulder at rear 1 mv, baseline reset delay at zero, and recorder with a chart speed of 5 mm/min.

Operating Conditions—Solutions of standards and samples are filled in glass vials, covered with aluminum foil, and placed in the sampler tray. At the same time the proportioning pump and air are turned on to transport the samples from the tray to the injection valve and to activate the pneumatic valves to inject the samples into the liquid chromatograph. Once the chromatographic and operating conditions are established, the control timer and integrator are activated to start the automated analysis. Integration of the chromatographic peak area of samples is compared to areas of standard peaks, and these ratios are used to calculate the analytical results.

RESULTS AND DISCUSSION

This paper describes the automation of HPLC and the chromatographic conditions that optimize the resolution of analgesics in a reasonable time. The automated HPLC system can be represented by the schematic diagram shown in Fig. 1.

The technique consists of a series of integral parts: HPLC sam-

pler, sample transport system, automatic injection valve, remote timer control unit, and liquid chromatograph.

HPLC Sampler—A commercial sampler is modified to form a suitable sampler for the HPLC. A three-pole double-throw switch is installed in the sampler to permit a remote timer unit to control the operation of the sampler. This switch permits the use of the liquid sampler in a normal mode and/or by the remote timer control. These modifications are shown in Fig. 2.

Another modification consists of placing a thin sheet of metal on top of the turntable, which is held in place by locating pins. This modification allows glass vials[12] covered with aluminum foil, held in place by a suitable plastic ring, to be placed in the sample tray of the liquid sampler. At the start of the cycle, a sharp probe is lowered into the glass vial, piercing the aluminum foil. The sample is drawn from the vial to the sample injection valve. After injection of the sample, the probe is raised from the vial into a wash reservoir and the turntable is indexed to the next sample. The operation of the probe, turntable unit, and injection valve is controlled by a simple cam timer and microswitches.

Sample Transport System—Transporting samples from the glass vials in the sampler to the sample injection valve is accomplished with a channel peristaltic pump[13] with 0.040 red acidflex tubing. When the sample probe pierces the aluminum foil covering

the sample vial, the sample is drawn through the injection valve loop to waste by the peristaltic action of the proportioning pump.

Automated Sample Injection Valve (Fig. 3)—The sample application is accomplished by a rotary switching valve. Operation of the valve from one position to the other is accomplished by pneumatic pistons controlled by the cam timer and microswitch. The commercial sample injection valve is modified to form a suitable injection valve for liquid chromatography by replacing the ceramic rotor with a stainless steel rotor. This valve has an external sample loop, which determines the size of sample applied. Activation is accomplished by pneumatic piston-driven actuators, which position the rotor through the 60° movement. Stops are installed in front of the valve to ensure proper alignment of the flow when the automated valve is rotated fully against each stop (60° apart).

Remote Timer Control—The remote timer associated with the liquid sampler and automated injection valve is used to operate the function of the sampler and to initiate sample injection into the liquid chromatograph (Fig. 2). An electric timer[14] with cams and microswitches is used. Once the precise chromatographic conditions are established, operating procedures for sequential analysis employing the cycle timer are adjusted to control sampling and duration of chromatography.

Chromatography—HPLC is a fast, reliable method for the determination of aspirin, phenacetin, and caffeine. The advantages of this method include fast separation time, sensitive detection, minimum sample preparation time, and precision.

Adsorption, reverse phase, liquid–liquid, and ion-exchange chromatography were evaluated using various supports and mobile phases to obtain the desired separation. Several problems were encountered with these types of chromatography including column bleed, excessive tailing, interferences from sample matrix, and undesirable separation. Analgesics were best chromatographed by the adsorption technique where an acetic acid–chloroform solvent was used with a siliceous stationary phase.

[14] Conrac.

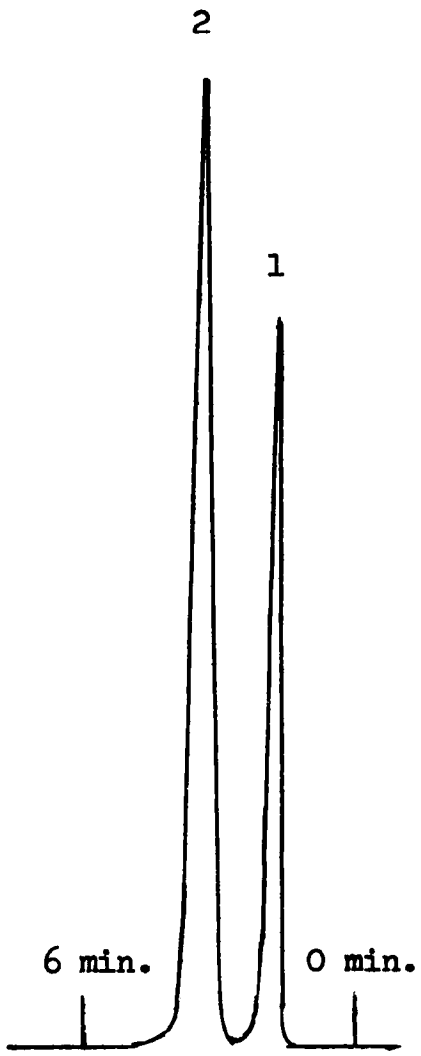

Figure 7—*Separation of salicylic acid (2) and aspirin (1). Chromatographic conditions were: Column 2; mobile phase, acetic acid–methylene chloride (1:99 v/v); flow rate, 1.0 ml/min; detection, 254 nm; and temperature, ambient.*

Figure 4 is a typical chromatogram depicting the separation of aspirin, phenacetin, and caffeine on Column 1. The chromatogram illustrates the range of structures that can be separated with symmetrical peaks using adsorption techniques. Separation is effected by varying the flow rate, changing the ratio of the mixture in the mobile phase, and using various controlled pore glass diameters. Hand-packed columns can be packed homogeneously with a reproducibility in performance of about ±10% within a given lot; however, there are variations in performance from lot to lot of a given packing material. Therefore, minor variations in chromatographic conditions may be necessary to reproduce the work described here.

To determine the precision of the automated procedure, the reproducibility of peak response was studied. A mixture of analgesics was prepared and repeatedly chromatographed. Figure 5 depicts 10 consecutive chromatograms, and a summary of results of integrator areas appears in Table I.

The detector sensitivity range for analgesics appeared to be adequate for most analyses. Linearity of the liquid chromatographic procedure was evaluated by running standard mixtures of various concentrations and plotting these concentrations against their corresponding peak areas. When measured peak areas were plotted, a linear relationship resulted between areas and concentration.

The separation and analysis of other analgesics in combination were applied to automated HPLC. Four common analgesics and caffeine were separated (Fig. 6) using the mobile phase of acetic

acid–chloroform–methylene chloride on Column 2. Aspirin eluted first, followed by salicylamide, phenacetin, caffeine, and acetaminophen. Since most analgesic combinations do not contain all five compounds, slight changes may be made in the mobile phase to reduce the elution time to less than 20 min.

The same chromatographic system can be used for rapid quantitative determination of free salicylic acid. Modifying the mobile phase accomplished the separation of free salicylic acid in analgesics containing aspirin (Fig. 7). This method of separation and detection, with minimum sample preparation, proved to be more rapid than literature methods.

Timed-Release Tablets Containing Quinine Sulfate

NICOLAS H. CHOULIS [x] and HARRY PAPADOPOULOS [x]

Abstract □ The release rates of quinine sulfate from slowly eroding, timed-release tablets prepared with various amounts of a swellable gum, carbomer, and cellulose acetate hydrogen phthalate at different compaction pressures were attained. For the dissolution test of the prepared tablets, the method described in NF XIII was followed. The concentration of the released quinine sulfate was determined spectrophotometrically.

Keyphrases □ Quinine sulfate timed-release tablets—release rates, effect of carbomer and cellulose acetate hydrogen phthalate concentrations □ Carbomer—effect on timed release of quinine sulfate from slowly eroding tablets □ Timed-release quinine sulfate tablets—effect of carbomer concentration on release rate

It has been reported that continuously effective therapeutic drug levels can be achieved over a period of time by incorporating the medicament in a solid, edible, pharmaceutically and medically acceptable vehicle, consisting of a copolymer of glyoxal and partially degraded gelatin, and by compressing the resulting mixture into a tablet. The copolymer was claimed to swell and decompose slowly in the presence of aqueous solutions, liberating the active ingredient gradually (1). A process for the preparation of slowly eroding tablets, involving the compression of a medicinal agent and a hydrophilic swellable gum was described (2). This process was based on the discovery that a gelled zone is formed on the surface when such a tablet comes in contact with aqueous media, which delays entry of water into the interior of the tablet. The incorporation of water-insoluble medicament in a gel, formed from cellulosic gums in organic solvents, was used to produce stable tablet products with delayed release (3).

reported that Higuchi's relationship adequately describes the dissolution process for tablets containing hydrophilic gums, although they cannot be considered as true matrix systems (5, 6).

In the present investigation the effect of the amount of a swellable gum, namely carbomer, on the release of quinine sulfate from slowly eroding, timed-release tablets is examined.

EXPERIMENTAL

Materials—Quinine sulfate[1], cellulose acetate hydrogen phthalate[2], and carbomer[3] were used. All other chemicals were analytical or USP grade, obtained from standard sources.

Procedures—Slowly eroding, timed-release tablets were formulated with a swellable gum, carbomer, to retard drug release. By adjusting the proportion of the gum, quantitative release of quinine sulfate was attained. Several formulations were prepared (Tables I–III).

The ingredients of each formulation, having the desired particle size less than 60 mesh, were mixed for 15–20 min with a twin-shell mixer[4]. Any aggregates formed during mixing were broken down with a spatula, thus producing additional shear mixing. Weighed amounts of the mixture of powders were compressed into tablets

[a] Tablets were prepared by direct compression with a compaction force of 4000 lb.

by compression in a 13-mm diameter set of die and punches lubricated with magnesium stearate.

For the dissolution test of the prepared tablets, the method described in NF XIII (7) was modified as follows. One tablet was placed in each 90-ml screw-capped bottle containing 60 ml of pH 1.2 dissolution fluid, previously warmed to 37°. The bottles were capped tightly, placed in the clamps of the rotating-bottle apparatus, and rotated at 40 ± 2 rpm in a water bath maintained at 37 ± 0.5°.

At the end of 1 hr, the apparatus was stopped and the bottles were removed. The pH 1.2 dissolution fluid from each bottle was decanted through a 40-mesh metal screen; as much residue was retained in the bottle as possible. Any residue remaining on the screen was returned to the original bottle, and 60 ml of pH 2.5 dissolution fluid was added. The decanted pH 1.2 dissolution fluid was retained for assay.

The process was repeated at the end of 2, 5, and 7.5 hr using pH 4.5, 7.0, and 7.5 fluid, respectively.

For the chemical assay of quinine sulfate, aliquots of the samples were appropriately diluted and the pH's of the final solutions were adjusted to either 1.2 or 7.5. The concentration of quinine sulfate was then determined spectrophotometrically at 345 nm (for

solutions of pH 1.2) and 331 nm (for solutions of pH 7.5), using the appropriate medium as the blank.

RESULTS AND DISCUSSION

The relationship between the amount of carbomer included in the tablets and the release rates obtained with the dissolution test is shown in Fig. 1. The proportion of carbomer in the tablets ranged from 75% for Formulation 1.1 to 20% for Formulation 1.6. Release rates from tablets containing 10–50% quinine sulfate are shown in Figs. 2 and 3. The amount of carbomer included in Formulations 2.1–2.4 was 40%, while 25% was used for Formulations 3.1–3.4.

The release rates did not differ substantially for compaction pressures from 1000 to 5000 lb/1.3266 cm^2. However, higher pressures decreased considerably the release rates, probably due to entrapment of drug within the matrix. Pressure of 4000 lb/1.3266 cm^2 for matrixes containing carbomer produced tablets of sufficient hardness without hindering the release of drug. The lubricant magnesium stearate might retard tablet dissolution slightly; replacement with magnesium lauryl sulfate is possible, but its toxicity has not yet been established (8).

The mechanism of drug release of the eroding type could be explained by the fact that the formation of a hydrated and gelled zone on the surface acts as a barrier to the further penetration of the liquid into the tablet interior (9). As the gelled zone slowly dissolves in the medium, a fresh surface is exposed to the liquid, with subsequent formation of a new gelled zone. Drug is liberated from this zone through a combination of diffusion and attrition processes. Part of the drug is diffused through the swelled area while the remainder is liberated when the hydrated zone is dissolved.

In Fig. 1 the release of drug from timed-release tablets containing carbomer is shown. The amount of carbomer has a marked influence on the release of drug; as the proportion of carbomer decreases, the release rate increases. This effect would be expected since the swelled zone is more susceptible to attrition as the proportion of the gum decreases. Therefore, the proportion of carbomer can be adjusted so that all drug is released in 7.5 hr (Formulation 1.5). However, the release pattern is similar to that of matrix tablets; *i.e.*, most of the drug is liberated during the initial period of the dissolution process. It was also found that when the proportion of the gum was 20% or less (Formulation 1.6), rather rapid disintegration occurred within 2 hr (Fig. 1).

As a filler or diluent, cellulose acetate hydrogen phthalate was used to enhance the permeability of the hydrated area at higher pH values. This use was based on the property of cellulose acetate hydrogen phthalate to be insoluble in acidic environment but soluble in media of pH 5 or higher. It was postulated that this effect could counterbalance the increased viscosity of carbomer gel at higher pH values (10). The proportion of drug in the tablets containing 40% carbomer (Formulations 2.1–2.4) had a negligible effect on release rates expressed as percentages (Fig. 2). However, the absolute amounts of drug released will be proportional to the total drug content. Similar results were obtained when the proportion of carbomer was 25% (Formulations 3.1–3.4, Fig. 3). No significant differences in drug release were observed when the drug and carbomer contents were kept constant and the quantity of cellulose acetate hydrogen phthalate was varied at a given pH (pH 5 or higher).

Comparison of Observed and Predicted Bioavailability of Nortriptyline in Humans following Oral Administration

MILO GIBALDI

Abstract □ The first-pass equation based on the dose, hepatic blood flow, and total area under the plasma level–time curve after oral administration was used retrospectively to predict the bioavailability of nortriptyline after oral administration of 1 mg/kg-single oral doses to monozygotic and dizygotic twin pairs. The predicted values of bioavailability ranged from 45 to 85%, consistent with experimentally derived estimates of nortriptyline availability.

Keyphrases □ Nortriptyline bioavailability in humans—predicted by first-pass equation, compared retrospectively to oral administration in twin pairs □ Hepatic metabolism, first-pass effect—comparison of observed and predicted nortriptyline bioavailability in humans

The availability of nortriptyline was assessed in three healthy subjects by comparing the areas under the plasma concentration *versus* time curves after oral and intramuscular administration of identical doses of the hydrochloride salt (1). The observed availability in these subjects ranged between 56 and 70% (mean of 64%). Complete GI absorption of nortriptyline is suggested by the fact that the recovery of the main urinary metabolite, 10-hydroxynortriptyline, was essentially the same following both routes of administration. The results suggest that, in humans, a significant fraction of the absorbed drug is lost to the systemic circulation during the first pass through the liver (1).

DISCUSSION

The following equation was developed to predict the degree to which a drug that is completely absorbed and eliminated exclusively by hepatoportal metabolism is subject to first-pass metabolism (2):

$$f = \frac{\text{flow rate}}{\text{flow rate} + \left(\text{dose} \Big/ \int_0^\infty C_0\, dt\right)} \qquad \text{(Eq. 1)}$$

where f is the fraction of the orally administered dose that actually reaches the systemic circulation (*i.e.*, the predicted availability), flow rate is the hepatic blood flow rate, and $\int_0^\infty C_0\, dt$ is the total area under the plasma concentration *versus* time curve after oral administration.

The value of Eq. 1 lies in the fact that it requires only concentration–time data after oral administration and a reasonable estimate of hepatic blood flow. This equation has been applied with reasonable success to studies in humans with propranolol (2) as well as with propoxyphene and alprenolol (3). Nortriptyline, like propranolol, propoxyphene, and alprenolol, is virtually completely metabolized in humans (4).

Extensive pharmacokinetic studies (5) in twin pairs receiving 1 mg/kg-single oral doses of nortriptyline hydrochloride afforded the opportunity to evaluate retrospectively the applicability of Eq. 1 as a predictor of nortriptyline availability in humans.

Table I—Apparent Clearance and Predicted Availability Values after Oral Administration of 1 mg/kg-Single Oral Doses of Nortriptyline Hydrochloride to Five Monozygotic Twin Pairs

Subject	Apparent Clearance[a], liters/min	Predicted Availability (f)

16	1.72	0.47
25	0.80	0.66
26	0.82	0.65
39	0.90	0.63
40	0.85	0.64
47	1.04	0.60
89	0.96	0.61
78	0.46	0.77
88	0.45	0.77
Mean ± 1 *SD*	0.94 ± 0.39	0.63 ± 0.09

[a] Calculated from Ref. 5.

EXPERIMENTAL

The term $(\text{dose}/\int_0^\infty C_0\, dt)$ in Eq. 1 is equivalent to the "apparent clearance" reported in Ref. 5 in terms of (liters per kilogram) (hour) and reexpressed in Tables I and II in terms of liters per minute. The predicted availability (f) of nortriptyline was calculated for each subject by substituting the individual apparent clearance and a mean blood flow rate of 1.53 liters/min (6) in Eq. 1. These values are also reported in Tables I and II.

RESULTS

As expected, the intrapair variation with respect to f averaged

Table II—Apparent Clearance and Predicted Availability Values after Oral Administration of 1 mg/kg-Single Oral Doses of Nortriptyline Hydrochloride to Six Dizygotic Twin Pairs

only 3% in the monozygotic twins; in fact, it was virtually negligible in four of five pairs. Intrapair variation with respect to predicted availability in the dizygotic twins averaged about 14%. The mean predicted availability was essentially identical in both groups. The predicted availabilities in all subjects ranged between 45 and 85%, which is consistent with the range of 56–70% observed in a study with three subjects (1). The mean predicted availability of 65% was in perfect agreement with the previously observed mean (1).

This retrospective study provides greater confidence in the reliability of Eq. 1 as a predictor of average bioavailability for drugs undergoing first-pass metabolism.

Effects of Acids and Bases on Salicylic Acid–Cetrimide Systems

LUCY S. C. WAN

Abstract □ The effects of acids and bases on the viscosity of salicylic acid–cetrimide systems were investigated. A viscosity reduction was produced by the addition of acids and was independent of the degree of saturation of the cetrimide solution with salicylic acid. The incorporation of base followed by that of acid increased and decreased the viscosity, respectively. This viscosity behavior was demonstrated in undersaturated systems and was not governed by the relative amounts of base or acid used. In oversaturated systems, only a lowering of viscosity was observed.

Keyphrases □ Salicylic acid–cetrimide systems—effects of various acids and bases on viscosity □ Cetrimide–salicylic acid systems—effects of various acids and bases on viscosity □ Viscosity—salicylic acid–cetrimide systems, effects of various acids and bases

Since solutions of alkaline sodium salts have been shown to effect different changes in the viscosity of salicylic acid–cetrimide systems (1), a study of the reaction of the viscosity of the systems to acid additives was considered desirable. It was also the purpose of this investigation to determine whether the viscosity change arising from the addition of either acid or base is retained when these additives are added alternately to the same system. This approach is an attempt to test the sensitivity of the viscous property to these additives. A literature survey did not reveal information on this particular area of research.

EXPERIMENTAL

Recrystallized salicylic acid, mp 158–159°, and cetrimide[1] BP were the same as those described earlier (2). The acids were citric acid[2], tartaric acid[3], phosphoric acid[4], acetic acid[5], lactic acid[6], 1 *N* hydrochloric acid[2], and dilute hydrochloric acid BP. The alkalies were 1 *N* sodium hydroxide[3] and 1 *N* potassium hydroxide[3]. These additives were selected because they are representative of relatively weak acids, strong acids, and alkalies and are likely to be included in suspension formulation studies in which salicylic acid–cetrimide systems are involved.

The viscosity was measured at 25° as reported previously (2) and the pH[7] was determined.

RESULTS AND DISCUSSION

Figure 1 shows that the viscosity of salicylic acid–cetrimide systems was lowered in the presence of citric acid; a higher concentration of citric acid resulted in a greater lowering. Similarly, tartaric, acetic, phosphoric, lactic, and hydrochloric acids decreased viscosity (Fig. 2). The viscosity reduction was unrelated to the degree of saturation of the surfactant solution with salicylic acid, as can be seen in the action of an acetic acid solution on undersaturated and oversaturated systems (Fig. 3). This behavior also applied to the other acids employed. However, when the quantity of salicylic acid present in the system was low, no appreciable alteration in the viscosity was recorded (Fig. 3). Table I shows that the pH remained practically constant with increasing volumes of acid solution, with the exception of hydrochloric acid where a decrease in pH was observed. Therefore, it appears that the presence of most of these acids led to the formation of buffer systems.

Salicylic acid was found to interact with cetrimide to form a viscous product (3). It is believed that macromolecules resulting from this interaction are responsible for the high viscosity obtained. In the presence of other additives, the viscosity of salicylic acid–cetrimide systems was shown to vary according to the compounds added and the state of saturation of the system (2, 4, 5).

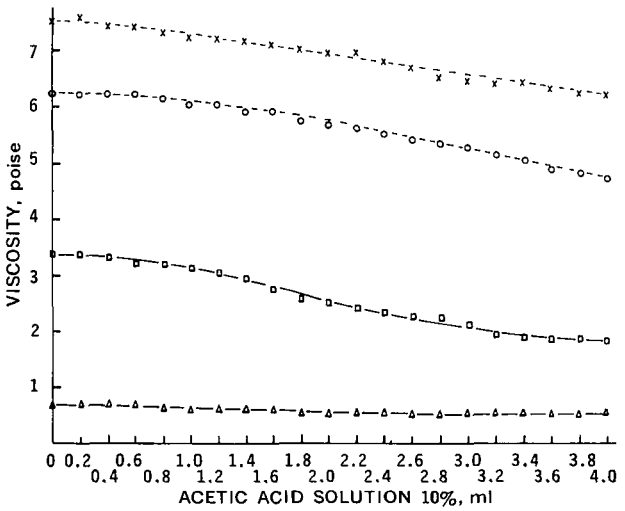

Figure 3—*Viscosity reduction by 10% acetic acid solution in dispersions (50 g) containing 5% cetrimide and such amounts of salicylic acid to form undersaturated and oversaturated systems at 25°. Key (salicylic acid, % w/v): ×, 1.8; ○, 1.6; □, 1.4; △, 1.2; —, undersaturated; and ----, oversaturated. Shear rate is 78.56 sec^{-1}.*

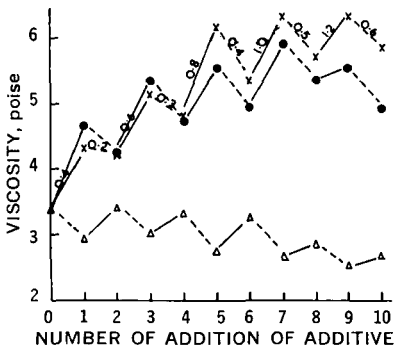

Figure 4—*Effect of various methods of adding base and acid to the viscosity of systems (50 g) containing 5% cetrimide and 1.4% salicylic acid at 25°. Key: ●, 0.6 ml of 1 N NaOH–0.3 ml of 1 N HCl; ×, 1 N NaOH–1 N HCl fixed at 2:1 but volume of additive varies as indicated in milliliters on graph; △, 0.6 ml of 1 N HCl–0.3 ml of 1 N NaOH; —, 1 N NaOH; and ---, 1 N HCl. Shear rate is 78.56 sec^{-1}.*

In preliminary experiments, it was observed that when the acid solutions were added to cetrimide solutions in the absence of salicylic acid, they had no effect on the viscosity. Hence, it was unlikely for this viscosity reduction to be brought about by a reaction between acid solutions and the surfactant. The viscosity decrease could not be attributed to a simple dilution effect, because the inclusion of water as an additive did not give a marked change in viscosity (4).

In the current investigation, the reduction in viscosity in both types of systems due to the added acids might arise from a breakup of the mesh-like structure of the system, the macromolecules becoming unstable in the presence of the acids. This condition indicates a high sensitivity of the macromolecules to these additives and the weakness of the links in the macromolecular network. The acid effect on viscosity is essentially the opposite to that of the sodium salts for undersaturated systems (1) but similar for oversaturated systems.

Instead of the usual method of adding the additive solution directly to the salicylic acid–cetrimide system, other procedures were adopted to ensure that the technique employed was not a contributing factor to the viscosity response obtained. First, the acid solution was added to the cetrimide solution and then the salicylic acid solution was added. Second, salicylic acid was added to the acid solution and this step was followed by the cetrimide solution addition. In both cases, a decrease in viscosity resulted. This finding suggests that the viscosity effect is not influenced by the manner of addition of the additive.

To examine further the mechanism of acid additive effect, a base was selected and, from preliminary studies, it was found that sodium hydroxide increased the viscosity of undersaturated systems but decreased that of oversaturated systems in the same way

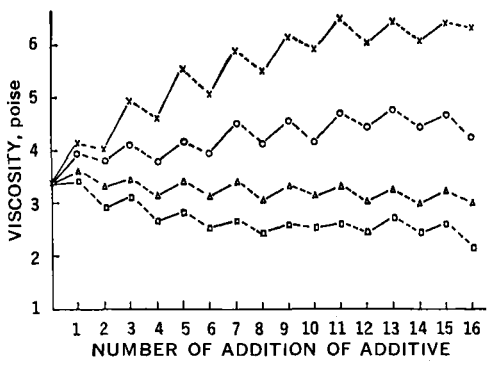

Figure 5—*Viscosity variation produced by different ratios of sodium hydroxide to citric acid in systems containing 5% cetrimide and 1.4% salicylic acid (50 g) at 25°. [a] pH of system without additive is 2.45.

as the other sodium salts reported (1). Several approaches were made to determine whether the viscosity change brought about either by an acid or a base can be further influenced by a number of alternate additions of each additive. When the volumes of solutions of sodium hydroxide and of hydrochloric acid were kept constant so as to maintain a fixed ratio of base to acid, the viscosity increased and decreased with each addition of the basic and acidic solutions, respectively (Fig. 4). Keeping the same ratio but varying the additive volume did not alter the pattern of viscosity variation (Fig. 4). This behavior was not restricted either to a strong acid and a strong base or to one ratio.

By replacing hydrochloric acid with a weaker acid, citric acid (Fig. 5), each of the ratios used produced the typical viscosity reaction to sodium hydroxide and to citric acid. It was noted that the larger the ratio, the smaller the viscosity rise and the greater the viscosity fall. When the order of additive addition was reversed (Fig. 4), an increase and a decrease with respect to the additives were produced. From these results, it may be concluded that the changes in viscosity in these systems due to the added base and the acid can be predicted and that the viscosity effect exhibited by either additive can be reproduced in the presence of the other.

These procedures were applied to salicylic acid–cetrimide systems which were more than saturated with salicylic acid (Fig. 6).

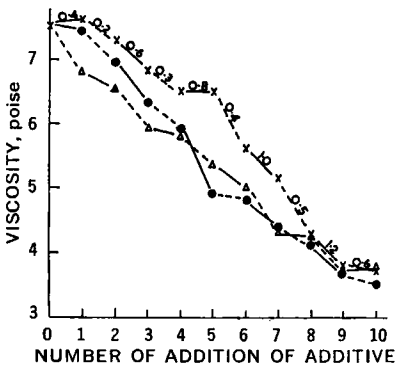

Figure 6—*Effect of different methods of adding base and acid on the viscosity of oversaturated systems (50 g) which contain 5% cetrimide and 1.8% salicylic acid at 25°. Key:* ●, *0.6 ml of 1 N NaOH–0.3 ml of 1 N HCl;* ×, *1 N NaOH–1 N HCl fixed at 2:1 but volume of additive is varied as indicated in milliliters on graph;* △, *0.6 ml of 1 N HCl–0.3 ml of 1 N NaOH;* —, *1 N NaOH; and* ---, *1 N HCl. Shear rate is 78.56 sec*$^{-1}$.

The normal rise and fall in viscosity (Figs. 4 and 5) were absent and only a lowering of viscosity occurred. Thus, two additives with contrasting properties have the same effect on these dispersions. Apparently, the viscosity behavior resulting from both types of additives was maintained. By varying the concentration of cetrimide but keeping the amount of salicylic acid constant and vice versa, systems undersaturated or oversaturated with salicylic acid were obtained. The effects of potassium hydroxide and hydrochloric acid solutions on such systems were also studied to ascertain that the observed viscosity changes were not limited to the sodium salt. The results were similar to those with sodium hydroxide and the same acid in corresponding systems.

The data presented show that the macromolecules in both types of salicylic acid–cetrimide systems are unstable to the additives. Recovery from a lower viscosity after the addition of acid additive to a greater value following the subsequent addition of alkali additive in an undersaturated system suggests that these systems are sensitive to these additives and that the viscosity change can be altered readily. This rapid recovery illustrates the degree of sensitivity.

This finding also supports the view that the bonding links involved in the formation of macromolecules are probably not strong and that there may exist a preferential reaction between sodium hydroxide and salicylic acid to produce sodium salicylate, which then interacts with the free cetrimide molecules, rather than between salicylic acid and cetrimide molecules, notwithstanding the previous presence of acid additive. Both reactions lead to an increase in viscosity. The insensitivity of the oversaturated systems may be due to the lack of free cetrimide molecules. Hence, the mechanism of macromolecule formation is not likely to involve complex interactions of such a nature as to give rise to a rigid structural system that is not easily affected by additives.

Opium Alkaloids XV: Isolation of Stepholidine

E. BROCHMANN-HANSSEN [x] **and W. J. RICHTER** *

Abstract □ A protoberberine alkaloid was isolated from opium and characterized as (−)-2,10-dihydroxy-3,9-dimethoxytetrahydroprotoberberine by spectroscopic methods and by comparison with (−)-stepholidine.

Keyphrases □ Opium alkaloids—isolation and identification of (−)-stepholidine □ (−)-Stepholidine—isolation, identification as opium alkaloid □ Alkaloids, opium—isolation and identification of (−)-stepholidine □ Protoberberine alkaloids—isolation and identification of (−)-stepholidine from opium

In recent years, several new alkaloids have been isolated from opium and the opium poppy or detected by isotope dilution techniques based on established or probable biosynthetic pathways. The phenolic alkaloid fraction has been a particularly rich source of such alkaloids. The present article describes the isolation of a phenolic protoberberine from opium. Alkaloids of this group are found in several plant families. Scoulerine (I) (1) and isocorypalmine (II) (2, 3) were isolated from opium, while coreximine (VI) was detected by an isotope dilution method based on its biosynthesis from reticuline (4).

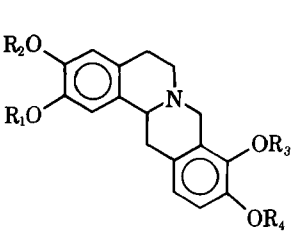
Preparative TLC of the opium fraction containing minor phenolic alkaloids revealed a new alkaloid, which was purified by column chromatography on neutral alumina and crystallized from methanol, mp 135–138°, $[\alpha]_D^{23}$ − 308° (ethanol).

DISCUSSION

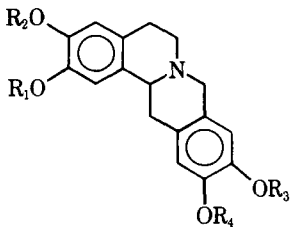
When subjected to GLC analysis[1], the new alkaloid produced a slightly tailing peak with a retention time of 23 min on a 3% OV-1 column at 230°. Silylation[2] gave a bis(trimethylsilyl) derivative (M = 471, determined by mass spectrometry[3]), which formed a sharp, symmetrical peak with increased retention time (31 min) under the same conditions, indicating that two active hydrogen atoms had been present. Correspondingly, the mass spectrum of the alkaloid displayed a molecular ion peak at *m/e* 327, for which high-resolution measurements[4] established a $C_{19}H_{21}NO_4$ composition.

The general fragmentation resembled the pattern characteristic of tetrahydroprotoberberine alkaloids (5–7), with the major fragments at *m/e* 178/177/176 and 150/149, suggesting a dihydroxydimethoxy compound having one hydroxy and one methoxy group in each of the rings A and D. In accordance with this finding, the NMR spectrum[5] in deuterochloroform with internal tetramethylsilane standard also revealed two methoxy singlets resonating at 3.80 and 3.86 ppm and four aromatic protons in the region of 6.5–6.85 ppm.

The optical rotatory dispersion spectrum[6] was very similar to spectra of (−)-scoulerine (I) (8), (−)-isocorypalmine (II)[7], and (−)-tetrahydropalmatine (III) (8). The small amplitude of the second Cotton effect (a = −144 in ethanol) was indicative of a



I: $R_1 = R_3 = H$, $R_2 = R_4 = CH_3$
II: $R_1 = H$, $R_2 = R_3 = R_4 = CH_3$
III: $R_1 = R_2 = R_3 = R_4 = CH_3$
IV: $R_1 = R_4 = H$, $R_2 = R_3 = CH_3$
V: $R_2 = R_4 = H$, $R_1 = R_3 = CH_3$



VI: $R_1 = R_4 = H$, $R_2 = R_3 = CH_3$

2,3,9,10-substitution pattern (8). This finding was confirmed by methylation of the alkaloid with diazomethane, which gave tetrahydropalmatine (III), identified by comparison with authentic material by TLC and GLC. In contrast to scoulerine, the new alkaloid gave no reaction with Gibb's reagent, suggesting that the phenolic functions had no unsubstituted *para*-position.

Mass spectrometric criteria recently developed for assignment of the substitution pattern of ring D of protoberberines, based upon the observation of $(M - OCH_3)^+$ fragments of due abundance[8], finally showed the methoxy group to be located at position 9. For this reason, the compound had to be either stepholidine (IV) (9) or its isomer with reverse substitution in ring A (V)[9]. Identity of the new opium alkaloid with stepholidine was borne out by comparison of the respective IR and mass spectra.

EXPERIMENTAL

Powdered opium of Indian origin [1.8 kg (4 lb)] was extracted, and a preliminary separation of alkaloid groups was carried out as described previously (10). The fraction containing the minor phenolic alkaloid was subjected to preparative TLC on silica gel with chloroform–methanol (9:1) and double development. A broad band, shown by analytical TLC to consist of several alkaloids, was collected, and the alkaloids were eluted from the silica gel with warm methanol. The solution was evaporated to dryness under reduced pressure, and the residue was chromatographed on a column of neutral alumina[10] with chloroform.

Twenty-milliliter fractions were collected with an automatic fraction collector. The first fraction contained porphyroxine, followed by scoulerine, *N*-methyl-14-*O*-desmethylepiporphyroxine, and an unknown alkaloid. The fractions containing this unknown alkaloid were combined and evaporated to dryness under reduced pressure, and the residue (25 mg) was crystallized from methanol, mp 135–138°[11] [lit. (9) 126–138° (*in vacuo*), 158–160° dec.], $[\alpha]_D^{23}$ − 308° (c = 0.192, ethanol) [lit. (9) $[\alpha]_D^{8}$ − 311° in ethanol]; λ_{max} (ethanol): 285 (log ϵ 3.77) and 226 (sh) (4.12) nm. Addition of alkali produced a bathochromic shift.

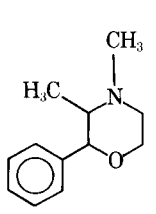
GLC Determination of Phendimetrazine in Serum

H. K. L. HUNDTˣ, E. C. CLARK, and F. O. MÜLLER

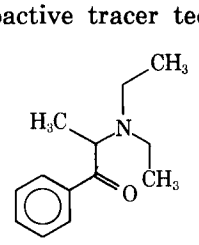
Abstract □ A sensitive, specific, and quantitative GLC method for the determination of phendimetrazine in serum is described. The procedure involves the addition of an internal standard to serum samples, followed by extraction at pH 13 into toluene. The extracted bases are back-extracted into 1 ml of 4 *M* hydrochloric acid and again into 100 μl of chloroform after making the 4 *M* hydrochloric acid extract basic with 1.5 ml of 4 *M* sodium hydroxide. The sensitivity of the method is such that 25 ng of material can be detected in 5 ml of serum

Keyphrases □ Phendimetrazine—GLC analysis in human serum □ GLC—analysis, phendimetrazine in human serum

Phendimetrazine (I) is an anorexigenic agent marketed in South Africa in the form of a standard formulation tablet. To satisfy the requirements of the local Drugs Control Council, the introduction of a timed-release preparation of I on the South African market necessitated the development of a sensitive quantitative method for the detection of I so that serum levels attained after administration of a single timed-release tablet (containing 105 mg of phendimetrazine bitartrate) could be compared with the levels attained after administration of a single tablet of the standard formulation (containing 35 mg of phendimetrazine bitartrate). Although various articles refer to the clinical and toxicological aspects (1–7) of I and its qualitative identification by TLC (8) and GC (9), only one reference dealing with the quantitative determination of phendimetrazine in plasma utilizing a ^{14}C-radioactive tracer technique (10) and one dealing with *in vitro* release studies of timed-release phendimetrazine (11) could be found.



I



II

This report describes a sensitive GLC method for I determinations, under conditions where only I was administered, using diethylpropion (II) as an internal standard.

Table I—Recovery of Phendimetrazine from Serum

Amount Added, ng/ml	Amount Recovered, ng/ml				Mean ± *SD*, ng/ml
20	20.2	20.7	20.9	19.4	20.30 ± 0.67
40	38.9	38.9	37.7	37.9	38.35 ± 0.64
60	59.0	61.2	61.8	62.3	61.08 ± 1.45
80	79.6	80.7	79.5	79.0	79.70 ± 0.71

EXPERIMENTAL

Reagents and Chemicals—The chemicals and reagents used were: 2 *M* sodium hydroxide[1], 4 *M* sodium hydroxide, 4 *M* hydrochloric acid[1], toluene[1], chloroform[1], phendimetrazine bitartrate[2], and diethylpropion hydrochloride[3].

Instrumentation—A gas chromatograph[4] equipped with a flame-ionization detector and a 183-cm × 6-mm glass column containing 3% SE-30 on Chromosorb W (AW HMDS), 80–100 mesh, was used. The injection port and detector were kept at 250°. The column temperature was kept at 140° for 8 min after injection and then programmed at 32°/min to 250°, where it was kept for 8 min. Nitrogen was used as the carrier gas at a flow rate of 80 ml/min. Quantitation was achieved by measuring peak heights. (Peak area calculation by a digital integrator was found to be less reliable.)

Measurement of I in Serum—To 5 ml of serum contained in a 20-ml glass-stoppered centrifuge tube were added 0.5 μg of internal standard (in 50 μl of water), 1 ml of 2 *M* sodium hydroxide, and 5 ml of toluene. The tube was shaken for 2 min (vortex) and centrifuged, and as much as possible of the organic phase was transferred to a 10-ml, glass-stoppered, tapered centrifuge tube contain-

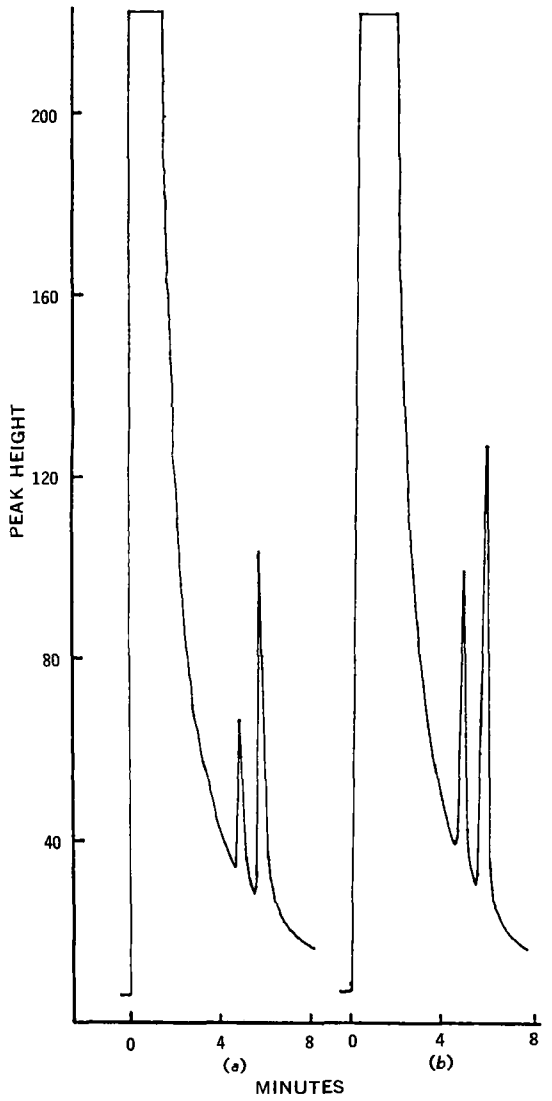

Figure 1—*Chromatograms of* (a) *I and II added to control serum and carried through extraction, and* (b) *material obtained from biological specimens after addition of II (internal standard).*

ing 1 ml of 4 *M* hydrochloric acid. After shaking for 2 min, the tube was centrifuged and the organic phase was removed by aspiration.

The aqueous phase was transferred to a special 5-ml glass-stoppered centrifuge tube equipped with a small nipple in which liquids denser than water can collect after centrifuging. The centrifuge tube was cooled for 2 min in an ice bath, the aqueous phase was made strongly alkaline by addition of 1.5 ml of 4 *M* sodium hydroxide, and the free bases were extracted into 0.1 ml of chloroform (vortex, 2 min). After brief centrifugation, 5 μl of the chloroform phase was injected into the gas chromatograph. The retention times of I and II were 292 and 345 sec, respectively.

Standard serum curves were constructed by plotting the peak height ratios (I/II) *versus* weight ratios (I/II) of standard samples which were run simultaneously with the unknown samples as previously described. The peak height ratio obtained from an unknown was then used to determine the amount of I present.

Absorption Studies—One tablet of the standard formulation was administered to each of five healthy human subjects who had fasted overnight. Blood was collected by venipuncture before administration of the drug and at intervals after administration. The serum was separated by centrifugation and frozen until assayed.

For assay, equal amounts of serum of each volunteer were pooled for each sample and the samples were analyzed in duplicate as previously described. After a washout period of 3 days, the same procedure was followed with the administration of one tablet of the timed-release preparation to the same volunteers.

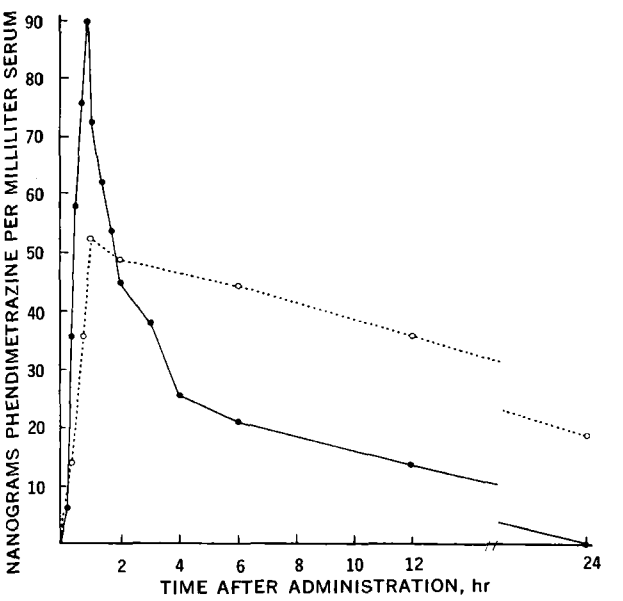

Figure 2—*Pooled serum levels of I after administration of standard formulation* (●) *and timed-release formulation* (○).

RESULTS AND DISCUSSION

Figure 1 represents the chromatogram of: *(a)* I and II added to control serum and carried through the extraction and GLC procedure, and *(b)* material obtained from biological specimens after the addition of II as the internal standard.

Figure 2 represents pooled serum levels of I after administration of the standard formulation and the timed-release formulation to the same five volunteers.

Gas chromatograms of control samples taken from the volunteers before any drug had been administered did not exhibit any peaks with retention similar to I or II. Possible interference by metabolites of I could not be checked because these metabolites were

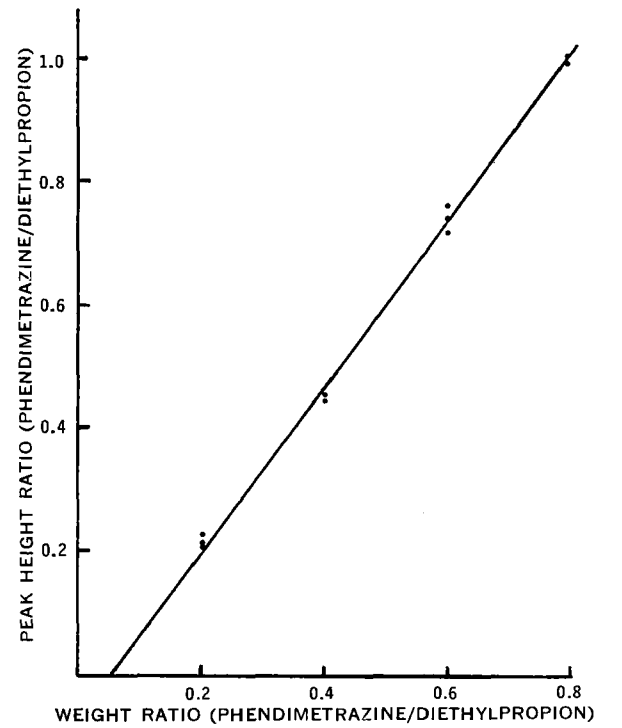

Figure 3—*Relationship between peak height ratio and weight ratio (phendimetrazine/diethylpropion). Five microliters was injected in each case out of 100 μl following extraction from serum.*

not available. However, a small peak with a retention time of 252 sec appeared occasionally in extracts of serum from volunteers but did not interfere with the assay; it was attributed to a metabolite.

A typical standard graph of peak height ratio (I/II) *versus* weight ratio (I/II) is presented in Fig. 3. A straight line with a slope varying between 1.31 and 1.35 and an intercept varying between 0.04 and 0.06 on the weight ratio axis was obtained by linear regression analysis over 1 month during which the analyses were performed. The intercept on the weight ratio axis corresponds to a loss of 0.8–1.2 ng of I on the GLC column during chromatography, thus imposing a lower limit of detection of I in serum by this method at about 5 ng/ml. A peak for I just begins to appear in the chromatogram at this concentration. A summary of the recovery results of I obtained with human serum when 20–80 ng/ml was added to the serum is presented in Table I.

This GLC method was applied to a large number of samples of human serum during a trial comparing serum levels attained after administration of a standard formulation with levels attained after administration of a timed-release formulation of I.

Colorimetric Determination of Formaldehyde *via* Free Radical Formation

JAMES W. MUNSON [x] and THOMAS G. HODGKINS

Abstract □ Aliphatic aldehydes react with 2,3-dimethyl-2,3-bis(hydroxylamino)butane and sodium periodate to form colored free radicals. These radicals were stabilized with pyridine in aqueous solution. Low levels of formaldehyde in aqueous solutions were determined utilizing this reaction.

Keyphrases □ Formaldehyde—stabilized colorimetric analysis in aqueous solution *via* reaction with 2,3-dimethyl-2,3-bis(hydroxylamino)butane and sodium periodate □ 2,3-Dimethyl-2,3-bis(hydroxylamino)butane—colorimetric reagent for determination of formaldehyde in aqueous solution □ Colorimetry—analysis, formaldehyde in aqueous solution using 2,3-dimethyl-2,3-bis(hydroxylamino)butane

Aldehydes have been shown to form stable free radicals when reacted with 2,3-dimethyl-2,3-bis(hydroxylamino)butane (I) (1) (Scheme I). The anhydro product (II) can be isolated directly or may be converted to the free radical (III) by the action of lead dioxide or sodium periodate. The free radicals are red or blue in solution. The color of these free radicals suggests that this reaction may be suitable for colorimetric determination of aldehydes.

Preliminary data suggested that only aliphatic aldehydes and ketones react with I to form a colored product in aqueous solution. A spot test based on this reaction was developed that allows detection of as little as 0.2 μg of aliphatic aldehydes (2). Aliphatic ketones gave a much smaller response, with 100–200 μg being the minimum detectable quantity.

Initial attempts to utilize this reaction in a quantitative manner were plagued by the instability of the color of the free radical. The half-life for the disappearance of color was about 7 min at 25°. This paper reports the stabilization of the color and the adaptation of this reaction to the determination of formaldehyde at low concentrations in aqueous solution.

EXPERIMENTAL

Materials—Formaldehyde stock solutions were analyzed by peroxide oxidation (3). Acetaldehyde was redistilled and chilled. A portion of acetaldehyde was added to a tared flask, sealed, and reweighed. Water was then added to give a known concentration. All other aldehyde stock solutions were prepared by dissolving weighed amounts of the redistilled aldehyde in water. 2,3-Dimethyl-2,3-bis(hydroxylamino)butane sulfate[1] was recrystallized from a 2-propanol–water mixture, mp 185° dec.

Anal.—Calc. for $C_6H_{18}N_2O_6S$: C, 29.27; H, 7.32; N, 11.38. Found: C, 27.78; H, 7.54; N, 11.12.

Sodium periodate[2] and the organic solvents were reagent grade and were used directly.

Effect of Solvent on Stability of Color—An aqueous reaction mixture containing formaldehyde (1.34×10^{-3} *M*) and 2,3-dimethyl-2,3-bis(hydroxylamino)butane sulfate (Ia) (1.76×10^{-2} *M*) was prepared and allowed to react for 1 hr at 25°. One-milliliter aliquots of the reaction mixture were added to a tube containing 1 ml of the solvent being studied and 1 ml of sodium periodate (0.094 *M*).

The absorbance[3] at 515 nm was measured as a function of time at 25°. Plots of $A_t - A_\infty$ *versus* time were linear for at least three half-lives of the color disappearance. Pseudo-first-order rate constants for this process were calculated from the slopes of these plots.

Effect of Pyridine Concentration on Stability—Reaction mixtures were prepared in the same manner as described in the previous section. The final solutions contained formaldehyde (4.47×10^{-4} *M*), Ia (8.22×10^{-3} *M*), and pyridine ranging from 0.41 to 8.24 *M*. Absorbance was measured as a function of time at 25°, and pseudo-first-order rate constants were calculated from plots of $A_t - A_\infty$ *versus* time.

Effect of Reaction Time on Extent of Color Formation—A reaction mixture containing Ia (1.32×10^{-2} *M*) and formaldehyde (2.76×10^{-3} *M*) was prepared and allowed to react at 25°. Aliquots (0.5 ml) were removed as a function of time and mixed with 0.5 ml of sodium periodate (3.7×10^{-2} *M*) and 2.0 ml of pyridine. The absorbance at 515 nm was measured at 1500 sec after the mixing of the final solution.

Effect of Ratio of Sodium Periodate to Formaldehyde on Extent of Color Formation—A reaction mixture was prepared containing Ia (1.32×10^{-2} *M*) and formaldehyde (2.68×10^{-3} *M*) and allowed to react for 5 min at 25°. Then 0.5 ml of the reaction mixture was added to 2.0 ml of pyridine and 0.5 ml of a sodium periodate solution. The absorbance was measured at 515 nm after 25 min.

Calibration Curve for Formaldehyde—Reaction mixtures were prepared containing Ia (1.32×10^{-2} *M*) and varying amounts of formaldehyde. The reaction mixture was allowed to stand at 25° for 5 min, and 0.5 ml was added to a cell containing 0.5 ml of sodium periodate (0.037 *M*) and 2.0 ml of pyridine. Absorbance at 515 nm was measured 25 min after the addition of the sodium periodate and pyridine.

600	0.588

[a] Formaldehyde substrate. [b] Time of reaction of Ia and formaldehyde before the addition of sodium periodate. [c] Absorbance measured 1500 sec after the addition of sodium periodate.

Reaction of Other Compounds—Reaction mixtures were prepared containing Ia (1.32×10^{-2} *M*) and some aldehydes and ketones. As a function of time, 0.5 ml of the reaction mixture was added to 0.5 ml of sodium periodate (0.037 *M*) and 2.0 ml of pyridine. Absorbance was measured at the appropriate wavelength after 25 min.

RESULTS AND DISCUSSION

Of the solvents tested (Table I), pyridine, acetonitrile, and tetrahydrofuran stabilized the color of the free radical. Only pyridine gave sufficient stability for analytical procedures. It was observed that the color increased immediately after the addition of the sodium periodate and then stabilized after 15 min. The color was quite stable after this time for at least 1 hr. During this span, the absorbance decreased at a rate of 0.8%/hr.

While these free radicals have been found to be stable in organic solvents, such as cyclohexane (1), their stability in primarily aqueous solution has not been reported. Although the solvents were not added in equimolar concentrations, an examination of the concentrations (Table I) does not suggest that any of the solvents approach the ability of pyridine to stabilize the color when the stability is compared on an equimolar basis.

Formaldehyde reacted very rapidly, the reaction being complete within 5 min at room temperature (Table II). Other aliphatic aldehydes reacted more slowly than formaldehyde under the same conditions (Table III). Acetone and benzaldehyde failed to react within 30 min under the same conditions and equivalent concentrations.

Increasing pyridine concentration in the final solution led to greater color stability (Table IV). A concentration of 8.2 *M* was chosen for convenience of sample handling. Furthermore, this concentration gave sufficient stability for the analytical procedure. The rate constants obtained for pyridine concentrations of 2.06 and 4.12 *M* were redetermined to check the apparent decrease in stability upon going from 2.06 to 4.12 *M* pyridine. These data are apparently real and at this time unexplained. All rate constants were determined at a single formaldehyde concentration.

The ratio of sodium periodate to formaldehyde (and by inference the anhydro product II) in the final solution was found to be

Pyridine, M	$10^5 k_{obs}$, sec^{-1}
0.41	9.8
2.06	0.92
4.12	1.7
8.24	0.45

[a] Formaldehyde, 4.47×10^{-4} M; Ia, 8.22×10^{-4} M; sodium periodate, 3.12×10^{-2} M; 25°.

critical in that sodium periodate must be in at least a twofold excess for maximal color development (Table V). Therefore, a relatively high concentration of sodium periodate should be used when a wide concentration range of aldehyde is to be studied.

A calibration curve for the determination of formaldehyde gave excellent results. The slope of the line was 1156 liters $mole^{-1}$ cm^{-1} (1-cm cell used) with an intercept of 0.008 when calculated by linear regression analysis. The sample correlation coefficient was 0.999 with a standard error of the estimate of 0.009 ($S_{y \cdot x}$). Formaldehyde concentrations down to 4×10^{-5} M can be determined using a 1-cm cell and a spectrophotometer[4] (no scale expansion). It is quite conceivable that lower concentrations could be determined if enough sample were available to allow for the use of longer path length cells. Above concentrations of 10^{-3} M, deviation from Beer's law was observed.

Although other aliphatic aldehydes reacted more slowly than formaldehyde, each gave a similar color yield. It is not unexpected that acetone and benzaldehyde did not react since much higher concentrations of these compounds must be present to give a positive spot test using a variation of this reaction (2). Furthermore, on the basis of spot test data, no interference from a variety of carboxylic acid derivatives is expected (2).

Nidation Inhibition by Simple Ergoline Derivatives

KAREL ŘEŽÁBEK *, JOHN M. CASSADY ‡, and HEINZ G. FLOSS ‡x

Abstract □ The ability of four ergoline-type compounds (elymoclavine, its *O*-benzoate and *O*-carbamate, and *N*-methyl-6,7-seco-elymoclavine) to inhibit nidation in rats was determined and found to parallel their prolactin-inhibiting activity.

Keyphrases □ Nidation—inhibition by four ergoline-type compounds, rats, relationship to prolactin-inhibiting ability □ Ergoline-related compounds—inhibition of nidation, relationship to prolactin-inhibiting ability □ Elymoclavine and related compounds—inhibition of nidation, rats

Research interest in the pharmacology of ergot alkaloids is currently focusing on two areas: their antihypertensive activity and their effect on hormone release from the anterior pituitary gland. The latter effect, primarily due to a direct inhibition of the synthesis and release of prolactin, manifests itself in the inhibition of some prolactin-dependent processes, *e.g.*, lactation in various animals and in humans, development of certain types of mammary tumors, and implantation of the fertilized egg (nidation) in rats and mice (1). While nidation inhibition in rats is generally thought to be predominantly or exclusively the result of prolactin inhibition, Flückiger and Wagner (2) obtained results that led them to conclude that 2-bromo-α-ergokryptine, a modified peptide ergot alkaloid which is undergoing clinical evaluation, has a specific nidation-inhibiting effect.

Since it has been shown (1, 3–5) that the peptide portion of these alkaloids is not required for activity, it was of interest to compare the ability of some simple ergolenes to inhibit prolactin release and nidation. For this comparison, four compounds were se-

[a] Significantly different from the parallel and summarized controls ($p = 0.05$). [b] Difference from controls not statistically significant.

lected which had been assayed for prolactin inhibition in rats (5). Three of these compounds (elymoclavine, its benzoate, and its carbamate) were active (95, 66, and 66% of inhibition shown by ergocornine as reference); the fourth (*N*-methyl-6,7-secoelymoclavine), although structurally closely related, had only borderline activity (40% of reference).

EXPERIMENTAL

Nidation inhibition by these compounds was determined using virgin female rats of the Wistar strain weighing 170–230 g at the beginning of the experiment. They were caged with fertile males and their vaginal smears were examined each morning. The day of finding spermatozoa in the vagina was considered Day 1 of the experiment, and from this day on the animal was caged separately from males.

The compounds to be tested were dissolved in 0.2% aqueous tartaric acid solution at concentrations of 1 or 0.1 mg/ml (except in the case of elymoclavine benzoate which required addition of 10% ethanol for solution). They were administered, *via* stomach tube, to groups of six or seven animals once a day on Days 6 and 7. Each animal received 1 ml of solution/day, *i.e.*, 1 or 0.1 mg of drug, corresponding to approximately 5 or 0.5 mg/kg. The time of administration and the doses were chosen on the basis of previous experience (4). Control animals received 1 ml of 0.2% tartaric acid solution.

On Day 20, the animals were killed and the uterus was examined. The number of well-developed fetuses and of resorbed fetuses was determined, and the well-developed fetuses were weighed in some experiments (Table I).

RESULTS AND DISCUSSION

The experiments clearly show that elymoclavine, elymoclavine benzoate, and elymoclavine carbamate completely suppress the nidation of embryos and thus pregnancy in rats when given orally in doses of 5 mg/kg on the 5th and 6th days after copulation. When given at the lower dose of 0.5 mg/kg, elymoclavine carbamate did not significantly reduce the number of animals found pregnant. D-6-Methyl-8-ergoline-1-yl-acetamide tartrate, a known potent lactation and nidation inhibitor, was effective at both the higher (Table I) and the lower dose (6). *N*-Methylsecoelymoclavine, when given in the dose of 5 mg/kg in the same way as the other drugs, had no significant effect on nidation but caused an interesting, unexplained 20% increase in weight of the fetuses.

It follows from the results of these experiments that, in the simple ergolene series, the nidation-inhibitory activity parallels prolactin-inhibiting ability at least qualitatively.

Positional Isomer of the Muscle Relaxant Dantrolene

THOMAS J. SCHWAN [x] **and K. O. ELLIS**

Abstract □ 3-[[5-(*p*-Nitrophenyl)furfurylidene]amino]hydantoin, a position isomer of dantrolene, was synthesized and evaluated for skeletal muscle relaxant activity.

Keyphrases □ Dantrolene positional isomer (3-[[5-(*p*-nitrophenyl)furfurylidene]amino]hydantoin)—screened for skeletal muscle relaxant activity □ 3-[[5-(*p*-Nitrophenyl)furfurylidene]amino]hydantoin (dantrolene positional isomer)—screened for skeletal muscle relaxant activity □ Skeletal muscle relaxant activity—3-[[5-(*p*-nitrophenyl)furfurylidene]amino]hydantoin (dantrolene positional isomer) screened

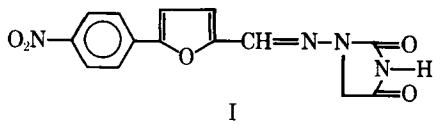
Dantrolene, 1-[[5-(*p*-nitrophenyl)furfurylidene]amino]hydantoin (I), was shown previously to demonstrate unique skeletal muscle relaxant activity (1, 2) by a direct action on skeletal muscle. It has been pharmacologically categorized as a skeletal muscle contraction antagonist (3). This report describes the synthesis of 3-[[5-(*p*-nitrophenyl)furfurylidene]amino]hydantoin (II), a positional isomer of I, and the evaluation of this compound for skeletal muscle relaxant activity.

DISCUSSION

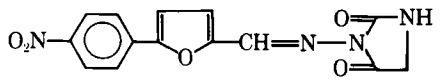
The reaction of 5-(*p*-nitrophenyl)-2-furaldehyde (III) with 3-aminohydantoin (IV) (4) by a previously described method (5) gave the target Compound II.

When using gross observational techniques similar to those described by Irwin (6), II did not produce any evidence of muscle relaxation or any other pharmacological activity at doses from 200 to 1600 mg/kg po. No toxicity was noted over the same dose range.

In the pithed rat gastrocnemius muscle preparation (7), a dose of 25 mg/kg iv administered in tetrahydrofurfuryl alcohol (0.75 ml/kg) caused a 25.3 ± 1.8% decrease in the twitch response. The solvent itself produced no significant effect on the twitch response, while dantrolene administered at the same dose caused a 70% decrease in the twitch response (7). This twitch inhibition indicates that II has slight contraction antagonist activity but that potency and effectiveness are less than that of dantrolene.



I



II

EXPERIMENTAL[1]

Compound II was prepared as follows. The reaction of III and IV by a previously described method (5) gave II, mp 233–234°. The analytical sample, mp 268–269°, was obtained by recrystallization from nitromethane; IR (μm): 5.61 and 5.80 (hydantoin C=O); NMR (dimethyl sulfoxide-d_6): δ 4.03 (s, 2, hydantoin CH_2), 7.28, 7.44 (doublets, J = 3.5 Hz, 2, furan C—H), 7.98, 8.28 (2 doublets, J = 9.0 Hz, 4, phenyl C—H), 8.28 (m, 1, N—H), and 9.23 (s, 1, =C—H).

Anal.—Calc. for $C_{14}H_{10}N_4O_5$: C, 53.50; H, 3.21; N, 17.83. Found: C, 53.51; H, 3.24; N, 18.03.

[1] Melting points were determined on a Mel-Temp apparatus and are uncorrected. The IR spectrum was determined as a mineral oil mull using a Perkin-Elmer 137B spectrophotometer. The NMR spectrum was obtained on a Varian A-60A instrument and was compared with tetramethylsilane as an internal standard.

GLC Analysis of Metronidazole in Human Plasma

N. F. WOOD

Abstract □ A sensitive procedure was developed for metronidazole in human plasma. The metronidazole is extracted from the plasma with chloroform and determined as the trimethylsilyl derivative by GLC using a flame-ionization detector. Myristyl alcohol is used as the internal standard for quantitation by relative peak height.

Keyphrases □ Metronidazole—GLC analysis in human plasma □ GLC—analysis, metronidazole in human plasma

Metronidazole (2-methyl-5-nitroimidazole-1-ethanol) (I) is an antiprotozoal agent that has been widely used for many years in the oral treatment of trichomoniasis. The methods most frequently used for determining metronidazole in biological fluids have been polarography (1, 2) and colorimetry involving reduction of the nitro moiety (2, 3). A comparative study (2) found that these methods gave inconsistent results and that even a biological method was more reliable. Recently, more specific chromatographic methods were reported: a TLC method for metronidazole in serum (4) and a GLC method for metronidazole in plasma (5).

The GLC method described in the present work was developed before publication of the method of Midha *et al.* (5); although similar in approach, it has some advantages over the Midha *et al.* method.

EXPERIMENTAL

GLC—A gas chromatograph[1] equipped with a flame-ionization detector was used. A 183 × 0.04-cm column packed with OV-1 (3%) on Gas Chrom Q was operated at 160° with a carrier of nitrogen at 70 ml/min. Detector flow rates were: hydrogen, 45 ml/min, and air, 300 ml/min. Electrometer attenuations were 10 × 16 or 10 × 32. Injection size was 2 μl. Retention times of trimethylsilyl derivatives were as follows: metronidazole, 4.1 min; 2-methyl-5-nitroimidazole-1-ylacetic acid, 5.1 min; and myristyl alcohol, 8.1 min. After each plasma analysis, it was found preferable to raise the column temperature to 200° for about 10 min to eliminate the possibility of strongly retained substances interfering with subsequent analyses.

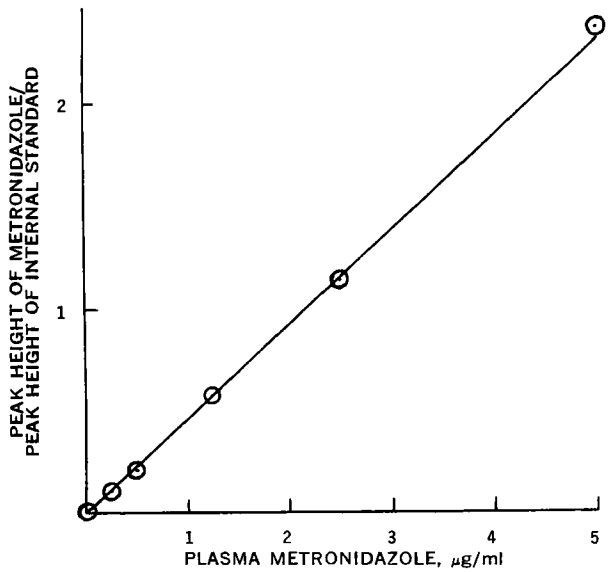

Figure 1—*Calibration chart for metronidazole.*

[1] Tracor MT-220.

Table I—Recovery of Metronidazole Added to Human Plasma

5.0	2	4.62–4.80	4.71	2.70	−5.80
Average recovered		102.9%			

[a] Corrected for blank of 0.05 μg/ml.

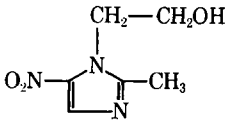
Method—Plasma (2 ml) adjusted to pH 8 was extracted with chloroform (1 × 20, 1 × 10, and 1 × 5 ml), and 100 μl of chloroform containing 5 mg/100 ml of myristyl alcohol was added to the extract. The extract was dried over anhydrous sodium sulfate for a few minutes and then decanted into an evaporation flask. After removal of chloroform using a rotary evaporator, the residue was transferred to a 1-ml vial with 0.5 ml of methanol. The methanol was removed in a stream of nitrogen, 50 μl of bis(trimethylsilyl)trifluoroacetamide was added, and the vial was immediately capped with a Teflon-coated rubber septum.

After standing overnight, the solution was examined by GLC and the ratio of the peak heights of the metronidazole and the myristyl alcohol derivatives was determined. Finally, the metronidazole was found by reference to a calibration chart relating the peak height ratio to plasma concentration. The calibration chart was prepared from standard mixtures of metronidazole with myristyl alcohol in bis(trimethylsilyl)trifluoroacetamide.

RESULTS AND DISCUSSION

The generally recommended dosage of metronidazole for women is one oral tablet of 250 mg three times daily. According to McFadzean (6), a single oral dose of 200 mg leads to a maximum serum level of 5 μg/ml after 1 hr; the serum level then decreases to 1 μg/ml after 24 hr. On this basis, the presently described method was developed so as to give good quantitation for metronidazole in plasma from 0.5 to 5 μg/ml.

GLC analysis of metronidazole as the trimethylsilyl derivative rather than as the parent compound itself was chosen because of superior peak shape and detector response. Moreover, it was anticipated that trimethylsilylation would improve the chances for detection of metronidazole metabolites, which would be expected to be more polar than metronidazole itself. Trimethylsilyl derivatives are usually sensitive to moisture and frequently unstable. Actually,



I

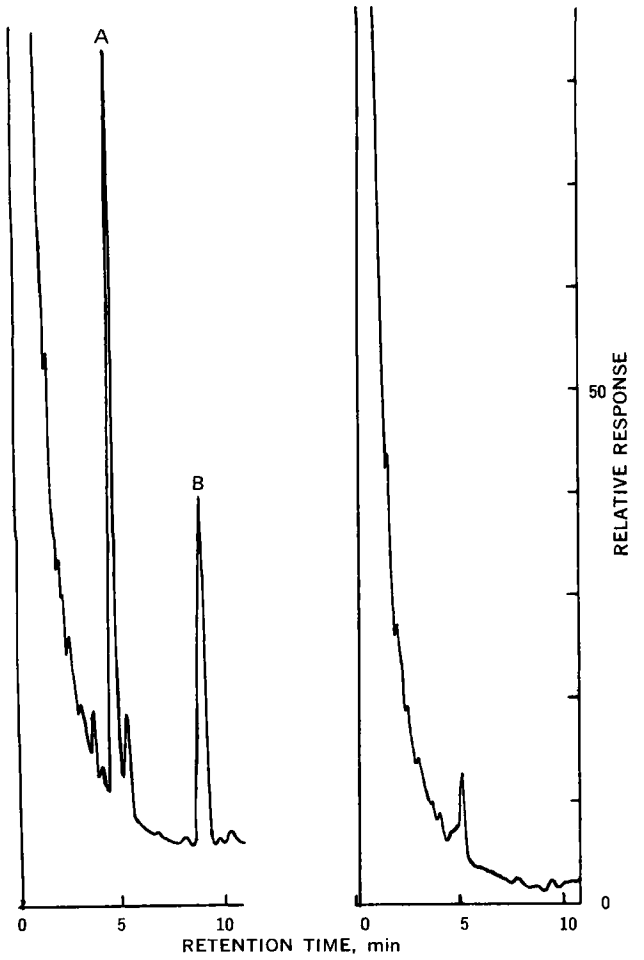


Figure 2—*Recovery of metronidazole from plasma. Chromatogram on left was obtained from a plasma sample with added metronidazole (5 μg/ml) and internal standard (5 μg/ml). Chromatogram on right was obtained from a control sample. Key: A, metronidazole; and B, internal standard.*

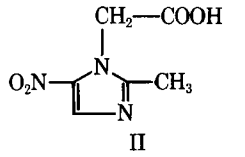
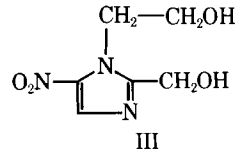
the derivatives of metronidazole and the chosen internal standard of myristyl alcohol are probably simple derivatives of primary alcohols (5) and, as such, do not suffer from these disadvantages. Indeed, the derivatives may be recovered from dimethylformamide solution by addition of water and extraction into hexane or chloroform. No peculiar behavior during GLC was noted.

A brief study was made of the conditions necessary for quantitative trimethylsilylation of a mixture of metronidazole and myristyl alcohol. In dimethylformamide–bis(trimethylsilyl)trifluoroacetamide (1:1), reaction was complete in less than 30 min; but it was obvious that at low levels of metronidazole, the tail of the dimethylformamide peak would interfere with quantitation. In bis(trimethylsilyl)trifluoroacetamide alone, reaction was complete in less than 1 hr at 50° and almost complete in 2 hr at room temperature. It was decided to trimethylsilylate the plasma extract by allowing it to stand in bis(trimethylsilyl)trifluoroacetamide at room temperature overnight.

Determinations of metronidazole were based on the ratio of the peak height of the metronidazole derivative to that of the internal



II



III

standard. Calibration charts relating this ratio to the concentration of metronidazole in plasma were prepared from standard mixtures of metronidazole with the internal standard in bis(trimethylsilyl)trifluoroacetamide. Such a chart is shown in Fig. 1, and it can be seen that a linear relationship exists in the 0–5-μg/ml range.

The results of some recovery experiments for standards of metronidazole added to human plasma are given in Table I. Typical chromatograms from a 5-μg/ml plasma sample and a control plasma sample are shown in Fig. 2.

Although 2-methyl-5-nitroimidazole-1-ylacetic acid (II) and 1-(2-hydroxyethyl)-2-hydroxymethyl-5-nitroimidazole (III) have been reported as metabolites of metronidazole in urine (7, 8), no clear evidence for metabolites of metronidazole in plasma was found in the present work during the analysis of several clinical samples. Compound III ought to lend itself to analysis since it is structurally related to metronidazole simply by having an additional primary alcohol moiety. Unfortunately, no sample of III was available. However, a submilligram sample of II was available, and some preliminary recovery experiments with plasma were performed. Results showed good recovery of II, giving a sharp chromatographic peak eluting immediately behind, and sharply resolved from, that of metronidazole.

The method described here is similar to that of Midha *et al.* (5). Midha *et al.* also carried out trimethylsilylation prior to analysis, but they used a reagent consisting of a mixture of hexamethyldisilazane and trimethylchlorosilane in acetonitrile rather than bis(trimethylsilyl)trifluoroacetamide. They were not able to analyze the resulting metronidazole derivative satisfactorily by GLC using a single liquid as the stationary phase as described here, but instead they had to resort to a mixture of three liquids. One practical difficulty in the application of the method of Midha *et al.* is that the internal standard, 1-(2-hydroxyethyl)-2-methoxy-5-nitroimidazole, may be difficult to obtain since it is quite a rare chemical and unavailable commercially.

Determination of 17-Hydroxycorticosteroids in Human Urine

W. FEINSTEIN and J. J. SCIARRA ˣ

Abstract □ A study was undertaken to develop a method that could be used as an indication of the absorption of steroids. It was demonstrated that 17-hydroxycorticosteroids in urine could be quantitatively determined *via* absorptivity values obtained through the use of standard hydrocortisone–alcohol solutions or standard solutions of hydrocortisone in urine utilizing the blue tetrazolium assay method. This method is dependent upon the hydrolysis of conjugated urinary steroids by beef liver glucuronidase. The resultant concentration of 17-hydroxycorticosteroids is determined colorimetrically using blue tetrazolium.

Keyphrases □ 17-Hydroxycorticosteroids—colorimetric analysis in human urine □ Steroids—colorimetric analysis of 17-hydroxycorticosteroids in human urine □ Colorimetry—analysis, 17-hydroxycorticosteroids in human urine

It has been shown by others that significant percutaneous absorption of steroids can take place from topical dosage forms. The percutaneous absorption that occurred when pharmaceuticals were applied over large body areas was investigated (1). The results from two patients treated with fluocinolone acetonide led to the conclusion that the depression of urinary steroid excretion was caused by suppression of endogenous adrenocorticosteroid production and that this suppression was a result of the absorption of the drug. One phenomenon associated with the administration of steroids is the decrease in concentration of 17-hydroxycorticosteroids in the urine.

Burch and Migeon (2) stated that this phenomenon presumably reflects a partial shutdown of adrenal gland activity because of the absorbed steroid. The extent of percutaneous absorption of this drug was noted to be dependent upon the lipid solubility of the drug. The biotransformation of the topically applied steroid to a compound of greater water solubility was studied by way of the urine concentration profiles of measured 17-hydroxycorticosteroids.

DISCUSSION

The 17-hydroxycorticosteroids that occur primarily in urine as conjugates of glucuronic acid can be hydrolyzed. Drekter *et al.* (3) developed a simplified method for the determination of urinary 17-ketosteroids by means of acid hydrolysis. They replaced the routine aqueous alkali wash with a solid alkali pellet wash to remove urine pigments, such as the acidic, phenolic, and pigmented constituents of hydrolyzed urine, which normally interfere with the results. Therefore, this technique reduces the blank readings significantly. In addition, they found that no interaction occurred between the solid sodium hydroxide pellets and the steroids present.

Several methods for hydrolyzing the steroid conjugates and extracting the free compounds were presented (4). It was noted that urine contains various reducing agents and the specificity of the assay method depends upon the efficiency of the extraction and the purification of the extract. The free 17-hydroxycorticosteroids resulting from the hydrolysis reaction can then be oxidized with sodium iodate or sodium bismuthate on the C_{20},C_{21}-dihydroxy position. The evolved formaldehyde then can be determined (5).

The oxidation reaction also produces 17-ketosteroids, which can be analyzed by the modified Zimmermann reaction (the ketosteroids are removed by borohydride reduction to the corresponding alcohols). The 17-ketogenic steroids are then oxidized by bismuthate and the resulting concentrations are determined either directly (6) or by the Pettenkoffer reaction (reaction between acetic acid solutions and the steroid when treated with furfural and sulfuric acid) (7). The normal range of 17-ketosteroids also gives this reaction.

The Kober reaction (involving acid hydrolysis, ether extraction, separation of ethers by chromatography, colorimetric measurement, and spectrophotometric correction for interfering chromogenic material) (8) is occasionally utilized for the analysis of free 17-hydroxycorticosteroids. However, all 17-hydroxyestrogens interfere with this reaction.

The only two specific reagents are those used in the Porter–Silber reaction (9), in which all 17,21-dihydroxy-20-one type steroids give a positive reaction, and the blue tetrazolium reagent (10), which is specific for primary ketol side chains. The Porter–Silber reaction requires 18 hr for color development and employs concentrated sulfuric acid to give increased values for the urine blank determination. The blue tetrazolium method employs no sulfuric acid and takes 90 min for color development (11).

The quantitative determination of 17-hydroxycorticosteroids in urine was studied using beef liver glucuronidase to hydrolyze conjugated urinary steroids and subsequently treating the sample with blue tetrazolium to measure the concentration of 17-hydroxycorticosteroids colorimetrically.

Table I—Absorbance as a Function of Hydrocortisone Concentration in Alcohol and Human Urine Using Blue Tetrazolium Assay

Alcohol		Human Urine	
Hydrocortisone, μg/ml	Net Absorbance (525 nm)	Hydrocortisone Added, μg/ml	Net Absorbance (525 nm)
1.667	0.210	0.62	0.075
3.333	0.408	1.24	0.150
5.000	0.620	1.86	0.250
8.333	1.020	3.10	0.350

EXPERIMENTAL

Test Solutions—For the blue tetrazolium solution, exactly 125 mg of blue tetrazolium was dissolved in 25 ml of absolute methanol. For the tetramethylammonium hydroxide test solution, 10 ml of a 10% tetramethylammonium hydroxide solution was diluted to 100 ml with absolute methanol.

Standard Preparation—Approximately 100 mg of hydrocortisone USP, accurately weighed, was dissolved in alcohol USP to make exactly 100 ml. Then 1 ml of the solution was diluted to exactly 100 ml with alcohol. This standard solution contained approximately 10 μg/ml.

Sample Preparation—Urine specimens were collected from normal, healthy adults, and the pH of the urine was immediately adjusted to 5.0 with acetic acid. The urine was divided into two portions; one portion was retained for use as the untreated specimen. The second portion was subdivided and to each aliquot were added varying amounts of hydrocortisone and urine to achieve final hydrocortisone concentrations of approximately 0.5, 1, 2, and 3 μg/ml.

Procedure—Aliquots of 2, 4, 6, and 10 ml of the standard solu-

tion were pipetted into separate 35-ml centrifuge tubes and the volume was brought to 10 ml with alcohol. To each standard solution and blank, 1 ml of blue tetrazolium solution was added. The tubes were mixed and exactly 1 ml of tetramethylammonium hydroxide test solution was added. The solution was mixed, allowed to stand for 90 min, and then placed into 1-cm silica cells. The absorbance of each standard solution was read against the blank in a suitable spectrophotometer at 525 nm (Table I).

Exactly 10 ml of the untreated urine from each specimen was pipetted into three 35-ml centrifuge tubes. A blank was prepared with 10 ml of purified water adjusted to pH 5.0 with acetic acid. Four milliliters of beef liver glucuronidase solution[1] was added to each sample and blank. These tubes were mixed, stoppered, and incubated overnight at 37°. After cooling to room temperature, 10 ml of carbon tetrachloride was added and the tubes were shaken for 5 min at very low agitation and centrifuged for 5 min. The aqueous phase was transferred to a second 35-ml centrifuge tube, and the extraction was repeated with 10 ml of carbon tetrachloride.

Twelve milliliters of the aqueous phase was transferred to a 125-ml separator, extracted with 50 ml of methylene chloride, and allowed to settle for 30 min. The organic phase was then transferred to a 125-ml flask. Thirty pellets of sodium hydroxide were added, the flask was shaken for 5 min, and the sample was then allowed to settle. The solution was filtered through filter paper[2] into a 50-ml centrifuge tube.

Twenty milliliters of the filtrate was pipetted into a 35-ml centrifuge tube and evaporated to dryness in a water bath at 30° with the aid of a gentle stream of air. The residue was dissolved in 10 ml of alcohol. The sample solutions and their blank were then treated with the blue tetrazolium solution and tetramethylammonium hydroxide solution, as indicated for the standard solution; the absorbance was read in a similar manner. The hydrocortisone-treated urine samples were assayed similarly, starting with the addition of the beef liver glucuronidase solution to 10-ml aliquots (Table I).

RESULTS

The analytical method (12) used for the determination of 17-hydroxycorticosteroids in urine was initially evaluated by adding known amounts of hydrocortisone to urine specimens. These evaluations indicated possible difficulties with the method. Therefore, this method was modified by omitting the sodium hydroxide backwash, substituting a solid sodium hydroxide wash, and utilizing the blue tetrazolium method in place of the Porter–Silber reaction. The results of the two standardizations are shown in Table I. These data demonstrate that there is no difference between the two standardization studies; that is, the absorptivity value for the hydrocortisone–blue tetrazolium reaction is essentially identical whether the solution is prepared in alcohol or urine.

Table II reports the results on 17-hydroxycorticosteroid recovery in untreated urine and is based on the absorptivity value calculated from the data presented in Table I. These studies demonstrate that 17-hydroxycorticosteroids in untreated human urine can be quantitatively determined *via* absorptivity values obtained through the use of standard hydrocortisone–alcohol solutions or standard solutions of hydrocortisone in urine.

Fluorocarbon Aerosol Propellants V: Binding Interaction with Human Albumin

WIN L. CHIOU ˣ and JAUE-HUEY HSIAO

Abstract □ Binding of trichloromonofluoromethane, dichlorodifluoromethane, and dichlorotetrafluoroethane was studied in aqueous 5% human albumin solution, using the partition coefficient method in sealed serum bottles. The partition coefficient and the fraction of fluorocarbons bound were highly dependent on fluorocarbon concentrations. The average binding sites per molecule of albumin were 2.17, 0.30, and 0.42 and the binding association constants were 1.11×10^3, 1.73×10^3, and $5.06 \times 10^3\ M^{-1}$, respectively. At the lowest concentration studied, 62.3, 25.5, and 65.6% were found bound to albumin, respectively. This appears to represent the first extensive study on any gas–albumin interaction.

Keyphrases □ Fluorocarbon propellants—binding to human serum albumin determined using partition coefficient method in sealed serum bottles □ Trichloromonofluoromethane—binding to human serum albumin □ Dichlorodifluoromethane—binding to human serum albumin □ Dichlorotetrafluoroethane—binding to human serum albumin □ Binding of fluorocarbon propellants to human serum albumin—determined using partition coefficient method in sealed serum bottles □ Interactions, gas–albumin—binding of fluorocarbon propellants to human serum albumin

Fluorocarbons such as trichloromonofluoromethane (bp 23.7°), dichlorodifluoromethane (bp −29.8°), and dichlorotetrafluoroethane (bp 4.1°) have been widely used as aerosol propellants in various pressurized aerosol packages. In 1973, an estimated 3 billion units were manufactured in this country (1). The possible acute and chronic toxicities of these previously regarded "inert" propellants have been the subjects of intensive studies in recent years (1–6).

Based on the partition coefficient study, it was shown previously that these volatile or gaseous fluorocarbons were much more soluble in human plasma than in water or normal saline (7). It was postulated that such a solubility enhancement might be partly due to the binding of the fluorocarbons to plasma proteins. This postulation was subsequently confirmed by the fluorocarbon–human albumin binding study with one single concentration, using the partition coefficient method (8). In that study, a surprisingly high degree of binding of the three fluorocarbons to the purified human and bovine albumins was found. Since the possible effect of concentration variation on the extent of protein binding for numerous nonvolatile compounds has been well established, it was decided to extend the investigation by using a wide range of fluorocarbon concentrations. This approach also allows the number of the binding sites per molecule of protein and the protein-binding association constant to be calculated.

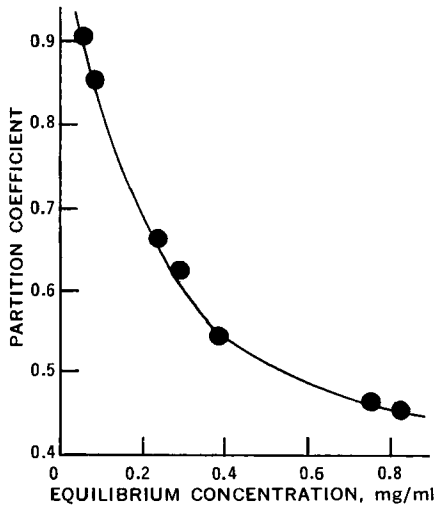

Figure 1—*Effect of concentration of trichloromonofluoromethane (both bound and unbound form) on its partition coefficient between 5% human albumin solution and air.*

EXPERIMENTAL

Materials—Only the three most widely used fluorocarbon propellants, trichloromonofluoromethane[1] (mol. wt. 137.4), dichlorodifluoromethane[1] (mol. wt. 120.9), and dichlorotetrafluoroethane[1] (mol. wt. 170.9), were studied. The crystallized and lyophilized human albumin (mol. wt. 69,000) was purchased commercially[2].

Preparation of Fluorocarbon–Albumin Solutions—The albumin solution (5% w/v) was freshly made by dissolving albumin into isotonic pH 7.4 phosphate buffer solution, prepared according to the method of Sorensen (9). One milliliter of this albumin solution was then pipetted into a 5-ml serum bottle[3], which was then sealed with a flange-type lacquer-coated stopper and aluminum cap (7). In the previous partition coefficient study (7, 8), the fluorocarbons were first dissolved in normal saline prior to introduction into plasma or protein samples. Due to their limited solubilities in normal saline or phosphate buffer and the high concentrations of the fluorocarbons used in the present study, their gaseous stock preparations were prepared by diluting the pure fluorocarbons from their liquid state (dichlorodifluoromethane and dichlorotetrafluoroethane were stored in pressurized steel cylinders at room temperature and trichloromonofluoromethane was stored in an aluminum container at 5°) into the sealed 50-ml empty serum bottles.

The albumin solutions, containing various amounts of the fluorocarbon, were prepared by transferring approximately 0.05–1 ml from the fluorocarbon stock preparations, using a gastight syringe[4], to the sealed 5-ml serum bottle containing 1 ml of the albumin solution. A 27-gauge disposable hypodermic needle was inserted briefly into the headspace of the serum bottle to reduce the pressure in the headspace to the atmospheric pressure. The three fluorocarbons were studied individually.

Determination of Partition Coefficients between Protein Solution and Air Phase—The fluorocarbon–albumin solution in the sealed serum bottle was shaken in a vortex mixer[5] for 30 min and allowed to stand at room temperature (25 ± 1°) for another 30 min. The preliminary study showed that the equilibration of the fluorocarbons between the protein solution and headspace was

[1] Supplied by E. I. du Pont de Nemours and Co., Wilmington, Del.
[2] Sigma Chemical Co., St. Louis, Mo.
[3] Wheaton Scientific, Millville, N.J.
[4] Hamilton.
[5] Vortex mixer, Fisher Scientific Co., Springfield, Mass.

reached under these conditions since the partition coefficient remained the same even after 1 hr of shaking. A much shorter period (less than 5 min) was required to obtain an equilibrium by the same method of shaking when the fluorocarbon dissolved in normal saline was first introduced into the protein solution as used previously (7, 8).

The concentration of the fluorocarbon in the headspace was analyzed directly by injecting an appropriate volume of the sample into the GC column using a 50- or 100-μl gastight syringe[4]. The GC operation conditions were identical to those reported previously (8, 10, 11). A proper dilution of the sample, using the sealed empty serum bottle, was made when the concentration of the fluorocarbon in the headspace was too high and the amount injected would have exceeded the linear response range of the electron-capture detector (10).

After determination of the fluorocarbon in the headspace, its concentration in the albumin solution was analyzed by transferring about 0.2 ml of the solution to a 3- or 5-ml vacuum tube[6] containing a known amount of cyclohexane. The tube was shaken in a shaker[7] for 5 min followed by centrifugation for 5 min in a clinical centrifuge[8]. The fluorocarbon concentration in the cyclohexane phase was determined by drawing 5–10 μl of the solution, using a 10-μl syringe[4], and injecting onto the GC column.

During the transferring of the fluorocarbon–albumin solution to the vacuum tube, the following special procedure was used to avoid loss of the fluorocarbon when the conventional pipet or syringe was employed. A 6.3-cm (2.5-in.) 22-gauge disposable hypodermic needle was cut to remove the hub and sharpened with a file. One end of the needle was inserted into the albumin solution of the inverted serum bottle, and the other end was then immediately inserted into the vacuum tube. When the liquid stopped flowing into the tube, another 23-gauge disposable needle was inserted into the headspace of the serum bottle to equilibrate the whole system to atmospheric pressure. The volume of the liquid transferred was measured by weighing after correction for its density. The exact volume (about 2.8 ml for a 3-ml tube and 4.8 ml for a 5-ml tube) of cyclohexane used in the extraction was also measured by weighing after correction for its density.

The extraction recovery of the fluorocarbons into the cyclohexane was essentially 100%. This recovery can be expected because of their high solubility in this solvent (7) and the relatively smaller volumes of the protein solution and headspace used. Throughout the present study, duplicate and excellent reproducible readings (less than 3% of variation) were obtained for each GC assay.

The partition coefficient, P_p, between the protein solution and the air phase was calculated according to the following equation:

$$P_p = \frac{C_p}{C_g} = \frac{C_c V_c}{C_g V_p} \qquad \text{(Eq. 1)}$$

where:

C_p = concentration of fluorocarbon in protein solution at the equilibrium state (weight per unit of volume)
C_g = concentration of fluorocarbon in air phase (*i.e.*, headspace) at the equilibrium state (weight per unit of volume)
C_c = concentration of fluorocarbon in cyclohexane extract
V_c = volume of cyclohexane used for extraction
V_p = volume of protein solution transferred for extraction

RESULTS AND DISCUSSION

Partition Coefficient Study—The partition coefficients of the three fluorocarbons between the 5% human albumin solution and the air phase were found to change with the total fluorocarbon concentration in the albumin solution at the equilibrium state. This finding is clearly demonstrated by a typical plot of the partition coefficient of trichloromonofluoromethane as a function of its total concentration in protein solution (Fig. 1). The partition coefficient decreased markedly and approached the value between the plain pH 7.4 phosphate buffer without protein and the air phase, P_f (8, 12). The P_f values for the three fluorocarbons (0.347 for trichloromonofluoromethane, 0.105 for dichlorodifluoromethane, and 0.032 for dichlorotetrafluoroethane) were independent of their total concentrations in the protein solution. These values are slightly higher than those previously reported for both water and normal saline systems (7). The discrepancies were caused by the depressing effect on the sensitivity of the electron-capture detector in the presence of water when the aqueous sample was injected directly onto the GC column (12) and by the inherent lack of a high degree of accuracy in the low partition media (such as partition coefficients less than 0.2) when the simple headspace method (7) was employed. This latter aspect will be dealt with in a future report.

Table I—Number of Fluorocarbon Binding Sites per Molecule of Human Albumin, n, and of the Binding Association Constant, K

Fluorocarbons	n	K, M^{-1}
Trichloromonofluoromethane	2.18	1.11×10^3
Dichlorodifluoromethane	0.30	1.73×10^3
Dichlorotetrafluoroethane	0.42	5.06×10^3

The concentration-dependent partition coefficient phenomenon could be rationalized by the classical drug–protein interaction. As the fluorocarbon concentrations increase, the protein binding sites become more saturated; therefore, the solubilities or partition coefficients tend to decrease. A detailed analysis of the binding properties will be discussed later. There appears to be some discrepancies between this study and the results published previously (7) that showed a concentration-independent partition coefficient phenomenon in the human blood and plasma systems. This previous finding could be attributed to the much lower concentrations of fluorocarbons used in that study. As will be shown later, the partition coefficients in the human albumin solution actually change only slightly in these lower concentration ranges.

Principles of Partition Coefficient Method to Study Protein Binding—Most reported protein binding studies were primarily limited to the nonvolatile compounds. The most common methods employed in the binding studies were equilibrium dialysis and ultrafiltration (13). Due to the existence of these fluorocarbons at the gaseous state at 25 or 37°, these conventional methods could not be easily adopted for their binding study. Since one can reasonably assume that only the free or unbound form is in equilibrium with the fluorocarbon in the headspace and that the partition coefficient is the same as that between the plain buffer solution without protein and the air phase, P_f, the data from the parti-

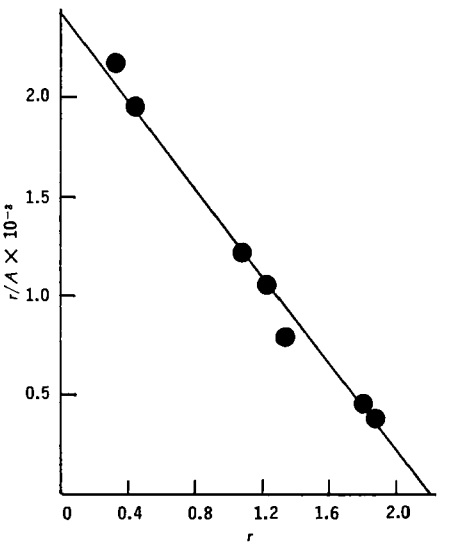

Figure 2—*Scatchard plot for the binding of trichloromonofluoromethane to human albumin.*

[6] Vacutainer, Becton-Dickinson Co., Rutherford, N.J.
[7] Catalog Number 65885, Precision Scientific Co., Chicago, Ill.
[8] Catalog Number 67477, Precision Scientific Co., Chicago, Ill.

tion coefficient study can be used to quantify the percentage of the fluorocarbon bound, the number of binding sites per molecule of protein, and the binding association constant. Mathematically, these values could be derived or determined as follows.

For the determination of the percent bound:

$$\% \text{ bound} = \frac{C_p - C_f}{C_p}(100) \qquad \text{(Eq. 2)}$$

where C_p and C_f are the total concentration (bound and unbound form) and the concentration of the unbound or free form in the protein solution, respectively.

Dividing Eq. 2 by C_g, the concentration in the headspace, one obtains (8):

$$\% \text{ bound} = \frac{C_p/C_g - C_f/C_g}{C_p/C_g}(100) \qquad \text{(Eq. 3)}$$

$$\% \text{ bound} = \frac{P_p - P_f}{P_p}(100) \qquad \text{(Eq. 4)}$$

To determine the number of fluorocarbon molecules bound per molecule of albumin *(r)*:

$$r = \frac{(C_p)(\text{fraction bound})(\text{mol. wt.}_{al})}{C_{al}(\text{mol. wt.}_f)} \qquad \text{(Eq. 5)}$$

where C_p and C_{al} are concentrations of the fluorocarbon and albumin expressed in the same unit, and mol. $wt._f$ and mol. $wt._{al}$ are their molecular weights, respectively.

The number of binding sites, n, and binding association constant, K, can be obtained from the Scatchard plot based on the following relationship (14):

$$\frac{r}{A} = nK - rK \qquad \text{(Eq. 6)}$$

where A is the molar concentration of the free form of the fluorocarbon. The plot of r/A *versus* r yields a straight line. The n value can be determined from the intercept on the abscissa and the nK value from the intercept on the ordinate.

Binding of Fluorocarbons with Human Albumin—Based on the partition coefficient data and Eq. 4, the percentages in the bound form for the three fluorocarbons at various concentrations can be calculated. The percentage bound decreased from 62 to 23, 23 to 8, and 60 to 24 as the total concentration increased from 0.06 to 0.83 mg/ml for trichloromonofluoromethane, from 0.03 to 0.27 mg/ml for dichlorodifluoromethane, and from 0.006 to 0.170 mg/ml for dichlorotetrafluoroethane. These concentration ranges are close to some reported fluorocarbon concentrations encountered in *in vitro* and *in vivo* toxicity studies (1, 15, 16).

A typical Scatchard plot for trichloromonofluoromethane is shown in Fig. 2. The two parameters, n and K, obtained from this and similar plots are summarized in Table I. All plots showed a straight line, which indicates that there are only primary binding sites for all three fluorocarbons. The highest binding constant found for dichlorotetrafluoroethane was not unexpected in view of its higher molecular weight and higher solubility in the lipoid medium (8), which may result in stronger van der Waals interaction and hydrophobic binding. Although the binding constant for dichlorodifluoromethane was slightly higher than for trichloromonofluoromethane, its binding capacity, n, was only about one-seventh of the latter. This finding explains why the percentages bound for dichlorodifluoromethane were much lower compared to trichloromonofluoromethane at similar concentrations.

When lower concentrations (about 130–8000 times lower) were used, the percentages bound were in good agreement with the predicted values, using the parameters listed in Table I. The binding data at these low concentrations are relevant because of the low blood levels that may be encountered clinically (17, 18) or in pharmacokinetic studies (10, 19, 20). The moderate to extensive protein binding found at these lower concentrations could explain in part the higher partition coefficients or solubilities of these fluorocarbons in blood and plasma of humans and other species (7, 20, 23). In light of these results, one can assume that these fluorocarbons may also be bound extensively to other macromolecules in various tissues of the body. This probably contributes partly to the high apparent volume of distribution of dichlorotetrafluoroethane in a dog estimated to be about eight times body weight based on the blood concentration (19). Similar findings for other fluorocarbons were also obtained with other dogs and will be reported.

Trichloromonofluoromethane has been shown *in vitro* to decrease significantly and irreversibly the invertase activity (21), and dichlorodifluoromethane has also been shown to inhibit markedly the *in vitro* o-diphenol oxidase activity (22). Hydrophobic binding and conformational modification of enzyme molecules have been proposed to explain the results, but no binding constants and binding sites were investigated in the two studies.

From a search of literature, it appears that no detailed binding studies on gas–protein interactions have been reported. The partition coefficient method proposed, using a sealed serum bottle and analyzing by the headspace and extraction method, appears to offer a simple and promising tool for studying the binding interactions between macromolecules and volatile or gaseous compounds.

There is some discrepancy in the percentage of dichlorodifluoromethane bound to the human albumin reported from this study and previous preliminary studies (8); the reason is unknown. Since the results from the previously reported concentration could not be reproduced and the present study employed a very wide range of concentrations, it is concluded that the value obtained from the present study is more reliable.

Drug Release from a Lipophilic Ointment Base as Influenced by Chain Length of Added Surfactant

ANNE MÉRIAUX-BROCHU and J. PAIEMENT ˣ

Abstract □ The release of sulfathiazole and salicylic acid from white petrolatum containing ethoxylated surfactants of varying ethylene oxide chain length was evaluated by the dialysis method. The rate of release of the drugs increased with the ethylene oxide number of the added surfactant.

Keyphrases □ Ointment bases, lipophilic—effect of ethoxylated surfactant chain length on drug release □ Lipophilic ointment bases—effect of ethoxylated surfactant chain length on drug release □ Drug release from lipophilic ointment bases—chain length effect of added ethoxylated surfactant

The rate of release of drugs from ointment bases has received considerable attention during the last 10–15 years and interesting reviews are now available on the subject (1–13). Looking closely into the literature, however, one notes that if some aspects of this phenomenon have been extensively studied and are now well understood, others have been only partially explored. One such area is the effect of surfactants on lipophilic ointment bases.

This paper reports an attempt to verify how the variation of the length of the ethylene oxide chain of an added nonionic surfactant could influence the rate of release of water-soluble drugs from a typical lipophilic base such as white petrolatum. It was also thought that such simple systems would provide a good model to verify the possibility that a correlation exists between the rheological parameters of the ointments and the rate of liberation of drugs incorporated in them (14).

EXPERIMENTAL

The dialysis method (7) is a simple and convenient way to study the rate of diffusion of drugs in ointment bases. The significance of the information provided by that method has also been critically examined (15). In the present investigation, the setup suggested by Billups and Patel (9) was used with some modifications: *(a)* the receiving compartment of the dialysis cell was a double-walled beaker through which water could be circulated, permitting temperature maintenance of the aqueous solution (100 ml) of the receiving compartment at 25 ± 0.1°; *(b)* a small cavity was formed in the bottom of the beaker for a stirring bar with the beaker resting on a magnetic stirrer; and *(c)* the size of the jars was such that a relatively large area (~25 cm^2) of ointment (covered with cellulose paper) could be in contact with the aqueous phase. By proceeding in this way, the aliquots removed for analysis could be read directly on a spectrophotometer and then returned to the cell, thus eliminating the necessity of making volume corrections.

The absorbance of sulfathiazole was determined at 283 nm, and that of salicylic acid was determined at 302 nm. (In the acidic form, salicylic acid shows two peaks of absorbance at 237.5 and 302 nm; in both cases, Beer's law is obeyed.) As expected (16), spectrophotometric analysis failed to reveal any trace of surfactant which might have diffused along with the drugs.

The first drug, sulfathiazole[1] (mp 200–201°), was dialyzed into a phosphate buffer solution of pH 6.0 and ionic strength (μ) = 0.1. The second drug, salicylic acid[2], was dialyzed into a buffer solution of pH 1.85 (hydrochloric acid plus sodium chloride to μ = 0.1). In this second case, the conditions were, of course, far from being physiological but they permitted comparison of both drugs in the same conditions with respect to the proportion of nonionized drug in the aqueous solution (~93%). Since these drugs are weak acids, the buffer systems seemed mandatory so that the conditions in the receiving compartment would not change during an experiment. The aqueous solubilities of the nonionized portion of sulfathiazole and salicylic acid were evaluated at 25° (at pH's where less than 1% of the drugs was ionized).

The nonionic surfactants studied were some alkylaryl polyether alcohols[3]. They were completely dehydrated before incorporation into the melted bases[4] at a concentration of 1.592×10^{-3} mole/100 g of base (this value corresponds to 1 g/100 g in the case of the surfactant containing 9–10 ethylene oxide units[5]). The drugs were passed through a screen (BP 100) and were also dehydrated; this step was essential with sulfathiazole. Then they were dispersed into the bases, with a mortar and a pestle, at room temperature. Great care was exerted always to proceed in the same way (with respect to the agitation brought by the magnetic stirrer, the position of the inverted cup, *etc.*) so that the results could be compared.

For the rheological studies, a cone-plate rotational viscometer[6] was used. The experimental conditions adopted were similar to those used by Boylan (17) in his rheological study of white petrolatum.

RESULTS AND DISCUSSION

Figure 1 shows some representative curves for the release of sulfathiazole from white petrolatum containing surfactants of varying ethylene oxide chain lengths. As can be seen, the rate of release of the drug kept increasing up to the most hydrophilic surfactant studied (containing 40 ethylene oxide units). Since salicylic acid had been shown to diffuse best with mixtures of surfactants (sorbitan esters and polysorbates) having a low hydrophilic–lipophilic balance (HLB) value (12), it was thought that that drug would provide a good point of comparison for sulfathiazole. Figure 2 shows that the general pattern of diffusion obtained with salicylic acid was very close to the one obtained for sulfathiazole.

In Fig. 3, the amount of either sulfathiazole or salicylic acid dialyzed after 120 min was plotted as a function of the logarithm of the number of ethylene oxide units of the added surfactant. For sulfathiazole, it was verified that the relation was linear at any time in the dialysis runs so long as the curves had started to flatten. For salicylic acid at dialysis times less than 120 min, the relation was not linear; it can be observed (Fig. 2), however, that some diffusion curves had not then started to flatten.

The effect of surfactants on the release of drugs from hydrophilic ointment bases has been extensively studied (1, 2, 5, 6). Since those systems contained water (~30%), it is expected that oil-in-water or water-in-oil emulsions were formed, depending on the HLB of the mixture of surfactants studied, giving essentially different systems than those studied here. The diffusion behavior of drugs in such emulsified systems has been well explained (11).

In dealing with lipophilic bases modified by nonionic surfactants, it is believed that the comparisons should be made on a "pseudomolar" basis (*i.e.*, a given number of moles of surfactant added to a given weight of base or a given volume of preparation). The reason becomes apparent when one considers, for instance, the case of the following pair: sorbitan monooleate (mol. wt. ~453) and polysorbate 80 (mol. wt. ~1470). One notes then that, at any given percentage (identical for both surfactants), the concentration of the ethoxylated surfactant is, on a molar basis, about four times lower than that of the other. Since the concentration of the added surfactant is also important [the rate of diffusion increases with increasing concentration up to an optimum concentration and then decreases (11)], comparison of the effect of a large molar concentration of a surfactant having, for example, a middle HLB value to that of a low molar concentration of a surfactant having a high HLB value might obscure the real phenomenon.

It is also possible that nonionic surfactants of different classes (*i.e.*, sorbitan esters and ethoxylated surfactants) do not work in the same way (or to the same extent) when added to lipophilic bases. Hence, it has been observed that the addition of sorbitan monooleate to white petrolatum decreased the rate of diffusion of sulfathiazole while the addition of polysorbate 80 increased it (11). These explanations are given as suggestions to account for the fact that the diffusion of some drugs was shown previously to decrease above a certain HLB value of the added surfactants (3, 4, 12) while this phenomenon was not observed here.

In the three figures, the absorbance of the drugs instead of their concentration is presented to emphasize that the *pattern* of diffusion of both drugs is quite similar. However, the concentration of salicylic acid was evaluated using its peak of second maximum absorbance in the UV region (at 237.5 nm, the peak of maximum absorbance, volume corrections would have been necessary). Salicylic acid diffused to a greater extent than sulfathiazole (~3 times more on a molar basis) per unit of time. This observation may reflect that salicylic acid is about three times more soluble than sulfathiazole on a molar basis (87 mg *versus* 55 mg/100 ml with the unionized portions being considered). In conclusion, it is suggested that these solubility considerations and the relation shown in Fig. 3 (this relation will have, however, to be substantiated with other drugs and other surfactant series) might give a clue as to the mode of diffusion of water-soluble drugs in ointment bases containing ethoxylated nonionic surfactants.

In the rheological part of this study, only sulfathiazole preparations were considered. Rheograms were obtained with the modified bases only (without the drug) and with the complete preparations (with the drug). The study was also extended to white petrolatum containing varying concentrations of polysorbate 80 (11), with and without incorporated sulfathiazole. Various parameters [*e.g.*, thixotropy, yield value, and spur value (18)] were examined and compared to verify if a correlation could be found between the rate of release of the drug and any of the parameters. So far, no correlation has been found. It is possible that such correlations could be obtained if the bases investigated are gels made with water-soluble polymers. Further research in that direction is in progress.

Antitubercular Activity of Substituted 5-Oxo-1-thiocarbamoyl-3-pyrazoline-4-alkanoic Acid Derivatives

ARTHUR A. SANTILLI [x], DONG H. KIM, and FRANCIS J. GREGORY

Abstract □ Several novel pyrazolin-5-ones prepared by the cyclization of variously substituted thiosemicarbazone derivatives of ethyl formylsuccinate, ethyl acetylsuccinate, and ethyl acetylglutarate were tested for antitubercular activity against *Mycobacterium tuberculosis*, human type, strain H37Rv, by a tube dilution technique. Minimum inhibitory concentrations (MIC) for these derivatives ranged from 0.05 to 100 μg/ml. The most active compound was ethyl 3-methyl-1-methylthiocarbamoyl-5-oxo-3-pyrazoline-4-acetate (MIC = 0.05–0.1 μg/ml).

Keyphrases □ 5-Oxo-1-thiocarbamoyl-3-pyrazoline-4-alkanoic acid derivatives—synthesis, antitubercular activity □ Pyrazolin-5-one derivatives—synthesis, antitubercular activity □ Antitubercular activity—synthesis and screening of substituted 5-oxo-1-thiocarbamoyl-3-pyrazoline-4-alkanoic acid derivatives

Various classes of thiosemicarbazones have been of interest to clinicians for their therapeutic value as antitubercular, antiviral, antileprotic, and antifungal agents (1–3). Recently, the synthesis of a group of variously substituted 5-oxo-1-thiocarbamoyl-3-pyrazoline-4-alkanoic acid derivatives (II*a*–II*l*), which were prepared by the cyclization of open-chain thiosemicarbazones (I) of diethyl formylsuccinate, diethyl acetylsuccinate, and diethyl acetylglutarate, was described (4). Spectral evidence indicates that these compounds also exist in their tautomeric 5-hydroxypyrazole form (II′*a*–II′*l*). Several of these derivatives were tested for their overall therapeutic value as anti-infective agents and were found to possess substantial antitubercular activity against *Mycobacterium tuberculosis*, human type. A summary of the biological test results in relation to chemical structure is reported here.

EXPERIMENTAL[1]

The open-chain thiosemicarbazones (I) were prepared by heating ethyl formylsuccinate, ethyl acetylsuccinate, or ethyl acetylglutarate with 1 equivalent of a suitably substituted thiosemicarbazide (Scheme I). Ring closures of these derivatives were carried out by warming the various thiosemicarbazones in ammonium hydroxide solution followed by acidification; the title compounds were obtained (Table I). The esters were readily converted to the corresponding acids by hydrolysis using sodium hydroxide solution.

Synthesis—The following example typifies the method used to prepare the title compounds. Further preparative details as well as the chemistry and spectral analyses for other compounds were previously published (4).

Diethyl Acetylsuccinate Thiosemicarbazone (I)—A mixture of 10.8 g of diethyl acetylsuccinate and 4.56 g of thiosemicarbazide in 250 ml of ethanol was heated under reflux for 17 hr. The ethanol solution was cooled in ice, and cyclohexane was added to precipitate the product. The product amounted to 13.1 g, mp 98–102°. The analytical sample (mp 98–100°) was obtained by recrystallization from ethanol–cyclohexane; IR (KBr): 2.90, 3.00, 3.12 (NH), 5.72, and 5.79 (ester C=O) μm.

Anal.—Calc. for $C_{11}H_{19}N_3O_4S$: C, 45.66; H, 6.62; N, 14.52; S, 11.08. Found: C, 45.64; H, 6.58; N, 14.65; S, 11.42.

Ethyl 3-Methyl-5-oxo-1-thiocarbamoyl-3-pyrazoline-4-acetate (IIa)—A mixture of 10 g of diethyl acetylsuccinate thiosemicarbazone and 250 ml of concentrated ammonium hydroxide solution was heated on a steam bath for approximately 30 min, at which

[1] Melting points were determined with a Thomas-Hoover capillary melting-point apparatus and are uncorrected. The IR spectra were determined in potassium bromide disks using a Perkin-Elmer model 21 spectrophotometer.

time the reaction mixture was filtered free of some undissolved particles. The solution was cooled in ice and acidified with concentrated hydrochloric acid. The precipitate which formed amounted to 3 g. The analytical sample (mp 146–148°) was obtained by recrystallization from ethanol; IR (KBr): 3.08 (NH), 5.72 (ester C=O), and 6.02 (lactam C=O) μm.

Anal.—Calc. for $C_9H_{13}N_3O_3S$: C, 44.43; H, 5.38; N, 17.27; S, 13.18. Found: C, 44.44; H, 5.40; N, 17.64; S, 13.43.

Biological—The compounds described here were tested for their bacteriostatic activity against *M. tuberculosis*, human type, strain H37Rv, by a tube dilution technique. The medium employed was Dubos oleic acid liquid medium. Stock cultures were maintained on Dorset egg agar. Stock solutions of 1000 μg/ml of drug were prepared in distilled water or dimethylacetamide, and aqueous solutions were sterilized by passage through a Swinny filter. One-milliliter quantities of each dilution were incorporated into 9 ml of medium to give final concentration values of 0.01–100 μg/ml. Tubes were seeded with 0.1 ml of standardized bacterial suspension and incubated for 2 weeks at 37°. The minimum inhibitory concentration (MIC), expressed in micrograms per milliliter, is the least amount of material required for complete inhibition of growth of *M. tuberculosis*.

RESULTS AND DISCUSSION

Compound IIc (Table I) showed the highest order of activity of the compounds tested (MIC ≈ 0.05–0.1 μg/ml). Activity diminished considerably when this compound was tested as the free acid (II*e*) or as a carboxamide (II*d*). Replacement of the methylthiocarbamoyl group by a thiocarbamoyl group (II*a*) also resulted in diminished activity. Replacement of the 3-methyl group in IIc by a hydrogen afforded II*f*, which showed a high order of activity similar to that of IIc.

An activity comparison for II*a* and II*i* indicates that no gain in potency results when the alkanoic acid chain is extended by one methylene group. A comparison of IIc with 3-methyl-5-oxo-3-pyrazoline-4-acetate (4) (MIC = 0.5 μg/ml) indicates that the methylthiocarbamoyl group must contribute significantly toward activity in this series since potency diminished considerably in its absence. Similarly, removal of the alkanoic acid group appears to have a deleterious effect on activity. This supposition is based on the fact that a sharp decline in potency was observed when 3-methyl-5-oxo-1-methylthiocarbamoyl-3-pyrazoline (4) (MIC = 1 μg/ml) was compared with IIc. The clinical agent isoniazid was used as the standard for comparison. When tested in this assay, its MIC was 0.005–0.01 μg/ml.

Preparation and Baeyer–Villiger Reaction of Certain 2-Carbalkoxycyclopropyl Methyl Ketones

JOSEPH G. CANNON ˣ and JOHN E. GARST

Abstract □ Treatment of mixed anhydrides derived from *cis*- and *trans*-2-carbobenzyloxycyclopropanecarboxylic acids and ethyl chloroformate with ethoxymagnesio di-*tert*-butyl malonate and subsequent treatment of the resulting adducts with *p*-toluenesulfonic acid afforded *cis*- and *trans*-benzyl 2-acetylcyclopropanecarboxylates in good to excellent yields, with retention of the original stereochemistry of the systems. These methyl ketones and an open chain congener, benzyl levulinate, were inert toward *m*-chloroperbenzoic acid. The *cis*-isomer and benzyl levulinate underwent normal Baeyer–Villiger reactions mediated by trifluoroperacetic acid, forming moderate yields of the acetate ester insertion products.

Keyphrases □ 2-Acetoxycyclopropanecarboxylic acid esters—synthesis from 2-carbalkoxycyclopropyl methyl ketones, Baeyer–Villiger reaction, retention of stereochemistry □ 2-Carbalkoxycyclopropyl methyl ketones—Baeyer–Villiger reaction, synthesis of stereospecific 2-acetoxycyclopropanecarboxylic acid esters

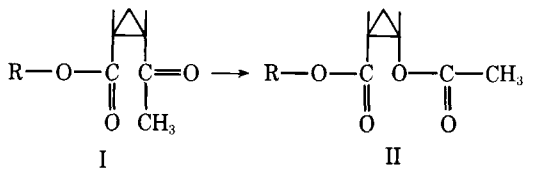
As a part of a synthetic program leading to partially rigid analogs of acetylcholine, a preparative route to *cis*-2-acetoxycyclopropanecarboxylic esters (II) was required. It was proposed that these systems should be attainable *via* Baeyer–Villiger oxidation of an appropriate methyl ketone (I) (Scheme I).

DISCUSSION

It was speculated that the malonic ester adduct (III) could be converted into I by decarboxylation of the malonic ester moiety and esterification of the ring carboxyl group. Treatment of *cis*-cyclopropane-1,2-dicarboxylic anhydride with sodio di-*tert*-butyl malonate gave a 3% yield of the expected product (III) (R = *tert*-butyl) and 33% of a neutral solid (IV), whose structure was assigned on the basis of spectral and analytical data and of literature precedent (1). Attempts to effect acid-catalyzed conversion of IV into a methyl ketone failed.

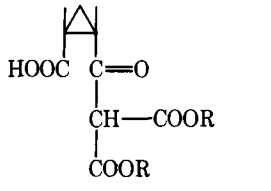
Treatment of *cis*-2-carbomethoxycyclopropanecarbonyl chloride with methoxymagnesio dimethyl malonate (V) gave a 24% yield of the predicted product (VI), whose NMR spectrum demonstrated broad resonance signals at δ1.10–2.80. These signals were typical of other *cis*-1,2-dicarbonyl cyclopropane systems encountered in the present work.

Repeated attempts to prepare *cis*-2-carbobenzyloxycyclopropanecarbonyl chloride led only to elimination of benzyl chloride and isolation of *cis*-cyclopropane-1,2-dicarboxylic anhydride. Reaction of the mixed anhydride (VII) with ethoxymagnesio di-*tert*-butyl malonate and treatment of the malonate adduct (VIII) with *p*-toluenesulfonic acid, according to a method of Fonken and Johnson (2), permitted good overall yields of the *cis*-methyl ketone (IX) (Scheme II). A similar reaction sequence on *trans*-2-carbobenzyloxycyclopropanecarbonyl chloride gave a 76% overall yield of the *trans*-isomer (X). Retention of the *cis*-geometry of IX was verified by comparison of its NMR spectrum with that of X. A reaction between the mixed anhydride (VII) and methylmagnesium iodide resulted in a mixture of the *cis*- and *trans*-isomers (IX and X).

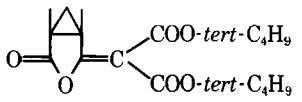


I II

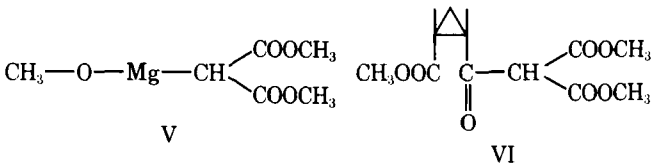
Scheme I



III



IV



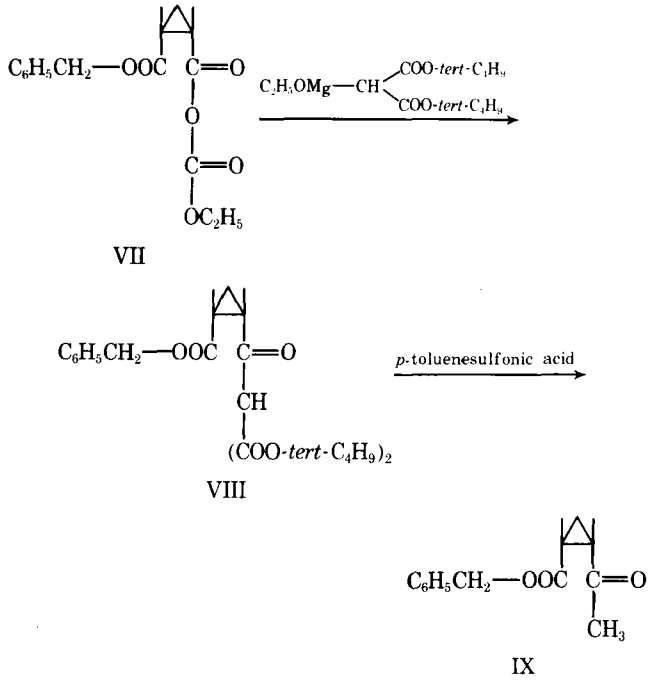
V VI

Sauers and Ubersax (3) reported a 20% yield of a mixture of Baeyer–Villiger products of methylcyclopropyl ketone, using *m*-chloroperbenzoic acid or trifluoroperacetic acid. The remaining 80% of the starting ketone was recovered unchanged. In the present work, *cis*-benzyl 2-acetylcyclopropanecarboxylate was unchanged (according to NMR analysis) after 10 days of stirring with *m*-chloroperbenzoic acid. Treatment of benzyl levulinate (XI), an open chain congener of the cyclopropane methyl ketone systems, with *m*-chloroperbenzoic acid failed to afford detectable reaction products after 10 days of stirring at room temperature. Baeyer–Villiger oxidation of benzyl levulinate into benzyl 3-acetoxypropionate (XIII) was achieved (in 65% yield) with trifluoroperacetic acid in an oxidant–ketone ratio of 4.4:1. This reagent, in a ratio of 8.8:1, converted *cis*-benzyl 2-acetylcyclopropanecarboxylate into the acetoxy insertion product (XII). When less oxidizing agent was employed, large amounts of unchanged starting ketone could be recovered.

EXPERIMENTAL[1]

Di-*tert*-butyl 2-Keto-3-oxa-[3.1.0]-bicyclohexyl-4-idene Malonate (IV)—Di-*tert*-butyl malonate (3) (65.1 g, 0.3 mole) in 200 ml of anhydrous benzene was added dropwise with stirring to 200 ml of anhydrous benzene containing 14.4 g (0.3 mole) of 50% sodium hydride in mineral oil, which had been washed with three 50-ml portions of hexane. The resulting mixture was refluxed for 2 hr, then 33.6 g (0.3 mole) of *cis*-cyclopropane-1,2-dicarboxylic anhydride (4) in 100 ml of anhydrous benzene was added dropwise, and this mixture was refluxed overnight. The solvent was removed under reduced pressure, and the solid residue was dissolved in 300 ml of water. This solution was extracted with ether and the extract was dried over magnesium sulfate. The water solution was reserved as Solution A and was utilized in the isolation of III. Evaporation of the ethereal solution gave a solid, which was recrystallized from hexane to yield 30.9 g (33%) of product, mp 117–119°; IR (potassium bromide): 3110 (cyclopropane CH), 2980 (*tert*-

[1] Boiling points are uncorrected. Melting points were determined in open glass capillaries, using a Thomas-Hoover Uni-Melt apparatus, and are corrected. Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tenn., and by the Microanalytical Service, College of Pharmacy, University of Iowa. NMR spectra were recorded on a Varian Associates T-60 instrument relative to an internal standard of tetramethylsilane. IR spectra were obtained with a Beckman IR-10 instrument.



Scheme II

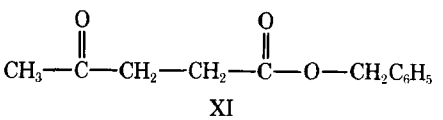
C_4H_9), 1814 (lactone C=O), 1720–1708 (ester C=O), and 1660 (C=C) cm^{-1}; NMR (deuterochloroform): δ 1.50 (s, 18H, *tert*-C_4H_9), 1.20–1.80 (m, 2H, ring CH_2), 2.10–2.60 (m, 1H, CHC=O), and 3.48–3.84 (m, 1H, CHC=C).

Anal.—Calc. for $C_{16}H_{22}O_6$: C, 61.92; H, 7.14. Found: C, 61.60; H, 7.14.

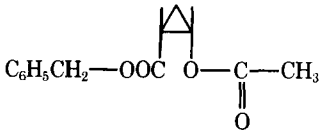
***cis* - 2 - [Di(carbo-*tert*-butoxy)acetyl]cyclopropanecarboxylic Acid (III)**—Acidification of Solution A from the preparation of IV with 6 *N* hydrochloric acid gave a solid, which was recrystallized from ether to afford 3 g (3%) of product, mp 129–130.5°; IR (mineral oil): 3350–2600 (acid OH), 1710 (acid C=O), 1734, and 1750 (ester C=O) cm^{-1}; NMR (deuterochloroform): δ 1.50 (s, 18 H, *tert*-C_4H_9), 1.15–1.60 (m, 2H, ring CH_2), 2.00–2.65 (m, 2H, ring CH), 4.39 [s, 1H, $CH(CO_2R)_2$], and 9.13 (broad s, 1H, CO_2H).

Anal.—Calc. for $C_{16}H_{24}O_7$: C, 58.55; H, 7.35. Found: C, 58.51; H, 7.44.

***cis*-Methyl 2-[Di(carbomethoxy)acetyl]cyclopropanecarboxylate (VI)**—Carbon tetrachloride (1 ml) was added to a mixture of 2.4 g (0.1 g-atom) of magnesium turnings, 42 ml of anhydrous methanol, and 13.2 g (0.103 mole) of dimethyl malonate. Within 3–5 min, the evolution of gas became vigorous and was moderated by external cooling. After the magnesium had dissolved, excess methanol was azeotroped with anhydrous benzene under reduced pressure. Fresh anhydrous benzene (100 ml) was added, and this solution was added dropwise with stirring to 15.9 g (0.098 mole) of freshly distilled *cis*-2-carbomethoxycyclopropanecarbonyl chloride (5); stirring was continued for 1 hr. After standing for 12 hr at room temperature, 200 ml of ether was added and the resulting solution was poured into 100 ml of 6 *N* hydrochloric acid. The organic layer was washed with water until the washings were neutral to litmus and was dried over magnesium sulfate. Evaporation of the volatiles left an oil, which was distilled at 120–124° (0.05 mm) to yield 6.0 g (24%) of product; IR (film): 1740



XI



XII

(ester C=O) and 1650 (C=C) cm^{-1}; NMR (deuterochloroform): δ 1.10–2.80 (m, 4H, ring H), 3.67 (s, 3H, CO_2CH_3), 3.80, 3.83 (2 s, 6H, malonate CH_3), 4.60 [s, 0.5H, $CH(CO_2R)_2$], and 13.71 (s, 0.5H, enol OH).

Anal.—Calc. for $C_{11}H_{14}O_5$: C, 51.16; H, 5.46. Found: C, 51.15; H, 5.16.

***cis*-Benzyl 2-Acetylcyclopropanecarboxylate (IX)**—To a stirred, cooled (0°) solution of 11 g (0.05 mole) of *cis*-2-carbobenzyloxycyclopropanecarboxylic acid (5) in 200 ml of anhydrous ether was added dropwise 5.1 g (0.05 mole) of triethylamine. After stirring for 10 min, 5.4 g (0.05 mole) of ethyl chloroformate was added dropwise over 5 min; stirring was continued at 0° for 0.5 hr. The reaction mixture was filtered and the filtrate was reserved as Solution A. Carbon tetrachloride (1 ml) was added to 13 g (0.06 mole) of di-*tert*-butyl malonate, 1.2 g (0.05 g-atom) of magnesium turnings, and 4 g (0.087 mole) of anhydrous ethanol. Evolution of gas began immediately, and 50 ml of anhydrous dimethoxyethane was added within 3–5 min. The temperature was maintained at 30–40°, and most of the magnesium had dissolved after 1 hr.

This reaction mixture was cooled to 0° and was added dropwise, with rapid stirring, to cooled (0°) Solution A. After stirring for 1 hr, the reaction mixture was allowed to come to room temperature overnight. It was then poured into 200 ml of cold (0°) 3 *N* hydrochloric acid, and this solution was extracted with three 100-ml portions of ether. The combined organic extracts were washed with water and extracted with 50 ml of 10% potassium carbonate solution and with three 100-ml portions of water. The organic phase was acidified by washing with 25 ml of 6 *N* hydrochloric acid and dried over magnesium sulfate, and the ether was removed under reduced pressure to afford 18.5 g of an oil. This oil was refluxed with 1.5 g of *p*-toluenesulfonic acid monohydrate in 100 ml of toluene for 5 hr; the solution was cooled and then extracted with 10% potassium carbonate solution until the washings were basic. The organic layer was washed with 20 ml of 6 *N* hydrochloric acid and then with several portions of water. After drying over magnesium sulfate, the volatiles were removed and the residue was distilled at 104–108° (0.05 mm) to afford 6.3 g (58%) of IX; IR (film): 1730 with a shoulder at 1700 (ester and ketone C=O) cm^{-1}; NMR (deuterochloroform): δ 0.92–1.40, 1.50–1.90, 2.00–2.35 (m, 4H, ring H), 2.20 (s, 3H, CH_3), 5.10 (s, 2H, CH_2Ar), and 7.34 (s, 5H, ArH).

Anal.—Calc. for $C_{13}H_{14}O_3$: C, 71.54; H, 6.46. Found: C, 71.72; H, 6.59.

***trans*-Benzyl 2-Acetylcyclopropanecarboxylate (X)**—Ethoxymagnesio di-*tert*-butyl malonate was prepared in the same manner as IX from 1 ml of carbon tetrachloride, 6.15 g (0.03 mole) of di-*tert*-butyl malonate, 0.7 g (0.029 g-atom) of magnesium turnings, 1.9 g (0.042 mole) of anhydrous ethanol, and 50 ml of anhydrous dimethoxyethane. The cooled (0°) solution was added dropwise over 10 min to 6.8 g (0.0285 mole) of *trans*-2-carbobenzyloxycyclopropanecarbonyl chloride (5) in 200 ml of anhydrous benzene. The reaction mixture was refluxed for 5 hr and was worked up as described for IX, yielding 4.7 g (76%), bp 99–102° (0.05 mm); IR (film): 1729 (ester C=O) and 1705 (ketone C=O) cm^{-1}; NMR (deuterochloroform): δ 1.25–1.55 (m, 2H, ring CH_2), 2.05–2.65 (m, 2H, 2CHCO), 2.27 (s, 3H, CH_3), 5.16 (s, 2H, $CH_2C_6H_5$), and 7.36 (s, 5H, ArH).

Anal.—Calc. for $C_{13}H_{14}O_3$: C, 71.54; H, 6.46. Found: C, 71.72; H, 6.63.

Benzyl 3-Acetoxypropionate (XIII)—Ninety percent hydrogen peroxide (11.4 g, 0.44 mole) was added dropwise over 0.5 hr to a stirred, cooled (0°) solution of 92 g (0.44 mole) of trifluoroacetic anhydride in 100 ml of methylene chloride. After cooling at 0° for 0.25 hr, the trifluoroperacetic acid solution was added dropwise to a rapidly stirred mixture of 120 g of anhydrous disodium phosphate, 200 ml of methylene chloride, and 20.6 g (0.1 mole) of benzyl levulinate (6). The resulting mixture refluxed within 0.5 hr and continued spontaneously for 2 hr. Refluxing was maintained for 4 hr total. The methylene chloride solution was filtered, and the solid on the filter was washed with two 300-ml portions of methylene chloride and then was refluxed for 10 min with an additional 300-ml portion of methylene chloride. The combined organic extracts were washed successively with 10% potassium carbonate solution, water, 6 *N* hydrochloric acid, and water and were dried over magnesium sulfate. The solvent was removed, and the residue was distilled through a 10-cm Vigreux column, bp 87–90° (0.04 mm). The yield was 10.2 g (63%); IR (film): 1741 (ester C=O) cm^{-1};

NMR (deuterochloroform): δ 2.00 (s, 3H, CH_3), 2.67 (t, 2H, CH_2CO_2R), 4.34 (t, 2H, CH_2OCOCH_3), 5.14 (s, 2H, $CH_2C_6H_5$), and 7.32 (s, 5H, ArH).

Anal.—Calc. for $C_{12}H_{14}O_4$: C, 64.85; H, 6.34. Found: C, 65.01; H, 6.27.

***cis*-Benzyl 2-Acetoxycyclopropanecarboxylate (XII)**—A procedure similar to that described for XIII was utilized with 10.9 g (0.05 mole) of IX and 57.2 g (0.44 mole) of trifluoroperacetic acid. The 3.3 g of crude oily product was treated with 4.8 g of Girard's reagent P[2] and 3 ml of acetic acid in 40 ml of refluxing methanol for 4 hr. Ice water (50 ml) was added to the hot solution, and it was brought to neutrality with solid potassium carbonate. This solution was extracted with methylene chloride, and the extract was washed with water and dried over magnesium sulfate. Removal of the solvent and distillation of the residual liquid at 113° (0.035 mm) gave 2.5 g (25%) of product; IR (film): 1730 (ester C=O) cm^{-1}; NMR (deuterochloroform): δ 1.08–2.23 (m, 3H, ring H), 1.93 (s, 3H, CH_3), 4.00–4.44 (m, 1H, $CHOCOCH_3$), 5.16 (s, 2H, $CH_2C_6H_5$), and 7.38 (s, 5H, ArH).

Anal.—Calc. for $C_{13}H_{14}O_4$: C, 66.66; H, 6.02. Found: C, 66.49; H, 6.18.

Synthesis and Biological Evaluation of 2-(9-Acridinyl)ethyl-*N*-substituted Carbamates and Their Hydrochlorides and 10-*N*-Oxides

JAMES T. STEWART [x] and RICHARD E. GAMMANS

Abstract □ The syntheses of 2-(9-acridinyl)ethyl-*N*-substituted carbamates and their hydrochlorides and 10-*N*-oxides are reported along with biological results in the areas of antineoplastic, antimalarial, and CNS activity screening. The compounds showed negative biological activity in the areas tested.

Keyphrases □ 2-(9-Acridinyl)ethyl-*N*-substituted carbamates, hydrochlorides, and 10-*N*-oxides—synthesis, pharmacological activity □ Antineoplastic activity—synthesis and screening of 2-(9-acridinyl)ethyl-*N*-substituted carbamates, hydrochlorides, and 10-*N*-oxides

Acridine derivatives have been tested extensively for potential medicinal activity. Antibacterial (1, 2), antimalarial (3), anthelmintic (4), analeptic (5), and antineoplastic (6–10) activities have been reported for many substituted acridines. The synthesis of new acridine derivatives containing urea, thiourea, thiocarbamate, and carbamate groupings has been reported from this laboratory (11, 12). While possessing little or no anticancer activity, a general pharmacological screen revealed activity in antibacterial, metabolic, parasitologic, and GI screening procedures for some derivatives.

In a continuation of a study into the synthesis and potential biological activity of new acridine compounds, this paper reports the synthesis and antineoplastic screening data for 2-(9-acridinyl)ethyl-*N*-substituted carbamates and their hydrochlorides and 10-*N*-oxides. In addition, biological results for some compounds in antimalarial and central nervous system (CNS) activity screening procedures are reported.

DISCUSSION

The incorporation of the carbamate and acridine moieties into one structure is of special interest, since each structure is singly present in compounds that have shown various degrees of antineoplastic activity (6–10, 13–15). The interaction of acridines with nucleic acids and inhibition of nucleic acid synthesis is well documented (16, 17). Acridines tend to accumulate selectively in tumor tissue (18, 19) showing inhibition of tumor growth, reduction of rate of growth, and, in some cases, regression of tumor size. Nevertheless, no clinically useful agent has been found among the acridines tested, most of which have been substituted 9-aminoacridines. Structures containing carbamate esters also have been reported to have potent antitumor activity (13, 14). Ethyl carbamate itself has been used both for the production of tumors in experimental animals and for the treatment of chronic leukemia and multiple myeloma (15). Some evidence also indicates that carbamates are involved in alkylation of DNA (20).

The mechanism by which these new acridine carbamates were expected to exert their antineoplastic effect was by selective absorption in cancerous tissue followed by a two-pronged attack upon the nucleic acids of the cancer cells. The acridine ring would be expected to interact with the nucleic acid bases, thus holding the carbamate portion in close proximity to the bases to facilitate alkylation by the carbamate.

***cis*-Benzyl 2-Acetoxycyclopropanecarboxylate (XII)**—A procedure similar to that described for XIII was utilized with 10.9 g (0.05 mole) of IX and 57.2 g (0.44 mole) of trifluoroperacetic acid. The 3.3 g of crude oily product was treated with 4.8 g of Girard's reagent P[2] and 3 ml of acetic acid in 40 ml of refluxing methanol for 4 hr. Ice water (50 ml) was added to the hot solution, and it was brought to neutrality with solid potassium carbonate. This solution was extracted with methylene chloride, and the extract was washed with water and dried over magnesium sulfate. Removal of the solvent and distillation of the residual liquid at 113° (0.035 mm) gave 2.5 g (25%) of product; IR (film): 1730 (ester C=O) cm^{-1}; NMR (deuterochloroform): δ 1.08–2.23 (m, 3H, ring H), 1.93 (s, 3H, CH_3), 4.00–4.44 (m, 1H, $CHOCOCH_3$), 5.16 (s, 2H, $CH_2C_6H_5$), and 7.38 (s, 5H, ArH).

Anal.—Calc. for $C_{13}H_{14}O_4$: C, 66.66; H, 6.02. Found: C, 66.49; H, 6.18.

Synthesis and Biological Evaluation of 2-(9-Acridinyl)ethyl-*N*-substituted Carbamates and Their Hydrochlorides and 10-*N*-Oxides

JAMES T. STEWART [x] and RICHARD E. GAMMANS

Abstract □ The syntheses of 2-(9-acridinyl)ethyl-*N*-substituted carbamates and their hydrochlorides and 10-*N*-oxides are reported along with biological results in the areas of antineoplastic, antimalarial, and CNS activity screening. The compounds showed negative biological activity in the areas tested.

Keyphrases □ 2-(9-Acridinyl)ethyl-*N*-substituted carbamates, hydrochlorides, and 10-*N*-oxides—synthesis, pharmacological activity □ Antineoplastic activity—synthesis and screening of 2-(9-acridinyl)ethyl-*N*-substituted carbamates, hydrochlorides, and 10-*N*-oxides

Acridine derivatives have been tested extensively for potential medicinal activity. Antibacterial (1, 2), antimalarial (3), anthelmintic (4), analeptic (5), and antineoplastic (6–10) activities have been reported for many substituted acridines. The synthesis of new acridine derivatives containing urea, thiourea, thiocarbamate, and carbamate groupings has been reported from this laboratory (11, 12). While possessing little or no anticancer activity, a general pharmacological screen revealed activity in antibacterial, metabolic, parasitologic, and GI screening procedures for some derivatives.

In a continuation of a study into the synthesis and potential biological activity of new acridine compounds, this paper reports the synthesis and antineoplastic screening data for 2-(9-acridinyl)ethyl-*N*-substituted carbamates and their hydrochlorides and 10-*N*-oxides. In addition, biological results for some compounds in antimalarial and central nervous system (CNS) activity screening procedures are reported.

DISCUSSION

The incorporation of the carbamate and acridine moieties into one structure is of special interest, since each structure is singly present in compounds that have shown various degrees of antineoplastic activity (6–10, 13–15). The interaction of acridines with nucleic acids and inhibition of nucleic acid synthesis is well documented (16, 17). Acridines tend to accumulate selectively in tumor tissue (18, 19) showing inhibition of tumor growth, reduction of rate of growth, and, in some cases, regression of tumor size. Nevertheless, no clinically useful agent has been found among the acridines tested, most of which have been substituted 9-aminoacridines. Structures containing carbamate esters also have been reported to have potent antitumor activity (13, 14). Ethyl carbamate itself has been used both for the production of tumors in experimental animals and for the treatment of chronic leukemia and multiple myeloma (15). Some evidence also indicates that carbamates are involved in alkylation of DNA (20).

The mechanism by which these new acridine carbamates were expected to exert their antineoplastic effect was by selective absorption in cancerous tissue followed by a two-pronged attack upon the nucleic acids of the cancer cells. The acridine ring would be expected to interact with the nucleic acid bases, thus holding the carbamate portion in close proximity to the bases to facilitate alkylation by the carbamate.

[a] Letters refer to the experimental procedures. [b] Procedure modified from general method described in Ref. 17.

The hydrochloride salts of the various acridine carbamates were prepared to increase polarity of the molecules and, therefore, their water solubility. The 10-*N*-oxide derivatives were also synthesized, since it has been reported that oxidation of the acridine ring nitrogen reduces the toxicity of the agent by increasing renal clearance (21).

EXPERIMENTAL[1]

Chemistry—The carbamates were synthesized by reaction of 2-(9-acridinyl)ethyl alcohol with sodium cyanate, trifluoroacetic acid (22), and/or the respective isocyanate (23). The starting alcohol was obtained in a few synthetic steps from commercial materials (24, 25). The hydrochlorides were prepared from the respective carbamates with ethereal hydrogen chloride solution, and the 10-*N*-oxides were prepared using *m*-chloroperbenzoic acid. The synthesized compounds are shown in Table I, together with their melting points, UV maxima, and elemental analysis data.

2-(9-Acridinyl)ethyl Carbamate (Procedure A)—A solution of 4.5 g (0.02 mole) of 2-(9-acridinyl)ethyl alcohol in 25 ml of methylene chloride was treated with 2.6 g (0.04 mole) of sodium cyanate. The resulting suspension was slowly stirred while 3.2 ml (0.04 mole) of trifluoroacetic acid was added dropwise over 5 min. The reaction mixture was then stirred at room temperature for 2 hr. After washing with one 5-ml portion of water, the methylene chloride layer was separated and dried over anhydrous sodium sulfate. The filtered solution was then evaporated to dryness on a steam bath, followed by neutralization of the residue with a saturated solution of sodium bicarbonate. The resulting precipitate was recrystallized from aqueous ethanol to give the 2-(9-acridinyl)ethyl carbamate.

*2-(9-Acridinyl)ethyl-*N*-substituted Carbamates (Procedure B)*—The respective isocyanate (0.03 mole) was added to a solution of 4.5 g (0.02 mole) of 2-(9-acridinyl)ethyl alcohol in 100 ml of dry benzene. The solution was heated at reflux for 4 hr. The reaction mixture was evaporated to dryness, and the residue was recrystallized from aqueous ethanol (Compound 2), benzene–cyclohexane (Compound 3), or acetone–petroleum ether (Compound 4).

*2-(9-Acridinyl)ethyl-*N*-substituted Carbamate Hydrochlorides (Procedure C)*—A solution of 0.02 mole of the respective carbamate in 30 ml of ether was saturated with hydrogen chloride gas. A precipitate, which formed immediately, was collected by filtration and purified by trituration in acetone (Compounds 5–7) or ethanol (Compound 8) to yield the desired hydrochloride salt.

*2-(10-Oxido-9-acridinyl)ethyl-*N*-substituted Carbamates (Procedure D)*—A solution of 0.025 mole of *m*-chloroperbenzoic acid in 5–10 ml of chloroform was added to a solution of 0.02 mole of the respective carbamate dissolved in 25 ml of chloroform. The mixture was stirred for 3 hr at room temperature followed by evaporation to dryness. The resulting residue was washed with four 10-ml portions of ether followed by recrystallization of the residue with cyclohexane–chloroform.

[1] Melting points were taken in capillary tubes on a Thomas-Hoover apparatus and are uncorrected. Elemental analyses were obtained from Atlantic Microlabs, Atlanta, Ga. IR spectra were recorded on a Perkin-Elmer model 237 B spectrophotometer and were as expected. UV spectra were recorded on a Perkin-Elmer model 202 spectrophotometer.

[a] Doses were administered every 4th day for two doses unless otherwise noted. [b] Cell culture (KB): ED_{50} at 44 μg/ml. [c] Cell culture (KB): ED_{50} at 1.0×10^2 μg/ml. [d] Cell culture (KB): ED_{50} at 73 μg/ml. [e] Cell culture (KB): ED_{50} at 14 μg/ml. [f] Cell culture (KB): ED_{50} at 94 μg/ml. [g] Cell culture (KB): ED_{50} at 90 μg/ml. [h] Cell culture (KB): ED_{50} at 23 μg/ml. [i] Doses were administered every 4th day for three doses.

Biological[2]—Compounds 1–11 were tested against L-1210 leukemia according to the standard protocol[3] of the Division of Cancer Treatment, National Cancer Institute, National Institutes of Health. None of the compounds screened exhibited anticancer activity patterns considered adequate to justify expanded testing or further extension of the present group (Table II). Activity is defined as percent T/C (test/control) of 125 or greater. The term "survivors" in Table II is a measure of toxicity and was determined at Day 5 after the first injection.

Compounds 3 and 6 were tested for antimalarial activity. The activity was assessed against *Plasmodium berghei* in mice by the method of Osdene *et al.* (28). Both compounds were found to be inactive.

Compound 4 was tested for potential CNS activity by the method of Iturrian and Johnson (29). In the procedure, the carbamate was administered to audioconditioned mice at a level of 150 mg/kg. Data showed that the compound failed to block the running or tonic components of the audiogenic seizure.

Compound 12 was not submitted for biological testing due to insufficient quantities available from the synthetic program.

[2] The antineoplastic screening data were made available through courtesy of Drug Development Branch, Drug Research and Development, Division of Cancer Treatment, National Cancer Institute. The antimalarial test results were provided by the Walter Reed Army Institute of Research. The CNS activity data were provided by the Department of Pharmacology, School of Pharmacy, University of Georgia.

Bioavailability of Aspirin from Commercial Suppositories

MILO GIBALDI ˣ and BARBARA GRUNDHOFER

Abstract □ A comparison of the bioavailability of salicylate from five brands of commercially available aspirin rectal suppositories in an adult panel is presented. All brands show slow absorption compared to oral administration of the drug in tablet form. At best, about 40% of the dose (on the average) was absorbed when retention time in the bowel was limited to 2 hr. However, four out of the five brands gave substantially lower absorption rates so that only about 20% of the aspirin is available.

Keyphrases □ Aspirin—bioavailability from commercial suppositories, humans □ Suppositories—bioavailability of aspirin, humans □ Bioavailability—aspirin from commercially available suppositories, humans

Salicylate absorption after rectal administration of an aspirin suppository[1] to eight children and four adults was recently studied (1). The absorption of the drug from the suppository was exceedingly slow, about an order of magnitude slower than that observed after oral administration of conventional tablets. Accordingly, the amount of drug absorbed was highly dependent on the time between insertion and the first defecation (retention time). Retention times as long as 4–5 hr resulted in absorption of only about 60% of the dose.

Several other brands of aspirin suppositories were available locally in community pharmacies and still another brand was used exclusively in a local hospital. Given the relatively poor bioavailability characteristics of suppository Product L, it was of interest to study salicylate absorption from other brands of aspirin suppositories. Accordingly, five products were compared in adult subjects. The bioavailability characteristics of the four other brands of aspirin suppository were substantially poorer than that observed with Product L.

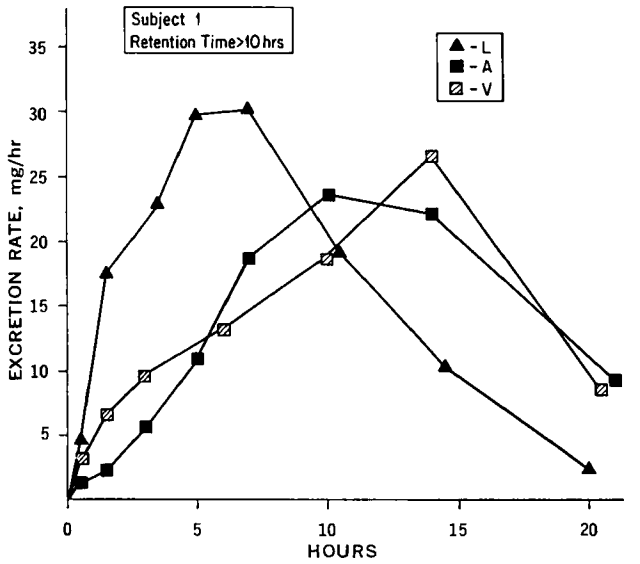

Figure 1—*Excretion rate of total salicylate* versus *time profiles after rectal administration and prolonged retention of various brands of 10-grain aspirin suppositories.*

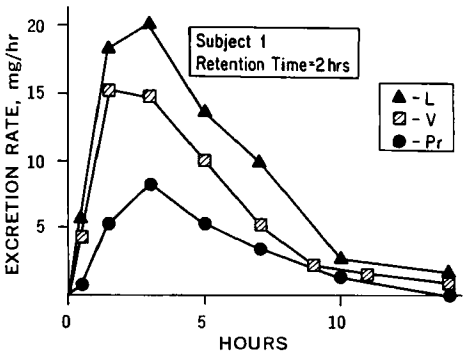

Figure 2—*Excretion rate of total salicylate* versus *time profiles after rectal administration of various brands of 10-grain aspirin suppositories.*

EXPERIMENTAL

The various aspirin suppositories were either purchased from local pharmacies or obtained from the pharmacy of a local hospital. The products were coded[2] A, L, Pp, Pr, and V. Each product claimed to contain 10 grains (600–650 mg) of aspirin. Two suppositories of each brand were assayed in duplicate for total salicylate. Expressed in terms of label claim, they were found to contain 103 and 105% (A), 108 and 105% (L), 106 and 86% (Pp), 117 and 115% (Pr), and 110 and 118% (V).

The adult panel consisted of four male volunteers, 24–35 years of age, three of whom received all five products. Each subject was instructed to insert a suppository shortly after arising in the morning and then either to evacuate his bowel as thoroughly as possible exactly 2 hr after insertion or to retain the suppository as long as possible. In the latter situation, retention times varied from 11 to >24 hr. In all cases, at least 1 week elapsed between studies.

Immediately prior to drug administration, the subjects voided their bladders and a specimen was obtained to serve as a blank. Urine was collected at appropriate intervals for 28–32 hr. The volume of each urine collection was determined and a sample was retained for drug analysis. Urine samples were hydrolyzed with an equal volume of concentrated hydrochloric acid in sealed ampuls overnight at 100°. The samples were then analyzed for total salicylate according to a modification of Brodie *et al.* (2) using carbon tetrachloride. Absorbance of the resulting ferric–salicylate complex was determined at 530 nm on a spectrophotometer[3] and corrected for blank values on an individual basis. Concentrations were determined from a previously constructed standard curve.

1.5	25.6 ± 7.0	8.9 ± 4.9	10.9 ± 4.9	9.7 ± 3.9	13.2 ± 4.5

[a] Mean ± 1 *SD*. [b] Parenthetical values denote the number of subjects.

RESULTS AND DISCUSSION

Bioavailability is defined as the rate and extent of absorption of a drug from a dosage form. In the case of relatively low doses of aspirin (as used in the present study), it is well known that initial urinary excretion rates of total salicylate reflect the relative absorption rate of the drug and that the cumulative amount of total salicylate ultimately excreted in the urine serves as a quantitative index of the extent of absorption.

Table I shows the average initial excretion rates of total salicylate after rectal administration of the various products. The excretion rates at 0.5, 1.0, and 1.5 hr after insertion of Product L were at least two to three times greater than those observed with any other product. This difference is further illustrated in Fig. 1, where the urinary excretion rates of total salicylate are plotted as a function of time after administration of Products L, A, and V. The time of occurrence of maximum excretion rate was considerably less after Product L than that found after Products A and V. Moreover, the greatest peak excretion rate was observed after administration of L. Clearly, the absorption rate of aspirin must be considerably greater after rectal administration of Product L than after administration of the other suppositories studied. This finding is indeed remarkable when one considers how slowly aspirin is absorbed from Product L (1).

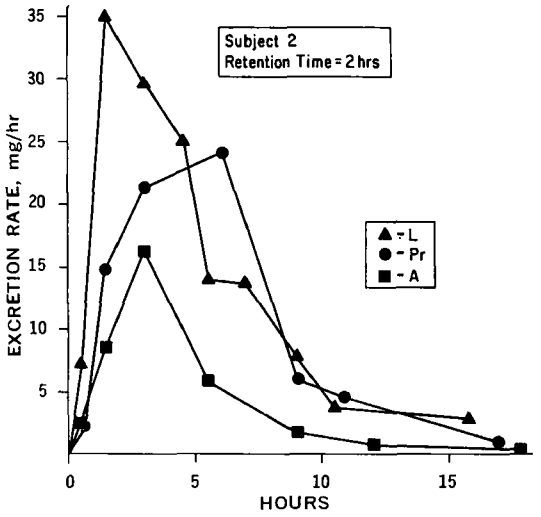

Figure 3—*Excretion rate of total salicylate* versus *time profiles after rectal administration of various brands of 10-grain aspirin suppositories.*

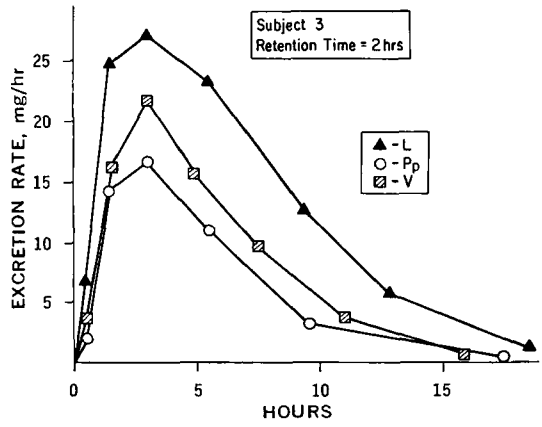

Figure 4—*Excretion rate of total salicylate* versus *time profiles after rectal administration of various brands of 10-grain aspirin suppositories.*

When drug products intended for rectal administration manifest such prolonged absorption patterns, the extent of absorption is obviously dependent on retention time. As shown in Table II, even after administration of the product from which aspirin is most rapidly absorbed (L), only about 40% of the dose was absorbed when the retention time was limited to 2 hr. During a similar 2-hr period, only about half that amount of aspirin was available, on the average, from Products A, Pp, Pr, and V, which released the drug still more slowly.

Differences between products with respect to the amount of aspirin absorbed in individual subjects are readily apparent in Figs. 2–4 when the total area under the excretion rate *versus* time plot is considered. In all three subjects, the cumulative amount of total salicylate ultimately excreted after a 2-hr retention of an aspirin suppository was consistently greater after administration of Product L. No consistent differences were obvious among the other four products.

The present results are readily extrapolated to permit one to conclude that the shorter the retention time the greater will be the difference between Product L and the other products tested with respect to the amount of drug absorbed, but in all cases the amount will be decreased. On the other hand, as shown previously (1) in studies with L, the greater the retention time the greater is the availability of aspirin. It follows that longer retention times tend to diminish differences among products with respect to the extent of drug absorption and that ultimately such differences disappear (Table II). When the aspirin suppository was retained for periods exceeding 10 hr, in most cases absorption of the drug was nearly complete and no differences among products were apparent.

Despite the substantial differences in bioavailability characteristics found to exist among various commercially available aspirin suppositories, the rate of absorption of aspirin from all products studied was sufficiently slow to raise considerable doubt as to whether efficacious body levels of aspirin or salicylate are attained after a single dose. The exceedingly slow absorption also suggests the possibility of a significantly reduced extent of absorption of the administered dose if the patient defecates even several hours after insertion of the suppository. It is anticipated that this prob-

Central *versus* Peripheral Anticholinergic Activity as Assessed by Two *In Vivo* Procedures in Mice

JEFFREY B. MALICK [x] and ALLEN BARNETT

Abstract □ The activity of tertiary and quaternary anticholinergic drugs was compared in two different test procedures designed to measure cholinolytic activity in mice. The four drugs utilized were atropine sulfate, atropine methylnitrate, scopolamine hydrobromide, and scopolamine methylnitrate. The results led to the conclusion that one of these test procedures, the induction of mydriasis (increase in pupil size), primarily measures peripheral anticholinergic activity whereas the other procedure, inhibition of physostigmine lethality, primarily measures anticholinergic activity in the CNS. These two test procedures can be utilized to characterize the nature of the cholinolytic properties of prospective therapeutic drug candidates.

Keyphrases □ Anticholinergic activity—determination of central *versus* peripheral cholinolytic activity, tertiary and quaternary derivatives of atropine and scopolamine, mice □ Mydriasis induction as measure of peripheral anticholinergic activity—tertiary and quaternary derivatives of atropine and scopolamine, compared to physostigmine-induced lethality inhibition (central activity), mice □ Physostigmine-induced lethality inhibition as measure of central anticholinergic activity—tertiary and quaternary derivatives of atropine and scopolamine, compared to mydriasis induction (peripheral activity), mice □ Atropine and scopolamine, tertiary and quaternary derivatives—central *versus* peripheral cholinolytic activity, mice □ Scopolamine and atropine, tertiary and quaternary derivatives—central *versus* peripheral cholinolytic activity, mice

The measurement of anticholinergic activity is important in the evaluation of drug candidates for humans. Peripheral anticholinergic liability is considered to be an undesirable side effect of many therapeutic agents, particularly with regard to antidepressants (1) and antihistamines (2). Central [*i.e.*, within the central nervous system (CNS)] anticholinergic activity may not be as troublesome (except at toxic doses) and, in fact, may even be desirable under certain circumstances. Central anticholinergic drugs (*e.g.*, scopolamine) produce sedation in humans, and amitriptyline, a potent central anticholinergic and sedative drug, may be the antidepressant of choice in cases of agitated depression, a condition in which sedative effects have utility (3).

In the present studies, two test procedures in mice were evaluated for their ability to detect central *versus* peripheral anticholinergic activity. To evaluate these procedures, tertiary and quaternary forms of atropine and scopolamine were utilized. The tertiary forms readily cross the blood–brain barrier whereas the quaternary forms are retarded by the blood–brain barrier and, consequently, are concentrated to a much lesser extent in the CNS than they are in the periphery following parenteral administration. Thus, by comparing the relative potency of these agents in the two procedures, the induction of mydriasis and the antagonism of physostigmine-induced lethality, the extent that each can predict central or peripheral anticholinergic activity was determined.

EXPERIMENTAL

Male CF No. 1-S mice, 18–22 g, were used. All drug doses were calculated in terms of milligrams per kilogram of free base, and all drugs were dissolved in distilled water. The volume of injection was 10 ml/kg for both the intraperitoneal and subcutaneous routes of administration. The drugs used were atropine sulfate, atropine methylnitrate, scopolamine hydrobromide, and scopolamine methylnitrate.

Induction of Mydriasis (Increased Pupil Size) in Mice—Mice were administered test drugs and were tested for mydriatic activity 30 min later. These studies were performed under double-blind conditions such that the investigator did not know what drugs or doses were being tested. Normal pupil size was scored as 0 and increases in pupil size were scored as 1, 2, and 3 (slight, moderate, and maximal increases in size, respectively). A score of 2 was approximately 50% of maximal pupil size, which was a modification of the scoring system of Janssen and Niemegeers (4).

Any mouse exhibiting a pupil size of 2 or greater was considered to be significantly affected. Mean pupil sizes for each group were also calculated. The dose intervals for each test drug were kept constant (0.5 $\log_{10}$ units). The MED_{50} (minimal effective dose) for producing a significant increase in mydriasis in 50% or more of the mice tested was determined for each test drug. The ED_{50}'s could not be calculated since there were very small intervals between doses at which no animals exhibited significant effects and doses producing effects in 100% of the mice.

Inhibition of Physostigmine-Induced Lethality in Mice—

lem would be most pronounced with Products A, Pp, Pr, and V. 	0.1	3.0	6/6	

[a] Drug administered 30 min prior to testing. [b] Pupil size scored as follows: 0 = normal size, 1 = slight increase, 2 = moderate increase, and 3 = marked increase. [c] Number of mice exhibiting a significant increase in pupil size (score of 2 or greater). [d] Minimal effective dose for producing significant mydriasis in 50% or more of the animals tested.

The method used was a modification of the technique reported by Collier *et al.* (5). Physostigmine salicylate (1.0 mg/kg sc) produced 100% lethality when administered to mice grouped 10 per cage [12.7 × 28 × 12.7 cm (5 × 11 × 5 in.)] 20 min after drug administration. Test agents were administered intraperitoneally 30 min prior to physostigmine. Inhibition of lethality was then calculated as percent of control. The ED_{50}, the dose that prevented lethality in 50% of the mice, was calculated for each drug by the Maximum Likelihood Probit Analysis Method (6).

RESULTS AND DISCUSSION

The induction of mydriasis by the four anticholinergic drugs is summarized in Table I. All four drugs produced dose-related increases in pupil size, as indicated by mean pupil size. The MED_{50}'s for induction of mydriasis by atropine sulfate, atropine methylnitrate, scopolamine hydrobromide, and scopolamine methylnitrate were 0.3, 0.1, 0.1, and 0.03 mg/kg ip, respectively. The quaternary forms of the anticholinergic drugs were more potent as mydriatics than their respective tertiary forms; both atropine methylnitrate and scopolamine methylnitrate were approximately three times as potent as their respective tertiary forms.

Table II summarizes the results of studies to determine the relative potency of the four anticholinergic drugs as inhibitors of physostigmine-induced lethality in mice. The ED_{50}'s for atropine sulfate, atropine methylnitrate, scopolamine hydrobromide, and scopolamine methylnitrate were 1.6, 12.8, 0.35, and 6.1 mg/kg ip, respectively. Although all four drugs inhibited the lethality produced by physostigmine, a cholinesterase inhibitor, the tertiary forms, in contrast to the results obtained in the mydriasis studies, were considerably more potent than their respective quaternary forms. Atropine sulfate was eight times more potent than atropine methylnitrate, and scopolamine hydrobromide was 18 times more potent than scopolamine methylnitrate in this procedure. This result was believed to be due to the blood–brain barrier impeding the passage of the quaternary derivatives into the CNS.

Table III summarizes the potency ratio comparisons of the various drugs in the two anticholinergic test procedures. As mentioned, there was a reversal of the potency relationships when appropriate tertiary and quaternary derivatives were compared such that the quaternary forms were more potent mydriatic agents whereas the tertiary forms were more potent inhibitors of physostigmine lethality. When scopolamine hydrobromide was compared to atropine sulfate, the former was approximately three to four times more potent than the latter in both procedures. The same relationship between the quaternary derivatives held true; *i.e.*, scopolamine methylnitrate was approximately two to three times more potent than atropine methylnitrate as an anticholinergic in both procedures (Table III).

From these results, it was concluded that the induction of my-

Table II—Antagonism of Physostigmine-Induced Lethality in Mice

Table III—Potency Ratio Comparisons of the Activities of Anticholinergic Drugs in Two Procedures in Mice

Comparison	Induction of Mydriasis Potency Ratio[a]	Antagonism of Physostigmine Lethality Potency Ratio (95% Confidence Limits)[b]
Atropine sulfate *versus* atropine methylnitrate	0.33	8.1 (5.0–14.7)
Scopolamine hydrobromide *versus* scopolamine methylnitrate	0.30	18.1 (12.3–27.7)
Scopolamine hydrobromide *versus* atropine sulfate	3.00	4.7 (3.2–7.2)
Scopolamine methylnitrate *versus* atropine methylnitrate	3.33	2.1 (1.3–3.5)

[a] Calculated from MED_{50}'s from Table I. [b] The potency ratio and 95% confidence limits were calculated by Maximum Likelihood Potency Probit Analysis (6) from data in Table II.

driasis was primarily a peripheral anticholinergic response since both the tertiary and quaternary derivatives of atropine and scopolamine were potent inducers of mydriasis. It also was concluded that inhibition of physostigmine-induced lethality was primarily a measure of central anticholinergic activity since the quaternary derivatives were much less potent inhibitors of physostigmine-induced lethality than their respective tertiary forms.

A careful evaluation of a drug's relative activity in these two procedures in the same species, the induction of mydriasis and the inhibition of physostigmine lethality, should predict its relative activity as a central and a peripheral anticholinergic in humans.

Tissue Distribution of *N*-^{14}C-Azure C (Methylthionine) in the Rat

R. ENG, S. LINDBERG, K. WHITE, and L. A. SPITZNAGLE [x]

Abstract □ The distribution of radioactivity at 5-, 10-, and 15-min intervals following the intravenous administration of *N*-^{14}C-azure C was determined. The concentrations of radioactivity observed indicated that radioactive derivatives of azure C would not be useful pancreas or parathyroid scanning agents.

Keyphrases □ Azure C, radiolabeled—tissue distribution, considerations related to use as pancreas or parathyroid scanning agent □ Methylthionine, radiolabeled—tissue distribution, considerations related to use as pancreas or parathyroid scanning agent □ Scanning agents—tissue distribution of radiolabeled azure C

The report (1) that the intravenous administration of the phenothiazine dye tolonium chloride (toluidine blue O) caused a blue coloration of the pancreas and parathyroid glands but not of surrounding organs generated much interest and has been verified in experimental animals (2–4) and humans (5–7). Toluidine blue O has been used for the identification of the parathyroid gland at surgery (5–7) and as an aid in the diagnosis of small oral cancers (8), and it has been suggested as a potential parathyroid and pancreas scanning agent if labeled with a suitable radionuclide (2–4, 6, 7). Recent studies with an iodinated analog of toluidine blue O labeled with ^{131}I showed it to be useful for imaging parathyroid adenomas (9).

DISCUSSION

Kang and DiGiulio (3) found the highest concentrations of toluidine blue O in the parathyroids, heart, pancreas, kidneys, stomach, lungs, thyroid, muscles, liver, and blood, in that order. They extracted the excised tissues with ethanol and measured the dye concentrations colorimetrically. Mortenson and McRae (2) reported similar results using a similar assay. In both studies, rather low concentrations were observed in the organs surrounding the pancreas, suggesting the development of a pancreas scanning agent provided a suitable labeled derivative could be prepared.

Larose *et al.* (10) studied the distribution in rats of an iodinated derivative of toluidine blue O labeled with ^{125}I. Using an assay method that allowed the measurement of tissue radioactivity without extraction, they found the concentrations of radioactivity in the pancreas, liver, and kidneys to be similar for up to 60 min after intravenous administration. Likewise the parathyroid was observed to have concentrations of radioactivity similar to those found in the thyroid gland. They concluded that iodinated toluidine blue O was an unsatisfactory scanning agent for the pancreas and parathyroid glands.

Archer *et al.* (11) also studied the tissue distribution of a ^{125}I-labeled derivative of toluidine blue O. However, they extracted the tissues with ethanol and measured the radioactivity of the extracts. Their results differed from those of Larose *et al.* (10) in that the parathyroid extract contained approximately three times the concentration of extractable radioactivity as did the thyroid. The pancreas extract contained only a slightly higher concentration of radioactivity than the liver extract, indicating that iodinated toluidine blue O was an unsatisfactory scanning agent for the pancreas. However, these investigators observed that the percentage of the injected dose taken up by the pancreas was much greater when unlabeled toluidine blue O was given instead of iodinated toluidine blue O.

Preliminary work in this laboratory confirmed the results of Klopper and Moe (1); 30 min after the intravenous administration of toluidine blue O, extracts of the pancreas had 10 times the concentration of dye compared to extracts of the liver when measured colorimetrically (12). In a preliminary investigation of the distribution of ^{35}S-labeled toluidine blue O (12), concentrations of radioactivity in the pancreas, liver, and kidneys were found to be similar. These results seemed to confirm the conclusions of Larose *et al.* (10) and Archer *et al.* (11) that labeled derivatives of toluidine blue O were unsatisfactory pancreas scanning agents.

One possible explanation of the blue coloration of the pancreas consistent with these results is that the dye molecule may be

driasis was primarily a peripheral anticholinergic response since both the tertiary and quaternary derivatives of atropine and scopolamine were potent inducers of mydriasis. It also was concluded that inhibition of physostigmine-induced lethality was primarily a measure of central anticholinergic activity since the quaternary derivatives were much less potent inhibitors of physostigmine-induced lethality than their respective tertiary forms.

A careful evaluation of a drug's relative activity in these two procedures in the same species, the induction of mydriasis and the inhibition of physostigmine lethality, should predict its relative activity as a central and a peripheral anticholinergic in humans.

Recent studies with an iodinated analog of toluidine blue O labeled with ^{131}I showed it to be useful for imaging parathyroid adenomas (9).

DISCUSSION

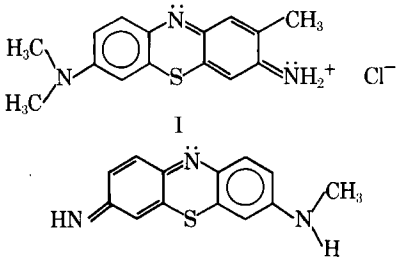
Kang and DiGiulio (3) found the highest concentrations of toluidine blue O in the parathyroids, heart, pancreas, kidneys, stomach, lungs, thyroid, muscles, liver, and blood, in that order. They extracted the excised tissues with ethanol and measured the dye concentrations colorimetrically. Mortenson and McRae (2) reported similar results using a similar assay. In both studies, rather low concentrations were observed in the organs surrounding the pancreas, suggesting the development of a pancreas scanning agent provided a suitable labeled derivative could be prepared.

Larose *et al.* (10) studied the distribution in rats of an iodinated derivative of toluidine blue O labeled with ^{125}I. Using an assay method that allowed the measurement of tissue radioactivity without extraction, they found the concentrations of radioactivity in the pancreas, liver, and kidneys to be similar for up to 60 min after intravenous administration. Likewise the parathyroid was observed to have concentrations of radioactivity similar to those found in the thyroid gland. They concluded that iodinated toluidine blue O was an unsatisfactory scanning agent for the pancreas and parathyroid glands.

Archer *et al.* (11) also studied the tissue distribution of a ^{125}I-labeled derivative of toluidine blue O. However, they extracted the tissues with ethanol and measured the radioactivity of the extracts. Their results differed from those of Larose *et al.* (10) in that the parathyroid extract contained approximately three times the concentration of extractable radioactivity as did the thyroid. The pancreas extract contained only a slightly higher concentration of radioactivity than the liver extract, indicating that iodinated toluidine blue O was an unsatisfactory scanning agent for the pancreas. However, these investigators observed that the percentage of the injected dose taken up by the pancreas was much greater when unlabeled toluidine blue O was given instead of iodinated toluidine blue O.

Preliminary work in this laboratory confirmed the results of Klopper and Moe (1); 30 min after the intravenous administration of toluidine blue O, extracts of the pancreas had 10 times the concentration of dye compared to extracts of the liver when measured colorimetrically (12). In a preliminary investigation of the distribution of ^{35}S-labeled toluidine blue O (12), concentrations of radioactivity in the pancreas, liver, and kidneys were found to be similar. These results seemed to confirm the conclusions of Larose *et al.* (10) and Archer *et al.* (11) that labeled derivatives of toluidine blue O were unsatisfactory pancreas scanning agents.

One possible explanation of the blue coloration of the pancreas consistent with these results is that the dye molecule may be



I

II

"decolorized" by the liver and kidneys but not by the pancreas.

An observation in this laboratory that toluidine blue O can easily be *N*-demethylated (13) suggested that the data might be explained by *N*-demethylation of toluidine blue O in the liver and kidneys but not in the pancreas.

If both *N*-methyl groups were removed from toluidine blue O (I) in the liver and the kidneys but not in the pancreas, then the resulting dye (2-methylthionine) would probably not be visible when the viscera was observed, nor could the concentration of the dye be measured accurately at 625 nm. Therefore, the distribution of a dye molecule labeled in the *N*-methyl group, rather than in the phenothiazine ring, was of interest. If such a dye were rapidly *N*-demethylated by the liver and kidneys but not the pancreas, it might be possible to produce a pancreas scanning agent by labeling such a dye with an ^{11}C-*N*-methyl group.

Since toluidine blue O contains two amino groups that are not symmetrical, it would be difficult to label the *N*-methyl groups. Therefore, the distribution of azure C (*N*-methylthionine, II), an aminophenothiazine dye with similar chemical properties to toluidine blue O which can easily be labeled with ^{14}C in the *N*-methyl group, was studied.

The purpose of the present study was to determine if the concentration of radioactivity in the pancreas and parathyroid glands following the administration of an aminophenothiazine dye labeled in the *N*-methyl group would be sufficient to warrant further efforts to develop pancreas and parathyroid scanning agents from such dyes.

EXPERIMENTAL

Chemicals—The dyes[1] were labeled 80–90% pure. All other chemicals were reagent grade and were used as received.

^{14}C-Azure C was prepared as previously reported (14), and TLC indicated the radiochemical purity to be greater than 89%. The dye was dissolved in water prior to injection.

Animals—The animals used were Sprague–Dawley rats, 200–250 g, and they were maintained on rat chow and water *ad libitum* prior to use.

Tissue Distribution—The animals were anesthetized with pentobarbital sodium, and 5 μCi of ^{14}C-azure C was injected *via* an exposed femoral vein. The animals were sacrificed after 5, 10, or 15 min. Thyroid, parathyroids, heart, pancreas, adrenals, liver, kidneys, spleen, stomach, and a sample of blood were removed as rapidly as possible. The organs were frozen immediately in dry ice to prevent dehydration. The tissue samples were weighed while still frozen.

Tissue samples too large to be dissolved directly were minced with a razor blade and then homogenized[2] in distilled water equal to the tissue weight. The tissues and aliquots of the tissue homogenates were dissolved by heating at 50–60° in liquid scintillation counting vials containing 1 ml of a solubilizer[3]. The dissolved samples were decolorized by slowly adding 30% H_2O_2. The dissolved and decolorized samples were then counted[4] at 5°. The sample counts were corrected for quenching by the external standard ratio method, which had been shown to give a linear relationship between external standard ratio and counting efficiency over the range of counting efficiencies obtained by this method of sample preparation.

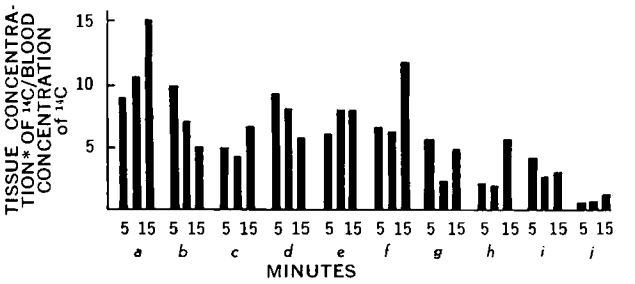

Figure 1—*Tissue distribution of ^{14}C activity at 5, 10, and 15 min after the intravenous administration of ^{14}C-azure C. (*Average from six animals at each time.)* Key: a, *adrenal;* b, *parathyroids;* c, *thyroid;* d, *lung;* e, *liver;* f, *kidney;* g, *heart;* h, *stomach;* i, *pancreas; and* j, *muscle.*

RESULTS

The ratios of tissue–blood radioactivity 5, 10, and 15 min after the intravenous administration of ^{14}C-azure C are shown in Fig. 1. The distribution of radioactivity is similar to that found after the administration of ^{35}S-toluidine blue O (12) or an ^{125}I-labeled analog of toluidine blue O (10). These results indicate that the blue coloration of the pancreas observed after administration of azure C is probably not due to rapid demethylation of the dye in the liver and kidneys. These results, when considered with the previous data obtained with toluidine blue (2, 3, 10–12), suggest that the pancreas turns blue after the dye administration because of its thickness and translucent appearance in comparison with surrounding organs. The results also indicate that ^{11}C-labeled azure C would not be a good parathyroid or pancreas scanning agent.

Amino Acid Esters of Phenolic Drugs as Potentially Useful Prodrugs

Keyphrases □ Phenolic drugs—use of amino acid esters as prodrugs □ Amino acid esters of phenolic drugs—use as prodrugs □ Prodrugs—consideration of amino acid esters of phenolic drugs

To the Editor:

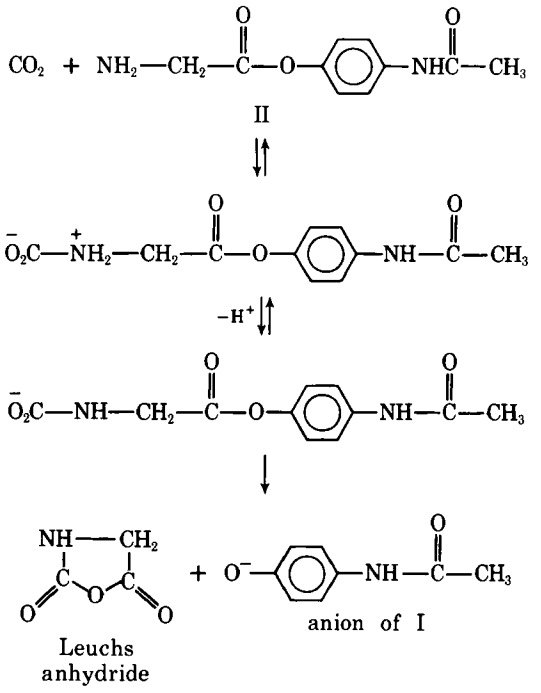
It is sometimes desirable to make temporary chemical modifications to drug molecules for the purpose of increasing their chemical stability, of changing their solubility or rate of dissolution, or of modifying their distribution within the body. If such chemically modified drugs are transformed to the parent drug before they elicit a pharmacological response, they are referred to as prodrugs (1).

It is frequently desirable to formulate phenolic drugs as prodrugs, because many of them have low water solubility as neutral molecules and they are all subject to oxidative degradations *in vitro* and conjugative metabolism *in vivo*. Amino acid esters of phenolic drugs appear to be attractive candidates for consideration as prodrugs for the following reasons:

1. Prodrugs with either higher or lower water solubility can be made following appropriate selection of the amino acid. For example, the aqueous solubilities at 25° of acetaminophen (*p*-acetamidophenol) (I), the hydrobromide salt of its glycine ester (II), and the hydrochloride salt of its β-aspartic acid ester (III) were calculated to be 0.10, 0.48, and 0.023 *M*, respectively.

2. Considerable differences in the stability against hydrolysis have been found for different amino acid esters of a particular phenol. Hence, the $t_{1/2}$ values (half-lives) for hydrolysis of II and III and for the α-aspartic acid ester of I (IV) in water at pH 7.0 and 25° were 49, 155, and 2.65 min, respectively. The $t_{1/2}$ values at pH 2.0 were 1850, 2850, and 76 min, respectively. These half-lives were observed when no general acids or bases or other catalytic species were present in the solution.

3. The hydrolyses of amino acid esters of phenols are likely to be catalyzed by general bases and nucleophilic species; even in the absence of any enzyme-facilitated hydrolysis, the hydrolyses are likely to be rapid within the body to yield the phenolic parent drug. The hydrolysis of the ester II was subject to general base and nucleophilic catalysis, and the catalytic rate constants (assuming that the rate-determining step of the reaction involves one molecule of the protonated form of the ester and one molecule of general base or nucleophilic species) were calculated to be $2.04 \times 10^{-3}\ M^{-1}\ min^{-1}$ for formate ion, $5.80 \times 10^{-3}\ M^{-1}\ min^{-1}$ for acetate ion, $120 \times 10^{-3}\ M^{-1}\ min^{-1}$ for dihydrogen phosphate ion, and $4120 \times 10^{-3}\ M^{-1}\ min^{-1}$ for tromethamine.



Scheme I

The rate laws for hydrolysis in glycine and tromethamine buffers also included a term that was second order in the amine. In addition, the rates of hydrolysis were dramatically catalyzed by dissolved carbon dioxide. Whereas the $t_{1/2}$ value for the hydrolysis of II in a $5 \times 10^{-2}\ M$ tromethamine buffer (pH 7.44) at 25° was 7.7 min, the $t_{1/2}$ value in a $2 \times 10^{-3}\ M$ solution of sodium bicarbonate in the same buffer (pH 7.44) was 4.9 min—the reaction rate constant had increased by more than 50%. Blood and other body fluids contain similar or larger concentrations of dissolved carbonic acid species (2). At pH 7.44, 6.75, and 6.00, the apparent catalytic rate constants for the total concentration of carbonic acid species (H_2CO_3, HCO_3^-, and CO_3^{-2}) were 23.07, 7.32, and 0.96 $M^{-1}\ min^{-1}$, respectively. These data can best be rationalized by postulating that carbon dioxide catalyzes the reactions *via* the sequence of reactions shown in Scheme I.

This reaction sequence is similar to one postulated by Hay and Main (3) to account for the effects of carbon dioxide on the hydrolysis of α-amino acid esters of *p*-nitrophenols. The only difference is that whereas Hay and Main concluded that the formation of the carbamate was the sole rate-determining step for hydrolysis of *p*-nitrophenol esters, the reactions of II can best be rationalized by concluding that both this step and the step that results in the formation of the Leuchs anhydride are rate determining.

The rate of hydrolysis of II was significantly increased over what was found in water at 25° when the solution temperature was increased to 37° and rabbit blood plasma was added to the solution. In a 3×10^{-2} *M* solution of tromethamine (pH 7.40) to which 1 and 3% blood plasma had been added, the $t_{1/2}$ values were

14 and 4.9 min, respectively, at 37°. Catalysis in these solutions is probably the result of a combination of general base, nucleophilic, carbon dioxide, and even some enzyme catalysis. Therefore, it is expected that many amino acid esters of phenolic drugs would be rapidly tranformed to the drug under *in vivo* conditions.

4. Many amino acids are normal dietary constituents or are substances with little toxicity. Thus, the compound formed along with the drug when the prodrug is hydrolyzed is unlikely to cause toxic reactions.

Detailed results of a kinetic study of the reactions of II, III, and IV in aqueous solutions together with some mechanistic considerations will be published subsequently.

Phenol Formation from Alkylparabens by Bacteria

Keyphrases ◻ Phenol—formation from alkylparabens by bacteria ◻ Parabens, alkyl—role in formation of phenol by bacteria ◻ Preservatives—phenol formation from alkylparabens by bacteria

To the Editor:

Alkylparabens are widely used as preservatives for various pharmaceutical preparations such as injections, solutions, emulsions, and suspensions. They are also used in cosmetic preparations containing various fats and oils susceptible to microbial attack. Alkylparabens are also involved in gelatin preparation from animal sources to prevent proliferation of contaminated bacteria.

When a paste of gelatin containing alkylparabens was incubated at room temperature, we found that phenol formation was followed by the liquefaction of gelatin.

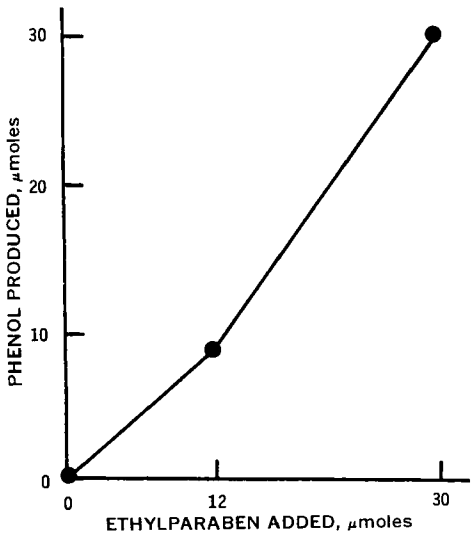

Figure 1—*Effects of various levels of ethylparaben on phenol formation, using resting cells as the enzyme source. Reaction mixtures contained ethylparaben and 7.6 × 10^{10} cells in a final volume of 12 ml. The mixed cell suspension containing strains 3, 4, and 5 was added. Reaction mixtures were incubated at 37° without shaking for about 110 hr. Viable cell counts in the reaction mixtures after incubation at the lowest and highest levels were estimated as 2.9 × 10^9 and 1.7 × 10^9, respectively. Each experiment was carried out with two flasks.*

With the advancement of the Good Manufacturing Practices, microbial contamination, even in nonsterile drugs in either final products or raw materials, has become of concern for the quality control of pharmaceutical manufacturing processes. This communication is concerned with the finding that alkylparabens are decomposed to phenol by the cooperative action of two different bacteria.

Three microorganisms were isolated from the pharmaceutical manufacturing processes using gelatin; they were identified as *Klebsiella aerogenes* (strain 3), *Pseudomonas aeruginosa* (strain 4), and *Pseudomonas aeruginosa* (strain 5). They are able to grow in a gelatin paste containing alkylparabens.

Each microorganism was grown on soybean casein digest agar slant medium (1) for 18 hr at 37° without shaking. The grown cells were harvested aseptically by centrifugation, washed once with sterile water, and suspended in sterile water. The cell suspensions thus prepared were kept in a refrigerator until use and were used for the following experiments.

Counting of viable cells was carried out by means of the plate method, using soybean casein digest agar as the test medium as described in USP XVIII (1). Various alkylparabens[1] and *p*-hydroxybenzoic acid[2] were obtained commercially. Other reagents used were of the best quality commercially available. TLC[3] was carried out according to the methods described by Sadamatsu *et al.* (2). Phenol was determined by literature methods (3, 4).

Phenol Formation from Alkylparabens by Bacteria

Keyphrases ◻ Phenol—formation from alkylparabens by bacteria ◻ Parabens, alkyl—role in formation of phenol by bacteria ◻ Preservatives—phenol formation from alkylparabens by bacteria

To the Editor:

Alkylparabens are widely used as preservatives for various pharmaceutical preparations such as injections, solutions, emulsions, and suspensions. They are also used in cosmetic preparations containing various fats and oils susceptible to microbial attack. Alkylparabens are also involved in gelatin preparation from animal sources to prevent proliferation of contaminated bacteria.

When a paste of gelatin containing alkylparabens was incubated at room temperature, we found that phenol formation was followed by the liquefaction of gelatin.

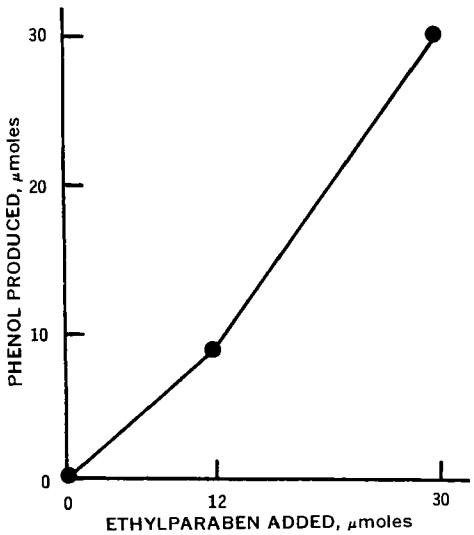

Figure 1—*Effects of various levels of ethylparaben on phenol formation, using resting cells as the enzyme source. Reaction mixtures contained ethylparaben and 7.6 × 10^{10} cells in a final volume of 12 ml. The mixed cell suspension containing strains 3, 4, and 5 was added. Reaction mixtures were incubated at 37° without shaking for about 110 hr. Viable cell counts in the reaction mixtures after incubation at the lowest and highest levels were estimated as 2.9 × 10^9 and 1.7 × 10^9, respectively. Each experiment was carried out with two flasks.*

With the advancement of the Good Manufacturing Practices, microbial contamination, even in nonsterile drugs in either final products or raw materials, has become of concern for the quality control of pharmaceutical manufacturing processes. This communication is concerned with the finding that alkylparabens are decomposed to phenol by the cooperative action of two different bacteria.

Three microorganisms were isolated from the pharmaceutical manufacturing processes using gelatin; they were identified as *Klebsiella aerogenes* (strain 3), *Pseudomonas aeruginosa* (strain 4), and *Pseudomonas aeruginosa* (strain 5). They are able to grow in a gelatin paste containing alkylparabens.

Each microorganism was grown on soybean casein digest agar slant medium (1) for 18 hr at 37° without shaking. The grown cells were harvested aseptically by centrifugation, washed once with sterile water, and suspended in sterile water. The cell suspensions thus prepared were kept in a refrigerator until use and were used for the following experiments.

Counting of viable cells was carried out by means of the plate method, using soybean casein digest agar as the test medium as described in USP XVIII (1). Various alkylparabens[1] and *p*-hydroxybenzoic acid[2] were obtained commercially. Other reagents used were of the best quality commercially available. TLC[3] was carried out according to the methods described by Sadamatsu *et al.* (2). Phenol was determined by literature methods (3, 4).

[1] Wako Pure Chemicals Co.
[2] Tokyo Kasei Co.
[3] DC Fertigplatten Kiesel gel G 60 F 254 from Merck was used.

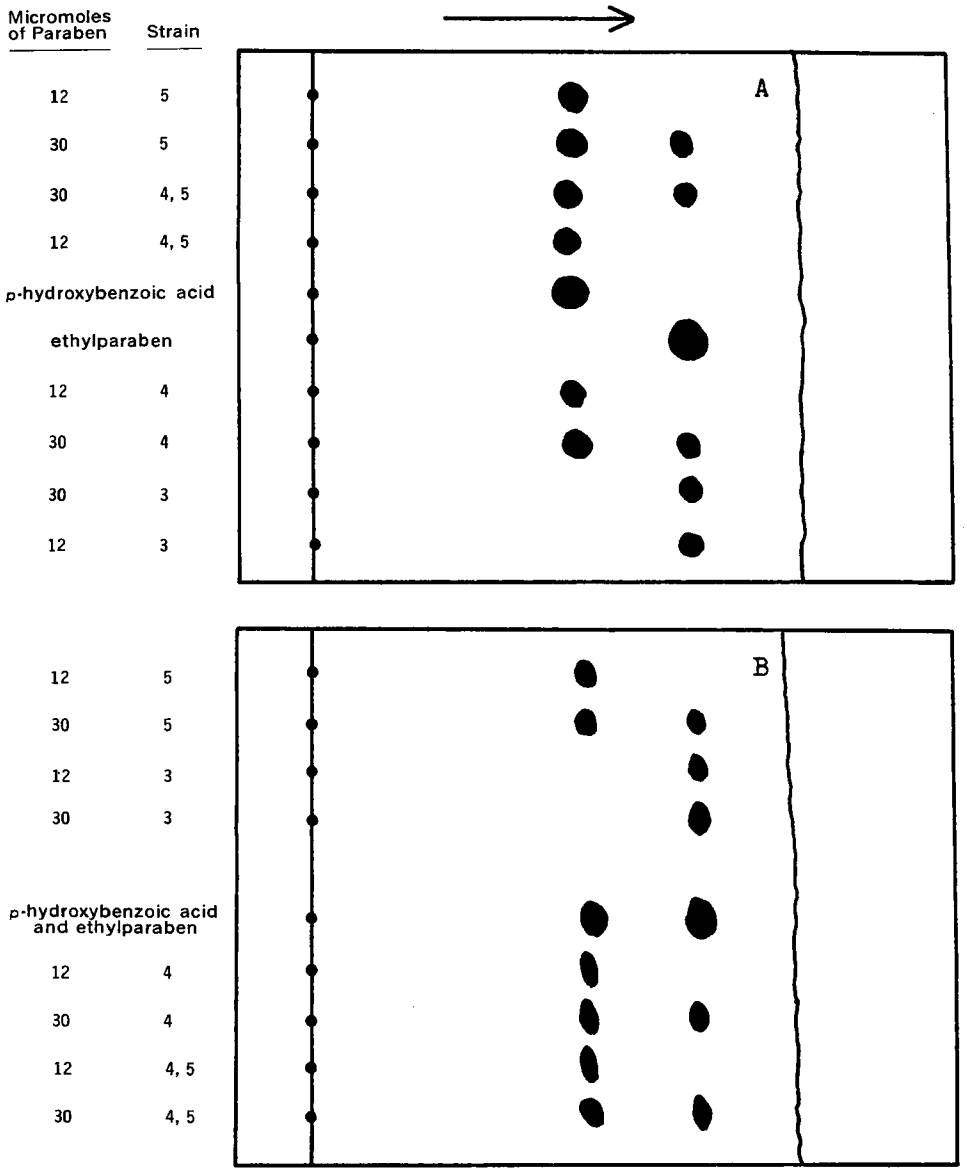

Figure 2—*TLC identification of esterolytic activity formed by strains 3 and 5. Reactions were carried out in the same manner as described in Table I. Developing solvents used were: A, chloroform–propionic acid (1:4); and B, benzene–dioxane–acetic acid (90:25:4). Spots were detected with a UV lamp.*

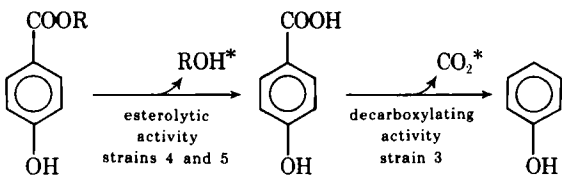
When the mixed cell suspensions of strains 3, 4, and 5 were added to the sterilized ethylparaben solution and incubated at 37° for about 110 hr, phenol was formed, depending on the amount of ethylparaben added (Fig. 1). Table I shows that neither strain 3, 4, nor 5 was capable of forming phenol from ethylparaben, but strain 3 was able to form phenol from *p*-hydroxybenzoic acid. It was also able to produce phenol from ethylparaben in combination with strains 4 and/or 5. Phenol was also formed from methyl-, propyl-, and butylparabens under the same conditions.

TLC patterns of the reaction mixture (Fig. 2) showed that *p*-hydroxybenzoic acid was formed from ethylparaben with strains 4 and/or 5, whereas ethylparaben remained unchanged with strain 3.

These findings can be explained if it is assumed (Scheme I) that both strains 4 and 5 have esterolytic activity and that strain 3 contains a decarboxylating system. It is also suggested that the rather rapid hydrolysis of alkylparabens by esterolytic activity of either strain 4 or 5 favors the survival of strain 3, which plays the leading role in the phenol formation from alkylparabens *via* *p*-hydroxybenzoic acid.

Previous studies (5) showed that *K. aerogenes* can form phenol from *p*-hydroxybenzoic acid, suggesting the presence of a decarboxylase system in the microorganisms. On the other hand, tyrosine phenol lyase



*Scheme I—Speculated mechanisms of phenol formation from alkylparabens (R = methyl, ethyl, propyl, and butyl; * = speculated)*

Table I—Effects of Various Parabens and *p*-Hydroxybenzoic Acid on Phenol Formation in the Presence of Single or Combined Cell Suspension as Enzyme Source[a]

Microorganisms Added (Strain)	Substrate, 12 μmoles (1.2 m*M*)					
	No Substrate	*p*-Hydroxybenzoic Acid	Methylparaben	Ethylparaben	Propylparaben	Butylparaben
3	0	11.4 12.2	—	0	—	—
4	0	0	—	0	—	—
5	0	0	—	0	—	—

3 and 5	0	9.9 9.7	—	9.4 9.3	—	—
4 and 5	0	0	—	0	—	—
3, 4, and 5	0	8.3 9.8	8.5 9.7	9.1 9.9	8.8 9.6	8.9 9.3

[a] Each figure in the table shows the amount of phenol formed (micromoles). Reaction conditions were those given in Fig. 1, except that each viable cell count of strains 3, 4, and 5 added was 5.9×10^{10}, 1.3×10^{10}, and 2.1×10^{10}, respectively, in a final volume of 10 ml.

has also been studied intensively by many investigators (6–10), who found that it catalyzes direct splitting of alanine from tyrosine to form phenol. In our studies with tyrosine as the substrate in place of alkylparabens, however, phenol was not produced.

Various alkylparabens are used or prescribed to prevent proliferation of contaminated microorganisms in pharmaceutical preparations. However, *P. aeruginosa* (NCTC 7244) was found to utilize alkylparabens as a carbon source and to grow well in an eye drop solution containing them (11). Furthermore, as described in the present communication, microorganisms such as strain 3 *(K. aerogenes)* metabolize *p*-hydroxybenzoic acid into phenol under restricted nutritional conditions.

Pseudomonas or *Klebsiella* species and other organisms have been isolated from various nonsterile pharmaceutical or cosmetic preparations and the production environment (12). It also has been shown that serious spoilage of drugs is brought about by these microorganisms. Although the mechanism of deterioration has not been elucidated from the standpoint of bacteriological metabolism, this communication presents a typical example concerning drug deterioration by microorganisms.

Antiviral Activity of Gossypol and Apogossypol

Keyphrases □ Gossypol—screened for antiviral activity □ Apogossypol—screened for antiviral activity □ Antiviral activity—gossypol and apogossypol

To the Editor:

The pigment gland of the cotton seed contains an array of organic compounds including gossypol (I), which has been demonstrated to have antibacterial (1), antiviral (2–4), and antitumor (5) activities as well as mammalian toxicity (6, 7). Apogossypol (II), which has lower mammalian toxicity, is formed by deformylation of gossypol with base (8). The following report of preliminary findings establishes that apogossypol retains the potent antiviral activity of gossypol.

Gossypol can inactivate influenza virus infectivity *in vitro*, and influenza virus inactivated by treatment with gossypol was given to mice with a resultant 96–100% protection rate (2–4). Since little is known about either the mechanism of action or the activity spectrum of gossypol, an investigation of the *in vitro* inactivation of viruses by this compound and the less toxic apogossypol was initiated.

Table I—Effects of Various Parabens and *p*-Hydroxybenzoic Acid on Phenol Formation in the Presence of Single or Combined Cell Suspension as Enzyme Source[a]

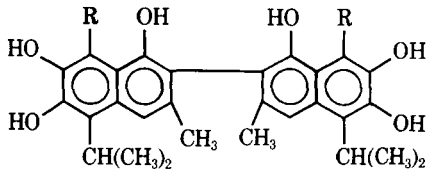
The pigment gland of the cotton seed contains an array of organic compounds including gossypol (I), which has been demonstrated to have antibacterial (1), antiviral (2–4), and antitumor (5) activities as well as mammalian toxicity (6, 7). Apogossypol (II), which has lower mammalian toxicity, is formed by deformylation of gossypol with base (8). The following report of preliminary findings establishes that apogossypol retains the potent antiviral activity of gossypol.

Gossypol can inactivate influenza virus infectivity *in vitro*, and influenza virus inactivated by treatment with gossypol was given to mice with a resultant 96–100% protection rate (2–4). Since little is known about either the mechanism of action or the activity spectrum of gossypol, an investigation of the *in vitro* inactivation of viruses by this compound and the less toxic apogossypol was initiated.



I: R = CHO
II: R = H

The toxicity of gossypol[1] and apogossypol[1] for HEp-2 cell cultures was determined to delineate the concentrations of gossypol that could be utilized in the antiviral assays. The HEp-2 cell cultures were incubated for 1 hr with varying concentrations (0.5–20 μg/ml) of gossypol in Hank's balanced salt solution; this solution then was removed and replaced with maintenance medium (Eagle's minimum essential medium containing 2% heat inactivated fetal calf serum). The cell cultures were observed for cytopathic effect and cell viability.

Gossypol concentrations of 5 μg/ml (9.6×10^{-6} *M*) and lower were not toxic for the HEp-2 cells, whereas cells incubated with gossypol at concentrations of 10 μg/ml and higher exhibited a rapid toxic effect accompanied by a decrease in cell viability. Under these conditions, apogossypol gave no indication of toxicity to HEp-2 cells at a concentration of 50 μg/ml (1.14×10^{-4} *M*).

The antiviral activity of gossypol was assayed against polio virus, parainfluenza-3 virus, and herpes simplex virus, and the antiviral activity of apogossypol was determined against poliovirus and herpes simplex. Virus suspensions in Hank's balanced salt solution were incubated for 30 min at 25° with gossypol or apogossypol; samples then were removed at intervals and assayed for infectivity by determining the number of plaque-forming units per milliliter (10). Parainfluenza-3 and herpes simplex were inactivated by incubation with apogossypol; however, there was no apparent activity exerted against poliovirus by either agent. As shown in Fig. 1, the potency of apogossypol against herpes simplex is somewhat less than that of gossypol.

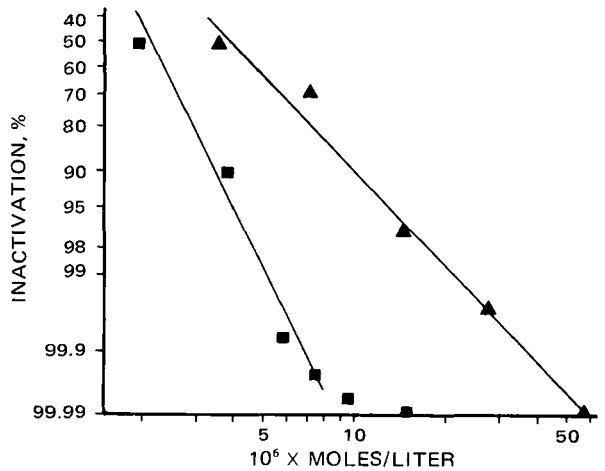


Figure 1—*Dose–response curves for gossypol (■) and apogossypol (▲). Data for gossypol are averages of two independent determinations (three replicates per determination). Data for apogossypol are averages of four independent determinations (three replicates per determination).*

Although the compounds have similar structures, the nature of the viral inactivation differs. This difference is reflected by the different slopes of the dose–response lines and the ability to inactivate the virus totally. Apogossypol can inactivate the virus completely (no plaque-forming units observed) at concentrations above 12.5 μg/ml (2.86×10^{-5} *M*) with no apparent toxicity to the HEp-2 cell cultures. Gossypol can decrease the number of plaque-forming units by a factor of 10^5, but the concentration required is also toxic to the HEp-2 cells. This toxicity probably accounts for the nonlinearity of the dose–response line at gossypol concentrations greater than 10^{-5} *M*.

Since the host cell would tolerate concentrations of gossypol and apogossypol that were antiviral *in vitro*, experiments were performed to determine whether treatment with gossypol could affect intracellular replication. Cell monolayers were infected with herpes simplex to produce approximately 100 plaques/plate. At the indicated intervals, 1 ml of Hank's balanced salt solution containing 5 μg of gossypol was added to each of three infected monolayers and incubated at 25° for 1 hr. Figure 2 shows that the antiviral effect of gossypol was apparent only during the initial stages of adsorption. Incubation with gossypol did not alter the result of infection after the virus entered the cell[2]. Similar results were observed using apogossypol in a concentration of 25 μg/ml.

These experiments demonstrate that:

1. Apogossypol is considerably (at least 10-fold) less toxic to HEp-2 cells in culture than is gossypol.
2. Apogossypol and gossypol both inactivate the enveloped virus parainfluenza-3 and herpes simplex *in vitro*.
3. The nonenveloped poliovirus is not affected by either agent.
4. Incubation of infected cells with gossypol or apogossypol does not alter subsequent plaque formation, indicating that the antiviral effect does not occur within the cell.

The molecular mechanism of viral inactivation by these compounds has not been determined. The presence of the reactive aldehyde substituents, which might react with free amino groups of proteins, has been postulated to be of importance in the biological activity of gossypol, including the mammalian toxicity (6). Likewise, previous investigators showed that gossypol inhibits the conversion of pepsinogen to pepsin by forming an imine with the ε-amino group of a lysine residue in pepsinogen (11–13). While a simi-

[1] Samples of gossypol (as the acetic acid complex) were provided by Dr. Walter Pons of the U.S. Department of Agriculture and by Dr. Harold Lewis of Cotton Inc. These samples were converted to free gossypol and recrystallized three times from chloroform, mp 199–200° [lit. (9) 200°]. Apogossypol was synthesized by the method of Clark (8) and stored in sealed (vacuum) tubes until assayed.

[2] The time required for the virus to enter the cell was established in a similar experiment using antiherpes serum rather than gossypol or apogossypol to inactivate the virus.

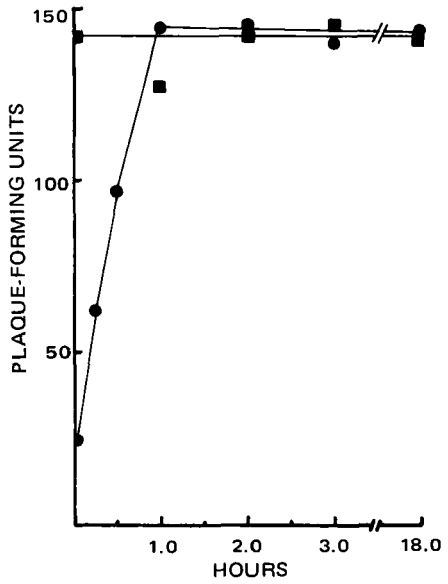

Figure 2—*Plot of time between inoculation with herpes simplex and treatment with gossypol (5 μg/ml)* versus *the plaque-forming units observed. Key:* ■, *control; and* ●, *gossypol treated.*

lar mechanism may be operative in viral inactivation, it does not appear likely due to the good activity of apogossypol.

An alternative mechanism of antiviral activity could be that these compounds bind to the virion envelope and cause the subsequent destruction of the integrity or loss of the envelope. If the membrane is the site of action, the basis for the selective toxicity to the viral particle might result from the structural differences between the envelope membrane of herpes and the outer membrane of the host cell (14). An alternative basis of the selective toxicity to the viral particle might be that the host cell has the capacity to repair membrane damage or inactivate gossypol and apogossypol. The viral particle, which is metabolically dormant, would not be expected to have either of these capabilities.

Demonstration of Claimed "Controlled-Release" Properties of a Drug Formulation

Keyphrases □ Controlled-release properties of drug formulations—claimed *versus* actual, blood level profiles compared to "plain-release" blood level profiles □ Timed-release formulations—claimed *versus* actual "controlled-release" properties, blood level profiles compared to "plain-release" blood level profiles

To the Editor:

The concept of a "controlled-release" formulation of a drug is, by now, a familiar one. The basic idea is that of delaying or prolonging the *in vivo* release of an orally administered drug. Controlled-release formulations are often termed "slow release," "sustained release," or "delayed release." The advantages of such formulations are obvious; a sustained-release formulation, for example, which prolongs blood levels over a greater period and eliminates high peaks of drug concentration, allows the possibilities of less frequent dosing and the elimination of side effects related to peaks in the blood level profile.

Two questions might reasonably be asked concerning a purportedly controlled-release formulation. First, is it efficacious in the dosage schedule recom-

Demonstration of Claimed "Controlled-Release" Properties of a Drug Formulation

Keyphrases □ Controlled-release properties of drug formulations—claimed *versus* actual, blood level profiles compared to "plain-release" blood level profiles □ Timed-release formulations—claimed *versus* actual "controlled-release" properties, blood level profiles compared to "plain-release" blood level profiles

To the Editor:

The concept of a "controlled-release" formulation of a drug is, by now, a familiar one. The basic idea is that of delaying or prolonging the *in vivo* release of an orally administered drug. Controlled-release formulations are often termed "slow release," "sustained release," or "delayed release." The advantages of such formulations are obvious; a sustained-release formulation, for example, which prolongs blood levels over a greater period and eliminates high peaks of drug concentration, allows the possibilities of less frequent dosing and the elimination of side effects related to peaks in the blood level profile.

Two questions might reasonably be asked concerning a purportedly controlled-release formulation. First, is it efficacious in the dosage schedule recom-

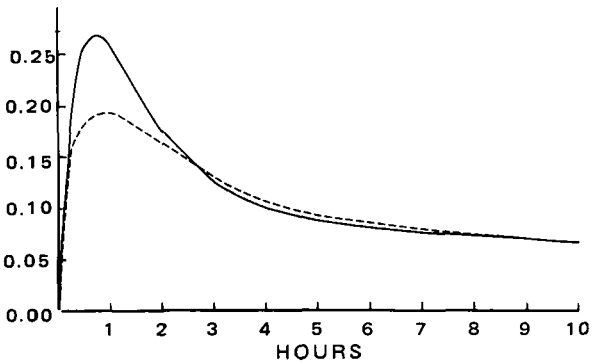

Figure 1—*Illustrative blood level curves. Key: – – –, controlled-release formulation; and —, plain-release formulation.*

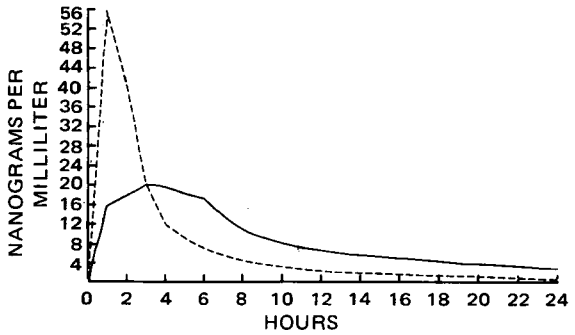

Figure 2—*Blood level curves from a 40-mg plain-release tablet of caramiphen (- - -) and from a 40-mg controlled-release formulation of caramiphen (—).*

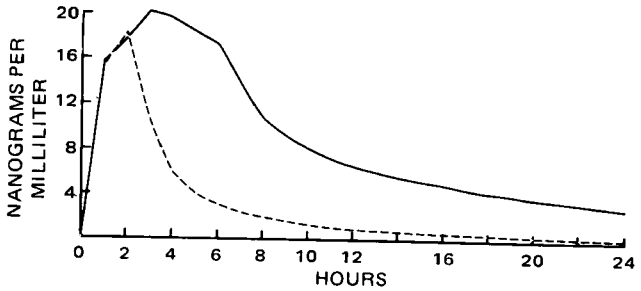

Figure 4—*Blood level curve from a 40-mg controlled-release formulation of caramiphen (—) and predicted blood level curve from a regimen of 11 mg of caramiphen at zero hr and 5 mg at 1 hr, both in plain-release tablets (- - -).*

mended? And second, does it indeed have the property of controlled release claimed for it? The fact that a once-a-day administration of a certain amount of drug in a controlled-release formulation proves to be as efficacious as a conventional regimen of the same amount of drug given in three divided doses taken over 24 hr is, in itself, no proof of controlled release. Figure 1 should make this clear. The single, plain dose might be highly effective therapeutically but never administered in this fashion because of, for example, the intolerable side effects associated with the high peak blood level. The purportedly controlled-release formulation might also be effective therapeutically in a once-a-day regimen without the accompaniment of side effects. However, one could hardly claim the controlled-release property for it on the basis of the blood level profile shown in Fig. 1. What appears to have happened is that the formulation simply makes the drug less available at the critical point where side effects might occur.

Apparently, the efficacy of a purportedly controlled-release formulation in the proposed regimen and its controlled-release character are independent questions requiring their own proof. Establishment of either one cannot be used to infer the presence of the other; the proof that a formulation possesses a controlled-release characteristic must be tackled directly. For example, if the drug in question generates a pharmacological response that can be measured with reasonable precision, a study measuring this response can be made the basis of a demonstration of the controlled-release property. In many cases, however, the most convenient approach will be through a pharmacokinetic study. A number of pharmacokinetic methods can be devised to demonstrate the controlled-release of a formulation; one that seems to represent the most generally satisfactory approach to the problem will be described here.

The method proposed is that of determining the regimen of divided doses to which the controlled-release formulation is equivalent in the sense that it generates an equivalent blood level profile over time. To illustrate the method, consider the blood level profiles (based on the mean from a number of subjects) obtained with two formulations of caramiphen: a 40-mg plain-release tablet and a 40-mg controlled-release formulation. Linear pharmacokinetics are assumed so that the predicted blood levels from any dose of caramiphen in the plain-release tablet can be obtained from the dotted line in Fig. 2 by scaling up or down by the appropriate factor.

One then determines what dose of plain-release drug given at $t = 0$ appears to match the beginning of the controlled-release blood level curve. Scaling the dotted line curve in Fig. 2, one finds that 11 mg given in a plain-release tablet appears to be a good match (Fig. 3). To match further the controlled-release blood level curve, one then finds that 5 mg in a plain-release form appears to be needed at 1 hr (Fig. 4). Further doses are added where required to match the controlled-release blood level curve until the allotted 40-mg dose is used up. The only principles involved are those of linear pharmacokinetics, involving scal-

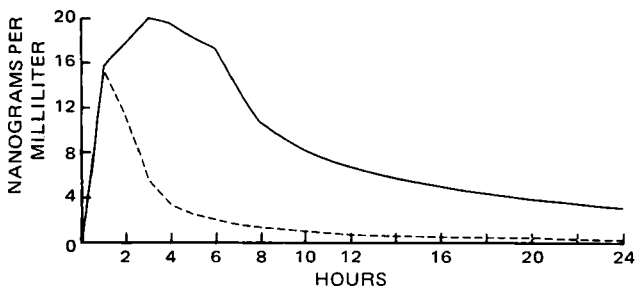

Figure 3—*Blood level curve from a 40-mg controlled-release formulation of caramiphen (—) and predicted blood level curve from 11 mg of caramiphen in a plain-release tablet administered at zero hr (- - -).*

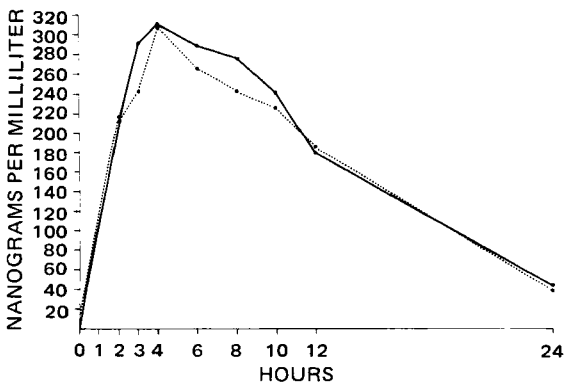

Figure 5—*Blood level curves from a 150-mg controlled-release formulation of phenylpropanolamine (—) and from a regimen totaling 150 mg of phenylpropanolamine given in various doses at 0, 1, 2, 3, 5, 6, and 7 hr (- - -).*

ing of curves, superpositioning, and adding of superposed curves.

Of course, one could fit a compartment model and proceed in a similar manner, but I have already expressed a preference for using simple empirical techniques (1). What is required to achieve the curve matching expeditiously is a small digital computer with an oscilloscope-type display[1]. One sets up the controlled-release blood level curve as background on the oscilloscope and then tries to match it by trial and error, which usually requires 5–10 min.

At this point, by *theoretical* pharmacokinetic computations, a regimen of plain-release doses has been derived which is predicted to match the controlled-release formulation with respect to its blood level curve. The next step is, of course, to verify the validity of these theoretical calculations with an actual comparative trial in human subjects. Figure 5 shows the actual mean blood level curves of phenylpropanolamine obtained in a crossover trial in 12 subjects. A controlled-release formulation of 150 mg was compared with the following regimen:

hours	dose, mg
0	52.4
1	21.4
2	23.8
3	23.8
5	9.6
6	9.6
7	9.4

This regimen was derived from pharmacokinetic computations of the type described. The blood level curves obtained in Fig. 5 appear to show a good match; apparently this regimen of divided doses does give rise to essentially the same blood level profile as the controlled-release formulation.

The question still exists as to whether the divided dose regimen is sufficiently dispersed over time to merit the title controlled release for the formulation that it appears to mimic. As an extreme example, the controlled-release description would probably not be merited for a formulation that appears to be equivalent to a divided dose regimen of 145 mg at zero hr and 5 mg at 1 hr. Obviously, some arbitrary rules are needed. Nevertheless, the proposed method offers a reasonable way of handling the problem of demonstrating controlled release.

So that no misunderstanding occurs, it should be noted that no claim is made that the divided dose regimen is a model of how the controlled-release formulation behaves *in vivo* but rather that it gives rise to blood levels equivalent to those generated by the controlled-release formulation.

Antitumor Agents XIV: Molephantinin, a New Potent Antitumor Sesquiterpene Lactone from *Elephantopus mollis*

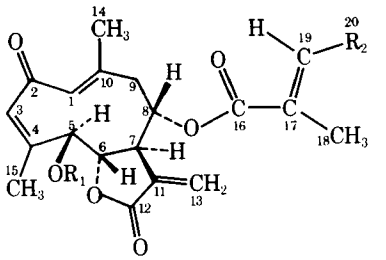
Keyphrases □ *Elephantopus mollis* H.S.K.—isolation and structure determination of molephantinin, antitumor activity □ Molephantinin—isolation, structure determination, and antitumor activity □ Antitumor agents, potential—molephantinin, constituent of *Elephantopus mollis* H.S.K. □ Structure-activity relationships—sesquiterpene lactones as antitumor agents

To the Editor:

We recently reported the isolation and structure determination of two novel cytotoxic germacranolides, molephantin (IV) (1) and phantomolin (2), from *Elephantopus mollis* H.S.K. This report[1] involves the isolation of an additional new sesquiterpene lactone, molephantinin (I), from the winter collection of this same plant. Molephantinin showed significant (T/C ≥ 125%) inhibitory activity against the Walker 256 carcinosarcoma in rats (T/C = 397%) at the 2.5-mg/kg level[2].

Molephantinin was isolated from the mother liquor after the removal of molephantin and phantomolin by silica gel column chromatography. Molephantinin, mp 223–225°, has the composition $C_{20}H_{24}O_6$ and shows an IR spectrum very similar to that of molephantin, indicating the presence of a hydroxy group (3420 cm^{-1}), a γ-lactone (1775 cm^{-1}), and the conjugated enone system (1713 and 1650 cm^{-1}). The NMR spectrum of molephantinin is superimposable with that of molephantin, except for the signal patterns in the acid portion of the ester. These differences were observed in molephantinin as the broad vinyl multiplets at δ 6.92 (1H, H-19) and the vinyl methyl multiplets at δ 1.83 (6H, H-18 and H-20), which are the typical signals for the tigloyl group (5, 6).

Added confirmation for these assignments was obtained by a comparison of the mass spectra of molephantinin and molephantin. The base peak in the mass spectrum of molephantinin is at *m/e* 83, due to



I: R_1 = H, R_2 = CH_3
II: R_1 = $COCH_3$, R_2 = CH_3
III: =O replaces R_1O ⟋ H, R_2 = CH_3
IV: R_1 = H, R_2 = H
V: R_1 = $COCH_3$, R_2 = H

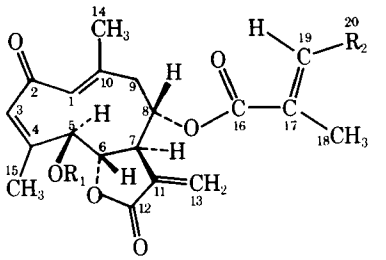
Added confirmation for these assignments was obtained by a comparison of the mass spectra of molephantinin and molephantin. The base peak in the mass spectrum of molephantinin is at *m/e* 83, due to



I: R_1 = H, R_2 = CH_3
II: R_1 = $COCH_3$, R_2 = CH_3
III: =O replaces R_1O ⟋ H, R_2 = CH_3
IV: R_1 = H, R_2 = H
V: R_1 = $COCH_3$, R_2 = H

[1] For Part XIII, see Ref. 3. For Part XII, see Ref. 2.
[2] Antitumor activity was assayed by Dr. I. H. Hall, Department of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, by a literature method (4).

the cleavage of a tiglic acid ester (7). In molephantin the base peak is at *m/e* 69, due to the methacrylate side chain. Acetylation of molephantinin with acetic anhydride in pyridine gave an acetate (II), $C_{22}H_{26}O_7$, *m/e* 402.1670 (M^+), mp 131°, which also showed comparable IR and NMR spectra to those of molephantin acetate (V).

Extensive NMR decoupling (100 MHz) led to the following assignment of protons, which was consistent with the structure of molephantinin acetate as depicted in II: δ 6.92 (1H, br m, H-19), 6.57 (1H, s, H-5), 6.36 (1H, s, H-1), 6.34 (1H, d, J = 2.5 Hz, H-13), 6.04 (1H, br s, H-3), 5.77 (1H, d, J = 2.0 Hz, H-13), 5.21 (1H, dt, J = 4.0, 10.5 Hz, H-8), 4.34 (1H, d, J = 3.5 Hz, H-6), 3.40 ([H, m, H-7), 2.62 (2H, m, H-9), 2.07 (3H, s, $OCOCH_3$), 1.98 (3H, d, J = 1.5 Hz, H-15), 1.83 (6H, m, H-18 and H-20), and 1.80 (3H, d, J < 1.0 Hz, H-14). For example, irradiation of the multiplet centered at δ 6.92 caused the six-proton multiplet at δ 1.83 to collapse to a singlet. Thus, the multiplet at δ 1.83 could be assigned to the methyl groups at C-18 and C-19.

Irradiation of the broad singlet at δ 6.04 (H-3) caused a three-proton doublet at δ 1.98 to collapse to a singlet, which could thus be assigned as the C-4 methyl signal, as was also observed in the decoupling experiment of molephantin acetate. Irradiation of the C-6 proton at δ 4.34 caused only a sharpening in the multiplet at δ 3.40, which was assigned to the C-7 proton, suggesting that the protons at C-5 and C-6 are not coupled to each other. Drieding models of this compound indicated the feasibility of this suggestion since the dihedral angle between H-5 and H-6 is approximately 90°.

Oxidation of molephantinin with Jones reagent afforded dehydromolephantinin (III), mp 136°, $C_{20}H_{22}O_6$, whose spectral data were in accord with the assigned Structure III. The circular dichroism curve of molephantinin shows a strong positive Cotton effect at 244 nm, indicating that molephantinin possesses the same stereochemistry and absolute configuration as molephantin.

The foregoing evidence leads to the formulation of the complete structure of molephantinin as I. Studies on the structure–activity relationships among molephantinin-related sesquiterpene lactones are currently in progress.

^{13}C-NMR Study of Aqueous Glutaraldehyde Equilibria

Keyphrases □ Glutaraldehyde—aqueous equilibria determined using ^{13}C-NMR, estimation of free aldehyde, relationship to pH, antibacterial activity □ Antibacterial activity—glutaraldehyde free aldehyde content determined by ^{13}C-NMR □ NMR spectroscopy—determination, aqueous glutaraldehyde equilibria, estimation of free aldehyde, relationship to pH

To the Editor:

Recently the insensitivity to concentration and pH of the free aldehyde content of aqueous glutaraldehyde was reported (1). The percentage of free aldehyde was calculated on the basis of the absence (2) of dialdehyde and found to be around 47% from integral ratios of ^{1}H-NMR peaks. This amount is twice as large as estimates based on ^{13}C-NMR spectra. Moreover, the ^{13}C-NMR results of Whipple and Ruta (3) and our own results indicate clearly two types of free aldehyde carbonyl groups, which must be due to the free dialdehyde and the hemihydrate, respectively. Our study covered a pH range of 1–8 and concentrations of 25–3% and confirmed previous studies that the equilibria among the dialdehyde, the hemihydrate, the dihydrate, and the cyclic hemiacetal are not greatly affected by pH or concentration.

Although ^{13}C-NMR spectra are more easily interpreted than ^{1}H-NMR spectra (because of larger shifts and absence of spin–spin coupling), the use of peak intensities in spectra obtained by the pulsed Fourier transform technique can be misleading. Possible problems arising from the processing of the

the cleavage of a tiglic acid ester (7). In molephantin the base peak is at *m/e* 69, due to the methacrylate side chain. Acetylation of molephantinin with acetic anhydride in pyridine gave an acetate (II), $C_{22}H_{26}O_7$, *m/e* 402.1670 (M^+), mp 131°, which also showed comparable IR and NMR spectra to those of molephantin acetate (V).

Extensive NMR decoupling (100 MHz) led to the following assignment of protons, which was consistent with the structure of molephantinin acetate as depicted in II: δ 6.92 (1H, br m, H-19), 6.57 (1H, s, H-5), 6.36 (1H, s, H-1), 6.34 (1H, d, J = 2.5 Hz, H-13), 6.04 (1H, br s, H-3), 5.77 (1H, d, J = 2.0 Hz, H-13), 5.21 (1H, dt, J = 4.0, 10.5 Hz, H-8), 4.34 (1H, d, J = 3.5 Hz, H-6), 3.40 ([H, m, H-7), 2.62 (2H, m, H-9), 2.07 (3H, s, $OCOCH_3$), 1.98 (3H, d, J = 1.5 Hz, H-15), 1.83 (6H, m, H-18 and H-20), and 1.80 (3H, d, J < 1.0 Hz, H-14). For example, irradiation of the multiplet centered at δ 6.92 caused the six-proton multiplet at δ 1.83 to collapse to a singlet. Thus, the multiplet at δ 1.83 could be assigned to the methyl groups at C-18 and C-19.

Irradiation of the broad singlet at δ 6.04 (H-3) caused a three-proton doublet at δ 1.98 to collapse to a singlet, which could thus be assigned as the C-4 methyl signal, as was also observed in the decoupling experiment of molephantin acetate. Irradiation of the C-6 proton at δ 4.34 caused only a sharpening in the multiplet at δ 3.40, which was assigned to the C-7 proton, suggesting that the protons at C-5 and C-6 are not coupled to each other. Drieding models of this compound indicated the feasibility of this suggestion since the dihedral angle between H-5 and H-6 is approximately 90°.

^{13}C-NMR Study of Aqueous Glutaraldehyde Equilibria

Keyphrases □ Glutaraldehyde—aqueous equilibria determined using ^{13}C-NMR, estimation of free aldehyde, relationship to pH, antibacterial activity □ Antibacterial activity—glutaraldehyde free aldehyde content determined by ^{13}C-NMR □ NMR spectroscopy—determination, aqueous glutaraldehyde equilibria, estimation of free aldehyde, relationship to pH

To the Editor:

Recently the insensitivity to concentration and pH of the free aldehyde content of aqueous glutaraldehyde was reported (1). The percentage of free aldehyde was calculated on the basis of the absence (2) of dialdehyde and found to be around 47% from integral ratios of ^{1}H-NMR peaks. This amount is twice as large as estimates based on ^{13}C-NMR spectra. Moreover, the ^{13}C-NMR results of Whipple and Ruta (3) and our own results indicate clearly two types of free aldehyde carbonyl groups, which must be due to the free dialdehyde and the hemihydrate, respectively. Our study covered a pH range of 1–8 and concentrations of 25–3% and confirmed previous studies that the equilibria among the dialdehyde, the hemihydrate, the dihydrate, and the cyclic hemiacetal are not greatly affected by pH or concentration.

Although ^{13}C-NMR spectra are more easily interpreted than ^{1}H-NMR spectra (because of larger shifts and absence of spin–spin coupling), the use of peak intensities in spectra obtained by the pulsed Fourier transform technique can be misleading. Possible problems arising from the processing of the

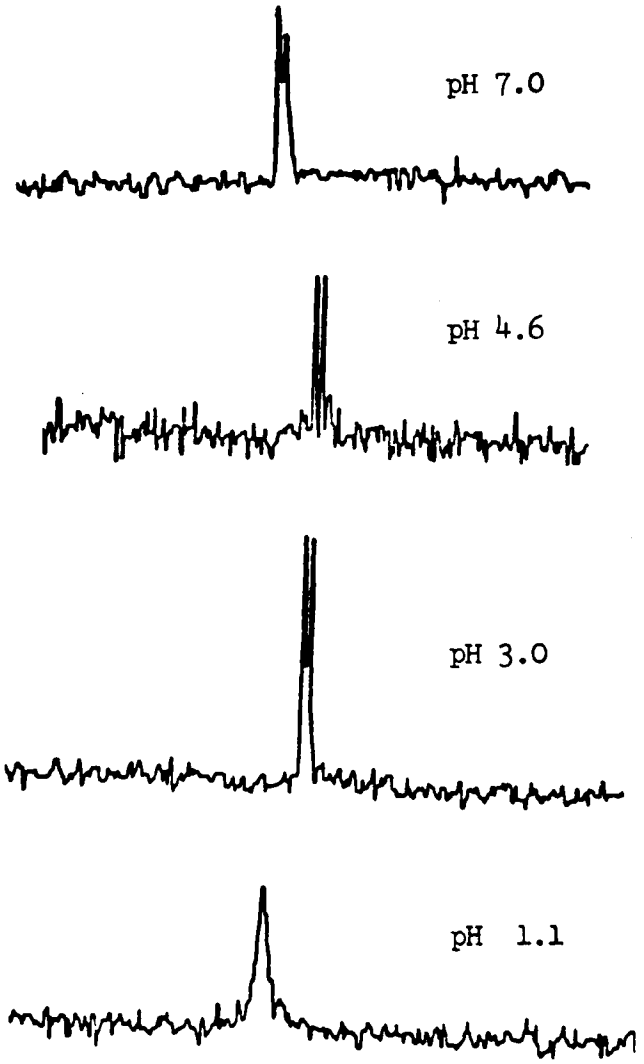

Figure 1—*^{13}C-NMR line shape dependence on pH of aqueous glutaraldehyde (carbonyl region).*

transient signal, such as sensitivity enhancement and digitization, can usually be avoided by peak area integration. However, equal numbers of carbon atoms in different sites can give dissimilar peak intensities due to a differing spin-lattice relaxation time, T_1, and nuclear overhauser enhancement due to proton decoupling (4). Whipple and Ruta (3) used a pulse delay and compared methylene carbon peaks to mitigate this problem. We used a smaller (2 μsec, 13°) pulse width with no delay and peak intensities of the carbons attached to oxygen at 209.2 and 208.4 (free aldehyde) and 91.0–95.2 (hydrated and cyclic forms) ppm.

Our results, at 38° in aqueous solution (with 10% D_2O for the heteronuclear lock[1]), are consistent with those of Whipple and Ruta when differences in temperature are taken into account. Since the relevant carbonyl peaks were of almost equal area, we found twice as much monohydrate as dialdehyde. The total free aldehyde content was equivalent to 28 free aldehyde groups/100 molecules of glutaraldehyde, compared to 24% found by Whipple and Ruta (3) at the lower temperature of 23°. This finding is in agreement with their predictions of the effects of temperature on the equilibria involved.

In the absence of the raw data of King *et al.* (1), we recalculated the proton NMR data of Hardy *et al.* (2), using our dialdehyde–monohydrate ratio of 1:2. We found that their intensity ratios can be adequately explained on this basis to give, on an average, 4% dialdehyde, 8% monohydrate, 54% dihydrate[2], and 34% hemiacetal. These results give about 16% free aldehyde group instead of the 43% calculated by Hardy *et al.* (2), which is in better agreement with the now available ^{13}C-NMR data. The 47% free aldehyde found by King *et al.* (1) would similarly decrease.

Finally, we wish to report preliminary evidence of pH-dependent linewidths in the ^{13}C-NMR spectrum of glutaraldehyde (Fig. 1). Sharp resonances are observed around pH 3–5, while line broadening is evident above and below this range. We attribute this line broadening to an increase in the rate of interconversion of one form into another. Previously, Wolman (5) suggested that the effectiveness of neutral buffered formalin in histological and histochemical work was due to the rapid conversion at neutral and alkaline pH of the polymerized form of HCHO to the monomer. Although this theory met with some skepticism (6), we feel that similar kinetic factors might best explain the pH-dependent activity of glutaraldehyde in the light of our ^{13}C-NMR findings.

Therefore, in view of the insignificance of pH and concentration dependence on the equilibria themselves, we suggest that the rates at which the equilibria are established (or maintained as the active components are depleted *in situ*) are important in considerations of antibacterial activity. This alternative interpretation of the pH dependence of antibacterial activity of commercial glutaraldehyde solutions is being investigated further.

[2] For comparison only with original data. Whipple and Ruta (3) indicated that peaks in this area have been misassigned to the dihydrate and should belong to *cis*- and *trans*-forms of the hemiacetal. This reassignment would not affect the analysis for free aldehyde.

Contact Angles on Human Skin

Keyphrases □ Contact angles—human skin, previously developed equations discussed □ Skin, human—determination of contact angles, equations

To the Editor:

Several reports of contact angle measurements of various liquids on human skin have appeared in recent years (1–4). Although these papers differed in the reported values of the contact angles, especially for water, there was general agreement that human skin behaves as a low energy solid. Rosenberg *et al.* (3) made their measurements on specially cleaned viable and excised skin and calculated the surface energy of skin due to dispersion forces (γ_S^D) using Eq. 1:

$$\cos\theta = \frac{-\gamma_L + 2\sqrt{\gamma_S^D\gamma_L^D} - \pi_S}{\gamma_L - \pi_L} \qquad \text{(Eq. 1)}$$

where θ is the contact angle, γ_L is the surface tension of the liquid, γ_L^D is the dispersion force component of the surface tension of the liquid, π_S is the reduction in surface energy of the solid due to adsorption of vapor from the liquid drop, and π_L is the reduction in surface tension of the liquid due to spreading of the solid. The investigators assumed π_S and π_L to be negligible, as is often done when dealing with low energy surfaces.

Similarly, El-Shimi and Goddard (4) neglected these spreading terms in their analysis of the dispersion force (γ_S^D) and polar (γ_S^P) contributions to the surface energy of skin, using Eq. 2:

$$\cos\theta = \frac{-\gamma_L + \dfrac{4\gamma_S^D\gamma_L^D}{\gamma_S^D + \gamma_L^D} + \dfrac{4\gamma_S^P\gamma_L^P}{\gamma_S^P + \gamma_L^P}}{\gamma_L} \qquad \text{(Eq. 2)}$$

In addition to the symbols previously defined, γ_L^P is the polar contribution to the surface tension of the liquid.

Skin presents a complex surface whose properties are influenced by a variety of endogenous, secreted, and excreted substances. Mono-, di-, and triglycerides and free fatty acids are among the lipids found most abundantly on the skin (5); these substances are known to spread on water, lowering its surface tension significantly (6). According to a recent report, sweat collected from thermally stimulated subjects had surface tension values lower than that of water by about 13–19 dynes/cm, depending on the skin region used (7).

There is, therefore, good reason to think that π_L may have a value other than zero in many cases. The value of π_L will be a function of the liquid, the nature of the skin area, the history (or pretreatment) of the skin sample, and the area of contact between the liquid drop and the skin. If the spreading process is time dependent, then the contact angle will decrease with time, an effect observed by one investigator (1). The large variation found in the contact angle of water on skin (1–4) is probably related to differences in lipid adsorption at both the water–air and skin–water interfaces.

Unfortunately, neither Eq. 1 nor 2 is adequate for quantitating the effect of skin surface lipids on the contact angle. Equation 2 does not contain π_L. Equation 1 does contain π_L, but no provision is made for changes in adsorption at the solid–liquid interface. For liquids whose contact angles are greater than 90°, Eq. 1 predicts that a rise in π_L will cause an increase in the value of the contact angle. Actually, the opposite takes place (8).

Thus, it appears that approaches that have been successful in characterizing other low energy surfaces are of only limited usefulness when applied to skin. More data on the adsorption of surface lipids would be helpful in understanding wetting and spreading on skin.

measure real differences in the dissolution rate of unit doses within a batch if these differences exceed ±2.8% of the average assay. However, analysis of their data (Table I) indicates that the intertablet variations gave rather large-range values. This study was undertaken to investigate the nature of the large-range values obtained with the automated apparatus.

Since the authors claimed the accuracy and reproducibility of the instrumentation by showing negligible variation caused by the electrical imbalance (<1%) and instrumentation, possible explanations for the large intertablet variation may be: (*a*) differences in the active ingredient content of the tablets, (*b*) differences in the disintegration properties of the tablets, and/or (*c*) uneven distribution of drug particle size among tablets.

An examination of Table I reveals that the range values were much higher in the period represented by 20–80% dissolution. This finding indicates that the disintegration properties, rather than content uniformity, of the tablets were largely responsible for the variations observed. For example, if some tablets in a given batch disintegrated much faster than the others, the faster disintegrating tablets would tend to yield faster dissolution rates as compared to the slower disintegrating tablets. Thus, the "average" dissolution rate of this batch of tablets would exhibit large intertablet variations.

To minimize differences due to content uniformity and manufacturing variables, a batch of 200-mg salicylic acid tablets was prepared by individually weighing 200 mg of salicylic acid for each tablet and compressing the tablets using a hydraulic press[1]. All tablets were prepared using identical compression force for the same time period, thus assuring that the tablets were uniform. Quick checks of the disintegration and hardness revealed that the tablets were identical in these respects.

Dissolution was followed in an automated apparatus[2] similar to the one described by Johnson *et al.* (1), using 900 ml of simulated gastric fluid (without enzymes), according to the USP–NF method (2, 3). A 1.9-ml/min flow rate[3] through a flow cell[4] and a recording spectrophotometer[5] were used. From the results (Table II), it is evident that the intertablet variations were somewhat greater than the accuracy and reproducibility claimed for the apparatus. Therefore, the large variations found by Johnson *et al.* could be due to differences in disintegration and other physical properties of the tablets as well as to the nonreproducibility of the apparatus. Further work is in progress to determine the factors responsible for these variations.

Synthesis and Neuromuscular Blocking Activity of a 3,3′-Bisbufotenidine Analog

Keyphrases □ 3,3′-Bisbufotenidine analog—synthesized and screened as possible muscle relaxant, neuromuscular blocking activity □ Bufotenidines—synthesis and screening of 3,3′-bisbufotenidine analog, neuromuscular blocking activity □ Neuromuscular blocking activity—3,3′-bisbufotenidine analog, effect of size □ Muscle relaxants, potential—synthesis and screening of 3,3′-bisbufotenidine analog, neuromuscular blocking activity

To the Editor:

In correlating the neuromuscular blocking activity of some indole-3-alkylamines with their chemical structures, it was previously demonstrated (1–4) that the presence of two hetero atoms (O and N) in the molecule, intervened by six carbon atoms through the shortest route, is essential. It was also shown that the degree of activity, although not restricted to quaternary amines only, was a function of the pKa of the test compounds.

Accordingly, the neuromuscular blocking activity of bufotenidine (I) was found to be the most potent among the series of compounds (I–IV) tested. Bufotenidine itself, however, showed a significant difference in its activities *in vivo* and *in vitro*. Thus, the antiacetylcholine effect of I on the rectus abdominis muscle of the frog was almost equipotent to that of tubocurarine, while its effect on the reversal of neostigmine block on sciatic nerve–gastrocnemius muscle preparation of albino rats was five to six times less than the latter. The possibility that the size of the molecule may be responsible for this difference in activity was repeatedly considered theoretically (2–5) but not tested by observation. We have now obtained evidence to support this contention.

For these purposes, the bisbufotenidine analog (V) was synthesized from 5-*O*-benzylbufotenine (VI), and its neuromuscular blocking activity was tested both *in vitro* and *in vivo*. The synthesis was based on two previous reports: *(a)* that indolyl magnesium halides are ionic in tetrahydrofuran solution (6), and *(b)* that cyclization of an ethereal suspension of N_a-dipteryl magnesium iodide with anhydrous ferric chloride affords *rac*-chimonanthine (7).

Accordingly, 3-(2-*N*,*N*-dimethylaminoethyl)-5-benzyloxyindole (5-*O*-benzylbufotenine) (VI) was first subjected to ionization of N_a by formation of the Grignard reagent (VII), followed by oxidation with anhydrous ferric chloride to yield V as the major product. Methyl magnesium iodide was prepared from magnesium turnings (0.95 g) and methyl iodide (5.5 g) in anhydrous ether (300 ml) under a nitrogen cloud. A solution of 5-*O*-benzylbufotenine (11.5 g) in ether (500 ml) was added dropwise in 1 hr to the stirred solution of methyl magnesium iodide. The resulting suspension was stirred for a further 2-hr period, and then a solution of anhydrous ferric chloride (7 g) in ether (200 ml) was added dropwise.

The reaction was stirred for 12 hr and then treated with an aqueous solution of ammonium chloride to effect mild acidic hydrolysis of the product. The ethereal layer was separated, the aqueous solution was made basic (pH ~10), and the liberated bases were extracted with ethyl acetate. The gelatinous precipitate of ferrous hydroxide was adsorbed on powdered cellulose. The solids were removed by filtration, and the residue was again extracted with hot ethyl acetate. The total extractives (8.4 g), obtained from the ether and ethyl acetate extracts, revealed four major spots due to quaternary bases, in addition to the unreacted indolealkylamine (VI, 54%), on TLC analysis [silica gel G[1], benzene–ethyl acetate (4:1)].

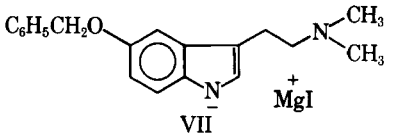
V

II: $R_1 = R_2 = CH_3$, $R_3 = H$
III: $R_1 = R_3 = H$, $R_2 = CH_3$
IV: $R_1 = R_2 = R_3 = H$
VI: $R_1 = R_2 = CH_3$, $R_3 = CH_2C_6H_5$



VII

The benzyl group was removed from the mixture of products by treatment with trifluoroacetic acid (20 ml) at room temperature for 18 hr (8). Column chromatography of the resulting mixture of phenolic bases over a magnesia silica gel[2] and a resin[3] gave the major product (1.72 g, 22%) as a microcrystalline solid. The compound, mp 210–214°, $C_{24}H_{32}N_4O_2Cl_2$ (elemental analyses and potentiometric titration), showed spectral properties, *e.g.*, UV: λ_{max} (ethanol) 238 (log ϵ 4.02) and 295 nm (log ϵ 3.61) [indicating the presence of a quaternary N_a—C—N_b^+ system since, on dequaternization with lithium aluminum hydride in tetrahydrofuran, the maxima were shifted to λ 248 and 307 nm (9)]; PMR (CD_3OD): δ 3.24–3.30 (12H, N^+—CH_3), 4.28–4.31 (2H, N—CH—N^+), and 6.8–7.4 (6H, Ar—H). The mass spectrum of the dequaternized product (phenolic tertiary base) showed, aside from the molecular ion peak at *m/e* 378 (14%), significant fragment ion peaks at *m/e* 188 (22), 187 (16), 146 (68), and 43 (base peak), characteristic of symmetrical scission of the dimeric indolic base. On the basis of these data, the major product was assigned Structure V.

The bisbufotenidine analog (V) exhibited the expected pronounced curariform activity on the rectus abdominis muscle of the frog, inhibiting acetylcholine-induced spasm without affecting the potassium

[1] E. Merck.
[2] Florisil.
[3] Amberlite CG-400 (Cl^-).

chloride-induced contractions. The inhibition was reversible and the spasmolytic ED_{50} was 0.82 μg/ml. Bufotenidine and tubocurarine, in parallel assays, showed spasmolytic ED_{50}'s of 1.45 and 1.38 μg/ml, respectively. Subsequently, the effect of the quaternary dimeric alkaloid (V) to hasten the reversal of tetanic response due to neostigmine (0.3 mg/kg iv) on sciatic nerve–gastrocnemius muscle preparation of albino rats (10) was studied. The response, in absence of the test compounds, started recovering in about 10–15 min and was almost completely recovered by 30–40 min. The reversal process was brought to completion by 10–15 min after the administration of bufotenidine (I, 0.2 mg/kg iv), bisbufotenidine analog (V, 0.01 mg/kg iv), or tubocurarine (0.015 mg/kg iv).

The curarimimetic activity of V was also tested in chicks according to the method described by Lewis (11). The test compounds were injected intravenously through the alar vein in groups of 10 chicks. All three compounds showed flaccid paralysis of the limbs with flexion of the head of chicks in doses of 50, 4, and 10 μg for I, V, and tubocurarine, respectively. From these results, it appears that the bisbufotenidine analog could be of potential therapeutic importance as a muscle relaxant. The nominal side effects encountered during its routine pharmacological screening may not pose any serious obstacle to its possible use as an adjuvant to anesthesia.

BOOKS

REVIEWS

Pharmaceutical Calculations. By JOEL L. ZATZ. Wiley, 605 Third Ave., New York, NY 10016, 1973. 311 pp. 17 × 25.5 cm. Price $7.95.

Using the format of linear programming with occasional branched remedial sequences, this book adequately presents the most important aspects of pharmaceutical calculations. The book actively involves the student in the learning process by requiring frequent responses and solutions to short questions and problems. The material is presented in 11 chapters covering the interconversion of pharmaceutical systems of weights and measures, elementary prescription notation and drug dosing, formula adjustment, calculation of percentages and other expressions of concentration, stock solutions, dilutions and concentrations, and milliequivalents. Zatz is careful and thorough in his presentation of unit labels in the basic review of mathematical operations and in his treatment of scientific notation. Accuracy of measurement using pharmaceutical equipment is conveniently linked to a presentation of factors affecting percent error and ways of determining significant figures.

The first seven chapters contain useful concise statements of objectives and goals, usually with some indication of the competence the student may be expected to achieve from a study of each chapter. The last four chapters are not consistent in their introductions, thereby losing some of the cohesiveness of the book. Furthermore the use of a cumbersome and oftentimes confusing symbol for minim, coupled with the dual use of the letter j as a general symbol for an unknown quantity as well as the final "i" in a roman numeral, represents typesetting shortcomings of this first edition that can seriously mislead all but the most astute students. For all of his intent to present problems and methods in a logical straightforward manner, the author makes the student unnecessarily dependent upon the arbitrary use of ratios and proportions in a large number of problem groups.

While the book may be helpful to some students undertaking individualized or self-paced study in pharmaceutical calculations, it will be most useful in a course where it finds companion explanation and clarification by the professor, particularly in the areas of methods and rationale for the calculation of apothecary percent w/v and ratio strength. The book can function as a helpful guide and workbook for the student, but its contents may require supplementary problem sets for mastery. The book is generally effective in its scope, variety of problems, and presentation style. It

The National Formulary, Fourteenth Edition. Prepared by the National Formulary Board with the approval of the Board of Trustees, by authority of the American Pharmaceutical Association. Published by the American Pharmaceutical Association, 1974. Distributed by Mack Publishing Co., 20th & Northampton Sts., Easton, PA 18042. lxxix + 1124 pp. 14.5 × 23.5 cm. Price $24.00 (domestic and foreign).

In view of the recent acquisition of the National Formulary by the United States Pharmacopeial Convention, Inc., this latest edition of the National Formulary (NF XIV) proves to be a fitting vehicle, even if not so originally designated, for the National Formulary Board of the American Pharmaceutical Association to conclude its traditional responsibilities in setting forth standards of identity, strength, quality, purity, packaging, storage, and labeling of drugs and related articles. Maintaining the policy established for the two previous editions, the recognition of drug substances provided for the admission of articles only on the basis of their therapeutic value.

Of the total of 1009 articles recognized as therapeutic agents or pharmaceutic aids in NF XIV, 318 are newly admitted. The articles newly admitted to NF XIV are broadly representative of classes of agents valuable in modern therapeutics including antibacterials (cephaloglycin), antihypertensives (pentolinium tartrate), antineoplastics (floxuridine), antipsychotics (thiothixene), diagnostic aids (macroaggregated iodinated I 131 serum albumin), and immunizing agents (inactivated mumps virus vaccine). In addition to the monographs, general test chapters, reagent specifications, and general information chapters comprise one-fifth of this edition.

As a result of the efforts of the USP–NF Joint Panel on Primary Requirements, the NF XIV and USP XIX General Notices and Requirements do not differ from each other in substance or intent with regard to the interpretation and application of the official standards, tests, assays, and other specifications—although major differences are noted in the section pertaining to the information included under *Categories and Doses* (*Categories, Doses, and Dispensing Information* in USP XIX). Substantial changes have been made, however, with respect to the General Notices of both previous compendia volumes.

Several new features differentiate NF XIV from the previous edition, NF XIII. The monographs for articles recognized as therapeutic agents and those for articles recognized as pharmaceutic aids are presented in separate sections. Following the principle promulgated by the USAN Council, the word order for monograph titles of most organic compounds ensures that the pharmacologically active portion appears first; *e.g.*, Butabarbital Sodium instead of Sodium Butabarbital as used in NF XIII. Additionally, the assistance of the USAN Council was sought for the purpose of obtaining specific recommendations for complying with provisions of the Federal Food, Drug, and Cosmetic Act regarding the use of "simple and useful names." As a direct result, several new official names appear in NF XIV, replacing either previously official compendia names or previously established names for the article (in the case of articles newly admitted to NF XIV). The chemical data section has been expanded to include the current Chemical Abstracts indexing name that utilizes the recently revised Chemical Abstracts nomenclature system. The Chemical Abstracts Service (CAS) registry numbers have also been added to this section.

A new monograph format was adopted to provide a distinctive manner for setting aside the informational matter, such as category, dose information, sizes available, description, and solubility, that is of particular interest to pharmacists and other users of the compendium. The official definition follows this informational section; the monograph standards, test procedures, and specifications follow the official definition in the familiar two-column format which has been utilized in recent NF editions. However, those specifications and requirements of primary concern for pharmacy practitioners—those regarding packaging, storage, and labeling—have been removed from the end of the monograph (their placement in NF XIII) and prominently placed immediately below the official definition and preceding the chemical tests and assays.

Specific revisions in the compendial tests and assays include the extension of content uniformity requirements to sterile suspensions in addition to their application to tablets, capsules, and sterile solids; the adoption—with caution—of the concept of system suitability tests in procedures using complex instrumentation, as a means of establishing that the entire analytical system is functioning properly to successfully complete the specified test or assay; and the use of newer analytical techniques, such as nuclear magnetic resonance spectroscopy in the case of amyl nitrite, to ensure drug standardization. Where applicable, a new specification entitled *Reference standards* that describes the pertinent storage and drying conditions (unless otherwise indicated in the monograph) for the reference standard materials used in the monograph procedures has been added.

The inclusion in this edition of new general test chapters for procedures such as high-pressure liquid chromatography, nuclear magnetic resonance spectroscopy, and thermal analysis provides for the application of the most advanced knowledge and sophisticated analytical techniques to compendial requirements. The inclusion of the new general test chapter entitled *Containers—Permeation* realizes the proposed official standard for tightness of drug containers that was announced by the NF Board in January 1974.

The individual sections pertaining to general information, reagent specifications, and index complete this volume.

Purchasers of the bound volume of the NF XIV are entitled to receive the *First Supplement* (a composite first supplement with that for USP XIX) at no additional charge. This supplement was published in April and will become official simultaneously with the main volume (July 1, 1975). And, since the American Pharmaceutical Association has relinquished its responsibility for the National Formulary to the United States Pharmacopeial Convention, Inc., all correspondence relating to supplements, standards specifications, and ordering of NF reference standards should be addressed to the National Formulary, 12601 Twinbrook Parkway, Rockville, MD 20852.

The consolidation of NF and USP, to quote Dr. John V. Bergen from his *Preface* to NF XIV, "carries the enthusiastic endorsement and support of the National Formulary Board, which believes this action to be in the best interest of the official compendia, of the professions of pharmacy and medicine, and—most important—of the public . . . [and provides a] new compendial organization which represents a combined voice, a combined resource, and a combined scientific and professional force in drug standardization."

The *Journal of Pharmaceutical Sciences* is published monthly by the American Pharmaceutical Association at 2215 Constitution Ave., N.W., Washington, DC 20037. Second-class postage paid at Washington, D.C., and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in this journal are published on the authority of the writer over whose name they appear and are not to be regarded as necessarily expressing the policies or views of the American Pharmaceutical Association.

Offices—Editorial, Advertising, and Subscription Offices: 2215 Constitution Ave., N.W., Washington, DC 20037. Printing Offices: 20th & Northampton Streets, Easton, PA 18042

Annual Subscriptions—United States and foreign, industrial and government institutions $50, educational institutions $50, individuals *for personal use only* $30; single copies $5. All foreign subscriptions add $5 for postage. Subscription rates are subject to change without notice. Members of the American Pharmaceutical Association may elect to receive the *Journal of Pharmaceutical Sciences* as a part of their annual $55 (foreign $60) APhA membership dues.

Claims—Missing numbers will not be supplied if dues or subscriptions are in arrears for more than 60 days or if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. The Association cannot accept responsibility for foreign delivery when its records indicate shipment has been made.

Change of Address—Members and subscribers should notify at once both the Post Office and the American Pharmaceutical Association, 2215 Constitution Ave., N.W., Washington, DC 20037, of any change of address.

THE VALUE OF CONGRESSIONAL OVERSIGHT

Early June brought word that yet another U.S. Congressional subcommittee would soon begin investigating the Food and Drug Administration and its overall performance. With this latest entry, at least half-a-dozen Senate and House committees and subcommittees are now in some stage of investigation of the agency, its operation, and its decisions.

In our view such investigations are generally a good thing. They create a sense of accountability that is desirable in any system of government, and particularly in a government built on a series of checks and balances.

Indeed, there are many who believe that for too many years—during the 1950's and early 1960's especially—FDA escaped the eye of Congressional scrutiny. In the view of these critics, a loose and permissive climate developed which, in turn, resulted in the evolution of a comfortable bureaucracy staffed with officials engaged in activities which sometimes seemed suspicious or self-serving. This picture of incompetence or malfeasance led to allegations of various questionable practices, of sloppy methods of operation, of decisions not for the public benefit, and of serious conflicts of interest.

At that time, the agency was just a fraction of its current size. Hence, if the FDA had continued to operate freely as it had been doing, the nation might now be faced with a crisis of public confidence in the area of food and drug regulation—a crisis which could have dwarfed the recent scandals surrounding other governmental agencies.

But largely due to the spotlight of Congressional attention, the necessary housecleaning already had been attended to, and continued surveillance seems to have prevented any major reoccurrence of these problems.

Granted, then, that such review is a good thing, the next question is at what point does a "good thing" become too much. That is, as in any process, when a certain optimum limit is exceeded, we reach a point of diminishing returns.

In the case of Congressional committee investigations, witnesses must devote an enormous amount of time and effort to advance preparation for such testimony, as well as to the appearance itself and the subsequent follow-through. To do less is to run the real risk of appearing foolish at best and to court personal disaster at worst. Consequently, if this process of testifying is duplicated and even replicated due to multiple concurrent investigations, the energies of an organization or agency can be disproportionately spent—or even exhausted—in defending and justifying its past actions. When this occurs, the pendulum may swing too far, causing so much time and resources to be drained off that little in the way of new action can be undertaken.

We are concerned that FDA is in danger of reaching such a condition due to the recent proliferation of investigations of the agency by Congressional committees. If the Commissioner and his staff find themselves spending so much time answering to Congress that they are unable to undertake or initiate new programs, then the public will be poorly served. Indeed, if progress were to be halted in this manner, one might properly conclude that the public health would be as poorly served as agency critics claim when the agency was completely escaping Congressional oversight and enjoying a free-wheeling existence. In our view, this would represent a most unfortunate development.

This review article is a continuation of the annual review of pharmaceutics begun in 1963. As in past reviews in this series (1–13), the scope has been limited to the overall area of pharmaceutics since other specific subjects in pharmaceutical sciences are pub-

lished elsewhere. The authors have used selected sections of *Chemical Abstracts* as well as 40 journals as the sources for this article.

It is hoped that this review will be of continued usefulness to the pharmaceutical scientist wherever pharmaceutical information is needed. The overall format remains essentially the same as that of the last several years; however, some changes have been made to reflect minor organizational improvements.

GENERAL PHARMACY

A four-part series (14–17) reported on a wide variety of pharmaceutical aspects considered during formulation. Topics discussed included dissolution and absorption of drugs, stability studies, physical pharmacy, microbiology, and tableting. A review article on the development of new drugs on a rational basis discussed the selection of factual leads, molecular modification, and perspectives on drug design (18). Two articles gave the current status of prostaglandins as potentially useful drugs (19, 20). Various properties of camptothecin were reviewed including synthesis, structure, and pharmacological activity (21). The pharmaceutical uses of polymers, both water soluble and insoluble, were discussed (22), and the characteristics and uses of gelatin in pharmacy and medicine were presented (23).

Preservatives—Good manufacturing practice guidelines were reviewed with respect to the prevention of bacterial and other contamination (24). The effectiveness of preservatives and their influences on different containers and on bacterial counts of 45 commonly used compounds in drug manufacturing were also discussed. A modified USP XVIII technique was used to test the efficacy of preservatives in emulsions, and the influence of pH on bacteriostatic activity was stressed (25). The choice of an appropriate preservative and the proper level for a cosmetic product in its final package were reviewed (26). The relationship between the antibacterial activity of glutaraldehyde and pH was studied (27). The antipseudomonal effect of polymyxin and phenylethanol was studied alone and in combination (28). The combination had an additive effect on sensitive *Pseudomonas aeruginosa,* while the behavior of resistant strains indicated that cross-resistance occurs between polymyxin and phenylethanol.

The binding of various preservatives, alone and in combination, to cetomacrogol was investigated (29). Data for the compounds alone indicated that all preservatives combined with two distinct classes of sites on the cetomacrogol micelle. A dynamic dialysis method for estimating the binding of preservatives to nonionic surfactants was studied (30), and Scatchard plots for the interaction of methylparaben and propylparaben with cetomacrogol at 25° indicated that there were two classes of binding sites. The minimum inhibitory concentrations (MIC) of five different mercurials against *Staphylococcus aureus* and *P. aeruginosa* were determined (31). Mercuric chloride was the most efficient bactericide, followed by the phenylmercuric salts; thimerosal was the least active.

Table I—Additional References on Preservatives

Reference	Topic
39	Methods for testing disinfectants and antiseptics
40	Preservation of shampoos and foam bathing agents
41	New preservatives for cosmetic and industrial use
42	Chemical and toxicological factors related to preservatives
43	Interaction of preservatives with surfactants and high molecular weight substances
44	Effects of formulation on preservative availability in fixed oil emulsified systems
45	Physicochemical and bactericidal properties of quaternary ammonium compounds in dispersed systems

A number of papers appeared on the preservation of creams and emulsions (32–37). The effect of ^{60}Co γ-irradiation on oil–water emulsion ointments and hydrogels, both contaminated with two test spores, was investigated (38).

Other papers on preservatives are listed in Table I.

Flavor, Aroma, and Color—Several compounds were classified as to odor type (46), but additional research into the field of olfaction and chemistry is needed to prove a definite relationship between structure and odor. The problems and methods involved in improving the taste and odor of drugs were reviewed (47). The behavior of perfumery ingredients in products was investigated by a new technique involving GLC of perfumery ingredients from product bases (48). The method was used to show how materials behave in soaps and laundry powders after various storage conditions. The formulation of floral perfume bases was given (49), and the perfumery of soap was discussed (50).

Model interaction energy calculations using the monopoles-bond polarizabilities method were used to explain the different sweetness levels in a series of 2-amino-4-nitrobenzenes (51). The taste-masking properties of sorbitol were compared to simple sugar syrup (52). The coverings of the bitter taste of quinine hydrochloride solutions, the salty taste of sodium chloride, and the astringent taste of alum by the two sweetening agents were compared. According to statistical evaluation, the taste-masking ability of sorbitol is equivalent to sugar syrup of the same concentration.

Coloring agents, including their legal requirements, for cosmetics were discussed (53). Another article reviewed the physical meaning of color, the chemical composition of dyes, and general and legal requirements of cosmetic dyes (54). Sixteen pharmaceutical coloring agents were studied with respect to solubility, light fastness, heat resistance, stability in relation to pH and oxidizing and reducing agents, and compatibility with drugs in common use (55).

The influence of the surfactants sodium lauryl sulfate, sodium salts of fatty acid methyltaurides, alkyltrimethylammonium chlorides, and betaines on the coloring of hair was investigated (56). The coacervation of alkyltrimethylammonium bromides by various colorants (tartrazine, amaranth, carmoisine, and

erythrosine), in concentrations of 0.15 and 15 mmoles/liter of the dyes and in the presence of certain salts, was studied (57). Both phase separation and microscopic techniques were used at 5–95°. Phase separation diagrams were prepared, the mechanism of interaction was discussed, and the limits of compatibility of dyes with surfactant were defined.

The influence of sunscreening agents on the color stability of tablets coated with FD&C Red No. 3 and FD&C Blue No. 1 was investigated (58, 59). The sunscreening agent giving the best protection against the fading of the red colorant was 2-ethoxyethyl *p*-methoxycinnamate, but none of the agents gave significant protective action for the blue dye. A general discussion of the stability of coloring agents in pharmaceuticals included the following topics: principal photochemical modifications of coloring agents, methods of measuring color changes, measurement of reflectance, and effects of additives for protection against UV and visible light (60).

Stability—Since fructose is sweeter than sugar (factor 173/100), syrups containing fructose were stability tested at various temperatures and found to be very stable at room temperature and also more resistant to microbial proliferation than normal syrups (61). The browning of dextrates in solid–solid mixtures containing dextroamphetamine sulfate was studied by using diffuse reflectance spectroscopy (62). The changes in the physical and chemical properties of aluminum hydroxide gel prepared by the modified Ivanov method were studied (63). The gel prepared by this method remained practically unchanged after 7 years of storage at 4–37°. The degradation of propantheline bromide in the presence of aluminum hydroxide was studied (64), and the decomposition was more rapid in the presence of aluminum hydroxide than in water. The effect of varying climatic conditions such as temperature, humidity, sunlight, and tropical areas on stability was discussed and examples were given (65).

Solid Dosage Forms—Aspirin tablet stability was studied in various plastic and glass containers, which are more commonly used overseas (66). The amount of salicylic acid in the tablets was determined after the containers were stored at 25° and humidities of 30, 60, and 90%. A series of three articles described various experimental attempts to stabilize aspirin including coacervation, recrystallization, and spraying (67–69). Poly(methyl methacrylate) and silicone oil improved the stability of aspirin in tablets, while the coacervation method using ethylcellulose was the most advantageous.

A study was reported concerning the effects of storage in typical British dispensing containers of the glyceryl trinitrate content in tablets of the British Pharmacopoeia (70). Gitoxin, digitoxin, and cordigit tablets were significantly less active after storage under UV light for 10 hr; however, abicine was not affected (71).

Solutions—Aspirin was found to be extraordinarily stable in silicone fluids (72). Its stability also was improved in a polyethylene glycol base by the use of citric and tartaric acids (73). The effect of six kinds of commercial polyphosphates in preventing the oxidation of ascorbic acid and sodium ascorbate solutions in the presence of Cu^{+2} was studied, and the polyphosphates were grouped in three classes according to their effectiveness (74). Nitroglycerin was stable only at a pH <5 unless alcohol was in high concentration (75).

The degradation of ergotamine tartrate in aqueous solutions was investigated at 100° in the 2.5–4.0 pH range (76). Based on this work, the pH of an injectable solution should be 3.6. The major decomposition products of phenylephrine hydrochloride were determined after storage over a wide pH range (77). Methyl and ethyl *p*-hydroxybenzoates were reported to be stable at pH 4 from 40 to 121°, but considerable hydrolysis occurred at pH 1 (78). The stability of prostaglandins E_1, E_2, and E_3 was studied in solvents useful for clinical trials as well as in solvents used for their isolation from biological systems (79). Tryptophan stability was studied in clear glass and amber vials at 5, 25, and 50°; this compound was found to be more stable in amber vials, decreasing only 4% in potency after 6 months at room temperature (80).

The effect of sodium hydrogen sulfite on the stability of epinephrine (adrenaline) solutions was studied (81). The hypothesis that orally administered lanatoside C was converted to digoxin in the gut partly by gastric acidity and partly by intestinal microflora was tested (82). Significant conversion of lanatoside C to digoxin took place at 37° *in vitro* below pH 3.

Ophthalmics—The kinetics of the hydroxide-ion-catalyzed hydrolysis and epimerization of pilocarpine in aqueous solution were investigated utilizing pH-stat titrimetry and NMR spectroscopy (83). Both hydrolysis and epimerization followed pseudo-first-order kinetics. The stability of *l*-epinephrine solution was strongly influenced by pH, with weakly acid solutions being stable for more than 1 year (84). Hydroxyquinoline sulfate, 0.01%, was found to be a satisfactory stabilizer. A mydriatic eye drop containing 0.5–1.0% cyclopentolate was stable for 1 year (85).

Injectable Products—Isoproterenol was inactivated in the presence of metallic ions and was very rapidly decomposed in Krebs solution, but the solution can be stabilized by the addition of edetic acid (86). A crystal growth study of chloramphenicol and prednisolone in injection suspensions led to the definition and the development of a reproducible method to control particle size and included number of particles to be counted, sample preparation, and method of dilution (87). The effects of pH, buffer components, magnesium and calcium salts, ethylenediaminetetraacetic acid, and a number of antioxidants on the stability of oxytetracycline solutions were studied (88). Formulas containing magnesium chloride, *p*-hydroxybenzoic acid, dimethylformamide, propylene glycol, and sodium sulfite at pH 7.5 were the most stable.

The stability of phenylbutazone sodium injectable solutions was improved in the presence of propylene glycol, sodium metabisulfite, and diethylenetriaminepentaacetic acid (89). The stability of urea solutions, which were heat sterilized to destroy pyrogenic

130	Stability of monofluorophosphate and fluoride ions in a dentifrice containing calcium carbonate

impurities, was studied; it was found that urea was partially destroyed (90). One percent solutions of morphine hydrochloride and 2% omnopone in polyethylene injection vials were stabilized by use of 6% glycerin and 0.05% disodium edetate (91). The effect of ^{60}Co irradiation on strychnine nitrate and neostigmine (proserine) injection solutions was investigated; frozen solutions were very stable and the decomposition products were less toxic than the starting compounds (92).

The stability of sulfathiazole sodium and sulfamethazine (sulfadimidine) sodium solutions for injection was investigated (93). Thermal degradation rates of reserpine were obtained by measuring the remaining intact drug and found to follow first-order kinetics at various concentrations (94). Further work by the same investigators included the effects of ionic strength, dielectric constant, inert gas, and stabilizers on reserpine stability (95). A proposed formula contains propylene glycol, phosphoric acid, sodium dihydrogen phosphate dihydrate, and sodium sulfite.

Other stability studies on injectable products concerned Ringer–lactate concentrate in ampuls (96), stability of glaucine hydrochloride (97), and securinine nitrate (98).

Semisolids—The concentration of prednisolone in an ointment was decreased by the addition of phenol and diphenhydramine and, especially, by adsorption to zinc oxide or potato starch (99). The degradation of 1% hydrocortisone in polyethylene glycol ointment USP was investigated at several temperatures (100). Decomposition at the C-17 side chain as well as ring A was followed by two different analytical procedures, and the side chain decomposed at the faster rate. Anthralin was found to deteriorate in zinc oxide paste, but this was remedied by the addition of salicylic acid which reacts with the surface zinc oxide to form zinc salicylate (101).

Several studies appeared on the stability of drugs in suppositories. The stability of chloral hydrate in various bases, including polyethylene glycol and estarine D (102), was studied. The effect of various factors on the oxidation of promethazine suppositories was investigated (103). Stabilized vitamin A in suppositories with massa estarinum C showed a similar but higher stability than vitamin A palmitate (104). The decomposition of hexahydroadiphenine hydrochloride in suppositories prepared with either aged or normal cocoa butter and aged Witespol H_{15} converted the drug to its base and *N*-oxide (105). The mechanism of the decomposition, independent of the type of suppository base, was discussed in detail.

Additional references on stability are given in Table II.

Kinetics—The effect of pH (2.75–9.16) and temperature (40 and 50°) on the hydrolysis of methyl-, propyl-, and *n*-butylparabens was studied at 70° in 0.1 *M* phosphate buffer solution at an ionic strength of 0.3; kinetic constants were calculated (131). The influence of cetrimonium bromide on base-catalyzed hydrolysis of *para*-substituted ethyl benzoates was investigated and led to the hypothesis that the observed rate modifications were dependent not only on the *para*-substituent and the surface pH of the micelle but also on the dielectric constant at the surface of the micelle (132).

The kinetics of the alkaline hydrolysis of benzocaine and some homologs in the presence of a nonionic surfactant were studied (133). It was concluded that these compounds were probably associated with the polyoxyethylene portion of the micelle and that the observed change in the rate of hydrolysis was attributed to both a decrease in the rate of hydrolysis and an increase of solubility within the micellar phase. Ethinyl estradiol did not undergo thermal decomposition at 110° over 72 hr, and decomposition depended on excipients such as lactose, starch, polyvinylpyrrolidone, talc, alcohols, and parabens (134). Thermal decomposition under the conditions established produced estrone, estradiol, and doisynolic acid.

The *in vitro* hydrolysis of oxazepam succinate half-ester by a stereospecific soluble esterase from different animal species was reported (135). The kinetics of hydrolysis of salicylamide were investigated under varying conditions of temperature, pH, and ionic strength (136). The hydrolytic degradation of the drug was found to be first order throughout the entire pH range. The conversion of a steroid oxime, 17α-acetoxy-6α-methyl-4-pregnen-3,20-dione 3-oxime, to the corresponding diketone in acidic media

was found to be first order at 37° (137). The effects of incorporating ester groupings at the oxime function or at C-17 position and modifications in the B ring were also investigated; only the length of the ester chain had a profound effect on the rate constant.

A simple experimental procedure was described to obtain estimates of the activation energy and preexponential factor for drug decomposition from a single experiment (138). A computer program was written involving numerical integration, and the method was illustrated using the decomposition of riboflavin in alkaline solution.

Other general kinetic studies are listed in Table III.

Antibiotics—The stability of procaine and potassium salts of penicillin G in oleaginous systems containing colloidal silica was studied (155). Results indicated that instability of penicillin G in these bases was due to the surface acidity of the silica in conjunction with the ester constituents of the oils. The formation of hydrolysis products of Bulgarian penicillin G was dependent on temperature, pH, and storage time; the development of the degradation products, penicillenic and penicilloic acids, was the cause of allergic reactions (156). The kinetic degradation of methicillin, penicillin V (phenoxymethyl penicillin), and their penicillenic acids was studied in an effort to explain their role in penicillin hypersensitivity phenomena (157).

Another paper also described the kinetics of penicillin stability because of the proposed role of the degradation products in causing allergic response (158). Papers also appeared describing the stability of semisynthetic penicillins and 6-aminopenicillanic acid in aqueous solution (159), as well as carbenicillin degradation in aqueous solutions (160). Three ampicillin studies were concerned with the effect of pH on the stability of ampicillin sodium solutions (161), the stability of ampicillin in aqueous suspension (162), and the stability of betacillin in aqueous solution (163).

Various factors affecting the stability of tetracycline hydrochloride in ointments were studied; included were the effects of preservatives, aseptic processing, light, temperature, and the type of base (hydrophilic or lipophilic) (164). A number of tetracyclines was studied by differential thermal analysis and differential gravimetric analysis (165). A review article on the chemical stability of tetracyclines in aqueous solution listed references on the formation of epimers, anhydro compounds, isomers, and various oxidation products (166). The addition of solubilizers, urea, thiourea, polysorbate 20, and polyethylene glycol 6000 to tetracycline solutions significantly reduced epimerization of the drug (167); it was suggested that occasional kidney damage may be caused by the epimerization.

Stability kinetic studies of oxytetracycline hydrochloride in solutions were performed (168). The effect of different pH's and buffers on the solubility and stability was determined. Also the effect of magnesium, calcium, edetate (EDTA), pyridine derivatives, aromatic oxyacids, water-soluble antioxidants, and inert gases on the stability of the drug in solution was studied. Two stable injection formulations were presented. Another study found that the addition of glycerin, propylene glycol, polyethylene glycol 400, dimethyl sulfoxide, and water was detrimental to oxytetracycline in ointments (169). Rolitetracycline was found to hydrolyze rapidly in dilute aqueous solution (170), and the base was less stable than the nitrate salt. Other workers reported that rolitetracycline was hydrolyzed to tetracycline and 4-epitetracycline in aqueous solutions at 25° (171); both the base and salts were >50% hydrolyzed in 3 hr and the degradation was probably first order. The dehydration kinetics of epitetracycline in solution to form epianhydrotetracycline were investigated (172), and the reaction was found to be first order with respect to epitetracycline and hydronium-ion concentrations.

183	Stability of parenteral solutions of cefazolin sodium

Two papers appeared on the intravenous solution stability of amphotericin B stored in 5% dextrose–water solution (173, 174). No appreciable loss in activity was found with the antibiotic alone or in the presence of hydrocortisone and heparin, even when exposed to light; however, sodium and chloride ions were very deleterious to stability of amphotericin, reducing the potency 25% in 4 hr.

Other references relating to antibiotic stability are listed in Table IV.

Vitamins—A number of factors improved the stability of multivitamin oral liquid preparations (184). These factors included the use of glass-distilled water, 0.01% disodium edetate, 0.05% sodium glutamate, and 0.01% cysteine hydrochloride; purification of sucrose with activated carbon; and protection from light and oxygen. Two other articles discussed general vitamin stability in pharmaceutical preparations (185, 186).

The effect of two nonionic surfactants on the aerobic oxidation of ascorbic acid and thermodynamic properties was obtained for vitamin C solutions containing 1% surfactant (187). On storage at 37° and 100% relative humidity, the stability of ascorbate salts was Ca > Mg > Na > K, although they were much less stable than the free acid and the stability was even lower in talc and silica formulations (188). The effect of pH on the rate of coloration of 1% ascorbic acid in 60% sorbitol solution at 37 and 47° was studied, and kinetic constants were calculated (189).

The compatibility of vitamin B_1 preparations in combination with other drugs was studied. Vitamin C did not affect various B_1 derivatives, but those containing B_{12} were decomposed (190). Tablet stability of vitamin U was determined (191, 192), and the effect of fillers on the stability was reported (193). Excipients such as mannitol, lactose, and dicalcium phosphate imparted high stability to vitamin U, but aluminum hydroxide and magnesium hydroxycarbonate had adverse effects on the stability of tablets in storage.

Additional references on vitamin stability are listed in Table V.

PHARMACEUTICAL TECHNOLOGY

New drug forms resulting from present technological developments, with emphasis on microencapsulation, were reviewed (205). The clinical and design aspects of medicines for oral administration were discussed (206–208). Preparations of gastric antacids were checked for onset and duration of buffer effect against artificial gastric fluid by an *in vitro* test method (209).

Sterile Products—A new sterile products laboratory incorporating the latest developments in the field was described (210), and the anticipated revisions in current good manufacturing practice regulations were reviewed (211).

Several papers concerning particulate contaminant problems were published. An assay procedure utilizing the scanning electron microscope for counting asbestos and other inorganic fibers in fluids was described, along with a method for testing the membrane filter retention of asbestos fibers (212). Examination of 22 sterile solid products for particulate matter using the standard membrane filtration technique indicated that this class of products contained an appreciable number of particles, of which more than 95% are 5–50 μm in size; small volume injections in a similar manner contained approximately half the total number of particles on a per vial basis (213).

Polyvinyl chloride and glass large volume parenteral containers were examined to determine the effects of agitation, storage, and additive handling on the generation of subvisual particulate matter, and it was found that shaking and temperature generated small particles in the polyvinyl chloride containers (214). Particle contaminants from saline and dextrose intravenous solutions were sized and counted using the Prototron instrument (215). Various particle contaminants were identified and these included salt crystals, starch grains, glass fibers, mica flakes, and metal shavings. The general problem of asbestos and other fibers in parenteral solutions was reviewed (216–218), and the particulate contamination of dextran for intravenous use was studied (219).

The incidence and potential for microbial contamination of glass bottle and plastic bag systems used for intravenous fluid administration were estimated from results obtained in a study simulating both hospital and centralized admixture program use (220). Two other articles discussed the microbial contamination of packaged fluids after sterilization (221, 222).

The methods of particle counting in infusion fluids were discussed (223). Another article compared the Coulter counter, the HIAC automatic counter, and a microscopic membrane method in their ability to measure different types and sizes of contamination (224). The use of the Silting index was suggested as an alternative to particle counting (225); this method

is based upon the tendency of particles to clog a filter, and the flow rate decrease is proportional to the particulate contamination in the test fluid.

Preparative methods for purifying water were described including vapor pressure distillation (226), reverse osmosis (227), ozonation (228), and filtration (229). Removal of pyrogen in physiological saline solution was studied by filtration through Chamberland 25C, Seitz Sheet EKS-I, and activated-carbon Chamberland (230).

A report pointed out the possibility of the precipitation of poorly water-soluble drugs contained in a nonaqueous vehicle when the solution was mixed with human plasma (231). The compatibility of certain vitamins combined with other parenteral solutions was studied (232).

Other papers concerning sterile products are listed in Table VI.

Ophthalmics—The action and uses of a number of topical ophthalmic drugs were discussed (249). The development of radiosterilized tetracycline ointment was reported, and the cost savings feature of cobalt 60 γ-ray sterilization in the final package made it an attractive alternative to conventional aseptic manufacturing and packaging (250). It was found that the amount and rate of drug loss through drainage for a single drop of topically applied ophthalmic solution increased with increasing volume of instilled solution (251). However, the concentration of drug in the precorneal tear film immediately after installation of drug was higher with larger instilled volumes. Ocular absorption of drugs using various vehicle modifications was reported (252, 253). The formulation of a semisolid oleaginous ointment base employing a polyethylene[1], fused micronized silica, and sodium stearate was studied (254, 255).

Other references on ophthalmics are listed in Table VII.

Sterility and Sterilization—An approach to the establishment of parenteral solution sterilization cycles was offered (261). A comparative study of seven media and two systems for sterility testing was presented (262). The use of ethylene oxide as a sterilant was the topic of many reports. Articles sterilized with ethylene oxide released the gas at rates depending on materials and methods of manufacture (263). A mixture of ethylene oxide and acetic acid (1:1) was as effective as a mixture of ethylene oxide and carbon dioxide but was more rapidly desorbed. Extracts of polypropylene syringes that had been sterilized with ethylene oxide did not inhibit growth of *Staph. aureus*, were not toxic to mice after intravenous injection, and did not cause hemolysis upon addition to erythrocyte suspensions (264).

Naturally contaminated samples of sodium alginate treated with ethylene oxide showed a significant drop in viable microbe content without affecting viscosity (265). Ethylene oxide sterilization procedures were discussed as potential generators of chemical toxicities by way of an alkylating agent reaction mechanism (266). Detection procedures for ethylene oxide, ethylene glycol, and ethylene chlorohydrin residues in sterilized materials were reviewed, and 65 references were given. The role of packaging on ethylene oxide permeability was reported. Both 100% ethylene oxide and a dichlorodifluoromethane–ethylene oxide mixture were studied in conjunction with the following materials: 4-mil polyethylene, polyethylene/tyvek, paper, and paper/polyethylene terephthalate (Mylar) (267). Both the packaging and the sterilization cycle played a role in effective sterilization using ethylene oxide. It was found that hard and soft polyvinyl chloride as well as cellophane were sometimes more gas permeable for the mixture of ethylene oxide and methyl formate than pure ethylene oxide (268).

A discussion on the principal factors affecting sterilization, *i.e.*, gas concentration, temperature, humidity, and time, was presented and a detailed sterilization cycle was given (269). Various polyvinyl chloride and rubber materials were sterilized with ethylene oxide, and the residual amount of gas was determined as well as the biological compatibility (270). It was found that the desorption rate was markedly faster at 50° than at ambient temperature. The treatment of naturally contaminated materials was inves-

303	Sterility of a sterile powder-filling line

tigated (271), and the inactivation kinetics of ethylene oxide were discussed with respect to concentration, temperature, relative humidity, and other effects (272).

A number of papers discussed radiation sterilization of various plastics. Samples of plasticized polyvinyl chloride were irradiated with 2.5-Mrad doses of γ-radiation from ^{60}Co and 2.8–3.4-Mrad doses of β-radiation from a linear electron accelerator (273). Electron beam sterilization could be used for this plastic if it was not to be in direct contact with blood. Another paper pointed out that γ-irradiation prior to sterilization with ethylene oxide enhanced 2-chloroethanol formation in a surgical, hospital grade, polyvinyl chloride tubing (274). Another study indicated that polymethacrylate, cellulose derivatives, and polytetrafluoroethylene products were unsuitable for radiation sterilization but that polyvinyl chloride, polyethylene, polypropylene, polyethylene terephthalate, polyamides, polystyrene, silicone rubber, and rubber materials were sterilized satisfactorily (275).

Six kinds of polystyrene were irradiated with 4–5 Mrad of γ-radiation from ^{60}Co, and a study of their chemical and physical–chemical properties showed no harmful effect from this treatment (276). The practical application of radiosterilization of an ophthalmic and nasal ointment of neostigmine bromide, 1%, and dexpanthenol, 5%, with ^{60}Co as the radiation source was studied (277). Two levels, 2.5 and 4.5 Mrad, were used; sterility was achieved with the higher dose. The chemical stability of these drugs was satisfactory, but the tubes exhibited gas formation and an increase in volume and leakage. Two papers reported the sterilization of dry ampuls containing chlordiazepoxide hydrochloride (278, 279).

A series of selected colorants composed of eight FD&C dyes, seven lakes, and four D&C dyes was subjected to 2.5 Mrad of γ-irradiation from a cobalt 60 source over approximately 10 hr (280); no changes were found in these materials and they were all shown to be sterile. Another study reported that colorants were not affected by thermal or radiation sterilization, but decomposition occurred when they were tested in an experimental tablet mass (281). Other papers reported on the use of high frequency sterilization (282) and formaldehyde gas as a sterilant (283). Some drugs were decomposed by the high frequency method.

Three papers discussed experiences using biological indicators (284–286). The use of isopropyl myristate as a solvent in the sterility testing of oleaginous-based ointments was investigated (287, 288).

Other references pertaining to sterility and sterilization are listed in Table VIII.

Tablets and Capsules—Content uniformity criteria, including tests currently in the USP and NF, were studied using computer simulation (304). The results were compared with selected tests by variables for reliability, flexibility, and simplicity. Another paper reviewed the quality control aspects of compressed tablets (305). The formulation of effervescent aspirin tablets was investigated (306). Various methods, *i.e.*, sugar coating and press coating, were studied along with other factors to prepare a tablet containing pepsin and pancreatic enzymes (307).

Tablets containing pancreatin and barium sulfate were subjected to the USP XVIII disintegration test with and without plastic disks (308). The same tablets were given to two groups of people, one with normal stomachs and the other with reduced stomachs; the fate of the tablets in the digestive tract was radiographically documented. General background information and some advantages of formulation into soft gelatin capsules were published (309). A review on formulation of products in hard gelatin capsules discussed the rate of dissolution, release of the active ingredient as a function of particle size, porosity of the active ingredient, and addition of surface-active agents, diluents, and lubricants (310).

Additional general references on tablets are: *in vitro–in vivo* correlation and aging studies of commercial hydrochlorothiazide tablets (311), design of tests for content uniformity (312), degree of disintegration and solubility of tablets as characteristics of their high quality (313), and review of apparatus and methods for improving tablet formulations (314).

Comminution, Mixing, Granulating, and Drying—The milling of pharmaceutical solids was reviewed (315). Another report discussed the problem of obtaining fine particle sizes and the measurement of tensile strength, hardness, and breaking strength of particles, as well as the types of mills used (316). Various physical factors affecting blending of solids were presented together with methods of measuring mixedness (317). The mixedness of 10% ^{113m}In–phenobarbital triturations using three different fillers was evaluated (318). A mixture of fine and crystalline lactose was better than crystalline lactose alone or starch (corn) mixed with fine lactose.

The homogeneity of multicomponent powder mixtures was studied, and a numerical value for mix-

edness was mathematically derived (319). A twin-shell blender was used to investigate the blending procedures used in mixing aspirin–lactose (1:99) blends (320). Powders having good flow were less apt to show unmixing tendencies, and better blends were obtained when the amount of solvent was limited since this prevented excessive drug migration. A vertical cone mixer was used to mix a single active component, fenfluramine hydrochloride, with a number of diluents used for production-scale tablet preparations (321). The mixing operation was followed by the analysis of the drug in a number of samples equivalent to the final tablet size.

Reserpine was spray coated onto calcium sulfate granules of different porosities, and the relation between the macroporous nature of the granules and their reserpine content was investigated (322). The effect of fines on the physical properties of a starch–lactose granulation and the corresponding tablets was reported (323). An apparatus was made to measure granulating pressure so that it might be related to the amount of binder used as well as to its surface tension (324). Mathematical calculations were made relating power consumption during granulation of viscoplastic materials in a blade-type mixer (325). Mathematical formulations were also derived for calculating the dynamic coefficient of friction for materials used in the wet granulation process in a blade-type granulator, and the accuracy was checked by experimental runs with various drugs (326).

It was reported that compression of a barbital sodium granulate was greatly affected by moisture content (327). Various solvents were evaluated for use in granulating fusidate sodium (328). The relationship between moisture content and the quality of finished tablets of various drugs was investigated (329), and the optimum conditions of drying urodan granules in a fluid bed dryer were studied (330).

Other references on comminution, mixing, granulating, and drying are listed in Table IX.

Powder Characteristics—The flow of powders and granular solids in an excentric tablet press with the punches removed was measured (337), and the results varied widely compared with those obtained with a flowmeter. Six kinds of granules from four powdered materials, lactose, calcium carbonate, barium sulfate, and zinc oxide, were prepared by extrusion and crushing procedures (338). Physical properties were measured and related to flow rate. The influence of particle shape, hygroscopicity, electrostatic charge, and particle size on powder flow was reviewed (339). A statistical study of tablet uniformity in which the drug medazepam was mixed with three fillers at two particle sizes and two dosage levels was reported (340).

The cohesive force effect of magnesium stearate addition (0.2–1.0%) to salicylic acid was investigated (341). An equation was developed to estimate accurately the flow rates of powders from circular orifices in which flow is dependent on orifice opening, specific gravity of the powder, and a fluidity index obtained by the variable rotating cylinder method (342). Magnesium carbonate, encapsulated with various polymers, showed variations in resultant physical properties such as angle of repose and flow and could be tableted (343). The effect of the choice of excipient on the mixture quality of the unmilled drug, cyclopenthiazide, was investigated, and segregation of the drug mixture could be avoided by using wheat or maize starch in place of lactose (344). The effects of certain process variables were determined for the spheronization process (345).

Various methods of measuring the tensile strength of compacted powders were described including transverse compression using squares and disks as well as the direct tensile stressing of lightly pressed powder (346). The failure properties of lactose, calcium carbonate, and ultramarine were determined, and it was found that narrow size fractions behaved as simple powders (347). The packing properties of moist bulk solids were studied using glass powder, potassium chloride, and calcium phosphate (348). Powder bed densities were found to be dependent on the concentration of calcium stearate and the cumulative number of revolutions in a V-type blender (349).

Compression—The compressibility of sulfanilamide granules and starch was studied by means of a rotary tablet machine fitted with strain gauges (350). The effect of various factors including the method of granulation, residual moisture content, and binder concentration was reported. A follow-up study determined the effect of nonionic surfactants on the compressibility of sulfanilamide granules (351). The strength of compressed tablets was markedly improved in the presence of 1% silica (Aerosil), whereas certain cellulosic materials improved disintegration times (352). Photomicrographs of potential tablet disintegrants in polarized light before and after water treatment revealed the relationship between swelling factors and tablet disintegration. A variety of dextrose (Celutab) was found to be suitable for the preparation of tablets containing aspirin, phenacetin, and caffeine citrate by direct compression (353). Physical changes due to high frequency and tray drying of tablet cores containing a strongly moisture binding antibiotic, which had different coatings in selected solvents, were studied (354). Drying was shown to result in improved stability of aspirin-containing tablets.

No constant relationship was found between tablet compressive force and the tablets *in vivo* and *in vitro* properties (355). A timed-release salicylamide tablet

Table X—Additional References on Compression

was made using two types of sodium carboxymethylcellulose; compressive force affected release only slightly with one type of the cellulose polymer but was slowed with the other type (356). The dissolution rate and surface area of phenacetin tablets made with wheat starch and talc were investigated (357).

The relationship between compression stress and displacement of the upper punch was studied to clarify the viscous behavior of powder when a compressed sample was recompressed (358). There appeared to be a hysteresis loop in the stress–displacement diagram; from the loop area, loss energy, depending on the viscosity of the sample, was calculated. The relationships among axial pressure, radial die wall pressure, and density changes in beds of powder undergoing compression were studied using a single-punch instrumented tablet machine (359); data were developed for aspirin, sodium chloride, acetaminophen (paracetamol), and sucrose. Tablets formed from dendritic sodium chloride crystals, which had a larger shape index than cubic crystals of the same size fraction, were stronger than tablets formed from cubic crystals (360).

A new method for determining the tensile strength of tablets was proposed utilizing two fulcrums and a knife edge (361). The results agreed well with tensile strength values obtained from diametral compression. A report on the use of an industrial scale compactor compared the results of various granulation procedures using aspirin, potassium chloride, and a sulfonamide (362). The criteria for using different materials for the dies of rotary tablet machines were discussed, and recommendations for the types of steels for press-molding machines were given (363).

Other references on compression are listed in Table X.

Effects of Excipients—A compressible starch (STA-Rx 1500) was compared as a compression vehicle with potato, maize, and rice starches, Dry Flo starch, cellulose (Solka-Floc), microcrystalline cellulose (Avicel pH 101), and anhydrous lactose USP in aspirin tablets (376). The resulting tablet properties were measured; the compressible starch (STA-Rx 1500) was found to be a good vehicle, but magnesium stearate adversely affected tablet properties. The use of potato starch as a disintegrant was reviewed, and water contents were given after drying and after storage at various humidities (377). High concentrations of starch were used in hard gelatin capsules to improve the release of phenobarbital (phenobarbitone) (378).

Two special directly compressible blends of microcrystalline cellulose with starch and calcium sulfate were investigated (379). It was shown that hydroxypropyl cellulose could be a useful binder in direct compression tablet formulations when properly combined with potato starch and lactose (380). It was demonstrated that tensile strength of lactose tablets decreased as the fatty acid composition of tablets increased (381). The presence of glucose in industrial lactose at various stages of purification and the effect of glucose on the quality of lactose for pharmaceutical use were determined (382). The pore structure of tablets made from wet massed granules and from crystalline granules was compared (383). Tablets made from crystalline granules showed a monosized pore structure regardless of granule size or compression pressure. Direct compression formulations containing microcrystalline lactose, dicalcium phosphate, microcrystalline cellulose, and starch derivatives were characterized using an instrumented rotary tablet machine (384).

L-Leucine and L-isoleucine were investigated as tablet lubricants and compared to other widely available lubricants (385). The addition of 5% L-leucine and 1–5% L-isoleucine gave almost the same effect as 1% magnesium stearate. The use of magnesium lauryl sulfate in tableting was evaluated using ejection force and compressibility measurements (386). A calcium carbonate–starch paste granulation was suggested as a diluent for tablets (387).

The effect of the binders, cellulose acetate phthalate, ethylcellulose, and shellac on the release of thioridazine from tablets was investigated (388). The effect of disintegrants and lubricants on the antimicrobial activity of tetracycline hydrochloride and chloramphenicol after tableting was determined (389, 390). These components caused activity losses of these antibiotics to varying degrees.

A method for the rapid evaluation of the effect of excipients on color fading was suggested; it involved the use of a fadeometer to accelerate light-induced fading followed by spectrophotometric evaluation (391). A photographic technique was developed to measure the degree of mottling of calcium phosphate tablets colored with FD&C Blue No. 1 (392). Optimization of the photographic process was described, and mottling values calculated by this method correlated well with the visual appearance of the tablets. Inclusion of wheat and potato starch (20%) in granule formulations reduced mottling and increased elasticity, suggesting that the elasticity of the granules enables them to retain their original shape after deformation under pressure (393).

Tablet Coating—Acrylate-based products were suitable for the manufacture of film tablets and other coated dosage forms (401). The use of polyvinyl alcohol in preparing tablet coatings with and without sugar was described (402). Drug coating materials soluble in the small intestine were prepared from succinate monoesters or succinate maleate monoesters of cellulose ethers (403). Various quantities of cellulose acetate phthalate were applied to barium sulfate tablets, and the homogeneity of the films was assessed by a statistical study of thickness (404). The results showed a linear relation at constant pH between the resistance time and the quantity of the film applied per tablet.

Cellulose acetate phthalate was used to coat soft gelatin capsules repeatedly by dipping, and the resultant product was resistant to gastric fluid for 2 hr and to intestinal fluid for 20 min (405). A dipping experiment was also successful for enteric coating tablets (406). A fluidized-bed apparatus was used to apply various aqueous coatings such as cellulose acetate in ammonia solution, methylcellulose, and hydroxypropyl methylcellulose (407). The effects of solids loading on moisture permeability of methylcellulose–ethylcellulose films with two mineral talcs and titanium oxide were investigated (408). Water vapor transmission reduction was directly proportional to the amount of either talc added but reached a minimum at an intermediate solids loading value for titanium dioxide.

Suspensions—The techniques of suspension formulation and stabilization were reviewed; the general topics discussed were particle size and shape, surface-active agents, deflocculating agents, and the principles of rheology (417). The flocculation, dispersion, and caking in sulfonamide suspensions by a cationic agent were studied (418). A monolayer adsorption was reported for sulfisomidine, whereas multilayer adsorption was found for sulfadiazine, sulfaphenazole, and sulfameter (sulfamonomethoxine). The effects of two electrolytes, aluminum chloride and monobasic potassium phosphate, as well as two cationic surfactants, on the stability of a monodisperse system of calcium phosphate were investigated (419). The proper flocculating agent and concentration needed were established.

The flocculating properties of xanthan gum on suspensions of zinc oxide, sulfaguanidine, bismuth subcarbonate, and bismuth subnitrate were investigated under various conditions and in the presence of 1% potassium chloride, 1% calcium chloride, 25% ethanol, and 25% ethanol–1% potassium chloride (420). The studies indicated that xanthan gum acts *via* polymer bridging as an effective flocculating agent for some suspensions and that flocculation occurs at polymer concentrations well below those needed to produce a viscous suspending medium.

Additional articles on suspensions are listed in Table XIII.

Emulsions—A review and discussion with 13 references on the experimental determination of the hydrophilic–lipophilic balance (HLB) value for a system and the selection of an emulsifier were presented (430). Another review with 40 references was given on the HLB, the phase inversion temperature, and the cohesive energy ratio systems for emulsifier selection (431). The problems posed by emulsion manufacture, especially the technical variables involved, were reviewed (432). A technique was described in which the addition of a thickener to an emulsion at the critical HLB allowed the preparation of stable emulsions

(433). Linear HLB was defined, and its use in the preparation of emulsions and their evaluation were explained (434).

HLB values were determined by the Huebner method for 24 surface-active agents involving the following groups of compounds: oxyethylenated wool wax alcohols, fractions of liquid lanolin, oxyethylenated castor oil, oxyethylenated C_{10-18} aliphatic alcohols, and oxyethylenated alcohols of sperm whale oil (435). Phase inversion temperatures were determined for mixtures of several systems including cyclohexane–sorbitol–mono- and diglycerides of fatty acids (Arlacel 186) (436). Various methods used to determine the type and stability of emulsions were reviewed including phase coloring, the drop method, the dilution method, the conductivity method, and microscopic examination (437).

The influence of different thickeners on the characteristics of petrolatum emulsions at a critical HLB value was investigated; stable creams and ointments were prepared with stearyl alcohol or with carbomer 961 as adjuvants (438). The properties of emulsions containing liquid paraffin, glycerol, water, and blends of polysorbate 60 and sorbitan monooleate were studied over a temperature range of 25–80° (439). The formation of clear solutions at 70° depended on the polysorbate–sorbitan ratio and oil content, and the micelle diameter (13–45 nm) increased with increasing oil content and decreasing surfactant–glycerol ratio. A similar study was carried out on microemulsions containing sodium oleate, amyl alcohol, water, and liquid paraffin (440). The relative viscosity relationships for some of the microemulsions (440) were determined (441).

Polysorbate 20 and polysorbate 81 were compared as emulsifiers for carbon tetrachloride and C_5, C_6, C_7, C_{10}, and C_{16} saturated alkyl hydrocarbons (442). Microscopic examination and particle-size measurements were made, and polysorbate 20 was found to be a better emulsifier than polysorbate 81 on oil-in-water emulsions as the carbon number of the hydrocarbons in the dispersed phase became smaller. Nonaqueous emulsions of glycerin and mineral oil were formed using anionic, cationic, and nonionic surfactants (443). Although stable emulsions were prepared by employing surfactants from all three groups, more stable emulsions were obtained when ionic surfactants were used.

A method of measurement of the spontaneity of self-emulsifiable oils was developed (444). The system involved light scattering by dispersed oil droplets and collection of the scattered light by fiber optics onto an array of silicon photodiodes. A very stable emulsion of benzyl benzoate was prepared using triethanolamine oleic acid (445). The physical properties and the capacity of gas transport of fluorocarbon emulsions were reported (446). The manufacture and application of essential oil emulsions in microbiology were discussed (447). Thyme and verbena essential oils were used for the study.

Additional references on emulsions appear in Table XIV.

Semisolids—The quality and stability of mass-produced ointments were assessed (463), and the quality of rectal ointment bases was evaluated (464). Paraffin oil gels made with 5% polyethylene as a gel-forming agent were studied (465). The gels have low flow points and a low degree of thixotrophy, and their viscosities are only slightly influenced by temperature. The effect of adding up to 20% of six different sorbitan emulsifiers on the rheological properties of a microcrystalline paraffin and a white wax–cetyl stearyl alcohol mixture was determined (466). There were small differences in the rates of flow, deformations under load, and restoring tendency between the two sample ointment bases and between materials based on solid *versus* liquid emulsifiers.

Approximate solubilities in common ointment bases were given for salicylic acid, chloramphenicol, prednisolone and its hydrate, thiosinamine, and neomycin sulfate (467). Solubilities in components such as yellow petrolatum, emulsifying alcohols, paraffin waxes, and polyethylene glycols 600 and 1500 were also determined. Bubbles formed in ointments during manufacturing and their enlargement during storage were investigated (468). The influence of the concentration of polyethylene oxide of different molecular weights on the rheological index (degree of penetration) was studied (469). The use of propylene glycol in oral preparations, as a dermatological vehicle, and as a parenteral vehicle was reviewed (470). Its physical and chemical properties were given and its toxicology was discussed.

Ointments containing drugs in suspension were studied for dispersity by a photometric method and a microscopic method (471). The former procedure permitted determination of changes in dispersion caused by comminution, generally gave better precision, was simple and rapid, and required less time and effort. Separation of fluid from ointments was investigated by means of a test used for lubricating greases involving cone mesh filtration (472). The experimental data followed a mathematical relationship and correlated well with bleeding that occurred in the container during room temperature storage. The bleeding of hydrocarbon ointment bases was af-

fected by both the dispersing methods and the concentration of polyethylene (473).

The melting characteristics of ointments and creams were investigated by differential thermal analysis, and an interpretation of their structure was made (474). Another paper using similar methodology gave a further explanation of the melting behavior of semisolids (475). Two papers were concerned with the absorption of materials by gel bases. The consistency of petrolatum and polyethylene glycol gels was studied after addition of peanut oil and camphor (476). The amount of water uptake in mineral oil gels after addition of varying amounts of nonionic emulsifier was determined (477). Radiation had a relatively weak effect on yellow petrolatum, with viscosity being significantly reduced and penetrability and exudation being increased (478). With synthetic petrolatum, penetrability decreased and viscosity increased; polyethylene gels were more strongly affected than the petrolatums. The crystallinity of the solid phases in artificial petrolatum containing either paraffin or polyethylene was changed by extraordinary cooling rates (479). In every case where slow cooling was used, the gels showed microcrystalline structure of the solid phase and good ointment properties; these data were obtained by using a polarization microscope.

A general method using the solubility parameters of polymers was helpful for predicting the relative *in vitro* diffusion rate of an agent dissolved in a carbomer-based gel (480). A review on the selection of semisolid formulations, especially of corticosteroid compounds, discussed how to achieve maximum therapeutic effectiveness while maintaining an elegant and stable product (481). Models used in the description of diffusion processes were applied to drug release from semisolids (482). Two models, an exponential model for finite systems and a nonexponential model for semifinite and infinite systems, were evaluated for their suitability in describing literature data for the release of substances from semisolids.

The dynamics of drug release from ointment bases using the system of 2% salicylic acid, petrolatum, sorbitan monooleate, and 10% dimethyl sulfoxide were reported (483). The releases of a wide variety of common antibiotics from 26 ointment bases were studied and bases were recommended for each product (484). The release of benzocaine from oleaginous, absorption, emulsion, and water-soluble ointment bases *via* dialysis through a cellulose membrane to an aqueous sink was studied at 37.5° (485). The release of benzocaine from commercial and experimental preparations was compared. The diffusion of fluorescein from ointment bases containing methylcellulose was reported (486). Topical availability of hydrocortisone from different ointment bases was determined by the stripping method and reduction of erythema; brand products as well as experimental formulations were evaluated (487). In general, polyethylene bases, hydrogels, and petrolatum bases are biopharmaceutically poor vehicles compared to either oil-in-water or water-in-oil emulsions.

The effects of rheological properties of an ointment base and size of salicylic acid particles on its release from the ointment and absorption by skin were determined (488). Both *in vitro* and *in vivo* tests showed that the release rate and absorption of salicylic acid were mostly affected by the particle size and to a lesser extent by rheological properties. The release of papain from various ointments was increased by the addition of 5% sodium lauryl sulfate (489). The addition of 0.1% chlorocresol and 0.1% sodium metabisulfite suppressed oxidation.

Other references on semisolids are listed in Table XV.

Suppositories—Factors that affect absorption of rectally administered drugs and the considerations to be taken in suppository formulation were reviewed (501). Formulation and pharmacokinetic studies of suppositories, with particular emphasis on factors influencing drug absorption through the anorectal tract, physical–chemical properties, use of surfactants, and active ingredient concentration, were reviewed (502). Cumidin red was used to test the release rate of suppositories made with polyethylene glycols with stearin base and emulsifiers (503). The consistency of lipophilic suppository bases and drug-containing suppositories was evaluated by determination of the cone flow point, the breaking strength, and the disintegration time (504). Zinc oxide labeled with ^{113m}In was used as a tracer to determine the degree of mixing with cocoa butter (505). The degree of drug release from 10 suppository bases was determined using an apparatus consisting of a semipermeable membrane and peristaltic pump to provide circulation of dialyzing fluid (506).

The aminophylline content of commercial and of laboratory prepared suppositories, all kept at 18–27°, was analyzed periodically; all commercial products were chemically and physically unstable (507). The best results were observed in a laboratory composition containing hydroxylamine hydrochloride as a stabilizer in anhydrous suppositories. The preparation of teturam suppositories with fatty bases was reported (508). The oral absorption and rectal absorption of cystamine hydrochloride were compared, and the rate of drug release from various suppository bases was also determined (509, 510). Work on *in vitro* and *in vivo* drug availability from digitalis sup-

530	Medicated dry foam for local therapy in infected burns

positories was reported (511, 512). The consistency of suppository bases containing polysorbate 20 and polysorbate 61 was evaluated (513).

Aerosols—A wide ranging review of pharmaceutical and cosmetic aerosols was published (514). An evaluation of inhalation aerosols using a simulated lung apparatus was reported, and the compatibility of ^{14}C-labeled phenylephrine hydrochloride in polyethylene nasal spray containers was presented (515). Pharmaceutical quality control of aerosol foams was discussed (516, 517). A review of aerosol medicinal foams with respect to structure, properties, and classification was reported (518); quick-breaking aerosol foams and their relation to cosmetics also were reviewed (519). Major factors affecting the time for a foam to break were: water–alcohol ratio, total alcohol content, type and amount of surfactant, and type of propellant. The development of pharmaceutical and cosmetic aerosol emulsions was explained, and the type of material obtained, foam or droplets, was dependent on whether the propellant was in the internal or external phase of the emulsion (520). Various factors, such as powder concentration, surface activity, propellant concentration, and orifice diameter, influencing the diameter of solid particles of an aerosol were investigated and a mathematical equation was developed (521).

The development and evaluation of an inhalation aerosol of nitroglycerin were reported (522). An *in vivo* method for determining effectiveness of spray-on bandages containing anti-infectives was developed (523). Standardized, contaminated wounds in guinea pigs served as the testing system, and the inflammatory response of the wounds was evaluated using several indexes including skin temperature, degree of induration, and presence of pus. A multistage liquid impinger was used to determine the particle-size distribution of aerosols generated by six pressurized inhalers containing isoproterenol (isoprenaline) (524). Inhalers of the suspension type had a higher percentage of size ranges likely to penetrate to the lower airways than the solution type.

Additional references on aerosols are listed in Table XVI.

Timed-Release Preparations—Various aspects of pharmaceutical preparations designed to give a prolonged effect were reviewed (531). The report included a discussion of depot preparations, methods of drug molding, biopharmaceutical and pharmacokinetic aspects of sustained release, and release by zero- and first-order kinetics from insoluble matrix compounds. Formulation of oral, long-acting, solid dosage forms was the topic of another article (532).

A number of papers discussed various mechanisms used to obtain controlled-drug release. Further work was reported on preparations obtained by flocculating an acrylic latex with a solution of an amine drug (533). The interaction between methapyrilene and latexes was studied, and it was found that a compressed mixture of the drug and polymer provided sustained release in GI fluids. The influence of shape factors on the kinetics of drug release from matrix tablets was reported in two papers (534, 535). The rate of drug release varied with tablet shape, but rate constants that were independent of shape were included in the expression. Therefore, it was possible to predict drug release from tablets having identical compositions but varying widely in shape and size. The release of salicylic acid and ephedrine was measured *in vitro* after compounding into tablets containing stearyl alcohol, and it was found that release profiles could be described by a nonlinear expression for both cylindrical and biconvex tablets.

Tablets containing quinidine compressed in a polyvinyl chloride matrix were exposed to γ-radiation, and the drug release was then determined (536). The rate of drug release was proportional to the radiation dose and was correlated to the degree of cross-linking of the matrix. Timed release of acetaminophen was observed from spherical polystyrene beads (537). Factors influencing the rate of release of ethynodiol diacetate, a synthetic progestin, from solid silicone polymer vaginal devices were evaluated, and the cumulative amount of drug released was proportional to the square root of time (538). The release of methapyrilene, pentobarbital, and salicylic acid dispersed in films composed of different ratios of hydroxypropyl cellulose and polyvinyl acetate was investigated (539). The results indicated that drug release followed a diffusion-controlled matrix model, where the quantity released per unit area was proportional to the square root of time. Release rates were also proportional to drug concentration but independent of film thickness.

Two articles reported on the use of microencapsulation for sustained or controlled release of a drug (540, 541). The method whereby an injectable product could be prolonged was reviewed (542). Two depot-type vitamin B_{12} preparations were studied *in vivo* over 2 years (543). One preparation gave satisfactory levels when injected once every 8 weeks, but the other preparation required more frequent dosing.

Dissolution studies were made on seven samples of propantheline tablets from six manufacturers (544). Considerable variation occurred between individual tablets of two samples, and one sample exhibited great delay (over 2 hr) in disintegration as compared to 4–34 min for the other samples. The effect of three factors—surfactant type, surfactant concentration, and time—on the release of sulfosalicylic acid from polyvinyl chloride matrixes was studied (545). Drug

557	Delayed release of niacin (nicotinic acid) in compressed tablets
558	Sustained release for fertility control

release was proportional to the square root of time and could be controlled by the use of surfactants. Sustained-release pellets and capsules prepared with polyglycerol esters indicated that these compounds had significant dissolution-retarding properties (546).

A nonirritating coated tablet of potassium chloride containing a dissolution-retarding additive from aqueous solution was developed (547). Retardant materials evaluated were carnauba wax, agar, alginic acid, stearic acid, cellulose acetate phthalate, hydroxypropyl methylcellulose, polyethylene glycol 6000, and cetostearyl alcohol. The sintering of matrix tablets prepared from a vinyl acetate–vinyl chloride copolymer increased the tensile strength of the tablets but also increased the rate of release of potassium chloride from the matrix (548). Electron-scanning photomicrographs showed that sintering at 100° for 1 hr caused the polymer particles, which had been deformed during compression, to regain their shape. The strength of plastic matrix tablets (Duretter) was correlated to their likelihood of being recovered in the feces after administration to human subjects (549).

Other references on timed-release preparations, particularly on specific drugs, are listed in Table XVII.

Cosmetics—*Microbiological Contamination*—The uses of X-irradiation and chemical compounds for the preservation of cosmetic preparations were discussed (559). Chemical preservatives were examined in detail, and a table of dissociation constants of acidic preservatives was given. Various *Staphylococcus* strains were isolated from cosmetic creams and lotions, and the pathogenicity was determined by culturing in various media (560). Larger amounts of *Staphylococcus* with higher pathogenicity were isolated from less expensive products. Factors that affect microbial growth in various cosmetic and toilet preparations were discussed; these included temperature, pH, oxygen, surface tension, and water quality (561). A study concerned with the resistance of bacteria compared the relative merits of "in use" and laboratory methods for the evaluation of antimicrobial products (562).

Formulation and Technology—The uses, properties, and formulations of dermatological skin lotion vehicles were reviewed (563). Cosmetic dermatitis factors were discussed along with case histories of typical cosmetic products causing irritation and allergenic reaction (564). The pharmaceutical aspects of skin therapy including the management of skin disorders, dermatological vehicles, skin penetration, and percutaneous absorption were reviewed (565). Various problems of black skin were considered, and recommendations for lotion formulations were made (566). The relationships of estrogens and androgens to sebaceous gland function and various kinds of hair growth were explained (567). A review article on the substantivity of cosmetic ingredients to skin, hair, and teeth discussed the advantages and disadvantages of substantive effects, various ways of achieving them, and methods for detection and assessment (568). The necessary properties for the obtainment of a protective epidermal skin barrier were given (569). Three classes of formulations were evaluated: a gelled oil, a water-in-oil emulsion, and an oil-in-water emulsion.

By using basic diffusion theory, mathematical models were obtained that correlate moisture loss to the thickness of topical substances during actual field usage (570). Under these conditions, there was a thickness below which the product did not have a perceptible effect on transepidermal moisture loss rate. Two factors, elastic modulus and stress relaxation, were used to characterize the mechanical properties of the stratum corneum (571). Both properties depended on the moisture content of the stratum corneum or the ambient relative humidity. Water vapor absorption and water vapor transmission were also dependent on relative humidity. In another report by the same investigators, it was shown that cosmetic humectants increase transepidermal water loss *in vitro*, and an attempt was made to explain this phenomenon (572). A depilometer was designed to simulate practical use conditions as closely as possible (573). Thus, important formulation variables could be studied quickly; in-use tests gave good correlation with the depilometer findings.

The cuticle of human hair was isolated in bulk by a new method involving vigorous agitation of fibers in water (574). The cuticle fractions were shown to be of high morphological purity using various techniques of electron microscopy, and the significance of amino acid analyses was discussed. Papain and dithiothreitol were used to separate the A-layer and cell membrane complex from human hair cuticle (575). The digestion was followed gravimetrically, and an electron microscope examination of the digested hair sections demonstrated that the components were clearly separated. The gross and fine structures of hair were discussed, and excellent scanning electron microscope microphotographs were included with the article (576). Scanning electron microscopy was used to evaluate hair care products while the hair was still attached to the head (577).

The effect of critical micelle concentration (CMC) on the detergent action of shampoos at equivalent micellization indexes was studied (578). The amounts

of surfactants required to clean greasy hair at physiological standards were calculated (579). Two modes of analysis were utilized to evaluate antidandruff shampoos on groups as small as 10 persons (580). One method was subjective, and the amount of scaling was scored on a 0–10 scale; the second method involved the counting of the number of horny cells produced using a hemocytometer.

Two techniques were used to demonstrate the penetration of proteins into hair strands (581). One method involved chemical analyses of hair scrapings, and the other method involved staining cross sections of hair with ninhydrin. A second paper on factors controlling the action of hair spray investigated the adhesion of hair spray resins to hair fibers (582). The properties of the resin and solvent system were important for the ability of the hair to withstand impact and bending.

A standardized swabbing technique was developed to evaluate changes of axillary microflora, and seasonal differences were found in levels of some bacteria (583). A new method of deodorization was suggested; it involved clathrate formation using zinc ricinoleate and 0.1–2% synergistic additives such as polyhydroxylated fatty acids or resin acids (584, 585).

The history of sunscreen preparations was given, and several natural and synthetic compounds were evaluated and compared (586). A new sunscreen containing 4-(3′,4′-methylenedioxobenzylidene)-1-benzyl-2,3-dioxopyrrolidine in combination with mexenone (Uvistat 2211), titanium dioxide, and burnt sugar solution was suitable for patients who display abnormal sensitivity to UV irradiation (587).

Additional references on formulation and technology of cosmetics are listed in Table XVIII.

Packaging—The requirements for quality, packaging, and transportation of active materials and adjuvants used in the pharmaceutical industry were presented (637). Another review discussed the types of materials that should be considered for pourable liquids, sterile products, and semisolid and solid dosage forms in bulk and unit dose containers (638). Use of glass, metal, and plastics was explored; each group was described with reference to their advantages and disadvantages. The progress in the development of child-resistant packaging systems was explored (639). Three papers discussed various aspects of the use of polyvinyl chloride and plastics as packaging materials. Physicochemical control of plastic materials used in the packaging of unit dose drugs was reviewed (640). The toxic effect of various additives used in the manufacture of polyvinyl chloride was discussed (641), and the importance of physical and chemical tests was stressed (642). A paper from the Netherlands reviewed pharmacopeial requirements, including chemical and toxicological testing, of plastic materials used as containers for intravenous injections (643).

The economics of blister and skin packaging were reported (644), and the technology of shrink wrapping, particularly for toiletries, was discussed (645). A comparative test for the evaluation of the tightness of various prescription containers was developed (646). The test consisted of placing a weighed amount of calcium chloride in a container, closing it, and following the weight gain after storage in an 86% relative humidity chamber. Glass vials with lined phenolic screw-capped closures provided the best protection, while polystyrene vials with a child-resistant closure were the least effective. The unit packaging of solid dosage forms, powders, and granules in blisters or flexible pouches was discussed (647). A

new method of hermetically packaging solid drugs was tested and found to be satisfactory (648). The method involved "cold welding" of aluminum foil under pressure. The packaging of suppositories using various plastic materials was reported (649). A survey of cartoning equipment and a buyer's guide to equipment now on the market were presented (650).

Plastic packaging of infusion and injection solutions was discussed, with particular reference to polyethylene, polypropylene, and polyvinyl chloride (651). The major factors involved in the design and manufacture of packaging to preserve sterility of the contents were enumerated; these included the suitability of the packaging material for sterilization, the resistance of the material to bacteria, the type and strength of the package, and the type of package opening (652). Several approaches to meeting the needs of users of small volume, prefilled, syringe products were presented (653). Development aspects unique to small volume, prefilled, disposable syringes were enumerated. Two-compartment injection systems were described together with their inherent advantages for powder or lyophilized formulations (654).

Instruments and Equipment—A continuing series of articles concerned with pharmaceutical engineering presented the fundamentals of laminar flow (655) and the principles of fluidized beds (656). The ideal physical plant conditions of temperature and humidity in a number of specific pharmaceutical operations were presented (657). The quantity and quality of the air in the plant were discussed with respect to particle content and the means of controlling it.

Various papers were concerned with particular pharmaceutical processes such as drying, coating, and metal particle detection. An accurate automatic control for dryers was devised (658). Equipment available for the polymer film coating of tablets by coating pan, fluidized-bed, spraying, and dipping techniques was examined and compared (659). Tablets and granules of any shape were coated using a new machine equipped with two brush rollers (660). Coating material was fed to the brushes by a roller which was in contact with a reservoir; the equipment was capable of coating tablets with as little as 1 mg of coating material/tablet.

A survey of pumping technology was presented, and some recent developments were of particular importance to the pharmaceutical industry (661). An instrument was developed that automatically detected small metallic particles possessing ferro-, para-, or diamagnetic properties (662). A review of the practical applications of spray drying was presented with a detailed description of the spraying agents used (663). A report appeared on the spray drying of aspirin (664). Scanning electron microscope and electron diffraction studies of spray-dried aspirin with methylcellulose revealed that a noncrystalline amorphous sample of the drug was formed at a 70% polymer concentration. Increased amounts of aspirin in the product led to the formation of crystalline products.

The developments in mixing and grinding technology were examined, and machine and design changes were emphasized (665). A Nauta mixer was evaluated by mixing a tablet preblend containing 10% phenobarbital (phenobarbitone), 1% secobarbital (quinalbarbitone), and 1% butethal (butobarbitone) with 88% lactose (666). Each component behaved in a unique manner during mixing, with adequate mixing occurring at different times.

An instrument was described that will produce a standardized skin abrasion test for skin irritants (667). The same degree of abrasion can be reproduced without bleeding. Further work on the evaluation of vaginal odors by means of GLC was reported (668). Refinements in methodology allowed the technique to be sufficiently sensitive to indicate significant ($p < 0.05$) changes in 10 subjects.

Additional references on instruments and equipment are listed in Table XIX.

PHYSICAL PHARMACY

Several review articles were devoted to polymorphism where various polymorphs were characterized by X-ray diffraction patterns, IR spectrophotometry, and dissolution rates. Dissolution rate is the most important characteristic in pharmaceutical formulations because it affects the bioavailability of various formulations (674, 675). The thermal analysis of pharmaceuticals including solvation, polymorphism, impurities, interactions, stability, and compatibility was also discussed (676). The relationships of various polymorphic forms of pharmaceuticals to their biological activity were reviewed (677). Phase solubility in combination with IR spectrophotometry was used for studying the polymorphism of progesterone, cortisone acetate, and prednisolone (678).

Upon crystallization from various solvents, barbital, amobarbital, butethal (butobarbital), hexobarbital, and phenobarbital were found to be polymorphic by thermomicroscopy, microsublimation, and X-ray diffraction (679). The effect of polymorphism on the dissolution behavior and GI absorption of chlortetracycline hydrochloride was studied (680). After oral administration to humans, the cumulative amounts of chlortetracycline hydrochloride excreted by two polymorphs were compared. The results suggest that the more soluble β-form was absorbed much faster than the α-form and was more bioavailable than the α-form. Depending on the method of preparation, hydroflumethiazide crystallized as an anhydrous form, a desolvated crystal species, and an ethanolic solvate, which, under normal atmospheric conditions,

converted to the desolvated crystal, losing all except a small fraction of the solvent from the crystal lattice (681).

Two new polymorphic modifications and a solvent-containing form of indomethacin were described and characterized by their thermal data, IR spectra, and solubilities (682). Solid-state studies were done on the polymorphs of methylprednisolone (683). The metastable crystalline form underwent a transformation to a form other than the stable Form I upon exposure to high humidities, moderately high temperatures, or UV radiation.

Cameroni and coworkers studied the polymorphism of progesterone. In their first paper, they reported on the preparation and characterization of the various polymorphs (684). They studied the use of differential calorimetry with various progesterone crystalline forms (685), and the solubility and thermodynamic data of two crystalline forms were also developed (686). The densities, refractive indexes, and X-ray diffraction measurements of four polymorphic forms of sulfanilamide were studied (687). The data suggested that the forms have very similar structures.

Effects of some process conditions on the particle size and polymorphic form of phenobarbital (phenobarbitone) prepared by acid–base precipitation were studied (688). The presence of water profoundly influenced the behavior of the solid product, and the significance of this phenomenon was discussed. More than 20 progesterone steroids and 30 testosterone-type compounds were tested for hydrate formation to evaluate their stability in solutions and in pharmaceutical preparations (689). Hydrates were observed with 21-acetoxypregnenolone, fluorogestone acetate, 4-chlorotestosterone, testosterone, and stanozolol.

A review of mass transport phenomena and models covered passive diffusion, diffusion in an isotropic medium, diffusion through laminated structures, the influence of some specific permeant and barrier properties on mass transport including diffusant solubility as a flux-limiting factor, and factors affecting diffusivity (690). The effect of sodium carboxymethylcellulose on sodium salicylate transport was studied (691). The drug release rate out of the polyelectrolyte solution was found to be faster than that without carboxymethylcellulose. This transport-enhancing action of sodium carboxymethylcellulose was probably due to the electrical charge between the coion and the polyelectrolyte.

By means of a diffusion cell consisting of two compartments partitioned with a cellophane membrane, the influence of surfactants, thickening agents, and pH on the rate of drug transport of three flavonoid compounds was studied (692). Association and complexing of oxytetracycline in its solutions at pH 1.65 were studied by diffusion transport through inert membranes (693). Association occurred in solutions $>5 \times 10^{-3}$ *M*. The diffusion of aerosols was tested at low temperatures where classical Brownian movement theory is not applicable (694). At room temperature, the diffusion coefficient calculated from experimental penetrations agreed with the theoretical coefficients. However, at −16 and −72°, the experimental coefficients were 150–500% greater than the theoretical values.

Microencapsulation of solid stearyl alcohol particles by complex coacervation was studied (695). Wall thickness decreased with increasing ratios of solid particles and increased as the particle diameters increased. Microencapsulated aspirin with ethylcellulose was examined as to its dissolution rate in pH 1.1–8.3 media (696). The rate was slower in acidic pH. Release of aspirin from the microcapsule was also examined microscopically. Aspirin leached out of the capsule, leaving the capsule membrane almost intact.

Additional references relating to physical pharmacy are listed in Table XX.

Dissolution—Phenylpropanolamine hydrochloride was found to be released from a typical wax matrix by a diffusion mechanism (721). After an initial rapid release of drug from the tablet, the amount dissolved was proportional to the square root of time. Dissolution of human gallstones was evaluated in a water solution containing a mixture of limonene with polyoxyethylene hydrogenated castor oil and ethanol; the solution was able to dissolve completely 1.4–3.2 g of cholesterol-containing human gallstones in 2 hr *in vitro* (722). Bile salt solutions slowly dissolved cholesterol gallstones *in vitro*, chenodeoxycholate and

deoxycholate being about fourfold more potent than cholate (723).

Experimental results suggested that various lots of drug formulations that meet compendial dissolution requirements may contain fractions of poorly soluble tablets (724). If the assumption is made that dissolution behavior and drug absorption *in vivo* are related for certain drugs, such formulations give rise to suboptimal therapy. A modification of the compendial test was presented with the objective of increasing the probability of identifying lots containing a fraction of poorly soluble tablets. The dissolution rate of nitrofurantoin from commercial suspensions and tablets containing microcrystalline drug particles and from capsules containing macrocrystalline drug particles was determined at 37° in simulated gastric and intestinal fluids using the stirrer-flask method (725). The dissolution rate of nitrofurantoin from the suspension and capsule dosage forms at pH 7.2 was significantly faster than at pH 1.12. In contrast, the drug from the tablet dosage dissolved in the pH 1.12 dissolution medium at a rate twice that observed at pH 7.2.

A nonlinear expression describing the dissolution of drug particles under sink conditions and low agitation intensity was presented (726). By using the beaker method, the dissolution of salicylic acid particles having a relatively narrow size distribution was followed to nearly complete solution. It was found that the process could be described by the nonlinear expression and that a dissolution rate constant having the dimension of reciprocal time could be obtained. Dissolution rates of salicylic acid in micellar solutions of polysorbate 20 were determined at pH 1–4 (727). At any one pH, as the concentration of the polysorbate 20 was increased up to 12% (w/v), the dissolution rate increased; but the further increase up to 20% (w/v) polysorbate 20 only slightly increased the dissolution rate. At any one concentration of polysorbate 20, the dissolution rate increased linearly as the pH was increased.

The effects of particle size on dissolution and GI absorption rates of drugs were reviewed (728). When the influence of particle size on dissolution behavior of sulfonamides was evaluated, it was found that at a particle size below 300 μm, the lines obtained by plotting dissolution rate *versus* time had positive intercepts; at above 300 μm, the lines passed closely through the origin (729). The findings indicated that the critical particle size is at about 300 μm in the initial dissolution process.

It was shown that dissolution rates and equilibrium solubilities of digoxin samples before and after dry grinding in a mortar mill may influence dissolution behavior (730). The need for a specification for digoxin that not only controls surface area but also exercises some control of the crystal properties was suggested. The influence of the tablet manufacturing method and drug particle size on the dissolution rate was studied (731). The rate of dissolution of the active ingredient was faster with a particle size of 50 μm than for formulations made with particle sizes of 180–200 μm.

Dissolution characteristics of three crystal forms of aspirin were evaluated (732). The dissolution process of the highest melting form could be represented by the general Noyes–Whitney equation, which assumes that diffusion is the rate-controlling process; the dissolution of the lower melting forms did not obey this model so it was necessary to postulate that the interfacial reaction was not instantaneous. Bundgaard (733) claimed that the differences in the rates of dissolution of aspirin were due to differences in the content of the acetylsalicylic anhydride impurity. When using the rotating-disk method, it was shown that the dissolution rate of aspirin was independent of crystal growth, salicylic acid content, habit, and particle size (734). The dissolution of the eutectic mixtures of aspirin and urea, when evaluated in 0.1 *N* hydrochloric acid, was about the same as pure aspirin; in the 35% solid solution, the dissolution was appreciably enhanced (735).

Shah and Ochs (736) designed and evaluated the rotating-filter–stationary basket *in vitro* dissolution test apparatus. An automated procedure for the determination of *in vitro* dissolution rates from two-component (outer layer plus sustained-release core) sulfonamide tablets was described (737). The dissolution rates *in vitro* for film-coated tablets were dependent on the solubility of the film. An automated dissolution rate apparatus, meeting requirements of the USP–NF dissolution test and applicable to various other agitation systems in common usage, was described (738). The equipment allows simultaneous determination of the dissolution *rate of six* unit doses, enabling the evaluation of a statistically significant number of samples.

Dissolution rates of eight products containing levodopa in three strengths, made by two different manufacturers, were determined using a continuous-flow dissolution apparatus (739). Significant difference was observed in the 250-mg capsules made by different manufacturers. A significant difference also was observed in a 250-mg tablet and a 250-mg capsule of the same manufacturer. Comparisons were made between different methods for the determination of dissolution rates of drugs from tablets using the USP XVIII method and the beaker method (740). The reproducibility of the USP method was better than or equal to the reproducibility of the beaker method. Comparisons of dissolution profiles of tablets and capsules were made using the USP, Levy, and three different size magnetic basket methods (741). The five different dissolution methods produced significantly different dissolution profiles at selected times for both the tablets and capsules studied.

By using the USP method and the shaking beaker method, the dissolution rate of methandrostenolone and phenobarbital tablets was studied (742). The USP method gave a greater dissolution rate. A theoretical model of dissolution was developed in terms of the diffusion layer theory (743). This model was programmed on an analog computer, and theoretical dissolution curves were obtained. Experimental dissolution curves were compared with simulated curves, and the fit of the data allowed the estimation of the

Solubility–Solubilization Phenomena—Cholesterol solubility in model bile systems was evaluated (763). It was found that there were significant behavioral differences in the rate of solution with the various crystalline forms. The solubility of the equilibrium species, hydrated cholesterol, and of fresh human gallstones was found to be approximately 5 mole %. The surface areas for 73 aliphatic hydrocarbons and alcohols, for which solubility and boiling point data are available, were calculated (764). The solubility of the alcohols and hydrocarbons could be quantitatively related to a combination of the hydrocarbon and hydroxy surface areas of the molecules.

The solubility of antipyrine derivatives was determined in water and several organic solvents (765). Aminopyrine and isopropylantipyrine exhibited solubility minimums near 25 and 15°, respectively, corresponding to a zero heat of solution. The rates of solution in butanol of compressed plates of modifications I–III of sulfanilamide were determined along with the solubilities at various temperatures (766). A method of calculating heats of transition from the rates of solution was also described. Differential scanning calorimetry was used to determine the solubility of the metastable form of testosterone (767).

Selected surfactants, above and below the CMC, were evaluated for their solubilizing effects on suspensions of aspirin crystals (768). Ranked in order of decreasing solubilizing effectiveness were: cetylpyridinium chloride > polysorbate 20 > benzalkonium chloride > polysorbate 80 > dioctyl sodium sulfosuccinate. The effects of sodium chloride and urea, separately and together, were evaluated on the solubility of methyl *p*-hydroxybenzoate in water (769). Sodium chloride decreased and urea increased the solubility. Solubilizers formed soluble and/or insoluble complexes with tetracycline and its derivatives (770). In all cases, oxytetracycline interacted less than tetracycline. The solubilization of the surfactants was assumed to be due to normal micellar solubilization rather than complexation.

The cosolvent capacity of 1,2-propylene glycol, 1,3-butanediol, and 2,3-butanediol in the solubilization of phenylethylbarbituric acid was studied (771). The solubilizing effect of the aqueous dispersions obtained with these polyols was mainly due to the modification of the dielectric constant of the water, with existence of a complex mechanism, rather than to the direct action of the polyol itself. Solubilities of certain barbiturates in poly(oxyethylene) monoalkyl ethers of varying hydrophobic chain length were studied (772). Solubilization increased with the increasing hydrophobic chain length of the solubilizer due to formation of larger micelles. The effect of monosaccharides on the solubility of barbituric acid and its derivatives was studied (773). The solubility of barbituric acid increased with the increasing monosaccharide concentration, the increase being more pronounced in solutions containing galactose. Calcium *p*-aminosalicylate formed an isonicotinic acid hydrazide–calcium chelate in aqueous solution with isonicotinic acid hydrazide (isoniazid) and resulted in monocalcium *p*-aminosalicylate with increased solubility (774).

Other papers concerning solubility–solubilization phenomena are listed in Table XXII.

meability of films of ethylcellulose and polyethylene glycol to caffeine was studied (787). The rate of caffeine transfer across the films increased linearly with the reciprocal of thickness and caffeine concentration. The permeability of plastics, in particular, in relation to drug products with regard to physical factors and to intrinsic and total permeability was evaluated (788). Gravimetric, manometric, and hygrometric methods were used for the permeability evaluation. Comparisons of dimethylpolysiloxane and trifluoropropylmethylpolysiloxane systems were made, using nicotine base as the permeating species (789). The drug permeability through dimethylpolysiloxane was >20 times more rapid than through the trifluoropropylmethylpolysiloxane system.

The permeation of phenylbutazone through polydimethylsiloxane was studied under conditions of varying membrane thickness, stirrer speed, and pH (790). The results were described in terms of the two-phase model of general transport theory and provided experimental evidence of its usefulness. The influence of surfactants on the transfer of salicylate and salicylamide was studied in everted rat intestine (791). Sodium tauroglycocholate, sodium oleate, sodium lauryl sulfate, polysorbate 20, and sorbitan monolaurate increased the transfer rate of both sodium salicylate and salicylamide across the everted rat intestine.

The effects of pH and various substances on the permeation of phenylbutazone through the everted rat intestine and polydimethylsiloxane were studied (792). The classical pH–partition hypothesis was not obeyed. Phenylbutazone permeation rates in one or both membranes decreased in the presence of gelatin, methylcellulose, polyvinylpyrrolidone, skim milk, albumin, sodium lauryl sulfate, polysorbate 80, and cetrimonium bromide. The effects of excipients and various additives on the permeation of chlordiazepoxide through polydimethylsiloxane membranes also were studied (793). No effect on the permeability coefficient was observed in the presence of starch, calcium hydrogen phosphate, gelatin, lactose, silica, sucrose, cholesterol, or porcine mucin. The coefficient increased in the presence of magnesium stearate and decreased with talc, sodium saccharin, skim milk, egg lecithin, beef albumin, egg albumin, polysorbate 80, cetrimonium bromide, and sodium lauryl sulfate, indicating an interaction of these substances with the drug.

The effect of hyaluronidase on the activity of two ointments containing antibiotics was studied by the evaluation of the active transport of sodium through the isolated skin of frog and by the measurement of the current necessary to cancel the electrical potentials of the membrane covered with ointments (794). The antibiotics evaluated were tetracycline, chloramphenicol, neomycin, erythromycin, nystatin, streptomycin, kanamycin, griseofulvin, and penicillin. Interrelationships between skin, vehicle, and drug during penetration into skin were reviewed (795).

The permeation of water vapor through cellulose acetate phthalate polymer films applied in various ways to hygroscopic solid surfaces was determined at several different temperatures (796). The data indicated that the activation energy of the absorption processes was determined by the film, while the method of film application affected the actual rates of permeation at a given temperature.

Models used in the description of diffusion processes were applied to the drug release from semisolids (797). Two models, an exponential model for finite systems and a nonexponential model for semi-infinite and infinite systems, were evaluated for their suitability in describing literature data for release of substances from semisolids. The exponential model derived for finite systems was found applicable in all of the literature cases, while the nonexponential model had restricted applicability. The effects of systematic alteration of vehicle composition on the release rate of drug from their vehicle were studied (798). Equations were developed that quantitatively predicted the rate of transport of a drug across a membrane separating two identical binary aqueous solvents. Separate equations were derived for solutions and for suspensions; they accounted for both the resistance of the membrane and the resistance of the solvent to drug diffusion.

The release of sodium lauryl sulfate and cetrimide from ointment bases containing complex emulsifiers was studied (799). Cetostearyl alcohol blocked the release of sodium lauryl sulfate into agar, but doubling the sodium lauryl sulfate concentration enhanced its release. A stabilized shea butter in the form of an ointment base was developed and found to release medicaments at a faster rate than the British Pharmacopoeia ointment bases. The assessment of release of medicaments by microbiological method and through a dialysis membrane gave promising results (800). The rate of drug release from a gel medium was determined by placing a salicylic acid-containing gel in a 1-cm diameter hole in a ferric chloride-containing agar plate and measuring the colored ring formed. Two gels were used, one based on liquid paraffin and the other on castor oil. The gel based on castor oil was more viscous but released salicylic acid faster.

The effects of various sorbitan surfactants on drug release were determined (801). The drug release increased with increased HLB value and decreased with increased chain length. Effects of polysorbate 80, sorbitan monostearate, water, and physicochemical structure of the ointment on potassium iodide release from lard and white petrolatum were studied (802). Addition of 3% polysorbate 80 retarded potassium iodide release from lard but accelerated the release from white petrolatum. A reverse effect was observed with a 3% addition of sorbitan monostearate. Release of iodine in a potassium iodide solution was studied from ointment bases, comprised of petroleum or a melt of petroleum with sunflower oil and various oxyethylenated aliphatic alcohols as emulsifiers, into an agar gel (803). The bases were water-in-oil emulsions. Release of iodine increased with the increasing water content of the base and decreased with the increasing number of carbon atoms in the hydrophobic portion of the molecule of an emulsifier.

The releasing ability of four different ointment bases containing salicylic acid was evaluated by an *in vivo* test on rats and by four different *in vitro* tests (804). The salicylic acid releases from the various bases in the *in vivo* test decreased in the following order: Unguentum leniens, Unguentum emulsificans hydrosum, Unguentum alcoholum lanae hydrosum, and Unguentum macrogoli.

The effects of small-scale preparation techniques on the diffusion of salicylic acid from various ointment bases were studied (805). The method of mechanical incorporation of the drug in cold petrolatum base, using a spatula, appeared to result in higher rates of salicylic acid diffusion than those encountered with ointments prepared by fusion, regardless of drug concentration and the presence or absence of a surfactant. The drug release pattern of micronized ethynodiol diacetate from silicone devices was investigated in polyethylene glycol containing elution media with a wide range of solubility and partition properties (806). When high drug solubility was maintained, the drug release pattern was matrix controlled. As the drug solubility in the elution medium was decreased, the drug release process shifted from matrix controlled to partition controlled.

The *in vitro* release pattern of nitrofurantoin embedded in polyvinyl acetate–crotonic acid copolymers was studied in artificial intestinal juice (807). *In vivo* studies were also done on conventional and slow-release nitrofurantoin tablets. Both *in vivo* and *in vitro* results indicated that the copolymer with 8% crotonic acid was effective for prolonging the release and excretion of nitrofurantoin. The water solubility and chemical reactivity of hydrocortisone and hydrochlorothiazide were studied, and the type of matrix useful for their preparation as a sustained-release dosage form was determined (808). Acetohexamide incorporated into silicone rubber disks was released into water in microgram quantities for over 6 months (809). Based on these data, these disks were recommended as sustained-release polymeric capsules for acetohexamide.

The effect of some variables involved in the manufacture of nylon microcapsules *via* an interfacial polymerization on the release rate of core material from the microcapsules was evaluated (810). The presence of emulsifiers in the external phase had no significant effect on the release of core material; sodium hydroxide, as an acid acceptor, did not enhance the retentive properties of the microcapsules; and the choice of organic solvent not only affects the release of the core material but may govern the collection method.

Complexation—Studies related to complexation phenomena are categorized into: *(a)* interactions of drugs with biological substances, and *(b)* interactions of drugs with nonbiological substances.

Interactions of Drugs with Biological Substances—A quantitative comparison of various methods of fundamental binding parameter estimation was presented (825). For optimal reliability, the choice of a particular approach should be made on a critical assessment of the experimental procedure and various calculated statistical criteria rather than on the ease of data treatment. By using nonlinear regression, an improved parameter estimate in drug protein binding studies was devised. In addition, a kinetic approach to drug–protein binding was developed (826). Computer analysis of drug–protein binding data was evaluated (827). A stepwise equilibrium model was recommended as the standard procedure for the investigation of drug–protein interactions.

The binding constants and the number of binding sites for the binding of 11 sulfonamide and seven penicillin derivatives to bovine serum albumin were determined using a fluorescence probe method (828). The results demonstrated that these drugs bind to hydrophobic sites of the serum albumin. New fluorescence probes for drug–protein binding studies were developed (829). The binding of various ingredients was studied, and the results showed that the fluorescence of these acridine derivatives was essentially a combination of fluorescence of acridine and the substitution effects. A dynamic dialysis technique, utilizing a constant flow of buffer solution, yielded the same drug–protein binding information as did equilibrium dialysis (830).

The application of membrane ultrafiltration to the determination of protein binding of drugs was studied (831). Reproducibility between the experiments was good, as was agreement between the binding data obtained by this method and those obtained by equilibrium dialysis. The characterization of drug–protein interactions by classical methods was reviewed (832). Methods discussed were dialysis, ultrafiltration, and gel filtration. The mechanisms of drug–protein interactions also were reviewed (833). The ef-

fects of binding on drug elimination and drug displacement were discussed.

The binding of ascorbic acid and fatty acid ascorbyl esters to bovine serum albumin was studied (834). The analysis of the binding data showed that the albumin possessed a single binding site for these chemicals and that there were marked differences in their binding strength, which increased in the order of ascorbic acid, benzoate, octanoate, and decanoate. The binding of atropine to albumins or γ-globulins from human blood serum was studied (835). The binding significantly increased with an increase in pH above 6.0 or 7.1, respectively. The *in vitro* binding of phenytoin (diphenylhydantoin) to the protein in plasma from 97 volunteers was studied using ultrafiltration (836). The protein binding of phenytoin was significantly decreased in patients with renal disease, hepatic disease, or hepatorenal disease.

Comparative binding of disopyramide phosphate and quinidine sulfate to human plasma proteins was studied (837); the two drugs did not compete for the same binding sites on protein molecules. Glisoxepide, a new antidiabetic drug, was 93% bound by human serum proteins, independent of its concentration (838). When evaluating the competitive binding capacity with phenprocoumon, it was found that glisoxepide did not displace it. Protein binding of indomethacin was studied (839). Binding of indomethacin to human plasma albumin was increased by the presence of phenylbutazone and decreased by the presence of ibuprofen and salicylate. Binding coefficients of various antibiotic affinities to blood protein in a kinetic–biological model suggested that low protein binding was associated with good antibiotic activity (840).

In balanced dialysis experiments, scopolamine hydrobromide interacted with blood serum albumin and γ-globulin (841). An increase in the pH of the solutions from 6.9 to 7.3–7.8 was accompanied by a significant increase in the alkaloid binding with the proteins. The interaction of tolbutamide, glyburide (glibenclamide), chlorpropamide, and tolazamide with serum albumin was studied (842). Glyburide, the most strongly bound of the four compounds, was bound to only one class of sites. The other three compounds were bound to at least two sites. When the interactions of sulfonylureas with plasma proteins were studied, glipizide and glyburide bound to different but closely located sites on the protein with greater affinities (843).

The binding of tolbutamide and glyburide to human serum albumin was examined in varying concentrations of phosphate and tromethamine buffer and in phosphate containing sodium chloride (844). Binding of tolbutamide was affected little by changes in phosphate concentration but was particularly sensitive to the presence of tromethamine and chloride ions. The interaction of tetracycline with human serum lipoproteins and albumin was studied (845). Albumin possessed two binding sites for tetracycline, one a high affinity, low capacity site and the other a low affinity, high capacity site. Tetracycline appeared to dissolve in the lipophilic portion of the lipoprotein molecule rather than to be associated with specific binding sites.

Nazareth *et al.* (846, 847) studied the binding of L-thyroxine to serum albumins. They studied the use of 2-(4′-hydroxybenzeneazo)benzoic acid to mirror L-thyroxine binding to, and displacement from, serum albumin. Free fatty acid concentrations within the physiological range were found to affect drug

binding to plasma albumin in two ways: at low molar ratios of free fatty acid to albumin, an allosteric effect predominated; at higher molar ratios, there were both allosteric and competitive binding effects (848).

The binding of calcium and magnesium ions to human erythrocyte membranes was investigated (849). At least three different kinds of sites were concerned in the binding of calcium or magnesium to the membrane. Binding of pentazocine to human whole blood, plasma, and blood cells was investigated in 20 normal subjects and 22 patients by means of equilibrium dialysis (850). Plasma protein binding was 56–66% in the control subjects and 48–75% in the patients. In control subjects, 48% of the total amount of pentazocine in whole blood was present in blood cells and 33% was bound to plasma proteins. The remaining 19% was in the plasma water. A constant degree of binding of quinidine to a red blood cell hemolysate preparation was found for a clinically significant range of concentrations at 37° using the method of equilibrium dialysis and ultracentrifugation (851). Quinidine appeared to be bound to a single binding site.

Additional references on interactions of drugs with biological substances are given in Table XXIV.

Interactions of Drugs with Nonbiological Substances—Moorhatch and Chiou (882) evaluated the interactions between drugs and plastic intravenous fluid bags. They studied the adsorption characteristics of 17 drugs, of which three (vitamin A acetate, warfarin sodium, and methohexital sodium) were found to be significantly adsorbed. They also studied the leaching of chemicals from commercial polyvinyl chloride intravenous fluid bags. Absorbances of media such as distilled water, normal saline, 5% dextrose solution, 5% alcohol solution, and aqueous buffer solution with pH values ranging from 3.5 to 9.5 were all quite low within 48 hr of study, indicating insignificant leaching of UV-absorbing material. Absorbances of 0.01–0.04% of polysorbate 20 and 80 solutions were quite high, indicating leaching of a significant amount of chemicals from the bags. The preliminary study indicated that the plasticizer, bis(2-ethylhexyl) phthalate, or other type of phthalate plasticizer may be a major leached chemical (883).

Chloramphenicol seemed to be solubilized by complexation with polysorbate 80 throughout the neutralization range of the interaction (884). Maximum complexation took place at around pH 3.0, the disappearance of the complex began beyond pH 3.4, and interaction ceased at pH 10. The interaction of theophylline with sodium benzoate was examined by NMR (885). Chemical shifts of theophylline protons were determined as a function of sodium benzoate concentration in deuterium oxide at 30°. Signals of both methyl groups underwent significant upfield shifts, indicating vertical or plane-to-plane stacking. The decomposition of aqueous solutions of common antimicrobial agents, sodium metabisulfite, and vitamins was accelerated by storage in polyethylene containers, indicating interactions between the container and its contents (886).

The *in vitro* binding of drugs by colestipol hydrochloride depended not only upon ionic strength, pH, and type of competing ion but also upon whether association could occur with other molecules (887). Where feasible, the initial input ratio of drug to binding agent was equivalent to the ratio if both were administered orally and in therapeutically effective amounts. The water-soluble drugs ascorbic acid, aspirin, salicylic acid, phenobarbital-^{14}C, sulfadiazine, penicillin G, and lincomycin hydrochloride were less than 30% bound to colestipol hydrochloride, while warfarin and tetracycline hydrochloride were bound 59 and 30%, respectively. The interaction of phenobarbital and ethanol given intraperitoneally to mice was studied (888). Dose–response relationships were established for incidence of death, sleeping time, and time of onset of sleep. When the two drugs were administered together, sleep occurred more rapidly than was calculated as likely on the basis of the effects of the drugs given individually. On the other hand, sleep was of shorter duration and the incidence of death was less than anticipated.

such as tuberculoprotein, nucleic acid, and polysaccharide were studied (889). The degree of binding was a function of the concentration of these macromolecules. Interactions of iodine with ethylene glycol, diethylene glycol, triethylene glycol, and polyethylene glycols of molecular weight between 200 and 11,000 in ethanol and in carbon tetrachloride were investigated (890). The absorbance of an ethanol solution of iodine at 360 nm increased by the addition of polyethylene glycols. A new peak was observed at 380 nm by the addition of polyethylene glycols of a molecular weight above 300 to the carbon tetrachloride solution of iodine. The complexes of polyethylene oxide with guanidine hydrochloride and with phenobarbital were subjected to differential scanning calorimetry, polarized IR spectroscopy, and X-ray fiber photography, confirming the formations of the complexes; the structures of polyethylene oxide molecules in the complexes were discussed in comparison with a polyethylene oxide–urea complex or with original samples of polyethylene oxide (891).

Additional references on interactions of drugs with nonbiological substances are listed in Table XXV.

Surface Phenomena—The publications dealing with surface phenomena are divided into four major categories: *(a)* interface studies, *(b)* adsorption studies, *(c)* general properties of surfactants, and *(d)* micelle studies. However, because of the obvious overlap among these categories, the reader with special interest in this field should consider the entire section.

Interface Studies—Studies were done on surface films of sorbitan esters at the air–water interface (913). The effects of continuous and discontinuous compression methods on the surface pressure–area isotherms were studied. The slower, continuous compression method gave surface pressure–area isotherms that tended toward a smaller area than the faster, discontinuous method of compression. Cumulative results derived from the effects of compression–decompression studies on hysteresis areas, surface pressure relaxation with time from preselected pressures, and recycling experiments were used to explain molecular behavior at the air–water interface (914). A physical model was developed that considered bulk diffusion, interfacial resistance, interfacial area, and oil–water partition coefficient. The model was used to analyze the data obtained from the rate experiments and to determine the interfacial permeability coefficients. Results of the experiments on the transport of sterols from aqueous sodium taurocholate–lecithin and aqueous cholate–lecithin systems into hexadecane strongly suggested that the kinetics of transport of cholesterol, desmosterol, and hydroxycholesterol were interfacially controlled and involved a two-step process. First there was a collision of the solute–micelle complex with the oil–water interface, and this step was followed by the release of the solute from the micelle in a largely polar environment at the interface (915).

Aggregation and interfacial properties of association colloids of benzalkonium chloride and macromolecular colloids of sodium carboxymethylcellulose and guar gum were studied (916). From the data, it seems that a different drag-reducing mechanism existed for sodium carboxymethylcellulose than for guar gum. Sodium chloride significantly reduced the drag-reducing property of sodium carboxymethylcellulose but did not seem to affect drag retention by guar gum. The effects of variations in temperature on drag reduction were different with sodium carboxymethylcellulose than with guar gum.

The interfacial tension of 10 polar liquids against hexane and tetradecane and the contact angle against paraffin, polyethylene, and polytetrachloroethylene were measured (917). Work-of-adhesion values against any one nonpolar phase, calculated from these data, were independent of the polar liquid used. The kinetic and thermodynamic aspects of *in vitro* interphase transfer of sulfonamides were studied (918, 919). Based on the kinetic and thermodynamic parameters, possible mechanisms for interphase transfer of unionized sulfonamides were proposed. The influence of phospholipids on the transport of antibacterial agents across nonaqueous barriers was studied (920). The results indicate that binding of penicillin G and ampicillin with phospholipids occurred at the oil–water interface, which influenced the further transport of the antibiotics through the nonaqueous phase.

Additional references on interface studies are listed in Table XXVI.

Adsorption Studies—The uptake of digoxin and digitoxin by some antacids was studied (929). Magnesium trisilicate showed the highest adsorptive effect, the extent of adsorption being up to 99% for the two glycosides. Antacid preparations containing magnesium trisilicate adsorbed digoxin from a pediatric elixir to the extent of about 95%. The effect of antacids, when concurrently administered with oral digoxin, on the bioavailability of the drug was discussed. Activated charcoal was capable of adsorbing organic vapors commonly used in anesthesia (930). The stability of activated charcoal after the adsorption of halothane was determined despite the passage of high and low halothane free gas flows through the canister.

Physicochemical studies were done on the adsorption of polysiloxane polymers onto hydroxyapatite

(931). The molecular configuration of the polymer adsorbed onto a solid surface was essentially a function of: *(a)* the strength of the polymer adsorption onto the solid surface, *(b)* the degree of polymer solvation by the solvent, and *(c)* the extent to which the solvent could compete with the polar anchoring segments of polymer molecules for the surface sites. The adsorption of benzoic acid on sulfamethazine particles was found to be pH dependent (932). At pH values above 4.2, a gradual suppression of the adsorption occurred; at pH 4.9 and above, no adsorption was noted. The effect of sodium citrate on adsorption was attributed to pH and ionic strength effects.

Adsorption of phenothiazines from aqueous solution by silica (Aerosil) was studied (933). The results obtained were compared with the adsorption on carbon black. The adsorption of benzocaine by nylon 6 powder from aqueous solution was examined under varying environmental conditions (934). The extent of adsorption increased with an increase in electrolyte concentration and with pH up to about 4. Increasing temperature reduced the amount of drug adsorbed. In all cases, the adsorption isotherms were linear over the concentration ranges studied. The adsorption of atropine and scopolamine by magnesium trisilicate was studied (935). At relatively low initial concentrations, the adsorption data were shown to fit a Langmuir plot; values for monolayer adsorption were 14.9 and 3.8 mg/g for atropine and scopolamine, respectively.

A method was developed for determining the adsorption rate of water-soluble dyes by soft gelatin capsules (936). This method was used for determining the diffusivities and activation energies of five FD&C water-soluble dyes. The activation energies of these dyes were in either of two groups, which had ranges of 25.1–25.7 and 34.8–36.0 kcal/mole. The adsorption behavior of steroids on silicic acid surfaces was studied (937). Hydrocortisone acetate was bound to the extent of 0.16 mg to 1 g of silica (Aerosil 200) from a saturated solution. The corresponding adsorption value of ethinyl estradiol was 0.26 mg/g of silica (Aerosil 200).

The adsorption isotherms of water vapors on sodium chloride crystals were plotted (938). True adsorption occurred only when the vapor pressure was less than the pressure over saturated sodium chloride solutions at the corresponding temperatures. With great water vapor pressures, a saturated solution film formed on the sodium chloride crystal surface, and the apparent water adsorption was due to isothermal condensation. The true adsorption of water vapor on sodium chloride crystals was caused by physical forces.

Additional references on adsorption studies are listed in Table XXVII.

General Properties of Surfactants—A study of variations of the surface tension coefficient of chlorpromazine aqueous solutions in relation to concentration and UV irradiation showed that the isotherm had an exponential curve characteristic of negative surfactant substances (967). The wetting behavior of aqueous sodium lauryl sulfate solutions on polyethylene terephthalate, nylon 11, graphite, and aluminum powders was studied (968). By using the Washburn equation for the flow of liquid through a capillary, it was possible to calculate, from the rate of penetration, the magnitude of the advancing contact angle, and the work of adhesion between the liquid and the powder. A linear dependence of HLB values of ethoxylated aliphatic nonionic surfactants on molecular weights was found on the basis of two simplifying assumptions. Surfactants of different polyoxyethylene chain lengths attached to the same hydrocarbon chain, and surfactants of different hydrocarbon chain lengths attached to the same polyoxyethylene chain (969).

mixtures were reviewed (970). An optical method for the determination of surface tension was described; the method was based on the determination of the slope of the tangent lines to menisci on the plane vertical walls immersed in the liquid (971). The method was independent of wetting phenomena and gave results in agreement with literature data. The surface tension and wetting capacity of biodegradable preparations such as Azolate A_2 and alkyl sulfate or their compounds with metasilicate and sodium tripolyphosphate were evaluated at 480° and a pressure of 20 atmospheres (972). The surfactants had adequate surface tension and wetting capacity at high temperatures and pressures and were thus recommended for use in crude oil extraction from deep-seated strata.

The manufacture of carbohydrate-based surfactants and their use in food, cosmetics, and pharmaceuticals were reviewed (973), as were the softening, washing, emulsifying, and foam-stabilizing properties of surfactants (974). Also reviewed were the various methods used in determining and calculating the HLB of surfactants and oils (975).

Additional studies on general properties of surfactants are listed in Table XXVIII.

Micelle Studies—Experiments were done to obtain new information on the solubility behavior of nonionic surfactants in nonpolar media, glycerol, and sorbitan monofatty acid esters (998). The results obtained were discussed on the basis of the thermodynamic functions calculated from the temperature dependence on the critical aggregating or micellar concentration and from the phase diagrams constructed with both the solubility and the aggregating or micellar concentration curves. The effect of the HLB on micelle formation for a homologous series of nonionic surfactants was studied (999). The HLB value increased as the aggregation number decreased, indicating a reduced tendency for micelle formation.

The CMC's of a series of polysorbates were determined using a surface tension method (1000). The CMC values obtained did not vary to any appreciable extent from those determined by other techniques, indicating that the procedure adopted was reliable, simple, and fast. Phase studies and particle-size analysis of solutions formed with nonionic surfactants were evaluated (1001). The micellar size was increased by increasing the oil content and by decreasing the surfactant–glycerol ratio. Also studied were the phase diagram and particle-size analysis of solutions formed with an ionic surfactant. Phase diagram studies were carried out on oil-in-water solubilized micellar solutions containing sodium oleate, amyl alcohol, water, and varying amounts of liquid paraffin (1002). Light-scattering measurements indicated an increase in micellar diameter following an increase in the concentration of liquid paraffin and a decrease in the surfactant–alcohol ratio.

Viscosity studies were carried out on a series of oil-in-water solubilized micellar solutions of liquid paraffin, glycerol, and water and blends of sorbitan monooleate and polysorbate 60 (1003). The effect of the surfactant concentration on the viscosity was discussed in terms of interaction between the polyoxyethylene chains at the surface of the micelles. The micellar properties of the antihistamine drugs diphenhydramine hydrochloride, bromodiphenhydramine hydrochloride, chlorcyclizine hydrochloride, and diphenylpyraline hydrochloride were studied in aqueous solutions (1004). The ζ-potentials of the micelles were calculated from their electrophoretic mobilities, as determined by a dye-tracer technique.

The solution properties of a series of phenothiazine hydrochlorides were studied using light-scattering, viscosity, conductivity, dialysis, and NMR techniques (1005). The aggregates formed were considered to be true micelles, which in water are probably compounds of about 10 monomers vertically stacked with the alkyl side chain and nitrogen group alternating to form an approximately spherical unit in solution. The usefulness of an analytical centrifuge in investigating micellar properties of drugs was evaluated (1006). Various examples of micelle forms of drugs were discussed, as was the working hypothesis that the same binding forces that hold together the aggregate found at high concentrations may be responsible for the binding of monomer to biological structures. The addition of ethanol, propanol, butanol, dioxane, or urea to aqueous solutions of hexaethylene glycol monoundecyl ether, heptaethylene glycol

monodecyl ether, or OP-10 increased the critical concentrations of micelle formation of these surfactants (1007). The alcohols, which stabilized the aggregates of water molecules, decreased the mobility of the surfactant molecules and diminished the number of collisions in unit time.

The kinetics of the formation of sodium lauryl sulfate micelles between 7.5 and 20° were studied by a pressure jump apparatus (1008). The theoretically predicted $1/\tau$ linear increase with increasing sodium lauryl sulfate concentration could not be confirmed, but the relaxation process became detectable at concentrations well below the CMC. Ultrasonic relaxation data were used to determine the kinetics of micellization of ionic surfactants sodium pentyl sulfate, sodium nonane sulfonate, and octylammonium chloride in aqueous solution, and a two-state kinetic model for micellization was used to describe the interchange of monolayers with the micelles by an adsorption mechanism governed by the Langmuir adsorption theory (1009).

Additional references on micelle studies are given in Table XXIX.

Dispersion Stabilization—Mixtures of phosphated nonylphenol ethoxylate, phosphated fatty alcohol ethoxylate, and *n*-hexane formed "oils," which may spontaneously emulsify when added to water (1042). However, the degree of spontaneity and the stability of the resulting dispersions varied according to the constitution of the system. Studies of the equilibrium phase diagrams suggested that the anomalies may be attributed to the presence of liquid crystalline phases of different types formed in the presence of water. The stabilization of emulsions by solid emulsifiers was evaluated (1043). The effects of surface-active compounds, which are often found in hydrocarbon oils, also were studied (1044). The surface-active compounds interacted with the solid emulsifiers and were related to the stabilization of the emulsion by coagulation structure formation. To determine the optimal HLB of oils, oil-in-water emulsions of castor and paraffin oils were prepared with complex emulsifiers, such as polysorbates and sorbitan esters, in appropriate ratios according to the Griffin formula. The optimum HLB depended upon the concentration of the oil phase (20 or 40%) and was not specific for a certain oil.

The stabilization of pharmaceutical suspensions was evaluated by checking the ζ-potential of suspensions of erythromycin propionate and troleandomycin (1045). Rising concentrations of the dispersed phase led to a reduction of the value of the ζ-potential. Suspensions prepared with surfactant solutions with high HLB values characteristically showed high ζ-potential values. Calcium caproate was studied as an emulsifier in the stabilization of xylene in water emulsions (1046). The effect of inorganic electrolytes on the emulsion flocculation was studied by observing ζ-potentials. The potential barriers and stability of the emulsions were high.

Stabilization of disperse systems by surfactants was studied in relation to the formation of structure and electrostatic repulsion (1047). The oil phase was *o*-xylene. The monomers were styrene and vinyl acetate. The emulsifiers used were the ionized sodium salt of butylnaphthalenesulfonic acid and alkyl benzenesulfonic acid and nonionized polyoxyethylated alkyl phenols and polypropylene oxide. Studies of the emulsions showed that the stabilization was due to

the formation of structure at interfaces. By using phase diagrams, the effects of the polarity of oils and the structure of emulsifier on emulsions stability were studied in oil-in-water formulations (1048). The liquid crystal phases, in particular the lamellar phase, formed from the three components of the emulsion appeared to have definite influence on the stability of emulsions.

Additional references on dispersion stabilization are given in Table XXX.

Rheology—The physicochemical principles involved in rheological measurements were reviewed (1063). The use of instrumentation including the Brookfield viscometer, the Brookfield viscometer with Helipath, the Brookfield plate and cone viscometer, and the Rotovisco viscometer were evaluated. Comparative data were presented for typical lotion, cream, and suspension products as measured with each of these instruments. The practical application of such data to formulations, stability, and processing studies was illustrated.

Sulfonamide drug suspensions were aged for 1 year at room temperature, and their rheological behavior was found to be similar to that of freshly prepared suspensions (1064). Drug content and particle-size distributions of aged and fresh preparations were similar. The data obtained from stability controls were in agreement with predictions based on rheological data. When measurements were made with and without the Helipath stand, the flow curves of bentonite gel, determined at 21°, showed that the area and shape of the hysteresis loop were different, emphasizing the importance of considering the basis and exact way by which rheological values were obtained (1065).

The effects of lemon and rose perfume oils, sodium chloride, and various ethoxylated oleyl and lanolin esters on the viscosity of a standard foam bath were studied (1066). Addition of 4% lemon and rose perfume plus an emulsifier sharply decreased the viscosity, while the rose perfume alone caused inhomogeneity. Sodium chloride increased the viscosity, with a maximum viscosity at ~2% sodium chloride. The suitability of the Hoeppler consistometer for testing ointment consistency was evaluated (1067). The Hoeppler consistometer determination of dynamic viscosity gave absolute values (in centipoises). Davis (1068) reviewed the Weissenberg rheogoniometer and digital transfer function analyzer and found them to be the equipment of choice for studies of mucoid fluids and mucolytic activities. Saliva and gastric mucin were useful in *in vitro* systems for screening mucolytic agents. Bottari (1069) reviewed Newtonian, plastic, pseudoplastic, dilatant, and thixotropic flow instrumental methods for the determination of rheological properties and their applications to cosmetics.

PHARMACEUTICAL ASPECTS

Antibiotics—The solubilities of the sodium and potassium salts of benzylpenicillin were determined in butanol and in butanol containing 0.5–3% water (1075). Also determined was the hygroscopicity of salts. Results of storage at 82.5 and 95.5% relative humidity showed the degradation products formed faster with the sodium salt. Oxytetracycline preparations in propylene glycol were incubated at 50, 60, and 70°, and changes in color and biological activity were measured at certain time intervals (1076). These data were used to calculate a low limit of antibacterial activity after 3.4–3.6 years of 30%. Appearance of an undesirable intense color was predicted after 4.73 years for the propylene glycol solution.

Polysorbate 80 decreased the biological activity of levorine but not that of amphotericin B, when added at 1.6 mg/mg of antibiotic before a 100-hr storage period at 40° (1077). In experiments with *Torula utilis* cultures, the rate of amphotericin B diffusion from ointments containing polysorbate 80 was greater than that from ointments containing lanolin of wool and wax alcohols. Polysorbate 80 also increased the resorption of the antibiotic by the skin of mice. The use of several flocculants and wetting and suspending agents was studied in the development of an oral troleandomycin suspension (1078). The influence of water, dimethyl sulfoxide, propylene glycol, polyeth-

ylene glycol 400, glycerol, and ethanol on the release of tetracycline hydrochloride from white petrolatum was determined and compared with a tetracycline–urea complex (1079). Water was most effective with tetracycline hydrochloride and dimethyl sulfoxide with tetracycline–urea complex.

Bauer (1080) reviewed the formulation of antibiotics including appropriate dosage form, route of administration, and physiological and morphological conditions at the site of resorption. Also important was the nature of the active ingredient such as its chemical, physical, pharmacokinetic, and toxicological properties. The effects of particle size and shape on the flow and failure properties of procaine penicillin powders were studied (1081). The effects of moisture content and gelatin binding agent on the mechanical and failure properties of an oxytetracycline formulation were also evaluated (1082).

Radiopharmaceuticals—The rapid incorporation of short-lived cyclotron-produced radionuclides into radiopharmaceuticals was reported (1083). Production methods were described for two sterile, pyrogen-free preparations of 10-min ^{13}N and were used clinically. It was found that cobalt 60 was a constant contamination of pharmaceutically prepared iron 59. For research studies, where the iron 59 preparation has decayed several half-lives, establishment of the level of cobalt 60 contamination prior to use seems desirable (1084). The chemistry of ^{99m}Tc, used as a tracer in medicine, was discussed; this information might help achieve a better understanding of the use of radiopharmaceuticals containing ^{99m}Tc and a more rapid development of additional useful formulations (1085). The mechanism of labeling of human serum albumin with ^{99m}Tc was also discussed. Sterile ^{43}KCl was prepared from $^{43}CaCl_2$ by neutron bombardment (1086). The chlorides were taken up in tetralithium edetate (Li_4EDTA), lithium hydroxide was added to pH 10, and the salts were separated on an ion-exchange resin (Dowex 50x12Li^+).

Aulagner *et al.* (1087) reviewed the phenomenon of radioactivity, the detection of and protection against ionizing radiation, the application of radiopharmaceuticals to diagnosis and therapy, and the use of preparations obtained from isotopic generators for organ scanning. The method of preparation of albumin labeled with ^{99m}Tc and its application to other radiopharmaceuticals were discussed (1088). Stability studies were made on 4-iodoantipyrine labeled with iodine 131 when mixed with sodium nitrate (1089). The quantity of sodium nitrate required for stabilization depended on the specific activity of the preparation.

The preparation of ^{113}In-SMAA was described (1090). This radiopharmaceutical was free from side effects and was the most appropriate indium compound for lung scintigraphy. A simple laboratory method of preparation of ^{99m}Tc-labeled iron hydroxide aggregates was described (1091). The formulation was used for lung scanning. The development of radiopharmaceuticals for application in the evaluation of diseases of the kidney and urinary tract was reviewed (1092). A portable, external, two-channel radiotelemetrical GM-detector unit, for measurements of radionuclide tracers *in vivo*, was developed (1093). The equipment was suggested for local tracer studies when continuous long-term measurements are needed.

BIOPHARMACEUTICS

The various publications dealing with biopharmaceutics were subdivided according to the area of special interest. However, because of the obvious overlap in subject matter, the reader seeking a thorough review should consider the entire section.

As in previous years, the bioavailability of digoxin attracted the most attention in the field of biopharmaceutics. In a series of five papers, Greenblatt and coworkers evaluated the various aspects of digoxin bioavailability. They recommended intravenous digoxin as a bioavailability standard and found that slow infusion was preferable over rapid injection as an intravenous standard in bioavailability testing (1107). They also evaluated the bioequivalence of digoxin as an elixir and a rapid dissolution tablet (1108). A comparison of 1- and 6-day urinary digoxin excretion in single-dose bioavailability studies was made; 24 hr of urine collection was sufficient for single-dose studies of digoxin bioavailability (1109). The same authors also evaluated the digoxin bioavailability in single-dose studies. They compared the intravenous infusion, intramuscular injection, oral elixir, and oral tablet. The area under the 8-hr serum concentration curve correlated with cumulative urinary excretion but showed greater between subject variation. The intramuscular digoxin and digoxin elixir were significantly more bioavailable than the tablet but not sufficiently absorbed to serve as bioavailability standards (1110).

The bioavailability of digoxin tablets and elixir in the fasting and postprandial states was evaluated. In

the same individual, variations in bioavailability between fasting and postprandial states were similar in magnitude to those after repeated fasting administration. Postprandial administration of digoxin did not significantly alter completeness of absorption but altered the rate (1111). In correlating the plasma levels of digoxin in cardiac patients with dose and measures of renal function, it was found that the readily obtainable parameters did not allow accurate prediction of plasma concentration of digoxin in the individual patient, based on the data collected in a panel of cardiac patients. Therefore, serial measurements of plasma concentration of digoxin were necessary in individual patients taking digoxin (1112). The effect of route of administration on the uptake and elimination of digoxin and the relationship of serum digoxin levels to cardiac arrhythmias were investigated in 15 children with congenital cardiac defects who were receiving maintenance doses of digoxin (1113). The highest serum digoxin concentrations were noted 1 hr after oral and parenteral administration. In the limited number of patients studied, there was no apparent relationship between the serum digoxin level and the onset or persistence of cardiac arrhythmias.

Shaw (1114) evaluated the various digoxin tablets marketed in the United Kingdom. He found that they differed markedly in the fraction of the dose adsorbed. Hazards to the patient were not entirely avoided by brand name prescribing, and it was suggested that new pharmacopeial standards were needed for uniform potency. The bioavailability characteristics of a rapidly dissolving digoxin–hydroquinone complex were evaluated, and the complex was found to be faster dissolving than digoxin alone (1115). Four commercially available digoxin tablet brands were characterized by determination of dose uniformity, dissolution rate of digoxin, and tablet disintegration time (1116). Large differences in the dissolution rate of digoxin were observed. Two batches of one brand were found to have a low dose uniformity, whereas the others were well within the pharmacopeial limits.

The comparative bioavailability of two oral preparations of digoxin in healthy volunteers was investigated (1117). They showed no differences with respect to disintegration time, content uniformity, peak serum levels, and cumulative areas under the curve for 8 hr after oral administration of 0.25-mg doses to healthy subjects. Evaluation of pharmacological response intensities showed evidence for variable digoxin absorption (1118). Ball milling or Muller milling digoxin with a 20-fold excess of lactose, sucrose, dibasic calcium phosphate, or microcrystalline cellulose significantly enhanced its dissolution rate (1119). Tablets prepared with such triturations also exhibited superior rates of dissolution. Those prepared with the digoxin–lactose trituration gave plasma levels in rats that were 89.6% of the values from an oral solution of digoxin.

A method was described for the reduction of digitalis glycoside intoxication by rational dosing procedures (1120). Variations in digoxin bioavailability also were evaluated by mean serum digoxin levels obtained 0–6 hr after oral administration of 0.5-mg digoxin tablets (1121). There was a twofold difference in the mean serum peak concentration and the urinary excretion of the two brands studied. Low serum digoxin levels were found in eight institutionalized patients with congestive heart failure despite daily administration, in standard dosage, of a digoxin preparation for 4 weeks (1122). All eight patients developed serum levels within the accepted therapeutic range after receiving another digoxin preparation for 1 week. Analysis revealed that the first preparation did not meet USP requirements of content uniformity. *In vitro* testing demonstrated marked differences in dissolution characteristics between preparations.

Relative bioavailabilities of commercial digoxin tablets were investigated, using a digoxin elixir (Lanoxin) as the most available oral dosage form (1123). Bioavailability of digoxin tablets was calculated from the 0–12- and 0–24-hr areas under the serum level–time curve and from 48-hr cumulative urinary excretion data. Results obtained by the three different methods of calculation were in agreement with each other. Digoxin was reproducibly absorbed from the elixir, as shown by relatively small intrasubject and intersubject variations.

Bioavailability of 14 nitrofurantoin products was evaluated *in vitro* and *in vivo* (1124). All products tested met USP XVIII specifications for drug content, disintegration time, and dissolution rate. Statistically significant differences were observed in bioavailability, as determined from crossover urinary excretion studies in 14 human volunteers. Bioequivalency of generic and brand name chlorpromazine was evaluated (1125). Because of consistent similarities between generic and brand name chlorpromazine for the wide ranges of dimensions evaluated, it was concluded that the two compounds were bioequivalent.

A four-way crossover study was performed to establish the bioavailability of phenytoin (diphenylhydantoin) (1126). Single 100-mg doses of phenytoin sodium were administered as an aqueous solution and compared with a new phenytoin 100-mg capsule and a commercially available 100-mg capsule. Phenytoin capsules from both manufacturers gave plasma levels that were not significantly different at any sampling time. Although phenytoin in solution form was absorbed more rapidly, higher initial plasma levels were produced with the solution form. Plasma level curves of oral doses of naproxen ranging from 125 to 900 mg were studied in normal subjects (1127). Areas under plasma concentration–time curves increased linearly with dose increments up to 500 mg twice a day, but larger doses resulted in a plateau effect. Experiments with tritium-labeled naproxen showed that there was no difference in the fraction of drug excreted in the stools whether the dose was 250 or 900 mg, eliminating incomplete absorption as a factor. Accelerated renal clearance at high doses because of disproportionate increases in the amount of unbound drug appeared to be the most likely explanation for the plateau effect.

The disposition of propoxyphene and its major

biotransformation product norpropoxyphene was studied in normal subjects following a single 130-mg oral dose (1128). The peak plasma level of propoxyphene occurred at 2 hr, followed by a rapid elimination with an average apparent half-life of 3 hr. The plasma level of norpropoxyphene reached a peak at 4 hr and slowly decayed with an apparent half-life of 16.8 hr. The data indicated that individual differences in absorption and biotransformation may have been responsible for the substantial variation of the plasma propoxyphene levels seen in subjects receiving the same dose.

A single-dose, crossover, comparative study of 25- and 100-mg spironolactone tablets was undertaken in 39 healthy males (1129). Following a total dose of 200 mg of each dosage form, the primary discriminators for comparing the two dosage forms were found to be the plasma metabolite levels at 3 and 4 hr, peak plasma metabolite level, and total 24-hr area under the plasma level curve. Total serum iodine levels were measured for 24 hr in human subjects following a single, oral, therapeutic dose of organically bound iodine administered as iodinated glycerol (1130). Peak levels were obtained 1–2 hr after administration of a single dose, with a gradual fall to almost basal levels at 24 hr. The experiment with continued dosing for 6 days indicated that once peak blood levels were reached, they continued at this concentration until the drug was discontinued.

The concentration of theophylline in the plasma and saliva of seven normal adults receiving single oral doses of 200-mg theophylline/m^2 of body surface area was determined spectrophotometrically over 8 hr (1131). There was an excellent linear relationship between theophylline concentrations in plasma and saliva over a plasma concentration range of 4–14 μg/ml. The results suggested that theophylline determination in saliva may be a convenient, painless, and noninvasive method for routine monitoring of theophylline levels. To determine bioavailability of theophylline in a new sustained-release form, plasma drug concentration–time curves were determined for five normal male subjects after an intravenous dose of 4 mg/kg and after an oral dose of 700 mg as two oral tablets (1132). The absolute bioavailability of the oral dosage was 77.1 ± 5.4%.

Chrai (1133) studied the influence of precorneal factors on the bioavailability of topically applied drugs. Urinary excretion data were used to determine the bioavailability of crystal forms II and III of sulfameter in humans (1134). Agreement was observed between the ratio of absorption parameters of the two forms determined in the present study and those previously obtained from blood level data. Although the urinary data revealed a significant difference in the rate of absorption of the two forms, no significant difference was observed in the extent of absorption of both forms as indicated by the 72-hr urinary excretion data.

The *in vivo* dissolution rates of prednisolone from five commercially available 5-mg prednisolone tablets were determined in distilled water (1135). A two-way crossover bioavailability study was also preformed in 12 human male adult volunteers, comparing the fastest and the slowest dissolving brands. Statistical analysis of the data for the two brands showed no significant differences between average plasma levels of prednisolone at any sampling time. The results suggested that on the average the *in vivo* rates of dissolution of the two brands were essentially the same. Wagner and Johnson (1136) reviewed the relationship between the rate of drug dissolution *in vitro* and biological availability and suggested that the dissolution rate may be the rate-limiting step in drug absorption, hence limiting its bioavailability from solid dosage forms. Correlation of *in vitro* dissolution measurements with *in vivo* parameters makes it easier to control the factor of bioavailability.

A modified *in vitro* permeability technique permitted the hydration of the stratum corneum to be maintained very close to its natural state (1137). Penetrant molecules were applied by adding a few microliters of acetone solution to the stratum corneum surface. The acetone quickly evaporated, leaving a residue of solid penetrant. The time course of penetration of the solid material through the epidermis was observed as a function of applied dose, mild hydration, and solvent contact time. Remarkedly steady and uniform penetration persisting over several weeks was observed. Diffusion through the stratum corneum rather than sorption of the solid at the surface appeared to be rate limiting.

The development and evaluation of ointment and cream vehicles for a new topical steroid, flucloronide (fluclorolone acetonide), were described (1138). Enhanced drug release and superior vasoconstrictor activity were demonstrated by flucloronide when prepared in vehicles in which it was entirely solubilized. A gel or cream base containing 0.025% betamethasone benzoate was a suitable formulation for topical treatment of steroid responsive dermatoses in comparison with other steroids (1139). The cream was significantly less efficacious than the gel. Percutaneous absorption of escin-^{3}H in mice and rats was studied (1140). A horizontal diffusion was observed in the skin of mice. Only small amounts of escin were found in inner organs, bile, and urine. Higher escin concentrations were detected only in the part of the muscular system beneath the site of application.

Additional references on biopharmaceutics are listed in Table XXXIII.

Effects of Physicochemical Properties—Microcrystals of aspirin of 100 × 25 × 2-μm size, given orally to volunteers, were excreted in urine more rapidly than aspirin crystals of 1000 × 300 × 250-μm size (1191). Apparently, smaller crystals were more readily absorbed by the digestive tract than were larger ones. The influence of three granulometric fractions of aspirin on rectal absorption in rabbits was examined (1192). Particle size of the drug influenced the absorption, as had been established for GI absorption of drugs. A correlation between dissolution rate and release of the drug from suppositories was established. The particle-size effect of sulfathiazole on availability after subcutaneous administration was evaluated (1193). The particle size influenced the absorption and dissolution rates when sulfathiazole was administered as aqueous suspensions subcutaneously.

Structure–activity relationships of some organic hydroxy acids with reference to their choleretic activity were studied (1194). Of the nine hydroxy acids tested, 3,4-dimethoxycinnamic acid was the most potent choleretic. Acids that possessed an unsaturated carbon–carbon bond and a methoxy group possessed a stronger action, and acids that contained a free hydroxy group possessed a weak action. A study was made to determine the relationship between the structure of phenylalkylamines and their psychotomimetic activity (1195). Optimum activity was associated with: *(a)* an isopropylamine side chain, with a *R*-(−) configuration at the carbon atom alpha to the amino group; and *(b)* 2,5-dimethoxy substitution, together with an alkyl or halo group at position 4, which is probably limited in bulk to *n*-propyl or bromo.

The anticancer activities of some dihydrofolate reductase-inhibiting 2,4-diaminopyrimidine derivatives, solapalmitine-related *N*-acylamines, bis(1-aziridinyl) phosphinyl carbamate derivatives, and aromatic nitrogen mustards were correlated with substituent constants (1196). For the 2,4-diaminopyrimidines, activity correlated with Taft's steric constants for substituents in the 5-position, demonstrating that anticancer activity in these compounds was related to the steric bulk of the 5-substituent. The carbonic anhydrase inhibitory activities of 17 sulfonamides were compared with their structures, based on quantum chemical calculations performed within the framework of the extended Hückel theory (1197). Correlations were found between the activity of molecules and the reduced Mulliken overlap populations relative to the SO_2 group. Screening of 300 chalcone, flavanone, flavone, flavonol, and acetophenone derivatives showed that 44 compounds had hypotensive, analgesic, anti-inflammatory, antithrombic, sedative, or antifungal activity (1198). Halosubstituted flavones were more active than corresponding flavanones, but all flavanone derivatives were inactive, suggesting that pharmacological activity was dependent on the presence or absence of a double bond in the 2–3 position.

Based on the theory of quantum statistics, a method was developed for the correlation of drug action and chemical structure (1199). It was applied to the interaction of distinguishable biological receptors and in distinguishable drug molecules. Calculations for several local anesthetic drugs illustrated the usefulness of the method. A Hansch analysis of the anabolic activities in the rat of butyrate to undecanoate normal fatty acid ester of nandrolone was made (1200). Two peaks of activity were observed in plots of organ weight against time for each ester and were assigned to release into the blood from the site injection and from body fat, respectively. Anabolic activities were measured as an increase in weight of levator ani over control weight, multiplied by duration of response. A binomial relationship was obtained between log anabolic activity and the log ethyl oleate–water distribution coefficient. Kasuya (1201) studied the structure–activity relationships of androgens and evaluated the metabolism and target organ uptake of the various compounds.

An aqueous suspension of ampicillin, when compared to ampicillin sodium, yielded a higher and longer lasting blood level and was eliminated less in urine (1202). The bile concentration was two to three times higher than the blood level in rabbits injected with ampicillin intramuscularly. The bioavailability of aminosalicylic acid and its sodium, potassium, and calcium salts was evaluated in humans (1203, 1204). Absorption of aminosalicylic acid and its three salts was essentially complete. Dissolution of aminosalicylic acid appeared to be the rate-limiting factor in its absorption, and the type of salt administered affected the rate of absorption. Although absorption of all four compounds was complete, the areas under the plasma concentration–time curve, or bioavailable drug, were dependent on the rate of absorption. The data presented showed evidence of rate-limited metabolism, especially in the first pass.

Additional studies on the effects of physicochemical properties are listed in Table XXXIV.

Effects of Formulation—The effects of formulations in various digoxin preparations were evaluated. Binnion (1236) studied tablets from four different manufacturers and found that the disintegration times for these tablets were different and did not correlate with the plasma levels in subjects who took them. The tablet with the slowest disintegration rate produced satisfactory plasma digoxin concentrations. Another tablet, with slow dissolution rate, failed consistently to produce a therapeutic plasma level. The author recommended that all packages containing digoxin tablets should be labeled with data on their dissolution characteristics but that none should be sold unless these data are consistent with biological availability. Also the *in vitro* dissolution was correlated with bioavailability of various oral digoxin preparations (1237). Plasma concentrations were measured by radioimmunoassay. For rapidly releasing preparations, the dissolution rate did not control absorption. Absorption from slowly releasing tablets was reduced but only partially controlled by dissolution rate.

By using various methods of estimating digoxin absorption, the absolute bioavailability of 0.25-mg digoxin tablets was found to be 62%, and an equivalent dose of digoxin solution was determined to be 77% (1238). Of the various methods studied, the urinary excretion of digoxin was the most valid measure of bioavailability of oral digoxin preparations. The bioavailability and dissolution properties of two commercial digoxin tablets and an elixir were evaluated (1239). The elixir form gave much higher blood levels than either tablet during the first two sampling

times, but the two tablets showed nearly identical blood levels and relative bioavailabilities. A previously reported dissolution rate test method showed wide differences between the two tablets and thus failed to correlate with the similar bioavailabilities observed *in vivo*.

The *Federal Register*, for the first time, reported some guidelines for marketing oral digoxin tablets (1240). It was proposed that digoxin tablets be withheld from distribution until released by the Food and Drug Administration after testing to meet USP XVIII requirements and dissolution tests and that the quantity of digoxin dissolved in 1 hr should not be more than 95% of the assayed amount or that the quantity dissolved at 15 min should not be more than 90% of that assayed amount.

The effect of (−)-Δ^9-*trans*-tetrahydrocannabinol was studied in mice following four routes of administration: oral, subcutaneous, intraperitoneal, and intravenous (1241). For each route, four different vehicles were used: bovine serum albumin, polysorbate 80, polyvinylpyrrolidone, and propylene glycol. The anticonvulsant activity of the parent drug was strongest in the propylene glycol vehicle with subcutaneous and intraperitoneal routes and equal in the propylene glycol and polyvinylpyrrolidone vehicles with the oral route. With these three routes, bovine serum albumin and saline appeared to be inadequate vehicles for studying the anticonvulsant activity of (−)-Δ^9-*trans*-tetrahydrocannabinol.

A correlation between the ear temperature-lowering effect and blood level was investigated in rabbits and dogs after oral administration of two different dosage forms of ethylphenylephrine: an uncoated tablet, which showed a rapid dissolution rate *in vitro*, and a sustained-release capsule, which showed a gradual dissolution rate (1242). Absorption of the drug from the uncoated tablet was more rapid than from the sustained-release capsule. Plasma concentration and urinary excretion of proxyphylline were studied in healthy volunteers after the administration of the drug intravenously and orally as ordinary tablets and slow release tablets of the insoluble matrix type (1243). The rate of absorption from the slow release tablets was limited by the dissolution from the tablets, and the *in vitro* release agreed closely with the calculated absorption. Administration of slow release tablets twice a day for 5 days gave about the same plasma levels as ordinary tablets given three times a day, and the bioavailability was the same from both preparations.

A competitive protein-binding method was used to evaluate two prednisolone preparations: a conventional form and an enteric-coated formulation (1244). Except for the delay due to the coating, they were completely comparable, since maximum levels reached, areas under plasma concentration–time curves, and apparent disappearance half-lives were almost identical. Diethylpropion 25-mg capsules and 75-mg sustained-release tablets were tested in humans under acidic conditions, and the results compared with those obtained previously after administration of the drug in aqueous solution (1245). The bioavailabilities were comparable in each case, and the metabolic fate of the drug was not modified by these pharmaceutical formulations. Under conditions of uncontrolled urinary pH, the recoveries of diethylpropion and all basic metabolites except norepinephrine were greatly reduced.

The dissolution rates of oxyphenbutazone in two commercial samples of sugar-coated tablets and one soft gelatin capsule were determined (1246). Clinical trials to compare tolerance indicated that the soft gelatin capsules led to less complaints of gastric irritation. The bioavailability of two experimental ampicillin capsule formulations was greater than 85% of the standard product, indicating that the processes involved in the manufacture of these formulations (dry granulation *versus* direct encapsulation) had little influence on ampicillin systemic availability (1247). In two test panels of 10 subjects each, plasma levels and urinary excretion of two drugs, acetaminophen and nitrofurantoin, were measured to compare bioavailability when the drugs were formulated as commercial tablets and as specially formulated gelatin capsules (1248). No significant differences in the relative efficiency of absorption were obtained between tablets and capsules with either drug.

Pagay and coworkers (1249, 1250) studied the rectal absorption of acetaminophen from an aqueous solution and from several polyethylene glycol base dosage forms. A relationship was observed between acetaminophen bioavailability and the dielectric properties of the vehicles utilized. The *in vitro* dissolution

rates of acetaminophen in these dosage forms were also studied and were somewhat related to the time of occurrence of the maximum urinary excretion rate.

Additional references on effects of formulation are found in Table XXXV.

Absorption Control and Alteration—Segre *et al.* (1271) studied the pharmacokinetic interactions between aspirin and other nonsteroidal anti-inflammatory drugs including naproxen. The results showed that simultaneous oral administration of aspirin and naproxen in humans resulted in a small, but statistically significant, lowering of plasma levels of naproxen. This effect was not mediated by competition for drug absorption but was associated with enhanced renal clearance of naproxen or its metabolites. The bioavailability of digoxin was evaluated in the presence of antacids containing magnesium trisilicate (1272). The results indicated that antacids may impair the bioavailability of the drug.

The effects of 1,25-dihydroxycholecalciferol on calcium absorption, muscle weakness, and bone disease in chronic renal failure was investigated (1273). 1,25-Dihydroxycholecalciferol given for 4–8 days increased intestinal calcium absorption without causing large changes in plasma calcium or phosphate. Effects of caffeine on the absorption and analgesic efficacy of acetaminophen (paracetamol) were studied in rats (1274). There was a dose-dependent decrease in the GI absorption of acetaminophen. The administration of aluminum hydroxide gel delayed and depressed the GI absorption of isoniazid in rats and patients with active tuberculosis, whereas magaldrate had less pronounced and more variable effects (1275). The depressed absorption of isoniazid was probably related to delayed gastric emptying as a result of the presence of Al^{+3} in the stomach.

Tetracycline in aqueous solution containing 50 mg of iron caused an ~80 and ~65% inhibition of iron absorption in subjects with normal iron stores or depleted iron stores, respectively, by complex formation (1276). This effect was decreased when tetracycline was given before and iron was given after the meals. The effects of potassium ion on the intramuscular absorption of some anionic drugs were examined using the rat thigh muscle clearance method (1277). In the presence of potassium ion, a specific and reversible inhibition was noted in the absorption of anionic drugs such as isonicotinic acid, aminobenzoic acid, and sulfa drugs. The effect of ethanol on intestinal absorption of theophylline was evaluated (1278). Theophylline absorption was significantly increased by 5% ethanol and was decreased by 20% ethanol.

The effect of salicylic acid on antibacterial activity and distribution of sulfadimethoxine was studied in rabbits (1279). The antibacterial activity of sulfadimethoxine following intravenous administration of sulfadimethoxine was significantly increased by the concurrent administration of salicylic acid. The effects of the polysorbates on the intramuscular absorption of the water-soluble, micelle-free drugs were investigated in the rat (1280). The presence of a low concentration of the polysorbates caused a pronounced decrease in the absorption rates of drugs, and the reduction was reflected in their plasma levels. Absorption rates of the drug in the muscle were dependent on the concentration rather than the absolute amount of the surfactant. The GI absorption of 1% phenobarbital or phenobarbital sodium, administered orally to rats, was enhanced by polysor-

bate 80 and sodium lauryl sulfonate, especially at doses lower than the CMC, and was depressed by polyvinylpyrrolidone and methylcellulose (1281).

The effect of polysorbate 80 on the intestinal absorption of nine micelle-free drugs was examined in the rat (1282). Regardless of the ionic nature of the compounds, two levels of the effect were observed, namely an absorption-enhancing effect at a relatively low concentration range and a small inhibitory effect at high concentrations of the surfactant. The effects of surfactants on absorption through membranes were studied (1283). Pentobarbital absorption was enhanced in the goldfish by dioctyl sodium sulfosuccinate and poloxalene.

A prodrug approach to the enhancement of the rate of dissolution of allopurinol was studied (1284). These prodrugs had lower melting points, higher solubilities, and, consequently, greater rates of dissolution than did allopurinol. The prodrug concept was reviewed as a method of overcoming pharmaceutical problems (1285). The effect of food intake and sleep on the absorption of acetaminophen was studied (1286). The rate of absorption of acetaminophen was found to be more rapid in human subjects under fasting conditions than when it was given immediately following food. Differences in absorption rate were confirmed by the excretion rate, but the overall elimination of drug was not affected by urine flow nor was it altered during the sleep period.

The effect of food on the absorption characteristics of nitrofurantoin from a commercial capsule dosage form containing macrocrystalline drug and a commercial tablet dosage form containing microcrystalline drug was assessed in human subjects by a urinary excretion method (1287). In fasting subjects, less nitrofurantoin was absorbed and at a slower rate; lower body levels were obtained when the capsule rather than the tablet dosage form was orally administered. When each was administered with food, the absorption of nitrofurantoin was appreciably delayed. Food in the GI tract produced an increase in the peak body levels of nitrofurantoin from the macrocrystalline form.

The effect of fasting on the oral absorption and excretion of sodium salicylate and aspirin was studied in rabbits (1288). The attainment of the maximum blood levels of these drugs in the fasted rabbits was somewhat slower than in the nonfasted rabbits. However, the extents of absorption were the same in the fasted rabbits as in the nonfasted rabbits. The peak serum levels of amoxicillin and ampicillin were detected 2 hr after oral administration of 500 mg of either drug to a nonfasting subject, the peak values being 5.9 and 2.1 μg/ml, respectively (1289). In contrast, the peak serum level of amoxicillin was found at 3 hr after an oral dose of amoxicillin plus probenecid.

Additional references on absorption control and alteration are listed in Table XXXVI.

Absorption Mechanisms—The effects of surfactants, such as sodium glycocholate, on the absorption and metabolism of the model compounds *O*-benzoylthiamine disulfide and thiamine disulfide were evaluated by both *in situ* and *in vivo* experiments using rats (1323). The *in situ* results indicated that, in the presence of a biosurfactant, the increasing or decreasing effect of a synthetic surfactant on drug absorption and metabolism could be canceled by the possible formation of new mixed micelles consisting of the drug and both surfactants. Results were confirmed by oral experiments using the drug–micellar solution in rats. Based on *in vitro* and *in vivo* studies in rats, it was established that α-tocopherol deficiency affected the passive absorption of barbital, phenol red, and salicylate, probably by altering the GI membrane (1324).

Bromphenol blue and *p*-acetylaminohippuric acid were studied with rats to understand the basic principles of the hepatobiliary transport process (1325). The results suggested that these organic anions were transported from blood into bile by at least two processes (hepatic uptake and biliary excretion) and that the hepatic uptake of these compounds was mainly due to the binding to substances in the liver cells. Atropine sulfate, when recirculated through the rat intestine *in vivo*, was absorbed as a function of pH but not concentration (1326). Similar results were observed when atropine sulfate was instilled in rat intestinal loops for 30–120 min. Thus, atropine did not inhibit its own absorption in the intestine, where the blood vessels are not supplied with cholinergic vasodilators. The difference in absorption at different pH's might indicate that the diffusion of the drug was dependent on the degree of its ionization.

The effects of altered urinary pH on the renal excretion of doxycycline were studied in humans (1327). Alkalinization of the urine resulted in higher cumulative amounts of doxycycline excretion during both single- and multiple-dose regimens. The increased excretion was reflected in larger renal clearances and shorter half-lives for both regimens when the alkaline condition was compared to the control condition. A model was developed to study the GI absorption of drugs and dosage forms in the unanesthetized rhesus monkey (1328). The absorption of an ionizable acidic drug, an ionizable basic drug, and a nonionized drug from the stomach and the intestines was compared. The nonionized form of the drug was

absorbed faster than the ionized form at any particular site in the GI tract.

A general physical model was described for the simultaneous active and passive transport of conjugated and unconjugated bile acids from nonmicellar solutions in the ileum (1329). It reduced to the passive absorption mechanism in the duodenum and the jejunum. Theoretical computations indicated that the stagnant water layer may be the rate-determining barrier.

Additional references on absorption mechanisms are listed in Table XXXVII.

PHARMACOKINETICS

A modern view of pharmacokinetics was presented, suggesting that both linear and nonlinear systems must be included (1339). Special attention was given to the equations used to describe nonlinear kinetics, the recognition of nonlinearities, nonlinear models, and the fitting of data. Seven guidelines were presented for use in possible future pharmacokinetic studies involving drug kinetics. After reviewing the present status of pharmacokinetics, the methods for pharmacokinetic analysis were outlined (1340). Special emphasis was given to the determination of drug bioavailability from various dosage forms. Use of pharmacokinetics in determining sites of drug action and in determining a clinical metabolic profile was suggested.

The effect of the route of administration on drug disposition was reviewed (1341). The authors suggested that while the first-pass effect is a fairly generally understood phenomenon in the gross sense, it is not commonly appreciated that the rate at which the drug is delivered to the liver can influence the fraction of the administered dose that reaches the fluids of distribution. The drug molecules being absorbed *via* the hepatic portal vein intermix with previously absorbed drug recycling in the hepatic artery. The concentration of the drug returning *via* the hepatic artery is affected by the volume of distribution of the drug into body tissues.

The importance of tissue distribution in pharmacokinetics was discussed (1342). Mechanisms of drug distribution were summarized, and the differences between intracellular and extracellular pH, active transport system for drugs, distribution of drugs between fat and water in adipose tissue, reversible binding of drugs to phospholipids and to various macromolecules including proteins, nucleic acid, and melanin were presented. Examples were presented of pharmacokinetic analysis which influence the practice or principles of practical therapeutics. The action of the organism on the drug was summarized in terms of pharmacokinetic parameters: absorption, distribution, metabolism, and excretion. These parameters were examined with respect to drug accumulation, relation of pharmacokinetic data to therapeutic effects, saturation phenomena, effect of kidney disease, variation of pharmacokinetic parameters in individual patients due to age, pH of body fluids, and states of wakefulness (1343).

A general consideration of cancer chemotherapy was presented, consisting of a brief description of cell kinetics and some biochemical events (1344). Models of local tissue and cell uptake of drugs were presented, including various diffusion and mass transport steps. The complex interactions of saturable transport, cell binding, and other pharmacokinetic parameters on the concentration levels of methotrexate in rat bone marrow and other tissues were studied.

A simple equation was presented by which the first-order rate constant for drug absorption into the central compartment of any linear mammillary pharmacokinetic model can be calculated (1345). No specific knowledge of the distribution or elimination characteristics of the drug was required. The meaning of clearance for drugs that are exclusively eliminated from a peripheral compartment of a multicompartment mammillary system was examined (1346). The utility of the various pharmacokinetic parameters employed to interpret drug elimination was discussed. Practical pharmacokinetic techniques for drug consultation and evaluation were described (1347). Psychotherapeutic drugs were used as prototypes for illustrating some considerations in pharmacist-generated dosage regimens.

Pooling of Michaelis–Menten equations for models having parallel paths for formation of two or more metabolites was discussed (1348). A theory that explains phenomena exhibited by pooled nonlinear pharmacokinetic systems and equations relating pooled Michaelis–Menten constants (V_p, K_p) to microscopic constants (V_i, K_i) were presented. The suitability of this type of pooling for use in pharmacokinetic modeling was discussed, as was the use of pooling concepts in the design of clinical studies. Ballard (1349) reviewed the effect of temperature on pharmacokinetics. He discussed the effects of body and environmental temperature on human physiological changes and physicochemical properties, absorption, distribution, and metabolism of drugs.

Pharmacokinetic parameters of amikacin and kanamycin were compared in a crossover study using healthy adult male volunteers (1350). Apparent volumes of distribution, serum half-lives, and renal clearance were compared and were found to be virtually identical. The pharmacokinetics of intravenously administered amobarbital and its major metabolite hydroxyamobarbital were studied (1351). The metabolism of amobarbital was a saturable process and largely zero order over the entire dose range studied.

Pharmacokinetic studies in amphetamine-dependent subjects, using large intravenous doses, were undertaken to relate measurable pharmacokinetic parameters to the clinical manifestations of amphetamine abuse (1352). Subjects having an acidic urine exhibited a relatively mild psychosis, while the psychotic symptoms were aggravated in patients with an alkaline urine. Chlorphenesin carbamate serum levels during subchronic administration to normal human volunteers were studied (1353). A one-compartment open model appeared to have predicted adequately the equilibrium serum concentrations of chlorphenesin carbamate.

Analog and digital computing techniques were

used to elucidate the pharmacokinetic parameters involved in the metabolism and excretion of diethylpropion and its metabolites in humans (1354). Rate constants for the various processes were evaluated for the complex reaction scheme. The values of the rate constants were used as the basis for discussion of the relative importance of some metabolic routes.

Several papers were presented on the pharmacokinetics of digoxin. During chronic therapy with 0.25 mg of digoxin, mean plasma digoxin levels measured by radioimmunoassay were 0.7 ng/ml and the daily urine excretion of digoxin was about 44% of the daily given dose (1355). When the levels of orally given 0.25-mg digoxin tablets were measured by peak serum digoxin concentration as well as by area under serum digoxin concentration–time curve, the bioavailability of digoxin appeared to be higher in the fasted subjects than in fed ones (1356). After intravenous administration, the pharmacokinetics of digoxin were described by a two-compartment open model. Digoxin was strongly distributed to tissues, as reflected by a mean ratio of k_{el}/B = 9.24 and an average volume of distribution at steady state of 5.95 liters/kg (1357).

Pharmacokinetic design of digoxin dosage regimens in relation to renal function was studied (1358). Calculation of a dosage schedule to produce predetermined steady-state serum concentrations of digoxin was dependent on four major variables: bioavailability, biotransformation rate constant, renal clearance, and apparent volume of distribution. Loading and maintenance doses of digoxin in patients of normal renal function and those with severely impaired renal function were studied (1359). It was found that loading doses for patients with severely impaired renal function should be half those for patients with normal renal function.

A dose–effect curve constructed from ventricular rate slowing and oral maintenance doses for digoxin provided evidence for assuming that occupation theory correctly described drug–receptor site interaction (1360). The influence of allopurinol on drug metabolism was studied in humans. Its administration in conjunction with the anticoagulant warfarin did not alter their dose requirements (1361).

Furosemide, as tablets or aqueous solution, was taken orally by normal subjects during a fast and postprandially (1362). Comparative studies were conducted using intravenous furosemide. No significant differences were found between the tablets and the aqueous solution. During fasting, detectable drug levels appeared in the serum within 10 min. The postprandial studies displayed delayed appearance and low peak serum concentration. Salivary and urinary excretion of lithium was studied in three healthy male subjects after oral administration of two or three different doses (1363). In all individuals, the concentration of lithium in the salivary fluid was 2.2–3.3 times as high as the concentration in plasma. Thus, once the saliva–plasma concentration ratio is established, the measurement of saliva concentrations can provide all of the pharmacokinetic information necessary for rational dosage regimens.

Serum levels of methaqualone were determined in eight unfasted subjects following single- and multiple-dose administration (1364). The data were analyzed by a two-compartment open model. The significance of pharmacokinetic parameters in relation to bioavailability and the biological disposition of single- and multiple-dose methaqualone administration was discussed. Acetaminophen (paracetamol) was administered intraperitoneally or intravenously to male rats (1365). Its availability in the systemic circulation after intraperitoneal administration was 34% of that after intravenous administration. This finding suggested a high first-pass metabolism of intraperitoneally administered drug, which was confirmed using the rat isolated perfused liver.

The absorption of orally administered pivampicillin, an ester that hydrolyzes to ampicillin *in vivo*, was studied in healthy males and compared to ampicillin administered intravenously, intramuscularly, and orally (1366). Renal clearances and serum half-lives for pivampicillin were the same as those for ampicillin. The clinical efficacy, tolerance, and pharmacokinetics of a new aminoglycoside antibiotic, sisomicin, were studied in elderly male patients suffering from complicated urinary tract infections (1367). After intramuscular injection, serum levels of the antibiotic declined, with a half-life of about 3 hr after the initial dose. The pharmacokinetics of thiothixene was studied in psychotic patients on long-term therapy (1368). Drug plasma concentrations reached an early peak following an oral dose and declined slowly thereafter. Despite considerable differences in doses, peak plasma concentrations fell within a relatively narrow range, indicating that, during earlier adjustments of dose to achieve therapeutic control, optimum plasma concentrations were also being achieved.

Matin *et al.* (1369) studied the pharmacokinetics of tolbutamide and found a good linear relationship between tolbutamide concentration in saliva and plasma; salivary levels were 1.2% of plasma levels. The pharmacokinetics and pharmacodynamics of enantiomers of warfarin were studied in humans (1370). In nine subjects, the plasma half-life of *R*-warfarin after a single oral dose was significantly longer than that of *S*-warfarin. Similar pharmacokinetic studies on the warfarin enantiomers were conducted with rats (1371).

There has been a new stress on determining the various pharmacokinetic parameters of different drugs used during the diseased state. Jackson and McLeod (1372, 1373) discussed the dosing concentration of antimicrobial agents when used in patients with renal impairment. They discussed the pharmacokinetics of the following drugs: bacitracin, chloramphenicol, chloroquine, clindamycin, dapsone, erythromycin, lincomycin, neomycin, vancomycin, the urinary tract anti-infectives, sulfonamides, and trimethoprim.

The pharmacokinetics of cefazolin were studied in normal and uremic patients after single and multiple intramuscular doses (1374). In normal subjects, cefazolin gave maximum serum concentrations of 30–50

μg/ml 1 hr after a single 500-mg injection, with a serum half-life of about 2 hr. Higher serum levels were obtained after identical doses to uremic subjects, and serum half-lives increased with decreasing renal function. Also studied were the pharmacokinetics of cefazolin in the presence of normal and impaired renal functions (1375). The mean serum half-life of cefazolin sodium was 1.6 hr in normal patients and about 42 hr in patients with impaired renal function.

The pharmacokinetics of furosemide in normal subjects and functionally anephric patients were studied (1376). The plasma half-life was increased from 29.5 min in normal patients to 80.7 min in anephric patients. The pharmacokinetics of furosemide in advanced renal failure, where the renal furosemide clearance was reduced (1377), were also discussed. The anticoagulant half-life of heparin in human subjects with normal and impaired renal functions was studied (1378, 1379). The anticoagulant half-life of heparin was found to be dose related. The normal renal function group gave a mean anticoagulant half-life of 36.8 min for the 0.6-unit/ml dose and 22.7 min for the 0.3-unit/ml dose. The chronic renal failure population had a mean half-life of 47.5 min for the 0.6-unit/ml dose and a mean half-life of 32.6 min for the 0.3-unit/ml dose.

The pharmacokinetics of metolazone were studied in normal adult volunteers after oral or intravenous administration and after oral administration in patients requiring diuretic therapy for severe renal failure, for moderate renal failure, and for heart disease (1380). Clearance of metolazone from the central compartment was approximately equal to creatinine clearance and ranged from 110 ml/min in normal subjects to 20 ml/min in severe renal failure. The absorption was 64% in normal controls, but as little as 40% of the oral dose was absorbed in some patients. The plasma half-life of phenylbutazone in patients with impaired liver function was studied (1381). Preliminary evidence was presented for a significant correlation between the apparent elimination rate constant of phenylbutazone and the galactose elimination capacity in cirrhotic patients.

Eight volunteers with normal renal function and 11 patients with chronic renal insufficiency were each given propranolol while in the fasting state (1382). Absorption was rapid in both groups. In the patients, propranolol appeared in the serum within 0.5 hr of oral administration and maximum concentrations, with a mean of 154.6 ng/ml, appeared in 1.5 hr; in the control group, maximal concentrations, with a mean of 51.1 ng/ml, developed in 2 hr. The pharmacokinetics of the antibacterial combination sulfamethoxazole and trimethoprim in patients with normal or impaired kidney function were studied (1383). Following oral administration, the elimination rate of sulfamethoxazole and, to a lesser extent, trimethoprim was decreased by renal impairment. Also studied were the pharmacokinetics of 4,5-bis(*p*-methoxyphenyl)-2-phenylpyrrole-3-acetonitrile in normal and polyarthritic rats (1384).

1425	Absorption, distribution, and excretion of 8-chloro-6-phenyl-4*H*-*s*-triazolo(4,3-*a*)(1,4)-benzodiazepine in rats
1426	Species differences in metabolism of 8-chloro-6-phenyl-4*H*-*s*-triazolo(4,3-*a*)(1,4)benzodiazepine
1427	Multicompartmental analyses of bi- and triexponential plasma disappearance curves after intravenous injection of ^{14}C-cholic acid, sulfobromophthalein, and ^{14}C-bilirubin, and their significance for quantitative studies of the hepatic excretory function
1428	Distribution and excretion of iodochlorhydroxyquin (clioquinol) in animals
1429	Pharmacokinetics of clonazepam in humans
1430	Pharmacokinetic profiles of clonazepam in dogs and humans and of flunitrazepam in dogs
1431	Comparative pharmacokinetics of coumarin anticoagulants; relationship between distribution, elimination, and anticoagulant action of warfarin
1432	Comparative pharmacokinetics of anticoagulant effect of coumarin drugs in humans and rats
1433	Comparative pharmacokinetics of coumarin anticoagulants; relationship between distribution, elimination, and anticoagulant action of dicumarol
1434	Pharmacokinetics of cyclohexylamine in humans
1435	Distribution of daunomycin and adriamycin in mice
1436	Pharmacokinetics of diatrizoate sodium and iodipamide sodium under hemodialysis
1437	Absorption, excretion, and distribution of 3′,4′-dideoxykanamycin B in rats
1438	Absorption, excretion, and distribution of 3′,4′-dideoxykanamycin B in rabbits and dogs
1439	Pharmacokinetic analysis of 3′,4′-dideoxykanamycin B in pediatric field
1440	Pharmacokinetics of ^{14}C-dimethothiazine
1441	Pharmacokinetics of 4-[3-(dimethylamino)-propylidene]-4,9-dihydrobenzo[*e*]thieno[2,3-*b*]thiepine-10-^{35}S (dithiadene-10-^{35}S)
1442	Metabolic fate of *N*,*N*-dimethyl-*N*′-(*p*-phenoxyphenyl)sulfamide in rats, dogs, and humans
1443	Fate and metabolism of dimethyl sulfoxide
1444	Pharmacokinetic studies of phenytoin (diphenylhydantoin)
1445	Half-life of diphenylpyraline in humans
1446	Diazepam metabolism in normal humans; serum concentrations and clinical effects after intravenous, intramuscular, and oral administration
1447	Diazepam metabolism in normal humans; serum concentration and clinical effect after oral administration and accumulation of diazepam
1448	Pharmacokinetic analysis of 3′,4′-dideoxykanamycin B in humans
1449	Review on pharmacokinetics and bioavailability of digitalis
1450	Absorption, metabolism, and excretion of cromoglycate disodium in nine animal species
1451	Effect of phenobarbital on pharmacokinetics of erythromycin
1452	Pharmacokinetics of fluorocarbon aerosol propellants
1453	Pharmacokinetic studies on flupentixol and flupentixol decanoate in animals and humans
1454	Pharmacokinetics and metabolism of fominoben in humans
1455	Pharmacokinetics of gentamicin in cerebrospinal fluid and eye compartments
1456	Pharmacokinetics of glibornuride
1457	Pharmacokinetics and pharmacodynamics, as well as metabolism, following orally and intravenously administered ^{14}C-glipizide
1458	Pharmacokinetics of glipizide in humans
1459	Pharmacokinetics of radioactively labeled glisoxepide in animals
1460	Pharmacokinetics and metabolic spectrum of glisoxepide in humans
1461	Absorption, distribution, metabolism, and excretion of glycopyrrolate in mice
1462	Pharmacokinetics of glymidine and tolbutamide in acute and chronic liver diseases
1463	Absorption, metabolism, and excretion of ^{14}C-griseofulvin in humans
1464	Absorption and elimination of ^{35}S-gutimine following intraperitoneal administration
1465	Metabolism of heptabarbital (heptabarbitone)
1466	Disposition of hydralazine in humans, and a specific method for its determination in biological fluids
1467	Comparative studies on distribution, excretion, and metabolism of hydroxyzine-^{3}H and its methiodide-^{14}C in rats
1468	Imipramine protein binding and pharmacokinetics in children
1469	Pharmacokinetics of isoniazid in Caucasian race
1470	Pharmacokinetics of isoniazid in humans
1471	Pharmacokinetic and metabolic studies with lanatoside C, α- and β-acetyldigoxin, and digoxin in humans
1472	Pharmacokinetics of levodopa and its metabolites
1473	Hypothesis for rapid attainment and maintenance of lidocaine plasma levels
1474	Pharmacokinetic studies with maprotiline
1475	Pharmacokinetics of menadione and menadione sodium bisulfite in animals
1476	Pharmacokinetic properties of meprobamate in dogs; an example of dose dependency in elimination kinetics
1477	Pharmacokinetic studies after administration of ^{14}C-dipyrone (^{14}C-metamizole) to rats, dogs, and humans
1478	Pharmacokinetics and availability of methanesulfonic acid derivative of dapsone (*p*,*p*′-diaminodiphenylsulfone) in rabbits
1479	Review of pharmacokinetics of methotrexate
1480	Absorption, metabolism, and distribution of ^{14}C-*O*-methyldopa and ^{14}C-levodopa after oral administration to rats
1481	Pharmacokinetics of antimicrobial agent mydecamycin
1482	Pharmacokinetic studies on mydecamycin
1483	Pharmacokinetics of ^{3}H-naftazone in humans
1484	Pharmacokinetics of nalidixic acid: serum and urinary levels with normal renal function
1485	Pharmacokinetics of naloxone
1486	Metabolism of nealbarbital (nealbarbitone)
1487	Absorption of neomycin from alimentary tract of a pig

(continued)

Table XXXVIII—*Continued*

Reference	Topic
1488	Pharmacokinetic and genetic studies of nortriptyline and desipramine in human subjects
1489	Aspects of pharmacokinetics of opiates
1490	Compartmental study on pharmacokinetics of D-penicillamine
1491	Metabolism of D-penicillamine
1492	Pharmacokinetics of dihalo-substituted isoxazolyl penicillins
1493	Pharmacokinetic evaluation of penicillin and cephalosporin derivatives in serum and milk of lactating cows and ewes
1494	Pharmacodynamic and pharmacokinetic study of modern semisynthetic penicillins
1495	Pharmacokinetics of pentazocine and its optical isomers
1496	Analysis of intersubject variation in pentazocine metabolism
1497	Dose and dosage form-dependent pharmacokinetics of phenacetin and its metabolite in humans
1498	Pharmacokinetic studies on 2-phenyl-4-(*p*-chlorophenyl)thiazol-5-ylacetic acid
1499	Urinary metabolites of phylloquinone and α-tocopherol
1500	Metabolism and kinetics of piribedil in humans and rats
1501	Absorption and distribution of 4-prenyl-1,2-diphenyl-3,5-pyrazolidinedione in rats
1502	Excretion of probenecid and its metabolites in bile and urine of rats
1503	Pharmacokinetics of procainamide
1504	Pharmacokinetics as a guideline for procainamide and theophylline dosing regimens
1505	Computerized dosage regimens for procainamide
1506	Pharmacokinetic studies on propanidid
1507	Clinical investigations on pharmacokinetics of propiram-^{14}C fumarate
1508	Chemical study on pharmacokinetics of propiram fumarate
1509	Influence of dose and infusion rate on propranolol bioavailability
1510	Pharmacokinetics of distribution and elimination of sodium di-*n*-propylacetate in mice and dogs
1511	Pharmacokinetic studies on proxyphylline administered intravenously and orally to humans
1512	Pharmacokinetics and tolerance of quinidine sulfate and dihydroquinidine gluconate in horses and dogs
1513	Pharmacokinetic disposition of quinidine in rhesus monkeys
1514	Absorption and clearance of secobarbital, heptabarbital, methaqualone, and ethinamate
1515	Use of a mathematical model of streptomycin pharmacokinetics for providing necessary blood levels under conditions of intravenous infusion
1516	Plasma levels and urinary excretion of K-strophanthoside-^{3}H administered rectally to humans
1517	Pharmacokinetics of sulfadiazine–nitrofurantoin during normal kidney function
1518	Dosage regimens of sulfonamides based on pharmacokinetic parameters
1519	Pharmacokinetic study on metabolism and excretion of sulpyrine in rats
1520	Distribution, excretion, and metabolism of N^1-(2-tetrahydrofuryl)-5-fluorouracil
1521	Pharmacokinetics and metabolism of ^{3}H-thebaine
1522	Pharmacokinetics of thiamphenicol: behavior in acute and chronic hepatic insufficiency
1523	Pharmacokinetics of thiamphenicol: behavior in renal insufficiency under dialysis conditions
1524	Absorption, distribution, excretion, and metabolism of tinidazole
1525	Pharmacokinetic profile of trimethoprim–sulfamethoxazole in humans
1526	Pharmacokinetic studies with trimethoprim and different doses of sulfadiazine in healthy subjects
1527	Absorption and urinary excretion of trimethoprim, sulfamethoxazole, and trimethoprim–sulfamethoxazole
1528	Pharmacokinetics of trimethoprim and sulfamethoxazole in normal subjects and in patients with renal failure
1529	Metabolism of trimethoprim in humans, and measurement of a new metabolite
1530	Excretion of trimethoprim and sulfamethoxazole in patients with renal failure
1531	Similarity of warfarin half-lives in human subjects
1532	Review of pharmacokinetic factors affecting epidermal penetration and percutaneous absorption
1533	Review of pharmacokinetics and dosage regimens
1534	Review of one-compartment open model pharmacokinetics comparing excretion following intravenous administration with and without metabolism
1535	Review of pharmacokinetics of one-compartment open model at constant intravenous infusion and after a single dose
1536	Review of pharmacokinetic and biopharmaceutical fundamentals
1537	Contribution of pharmacokinetics to drug design
1538	Significance of pharmacokinetics in drug therapy
1539	Mathematical aspects of pharmacokinetics and toxicokinetics
1540	Pharmacokinetics in relation to age
1541	Apparent biological half-life values determined by drug administration by methods other than rapid intravenous injection
1542	Mathematical procedures for evaluating pharmacokinetic studies
1543	Dose-dependent drug metabolism during absorptive phase
1544	Pharmacokinetic considerations in clinical drug trials
1545	Pharmacokinetics as foundation for drug therapy
1546	Application of pharmacokinetic principles to elucidation of polygenically controlled differences in drug response
1547	Kinetics of drug–drug interactions
1548	Structural effects in drug distribution using whole animal pharmacokinetics
1549	Statistical estimations in pharmacokinetics
1550	Importance of use of appropriate pharmacokinetic model to analyze *in vivo* enzyme constants
1551	Critical evaluation of use of effective protein fractions in developing pharmacokinetic models for drug distribution
1552	Safe method for rapidly achieving plasma concentration plateaus
1553	Linearity and superposition in pharmacokinetics
1554	Importance of type of dosage form and saturable acetylation in determining bioactivity of aminosalicylic acid
1555	Simulation of blood level of drugs by digital computer
1556	Significance of blood levels of drugs
1557	Design and analysis of comparative blood level trials
1558	Pharmacokinetic consequences of plasma protein binding of drugs

Kinetics and Mechanisms of Degradation of the Antileukemic Agent 5-Azacytidine in Aqueous Solutions

ROBERT E. NOTARI ˣ and JOYCE L. DeYOUNG *

Abstract □ The hydrolytic degradation of 5-azacytidine was studied spectrophotometrically as a function of pH, temperature, and buffer concentration. Loss of drug followed apparent first-order kinetics in the pH region below 3. At pH <1, 5-azacytosine and 5-azauracil were detected; at higher pH values, drug was lost to products which were essentially nonchromophoric if examined in acidic solutions. The apparent first-order rate constants associated with formation of 5-azacytosine and 5-azauracil from 5-azacytidine are reported. Above pH 2.6, first-order plots for drug degradation are biphasic. Apparent first-order rate constants and coefficients for the biexponential equation are given as a function of pH and buffer concentration. A reaction mechanism consistent with the data is discussed together with problems associated with defining the stability of the drug in aqueous solutions. At 50°, the drug exhibited maximum stability at pH 6.5 in dilute phosphate buffer. Similar solutions were stored at 30° to estimate their useful shelflife. Within 80 min, 6×10^{-4} *M* solutions of 5-azacytidine decreased to 90% of original potency based on assumptions related to the proposed mechanisms.

Keyphrases □ 5-Azacytidine—kinetics and mechanisms of degradation in aqueous solutions, effect of pH, temperature, and buffer concentration □ Hydrolysis, 5-azacytidine in aqueous solutions—kinetics and mechanisms, effect of pH, temperature, and buffer concentration □ Antileukemic agents—5-azacytidine, kinetics and mechanisms of degradation in aqueous solutions

The synthesis of 5-azacytidine (I) was reported in 1964 (1). The compound has antimicrobial and antitumor activities (2–4) and is currently being evaluated clinically in the treatment of human leukemias.

The clinical use of this drug makes it desirable to determine kinetic data on its reactivity in aqueous solutions. Such information is especially important in consideration of its relative instability when compared to cytidine itself. Especially notable are the ease with which the triazine ring hydrolyzes and the lability of the sugar–triazine bond (5). Although most hydrolysis products of I have been identified (5), lit-

Kinetics and Mechanisms of Degradation of the Antileukemic Agent 5-Azacytidine in Aqueous Solutions

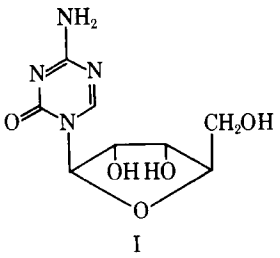
ROBERT E. NOTARI ˣ and JOYCE L. DeYOUNG *

Abstract □ The hydrolytic degradation of 5-azacytidine was studied spectrophotometrically as a function of pH, temperature, and buffer concentration. Loss of drug followed apparent first-order kinetics in the pH region below 3. At pH <1, 5-azacytosine and 5-azauracil were detected; at higher pH values, drug was lost to products which were essentially nonchromophoric if examined in acidic solutions. The apparent first-order rate constants associated with formation of 5-azacytosine and 5-azauracil from 5-azacytidine are reported. Above pH 2.6, first-order plots for drug degradation are biphasic. Apparent first-order rate constants and coefficients for the biexponential equation are given as a function of pH and buffer concentration. A reaction mechanism consistent with the data is discussed together with problems associated with defining the stability of the drug in aqueous solutions. At 50°, the drug exhibited maximum stability at pH 6.5 in dilute phosphate buffer. Similar solutions were stored at 30° to estimate their useful shelflife. Within 80 min, 6×10^{-4} *M* solutions of 5-azacytidine decreased to 90% of original potency based on assumptions related to the proposed mechanisms.

Keyphrases □ 5-Azacytidine—kinetics and mechanisms of degradation in aqueous solutions, effect of pH, temperature, and buffer concentration □ Hydrolysis, 5-azacytidine in aqueous solutions—kinetics and mechanisms, effect of pH, temperature, and buffer concentration □ Antileukemic agents—5-azacytidine, kinetics and mechanisms of degradation in aqueous solutions

The synthesis of 5-azacytidine (I) was reported in 1964 (1). The compound has antimicrobial and antitumor activities (2–4) and is currently being evaluated clinically in the treatment of human leukemias.

The clinical use of this drug makes it desirable to determine kinetic data on its reactivity in aqueous solutions. Such information is especially important in consideration of its relative instability when compared to cytidine itself. Especially notable are the ease with which the triazine ring hydrolyzes and the lability of the sugar–triazine bond (5). Although most hydrolysis products of I have been identified (5), lit-



I

tle has been done concerning the kinetics and mechanism of its degradation.

The purpose of this report is to describe the results of studies on the hydrolysis of I and the related compounds 5-azacytosine (II) and 5-azauracil (III).

EXPERIMENTAL

Analytical Methods—Beer's law plots were constructed for 5-azacytidine, 5-azacytosine, and 5-azauracil in 0.1 *N* HCl using a recording spectrophotometer[1]. Molar absorptivities were 2.36×10^3 for 5-azacytidine at 255 nm; 3.35×10^3, 4.33×10^3, and 5.98×10^3 for 5-azacytosine at 230, 235, and 250 nm, respectively; and 3.67×10^3, 3.80×10^3, and 1.50×10^3 for 5-azauracil at 230, 235, and 250 nm, respectively.

Concentrations of components in mixtures of 5-azacytosine and 5-azauracil were calculated using:

$$10^3[\text{II}] = 0.217A_{250} - 0.088A_{230} \quad \text{(Eq. 1)}$$

$$10^3[\text{III}] = 0.353A_{230} - 0.198A_{250} \quad \text{(Eq. 2)}$$

which were derived from simultaneous equations for total absorbance, *A*, at 230 and 250 nm for mixtures of 5-azacytosine and 5-azauracil in 0.1 *N* HCl. Good agreement was obtained between the results of the assay and the known concentrations in synthetic mixtures.

Mixtures of 5-azacytidine and the two bases were assayed utilizing the differential stability of the components. The absorbance at 255 nm of solutions containing all three components in 0.1 *N* HCl was determined. These solutions were then made 0.05 *N* in sodium hydroxide and allowed to stand at room temperature for 40–50 min. This period was sufficient to degrade 5-azacytidine completely to nonchromophoric products without loss of 5-azacytosine or 5-azauracil. Samples were reacidified with 0.1 *N* HCl, and the absorbances at 235, 250, and 255 nm were determined. The 235- and 250-nm values were used to calculate the concentrations of 5-azacytosine and 5-azauracil:

$$10^3[\text{II}] = 0.234A_{250} - 0.092A_{235} \quad \text{(Eq. 3)}$$

$$10^3[\text{III}] = 0.368A_{235} - 0.267A_{250} \quad \text{(Eq. 4)}$$

After correcting for dilution, the absorbances of the sample before and after treatment with alkali were used to calculate the 5-azacytidine concentration:

$$\text{I} = \Delta A_{255} / \epsilon_{255} \quad \text{(Eq. 5)}$$

This assay method was shown to be satisfactory using synthetic mixtures.

Kinetics of 5-Azacytosine and 5-Azauracil Hydrolysis in Hydrochloric Acid Solutions—Reaction solutions containing 2×10^{-4} *M* 5-azacytosine or 3×10^{-4} *M* 5-azauracil in 0.1 and 0.25 *N* HCl were placed in constant-temperature baths. Samples of the 5-azacytosine reactions were withdrawn as a function of time and assayed for substrate and 5-azauracil as described previously. The spectra of the 5-azauracil reactions decreased with time, with no evidence of formation of a new chromophore. Rate constants for its loss were calculated directly from absorbance data.

Table I—Apparent First-Order Rate Constants (hour^{-1}) for Hydrolysis in Hydrochloric Acid at 70°

Substrate	[HCl], *N*	k_{obs}	k_{23}	k_{25}	k_{36}
5-Azacytosine[a]	0.10	0.376	0.121	0.255	0.0495[b]
	0.25	0.238	0.119	0.119	0.0636[b]
	[HCl], *N*	k_{obs}	k_{12}	k_{13}	k_{14}
5-Azacytidine[c]	0.10	1.98	0.111	0.110	1.77
	0.25	1.05	0.136	0.101	0.810

[a] See Scheme I. Concentration is 2×10^{-4} *M*. [b] Determined from hydrolysis of 5-azauracil (3×10^{-4} *M*). [c] See Scheme II. Concentration is 2×10^{-4} *M*.

TLC of Reaction Solutions of 5-Azacytosine and 5-Azauracil—Samples of the reactions of approximately 0.01 *M* 5-azacytosine and 0.01 *M* 5-azauracil in 0.10 *N* HCl at 70° were taken after about 50 and 100% of the substrate had reacted. These samples were neutralized and spotted along with authentic samples of 5-azacytosine and 5-azauracil on TLC plates coated with 0.25 mm silica gel GF_{254}. The plates were developed in 1-butanol–acetic acid–water (100:10:30) for a distance of about 10 cm, air dried at room temperature, and examined with a shortwave UV lamp.

Kinetics of 5-Azacytidine Hydrolysis in Hydrochloric Acid Solutions—Reaction solutions containing 5-azacytidine in excess hydrochloric acid were prepared as shown in Tables I and II. The absorbance of reactions in solutions less concentrated than 0.1 *N* HCl was determined by diluting aliquots of the reaction with hydrochloric acid to give a final concentration of 0.25 *N* HCl. In these solutions, the UV absorption spectrum of 5-azacytidine decreased with time without the appearance of any new absorbances. Absorbance data were used directly to calculate the apparent first-order rate constants.

In solutions containing 0.1 *N* or stronger hydrochloric acid, there was evidence that a fraction of the 5-azacytidine decomposed to form 5-azacytosine and 5-azauracil. In these cases, the reactions were assayed using the described differential stability method. At 70°, Eqs. 3, 4, and 5 were used to assay for 5-azacytidine, 5-azacytosine, and 5-azauracil, respectively. In the 50° reactions, the differential absorbance due to 5-azacytidine (Eq. 5) was used to calculate the apparent first-order rate constants for loss of substrate.

Kinetics of 5-Azacytidine Hydrolysis in Buffers—Reaction solutions containing 5-azacytidine in excess buffer were prepared as shown in Table III. Solutions were placed in constant-temperature baths; aliquots were removed at appropriate times, chilled, and diluted with an equal volume of hydrochloric acid to give a final concentration of 0.25 *N* HCl. The absorbance of these solutions was measured at 255, 260, and 265 nm. Since absorbance values decreased with time to become zero when the reaction was complete, absorbance data were used directly in the calculation of

Table II—Apparent First-Order Rate Constants for Hydrolysis of 5-Azacytidine[a] at 50° in Hydrochloric Acid

[HCl], *N*	pH[b]	k_{obs}, hr^{-1}
0.80	0.22	0.0595
0.50	0.44	0.0764
0.25	0.73	0.118
0.097	1.12	0.239
0.0097	2.06	1.12
0.005	2.39	1.39

[a] Reactions in 0.80, 0.50, 0.25, and 0.005 *N* HCl contain 4×10^{-4} *M* substrate. Substrate concentration in 0.097 and 0.0097 *N* HCl reactions is 6×10^{-4} *M*. [b] The pH of hydrochloric acid solutions was calculated using activity coefficient values from the literature (6).

[a] See text for explanation of these constants and the method used to calculate them. Average of results for two or three wavelengths. [b] Obtained from intercept of plot of *k versus* buffer concentration. [c] Average of values in presence of buffer. [d] It was not feasible to separate the two phases for analysis. The rate constants given were obtained from the first 17% of the reaction. See text for further details. [e] Reaction appears first order over at least two half-lives.

rate constants. In phosphate buffers of pH 7.6 and 6.5, spectra of nonacidified samples were also obtained. At wavelengths greater than 240 nm, there was eventual loss of the UV absorption spectrum. Absorbance data in this region were used directly for the calculation of rate constants.

In two additional experiments, samples of 5-azacytidine (10^{-2} *M*) were reacted in buffer for a sufficient time to ensure that the initial rapid phase of the reaction was completed. Both reactions were conducted at 70°, one in 0.33 *M* phosphate buffer at pH 7.59 for 10 min and the other in 0.04 *M* phosphate buffer at pH 6.52 for 1 hr. Aliquots from each reaction were added to 10 times their volume of hydrochloric acid at 70° to yield a final reaction condition of 0.1 or 0.25 *N* HCl (Table IV). These reactions were then followed at 70° using the differential assay for 5-azacytidine described earlier (Eq. 5).

Evidence for 5,6-Addition to 5-Azacytidine—The UV spectra of 5-azacytidine and 5-azacytosine were recorded at each of three conditions: 0.1 *N* HCl, 0.001 *N* HCl, and pH 6.5 phosphate buffer. Each solution was then altered to match one of the others so that the sequence represents all possible combinations of the three conditions. Precautions were taken to eliminate any changes in absorbance due to passage of time or dilution of sample. In this way, UV spectra for solutions of authentic samples were compared to those that had been previously prepared and recorded at one or more of the other conditions as described under *Results*.

Solutions of 5-azacytidine (6×10^{-5} *M*) and 5-azacytosine (1.5×10^{-5} *M*) were prepared in 0.025, 0.005, and 0.001 *M* aqueous bisulfite previously adjusted to pH 3.67 ± 0.06. A fourth solution of 5-azacytidine in 0.001 *M* bisulfite containing 0.024 *M* NaCl was also prepared. Immediately after dissolution of the substrate, UV spectra were recorded as a function of time.

Spectrophotometric Determination of pKa Values for 5-Azacytosine—The pH of a solution containing 10^{-4} *M* 5-azacytosine in buffer (0.08 *M* acetic acid–0.008 *M* sodium acetate–0.492 *M* sodium chloride) was measured, and the UV spectrum of the solution was obtained. The pH was then adjusted using hydrochloric acid or sodium hydroxide to obtain a series of spectra ranging from the cationic form of 5-azacytosine to the anionic form. To check for degradation, a sample at high pH was adjusted to a previously obtained lower pH value and the two spectra were compared to show that no irreversible changes had occurred.

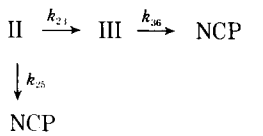
RESULTS

Apparent First-Order Rate Constants in Hydrochloric Acid Solutions—Good first-order plots were obtained when ex-



Scheme I

perimental data were graphed according to:

$$\ln X = \ln X_0 - k_{obs}t \quad \text{(Eq. 6)}$$

where t is time, X is the concentration of unreacted 5-azacytidine or 5-azacytosine, and X_0 is the initial concentration. When appropriate, data were plotted according to:

$$\ln A = \ln A_0 - k_{obs}t \quad \text{(Eq. 7)}$$

where A is the absorbance due to unreacted substrate at 255, 260, or 265 nm for 5-azacytidine or at 230 or 250 nm for 5-azauracil. The apparent first-order rate constants for loss of 5-azacytidine and 5-azacytosine (k_{obs}) and 5-azauracil (k_{36}) are listed in Table I.

TLC of Reaction Solutions of 5-Azacytosine and 5-Azauracil in 0.10 *N* Hydrochloric Acid—The 50 and 100%-reacted samples of 5-azacytosine showed faint spots at the same R_f value as an authentic sample of 5-azauracil. The 100%-reacted sample showed no trace of starting material. The 5-azauracil reaction showed a disappearance of the spot due to the uracil without development of any other compounds absorbing UV light. The R_f values obtained were 0.38 for 5-azacytosine and 0.58 for 5-azauracil.

Kinetics of 5-Azacytosine and 5-Azauracil Hydrolysis in Hydrochloric Acid Solutions—The observed spectral changes during the reactions and the results of the TLC experiments pointed to the applicability of Scheme I to 5-azacytosine hydrolysis. Nonchromophoric products are designated as NCP. A value for k_{36} may be obtained directly from 5-azauracil hydrolysis, while k_{23} and k_{25} were obtained from k_{obs} by:

$$k_{obs} = k_{23} + k_{25} \quad \text{(Eq. 8)}$$

and:

$$k_{23} = f k_{obs} \quad \text{(Eq. 9)}$$

where f is the fraction of 5-azacytosine that deaminates to 5-azauracil. The method used to calculate f is described below. In the case of a sequential reaction with parallel first-order loss, as in Scheme I, the concentration of III as a function of time is given by:

$$[III] = \{k_{23}[II]_0/(k_{36} - k_{23} - k_{25})\}\{e^{-(k_{23}+k_{25})t} - e^{-k_{36}t}\} \quad \text{(Eq. 10)}$$

where $[II]_0$ is the initial concentration of 5-azacytosine. The area under a plot of [III] *versus* time is found by integrating Eq. 10 from zero to infinity:

$$(\text{area III})_1 = f[II]_0/k_{36} \quad \text{(Eq. 11)}$$

where f is the same as in Eq. 9. Similarly, for the simple first-order loss:

$$III \xrightarrow{k_{36}} NCP \quad \text{(Eq. 12)}$$

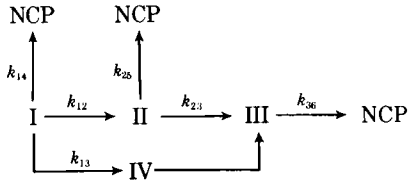
Integrating the equation for III yields:

$$(\text{area III})_2 = [III]_0/k_{36} \quad \text{(Eq. 13)}$$

Application of Eqs. 11 and 13 to experimental data allows the calculation of f. The concentration of 5-azauracil produced from 5-azacytosine was plotted as a function of time. During formation from 5-azacytosine, the area under this curve was estimated by the method of trapezoids. After the 5-azacytosine was exhausted, the remaining area was calculated from:

$$(\text{area})_{t\to\infty} = [III]_t/k_{36} \quad \text{(Eq. 14)}$$

where $[III]_t$ is the concentration of 5-azauracil at time t, and k_{36} is the apparent first-order rate constant for 5-azauracil loss under



Scheme II

identical conditions. The sum of the two areas provides the total area, $(\text{area III})_1$. The area under the concentration *versus* time curve for hydrolysis of an equimolar solution of 5-azauracil, $(\text{area III})_2$, was also calculated from Eq. 14. Since $[II]_0 = [III]_0$, Eqs. 11 and 13 may be combined to yield:

$$(\text{area III})_1/(\text{area III})_2 = f \quad \text{(Eq. 15)}$$

The rate constants obtained are listed in Table I. These were used in an analog computer[2] program to simulate the time course of the various reaction components. A typical plot is shown in Fig. 1, which shows good agreement between observed and computer-generated values.

Kinetics of 5-Azacytidine Hydrolysis in Hydrochloric Acid Solutions—The proposed path for 5-azacytidine hydrolysis in 0.1–0.8 *N* HCl is shown in Scheme II. The apparent first-order rate constants k_{12}, k_{14}, and k_{13} were determined in a manner similar to that used for k_{23} and k_{25}. For example:

$$k_{12} = f(k_{obs}) \quad \text{(Eq. 16)}$$

where f is the fraction of 5-azacytidine that hydrolyzes to 5-azacytosine. This fraction is obtained using Eq. 15, replacing $(\text{area III})_1$ with the area under the concentration curve for 5-azacytosine produced from 5-azacytidine and replacing $(\text{area III})_2$ with the area starting with 5-azacytosine itself.

Since the values for k_{25}, k_{23}, k_{36}, and the time course for II are all known (Scheme II), they can be employed to define the time course for $[III]_{II}$ (the 5-azauracil arising from 5-azacytosine). The difference between the observed values for III as a function of time, [III], and the expected values, $[III]_{II}$, defines the time course for III arising from IV *via* k_{13}:

$$[III]_{IV} = [III] - [III]_{II} \quad \text{(Eq. 17)}$$

The fraction of I converted to III by this route was used to calculate the value for k_{13}; this value, in turn, was employed to calculate k_{14} from:

$$k_{14} = k_{obs} - k_{12} - k_{13} \quad \text{(Eq. 18)}$$

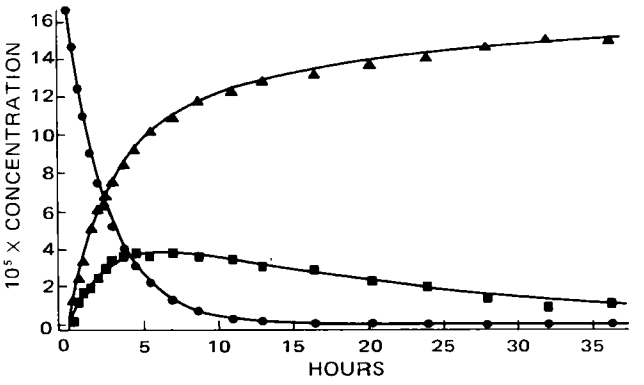


Figure 1—*Time course for 5-azacytosine (●), 5-azauracil (■), and nonchromophoric products (▲) during the hydrolysis of 5-azacytosine in 0.1* N *HCl at 70°. The lines were generated using an analog computer programmed with rate constants listed in Table I.*

[2] EAI, model TR 20.

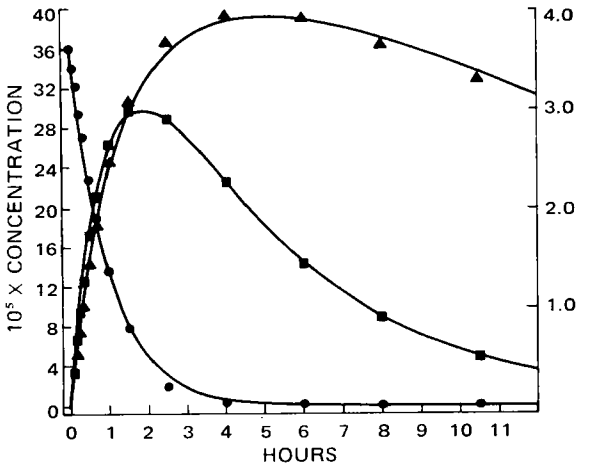

Figure 2—*Time course for 5-azacytidine (●), 5-azacytosine (■), and 5-azauracil (▲) during the hydrolysis of 5-azacytidine in 0.25 N HCl at 70°, showing the agreement between the experimental points and the computer-generated lines. The scale for 5-azacytosine and 5-azauracil is given on the right ordinate.*

These analyses were carried out for the reaction conditions listed in Table I. Typical plots are shown in Fig. 2. The k_{obs} values obtained at 50° are listed in Table II.

Kinetics of 5-Azacytidine Hydrolysis in Buffer Solutions—In buffers at pH 4.6 or higher, the plots of absorbance *versus* time were distinctly biphasic. Acidified samples gave plots similar to Fig. 3, showing a rapid initial decrease in absorbance, followed by a much slower second phase. When the spectra of buffered samples were determined, there was a rapid initial increase in absorbance followed by a slower decrease (Fig. 4).

The biphasic curves were analyzed by feathering the data using commonly employed methods[3]. Treated in this way, each reaction produced two linear first-order plots (Figs. 3 and 4). If the data are normalized relative to the initial absorbance values, a single equation, wherein the algebraic sign for the coefficient A is negative in buffer and positive in acid, may be used to describe the biphasic

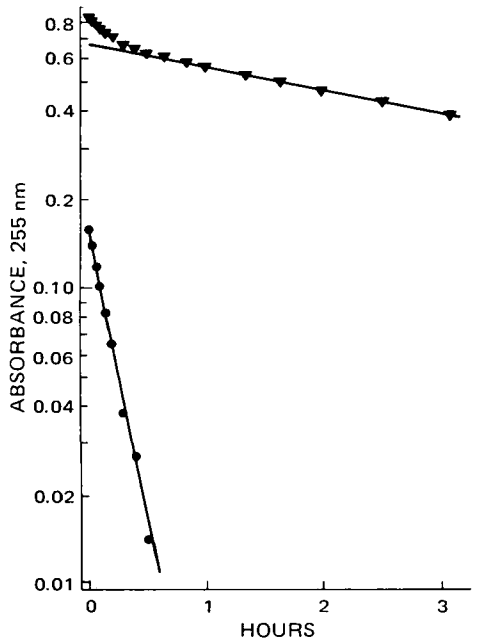

Figure 3—*Absorbance of acidified samples at 255 nm as a function of time (▼) for 5-azacytidine hydrolysis at 50°, pH 6.52, showing lines of slope* k_a *(●) and* k_b *(▼) obtained by feathering.*

[3] For a typical example of this method of data analysis, see Ref. 7.

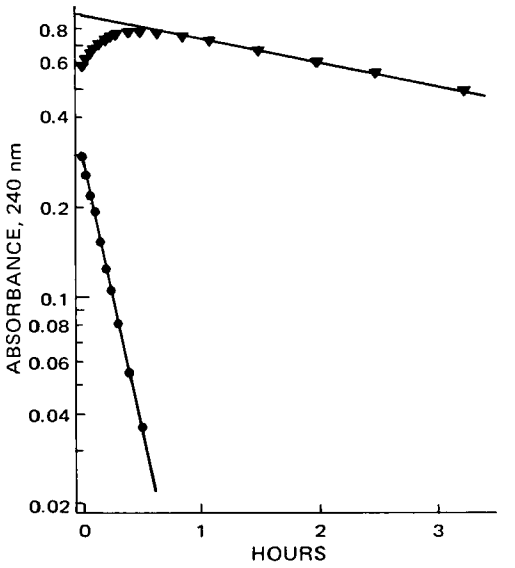

Figure 4—*Absorbance at 240 nm as a function of time (▼) for nonacidified samples of 5-azacytidine at 50°, pH 6.52, showing lines of slope* k_a *(●) and* k_b *(▼) obtained by feathering.*

curves:

$$F(A) = \pm Ae^{-k_a t} + Be^{-k_b t} \qquad \text{(Eq. 19)}$$

where $F(A)$ is the fraction of absorbance remaining; A and $-k_a$ are the intercept and slope of the rapid phase, respectively; and B and $-k_b$ are the intercept and slope of the slow phase, respectively. Rate constants are independent of the pH of analysis. Their values, together with the coefficients in acid, are given in Table III.

Table IV compares first-order rate constants for hydrolysis of 5-azacytidine in hydrochloric acid at 70° to those obtained for 5-azacytidine previously reacted in phosphate buffer. Although the buffer reactions had proceeded into the second phase, the observed rate constants after transfer to hydrochloric acid were the same as those for authentic samples.

At pH 3.58, the plots of ln (A) *versus* time showed definite curvature but were not distinctly biphasic. In fact, the plots were adequately described by a first-order equation over approximately the first half-life. Rate constants, estimated using data representing the first 17% of the reaction, are reported in Table III.

Hydrolysis was apparent first order at pH 2.58, and the rate constants were obtained using Eq. 7 (Table III).

Effect of Buffer on Hydrolysis Rate—Plots of k_a, k_b, or k_{obs}

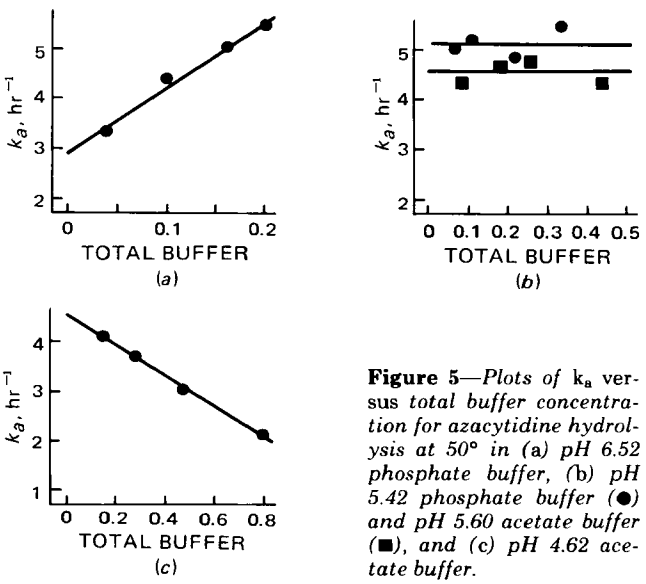

Figure 5—*Plots of* k_a *versus total buffer concentration for azacytidine hydrolysis at 50° in (a) pH 6.52 phosphate buffer, (b) pH 5.42 phosphate buffer (●) and pH 5.60 acetate buffer (■), and (c) pH 4.62 acetate buffer.*

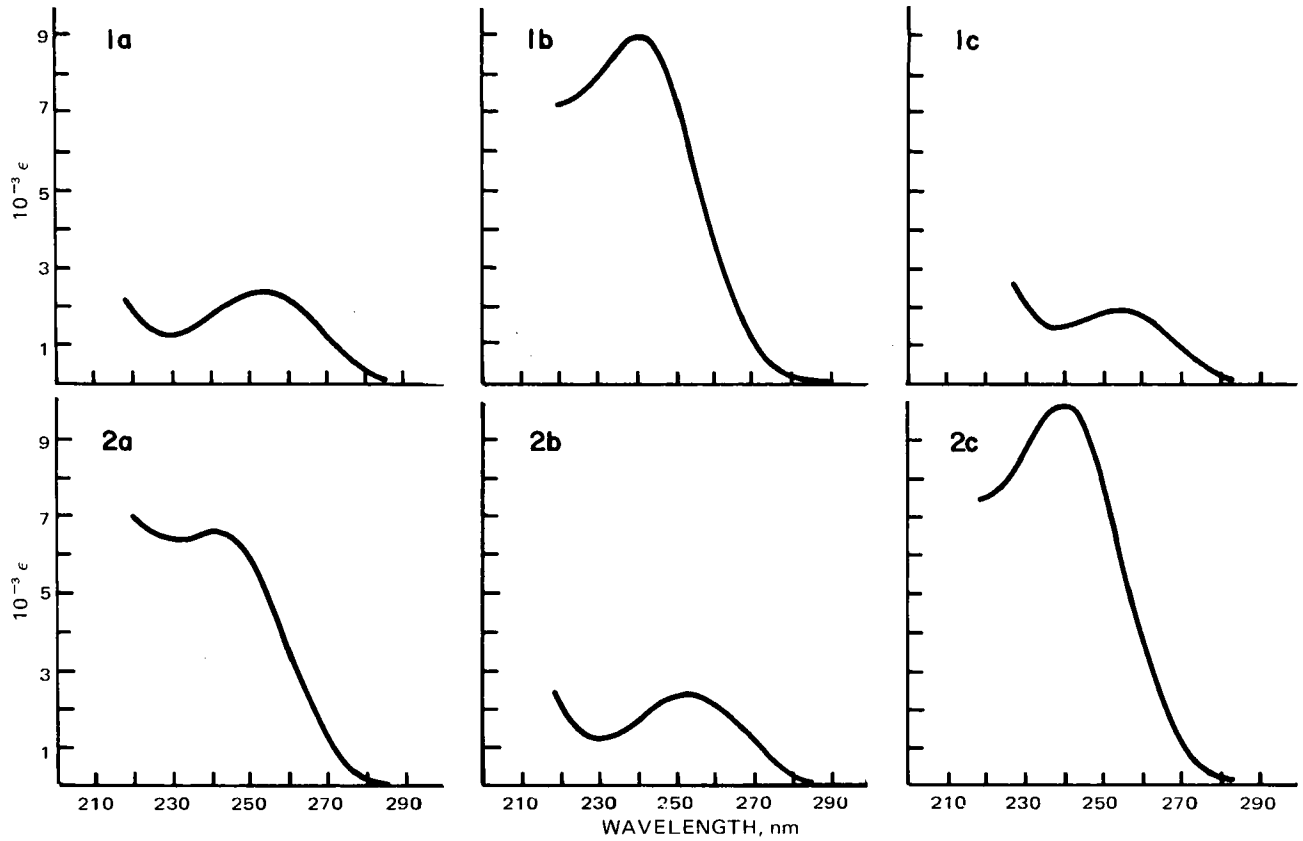

Figure 6—*Plots of apparent molar absorptivity* versus *wavelength for 5-azacytidine in solutions that were originally acid (1a), then adjusted to neutrality (1b), and reacidified (1c), or that were prepared at neutral pH (2a), were acidified (2b), and were reneutralized (2c).*

versus buffer concentration were extrapolated to zero buffer using least-squares linear regression analysis to obtain the values for these constants in the absence of buffer (Table III). In all cases, buffer plots of k_b were linear and showed a positive slope. But plots for k_a had positive slopes at pH 6.52 and 7.59, showed no buffer catalysis at pH 5.60 and 5.42, and indicated inhibition by the buffer at pH 4.62 (Fig. 5). No buffer sensitivity was seen for k_{obs} at pH 3.58 or 2.58.

Evidence for Addition across 5,6-Double Bond of 5-Azacytidine—If the UV spectrum of a 5-azacytidine solution is recorded as a function of pH, that spectrum is dependent on the order of the pH adjustment as well as on the pH itself (Fig. 6). For example, a neutral solution (2*a* in Fig. 6) has a spectrum that is less intense than that of a solution of equal concentration and pH that has been prepared from a previously acidic solution (1*b* in Fig. 6).

Clearly, acid at least partially converts the 5-azacytidine to a form that has a greater absorptivity at neutral pH than the 5-azacytidine itself. However, this rapid conversion does not occur at neutral pH since acidification of an originally neutral sample results in a solution whose spectrum is identical to that of an authentic sample in acid. Furthermore, if the neutral solution that was made acidic is readjusted to neutrality, the spectrum resembles one from an authentic sample in acid adjusted to neutrality (1*b* and 2*c* in Fig. 6).

The degree of difference between a neutralized solution (such as 1*b* in Fig. 6) and a neutral solution (2*a* in Fig. 6) depends upon the acidity of the initial solution. In Fig. 6 the initial acid concentration was 0.1 *N* HCl, and the apparent absorptivity at the absorption maximum for the solution adjusted to pH 6.5 was 9.03×10^3. When the initial acidity was 0.001 *N* HCl, the maximum absorptivity at pH 6.5 was 7.37×10^3. It was consistently observed that solutions made neutral and then reacidified showed decreased maximum absorptivities compared to the original acidic spectra as illustrated for the example in Fig. 6. These changes cannot be attributed to time or dilution factors. This decrease was not observed when solutions were adjusted from 0.1 to 0.001 *N* HCl and back to 0.1 *N*.

When experiments identical to those illustrated in Fig. 6 were carried out using 5-azacytosine, all spectra in 0.1 *N* HCl were identical, as were all spectra at pH 6.5.

Increasing concentrations of bisulfite brought about a progressive loss in intensity of spectra of both 5-azacytidine and 5-azacytosine. When spectra changed with time, initial absorbances were estimated by extrapolating plots of absorbance *versus* time to zero time. When these estimates were used, 5-azacytidine showed apparent molar absorptivities at 240 nm of 5.78×10^3, 3.60×10^3, and 1.38×10^3 in 0.001, 0.005, and 0.025 *M* bisulfite, respectively. Increasing the ionic strength by addition of sodium chloride did not alter the spectrum of the 0.001 *M* solution. In 0.001, 0.005, and 0.025 *M* bisulfite, 5-azacytosine had apparent molar absorptivities of 3.65×10^3, 1.55×10^3, and 0.37×10^3, respectively.

Spectrophotometric Determination of pKa Values for 5-Azacytosine—Absorbances at λ_{max} for the anionic form were plotted *versus* pH. Absorbances were corrected for dilution caused by the pH adjustment using:

$$A_{corr} = A_{exp}(V/V_0) \qquad \text{(Eq. 20)}$$

where V is the volume after addition of acid or base, and V_0 is the original volume. Figure 7 shows the plot obtained. The two pKa values were estimated from the midpoints of the curves and by use of Eqs. 21 and 22 for the pKa's of the conjugate acid and neutral molecule, respectively (8):

$$\text{pKa} = \text{pH} + \log[(A_I - A)/(A - A_N)] \qquad \text{(Eq. 21)}$$

$$\text{pKa} = \text{pH} + \log[(A - A_N)/(A_I - A)] \qquad \text{(Eq. 22)}$$

The absorbance of the solution when all the substrate is ionized is represented by A_I; A_N represents a solution of the neutral molecule; and A is the observed absorbance at the given pH. Two or three pH values within 0.5 pH unit of the pKa's were used. The average pKa values were 2.64 for the protonated molecule and 8.10 for the neutral species.

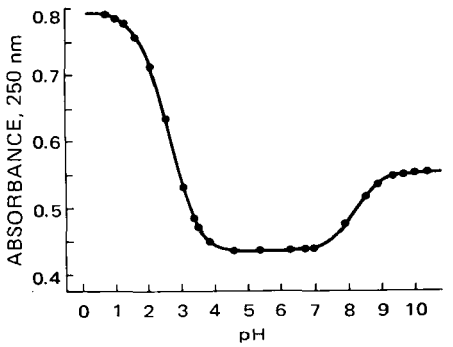

Figure 7—*Absorbance at 250 nm* versus *pH for 1 × 10⁻⁴ M 5-azacytosine.*

DISCUSSION

Kinetics of 5-Azacytidine Hydrolysis in Hydrochloric Acid Solutions—Scheme II outlines the proposed path for 5-azacytidine loss in acid. The formation of 5-azacytosine and 5-azauracil was expected from previously reported results (5) and was confirmed by UV assay. TLC and spectral changes demonstrated that 5-azauracil was produced from the hydrolysis of 5-azacytosine. This was the expected source for the 5-azauracil in the nucleoside hydrolysis.

However, as may be seen in Fig. 2, the data indicate the immediate and rapid production of 5-azauracil. If it were produced solely from 5-azacytosine, a lag phase would be evident. Therefore, it was necessary to postulate the production of 5-azauracil by another, more rapid route. The most logical path involves formation of 5-azauridine as a reactive intermediate. It is proposed to have only a transitory existence and a low concentration and may be said to be in the steady state. This is supported by the absence of a lag time for the formation of 5-azauracil from 5-azacytidine. A lag phase would be expected if 5-azauridine had an appreciable lifetime. Moreover, there was no spectral evidence for the existence of 5-azauridine in the reaction samples.

The steady-state assumption requires that 5-azauridine be very unstable in the reaction system. This assumption is reasonable in view of what is known about the reactivity of the molecule. It is reported to cleave easily in hydrochloric acid at room temperature to form 5-azauracil and ribose. In dilute aqueous ammonia, 1β-D-ribofuranosylbiuret is formed. At pH 5 at room temperature, the UV spectrum of a solution disappeared in less than 1 hr (1).

The absence of 5-azauridine UV absorption was substantiated in the following manner. In neutral solution and as a solid, 5-azauridine actually exists in a form that exhibits no absorbance in the near UV (1). In ~0.1 *N* HCl, solutions have an apparent absorptivity of ~1000 at the λ_{max} of 241 nm (1, 9). Therefore, significant amounts in the reaction would be detected in the UV spectra of the reaction samples. This was tested by using the concentrations calculated for 5-azacytidine, 5-azacytosine, and 5-azauracil at various times during the reaction to generate spectra for the reaction mixtures. These calculated spectra were identical to the actual spectra in the region examined, 235–270 nm. This could not occur in the presence of an appreciable concentration of 5-azauridine unless its spectrum exactly matched that of one of the other components or their absorptivities differed by a constant factor at all wavelengths. Since 5-azacytosine, 5-azauracil, and 5-azacytidine have λ_{max} values of 247, 233, and 255 nm, while 5-azauridine is reported to have its λ_{max} at 241 nm, neither of these conditions can be met.

Since all of the 5-azacytidine loss could not be accounted for by the production of 5-azacytosine and 5-azauracil, it was necessary to include a third path for loss of the substrate to produce nonchromophoric products, probably resulting from fission of the triazine ring (5) (represented by k_{14} in Scheme II). While it is possible that 5-azauridine also contributes to the formation of nonchromophoric products, this pathway would be kinetically equivalent since 5-azauridine is in the steady state.

Data for 5-azacytosine hydrolysis were used to complete Scheme II. Rate constants shown in Scheme II were calculated at 70° (Table I). The observed first-order rate constant for loss of 5-azacytidine decreased at lower pH. This trend was seen also at 50°, as shown in Table II. As the acid concentration was increased, however, a larger fraction of 5-azacytidine formed 5-azacytosine and 5-azauracil (24% in 0.25 *N* HCl as opposed to 11% in 0.1 *N* HCl). 5-Azacytosine showed a similar pH dependency. Only 32% of the 5-azacytosine formed 5-azauracil in 0.1 *N* HCl, and 50% followed this route in 0.25 *N;* the overall rate constant for loss decreased in the more concentrated acid.

Therefore, it appears that increased acid concentration decreases ring opening reactions that produce nonchromophoric products, thereby forcing more substrate to undergo deamination and, in the case of 5-azacytidine, sugar loss. Since these latter two reactions are relatively insensitive to pH changes over the region examined, the overall rate of substrate loss decreased.

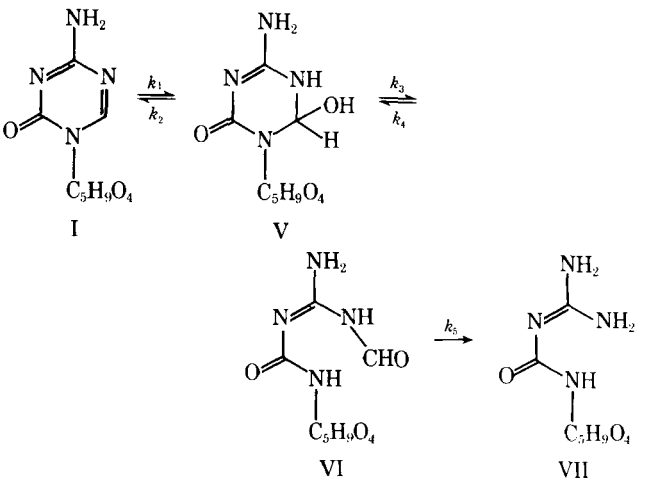
5-Azacytidine Hydrolysis in Presence of Buffers—In formic acid buffer, pH 2.6 and 50°, the loss of absorbance of a 5-azacytidine solution follows first-order kinetics, with the final absorbance being essentially zero. This same behavior is seen in hydrochloric acid solutions more dilute than 0.1 *N*. However, at pH 3.6 the absorbance plots of acidified samples are no longer linear. From pH 4.6 to 7.6, the absorbance plots are biphasic (showing a rapid initial drop in absorbance) and can be separated into two phases by the method of feathering (7) (Fig. 3). Reactions at pH 7.6 and 6.5, followed using nonacidified samples, were also biphasic. In this case the initial change was a rapid increase in absorbance, which was then followed by a slower decrease. An example is shown in Fig. 4. The apparent first-order rate constants obtained by feathering were the same whether acidified or nonacidified samples were used.

Several possible causes of this biphasic behavior were considered: (*a*) the presence of an impurity; (*b*) an A → B → C reaction where the initial phase represents the loss of A to B and the second phase represents the loss of B to C; and (*c*) a reaction with an initial reversible step (or steps) such as A ⇄ B → C (or A ⇄ X ⇄ B → C). The first possibility was eliminated by running a pair of reactions using 5-azacytidine purchased from two suppliers[4]. The absorbance *versus* time plots were identical, making an impurity an unlikely cause for the nonlinear behavior.

Samples taken during the second phase of the reactions, diluted in acid as shown in Table IV, and allowed to react at 70° showed rate constants that agreed with those found for 5-azacytidine. In addition, samples taken throughout the reaction and acidified had spectra that were essentially identical with that of 5-azacytidine at wavelengths longer than 240 nm. Therefore, it appears that 5-azacytidine is present throughout the reaction. This indicates that the formation of B must be reversible, thus eliminating the second reaction scheme.

A pathway with a reversible step is supported by the work of other investigators who reported the reversible formation of the *N*-formyl derivative of ribosylguanylurea (VI in Scheme III) in the decomposition of 5-azacytidine in buffer solutions (5).

By using results of previous work with 5-azacytidine and what is



Scheme III

[4] Schwarz/Mann and Aldrich.

known about the hydrolysis of imines, together with the experimental observations reported here, it is possible to develop a reaction scheme for 5-azacytidine in the presence of buffers as depicted in Scheme III.

Studies of imine hydrolysis (10) indicate that water attack to form a carbinolamine intermediate (V) is fast at low pH since attack proceeds by way of the protonated imine. Loss of free amine (V → VI) becomes the rapid step at higher pH values. This is consistent with the results of pH change experiments, which indicate that formation of an intermediate is rapid in acid but slow at neutral pH, while the reaction of this intermediate to form a third compound is rapid in buffer. This interpretation is also strengthened by the fact that more intermediate appeared to form at pH ~1 (0.1 *N* HCl) than at pH ~3 (0.001 *N* HCl). Based upon what is known about cytosine and its nucleosides (11), the pKa of 5-azacytidine should be little different from the 2.59 found for 5-azacytosine. Therefore, at pH 1, the sample, being nearly all in the protonated form, should contain more hydrate than the pH 3 sample, where more than half of the compound is not protonated.

If water adds across the 5,6-double bond, it seems reasonable that a better nucleophile, such as bisulfite, that is known to attack double bonds of heteroaromatic molecules (12, 13) would also add. Indeed, it was found that with increasing concentrations of bisulfite, the absorbance of 5-azacytidine solutions became progressively less intense, indicating an essentially nonchromophoric product as might be expected from an addition that brings about a loss of conjugation (14).

Although bisulfite adds to 5-azacytosine under the same conditions used for addition to 5-azacytidine, no evidence of hydrate formation was seen when 5-azacytosine was carried through the same pH adjustment experiments as the nucleoside. This finding suggests that the sugar group may be important in the hydration reaction. The 5′-hydroxy could act as a general base, making water a better nucleophile. It is especially well suited to act through a "concerted" mechanism, such as that proposed (15) for the addition of alcohols to phthalimidium cations.

The lack of significant hydrate formation with 5-azacytosine is also demonstrated by the spectral curve for pKa determination (Fig. 7). The protonated form of the molecule has a higher absorptivity than the neutral form. Conversely, 5-azacytidine absorbs less in acid than at neutral pH, presumably due to formation of the nonabsorbing intermediate. This loss of absorbance can be used to estimate the fraction of 5-azacytidine present in the hydrated form in acidic solution. Cytosine nucleosides and bases typically absorb more in the protonated than in the neutral form.

For example, the maximum absorbance of protonated forms of 6-methylcytidine and 6-methylarabinosylcytosine is about 1.7 and 1.6 times greater than that of the neutral molecules at the same wavelength. The protonated form of the base 6-methylcystosine absorbs 1.8 times as strongly as the uncharged form (11). At the wavelength of maximum absorption, protonated 5-azacytosine absorbs 1.6 times more than its neutral form. Without hydration, 5-azacytidine would be expected to exhibit the same pattern. Comparison of the observed absorptivity of 5-azacytidine in acid to that projected from the absorptivity of the unprotonated form (using the typical ratios just described) implies that roughly 70% of the 5-azacytidine exists as the hydrate in 0.1 *N* HCl.

Although the structure for Compound VI in Scheme III was proposed previously, it was neither successfully isolated from the reactions nor synthesized (5). Attempts at synthesizing compounds of this type by formylation of guanylurea led to recovery of either starting material or 5-azacytosine. Formation of 5-azacytosine in this way confirms the reversibility of the ring-opening step. The strong absorbance of analogous compounds such as *N*-formyl-*N*′-cyanoguanide was cited as evidence for formation of a compound like VI, since it could thereby account for the initial increase in absorbance observed in buffered samples (5). The fact that this increase occurs with no apparent lag phase emphasizes that loss of V to VI is rapid compared to formation of V from I.

Pithova *et al.* (5) identified ribosylguanylurea (VII) as a product of the hydrolysis of 5-azacytidine and showed that VII further decomposes to yield guanidine. In the present experiments, a λ_{max} of 221 nm at pH 7.6, observed in spectra for reaction mixtures, was attributed to the formation of VII. First-order plots using absorbance indicated that VII did not show appreciable absorbance at wavelengths longer than 240 nm in acid or buffer.

[a] All rate constants were obtained from semilog plots of I + V *versus* time unless otherwise noted. Apparent first-order rate constants are expressed as time^{-1}. [b] Obtained from data for I only. [c] Obtained from plots of 0.3 (I + V) + VI.

As stated under *Results*, the values of k_a and k_b obtained experimentally were the same using UV absorption data for the buffered reactions with or without acidification. It was of interest to determine whether Scheme III could provide data that would behave in this manner. Therefore, Scheme III was programmed using an analog computer. The values of the microconstants used are listed in Table V. Various components or combinations of components were studied as a function of time to simulate the spectral changes seen during the reactions.

According to Scheme III, I, V, and VI are present throughout the reaction. Using acidified samples, VI does not absorb at the wavelengths used for kinetic studies. When samples are acidified, I and V equilibrate so that the absorbance obtained actually reflects the sum of their concentrations in the reaction, although V has very little, if any, absorbance. In buffered samples, I and VI are responsible for the largest part of the absorbance, with VI absorbing more strongly than I.

With these considerations in mind, the analog program was adjusted to provide various kinds of data. The time course of I + V *versus* time was used to represent acidified samples. To simulate spectral changes seen with buffered samples, 0.3 (I + V) + VI was generated. The factor 0.3 was arbitrarily chosen to simulate the effect of differences in absorptivity. The time course of I alone was

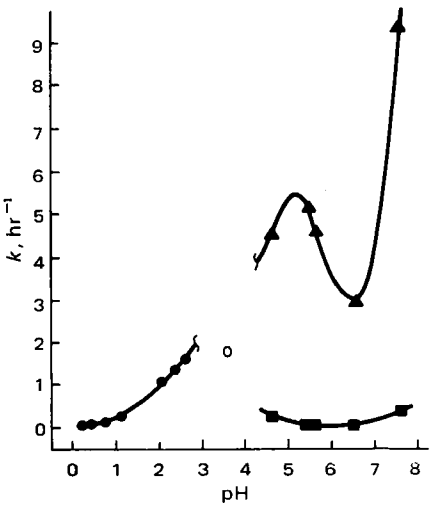

Figure 8—*Apparent first-order rate constants* k_a (▲), k_b (■), *and* k_{obs} (●) *for hydrolysis of 5-azacytidine at 50° as a function of pH. The point at pH 3.58 (○) was obtained as described in the text.*

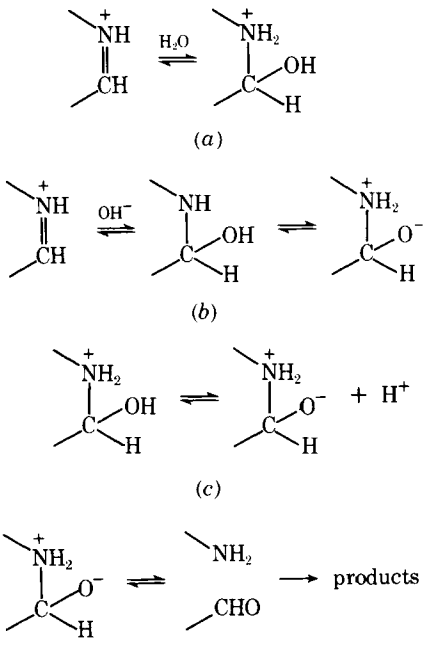


Scheme IV

also defined. Plotting and feathering the data as described earlier gave estimates for k_a and k_b. These values were the same regardless of which simulation was used (Table V).

Hydrolysis of 5-Azacytidine as a Function of pH—Figure 8 shows a plot of observed first-order rate constants for 5-azacytidine hydrolysis as a function of pH. It is obvious from Scheme III that these are complex kinetic constants composed of several microconstants. This situation precludes an unequivocal interpretation of the pH–rate profile. However, Scheme III can be used in conjunction with present data to suggest mechanisms consistent with observed pH effects.

Both rate constants k_a and k_b are shown for the biphasic region (pH >4) in Fig. 8. Based on Scheme III, k_b may be defined as:

$$k_b = fk_5 \qquad \text{(Eq. 23)}$$

where f is the fraction of (I + V + VI) present as VI. The values for k_5 cannot be calculated from the observed constant k_b, since the value for f is not known. However, it is apparent from Fig. 8 that the product fk_5 is relatively independent of pH. Conversely, k_a is pH dependent. Although it is recognized that k_5 can affect the value of k_a, the observed pH dependency is most likely due to changes in the relative rates of the reversible steps for hydrolysis of I to VI. In the 4.5–6.5 pH region, hydrolysis of the triazine ring may be visualized as a series of steps analogous to those postulated for imine hydrolysis (Scheme IV).

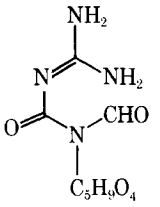
As in imine hydrolysis (10, 16), formation of protonated carbinolamine or neutral carbinolamine (Scheme IV, *a* and *b*) *via* the reactive cationic substrate (IH^+) would be the slowest reversible step at pH 6.5. As the pH decreases, the concentration of IH^+ increases; therefore, the apparent first-order rate constant increases. This increase would be expected to continue until protonation of I was complete, but increasing acidity inhibits formation of the zwitterion (Scheme IV, *c*) so less of it is available to react. Thus, near pH 5 the observed rate constant begins to decrease.

As the pH decreases further, first-order plots become linear instead of biphasic. Although the rate of formation of protonated V (VH^+) from IH^+ becomes faster, the fraction in the reactive form (zwitterion) decreases. The apparent first-order rate constant for loss of IH^+ is now attributed to cleavage of the carbinolamine (Scheme IV, *d*) as described by Scheme V.

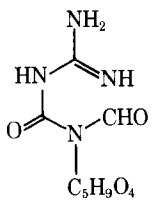
$$IH^+ \underset{\text{fast}}{\rightleftharpoons} VH^+ \underset{\text{slow}}{\rightleftharpoons} VI \underset{\text{fast}}{\longrightarrow} VII$$

Scheme V

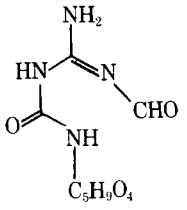
Since the hydration of substrate to form VH^+ is fast, the overall loss appears to be simple first order. The observed constant continues to decrease with increasing acidity due to the decreasing fraction of reactive species in the form of zwitterion. Eventually, loss of IH^+ by this path becomes sufficiently slow that formation of 5-azacytosine and 5-azauracil becomes important at a pH of about 1, but k_{obs} continues to decrease in this region, presumably *via* the reduction of zwitterion.



VIII



IX



X

The observed increase in k_a at pH 7.6 may result from a pathway involving base-catalyzed water attack on the neutral molecule as observed for certain imines (10).

Scheme IV shows the result of 5,6-addition of water. Cleavage of the ring would then result in Compound VIII. Addition across the 1,6-bond would be necessary to obtain Structure VI, which was suggested previously (5). Such addition appears possible starting from the resonance form of IH^+, which has the positive charge at C-6. Addition of water could then occur across the 5,6- or the 1,6-bond. Since a positive identification of the compound was not made (5) and both VI and VIII yield the same product upon hydrolysis of the amide, both routes are possible. Initial protonation could also occur at the 3-nitrogen, leading to Compounds IX and X, which differ from VI and VIII only in the position of a proton.

Implications for Stability Prediction—This report is the first one to suggest the formation of the proposed 5,6-hydrate of 5-azacytidine. While the hydrate was not isolated, considerable indirect evidence has been presented in support of its existence. Regardless of the exact structure for the proposed intermediate, its facile formation in acidic solutions of 5-azacytidine is readily apparent. The undetermined biological significance of this previously unreported intermediate, along with the complexity of the observed first-order rate constants (as illustrated by the analog simulations), indicates the difficulty in predicting stability of 5-azacytidine potency in solutions.

For example, although the apparent rate constants for loss in acidic solutions are less than the k_a values obtained in buffers, a large fraction (about 0.7) of the drug forms the proposed hydrate immediately upon dissolution in acid. The rate constant observed in acid applies only to the loss of drug after the initial equilibration between drug and hydrate has taken place. Therefore, if the hydrate is not itself biologically active or is not bioreversible to drug, most potency is lost long before predictions based on the observed rate constant would have indicated significant hydrolysis.

Equation 19 describes the absorbance changes for 5-azacytidine in buffer solutions. The rate constant values are the same with or without acidification, but the values of the coefficients A and B differ. Provided that Scheme III applies, it is assumed that neither VI nor VII absorbs in acid at the wavelengths used in this study. It is also assumed that the proposed hydrate (V) does not accumulate to a significant extent at neutral pH. Although these assumptions were not proven, they were justified in previous discussion. By using these assumptions, the absorbance of acidified samples of reactions run in the buffer region may be attributed to 5-azacytidine and Eq. 19 may be written:

$$\text{percent remaining} = 100\,(Ae^{-k_a t} + Be^{-k_b t}) \qquad \text{(Eq. 24)}$$

Table VI—Times to Reach 90, 80, and 70% of Original Concentration of 5-Azacytidine in Buffer Solutions at 50° (Predicted using Eq. 24)

pH	Total Buffer[a]	Minutes		
		90%	80%	70%
	Phosphate

	0.066	6	18	52
	Acetate			
5.60	0.44	6	15	34
	0.088	6.5	18	56
4.62	0.80	4	10	16
	0.16	5	11	20

[a] Adjusted to μ = 0.5 with sodium chloride (Table III). [b] At 30°.

This equation may be used to calculate the percent drug remaining at any time by employing data for acidified samples, provided the above conditions are met. Failure of the first condition would lead to inapplicability of the biexponential equation. If the second assumption does not hold, the actual percent remaining will be less than that calculated from Eq. 24.

The percent drug remaining can be calculated using the appropriate constants in Eq. 24, keeping in mind the assumptions involved. For example, the values for A, k_a, B, and k_b listed in Table III were used to estimate the time required to lose 10, 20, and 30% in a variety of buffers at 50°. Results are shown in Table VI, where it can be observed that each succeeding 10% loss requires a longer time. This result is due to the transition from the rapid initial phase to the slower terminal phase. It is apparent that 5-azacytidine is decidedly unstable under these conditions. The maximum time required to lose 10% of the drug is 11 min, and 20% is lost in 32 min under these conditions.

To estimate the loss of potency under potential clinical conditions, a reaction was studied at 30° at the pH of maximum stability observed at 50° (0.02 M Na_2HPO_4–0.02 M NaH_2PO_4–0.42 M NaCl, pH 6.5). Within 30 min, 5% of the drug was lost; after 80 min, 10% was lost; and 20% was gone in 225 min. This apparent instability of 5-azacytidine suggests that it would be prudent to prepare solutions shortly before use to avoid significant degradation. However, it requires more than 2 hr for potency to decrease from 90 to 80% and the decrease from 80 to 70% would take even longer. It is likely that solutions used within 6 hr contain at least 70% of the original drug.

Determination of Dicumarol Metabolites in Bile of Rats

WALTER D. CONWAY ˣ, FRANCIS H. LEE, and LAWRENCE NEUFELD

Abstract □ After intravenous administration of dicumarol-^{14}C to rats, the bile excreted over the next 24 hr contained from 32 to 46% of the administered radioactivity. At least three primary metabolites and a small amount of unchanged dicumarol were present in the bile. Over 91% of the primary metabolites was converted to dicumarol and 7-hydroxydicumarol by hydrolysis with β-glucuronidase. Some primary metabolites were hydrolyzed simply by acidification to pH 3 or by treatment under the acidic conditions utilized in the enzymatic hydrolysis. The three primary metabolites contain carboxylic acid groups, as indicated by their electrophoretic mobility–pH profiles, and some are simple glucuronides of dicumarol and 7-hydroxydicumarol. The possibility that others are derivatives of these compounds in which a coumarin lactone ring is opened cannot be ruled out. When the metabolites released by either acidification or enzymatic hydrolysis were chromatographed in *n*-butanol–3 *M* ammonia, artifacts were produced, presumably as a result of decomposition of 7-hydroxydicumarol. The question is raised whether a previously reported metabolite (B055) is an artifact.

Keyphrases □ Dicumarol and metabolites—biliary excretion after intravenous administration of dicumarol-^{14}C, rats □ Biliary excretion—dicumarol and metabolites after intravenous administration of dicumarol-^{14}C, rats

The anticoagulant drug dicumarol (I) was prepared in the early 1940's and is still utilized in therapy (1, 2). It is known to be almost totally metabolized in the body, and several investigators reported separation of from four to seven metabolites in the feces, urine, or bile of rats by paper chromatography (3–9). None of these metabolites has been identified, and it is not known whether any possesses physiological activity (10). While biliary excretion has been recognized as a major pathway for elimination of dicumarol, few studies have been made on bile (8, 9, 11, 12), and in only two of these (8, 9) were the metabolites separated.

The most extensive study (7) of the structure of a metabolite concerned a metabolite isolated from the feces of rats and designated as B055 to signify its mobility of 0.55 in the paper chromatographic system of *n*-butanol–3 *M* ammonia (1:1). This metabolite contained a hydroxy group in position 7 of one coumarin ring; it was neither a glucuronide nor identical with 7-hydroxydicumarol (II).

In the present study, the excretion of radioactivity in the bile, urine, and feces of rats was measured after intravenous administration of dicumarol. Metabolites were separated by high-voltage paper electrophoresis and by paper chromatography. The amounts of I and II were measured by the reverse isotope dilution technique in aliquots of 0–24-hr bile treated alternatively as follows: (*a*) with β-glucuronidase, (*b*) by incubation with buffer in the absence of enzyme, and (*c*) by chloroform extraction of unhydrolyzed bile.

II

EXPERIMENTAL

Dicumarol-4,4′-^{14}C (specific activity 0.74 μCi/mg) was synthesized by a modification of the method of Underwood (13) and was administered to one rat. Dicumarol-methylene-^{14}C (specific activity 11.8 μCi/mg) was prepared by the method of Lee *et al.* (14, 15) and administered to two rats. Only one radioactive spot was observed when electrophoresis and paper chromatography were carried out in the systems to be described. 7-Hydroxydicumarol was prepared by the method of Abramovitch and Gear (16) and was identical with an authentic sample[1].

Electrophoresis—Separations by high-voltage paper electrophoresis were run on Whatman 3 MM paper for 30 min at 5000 v at 20° using an enclosed apparatus with two cooling platens[2]. The electrophoregrams were dried and the radioactive zones were detected by scanning in a gas flow counter using methodology previously described (17). Scanner settings were 50 cm/hr, time constant 10 sec, and 5 × 50-mm open window.

Paper Chromatography—Bile samples were examined by applying aliquots of bile as a streak across the entire width of 4 × 40-cm strips of Whatman No. 1 (10-μl aliquot) and No. 3 MM (15-μl aliquot) papers, followed by descending development using *n*-butanol–3 *M* ammonia (1:1, v/v) (3–9). Aliquots (10 μl) of 0.2% solutions of dicumarol and 7-hydroxydicumarol in 0.1 *N* NaOH were applied to the same paper strips as reference compounds. The reference compounds were located by their fluorescence under short wavelength (254 nm) UV light. Radioactive zones were located by scanning in the same manner as for electrophoregrams.

Animal Treatment—Polyethylene 10 cannulas were secured with ligatures in the proximal and distal portions of the bile ducts of male Sprague–Dawley rats (~200 g) under ether anesthesia. The bile duct was then ligated in two places between the cannulas and severed between the ligatures. The cannulas were led through puncture wounds in the backs of the animals, and the exteriorized ends were connected with a 1.5-cm length of 27-gauge needle tubing, thereby permitting normal circulation of bile. The procedure is similar to that recently described by Rietbrock and Abshagen (18). Animals were housed in a restraining cage and given water and food *ad libitum*.

Twenty-four hours after surgery, the cannula was opened to permit collection of bile. Approximately 1 ml of a solution of dicumarol in 0.1 *N* NaOH was administered *via* the femoral vein. Samples of urine and bile were collected at 24-hr intervals. The bile collection vessel was immersed in ice throughout the collection period, and samples were counted and analyzed as soon as possible after collection. In one rat the 0–48-hr feces were collected on a screen.

Enzymatic Hydrolysis—Samples of bile were hydrolyzed with β-glucuronidase using the following microprocedure. A 100-μl aliquot of bile was diluted with water to 1 ml, and 100 mg of monobasic potassium phosphate was added followed by approximately 1 mg of the appropriate nonradioactive carrier (either dicumarol or 7-hydroxydicumarol) in approximately 75 μl of 0.2 *N* NaOH. The

		24–48	5.5	8.4	—	13.9
		0–48	37.3	26.6	—	63.9

[a] Specific activity 0.74 μCi/mg. [b] Specific activity 11.8 μCi/mg.

sodium hydroxide was added in 5-μl increments under the control of a microglass electrode to a final pH of 5.4. Then 5 μl of 4 *M* acetate buffer (prepared to yield a solution of pH 5.4 when diluted 25-fold) containing 6.3 mg/ml of bovine serum albumin and 100 μl of a β-glucuronidase preparation[3] were added. The sulfatase contained in the β-glucuronidase preparation is inhibited by the phosphate incorporated into the mixture (19). The sample was incubated at 37° in a water bath for 24 hr. When larger quantities of bile were hydrolyzed, the volumes of reagents were increased proportionately.

Reverse Isotope Dilution—The sample of hydrolyzed bile was extracted with two 20-ml portions of chloroform, and a 100-μl aliquot of each extract was counted to determine the recovery of radioactivity. One hundred milligrams of the appropriate carrier (either dicumarol or 7-hydroxydicumarol) was added to the combined chloroform extracts, and the solution was evaporated to dryness. The residue was recrystallized four to six times from 20 ml of acetic acid. Samples of solid were removed after each recrystallization, dried, and dissolved in 1–2 ml of boiling acetic acid, which, in turn, was dissolved in a dioxane-based scintillation fluid for assay of radioactivity.

Total radioactivity associated with the added carrier was calculated from the mean count rate of samples from the last two recrystallizations after constant specific activity had been reached. Samples of untreated bile or bile incubated without enzyme were similarly treated. In some cases, aliquots of bile or hydrolyzed bile were simply evaporated *in vacuo*, carrier was added, and the residue was recrystallized from acetic acid.

Liquid Scintillation Counting—Total radioactivity in urine, bile, and other solutions was assayed by dissolution of aliquots in a scintillation fluid consisting of dioxane (946 ml), water (50 ml), 2,5-diphenyloxazole (9.5 g), 1,4-bis[2-(5-phenyloxazolyl)]benzene (0.3 g), and naphthalene (142 g) and counting at ambient temperature using a liquid scintillation spectrometer[4].

Feces were homogenized with an approximately equal weight of 2% polysorbate 80[5]; a weighed aliquot was dried and prepared for scintillation counting by a modification of the plastic bag combustion technique (20). Samples of urines and combusted feces were counted for 10 min, providing over 10,000 accumulated counts, and were corrected for efficiency by the internal standard technique using a 109,000-dpm aliquot of toluene-^{14}C counted for 1 min.

RESULTS AND DISCUSSION

Excretion of Radioactivity—In early studies in this laboratory using anesthetized rats, the excretion of radioactivity in bile appeared to be somewhat less than would be expected from the reported excretion in feces of normal, conscious rats (6). Therefore, in subsequent experiments, the drug was administered to conscious animals after recuperation from surgery.

To allow animals sufficient time to recover from surgery and at the same time prevent the depletion of bile salts, which would occur with a simple exteriorized cannula, two cannulas were installed, as described in the *Experimental* section. This system permitted normal circulation of bile during the 24-hr recuperation. The drug was then administered intravenously and bile, urine, and feces were collected from the conscious animals.

Substantial amounts of radioactivity were obtained in the 0–24- and 24–48-hr bile (Table I), although these quantities are still somewhat less than the mean excretion of 57.2 and 10.6% in the 0–24- and 24–48-hr feces, respectively, of three normal rats dosed intravenously by Christensen (6). The excretion observed in urine was quite comparable to his values of 17.7 and 3.0% for 0–24- and 24–48-hr periods, respectively. This finding suggests that biliary excretion slows down as bile constituents are depleted over the long collection period.

Analysis by Electrophoresis—Analysis of 0–24-hr bile samples by direct application to paper, without extraction, and electrophoresis at pH 6.25 (Fig. 1) demonstrates the presence of at least three major components along with minor amounts of 7-hydroxydicumarol and dicumarol. Similar results were obtained by electrophoresis at pH 3.70 and 8.10.

Portions of the pH–mobility profiles of these metabolites in the bile of Rat 9 are presented in Fig. 2. Similar results were obtained for Rats 7 and 10. Lack of mobility below pH 2.7 rules out the possibility of a sulfuric acid ester metabolite (17), which would be ionized at low pH and would migrate substantially. The pKa in the region of 3.2, indicated by the pH–mobility profiles of three metabolites, is characteristic of carboxylic acids. The profile of the slowest moving component, accounting for about 9% of the radioactivity, is consistent with the profile observed for dicumarol.

After hydrolysis of bile (Rat 10) with β-glucuronidase, direct electrophoretic analysis of the hydrolysate (Fig. 3) demonstrates the absence of the metabolites originally present and the appearance of incompletely resolved zones in the vicinity of reference spots of authentic dicumarol and 7-hydroxydicumarol. Lack of exact correspondence of the zones observed by scanning with the positions of the authentic reference compounds should not be regarded as evidence of nonidentity. Under the conditions used for the electrophoresis, in which the authentic reference compounds

After Evaporation of Bile and Recrystallization of Residue and Carrier from Acetic Acid			
7	11.6	21.4	33.0[b]

[a] One hundred microliters of bile was incubated with buffer or buffer plus β-glucuronidase and extracted with two 20-ml portions of chloroform; 100 mg of carrier was added to the chloroform, recovered, and recrystallized from acetic acid. [b] Four milliliters of bile was evaporated *in vacuo*, and 100 mg of carrier was added and recrystallized from acetic acid. [c] Not incubated with buffer but extracted and treated as in Footnote *a*.

were run in a channel adjacent to the bile on the electrophoregram, a discrepancy in relative mobility of the magnitude observed in Fig. 3 is commonly observed. The reference compound typically runs slightly faster than the corresponding compound in the biological fluid.

Analysis by Reverse Isotope Dilution—The composition of 0–24-hr bile samples, as determined by reverse isotope dilution analysis, is summarized in Table II. After hydrolysis with β-glucuronidase, 91.5–95.1% of the radioactivity in the 0–24-hr bile was accounted for as dicumarol and its 7-hydroxy derivative. Very little dicumarol or its 7-hydroxy derivative was present in the bile prior to subjecting it to the conditions for enzymatic hydrolysis. This finding is particularly evident from the results on the bile from Rat 9 where the bile was simply extracted with chloroform; 20% of the radioactivity in the bile was extractable into chloroform, but only a small portion of this amount, corresponding to 1.5 and 2.3% of the bile radioactivity, was characterized as dicumarol and 7-hydroxydicumarol, respectively, by reverse isotope dilution.

Either incubation with buffer alone or direct recrystallization of bile and carrier from acetic acid converts a significant portion of the nonhydroxylated metabolites to dicumarol, apparently all of them in the case of Rat 9. From 20 to 52% of the 7-hydroxylated metabolites are converted to 7-hydroxydicumarol by similar treatment.

If it is assumed that some conjugates are labile under acidic conditions, the data are consistent with the conclusion that the metabolites excreted in bile are predominantly simple glucuronides of

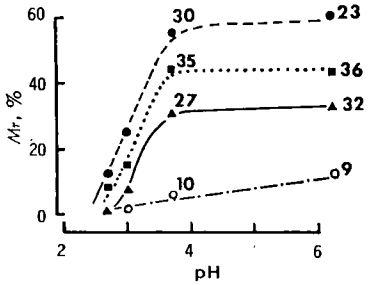

Figure 2—*Mobility* (M_r) *of metabolites in 0–24-hr bile of Rat 9 in the pH 2–6 region expressed as percent of mobility of* p-*nitrobenzenesulfonic acid. Numerals indicate percentage of bile radioactivity associated with the zone. Symbols* (○, ▲, ■, *and* ●) *represent the four zones observed.*

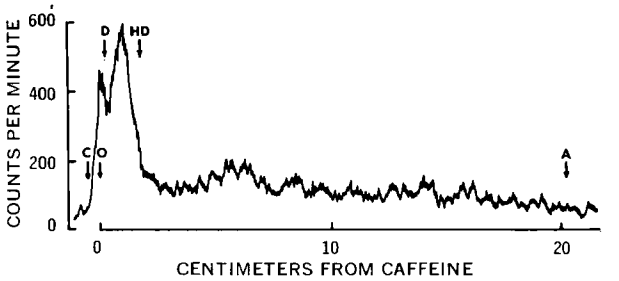

Figure 3—*Electrophoretic separation of components in the 0–24-hr bile of Rat 10 after hydrolysis with β-glucuronidase, using phosphate buffer, pH 6.25, ionic strength 0.05. Positions of origin (O), caffeine (C),* p-*nitrobenzenesulfonic acid (A), dicumarol (D), and 7-hydroxydicumarol (HD) reference spots are indicated.*

dicumarol and 7-hydroxydicumarol. At least 50% of the 7-hydroxylated metabolites, equivalent to at least 20% of the radioactivity in bile, appear to be simple glucuronides of 7-hydroxydicumarol. The nonhydroxylated metabolites may include a fairly labile glucuronide as well as other substances that can be converted to dicumarol under acidic conditions. Compounds similar to III, a metabolite of ethyl biscoumacetate, reported by Pulver and Kaulla (21) would behave in this manner.

Analysis by Paper Chromatography—Paper chromatography in *n*-butanol–3 *M* ammonia (1:1) has been utilized extensively in studies of the metabolic fate of dicumarol (3–9). The evidence presented here indicates that several artifacts are generated by chromatography of dicumarol metabolites in this system. The resulting confusion is no doubt responsible for the protracted period over which the disposition of dicumarol has been studied.

When bile is applied directly to paper and chromatographed in *n*-butanol–3 *M* ammonia (1:1), substantially all radioactivity remains near the origin (upper curve, Fig. 4). Little or no radioactivity is seen in the regions of control spots of dicumarol or 7-hydroxydicumarol or in the region expected for the reported metabolite B055. Acidification to pH 3 and extraction with ethyl acetate, as described by Buttar *et al.* (9), removed more than 95% of the radioactivity from bile. Chromatography of the ethyl acetate extract in the butanol–ammonia system revealed at least five components (lower curve, Fig. 4).

Similar chromatograms were obtained from the β-glucuronidase hydrolysate of 0–24-hr bile from Rat 10 by direct application of the hydrolysate to the paper (upper curve, Fig. 5) and from an extract (lower curve, Fig. 5) prepared by adjustment of the hydro-

III

lyzed bile to pH 3 and extraction with ethyl acetate (9).

The R_f values for the peaks and the percentages of bile radioactivity represented by the areas designated a, b, c, d, and e in the chromatograms shown in Fig. 5 are compared in Table III with the corresponding values obtained by Buttar *et al.* (9) by chromatography of an ethyl acetate extract of β-glucuronidase-hydrolyzed bile. The present results are in good agreement with those of Buttar *et al.* and confirm their conclusion that component e cochromatographs with dicumarol. The data presented here indicate that component c cochromatographs with 7-hydroxydicumarol.

The suggestion of the presence of at least five metabolites by the chromatographic data is at variance with the conclusion clearly indicated by reverse isotope dilution that virtually all radioactivity in bile is accounted for by dicumarol and its 7-hydroxylated derivative. This inconsistency arises only when the bile is hydrolyzed with enzyme (Fig. 4) or is simply acidified prior to extraction and chromatography (lower curve, Fig. 4) in the alkaline system. The additional components are not generated by chromatography of bile, which is neither acidified nor extracted (upper curve, Fig. 4). The reverse isotope dilution data (Table II) do suggest that some conjugates in bile are labile under acidic conditions.

Chromatography of dicumarol-^{14}C added to bile collected from an unmedicated rat chromatographed as a single zone, which corresponded to a reference spot of dicumarol in the *n*-butanol–3 *M* ammonia system. This finding eliminated the possibility of dicumarol decomposition or binding to biliary components to yield multiple spots.

Chromatography of nonradioactive 7-hydroxydicumarol produced two spots at R_f 0.38 and 0.65. The lower R_f spot was judged to be the unchanged 7-hydroxy compound by the similarity of the color produced on spraying with diazotized *p*-nitroaniline to that of the unchromatographed compound and also by the similarity of the R_f value to the value of 0.33 reported for it in this system by Christensen (7). After 3 days of standing in 3 *M* ammonia prior to chromatography, the spot at R_f 0.65 disappeared and at least five additional spots formed, ranging in R_f from 0.1 to 0.78. In contrast, nonradioactive dicumarol appeared to be stable after 3 days of standing in 3 *M* ammonia. Chromatography in the *n*-butanol–3 *M* ammonia system required at least 6 hours, which provided ample time for hydrolytic, oxidative, and possibly photochemical decomposition to occur.

Therefore, several metabolites observed by previous investigators apparently are artifacts resulting from the decomposition of 7-hydroxydicumarol by the widely used *n*-butanol–3 *M* ammonia solvent system. The 7-hydroxydicumarol can be released from some of its conjugates simply by acidification. The major artifact (Figs. 4 and 5) exhibits an R_f value in the range of the B055 metabolite (7). This raises the question of whether B055 is actually an artifact derived by decomposition of 7-hydroxydicumarol in the *n*-butanol–3 *M* ammonia solvent system in which the biological material was repeatedly chromatographed during the isolation procedure (7).

Correlations between Physical and Drug Release Characteristics of Polyethylene Glycol Suppositories

IAN W. KELLAWAY and CHRISTOPHER MARRIOTT [x]

Abstract □ The mechanical strength and elastic moduli of blocks of polyethylene glycol with a range of molecular weights were determined. A rotating-basket dissolution test was used to measure the release characteristics of prednisolone from similar blocks. The effects of blending bases of different molecular weight and of the addition of water also were determined. Linear relationships were found for the mechanical strength, molecular weight, and release rate, but no simple relationship could be observed for the elastic moduli.

Keyphrases □ Polyethylene glycol suppositories—relationships between physical characteristics (mechanical strength, molecular weight, and elastic moduli) and drug (prednisolone) release rates □ Suppositories, polyethylene glycol—relationships between physical characteristics and drug release rates □ Drug release characteristics of polyethylene glycols—relationship to polymer molecular weight, mechanical strength, and elastic moduli

Polyethylene glycols are among the most widely used of the hydrophilic polymer suppository bases. Drug liberation occurs as a result of base dissolution into the aqueous environment of the rectum, differing radically from the classical lipophilic bases which melt at body temperature and act as a lipid reservoir from which drug molecules partition prior to absorption.

Salicylate release from polyethylene glycol bases has been examined by several workers (1–5). High plasma levels of salicylic acid and sodium salicylate have been achieved (1) and the *in vitro* release of two different salicylates did not differ significantly (2). To achieve rapid drug release, polyethylene glycols have been recommended for aspirin formulations whereas cocoa butter (theobroma oil) is the base of choice for both sodium salicylate (4) and choline salicylate (3). The use of polyethylene glycols in some instances has produced similar plasma levels to an equivalent oral dose (4, 5). It has been suggested that salicylate liberation and absorption from polyethylene glycol suppositories may be influenced by salicylate–polyethylene glycol complexation (6–8).

Studies on drugs incorporated into a polyethylene glycol matrix include those on acetaminophen (9), iodoform and 2,4,6-triiodophenol (10), thiazinamium and indomethacin (11), chloramphenicol (12, 13), sulfonamides (14), antipyrine (phenazone) and sodium barbital (15), diphenhydramine and its hydrochloride salt (16), oxytetracycline (17), and other antibiotics (18). When selecting a suppository base, it is generally true that lipophilic drugs are best formulated in hydrophilic bases (19) and water-soluble compounds are best formulated in lipophilic bases (20) for rapid and complete release.

Rheological investigations of suppository bases have been confined to the molten or semisolid state (21–25) and determinations of "hardness" of the solid bases (4, 26–29). Baichwal and Lohit (25) ob-

Correlations between Physical and Drug Release Characteristics of Polyethylene Glycol Suppositories

IAN W. KELLAWAY and CHRISTOPHER MARRIOTT [x]

Abstract □ The mechanical strength and elastic moduli of blocks of polyethylene glycol with a range of molecular weights were determined. A rotating-basket dissolution test was used to measure the release characteristics of prednisolone from similar blocks. The effects of blending bases of different molecular weight and of the addition of water also were determined. Linear relationships were found for the mechanical strength, molecular weight, and release rate, but no simple relationship could be observed for the elastic moduli.

Keyphrases □ Polyethylene glycol suppositories—relationships between physical characteristics (mechanical strength, molecular weight, and elastic moduli) and drug (prednisolone) release rates □ Suppositories, polyethylene glycol—relationships between physical characteristics and drug release rates □ Drug release characteristics of polyethylene glycols—relationship to polymer molecular weight, mechanical strength, and elastic moduli

Polyethylene glycols are among the most widely used of the hydrophilic polymer suppository bases. Drug liberation occurs as a result of base dissolution into the aqueous environment of the rectum, differing radically from the classical lipophilic bases which melt at body temperature and act as a lipid reservoir from which drug molecules partition prior to absorption.

Salicylate release from polyethylene glycol bases has been examined by several workers (1–5). High plasma levels of salicylic acid and sodium salicylate have been achieved (1) and the *in vitro* release of two different salicylates did not differ significantly (2). To achieve rapid drug release, polyethylene glycols have been recommended for aspirin formulations whereas cocoa butter (theobroma oil) is the base of choice for both sodium salicylate (4) and choline salicylate (3). The use of polyethylene glycols in some instances has produced similar plasma levels to an equivalent oral dose (4, 5). It has been suggested that salicylate liberation and absorption from polyethylene glycol suppositories may be influenced by salicylate–polyethylene glycol complexation (6–8).

Studies on drugs incorporated into a polyethylene glycol matrix include those on acetaminophen (9), iodoform and 2,4,6-triiodophenol (10), thiazinamium and indomethacin (11), chloramphenicol (12, 13), sulfonamides (14), antipyrine (phenazone) and sodium barbital (15), diphenhydramine and its hydrochloride salt (16), oxytetracycline (17), and other antibiotics (18). When selecting a suppository base, it is generally true that lipophilic drugs are best formulated in hydrophilic bases (19) and water-soluble compounds are best formulated in lipophilic bases (20) for rapid and complete release.

Rheological investigations of suppository bases have been confined to the molten or semisolid state (21–25) and determinations of "hardness" of the solid bases (4, 26–29). Baichwal and Lohit (25) ob-

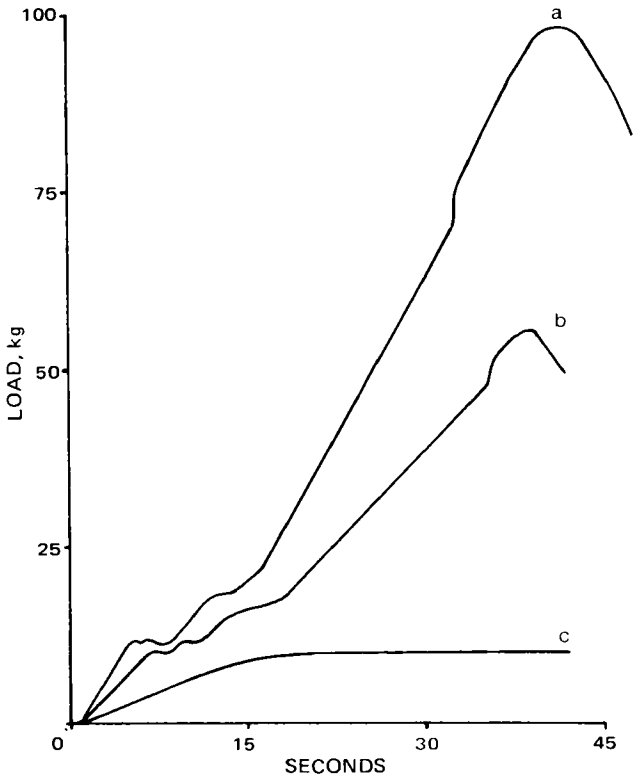

Figure 1—*Transmitted load-time curves for: (a) polyethylene glycol 6000, (b) 60% polyethylene glycol 6000 and 40% polyethylene glycol 1000, and (c) polyethylene glycol 1000. The rate of strain was 60 mm hr*$^{-1}$.

Table I—Characterization of Polyethylene Glycols $CH_2(OH)(CH_2OCH_2)_mCH_2OH$

Polyethylene Glycol	m	Molecular Weight Range	Mean Molecular Weight	Melting Point
400	8—10	380—420	400	<10°
1000	20—23	950—1050	1000	33.3—33.4°
1540	28—36	1300—1600	1450	43.1—43.3°
4000	69—84	3100—3700	3400	57.4—57.6°
6000	115—160	6000—7500	6750	60.7—61.0°

served that drug release from cocoa butter (theobroma) bases was inversely related to the consistency, expressed as a viscosity index. Sharova *et al.* (29) found that breaking strength increased with molecular weight for polymers of polyethylene oxide.

The purpose of this study was to examine drug release characteristics from polyethylene glycols in relation to polymer molecular weight and as a function of breaking load and elasticity of the bases.

EXPERIMENTAL

Preparation of Suppositories—Polyethylene glycols 400, 1000, 1540, 4000, and 6000 were used[1]. Cylindrical "suppositories," 15 mm in diameter and length and approximately 3 g in weight, were prepared by pouring the molten base into a brass mold mounted on a glass plate. Prednisolone BP, micronized[2] (0.625%, w/w), was dissolved in the molten base to produce blocks for drug release testing; water, if required, was added immediately prior to pouring. All blocks were removed from the molds 1 hr after pouring and stored in well-closed containers at 5°. The blocks were allowed to attain room temperature prior to testing.

Prednisolone Release Determinations—A rotating-basket dissolution apparatus was used and enabled determinations at 37 ± 0.2° to be made simultaneously on four independent blocks. Each block was placed vertically in a basket rotating at 125 rpm. Two liters of distilled water was used as the dissolution medium for each block, and 5-ml samples were withdrawn every 120 sec from a fixed point in the medium. Each sample was analyzed for prednisolone content at 247 nm in a UV spectrophotometer[3].

Breaking Load and Elasticity Determinations—The blocks were placed face on in a compression unit against a 100-kg load cell[4] at 22 ± 0.5°. Compression was carried out at a constant strain rate of 60 mm hr^{-1}. The breaking load was measured as the transmitted force in kilograms at failure, and the elastic modulus was determined from the initial slope of the stress–strain curve (Fig. 1). Division of the load by the area of the block face produces the stress, and the corresponding strain can be derived by dividing time by the recorder speed. The elastic modulus can then be calculated from the ratio of stress to strain:

$$\text{elastic modulus } (Nm^{-2}) = \frac{\text{load (kg)}}{\text{area of block } (m^2)} \times \frac{\text{recorder speed } (m\,sec^{-1})}{\text{seconds}} \quad \text{(Eq. 1)}$$

A recorder[5] speed of 200 mm min^{-1} was used for all compression tests. A minimum of three tests was performed on each formulation.

Table II—Effect of Pouring Temperature on the Breaking Load of Polyethylene Glycol 6000

80°	96
85°	96

RESULTS AND DISCUSSION

The release of prednisolone from polyethylene glycols 1000, 1540, 4000, and 6000 is shown in Fig. 2. Unlike the curves for salicylate release (4), no linear region was observed. Since semilogarithmic plots were also nonlinear, the release of prednisolone from

polyethylene glycol suppositories follows neither zero-order nor first-order kinetics.

The times for release of 25, 50, 75, and 100% (t_{25}, t_{50}, t_{75}, and t_{100}, respectively) of the prednisolone were determined graphically from the dissolution–time plots. When these times were plotted against the "average" molecular weights (Table I), significant linear relationships ($p > 0.999$) were obtained (Fig. 3). Extrapolation to the ordinate was not undertaken, since release times corresponding to liquid polyethylene glycols would have dubious practical significance. Figure 3 includes data for the "pure" compounds and bases formulated by blending polyethylene glycol 1000 with both 4000 and 6000.

The molecular weights of the blends were calculated as weight averages according to:

$$\bar{M}_w(\text{blend}) = \frac{N_1M_1^2 + N_2M_2^2}{N_1M_1 + N_2M_2} \qquad \text{(Eq. 2)}$$

where M_1 and M_2 are the "average" molecular weights of the two polyethylene glycols, and N_1 and N_2 are the numbers of moles of each in the blend. Therefore, it appears feasible that any desired release rate of prednisolone from polyethylene glycol suppositories can be achieved by the selection of a suitable base or blend of bases to produce the appropriate mean molecular weight.

Table III—Effect of Storage Time on the Breaking Load of Polyethylene Glycol 1540

Storage Time, hr	Breaking Load, kg

5	31
21	32
43.5	32
72	32
120	32

Collins *et al.* (30) suggested that the appearance and mechanical properties of polyethylene glycol suppositories are dependent upon the temperature of pouring and recommended the use of a temperature just above the congealing point to prevent glazing of the surface. Krowczynski (31), however, using 24 different bases, concluded that the preparative technique had no effect on the drug release characteristics. To examine the effect of the preparation procedure on breaking strength, polyethylene glycol 6000 blocks were prepared by pouring the base at different temperatures above the congealing point. The results (Table II) indicate that the breaking strength is independent of pouring temperature, except when this temperature is close to the congealing point. It is possible that crystallization may be occurring prior to pouring, giving rise to a nonhomogeneous polymer matrix within the block interior.

Aging effects were monitored in blocks of polyethylene glycol 1540 stored at 5° in well-closed containers for between 2 and 120 hr. No significant differences could be observed in the breaking loads over this aging period (Table III). All other tests, however, were carried out on blocks that had been aged for between 4 and 24 hr.

Figure 4 illustrates the linear relationship that existed between the breaking load and mean molecular weight of the base. Bases with molecular weights less than 1000 were produced by blending polyethylene glycol 1000 with polyethylene glycol 400. The computed line intersects the abscissa at a molecular weight corresponding closely to the transition between solid and liquid polyethylene glycols at 22°. Therefore, knowledge of the approximate molecular weight serves as a useful guide to base hardness.

When the elastic moduli of the bases were calculated from the compression tests, no simple linear correlation with molecular weight was evident. This finding may be due to the relatively in-

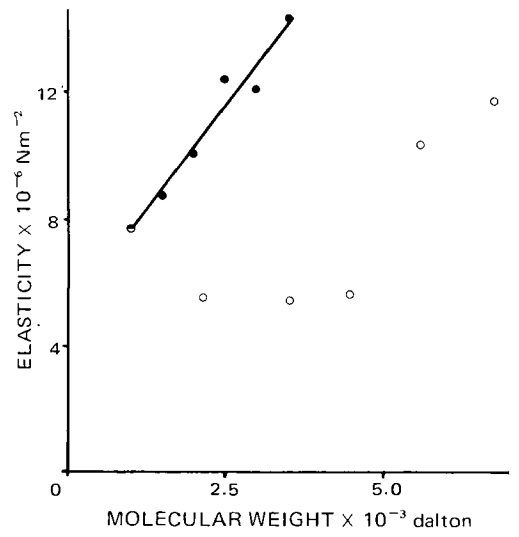

Figure 5—*Elasticity-molecular weight relationships for 4000–1000 blends (●) and 6000–1000 blends (○).*

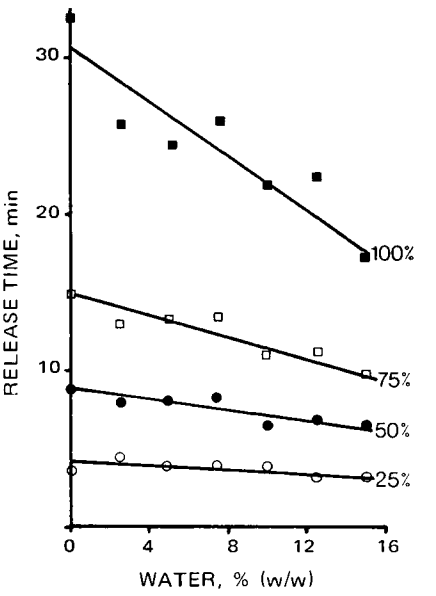

Figure 6—*Effect of water addition to polyethylene glycol 4000 on* t_{25}, t_{50}, t_{75}, *and* t_{100}.

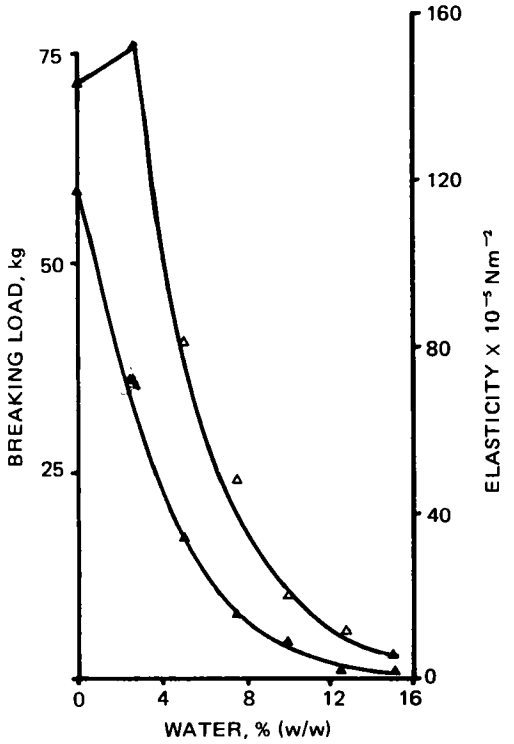

Figure 7—*Effect of water addition to polyethylene glycol 4000 on breaking load (▲) and elasticity (△).*

sensitive technique used. Figure 5 illustrates the effect of blending polyethylene glycol 1000 with polyethylene glycols 4000 and 6000; the former resulted in a linear plot, the latter in a curvilinear one. An explanation of the different behavior exhibited by 6000–1000 blends could involve differences in the matrix structure of polyethylene glycol 6000 when compared with those of the 4000 and 1000 bases. The observation that, with the nonblended bases, polyethylene glycol 6000 was the only compound to produce a clean fracture when compressed to failure may support this suggestion.

It is common pharmaceutical practice to add water to polyethylene glycols when they are used as suppository bases in an attempt to counteract the irritant action on the rectal mucosa occasionally encountered due to water removal by osmosis. The effect of the addition of water to polyethylene glycol 4000 on prednisolone release (Fig. 6), breaking load, and elastic modulus (Fig. 7) were examined. A linear decrease in release times with increasing water content was observed. Breaking load and elastic modulus were also found to decrease but in a nonlinear manner to the maximum water content of 15% (w/w). Concentrations exceeding this figure produced blocks that could not be ejected whole from the molds.

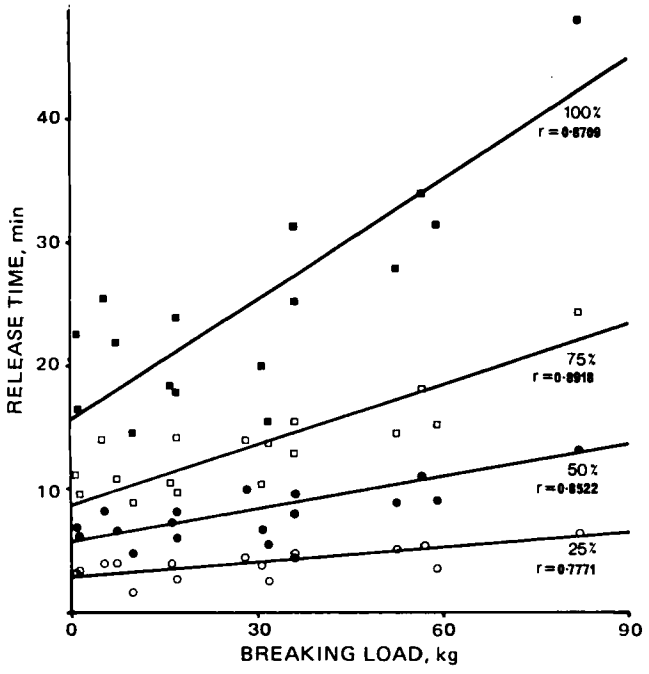

Figure 8—*Significant (>0.999) linear relationships existing for* t_{25}, t_{50}, t_{75}, *and* t_{100} *as a function of breaking load.*

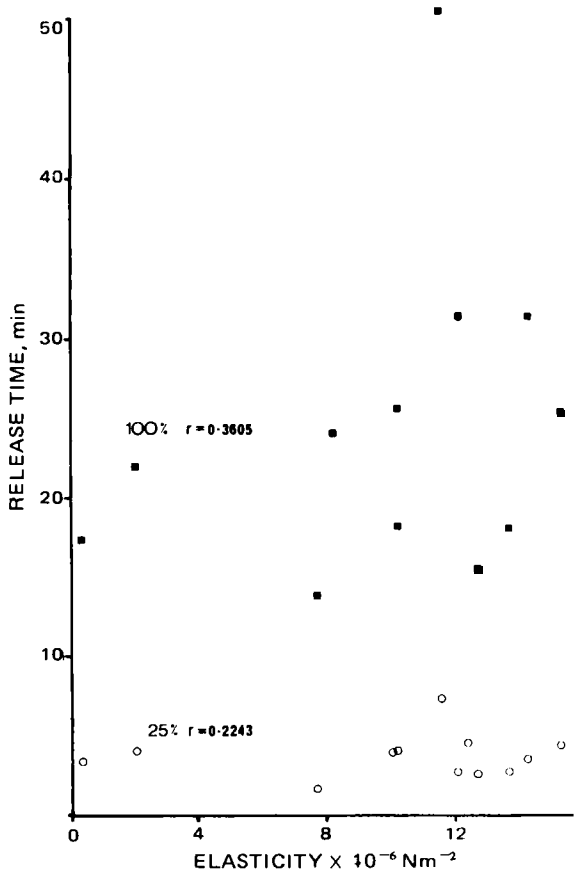

Figure 9—*Nonsignificant (<0.90) correlation between* t_{100} *and* t_{25} *and elasticity.*

It was also possible to relate prednisolone release times to the breaking load of the base when linear relationships were observed (Fig. 8). The significance of the correlation coefficient was >0.999 but was reduced to <0.90 when the elastic modulus was substituted for the breaking load (Fig. 9). Only 25 and 100% release data are included in this latter figure for the sake of clarity. It is considered that the relationship demonstrated between breaking load and release times may prove useful as a formulation guide for lipophilic drugs in polyethylene glycol suppository bases.

Comparison of IR Spectroscopic Analysis and X-Ray Diffraction of Aluminum Hydroxide Gel

STEVEN L. NAIL [*], JOE L. WHITE [‡], and STANLEY L. HEM [*x]

Abstract □ Data are presented which demonstrate that IR spectrophotometry is more sensitive than X-ray diffraction to structural changes occurring in aluminum hydroxide gel during aging. By examining changes in peak shape and position in the IR spectrum, evidence is seen for an increasing degree of order as the gel ages. The increased order may be responsible for the loss of acid reactivity observed during aging. IR analysis is also recommended for routine monitoring of aluminum hydroxide gels.

Keyphrases □ Aluminum hydroxide gel—monitoring of structural changes during aging, IR and X-ray diffraction methods compared, relationship to decreased acid reactivity □ IR spectrophotometry—monitoring, structural changes in aluminum hydroxide gel during aging, compared to X-ray diffraction method □ X-ray diffraction—monitoring, structural changes in aluminum hydroxide gel during aging, compared to IR spectrophotometric method

Aluminum hydroxide gel is an effective antacid, although many aspects of its structure and acid reactivity are not fully understood. The initial precipitate resulting from the reaction of a soluble aluminum salt with a base is probably a highly random structure. With aging, structural rearrangement occurs to form a more thermodynamically stable system. For example, a polymerization-like process may produce a highly ordered system resistant to attack by acid (1–4). The rate of this process has been related to many factors including pH of precipitation (5), type and concentration of ions present (6–8), temperature (9), and order of addition of the reactants (10). The end-product of the aging process is usually a crystalline form of aluminum hydroxide (1–4, 6–8, 11, 12). These crystalline structures are resistant to attack even by concentrated acid.

It has been demonstrated that aluminum hydroxide gels, which are essentially nonreactive as measured by the USP acid-consuming capacity test, retain an amorphous X-ray diffraction pattern (5). Since X-ray diffraction appears to be relatively insensitive to the structural changes occurring during aging that result in a diminished acid reactivity, a more sensitive method is needed to study these structural changes. The purposes of this report are to demonstrate the usefulness of IR spectrophotometry

Aluminum hydroxide gel is an effective antacid, although many aspects of its structure and acid reactivity are not fully understood. The initial precipitate resulting from the reaction of a soluble aluminum salt with a base is probably a highly random structure. With aging, structural rearrangement occurs to form a more thermodynamically stable system. For example, a polymerization-like process may produce a highly ordered system resistant to attack by acid (1–4). The rate of this process has been related to many factors including pH of precipitation (5), type and concentration of ions present (6–8), temperature (9), and order of addition of the reactants (10). The end-product of the aging process is usually a crystalline form of aluminum hydroxide (1–4, 6–8, 11, 12). These crystalline structures are resistant to attack even by concentrated acid.

It has been demonstrated that aluminum hydroxide gels, which are essentially nonreactive as measured by the USP acid-consuming capacity test, retain an amorphous X-ray diffraction pattern (5). Since X-ray diffraction appears to be relatively insensitive to the structural changes occurring during aging that result in a diminished acid reactivity, a more sensitive method is needed to study these structural changes. The purposes of this report are to demonstrate the usefulness of IR spectrophotometry

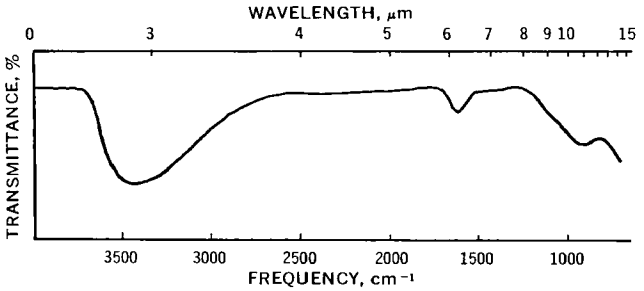

Figure 1—*IR spectrum of freshly prepared aluminum hydroxide gel.*

in studying the structural characteristics of aluminum hydroxide gel and to point out its application in relating structural changes to decreased acid reactivity.

EXPERIMENTAL

Materials—All chemicals used were either official or reagent grade.

Preparation of Aluminum Hydroxide Gel—Aluminum hydroxide gel was prepared by the reaction of aluminum chloride and strong ammonia solution at pH 7.0 (5).

Analytical Procedures—The acid-consuming capacity test (11) was modified by titrating to pH 3.5 rather than using bromophenol blue TS, as given in the USP. Duplicate determinations were made for each sample. The antacid property of the aluminum hydroxide gel is given as a percentage of the theoretical acid-consuming capacity.

For X-ray analysis, a sample of gel was air dried at room temperature and ground to a fine powder with an agate mortar and pestle. Powder mounts were prepared using aluminum McCreery mounts. The diffraction pattern was recorded from 6 to 30° 2θ[1] under the following conditions: CuK_α radiation, 40 kv, 20 mamp, 500 cps full scale, and 2°/min scan speed.

IR spectra[2] of gel samples were obtained by air drying a film of the gel on a zinc sulfide[3] window. Spectra of gibbsite[4], bayerite[4], and boehmite[4] standards were obtained by pressing a disk containing 1 mg of the standard material with 300 mg of potassium bromide.

RESULTS

The IR spectrum shown in Fig. 1 is typical of a freshly prepared aluminum hydroxide gel. The broad diffuse peak centered at about 3400 cm^{-1} corresponds to the O—H stretching frequency of structural hydroxy and adsorbed water. The band at 1640 cm^{-1} is the H—O—H bending vibration of adsorbed water. The broad peak at about 900 cm^{-1} represents an O—H deformation vibration. A peak at 1410 cm^{-1} is sometimes seen and is due to ammonium ion that was not totally removed by washing. Gels containing carbonate have a peak in the 1400-cm^{-1} region as well as a peak at 1550 cm^{-1}.

The O—H stretching and O—H bending frequencies are markedly affected by their chemical environment. The broad absorption band in the 2900–3700-cm^{-1} region of the IR spectrum of the fresh gel (Fig. 1) indicates O—H groups in many environments, thus indicating the highly disordered nature of the fresh gel (13).

The presence of adsorbed water causes some obliteration of structural detail in the O—H stretching region of the spectrum. For this reason, it is best to prepare the sample as an air-dried film on zinc sulfide or silver chloride windows. The use of a potassium bromide disk is not advisable due to the hygroscopic nature of potassium bromide. For the highly crystalline standard materials, the use of the potassium bromide pressed disk technique is satisfactory because the absorption bands are sufficiently well defined that small amounts of adsorbed water do not affect the spectrum. Air-dried films are also suitable for a vacuum heating treatment or deuteration to remove water.

Table I—O—H Vibrations in Stretching and Bending Regions for Crystalline Aluminum Hydroxides

Phase	Frequency, cm^{-1} O—H Stretching Region	Frequency, cm^{-1} O—H Bending Region	
Gibbsite	3612 3520 3440 3395	1030 970	
Bayerite	3650 3540 3460	1010 970	doublet
Boehmite	3300 3095	1150 1070	

The hydroxy groups in the aluminum trihydroxides, gibbsite and bayerite, are part of a highly ordered structure and have characteristic absorption bands in both the O—H stretching and O—H deformation regions. These crystalline aluminum hydroxides are easily identified by their IR spectra (Table I). Gibbsite has well-defined bands at 3612, 3520, 3440, and 3395 cm^{-1} in the O—H stretching region. An intense peak occurs at 1030 cm^{-1} with a smaller peak at 970 cm^{-1}, both of which are O—H deformations.

The general features of the bayerite spectrum are similar to gibbsite with peak positions shifted to 3650, 3540, and 3460 cm^{-1}. A doublet at 1010 and 970 cm^{-1} occurs in the O—H deformation region.

Band positions for boehmite, an aluminum oxide hydroxide, are also shown in Table I. The O—H stretching frequency region is characterized by two broad peaks at 3300 and 3095 cm^{-1}. The O—H deformation frequencies are at 1150 and 1070 cm^{-1}.

Figure 2 shows X-ray diffraction patterns for the gel at various

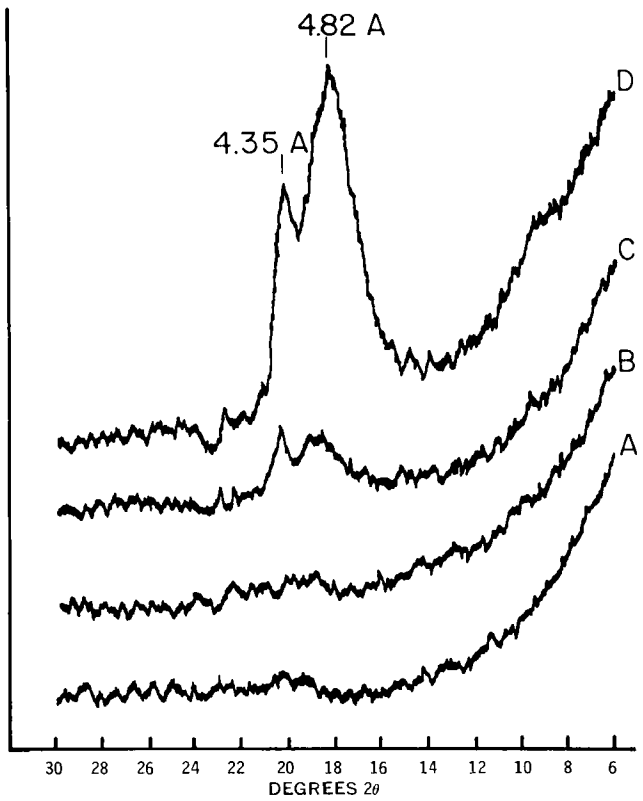

Figure 2—*Change in X-ray diffraction pattern of aluminum hydroxide gel during aging at 25°. Key: A, 57 days; B, 65 days; C, 71 days; and D, 124 days.*

Table II—X-ray Powder Diffraction Patterns of the Five Most Intense Peaks for Crystalline Aluminum Hydroxides[a]

Gibbsite		Bayerite		Boehmite	
Interplanar Spacing, Å	Relative Intensity, %	Interplanar Spacing, Å	Relative Intensity, %	Interplanar Spacing, Å	Relative Intensity, %
4.84	100	4.72	100	6.11	100
4.34	40	4.36	70	3.16	65
4.30	20	3.19	25	2.34	53
2.37	20	2.21	67	1.86	32
2.03	12	1.71	26	1.85	27

[a] Taken from K. Wefers and G. M. Bell, Alcoa Research Laboratories Technical Paper No. 19, 1972, p. 38.

aging times. The gel retains an amorphous pattern until about 70 days after preparation, at which time a rather broad peak is seen from 18.5 to 19.2° 2θ (4.77–4.62 Å) with a sharper peak at 20.4° 2θ (4.35 Å). After 124 days of aging, well-defined peaks are seen at 18.3° 2θ (4.82 Å) and at 20.4° 2θ (4.35 Å).

Table II lists the predominant X-ray diffraction peaks for gibbsite, bayerite, and boehmite. A comparison of the X-ray diffraction pattern of the 70-day sample with the spacings in Table II clearly indicates that a crystalline aluminum hydroxide phase has formed, although the X-ray diffraction pattern is too diffuse to identify the crystalline phase clearly. With further aging, the crystalline phase is clearly identified as gibbsite.

The O—H stretching frequency region of the IR spectrum is shown for various aging times in Fig. 3. The gel aged 5 days has an IR absorbance pattern characteristic of a highly disordered structure. As the gel ages, an inflection point occurs at 3520 cm^{-1}. This shoulder develops into a well-resolved peak. A shoulder is seen developing at 3612 cm^{-1} along with a peak at 3470 cm^{-1}.

The spectral changes in the O—H deformation region are shown in Fig. 4. The fresh gel shows a broad peak centered at 900 cm^{-1}. As the gel ages, a shoulder develops at 1020 cm^{-1} and eventually becomes a well-resolved peak.

A plot of the log of the acid-consuming capacity of the gel *versus* time at room temperature is shown in Fig. 5. The loss in acid reactivity follows apparent first-order kinetics. The slope and y-intercept are -5.93×10^{-3} day^{-1} and 93.5%, respectively, by linear regression analysis. The linear correlation coefficient is −0.99.

DISCUSSION

Based on X-ray diffraction, the first evidence of crystallinity is seen after about 70 days of aging. It is not possible at that time to identify the polymorph present; however, the characteristic X-ray diffraction pattern of gibbsite developed in later samples.

By examining the same gel by IR spectrophotometry, a slight inflection is seen at 3520 cm^{-1} after 42 days and it clearly develops into a gibbsitic peak after less than 70 days.

The O—H deformation region of the spectrum is also sensitive to the degree of order of the gel. The deformation peak undergoes a marked shift to higher frequency, and a sharpening of the band occurs as the gel ages. An absorption pattern develops characteristic of gibbsite.

The IR spectrum indicates that gibbsite or a precursor of gibbsite is the major crystalline phase that is forming as the gel ages. The sharp peak at 3650 cm^{-1} characteristic of bayerite and the doublet at 970 and 1010 cm^{-1} are not seen in the IR spectrum, indicating that the developing order is leading to gibbsitic material.

The value of IR analysis of aluminum hydroxide gel is also seen

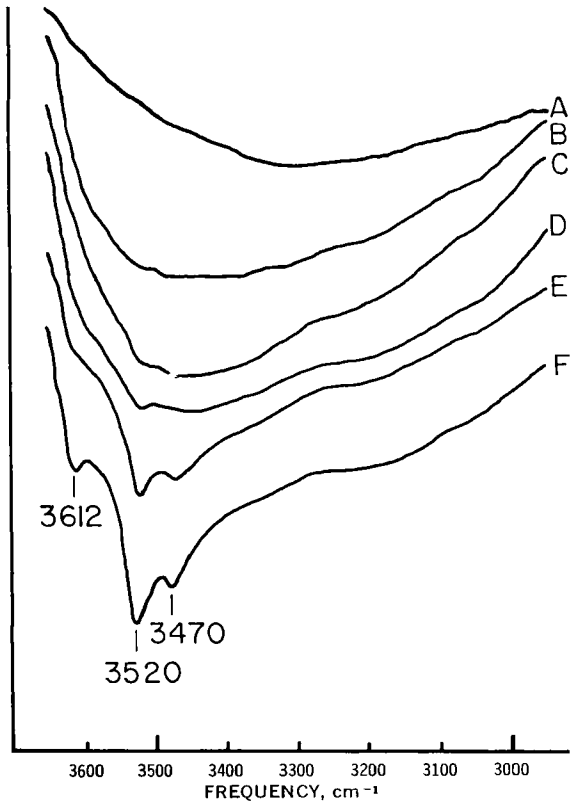

Figure 3—*Change in O—H stretching frequency region of IR spectrum of aluminum hydroxide gel during aging at 25°. Key: A, 5 days; B, 42 days; C, 54 days; D, 61 days; E, 69 days; and F, 124 days.*

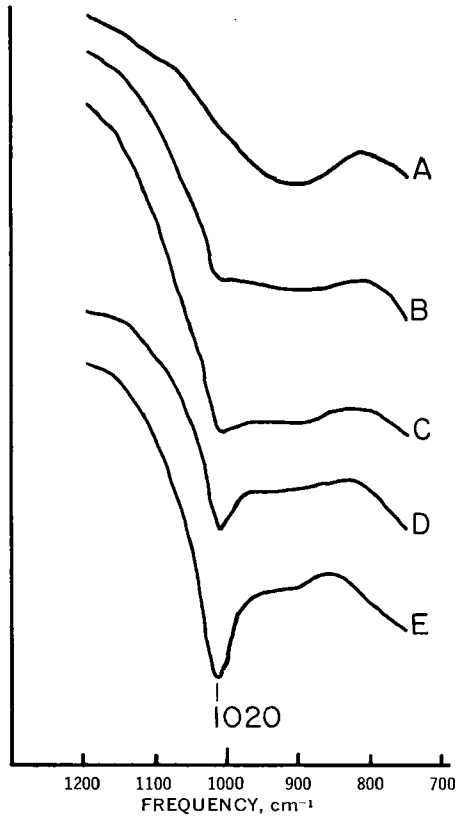

Figure 4—*Change in O—H bending frequency region of IR spectrum of aluminum hydroxide gel during aging at 25°. Key: A, 5 days; B, 54 days; C, 61 days; D, 70 days; and E, 124 days.*

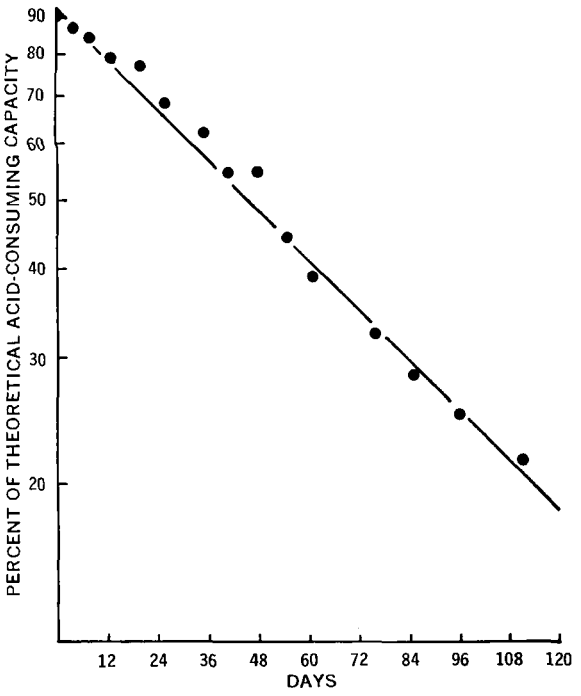

Figure 5—*Change in acid-consuming capacity of aluminum hydroxide gel during aging at 25°.*

when the degree of acid reactivity is compared to IR and X-ray spectral changes. When using IR spectrophotometry, evidence of crystallinity is first seen when the gel is about 50% reactive. X-ray diffraction does not indicate any structural change until the gel is less than 35% reactive. The X-ray diffraction pattern is too diffuse at this point to permit identification of the crystalline phase.

The IR spectra also yield information concerning structural changes occurring during aging. A freshly prepared gel has a diffuse band in both the O—H stretching and deformation regions, indicating a highly unordered structure with many types of environments associated with O—H. As the gel ages, definite absorption bands develop as the hydroxys become part of an ordered structure. Increasing degrees of ordering are apparent from the shape and position of the bands in comparison to the reference IR spectra. This type of analysis yields insight into the mechanism responsible for reactivity losses that occur upon aging.

IR analysis offers additional advantages over X-ray diffraction in terms of lower cost of instrumentation and more universal access to IR spectrophotometers. It is suitable for routine monitoring of aluminum hydroxide gels.

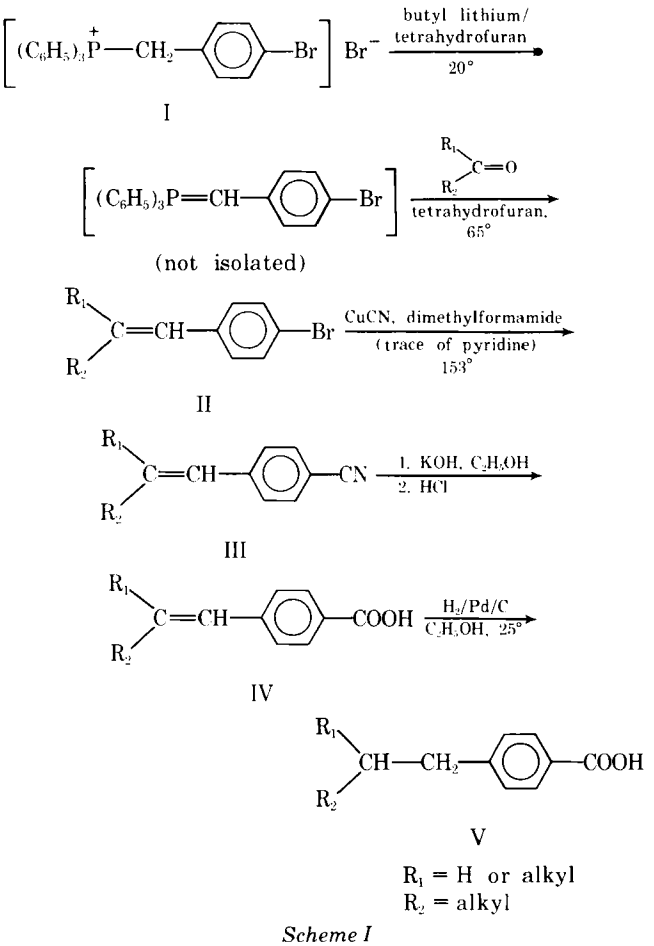
Potential Fibrinolytic Agents: Versatile Synthetic Route to Novel 4-(Branched alkyl)benzoic Acids *via* β-Monosubstituted or β,β-Disubstituted Styrene-4-carboxylic Acids

LARRY J. LOEFFLER ˣ **and SUSAN B. DELOREFICE** *

Abstract □ A versatile and unambiguous synthetic route to some novel 4-(branched alkyl)benzoic acids *via* their β-monosubstituted or β,β-disubstituted styrene-4-carboxylic acid precursors is described. The procedure starts with readily available aldehydes or ketones and the common intermediate *p*-bromobenzyltriphenylphosphonium bromide in a Wittig reaction and proceeds in good yield through *p*-bromostyrene and *p*-cyanostyrene intermediates. Several benzoic acid derivatives were of potential biological interest as fibrinolytic agents.

Keyphrases □ 4-Alkylbenzoic acids, branched—synthesis *via* β-mono- or β,β-disubstituted styrene-4-carboxylic acids, potential fibrinolytic agents □ Styrene-4-carboxylic acids, β-mono- and β,β-disubstituted—precursors in synthesis of 4-(branched alkyl)benzoic acids, potential fibrinolytic agents □ Fibrinolytic agents, potential—synthesis of 4-(branched alkyl)benzoic acids *via* β-mono- or β,β-disubstituted styrene-4-carboxylic acids

This report describes an unambiguous synthetic route to some novel 4-(branched alkyl)benzoic acids and their β-monosubstituted or β,β-disubstituted styrene-4-carboxylic acid precursors, starting from readily available symmetrical or unsymmetrical dialkyl ketones or carboxaldehydes and *p*-bromobenzyltriphenylphosphonium bromide in a Wittig reaction (Scheme I). Such compounds were of interest because of anticipated activity in the activation of the fibrinolytic system for the dissolution of fibrin blood clots. This interest was generated by observations that many compounds with similar features (*i.e.*, aromatic acids with bulky substituent groups such as *o*-thymotic acid) exhibited fibrinolytic activity in an *in vitro* test system involving plasminogen activation (1). Test results, however, subsequently indicated activity for derivatives IV and V only at levels judged too high for potential therapeutic utility (see *Experimental*).



Scheme I

DISCUSSION

An interest in benzoic acids substituted in the *para*-position with a branched hydrocarbon moiety quickly led to the finding that very few such compounds had been reported. In fact, nearly all *p*-alkylbenzoic acids previously reported are *n*-alkyl compounds (2–5), simple three- to five-carbon branched alkyl derivatives (3, 6), or, in a few cases, highly symmetrical larger branched chain compounds (such as that with a 2,2,4,4-tetramethylpentyl substituent) (3, 6, 7).

The only generally applicable synthetic procedures for preparing saturated compounds appear to be those involving Friedel–Crafts *para*-acetylation of alkylbenzenes, followed by oxidative degradation of the acetyl group to a carboxyl group or *para*-acylation (or alkylation) of toluene, followed by oxidation of the methyl group to a carboxyl group. As expected, these procedures may be complicated in the Friedel–Crafts step by benzene ring position isomerization, dialkylation or dealkylation, or isomerization in the side chain (8–11). Also less than desirable are low yield oxidation procedures and often high temperature catalytic oxidations (3, 4, 6, 7).

The synthesis of unsaturated styrene carboxylic acids usually involves dehydration of an alcohol, which, with β-substituted compounds, might proceed in more than one manner to give contaminating double bond isomers.

The synthetic route (Scheme I) starts with the phosphonium salt *p*-bromobenzyltriphenylphosphonium bromide (I). Treatment of I in tetrahydrofuran with butyl lithium at 25° affords the orange phosphorane solution to which either a straight chain or branched aldehyde or unhindered straight chain or branched ketone is added, giving the *p*-bromostyrene (II), normally after refluxing several hours in tetrahydrofuran. Compounds and yields prepared by this method are shown in Table I.

Conversion of the bromo compounds (II) to the corresponding nitriles (III) with cuprous cyanide in refluxing dimethylformamide (trace of pyridine) proceeds smoothly, affording products and yields listed in Table II. Hydrolysis of the nitriles (III) to the unsaturated acids (IV) is readily accomplished with potassium hydroxide in refluxing ethanol (Table III). Where the unsaturated acids (IV) are *cis–trans*-isomer mixtures (*i.e.*, $R_1 = R_2$) (not shown

[a] *cis–trans*-Isomer mixtures.

in Table III), these materials are hydrogenated directly to the saturated acids (V) (Table IV), as are the purified unsaturated acids (IV). Nearly quantitative yields are observed in the hydrogenation step.

Several points concerning this synthetic scheme and the compounds prepared thereby deserve special mention. Of primary significance is the fact that the route outlined is simple and completely unambiguous with regard to the position of the double bond in the unsaturated acids produced; moreover, it allows for no isomerization of alkyl groupings. Therefore, it appears to have distinct advantages over routes utilizing Friedel–Crafts reactions or possible ones involving alcohol formation through a Grignard-type reaction, followed by formation of a double bond through elimination of water or a halogen acid. Success of the latter approach seems unlikely. Great difficulty was experienced in preparing Grignard reagents from secondary alkyl halides (particularly with large alkyl groups) to add to *p*-bromobenzaldehyde. Likewise, the successful use of alkyl ketones or aldehydes to add to a 4-substituted benzyl magnesium halide appears doubtful because of a complicating *para*-substituent (*i.e.*, halogen, cyano, or ester).

With bromo intermediates (II), nitriles (III), and unsaturated acids (IV), where $R_1 = R_2$, varying mixtures of *cis–trans*-isomers were observed, and relative proportions could be quantitatively estimated by vapor phase chromatography in the cases of II and III. No attempt was made to separate isomers on a preparative scale; however, monitoring of distillation fractions indicated that this would probably be feasible in most cases.

Attempted use of the phosphonium salt 4-cyanobenzyltriphenylphosphonium bromide as the Wittig reactant in place of the 4-bromo compound failed completely, presumably because of the deleterious effect of the electron-withdrawing cyano group on the nucleophilic reactivity of the ylid carbon atom. The use of ketones branched on the α-carbon atoms (*i.e.*, 3,5-dimethyl-4-heptanone or phenyl *n*-heptyl ketone) retarded the reaction under conditions employed (refluxing tetrahydrofuran) to such an extent that synthetic utility was eliminated.

Preparation of the unsaturated acid (IV*a*) by reaction of *p*-bromostyrene (II*a*) with magnesium and subsequent carbonation afforded small amounts of product; however, dissolution of magnesium was very sluggish and this route was abandoned.

Attempted hydrolysis of *p*-cyanostyrenes (III) with hydrochloric acid rather than base led rapidly to extensive decomposition of the starting material and none of the desired products.

It appears from the examples discussed that this synthetic route

[a] See Footnote *b*, Table III. [b] From IV. [c] From III.

will be general for aldehydes, including those branched in the α-position, and for ketones, except those with α-branching, at least under the reaction conditions employed in these experiments. It seems reasonable that *meta*-substituted acids also could be readily produced by this method, starting with *m*-bromotoluene.

It may be possible to employ this method for the synthesis of 4-alkylbenzoic acids or styrene carboxylic acids with branching on the α-position of the *para*-substituent, starting with an α-branched *p*-bromobenzyl bromide. However, α-substituents, particularly if large, may hinder successful completion of the Wittig reaction.

EXPERIMENTAL[1]

Chemical Synthesis—*p*-Bromobenzyl bromide, mp 60–61.5°, was prepared from *p*-bromotoluene[2] according to the method of Weizmann and Patai (12). The reaction of this material with triphenylphosphine[2] in toluene, according to the procedure of Hoffmann (13), gave the phosphonium salt (I), mp 278°, which was dried *in vacuo* and stored over phosphorus pentoxide. All ketones and aldehydes were freshly distilled, their purity was determined by vapor phase chromatography, and they were stored under nitrogen over 4A molecular sieves. The solvents used (tetrahydrofuran and dimethylformamide) were distilled and stored over 4A molecular sieves.

Wittig Reaction: 4-(2-Ethyl-1-buten-1-yl)bromobenzene (IIa)—To a stirred suspension of 32.8 g (64 mmoles) of *p*-bromobenzyltriphenylphosphonium bromide (I) in 80 ml of dry distilled tetrahydrofuran (under nitrogen) was added, over 30 min, 40 ml of 1.60 *N* *n*-butyl lithium in hexane (64 mmoles); the temperature was kept between 20 and 25°. The highly colored (orange-yellow) suspension was stirred for an additional 1 hr, 100 mg of benzoic acid was added, and 6.55 g (76 mmoles, 20% excess) of freshly distilled diethyl ketone was added dropwise over 30 min. Little if any temperature increase was observed.

The mixture was then heated to reflux for 24 hr under nitrogen, during which time the color gradually faded. The mixture was neutralized with a small amount of dilute hydrochloric acid, the solvent was removed *in vacuo*, and the residue was steam distilled until the distillate was clear. The combined distillates were extracted with ether; the extracts were dried over magnesium sulfate, filtered, and evaporated to a yellow oil. Vacuum distillation afforded a small amount of starting diethyl ketone in early fractions and then 10.0 g (65.3%) of a colorless oil, bp 88.5–89° (0.7 mm). The material was estimated to have a purity of 98% by vapor phase chromatography; IR (near): 1630 (weak, double bond) cm^{-1} and no evidence of carbonyl absorption.

[1] All melting points were determined using a Thomas-Hoover Uni-Melt capillary melting-point apparatus and are uncorrected. NMR spectra were obtained using a Varian A60-A NMR spectrometer. Chemical shifts (δ) are reported in parts per million (ppm) downfield from an internal tetramethylsilane standard. Vapor phase chromatography was done on an F&M model 810 instrument, employing a 0.6-cm × 1.8-m (0.25-in. × 6-ft) glass column of 5% QF-1 on acid-washed dimethylchlorosilane on Chromosorb BG (100–120 mesh).

[2] Aldrich Chemical Co.

Although all Wittig reaction mixtures were refluxed for about 24 hr, reactions with aldehydes appeared to proceed quite rapidly, even at room temperature, as judged by the fading of the phosphorane color. With ketones, the addition of a trace of benzoic acid appeared to catalyze the reaction significantly. All *p*-bromostyrenes were separated from the by-product triphenylphosphine oxide by steam distillation except II*i* and II*j*, which were not volatile. In these cases, materials were purified by fractional crystallization from ethanol or chloroform–hexane mixtures. The purity of the *p*-bromostyrenes (II*a*–II*h*) was estimated by vapor phase chromatography. Good resolution of *cis*–*trans*-isomers was achieved with II*e*–II*h*, and relative quantities of each in various distillation fractions could be estimated readily from peak areas.

*Nitrile Preparation: 4-(2-Ethyl-1-buten-1-yl)benzonitrile (III*a*)*—A mixture of 4.78 g (20 mmoles) of II*a* (98% pure by vapor phase chromatography), 2.0 g (22 mmoles) of cupric cyanide, 20 ml of dry dimethylformamide, and 12 drops of pyridine was heated to reflux in an oil bath (180°) for 20 hr under nitrogen. The dark mixture (suspension) was cooled and poured into a mixture of 40 ml of concentrated ammonium hydroxide and 40 g of ice. The mixture was extracted thoroughly with ether, and more cold aqueous ammonium hydroxide was added until the solids were completely dissolved. The combined ether extracts were washed thoroughly with dilute ammonium hydroxide, water, 3 *N* HCl, saturated sodium bicarbonate, and water and then were finally dried over magnesium sulfate.

Evaporation of the filtered ether extracts left a brown liquid, which was distilled *in vacuo*, giving a main fraction of 3.12 g (84.1%) of nearly colorless liquid, bp 102–103° (0.6 mm). Vapor phase chromatography indicated greater than 99% purity. The material was redistilled for analysis, bp 85–86° (0.1 mm); IR (KBr): 1635 (C=C, s) and 2220 (C≡N, vs) cm^{-1}.

Anal.—Calc. for $C_{13}H_{15}N$: C, 84.28; H, 8.16; N, 7.56. Found: C, 84.07; H, 7.93; N, 7.70.

The nitriles prepared were examined for homogeneity by vapor phase chromatography (Table II). In III*f*–III*h*, it was readily possible also to resolve *cis*- and *trans*-isomers and to estimate relative percentages of each in crude materials and various distillation fractions. NMR spectra of nitriles supported fully the assigned structures.

*Nitrile Hydrolysis to Unsaturated Acids: 4-(2-Ethyl-1-buten-1-yl)benzoic Acid (IV*a*)*—To a solution of 3.0 g of potassium hydroxide in 15 ml of ethanol were added 1.50 g (8.1 mmoles) of III*a* and 10 mg of hydroquinone, and the mixture was heated to reflux in a stainless steel flask overnight. After the addition of 20 ml of water, ethanol was removed *in vacuo* and the aqueous solution was chilled and acidified with 6 ml of concentrated hydrochloric acid. The copious white precipitate was extracted into several portions of ether, and the combined extracts were dried over magnesium sulfate.

Filtration and evaporation of the filtrates left 1.57 g of white solid, mp 121–128°. Recrystallization from acetonitrile and finally sublimation at 90–100° (0.1 mm) gave the analytically pure material, mp 129–133° (1.21 g, 73.5%); TLC [fluorescent silica, benzene–dioxane–acetic acid (90:25:4)]: R_f 0.52; NMR (deuterochloroform): δ 0.93 (t, 3H, J = 7 Hz, CH_3), 0.97 (t, 3H, J = 7 Hz, CH_3), 2.09 (q, 2H, J = 7 Hz, CH_2), 2.15 (q, 2H, J = 7 Hz, CH_2)[3], 6.15 (s, 1H, vinyl proton), 7.18 (d, 2H, J = 8 Hz, protons *ortho* to alkyl group), 7.97 (d, 2H, J = 8 Hz, protons *ortho* to carboxyl group), and 12.43 (s, 1H, carboxyl) ppm; IR (KBr): 1670 (COOH) and 1645 (sh) (double bond) cm^{-1}.

Anal.—Calc. for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90. Found: C, 76.42; H, 7.72.

All "symmetrical" unsaturated acids (IV*a*–IV*d*) were highly crystalline and were purified easily by sublimation or recrystallization from acetonitrile or ethanol. Nonsymmetrical unsaturated acids all appeared to be mixtures of *cis*–*trans*-isomers and were noncrystalline or broadly melting solids. Their purity, however, was judged as good by TLC and all were hydrogenated readily to crystalline saturated acids (V*e*–V*j*). Attempted hydrolysis of unsaturated nitriles with strong mineral acid rather than base led to extensive decomposition and was completely unsuccessful.

[3] These two pairs of triplets and quartets overlap each other, being displaced from each other by only about 4–5 Hz. This presumably arises because one ethyl group is *trans* to the phenyl ring while the other is *cis* to it.

*Hydrogenation of Unsaturated to Saturated Acids: 4-(2-Ethyl-1-butyl)benzoic Acid (V*a*)*—To a solution of 760 mg (3.7 mmoles) of IV*a* in 50 ml of 95% ethanol was added 100 mg of 5% Pd/C[4]. The mixture was shaken at room temperature on a Paar apparatus under an atmosphere of hydrogen at about 2.1 kg/cm^2 (30 $lb/in.^2$). After 2 hr, the catalyst was removed by filtration through sintered glass, and the filtrate was evaporated *in vacuo*, leaving a white solid, mp 132.5–135°. Sublimation at 120° (0.5 mm) gave 700 mg (91.5%) of material, which was further purified by recrystallization from acetonitrile and sublimation, mp 134.5–135°; TLC [fluorescent silica, benzene–dioxane–acetic acid (90:25:4)]: R_f 0.62; NMR (deuterochloroform): δ 0.7–1.8 (m, complex, 11H, $CH_3CH_2CHCH_2CH_3$), 2.62 (d, 2H, J = 6 Hz, CH_2), 7.23 (d, 2H, J = 8 Hz, aromatic protons *ortho* to alkyl substituent), 8.03 (d, 2H, J = 8 Hz, aromatic protons *ortho* to carboxyl group), and 12.28 (s, 1H, COOH) ppm; IR (KBr): 1670 (COOH) cm^{-1}.

Anal.—Calc. for $C_{13}H_{18}O_2$: C, 76.69; H, 8.79. Found: C, 76.00, H, 8.69.

All saturated acids reported in Table IV were readily purified by sublimation and/or recrystallization from acetonitrile or ethanol. NMR spectra of all saturated acids supported completely the assigned structures.

Fibrinolytic Testing—Saturated and unsaturated compounds (IV and V) were tested utilizing the hanging clot method described by Baumgarten *et al.* (14). Measurable lytic activity was observed at levels of 1 mg/ml but not at lower levels normally required for activity in *in vivo* systems and for clinical utility (1).

Technique for Assessment of Local Effects of Substances Found in Bile upon Opening Pressure of Choledochoduodenal Junction

MARTIN F. TANSY ˣ, DAVID L. INNES, JOHN S. MARTIN, and FRANK M. KENDALL

Abstract □ An assessment of the localized influences of various chemicals found in bile was made by applying them to the interior of the canine choledochoduodenal junction. Test agents were isolated by air bubbles and introduced into the terminal lumen of the intramural portion of the common bile duct *via* the pressure measurement catheter; they remained in the duct for approximately 1.5 min. The system was flushed and opening pressures were then measured. Responses were measured in terms of alterations in ductal opening pressures generated by a linear pressure ramp. Histamine, serotonin, and bethanechol markedly increased ductal opening pressures, whereas epinephrine and norepinephrine decreased opening pressures. None of the agents affected either cardiovascular or small intestinal motor activity in the vicinity of the sphincter when administered in this manner. The results suggest that the presence in bile of certain neurohumoral transmitters and neurohumoral-like agents may directly affect the canine choledochoduodenal sphincter function.

Keyphrases □ Choledochoduodenal junction, canine—effect of neurohumoral transmitters and neurohumoral-like agents present in bile on opening pressure of choledochoduodenal sphincter □ Bile neurohumoral transmitters and neurohumoral-like agents—technique for determining effect on opening pressure of choledochoduodenal junction, dogs

Experimentally, it has been difficult to evaluate discrete drug-induced effects on the sphincter of Oddi *in situ* without encountering the disturbing influence of the surrounding smooth musculature of the duodenum. For anatomical reasons (1), this difficulty has been found to be particularly true in the dog.

The effects of intravenous and intraarterial injections of drugs on the canine sphincter of Oddi have received much attention, but repeated results have sometimes been inconsistent. Presumably, the reason for injecting drugs into the arterial supply to the terminal bile duct is to affect the sphincter of Oddi selectively. However, because of the close anatomical relation between the terminal bile duct and the duodenum, it is probable that an injected drug would reach the surrounding duodenum even though it reached the terminal bile duct first. Of course, drugs injected intraarterially also may exert their effects on the sphincter of Oddi indirectly by affecting the vasculature.

An alternative way of selectively affecting the sphincter of Oddi would be to introduce drugs into the lumen of the terminal bile duct. This proposal is in conformity with an interesting series of experiments on the action of some antibiotics on the extrahepatic biliary tract (2–5). In one experiment (3), intraductal erythromycin increased the motility and tone of the terminal bile duct in the guinea pig, cat, dog, and monkey. In subsequent experiments (6), intraductal aminosiderin decreased the motility and tone of the normal and hypertonized choledochus in the same species of animals. The consensus was that antibiotics eliminated in the active form in the bile can interfere with both the tone and motility of the extrahepatic biliary tract.

Published work so far has dealt primarily with intraductal antibiotics. However, biliary excretion into the lumen of the intestine is a major pathway of elimination of a whole host of drugs and drug metabolites. An excellent summary of the literature data relating to biliary excretion of drugs in animals and humans is available (7).

It was considered worthwhile to determine whether various normal constituents of bile, as well as pharmacological agents known to be excreted in the bile, can produce a discrete, localized effect upon the choledochoduodenal junction, which may or may not be similar to their action when administered intragastrically or systemically.

EXPERIMENTAL

Animals and General Procedure—Thirty-four adult mongrel dogs were used. All experiments were undertaken after the animals had been fasted overnight with water *ad libitum*. The animals were anesthetized at first with intravenous injections of thiopental sodium[1] (25 mg/kg), followed by maintenance with a mixture of α-chloralose (5%, dissolved in polyethylene glycol 200) and urethan (50% in 0.9% saline solution). Further injections of the chloralose–urethan mixture were given when necessary.

Surgical and Recording Procedure—Along with a tracheotomy, a thoracotomy and laparotomy were performed in each dog through a long midline incision. A tracheal cannula was routinely inserted. Systemic pressure was measured from a cannula inserted into a femoral artery. Through an ileostomy, an open-tip catheter with a balloon attachment was introduced into the upper jejunum. For recording biliary flow, another catheter was inserted into one hepatic duct toward the liver and the other end was connected to a photoelectric cell drop counter.

Measurements of sphincter opening pressures were conducted as follows. A polyethylene catheter was inserted into the common bile duct *via* the fundus of the gallbladder. The end of the catheter was advanced through the duct toward the duodenum until palpation indicated that it was *juxta* the sphincter of Oddi. The catheter was secured by tying it at its insertion into the fundus of the gallbladder. A longitudinal duodenotomy was performed at a point opposite the opening of the choledochoduodenal junction to permit visualization of the sphincter.

Duodenal stabilization was effected in such a manner that the sphincter opening could be completely immersed in a pool of clear saline. The perfusion system was filled with warmed normal saline containing a blue food dye. It was thus possible to confirm an opening of the sphincter by direct visualization of a thin stream of blue fluid in the clear pool of saline covering the aperture. The

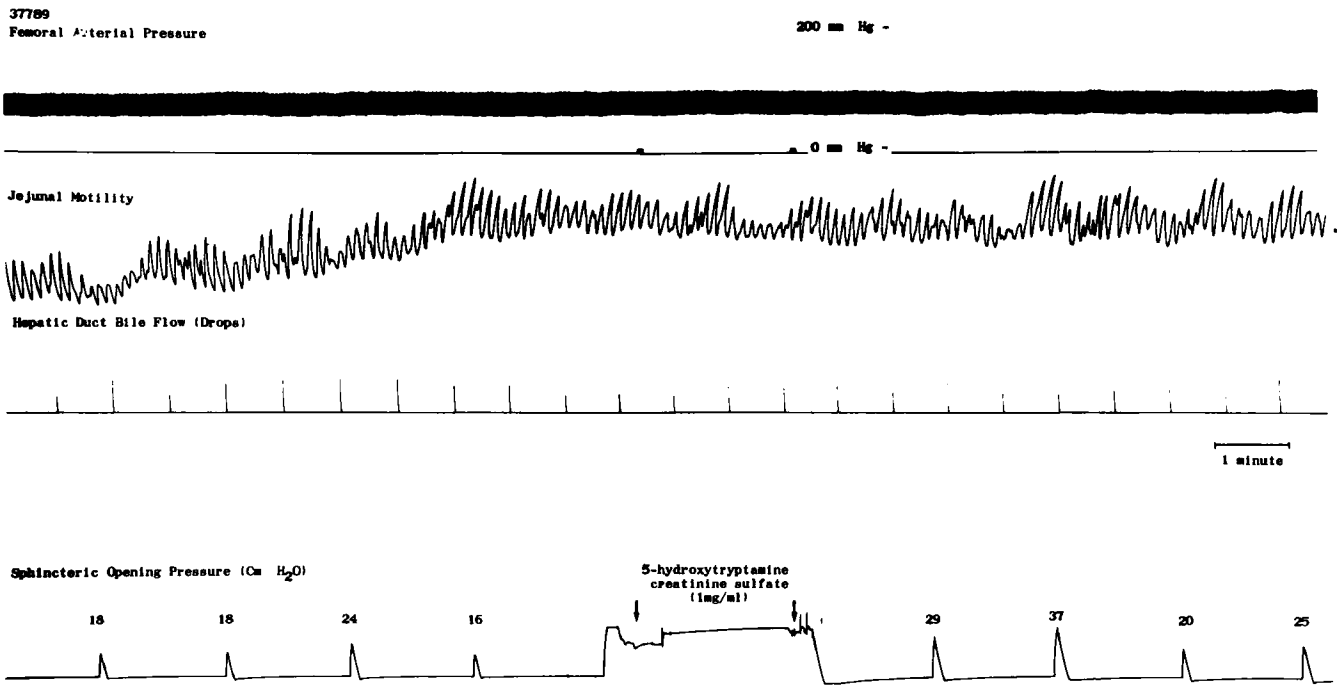

Figure 1—*Polygram depicting the time course of femoral arterial blood pressure, intrajejunal pressure activity, bile flow rate as measured with a drop recorder, and ductal opening pressure in a bilaterally vagotomized dog. Serotonin was introduced into the terminal bile duct during the period indicated by arrows. The extraductal events were not altered during or following drug administration. The pressure limb rise and plateau configuration seen in this figure represent the measurement system pressure during the introduction and subsequent stasis of a test agent. The drop in pressure limb represents the rapid washout of the small fluid volume (0.2 ml) and the reversal of the infusion pump.*

dyed saline flowing through the choledochus was drained outside the duodenum by a large outflow tube inserted into the duodenal lumen.

The perfusing catheter was connected to a constant-flow infusion pump through a "T" tube. The side arm was connected by valves to a fluid reservoir, pressure transducer, and tall manometer tube. The pressure transducer was simply calibrated in terms of the height of the column of saline in the manometer tube. In essence, the compliance represented by the fluid column is so large with respect to the lumped compliances of both the terminal common duct and the polyethylene catheter that the entire system compliance is substantially that of the manometer. Thus, infusion at a constant flow results in a linear rate of pressure rise in the duct.

Initial experiments (8) had shown that a pressure ramp value of 7 cm/sec was satisfactory. This value is in substantial agreement with that utilized previously (9, 10). Femoral blood pressure, upper jejunal pressure, hepatic duct flow, and sphincter opening pressures were recorded with an ink-writing polygraph.

Chemicals—The following were used: histamine dihydrochloride[2], epinephrine hydrochloride[2], norepinephrine hydrochloride[2], 5-hydroxytryptamine creatinine sulfate[2], magnesium sulfate[2], papaverine[2], secretin[2], bethanechol chloride[3], morphine sulfate[3], lidocaine hydrochloride[4], penicillin G potassium[5], cephaloridine[5], chloramphenicol succinate[6], rifampin[7], and cholecystokinin[8].

All drugs were administered intraductally. Drugs were introduced into the region of the sphincter by administration through the pressure measurement catheter and allowed to remain for a definite period. Both ends of the solution column were marked by air bubbles. It was thus possible to determine when the drug arrived at its intended site of action, because the blue marker dye abruptly disappeared. Similarly, removal of the test agent was also clearly marked by reappearance of the dye marker. Drug sequences were randomized among the various experiments. Following intraductal stasis, each drug was flushed from the ductal lumen with copious amounts of saline to ensure that chemical or functional interactions would be minimized.

Each series of experimental opening pressure determinations following drug administration was immediately preceded by a control series of determinations. Mean opening pressures for each posttreatment series were statistically compared to the mean values of the preceding pretreatment values under the null hypothesis that mean posttreatment opening pressures were the same as pretreatment values. The alternative hypothesis stated that posttreatment mean values were different, with rejection of the null hypothesis being made at the 5% level of confidence for a two-tailed test.

RESULTS AND DISCUSSION

Figure 1 is a complete polygram depicting arterial blood pressure, intrajejunal pressure activity, and biliary flow preceding, during, and following the intraductal administration of serotonin. It can be readily seen that these parameters were unaffected. Sphincter opening pressures measured after washout of the drug were increased.

Table I summarizes the mean opening pressures observed prior to and subsequent to the intraductal administration of histamine, norepinephrine, epinephrine, serotonin, and bethanechol. Histamine, serotonin, and bethanechol administrations were subsequently associated with elevated mean opening pressures, while norepinephrine and epinephrine were associated with subsequently lowered mean opening pressures. In all cases, the differences in mean values were significant.

The data shown in Table I were obtained from polygrams that also recorded vascular activities and jejunal pressure activity as depicted in Fig. 1. Although not shown, these polygrams revealed that in no case was the intraductal administration of any of these agents effective in altering either ongoing cardiovascular activity or intestinal motor function in the near vicinity of the choledochoduodenal junction.

Preliminary experiments with other agents revealed that rifampin (12 trials in two dogs) was also associated with apparent in-

37600	26.3 ± 3.25 (8)	79.1 ± 6.47 (8)

[a] Difference in mean opening pressures are significant in each experiment. [b] Opening pressure measurements are in centimeters of saline; ± indicates 1 *SD*; parentheses contain number of observations.

creases in opening pressures. The following agents did not appear to produce any qualitative changes in sphincter opening pressures when administered intraductally: lidocaine (18 trials in two dogs), magnesium sulfate (18 trials in two dogs), papaverine (18 trials in two dogs), morphine sulfate (22 trials in five dogs), cephaloridine (12 trials in two dogs), penicillin G potassium (12 trials in two dogs), chloramphenicol (12 trials in two dogs), secretin (18 trials in four dogs), and cholecystokinin (15 trials in two dogs).

A histological description of the terminal ductal mucosa probably illuminates the observations made with respect to the marked elevation of mean opening pressures produced by the intraductal administration of histamine and bethanechol. According to Bhatnagar *et al.* (11), the mucosal coat of the interior of the canine common bile duct is continuous with the lining membrane of the hepatic ducts and gallbladder and also with that of the duodenum. The epithelium is of columnar variety.

This description is characteristic of highly vascularized tissue, and the effect noted in the present study was probably due to a parasympathomimetic edematous effect which is similar to the increase in upper airway resistance common in such reactions as allergic rhinitis. The inhibitory effect of intraductal norepinephrine, and to a lesser extent epinephrine, was probably produced by local vasoconstriction, a phenomenon that is analogous to shrinking the edematous nasal membrane with this type of agent.

The intraductal administration of serotonin also significantly elevated mean opening pressures. Although the functional significance of this observation is not at all clear, the observation itself again points directly to the as yet baffling question of just what is the functional significance of the serotonin content of the large enterochromaffin cell population of the intramural portion of the common duct or, for that matter, of the pancreatic duct (12).

A few of the remaining results were generally supportive of data collected previously by other investigators, and only a few points require discussion. The observation that the intraductal administration of lidocaine was ineffective in altering mean opening pressures supports the observations of McCarthy and Picazo (13) in humans. The observation that rifampin tended to increase ductal opening pressures is in agreement with the results of Benzi *et al.* (3), who noted that intraductal administration of rifampin (rifamycin SV) induced a hypertonus of the canine choledochus.

In light of these findings, it is believed that intraductal administration of various test agents may have revealed an interesting facet to the evaluation of various experimental observations relative to ductal control mechanisms. Thus, the observation that intraductal administration of cholecystokinin has no effect upon mean ductal opening pressures is in opposition to the experimental findings of others that intravenous administration of the same substance lowers mean opening pressures. However, intravenous administration of cholecystokinin also causes relaxation of the duodenal musculature in the region of the ampulla (14). Undoubtedly, the relaxing action of cholecystokinin on the duodenum would increase flow through the terminal duct in this species. The difference in effects accompanying the administration of an agent by different routes indicates that a procedure that introduces an agent *via* a route permitting widespread systemic action is dangerous if the purpose of the study is to determine whether a highly discrete and localized effect does occur *in situ*.

The same argument may be advanced with respect to the systemic administration of other agents such as morphine or epinephrine, especially when the *in vivo* and *in vitro* sphincter effects are already known to be different. For example, according to Persson (15), *in vivo* morphine is active locally on the cat choledochoduodenal junction but inactive when added to the bath fluid of the isolated feline sphincter of Oddi. On the other hand, isolated spiral strips cut from the terminal bile duct respond to epinephrine by contracting (16). However, when the terminal bile duct remains surrounded by the wall of the duodenum into which it is inserted, the action of intravenous epinephrine seems to depend on the tone and motility of the duodenum (17).

CONCLUSIONS

It appears that the intraductal technique of administering drugs permits a very localized and quantitative estimation of the effects of various test agents on the tone and motility of the choledochoduodenal junction. This technique may eventually prove of value in the evaluation of the effects of therapeutic agents and/or their metabolites that are secreted in the bile if it is applied systematically, as part of well-defined protocols, so that adequate experience can be obtained to permit a judgment of its merit.

Binding Study of Sulfonylureas and Phenothiazines to Bovine Serum Albumin Using Difference Spectrophotometry

H. ZIA[*§] and JAMES C. PRICE [‡x]

Abstract □ 2-(4′-Hydroxybenzeneazo)benzoic acid is a spectrophotometric probe which shows absorption spectrum changes upon binding to protein. Difference absorption spectra of this probe were used as an indirect measurement of the binding of selected sulfonylurea and phenothiazine drugs to bovine serum albumin. The results obtained using the spectrophotometric probe were similar to data obtained from other methods, especially fluorescent methods. Of the four sulfonylureas studied, tolbutamide showed the highest binding affinity, followed by glyburide, glipizide, and acetohexamide, in that order. The data collected for phenothiazine drugs indicated that chlorpromazine has the highest affinity, followed in order by trifluoperazine, perphenazine, fluphenazine, and promazine. Correlation of these results with chemical composition indicated that the interaction of phenothiazine drugs with bovine serum albumin was of a hydrophobic nature.

Keyphrases □ Sulfonylureas and phenothiazines—binding to bovine serum albumin, difference spectrophotometry using 2-(4′-hydroxybenzeneazo)benzoic acid □ Phenothiazines and sulfonylureas—binding to bovine serum albumin, difference spectrophotometry using 2-(4′-hydroxybenzeneazo)benzoic acid □ Spectrophotometry, difference—determination, binding of sulfonylureas and phenothiazines to bovine serum albumin using 2-(4′-hydroxybenzeneazo)benzoic acid □ 2-(4′-Hydroxybenzeneazo)benzoic acid—used to determine binding of sulfonylureas and phenothiazines to bovine serum albumin, difference spectrophotometry

The phenomena of drug–protein binding and of competitive binding of drugs for available protein sites have been the subjects of many investigations and have been reviewed (1). Various experimental procedures and analysis methods have been used to study drug–protein interactions. These include equilibrium dialysis (2), ultrafiltration (3), gel filtration (4), NMR rate measurements (5), and fluorescence techniques (6).

Compared to dialysis or ultrafiltration techniques, spectrophotometric and/or fluorescence probe techniques are capable of providing data similar to what could be obtained through dialysis or ultrafiltration studies but are less time consuming, simpler, and more reproducible. It also may be possible to estimate the nature of binding and binding sites from the chemical structure and spectral properties of the probes used (7).

In spite of their usefulness in protein binding studies, fluorescence probes cannot be used successfully in certain instances such as the lack of a fluorescence change upon binding and/or a change of fluorescence due to a mechanism other than binding (*e.g.*, photoxidation).

Although fluorescence probes have been explored in recent years, little information has been generated concerning spectrophotometric probes. In 1968, Moriguchi and coworkers (8–11) studied the binding of the 2-(4′-hydroxybenzeneazo)benzoic acid probe to bovine serum albumin. Recently, Nazareth *et al.* (12) used this probe as an agent that reflects the binding of L-thyroxine to serum albumin. However, in this study they employed ultrafiltration to separate the free probe from serum albumin to calculate the ratio of bound drug to protein.

The usefulness of spectrophotometric probes in the study of the binding of drugs to protein has not been adequately explored. In addition, certain procedures and methods of data treatment reported for fluorescence probes (13, 14) appear to be useful for the spectrophotometric probe technique. This study was made to explore the usefulness of 2-(4′-hydroxybenzeneazo)benzoic acid as a spectrophotometric probe in studying the interaction of sulfonylurea and phenothiazine drugs with bovine serum albumin and to define, if possible, the binding parameters of some of these drugs.

tral grade, and all other chemicals were reagent grade.

Apparatus—Absorption spectra and difference absorbance measurements were made with a double-beam spectrophotometer[9] equipped with tandem cell holders.

Absorbance Difference Titrations—The absorbance difference titrations in the absence and presence of drugs were carried out manually with microsyringes[10]. The probe was dissolved in methanol at a concentration of 1 × 10^{-2} *M*. The bovine serum albumin solutions were buffered at pH 7.4 with 0.05 *M* phosphate for sulfonylureas and 0.05 *M* tromethamine for phenothiazines.

Two 3.00-ml quantities of bovine serum albumin solution were pipetted into two cells and two 3.00-ml quantities of buffer solution were pipetted into two other cells; these cells were placed in the reference and sample beams in such a manner that a buffer cell and a protein solution cell were in tandem in each beam. After running a baseline, the contents of the buffer solution cell in the reference beam and the protein solution cell in the sample beam were titrated with successive additions of 3 μl of probe solution and absorbance differences were measured.

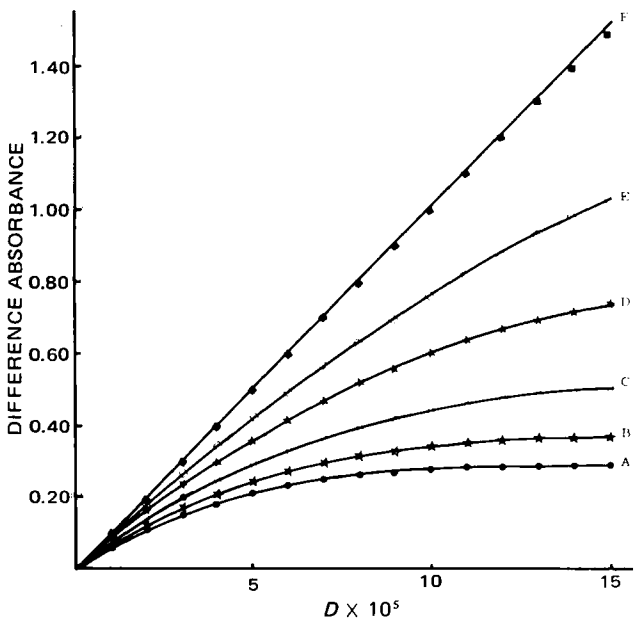

Figure 2—*Absorbance differences as a function of the 2-(4′-hydroxybenzeneazo)benzoic acid concentration, D, at various bovine serum albumin concentrations: A, 3.45 × 10^{-5} M; B, 4.6 × 10^{-5} M; C, 6.9 × 10^{-5} M; D, 13.8 × 10^{-5} M; and E, 55.2 × 10^{-5} M. The theoretical line (F) is based on calculated values of absorbance difference for high concentrations of bovine serum albumin.*

[10] Hamilton Co., Reno, Nev.

Because of low solubility in water, all sulfonylureas were dissolved in 0.1 *N* NaOH solution with the exception of glyburide, which was dissolved in methanol. The addition of the microliter quantities of the sodium hydroxide solutions of the drugs did not change the final pH of the cell solutions more than 0.05 pH unit. The phenothiazine drugs were dissolved in tromethamine buffer with the exception of perphenazine, which was dissolved in methanol. All absorbance difference measurements were made at ambient temperature.

Data Treatment—The absorbance difference observed upon addition of the probe to bovine serum albumin was measured for each successive addition in the absence and presence of the competitive drugs at 482 nm. These data were used to calculate the fraction of bound probe, *X*, using the following equation:

$$X = \frac{\Delta A_l}{\Delta A_h} \qquad \text{(Eq. 1)}$$

where ΔA_l and ΔA_h refer to the absorbance difference of a given concentration of probe in solutions of low and high protein concentration, or the absorbance difference in the absence and presence of excess sites, respectively. To determine the value of ΔA_h for a given concentration of probe, absorbance difference titrations were carried out at several different protein concentrations and the values of ΔA_h were taken to be values extrapolated to the intercepts of plots of $1/\Delta A$ *versus* $1/[P]$, where $[P]$ represents the total concentration of protein.

After values for the fraction of bound probe were found for all points along the titration curve, the data were treated according to the Scatchard (15) equation:

$$\bar{V}/[D] = nK_a - \bar{V}K_a \qquad \text{(Eq. 2)}$$

where $\bar{V}$ is the number of moles of bound probe per mole of protein, $[D]$ is the concentration of free probe, n is the number of binding sites on the protein, and K_a is the intrinsic association constant of the complex. In addition, plots of $\log \bar{V}/(n - \bar{V})[D]$ *versus* $\bar{V}$ were drawn (13).

The competitive binding of two different groups of drugs, sulfonylureas and phenothiazines, were studied using 2-(4′-hydroxybenzeneazo)benzoic acid as the indicating probe. The binding of the probe to bovine serum albumin was determined in the presence and absence of competitive drugs by varying the concentration of the probe at constant albumin and drug concentrations. The binding constants of competitive drugs were calculated by using the equation of Klotz *et al.* (16):

$$K_b = \frac{n[P_t]K_a[D] - K_a[D][PD] - [PD]}{[B_t]K_a[D] - n[P_t]K_a[D] + K_a[D][PD] + [PD]} \times \frac{K_a[D]}{[PD]} \qquad \text{(Eq. 3)}$$

where:

K_b = association constant for competitor
K_a = association constant for probe
$[D]$ = concentration of free probe
$[PD]$ = concentration of bound probe
n = number of binding sites
$[P_t]$ = total concentration of protein
$[B_t]$ = total concentration of competitor

RESULTS AND DISCUSSION

The usefulness of a dye probe for the study of drug–protein binding comes from the fact that the absorption spectrum of the dye changes as a result of binding to the albumin. Figure 1 shows typical absorption difference spectra at constant serum albumin concentration with several concentrations of 2-(4′-hydroxybenzeneazo)benzoic acid. These spectra have a maximum at 482 nm,

Table I—Association Constants of Sulfonylureas to Serum Albumins

Compound	Blood Fraction	Method	Association Constants, M^{-1}	Reference
Acetohexamide	HSA[a]	Dialysis	$K^b = 3.39 \times 10^4$	19
	BSA[c]	Fluorescence	$K^d = 3.76 \times 10^4$	20

[a] HSA = human serum albumin. [b] The pH and temperature of the solution were 7.4 and 40°. [c] BSA = bovine serum albumin. [d] The pH and temperature of the solution were 7.4 and 25°. [e] The pH and temperature of the solution were 7.4 and 37°.

and the absorbance difference increases as the concentration of the probe increases.

The absorbance difference data measured at 482 nm for probe–bovine serum albumin are plotted as a function of probe concentration in Fig. 2. The values of the points on the theoretical line are taken from the extrapolated values of the plots of $1/\Delta A$ *versus* $1/[P]$ (see *Data Treatment*).

Scatchard plots for the binding of probe to bovine serum albumin are shown in Fig. 3. At various concentrations of protein, the Scatchard plots gave lines that, like fluorescence results, are not truly linear in all ranges of concentration (13). The curvatures of Scatchard plots are generally considered to indicate that probe molecules bind to more than one class of sites on the protein. Recently, based on fluorescence results, it was suggested that the intrinsic association constants may not be equal even in the same class of binding sites (13).

Although these considerations are likely in some instances, another possibility is suggested by the spectrophotometric data collected here. It can be postulated that, in the range of concentration studied, the spectral changes are due to the formation of a charge transfer complex of only one probe molecule with one serum albumin molecule. This possibility is indicated by the fact that the value of $\bar{V}$ in the range of concentration studied never exceeded 1 and, as seen in Fig. 3, that line *C* with the lowest concentration of albumin starts to fall off as $\bar{V}$ exceeds the value of 0.85.

It has been reported from equilibrium dialysis studies that dyestuffs may bind to as many as 11 and/or 22 sites on serum albumin (17, 18). Although physical interpretation of these sites is questionable, it is possible that there are additional binding sites for probe molecules that do not cause spectral changes and that cause negative deviations from linearity of Scatchard-type data plots.

Figure 4 shows the results as plotted according to a modified Scatchard equation (13). In this figure, the values of log $\bar{V}/(n - \bar{V})[D]$, where n is assumed to be 1, are plotted against $\bar{V}$. The lines are linear except at the extremes of concentration.

For the purpose of competitive binding, the fact that the curves of Fig. 3 are not completely linear in all ranges of concentration need cause little concern, because the probe molecules are only used as a relative measure of the binding of drugs and the albumin may not be molecularly homogeneous with respect to its binding properties. It may only be necessary either to select a range of concentration within which the binding data can be mathematically treated or to substitute corresponding values of K for each point along the Scatchard plot into Eq. 3 to calculate the binding constants of the competitor drugs. In fact, for fluorescence data where probe molecules are said to bind to one class of sites, the low values of $\bar{V}$ have been disregarded to obtain a straight line with a high significance factor (13, 16). It is evident that the same treatment can be applied to the data in Fig. 3 to find the values of K and n for the range of concentration within the linear portion of the plot.

Moriguchi *et al.* (8) studied the binding of 2-(4′-hydroxybenzeneazo)benzoic acid to bovine serum albumin Fraction V and expressed their results by a modified Langmuir-type equation:

$$\log [\bar{V}(n - \bar{V})] = m \log [D] + m \log K \quad \text{(Eq. 4)}$$

where m is an empirical parameter and varies with factors such as protein concentration, buffering agent, and temperature.

By this method and by using an estimated value of molar absorptivity that is known to be dependent on factors such as solvent and temperature, the value of n was determined by trial and error so that the plot of log $[\bar{V}(n - \bar{V})]$ *versus* log $[D]$ was linear. In this way, the authors found the values of n and log K to be equal to 2 and 4.2 ± 0.1, respectively, while the value of m varied from 0.96 to 0.86 for albumin concentrations of 0.25×10^{-4}–1×10^{-4} *M*.

Nazareth *et al.* (12) used the same probe to reflect the binding

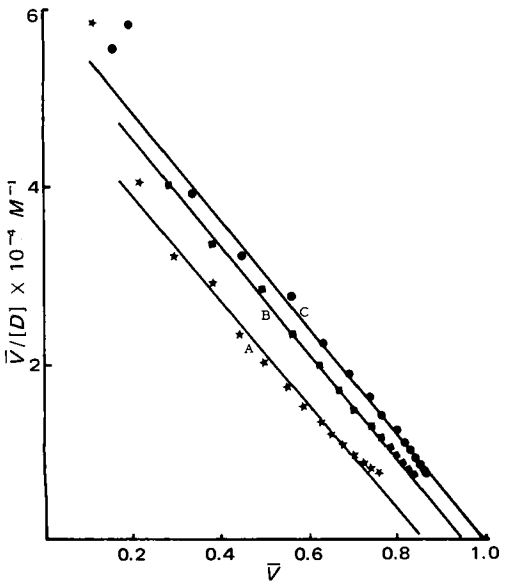

Figure 3—*Scatchard plots of 2-(4′-hydroxybenzeneazo)benzoic acid binding to various bovine serum albumin concentrations in 0.05* M *phosphate buffer, pH 7.4. Key:* ●, 3.45×10^{-5} M; ■, 4.6×10^{-5} M; *and* ★, 6.9×10^{-5} M.

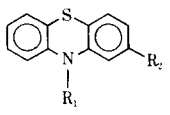
Table II—Association Constants of Selected Phenothiazines to Bovine Serum Albumin



Generic Name	R_1	R_2	Association Constant $\times 10^{-4}\ M^{-1}$
Chlorpromazine hydrochloride	Cl	$-CH_2CH_2CH_2N(CH_3)_2$	2.57
Trifluoperazine hydrochloride	CF_3	$-CH_2CH_2CH_2N\langle\rangle NCH_3$	2.32
Perphenazine	Cl	$-CH_2CH_2CH_2N\langle\rangle NCH_2CH_2OH$	1.96
Fluphenazine hydrochloride	CF_3	$-CH_2CH_2CH_2N\langle\rangle NCH_2CH_2OH$	1.82
Promazine hydrochloride	H	$-CH_2CH_2CH_2N(CH_3)_2$	1.04

of L-thyroxine to serum albumin. Ultrafiltration was used to determine the ratio of bound drug to protein, and low values of $\bar{V}$ were utilized to draw reciprocal plots to show the binding and displacement of probe to and from primary sites of albumin.

A comparison of the spectrophotometric method reported here with the methods of Moriguchi *et al.* (8) and/or Nazareth *et al.* (12) together with the results obtained from each method illustrates the usefulness and simplicity of the spectrophotometric method. It is recognized that the determination of binding parameters may depend on the experimental methods used. For some classes of components, the results obtained from spectrophotometric and fluorescence techniques are different from those of other methods, probably because only the primary (strong) binding sites causing spectral changes are detected, whereas the results obtained from other methods such as dialysis often show larger numbers of binding sites.

Competitive Binding between 2-(4′-Hydroxybenzeneazo)benzoic Acid and Sulfonylureas—A typical difference absorption spectrum in the presence and absence of a drug (glyburide) is shown in Fig. 5; the addition of competitive drug decreased the absorbance differences, presumably because the bound probe was displaced from the protein. The results of difference absorbance measurement at 482 nm in the presence and absence of fixed amounts of each sulfonylurea are shown as Scatchard plots in Fig. 6. The bovine serum albumin and sulfonylurea concentrations were held constant at 6.9×10^{-5} and 5×10^{-5} *M*, respectively, while the concentration of probe was varied from 1×10^{-5} to 11×10^{-5} *M*.

The binding constants calculated using the equation of Klotz *et al.* (16) are shown along with literature data in Table I. It can be seen from Table I and Fig. 6 that, as the association constants of the competitor sulfonylureas increase, the slopes of Scatchard plots decline. These findings, together with the fact that binding of probe decreases when it is in competition with sulfonylureas, appear to indicate that these drugs bind to the bovine serum albumin *via* the same site or closely located sites on the protein.

The conclusion to be drawn from Table I is that the binding constants found by the spectrophotometric probe technique are comparable to fluorescence data but are different from dynamic dialysis where more than one class of sites is detected. Among the four sulfonylureas studied, tolbutamide had the highest binding affinity followed in order by glyburide, glipizide, and acetohexamide.

Displacement of 2-(4′-Hydroxybenzeneazo)benzoic Acid by Phenothiazines—The determination of binding constants of phenothiazine drugs to serum albumin by the usual fluorescence probe technique is somewhat difficult because of rapid photoxidation and the consequent rapid change in fluorescence. Equilibrium dialysis is also ruled out because of the length of time required during which drugs are oxidized. Since the spectrophotometric probe technique utilizes very low light levels (compared to the fluorescence technique) and the analysis time is short, it has strong advantages over the other methods for this class of drugs.

In this study, the bovine serum albumin and phenothiazine concentrations were held constant at 4.6×10^{-5} and 1.5×10^{-4} *M*, respectively, while the concentration of the probe was varied from 1×10^{-5} to 15×10^{-5} *M*. Figure 7 shows Scatchard plots of the ef-

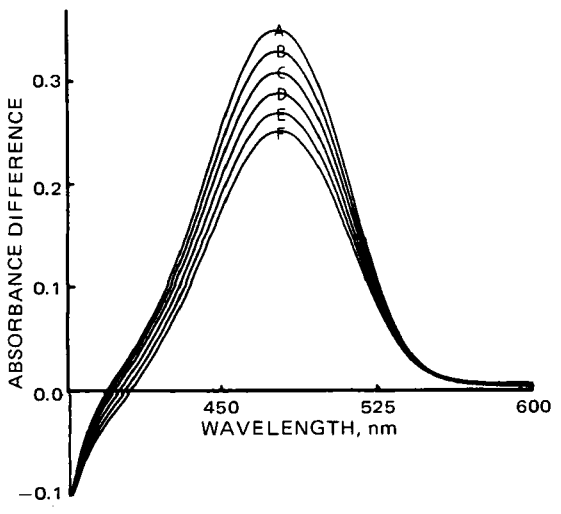


Figure 5—*Absorbance difference spectra for solutions containing bovine serum albumin (6.9×10^{-5} M) and 2-(4′-hydroxybenzeneazo)benzoic acid (6.5×10^{-5} M) in absence (curve A) and presence (curves B, C, D, E, and F) of 1.25×10^{-5} M increments of glyburide.*

fect of adding different phenothiazine drugs to probe–bovine serum albumin solutions, and Table II shows calculated association constants. Chlorpromazine showed the greatest displacement of probe, followed by trifluoperazine, perphenazine, fluphenazine, and promazine. Furthermore, the binding was enhanced by direct or indirect halogen substitution on the phenothiazine moiety. Promazine, with no substitution at the 2-position, had the lowest value of K; chlorpromazine, having one chloride in the 2-position, had the highest value of K.

In addition, the side chain substitution at the 10-position also has considerable effect on the binding of these drugs. This is shown by trifluoperazine and fluphenazine, which have the same substitution at the 2-position but differ by their side chain at the 10-position. The hydroxy group on the fluphenazine appears to reduce the binding capacities. These results seem to indicate that interaction of phenothiazine drugs with bovine serum albumin is hydrophobic in nature. This conclusion is supported by the fact that the greater the hydrophobicity of the drug molecule, the greater is the value of the association constant.

The fact that Scatchard plots in the presence of phenothiazine drugs do not converge at the same intercept probably indicates that the site of binding for these drugs is not identical to that of the probe. It is likely that the binding of these drugs alters the conformation of the protein, thereby causing displacement of the probe. It is hoped that further work with these drugs will help explain the significance of these results.

SUMMARY

Difference spectrophotometry was used to show the displacement of a spectrophotometric probe [2-(4'-hydroxybenzeneazo)-benzoic acid] from bovine serum albumin by two classes of drugs, sulfonylureas and phenothiazines. It was shown that the difference absorbance data obtained could be treated in a manner similar to those obtained from fluorescence probe measurements.

Among the four sulfonylureas studied, tolbutamide showed the largest displacement of probe and the highest calculated binding affinity followed in order by glyburide, glipizide, and acetohexamide. These results closely paralleled reported results obtained by other techniques.

Among the phenothiazines, chlorpromazine showed the highest probe displacement and calculated binding affinity followed in order by trifluoperazine, perphenazine, fluphenazine, and promazine. These results indicated that the order of binding affinity was based on the hydrophobicity of the phenothiazine, with the more hydrophobic molecules being more strongly bound.

It is concluded that the use of difference spectroscopy to study indirectly the binding of drugs by measuring the displacement of a spectrophotometric probe offers several advantages over other methods. These advantages include convenience and fewer problems of oxidation and decomposition because of the short analysis time required and the low light intensities used. Interference from the fluorescence of drug molecules is also less of a problem than when fluorescent probes are used.

Effect of Uridine Diphospho-*N*-acetylglucosamine and Sodium Salicylate on L-Glutamine–D-Fructose-6-phosphate Aminotransferase Activity from Rat Gastric Mucosa

JAMES CHAN and K. H. LEE ˣ

Abstract □ Mechanisms of inhibitory action of sodium salicylate on L-glutamine–D-fructose-6-phosphate aminotransferase, prepared from rat gastric mucosa, were studied. Sodium salicylate at lower concentrations (10–20 m*M*) inhibited reversibly aminotransferase activity by competing with fructose-6-phosphate. At higher concentrations, sodium salicylate inactivated the enzyme irreversibly, with an inactivation rate following first-order kinetics with respect to the enzyme concentration. Uridine-5′-diphospho-*N*-acetylglucosamine is an endogenous feedback inhibitor. It inhibited the aminotransferase-catalyzed reaction also by competing with fructose-6-phosphate but with an inhibiting activity 1000 times that of sodium salicylate. Uridine-5′-diphospho-*N*-acetylglucosamine reduced the salicylate inhibition of the enzymic reaction and protected the enzyme from salicylate-induced irreversible inactivation. At a fixed concentration of uridine-5′-diphospho-*N*-acetylglucosamine (7×10^{-6} *M*), an increase of salicylate concentration produced an increase in enzyme activity as compared with the control.

Keyphrases □ L-Glutamine–D-fructose-6-phosphate aminotransferase activity—inhibition by sodium salicylate and uridine-5′-diphospho-*N*-acetylglucosamine, rat gastric mucosa □ Sodium salicylate—inhibition of L-glutamine–D-fructose-6-phosphate aminotransferase activity from rat gastric mucosa □ Uridine-5′-diphospho-*N*-acetylglucosamine—inhibition of L-glutamine–D-fructose-6-phosphate activity from rat gastric mucosa □ Gastric mucosa—effect of uridine diphospho-*N*-acetylglucosamine and sodium salicylate on L-glutamine–D-fructose-6-phosphate aminotransferase activity

Sodium salicylate has been reported to inhibit the activities of many enzymes involved in mucopolysaccharide synthesis including L-glutamine–D-fructose-6-phosphate aminotransferase (EC 2.6.1.16) (1–4), acetylcoenzyme A synthetase (EC 6.2.1.1) (5, 6), uridine-5′-diphospho-*N*-acetylglucosamine-uridine-5′-diphospho-*N*-acetylgalactosamine epimerase (EC 5.1.3.1) (7), uridine-5′-diphosphoglucose dehydrogenase (EC 1.1.1.22) (8), and uridine-5′-diphospho glucuronyltransferase (EC 2.4.1.17) (9).

L-Glutamine–D-fructose-6-phosphate aminotransferase is located at a branch point in carbohydrate metabolism and competes for fructose-6-phosphate with other pathways utilizing hexose monophosphates such as glycolysis, glycogenesis, and the hexose monophosphate shunt. Depending on the tissue, 1.5–20% of the fructose-6-phosphate is converted to hexosamine (10, 11). The aminotransferase enzyme has the lowest extractable activity of the enzymes in the hexosamine pathway (12) and has been reported to be the rate-limiting enzyme in hexosamine biosynthesis (10).

In addition, several reports indicated that hexosamine biosynthesis was subjected to feedback regulation by uridine-5′-diphospho-*N*-acetylglucosamine (13–16). This feedback inhibition is on the initial enzyme of the pathway, catalyzing the apparent irreversible formation of glucosamine. Perrey (2) suggested that there may be a possible correlation between the inhibition of the aminotransferase enzyme in the rat gastric mucosa by sodium salicylate and gastric lesions.

In view of the potentially important role of this enzyme and implications resulting from its inhibition, this study presents the mechanisms of action of sodium salicylate and uridine-5′-diphospho-*N*-acetylglucosamine on L-glutamine–D-fructose-6-phosphate aminotransferase prepared from the rat gastric mucosa and the interaction between the two inhibitors.

EXPERIMENTAL

Materials and Chemicals—The following were used: D-glucose-6-phosphate sodium salt, D-fructose-6-phosphate sodium salt, L-glutamine hydrochloride, uridine-5′-diphospho-*N*-acetylglucosamine[1], sodium salicylate[2], and cross-linked dextran gel[3].

Preparation of L-Glutamine–D-Fructose-6-phosphate Aminotransferase—The enzyme was prepared by the method described by Bates and Handschumaker (16) with some modifications. Sprague–Dawley male rats[4] (120–150 g) were decapitated, and the stomachs were removed and placed into an ice-cold extraction medium containing 10 m*M* glucose-6-phosphate, 20 m*M* glu-

tamine, 85 m*M* potassium phosphate buffer (pH 7.4), 0.1% mercaptoethanol, and 1 m*M* ethylenedinitrilotetraacetic acid disodium salt.

Each stomach was cut along its greater curvature and spread on a watchglass placed over ice, and the mucosal layer was scraped with a small spatula. The mucosal scrapings were homogenized in a hand homogenizer[5] with the volume to weight of the extraction medium. The homogenate was centrifuged at 35,000×*g* for 60 min in a refrigerated ultracentrifuge[6]. The clear supernatant fraction was passed through columns (20 × 1.5 cm) of cross-linked dextran gel[3] previously equilibrated with the extraction medium and maintained between 0 and 4°. The protein-containing fraction containing the enzyme was eluted with the extraction medium.

L-Glutamine–D-Fructose-6-phosphate Aminotransferase Assay—The activity of the enzyme was determined by the rate of formation of glucosamine. The reaction mixture contained, in 4 ml, 85 m*M* potassium phosphate buffer (pH 7.4), 1 m*M* ethylenedinitrilotetraacetic acid disodium salt, 0.1% mercaptoethanol, 1 ml of the eluted mucosal supernatant protein fraction (0.4–0.5 mg of protein/ml), and graded concentrations of glucose-6-phosphate, L-glutamine, sodium salicylate, and uridine-5′-diphospho-*N*-acetylglucosamine as indicated. The incubation was carried out in a 25-ml flask on a Dubnoff shaker at 37° for 45 min.

Enzyme activity was terminated by heating the samples in boiling water for 2 min. After cooling to room temperature, the mixtures were centrifuged at 35,000×*g* for 15 min, and the supernatant fraction was removed for glucosamine determination using the method described by Benson and Friedman (17). Protein concentrations were determined by the biuret method (18).

Inactivation Studies—The enzyme was preincubated with sodium salicylate in the absence of glucose-6-phosphate. The preincubation mixture contained, in 3 ml, 85 m*M* potassium phosphate buffer (pH 7.4), 1 m*M* ethylenedinitrilotetraacetic acid disodium salt, 0.1% mercaptoethanol, 20 m*M* glutamine, and 1 ml of the mucosal supernatant protein fraction. After the preincubation period, the samples were passed through columns (20 × 1.25 cm) of the dextran gel; the columns had been equilibrated with a solution containing 85 m*M* phosphate buffer (pH 7.4), 20 m*M* glutamine, 1 m*M* ethylenedinitrilotetraacetic acid disodium salt, and 0.1% mercaptoethanol. The procedure was carried out between 0 and 4°.

The protein fraction, characterized by a pink band, was collected and 1 ml was added to 2 ml of the incubation medium containing 85 m*M* phosphate buffer (pH 7.4), 20 m*M* glutamine, 1 m*M* ethylenedinitrilotetraacetic acid disodium salt, 0.1% mercaptoethanol, and fructose-6-phosphate to give a final concentration of 10 m*M*. This mixture was incubated for 30 min, and enzyme activity was determined by glucosamine assay.

Protection Studies—Fructose-6-phosphate, glutamine, and uridine-5′-diphospho-*N*-acetylglucosamine were studied as compounds that could afford some protective effect on salicylate-induced inactivation of the enzyme. The enzyme was preincubated with salicylate and one of these compounds. The preincubation mixture contained, in 3 ml, 85 m*M* phosphate buffer (pH 7.4), 1 m*M* ethylenedinitrilotetraacetic acid disodium salt, 0.1% mercaptoethanol, 1 ml of the mucosal supernatant protein fraction, and one of the following: 20 m*M* glutamine, 10 m*M* fructose-6-phosphate, or 3.5 × 10^{-6} *M* uridine-5′-diphospho-*N*-acetylglucosamine.

After preincubation, the samples were treated as described under *Inactivation Studies*. In experiments where preincubation in the absence of glutamine and/or fructose-6-phosphate was indicated, they were not present in the homogenizing medium and were added only to the final incubation mixture for glucosamine synthesis.

Interaction Studies—In studies involving the interaction of sodium salicylate and uridine-5′-diphospho-*N*-acetylglucosamine, the reaction mixture contained, in 4 ml, 10 m*M* glucose-6-phosphate, 20 m*M* glutamine, 85 m*M* potassium phosphate buffer (pH 7.4), 1 m*M* ethylenedinitrilotetraacetic acid disodium salt, 0.1% mercaptoethanol, 1 ml of the mucosal supernatant protein fraction, and varying concentrations of salicylate and uridine-5′-diphospho-*N*-acetylglucosamine. The incubation was carried on for 30 min, and the enzyme activity was determined by glucosamine assay.

No correction was applied for the fact that glucosamine-6-phosphate, on a molar basis, gave 85% of the color produced by glucosamine (19). Throughout this work, it was assumed that the isomerization of glucose-6-phosphate to fructose-6-phosphate was not rate limiting due to the presence of hexose isomerase in the enzyme extracts (16). In fact, Pogell and Gryder (20, 21) found that glucose-6-phosphate was a better substrate for the crude enzyme. Experiments using glucose-6-phosphate and fructose-6-phosphate gave essentially identical results. The production of glucosamine-6-phosphate was proportional to time for 60 min under experimental conditions, and the presence of inhibitors did not alter this linearity of product formation.

RESULTS

Figure 1 shows the effect of salicylate on L-glutamine–D-fruc-

Key:* ●, *control;* ◑, *40 m*M *salicylate and 3.5* × 10^{-6} M *uridine-5′-diphospho-*N*-acetylglucosamine;* ○, *40 m*M *salicylate and 10 m*M *fructose-6-phosphate;* □, *40 m*M *salicylate and 20 m*M *glutamine; and* △, *40 m*M *salicylate.*

acted as a noncompetitive inhibitor with respect to glutamine. Using uridine-5′-diphospho-*N*-acetylglucosamine as the inhibitor, similar double reciprocal plots depict this compound to be a competitive inhibitor with respect to glucose-6-phosphate (Fig. 3) and a noncompetitive inhibitor with respect to glutamine (Fig. 4).

It appears that both sodium salicylate and uridine-5′-diphospho-*N*-acetylglucosamine acted as competitive inhibitors of the enzyme with respect to glucose-6-phosphate and as noncompetitive inhibitors with respect to glutamine. The inhibitor dissociation constants (K_i) for competitive inhibition for salicylate and uridine-5′-diphospho-*N*-acetylglucosamine were 7.5 × 10^{-3} *M* and 1 × 10^{-6} *M*, respectively, indicating about a 700,000-fold difference in activity.

Salicylate was found to be capable of inactivating L-glutamine-D-fructose-6-phosphate aminotransferase at higher concentrations and longer exposure times. This inactivation was apparently irreversible since passage through columns of the dextran gel did not restore original enzyme activity. The results indicated that the rate of inactivation (Fig. 5) appears to follow first-order kinetics with respect to the enzyme and a much higher order with respect to the salicylate concentration. The results further indicate that under the conditions where reversible inhibition was studied (salicylate concentrations of 10–15 m*M* and 45-min exposure time), no significant inactivation of the enzyme occurred. Therefore, in Figs. 1 and 2 the observed inhibition resulted only from a reversible inhibition of the enzymatic reaction.

The two substrates, fructose-6-phosphate and glutamine, as well as the endogenous feedback inhibitor, uridine-5′-diphospho-*N*-acetylglucosamine, were studied as compounds that may afford protection for the enzyme from inactivation by sodium salicylate.

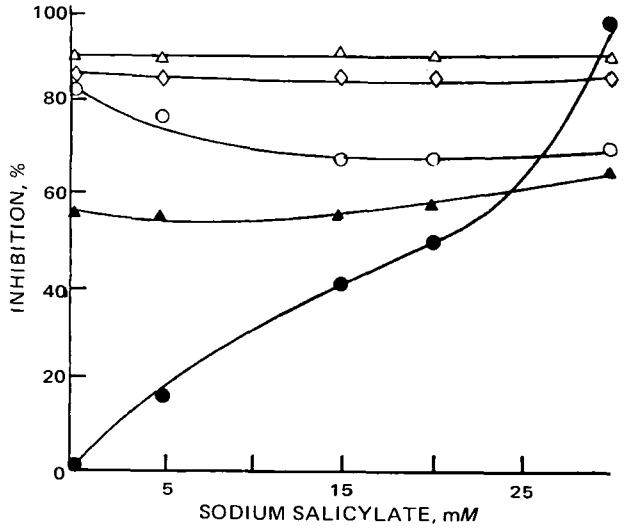

Figure 7—*Effect of sodium salicylate on the activity of* L-*glutamine*–D-*fructose-6-phosphate aminotransferase activity in the absence and presence of uridine-5′-diphospho-*N*-acetylglucosamine. Concentrations of uridine-5′-diphospho-*N*-acetylglucosamine are as follows:* ●, *none;* ▲, *3.5* × 10^{-6} M; ○, *7* × 10^{-6} M; ◇, *1.4* × 10^{-5} M; *and* △, *2.8* × 10^{-5} M.

The results (Fig. 6) indicated that fructose-6-phosphate at 1 × 10^{-2} *M* and uridine-5′-diphospho-*N*-acetylglucosamine at 3.5 × 10^{-6} *M* can protect the enzyme against inactivation by 40 m*M* of salicylate. Glutamine up to 20 m*M* showed no ability to protect the enzyme.

The addition of sodium salicylate to a system inhibited by uridine-5′-diphospho-*N*-acetylglucosamine modified the inhibition (Fig. 7). At a fixed concentration of uridine-5′-diphospho-*N*-acetylglucosamine (7 × 10^{-6} *M*), an increase in salicylate concentration gave rise to activation. Since both salicylate and uridine-5′-diphospho-*N*-acetylglucosamine inhibited the enzyme in a similar manner, such an activation effect caused by two inhibitors acting in concert may be interpreted as a competition for a common site.

DISCUSSION

The results indicated that sodium salicylate can inhibit L-glutamine–D-fructose-6-phosphate aminotransferase either by inhibiting the enzyme-catalyzed reaction by a reversible competitive inhibition with respect to fructose-6-phosphate or by an irreversible inactivation of the enzyme *via* a yet undefined mechanism. In the range of 10–15 m*M*, the inhibition observed was reversible; at concentrations of 30 m*M* or greater, irreversible inactivation was observed also.

Fructose-6-phosphate and uridine-5′-diphospho-*N*-acetylglucosamine were capable of protecting the enzyme against salicylate-induced inactivation as well as of modifying the reversible inhibition of the enzyme. The results further indicated that uridine-5′-diphospho-*N*-acetylglucosamine and sodium salicylate apparently bind to the same site on the enzyme. Based on the consideration of the chemical structures of the two compounds, one can conceive of salicylate binding to the same site occupied by the pyrimidine ring of uridine. Other uridine diphospho sugars such as uridine diphospho galactose and glucose have been reported to inhibit the enzyme at concentrations $\frac{1}{100}$ that of uridine-5′-diphospho-*N*-acetylglucosamine (13).

Kornfeld (13) was able partially to desensitize the enzyme to inhibition by uridine-5′-diphospho-*N*-acetylglucosamine, suggesting that the inhibitor site was distinct from the active site. This finding further suggests that the binding of salicylate and uridine-5′-diphospho-*N*-acetylglucosamine to the "inhibitor" site resulted in the increase in K_m of fructose-6-phosphate, which is characteristic of competitive inhibition (22). The enzyme has a reported molecular weight of 360,000–400,000 but does not exhibit the sigmoid dependence of velocity and modifier concentration, a property in common with the classical allosteric enzymes (23).

This study indicates that for salicylate to inhibit L-glutamine–D-fructose-6-phosphate aminotransferase *in vivo*, the *in vivo* concentration of the endogenous feedback inhibitor, uridine-5′-diphospho-*N*-acetylglucosamine, as well as of fructose-6-phosphate and salicylate would be important. Work by Hardingham and Phelps (10) and Winterburn and Phelps (14) indicated that the enzyme was inhibited in excess of 90% by the feedback inhibitor *in vivo* in the rat skin and rat liver. If this type of inhibition occurred in the general gastric mucosa, it would mean that the binding site for salicylate would be occupied by the feedback inhibitor *in vivo*. In addition, the presence of a feedback loop tends to correct for any deviation from the normal metabolic flux of uridine-5′-diphospho-*N*-acetylglucosamine. If salicylate should inhibit the formation of glucosamine-6-phosphate, it would reduce the level of uridine-5′-diphospho-*N*-acetylglucosamine which, in turn, would release more enzyme from inhibition, restoring the original metabolic flux of glucosamine-6-phosphate. These factors seem to suggest that L-glutamine–D-fructose-6-phosphate aminotransferase would not be a sensitive site for salicylate inhibition *in vivo*.

Formulation of *De Novo* Substituent Constants in Correlation Analysis: Inhibition of Dihydrofolate Reductase by 2,4-Diamino-5-(3,4-dichlorophenyl)-6-substituted Pyrimidines

CORWIN HANSCH *, CARLO SILIPO *, and EDWARD E. STELLER

Abstract □ A correlation equation based solely on *de novo* constants was formulated for 105 2,4-diamino-5-(3,4-dichlorophenyl)-6-substituted pyrimidines acting as inhibitors of dihydrofolate reductase. An equation with seven indicator variables gives a correlation with a correlation coefficient of 0.903 and a standard deviation of 0.229. The technique used is a modification of the Free–Wilson approach. The results indicate that correlation equations with fewer parameters than the theoretical required to account for all molecular changes may often be encountered. It is also shown that cross-product terms can be used to establish the significance of cooperative substituent effects.

During the past decade, the use of computers and statistical techniques in the correlation of chemical structure with biological activity has been developing at a continually increasing rate. It is difficult now even for specialists in structure–activity work to keep up with new techniques. Medicinal chemists are beginning to work with tools developed in the fields of psychology and economics—areas long plagued by multivariable problems. Discriminate analysis (1), pattern recognition (2), factor analysis (3), cluster analysis (4), multidimensional scaling (5), and regression analysis (6, 7) are being applied to various structure–activity problems. These techniques will be coupled with the computerized manipulation of organic structural data to develop increasingly more powerful analytical tools (8) for drug design.

BACKGROUND

Regression analysis has been extensively employed in two ways. The most experience has been obtained in relating biological activity of sets of congeners to physicochemical properties using constants from model systems (6, 7). An alternative method, first used by Bruice *et al.* (9) and then more fully developed by Free and Wilson (10), derives *de novo* substituent constants directly from the biological activities of a set of congeners. The Free–Wilson approach was succinctly stated as (11):

$$A_n = \sum_p \sum_s a_{n,ps} + \mu \qquad \text{(Eq. 1)}$$

where A is a biological response, μ is the activity contributed by the constant portion (parent structure) of the congeneric set, and a is the contribution of activity by each substituent s located on position p of the parent structure. Equation 1 can be used to account for any structural feature in a set of congeners contributing to the total activity of each congener in a strictly additive fashion. The use of Free–Wilson-type constants, which can be regarded in a general sense as discrete variables [indicator variables (12)], can be combined with continuous variables such as π or σ to extend greatly one's ability to formulate correlation equations (13–17)[1].

Following the Free–Wilson approach strictly, one would need a discrete variable for every specific structural change present in a set of congeners. This requirement places one in a dilemma; one must either make a rather large number of derivatives to be certain of formulating meaningful constants or use relatively few derivatives to obtain rather unreliable constants. The authors have found that, in some cases, changes that might seem rather different from a chemist's point of view can be covered by a single indicator variable (14)[1]; this opens up new possibilities in the development of correlation equations.

It was found in the present study of the congeners listed in Table I that the continuous variables π, MR (molar refractivity), and σ were of no value in the formulation of the structure–activity relationship. However, a quite good correlation equation for 105 of the congeners of Table I could be formulated (Eq. 7)[2] using only seven indicator variables. The distinct structural features of the compounds of Table I are summarized in Table II.

By taking certain liberties with Eq. 1, matters can be simplified greatly by assuming that a given substituent Z or SO_2F always makes the same contribution to A, regardless of the length and geometry of the two bridges connecting the two phenyl rings to the parent structures. Even with this simplification, to follow Eq. 1 strictly, one would need to formulate 36 *de novo* constants, with many based on one or two data points. Previous experience has shown that enzyme inhibitors do not always show such high specificity or, to put it another way, test systems are not always sensitive enough to detect small biological responses.

After first discovering that the functions π and MR were of no value in correlating the data of Table I, the indicator variables of Table III were studied. The features of Table III were parameterized by assigning a value of 1 for their presence or of 0 for their absence. Some attempts were made to combine certain variables; I-18 was used to account for I-12 + I-13, I-21 for I-8 + I-9, and I-22 for I-10 + I-11. These combinations proved to be less significant than the single variables.

Three variables (I-19, I-20, and I-27) were studied to test the possibility that enzymes from different sources showed different activity. Only I-20 was necessary in the final analysis; that is, for practical purposes, enzyme from liver, L-1210/FR8, or L-1210/DF8 behaved in the same way.

The irreversible activating effect of the various inhibitors is also listed in Table I. Log $1/C$ values are for reversible inhibition. No obvious relationship is seen between the two types of inhibition.

The degree of independence of the important variables is given in Table IV; collinearity is not a problem. The biological data are from Refs. 18–26.

RESULTS

A reasonable alternative in starting an analysis with such a large number of variables, where it is impossible to derive equations with all possible linear combinations of variables, is to first formu-

[1] C. Silipo and C. Hansch, to be published.
[2] Equations 2–12 are shown in Table V.

Table I—Inhibition Constants and Indicator Variables for the Inhibition of Dihydrofolate Reductase by 2,4-Diamino-5-(3,4-dichlorophenyl)-6-substituted Pyrimidines

[a] The function w is either CH_2 or O; this is parameterized by $w - 1 = 1$ for $w = CH_2$. [b] From Refs. 18–26. [c] Calculated from Eq. 8. [d] Percent irreversible inactivation from Refs. 18–26. [e] 1 = enzyme from liver, 2 = enzyme L-1210/DF8 leukemia, 3 = L-1210/0 leukemia, and 4 = L-1210/FR8 leukemia. [f] These points not used in deriving Eqs. 2–12.

late an equation with the largest number of terms possible. Often all variables cannot be considered because high collinearity of certain vectors yields singular matrixes which cannot be solved for the regression coefficients. In the present instance, 22 variables of Table III (*I*-3, *I*-6, *I*-16, *I*-18, *I*-21, *I*-22, and cross-product variables not included) gave a correlation equation with $s = 0.240$ and $r = 0.910$. Adding four cross-product terms (*I*-4·*I*-8, *I*-4·*I*-17, *I*-8·*I*-17, and *I*-4·*I*-8·*I*-17) gave a 26-variable equation with $s = 0.212$ and $r = 0.934$. This equation constitutes a kind of upper limit, which one would hope to approach with fewer terms. Equations 8 and 11 come close to this type of approach.

Such brute force methods cannot be used with cross-product terms. The enormous number of such terms is given by the expression $2^n - (n + 1)$, where n is the number of primary terms. Hence, for only 10 variables, there would be 1013 possible cross-product terms! The possibilities are truly enormous for interactions of a complex inhibitor with a macromolecule.

To search for patterns of cooperative activity among the different structural units, the authors explored the 15 cross-product terms of Table III. These possibilities were selected simply by study of the residuals of the best equations. It seems unlikely that a mechanical machine approach can be developed to uncover the significant interactions among such a large number of variables. The human mind is the most efficient pattern recognizer at this level of complexity.

After considering thousands of regression equations, the following variables were found to be the most significant: *I*-1, *I*-2, *I*-7, *I*-8, *I*-9, *I*-10, *I*-13, *I*-15, *I*-20, *I*-4·*I*-8, and *I*-8·*I*-17. Equations with all possible linear combinations of these variables were derived (2047). The "best" equation (that with the lowest standard deviation) in each class is listed in Table V. The terms appear quite independent and fall into place in regular order. All of the terms in the equations of Table V are significant as judged by the *F* test, except Eq. 11 ($F_{1,60\ \alpha 0.001} = 12.0$; $F_{1,60\ \alpha .05} = 4.1$; $F_{1,60\ \alpha .1} = 2.8$). There is little reduction in the variance in the equations above Eq. 8:

$$\log 1/C = 0.365(\pm 0.12)I\text{-}1 - 1.013(\pm 0.12)I\text{-}8 - 0.784(\pm 0.19)I\text{-}9 + 0.419(\pm 0.20)I\text{-}13 - 0.220(\pm 0.09)I\text{-}15 + 0.513(\pm 0.18)I\text{-}20 + 0.674(\pm 0.23)I\text{-}4\cdot I\text{-}8 + 7.174(\pm 0.07)$$

n	r	s	
105	0.903	0.229	(Eq. 8)

The *F* statistic also drops sharply at this point. Equation 8 would seem to be the best point from which to make projections.

It is interesting that the cross-product term *I*-4·*I*-8 plays a significant role in Eq. 8. The positive coefficient with this term means that the cooperative activity of a 3-CH_3 and a 4-NHCONH— bridge adds significantly to the activity. This is not a "pure" cross-product term, since *I*-4 does not occur in Eq. 8 except in the product form. The 3-CH_3 appears to make a significant contribution to activity only when the 4-NHCONH— bridge is present. When the 3-CH_3 is present with other bridges, the data points are well fit (except Compound 100), although there are no variables in Eq. 8 to account for this function. If *I*-4 is used alone, the correlation is poorer than when *I*-4·*I*-8 is used; use of this cross-product with *I*-4 gives an equation with a low coefficient with *I*-4. The 3-Cl substituent does not behave in this fashion.

In Table V, it is seen that the two most significant variables reflect structural changes that produce lower activity (*I*-8 and *I*-9). A most interesting point is Compound 96 (an alternative parent compound), which is the only congener showing only reversible activity; this highlights the unusual specificity of the SO_2F function.

Six points in Table I were not used in the regression analysis. Four of these (Compounds 20, 22, 23, and 25) contain the bridge —CH_2NHCO— or —$CH_2NHCONH$—; however, the use of *I*-10, *I*-11, and *I*-22 and the study of many cross-products failed to improve the correlation of these compounds since other congeners containing these functions are well fit. It seems strange that these four are so poorly fit and one wonders if it could be due to experimental error. Data point 2, which is also poorly fit, is unique in that it contains di-*ortho*-substitution.

If Compound 108 is taken as the parent structure, it can be seen from Table I that only three congeners with slightly greater activi-

DISCUSSION

In designing the inhibitors considered in this study, Baker and coworkers (18–26) drew on their experience gained from the study of a large number of heterocyclic inhibitors of dihydrofolate reductase. The 3,4-dichlorophenyl moiety in the 5-position probably provides close to optimal lipophilic interaction with the lipophilic pocket in this area of the enzymes (13)[1]; however, this point is worthy of more study. Substituents in the 6-position of the pyrimidine ring do not appear to interact with lipophilic space (no correlation with π), nor does MR account for substituent effects in this part of enzymic space. Substituents Y and Z have little or no effect on activity. It seems that most of the substituents of the 6-position must project into a very loosely structured part of the enzyme or into the surrounding aqueous phase.

The more flexible bridges, those containing a CH_2 unit in addition to an amide moiety, have little or no effect on activity either way. These more flexible bridges allow maximum freedom (from negative steric effects) to the second phenyl ring and its substituents. Two of the rigid bridges, —NHCONH— and —NHCO—, have very deleterious effects on activity; this result seems to be connected to the positioning of the second phenyl ring. Strangely, the 4-$NHSO_2$— bridge (*I*-13) does make a small contribution to activity. Congeners with this function are, on the average, 10 times as active as those having the 4-NHCO— bridge. What property of $NHSO_2$ is responsible for this activity is not obvious. Similar hydrophobicity is shown by $\pi_{NHSO_2C_6H_5} = 0.45$ and $\pi_{NHCOC_6H_5} = 0.49$. The electronic effect of SO_2— on the phenyl ring can be ruled out since CH_2NHSO_2 does not show special activity. This leaves one with the conclusion that the geometry of the two groups may be the critical factor.

One must bear in mind that structural features not parameterized by specific variables do not make significant contributions to the activity μ (Eq. 1) of the parent structure. One value of the present analysis is that it clearly indicates, in an objective way, structural features that are not worth further study. While these features are often carried in the mind of the active investigator in a qualitative sense, they are quite difficult for a person new to the work to discover. Correlation equations quickly bring the salient features of a very complex set of data into focus.

The value of the present analysis does not reside in its ability to suggest new congeners for synthesis; rather, it demonstrates that a highly complex set of data, whose structural properties produce a set of discontinuous perturbations in a macromolecule, can be brought into coherent order with a relatively small number of variables. This constitutes a valuable modification of the Free–Wilson approach.

Moreover, the results of this analysis suggest that the Free–Wilson approach can be further extended by the use of cross-product terms. This use of cross-product terms may prove to be of considerable value in establishing the significance of special patterns or

constellations of atoms not normally parameterized in structure–activity relationships.

The importance of correlation equations can only be fully appreciated when X-ray crystallographic studies of inhibitor binding with the enzyme are undertaken. The terms of the correlation equations should be of great help in interpreting the interactions of micro- and macromolecules.

Dissolution Profile in Relation to Initial Particle Distribution

PETER VENG PEDERSEN ˣ **and K. F. BROWN**

Abstract □ A general equation was derived describing the complete and exact dissolution profile of powders under sink conditions. It is applicable to powders having any initial particle-size distribution, with particles dissolving according to any explicit equation. It was applied to develop an equation for the dissolution of log-normal powders that is more generally applicable than previous approaches. The effect of change in initial particle-size distribution parameters on the dissolution profile is illustrated.

Keyphrases □ Dissolution profile—powders under sink conditions, general equation, relationship of initial particle-size distribution, applicability to dissolution of log-normal powders □ Particle-size distribution—effect on dissolution profile, general equation, applicability to dissolution of log-normal powders □ Powders—dissolution profile under sink conditions, general equation, relationship of initial particle-size distribution, applicability to dissolution of log-normal powders

Several investigators (1–4) considered the problem of exactly describing the dissolution profile of powders in relation to their particle-size distribution. These authors have been concerned with powders initially consisting of particles with log-normal size distribution. Earlier attempts made use of approximations (1) or computer simulations (2). More recently, Brooke (3) developed an equation that permits calculation of the dissolution profile of such powders without the aid of a computer. This equation was later presented in a form to account for truncated log-normal distributions (4), but in this paper it is shown not to be generally applicable for all timelengths.

A general equation that exactly describes the entire dissolution profile of powders under sink conditions would be of considerable value. Such an equation should be valid for particles having any initial size distribution and dissolving according to any explicit equation. In particular, it should be applicable to the dissolution of log-normal powders, which are frequently encountered.

THEORY

Consider a powder consisting of particles which initially ($t = 0$) has a weight density (probability) distribution $f_0(w_0)$. Let the particles dissolve independently of each other according to:

$$w = g(w_0,t,A) \qquad \text{(Eq. 1)}$$

where w and w_0 are the particle weights at time t and $t = 0$, respectively; and A represents collectively the dissolution parameters such as solubility, particle density, and the particle shape factor. The inverse dissolution function is defined as:

$$w_0 = g^{-1}(w,t,A) \qquad \text{(Eq. 2)}$$

Using the rules of transformation of independent variables (5), the particle weight density function at time t becomes:

$$h(w) = f_0[g^{-1}(w,t,A)]\frac{d}{dw}g^{-1}(w,t,A) \qquad \text{(Eq. 3)}$$

For Eq. 3 to hold, the following conditions for g must be satisfied: *(a)* g^{-1} must be a strictly increasing function of w for all t values, *(b)* g must decrease strictly with time until equal to zero, and *(c)* g must remain equal to zero beyond that time. The latter two conditions ensure that the dissolution function reflects the actual physical conditions of the dissolution process. The first condition will rarely be violated because, in application, g is nearly always a strictly increasing function of w_0 for all t values. It is obvious that the second condition must be met by any dissolution equation.

The third condition is not satisfied for most equations in the literature (1, 6, 7). To overcome this problem, it is necessary to redefine the particle weight density function such that it is generally applicable:

$$f(w) = \frac{h(w)}{\int_0^\infty h(w)dw} \qquad \text{for } w > 0 \qquad \text{(Eq. 4a)}$$

$$f(w) = 0 \qquad \text{for } w \leq 0 \qquad \text{(Eq. 4b)}$$

where division by the integral is necessary to satisfy the condition that the total integral (from $-\infty$ to $+\infty$) of $f(w)$ must be equal to 1.

The weight of undissolved powder, W, at any time, t, is equal to the product of the number of particles remaining, N_t, and the mean particle weight, which for a large number of particles is the same as the expected value of w, $E_t(w)$. Therefore, the following general equation can be written:

$$W = N_t E_t(w) \qquad \text{(Eq. 5)}$$

The number of particles remaining at time t is:

$$N_t = N_0 \int_0^\infty h(w)dw \qquad \text{(Eq. 6)}$$

where the initial number of particles, N_0, is equal to the initial powder weight, W_0, divided by the initial mean particle weight:

$$N_0 = \frac{W_0}{\int_0^\infty w_0 f_0(w_0)dw_0} \qquad \text{(Eq. 7)}$$

The mean particle weight at time t is given by:

$$E_t(w) = \int_{-\infty}^{\infty} w f(w)dw \qquad \text{(Eq. 8)}$$

which, according to Eq. 4*a*, can be written:

$$E_t(w) = \frac{\int_0^\infty w h(w)dw}{\int_0^\infty h(w)dw} \qquad \text{(Eq. 9)}$$

Substituting Eqs. 6, 7, and 9 into Eq. 5 yields:

$$\frac{W}{W_0} = \frac{\int_0^\infty w h(w)dw}{\int_0^\infty w_0 f_0(w_0)dw_0} \qquad \text{(Eq. 10)}$$

This equation relates to unbounded particle weight distributions. In practice, the distribution is always bound, so the limits of integration must be changed accordingly.

Let m_0 and M_0 denote the initial weights of the smallest and largest particle, respectively[1]. These values then represent the lower and upper boundaries, respectively, of $f_0(w_0)$; $f(w)$ will be correspondingly bounded by $Pg(m_0,t,A)$ and $Pg(M_0,t,A)$. The operator P is introduced to ensure that the limits are never negative. Therefore, by definition, P is equal to 1 in the time period before the operand becomes zero and is equal to zero beyond that time. When these limits are introduced into Eq. 10 and $h(w)$ is written according to Eq. 3, the following expression is obtained:

$$\frac{W}{W_0} = \frac{\int_{u=Pg(m_0,t,A)}^{u=Pg(M_0,t,A)} w f_0[g^{-1}(w,t,A)] \frac{d}{dw} g^{-1}(w,t,A) dw}{\int_{m_0}^{M_0} w_0 f_0(w_0) dw_0} \qquad \text{(Eq. 11)}$$

If $g^{-1}(w,t,A)$ and w_0 in the integrals are considered as dummy variables and called x, Eq. 11 simplifies to:

$$\frac{W}{W_0} = \frac{\int_{L_1}^{L_2} g(x,t,A) f_0(x) dx}{\int_{m_0}^{M_0} x f_0(x) dx} \qquad \text{(Eq. 12}a\text{)}$$

Because of this transformation and the properties of the operator P, the limits of integration, L_1 and L_2, have the following values:

$L_1 = m_0$ for t such that $Pg(m_0,t,A) > 0$ (Eq. 12b)

$L_1 = g^{-1}(0,t,A)$ for t such that $Pg(m_0,t,A) = 0$ (Eq. 12c)

$L_2 = M_0$ for t such that $Pg(M_0,t,A) > 0$ (Eq. 12d)

$L_2 = g^{-1}(0,t,A)$ for t such that $Pg(M_0,t,A) = 0$ (Eq. 12e)

The time at which $g(m_0,t,A) = 0$ is the critical time, that is, the time when the dissolving particles begin to disappear. When $g(M_0,t,A) = 0$, all particles are dissolved. Beyond that time, $L_1 = L_2$, thus making W/W_0 equal to zero.

Equation 12a requires knowledge of the initial weight distribution $f_0(w_0)$, but more often the initial size distribution is of greatest interest. Consider particles that are spherical and remain so during the dissolution; in this case, $w = \rho\pi a^3/6$, where ρ and a are the particle density and diameter, respectively[2]. Transformation in Eq. 11 from the initial weight distribution to the initial size distribution is then easily achieved; and by a similar procedure to that used to obtain Eq. 12a from Eq. 11, the following equation is derived:

$$\frac{W}{W_0} = \frac{\int_{R_1}^{R_2} g\left(\frac{\rho\pi}{6} x^3,t,A\right) l_0(x) dx}{\int_{d_0}^{D_0} \frac{\pi\rho}{6} x^3 l_0(x) dx} \qquad \text{(Eq. 13}a\text{)}$$

where:

$R_1 = d_0$ for t such that $Pg\left(\frac{\rho\pi}{6} d_0^3,t,A\right) > 0$ (Eq. 13b)

$R_1 = \left[\frac{6}{\rho\pi} g^{-1}(0,t,A)\right]^{1/3}$ for t such that $Pg\left(\frac{\rho\pi}{6} d_0^3,t,A\right) = 0$ (Eq. 13c)

$R_2 = D_0$ for t such that $Pg\left(\frac{\rho\pi}{6} D_0^3,t,A\right) > 0$ (Eq. 13d)

$R_2 = \left[\frac{6}{\rho\pi} g^{-1}(0,t,A)\right]^{1/3}$ for t such that $Pg\left(\frac{\rho\pi}{6} D_0^3,t,A\right) = 0$ (Eq. 13e)

[1] These values are not intended to be absolute but rather represent limits giving the best fit when the actual particle distribution is approximated by any particular function. Therefore, they also represent truncation limits of the function.

[2] The derivation is valid for particles of other shapes as long as they remain unchanged during dissolution and an appropriate shape factor is used in place of $\pi/6$.

In Eq. 13a, d_0 and D_0 are initial diameters of the smallest and largest particles, respectively[1]; l_0 is the initial particle-size density function.

Equations 12a and 13a rigorously describe the entire dissolution profile of any powder if its initial particle weight density function, f_0, or initial particle-size density function, l_0, is known, together with the particle dissolution function, which can be any explicit expression. With appropriate choice of limits of integration, the equations are applicable to truncated as well as "ideal" distributions. The time-dependent integral in the numerator of Eqs. 12a and 13a reduces to the constant integral in the denominator at zero time, thus making the ratio W/W_0 equal to 1 as expected.

RESULTS AND DISCUSSION

The general mathematical models expressed by Eq. 12a or 13a require the use of a computer for numerical evaluation because they are in integral form. However, if the initial particle weight or particle-size distribution can be approximated by some simple function, then the model can often be solved in terms of an expression suitable for evaluation without the use of a computer.

Consider a powder consisting of spherical particles of initial diameters a_0, distributed such that $\ln a_0$ approximates a normal distribution with mean μ and standard deviation σ, truncated at $\ln d_0 = \mu - i\sigma$ and $\ln D_0 = \mu + j\sigma$, where i and j are truncation parameters. The density function of $\ln a_0$ is then given by:

$$u(\ln a_0) = \frac{N(\ln a_0,\mu,\sigma)}{\int_{\ln a_0=\mu-i\sigma}^{\ln a_0=\mu+j\sigma} N(\ln a_0,\mu,\sigma) d \ln a_0}$$

$$\mu - i\sigma \leqslant \ln a_0 \leqslant \mu + j\sigma \qquad \text{(Eq. 14)}$$

where the normal density function N is defined as $N(x,\mu,\sigma) = [1/(\sigma\sqrt{2\pi})]\exp[-(x-\mu)^2/2\sigma^2]$. Because the distribution is truncated, the integral in Eq. 14 is introduced to satisfy the requirement that the total integral of $u(\ln a_0)$ must be equal to 1. By using standard transformation techniques (5), the initial particle-size density function, l_0, then becomes:

$$l_0(a_0) = \frac{a_0^{-1} N(\ln a_0,\mu,\sigma)}{\int_{d_0}^{D_0} a_0^{-1} N(\ln a_0,\mu,\sigma) da_0} \qquad d_0 \leqslant a_0 \leqslant D_0 \qquad \text{(Eq. 15)}$$

Let the particles dissolve according to the Hixson–Crowell (6) cube root law:

$$w = (w_0^{1/3} - kt)^3 \qquad \text{(Eq. 16)}$$

where k is a positive constant. The inverse dissolution function is then:

$$w_0 = (w^{1/3} + kt)^3 \qquad \text{(Eq. 17)}$$

After the initial particle-size distribution (Eq. 15) and the particle dissolution equation (Eq. 16 and its inverse Eq. 17) are defined, the relationship giving the dissolution profile can then be derived by means of Eq. 13a (for derivation, see *Appendix*):

$$W/W_0 = \left[\frac{F\left(\frac{T_2-\mu}{\sigma} - 3\sigma\right) - F\left(\frac{T_1-\mu}{\sigma} - 3\sigma\right)}{F(j-3\sigma) - F(-i-3\sigma)}\right]$$

$$- 3(Kt)\left[\frac{F\left(\frac{T_2-\mu}{\sigma} - 2\sigma\right) - F\left(\frac{T_1-\mu}{\sigma} - 2\sigma\right)}{F(j-3\sigma) - F(-i-3\sigma)}\right] e^{-\mu+5\sigma^2/2}$$

$$+ 3(Kt)^2\left[\frac{F\left(\frac{T_2-\mu}{\sigma} - \sigma\right) - F\left(\frac{T_1-\mu}{\sigma} - \sigma\right)}{F(j-3\sigma) - F(-i-3\sigma)}\right] e^{-2\mu+1\sigma^2}$$

$$- (Kt)^3\left[\frac{F\left(\frac{T_2-\mu}{\sigma}\right) - F\left(\frac{T_1-\mu}{\sigma}\right)}{F(j-3\sigma) - F(-i-3\sigma)}\right] e^{-3\mu+9\sigma^2/2} \qquad \text{(Eq. 18}a\text{)}$$

where:

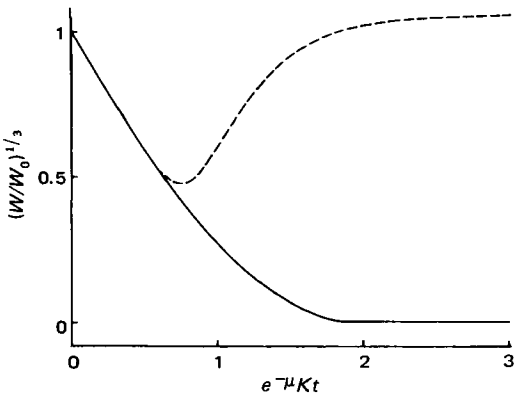

Figure 1—*Plot of the cube root of fraction undissolved* versus $e^{-\mu}Kt$ *for hypothetical log-normal powder, with* $\sigma = 0.3$ *and truncated at* $\mu \pm 2\sigma$ *(*i = j = 2*). The unbroken curve is calculated according to Eq. 18a, and the stippled curve is calculated according to an equation given by Brooke (4).*

$$T_1 = \mu - i\sigma \quad \text{for } \ln Kt \leqslant \mu - i\sigma \quad \text{(Eq. 18b)}$$

$$T_1 = \ln Kt \quad \text{for } \ln Kt > \mu - i\sigma \quad \text{(Eq. 18c)}$$

$$T_2 = \mu + j\sigma \quad \text{for } \ln Kt \leqslant \mu + j\sigma \quad \text{(Eq. 18d)}$$

$$T_2 = \ln Kt \quad \text{for } \ln Kt > \mu + j\sigma \quad \text{(Eq. 18e)}$$

The function, F, is the commonly tabulated area under the standard normal curve function, defined by:

$$F(x) = \int_{-\infty}^{x} \frac{1}{\sqrt{2\pi}} e^{-x^2/2}\, dx \qquad \text{(Eq. 19)}$$

The positive constant, K, is used for simplification in place of the expression $(6/\rho\pi)^{1/3}k$. The change in T_1 at timelength $Kt = e^{\mu - i\sigma}$ (critical time) corresponds to the time when the smallest particles, initially having a diameter $d_0 = e^{\mu - i\sigma}$, begin to disappear. The change at $Kt = e^{\mu + j\sigma}$ $(= D_0)$ signifies the end of the dissolution process, so W/W_0 becomes zero after that timelength.

Equation 18*a* describes the complete dissolution profile of log-normal powders and any sieve fraction of such powders. It assumes that the particles dissolve according to the cube root law (Eq. 16), which also can be written in the form $a = a_0 - (6/\rho\pi)^{1/3}kt$ or $a = a_0 - Kt$ for spherical particles, where a_0 and a are the particle diameters at times zero and t, respectively. This relationship is similar to the equation $a = a_0 - \tau$ used previously (2–4) in which τ denotes the timelength.

Brooke (4) derived an equation similar to Eq. 18*a* for log-normal powders. Directions were given for the changes required in the equation at the critical time. However, in his equation the first term is constant, equal to 1. Therefore, his equation is incorrect if applied to dissolution *after* the critical time. The error so introduced becomes quite substantial for large timelengths and large values of σ.

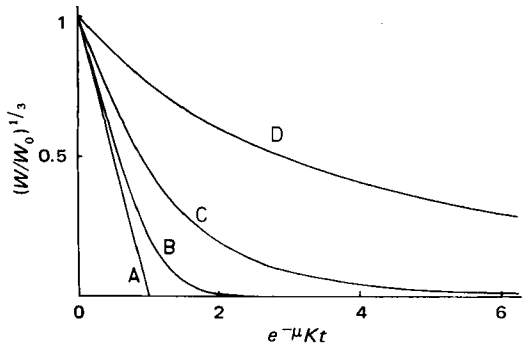

Figure 2—*Effect of the particle-size distribution parameter,* σ*, on plots of the cube root of fraction undissolved* versus $e^{-\mu}Kt$*, calculated according to Eq. 18a for hypothetical ideal* (i = j = *10) log-normal powders. Key: A,* $\sigma = 0$*; B,* $\sigma = 0.2$*; C,* $\sigma = 0.4$*; and D,* $\sigma = 0.7$

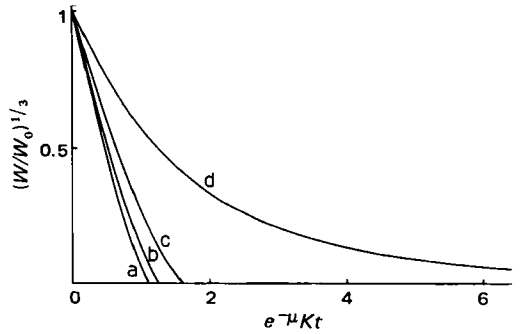

Figure 3—*Effect of upper end truncation on the dissolution profile of powders having a log-particle diameter distribution that is normal, with* $\sigma = 0.5$*, and truncated at* $\mu - 10\sigma$ *and* $\mu + j\sigma$*, where* j = *0.25 (a), 0.5 (b), 1 (c), and 10 (d).*

Brooke calculated values of W/W_0 for various values of τ/e^{μ} (the latter terminology corresponds to $e^{-\mu}Kt$ used here). This procedure represents an ingenious method of "scaling time" (by the factor $e^{-\mu}K$) so the dissolution profile becomes independent of the parameters μ and k (Eq. 16) and only depends on σ, enabling the effect of σ alone to be assessed. In this work, however, cube root-type plots of $(W/W_0)^{1/3}$ *versus* $e^{-\mu}Kt$ are used for better comparison with the fundamental particle dissolution equation (Eq. 16), which obeys the cube root law.

Figure 1 shows such a plot for powders truncated at $\mu \pm 2\sigma$ $(i = j = 2)$ and having $\sigma = 0.3$. The curvature of the unbroken line, calculated according to Eq. 18*a*, is logically expected. The stippled line represents the dissolution profile calculated according to Brooke's equation (Eq. 4 of Ref. 4)[3]. The two profiles are, as expected, identical until critical time ($e^{-\mu}Kt = 0.5488$), but the later part clearly demonstrates the limitation of his equation.

Figure 2 demonstrates the effect of σ on the dissolution profile for a powder initially having an ideal distribution $(i = j = 10)$.

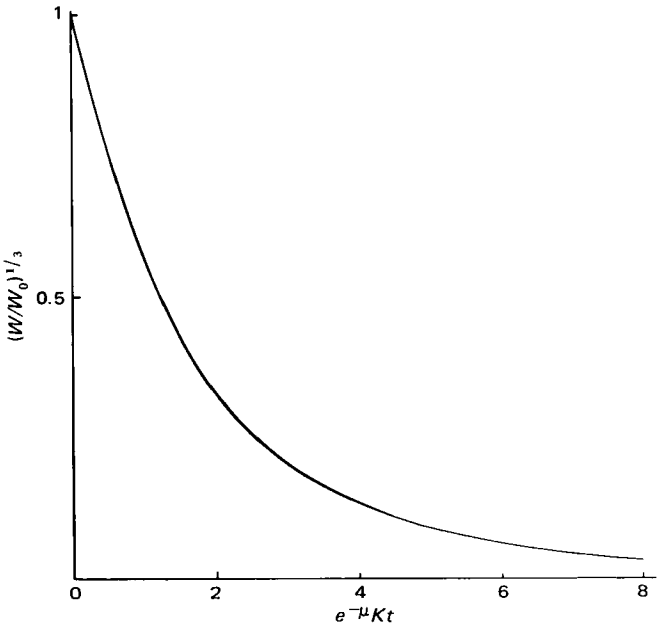

Figure 4—*Effect of lower end truncation on the dissolution profile of powders having a log-particle diameter distribution that is normal, with* $\sigma = 0.5$*, and truncated at* $\mu - i\sigma$ *and* $\mu + 10\sigma$*, where* i = *0.25, 0.5, 1, and 10. The four curves are essentially coincidental.*

[3] A Cyber 76 digital computer equipped with Calcomp plotter was used for calculations and plots. Numerical evaluations were tested to six digits.

Powders of uniform particle size, *i.e.*, $\sigma = 0$, give linear cube root plots as expected, while the deviation from linearity is significant for larger σ values. An increase in σ results in a decrease in the initial slopes of the curves, which is consistent with calculations made by Brooke (4). Among powders having the same logarithmic mean diameter, μ, those with broadest distribution will have the slowest initial release rate.

Figures 3 and 4 show the effect of truncation on the dissolution profile when the initial log (particle diameter) – distribution approximates a normal distribution ($\sigma = 0.5$) with various degrees of upper (Fig. 3) and lower (Fig. 4) end truncation. Comparison of the two figures indicates that the effect of truncation at the low end is very small and considerably less than that of truncation at the upper end. The curves for $i = 10$, 1, 0.5, and 0.25 are so close that they are coincidental in the plot (Fig. 4), while they are clearly separate for $j = 10$, 1, 0.5, and 0.25 in Fig. 3. Figure 3 also shows that the magnitude of the slopes of the curves increases with increasing truncation. The most marked effect of truncation at the upper end is that the time for complete dissolution is drastically reduced.

APPENDIX

After inserting Eqs. 15, 16, and 17 into Eq. 13*a*, the integral in the numerator, I_n, of Eq. 13*a* becomes:

$$I_n = \frac{\int_{R_1}^{R_2}\left[\left(\frac{\rho\pi}{6}\right)^{1/3} w - kt\right]^3 w^{-1}N(\ln w,\mu,\sigma)dw}{\int_{d_0}^{D_0} w^{-1}N(\ln w,\mu,\sigma)dw} \quad \text{(Eq. A1)}$$

It was indicated previously that $W/W_0 = I_n/(I_n)_{t=0}$. By using this fact, W/W_0 can be written:

$$\frac{W}{W_0} = \frac{\int_{R_1}^{R_2}\left[w - \left(\frac{6}{\rho\pi}\right)^{1/3} kt\right]^3 w^{-1}N(\ln w,\mu,\sigma)dw}{\int_{d_0}^{D_0} w^{2}N(\ln w,\mu,\sigma)dw} \quad \text{(Eq. A2)}$$

In Eq. A2, the time-independent integral in the denominator is equal to the time-dependent integral in the numerator evaluated at zero time. To evaluate the numerator of Eq. A2, employing a technique similar to that used to derive the moment-generating function for a normal distribution (5), the following useful equation can be obtained, which is similar to Eq. 12 given by Brooke (3):

$$\int_q^r x^s N(\ln x,\mu,\sigma)dx = \left[F\left(\frac{\ln r - \mu}{\sigma} - (s+1)\sigma\right) - F\left(\frac{\ln q - \mu}{\sigma} - (s+1)\sigma\right)\right] e^{[s+1)[\mu+(s+1)\sigma^2/2]} \quad \text{(Eq. A3)}$$

where the function, F, is the area under the standard normal curve function given by Eq. 19. Thus, to evaluate the numerator, I, in Eq. A2, $(w - Kt)^3 w^{-1}$ is expanded as $w^2 - 3(Kt)w + 3(Kt)^2 - (Kt)^3 w^{-1}$ [letting $K = (6/\rho\pi)^{1/3}k$ for simplicity]. The formula is then applied term by term by putting $s = 2$, 1, 0, and -1; $r = R_2$; and $q = R_1$ and by treating t as a constant for purposes of integration. Equation 18*a* is then derived using $W/W_0 = I/(I)_{t=0}$ and noting that $\ln d_0 = \mu - i\sigma$ and $\ln D_0 = \mu + j\sigma$.

Microdetermination of Ergocalciferol (Vitamin D_2) in Pharmaceutical Preparations by Differential Spectroscopy Using Trifluoroacetic Acid in the Absence of Vitamin A

SAMIR A. GHARBO ˣ and LEO A. GOSSER

Abstract □ A differential spectroscopy method for the determination of microgram quantities of ergocalciferol, using trifluoroacetic acid and hydrogen peroxide, was applied to commercially available pharmaceutical preparations. Tablets were powdered and extracted with methanol after being made basic with diethylamine. The methanol was concentrated, chloroform was added, and the mixture was chromatographed on neutral alumina using chloroform as the eluent. Ergocalciferol was determined in an aliquot of the eluate by differential spectroscopy and was compared with a reference ergocalciferol standard treated similarly. The method applied to low potency formulations (2.5–6 μg/tablet) is simple and quantitative, needs less than 5 hr for completion, and has a precision of <±2%. A simple and accurate chromatographic method for the determination of ergocalciferol in stabilized powders and high potency tablets, which precludes the necessity of solvent–solvent extraction, was also developed. The results are comparable with those obtained by the rat bioassay and the USP XVIII chemical assay.

Keyphrases □ Ergocalciferol in pharmaceutical preparations—differential spectroscopic analysis using trifluoroacetic acid, absence of vitamin A □ Vitamin D_2 in pharmaceutical preparations—differential spectroscopic analysis using trifluoroacetic acid, absence of vitamin A □ Differential spectroscopy—analysis, ergocalciferol in pharmaceutical preparations not containing vitamin A

Ergocalciferol (vitamin D_2), one of the fat-soluble vitamins (1), is essential for the prevention of rickets. The determination of ergocalciferol in nutritional and pharmaceutical products and biological materials has been the subject of extensive research work. Studies on the metabolism of ergocalciferol, its toxicity when taken in excess (2), and its consideration as a drug if assimilated in quantities greater than 400 IU/day (40 IU = 1 μg) (3) have made its evaluation even more necessary.

The rat bioassay for ergocalciferol (4) is time consuming, expensive, and imprecise. Several chemical and physicochemical methods of determination are applicable to pure ergocalciferol (5), but a tedious cleanup is usually necessary before quantitation. Saponification in an alcoholic medium followed by partition with organic solvent (6) and column chromatography (7) is the usual route taken for the extraction and purification of ergocalciferol from the sample. The main difficulty in obtaining quantitative recoveries of the vitamin is its potential instability due to the effects of heat, oxygen, and water (8).

Kobayashi and Adachi (9) determined ergocalciferol and its isomers in mixtures by GLC after separation by TLC. Mulder *et al.* (10) evaluated the chemical analysis of ergocalciferol in concentrates (≥25,000 IU/g) by the most widely used antimony trichloride colorimetric method. Kneczke and Andersson (11) modified the USP XVIII chemical method, using hydroquinone as the antioxidant, and compared the results with and without saponification of different preparations containing ergocalciferol with a bioassay method.

"Reversed-phase partition" high-pressure liquid chromatography was used for the separation and quantitation of the fat-soluble vitamins and the D vitamins (12). The technique was applied to multivitamin capsules and tablets, but the study was for chromatographic reproducibility and not for the reproducibility of the extraction methods. Fat-soluble vitamins were separated by gel filtration, and vitamin D was determined in the presence of vitamin A and α-tocopherol (13).

Recently, a stable and sensitive differential spectroscopy method for the determination of ergocalciferol, using trifluoroacetic acid and hydrogen peroxide, was developed (14). This paper deals with the application of this procedure to the determination of ergocalciferol when present in microgram quantities in commercially available pharmaceutical preparations containing no vitamin A. A simple chromatographic procedure also was developed for preparations containing milligram quantities using the trifluoroacetic acid colorimetric method recommended by Clements *et al.* (15).

EXPERIMENTAL

Instrumentation and Apparatus—A spectrophotometer[1], a rotary evaporator, a stir-hot plate, an electric micromill, and a chromatographic glass column (250 × 25 mm i.d. with a 250-ml capacity reservoir) were used.

Reagents and Chemicals—The following were used: ethanol[2] (anhydrous), methanol[3] (anhydrous), chloroform[4], diethylamine[5], trifluoroacetic acid[6] (extremely corrosive acid), hydrogen peroxide (30%), aluminum oxide (neutral)[7], silicic acid[8], and ergocalciferol (USP reference standard). Hydroquinone[6] solution (0.1%) was prepared by dissolving hydroquinone in a minimal amount of ether and diluting to volume with chloroform.

Procedure A: For Low Potency Preparations—Carry out all operations in subdued artificial light.

Preparation of Alumina Column—Pour about 20 ml of methanol into the chromatographic column and lightly tamp a pledget of

[1] Coleman 124, Perkin-Elmer.
[2] U.S. Industrial Chemicals Co.
[3] Mallinckrodt, O.R.
[4] Mallinckrodt, A.R.
[5] Matheson Coleman & Bell, ACS.
[6] Matheson Coleman & Bell.
[7] Woelm.
[8] SilicAR CC7, Mallinckrodt.

cotton into the bottom, ridding the cotton of air bubbles. Weigh 15 g of neutral aluminum oxide and transfer to a small flask. Add about 20 ml of methanol, swirl to eliminate air bubbles, and transfer completely to the prepared column using 20–30 ml of methanol. Drain the methanol to about 0.5 cm above the alumina. Add 50 ml of chloroform, level the surface of the alumina by tapping the sides of the column, and drain the solvent to about 1 cm above the alumina. Wrap the stem of the column with aluminum foil and set aside until needed.

Preparation of Standard Solution—Accurately weigh about 20 mg of reference standard ergocalciferol from a freshly opened vial into a 100-ml volumetric flask. Dissolve in and dilute to volume with chloroform (Standard Solution A-I). Dilute 5.0 ml of this solution to 100 ml with chloroform (Standard Solution A-II). Prepare a third solution by diluting 5.0 ml of Standard Solution A-II to 100 ml with chloroform (Standard Solution A-III).

Determination of Ergocalciferol in Standard Solution—Accurately pipet 10.0 ml of reference standard ergocalciferol solution in chloroform (A-III, 0.5–0.7 μg/ml) in a small flask and add 1 drop of diethylamine. Evaporate the mixture completely on a rotary evaporator at 30–35°, add 5 ml of anhydrous ethanol, and evaporate again completely. Then add 5 ml of chloroform and evaporate completely.

Flush the flask for a few seconds with a stream of nitrogen to eliminate the last traces of chloroform. Pipet 1.0 ml of 0.1% hydroquinone solution to dissolve the residue. Using a fast delivery pipet, add exactly 1.0 ml of trifluoroacetic acid, swirl quickly two or three times, and transfer to a 1-cm cell within 30 sec (cover the cell).

Record the absorbance at 490 nm as a function of time, using a mixture of chloroform and trifluoroacetic acid (1:1) as the reference solution. Determine the highest absorbance value obtained within the first 3 min. Record the spectrum between 520 and 480 nm to ensure that the peak is at 490 ± 2 nm. Add 2 drops of hydrogen peroxide from a disposable pipet to the sample solution in the cell and shake once to mix. Record the absorbance value at 490 nm obtained 2 min ± 10 sec after the addition of the hydrogen peroxide. The difference between the two absorbance values (A_{std}) is proportional to the amount of ergocalciferol in the standard solution.

Preparation of Sample Solution and Determination of Ergocalciferol—Accurately weigh a number of tablets and determine the average tablet weight. Grind the tablets to a powder, using the electric micromill for 40–50 sec or a mortar and pestle. Accurately weigh sufficient powdered tablets to contain a total of about 25 μg of ergocalciferol and transfer to a 125–250-ml amber-colored erlenmeyer or extraction flask. Add 25 ml of methanol and 0.1 ml of diethylamine. Reflux the mixture in a water bath at 65–70° for 2 hr, using a magnetic stirrer for additional agitation. Remove the magnet and rinse it with chloroform by using a disposable pipet; add the rinse to the flask. Add 20 ml of chloroform and concentrate the mixture to about 10 ml with a rotary evaporator at 30–35°. Cool under the tap and add 30 ml of chloroform.

Transfer the mixture quantitatively through a wide mouth funnel to the prepared alumina column, rinsing the flask and funnel with about 10 ml of chloroform. Wash the sides of the column with about 5 ml of chloroform and then allow the mixture to stand for about 5 min to permit the powder to settle in the column. Allow the solvent to flow slowly (80–120 drops/min) into an amber-colored, 100-ml volumetric flask. Drain the column to the level of the powder and then carefully add 10-ml portions of chloroform, draining the column each time (use at least 30 ml of additional chloroform for elution). Collect exactly 100 ml of eluate. The colored zone, due to dyes in the tablets, if present should not have progressed more than halfway through the alumina.

Pipet 20.0 ml of the eluate into a 50-ml, amber-colored erlenmeyer flask and proceed as directed for Procedure A under *Determination of Ergocalciferol in Standard Solution*, starting with "Evaporate the mixture completely on a rotary evaporator at 30–35°, . . ." The difference between the two absorbance values (A_{spl}) is proportional to the amount of ergocalciferol present.

Calculations—The amount of ergocalciferol is calculated using:

$$\mu g \text{ ergocalciferol / tablet} = \frac{A_{spl}}{A_{std}} \times \text{weight of standard (mg)} \times \frac{\text{average tablet weight (g)}}{\text{sample weight (g)}} \times 1.25 \qquad \text{(Eq. 1)}$$

Procedure B: For High Potency Preparations—Carry out all operations in subdued artificial light.

Preparation of Silica Column—Pour about 40 ml of chloroform into the column and lightly tamp a small pledget of cotton into the bottom. Weigh 5 g of silicic acid[8] in a 50-ml erlenmeyer flask, add 15 ml of chloroform, mix well, and quickly pour through a funnel into the column. Wash the flask and the sides of the column with 2 × 10 ml of chloroform. Withdraw 40–45 ml of solvent, wrap the column with aluminum foil, and set aside until needed.

Preparation of Standard Solution—Accurately weigh about 35–40 mg of reference standard ergocalciferol from a freshly opened vial into a 100-ml volumetric flask. Dissolve in and dilute to volume with chloroform (Standard Solution B-I). Dilute 10 ml of Standard Solution B-I to exactly 100 ml with chloroform (Standard Solution B-II).

Determination of Ergocalciferol in Standard Solution—Accurately pipet 8.0 ml of reference standard ergocalciferol Solution B-II in a small flask and add 2.0 ml of trifluoroacetic acid. Swirl the mixture three or four times and transfer to a 1-cm cell. Record the absorbance at 403 nm as a function of time, using a mixture of chloroform and trifluoroacetic acid (4:1) as the reference solution. Determine the highest absorbance value (A_{std}) obtained within 10 min; the absorbance value will depend on the quality of the trifluoroacetic acid and may vary from day to day, which necessitates running a standard.

Determination of Ergocalciferol in Sample Solution—Weigh accurately an amount of sample (powder or powdered tablets) to contain 3.5–4.0 mg of ergocalciferol and transfer to a small flask. Add water (2.5 times the amount of sample) and mix well for 3–4 min to get a homogeneous slurry containing no lumps. Wash the sides of the flask with ethanol equal in volume to one-third the amount of water and mix gently for 2–3 min. Swirl the mixture, add silicic acid[8] in an amount equal to four times the volume of water, and mix quickly with a spatula to get a homogeneous mobile powder within 60 sec. Immediately add chloroform in an amount equal to four times the amount of the silica and mix well.

Transfer the slurry to the previously prepared silica column through a wide mouth funnel and wash the flask, funnel, and sides of the column with 2 × 10 ml of chloroform. Allow the solvent to drip fast into an amber-colored, 100-ml volumetric flask until it reaches the level of the adsorbent. Wash the flask and sides of the column with 10-ml portions of chloroform, draining each time. Collect exactly 100 ml of eluate. Pipet 8.0 ml of eluate in a small flask and continue as directed for Procedure B under the *Determination of Ergocalciferol in Standard Solution*, starting with "add 2.0 ml of trifluoroacetic acid."

Calculations—The amount of ergocalciferol is calculated as follows:

$$\text{mg ergocalciferol/g} = \frac{A_{spl}}{A_{std}} \times \frac{\text{standard weight (mg)}}{\text{sample weight (g)}} \times \frac{1}{10} \qquad \text{(Eq. 2)}$$

RESULTS AND DISCUSSION

Due to the difference in the procedure for analysis, pharmaceutical preparations containing ergocalciferol can be divided into two categories: those containing vitamin A, which are numerous, and those devoid of it, which are few. The latter can be considered as high potency or low potency preparations according to the content of ergocalciferol and its administration per day relative to the daily requirement.

The problems of extraction of ergocalciferol in microgram quantities with minimal loss, especially from sugar-coated tablets (16), with subsequent purification and choice of a sensitive method of determination usually afford a challenge to the pharmaceutical analyst. In this laboratory the need arose for a simple quality control and stability assay for the determination of ergocalciferol in a vitamin–mineral supplement containing only 3.33–6 μg/sugar-coated tablet weighing 1.3–1.4 g (2.4–4.4 ppm).

Saponification with alcoholic potassium hydroxide or aqueous-alcoholic potassium hydroxide and extraction with ether or petro-

leum ether, or a combination of both followed by subsequent purification by alumina and/or silica chromatography, proved to be tedious and gave erratic and nonquantitative results. The presence of water and the dye in the sugar coating of the tablets were the main sources of difficulties in obtaining an extract pure enough for spectral analysis. The application of Procedure B and many modifications of it proved unsuccessful for the determination, because substances in the eluate interfered by giving an absorbance near 403 nm. Moreover, Procedure B was inadequate for the analysis due to the small amount of the vitamin in comparison to the bulk of the material and thus the need for relatively large quantities of water and adsorbent. It was the development of the stable and sensitive differential spectroscopy method at 490 nm that paved the way for an adequate analysis.

Procedure A proved to be simple, quantitative, and adequate for quality control purposes, with a precision of <±2%. The application of the method for stability studies is currently under investigation. The small amount of diethylamine is added before extraction to ensure that the methanolic milieu is on the slightly basic side to avoid destruction of the vitamin. Concentration of the methanol before chromatography is recommended, because higher percentages of methanol in the solvent contributed to the increase of interfering substances in the eluate. Interferences were detected by the increase in the value of absorbance at 490 nm after the addition of hydrogen peroxide.

The preliminary cleaning of the alumina with methanol and then chloroform is necessary to remove substances that affect the colorimetry. The slow flow of the solvent through the alumina is essential in adsorbing the dyes used in the sugar coating of the tablets; these dyes appear as a colored band in the upper part of the column. Anhydrous ethanol is added to the residue of the aliquot from the eluate and evaporated to remove mainly all traces of diethylamine. The low absorbance obtained at 490 nm after the addition of hydrogen peroxide (<0.08 as compared to 0.02–0.04 for reference standard ergocalciferol) shows that minimal interferences are eluted and are accounted for by the use of differential spectroscopy.

Procedure A, carried out on placebo tablets, verified that no significant interference was encountered. Quantitative recoveries within experimental error (±2%) of reference standard ergocalciferol added to placebo tablets showed that there was no loss through the assay procedure. The addition of sodium ascorbate or hydroquinone as an antioxidant before extraction did not improve the yield and sometimes interfered with the colorimetry.

Table I shows the results obtained with Procedure A for different samples compared with results obtained by the biological rat assay (17). The proposed method was also applied to commercially available tablets containing low potency amounts of ergocalciferol.

Variation in the results for the different lots of Product A (86–106% of the theoretical amounts) was expected due to the differences in the amounts of ergocalciferol in the lots of stabilized powder used in the tablets. In addition, low assay values could be attributed to the complex effect of heat, pressure, and long exposure to air and light during the manufacturing procedure of granulation, drying, compression, subbing, and sugar coating. Product C contained a comparatively large amount of salicylamide per tablet, which affected the accuracy of the differential spectroscopy analysis. The main bulk of the salicylamide was eliminated by concentration of an aliquot from the eluate, precipitation by addition of hexane, and filtration through cotton.

Although Procedure A takes 4–5 hr for completion, four assays can be carried out within 8 hr. The main advantages of the method are that the inconvenience of liquid–liquid partition extraction is avoided and the effect of spectral interferences can be accounted for. The differential spectroscopy method is currently under investigation for use in preparations containing vitamin A.

Ergocalciferol could be obtained commercially in the dry state, suitable for the preparation of granulations, as a stabilized form containing >2.5 mg ergocalciferol/g of powder. This stabilized powder contains mainly dicalcium phosphate, acacia, coconut oil, and preservatives as excipients. Procedure B was developed for quality control analysis of the powder as a raw material. The powder is mixed with water, which is necessary to dissolve the acacia and release the vitamin. A suitable amount of ethanol is added to dissolve the vitamin without precipitating the acacia, which would occlude some of the vitamin and thus cause a loss. Addition of the silicic acid is used to adsorb the water and also to distribute the vitamin on a large surface area and thus facilitate its extraction.

Chloroform quantitatively elutes ergocalciferol from the column. The trifluoroacetic acid colorimetric method recommended by Clements *et al.* (15) was chosen due to its simplicity and obvious advantages over the antimony trichloride method.

Procedure B was also applied to commercially available tablets containing milligram quantities of ergocalciferol. The results obtained (Table II) were compared with those obtained for samples from the rat bioassay (17) and the USP XVIII chemical method (7). Recoveries of reference standard ergocalciferol added to the stabilized powder in quantities of 0.3 and 3.0 mg for each gram of powder were 99 and 97%, respectively, which are within experimental error of the assay.

The results of Procedure B (Table II) are mostly slightly higher than those of the USP chemical method. A loss through the long procedure of saponification, solvent–solvent extraction, and column chromatography in the latter method is a possibility. The biological assay gave higher results than Procedure B for most samples. Procedure B (average deviation ≤2.6%) takes only 1.5 hr for completion; for quality control purposes, it is a suitable assay for high potency ergocalciferol preparations.

SUMMARY

Ergocalciferol could be assayed when present in microgram quantities in tablets by refluxing followed by column chromatography and differential spectroscopy using trifluoroacetic acid and hydrogen peroxide. The simplicity and accuracy of Procedure A make it adequate for quality control analysis. Preparations containing milligram quantities of ergocalciferol could be assayed for their ergocalciferol content (Procedure B) by partition/extraction chromatography followed by spectrophotometry using trifluoroacetic acid.

Quantitative Determination of Phenol in Phenolated Calamine Lotion USP

V. DAS GUPTA [x] and KATHRYN A. BOMER

Abstract □ A method for the quantitative analysis of phenol in phenolated calamine lotion USP is described. The method is based on spectrophotometrically measuring the color produced by reacting phenol with either ferric chloride or ferric nitrate. Beer's law is followed. The effect of ferric-ion concentration on the sensitivity of the assay method is reported.

Keyphrases □ Calamine lotion, phenolated—colorimetric analysis of phenol □ Phenolated calamine lotion—colorimetric analysis of phenol

Phenolated calamine lotion is an official USP (1) product. Although phenol is a potent therapeutic agent, the USP does not require its quantitative analysis in phenolated calamine lotion.

Kiposki and Allen (2) reported a bromometric method for the analysis of phenol. Stanko and DeKay (3) recommended a complicated colorimetric method for the quantitative analysis of phenol in phenolated calamine lotion based on reaction with copper sulfate. This report describes a simple colorimetric assay method for the analysis of phenol in phenolated calamine lotion USP. The method is based on an identification test with ferric chloride as described for phenol USP (4).

EXPERIMENTAL

Reagents and Chemicals—All chemicals and reagents used were USP, NF, or ACS grade. $FeCl_3 \cdot 6H_2O$[1], $Fe(NO_3)_3 \cdot 9H_2O$[2], and phenol loose crystals[3] were purchased and used without further purification.

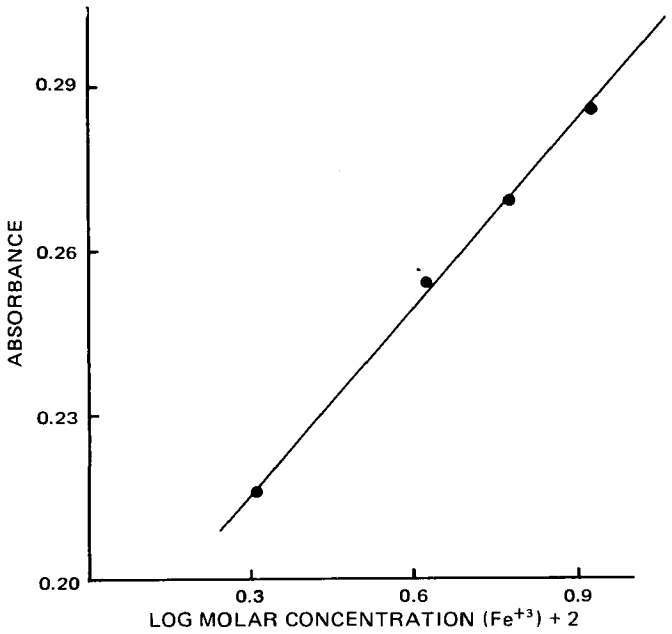

Figure 1—*Plot of log ferric-ion concentration* versus *absorbance.*

Table I—Assay Results on Phenolated Calamine Lotion and Calamine Lotion USP

Assay Number	Results, %	
	Phenolated Calamine Lotion	Calamine Lotion
1	100.2	0.0
2	100.5	0.0
3	100.2	0.0
Average deviation ± 0.13%		

Preparation of Solutions—All solutions of phenol, ferric chloride, and ferric nitrate were prepared (w/v) in distilled water using a simple solution method.

Preparation of Phenolated Calamine Lotion USP—A phenolated calamine lotion was prepared according to the USP (1).

Selection of Wavelength of Maximum Absorption—A 2.0-ml quantity of phenol solution (0.5%) was mixed with 2.0 ml of ferric chloride solution (4%), and the mixture was brought to volume (10.0 ml) with distilled water. The solution was scanned in the visible range using a spectrophotometer[4], and a broad peak was recorded between 528 and 556 nm. For further investigations, a wavelength of 550 nm was selected.

Effect of Ferric-Ion Concentration on Sensitivity of Assay Method—A 2.0-ml quantity of phenol solution (0.05 *M*) was mixed with 2.0, 4.0, 6.0, or 8.0 ml of ferric chloride solution (0.1 *M*), and the mixture was brought to volume (10.0 ml) with distilled water. The absorbance of the solution was measured at 550 nm against a reagent blank, prepared by substituting distilled water for phenol solution (Fig. 1).

Preparation of Calibration Curves—A 2.0-ml quantity of ferric chloride[5] solution (either 2 or 4%) was mixed with 2.0, 2.5, 3.0, 3.5, or 4.0 ml of phenol solution (0.5%), and the mixture was brought to volume (10.0 ml) with distilled water. The absorbance of each solution was measured as already described (Fig. 2).

Assay Procedure for Phenolated Calamine Lotion USP—A 10.0-ml quantity of phenolated calamine lotion was transferred on a filter paper. The filtrate was collected in a suitable container, and the precipitate on the filter paper was washed with 3 × 10-ml portions of distilled water. The precipitate was then rinsed with small portions of distilled water to bring the filtrate to volume (50.0 ml). It was mixed and refiltered when necessary. Then 8.0 ml of the clear filtrate was mixed with 2.0 ml of ferric chloride solution (4%), and the absorbance was measured at 550 nm as already described. The results, calculated by using the standard curve, are presented in Table I.

[4] Beckman model DB.

[5] Ferric nitrate may be substituted for ferric chloride on a mole per mole basis.

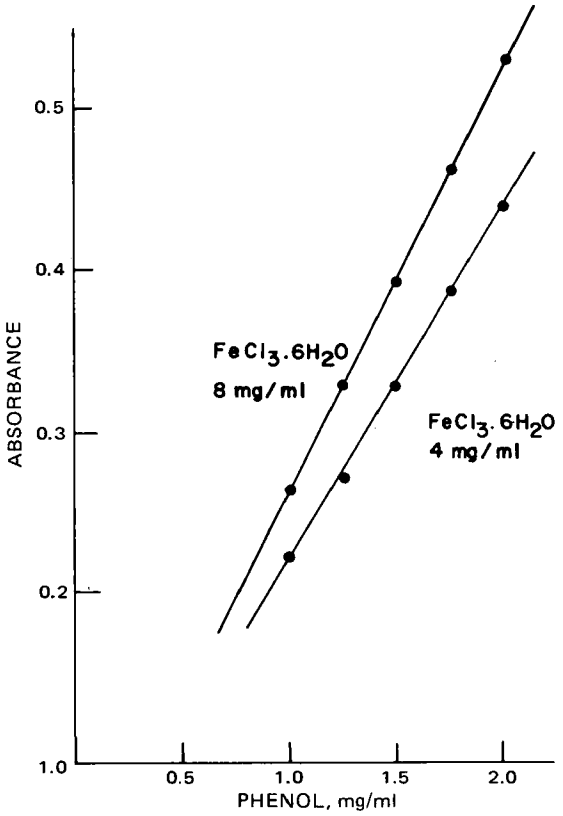

Figure 2—*Standard curves for phenol.*

Interference from Other Ingredients—The described procedure was repeated using calamine lotion USP. The results are presented in Table I.

DISCUSSION AND CONCLUSIONS

The results (Table I) show that phenol can be assayed in phenolated calamine lotion USP using a simple method (reaction with ferric chloride or ferric nitrate). Beer's law is followed (Fig. 2) at different concentrations of ferric ion. The concentration of ferric ion may be increased for more sensitivity in the assay technique, and the blank value is increased also. The log of the ferric-ion concentration is linearly related to absorbance (Fig. 1).

The reaction between phenol and ferric ion may be an oxidation–reduction or the formation of a complex. There is no interference from the other ingredients (Table I). It is important to keep the ferric-ion concentration constant since the sensitivity is dependent on this factor (Fig. 1). A 4.00% solution of ferric chloride is recommended for routine use for the quantitative analysis of phenol in phenolated calamine lotion USP.

Liquid Chromatography in Pharmaceutical Analysis III: Separation of Diuretic–Antihypertensive Mixtures

I. L. HONIGBERG ˣ, J. T. STEWART, A. P. SMITH, and D. W. HESTER

Abstract □ High-pressure liquid chromatography was used to optimize the resolution of therapeutic agents commonly found in antihypertensive preparations. Seven widely prescribed drugs were investigated. The compounds were chromatographed on reversed-phase octadecyltrichlorosilane (C_{18}) or diphenyldichlorosilane (phenyl) columns, using mixtures of acetonitrile or absolute methanol and distilled water buffered with ammonium acetate, ammonium chloride, or ammonium carbonate. By calculating approximate resolution values, the separation of selected drug mixtures can be predicted.

Keyphrases □ Diuretic–antihypertensive mixtures—high-pressure liquid chromatographic separation, effect of solvent composition, pH, and stationary phase polarity □ Antihypertensive–diuretic mixtures—high-pressure liquid chromatographic separation, effect of solvent composition, pH, and stationary phase polarity □ Multicomponent dosage forms—high-pressure liquid chromatographic separation of diuretic–antihypertensive mixtures □ High-pressure liquid chromatography—separation, diuretic–antihypertensive mixtures

High-pressure liquid chromatography (HPLC) has been successfully applied to the analysis of multicomponent pharmaceutical dosage forms in this laboratory (1, 2). In a continuation of the study of multicomponent dosage forms, this paper reports an investigation of the parameters associated with the separation and detection of diuretic–antihypertensive agents.

The compounds studied are included in listings of most prescribed drugs used singly or in combination for the treatment of hypertension. The drugs are chlorothiazide, hydrochlorothiazide, triamterene, hydralazine hydrochloride, guanethidine sulfate, methyldopa, and reserpine. A preliminary report on the sequential quantitative analysis of a chlorothiazide–reserpine mixture was published (2).

Chlorothiazide and hydrochlorothiazide in single entity and combination dosage forms have been analyzed by many methods including absorption spectroscopy (3–5), colorimetry (6), amperometry (7), bromatometric and bromo–chlorometric titrimetry (8), complexometric titrimetry (9), and nonaqueous titrimetry (10, 11). Triamterene can be measured by absorption spectroscopy, fluorescence, and TLC fluorometry (12–14), while hydralazine and guanethidine have been assayed by various titrimetric methods (15, 16). Fluorescence methods have been utilized for the determination of methyldopa (17) and reserpine (3, 18). Other procedures reported for these latter drugs include polarography (19) and colorimetry (20, 21).

The HPLC operating parameters investigated were limited to solvent composition, pH, and stationary phase polarity. The use of these data can be readily applied to the separation of selected multidrug dosage forms. This use has been exemplified by the separation and quantification of chlorothiazide–reserpine at unit-dosage levels (2).

EXPERIMENTAL[1]

Reagents and Chemicals—Powdered samples of chlorothiazide[2], hydrochlorothiazide[2], triamterene[3], hydralazine hydrochloride[4], guanethidine sulfate[4], methyldopa[2], and reserpine[4] were used in the analytical procedure. All other chemicals and solvents were the highest grade commercially available.

Mobile Phases—The mobile phases consisted of various concentrations of acetonitrile or absolute methanol mixed with aqueous solutions of 0.1 or 1% ammonium acetate, 0.5 or 1% ammonium chloride, and 0.2 or 1% ammonium carbonate. The solutions were prepared fresh daily.

Drug Solutions—Each drug was prepared as a 0.5% solution using the appropriate mobile phase.

Chromatographic Separation—The degassed mobile phase was pumped through columns containing either monomolecular layers of octadecyltrichlorosilane (C_{18}) or diphenyldichlorosilane (phenyl) chemically bonded to a high-efficiency pellicular packing, consisting of solid glass cores with a porous silica surface[5]. A flow rate of 1.4 ml/min (1000–2000 psig) was used until a stable baseline was obtained. The column and solvents were kept at ambient temperature. Replicate 20-μl injections of the sample solutions were made using a 25-μl syringe[6]. The chart recorder provided a record of the elution of the drugs from the column as peaks on a chromatogram.

RESULTS AND DISCUSSION

The purpose of this study was to determine the operating conditions for HPLC that would optimize the resolution of chemically unrelated therapeutic agents most commonly found in antihypertensive preparations. Three operating parameters were studied: *(a)* variations in solvent composition containing acetonitrile or absolute methanol with changing concentrations of distilled water; *(b)* variations in pH within the 5.5–9.0 range using ammonium acetate, ammonium chloride, or ammonium carbonate as inorganic buffers; and *(c)* variations in the nonpolar (reversed phase) stationary phase in which the pellicular packing differed in polarity.

The effects of these parameters on retention times and peak widths of the drugs are shown in Table I. In addition, multiple entries in Table I indicate those solvent systems (Table II) that generate multiplets for a component. These multiplets may arise from decomposition of the drug and/or the varied species of the drug possible at the mobile phase pH used. Significant tailing of single-drug entities is also noted.

The following generalizations can be inferred from the data in Table I. Retention time for many of the drugs increases as the polarity of the mobile phase increases. This generalization can be obscured when the solute travels as a multiple species such as methyldopa. It is also difficult to observe this effect for drugs that travel close to the void volume of the column and for which it is difficult to measure small differences in retention time. This situation is exemplified by chlorothiazide and hydrochlorothiazide. When

the pH of the mobile phase is adjusted so that the unionized species of the drug predominates, as calculated from its pKa value (15, 22, 23)[7], an increased retention time is noted for many of the drugs. Guanethidine, methyldopa, and triamterene are exceptions to this effect. A comparison of solvents containing equivalent amounts of acetonitrile–water and methanol–water showed that retention times are greater in the methanol-containing solvents. This finding is consistent with the observation of the effect of mobile phase polarity on retention time. The interplay of mobile phase pH and polarity and their effects on either the ionizability of the traveling solute or the ability to solvate the solute may evert the outlined generalizations.

Modifications in the polarity of stationary and mobile phases provided the following observations for the drugs examined. Chlorothiazide and hydrochlorothiazide traveled close to the solvent front in all systems. Triamterene could be separated from the thiazide diuretics in Solvent Systems E and K (Table III)[8]. The remaining solvent systems, such as exemplified by mobile phases I and N, did not adequately resolve these compounds. The drug was resolved best using the more polar mobile phases.

Hydralazine gave multiplets in most solvents. The exceptions were Solvents A, B, E, J, and K. Solvents A and E gave symmetrical peaks while B, J, and K showed tailing.

The aliphatic character of guanethidine precluded its detectability by UV absorption. Thus, differential refractometry was used to monitor the column effluent. Sensitivity was in the range of 50–100 μg for guanethidine. Acetonitrile–water mixtures were most effective in producing single symmetrical peaks for guanethidine at pH 7.35. However, as the pH of the mobile phase was made acidic, a doublet was observed.

Methyldopa was the most difficult to resolve from the other drugs in this study. In systems where the retention time of methyldopa was increased by the addition of water, excessive tailing was obtained. In mobile phases with pH >8, multiple peaks were obtained indicative of the several species of methyldopa possible in basic media. At pH <7, no multiplets were observed. In solvent systems where methyldopa eluted as a single peak, it could not be

[7] Guanethidine pKa value supplied by Dr. J. Mollica, Ciba-Geigy, Suffern, N.Y., personal communication, 1974.

[8] It is possible to calculate the approximate resolution *(Rs)* of two components by the equation: $Rs = 2(t_2 - t_1)/(w_1 + w_2)$, where t_1 and t_2 are retention times, and w_1 and w_2 are base peak widths of Compounds 1 and 2, respectively. Experience indicates that two components with an *Rs* value >1.5 show satisfactory resolution by this analytical technique.

Table III—Calculation of Approximate Resolution (*Rs*)[a] Values for Triamterene—Thiazide Mixtures

Drug Mixture	Mobile Phase[b] E	K	I	N
Triamterene	154[c]	271	145	119
	(38)[d]	(152)	(70)	(27)

Table IV—Calculation of Approximate Resolution (*Rs*)[a] Values for Hydrochlorothiazide—Hydralazine—Reserpine Mixture

Drug Mixture	Mobile Phase[b] E	F	K
Hydrochlorothiazide	108[c]	102	108
	(26)[d]	(25)	(37)
Hydralazine	220	224	306
	(79)	(155)	(133)
Rs =	1.95	1.36	2.3
Hydralazine	220	224	306
	(79)	(155)	(133)
Reserpine	>2400	1950	>2400
		(800)	
Rs =	>6.0[e]	3.6	>5.7[e]

[a] See footnote 8. [b] Letters refer to solvent compositions in Table II. [c] Retention time data from Table I. [d] Peak width data from Table I. [e] Calculated value based on retention time of 2400 sec and peak width of 800 sec for reserpine.

resolved from the thiazides. However, solvents systems such as D, J, and K could resolve methyldopa from reserpine; D and K could resolve methyldopa from both guanethidine and reserpine.

At high concentrations of acetonitrile, reserpine traveled with the solvent front. Its retention time was increased as the polarity of the solvent increased. In many instances, the retention time of reserpine was much greater than that of the remaining drugs tested and resulted in considerable band spreading. However, the reserpine peaks were symmetrical and would be suitable for quantification. In solvent systems with pH >8, several additional peaks were detected in addition to the reserpine band. This finding may be due to rapid decomposition of reserpine in alkaline media (24). Table IV illustrates resolution values for the three-component mixture of hydrochlorothiazide, hydralazine, and reserpine in some mobile phases. Solvent Systems E and K seem most suitable for separating the mixture, but E is better since hydralazine exhibits considerable tailing in mobile phase K. A flow programming procedure (changing flow rate with time) would be necessary with Solvent System E to decrease the retention time for reserpine.

Information contained in Table I presents operating parameters for HPLC that can be used to optimize the resolution of the multifarious drugs found in antihypertensive dosage forms. With the calculation of approximate *Rs* values as described previously, the separation of selected drug mixtures can be predicted.

Identification and Quantitation of Impurities in Dapsone Preparations

G. R. GORDON ˣ, D. C. GHOUL, and J. H. PETERS

Abstract □ Chromatographic and fluorometric procedures were developed to isolate and quantitate small amounts of 2,4′-diaminodiphenyl sulfone and 4-aminodiphenyl sulfone in pharmaceutical preparations of the antileprosy drug 4,4′-diaminodiphenyl sulfone (dapsone). Identification was accomplished by comparison with authentic compounds employing UV absorption, fluorometry, and mass spectrometry in addition to TLC and high-pressure liquid chromatography.

Keyphrases □ Dapsone—isolation, identification, and quantitation, pharmaceutical preparations □ TLC—determination, dapsone impurities in pharmaceutical preparations □ High-pressure liquid chromatography—determination, dapsone impurities in pharmaceutical preparations

Dapsone (4,4′-diaminodiphenyl sulfone, I) has emerged as the most efficacious drug in the therapy of leprosy (1). It is also of value in the suppression of chloroquine-resistant malaria (2, 3).

During studies on the purity of I, some samples were found to be contaminated[1] with 2,4′-diaminodiphenyl sulfone (II), 4-aminodiphenyl sulfone (III), and 4-amino-4′-chlorodiphenyl sulfone (IV). The purpose of this study was to isolate, identify, and quantitate any such impurities in several pharmaceutical preparations of I. These preparations were being used at that time by various clinical collaborators for the treatment of leprosy patients.

EXPERIMENTAL

Reagents and Standards—All reagents were of analytical grade except ethylene dichloride, which was purchased as a high purity solvent[2]. Compound I was technical grade[3] purified by crystallization from 95% ethanol. Compounds II–IV were used as received[1].

TLC and Microbore Column Chromatography—One dapsone tablet of the various pharmaceutical preparations (Table I) was triturated in 100 ml of 70% ethanol, and the insoluble excipients were removed by centrifugation at 2600×*g*. An aliquot of the clarified solution (containing approximately 250 μg of I) was streaked on a 250-μm thick silica gel plate[4]. The chromatogram was developed with chloroform. After air drying, the plate was viewed with a shortwave (254 nm) UV lamp[5]. The plate was then sprayed with a solution of 1 g of *p*-dimethylaminobenzaldehyde in 100 ml of ethanol containing 1.0 ml of concentrated hydrochloric acid.

Microbore column chromatography was performed using a glass column, 300 × 2.75 mm i.d.[6]. The column was slurry packed in small increments with silica gel[7] in ethyl acetate. A mixture of chloroform–carbon tetrachloride (70:30 v/v) was then pumped[8] through at a rate of 0.65 ml/min and 35.15 kg/cm² (500 psi). The absorbance of the column effluent liquid was measured at 280 nm using a UV monitor[9].

For chromatography, aliquots of each tablet solution (equivalent to 300 μg of I) were evaporated to dryness at 50° under a stream of nitrogen[10]. The residue was dissolved in 100 μl of chloroform, and 50 μl was injected into the solvent stream of the microbore column using a pneumatically actuated valve[11]. Individual fractions (≃0.3 ml) containing II and III were collected manually every 30 sec. After 42 fractions were collected, an additional 30-ml aliquot of the effluent liquid containing I was collected in a 50-ml volumetric flask. The latter collection was subsequently adjusted to 50 ml with additional solvent.

The first 42 fractions and 50 μl of the last collection were evaporated to dryness using nitrogen as previously described. To each residue was added 3 ml of ethylene dichloride, and the relative fluorescence was determined[12]. Fractions 1–24, containing III, were measured at 295/405 nm (activation/emission wavelengths); fractions 25–42, containing II, were measured at 295/375 nm; and the aliquot containing I was measured at 285/350 nm. The quantity of each compound was calculated by comparison to reference standards prepared for each chromatographic separation. Recoveries of the reference compounds from the chromatographic column were quantitative.

Spectrometry—UV spectra[13] of II and III isolated from dapsone preparations were obtained by pooling the respective fractions from several separations, evaporating the samples to dryness, and dissolving the residue in 95% ethanol. Reference spectra of authentic II and III were obtained in the same solvent. The fluorescent activation and emission spectra of II and III isolated by column chromatography were obtained from small aliquots of the ethanolic solutions used for UV spectrometry. After evaporating the ethanol, the residue was dissolved in ethylene dichloride. Similar spectra were obtained for authentic II and III. The mass spectra of II and III (authentic samples and isolated compounds) were obtained by subjecting samples to GC and then introducing the pure sulfone into the mass spectrometer[14] as it emerged from the gas chromatograph.

RESULTS

After TLC, Compounds I, II, III, and IV exhibited R_f values of 0.00, 0.11, 0.17, and 0.20, respectively. Compounds I and II exhibited a blue fluorescence, and Compounds III and IV yielded a yellowish-blue fluorescence under UV light. All yielded a yellow-to-orange color with the spray reagent. When aliquots of the various preparations of I were chromatographed, only bands corresponding to I, II, and III were detected. The retention times of I, II, and III after column chromatography were 44, 14, and 8 min, respectively. Each compound exhibited a linear relationship between peak height and quantity injected over the range of 0.5–2.0 μg. Only three peaks were found in the pharmaceutical preparations tested; they exhibited retention times identical to those of I, II, and III.

Because the fluorescence of all sulfones was considerably greater than their UV absorption per unit weight, all quantitative estimations were based upon fluorescent measurements. Figure 1 shows a

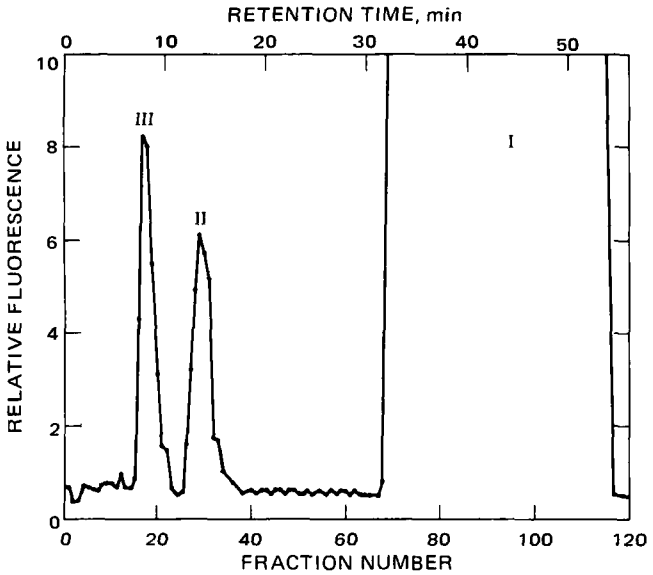

Figure 1—*Typical chromatographic separation and fluorometric quantitation of I, II, and III found in a pharmaceutical preparation of dapsone. The fluorescence of fractions 14–24 was determined at 295/405 nm (activation/emission wavelengths), of fractions 25–42 at 295/375 nm, and of fractions 67–116 at 285/350 nm.*

typical elution pattern of a dapsone preparation when the fluorescence of each fraction was measured. During each separation, I was always present in large amounts (150 μg) so the elution volume containing I (fractions 65–120) was routinely collected as a single sample beginning after fraction 42.

Figure 2 shows calibration curves obtained for I, II, and III in ethylene dichloride *via* fluorometry. The sensitivities (fluorescent intensity units per nanogram per milliliter) were 0.372, 0.236, and 0.173, respectively. Coefficients of variation for these sensitivity factors were 4.6, 3.9, and 6.3%, respectively, for 1 week of daily determinations. The lower limit of detection of II and III in 150 μg of I was about 0.05%.

Compound I exhibited fluorescence maxima of 285/350 nm (activation/emission) in ethylene dichloride (4). The recovery of I from the six pharmaceutical preparations averaged 96.9% (range 91.8–99.2%).

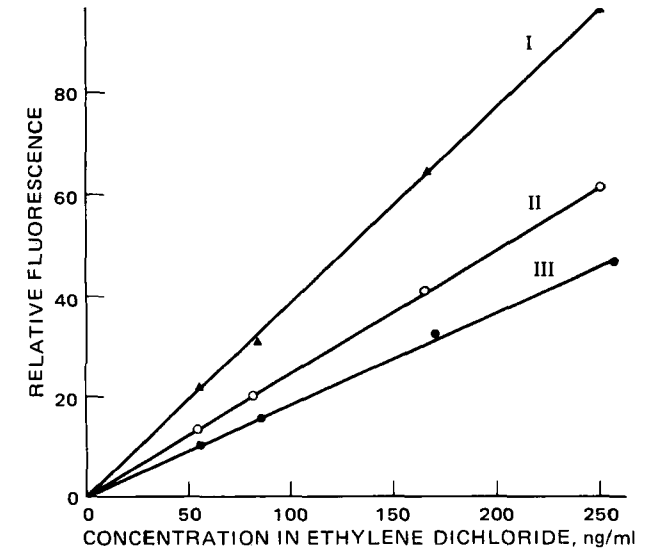

Figure 2—*Fluorescence calibration curves for I, II, and III. The activation/emission wavelengths were 285/350, 295/375, and 295/405 nm, respectively.*

Table I—Quantities of Impurities in Dapsone Preparations

Manufacturer[a]	Formulation	Percent of Impurity[b] II	III
1	25-mg tablet	0.16	0.64
1	50-mg tablet	0.31	0.76
2	25-mg tablet	0.49	0.65
2	50-mg tablet	0.80	0.99
3	100-mg tablet	0.35	0.51
4	100-mg tablet	0.20	0.27
5	Crystalline	3.3	2.7
6	Crystalline, technical grade	<0.05	0.70
6	Crystalline, technical grade, recrystallized	<0.05	0.18

[a] 1, P.C.B., Brussels, Belgium; 2, Laboratoire Lafran, Paris, France; 3, Ayerst Laboratories, New York, N.Y.; 4, Imperial Chemical Industries, Cheshire, England; 5, K&K Laboratories, Hollywood, Calif.; and 6, Merck & Co., Rahway, N.J. [b] Relative to the quantity of dapsone.

Compound II exhibited a UV_{max} at 280 nm, and the uncorrected maximum fluorescent wavelengths were 295/375 nm. The characteristics of the peak eluting at 14 min were identical to II, and its mass fragmentation spectrum was also identical to II. Since two other isomers of I, 3,4′- and 3,3′-diaminodiphenyl sulfone, yield mass spectral fragmentation patterns significantly different from I and II, possible confusion among these isomers and I and II is eliminated.

Compound III exhibited a UV_{max} at 290 nm, and its fluorescent characteristics were 295/405 nm. The peak that eluted at 8 min yielded these same characteristics in addition to exhibiting the same mass fragmentation pattern as authentic III.

The percentages of II and III found in several preparations of I are shown in Table I.

DISCUSSION

In the six tablet preparations of I, the quantity of II averaged 0.38% while the level of III averaged 0.64%. In one crystalline preparation (not pharmaceutical grade), the amounts of II and III were found to be considerably greater. The uncrystallized technical grade preparation contained 0.70% III, and the level of II was below the sensitivity of the procedure. On recrystallization, the level of III in this preparation was reduced to 0.18%.

The antimicrobial activities of II and III were compared with I. Using an *in vitro* assay method employing *Mycobacterium* sp. 607, Colwell *et al.* (5) showed that neither compound was as effective in preventing growth at concentrations at which I was very active. Likewise, the *in vivo* mouse foot pad test system showed that II and III were inactive in suppressing the multiplication of *M. leprae*[15] wherein I is very active (6).

The therapeutic regimen for the treatment of leprosy is generally 50 or 100 mg of I/day. Thus, preparations of I containing the levels of II and III found in these studies would result in a daily ingestion of less than 1.0 mg of either II or III. Although these quantities appear to be small compared with the daily dose of I, the long-term effects may be important because therapy using I in leprosy patients usually extends for many years and, in some cases, for the lifetime of the patients.

Rapid Fluorometric Determination of Procainamide Hydrochloride Dosage Forms

HENRY S. I. TAN [x] and CHERYL BEISER

Abstract □ A fluorometric procedure for procainamide hydrochloride was developed, and it offers improvements in ease, speed, and sensitivity over the official method. The new procedure is based on the reaction with fluorescamine in aqueous medium at pH 7.5 to form a fluorophore, with activation and emission wavelengths of 400 and 485 nm, respectively. The fluorescence is linear (r = 0.999) over the 0.04–1-μg/ml concentration range and is stable for at least 2 hr. Recovery data appeared to be accurate, quantitative, and reproducible. The overall recovery was 99.8% with a standard deviation of ±1.14 (n = 5). The method was successfully applied to commercially available dosage forms.

Keyphrases □ Procainamide hydrochloride—rapid fluorometric determination, bulk and dosage forms, fluorescamine reagent □ Fluorometry—analysis, procainamide hydrochloride dosage forms □ Fluorescamine—reagent in fluorometric analysis of procainamide hydrochloride dosage forms

The USP XVIII (1) assay procedure for procainamide hydrochloride capsules is time consuming, since it is based on a prior separation of the drug from the dosage form followed by a diazotization titration of the compound with standard sodium nitrite at low temperatures and starch iodide paper as the external indicator. This method is subject to variations between individuals in determination of the end-point. The assay method (2) for procainamide hydrochloride injections is also lengthy, since the sample must be evaporated and dried before the drug can be analyzed by nonaqueous titrimetry with standard perchloric acid.

Recently, it was reported (3–5)[1] that 4-phenylspiro[furan-2(3*H*),1′-phthalan]-3,3′-dione (fluorescamine) is a reagent for the detection of primary amines in the picomole range. Its reactions with amines is almost instantaneous at room temperature in aqueous solutions. The resulting fluorophores are fluorescent, whereas the reagent and its degradation products are nonfluorescent. This report presents a sensitive, simple, and accurate method for the assay of procainamide hydrochloride and its dosage forms with fluorescamine in an aqueous medium.

EXPERIMENTAL

Instruments—The following were used: a fluorescence spectrophotometer[2] with 1-cm cells, a mixer[3], and an analytical balance[4]. The response of the fluorescence spectrophotometer was calibrated daily, using a 0.5-μg/ml quinine sulfate solution in 0.1 *N* sulfuric acid, at activation and emission wavelengths of 350 and 445 nm, respectively.

Materials and Reagents—The following were used: procainamide hydrochloride[5], acetone[6], a 0.15% (w/v) solution of fluorescamine[7] in acetone, and pH 7.5 phosphate buffer. This buffer solution was prepared by adding 40.8 ml of 0.2 *M* sodium hydroxide to 50.0 ml of 0.2 *M* monobasic potassium phosphate in a 200-ml volumetric flask and diluting to volume with water. The pH of the resulting buffer solution was checked with a pH meter. All chemicals were analytical grade.

Preparation of Standard Curve—A stock solution of procainamide hydrochloride was prepared by dissolving 50.0 mg of the compound in 1000 ml of water. Further dilutions were made to obtain procainamide hydrochloride standard solutions containing 0.25, 0.5, 1.0, 1.5, 2.0, and 2.5 μg/ml. One milliliter of each solution was utilized for fluorescence development as described under *Assay Procedure for Procainamide Hydrochloride*. The stock and standard solutions were stable for at least 3 weeks.

Assay Procedure for Procainamide Hydrochloride—Pipet 1.0 ml of an aqueous solution containing 0.25–2.5 μg of procainamide into a 25 × 200-mm test tube. To this solution, add 1.0 ml of phosphate buffer (pH 7.5), and place the test tube on a vortex mixer. While shaking the tube vigorously, add 0.5 ml of the fluo-

was $y = 0.161x - 0.643$ with a standard error of the estimate of y on x of 1.36 and standard errors of the estimate of the intercept and slope of 1.06 and 0.0018, respectively. The fluorophore produced appeared to be stable for at least 120 min (Table II).

The concentration optimum of the fluorescamine reagent was determined by adding varying volumes of 0.15% fluorescamine in acetone to a series of 25 × 200-mm test tubes, each containing 1.0 ml of 0.5 μg/ml procainamide hydrochloride, and measuring the fluorescence against a blank[10] after diluting each solution to a total volume of 2.5 ml with pH 7.5 phosphate buffer. The results (Table III) indicated that 0.5 ml of the fluorescamine reagent gave the highest response. It was also established that, at constant volume, within certain limits the amount of pH 7.5 phosphate buffer did not affect the fluorescence.

The precision of the assay procedure was determined by running replicate studies on nine 1.00-ml aliquots of a standard procainamide hydrochloride solution containing 1 μg/ml. Each solution was assayed by the proposed procedure. The coefficient of variation for the nine replicate samples was 1.49% (Table IV).

RESULTS AND DISCUSSION

The reaction between procainamide and fluorescamine (Scheme I) presumably proceeds in several steps. There is a Michael addition of the amine to the acrylic function of fluorescamine, followed by ring closure and opening of the lactone ring.

The fluorophore obtained from the interaction between procainamide hydrochloride and fluorescamine shows activation and fluorescence wavelengths of 400 and 485 nm, respectively (Fig. 1), between pH 7.0 and 10.0. However, the fluorescence intensity is a function of the pH when alkaline borate buffer (pH 8.0–10.0) is used. In this case, the intensities decrease with increasing pH (Table I). When the phosphate buffer (pH 7.0–8.0) is used, the fluorescent intensities appear to be constant and are of greater magnitude than those in borate buffer (Table I). Based on these findings, the reaction was carried out in pH 7.5 phosphate buffer.

Under the experimental conditions, a linear relationship existed between fluorescent intensity and concentration over the 0.04–1-μg/ml concentration range (Fig. 2), with a correlation coefficient of 0.999. Regression analysis[9] showed that the regression equation

As little as 0.043 μg of procainamide hydrochloride can be assayed by the proposed method. The method, however, is reliable only for concentrations above 0.05 μg. Data presented in Table V indicate the accuracy of the procedure. The overall recovery for the six samples was 99.8% with a standard deviation of ±1.14. In comparison, the average recovery for two samples analyzed by the USP XVIII method was 97.6%.

Results obtained by applying the proposed fluorescence procedure to commercially available procainamide hydrochloride dosage forms are presented in Table VI. Comparison of the experimental data with those obtained by the compendial method shows a good correlation. Particularly in the analysis of the parenteral solution, the proposed procedure offers considerable improvement in speed over the USP XVIII method. Evaporation of the sample, which requires at least 60–75 min, and drying of the residue as directed by USP XVIII are completely eliminated.

It was also established that in the assay of the capsules the emptied capsules need not be soaked and agitated for 15 min as directed by the USP procedure. As long as care was taken to empty the

[9] Programa 101 Minicomputer, Olivetti Underwood Corp.

[10] Each blank contained the same amount of fluorescamine as in the solution studied but contained no procainamide hydrochloride.

250- or 500-mg capsules as completely as possible, the recovery appeared to be satisfactory (Table VI). Another advantage of the present method is the ease of performing the assay. The fluorescamine reagent is stable for several weeks. In contrast, the USP XVIII method for the capsules requires freshly prepared sodium nitrite solutions.

GLC Determination of 17α-Ethynylestriol 3-Cyclopentyl Ether

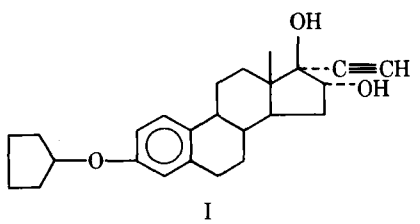
RAFIK H. BISHARA [x], BONNIE S. RUTHERFORD, and ALAN DINNER

Abstract □ A rapid, sensitive, and accurate GLC method of analysis of a new estrogenic drug, 17α-ethynylestriol 3-cyclopentyl ether, was developed. The drug and the internal standard, tetratriacontane, are dissolved in chloroform, and an aliquot is heated with *N*-trimethylsilylimidazole at 80° for 30 min. The silylated sample is chromatographed using a column packed with 1% methyl vinyl silicone gum on Gas Chrom Q. Quantitation is achieved by computer calculation of the peak area ratios. The observed peak is the 16α,17β-bistrimethylsilyl derivative of the new drug substance. The GLC method was applied to the quantitative determination of the estrogenic compound in a tablet formulation containing 25 μg/tablet.

Keyphrases □ 17α-Ethynylestriol 3-cyclopentyl ether—GLC analysis as trimethylsilyl derivative □ Estrogens—GLC analysis of 17α-ethynylestriol 3-cyclopentyl ether □ GLC—analysis, 17α-ethynylestriol 3-cyclopentyl ether

A new potent estrogenic hormone, 17α-ethynylestriol 3-cyclopentyl ether (I), useful in the treatment of spontaneous or induced menopausal syndrome, estrogen deficiency, or conditions when estrogen may be used therapeutically, has been synthesized (1, 2).

In the process of developing a GLC method for analyzing I, the literature concerning the GLC determination of estrogens was screened. Numerous publications deal with the GLC determination of estriol, both as the pure compound (3–6) and in biological materials (7–29). Although there are several reports of the GLC of free estriol (4, 5, 15, 17, 27), the use of estriol derivatives is preferred to prevent irreversible adsorption on the column and/or thermal decomposition of the underivatized hormone (30, 31). Higher volatility of the steroid derivative results in a shorter retention time, sharper peak, and improved sensitivity (31, 32).



I

The trimethylsilyl (21, 22, 25, 28, 33), acetate (19, 23, 24, 29, 33), heptafluorobutyrate (14, 34), and trifluoroacetate (6, 35, 36) derivatives are the most frequently used. The advantages of the trimethylsilyl derivatives relative to the acetate derivatives were discussed (37, 38). Other derivatives that were also reported for the GLC determination of estriol include the 3-methyl ether (39, 41), monochloroacetate (42), chloromethyldimethyl ether (43), chlorodifluoroacetate (43), 3-methyl-16,17-diacetate (44–46), 3-methyl-16,17-diheptafluorobutyrate (7), and 3-methyl-16,17-ditrimethylsilyl (13, 20, 39, 44) and iodomethyldimethylsilyl ethers (47). Several reported procedures were tried with no success for the analysis of I in this study. The purpose of this paper is to report the trimethylsilyl derivatization and GLC conditions for the quantitation of I.

EXPERIMENTAL

Equipment—A gas chromatograph[1] equipped with a flame-ionization detector was used. The detected signals were fed to a computer[2] for peak area integration and to a potentiometric recorder[3] with a chart speed of 38.1 cm (15 in.)/hr and a 1-sec full-scale response. Helium, with a flow rate of 60 ml/min, was the carrier gas. The flow rates of hydrogen and oxygen were adjusted to optimum sensitivity and low noise background in the electronic integrator and were found to be 40 and 300 ml/min, respectively.

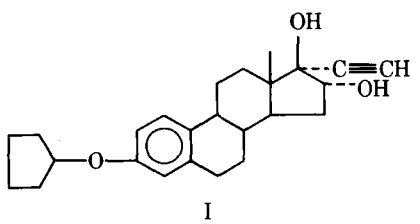
A new potent estrogenic hormone, 17α-ethynylestriol 3-cyclopentyl ether (I), useful in the treatment of spontaneous or induced menopausal syndrome, estrogen deficiency, or conditions when estrogen may be used therapeutically, has been synthesized (1, 2).

In the process of developing a GLC method for analyzing I, the literature concerning the GLC determination of estrogens was screened. Numerous publications deal with the GLC determination of estriol, both as the pure compound (3–6) and in biological materials (7–29). Although there are several reports of the GLC of free estriol (4, 5, 15, 17, 27), the use of estriol derivatives is preferred to prevent irreversible adsorption on the column and/or thermal decomposition of the underivatized hormone (30, 31). Higher volatility of the steroid derivative results in a shorter retention time, sharper peak, and improved sensitivity (31, 32).



I

The trimethylsilyl (21, 22, 25, 28, 33), acetate (19, 23, 24, 29, 33), heptafluorobutyrate (14, 34), and trifluoroacetate (6, 35, 36) derivatives are the most frequently used. The advantages of the trimethylsilyl derivatives relative to the acetate derivatives were discussed (37, 38). Other derivatives that were also reported for the GLC determination of estriol include the 3-methyl ether (39, 41), monochloroacetate (42), chloromethyldimethyl ether (43), chlorodifluoroacetate (43), 3-methyl-16,17-diacetate (44–46), 3-methyl-16,17-diheptafluorobutyrate (7), and 3-methyl-16,17-ditrimethylsilyl (13, 20, 39, 44) and iodomethyldimethylsilyl ethers (47). Several reported procedures were tried with no success for the analysis of I in this study. The purpose of this paper is to report the trimethylsilyl derivatization and GLC conditions for the quantitation of I.

EXPERIMENTAL

Equipment—A gas chromatograph[1] equipped with a flame-ionization detector was used. The detected signals were fed to a computer[2] for peak area integration and to a potentiometric recorder[3] with a chart speed of 38.1 cm (15 in.)/hr and a 1-sec full-scale response. Helium, with a flow rate of 60 ml/min, was the carrier gas. The flow rates of hydrogen and oxygen were adjusted to optimum sensitivity and low noise background in the electronic integrator and were found to be 40 and 300 ml/min, respectively.

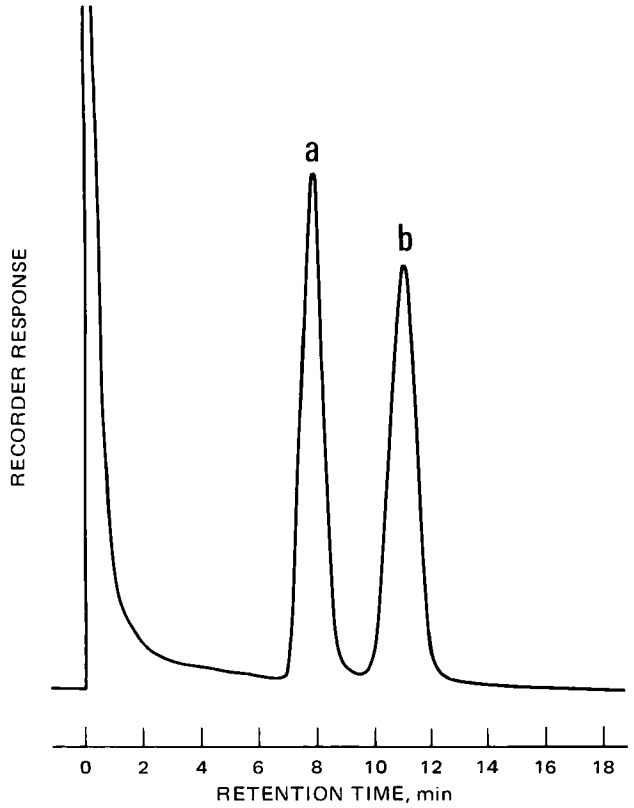

Figure 1—*Typical gas chromatogram of trimethylsilyl-derivatized Compound I. Key: a, 3-(cyclopentyloxy)-16α,17β-bis[(trimethylsilyl)oxy]-19-nor-17α-pregna-1,3,5(10)-trien-20-yne; and b, tetratriacontane.*

The U-shaped glass column (61 cm × 3 mm i.d.) was packed with 1% methyl vinyl silicone gum (UC-W98) on 80–100-mesh Gas Chrom Q[4]. The operating temperatures were: injection port, 260°; column, 225° (isothermal); and detector, 280°. All injections were made using a 10-μl syringe[5].

Reagents—The silylating reagent was *N*-trimethylsilylimidazole[6]. For the tablet assay, the reagent was diluted 1:5 with methylene chloride[7] previously dried over anhydrous sodium sulfate. The reference standard solution was prepared in chloroform[8]. Spectroquality carbon tetrachloride[9] was used for extracting the tablets.

Internal Standard Solution—*n*-Tetratriacontane[10], 2.4 mg/ml in chloroform, was used.

Reference Standard Solution—A I solution containing 2.0 mg/ml of chloroform was prepared. One-milliliter aliquots of the reference standard and internal standard solutions were pipetted and mixed together in a small screw-capped vial sealed with a Teflon septum. One milliliter of the silylating reagent was added by a tuberculin syringe[11], and the vial was heated for 30 min at 80° in a constant-temperature heating block[12]. The vials were then removed from the heating block, cooled to room temperature, and submitted for GLC.

Raw Material Solution—The raw material sample was prepared exactly as the reference standard solution.

Tablet Solution—The average tablet weight of 20 tablets was determined. A portion of the powdered tablet material, equivalent to 25 μg of I, was suspended in 10 ml of 0.05 *N* hydrochloric acid and extracted with three 30-ml portions of carbon tetrachloride.

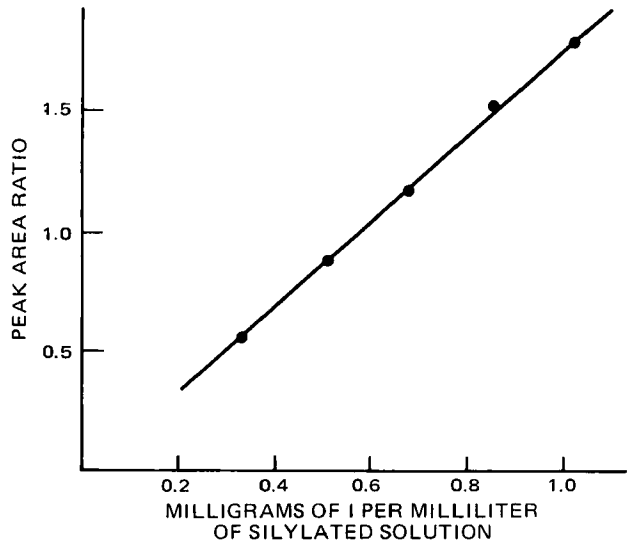

Figure 2—*Calibration curve demonstrating linear response of different amounts of trimethylsilyl Compound I to a constant concentration of tetratriacontane.*

One milliliter of internal standard solution (25 μg/ml) was added, and the solution was evaporated to near dryness. Then the remaining solution was transferred quantitatively to a small glass vial[6], 3.5-ml capacity, and evaporated.

A 0.25-ml aliquot of the silylating mixture was added to the residue, and the vial was sealed and heated as described for the reference standard. The reference standard solution used for the tablet assay was 25 μg/ml. One milliliter of this solution was mixed with 1 ml of the internal standard solution (25 μg/ml) in a small glass vial. After evaporation, 0.25 ml of the silylating mixture was added; then the vial was sealed and heated.

GLC—Four 3-μl portions of the standard solution were injected into the chromatograph to prime the column, and the instrument parameters were adjusted to obtain optimum response of the two peaks. The retention time was approximately 8.0 min for silylated I and 11.0 min for the internal standard, tetratriacontane.

When optimum conditions were obtained, duplicate injections were made of the standard solution, the sample solution, and the standard solution again. The peak areas obtained from the electronic integrator were used for the calculation of the percent purity of the raw material sample as shown in Eq. 1. Tablet potency was calculated as in Eq. 2.

GLC–Mass Spectrometry—A 70-ev electron-impact mass spectrum of the observed GLC peak was obtained[13].

Calculation—The ratio of the sample peak to the internal standard peak is calculated for each injection, and the duplicate ratios are averaged:

$$\%\ \text{purity} = \frac{R_{sa}}{R_{std}} \times \frac{\text{standard weight (mg)}}{\text{sample weight (mg)}} \times \text{standard purity} \times 100 \quad \text{(Eq. 1)}$$

where R_{sa} is the ratio of the silylated I peak area to tetratriacontane peak area in the sample solution, and R_{std} is the average ratio of the silylated I peak area to the tetratriacontane peak area of the standard solution before and after sample injections.

The potency of I in micrograms per tablet is calculated as follows:

$$\text{micrograms per tablet} = \frac{R_{sa}}{R_{std}} \times \frac{\text{standard weight } (\mu g)}{\text{sample weight (mg)}} \times \text{standard purity} \times \text{average tablet weight (mg)} \quad \text{(Eq. 2)}$$

where R_{sa} and R_{std} are defined as in Eq. 1.

RFS	3-Methoxy-19-nor-17α-pregna-1,3,5(10)-trien-20-yn-17-ol
RFS	19-Nor-17α-pregna-1,3,5(10)-triene-3,16α,17-triol
RFS	3-(Cyclopentyloxy)-16α,17α-(isopropylidenedioxy)-19-norpregna-1,3,5(10)-trien-20-yne

[a] P = synthetic precursor, PDP = probable degradation product, and RFS = related foreign steroids.

RESULTS AND DISCUSSION

A typical gas chromatogram is shown in Fig. 1. The first peak is the trimethylsilyl derivative of I, which is identified as 3-(cyclopentyloxy)-16α,17β-bis[(trimethylsilyl)oxy]-19-nor-17α-pregna-1,3,5(10)-trien-20-yne (II) by GLC–mass spectrometry. The mass spectrum of II shows a molecular ion at *m/e* 524, indicating silylation of the two hydroxy groups on ring D at the 16- and 17-positions. The observed fragmentation pattern is analogous to that described for the trimethylsilyl ether derivatives of estriol and other related steroids (48, 49). The second peak in the chromatogram is tetratriacontane, the internal standard. Relative to the internal standard peak, the retention time of II is 0.73.

Figure 2 shows the linear relationship of various amounts of I (0.34–1.02 mg/ml) to a constant amount of tetratriacontane (0.8 mg/ml).

Twelve related steroids were chromatographed using this method. Table I shows the chemical names of these related compounds and identifies them as precursors, possible degradation products, or related foreign steroids. All 12 tested compounds showed shorter retention times than that of II. Thus, the synthetic precursors and the known degradation products of I do not interfere with its GLC analysis.

Duplicate injections of five different raw material samples by a single analyst give a standard deviation of 0.004 and a relative standard deviation (*SD*/mean × 100) of 0.322%. The accuracy and precision of the tablet assay were determined by analyses of five replicate samples. A relative standard deviation of 0.80% and a relative error of −0.20% were obtained.

Aged and degraded samples of tablets containing I were evaluated by this method. The assay values show a decrease on aging for 1 year at high temperature (50°). No interferences or extraneous peaks were observed on the chromatograms.

PHARMACEUTICAL TECHNOLOGY

Effect of Physical Properties on Compression Characteristics

E. SHOTTON [x] and B. A. OBIORAH [*]

Abstract □ The transmission of force to the die wall was measured by a piezoelectric sensor, and the compression cycles of lactose granules of different shapes were compared. In addition, a nearly spherical fraction of spray-dried lactose was similarly compared with a crystalline sample. Better tablets were formed when the conversion of axial to radial pressure was high and the residual pressure on the die wall remained after removal of the top punch. With acetaminophen and phenacetin, the pressure on the die wall was low, as was the residual pressure, and capping occurred in both cases. With direct compression acetaminophen, higher die wall pressure was produced and capping did not occur. It is considered that these results can be explained by the ease with which the more nearly isodiametric particle can rearrange under pressure and by the elastic properties of the solid.

Keyphrases □ Lactose granules—effect of physical properties on compression characteristics □ Compression of lactose granules—effect of physical properties compared □ Die wall pressures—compared for various lactose granules, effect on tablet compressibility

The effect of crystal habit and particle shape upon the properties of cubic and dendritic crystals of sodium chloride and the tablets produced from these crystals was previously examined (1). For any particular material, the difference between applied and lower punch pressure depends on the coefficient of friction at the die wall and on the radial pressure.

Working with sodium chloride, aspirin, and hexamine (methenamine), Shotton and Ganderton (2) postulated that capping of hexamine was due to the failure of the material induced by axial elastic recovery after compression force was removed, and this capping occurred when the interparticulate bonds were sufficiently strong to resist separation of the crystals.

EXPERIMENTAL

The following materials were used: phenacetin[1], acetaminophen[2], direct compression acetaminophen[3], spray-dried lactose[4], and crystalline lactose[5]. Lactose granules[6] with the following composition by weight were also used: lactose, 50%; sucrose, 33%; maize starch, 16%; and magnesium stearate, 1%.

A vibratory sieving machine was used to obtain 30–40-mesh lactose granules, acetaminophen crystals, and phenacetin crystals, and an air jet sieve was used to obtain a 75-μm fraction of direct compression acetaminophen. The 40–45-μm fraction of the spray-dried and crystalline lactose powders was separated using a zig-zag classifier[7]. All materials were dried at 60° for 4 hr in a hot air oven and stored in wax-sealed screw-capped jars.

Different shape fractions of the lactose granules were obtained from the shape-sorting table described by Ridgway and Rupp (3). In Table I, 1, 4, 8, and 12 refer to the fractions obtained at these stations of this machine. The smaller the number of the station, the more spherical was the shape of the particles; the larger the number of the station, the more angular were the particles. The shape coefficient for the shape fractions of lactose granules was calculated from the average values of the particle volume, surface area, and projected diameter using the method of Heywood (4) as modified by Ridgway and Rupp (3).

Shape factor determinations were not carried out for the lactose powders because it was not possible to count accurately such fine particles. Microscopic examinations, however, showed that the spray-dried lactose was composed of spheroidal particles and that the crystalline lactose was highly angular. The shape-sorting table was unsuitable for the needle-shaped crystals of acetaminophen and phenacetin because these were broken down by vibration. The values of shape coefficient for lactose granules are presented in Table II.

[a] *Fa, Fb, Fd, Fe,* and *Fc* are applied force, transmitted force, force lost to the die wall, ejection force, and crushing force, respectively, expressed in newtons (N). Porosity values are expressed in percentage. Punch diameter is 12 mm. *R* is the ratio of *Fb/Fa.*

Table II—Values of Shape Coefficient for Lactose Granules (30—40 mesh)

Station[a]	Shape Coefficient
1	14.5
4	15
8	17
12	21.5

[a] Refers to the stations from the shape-sorting table; a sphere would have a shape coefficient of 6.

The powders were compressed in an instrumented single-punch machine. The top and bottom punches were instrumented as described by Shotton and Ganderton (5). The radial pressure was measured by inserting a piezoelectric transducer[8] through the die wall, and forces were recorded as previously described (1). Five tablets were prepared from each powder sample at approximately 45, 90, 135, and 180 MN m^{-2} compression pressures. Once the tableting pressure had been chosen for a particular material, the same machine setting was used for the compression of different shape fractions or forms where applicable.

To condition the die, the first two tablets of any compression exercise were rejected. The weight of material in each case, calculated from its true density, was sufficient to give a tablet of 4-mm length at zero porosity using a 12-mm diameter punch and die set. The material was introduced by hand into a die previously lubricated by applying, with a small camel-hair brush, a 2% solution of stearic acid in a mixture of equal parts of acetone and carbon tetrachloride and the solvents were allowed to evaporate.

The porosity of the tablet was obtained from the dimensions of the ejected tablet. In all cases, the crushing strength of the tablet was determined after 24 hr using the diametral crushing strength test described by Shotton and Ganderton (6).

RESULTS

Compacts that showed signs of capping or that were too fragile to be measured were regarded as unsatisfactory. Both the crystalline acetaminophen and phenacetin yielded unsatisfactory tablets, so it was not possible to determine the values of crushing strength and porosity. Tablets produced from direct compression acetaminophen, lactose powders, and lactose granules were satisfactory.

The results for the different tableting parameters at the highest compression pressure used are presented in Table I. With lactose, at the highest machine setting, greater values of applied force *(Fa)* were obtained for the spheroidal spray-dried powder than with the crystalline form. Similarly, the lactose granules gave greater values of applied force for the more nearly spherical particles than for the more angular ones. Also, the more spherical-shaped lactose granules and the spheroidal spray-dried lactose gave stronger tablets on compression than the more irregular granules and the crystalline powder.

[8] Kistler, 601H.

The force lost to the die wall *(Fd)* increased with increasing departure from the spherical, *i.e.*, increasing shape coefficient; thus, lower values of *R*, the ratio of transmitted and applied force, *Fb/Fa*, were obtained for the less spherical particles (Table I). The values obtained at four axial pressures are shown in Fig. 1 for the four shape fractions of lactose granules. These findings show that the force lost to the die wall $[Fd = (Fa - Fb)]$ increases as the particles depart increasingly from the spherical.

However, for the lactose powders, the crystalline form, which was highly angular, gave a smaller value for the ejection force *(Fe)*. The converse was true for the lactose granules.

The compression cycle plots for the various materials are illustrated in Figs. 2–4.

Recordings for pressure applied to the top punch and the corresponding pressures exerted on the die wall were made continuously during the down and up strokes of the top punch by a UV spot galvanometer on photographic paper. The die wall pressure was then plotted against the corresponding axial pressures to obtain the pressure cycle. The compression cycles for the lactose powders and granules as well as for direct compression acetaminophen had the same general form and seem to indicate that the crystals behave similarly to a Mohr body as described by Long (7).

The shape of the cycles obtained for acetaminophen and phenacetin crystals differed in some respects. The residual pressure on the die wall after the axial pressure returned to zero was lower than with lactose granules and powder and with direct compression acetaminophen. None of the materials gave a pressure cycle similar to that of a body with constant yield stress in shear since the value of the second upward slope of the line would be constant and equal to 1 for such a material.

DISCUSSION

In cases where a greater axial force, *Fa*, is recorded, the particles are probably more difficult to deform. Data obtained by Higuchi *et al.* (8) show that materials associated with high residual die wall pressure give correspondingly high ejection force. They concluded that residual elastic compressional energy remaining after partial recovery in the die appears to determine the amount of work required to remove the finished tablet. This conclusion is in agreement with friction theory.

Train and Hersey (9) postulated that the value of the force lost to the die wall *(Fd)* is the product of the shear strength of the compressed material and the true area of contact between compact and the die wall. Carrington (10) showed that a maximum value for *Fd* can only be obtained when the whole compact is moved relative to the die at the point of maximum compression.

In every case, a satisfactory tablet resulted when there was a good conversion of the applied pressure to the die wall. In such cases the residual die wall pressure, after the compression pressure returned to zero, was greater than that for the materials yielding unsatisfactory tablets. Thus, lactose powders and granules and direct compression acetaminophen gave satisfactory tablets. Versano and Lachman (11) found a direct proportionality between binding and the contact area of the solid surfaces on which these forces play a role. Materials such as lactose, which showed plastic flow from the pressure cycles, gave correspondingly good tablets due to a greater contact area being formed whereas acetaminophen and

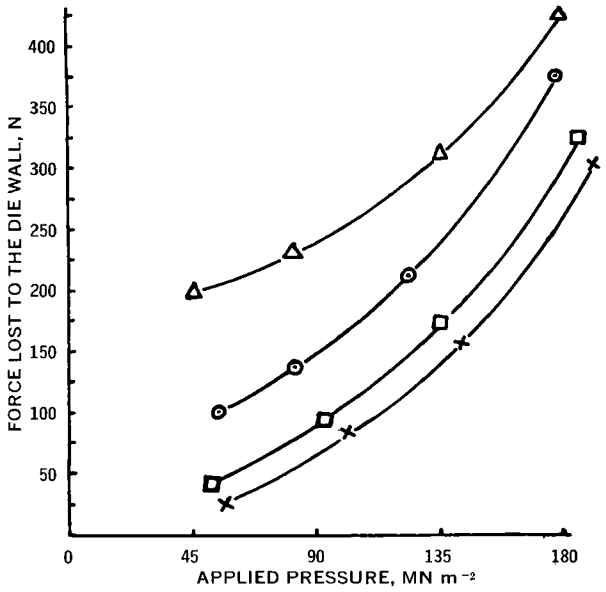

Figure 1—*Force lost to die wall for lactose granules at four machine settings. Key: ×, No. 1 shape fraction; □, No. 4 shape fraction; ○, No. 8 shape fraction; and △, No. 12 shape fraction.*

phenacetin crystals, in which recovery was mainly elastic, produced weak tablets. Also, the acetaminophen and phenacetin crystals were essentially needle-like and could be readily fractured.

None of the materials used gave pressure cycles identical with the theoretical pressure cycles described by Long (7), since these pressure cycles were for models of solid, isotropic bodies under uniaxial compression, assuming that die wall friction was absent. Leigh *et al.* (12) reported that materials giving the Mohr-type body of pressure cycle are prone to capping and lamination. In this study, there was no tendency to cap or laminate at the pressure used for lactose and direct compression acetaminophen, although these behaved like a Mohr body.

With the crystalline acetaminophen and phenacetin, the pressure cycles were more akin to those of an elastic body. With these latter materials, the initial transmission of pressure to the die wall was very small, probably due to difficulties encountered by the particles to rearrange. The values for the initial slopes were broadly in agreement with the Poisson ratio of the materials, and this ratio determines the degree of lateral expansion a body undergoes when subjected to a normal axial force. The values for the Poisson ratio obtained for acetaminophen and phenacetin from the slope were low, and the residual pressure on the die wall was also low after the axial pressure was removed. Thus, the compact had recovered axially and contracted radially, inducing considerable strain within the compact, because during the recovery process the

tablet was subjected to a residual pressure acting from the die wall and friction restricted peripheral movement. Under these conditions, separation or capping can occur along the stress loci.

Mohr's theory of failure can be used to explain this process. An isotropic solid material fails during compression by slip along a certain surface when shear stress acting along the surface reaches a limiting value, which depends on the major principal stress. The radial pressure is the major stress when the axial pressure returns to zero. This assumes that failure occurs initially while the compact is still in the die.

The dissipation of radial pressure for acetaminophen and phenacetin was greater than for the direct compression acetaminophen and was probably due to a greater axial recovery. This finding also indicates that the direct compression acetaminophen was subjected to more permanent deformation than the crystals; with the direct compression material, it is possible that the gelatin films may interfere with the bonding between the solid particles and that the gelatin films may yield under elastic recovery to give relaxation at the bond.

CONCLUSIONS

Certain predictions can be made by evaluating the die wall pressures. The indications are that materials that permit good conversion of applied pressure to the die wall yield satisfactory tablets. This finding may prove to be a useful tool in the search for materials that can be directly compressed to yield tablets. Furthermore, materials giving a low residual die wall pressure yield tablets that are too weak or that cap on ejection.

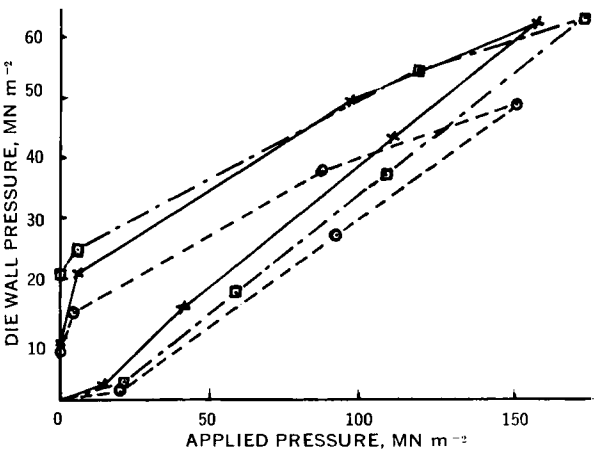

Figure 4—*Pressure cycles for direct compression acetaminophen, acetaminophen crystals, and phenacetin crystals. Key: ○, phenacetin (30–40 mesh); ×, acetaminophen (30–40 mesh); and □, direct compression acetaminophen.*

The acetaminophen and phenacetin crystals, which are essentially needle shaped, have a tendency to fracture easily and yield weak tablets. Investigations must be conducted with a much wider range of materials.

Application of Powder Failure Testing Equipment in Assessing Effect of Glidants on Flowability of Cohesive Pharmaceutical Powders

PETER YORK

Abstract □ Powder failure testing equipment was used successfully to study the effect of glidants on the flowability of two cohesive pharmaceutical powders, lactose and calcium hydrogen phosphate, using the flow factor as the flowability parameter. Fine silica, magnesium stearate, and purified talc were investigated as glidants; for each host powder–glidant mixture, an optimum concentration of glidant was observed beyond which no further increase in flowability occurred. The order of efficiency of glidants for both host powders was fine silica > magnesium stearate > purified talc. The mode of action of the three glidants is discussed.

Keyphrases □ Flow properties of cohesive powders—application of powder failure testing equipment (shear cell and tensile tester) □ Glidant—effect on flow factor for powder mixtures, optimum concentration, mode of action □ Powders—effect of glidants on flowability determined using powder failure testing equipment

Over recent years the increasing use of fine powders has emphasized the need for more information regarding their handling and mechanical properties. Fine powders, in general, exhibit nonfree-flowing (*i.e.*, cohesive) properties, which can cause serious problems such as caking of powders in storage and bridging in hoppers. Such problems can lead to the uneven flow of powders and to difficulties in filling operations in various pharmaceutical processes.

To improve the flowability of powders and granulations, a small amount of a second agent, or glidant (1, 2), is often added, usually in powder form. Examples of glidants commonly used in the pharmaceutical industry are talc, magnesium stearate, starch, and fine silica (3). Several postulates have been proposed to explain the mechanism of action of glidants:

1. Removal of electrostatic charges on the surface of the host powder (3, 4).

2. Distribution of glidant through the host powder, and the collection of very fine cohesive host particles onto glidant particle surfaces (5).

3. Selective adsorption of gases and vapors otherwise adsorbed onto the host powders (5).

4. Reduction of van der Waals forces by separation of host powder particles (3).

5. Reduction of interparticular friction and surface rugosity by glidant particles adhering to the surface of the host powder (3, 4).

Several techniques have been employed to study the effects of the addition of glidant to host powders and granulations. Several investigators measured the rate of flow of powder particles from hoppers through circular orifices and measured the flow rate under dynamic conditions (6–8). Other methods have included tablet weight variation (9), vibrating funnel (10), and angle of repose (6, 11, 12). In the latter test, the maximum angle between the surface of a heap of powder and the horizontal plane is measured and values reflect the magnitude of the static coefficient of friction between particles.

All of these tests are most successfully employed for assessing the flowability of relatively coarse powders and granules in the 100–400-μm range (13), and optimum glidant concentrations were derived for particular systems (3, 14). However, the results obtained are significantly affected by the conditions of the test. Angular tests, such as the angle of repose, only provide a qualitative basis for assessing the flow of powders (14). In addition, these techniques do not lend themselves to the study of the flowability of fine cohesive powders, because the measurements become inaccurate (5).

be investigated using powder failure testing equipment (13), *i.e.*, a shear cell and tensile tester, and their flow characteristics can thus be studied in a more scientific and quantitative manner. This investigation was conducted to determine whether this type of equipment can also be employed to study the effect of glidants on the flowability of cohesive pharmaceutical powders and to establish whether optimum glidant concentrations exist for such systems. Clearly, it would be beneficial to be able to select glidants on a scientific basis when they are required to improve the flow properties of cohesive powder formulations.

For comparison, the angle of repose test was also performed using the same powder–glidant mixtures.

EXPERIMENTAL

Materials—The host powders used, α-lactose monohydrate[1] and calcium hydrogen phosphate[2], were reagent grade and were selected as representative cohesive organic and inorganic pharmaceutical powders. The three glidants used were fine silica[3], magnesium stearate[4] BP, and purified talc[5] BP. The relevant physicochemical properties of the powders are listed in Table I.

Average particle sizes were determined using optical microscopy and surface area measurements by an air permeability technique[6], except for fine silica where the particle-size and surface area values in Table I are those quoted by the manufacturer. Particle densities were determined using the specific gravity bottle technique with appropriate immersion fluids.

All powders were dried in thin layers in a hot air oven at appropriate temperatures and were then stored over calcium chloride granules in desiccators.

Preparation of Powder Mixtures—Binary mixtures of lactose containing 0.25, 0.50, 1.0, 2.0, and 4.0% (w/w) of each of the three glidants were prepared by placing the weighed amounts of the powders together in a cylindrical jar and rotating the jar for 20 min to ensure adequate mixing. Similar binary mixtures were prepared to contain calcium hydrogen phosphate and glidant. After mixing, the powder systems were stored over calcium chloride granules in desiccators.

Angle of Repose Measurements—The angle of repose was determined using the funnel method (5). A funnel was positioned centrally over a shallow circular dish of known radius, r, and the powder system was poured evenly through the funnel until the circumference of the dish was touched by the heap of powder. The length of the side of the heap was measured using calipers, h, and the angle of repose, θ, was calculated from the expression $\cos \theta = h/r$. At least five measurements were recorded for the powders and powder mixtures.

Tensile Strength Measurements—The tensile tester was similar to that described by Ashton *et al.* (15); the cell was 9.5 cm (i.d.) and 1.0 cm deep. The mode of operation of the cell was described elsewhere (16), and tensile measurements of the two host powders and the powder–glidant mixtures were made at room temperature. The results for each system were subjected to least-squares regression analysis to enable the tensile strength of any system at a given bulk density to be predicted.

Annular Shear Cell Measurements—An annular-type shear cell was composed of a base, with an annular trough into which the powder was placed, and a close fitting lid containing 18 flights at 20° pitch, the depth of which determined the shear plane level in the powder bed. The inner and outer radii of the annular trough measured 5.6 and 7.6 cm, respectively.

Figure 1 shows a diagram of the cell with a powder sample ready for testing. The base, mounted on a turntable, was rotated at 1 revolution/hr, and the strain-gauge bar was restrained by pins, thus creating a torque in the bar. The developed torque was measured

from the output of four silicon semiconductor strain gauges[7] mounted on the bar to form a Wheatstone bridge circuit. Values of shear stress were estimated from the torque developed (17), since the strain gauges had been previously calibrated with known torques using a pulley system.

The bed was prepared by introducing powder in thin even layers into the annular trough in the base and then pressing lightly with an annular disk to ensure a level bed. The lid was then lowered onto the prepared bed, and a normal load was applied using the weight platform. The cell was then rotated with the strain bar restrained. Consolidation of the sample was achieved causing the sample to fail under a normal consolidating load until a steady state, as measured from the output of the strain gauges on a chart recorder, was observed. The lid was then returned manually to its original position, and the sample was sheared under a reduced normal load.

This procedure was repeated after consolidation using different normal loads to obtain a powder yield locus, *i.e.*, a graph of shear stress at failure *versus* normal stress for a given density condition. The failure stress under steady-state conditions for the consolidating normal load was taken to represent the end-point of the locus. Results were only used if the height of the bed did not differ by more than ±2% from the original value, and the bulk density of the sample was calculated from the weight and volume of the sample. Four yield loci were obtained for each powder system by using four different consolidating loads.

The annular-type shear cell has certain advantages over the cylindrical type (18) in that smaller quantities of powder are required (50–80 g) and measurements can be made in a much shorter time. However, the annular cell suffers from the fact that at any particular angular deflection, powder at the outer wall of the cell's annulus is strained more than that at the inner wall so there is a small variation in shear stress across the width of the sample. For this investigation, this effect was minimized by making the annular width small and by employing a low rate of shear (1 revolution/hr).

RESULTS AND DISCUSSION

The angle of repose is not a fundamental property of a powder, since the value obtained partly depends upon the technique of measurement (13). For a static heap of powder, the angle of repose has a limiting value. Particles in the surface layer of the heap exist in an equilibrium situation, with the gravitational force balanced by interparticular attractive and frictional forces. Any particle that lies above this layer will slide down the heap since the gravitational force will predominate (5).

Table II—Powder Flow Classification by Flow Factor (18)

Flow Factor	Powder Flow Classification
>10	Free flowing
4—10	Easy flowing
1.6—4	Cohesive
<1.6	Very cohesive

Representative results of angle of repose measurements are illustrated in Fig. 2 for the lactose–fine silica mixtures, and the graph shows a general decrease in the angle of repose with increasing glidant concentration. Significant scatter of results can be observed due to such factors as the nonuniformity of heap and the formation of a steep-sided peak at the end of the test resulting in a concave surface. Similar scatter of results was observed for the other host powder–glidant mixtures in the study. This type of angular test thus appears to be generally unsatisfactory for any accurate assessment of the flowability of cohesive powder–glidant mixtures.

Powder failure tests, however, provide an alternative approach. Of the several flowability parameters that can be derived from the results of failure tests, *e.g.*, cohesion (4), angle of internal friction (19), and index of flow (19, 20), it is essential to select the most relevant factor. Since the problems related to the gravity flow of cohesive powders, *e.g.*, flow from hoppers and flow into dies, reduce the efficiency of many pharmaceutical processes, for the present investigation the flow factor (F.F.) (18) was used to assess flowability. Increasing values of the flow factor indicate that a powder or powder mixture is becoming more free flowing under the effect of gravity (18) (Table II).

To obtain the flow factor from a powder yield locus, the tensile strength value was calculated at the bulk density of the locus (Fig. 3) and then data from each locus were analyzed by regression analysis, using the logarithmic form of the Warren Spring Laboratory yield locus equation (20):

$$\log \tau = K + \frac{1}{n} \log(\sigma + T) \qquad \text{(Eq. 1)}$$

$$K = \log \frac{C}{T^{1/n}} \qquad \text{(Eq. 2)}$$

where:

σ = normal stress (grams per square centimeter)
τ = shear stress at failure (grams per square centimeter)
C = cohesion (grams per square centimeter)
T = tensile strength (grams per square centimeter)
n = index of flow

Flow factors were then obtained using the locus equations by estimating f_c (unconfined yield stress) and σ_{max} (maximum normal stress) for each locus (18) (Fig. 3). These stresses are derived by drawing two Mohr semicircles tangential to the yield locus, one passing through the origin and intersecting the abscissa at f_c and the second passing through the end-point of the locus and giving σ_{max}. A computer program was written to carry out this analysis. The flow factor is then defined as the reciprocal of the slope of graphs of f_c *versus* σ_{max} for a number of loci obtained for an individual powder or mixture. In this present investigation, these graphs have a curvature, as illustrated in Fig. 4, and the flow factor

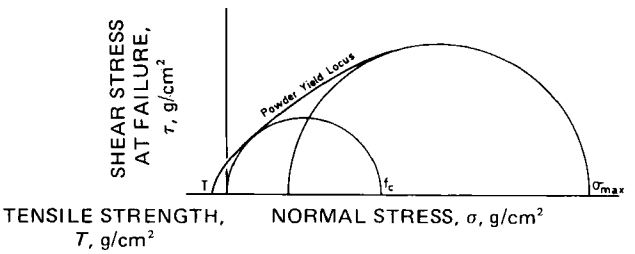

Figure 3—*Diagram illustrating the derivation of the unconfined yield stress,* f_c, *and maximum normal stress,* σ_{max}, *from a powder yield locus.*

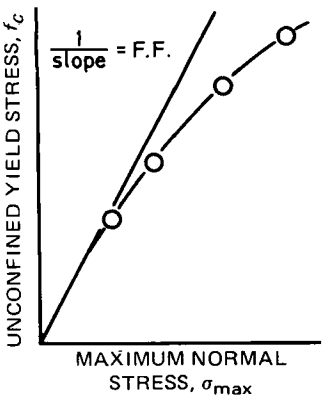

Figure 4—*Diagram illustrating the derivation of the flow factor (F.F.) from a graph of the unconfined yield stress,* f_c, versus *the maximum normal stress,* σ_{max}.

is determined as the reciprocal of the slope of the tangent to the graph at the origin (18).

Graphs of the flow factor *versus* the percentage (w/w) glidant in the mixtures with both lactose and calcium hydrogen phosphate are shown in Figs. 5, 6, and 7 for fine silica, magnesium stearate, and purified talc, respectively. The largest changes in the flow factor are produced by the addition of fine silica, with increases from 1.9 to 10.4 for lactose and from 3.9 to 10.5 for calcium hydrogen phosphate. Both increases represent a change in classification from cohesive to free flowing according to Table I. The optimum concentrations of fine silica, estimated from Fig. 5, were 0.85% (w/w) for lactose and 1.45% (w/w) for calcium hydrogen phosphate. Addition of further glidant to the host powder beyond these concentrations produced no additional increase in flow factor.

It has been proposed that the mechanism whereby fine silica operates to improve flowability is adherence to the surface of host powder particles (14). Approximate calculations of the concentration of glidant required to form an adsorbed layer one particle thick can be made, using the surface area measurement of the host powder and the average particle size of the glidant, assuming that the glidant particles are spherical and uniformly closely packed over the surface of the host powder. Such estimates are in close agreement with the optimum percentage concentration of fine silica as found by experiment (Table III), and this finding seems to support the proposed mechanism of action. If the fine silica particles were adsorbed onto host powder particles, a smoothing out of the host particle surfaces would take place, thus decreasing both friction and mechanical interlocking of particles during flow. In addition, the host–host interactions at particle contact points would be replaced by weaker glidant–glidant forces.

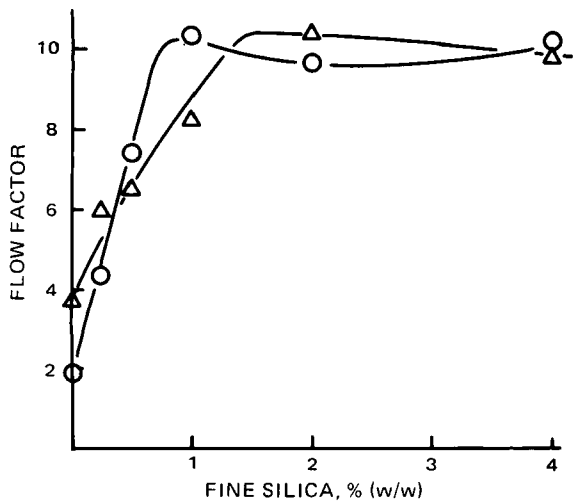

Figure 5—*Graphs of changes in the flow factor of host powder–fine silica mixtures at different concentrations of fine silica. Key:* ○, *lactose–fine silica mixtures; and* △, *calcium hydrogen phosphate–fine silica mixtures.*

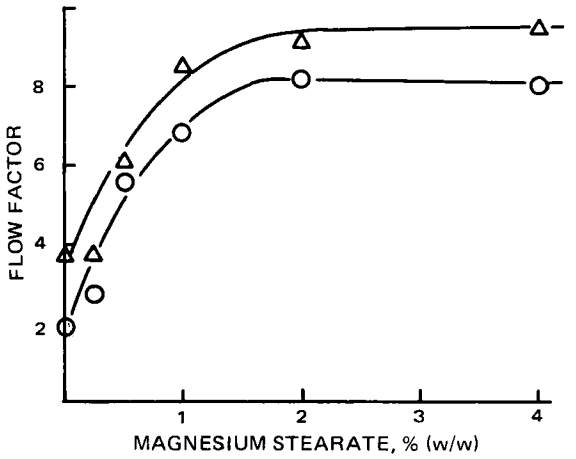

Figure 6—*Graphs of changes in the flow factor of host powder–magnesium stearate mixtures at different concentrations of magnesium stearate. Key:* ○, *lactose–magnesium stearate mixtures; and* △, *calcium hydrogen phosphate–magnesium stearate mixtures.*

Table III—Optimum Glidant Concentrations

	Optimum Glidant Concentration, % (w/w)			
	Fine Silica		Magnesium Stearate,	Purified
Host Powder	Experimental	Theoretical	Experimental	Talc, Experimental
α-Lactose	0.85	0.96	1.75	2.25
Calcium hydrogen phosphate	1.45	1.38	2.20	2.45

Magnesium stearate and purified talc do not produce such large increases in the flow factor as does the fine silica (Figs. 6 and 7), although the former glidant does improve the flowability of both lactose and calcium hydrogen phosphate from cohesive to easy flowing (Table II). In all cases, an optimum percentage glidant concentration can be estimated (Table III). Magnesium stearate, unlike fine silica, is hydrophobic and appears to function as a glidant by accumulating in voids between hydrophilic host particles (14), thereby reducing interparticular friction and attractive forces between host particles. To achieve a significant improvement in the flowability of cohesive powders, a larger percentage of magnesium stearate is required compared with fine silica, since the optimum concentrations of magnesium stearate are 1.75% (w/w) for lactose and 2.20% (w/w) for calcium hydrogen phosphate.

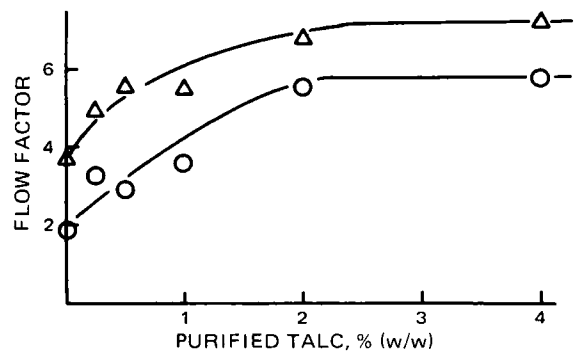

Figure 7—*Graphs of changes in the flow factor of host powder–purified talc mixtures at different concentrations of purified talc. Key:* ○, *lactose–purified talc mixtures; and* △, *calcium hydrogen phosphate–purified talc mixtures.*

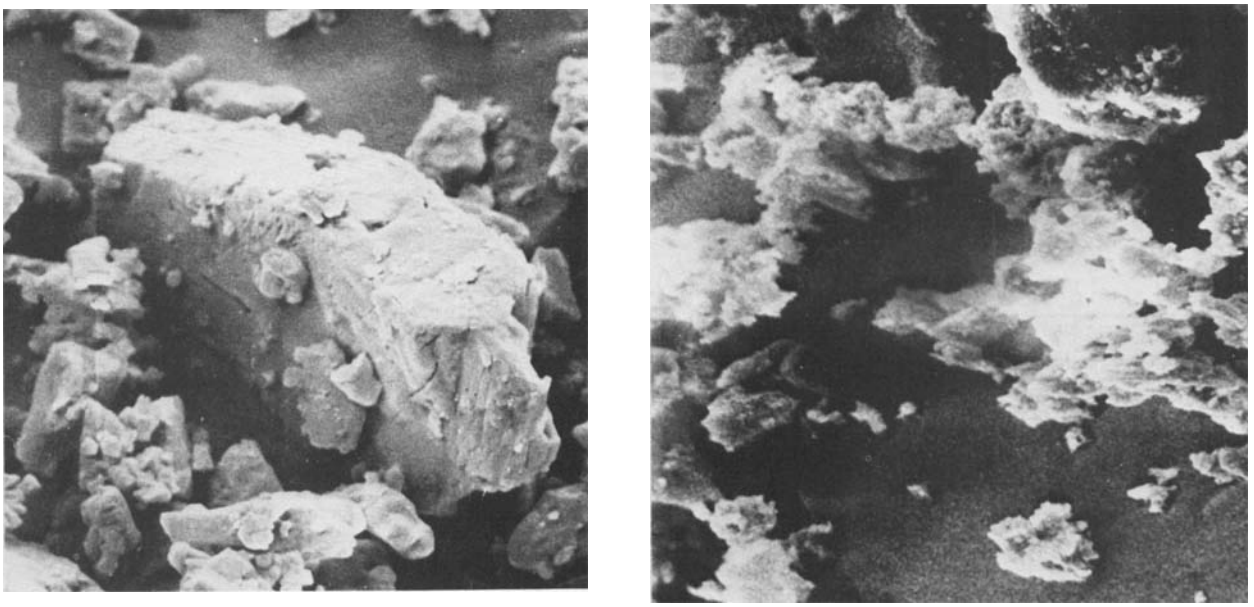

A B

Figure 8—*Electron scanning microscope photographs of host powder particles. Key: A, α-lactose (about 6500×); and B, calcium hydrogen phosphate (about 3250×).*

Figure 7 indicates that purified talc is the least effective of the three glidants studied, both in terms of the increase in the flow factor and in requiring the largest concentrations to achieve maximum improvement in flowability. Indeed, the increases in the flow factor do not appear to be sufficient to impart free-flowing properties to either of the host powders.

A possible mode of action for purified talc has been proposed in terms of its laminar crystalline structure which, when subjected to the low shearing forces created when powders flow, rolls up into a spherical structure (21). The presence of such spheres would then improve the flowability of the host powder.

The differences in optimum percentage concentration obtained for the three glidants with both host powders can be attributed to differences in the mechanism of action of the glidants, the physical and chemical nature of the materials, and the relative particle sizes of the host and glidant particles. Indeed, it is conceivable that if purified talc had an average particle size similar to that of the fine silica, it might also function by adsorbing to form a monoparticular layer over the host powder, thereby improving its efficiency as a glidant.

Higher values of optimum glidant concentration were derived for calcium hydrogen phosphate than for lactose with all three glidants studied. This finding can be explained not only by the larger surface area per gram of the calcium hydrogen phosphate but also by the different surface structure of the two powders (Fig. 8).

Electron scanning microscope photographs reveal that the lactose particles have a relatively smooth and angular structure, while calcium hydrogen phosphate particles possess a more convoluted and rougher surface. Thus, calcium hydrogen phosphate would be expected to require the presence of relatively more glidant particles to improve its flowability.

From this discussion, it is evident that powder failure testing equipment can be successfully used to assess the efficiency of glidants in improving the flowability of cohesive powders and also to select optimum glidant concentrations. This kind of equipment could be usefully employed in pharmaceutical formulation in cases where cohesive powders and mixtures cause powder flow problems.

SUMMARY

1. The angle of repose test was unsuitable for assessing the flowability of cohesive lactose and calcium hydrogen phosphate powders and their mixtures with glidants.

2. Powder failure testing equipment, *i.e.*, annular shear cell and tensile tester, were successfully employed to study the effects of three glidants (fine silica, magnesium stearate, and purified talc) on the flowability of cohesive lactose and calcium hydrogen phosphate powders. Flowability was assessed using the flow factor parameter.

3. For both host powders, the order of efficiency in increasing the flow factor was in the order fine silica > magnesium stearate > purified talc.

4. In all systems, optimum glidant concentrations were observed. For the same glidant, these values were higher for calcium hydrogen phosphate than for lactose; this finding is attributed to differences in the surface area and structure of the two powders.

Rapid, Sensitive Colorimetric Method for Determination of Ethinyl Estradiol

MOHAMED A. ELDAWY ˣ, A. S. TAWFIK*, and S. R. ELSHABOURI

Abstract □ A colorimetric procedure, based on the formation of an azo dye by condensation of diazotized 5-chloro-2,4-dinitroaniline with ethinyl estradiol, was developed. An alkaline solution of ethinyl estradiol is reacted with the reagent, and the resulting color is measured at 450 nm. Absorbance *versus* concentration is linear up to 10 μg/ml; the lower limit of detection is 1 μg/ml under the conditions studied. Replicate analysis showed good agreement, and an average recovery of 99.6 ± 0.3% was obtained for analyses of synthetic mixtures. Vitamins and minerals likely to be present along with ethinyl estradiol in certain geriatric formulations, as well as ordinary tablet excipients and coating materials, do not interfere with the precision of the method or development of the color. The method is applicable to progestin–estrogen preparations. Assay results on various single-component as well as contraceptive commercial samples are reported.

Keyphrases □ Ethinyl estradiol in progestin–estrogen and vitamin/mineral geriatric preparations—colorimetric analysis □ Progestin–estrogen contraceptive tablets—colorimetric analysis of ethinyl estradiol □ Geriatric formulations containing vitamins, minerals, and estrogens—colorimetric analysis of ethinyl estradiol □ Colorimetry—analysis, ethinyl estradiol in progestin–estrogen and vitamin/mineral geriatric preparations

Several methods for the analysis of ethinyl estradiol are available in the literature, including UV (1), GLC after suitable derivatization (2, 3), and colorimetric methods (4–8). The USP XVIII colorimetric procedure (9), which is a modification of the Kober reaction (4), suffers from several disadvantages exhibited by the rather limited solubility of ethinyl estradiol in isooctane. These disadvantages might be circumvented by using an isooctane–chloroform mixture instead as modified in the first supplement to USP XVIII. The Kober reaction, in spite of many modifications (10–12), is time consuming, and the color development is critically dependent upon reagent composition, reaction time, and temperature. Interference by other nonphenolic steroids also can occur (13).

The suitability of diazotized 4-amino-6-chloro-*m*-benzenedisulfonamide for the determination of a number of estrogens has been investigated (14). The method, although suitable for routine analysis, has rather low sensitivity. The lower limit of detection is 0.05 mg of estrogen/ml of sample solution. Commercially available dosage forms, especially geriatric formulations, are usually of very low dosage (0.008–0.05 mg/tablet or capsule). Consequently, the sensitivity of this procedure is such that single-tablet analysis of most commercial dosage forms is not feasible.

In spite of its high sensitivity, the Liebermann–Burchard reaction-based fluorometric method of James (15), with 0.5 μg/ml as a lower limit for detection, is not applicable to progestin–estrogen preparations. Progestational steroids produce a color in the Liebermann–Burchard reaction that quenches the fluorescence of ethinyl estradiol.

It has been observed in these laboratories that diazotized 5-chloro-2,4-dinitroaniline couples with phenolic compounds to form products with extremely stable colors; this finding offers the basis for a rapid and sensitive method for the determination of pharmaceuticals containing a phenolic hydroxy group (16). The suitability of this reagent for the determination of ethinyl estradiol was investigated, and a rapid and sensitive colorimetric method for the determination of ethinyl estradiol was developed. This method eliminates the disadvantages of the Urbanyi and James methods, as well as those of the Kober reaction.

EXPERIMENTAL[1]

5-Chloro-2,4-dinitroaniline—This compound was prepared by a reported procedure (17). Several crystallizations from ethanol yielded an analytical sample, mp 174°.

Reagents and Solutions—The following were used: 5-chloro-2,4-dinitroaniline (0.2% ethanolic solution), sodium nitrite (3% aqueous solution), 1 *N* hydrochloric acid, 2 *N* sodium acetate, 0.1 and 1 *N* sodium hydroxide, and absolute ethanol.

It has been observed in these laboratories that diazotized 5-chloro-2,4-dinitroaniline couples with phenolic compounds to form products with extremely stable colors; this finding offers the basis for a rapid and sensitive method for the determination of pharmaceuticals containing a phenolic hydroxy group (16). The suitability of this reagent for the determination of ethinyl estradiol was investigated, and a rapid and sensitive colorimetric method for the determination of ethinyl estradiol was developed. This method eliminates the disadvantages of the Urbanyi and James methods, as well as those of the Kober reaction.

EXPERIMENTAL[1]

5-Chloro-2,4-dinitroaniline—This compound was prepared by a reported procedure (17). Several crystallizations from ethanol yielded an analytical sample, mp 174°.

Reagents and Solutions—The following were used: 5-chloro-2,4-dinitroaniline (0.2% ethanolic solution), sodium nitrite (3% aqueous solution), 1 *N* hydrochloric acid, 2 *N* sodium acetate, 0.1 and 1 *N* sodium hydroxide, and absolute ethanol.

[1] A Hungarian-made Spektromom 203 spectrophotometer was used.

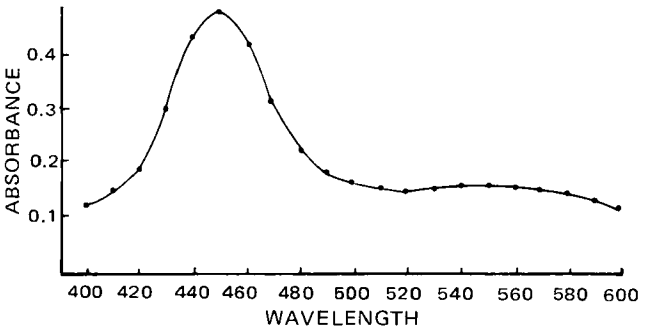

Figure 1—*Absorption spectrum of ethinyl estradiol with diazotized 5-chloro-2,4-dinitroaniline.*

Standard Ethinyl Estradiol Solution—Weigh accurately about 20 mg of ethinyl estradiol USP into a 10-ml volumetric flask and dissolve in ethanol. Dilute to volume with ethanol and then dilute 1 ml of this solution to 10 ml with 0.1 *N* sodium hydroxide. Pipet appropriate volumes so as to give solutions containing 1–10 μg/ml after color development.

Preparation of Assay Solutions—Extract an accurately weighed sample of the powdered synthetic mixture or tablets equivalent to about 0.5 mg of ethinyl estradiol with three 5-ml portions of ethanol. Centrifuge each portion, filter the ethanol extracts into a small beaker, and evaporate the ethanol to dryness. Transfer the contents of the beaker quantitatively with 0.1 *N* sodium hydroxide to a 10-ml volumetric flask and dilute to volume with additional 0.1 *N* sodium hydroxide. This solution is the assay solution.

For Contraceptive Tablets—Prepare as directed for the assay solutions. Transfer the contents of the beaker quantitatively with 0.1 *N* sodium hydroxide to a 10-ml volumetric flask, shake vigorously, transfer to a centrifuge tube, and centrifuge for 10 min. The clear solution is the assay solution for contraceptive tablets.

For Geriatric Formulations Containing Ethinyl Estradiol—Extract an accurately weighed sample of the powdered synthetic mixture equivalent to about 0.5 mg of ethinyl estradiol three times each with 5 ml of alcohol-free chloroform (18), centrifuge for 10 min, collect the extracts in a small beaker, and evaporate to dryness. Transfer the contents of the beaker quantitatively with 0.1 *N* sodium hydroxide to a 10-ml volumetric flask, and dilute to volume with additional 0.1 *N* sodium hydroxide. This solution is the assay solution.

Color Development—Into separate 10-ml volumetric flasks, pipet successively 1.0 ml each of 5-chloro-2,4-dinitroaniline, sodium nitrite, and hydrochloric acid solutions and mix well. Allow to stand for 2 min and add 1 ml of ethanol and 1 ml of standard solution, 1 ml of the assay solution, or 1 ml of 0.1 *N* sodium hydroxide solution to separate flasks. Add 2.0 ml of sodium acetate solution to each flask, and allow to stand for 20 min. Dilute each flask to volume with 1 *N* sodium hydroxide. Allow to stand for 30 min and determine the absorbance of the standard and sample solution at 450 nm in 1-cm cells against the blank using a suitable spectrophotometer.

RESULTS AND DISCUSSION

Initial investigations using lower concentrations of sodium nitrite solution resulted in inconsistent and nonreproducible spectral intensities for standard solutions. Accordingly, a study of the effect of sodium nitrite concentration on diazotization of 5-chloro-2,4-dinitroaniline and subsequent coupling with ethinyl estradiol was carried out using 1, 2, 3, 4, and 5% sodium nitrite solution. Use of the 3% sodium nitrite solution gave the highest color intensity. Destruction of the excess nitrous acid was not necessary since no interference in the subsequent color development and measurement was observed.

The normality of the sodium hydroxide used affected both the development of the color and the reproducibility of the method. Higher concentration of alkali resulted in lower absorption intensities. The most intense and reproducible absorption was obtained when ethinyl estradiol was dissolved in 0.1 *N* sodium hydroxide, coupled, and diluted to volume with 1 *N* sodium hydroxide.

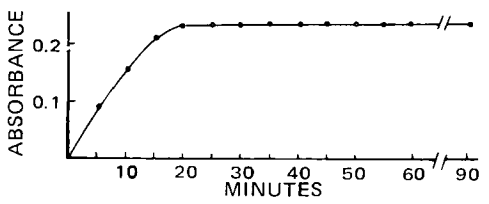

Figure 2—*Effect of coupling time on the absorbance of the final solution.*

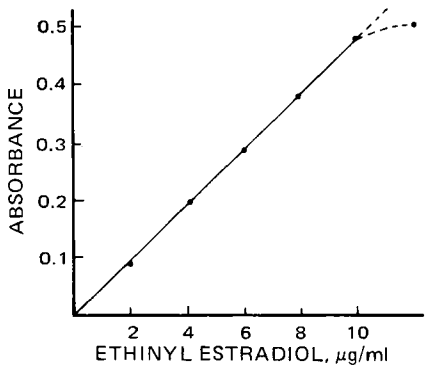

Figure 3—*Standard calibration curve for ethinyl estradiol with diazotized 5-chloro-2,4-dinitroaniline.*

The addition of 1 ml of ethanol to the diazotized solution of 5-chloro-2,4-dinitroaniline was necessary to avoid the turbidity observed in the absence of ethanol. The alcohol probably helps keep the coupling product in solution.

The absorption spectrum of the alkaline solution of the coupled product, resulting from the reaction of ethinyl estradiol with diazotized 5-chloro-2,4-dinitroaniline, is shown in Fig. 1 (absorption maximum at 450 nm). The molar absorptivity as calculated from the curve is 11.284×10^3.

The effect of coupling time under these conditions, after the addition of the alkali, on the absorbance of the final solution at 450 nm is shown in Fig. 2. Color intensity increased during the first 20 min and remained constant for at least 90 min.

The relationship between absorbance at 450 nm and concentration was linear up to 10 μg of ethinyl estradiol/ml of sample solution (Fig. 3).

The specificity of the method for ethinyl estradiol in the presence of several frequently encountered excipients is shown in Table I. A placebo was prepared containing some common tablet excipients (*e.g.*, lactose and starch); several different weights of the excipients, each approximating the sample weight of commercial tablets, were spiked with a known amount of ethinyl estradiol and the assay was performed. The average recovery was 100 ± 0.20%.

Multiple analyses were performed on different commercial samples of varying potencies. Agreement between replicate analyses was good, and all samples assayed 99.6% or better (Table II).

The method presented here is applicable to progestin–estrogen preparations. Synthetic mixtures, in which the ratio of the progestin norethindrone acetate to ethinyl estradiol was that of the average found in commercial formulations, as well as commercial coated contraceptive tablets containing this progestin along with ethinyl estradiol were satisfactorily analyzed by this method. Percentage recoveries were 99.86 ± 0.06%.

Other phenols will, of course, interfere in the determination of ethinyl estradiol by this method, as they would in the Kober reaction and the Urbanyi method. Although such interferences would not normally be expected, interference due to pyridoxine hydrochloride, which possesses a similar phenolic hydroxy group, was encountered. This problem was circumvented by extraction of ethinyl estradiol with alcohol-free chloroform in which pyridoxine hydrochloride is almost insoluble (19). Ascorbic acid does interfere with the development of the color and this interference is removed by the same method. Accordingly synthetic mixtures containing the minerals and vitamins shown in Table I, which are likely to be

Sample Type	Ethinyl Estradiol Declared, mg	Amount Found, mg/Tablet[a]	Recovery, %
Single component	0.050	0.0496	99.6 ± 0.4
Contraceptive	0.050	0.0499	99.96 ± 0.06

[a] Average of four determinations.

present along with ethinyl estradiol in certain geriatric formulations (20), were satisfactorily analyzed by this method. The amounts chosen were the averages found in commercial preparations (20).

The sensitivity of the method is such that single-tablet analysis, even at the lowest dosage, is feasible; this sensitivity is an improvement over the diazotized 4-amino-6-chloro-*m*-benzenedisulfonamide method (14). Another advantage is the applicability of the method to progestin–estrogen combinations, which is an improvement over the fluorometric method (15).

These improvements make this method more suitable for the determination of ethinyl estradiol and related estrogens in biological fluids, as well as for the determination of other compounds of pharmaceutical interest containing a hydroxy group (to be discussed in a future report).

Microbiological Diffusion Assay II: Design and Applications

F. KAVANAGH

Abstract □ Application of new equipment and new techniques was made to antibiotic diffusion assays. Accumulation of data and computation of potencies were made by an on-line computer. The system was tested by assaying cephalexin with the aid of *Bacillus subtilis* in an FDA single-dose design modified by reducing the number of standards to two. The influence of the thickness of the base layer and the form of the dose–response line were tested. Zone diameter was measured with a resolution of 0.01 mm. The potency of samples was measured with an error usually less than 3%. An error of 0.1 mm in measuring zone size would cause an error of 3% of potency. The usual calibration line was inadequate for extrapolation beyond a twofold range. A dose–response line derived from the Cooper equation was better for standard curves spanning more than a twofold range of concentrations. Precision was better on the plates with the 20-ml base layer. The two-dose method of assaying gave larger errors than the single-dose method. Large variances in measuring zone diameters are a reason for the low precision of diffusion assays and set an inherent limit on precision.

Keyphrases □ Antibiotics—microbiological diffusion assay, design and application □ Microbiology—diffusion assay of antibiotics, design and application □ Diffusion assay—microbiological assay of antibiotics, design and application

Most petri dish diffusion assays done in the United States for quantitation of antibiotics are variants of two Food and Drug Administration (FDA) designs. One is the Knudsen and Randall (1) two-dose assay, and the other is the alternate or single-dose method. The latter is usually thought of as the FDA method (2).

In the single-dose design, the calibration line is assumed to be straight. Sample responses are assumed to fall on a line parallel to the standard curve. Responses of samples and references are assumed to be influenced equally by factors, known and unknown, that affect zone size. If these assumptions are true, then sample responses can be corrected for the several factors, other than concentration of drug, causing plate-to-plate variations in zone size. As shown previously (3), the FDA correction is a good first approximation to complete correction for such variations.

During the last 25 years, the single-dose method has undergone evolution with respect to the spacing of concentrations of the standards but other details have not changed. For example, the 1949 (4) method for penicillin and streptomycin had 10 standards closely spaced on a linear scale covering a 2.5-fold range. The same concentrations were given by Grove and Randall (5). The number of concentrations was later reduced to five, with the middle one used as reference and spaced on a logarithmic scale to facilitate computation of the "best" straight line (6, 7).

Thus the method had assumed its present form by 1957. The number of concentrations of standards and their spacing were selected more for mathematical convenience than for analytical necessity. The full range of the tests was either 2.44- or fourfold. The best straight line was computed through the points by calculating the low point and the high point of the line by means of an unweighted least-squares procedure.

The practice of using many closely spaced points to determine a straight line originated when location of a point on the standard curve was uncertain and shape of the dose–response line had no theoretical basis. A line determined by a number of points was considered more precisely located than one established by only the end-points. Now that the theory of the method has been established and the precision of assays can be much higher than it once was, the intermediate points are redundant. Since the calibration line is straight by definition, any point on it (*e.g.*, either end concentration) could be used as the reference.

Three plates, each holding three zones of each of two concentrations of standards, are sufficient to establish the standard curve, thus reducing the method to the minimum. Such an assay was designed and applied to samples of known concentration. Limits to the precision of the assay were ascertained during the work. To do so required the determination of the precision of measuring zone size and the influence of the form of the dose–response line upon accuracy and precision. Concepts (3) described earlier were applied to these assays to minimize influence of operations upon accuracy and precision. Some data were used to investigate the two-dose method (1).

EXPERIMENTAL

Equipment and Operations—As shown previously (3), variations in agar thickness had only a second-order influence upon zone size attributable to thickness but a first-order influence caused by effective change in the concentration of bacteria of two layer plates. Variations in agar thickness were reduced by employing automatic pipetting equipment and placing the petri dishes containing molten agar on a level surface to cool. A flat slate slab installed on a bench top and carefully leveled with the aid of a machinist's level provided the level surface.

Plastic dishes were placed on the slab, and molten agar was added from an automatic pipetting machine at the rate of 60 or more/min. Both double- and single-layer plates were prepared; when a second layer was added, it was put on the first layer without moving the plates from the slab. Single-layer plates were preferred, but the type of plates that gave the more sharply defined zone edge was used.

The poured plates were not refrigerated because using plates of different temperatures can affect zone size (8) and increase variances.

Most cylinders used in the United States are made of stainless steel. The ends of the cylinders may be flat, finished with a radius, or have an inside bevel. Cylinders of the same type of end were used because the effective inside diameters are not the same for flat, rounded, or beveled ends. Cylinders must not leak due to either rough ends or rough handling of plates.

The cylinders were added by means of a semiautomatic dropper to a group of plates. Filling was by means of an automatic pipet delivering 0.2 ml of sample. The disposable tips of the pipets were changed between samples. One advantage of the automatic pipet was the impossibility of filling the cylinders to overflowing.

The effect of differences in heating rates upon assays was considered earlier (3). As Cooper and Linton (9) showed, the plates in the center of a stack of five heated much slower than those at the ends. A special incubator was designed to receive plates in a single layer and to incubate them at uniform temperature, thus avoiding the problems caused by incubating plates in a stack. The prototype incubator was constructed from chill-plates through which water circulated from a constant-temperature bath at 20 liters/min through the three shelves connected in series. The walls of the incubator were constructed from 5.1-cm (2-in.) thick, rigid, polystyrene foam insulation. Later, larger electrically heated versions were made and had six shelves measuring 41 cm (16 in.) deep × 86.3 cm (34 in.) long spaced 5.1 cm (2 in.) apart. Each shelf had its own thermoregulator and door and was a closed chamber isolated from all others.

The incubator shelves were so close together that the petri dishes could not be put on them individually. A holder designed for a different system (10) proved ideal. Each holder held three dishes. When the holder was placed on the shelf, each dish had the same air space between its bottom and the shelf as all others. Heat transfer, the same for all, was limited by transfer through the air film.

Zone diameters were measured with a modified antibiotic zone reader (11). Resolution of the measuring system was about 0.01 mm when recorded by computer. Four calibration lines were used. Equation 1 was used as a short-range interpolation formula following FDA practice, as a point-to-point line through an eightfold range of concentrations of standard, and as a best straight line through the same four points:

$$\log C = A + Bd \qquad \text{(Eq. 1)}$$

The fourth line was derived from the Cooper equation (12) as:

$$\log C = E + FX^2 \qquad \text{(Eq. 2)}$$

where X, the distance diffused, was computed from $X = \frac{1}{2}(d - 5.8)$. In this work, d was the zone diameter in millimeters, and 5.8 mm was the inside diameter of the cylinders.

The operational elements of the assay—plate pouring, cylinder dropping, cylinder filling, and incubation—were integrated into one system by using the concept of a work station. The operator sits at the work station, drops the cylinders, fills the cups of three plates in a carrier, covers the plates, inserts the carrier into the incubator, and proceeds to the next carrier. The 18 cylinders of a carrier can be filled in 1 min, a time too short to have much effect by reason of the different prediffusion times. Each shelf has space for seven carriers or a total of 21 plates.

If the modified FDA single-dose design is used, one carrier suffices for standards and the remaining six carriers on a shelf are for six samples.

Design of Assays—As already described, the assay is a slight modification of the single-dose method of FDA (7). One carrier of three plates holds the standards, which have the same number of responses per concentration as in the FDA design. The mean of the high standard and the mean of the low standard determine the calibration line. The higher concentration is the reference standard. There are three plates (one carrier) for each sample. One-half of the zones are reference and one-half are sample. The sample is diluted to fall between the two standards.

The reference concentration in these procedures as in that of FDA is one of the standards. This need not be so. The only restriction placed upon the reference is that it be the same on all plates. The reference concentration could be unknown. It is made one of the standards solely in the interest of efficiency. The reference is used to correct for certain variations in operations; it cannot correct for blunders, bad diluting, or misreading of zone sizes.

On the sample plates, the mean of the nine sample zones is corrected for deviation of the mean of the nine reference zones on the sample plates from the mean reference (high standard) on the standard plates. The corrected sample zone is used to interpolate its potency from the standard curve. Interpolation may be done

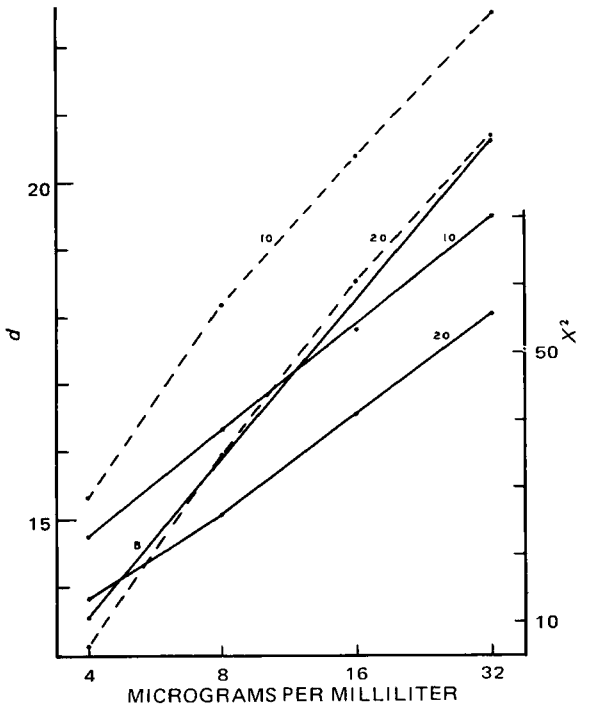

Figure 1—*Two forms of dose–response lines of a cephalexin*–B. subtilis *assay. The dashed lines are for* d versus *log* C, *and the continuous lines are for* X^2 versus *log* C, *where* d *is the zone diameter in millimeters and* X^2 *is the square of the distance diffused computed from* $X^2 = \frac{1}{4}(d - 5.8)^2$. *The numbers on the lines refer to volumes of the base layers. The straight line labeled B is the best straight line through the points for the 20-ml base layer as in the FDA method.*

manually or by computer. Only mean values are used in the calculations, and only one answer is obtained from the nine responses of a sample.

The zone sizes of the standards are not subjected to an FDA correction because none is required. The low concentration of the standard could be corrected for the plate difference between the plate high standard and the mean reference (high standard). The result would be the same as the mean of the nine responses of the low standard.

Application of the concepts and designs discussed in this and the previous paper (3) was made to an assay for cephalexin by a cylinder-plate method, employing *Bacillus subtilis* (ATCC 6633) as the test organism. This assay was selected because the antibiotic was stable and the zone edges were sharp. Zone sizes were accumulated and processed by an on-line computer system. Diameters are reported to 0.01 mm in the tables.

Two base layers (10 and 20 ml) were used with 5 ml of top layer. The plates were poured from the same bottle of molten agar, had the top layers poured from the same bottle of inoculated agar, and received the same solutions. All work was done by one person. Two extended standard curves were prepared at the same time from the same bottles of agar.

The precision of the measurement of zone sizes was obtained by having the same operator measure the same set of plates a second time. One person produced the data in Table I, and another produced the data in Table II.

RESULTS AND DISCUSSION

Single-Dose Assays—Results of the measurement of zone diameters are given in Tables I and II. Table I contains data for an eightfold standard line obtained on plates with either a 10- or 20-ml base layer. Data for the replicate measurements of the standard curve for the single-dose method of assay are given in Table II for the two base layers.

Several conclusions can be drawn from the data. Means of the two sets of measurements of zone diameters differed by 0.1 mm or less; one set of mean diameters is as good as the other. One-half of the comparisons differed by 0.06 mm or less. Only three differences, or one-twentieth of the total, were as great as 0.1 mm, which is the resolution of the manual zone reader when it is fitted with a millimeter scale. These results, as well as many others, indicate that measuring zone diameters with a resolution of 0.01 mm can give useful information. Precision of measurement was somewhat greater for zones formed on a 20-ml base layer.

The zone edge of *B. subtilis* inhibited by cephalexin was sharp enough for most measurements of diameter to be replicated within 0.08 mm or within 2% of potency. Most assay systems are less precise.

The standard deviations in Tables I and II include variances in actual zone diameters as well as measuring errors. One zone of 8-μg/ml concentration on Plate 3 of the 10-ml base layer was responsible for the rather large standard deviation. Zone diameters were more variable on plates with the 20-ml base layers.

Standard lines representing the data in Table I are plotted in Fig. 1 in three ways:

1. As zone diameter (*d*) *versus* logarithm of concentration (usual way for FDA type of assays).
2. As $\frac{1}{4}(d - 5.8)^2$ *versus* logarithm of concentration.
3. As the best straight line through the points obtained on the plates with the 20-ml base layers.

The second relationship was derived from the Cooper equation (12), assuming the inside diameter of the cup (5.8 mm) to be equivalent to a hole of that size. If the Cooper equation is a valid representation of the facts, the first set of lines should curve toward the concentration axis and the second set should be straight. Figure 1 shows that the Cooper expression is followed by the cephalexin–*B. subtilis* assay from 4 to 32 μg/ml. A low concentration of 6–7 μg/ml would give better zone edges than 4 μg/ml gave on the plates with 20 ml of base layer and would straighten the line.

The lines in Fig. 1 show quite clearly that for high accuracy assays, the usual dose–response relationship (Eq. 1) would add a small error for a narrow (twofold) range assay and a larger error to a wider range assay because the line is curved and not straight as assumed.

An assay for potency of three samples is given in Table III. Standards are at the top of the table. The six zones for one plate are on one line. The relative standard deviation (*RSD*) of zone sizes is reported as percentage. The values of *RSD* are not used in any computation and are given solely as a measure of quality of the work. A large *RSD* should alert the analyst to a problem. The computer program interpolated potencies of the unknowns from a line of the form *d versus* log *C*. The samples were the 8-μg/ml standard and two concentrations approximately 10% above and below it. These latter samples bracket the concentrations of most samples analyzed by a quality control laboratory.

A notable feature of the assays reported in Table III is the plate-to-plate uniformity of adjusted mean responses. The worst was the second plate of Sample 5. Its adjusted mean was 18.11 mm, which indicated a potency of 7.640 instead of the expected 8.00. Thus, the worst plate gave an error of −4.5%. Most mean plate deviations from the true values were less than 2% of potency.

Results of the assays are given in Table IV. The maximum error was +3%. Such an error would be caused by a 0.1-mm error in mean zone size. The difference between the 8-μg/ml standard used as samples and the values found could be caused by an error of 0.025 mm in the mean of the zone diameters. Better agreement is not to be expected because 0.02–0.03 mm is about the size of the difference in means between two sets of measurements of the same set of zones.

The resolution of the zone measurements was 0.01 mm, which was equivalent to 0.022 μg/ml at 8 μg/ml, or 1 part in 400 of concentration, or 1 part in 1800 of diameter, or 1 part in 600 of distance diffused. Therefore, rounding the potencies to three digits (Table IV) introduced little error even in the high accuracy assays reported here. Such rounding should be done in assays to avoid the appearance of unreal and unrealizable accuracy.

The results in Table IV indicate accuracy to be substantially independent of thickness of the base layer in the range from 10 to 20 ml. Extrapolation by less than 10% did not degrade accuracy greatly. However, the lines in Fig. 1 show that the usual extrapolation (Eq. 1) beyond the 8-μg/ml point with the slope determined by the 4–8-μg/ml region will cause error in potency. These errors come

from use of inappropriate standard lines and are not inherent in the assay.

Potencies of the 8.70-μg/ml samples were also obtained from lines drawn point to point to include the 4–16-μg/ml region of the standard curve.

The rationale for correcting the FDA and Cooper types of lines for plate-to-plate variations is fundamentally different. The FDA correction assumes slope of lines of standards and sample to be identical (intercept changes). This is the same as saying that the value of A in Eq. 1 may not be the same for all plates whereas B is the same.

According to the Cooper equation, factors (not concentration of antibiotic) causing first-order changes in zone size do so by affecting the slope of the line (intercept constant). Thus, in Eq. 2, F is affected by operational and environmental variations. In reality, B of Eq. 1 is also affected by the same factors. When using Eq. 2 to correct for operational variances (Table IV), the value of E is computed from the responses of the standard curve. The value of F is computed from the mean of the responses of the reference on the set of three plates in question and then the equation is used to interpolate values of sample concentrations. A different value of F is computed for each set of three plates. Results of these interpolations are given in Table IV for the 8.7-μg/ml sample.

If the extrapolated portion of the calibration line is to be used without degrading accuracy, the slopes of the lines above or below the adjacent standard must be the same. This restriction, when ap-

Table IV—Assay of Samples of Known Concentrations (Data from Table III)

[a] Interpolated from a three-point calibration line drawn point to point; same data as on line above. [b] Obtained from extrapolated standard curve for the 4–8-μg/ml region. [c] Line computed for the 8–16-μg/ml region; same data as for line above.

Table V—Two-Dose Assays of 8-μg/ml Standard

Agar Layer	Sample Number	Potency, μg/ml	*SD*	Error	Error, %
10 ml	1	8.274	0.34	+0.274	+3.43
	2	7.615	0.37	−0.385	−4.81
20 ml	1	7.851	0.11	−0.149	−1.86
	2	7.819	0.12	−0.181	−2.26

plied to the examples, requires that the lower standard be 4 μg/ml for plates with 10 ml of base layer and 8 μg/ml for 20-ml base layer plates and that Eq. 2 be used. If Eq. 1 is the interpolation formula, then the standard curve should be drawn point to point. The worst possible line is the best straight line through four or five widely spaced points (B in Fig. 1).

In diffusion assaying where at least four types of calibration lines are used, compensation of errors may occur through the use of an incorrect line. Therefore, agreement with an expected answer is not proof of correctness. The answer must also be obtained by procedures free from obvious technical errors.

The results in Table IV show that extrapolation can lead to significant errors because of changes in slope of the calibration line. Equation 2 probably is better than Eq. 1 as an interpolation formula and requires no more work when a computer is available. For assays done without special precautions and a computer, the FDA procedure is adequate. The data also show that potency of the sample should fall between the ends of the standard line and that the span of the line should, as a general rule, be restricted to twofold when the FDA method is used.

Previous theoretical treatment (3) showed that the unique feature of the FDA single-dose design, the method for correcting for plate-to-plate variations, gives a good first approximation to reality and is essential to high accuracy assays (Table IV).

Although errors of several percentages caused by manual interpolation of potencies from graphed calibration lines were avoided by having the computer make the interpolations mathematically, a further advantage was the practical one of removing restrictions upon the form of the calibration line. Although interpolation from the *d versus* log *C* plot on semilogarithmic paper is more conveniently done manually than from a plot of X^2 *versus* log *C*, this is not true for the computer.

The data in Tables I and II were subjected to an analysis of variance. Sources of variation were considered to be dose, plate, thickness of base layer, and measurement of zone size. The first three sources were significant ($p < 0.0005$); no interaction terms were significant. The first must be significant in order to have a test. A significant plate-to-plate variation indicates the necessity for correcting the variation in high accuracy assays. Significant variation caused by different thicknesses of agar layer was expected. The standard deviation of measurement was 0.05 mm. There was no difference in operators. Although the plate-to-plate differences in zone sizes were small, the analysis of variance found them to be significant because of the high resolution and consistency of the measurements.

The accuracy of diffusion methods is severely limited by several factors about which little, if anything, can be done. Among these is the inability of the operator to determine reliably the edge of the zone to better than 0.02 mm, even with a very favorable system. If the uncertainty in measuring zone size is independent of zone size, the percentage of uncertainty in the potency estimate is independent of potency and decreases as the slope of the calibration line increases.

Equation 2, not Eq. 1, is the dose–response line. Equation 1 is only a convenient empirical calibration line for short-range assays. The low precision of measuring distance diffused limits the accuracy of diffusion assays. Zone edges of certain essential assay systems never are sharp. Add to these the generally poor control over operations and accuracy becomes considerably poorer than that obtained here.

Diffusion assays are particularly susceptible to technique. Careless, indifferent, or improperly trained technicians produce assays of low accuracy and precision. Contributing to the degradation of technique is the belief that diffusion assays are biological and, as such, are inherently variable. Therefore, care is not needed because of the large "biological variation." The evidence to date supports the earlier (13) statement that the causes of "biological variation" in microbiological assaying have primarily a macro- and not a microbiological source.

Two-Dose Assays—The first official FDA microbiological assay for penicillin was the two-dose cylinder-plate method (1, 2). Both standard and sample are present on each plate at two concentrations. The ratio of concentrations is the same for standard and sample and can be either 1:2 or 1:4. Each plate has four zones, and four plates constitute the assay of a sample. Each plate contains a complete calibration line and, thus, becomes a complete assay of the sample.

This assay is statistically symmetrical; standard and sample are treated alike. The procedure for calculating the potency of the sample is that for a parallel line assay in which standard and sample lines have identical slopes. The identity of the slope is assured by using the responses from the standard and sample to compute a mean slope. The potency of the sample is the mean of the four potencies obtained from the four plates.

The data on standard curves given in Table II can be considered to be a two-dose assay in which a standard and two samples are on each plate. Three plates, not four, constitute assay of the samples in this example. For purposes of computation, the zone diameters on the first line under each plate number was assigned to the standards, the next row to Sample 1, and the third row to Sample 2. Thus, three potencies for each sample were obtained, one from each plate. The mean of the three values was reported as the potency of the sample in Table V.

All potencies differed from the true value of 8 by more than 1.5%. The standard deviations of the assays performed on plates with a 20-ml base layer were substantially less than those of plates with 10 ml of base layer. The assays on plates with a 20-ml base layer had the smaller errors. Comparison with the assays of the 8-μg/ml samples given in Table IV shows the latter to have the smallest errors.

One difference between the two types of assays is the amount of replication. Nine responses (one concentration) of sample were used in the single-dose method whereas only six (three at two concentrations) were used in the two-dose assay. The number of responses of standard was also smaller in the two-dose method. An assumption underlaying the two-dose method was the identity of slopes of the two dose–response lines. Departure from ideality was assumed to be caused by variances and not biases. Only two of the 12 pairs of slopes were identical. The ratio of the slope of the standard line to the sample line ranged from 0.94 to 1.3 for the plates with 10 ml of agar base layer and from 0.97 to 1.1 for the 20-ml plates.

The two-dose method has the theoretical advantage that each petri dish is a complete test; thus, the influence of plate-to-plate variations in zone size upon precision and accuracy is removed. Plate-to-plate variations in zone diameter could be large at the time (before 1945) when the method was developed. The method was not widely used and was soon abandoned in favor of the single-dose assay. One reason for abandoning it was the lack of identity of slopes of standards and samples, as illustrated by the results of this investigation. Were the differences in slopes real was the unanswerable question. Results of this investigation, which was done under much more favorable conditions than existed in 1945, indicate that the method was inferior to the single-dose method.

SUMMARY

Facilities and equipment used in this work were designed for plate assaying and were superior to most. Zone diameters were measured with a resolution of 0.01 mm. Control of other operations was such that the corrected mean zone diameter for a sample on one plate was indistinguishable from the corrected mean sample zone diameters on the other two of the set of three plates.

Acquisition and processing of the data by a computer not only reduced drudgery and error associated with manual operations but also removed practical restrictions upon form of the standard line. A calibration line of the form X^2 *versus* log *C* was better than the usual *d versus* log *C*. The principal assay used was the single-dose design of FDA modified to employ only two standards. The test assay, cephalexin–*B. subtilis*, had such sharp zone edges that most

measurements of diameter were replicated within 0.08 mm or within 2% of potency.

Using the equipment, procedures, and designs described here, proper computational procedures, and a very favorable assay system, a single determination (three plates) may be expected to be within 2% of the true value. Furthermore, no increase in effort or expense is required. As shown by the consideration of the influence of error of zone measurement upon error in sample potency, the tests cannot be greatly improved. The modified method requires fewer plates and less operator time than the standard FDA method. The accuracy of this plate method should be compared with the five- to 10-fold greater accuracy obtainable from an automated method for turbidimetric assays (14). Such differences in inherent accuracy is one reason to prefer turbidimetric methods when they are applicable.

The two-dose design of FDA was a less satisfactory method than the single-dose assay because it seemed to be excessively sensitive to the slope of the calibration line.

Automated Constant-Current Coulometric Assay System for Ascorbic Acid and Sodium Ascorbate

S. A. MOROS ˣ, C. M. HAMILTON, J. E. HEVERAN, J. J. DONAHUE, and S. OLIVERI-VIGH

Abstract □ The performance of an automated constant-current coulometric system for the assay of ascorbic acid and sodium ascorbate is described. After loading, it is capable of analyzing 25 samples and printing out the titer values with no operator attention for 2.5 hr. Under optimum conditions, ascertained by evaluating various electrochemical parameters, the accuracy and precision (95% ts) were found to be ±0.3%.

Keyphrases □ Ascorbic acid and sodium ascorbate—automated constant-current coulometric assay system □ Coulometry, constant current, automated—analysis, ascorbic acid and sodium ascorbate

Coulometric analysis of ascorbic acid, using both controlled-potential and constant-current methods, was reported previously. The constant-current method with iodine generated at the anode was used for the determination of small quantities (about 0.5 mg) of ascorbic acid with biamperometric ("dead-stop") end-point detection (1). The reproducibility was found to be ±0.1% *SD*. A platinum anode controlled at +1.1 v *versus* the saturated calomel reference electrode was used to oxidize 15–100 mg of ascorbic acid within 0.5–1 hr, with an average accuracy of ±0.7 mg (2).

The constant-current method employing electrogenerated iodine affords the electrochemical equivalent to the USP assay and offers a time advantage over the potentiostatic technique. Therefore, it was chosen for automation. A modular system (Fig. 1) consisting of an electrode station, electrolyte dispenser, current source, sample changer, control module, and

Automated Constant-Current Coulometric Assay System for Ascorbic Acid and Sodium Ascorbate

S. A. MOROS ˣ, C. M. HAMILTON, J. E. HEVERAN, J. J. DONAHUE, and S. OLIVERI-VIGH

Abstract □ The performance of an automated constant-current coulometric system for the assay of ascorbic acid and sodium ascorbate is described. After loading, it is capable of analyzing 25 samples and printing out the titer values with no operator attention for 2.5 hr. Under optimum conditions, ascertained by evaluating various electrochemical parameters, the accuracy and precision (95% ts) were found to be ±0.3%.

Keyphrases □ Ascorbic acid and sodium ascorbate—automated constant-current coulometric assay system □ Coulometry, constant current, automated—analysis, ascorbic acid and sodium ascorbate

Coulometric analysis of ascorbic acid, using both controlled-potential and constant-current methods, was reported previously. The constant-current method with iodine generated at the anode was used for the determination of small quantities (about 0.5 mg) of ascorbic acid with biamperometric ("dead-stop") end-point detection (1). The reproducibility was found to be ±0.1% *SD*. A platinum anode controlled at +1.1 v *versus* the saturated calomel reference electrode was used to oxidize 15–100 mg of ascorbic acid within 0.5–1 hr, with an average accuracy of ±0.7 mg (2).

The constant-current method employing electrogenerated iodine affords the electrochemical equivalent to the USP assay and offers a time advantage over the potentiostatic technique. Therefore, it was chosen for automation. A modular system (Fig. 1) consisting of an electrode station, electrolyte dispenser, current source, sample changer, control module, and

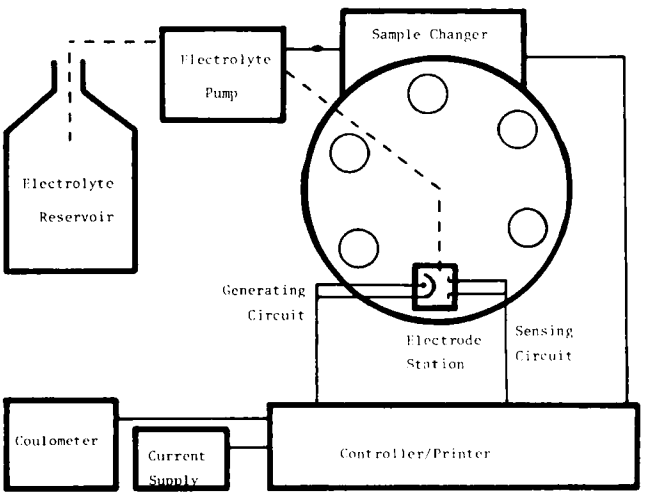

Figure 1—*System block diagram and interrelation of components.*

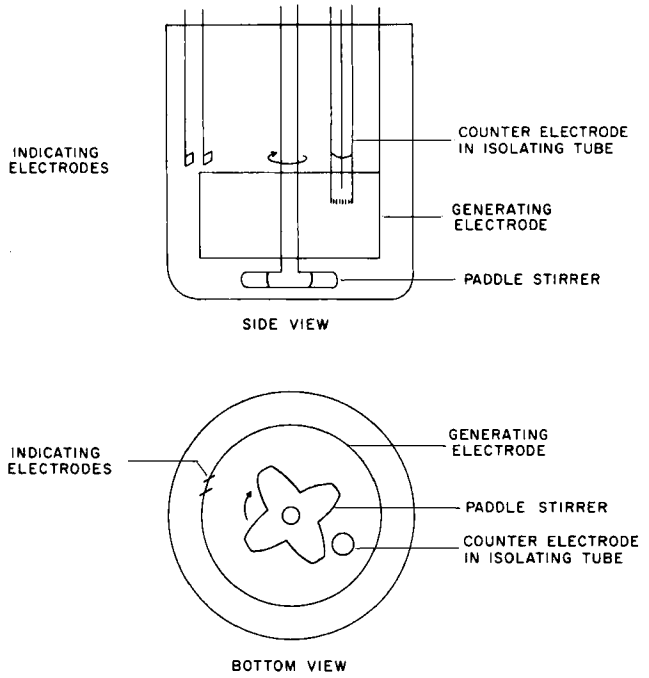

Figure 2—*Cell geometry.*

printer was assembled, and a study of various electrochemical parameters was undertaken to define the optimum conditions for the assay.

EXPERIMENTAL

Electrode Station—The electrode station was a cluster of components including the electrolyte delivery tip, the stirrer, and the generating and sensing electrodes, all mounted on a stationary arm bearing the stirring motor and appropriate electrical wiring. The glass stirrer consisted of four 2 mm-thick blades or paddles (each ~10-mm diameter) fused to the end of a 5-mm diameter glass rod to form a flat cloverleaf. At 560 rpm, efficient stirring was obtained without a vortex being formed or air entrained as observed with propeller-shaped stirrers.

The relative positions of the stirrer and electrodes, *i.e.*, cell geometry, are indicated in Fig. 2. The generating electrode (anode) was a cylinder of platinum screen (40-mm diameter × 25-mm height) coaxial with the shaft of the stirrer whose blades were positioned just below this electrode. The counter electrode (cathode) was a 5-mm length of platinum wire immersed in a few milliliters of electrolyte contained in a sintered-glass isolation tube located within the anode cylinder. The indicating electrode pair (5-mm platinum foil squares with the faces set parallel and 2 mm apart) was positioned outside the field between the anode and cathode.

Electrolyte Dispenser—A metering pump[1] delivered the requisite volume (80 ml) of electrolyte from a reservoir prior to each titration. The electrolyte, 0.5 *M* KI in 0.4 m*M* H_2SO_4, was treated with a steady stream of nitrogen passing through a submerged sintered-glass gas-dispersion tube to prevent air oxidation.

Current Source—A constant-current source, based on conventional operational amplifier circuitry, provided 25–200 mamp with an accuracy of ±0.2% at a voltage compliance of 18 v. The 10-μamp polarizing current for the indicating electrodes was similarly obtained from conventional transistor circuitry.

Sample Changer—By means of an elevator mechanism, a turntable[2] with 50 positions for 100-ml beakers presented 25 preweighed samples and rinse water alternately to a fixed electrode station where the electrolysis was carried out in the sequence given under *System Operation.* As each revolution was completed, the entire turntable was automatically displaced relative to the electrode station to present beakers in the next circle. After the last circle of samples was presented, the turntable returned to the starting position and the "end of cycle" signal was displayed.

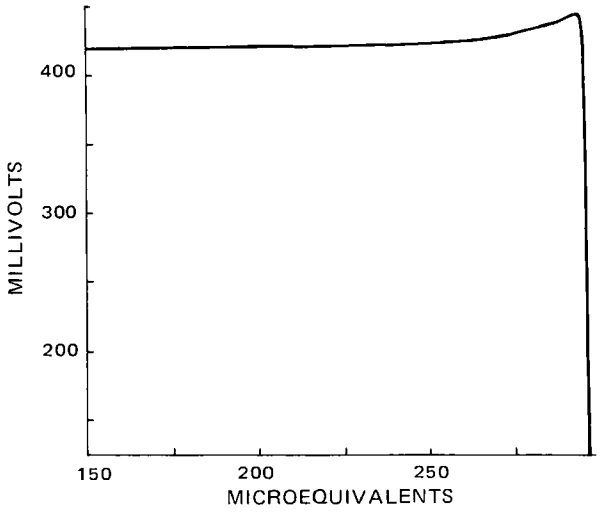

Figure 3—*End-point region of titration curve.*

Control Module and Printer—The operation of the entire system was controlled by a printing coulometer[3] incorporating the aforementioned current sources, a sensing and control circuit, a coulometer, and a printer. The sensing circuit displayed the potential across the indicating electrodes and compared it with a preset end-point potential, ending the titration when the potentials became equal. An adjustable time delay of up to 180 sec in the sensing circuit precluded false end-point signals, which could result from switching transients occurring at the start of the titration. An electronic integrator, accurate to 0.1%, provided a continuous digital readout in microequivalents and drove a printer for the final readout.

System Operation—The listed components formed a constant-current coulometric system operating in the following sequence. As each sample was presented to the electrode station, the electrolyte dispenser delivered electrolyte and the stirrer was activated. After 30 sec of stirring to dissolve the sample, the generating current was started to begin the titration. At the end-point, the control module stopped the generating current, printed both the sample number and titer in microequivalents, reset the integrator and printer, and sent a signal to the sample changer. This procedure resulted in the titrated sample being replaced by a beaker of rinse water for washing the electrodes and the next preweighed sample being presented to the electrode station.

Electrochemical Parameters—The generating current was selected to provide the highest titration rate possible consistent with 100% current efficiency for iodine generation. This current corresponded to a current density of 5 mamp/cm^2 of anode area in the 0.5 *M* KI electrolyte employed and did not increase significantly at higher concentrations. Above this current, the precision of the titration decreased and gas formation became evident at the anode.

The remaining electrochemical parameters were dictated by the titration curve; the end-point region is depicted in Fig. 3. The potential between the indicating electrodes rises gradually (20–30 mv) during the titration and more sharply just before excess iodine appears, whereupon the potential falls rapidly almost to zero. For the end-point, the comparator voltage was set 40 mv below the peak potential after several trials. This choice allowed for some variation in electrode response during a run but minimized the value and variability of the blank correction required for a larger difference.

The response of the indicating electrodes became less stable and the potential difference between them decreased during a series of titrations of ascorbic acid unless the electrolyte was acidified. The response was degraded during titration of sodium ascorbate to the

Sodium ascorbate					
E	30	120	0.1	26	0.5
F	30	120	0.1	17	0.9
E	30	120	0.4	50	0.3

extent that only a few samples could be titrated. In both cases, the formation of a coating on the indicating electrodes appeared to be involved; rinsing with a few drops of concentrated sulfuric acid restored the original electrode condition. Incorporating a trace of acid in the electrolyte minimized electrode contamination, so a full load of 25 samples could be titrated with the same end-point setting.

Other Analytical Parameters—The blank could not be directly determined because the potential obtained in acidified potassium iodide electrolyte was substantially lower than that obtained in the presence of sample. Instead, the blank was determined by extrapolating to zero sample weight, having titrated various weights of sample. Typical blank values were equivalent to 0.5% assay, but variations in these values were obtained with lots and suppliers of potassium iodide. These values were confirmed by manual titration with 0.1 *N* I_2 solution; the values ranged from 2 to 6 microequivalents of iodine/80 ml of electrolyte, values that would, if neglected, adversely affect the assay values.

Stability studies of acidified 0.5 *M* KI sparged with nitrogen showed no significant deterioration for up to 3 weeks.

A 30-mg sample size represents a compromise among such factors as titration time, weighing error, blank variability, and sample homogeneity. When using the maximum current for the electrochemical conditions (electrode area, stirring, temperature, *etc.*) employed, 5 min was required for titrating samples of the size recommended.

RESULTS AND DISCUSSION

Numerous determinations of the precision of the method were made on replicate samples of various lots of ascorbic acid or sodium ascorbate (Table I). Generating current levels of 200 mamp afford somewhat poorer precision than 120-mamp levels in the titration of ascorbic acid. Increasing the sample size to 100 mg (from the recommended 30 mg) improves the precision at the cost of prolonged titration time. The addition of acid permits the titration to be carried out in a reasonable time with excellent precision, ±0.2% (95% probability). Similarly, sodium ascorbate titrations are best carried out at the 0.4 m*M* acid concentration recommended. In this case, the use of a slightly lower acid concentration significantly reduces the precision of the measurement. In summary, the precision of the recommended method exceeds that of the USP XVIII (3) manual titration (different operators weighed and titrated the samples to avoid bias).

The automated system, standardized electronically, was compared to chemical standardization by ascorbic acid and arsenic trioxide to determine the accuracy of the system. Ascorbic acid, assayed as 100.0% by manual iodometric titrations, gave a coulometric value of 99.7%. Arsenic trioxide (National Bureau of Standards), when dissolved in base, acidified, and titrated, gave an average of 100.2% for 12 determinations.

The automated system described is capable of analyzing 25 samples in less than 4 hr, apportioned as follows: electrolyte and rinse preparations, 30 min; sample weighing, 35 min; titrator operation (100 mamp), 2.5 hr; cleanup, 15 min; and calculations, 10 min. The total time can be reduced by approximately 30 min if the remaining samples are weighed as the first few are being titrated. In any event, the operator's attention is required for only 90 min to carry out the auxiliary functions.

This automated system is similar in principle to the USP method and: *(a)* is equivalent to, or exceeds, the manual method in precision and accuracy; *(b)* is significantly less time consuming than the manual method; and *(c)* eliminates the need for preparation, standardization, and storage of the titrant.

While the prototype system is being evaluated for other applications, an equivalent system is in daily operation for monitoring the quality control of ascorbic acid production. Incorporating automatic weighing equipment and digital output capability would permit calculations to be performed by a computer, virtually eliminating all sources of human error.

Automated Spectrophotometric Assay of Cefazolin

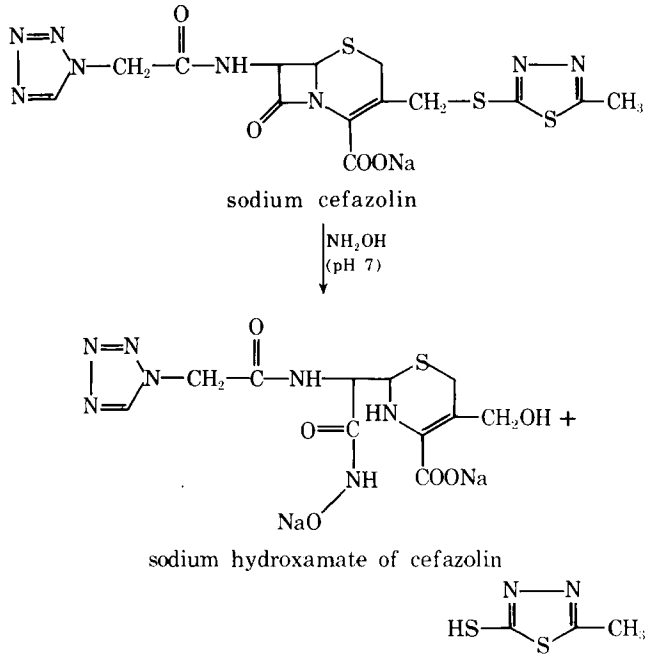
WALTER W. HOLL ˣ, MATTHEW O'BRIEN *, J. FILAN, THERESA R. MAZEIKA, ALEX POST, DONALD PITKIN, and PAUL ACTOR

Abstract □ An automated, stability-indicating, UV spectrophotometric assay for cefazolin is presented. The method employs a reaction with hydroxylamine and derives its stability-indicating power through comparison of reacted and unreacted aliquots of the sample. A double-probe sampling procedure is used. Good agreement with microbiological assays is obtained, and the coefficient of variation is about 1%.

Keyphrases □ Cefazolin—automated spectrophotometric assay, stability indicating, double-probe sampling procedure □ Automated methods—spectrophotometric assay of cefazolin, stability indicating, double-probe sampling procedure □ Spectrophotometry, automated—assay of cefazolin, stability indicating, double-probe sampling procedure

Cefazolin sodium, a potent new cephalosporin, is used parenterally and exhibits a broad spectrum of antibiotic activity (1–3). It is a certifiable antibiotic, and two methods of analysis have been approved by the Food and Drug Administration for certification. One method is an agar diffusion microbiological procedure (4), and the other is a manual colorimetric hydroxylamine procedure (4).

While such methods are adequate for certification, a more rapid method is desirable for production and stability studies where the number of samples becomes large. For this reason, an automated assay procedure that is both rapid and stability indicating was developed. The method employs the reaction between cefazolin and hydroxylamine to derive its stability-indicating characteristics. Hydroxylamine reacts with the β-lactam function of all cephalosporins and penicillins in an alkaline medium to produce a corresponding hydroxamic acid salt (5) (Scheme I).



Scheme I

In the case of cefazolin, the UV absorption spectra of the intact cephalosporin and its corresponding hydroxamic acid are different (Fig. 1). This difference makes it possible to assay for intact cefazolin in the presence of breakdown products or other UV-absorbing background materials which do not react with hydroxylamine. The procedure is to make a stock solution of the sample to be tested and then remove two identical aliquots. One aliquot is diluted to a suitable concentration for spectrophotometry, while the other is first reacted with hydroxylamine and then diluted.

The absorbance of both solutions is measured at 271 nm, and the difference is calculated. It is this absorbance difference that is proportional to the con-

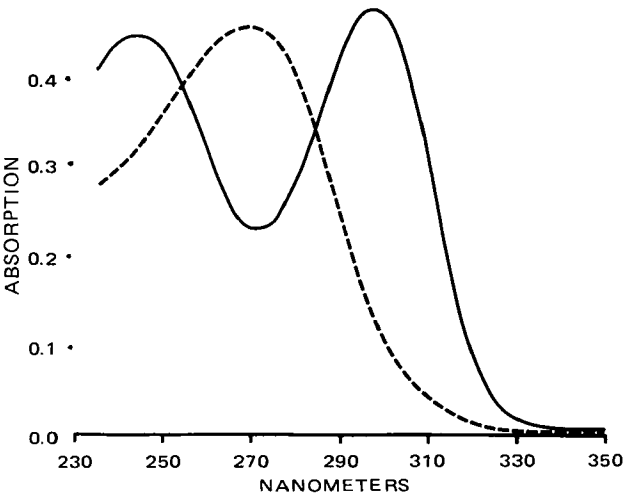


Figure 1—*Absorption spectra of cefazolin (- - -) and its hydroxamic acid salt (—).*

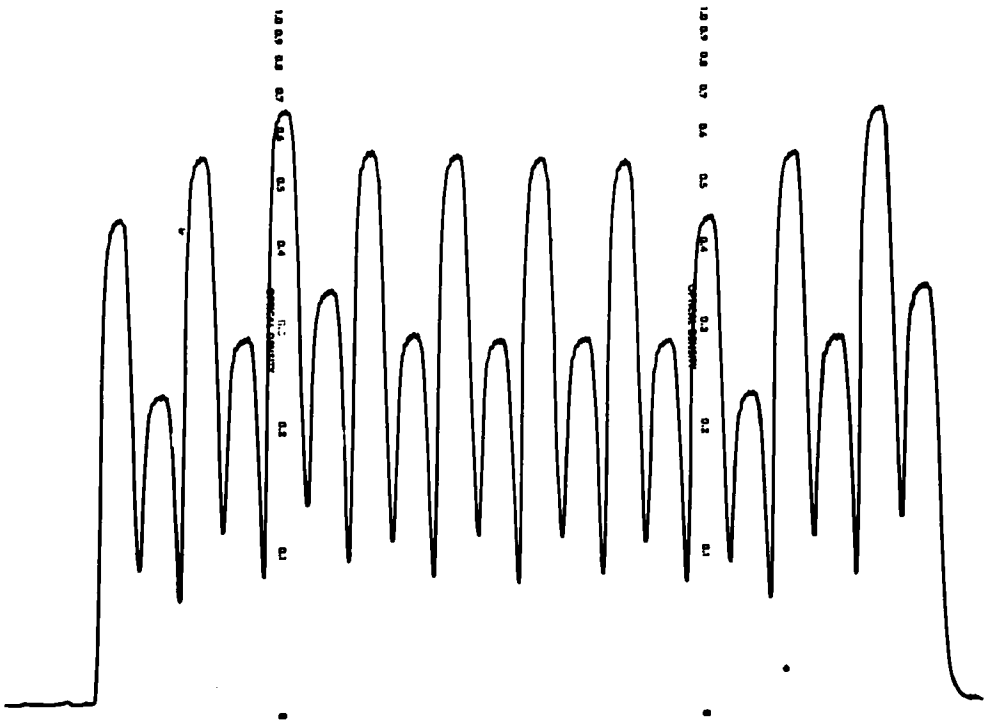

Figure 3—*Typical recording showing four samples preceded and followed by three standards.*

centration of intact β-lactam, cefazolin. The actual concentration is calculated by comparison with a reference standard run in the same manner.

EXPERIMENTAL

Reagents—The following were used:

1. A 0.5 *M* sodium bicarbonate aqueous solution.
2. Buffer, pH 4—Mix equal volumes of aqueous 0.1 *M* sodium acetate and 0.1 *M* acetic acid and adjust to pH 4.0.
3. Alkaline sodium acetate solution—Dissolve 34.6 g of sodium hydroxide and 4.1 g of sodium acetate in water and dilute to 1000 ml.
4. Hydroxylamine reagent—Mix 100 ml of aqueous 5 *M* hydroxylamine hydrochloride and 500 ml of alkaline sodium acetate solutions.

Standard Solutions—*Stock Standard Solution*—Weigh accurately about 100 mg of cefazolin reference standard and transfer to a 100-ml volumetric flask. Add 10 ml of 0.5 *M* sodium bicarbonate solution and swirl to dissolve the cefazolin. Dilute to volume with water and mix well.

Working Standard Solutions—Transfer 20, 25, and 30 ml of stock standard solution to separate 50-ml volumetric flasks. Dilute to volume with water and mix well.

Sample Preparation—Weigh accurately a portion of sample expected to contain about 100 mg of cefazolin and transfer to a 200-ml volumetric flask. Add 10 ml of 0.5 *M* sodium bicarbonate solution and swirl to dissolve the cefazolin. Dilute to volume with water and mix well.

Instrumentation—The following were used: a standard, continuous-flow, analyzer proportioning pump[1] with a manifold platter conforming to the flow diagram shown in Fig. 2 (6); a UV spectrophotometer[2] equipped with a low-volume flow cell[3]; strip-chart recorder suitable for recording the output of the spectrophotometer as a function of time; and a sampler modified to allow the installation and use of two solution pick-up probes, with its turntable drilled to accommodate two standard 2-ml sample cups side by side at each position.

The modification of the sampler allows the solution to be aspirated from two side-by-side cups simultaneously. Thus, two identical aliquots of sample can be aspirated into the analytical system, with one being reacted with the simultaneously aspirated hydroxylamine and the other simply being mixed with a volume of water equivalent to that of the hydroxylamine. This principle has utility in other situations where an unreacted sample blank is required. It has been applied in this laboratory to the iodometric procedure for cephalosporins as well.

This approach, first used by Strandjord and Clayson (7) for enzyme assays, is superior to the commonly used blank procedures which either make a separate run without one reagent for the blank or set up a parallel duplicate system devoid of one reagent. In the first method, instrumental drift or changes in pumping characteristics of the manifold tubes may introduce errors; the second method requires perfect matching of two systems, which is quite difficult to achieve. The double-probe technique overcomes both these problems, since sample and blank run through the exact same system side by side, virtually eliminating any effect of drift.

Procedure—A reagent baseline is established with the reagents flowing according to the flow diagram of Fig. 2. The sample cups are arranged in two concentric circles: an outer circle and an inner circle. Two cups of each cefazolin-containing solution, either standard or sample, are placed in neighboring positions in the outer circle of cups. A cup containing hydroxylamine reagent is placed in the position in the inner circle alongside one of the pair of cefazolin-containing cups; alongside the other is placed a cup of water. Thus, at one sampler position, sample solution plus hydroxylamine reagent is aspirated into the analytical system while another aliquot of the sample solution plus water is aspirated at the next position.

This procedure produces two peaks for each sample (or standard); one has been reacted with hydroxylamine and one has not. The difference between absorbances represented by these two peaks is proportional to the concentration of intact cefazolin in the solution. A typical recording is shown in Fig. 3. The concentration of the sample solution may be determined by plotting the absorbance difference *versus* concentration of the standards and reading the sample concentration from this graph.

F	94.0	95.2	1.2
Mean	95.1	95.1	0.7

Alternatively, since such a graph is linear (Fig. 4), an average response factor may be calculated from the standards and used to calculate sample concentration. If the automated system is equipped with an automatic peak detection device, the calculations can be done directly by computer. This mode of operation has been used successfully in this laboratory.

RESULTS AND DISCUSSION

As can be seen from Fig. 2, the method is extremely simple and requires only two reagents: the alkaline hydroxylamine reagent and the acidic buffer used to quench the reaction. The only critical part of the assay is the time of reaction between the cefazolin and the alkaline hydroxylamine. An experiment was carried out to determine the optimum reaction time, and the result was a reaction time of 6 min (Fig. 5). This time is achieved by a delay coil consisting of 10.5 turns of 2-mm i.d. glass tubing wound with a 14-cm diameter.

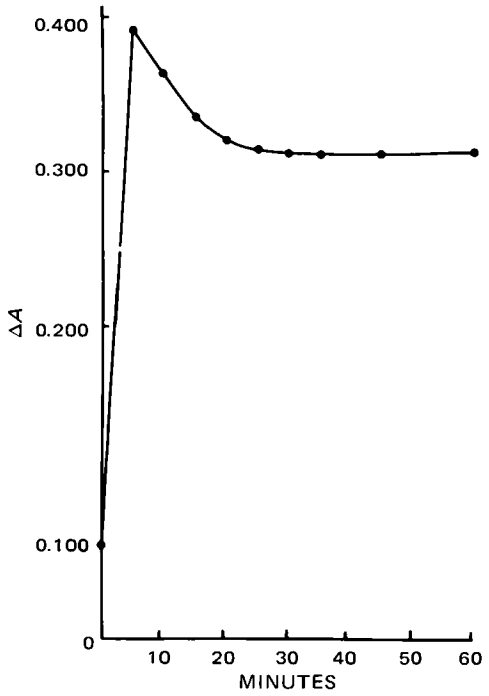

Figure 5—*Absorbance difference* versus *time of reaction between cefazolin and hydroxylamine.*

Table I shows the results of 10 successive determinations of the same sample solution run at one time. The standard deviation is 0.0047 mg/ml or 0.94%. Table II shows the results obtained by repeating five samples on two different days; the coefficient of variation of 0.74% is the same order of magnitude as that obtained on a single day. Table III shows a comparison of results obtained by this procedure with those of a microbiological procedure (8). These results show excellent agreement, as indicated by the mean difference of 0.7%.

Genetic Effects of Povidone-Iodine

THEODORE J. WLODKOWSKI, WILLIAM T. SPECK *, and HERBERT S. ROSENKRANZ ‡x

Abstract □ Povidone-iodine is capable of specifically altering the DNA of living cells. This alteration may result in the induction of mutations of the base-substitution type. Because of the known relationship between mutagenic potential and the ability to induce cancer in animals, the present findings raise serious questions concerning the safety of this topical disinfectant.

Keyphrases □ Povidone-iodine—genetic effects □ Mutagenicity—povidone-iodine □ Genetic effects—povidone-iodine

Povidone-iodine[1], an organic iodine complex reported to contain 1% free iodine (1), is widely used as a topical disinfectant. Because halogens, including iodine, are capable of reacting with nucleic acids and their constituents (2–5) and in view of the known relationship between the ability to react with DNA and mutagenesis and/or carcinogenesis (6–8), the potential genetic effects of povidone-iodine were investigated. The ability of povidone-iodine to modify intracellular DNA and to induce mutations in *Salmonella typhimurium* is now reported.

EXPERIMENTAL

Mutagenicity Testing—A series of histidine-requiring mutants of *Salmonella typhimurium* was constructed, which can be used to detect and classify mutagens. Two of these strains, TA1530 and TA1538, were used in this study; they can be induced to revert to histidine independence by base substitution and frameshift mutagens, respectively (9–11). To determine the mutagenicity of povidone-iodine, two procedures were used.

In the standard mutagenicity assay (9), bacteria are incorporated into an agar overlay. When the agar surface has solidified, a paper disk impregnated with the test agent is deposited on it. The plates are incubated for 54 hr at 37°, and the number of mutants (revertants to histidine independence) is determined. The diameters of the zones of growth inhibition are also measured.

A second, more quantitative, procedure was also used. Bacteria in liquid medium (Columbia base-broth-BBL) were chilled to 4°, and povidone-iodine was added. At intervals, portions of the cells were removed, the povidone-iodine was decomposed by addition of ascorbic acid (final concentration 0.1 *M*), and 10-fold serial dilutions of the treated bacteria were spread onto the surface of agar plates for the determination of the number of revertants to histidine independence (mutants) as well as of the number of viable cells. The medium for scoring mutants was a minimal medium supplemented with biotin (9) and containing a trace of histidine sufficient to support approximately two or three divisions (9). For the determination of the total number of viable cells, a nutrient broth base medium was used. Plates were incubated in the dark for 54 hr, and the number of colonies was counted. The first dilution tube used to make 10-fold serial dilutions for the determination of the number of viable cells also contained ascorbic acid (0.1 *M*); ascorbic acid is devoid of mutagenic activity and has no effect on the viability of the bacteria (12).

[1] Betadine.

Table I—Preferential Inhibition of DNA Polymerase-Deficient *E. coli*

Agent	Amount, μl	Diameter of Zone of Inhibition, mm: pol A^+	pol A_1^-
Povidone-iodine solution	20	73.0	>86
	10	50.6	81.4
	5	26.5	31.0
	3.3	19.2	25.6
	2	16.6	18.9
	1	14.2	15.7
Methyl methanesulfonate	10	37.4	55.1
β-Propiolactone	10	36.5	58.7
Propyleneimine	10	11.5	21.5
Chloramphenicol	30 μg	31.8	31.9

DNA Modifying Activity—Following exposure to agents capable of altering DNA, cells attempt to overcome this damage to their genetic material by a variety of DNA repair systems. One reaction involves the excision of the modified DNA segment, followed by "patching" of the removed section. The enzyme DNA polymerase I is active in several of these DNA repair processes (13). Therefore, mutant cells deficient in this enzyme (pol A_1^- bacteria) are more sensitive than the pol A^+ parents from which they were derived to the lethal action of agents capable of modifying the cellular DNA (13). Indeed, this prediction was fulfilled when DNA polymerase-deficient *Escherichia coli* (pol A_1^-) became available (14, 15).

Accordingly, a simple bioassay system was developed for detecting agents with the potential for altering cellular DNA. Numerous known mutagens and carcinogens gave positive results in this system; *i.e.*, they preferentially inhibited the growth of the pol A_1^- bacteria (15 and unpublished results). The technical aspects of the procedure were described in detail elsewhere (15) and basically involve the spreading of *E. coli* pol A^+ and *E. coli* pol A_1^- onto the surface of agar plates. When the surface of the agar has dried, paper disks impregnated with the test agent are deposited on top of the bacterial layer. The cultures are incubated at 37° for 12 hr, and the diameters of the zones of inhibition are measured. Agents known to modify cellular DNA produce a larger zone of growth inhibition on the pol A_1^--containing plate than on the corresponding pol A^+ one. Substances known to interfere with structures other than the DNA inhibit the two strains to the same extent (15).

RESULTS AND DISCUSSION

Povidone-iodine preferentially blocked the growth of the DNA polymerase-deficient *E. coli* strain (Table I), a property it shared with known mutagens and carcinogens (methyl methanesulfonate, β-propiolactone, and propyleneimine), which are known to derive activity from their ability to react with the cellular DNA. Chloramphenicol, which affects protein synthesis, inhibited the two strains to the same extent (Table I).

The mutagenicity of povidone-iodine for *S. typhimurium* could not be demonstrated in the standard mutagenicity assay (Table II), even though there was a zone of growth inhibition around the disks impregnated with this disinfectant. A number of known mutagens capable of inducing base substitution (methyl methanesulfonate, β-propiolactone, and ethyl methanesulfonate) and frame-

Table II—Mutagenicity Testing Using a Standard *S. typhimurium* Assay System[a]

Agent	Amount, μl	TA1530 Zone of Inhibition, mm	TA1530 Mutants per Plate	TA1538 Zone of Inhibition, mm	TA1538 Mutants per Plate

Water (control)	10	0	17	0	12

[a]The "standard" procedure developed by Ames (9) was followed. Bacteria were incorporated into the agar overlay while the test substance was present in a paper disk which was placed on the surface of the inoculated plates. The plates were incubated in the dark at 37° for 54 hr whereupon the diameters of the zones of inhibition were measured and the number of mutants (revertants to histidine independence) was determined.

shift (2-nitrofluorene) mutations were active in this standard assay (Table II).

Recent studies have detected a number of agents that act in the same manner as povidone-iodine; *e.g.*, they are positive in assays designed to detect *in vivo* modifications of the DNA but they do not respond in the standard *Salmonella* mutagenesis assay. Substances behaving in this manner include nitrofurans (16 and unpublished results), sodium hypochlorite (12, 17), and some haloalkanes (18). It was demonstrated that this behavior is due to the fact that agents in this group are strongly bactericidal [as evidenced by large zones of growth inhibition (Table II)], and the frequency of mutations is not detectable due to devitalization of the cells (12, 18).

In this connection, it must be stated that results in the standard mutagenicity assay are expressed as mutants per number of bacteria added to the plate and not as mutants per surviving cell. This difficulty was overcome readily if the cells were pulsed for a short duration with the potential mutagen, the latter was then removed, and the cells were processed for the enumeration of mutants and survivors by plating on selected media. Moreover, cellular survival could be increased by carrying out the procedure in an ice bath (4°). The mutagenicity of nitrofurans (unpublished results), haloalkanes (18), and hypochlorite (12) was demonstrated by this procedure.

When using the modified assay, the mutagenicity of povidone-iodine for *S. typhimurium* TA1530 was easily demonstrated. This effect was a function of both the povidone-iodine concentration and the duration of exposure (Fig. 1, curves A and B). Under experimental conditions similar to those described in Fig. 1A, povidone-iodine had no mutagenic effect on strain TA1538. At the dilutions plated, no mutations were detected at all (*i.e.*, even less than in untreated control). This finding presumably reflected the devitalizing effect of povidone-iodine. When the concentration of the latter was diminished (*i.e.*, situation similar to Fig. 1B) so as to increase the number of survivors, histidine-independent mutants could be scored. Their frequency, however, was not significantly different from that of the untreated control (Fig. 1C). These findings indicate that in *S. typhimurium*, povidone-iodine induces mutations of the base substitution but not of the frameshift type.

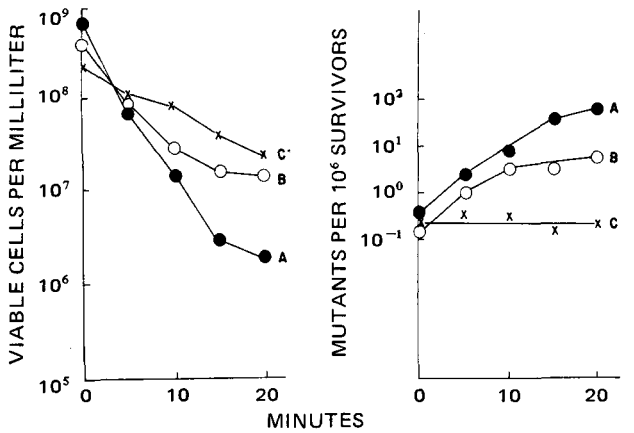

Figure 1—*Mutagenicity of povidone-iodine for* S. typhimurium. *The effects of povidone-iodine on the viability of* Salmonella *are given in the left panel, while the numbers of mutants induced per 10^6 survivors are given in the panel on the right. Key: A, effect of a 1/250 dilution of povidone-iodine solution on strain TA1530; and B and C, effects of a 1/1000 dilution of povidone-iodine solution on strains TA1530 and TA1538, respectively.*

CONCLUSIONS

The present results indicate that povidone-iodine, a widely used disinfectant, is capable of modifying the DNA of living cells and this modification, in turn, may result in mutagenic events. In view of the known relationship between mutagenic potential and the ability to induce cancer in mammals, the present findings raise some serious questions about the safety of povidone-iodine, especially in view of the residual iodine deposited at the site of application which may generate active iodine for prolonged periods. An evaluation of the potential genetic and carcinogenic hazards posed by the widespread use of povidone-iodine appears to be in order. These hazards will have to be balanced against the availability of a disinfectant of equal effectiveness and less potential toxicity.

The present findings reemphasize the importance of including tests that detect DNA modifications as well as mutations in the battery of standard microbial assays used to detect potential environmental mutagens and carcinogens.

GLC Determination of Heroin and Its Metabolites in Human Urine

S. Y. YEH ˣ and R. L. McQUINN

Abstract □ Heroin and its metabolites, 6-monoacetylmorphine, morphine, and normorphine, were determined in human urine with a GLC procedure. Heroin was extracted with chloroform at pH 4.5 and chromatographed at a temperature programmed from 200–250° by 8°/min. 6-Monoacetylmorphine and morphine were extracted with ethylene dichloride containing 30% isopropanol at pH 8.5, and normorphine was extracted at pH 10.4 with the same solvent. The extract was derivatized with trimethylsilylimidazole and chromatographed at 230° for the determination of 6-monoacetylmorphine and morphine and at 220° for normorphine and morphine.

Keyphrases □ Heroin and metabolites—GLC analysis in human urine □ Morphine, normorphine, and 6-monoacetylmorphine (heroin metabolites)—GLC analysis in human urine □ GLC—analysis, heroin and metabolites in human urine

Previous studies on laboratory animals *in vitro* and *in vivo* have indicated that heroin (3,6-diacetylmorphine) is rapidly deacetylated to 6-monoacetylmorphine and then to morphine (1–7). The major portion of a given dose of heroin can be accounted for in the urine as free morphine and morphine conjugate (8–13). Heroin, 6-monoacetylmorphine, and morphine have previously been estimated in biological materials with a methyl orange dye procedure, a Folin–Ciocalteu phenolic reagent (3), radioactive tracers (5), paper chromatography (7, 14), and GLC (12). This article presents an improved GLC procedure for the estimation of heroin and its metabolites, 6-monoacetylmorphine, morphine, and normorphine.

EXPERIMENTAL

Materials—Heroin hydrochloride[1] (containing about 5% 6-monoacetylmorphine as an impurity, as determined with the GLC procedure described here), normorphine hydrochloride[1], and morphine sulfate[2] USP were obtained.

Gas Chromatograph—A gas chromatograph[3] equipped with dual flame-ionization detectors and a dual pen recorder[4] was used. A 0.9-m (3-ft) × 2-mm glass column (Column 1) was packed with 3% OV-17 coated on Gas Chrom Q (60–80 mesh) and conditioned at 270° by passing nitrogen (30 ml/min) for 1 hr, then at 340° without nitrogen for 4 hr, and finally at 290° with nitrogen (16 ml/min) for 72 hr. A 1.5-m (5-ft) × 2-mm stainless steel column (Column 2) was packed with 3% SE-30 coated on Varaport (100–120 mesh). The temperatures of the injector and detector were set at 255 and 295°, respectively.

Determination of Heroin—A 5-ml aliquot of urine was placed in a 40-ml centrifuge tube, adjusted to about pH 4.5 with acetic acid, buffered with 1 ml of 1 *M* sodium acetate buffer at pH 4.5, salted with 1.6 g sodium chloride, shaken with 15 ml of chloroform in a shaker[5] at 280–300 oscillations/min for 10 min, and centrifuged at 2000 rpm for 10 min. After removal of the aqueous phase by aspiration, a 13-ml aliquot of the organic phase was transferred to a 15-ml conical centrifuge tube and evaporated to dryness under a stream of nitrogen in a water bath at 60–70°.

The tube was rinsed with 1 ml of chloroform by mixing on a mixer[6] for about 10 sec, and the chloroform was evaporated to dryness. To the residue was added 50 μl of cholestane solution (0.05 mg/ml in ethyl acetate) as an internal standard, and 1 μl of the solution was injected onto Column 2. The temperature of the column was programmed from 200 to 250° at 8°/min. A standard curve was prepared by adding authentic heroin hydrochloride (0.25–10 μg) to 5 ml of drug-free cigarette smoker's urine and analyzing by the described procedure.

Determination of 6-Monoacetylmorphine and Morphine—A 5-ml aliquot of urine was placed in a 40-ml centrifuge tube, adjusted to pH 8.0–8.5 with sodium hydroxide solution, buffered with 1 ml of 1 *M* phosphate buffer at pH 8.5, salted with 1.6 g of sodium chloride, shaken with 15 ml of ethylene dichloride containing 30% isopropanol in a shaker[5] at 280–300 oscillations/min for 10 min, and centrifuged at 2000 rpm for 10 min. After removal of the aqueous phase by aspiration, a 13-ml aliquot of the organic phase was transferred to a 40-ml centrifuge tube.

The alkaloids in the organic phase were back-extracted into the aqueous phase with 5 ml of 0.1 *N* HCl by shaking in the shaker for 5 min and centrifuging for 5 min. The organic phase was removed by aspiration without removing any of the acid phase (leaving a small drop of the organic phase in the bottom of the tube). The acidic phase was adjusted to pH 8.0–8.5, buffered, salted with 1.0 g of sodium chloride, and extracted with the organic solvent as already described. After removal of the aqueous phase by aspiration, a 13-ml aliquot of the organic phase was transferred carefully (so as not to include any aqueous phase) to a 15-ml conical centrifuge tube and evaporated to dryness under a stream of nitrogen in a water bath at 60–70°.

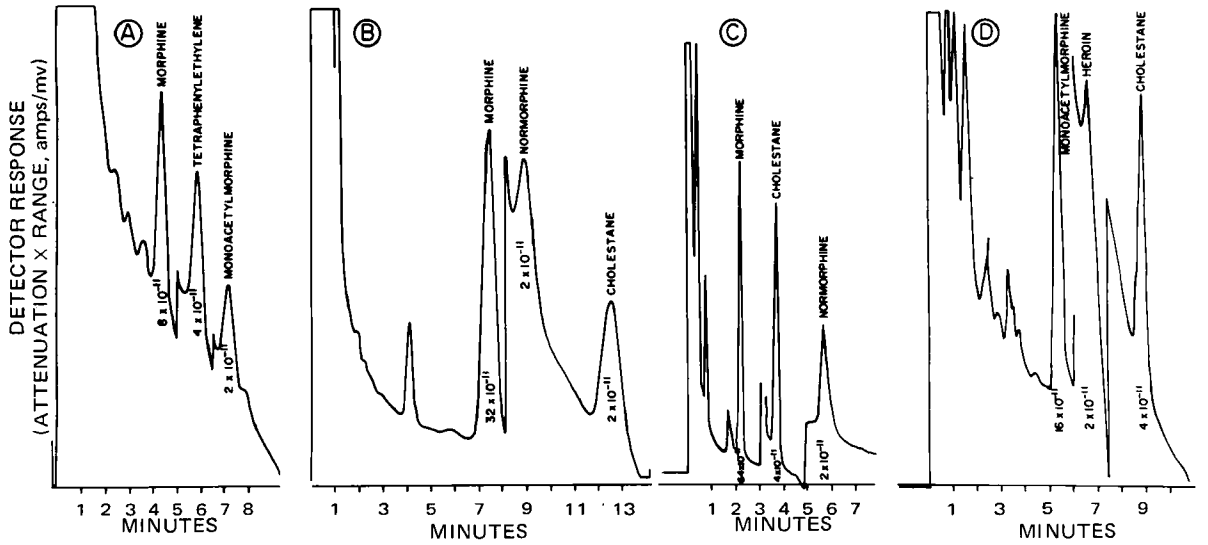

Figure 1—*Chromatograms of heroin, 6-monoacetylmorphine, morphine, and normorphine obtained from the extract of human urine after intravenous administration of 10 mg/70 kg of heroin hydrochloride.*

The tube was rinsed with 1 ml of methanol by mixing on a mixer[6] for about 10 sec and was then evaporated to dryness. The residue was used for GLC determination of 6-monoacetylmorphine and morphine after silanization with 25% trimethylsilylimidazole in pyridine[7]. Standard curves were prepared with five concentrations of 6-monoacetylmorphine and morphine added to 5 ml of drug-free cigarette smoker's urine and analyzed as already described.

Determination of Morphine and Normorphine—The procedure for extraction of normorphine and morphine was described previously (15). It was essentially the same as the procedure for extraction of 6-monoacetylmorphine and morphine, except that the urine samples were adjusted to about pH 10, buffered at pH 10.4 with 1 ml of 40% phosphate buffer (37% K_2HPO_4 and 3% K_3PO_4), and extracted with ethylene dichloride (glass distilled) containing 30% isopropanol by shaking for 30 min each time.

The residue of the urine extract was dissolved in 0.3 ml of methanol, 50 μl of internal standard solution was added, and the tube was mixed[6] for about 10 sec. Tetraphenylethylene (50 μg/ml in ethyl acetate) was used for the determination of 6-monoacetylmorphine and morphine, and cholestane solution (50 μg/ml in ethyl acetate) was used for the determination of normorphine. The solution was transferred to an acylation tube[8], and the centrifuge tube was rinsed with 0.1 ml of methanol and transferred to the acylation tube. The mixture was evaporated to dryness, and the residue was either silanized or acetylated.

Acetylation was accomplished by heating the residue with 0.2 ml of acetic anhydride and 0.1 ml of pyridine in a sealed acylation tube at 60–70° for 0.5 hr. The excess acetic anhydride was removed by evaporation and the residue was dissolved in 50 μl of ethyl acetate; 1 μl of the solution was injected onto Column 2. Silanized derivatives were prepared by mixing the contents of the tube with 50 μl of 25% trimethylsilylimidazole in pyridine and heating the mixture in an oil bath at 90–95° for 1 hr. One microliter of the solution was injected onto Column 1.

The ratios of the peak heights of heroin, 6-monoacetylmorphine, morphine, and normorphine to the peak height of internal standard were calculated. A linear relationship was found by plotting the peak height ratios *versus* concentrations. Heroin, 6-monoacetylmorphine, morphine, and normorphine concentrations in the urine sample were determined from the standard curves. The amount of injected heroin was converted to equivalent amounts of 6-monoacetylmorphine and morphine for calculation of the percentage of excretion.

Estimation of Free and Conjugated Morphine and Normorphine—Total morphine and normorphine in the urine were estimated, according to the precedure of Yeh and Woods (16), by autoclaving the specimen in a final concentration of 2.2 *N* HCl (20% by volume of concentrated hydrochloric acid) in a steam-jacketed autoclave at 15 lb of pressure and 115° for 30 min. After cooling, the sample was adjusted to about pH 10 and then extracted for GLC by the described procedure. Free morphine and normorphine were estimated from the unhydrolyzed specimens. Conjugated morphine was calculated as the difference between the total morphine and the free drug of morphine and 6-monoacetylmorphine.

RESULTS AND DISCUSSION

The chromatograms of heroin and its metabolites (6-monoacetylmorphine, morphine, and normorphine) extracted from the first urine samples of subjects after intravenous administration of 10 mg of heroin hydrochloride/70 kg are shown in Fig. 1. Normorphine, either in free or conjugated form, would be expected to be a metabolite of heroin since free and conjugated normorphine have been found in the urine of morphine-dependent subjects (15). The chromatograms of free 6-monoacetylmorphine and free morphine Fig. 1(A) were obtained from a silanized extract and chromatographed on Column 1 at a temperature of 230°. The retention times of silylmorphine, tetraphenylethylene, and silyl-6-monoacetylmorphine were 4.3, 5.8, and 7.1, respectively.

Chromatograms B and C show total morphine and total normorphine extracted from acid-hydrolyzed urine at pH 10.4. Chromatogram B was obtained from the extract that was silanized and chromatographed on Column 1 at 220°. The retention times of silylmorphine, silylnormorphine, and cholestane under these conditions were 7.4, 8.8, and 12.5 min, respectively. Chromatogram C was obtained from the extract that was acetylated and chromatographed on Column 2 at 250°. The retention times of diacetylmorphine, cholestane, and triacetylnormorphine were 2.3, 3.7, and 5.7 min, respectively.

Chromatogram D shows 6-monoacetylmorphine and heroin obtained from the extract chromatographed on Column 2, temperature programmed from 200 to 250° at 8°/min. The retention time of heroin and its metabolites changed slightly from column to column but the basic pattern remained the same. Free normorphine concentration was too low to be detectable in a 5-ml urine aliquot but was detected from larger samples extracted with XAD-2 resin[9].

The sensitivity of the procedure for determination of heroin was

[7] Tri-Sil-Z, Pierce Chemical Co., Rockford, Ill.
[8] Regis Chemical Co., Chicago, Ill.
[9] Amberlite XAD-2 resin, Rohm & Haas Chemical Co., Philadelphia, Pa.

0.2 μg/5 mg of urine. The extraction efficiency of the procedure could not be established, because the volatility of heroin hydrochloride appears higher than that of heroin (presumably heroin acetate) extracted with the solvent. The peak height of heroin hydrochloride (2–10 μg) was less than that of the same amount of heroin after extraction when chromatographed on Column 1. Column 2 seemed more sensitive than Column 1 when extracted heroin was chromatographed, although heroin hydrochloride did not emerge from Column 2.

The extract obtained from a single extraction contained many impurities, but these did not interfere with the detection or measurement of the heroin peak. Attempts to clean the extract by extraction of heroin into the aqueous phase with 0.1 *N* HCl and then back into the organic phase with chloroform at pH 4.5 were unsuccessful. 6-Monoacetylmorphine was also extracted with chloroform from the urine sample buffered at pH 4.5.

6-Monoacetylmorphine is quite stable under the conditions for extraction and silanization, as evidenced by the fact that a morphine peak was not observed in the chromatogram when authentic 6-monoacetylmorphine alone was added to the urine. Attention must be paid to the adjustment of the pH of the sample. Oberst (10) reported that 88% of heroin was hydrolyzed at 26° in 0.5 *M* sodium carbonate solution in 10 min. The biological sample obtained after administration of heroin should be frozen and analyzed as soon as possible. 6-Monoacetylmorphine was detected in 10 out of 10 frozen human urine samples and only in three out of 10 refrigerated urine samples after heroin administration.

The overall recoveries for 6-monoacetylmorphine and morphine in concentrations of 2–15 μg/5 ml of urine were 68–70 and 60–62%, respectively. The sensitivity of this procedure for the determination of 6-monoacetylmorphine hydrochloride and morphine sulfate was 0.25 μg/5 ml of urine. Morphine can be extracted from the sample buffered to pH 8.5 or 10.4 and determined simultaneously with either 6-monoacetylmorphine or normorphine.

The optimal conditions of reaction time and temperatures for derivatization of morphine and normorphine were studied with two silanizing reagents, bis(trimethylsilyl)trifluoroacetamide plus 10% trimethylchlorosilane and 25% trimethylsilylimidazole in pyridine. A clean chromatogram was obtained from the extract of a drug-free urine sample when trimethylsilylimidazole was used. The results from silanization of 100 μg of morphine sulfate and normorphine hydrochloride with 50 μl of 25% trimethylsilylimidazole in pyridine heated at 90–95° for 15, 30, and 60 min (six samples for each time period) were not significantly different. However, the chromatogram of drug-free urine extracts heated for 15 and 30 min with the silanizing reagent showed a small peak interfering with morphine (0.2 min after morphine peak). The peak height ratios for morphine were not significantly different when the extract was silanized at 60–70 or 90–95°, but the peak height ratios for normorphine were smaller at the lower temperature. Therefore, reaction at 90–95° for 60 min was used in the final procedure.

The sensitivity of silanized and acetylated morphine is comparable but the sensitivity for determination of silanized normorphine is somewhat greater than that for acetylated normorphine.

Cholestane interferes with the retention time of 6-monoacetylmorphine, so it is not suitable for use as an internal standard for 6-monoacetylmorphine determination. Tetraphenylethylene was used as an internal standard for the determination of both 6-monoacetylmorphine and morphine.

This procedure is currently being used in this laboratory for studying the urinary excretion of heroin and its metabolites following intravenous administration of heroin in humans.

Synthesis, Spectral Properties, and Antibacterial Activity of Synthetic Precursors of Macrocyclic Oxa- and Thia-Substituted Benzolactones and Benzoketones

PAUL R. JONES ˣ, CECIL E. MALMBERG, and CAROL McGRATTAN

Abstract □ Terminally difunctional compounds were synthesized by alkylation of salicylic acid, thiosalicylic acid (*o*-mercaptobenzoic acid), or their derivatives. Whereas methyl salicylate and thiosalicylic acid were smoothly etherified, salicylic acid was alkylated at the carboxyl. Characteristic IR and NMR spectral patterns in the synthesized compounds can be attributed to intramolecular hydrogen bonding or substituent effects and are consistent with observations already reported for similar compounds. Three synthesized compounds exhibited low but reproducible inhibitory effects on *Bacillus subtilis* growth.

Keyphrases □ Salicylic and thiosalicylic acid derivatives—synthesis, spectra, and antibacterial activity as precursors of macrocyclic oxa- and thia-substituted benzolactones and benzoketones □ Antibacterial activity—synthesis and screening of salicylic and thiosalicylic acid derivatives as precursors of macrocyclic oxa- and thia-substituted benzolactones and benzoketones

Metabolites possessing a macrocyclic ring *ortho*-fused to an aromatic nucleus are few in number (1). The four known *ortho*-fused macrocyclic lactone metabolites are curvularin, monorden (radicicol), zearalenone, and lasiodiplodin. The first three, containing a keto group as well, fit the general structure of the macrolides (2); lasiodiplodin is devoid of such an additional function.

Although curvularin shows no antibacterial or antifungal activity (3), *S*-zearalenone (4) and the saturated *S*-zearalanone (5) exhibit uterotrophic activity; monorden displays strong antifungal properties with low toxicity (6). Biological testing of lasiodiplodin has apparently not yet been reported.

Previous synthetic approaches to curvularin, zearalenone, and their close structural relatives have involved closing of the aliphatic macrocyclic ring by way of an aromatic, difunctional precursor. In the case of curvularin, this procedure required a troublesome Friedel–Crafts acylation to form the aryl–carbon bond (7). The approach to preparing analogs of the naturally occurring, *ortho*-fused metabolites was to choose an aromatic starting material, with appropriate *o*-substituents already in place, and, by means of efficient standard synthetic steps, to attach one or two functionally substituted long chains at these *o*-positions.

The choice of ethers or thioethers as one of the ring-forming functional groups seemed particularly attractive. They could be derived from readily available phenols or thiophenols by the Williamson synthesis and, once formed, would be inert to a wide variety of reaction conditions. Thus, by this approach, I and II with an array of substituents X and Y would be synthetically achievable. They, in turn, would be precursors to heterocyclic analogs (IV) of the *ortho*-fused metabolites.

EXPERIMENTAL[1]

The following are representative preparations of compounds of types I, II, and III.

11-(2-Carboxyphenoxy)hendecan-1-ol (I: *n* = 11, X = OH, Y = COOH)—To a magnetically stirred mixture of 3.04 g (0.02 mole) of methyl salicylate, 6.0 g of anhydrous potassium carbonate, and 250 ml of dried, distilled dimethylformamide was added a solution of 5.0 g (0.02 mole) of 11-bromohendecan-1-ol (8) dissolved in 70 ml of dimethylformamide. During the addition, which required 25 min, the temperature from external heating was allowed to rise from 33 to 60°. After the mixture had been stirred and heated at 60–70° for 2.5 hr, it was filtered and the filtrate was allowed to evaporate at room temperature for 2 days and was then partitioned between 100 ml of water and 2 × 60 ml of chloroform.

The combined organic phase was washed with 2 × 50 ml of 5% NaOH, 2 × 100 ml of water, 100 ml of dilute hydrochloric acid, and 2 × 100 ml of water, dried over magnesium sulfate, and concentrated to 5.2 g of oil; this oil was distilled (112°, 0.05 torr) to remove the starting bromo alcohol. The 3.6 g of residual oil was purified by column chromatography (silica gel, chloroform eluent) to afford 3.3 g (51%) of the hydroxy ester as a light-tan oil; IR (film): 3650–3200 (OH) and 1730 ($COOCH_3$) cm^{-1}; NMR (CCl_4): δ 7.75 (m, 1, ArH), 7.18 (broad m, 3, ArH), 4.0 (t, J = 7 Hz, 1.8, $ArOCH_2$), 3.85 (s, 2.7, $COOCH_3$), 3.54 (t, J = 7 Hz, 1.8, CH_2OH), 3.0 (s, 1.0, CH_2OH), and 1.9–1.2 (m, 18.2, $—(CH_2)_9—$) ppm.

The hydroxy ester (1.5 g) was saponified with potassium hydroxide–ethanol to give 1.1 g (78%) of 11-(2-carboxyphenoxy)hendecan-1-ol, mp 81.0–81.5°; IR ($CHCl_3$): 3615 (free OH), 3530–3200 (bonded OH), and 1735 (COOH) cm^{-1}; NMR ($CDCl_3$): δ 8.32 (m, 1, ArH), 7.70 (m, 1, ArH), 7.25 (m, 2, ArH), 6.0–5.5 (broad m, 1.8, COOH and CH_2OH), 4.3 (t, J = 7 Hz, 1.9, $ArOCH_2$), 3.7 (t, J = 7 Hz, 1.9, CH_2OH), and 2.0–1.2 (m, 18.3, $—(CH_2)_9—$) ppm. broad multiplet at 6.0–5.5 ppm disappears with the addition of D_2O. The acid proton was assigned on the basis of integration. Similar behavior occurs with 11-(2-carboxythiophenoxy)hendecan-1-ol.

Ethyl 11-(2-Carboxythiophenoxy)hendecanoate (II: n = 11, X = $COOCH_2CH_3$, Y = COOH)—To a stirred mixture of 4.35 g (0.028 mole) of thiosalicylic acid and 10 g of anhydrous potassium carbonate in 300 ml of dimethylformamide was added a solution of 7.50 g (0.026 mole) of ethyl 11-bromohendecanoate (9, 10) in 100 ml of dimethylformamide over 2.8 hr; the temperature ranged from 40 to 55°. Stirring at 60° was continued for an additional 4 hr. The mixture was filtered, and the filtrate was allowed to evaporate at room temperature until a yellow solid remained. This solid was partitioned between 100 ml each of chloroform and hydrochloric acid.

The aqueous layer and residual solid material were extracted twice with 75 ml of ether. The chloroform and ether extracts were combined and concentrated. The residual solid was washed with benzene and then recrystallized from hexane to afford 3.25 g (34%), mp 72–73°; IR (CCl_4): 3300–2500 (COOH), 1734 (ester), and 1689 (acid) cm^{-1}; NMR (CCl_4): δ 12.19 (s, 1.04, COOH), 8.18 (m, 1, ArH), 7.34 (broad m, 3, ArH), 4.08 (q, 1.82, J = 6 Hz, $COOCH_2$), 2.88 (t, 1.82, J = 6 Hz, CH_2S), 2.21 (t, 1.82, J = 6 Hz, CH_2COO), and 1.90–1.00 (m, 19.6, $-(CH_2)_8-$ and CH_2CH_3) ppm.

11-Hydroxyhendecyl Salicylate (III: n = 11, X = OH)—Addition of 7.0 g (0.027 mole) of 11-bromohendecan-1-ol in 100 ml of dimethylformamide to a stirred mixture of 3.84 g (0.0278 mole) of salicylic acid, 9 g of anhydrous potassium carbonate, and 260 ml of dimethylformamide was carried out as described for II. After being stirred and heated for 7 hr, the mixture was filtered and the filtrate was evaporated to a tan solid. After being washed with water, the solid was taken up in chloroform, which was washed sequentially with 2 × 20 ml of 5% $NaHCO_3$, 2 × 20 ml of 5% NaOH, 3 × 20 ml of water, dried (magnesium sulfate), and concentrated to 3.8 g (45%) of crude oil product.

Column chromatography (silica gel, chloroform eluent) afforded 1.5 g of oil which gave, after solidification in an ice bath and three recrystallizations from hexane, 1.1 g (13%) of white crystalline solid, mp 41–42°; IR ($CHCl_3$): 3630 (free OH), 3500–3150 (bonded OH), and 1675 (ester) cm^{-1}; NMR (CCl_4): δ 10.65 (s, 0.77, ArOH), 7.80 (m, 1, ArH), 7.40 (m, 1, ArH), 6.85 (m, 2, ArH), 4.34 (t, J = 6 Hz, 1.8, $ArCOOCH_2$), 3.56 (t, J = 6 Hz, 1.8, CH_2OH), and 1.90–1.10 (m, 19.5, $-(CH_2)_9-$ and CH_2OH) ppm. Both the phenolic proton signal at 10.65 ppm and the alcohol proton signal, appearing as a singlet at 1.45 ppm, disappear with the addition of D_2O.

Antibacterial Assay—Inhibition of *Bacillus subtilis*[2] growth was measured by placing a paper disk containing 20 μl of solution on an agar surface seeded with the organism and noting zones of growth inhibition after 20 hr of incubation (11). The "net zone of inhibition" (Table I) is the total diameter of the inhibition zone (millimeters) minus the diameter of the paper disk. All compounds were also tested against the green alga *Chlorella pyrenoidosa*[3] (No. 395) (12) and found to be inactive.

RESULTS

Synthesis—Whereas the synthesis of II by alkylation of thiosalicylic acid at the sulfur proceeded smoothly, attempts at alkylating salicylic acid led, unexpectedly, to III rather than to I. In fact, this tendency of salicylic acid to undergo alkylation at the carboxyl rather than the hydroxyl was noted by Herzig in 1894 (13). Later, it was reported (14) that the benzyl ether of salicylic acid could be obtained in a Williamson synthesis, provided a large excess of alkali was employed. Apparently the dianion of salicylic acid, which would lead to alkylation at the phenolic site, is formed only with difficulty. Nozu *et al.* (15) showed that salicylic acid behaves as a typical monobasic acid on titration. Compounds of type I were obtained by alkylating salicylate esters, a reaction that proceeded as expected. Saponification of the ethereal esters led to I.

Spectral Properties—Unusual IR spectral characteristics were encountered in some of the synthetic compounds. For example, in

[c] "Sadtler Nuclear Magnetic Resonance Spectra," Sadtler Research Labs., Inc., Philadelphia, Pa., 1965, No. 7214M. [d] Reference 17.

I, where Y=COOH, both the OH and C=O stretching vibrations were unusually high in the regions expected for a monomeric carboxylic acid (16). This finding can be attributed to extensive intramolecular hydrogen bonding of carboxyl with *ortho*-phenolic ether oxygen. As expected, the IR spectra of the corresponding thio compounds (II) were normal, with the OH appearing as a broad band at 3300–2500 cm^{-1} and the C=O appearing at 1690 cm^{-1}. The ester carbonyl stretching band in III was, on the other hand, at an unusually low frequency, probably because of another mode of intramolecular hydrogen bonding. Precedents for these spectral features are to be found in related compounds (Table II).

The proton NMR spectra displayed distinctive features in the aromatic region. In essence, the aromatic (Ar—H) proton *ortho* to a carboxyl or ester function was shifted downfield relative to the three remaining aromatic protons. This behavior, already noted in dideoxyzearalane and two related compounds (17), seems to be generally characteristic. The extent of shift, expressed as $\Delta\delta$ (*i.e.*, separation between the lowest field Ar—H proton and the remaining three aromatic protons), is dependent on the nature of the carbonyl function, being greater for carboxylic acid than for carboxylic ester. Although the shifts are undoubtedly dependent on other factors such as solvent and additional substituents, which have not yet been clarified, the trend can be clearly seen from the examples assembled in Table III, taken from this work and published literature. This NMR pattern has been valuable in corroborating the identity of isomeric Structures I and III.

Binding of Cupric Ions to Bovine Serum Albumin

DATTA V. NAIK, CHARLES F. JEWELL, Jr. *, and STEPHEN G. SCHULMAN ˣ

Abstract □ The binding of cupric ions to bovine serum albumin was investigated by using a cupric-ion-specific electrode. When using a modified form of the Scatchard equation, it was determined that there are at least two classes of binding sites on bovine serum albumin for cupric ions. One class has three binding sites of relatively strong affinity, with an average binding constant of 3.0×10^6. The other class has about 16 binding sites of relatively weak affinity, with an average binding constant of 2.0×10^4.

Keyphrases □ Cupric ions—binding to bovine serum albumin, determination of number and classes of binding sites, specific ion electrode □ Copper–protein binding interactions—studied using specific ion electrode □ Serum protein binding—binding of cupric ions to bovine serum albumin, studied using specific ion electrode

In the normal human body, the blood serum contains about 114 μg of copper/100 ml of serum. About 94% of this copper is tightly bound to the serum copper–protein ceruloplasmin, an α-globulin with a molecular weight of approximately 151,000. The function of ceruloplasmin is unknown, but it does possess polyphenol oxidase activity (1, 2); it may function in the oxidation of serotonin (3) and epinephrine (4). The remaining 6% of serum copper is loosely bound to serum albumin. The red blood cells also contain about 115 μg/100 ml of packed red blood cells. It has been suggested that there are at least two different fractions of copper in erythrocytes (5), one of which is labile and can be exchanged easily between plasma and red blood cells. The other fraction is present as a copper–protein called erythrocuprein, which contains about 0.34% copper, by weight, tightly bound to the protein.

A hereditary deficiency or absence of ceruloplasmin (6–8) often results in Wilson's disease (hepatolenticular degeneration). This disease results from inordinately high concentrations of copper in many organs and tissues due to a lack of control in absorption of dietary copper or excretion of copper that already has been absorbed or both.

Even though the amount of copper present in the different parts of the blood is known, the individual binding of copper to each component is not well understood. Klotz and Curme (9) studied the thermodynamics of the copper–bovine serum albumin interaction at pH 4.83 and reported that there are 16 binding sites. They had also determined $\Delta F°$ values for the binding of individual Cu^{+2} ions to the protein. However, the analytical method they used to calculate the Cu^{+2} ions in the copper–protein system was sensitive only to about 1×10^{-4} *M* of Cu^{+2} ions. Therefore, it was desirable to reinvestigate the binding of Cu^{+2} to bovine serum albumin with a more sensitive analytical method for the determination of free Cu^{+2} ions. In this regard, the copper-ion-specific electrode seemed very attractive because of its ease of operation. This report presents the use of the specific ion electrode to study the copper–protein binding interaction.

EXPERIMENTAL

Chemicals—The protein solution was prepared by dissolving crystalline bovine serum albumin[1] in distilled deionized water. A 0.100 *M* copper nitrate standard solution[2] was used to prepare the cupric-ion stock solution.

Apparatus—A cupric-ion-specific electrode[3], a single-junction reference electrode[4], and a digital pH/mv meter[5] were used for measurement of the electric potential from which the cupric-ion concentrations were calculated.

Procedure—Fifty milliliters of 5.0×10^{-6} *M* bovine serum albumin (molecular weight assumed to be 69,000), prepared in deionized distilled water, with ϵ at 280 nm equal to 4.60×10^4 liters $mole^{-1}$ cm^{-1} (10), was placed in a 100-ml beaker. The reference electrode, the cupric-ion electrode, and a thermometer were dipped into this solution, which was stirred magnetically. The temperature was maintained at 25.0° using a constant-temperature bath.

Copper nitrate solution, 1.0×10^{-2} *M*, was added to the bovine serum albumin in 10-μl increments with a micropipet[6]. Both the bovine serum albumin and the copper nitrate solutions were adjusted to pH 5.2 with trace amounts of sodium hydroxide or sulfuric acid, as appropriate. For samples below 10^{-3} *M* in total ionic strength, the difference in total ionic strength between samples and standards may be as large as a factor of 5 without resulting in serious errors (11). The 5.0×10^{-6} *M* protein and 1.0×10^{-2} *M*

copper nitrate solutions in distilled deionized water had a pH around 5, so only trace amounts of sulfuric acid or sodium hydroxide were needed to adjust the pH to 5.2. Such small quantities of acid or base are not expected to change the ionic strength enough to affect the measurement of the cupric-ion concentration. Ideally, the binding study should be carried out at the biological pH, which is 7.4; but at a pH of 6 or higher, some Cu^{+2} is hydrolyzed to hydroxo complexes, which may or may not precipitate. Hence, pH 5.2 was chosen for the present study.

The instrument was standardized before and after each titration, using various exact concentrations of pure copper nitrate solutions. By knowing the total amount of cupric ion added and the concentration of free cupric ions, the amount of copper bound was calculated.

RESULTS AND DISCUSSION

The potentiometric data for the titration of bovine serum albumin with copper nitrate are presented graphically in Fig. 1. Curve A is the standard curve for the known concentrations of cupric ions in the absence of the protein. Curve B represents the electromotive force in volts during the bovine serum albumin–copper nitrate titration as a function of total Cu^{+2} added.

The binding of cupric ions to bovine serum albumin, *P*, can be represented by a series of equilibria (Scheme I):

$$P + Cu^{+2} \overset{k_1}{\rightleftharpoons} P(Cu^{+2})$$
$$P(Cu^{+2}) + Cu^{+2} \overset{k_2}{\rightleftharpoons} P(Cu^{+2})_2$$
$$\vdots \qquad\qquad \vdots \qquad\qquad \vdots$$
$$P(Cu^{+2})_{i-1} + Cu^{+2} \overset{k_i}{\rightleftharpoons} P(Cu^{+2})_i$$

Scheme I

where $P(Cu^{+2})_{i-1}$ and $P(Cu^{+2})_i$ represent protein–copper complexes with $i-1$ and i cupric ions, respectively. The number i may vary from 1 to N, the maximum number of cupric ions that can bind to the protein. The k's are the respective equilibrium constants corresponding to each equilibrium.

The number of cupric ions bound per mole of bovine serum albumin, $\bar{n}$, at any point in the titration is related to the N equilibrium constants by the expression (12):

$$\bar{n} = \frac{\sum_1^N i\left(\prod_1^i k_i\right)[Cu^{+2}]^i}{1 + \sum_1^N \left(\prod_1^i k_i\right)[Cu^{+2}]^i} \qquad \text{(Eq. 1)}$$

where $[Cu^{+2}]$ indicates the equilibrium concentration of free cupric ions, and k_i is the equilibrium constant for the binding of ith cupric ion. If the individual equilibrium constants differ widely from each other (by at least two orders of magnitude) such that only one equilibrium is experimentally detectable at any point in the titration, Eq. 1 predicts that a plot of $-\log [Cu^{+2}]$ *versus* $\bar{n}$ should show N distinct inflection regions. The midpoint of these inflections should correspond to the respective equilibrium constants. Moreover, it also predicts that as $\bar{n}$ approaches N, $-\log [Cu^{+2}]$ should decrease sharply.

Figure 2 shows a plot of $-\log [Cu^{+2}]$ *versus* $\bar{n}$ for the bovine serum albumin–Cu^{+2} system. There are no clear inflection regions, a result that indicates strongly overlapping successive equilibria. The fact that a definitive saturation plateau has not been reached even at $\bar{n} = 12$ indicates that there are more than 12 binding sites. Therefore, the binding data should be analytically fitted to Eq. 1 (which will have $N + 1$ unknowns) to obtain precise binding parameters. However, if the N binding sites for cupric ions on bovine serum albumin are electrostatically noninteracting, and if the protein has identical affinity for each of the N cupric ions (*i.e.*, $k_1 = k_2 = k_3 \ldots = k_N$), then the relationship of $\bar{n}$ to the overall binding constant, K, becomes simpler and can be expressed by the Scatchard equation (13):

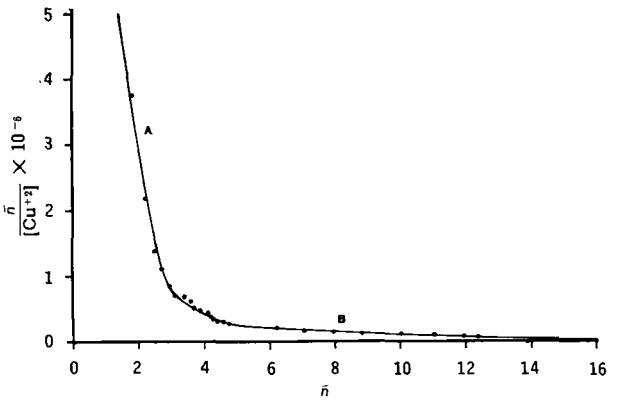

Figure 3—*Scatchard plot for the binding of* Cu^{+2} *ions to bovine serum albumin.*

$$\bar{n} = Nk[Cu^{+2}]/(1 + k[Cu^{+2}]) \qquad \text{(Eq. 2)}$$

which, on rearrangement, gives:

$$\bar{n}/[Cu^{+2}] = Nk - \bar{n}k \qquad \text{(Eq. 3)}$$

According to Eq. 3, a plot of $\bar{n}/[Cu^{+2}]$ *versus* $\bar{n}$ (known as a Scatchard plot) should be a straight line with the slope $= -k$ and the X intercept $= N$. Figure 3 shows the Scatchard plot for the bovine serum albumin–Cu^{+2} system. Clearly, these data do not fit Eq. 3. Klotz and Curme (9) also found that their data for the bovine serum albumin–Cu^{+2} system did not fit this linear expression. However, if it is assumed that there are two classes of binding sites that are widely different from each other in their binding affinities, the Scatchard Eq. 2 can be modified to:

$$\bar{n} = \{N_1k_1[Cu^{+2}]/(1 + k_1[Cu^{+2}])\} + \{N_2k_2[Cu^{+2}]/(1 + k_2[Cu^{+2}])\} \qquad \text{(Eq. 4)}$$

where N_1 is the number of binding sites of the first kind with a binding constant of k_1, and N_2 is the number of binding sites of the second kind with a binding constant of k_2. In this case, the ideal Scatchard plot, instead of being a straight line, is a hyperbola composed of two straight-line portions.

The binding data of the bovine serum albumin–Cu^{+2} system do yield a hyperbola made up of two straight-line portions (Fig. 3), indicating that there are at least two classes of binding sites on bovine serum albumin for cupric ions. The straight-line segment, A, of Fig. 3, gives an X intercept of about 3, indicating one class of binding has three sites. The slope of this line, which is equal to the average binding constant, is 3×10^6. The second straight-line segment, B, gives an X intercept of about 16, revealing that the second class of binding has about 16 sites. From the slope of segment B, the average binding constant for the latter sites is 2×10^4.

The number of binding sites for the second class of binding is the same as that reported by Klotz and Curme (9). However, they calculated the change in free energy of the individual 16 equilibria, the first of which had a k value of 1.8×10^4 ($\Delta F^\circ = -5908$ cal/mole at 25°). This value agrees with the value obtained from the Scatchard plot.

Thus, it appears that cupric ions bind to bovine serum albumin through at least two different classes of binding sites; one accom-

modates only about three cupric ions, which are relatively tightly bound, while the other accommodates about 16 cupric ions, which are rather weakly bound. It is possible that the first three cupric ions bind intimately by penetrating the protein while the rest of the cupric ions bind weakly to the surface of the protein.

Synthesis of 2-(4-Arylthiosemicarbazidocarbonylthio)benzthiazoles and Their Monoamine Oxidase Inhibitory and Anticonvulsant Properties

S. P. SINGH *, R. S. MISRA *, SURENDRA S. PARMAR *‡x, and STANLEY J. BRUMLEVE ‡

Abstract □ Ten 2-(4-arylthiosemicarbazidocarbonylthio)benzthiazoles were synthesized, characterized, and evaluated for their monoamine oxidase inhibitory and anticonvulsant activities. All substituted benzthiazoles inhibited activity of monoamine oxidase in rat brain homogenate where the degree of enzyme inhibition was higher with kynuramine as compared to tyramine and 5-hydroxytryptamine as the substrates. All substituted benzthiazoles possessed measurable anticonvulsant activity against pentylenetetrazol-induced convulsions.

Keyphrases □ 2-(4-Arylthiosemicarbazidocarbonylthio)benzthiazoles—synthesis, characterization, monoamine oxidase inhibitory and anticonvulsant activities □ Monoamine oxidase inhibitory activity—substituted benzthiazoles, relationship between enzyme inhibitory and anticonvulsant activities, rat brain homogenate □ Anticonvulsant activity—substituted benzthiazoles, relationship to monoamine oxidase inhibitory activity, mice

Benzthiazoles have been reported to possess diverse pharmacological properties (1, 2). Recent studies indicated anticonvulsant and monoamine oxidase [EC 1.4.3.4 monoamine: O_2 oxidoreductase (deaminating)] inhibitory properties of substituted benzthiazoles (3). In addition, the ability of hydrazines (4), semicarbazides (5, 6), and thiosemicarbazides (7) to inhibit monoamine oxidase and the anticonvulsant activities possessed by the inhibitors of monoamine oxidase (8) led to the synthesis of 2-(4-arylthiosemicarbazidocarbonylthio)benzthiazoles. In the present study, all substituted benzthiazoles possessed anticonvulsant activity and inhibited monoamine oxidase activity of rat brain homogenate.

The various substituted benzthiazoles were synthesized by following the methods outlined in Scheme I.

EXPERIMENTAL[1]

Chemistry—Ten 2-(4-arylthiosemicarbazidocarbonylthio)benzthiazoles were synthesized from 2-mercaptobenzthiazole. 2-Mercaptobenzthiazole was first treated with ethyl chloroformate in the presence of dry acetone and anhydrous potassium carbonate to yield 2-(ethoxycarbonylthio)benzthiazole, and then the resulting product was converted into 2-(hydrazinocarbonylthio)benzthiazole by refluxing with hydrazine hydrate on a steam bath in absolute ethanol. The hydrazide thus formed was refluxed with suitable arylisothiocyanates in dry benzene to form the desired 2-(4-arylthiosemicarbazidocarbonylthio)benzthiazoles (Compounds I–X).

2-(Ethoxycarbonylthio)benzthiazole—A mixture of 2-mercaptobenzthiazole (0.01 mole) in dry acetone, containing anhydrous potassium carbonate (0.011 mole) and ethyl chloroformate (0.01 mole), was refluxed on a steam bath for 16–18 hr. The mixture was filtered and the excess acetone from the filtrate was removed by distillation. The solid mass, which separated on cooling, was collected by filtration, washed with water, and recrystallized from ethanol, mp 63° [lit. (9) mp 64°].

[1] All compounds were analyzed for their carbon, hydrogen, and nitrogen content. Melting points were taken in open capillary tubes with partial immersion thermometer and are corrected.

modates only about three cupric ions, which are relatively tightly bound, while the other accommodates about 16 cupric ions, which are rather weakly bound. It is possible that the first three cupric ions bind intimately by penetrating the protein while the rest of the cupric ions bind weakly to the surface of the protein.

[a] Melting points were taken in open capillary tubes with a partial immersion thermometer and are corrected.

2-(Hydrazinocarbonylthio)benzthiazole—To a solution of 2-(ethoxycarbonylthio)benzthiazole (0.01 mole) in absolute ethanol was added 99–100% hydrazine hydrate (0.02 mole), and the mixture was refluxed on a steam bath for 10–12 hr. Excess ethanol was distilled and the precipitated crude product was collected, dried, and recrystallized from ethanol, mp 199–200° [lit. (9) mp 201°].

2-(4-Arylthiosemicarbazidocarbonylthio)benzthiazoles (I–X)—Equimolar portions of 2-(hydrazinocarbonylthio)benzthiazole and the suitable arylisothiocyanate were mixed in dry benzene, and the mixture was refluxed on a steam bath for 6 hr. The mixture was concentrated by removing benzene by distillation. The crude product, which separated on cooling, was collected by filtration; it was washed first with ether, then with dilute hydrochloric acid, and finally with water and was recrystallized from dimethylformamide (Table I).

Determination of Monoamine Oxidase Activity—*Spectrophotofluorometric Method*—Male albino rats, 100–150 g, were allowed food and water *ad libitum* until they were sacrificed by decapitation. The brains were removed immediately and homogenized[2] in the ratio of 1:9 (w/v) in ice-cold 0.25 *M* sucrose. The monoamine oxidase activity of rat brain homogenate was determined by incubation at 37° in air for 30 min, using kynuramine as the substrate (10). The reaction mixture in a total volume of 3 ml consisted of 0.5 ml of phosphate buffer (0.2 *M*, pH 7.5), 0.1 m*M* kynuramine, and 0.5 ml of brain homogenate (equivalent to 10 mg wet weight of the tissue).

The various 2-(4-arylthiosemicarbazidocarbonylthio)benzthiazoles were dissolved in propylene glycol (100%) and added to the brain homogenate to produce a final concentration of 0.5 m*M*. An equivalent amount of propylene glycol was added to the control tubes, and the mixture was incubated for 10 min before the addition of kynuramine. After the addition of kynuramine, the mixture was further incubated for 30 min. The reaction was stopped by the addition of 1 ml of 10% trichloroacetic acid (w/v), and the precipitated proteins were removed by centrifugation. Suitable 1-ml aliquots of the supernatant solution were taken in 2 ml of 1 *N* NaOH solution and were assayed for 4-hydroxyquinoline, formed during oxidative deamination of kynuramine by rat brain homogenate.

The 4-hydroxyquinoline formed was measured fluorometrically[3], using activating light of 315 nm and measuring fluorescence at the maximum of 380 nm. An increase in absorbance provided a direct measurement of 4-hydroxyquinoline formation, which was taken as an index of the monoamine oxidase activity. The percentage inhibition was calculated from the decrease observed in absorbance, and this value provided an index of the inhibitory property of these substituted benzthiazoles.

Warburg Manometric Method—The monoamine oxidase activity of rat brain homogenate was determined by the conventional Warburg manometric technique, using tyramine and 5-hydroxytryptamine as the substrates (10). The decrease in oxygen uptake for 1 hr during oxidative deamination of tyramine or 5-hydroxytryptamine in the presence of the substituted benzthiazoles was used as an index of enzyme inhibition. The reaction mixture in a final concentration consisted of 50 m*M* phosphate buffer (pH 7.5),

Table II—Monoamine Oxidase Inhibitory and Anticonvulsant Activity of 2-(4-Arylthiosemicarbazidocarbonylthio)benzthiazoles

Compound	Monoamine Oxidase Inhibition[a], %			Anticonvulsant Activity[b], % Protection	Pentylenetetrazol Mortality[c], % after 24 hr
	Kynuramine	Tyramine	5-Hydroxytryptamine		
I	30.0 ± 1.0	12.1 ± 0.7	14.8 ± 0.9	20	40
II	71.4 ± 0.8	29.2 ± 1.0	18.8 ± 0.9	20	60
III	61.4 ± 0.8	39.0 ± 0.9	28.3 ± 0.7	30	50
IV	74.3 ± 0.7	28.2 ± 0.9	19.2 ± 0.8	30	50
V	87.1 ± 0.6	24.6 ± 0.6	29.3 ± 1.0	50	50
VI	70.0 ± 1.0	29.6 ± 0.7	49.9 ± 0.8	10	90
VII	68.6 ± 1.0	23.8 ± 0.7	30.1 ± 0.7	50	70
VIII	65.0 ± 0.8	17.8 ± 0.9	26.0 ± 0.5	50	40
IX	77.9 ± 0.5	36.5 ± 0.6	46.9 ± 0.9	30	50
X	34.3 ± 0.8	7.9 ± 0.8	8.7 ± 1.1	60	40

[a] The reaction mixture and assay procedures are described in the text. Each experiment was done in triplicate, and the values are the means of three separate experiments ± *SE*. [b] Screening procedures for the determination of anticonvulsant activity are described in the text. [c] Mortality in pentylenetetrazol-treated mice was observed during 24 hr.

10 m*M* tyramine or 5-hydroxytryptamine, and rat brain homogenate (equivalent to 250 mg of fresh tissue weight) in a total volume of 3 ml.

The various substituted benzthiazoles were dissolved in propylene glycol (100%), used at a final concentration of 1 m*M*, and were incubated with the enzyme preparation for 20 min before tyramine or 5-hydroxytryptamine was added. The enzyme system was then incubated for an additional hour at 37°, using oxygen as the gaseous phase. Readings of oxygen uptake were made every 10 min.

Determination of Anticonvulsant Activity—Anticonvulsant activity of substituted benzthiazoles was determined (11) in mice, 25–30 g, of either sex. The mice were divided in groups of 10, keeping the group weights as near the same as possible. Each test compound was suspended in 5% aqueous gum acacia to give a concentration of 0.25% (w/v) and was injected in a group of 10 mice at a dose of 100 mg/kg ip. Four hours after the administration of the substituted benzthiazoles, the mice were injected with pentylenetetrazol (90 mg/kg sc). This dose of pentylenetetrazol not only produced convulsions in almost all untreated mice but also exhibited 100% mortality during 24 hr. No mortality was observed during 24 hr in animals treated with 100 mg/kg alone of the test compounds.

The mice were observed 60 min for seizures. An episode of clonic spasm that persisted for a minimum of 5 sec was considered a threshold convulsion. Transient intermittent jerks and tremulousness were not counted. Animals devoid of threshold convulsions during 60 min were considered protected. The number of mice protected in each group was recorded, and the anticonvulsant activity of 2-(4-arylthiosemicarbazidocarbonylthio)benzthiazoles was represented as percent protection. The mice were then observed for 24 hr, and their mortality was recorded.

RESULTS AND DISCUSSION

The inhibitory effects of 2-(4-arylthiosemicarbazidocarbonylthio)benzthiazoles on the monoamine oxidase activity of rat brain homogenate during oxidative deamination of different substrates and their ability to afford protection against pentylenetetrazol-induced convulsions are recorded in Table II. The results indicated greater sensitivity of these substituted benzthiazoles toward monoamine oxidase during oxidative deamination of kynuramine, as reflected by higher inhibition of monoamine oxidase compared to inhibition observed when tyramine or 5-hydroxytryptamine was the substrate. Similar changes in the degree of monoamine oxidase inhibition also have been observed with other inhibitors during oxidative deamination of different substrates (7, 12).

The presence of substituents on the phenyl group of the thiosemicarbazide moiety influenced their ability to inhibit monoamine oxidase. Introduction of a substituent in the phenyl ring of these substituted benzthiazoles increased the degree of monoamine oxidase inhibition, with the exception of α-naphthyl substitution (X), which caused lowering of inhibition when tyramine or 5-hydroxytryptamine was the substrate. Among halogen-substituted benzthiazoles (VII–IX), the iodo-substituted benzthiazole (IX) possessed maximum monoamine oxidase inhibitory activity.

All 2-(4-arylthiosemicarbazidocarbonylthio)benzthiazoles possessed measurable anticonvulsant activity and exhibited some protection against pentylenetetrazol-induced 24 hr mortality in experimental mice (Table II).

Cardiotonic Steroids II: 3-Deoxycardenolides and 3-Deoxycardanolides

THOMAS R. WITTY *, WILLIAM A. REMERS *x, and H. R. BESCH, Jr. ‡

Abstract □ A series of compounds related to 3-deoxydigitoxigenin was prepared and assayed for inhibition of myocardial Na^+,K^+-adenosine triphosphatase. Although the relatively high activity of 3-deoxydigitoxin was confirmed, the corresponding 3β,4β-epoxide and a mixture of 2,3-olefins and 3,4-olefins were less active. 3-Deoxy compounds with variations at the 14-position and the butenolide ring were much less active than the corresponding 3β-hydroxy analogs. Thus the activity of 3-deoxydigitoxigenin appears to be particularly susceptible to structural changes elsewhere in the molecule.

Keyphrases □ 3-Deoxydigitoxigenin analogs—synthesis and inhibition of Na^+,K^+-adenosine triphosphatase □ Cardenolide and cardanolide derivatives—synthesis of 3-deoxydigitoxigenin analogs, inhibition of Na^+,K^+-adenosine triphosphatase □ Cardiotonic steroids—synthesis of 3-deoxydigitoxigenin analogs, inhibition of Na^+,K^+-adenosine triphosphatase □ Structure–activity relationships—3-deoxydigitoxigenin analog inhibition of Na^+,K^+-adenosine triphosphatase

For many years it was accepted that a 3β-oxygen function was indispensable to the activity of cardiotonic steroids (1). Useful oxygen functions were exemplified by glycosides, ketals, esters, and the free hydroxy group. However, recent reports that 3-deoxydigitoxigenin (Ia) shows cardiotonic activity comparable to that of digitoxigenin (IIa) in the isolated frog heart (2) and in a Na^+,K^+-adenosine triphosphatase inhibition assay (3) appeared to refute this concept. These reports prompted a more extensive investigation on 3-deoxydigitoxigenin analogs, including compounds where the 14-substituent and the butenolide ring were varied (4).

One purpose of this investigation was to determine if the 3-deoxydigitoxigenin structure was more sensitive in biological activity to changes elsewhere in the molecule than was digitoxigenin. Another purpose was to generate some parent cardenolide and cardanolide structures (*e.g.*, IVa and IVb) since these compounds, although unlikely to have potent cardiotonic activity, might serve as starting points for structure–activity relationships.

RESULTS AND DISCUSSION

Synthesis—3-Deoxydigitoxigenin (Ia) was prepared from a mixture of 2,3- and 3,4-dehydrodigitoxigen isomers as described previously (2). This olefin mixture also was converted by *m*-chloroperbenzoic acid into two compounds, but only one could be purified. It is considered to be the 3β,4β-epoxide (V) for the following reasons. The NMR spectrum showed a broad, unsymmetrical pattern of peaks for the protons attached to the epoxide ring. This pattern is consistent with a 3,4-epoxide but not a 2,3-epoxide. Since the α-side of the 3,4-olefin from which V is derived has significant steric crowding (as determined from Dreiding models), *m*-chloroperbenzoic acid should form preferentially the β-epoxide. Literature precedent also exists for the selective formation of β-epoxides from ring A olefins in 5β-steroids (5).

Treatment of Ia with thionyl chloride gave the 14-olefin (IIIa), which was converted into 14β,15β-epoxide (VI) by *N*-bromoacetamide (Scheme I). Catalytic hydrogenation of IIIa gave 5β,14α-cardenolide (IVa) when palladium-on-barium sulfate was the catalyst, but the corresponding cardanolide [IVb, mixture of 20(*R*)- and 20(*S*)-epimers] was obtained when platinum was the catalyst. The pure 20(*R*)-epimer was reported previously (6). Hydrogenation of Ia in the presence of platinum gave 14β-hydroxycardanolide [Ib, mixture of 20(*R*)- and 20(*S*)-epimers], which afforded the 14-olefin (IIIb) upon treatment with thionyl chloride.

Table I—K_I Values for the Inhibition of Na^+,K^+-Adenosine Triphosphatase

Compound	K_I, μM
IIa (digitoxigenin)	0.043
Mixture of 2- and 3-dehydro-3-deoxydigitoxigenin	0.16
Ia (3-deoxydigitoxigenin)	0.076
V	0.65
IIIa	17.0
VI	100.0
IVb	>100.0
Ib	25.0
IIb (20,22-dihydrodigitoxigenin)	2.3

Biological Testing—Certain cardenolides and cardanolides were tested for their ability to inhibit a Na^+,K^+-stimulated, Mg^{+2}-dependent adenosine triphosphatase isolated from calf or canine myocardium (7). The ability of a large number of cardenolides to inhibit specifically this adenosine triphosphatase has been shown to correlate well with their positive inotropic activity (8, 9).

As recorded in Table I, the relatively high potency of Ia was confirmed. In this assay, it had 0.57 times the potency of digitoxigenin. No other compound had comparable activity, although the olefin mixture (2) was 0.22 times as potent as digitoxigenin. The 3β,4β-epoxide (V) had 0.066 times the activity of digitoxigenin, whereas the 14β,15β-epoxide (VI) had very poor activity (0.0004 times digitoxigenin). The 14-olefin (IIIa) was somewhat more active than VI, in contrast to the relative order of activity of 14-ene and 14β,15β-epoxide in the digitoxigenin-3-acetate series (4).

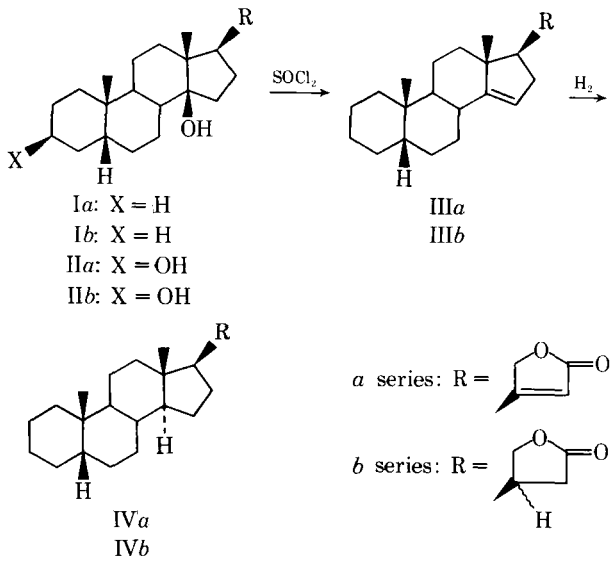
Of the saturated lactone compounds, 20,22-dihydrodigitoxigenin (IIb) (10) had 0.019 times the activity of digitoxigenin, but the 3-deoxy analog (Ib) had only 0.0017 times its activity. Thus, it appears that changes in the structure of 3-deoxydigitoxigenin result in much greater loss of activity than those occurring when corresponding changes are made in the digitoxigenin structure.

The parent 5β,14α-cardanolide (IVb) was too inactive to give a 50% inhibition value in the assay. Compounds IVa and IIIb lacked sufficient solubility for evaluation of their activities.

EXPERIMENTAL[1]

14-Hydroxy-3β,4β-oxido-5β,14β-card-20(22)-enolide (V)—A solution of 356 mg of the mixture of isomers, 14-hydroxy-5β,14β-carda-2,20(22)-dienolide and 14-hydroxy-5β,14β-carda-3,20(22)-dienolide (2), in 2.5 ml of methylene chloride was treated with 173 mg of *m*-chloroperbenzoic acid. After 2 hr, a small amount of sodi-

[1] Melting points were determined on a Mel-Temp apparatus and are uncorrected. IR absorption spectra were recorded on a Perkin-Elmer 237B spectrophotometer using $CHCl_3$ solutions or KBr disks. NMR spectra were determined in $CDCl_3$ using tetramethylsilane as the reference on a Varian XL-100 spectrometer. Mass spectra were determined on a Consolidated Electronics Corp. 21-110B mass spectrometer. Microanalyses were carried out by the Microanalytical Laboratory, Department of Chemistry, Purdue University. A Guilford recording spectrophotometer with a Hoake constant-temperature bath was used for the biological assay.



Scheme I

um bisulfite was added followed by 5% sodium bicarbonate solution. The organic layer was washed with water, dried (magnesium sulfate), and concentrated.

Chromatography of the crude product on silica gel, with chloroform–acetone (6:1) as the solvent, gave starting material followed by two new components. The first of these compounds, after two recrystallizations from acetone–petroleum ether, gave 70 mg of needles, mp 206–209°; IR (KBr): 5.75 (butenolide) μm; NMR: δ 5.84 (m, 1, vinyl of butenolide), 5.02 and 4.76 (each m, 1 each, methylene of butenolide), complicated asymmetrical multiplet with main peaks at 3.22, 3.19, 3.12, 3.07, 3.00, and 2.96 (2, protons on epoxide ring), 2.78 (m, 1, allylic 17-proton), and 0.89 (6, angular methyls) ppm.

Anal.—Calc. for $C_{23}H_{32}O_4$: C, 74.16; H, 8.66. Found: C, 74.22; H, 8.73.

The second component gave, upon concentration, a small amount of glassy solid, mp 75–87°, after recrystallization from acetone–hexane. It was not investigated further.

5β-Carda-14,20(22)-dienolide (IIIa)—A solution of 360 mg of 3-deoxydigitoxigenin (Ia) (2) in 24 ml of pyridine was cooled to −20° and treated dropwise with 1.2 ml of thionyl chloride in 12 ml of pyridine. After the mixture was stirred for 1 hr at 0°, it was worked up in the usual way (4) to give 270 mg (79%) of white crystals, mp 164–164.5°, after recrystallization from ethyl acetate–methanol.

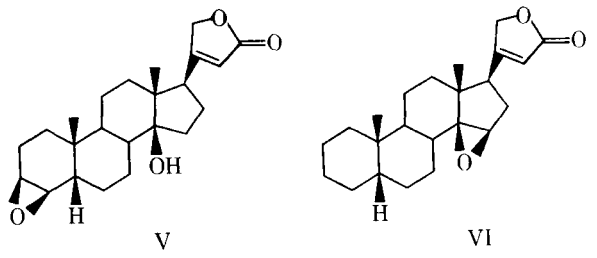
Anal.—Calc. for $C_{23}H_{32}O_2$: C, 81.13; H, 9.47. Found: C, 81.06; H, 9.52.

14β,15β-Oxido-5β,14β-card-20(22)-enolide (VI)—A solution of 200 mg of IIIa in 8 ml of acetone containing 0.8 ml of water was treated with 200 mg of *N*-bromoacetamide. The mixture was kept in the dark, and 60-mg portions of *N*-bromoacetamide were added at 24 and 48 hr. After 84 hr, the mixture was worked up in the usual way (4) and the product was purified by chromatography on silica gel with chloroform–acetone (6:1) as the solvent. Recrystallization of the product from ether gave colorless needles, mp 220–222°; the mass spectrum showed a molecular ion at M^+ 356.

Anal.—Calc. for $C_{23}H_{32}O_3$: C, 77.49; H, 9.05. Found: C, 77.24; H, 8.82.

5β,14α-Card-20(22)-enolide (IVa)—A mixture of 100 mg of 5β-carda-14,20(22)-dienolide (IIa), 20 ml of acetic acid, and 100 mg of 5% palladium-on-barium sulfate was shaken with hydrogen at an initial pressure of 1.1 kg/cm² (15 psi) for 5 hr. It then was filtered and concentrated to a solid, which was recrystallized from methylene chloride–methanol and then from methanol to give 33 mg of colorless needles, mp 154–155°; IR (KBr): 5.75 (butenolide) μm; NMR: δ 5.85 (m, 1, butenolide vinyl proton) ppm. The analytical sample was recrystallized once more from methanol, mp 166–166.5°.

Anal.—Calc. for $C_{23}H_{34}O_2$: C, 80.65; H, 10.01. Found: C, 80.40; H, 9.72.



5β,14α-Cardanolide [20(*R,S*)] (IVb)—A mixture of 150 mg of IVa, 35 ml of ethanol, and 100 mg of platinum oxide was shaken with hydrogen at an initial pressure of 0.7 kg/cm² (10 psi) for 1 hr. It then was filtered and concentrated to give 91 mg of a solid, mp 174–175°, after two recrystallizations from ethyl acetate–methanol; IR (KBr): 5.62 (saturated γ-lactone) μm. The NMR spectrum showed an angular methyl group at δ 0.66 ppm, which confirms the saturated lactone (11).

Anal.—Calc. for $C_{23}H_{36}O_2$: C, 80.18; H, 10.53. Found: C, 80.34; H, 10.70.

14-Hydroxy-5β,14β-cardanolide [20(*R,S*)] (Ib)—A mixture of 100 mg of Ia, 25 ml of ethanol, and 100 mg of platinum oxide was shaken with hydrogen at an initial pressure of 0.7 kg/cm² (10 psi) for 1 hr. It then was filtered and concentrated to a solid (101 mg), mp 170–172°, after recrystallization from ethyl acetate–methanol. Repeated recrystallizations from methanol failed to separate the mixture of 20(*R,S*)-epimers. The analytical sample had a melting point of 185–190° with softening at 175°; IR (KBr): 5.62 (saturated γ-lactone) μm. The NMR spectrum showed approximately equal peaks at δ 0.94 and 0.92 ppm, the 18-methyl groups for the epimers.

Anal.—Calc. for $C_{23}H_{36}O_3$: C, 76.62; H, 10.06. Found: C, 76.52; H, 9.98.

5β-Card-14-enolide [20(*R,S*)] (IIIb)—A solution of 90 mg of Ib in 3 ml of pyridine was treated at −20° with 0.3 ml of thionyl chloride. The solution was stirred for 1 hr at 0° and then worked up in the usual way (4). The product (26 mg) had a melting point of 166–167° after two recrystallizations from methylene chloride–methanol; IR (KBr): 5.62 (saturated γ-lactone) μm; NMR: δ 5.15 (m, 1, 15-vinyl proton) and 0.89 (s, 6, 18-methyl and 19-methyl) ppm.

Anal.—Calc. for $C_{23}H_{34}O_2$: C, 80.65; H, 10.01. Found: C, 80.63; H, 9.88.

Biological Assay—The Na^+,K^+-adenosine triphosphatase activity was determined by continuously monitoring at 340 nm the oxidation of NADH linked *via* a series of enzymatic reactions to the hydrolysis of ATP (12). This assay was described in detail previously (4).

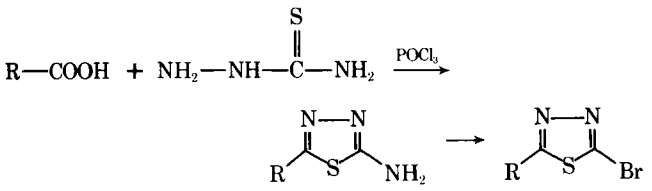
Synthesis and Pharmacological Activity of 5-Substituted 2-(*N,N*-Dialkylaminoethyl)amino- and 2-*N*-Methylpiperazinyl-1,3,4-thiadiazoles

I. LALEZARI *ˣ, A. SHAFIEE *, A. BADALY *, M. M. SALIMI ‡, M. A. KHOYI ‡, F. ABTAHI ‡, and M. R. ZARRINDAST ‡

Abstract □ 5-Substituted 2-amino-1,3,4-thiadiazoles were transformed to their corresponding 2-bromo derivatives. The reaction of the 5-substituted 2-bromo-1,3,4-thiadiazoles with *N,N*-dialkylaminoethylamines or *N*-methylpiperazine afforded the corresponding amino-1,3,4-thiadiazole derivatives. All prepared compounds displayed antihistaminic, anticholinergic, and norepinephrine-potentiating activities.

Keyphrases □ 1,3,4-Thiadiazoles, 5-substituted 2-(*N,N*-dialkylaminoethyl)amino and 2-*N*-methylpiperazinyl—synthesis, antihistaminic, anticholinergic, and norepinephrine-potentiating activities □ 2-(*N,N*-Dialkylaminoethyl)amino-1,3,4-thiadiazoles, 5-substituted—synthesis and pharmacological activity □ 2-*N*-Methylpiperazinyl-1,3,4-thiadiazoles, 5-substituted—synthesis and pharmacological activity □ Antihistaminic, anticholinergic, and norepinephrine-potentiating activities—synthesis and screening of 5-substituted 2-(*N,N*-dialkylaminoethyl)amino- and 2-*N*-methylpiperazinyl-1,3,4-thiadiazoles

In continuing studies on the chemistry and pharmacological activity of 1,3,4-thiadiazoles and their derivatives, it was of interest to introduce the =N—CH_2CH_2—N= moiety, the important group in known compounds with antihistaminic activity, to the 1,3,4-thiadiazole ring system. A previously reported method was used for the preparation of 2-amino-5-substituted-1,3,4-thiadiazoles (1, 2); the 2-amino compounds were then transformed to their corresponding 2-bromo compounds by a modified Sandmeyer reaction (3) (Scheme I).



Scheme I

The 2-bromo-5-substituted-1,3,4-thiadiazoles thus obtained were subjected to a nucleophilic substitution reaction with *N*-methylpiperazine or asymmetrical dialkylaminoethylamine (Scheme II).

filtration and the benzene solution was extracted with 5% hydrochloric acid. The aqueous layer was evaporated under reduced pressure, and the solid residue was recrystallized from absolute ethanol.

The free base of 5-phenyl-2-*N*-methylpiperazinyl-1,3,4-thiadiazole was prepared as follows. The hydrochloride was dissolved in water and made basic with concentrated sodium hydroxide, and the solid was separated and recrystallized from ethyl acetate, mp 112°.

Physical properties of the synthesized compounds are found in Tables I and II.

Antihistaminic and Anticholinergic Activities—Isolated guinea pig ileum was prepared according to the method of Magnus (4) and suspended in a 10-ml bath filled with Tyrode solution, which was aerated at 30°. The isotonic contractions were magnified sixfold and recorded with a frontal writing lever on smoked drum. The pA_2 values were determined by the method of Schild (5).

Table III—Antihistaminic, Anticholinergic, and Norepinephrine-Potentiating Effects of 5-Substituted 2-(*N,N*-Dialkylaminoethyl)amino- and 2-*N*-Methylpiperazinyl-1,3,4-thiadiazoles[a]

Atropine	—	9.84 ± 0.17 (4)	—
Diphenhydramine	9.74 ± 0.42 (4)	—	—
Cocaine	—	—	28.95 ± 10.83

[a] Values are expressed as mean ±*SE*. Numbers in parentheses indicate the number of experiments. When studying the norepinephrine-potentiating effect, Compounds 7*a*, 8*a*, and 9*a* were used in a concentration of 1×10^{-6} *M* and the other compounds were used in a concentration of 1×10^{-5} *M*.

Histamine and acetylcholine were used as agonists, and diphenhydramine and atropine were tested for comparison.

Norepinephrine-Potentiating Effect—Preliminary experiments revealed that some of these compounds potentiated the effect of norepinephrine on vas deferens; therefore, Compounds 4*a*, 7*a*, 8*a*, 9*a*, 3*b*, 13*b*, 14*b*, and 17*b* were tested on isolated rat vas deferens. The tissue was mounted in the bath under 1 g of tension. Isometric contractions were amplified and recorded[1] through a photosensitive myograph transducer. The test compounds were added 3 min before norepinephrine administration, and results were compared with contraction induced by norepinephrine in the absence of the compounds.

LD_{50} Determination—The toxicity of the sufficiently available compounds was determined in ordinary mice by the moving average method (6). The compounds were injected intraperitoneally; six animals were used for each dose.

RESULTS AND DISCUSSION

The potency of antihistaminic and anticholinergic activities is given in Table III and compared with diphenhydramine and atropine. The pA_2 values show that dialkylaminoethylamine derivatives possessed approximately three to four times more antihistaminic and anticholinergic potency than *N*-methylpiperazine derivatives.

Nitrophenyl, bromophenyl, and methoxyphenyl as well as trifluoromethyl compounds were found to be more active. Compounds substituted in the *para*-position were more active than the corresponding *ortho*- and *meta*-substituted derivatives. 5-Trifluoromethyl-2-*N*-methylpiperazinyl-1,3,4-thiadiazole was much more active than the corresponding 5-methyl, 5-ethyl, and 5-phenyl derivatives.

In the ethylenediamine series, compounds having a diethyl group were two to three times more active as compared with dimethyl derivatives, probably due to an increase in hydrophobicity.

It is also suggested that the lower activity in the piperazine series is due to the large size of the piperazine moiety of the molecule.

The potentiation of the effect of norepinephrine on α-receptors of vas deferens by these compounds, particularly 9*a*, is remarkable as compared with that of cocaine. This effect was significantly greater with the ethylenediamine series as compared with the piperazine series (Table III).

The LD_{50}'s of Compounds 2*b*, 3*b*, 4*b*, and 7*a* were 124.4 (107.4–144), 51.7 (44.2–60.5), 261.7 (222.7–307.5), and 148.2 (120.5–182.4) mg/kg, respectively. The trifluoromethyl group increased the toxicity of the compounds.

The animals showed hyperexcitability and tonic convulsions before death.

Interaction of Substituted Benzoic Acids with Polysorbate 20 Micelles

J. H. COLLETT [x] **and L. KOO**

Abstract □ Equilibrium solubilities of a series of substituted benzoic acids in different concentrations of polysorbate 20 at controlled pH were measured. The maintenance of pH was achieved using a pH-stat assembly. A linear relationship was found between the amount of benzoic acid solubilized and surfactant concentration. As solubilizate polarity increased, the amount solubilized also increased. Solubility data were analyzed, and the interaction between solubilizate molecules and micelles was calculated in terms of partition coefficients of ionized and unionized molecules between aqueous and micellar phases. A linear relationship between π values (log partition coefficients) of functional groups and aqueous–micellar partition coefficient was found.

Keyphrases □ Benzoic acid and derivatives—solubilization in polysorbate 20 at controlled pH, partition coefficients between aqueous and micellar phases □ Polysorbate 20—effect on solubilization of benzoic acid and derivatives at controlled pH, partition coefficients between aqueous and micellar phases □ Micellar–aqueous partition coefficients—benzoic acid and derivatives in polysorbate 20 □ Solubilization, benzoic acid and derivatives—effect of various polysorbate 20 concentrations at controlled pH

There are various methods of studying solubilization including equilibrium dialysis, molecular sieving, potentiometry, and solubility measurement. Although they all have limitations (1), they have been used to provide useful data of micellar solubilization of benzoic acid derivatives (2–5) and barbiturates (6) by micelles of nonionic surfactants. None of the reports has given information of the interactions of the ionized and unionized solubilizate moieties with the surfactant. Such information can be obtained for weakly ionizing compounds from analysis of equilibrium solubility data in surfactant solutions at different pH values (7).

This report describes the solubilization of a series of substituted benzoic acids in polysorbate 20. Partition ratios of ionized and unionized molecules between aqueous and micellar phases were calculated, and correlations between these values and substituent parameters of the solubilizate were examined.

EXPERIMENTAL

Materials—Polysorbate 20 (polyoxyethylene 20 sorbitan monolaurate) was used as received. It was characterized by its mass spectrum and proton magnetic resonance spectrum (8) and found to contain 21 oxyethylene units/molecule.

Benzoic acid and its 2-hydroxy, 3-hydroxy, 4-hydroxy, 4-chloro, 4-bromo, 4-iodo, 4-nitro, and 4-methoxy derivatives[1] were used as solubilizates. They were chosen because they represent typical weak acids with low aqueous solubility and are capable of being absorbed from the stomach in an unionized form.

Assay—Benzoic acids were assayed by UV absorption spectroscopy. The presence of polysorbate 20 at the concentration in the diluted solutions did not interfere with the assay either by absorption at the wavelengths used or by shifting the absorption peak.

Solubility—An excess of benzoic acid or its derivatives was added to 30-ml volumes of aqueous solutions containing different concentrations of polysorbate 20. The pH of the solution was adjusted by the addition of sufficient hydrochloric acid or sodium hydroxide. The volume of adjusting solution added was known, thereby permitting correction of polysorbate concentrations due to dilution. The pH was maintained by the addition of acid or alkali by the automatic control of a pH-stat assembly[2]. Solutions were stirred in a water-jacketed vessel at 25° during the initial pH adjustment.

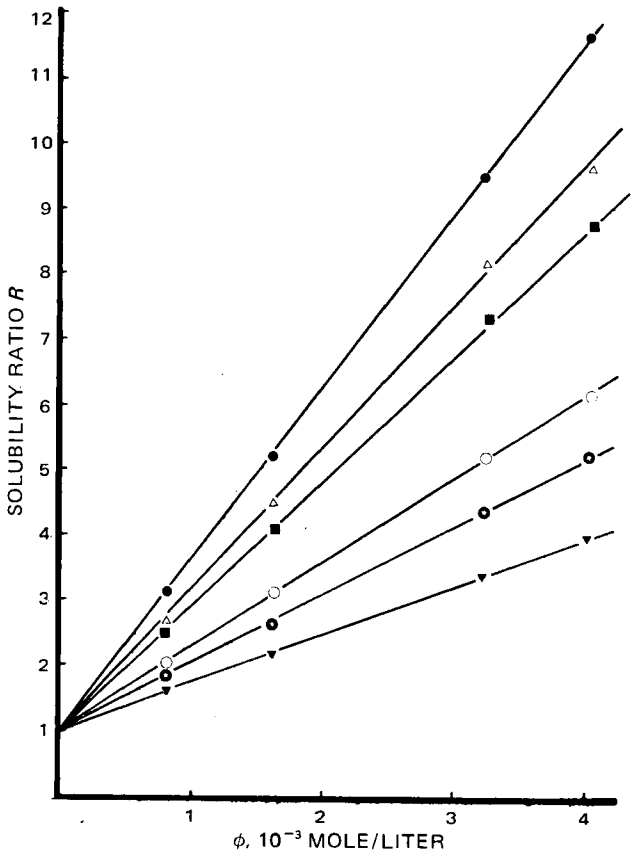

Figure 1—*Solubility of 4-chlorobenzoic acid in different concentrations of polysorbate 20 at different pH's. Key:* ●, *3.00;* △, *3.40;* ■, *3.62;* ○, *4.00;* ❂, *4.15; and* ▼, *4.40.*

After pH adjustment, the solutions were placed in 50-ml erlenmeyer flasks[3] and then shaken for 48 hr in a water bath at 25°; the pH was checked periodically. In the presence of surfactant, the addition of electrolytes not exceeding an ionic strength of 0.2 mole/liter had no effect on the solubility of the benzoic acids. This ionic strength is greater than that produced by the addition of hydrochloric acid or sodium hydroxide to control pH. After equilibration, aliquot samples were filtered through 0.45-μm filters[4] and assayed for benzoic acid content.

Density—Apparent densities of polysorbate 20 in 1, 2, 4, and 5% (w/v) aqueous solutions were determined at 25° using 50-ml density bottles.

[a] Column (a) represents the slope of solubility curves expressed in terms of molar ratios of solubilizate to polysorbate 20 concentration. [b] Column (b) represents the slope of solubility ratios obtained from plots of R against ϕ.

RESULTS AND DISCUSSION

Solubilities of the substituted benzoic acids in solutions containing graded concentrations of polysorbate 20 were measured at different pH values between 0.5 pH unit above and 1.0 pH unit below the pKa of the substituted benzoic acids. Typical solubility curves of 4-chlorobenzoic acid in solutions of different concentrations of polysorbate 20 at different pH values are shown in Fig. 1. At any one pH, solubility increased linearly with surfactant concentration. This observation is in agreement with other reports (1–4) and is attributed to solubilization of the acid by micelles of the surfactants.

The slopes of solubility curves for substituted benzoic acids at different pH values in graded concentrations of surfactant are shown in Table I. In each case, a linear relationship was observed, as would be expected for the solubilization of polar solubilizates. For each compound, the slope of molar ratio of solubilizate to polysorbate 20 concentration was similar at all pH values. The slope of the curves for each compound increased with decreasing polarity. A similar observation, that the amount of substituted benzoic acid solubilized by a surfactant increased as the polarity of the drug increased, has been reported (6).

Increased solubilization may have resulted from the smaller size of the benzoic acids. Although the polarity of solubilizate molecules is usually the most important factor determining their degree of solubilization, the molar volume of solubilizate has also been considered to be a significant factor. The volume of various hydrocarbons solubilized by potassium laurate was found to be inversely related to the molar volume of hydrocarbons (9). Alternatively, there may be some solubilization within the polyoxyethylene chains, and increased solubilizate polarity will result in an increased amount of solubilization at this site.

A treatment of solubility data (7, 10) based on the pseudophase model of surfactant solutions permits the individual quantification of the interactions of both ionized and unionized solubilizate molecules with surfactant. The concentration of solubilizate in the micellar phase is related to its concentration in the aqueous phase by:

$$P = \frac{(C_m)}{(C_a)} \qquad \text{(Eq. 1)}$$

where C denotes concentration; subscripts a and m refer to aqueous and micellar phases, respectively; and P is the micellar–aqueous partition coefficient. If concentrations are expressed in terms of the total volume of the system rather than the volumes of individual phases, then:

$$P = \frac{(C_m)}{(C_a)}\left(\frac{1}{\phi}\right) \qquad \text{(Eq. 2)}$$

where ϕ, the volume fraction of surfactant, is small (ϕ is the volume of the surfactant as a fraction of the total volume of the solution containing the surfactant).

The ratio, R, of solubility in surfactant to solubility in water is given by:

$$R = \frac{(C_m^-) + (C_m^0)}{(C_a^-) + (C_a^0)} + 1 \qquad \text{(Eq. 3)}$$

where superscripts 0 and − denote unionized and ionized solubilizate, respectively. A plot of R against volume fraction, ϕ, of surfactant has an intercept on the R axis of unity. The slope, S, of the plot is:

$$S = \frac{(C_m^-) + (C_m^0)}{(C_a^-) + (C_a^0)}\left(\frac{1}{\phi}\right) \qquad \text{(Eq. 4)}$$

Table I gives values of S obtained from plots of R against ϕ at several pH values. The slope, S, for any one compound decreases with an increase in pH. The higher solubilizing capacity of polysorbate 20 at pH values where the solute is predominantly unionized indicates that this form of the acid is solubilized to a greater extent than the ionized form.

Values of S at different pH's can be plotted against the fraction, fi, of ionized solubilizate present. At $fi = 1.0$, Eq. 4 becomes:

$$S = \frac{(C_m^-)}{(C_a^-)}\left(\frac{1}{\phi}\right) \qquad \text{(Eq. 5)}$$

and the value of S at $fi = 1.0$ is the partition coefficient of ionized molecules between surfactant micelles and water.

The micellar–aqueous partition coefficients of unionized benzoic acid derivatives and their respective lipophilicity expressed in terms of the hydrophobic–lipophilic constant, π (13), of the functional groups are presented in Table II (π is defined as $\pi = \log P_X - \log P_H$, where P_X is the partition coefficient of a derivative and P_H is the partition coefficient of the parent compound).

Table II—Partition Coefficient of Unionized Species and π (13) Values of the Respective Functional Group of Benzoic Acid Derivatives

Compound	Partition Coefficient of Unionized Moiety	π
Benzoic acid	43.5	0
2-Hydroxybenzoic acid	83.0	—
3-Hydroxybenzoic acid	28.5	−0.38
4-Hydroxybenzoic acid	30.8	−0.30
4-Chlorobenzoic acid	277.0	0.87
4-Bromobenzoic acid	445.0	0.98
4-Iodobenzoic acid	678.0	1.14
4-Nitrobenzoic acid	92.7	0.02
4-Methoxybenzoic acid	66.5	0.08

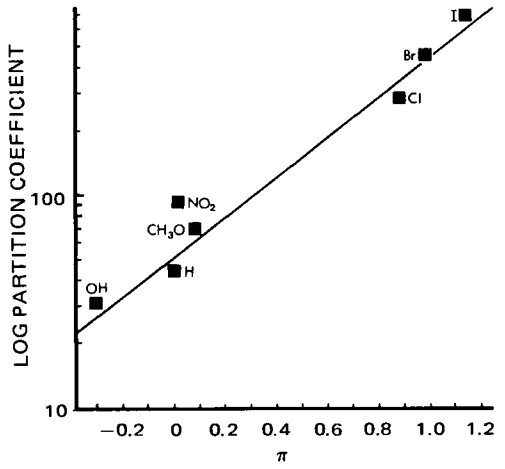

Figure 2—*Micellar–aqueous partition coefficients of substituted benzoic acids and π values of the functional groups.*

It can be seen in Fig. 2 that as the lipophilicity of the benzoic acid derivatives increases, the partition coefficient of the corresponding unionized molecules increases. 2-Hydroxybenzoic acid and 3-hydroxybenzoic acid are excluded from the plot because the hydroxy group is at positions other than the *para*-position; factors such as steric and electronic effects may contribute to the variations in their partition coefficient. The relationship between log partition coefficient and π is linear, with a slope of 0.885 and a correlation of 0.981.

The partition coefficient of 4-nitrobenzoic acid indicates a higher degree of solubilization than expected due to the negative inductive effect of the functional group, nitro, as compared with the positive effect of other groups (11), resulting in a greater interaction between the solubilizer and the solubilizate. When 4-nitrobenzoic acid is excluded, a better relationship can be obtained, with a slope value of 0.929 and a correlation of 0.994, indicative of a direct relationship between the micellar–aqueous partition coefficient of the unionized species and the π value of the substituent group. This relationship suggests that the unionized species is solubilized in a lipophilic region of the micelles.

Ismail *et al.* (6) reported an increase in the amount of substituted barbituric acids solubilized by polyoxyethylene stearates as solubilizate polarity decreased. The amount of each barbituric acid solubilized showed a rank-order correlation with their partition coefficients between 1-octanol and water. However, their work and that of Kakemi *et al.* (12) were limited to systems at pH 1.0.

The present data are particularly useful since, with a knowledge of micellar–aqueous partition coefficients of unionized parent compounds and of substituent π values, it is possible to calculate the amount of free drug present in micellar solution for other substituted derivatives. These calculations may find application in the interpretation of results from drug stability studies with micellar solutions and in drug absorption studies with micellar solutions.

Confirmation of Iminoacridan Structure of Singly Protonated 9-Aminoacridine

ANTHONY C. CAPOMACCHIA and STEPHEN G. SCHULMAN ˣ

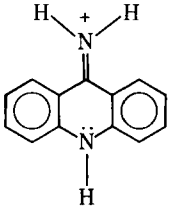
Abstract □ The occurrence of the second absorption band of singly protonated 9-aminoacridine, which arises from an acridinium ring-localized transition, at anomalously short wavelength indicates the disruption of the aromaticity of the central ring of the singly charged cation. The shifting of the two longest wavelength absorption bands and the fluorescence band of 10-methyl-9-aminoacridine monocation, a model of singly protonated 9-aminoacridine which is constrained to dissociate from the exocyclic nitrogen atom, to shorter wavelengths, upon dissociation, indicates the imine-like nature of the 10-methyl derivative. These observations support the conclusion that the predominant site of positive charge in singly protonated 9-aminoacridine is the exocyclic nitrogen atom, even though the heterocyclic nitrogen atom is the site of protonation of the neutral molecule.

Keyphrases □ 9-Aminoacridine—singly protonated, confirmation of iminoacridan structure □ Iminoacridan—confirmed as structure of singly protonated 9-aminoacridine □ Acridine derivatives—confirmation of iminoacridan structure of singly protonated 9-aminoacridine

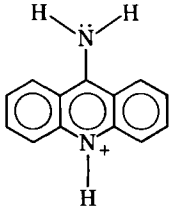
In a recent paper (1), it was shown that singly protonated 9-aminoacridine, the predominant prototropic species derived from 9-aminoacridine at physiological pH, existed in aqueous solution as the protonated iminoacridan (I) form rather than as the protonated aminoacridine (II). This finding is of pharmacological significance because of the ionic interaction of 9-aminoacridine and presumably other antimicrobials derived from 9-aminoacridine with DNA, an interaction whose geometrical characteristics are determined by the site of positive charge in the acridine derivative.

Previously (1), the anomalous shifting of the long wavelength absorption and fluorescence bands of singly protonated 9-aminoacridine with protonation, dissociation, and solvent polarity relative to the corresponding shifts of the singly protonated cation of 2-aminoacridine, a "typical" *N*-heterocyclic amine, was suggested to indicate that I was closest to the actual electronic structure of the 9-aminoacridine monocation.

Recently, in this laboratory, the *N*-methyl monocation of 9-aminoacridine (10-methyl-9-aminoacridinium iodide) was prepared and the pH dependences of its absorption and fluorescence spectra were studied. Moreover, the second absorption band of 9-aminoacridine, whose position in the electromagnetic spectrum is indicative of the extension of aromaticity in the aromatic ring (acridine), was examined as a function of pH. The results of these experiments confirm the assignment of Structure I as most representative of the electronic structure of singly protonated 9-aminoacridine.



I



II

EXPERIMENTAL

The pH measurements were made on a pH meter[1] with a combination silver–silver chloride glass electrode. Electronic absorption spectra were taken in 1-cm silica cells on a grating-type spectrophotometer[2]. Fluorescence measurements were taken on a fluorescence spectrophotometer[3] whose monochromators were calibrated against the line emission spectrum of xenon. Emission spectra were corrected for the wavelength response of the monochromator and phototube by means of a corrected spectra accessory employing a rhodamine-B quantum counter.

10-Methyl-9-aminoacridinium iodide was prepared by methylating 9-aminoacridine[4] according to the literature method (2). Spectra were taken of solutions that were 1×10^{-5} *M* in 9-aminoacridine or 10-methyl-9-aminoacridine. The spectrophotometric titration procedure employed was described previously (1).

RESULTS AND DISCUSSION

The longest wavelength absorption bands of acridines may be considered to be derived from the short axis polarized transition [$^1L_a \leftarrow {}^1A$ in Platts' nomenclature system (3)] of the parent hydrocarbon, anthracene. This band generally is most sensitive to substituents in what corresponds to α-positions of anthracene (4) (positions 1, 4, 5, 8, 9, and 10 in acridine) and, therefore, to protonation of the heterocyclic nitrogen atom of acridine. The second absorption bands of acridines are derived from the long axis polarized transition of anthracene ($^1L_b \leftarrow {}^1A$), are generally more structured and narrower than the ^1L_a bands, are sensitive in position to β-type substituents (4) (positions 2, 3, 6, and 7 in acridine), and are relatively insensitive to α-substituents (*e.g.*, a 9-amino group or protonation of the heterocyclic nitrogen atom) in acridine.

Thus, while the ^1L_a bands of α-substituted acridines appear in the absorption spectrum anywhere from 380 to >500 nm, the ^1L_b bands occur from 350 to 370 nm (5). Even in 2-aminoacridine, which has a β-substituent and no α-functional group other than the heterocyclic nitrogen atom, the O–O feature of the ^1L_b band always occurs within the latter interval, at 354, 370, and 356 nm in the dication, monocation, and neutral molecule, respectively. Hence, while the ^1L_a band in acridines is an "intramolecular charge-transfer band" whose position is determined by the interactions of the functional groups with the aromatic ring as well as by the size of the aromatic ring itself, the ^1L_b band in acridines is essentially a "ring-localized $\pi \rightarrow \pi^*$ transition" whose position is largely "fixed" by the size of the aromatic ring system. In anthracenes and the corresponding heterocyclic molecules, the ^1L_b band occurs between 350 and 370 nm; in naphthalenes, it occurs between 315 and 340 nm; and in benzenes, it occurs between 255 and 300 nm.

The ^1L_b bands of the various prototropic species derived from 9-aminoacridine indicate that the dication and anion are "well-behaved" acridine derivatives. The neutral molecule also is on the

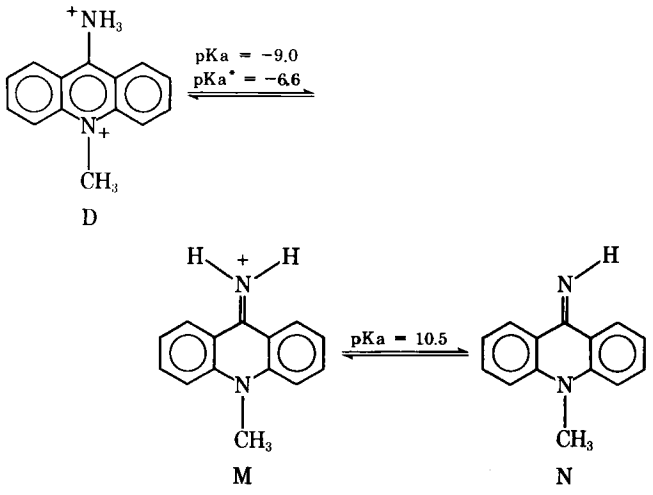
Table I—The O–O Vibronic Maxima of the Two Longest Wavelength Absorption Bands (λ^1L_a and λ^1L_b) and the Fluorescence Bands (λ) of the Various Prototropic Species Derived from 9-Aminoacridine and 10-Methyl-9-aminoacridinium Iodide

	λ^1L_b, nm	λ^1L_a, nm	λf, nm
9-Aminoacridine			
Dication ($H_0 - 10.0$)	366	440	475
Monocation (pH 1.0)	324	423	430
Neutral molecule (pH 12.0)	348	426	445
Anion (H_17.5)	353	443	470
10-Methyl-9-amino-acridinium iodide			
Dication ($H_0 - 10.0$)	368	445	480
Monocation (pH 1.0)	327	431	433
Neutral molecule (pH 12.5)	312	408	431

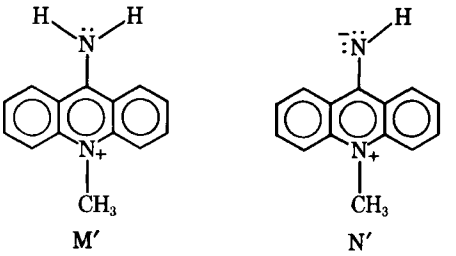
borderline of being a "typical" acridine derivative. However, the ^1L_b band of the monocation is at a much shorter wavelength than that indicative of an acridine ring system and suggests disruption of the aromaticity of the tricyclic system. Actually, the ^1L_b maximum at 324 nm is reasonable for an extended benzenoid system as represented by Structure I.

The 10-methyl-9-aminoacridinium ion has an electronic structure very much like that of the 9-aminoacridinium cation (Table I). The methylated cation can be protonated or dissociated according to Scheme I. An excited-state equilibrium occurs for the dication (D)–monocation (M) pair but not for the monocation–neutral (N) pair. The pKa* and pKa, as well as the spectral shifts occurring upon going from the dication to the monocation of the methylated derivative, are similar to the corresponding quantities measured for the dication–monocation interconversion of 9-aminoacridine (1) and therefore support the validity of using the *N*-methyl derivative as a model of the 9-aminoacridinium ion; which cannot dissociate from the heterocyclic function.

The dissociation of the monocation to form the neutral *N*-methyl derivative results in shifts of the long wavelength absorption (^1L_a) and fluorescence bands to shorter wavelengths. This result is expected for dissociation from a structure such as M to form one such as N because it indicates the electron-withdrawing nature of the exocyclic imino group (similar to but weaker than that of a carbonyl group).



Scheme I



If the alternative amino structures of M′ and N′ are taken to represent M and N, a shift of the ^1L_a and fluorescence bands to longer wavelengths would be expected upon dissociation, because of the increased lone-pair repulsion on the optical electron (stabilization of the charge-transfer excited state of N′ relative to that of M′) produced by dissociation of the electron donor amino group. These conclusions are supported by the positions of the ^1L_b bands of the 10-methyl monocation and neutral species at 327 and 312 nm, respectively. Both are at anomalously short wavelengths for acridinium ions (*i.e.*, M′ and N′) and also rule out the possibilities that the 10-methyl monocation is in the form M′ and that the neutral species is in the form N, a circumstance that might also be expected to yield a shift of the ^1L_a and fluorescence bands to shorter wavelengths upon dissociation.

The loss of acridine-like aromaticity in the monocation derived from 9-aminoacridine, as reflected in the short wavelength of the ^1L_b band and the imine-like dissociation and spectral behavior of the *N*-methylated monocation, supports the assignment of Structure I as that of singly protonated 9-aminoacridine. This conclusion is also supported by a recent X-ray diffraction study of 9-aminoacridine hydrochloride monohydrate (6), in which it was shown that the length of the bond joining the amino group to the aromatic ring is indicative of a double bond as represented in Structure I.

Anti-Inflammation Mechanism of Extract from *Eisenia bicyclis* (Kjellman) Setchell

DAVID M. WHITAKER and GARY P. CARLSON ˣ

Abstract □ An extract from *Eisenia bicyclis*, previously shown to possess anti-inflammatory activity, was found to stabilize lysosomal membranes *in vitro* as determined by measurement of inhibition of the marker enzyme β-glucuronidase. Some anti-inflammatory activity was also due to counterirritancy.

Keyphrases □ *Eisenia bicyclis* extract—mechanism of anti-inflammatory activity, lysosomal stabilization □ Anti-inflammatory activity—*Eisenia bicyclis* extract, lysosomal stabilization

Although a number of important steroidal and nonsteroidal agents are presently in use for the treatment of inflammation, the search continues for new anti-inflammatory drugs. Previous studies from this laboratory (1) indicated that an extract from the alga *Eisenia bicyclis* (Kjellman) Setchell, collected from the shores of Korea, contains a compound possessing anti-inflammatory activity. This material has been reported (2) to be a complex polymer which, on chemical degradation, yields glucose, phloroglucinol, and trimethylamine.

Several methods were used in the original studies (1) to demonstrate anti-inflammatory activity, including the inhibition of the denaturation of bovine serum albumin and the prevention of carrageenan-induced edema in the rat paw. However, the material was ineffective in suppressing rat paw edema due to the administration of complete Freund's adjuvant. Little could be determined from these initial studies regarding the mechanism of the anti-inflammatory action other than that it was not due to a thermogenic effect and that it did not involve the pituitary–adrenal axis.

It was of interest, therefore, to determine if the compound might be active by virtue of its ability to stabilize lysosomal membranes and thereby inhibit the release of lysosomal enzymes from the organelle. The release of these enzymes and subsequent tissue damage have been implicated in several types of inflammation such as chemical burns (3) and arthritis (4). That stabilization of the membrane could be achieved by anti-inflammatory drugs was demonstrated utilizing the release of the lysosomal marker enzymes β-glucuronidase and acid phosphatase (5). Comparison of the ability to stabilize the membranes was made with phenylbutazone[1], a well-known anti-inflammatory agent. In addition, it was important to determine if all or some of the anti-inflammatory effect might be due to counterirritancy.

Table I—Effect of Drugs on Lysosomal Membrane Stability *In Vitro*

Drug	Enzyme Activity[a] ± *SE* (4)[b]	
	Acid Phosphatase	β-Glucuronidase

EXPERIMENTAL

Materials and Methods—Adult male albino rats[2] were housed in air-conditioned rooms and allowed food and water *ad libitum*. The procedures for the preparation of hepatic lysosomal fractions and the determination of the activities of lysosomal β-glucuronidase and acid phosphatase were basically those of Ignarro (5). A 10% liver homogenate was prepared in 0.25 *M* sucrose–0.02 *M* tromethamine acetate buffer, pH 7.4, and centrifuged at 600×*g* for 5 min at 4° in a refrigerated centrifuge[3]. The supernate was decanted, mixed with an equal volume of the buffer, and recentrifuged at 3500×*g* for 15 min.

The resulting pellet was rinsed gently twice with 0.45 *M* sucrose–0.02 *M* tromethamine acetate buffer, pH 7.4, and resuspended in 4.0 ml of the buffer. The suspension was warmed to 25°, and 0.20-ml aliquots were added to 20-ml beakers containing 2.0 ml of 0.18 *M* sucrose–0.04 *M* tromethamine acetate buffer, pH 7.4, with either 0.1 ml of drug solution or water. Incubation was carried out at 37° for 0 or 15 min in a metabolic shaker[4] and terminated by centrifugation at 27,000×*g* for 15 min at 4° in polyethylene tubes.

To determine if the drug had any direct effect on the marker enzymes, the drug was added after the incubation period. To determine the total enzyme activity, 2.0 ml of 0.2% octoxynol[5] in 0.04 tromethamine acetate buffer, pH 7.4, replaced the buffer.

Acid phosphatase was determined by measuring the formation of *p*-nitrophenol from *p*-nitrophenyl phosphate, and β-glucuronidase activity was determined by measuring the formation of phenolphthalein from phenolphthalein glucuronide (5). One milliliter of the high-speed supernate and 1 ml of water were added to 1 ml of 0.3 *M* citrate buffer, pH 4.8. Incubation was initiated by the addition of 0.04 ml of substrate [*p*-nitrophenyl phosphate (79 mg/ml) or phenolphthalein glucuronide (63 mg/ml)]. Acid phosphatase incubations were terminated with 0.2 ml of 4 *N* NaOH, and absorbances were read at 405 nm. β-Glucuronidase assays were stopped with 0.4 ml of 2.2 *M* glycine–sodium hydroxide buffer, pH 12, and read at 540 nm.

Measurement of anti-inflammatory activity was made using a carrageenan-induced rat paw edema test system. The rat hindpaw was injected in the subplantar region with 0.1 ml of 1.0% carrageenan in saline, and the paw volume was determined by a plethysmographic method described by Van Arman *et al.* (6). The volume was measured 3 hr later, and edema formation was calculated as the difference.

Statistical analysis of the data from the lysosomal stabilization data comparing various doses was carried out using Duncan's new

Table II—Effect of Buffering *Eisenia* Extract on Carrageenan-Induced Rat Paw Edema

Treatment[a]	Mean Edema, $mm^3 \pm SE$ (6)[b]
Saline	1174 ± 99
Buffered[c] *Eisenia* extract	678 ± 176[d]

[a] Administered intraperitoneally 1 hr before carrageenan. [b] Number of animals. [c] Buffered at pH 7.4 with 0.2 *M* KH_2PO_4–Na_2PO_4. [d] $p < 0.05$.

multiple-range finding test. Comparison of the anti-inflammatory activity data utilized the Student two-tailed *t* test (7).

RESULTS AND DISCUSSION

The results of testing the activity of the *Eisenia* extract for ability to stabilize lysosomal membranes are presented in Table I. They have been corrected for any direct inhibition of the enzyme. Acid phosphatase was a poor indicator of lysosomal membrane condition, since the powerful stabilizing agent phenylbutazone, which was used as a positive control, inhibited enzyme release by only 7%. However, phenylbutazone (0.309 mg/ml) and the extract at a concentration of either 3.087 or 0.309 mg/ml offered significant inhibition of release of β-glucuronidase. At the lower extract concentration of 0.031 mg/ml, there was no protection.

Since some compounds have been shown to be anti-inflammatory because of their irritant properties (8), it was important to determine if the compound might be acting as an anti-inflammatory agent by virtue of its acidity; it normally was injected at pH 4.5. When the material was buffered at pH 7.4 and anti-inflammatory activity was assessed (Table II) using the carrageenan-induced rat paw edema model, there was only 42% inhibition of inflammation. This value is somewhat lower than the expected 88% (1), indicating that the protection afforded by the *Eisenia* extract is due in part to a nonspecific counterirritancy.

It appears that there are two mechanisms for the anti-inflammatory activity of the complex polymer isolated from *E. bicyclis* (Kjellman) Setchell. One is its ability to stabilize the membranes of lysosomes and inhibit the release of the destructive lysosomal enzymes, and the other is a counterirritancy effect.

Synthesis and Antimicrobial Activity of *N*-Substituted *N'*-Cyano-*S*-(triorganostannyl)isothioureas

EUGENE J. KUPCHIK *[x], MICHAEL A. PISANO [‡], ANDALI V. RAGHUNATH *, RAYMOND A. CARDONA *, NORA FORMAINI [‡], and CECILIA ALLEGUEZ [‡]

Abstract □ Six *N*-substituted *N'*-cyano-*S*-(trimethylstannyl)isothioureas were synthesized by the reaction of (trimethylstannyl)cyanamide with various organic isothiocyanates. The IR spectrum of each compound was obtained over the 4000–30-cm^{-1} range, and some bands were assigned. The six new compounds and five previously synthesized *N*-substituted *N'*-cyano-*S*-(triphenylstannyl)isothioureas were tested for and were found to exhibit antifungal activity. *N*-Phenyl-*N'*-cyano-*S*-(triphenylstannyl)isothiourea was also investigated for antibacterial activity and was observed to be especially inhibitory toward Gram-positive species. The antimicrobial activity of two compounds was compared to that of the oxygen analogs of these compounds.

Keyphrases □ *N'*-Cyano-*S*-(triorganostannyl)isothioureas, *N*-substituted—synthesis, IR spectra, antimicrobial activity □ Antifungal activity—synthesis of six and evaluation of 11 *N*-substituted *N'*-cyano-*S*-(triorganostannyl)isothioureas □ Antibacterial activity—evaluation of *N*-phenyl-*N'*-cyano-*S*-(triphenylstannyl)isothiourea

Recently, the synthesis of 13 *N*-substituted *N'*-cyano-*O*-(trimethylstannyl)isoureas (I*a*) and 12 *N*-substituted *N'*-cyano-*O*-(triphenylstannyl)isoureas (I*b*) was described (1). Six of these compounds were tested for and were found to exhibit antifungal activity; one (I*b*, R' = C_6H_5) was also investigated for an-

solutions of the organotin compounds, the fungi employed, the antimicrobial testing procedures, and the determination of growth inhibition were reported previously (1).

One organotin compound, *N*-phenyl-*N'*-cyano-*S*-(triphenylstannyl)isothiourea (Compound 9), was also investigated for antibacterial activity according to the procedure reported earlier (1).

RESULTS AND DISCUSSION

Synthesis—The five *N*-substituted *N'*-cyano-*S*-(triphenylstannyl)isothioureas (II*b*) used in this study were described previously (3). The six *N*-substituted *N'*-cyano-*S*-(trimethylstannyl)-isothioureas (I*b*) are new compounds and were prepared by allowing (trimethylstannyl)cyanamide to react separately with six different organic isothiocyanates (1:1 mole ratio) in refluxing ether (Table I). The IR spectra of these compounds are summarized in Table II. The IR spectra contained both the ν_{as}(SnC) band and the ν_S(SnC) band, indicating that the trimethyltin group may be nonplanar in these compounds (4).

Biological Results—The 11 *N*-substituted *N'*-cyano-*S*-(triorganostannyl)isothiourea compounds were investigated for inhibition of growth of 10 fungal species. One compound was also investigated for antibacterial activity. Table III shows the antifungal activity of the compounds tested. The data presented indicate that the trimethyltin compounds (Compounds 1–6) were significantly more active than the triphenyltin compounds (Compounds 7–11). The incidence of total inhibition of fungal growth, for example, was six times greater with the trimethyltin compounds as compared to the triphenyltin compounds. In addition, the latter compounds did not exhibit total inhibition at a level of 10 μg/ml, whereas the trimethyltin compounds did in four instances.

Of the 11 compounds tested, the most effective antifungal activity, as indicated by total inhibition of growth, was exhibited by *N*-methyl-*N'*-cyano-*S*-(trimethylstannyl)isothiourea (Compound 1). From the data compiled, it was possible to compare the growth-inhibiting properties of specific trimethyltin compounds with their triphenyltin analogs. Thus, for example, *N*-benzyl-*N'*-cyano-*S*-(trimethylstannyl)isothiourea (Compound 3) completely inhibited four of 10 fungi, whereas the triphenyltin analog (Compound 8) displayed only partial inhibition of growth. The latter compound, however, did possess activity against *Rhizopus stolonifer*, which was lacking in the trimethyltin derivative. Similarly, *N*-phenyl-*N'*-cyano-*S*-(trimethylstannyl)isothiourea (Compound 4) displayed greater overall antifungal activity than its triphenyltin counterpart (Compound 9).

The superior antifungal activity of the trimethyltin compounds was even more evident when *N*-*p*-nitrophenyl-*N'*-cyano-*S*-(trimethylstannyl)isothiourea (Compound 6) was compared with its triphenyltin analog (Compound 11). The former compound completely inhibited five of the 10 fungi whereas the latter compound displayed total inhibition against only two of the fungi. Of interest was the fact that the trimethyltin compound partially inhibited *Saccharomyces cerevisiae*, an activity shared by only one other compound, Compound 1.

Further comparisons were possible between two of the organotin compounds reported in the present investigation and their oxygen analogs, the antimicrobial activities of which were described previously (1). For example, Compound 4 completely inhibited the growth of three of the 10 fungi, whereas *N*-phenyl-*N'*-cyano-*O*-(trimethylstannyl)isourea (1) totally inhibited only one fungus.

Secondly, *N*-phenyl-*N'*-cyano-*S*-(triphenylstannyl)isothiourea (Compound 9) and its oxygen analog (1) both exhibited total inhibition of two of the 10 fungi tested. The former compound completely inhibited *Aspergillus niger* and *R. stolonifer* at a concentration of 100 μg/ml. The oxygen analog, on the other hand, was most active against *Myrothecium verrucaria* and *S. cerevisiae* at a similar concentration. The latter activity is noteworthy in that none of the 11 compounds reported in the present investigation completely inhibited *S. cerevisiae*.

The antibacterial activity of Compound 9 is shown in Table IV. This compound was remarkably active against the three Gram-positive species, displaying complete inhibition at a concentration of 1 μg/ml. In addition, partial inhibition of the Gram-negative organism, *Escherichia coli*, was evident. This latter activity contrasts with that of the oxygen analog, *N*-phenyl-*N'*-cyano-*O*-(triphenylstannyl)isourea, which was previously reported to be ineffective against *E. coli* (1). In addition, among the four Gram-positive species tested, total inhibition by the oxygen analog was accomplished only against *Micrococcus agilis* (1).

New Synthesis of *(RS)*-Carnitine Chloride

SHARON G. BOOTS and MARVIN R. BOOTS ˣ

Abstract □ A four-step synthesis of *(RS)*-carnitine chloride was developed using extremely mild reaction conditions and versatile intermediates. Crotyl chloride was converted to *tert*-butyl 3-butenoate using *tert*-butyl alcohol and triethylamine in ether. Treatment of *tert*-butyl 3-butenoate with *m*-chloroperbenzoic acid in chloroform afforded *tert*-butyl 3,4-epoxybutyrate. Reaction of this compound with trimethylamine hydrochloride in methanol, followed by mild acid hydrolysis of the *tert*-butyl ester, afforded *(RS)*-carnitine chloride.

Keyphrases □ *(RS)*-Carnitine chloride—four-step synthesis under mild reaction conditions from crotyl chloride □ Crotyl chloride—starting material in four-step synthesis of *(RS)*-carnitine chloride

The importance of *(R)*-(−)-carnitine chloride in the transport of fatty acids across membranes was demonstrated previously (1). Specifically, carnitine chloride catalyzes the oxidation of long chain fatty acids by participating in the enzyme-mediated transport of activated fatty acids from the cytoplasm to the β-oxidation sites within the mitochondria (2, 3). The objectives of this investigation were to develop a convenient and versatile synthetic route that could be readily adapted to the synthesis of not only carnitine chloride itself but also to carnitine analogs. The availability of carnitine analogs could provide valuable biochemical tools for investigating the structural requirements of carnitine chloride as a catalyst of fatty acid oxidation (4).

DISCUSSION

In 1966, Ozeki and Kusaka (5) described the synthesis of numerous 3-butenoate esters from crotyl chloride (I) and the appropriate alcohol in the presence of a variety of tertiary amines. It appeared that proper functionalization of the olefinic bond in one of the 3-butenoate esters would provide a convenient and relatively straightforward synthesis of *(RS)*-carnitine chloride (VI) and, thus, carnitine analogs. The *tert*-butyl ester was selected because of the extremely mild reaction conditions required for conversion to the free carboxylic acid (dilute hydrochloric acid at room temperature). Triethylamine was selected as the base because it provided the highest yield of the desired 3-butenoate ester, with only small amounts (3.1%) of the unwanted *cis*- and *trans*-2-butenoate esters (determined by GC).

Since the previous report (5) provided few experimental details and the reaction was not discussed from the standpoint of providing an extremely versatile synthetic intermediate, it was necessary to develop the appropriate reactions conditions to afford the desired *tert*-butyl 3-butenoate (II) in a yield that would be useful for completing the synthesis of VI. The small amount of the *cis*- and *trans*-2-butenoate esters produced during the preparation of II were of little concern because the following step in the synthetic sequence involved epoxidation of the olefinic bond. The mildest conditions possible were used that would eliminate the possibility of isomerization of the 3-butenoate ester to a mixture of the *cis*- and *trans*-2-butenoate esters during exposure to the *m*-chlorobenzoic acid.

It is also well known that α,β-unsaturated carbonyl compounds do not normally undergo epoxidation when subjected to the same reaction conditions as isolated olefinic bonds. The desired epoxy ester (III) was initially converted to the iodohydrin (IV) using the method of Cornforth (6). Compound IV was subsequently treated with trimethylamine in methanol to afford *tert*-butyl 4-dimethylamino-3-hydroxybutyrate methiodide (V*a*) which, when subjected to ion-exchange chromatography, afforded V*b*. The *tert*-butyl protecting group was then removed by the mild reaction conditions described to yield VI.

It was later found, after much experimental effort, that III could be directly converted into the ester V*b*, using trimethylamine hydrochloride in methanol, in a yield high enough to make the reaction synthetically feasible, thus eliminating one step in the synthetic sequence as well as the ion-exchange chromatography.

Secondly, *N*-phenyl-*N'*-cyano-*S*-(triphenylstannyl)isothiourea (Compound 9) and its oxygen analog (1) both exhibited total inhibition of two of the 10 fungi tested. The former compound completely inhibited *Aspergillus niger* and *R. stolonifer* at a concentration of 100 μg/ml. The oxygen analog, on the other hand, was most active against *Myrothecium verrucaria* and *S. cerevisiae* at a similar concentration. The latter activity is noteworthy in that none of the 11 compounds reported in the present investigation completely inhibited *S. cerevisiae*.

The antibacterial activity of Compound 9 is shown in Table IV. This compound was remarkably active against the three Gram-positive species, displaying complete inhibition at a concentration of 1 μg/ml. In addition, partial inhibition of the Gram-negative organism, *Escherichia coli*, was evident. This latter activity contrasts with that of the oxygen analog, *N*-phenyl-*N'*-cyano-*O*-(triphenylstannyl)isourea, which was previously reported to be ineffective against *E. coli* (1). In addition, among the four Gram-positive species tested, total inhibition by the oxygen analog was accomplished only against *Micrococcus agilis* (1).

Keyphrases □ *(RS)*-Carnitine chloride—four-step synthesis under mild reaction conditions from crotyl chloride □ Crotyl chloride—starting material in four-step synthesis of *(RS)*-carnitine chloride

The importance of *(R)*-(−)-carnitine chloride in the transport of fatty acids across membranes was demonstrated previously (1). Specifically, carnitine chloride catalyzes the oxidation of long chain fatty acids by participating in the enzyme-mediated transport of activated fatty acids from the cytoplasm to the β-oxidation sites within the mitochondria (2, 3). The objectives of this investigation were to develop a convenient and versatile synthetic route that could be readily adapted to the synthesis of not only carnitine chloride itself but also to carnitine analogs. The availability of carnitine analogs could provide valuable biochemical tools for investigating the structural requirements of carnitine chloride as a catalyst of fatty acid oxidation (4).

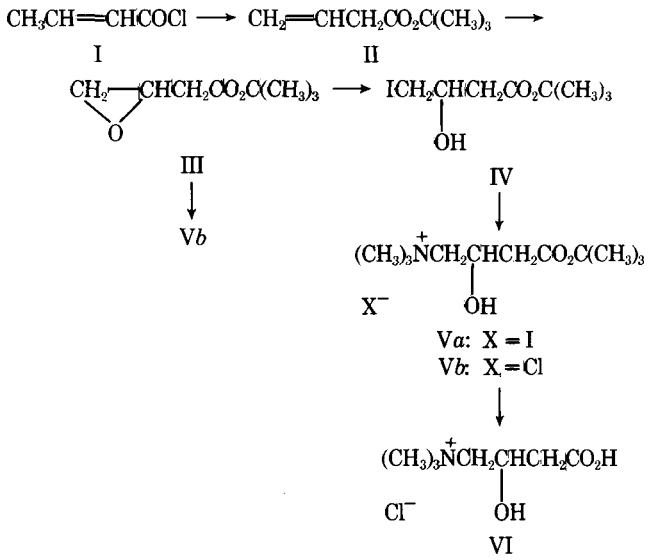
DISCUSSION

In 1966, Ozeki and Kusaka (5) described the synthesis of numerous 3-butenoate esters from crotyl chloride (I) and the appropriate alcohol in the presence of a variety of tertiary amines. It appeared that proper functionalization of the olefinic bond in one of the 3-butenoate esters would provide a convenient and relatively straightforward synthesis of *(RS)*-carnitine chloride (VI) and, thus, carnitine analogs. The *tert*-butyl ester was selected because of the extremely mild reaction conditions required for conversion to the free carboxylic acid (dilute hydrochloric acid at room temperature). Triethylamine was selected as the base because it provided the highest yield of the desired 3-butenoate ester, with only small amounts (3.1%) of the unwanted *cis*- and *trans*-2-butenoate esters (determined by GC).

Since the previous report (5) provided few experimental details and the reaction was not discussed from the standpoint of providing an extremely versatile synthetic intermediate, it was necessary to develop the appropriate reactions conditions to afford the desired *tert*-butyl 3-butenoate (II) in a yield that would be useful for completing the synthesis of VI. The small amount of the *cis*- and *trans*-2-butenoate esters produced during the preparation of II were of little concern because the following step in the synthetic sequence involved epoxidation of the olefinic bond. The mildest conditions possible were used that would eliminate the possibility of isomerization of the 3-butenoate ester to a mixture of the *cis*- and *trans*-2-butenoate esters during exposure to the *m*-chlorobenzoic acid.

It is also well known that α,β-unsaturated carbonyl compounds do not normally undergo epoxidation when subjected to the same reaction conditions as isolated olefinic bonds. The desired epoxy ester (III) was initially converted to the iodohydrin (IV) using the method of Cornforth (6). Compound IV was subsequently treated with trimethylamine in methanol to afford *tert*-butyl 4-dimethylamino-3-hydroxybutyrate methiodide (V*a*) which, when subjected to ion-exchange chromatography, afforded V*b*. The *tert*-butyl protecting group was then removed by the mild reaction conditions described to yield VI.

It was later found, after much experimental effort, that III could be directly converted into the ester V*b*, using trimethylamine hydrochloride in methanol, in a yield high enough to make the reaction synthetically feasible, thus eliminating one step in the synthetic sequence as well as the ion-exchange chromatography.



Scheme I

A four-step synthesis of VI is described (Scheme I). It uses extremely mild reaction conditions and provides versatile intermediates, which can readily be used for the preparation of a variety of carnitine analogs. No other published synthesis of VI (7) that the authors are aware of utilizes such mild reaction conditions and such versatile intermediates[1].

EXPERIMENTAL[2]

***tert*-Butyl 3-Butenoate (II)**—The procedure of Ozeki and Kusaka (5) was modified. To a solution of 28 ml (0.3 mole) of *tert*-butyl alcohol and 28 ml (0.2 mole) of triethylamine in 75 ml of ether was added dropwise with stirring, while maintaining the temperature at 25–30°, a solution of 18.8 ml (0.2 mole) of freshly distilled crotyl chloride in 10 ml of ether. After the addition was completed, the mixture was allowed to stir at 25° for 1 hr.

The mixture was then filtered, and the solid was washed thoroughly with ether. The filtrate was washed with a cold 5% sodium bicarbonate solution, water, a cold 5% hydrochloric acid solution, water, a cold 5% sodium bicarbonate solution, water, and then a saturated sodium chloride solution. The organic phase was dried over anhydrous sodium sulfate, and the solvent was removed at atmospheric pressure with a minimal amount of heating.

The residue was distilled to give 16.9 g (60%) of a colorless liquid, bp 52–54° (20–24 mm); IR (liquid film): 1730 (ester C=O) and 1642 (C=C) cm^{-1}; NMR ($CDCl_3$): δ 4.9–6.2 (m, 3H, CH_2=CH—), 2.9–3.0 (m, 2H, —CH_2—), and 1.45 [s, 9H, —$C(CH_3)_3$] ppm.

Anal.—Calc. for $C_8H_{14}O_2$: C, 67.6; H, 9.9. Found: C, 67.8; H, 9.9.

***tert*-Butyl 3,4-Epoxybutyrate (III)**—To an ice-cold solution of 8.4 g (0.06 mole) of II in 40 ml of chloroform was added dropwise, with cooling and stirring, a solution of 18.2 g (0.09 mole) of 85% *m*-chloroperbenzoic acid in 250 ml of chloroform. The solution was allowed to stand at 4° for 4 days. The resulting precipitate was removed by filtration, and the filtrate was stirred with 300 ml of a freshly prepared aqueous 10% sodium sulfite solution for 30 min (negative starch-iodide test). The organic phase was washed with a 5% sodium bicarbonate solution, water, and a saturated sodium chloride solution and then dried over anhydrous sodium sulfate.

The solvent was removed under reduced pressure to afford a yellow liquid, which was distilled to give 6.3 g (66%) of III as a colorless liquid, bp 40–42° (0.3 mm); IR (liquid film): 1728 (ester C=O) cm^{-1}; NMR ($CDCl_3$): δ 2.38–3.38 (m, 5H, CH_2—$CHCH_2$—) and 1.47 [s, 9H, —$C(CH_3)_3$] ppm.

Anal.—Calc. for $C_8H_{14}O_3$: C, 60.8; H, 8.9. Found: C, 60.5; H, 8.8.

***tert*-Butyl 4-Iodo-3-hydroxybutyrate (IV)**—The procedure of Cornforth *et al.* (6) was used. A mixture of 0.53 g (3.5 mmoles) of sodium iodide, 0.24 g (2.5 mmoles) of sodium acetate, 0.45 ml of acetic acid, and 2.5 ml of propionic acid was cooled to −30°. A 0.375-g (2.5-mmole) sample of III was added to the cooled solution. The mixture was stirred at from −30 to −20° for 30 min and then at 0° for 30 min. The mixture was poured into ether and an ice-cold 5% sodium bicarbonate solution. The organic phase was washed with water, a 10% sodium thiosulfate solution, water, and a saturated sodium chloride solution and then dried over anhydrous sodium sulfate.

The solvent was removed under reduced pressure to afford 0.616 g (88%) of a pale-yellow liquid, which was used immediately without further purification due to its apparent instability; IR (liquid film): 3420 (OH) and 1725 (ester C=O) cm^{-1}; NMR ($CDCl_3$): δ 2.5–4.2 [m, 6H, —$CH_2CH(OH)CH_2$—] and 1.46 [s, 9H, —$C(CH_3)_3$] ppm.

***tert*-Butyl 4-Dimethylamino-3-hydroxybutyrate Methiodide (V*a*)**—To a solution of 0.616 g (2.2 mmoles) of IV in 10 ml of methanol was added 5 ml (16 mmoles) of a 25% solution of trimethylamine in methanol. The mixture was allowed to stand at 25° for 19 hr. The solvent was then removed under reduced pressure to afford a white solid. The solid was slurried with anhydrous ether, filtered, and then dried under high vacuum at 25° to yield 0.711 g (95%) of V*a*, mp 138–139°.

Recrystallization from acetone–ether afforded an analytical specimen as white prisms, mp 146–148°; IR (mineral oil): 1715 (ester C=O) cm^{-1}; NMR (D_2O): δ 4.30–4.80 (m, 1H, —CH—), 3.50 [d, 2H, $(CH_3)_3$—$^+$NCH_2—], 3.26 [s, 9H, $(CH_3)_3{}^+$N—], 2.60 [d, 2H, —$CH_2CO_2C(CH_3)_3$], and 1.47 [s, 9H, —$C(CH_3)_3$] ppm.

Anal.—Calc. for $C_{11}H_{24}INO_3$: C, 38.3; H, 7.0; N, 4.1. Found: C, 38.0; H, 6.8; N, 3.9.

***tert*-Butyl 4-Dimethylamino-3-hydroxybutyrate Methochloride (V*b*)**—A 0.500-g (1.45-mmole) sample of V*a*, dissolved in 5 ml of methanol, was passed through a column (2-cm diameter) containing 8.1 g (4.3 mEq/g, dry basis) of resin[3] (chloride form, 50–100 mesh), which had previously been washed with 100 ml of water and then with 100 ml of methanol. Elution with 50 ml of methanol afforded 0.350 g (95%) of V*b* as a white solid. All attempts to purify this material by recrystallization failed because the isolated crystalline form proved to be extremely hygroscopic. (See later experimental details for analytical and spectral data for this compound.)

Preparation of V*b* Directly from III—A mixture of 0.656 g (4.2 mmoles) of III, 0.320 g (3.30 mmoles) of trimethylamine hydrochloride, and 2.0 ml of anhydrous methanol was allowed to stand at 25° for 5 days in a glass-stoppered flask. The methanol was removed under reduced pressure, and the residue was added to ether and water. The organic phase was washed an additional time with water, and the aqueous extracts were combined. The water was removed under high vacuum at approximately 30–40°, and then the traces of water remaining were removed by azeotropic distillation with four 10-ml portions of *tert*-butyl alcohol under reduced pressure. The resulting white solid was dried for 19 hr at 25° under high vacuum; the yield was 0.724 g (73%), mp 203–204°.

Recrystallization from methanol–acetone afforded an analytical specimen of V*b* as white prisms, mp 210–211°; IR (mineral oil): 1715 (ester C=O) cm^{-1}; NMR (D_2O): δ 4.30–4.60 (m, 1H, —CH—), 3.50 [d, 2H, $(CH_3)_3{}^+$NCH_2—], 3.26 [s, 9H, $(CH_3)_3{}^+$N—], 2.60 [d, 2H, —$CH_2CO_2C(CH_3)_3$], and 1.47 [s, 9H, —$C(CH_3)_3$] ppm.

Anal.—Calc. for $C_{11}H_{24}ClNO_3$: C, 52.1; H, 9.5; N, 5.5. Found: C, 52.1; H, 9.5; N, 5.5.

***(RS)*-Carnitine Chloride (VI)**—A solution of 0.114 g (0.45 mmole) of V*b*, 8 ml of water, and 0.4 ml of concentrated hydrochloric acid was stirred at 25° for 17 hr. The water was removed at 30–40° under high vacuum; then four 10-ml portions of *tert*-butyl alcohol were added, as already described, to remove the remaining water azeotropically. The resulting white solid was dried under high vacuum at 25° for 2 days; the yield was 0.0874 g (98%) of white prisms, mp 195–197° [lit. (8) mp 196°]. The IR (mineral oil)

[1] For a discussion of previous methods used for the synthesis of *(RS)*-carnitine chloride, see Ref. 7.

[2] Melting points were determined with a Thomas-Hoover capillary melting-point apparatus and are uncorrected. Elemental analyses were obtained from Galbraith Laboratories, Knoxville, Tenn. IR spectra were determined using a Perkin-Elmer model 237 spectrophotometer. NMR spectra were determined on a Perkin-Elmer model R-24 spectrometer either in deuterochloroform, using tetramethylsilane as the internal reference, or in deuterium oxide, using sodium 2,2-dimethyl-2-silapentane-5-sulfonate as the internal reference.

[3] Dowex 1-X2.

and NMR (D_2O) spectra were superimposable with an authentic specimen of *(RS)*-carnitine chloride[4].

Bioavailability of Digoxin Tablets in Relation to Their Dissolution *In Vitro*

Keyphrases □ Digoxin tablets—dissolution data compared to bioavailability □ Bioavailability of digoxin tablets—relationship to dissolution

To the Editor:

The bioavailability of digoxin tablets has been claimed to be related to their dissolution *in vitro*. Many investigators have correlated the dissolution rate of digoxin tablets to concentration of digoxin in serum or plasma and to values for areas under the serum level–time curves of tablets (1–6). They have concluded that the dissolution rate *in vitro* is adequate for predicting the bioavailability of commercial digoxin tablets. It has been reported recently, however, that despite the different dissolution rates of two different brands of digoxin tablets, the total amount of digoxin absorbed from these tablets was quite similar to that from digoxin elixir USP (7). The present paper reports that the dissolution test according to the USP (8) is not always effective for evaluating the bioavailability of commercial digoxin tablets.

The experiment was carried out with eight healthy volunteer female subjects, ranging in age from 23 to 50 years and in weight from 57 to 68 kg. The subjects had no history of GI, liver, or kidney disease, and none admitted to taking any medication regularly. One digoxin tablet[1] (0.25 mg) or 10 ml of digoxin standard solution[2] (0.025 mg/ml) was given with 100 ml of water to each subject at 9 am for 10 days under laboratory supervision in a crossover manner. Tablets were determined to meet USP specifications as to purity, disintegration time, and content uniformity.

After taking the drug, the subjects were not allowed to eat for 2 hr and were asked to abstain from alcoholic beverages during the experiment. For measuring serum digoxin levels, venous blood samples were taken on the 8th, 9th, and 10th mornings just previous to the next dose of the drug. After the last dose, samples were drawn at intervals of 0.5, 1, 2, 4, 8, and 24 hr.

Bioavailability of Digoxin Tablets in Relation to Their Dissolution *In Vitro*

Keyphrases □ Digoxin tablets—dissolution data compared to bioavailability □ Bioavailability of digoxin tablets—relationship to dissolution

To the Editor:

The bioavailability of digoxin tablets has been claimed to be related to their dissolution *in vitro*. Many investigators have correlated the dissolution rate of digoxin tablets to concentration of digoxin in serum or plasma and to values for areas under the serum level–time curves of tablets (1–6). They have concluded that the dissolution rate *in vitro* is adequate for predicting the bioavailability of commercial digoxin tablets. It has been reported recently, however, that despite the different dissolution rates of two different brands of digoxin tablets, the total amount of digoxin absorbed from these tablets was quite similar to that from digoxin elixir USP (7). The present paper reports that the dissolution test according to the USP (8) is not always effective for evaluating the bioavailability of commercial digoxin tablets.

The experiment was carried out with eight healthy volunteer female subjects, ranging in age from 23 to 50 years and in weight from 57 to 68 kg. The subjects had no history of GI, liver, or kidney disease, and none admitted to taking any medication regularly. One digoxin tablet[1] (0.25 mg) or 10 ml of digoxin standard solution[2] (0.025 mg/ml) was given with 100 ml of water to each subject at 9 am for 10 days under laboratory supervision in a crossover manner. Tablets were determined to meet USP specifications as to purity, disintegration time, and content uniformity.

After taking the drug, the subjects were not allowed to eat for 2 hr and were asked to abstain from alcoholic beverages during the experiment. For measuring serum digoxin levels, venous blood samples were taken on the 8th, 9th, and 10th mornings just previous to the next dose of the drug. After the last dose, samples were drawn at intervals of 0.5, 1, 2, 4, 8, and 24 hr.

[1] Digoxin Novum, Star Ltd., Pinnink. 53, SF-33100 Tampere 10, Finland.

[2] Digoxin, 0.00025 g (International Chemical Reference Substance Digoxin, WHO Centre for Chemical Reference Substances, Apotekens Centrallaboratorium, Solna 3, Sweden); propylene glycol, 0.4 g; alcohol, 0.1 g; and sterile water, a sufficient quantity to make 10 ml.

Table I—Percentage of Labeled Digoxin Found in Solution after 60 min, Basal Concentration of Serum Digoxin (Mean of the Last 4 Experimental Days), and Areas under the Serum Level–Time Curves (for 24 hr) on the 10th Experimental Day (Values are Means ± *SE*)

	Percent of Labeled Amount in Solution (n = 12)	Basal Concentration of Serum Digoxin (n = 8)		Areas under the Serum Level–Time Curves (n = 8)	
		ng/ml	Compared with Standard, %	ng/ml × hr	Compared with Standard, %
Digoxin tablets	57.8 ± 1.6	0.59 ± 0.05	95.2 ± 10.6	4.43 ± 0.69	95.0 ± 8.9
Digoxin standard solution	98.4 ± 0.7	0.62 ± 0.04		4.60 ± 0.46	
Probability level	$p < 0.0005$	$p > 0.3$[a]		$p > 0.6$[a]	

[a] Not significant.

The serum samples were analyzed for digoxin radioimmunologically utilizing specific antiserum[3], ^{3}H-digoxin[4], and a liquid scintillation spectrometer[5]. The bound radioactivity separated from free ^{3}H-digoxin during the assay procedure was counted for 10 min/sample. The dissolution of digoxin tablets was performed according to the USP method (8). Twelve tablets were dissolved individually in a cylindrical stainless-steel basket[6], which was dipped into 500 ml of diluted hydrochloric acid (3 in 500) and rotated for 60 min at 120 rpm. After dissolution medium samples were filtered with a filter of 0.45-μm porosity[7], digoxin concentration was measured fluorometrically[8].

The percentage of digoxin dissolved after 60 min from the tablets was compared with the percentage of drug recovered from the dissolution medium containing dissolved digoxin (10 ml of standard solution) equivalent to the labeled amount in the tablets. For this comparison, the Student t test was used. Data from *in vivo* experiments were tested by a t test for paired observations. Areas under the serum level–time curves were determined by a planimetrical technique.

The amount of digoxin dissolved after 60 min from the tablets corresponded to 57.8 ± 1.6% (mean ± *SE*) of the declared amount and varied from 49.0 to 69.5% (Table I). The respective percentage of drug recovered from the dissolution medium containing standard solution (10 ml) was 98.4 ± 0.7% (from 94.0 to 101.5%). Despite the rapid disintegration of each tablet in this medium (1–2 min), four tablets dissolved less than the required 55% of the labeled amount of drug.

The basal digoxin concentration in serum and areas under the serum level–time curves during the last experimental day are shown in Fig. 1 and Table I. During the treatment with tablets, the basal digoxin level was 95.2 ± 10.6% of that caused by the standard solution (mean of the last 4 experimental days), and the area under the serum level–time curve describing digoxin absorption from tablets in the alimentary tract was 95.0 ± 8.9% of that of the standard solution. There was no statistically significant difference between tablets and standard solutions in these parameters.

Previously, Klink *et al.* (7) demonstrated that the bioavailability of digoxin tablets may be excellent despite the poor dissolution *in vitro*. They did not, however, report whether their tablets disintegrated rapidly during the dissolution test or whether digoxin was released slowly from the surface. In the present study, the poor dissolution percentage may be partly explained by the fact that during the test an essential part of the grains of the disintegrated tablets fell through the wall of the rotating basket into a nonagitated part of the apparatus where the release of digoxin from the grains probably was negligible or too slow.

Although the tablets tested did not meet USP specifications for dissolution (8), the basal digoxin concentration in serum and the area describing digoxin absorption during the treatment with tablets did not differ significantly from those caused by the standard solution. These results agree with the concept of Klink *et al.* (7) that a single dissolution test may not show a good correlation between the GI ab-

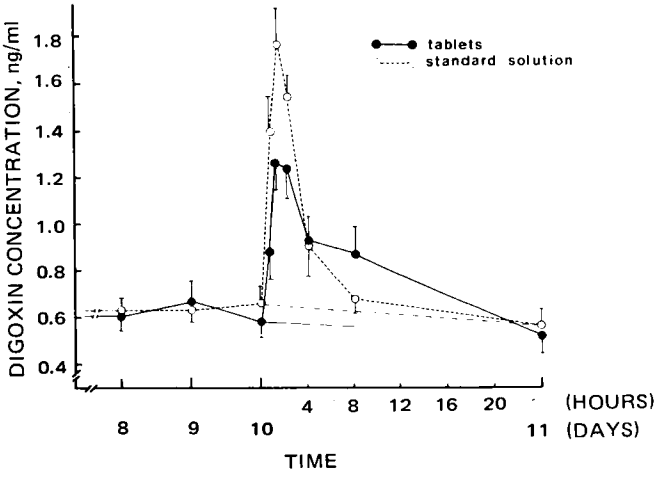

Figure 1—*Basal concentration of serum digoxin during the last 4 experimental days and the serum digoxin levels at each time of collection on the 10th experimental day following 10 consecutive daily administrations of 0.25 mg of digoxin (n = 8; values are means ± SE).*

BOOKS

REVIEWS

Proceedings of the USP Conference on Radiation Sterilization, The United States Pharmacopeia, Inc., Rockville, MD 20852, 224 pp. 16 × 22 cm. Price $10.00.

This volume consists of 15 papers devoted to an area of pharmaceutical and biomedical technology in which the United States has lagged behind several European nations, largely because of strict controls on testing of safety and efficacy imposed by federal agencies. Among the subjects considered in detail are instrumentation and experimental conditions employed in radiation sterilization, chemical dosimetry, the effects of ionizing radiations on microorganisms, and the evaluation of microbiological control systems for the determination of the efficacy of radiation sterilization.

Ionizing radiation offers an advantage over heat in the sterilization of thermally degradable materials. However, the high doses and dose rates required to effect sterilization, especially against radio-resistant bacteria, represent a problem because of the susceptibility of many materials to chemical and structural alterations as a result of their interactions with ionizing radiations. The treatment of bacteria-containing samples with UV light prior to high-energy irradiation provides a solution to this problem, at least in some cases, as bacteria preirradiated with UV light appear to require smaller doses of ionizing radiations to produce the same degree of sterilization observed in untreated bacterial samples. The cobalt-60 γ-ray source which, historically, was the first sterilization source employed on a wide scale is still preferred over other isotopic sources because of its high radiation flux, long-term stability, and relatively low cost and is favored over electronuclear sources such as the linear accelerator because of the high cost of the latter. It is suggested by several contributors to the volume that the cobalt-60 source is expected to maintain its preeminence for the forseeable future. It is also suggested that the search for and evaluation of better dosimeters and microbiological standards will be a major area of endeavor for some time to come. The need for improved microbiological controls is particularly acute because much of the testing of the efficacy of radiation sterilization has been carried out with bacteria which are unrepresentatively sensitive to radiation damage.

"Proceedings of the USP Conference on Radiation Sterilization" is a comprehensive, authoritative, and very readable account of a subject which is probably the major industrial application of ionizing radiations. Although it deals primarily with applications to biological test systems and surgical products, it is worthwhile reading for all pharmaceutical and biological scientists.

The United States Pharmacopeia, Nineteenth Revision. Prepared and Published by The United States Pharmacopeial Convention, Inc., Distributed by Mack Publishing Co., 20th & Northampton Sts., Easton, PA 18042, 1974. l + 824 pp. 21.5 × 28 cm. Price $25.00.

This latest revision of the *United States Pharmacopeia* (USP XIX) continues its respected tradition by providing legally recognized standards for identity, strength, quality, and purity for nearly 1300 important and well-established drugs and their dosage forms in use in the United States. Additionally, about one-fourth of this volume is devoted to general chapters, reagent specifications, and tables.

Among other noticeable changes introduced in USP XIX and not found in its predecessor, USP XVIII, are the considerable revisions in the *General Notices and Requirements (General Notices).* Of particular note are those relating to containers (*e.g.*, definitions for single-unit, multiple-unit, and unit-dose), labeling (*e.g.*, expiration date requirement), and the use of newer metric abbreviations.

Further changes are found in the many new features that characterize the revised format and style of USP XIX. A larger page size and two-column format were utilized to maximize the amount of textural content per page; USP XIX includes 1284 monographs in 570 pages in contrast to USP XVIII's 1103 monographs in 788 pages. The running heads now include an alphabetic keyword in boldface type designating the title of the first monograph or chapter on the left-hand page or the last monograph or chapter on the right-hand page.

The monographs themselves are divided into two sections: the first section contains monographs on drug substances and dosage forms and the second section contains monographs on articles known as pharmaceutic ingredients. The word order for the monograph titles of most organic compounds follows the USAN principle that the pharmacologically active portion appears first, *e.g.*, Oxacillin Sodium rather than Sodium Oxacillin as used in USP XVIII. An additional chemical subtitle comprising the inverted name currently in the Indexes used by the Chemical Abstracts Service (CAS) of the American Chemical Society has been included in most monographs. As such they provide direct access to the literature as indexed in *Chemical Abstracts.* Also, for convenience, CAS registry numbers have been added to the chemical data section.

The format for the monographs has been modified to present the primarily informational sections first, followed by the specific compendial requirements that must be met by the article (the latter being introduced by a bold-face double-arrow symbol). These informational sections of most concern to the physician and pharmacist include category, dose information, sizes available, dispensing information, description, and solubility. The category and dose statement information that appeared in the drug monographs in USP XVIII has been moved and now appears instead in the dosage form monographs. The dose information itself has been expanded frequently to include a *Usual pediatric dose.* However, the *General Notices* cautions that the provision for this information is not to be construed as a recommendation or indication that the drug should be used in the pediatric patient but is intended to be only a guide to the physician after the prescribing decision has been made. The *General Notices* further recommends strongly that the package insert or full disclosure information about the drug be consulted. For the convenience of the physician who chooses to use body surface area as a basis for pediatric dose, a nomogram on the flyleaf opposite the inside back cover has been provided to simplify square meters of body surface calculations.

An entirely new section entitled *Dispensing information* has been added to individual dosage form monographs. This section, which consists of labeling suggestions, statements of advice that may be directed toward the patient, and notes that may be considered by the pharmacist, is intended for use in the prescription dispensing situation. According to the *General Notices,* the information is not complete, is intended to serve only as a basic reminder or general guide to the pharmacist and as a general reminder to the physician, and is not intended to limit or influence the professional judgment of the pharmacist in determining correct and proper patient information in accordance with the best interests of the patient or the particular circumstances involved.

Some specific revisions in the compendial requirements for articles include: a larger number of monographs with *in vitro* dissolution test requirements; extended content uniformity requirements for active drug substance in solid dosage forms (*e.g.*, all 50-mg or smaller tablets); and expanded availability and use of reference standards.

The general chapters also have been divided into two sections: those pertaining to compendial requirements are grouped under the heading *General Tests and Assays* and those containing no standards, tests, assays, or other mandatory specifications for any compendial article are grouped together as *General Information, Processes, Techniques, and Apparatus.*

Of particular interest, a new chapter on *Automated Methods of Analysis* has been included in this latter section as has a new pharmacist-oriented chapter on *Stability Considerations in Dispensing Practice.* A new general test chapter entitled *Containers—Permeation* is introduced and describes a moisture permeation test capable of demonstrating whether a multiple-unit container is tight enough to protect its contents from evaporation and gain of moisture. And, in conjunction with this requirement, official standards are set to determine compliance with existing definitions for well-closed and tight containers.

Sections on reagent specifications, pertinent tables, and an index round out this current volume.

Purchasers of the bound volume of USP XIX are entitled to receive the *First Supplement* and also a copy of the current edition of the *USP Guide to Select Drugs,* at no additional charge. And since formal negotiations were completed in January 1975 whereby the USP Convention acquired the National Formulary and thereby assumed full responsibility for publishing all supplements to the newly published edition, NF XIV, this first supplement will actually be a combined supplement to both USP XIX and NF XIV. The supplement was published in April and became official simultaneously with the main volumes of both compendia on July 1.

The exact nature of future publication plans for the compendia is still yet to be determined, but to quote Dr. William M. Heller from his *Foreword* to USP XIX, "[the] historic consolidation of USP and NF brings together two significant traditions, with all the strengths of both now united and at the ready to fulfill still larger purposes which demand our efforts and energies."

Staff Review

Sprowls' American Pharmacy, 7th Edition. Edited by LEWIS W. DITTERT. Lippincott, Philadelphia, PA 19105, 1974. 511 pp. 18 × 26 cm. Price $19.50.

For all those educators familiar with the series of editions of the "American Pharmacy" texts little can be said of the latest high quality revision in the 7th Edition. Although we now see a new Editor-in-Chief in Professor Lewis W. Dittert and a change in names of some of the chapter contributors from the previous 6th Edition, upon complete review, we see a finished product in keeping with the tradition of excellence brought to us by the previous contributors and the late Editors-in-Chief Rufus A. Lyman and Joseph B. Sprowls.

In the first five editions of this series, the attention was focused on compounding of medicinals primarily discussing specifics of the then official preparations. With the 6th Edition the attention was turned to the manufacturing of dosage forms at the industrial level. This appears to be the goal of the present 7th Edition as well. To this end, the goal is reached in a better than adequate format since the theory and practice given in this text are most appropriate to the industrial formulator. In no way should this detract from its use in preparing a dispensing pharmacist for a future role since some exposition is given for compounding on the extemporaneous level as well. Similarly, pharmaceutical heritage of the various dosage forms is given either as an historical overview in the first chapter or as an introduction to the chapters dealing with the particular groups of dosage forms.

This newest edition has had some changes of chapter headings compared to the previous one, but the new organization allows for integration of subject matter. As an example, the previous edition contained a separate chapter on "Galenicals" (reviewer's condensed title) which is now condensed and incorporated into the chapter on "Solutions Using Mixed Solvent Systems." As one might also expect, the topic of "Pills" is now relegated to a paragraph or two in the "History of Dosage Forms."

For those unfamiliar with this series, it may be said that the organization of subject matter is well suited to a syllabus in a modern course in pharmaceutics or pharmaceutical technology. It begins with the historic development of pharmaceuticals to the present day standards. This is followed by a short review chapter on pharmaceutical measurements. The next three chapters (3, 4, and 5) logically introduce the student to solutions. The first of these chapters briefly discusses the solubility phenomenon with exten-

Similarly, pharmaceutical heritage of the various dosage forms is given either as an historical overview in the first chapter or as an introduction to the chapters dealing with the particular groups of dosage forms.

This newest edition has had some changes of chapter headings compared to the previous one, but the new organization allows for integration of subject matter. As an example, the previous edition contained a separate chapter on "Galenicals" (reviewer's condensed title) which is now condensed and incorporated into the chapter on "Solutions Using Mixed Solvent Systems." As one might also expect, the topic of "Pills" is now relegated to a paragraph or two in the "History of Dosage Forms."

For those unfamiliar with this series, it may be said that the organization of subject matter is well suited to a syllabus in a modern course in pharmaceutics or pharmaceutical technology. It begins with the historic development of pharmaceuticals to the present day standards. This is followed by a short review chapter on pharmaceutical measurements. The next three chapters (3, 4, and 5) logically introduce the student to solutions. The first of these chapters briefly discusses the solubility phenomenon with exten-

sive tables of currently official solutions classed on method of preparation. A table of important formerly official solutions is also included. Chapter 4 covers waters, syrups, and juices whereas Chapter 5 then expounds on spirits, elixirs, and extracted products.

Chapter 6 illustrates the use of some timely physicochemical elements into the text which is employed in subsequent chapters as it discusses the colloidal state in theory and practice (including rheology) along with elements of surface chemistry. This is expanded upon in Chapter 7 as it focuses on suspensions, emulsions, and lotions. It is in this chapter that micromeritics is inserted rather than in a later chapter covering solids.

The next two chapters discuss semisolids. Chapter 8, for example, includes coverage of ointments, creams, and pastes with an introduction to percutaneous absorption, whereas Chapter 9 deals solely with suppositories, rectal anatomy, and rectal absorption.

Chapter 10 introduces the student to powdered dosage forms. Here large and small scale handling of powders is treated along with the preparation of folded powders and capsules. An extensive chapter on tablets naturally follows in Chapter 11. It is here that greatest emphasis is placed on the industrial procedures and equipment.

The format continues in its progressive orientation to industrial pharmacy by concluding with three highly specialized chapters. That is, Chapter 12 covers gas dispersions (aerosols and sprays) while Chapter 13 deals with radiopharmaceuticals and finally Chapter 14 concludes the text by treating sterile products.

All in all, it is a well-organized and easy to read text in pharmaceutics and although its progression of treatment may not fit an individual syllabus in pharmaceutics, all pertinent points are covered. In particular, it is gratifying to see the extensive use of tables of official products being preceded by general principles. The main drawback is that it has been published four years after the publication of USP and NF.

THE FIFTH FREEDOM: SCIENTIFIC COMMUNICATION

The United States is about to celebrate its 200th birthday. In case this fact had somehow escaped anyone, the month of July was filled with a host of commemorative activities which served to launch a year-long period of such features intended to culminate on July 4, 1976.

This editorial will serve as our way of contributing to the bicentennial effort, and adding our voice in reaffirmation of the ideals which prompted the American colonists to establish "a new nation, under God, with liberty and justice for all."

One of the basic freedoms or rights which these founding fathers established as a fundamental feature of the new nation was freedom of the press. This concept was novel in its time and even today has not gained acceptance through much of the world. We are proud to be able to say that provision for such expression is embodied in this Journal, not only through our editorials but more broadly through the Open Forum page. This Journal feature constitutes a vehicle for any reader to "sound off" and offer comments and opinions—which, within the most reasonable restrictions, are assured publication without being subject either to editing by the staff or to review by referees.

Mention of the press and the Revolutionary War period also brings to mind the major role played by the public press during colonial times in stimulating thinking, nurturing new concepts, and spreading ideas. Indeed, one can justifiably speculate that in the absence of the public press, the American Revolution might never have come about. Even the most casual or brief reading of history of that period dramatically reveals the tremendous impact of contemporary publications and the importance attached to them by the colonists.

Many other examples could be cited as to the power of the written word in stimulating thought processes and in communicating information whereby progress can be achieved. Not the least of these, by far, is the system which has been employed for the reporting of and dissemination of results of research in the basic and applied sciences. The most prominent element in this system has been the technical journal, of which this Journal is a typical representative.

But in recent years the scientific press generally has fallen upon hard times. Constricting subscription budgets, broad availability of photocopy machines, dropping circulation figures, soaring paper and printing costs, and rising postage rates are just some of the factors which have combined to put a financial squeeze on most technical journals and their publishers.

It is our guess that we shall see at least two effects of this squeeze within the coming decade. First, there will be a major "shake-out" in which most of the weaker journals will fall by the wayside and cease to exist. Second, among surviving journals there will be a substantial change in the mechanical way that they package and transmit the information intended for delivery to the reader; for example, journals may publish only abstracts of papers with the full text on deposit at some central source, or, instead of being printed on paper, journals may be issued entirely on microfiche.

Whatever the shape of things to come, it appears certain that significant changes will occur. In considering these new approaches, in adapting to them, and in accepting them, it is important to recognize that it is only through this means that viable communication can be maintained within the scientific community. To cling to our present system indefinitely will spell doom for the communication of research results generally.

If the scientific press strangles economically, it would be just as disastrous for the future of research as a political edict shutting down the public press would be in abruptly halting the advance of civilization. Hence, it is important for us to recognize that our basic goal is the survival of a system of scientific communication, whatever its eventual format may happen to be. —EGF

Osmolarity Values

Interest in the quality of drug products has continued to increase during the 5-year preparation of USP XIX. Several new discerning techniques of determining the identity, quality, purity, and strength have been included[1]. High-pressure liquid chromatographic methods, X-ray diffraction spectrometric methods, and atomic absorption spectrometric methods have been included as new pharmacopeial tests. Other strides in the new compendial requirements include particulate matter standards on large volume parenterals, pharmaceutical container standards, and expiration dates on drug products.

During the past revision period, the USP advisory panel on electrolytes and parenteral therapy unanimously recommended that the osmolarity value be included in the labeling for parenteral electrolytes and large volume parenterals which are commonly given intravenously. The objective of this recommendation was to alert physicians to the fact that they may be injecting solutions that are markedly hypotonic or hypertonic[2].

A brief survey of USP XIX indicates that for several preparations the osmolarity value must be stated on the label in milliosmoles per liter. Furthermore, different sizes and concentrations of these preparations are commercially available.

An array of concentration ranges of different parenteral preparations are official in USP XIX—*viz.*, calcium chloride (2–10%), calcium gluconate (1%), calcium levulinate (10%), dextrose (2.5–50%), dextrose and sodium chloride (2.5–25% and 0.11–0.9%, respectively), Ringers injection (0.85% sodium chloride, 0.3% potassium chloride, and 0.33% calcium chloride), magnesium sulfate (10–50%), mannitol (5–25%), mannitol and sodium chloride (5–15% and 0.45%, respectively), potassium chloride (8–24%), sodium bicarbonate (1.4–8.4%), sodium chloride (0.9%), and sodium lactate (0.19–5.6%). In view of the multitude of commercially available preparations, ranging from very dilute to saturated and/or supersaturated concentrations, the label requirement of the osmolarity value will become somewhat confused. Not only are these relative values of different preparations impractical to measure in concentrated solutions using a conventional osmometer, but they also markedly deviate from the expected values. In principle, the osmotic relationships can be considered in relation to other colligative properties and are indeed valid only for dilute solutions.

Additionally, our experience has demonstrated that some concentrated solutions are out of the measurable limits, some do not freeze, and some show deviations from calculated values when subjected to the normal operating conditions of the osmometer.

In view of the apparent controversy and confusion, additional guidelines are warranted if the manufacturer is to serve the community in a meaningful manner and the desired objectives are to be achieved. Unfortunately, the USP did not indicate any statement(s) in regard to this requirement. It is hoped that more uniform labeling can be developed for transmitting important information to various health-care professionals. Finally, it is surprising that this problem failed to attract our attention in the comment-proof stage of USP XIX.

Propylene Glycol USP—Harmful or Fatal If Swallowed!

A major supplier[1] of propylene glycol clearly indicates on the container label that the product is of USP quality. On the same label in red letters, half the size of the name of the product, is the word "CAUTION!" followed by the statements "Harmful or fatal if swallowed. Do not take internally." I am aware that propylene glycol is used as a solvent for vitamins taken orally as well as for other products administered by the oral route. A paper by Zaroslinski *et al.*[2] refers to propylene glycol having a relatively low order of toxicity and possessing pharmacological inertness. I know of at least one major hospital pharmacy that uses propylene glycol as a solvent for certain oral medications.

I do not understand how a well-known purveyor of a product which purports to meet the specifications of the USP can be allowed to include false, misleading, and patently incorrect information on a container label.

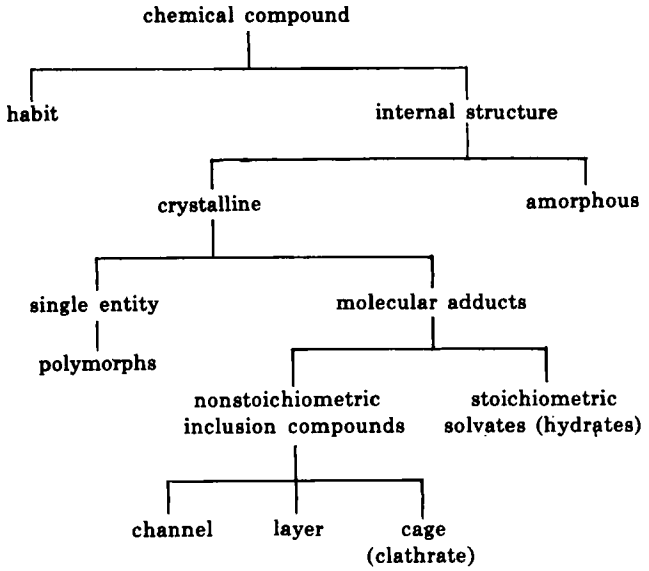
Conclusions 1286

Once the molecular chemistry of a potential drug is established and understood, most chemists feel that the compound is ready for formulation and clinical testing. Yet, every year, numerous papers appear showing that the performance of different drugs depends on, among other parameters, the habit and crystalline modifications of the active drugs. One crystal habit of a drug may tablet well while another may cause trouble, but both have the same melting point and apparently the same X-ray pattern. One crystalline modification may show five to 10 times the absolute solubility and bioavailability of another polymorph of the same drug. A drug marketed by Company A gives a stable suspension; the same com-



Scheme I—Outline Differentiating Habit and Crystal Chemistry of a Chemical Compound

pound, marketed by Company B, is stable only for a short time before the suspension is caked. These cases are not unusual. The majority of drugs marketed in various dosage forms probably can exist in different habits and crystalline modifications.

Since 1969, a series of review articles has dealt with polymorphism and its pharmaceutical application (1–5), but there is still confusion in the terminology used to identify different crystalline modifications of solids deviating from the basic definition of polymorphs (6–8). The intent of this work is not to review again the field of polymorphism but rather to review, in a broader sense, the different crystalline modifications of solids of pharmaceutical importance and their pharmaceutical application. Scheme I represents the outline to be followed in this review to differentiate habits and crystalline modifications of solids, *e.g.*, noncrystalline amorphous solids, polymorphs, solvates, and clathrates.

PHYSICAL APPEARANCE OF SOLIDS-HABITS

Definition—Habit is the description of the outer appearance of a crystal. If the environment of a growing crystal affects its external shape without changing its internal structure (which affects the polymorphism of a crystal), a different habit results. These

alterations are caused by the interference with the uniform approach of crystallizing molecules to the different faces of the crystal.

Crystal growth may be impeded by adjacent crystals growing simultaneously or contacting container walls. As a result, the development of plane faces may be inhibited or, in the case of late crystallizing crystals, an irregularly shaped crystal may occur since it is constrained to occupy only the spaces left between substances already crystallized. Such irregularly shaped crystals are described as anhedral or allotriomorphic (A, Fig. 1); those bound by plane faces are termed euhedral or idiomorphic (B, Fig. 1) (9). Anhedral crystals, although irregularly shaped, have a regular arrangement of building units which may be proved by X-ray diffraction.

Euhedral crystals are shown in Fig. 2:

A. Tabular crystal—moderate development of a pair of parallel faces, at the expense of the others, produces a tabular crystal.

B. Platy crystal—excessive development of the parallel faces as described in the tabular habit produces a platy crystal.

C. Prismatic crystal—crystal has a columnar form.

D. Acicular crystal—prism is elongated so much as to be needle like.

E. Bladed crystal—acicular crystal is flattened.

Factors that May Affect Crystal Habits—*Supersaturation*—The degree of supersaturation of the mother liquor or a supersaturation difference on opposite sides of the growing crystal may affect crystal habits. As supersaturation is increased, the crystal form tends to change from granular to needle like. A thin needle or dendrite loses less heat by conduction than a thicker crystal, so it grows faster. The effect of supersaturation on the change in the external form is given by a curve of high order which is characteristic of the substance:

$$y/x = k\Delta G^n \qquad \text{(Eq. 1)}$$

where y/x is the ratio of crystal length to breadth; k is a coefficient of proportionality which depends on the conditions of crystallization, especially on diffusion; G is the degree of supersaturation, in moles/

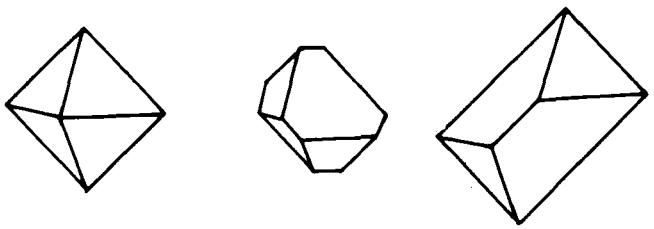

Figure 4—*Unevenly developed octahedra of magnetite. (Reproduced, with permission, from Ref. 9.)*

1000 moles of solvent, at the moment of formation of the nuclei of crystallization; and n is a number, above unity, dependent on the crystallographic classification and chemical composition of the substance (10).

Rate of Cooling and Degree of Solution Agitation—When naphthalene is rapidly crystallized by rapid cooling from ethanol or methanol, it gives thin plates; when it is slowly crystallized by evaporation, it yields compact crystals. The rate of cooling is effective in altering crystal habits because of its influence on the degree of supersaturation (11).

Nature of Crystallizing Solvent—The interaction between the solute and the solvent is important in controlling the crystal habit. For example, resorcinol crystallizes from benzene into fine needles, but it crystallizes from butyl acetate into squat prisms. Similarly, iodoform crystallizes as hexagonal bipyramids from aniline and as prisms from cyclohexane. This difference is due to the affinity of a solvated solvent to be adsorbed on certain crystal faces and thus to inhibit the growth of those particular crystalline faces (12).

Presence of Cosolutes, Cosolvents, and Adsorbable Foreign Ions—The addition of any new substance in a crystallizing medium may affect the habit of the crystal formed. Sodium chloride, which normally develops only cubic {100} faces, develops octahedral {111} faces when grown in the presence of urea (13, 14). Whetstone (15–18) studied crystal habit modifications due to the addition of impurities as crystal poisons. He found that the crystal habit change by dyes depended on anionic and cationic substituent groups and the nature of substitution. For further examples, the reader is referred to the review works of Tipson (11) and Biles (19).

Constancy of Conditions—Because any small change in these variables may affect the habit of the growing crystal, duplication of the habit of any crystal requires crystallization under identical conditions.

An excellent example of different habits of the same compound can be seen in calcite, $CaCO_3$ (20), where crystals can occur in acute or obtuse rhombs, hexagonal prisms, and many types of scalenohedra (Fig. 3). All of these geometric forms are built from the same unit rhombohedron of calcite, which can be shown readily by their optical properties and X-ray diffraction patterns.

Although habit is the description of the outer appearance of a crystal, crystals showing the same habit may appear different superficially. A good example is the three geometric forms of magnetite, Fe_3O_4, represented in Fig. 4, where all are octahedra of the cubic system but with uneven developments. Measurement of the interfacial angles would reveal true symmetry. Such measurements are the only morphological bases for crystal classification and identification of habits.

Characterization of Habits—The angle between two crystal faces can be described in two ways: (*a*) included or edge angle between two faces, and (*b*) interfacial or polar angle, the angle between the normals to the faces of the crystal (Fig. 5). The interfacial angle is commonly used in optical crystallography.

The interfacial angles of crystals are measured by instruments known as goniometers (9, 21). The simplest, the contact goniometer, is a semicircular protractor with a movable arm pivoted at the circle center. When the two faces enclosing the angle to be measured are fitted closely to the base and the movable arm, the value of the angle may be read off directly from the graduated half circle. Contact goniometers are used only on large crystals with dull faces for which the reflecting goniometer cannot be used.

In the reflecting goniometer (Fig. 6), the crystal to be measured is mounted on a stout needle. The needle is attached to the spindle of a graduated rotatable

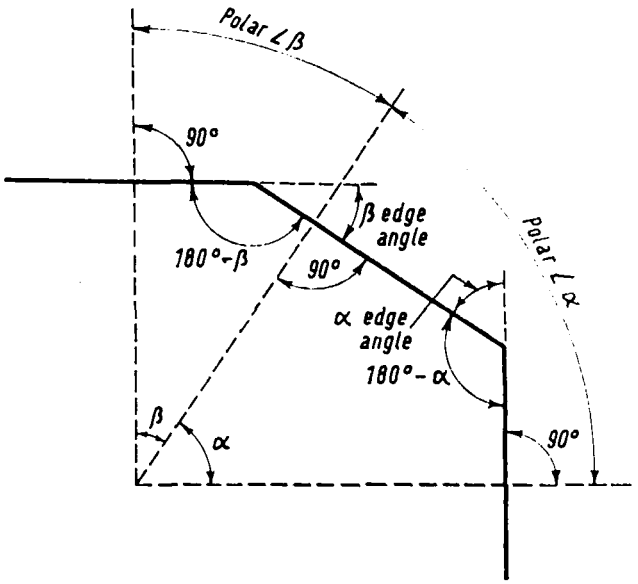

Figure 5—*Horizontal section across three vertical faces to show the relationship between included (edge) and polar angles. (Reproduced, with permission, from Ref. 9.)*

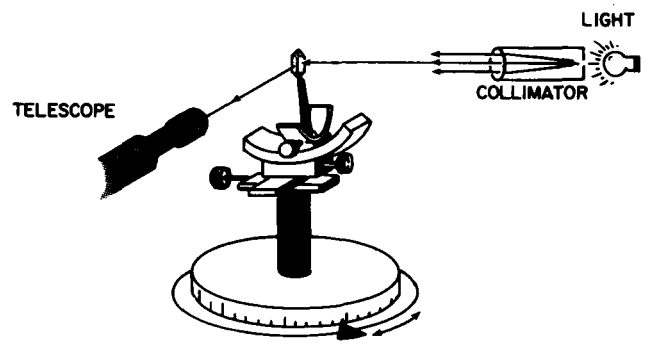

Figure 6—*Schematic of the reflecting goniometer.*

drum, which can be read to 1 min of arc by means of a vernier. The needle is provided with lateral and tilting adjustments, so that any zone of the crystal may be brought parallel to the axis of rotation of the drum. After this is done for one zone, parallel light from a collimator, fitted with a slit, is directed at the crystal and, by turning the drum, is reflected from each face of the zone in turn into a telescope provided with crosshairs. The reading is taken whenever the image of the slit coincides with the intersection of the crosshairs. The differences between these readings supply the angles between the normals to the faces (9).

Pharmaceutical Application of Habits—Crystal habits may influence several pharmaceutical characteristics.

Suspension Syringeability—The influence of suspension syringeability is mostly mechanical. For example, a suspension of plate-shaped crystals may be injected through a small needle with greater ease than one with needle-shaped crystals of the same overall dimensions (22).

Tableting Behavior—Shell (22), in his work on X-ray and crystallographic applications in pharmaceutical research, showed the effect of crystal habit on tablet properties. To evaluate the tableting behavior as influenced by crystal habit, he quantitatively described crystal habits by measurement of preferred orientation and related this parameter to compression characteristics of the powder. He took the ratio of the relative peak intensities of critical lines in the X-ray diffraction pattern and used them as average habits of crystals. In the compound studied, he found that the higher the 001 orientation ratio to the 010 orientation, the better was the tableting behavior.

Dissolution of Crystalline Material—If a crystal changes its habit due to crystal poisoning by a dye, then, in an indirect way, as reported by Piccolo and Tawashi (23), the adsorbed dye may inhibit the dissolution of drug crystals, which, in turn, may affect the bioavailability of the material.

Although the concept of habits of solids has been recognized since ancient times, the internal structure of solids, *i.e.*, the arrangements of atoms, was not understood until the introduction of X-ray crystallography by William and Lawrence Bragg. Solids in general are divided into two categories: (*a*) amorphous, where there is no regularity in the structure, and (*b*) crystalline, where the atoms are arranged in regular arrays. The crystalline form is the most frequent of the two and includes the metals and most minerals.

NONCRYSTALLINE SOLIDS-AMORPHOUS FORM

Definition—The most common amorphous solid is glass. Its atoms are put together in a nonuniform array compared to its crystalline form. Figure 7 represents the two forms of silica, which exists either as a crystal or as a glass. Cristobalite is the high-temperature form of quartz (SiO_2), while the glass structure looks like a distorted structure of cristobalite.

Randall and coworkers (24–28) reported that when a substance is capable of existing in both amorphous and crystalline forms, then the X-ray pattern given by the amorphous form may be regarded as a very diffuse version of the crystal pattern. There is, in fact, no sharp distinction between crystalline and amorphous states. If, starting with a coarsely crystalline solid, the size of the crystals could be reduced by stages and an X-ray diffraction photograph could be taken at each stage, the photographs would become diffuse when the crystal size fell below about 10^{-5} cm. With reduction of crystal size, the reflections become increasingly diffuse until the limit is reached at 10^{-7}–10^{-8} cm, the region of atomic dimensions, where the word crystal, with its implication of precise pattern repetition, ceases to be appropriate.

One cannot speak of a crystal only one unit cell in diameter, because the term unit cell implies repetition; this is the justification for the use of the term amorphous in describing glass-like substances, although the word noncrystalline might be preferable.

Preparation of Amorphous Solids—Preparation of amorphous solids, if feasible, does not follow a routine procedure. Methods mentioned by previous workers include lyophilization of fluprednisolone in *tert*-butanol (29), rapid quenching of chloramphenicol palmitate solution in hydrophilic solvents (30), and rapid quenching of melted chloramphenicol palmitate in the refrigerator to −10° (31). Precipitation is also used to prepare the amorphous prompt insulin zinc suspension of USP XVIII (32). It is prepared by precipitation of insulin and zinc chloride at a specified pH.

Characterization of Amorphous Solids—The only positive way to differentiate amorphous from crystalline solids is by means of X-ray powder diffraction. The X-ray powder diffraction of amorphous

Table I—Novobiocin Plasma Levels in Dogs following Oral Administration of Different Solid Forms[a]

Hours after Dose	Novobiocin Sodium, μg/ml Plasma	Amorphous Novobiocin Acid, μg/ml Plasma	Crystalline Novobiocin Acid
0.5	0.5	5.0	N.D.[b]
1	0.5	40.6	N.D.[b]
2	14.6	29.3	N.D.[b]
3	22.2	22.3	N.D.[b]
4	16.9	23.7	N.D.[b]
5	10.4	20.2	N.D.[b]
6	6.4	17.5	N.D.[b]

[a] Dose = 12.5 mg/kg. [b] Not detectable.

solids gives very diffuse reflections where the *d* distances, the distance between parallel planes in which the atoms of the crystal lie, cannot be determined as is done with crystalline solids.

Pharmaceutical Application of Amorphous Solids—Although it is feasible to prepare amorphous solids, there are few instances where advantage has been taken of this class of compounds. One main reason is their thermodynamic instability, since they are the most energetic form and tend to revert to a more stable form. This is particularly true when the formulation is in aqueous suspension.

Mullins and Macek (33), working on pharmaceutical properties of novobiocin, identified two forms of novobiocin: crystalline and amorphous. In tablet and capsule formulations, novobiocin is used as the sodium salt, which is active orally but is unstable chemically in a solution. The insoluble forms of novobiocin acid are more stable chemically. But the crystalline novobiocin acid is poorly absorbed and does not provide therapeutically adequate systemic levels following oral administration. The amorphous acid is readily absorbed and is therapeutically active. This difference in availability is due to differences in solubility in aqueous systems.

When an excess of crystalline or amorphous novobiocin acid in less than 10-μm size was shaken in 0.1 *N* hydrochloric acid at 25°, the amorphous solids were at least 10 times more soluble than the crystalline acid. This difference in solubility might be expected to favor the absorption of the amorphous solid from the GI tract. Data showing differences in novobiocin plasma levels following oral administration of 12.5 mg/kg each of amorphous novobiocin acid, crystalline novobiocin acid, and the sodium salt are shown in Table I.

Unless special precautions are taken to maintain the solid in suspension in the amorphous state by the addition of materials to suppress crystallization, amorphous novobiocin converts slowly to a crystalline form. The formulation becomes less and less absorbable and finally loses therapeutic effect entirely. A search was made for additives that would significantly retard or even prevent crystallization of aqueous suspensions of amorphous novobiocin, and some agents provided adequate protection for significant periods. The best agents found were methylcellulose, polyvinylpyrrolidone, and several alginic acid derivatives such as sodium alginate and propylene glycol algin.

In formulating injectable insulin, the duration of the action is controlled by its crystallinity. Insulin precipitates as an insoluble complex when reacted with zinc chloride and, depending on the pH, it may precipitate either as an amorphous or crystalline phase. Prompt insulin zinc suspension USP consists of amorphous insulin zinc complex. It is readily absorbed when injected and has a relatively short duration of action.

Extended insulin zinc suspension USP is made up of crystalline zinc complex. It is very slowly absorbed and has a longer duration of action. Insulin zinc suspension USP is made up of a mixture containing seven parts of crystalline and three parts of amorphous insulin zinc complex, and it is intermediate in duration of action. Another difference in the formulations is their particle sizes; prompt insulin is made up of small particles, and extended insulin is made up of large particles. This is another example where the rate of absorption and duration of action are determined both by particle size and degree of crystallinity (32).

Crystalline solids produced by the different methods of crystallization may crystallize out as single entities or as molecular adducts, where the adduct is one of the solvents of crystallization. The solid crystalline phase of a single entity is said to be polymorphic when it is crystallized at least in two different arrangements of the molecules.

SINGLE-ENTITY CRYSTALLINE SOLIDS-POLYMORPHS

Haleblian and McCrone (1) reviewed the pharmaceutical applications of polymorphism. This section presents some papers dealing with the pharmaceutical application of polymorphism appearing since 1969.

One welcome addition to the field of polymorphism is Kuhnert-Brandstätter's book on "Thermomicroscopy in the Analysis of Pharmaceuticals" (34). To show how frequently polymorphism occurs in pharmaceuticals and how numerous the modifications of a substance may be, the author described three representative groups in detail. Of the barbiturates used medicinally, she found that about 70% were polymorphic. A fairly large number of these barbiturates possessed four or five crystalline modifications.

The other groups described were the steroid hormones and sulfonamides; she found 42 polymorphic steroids in the former group and 30 polymorphic sulfonamides and related compounds in the latter group. She also compiled the microscopic behavior of hundreds of pharmaceuticals when subjected to heat and identified the presence of any existing polymorphs.

Another important paper is Buerger's review (35) of the basics of transformation theory and the forms involved in the transformation, namely the polymorphs. He discussed the reasons why some poly-

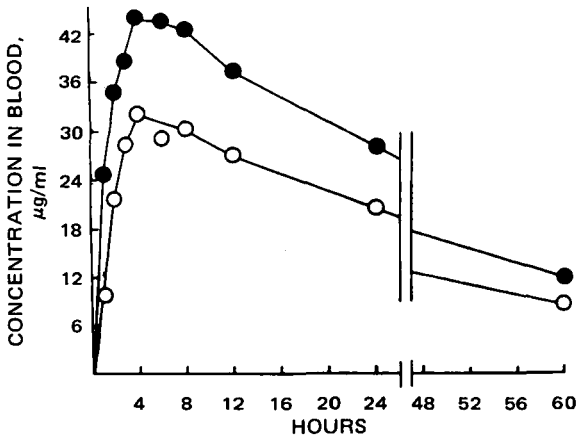

Figure 8—*Mean blood concentration curves of sulfameter crystal Forms II and III. Key: ●, Form II; and ○, Form III. (Reproduced, with permission, from Ref. 49.)*

morphic changes happen faster than others. Kinetic theory predicts that, if the transformation from one polymorphic structure to another is opposed by a potential barrier of magnitude B, the speed of transformation is proportional to $1/e^{B/kT}$.

For some structural changes, when the temperature reaches the transformation temperature, many or all of the atoms can immediately surmount the barrier. Therefore, the transformation is rapid. In other structural changes, few atoms have the thermal energy to surmount the barrier. Appreciable time then is needed for one structure to change to the other through temperature variation; the transformation is relatively sluggish (35).

Examples of Polymorphism—A recent major advance in the field of polymorphism has been the X-ray crystallographer's interest in compounds exhibiting polymorphism. Investigations using single crystals have, for the first time, given the absolute configuration of different compounds exhibiting polymorphism. Perrin and Michel (36, 37) solved the structure of p-chlorophenol where the α-form, the stable modification, is a monoclinic crystal while the β-form is a metastable crystal stable at $-10°$ but also belongs to the monoclinic system. Kahn *et al.* (38), working with cyclohexane, solved the structures of both Phases I and II, the stable phases, but could not solve the structure of Phase III. Phase III is a metastable form, and single crystals are not obtainable.

Of special pharmaceutical importance is the work of Busetta *et al.* on estrone (39). They found that Phases I and II crystallize as orthorhombic crystals while Phase III crystallizes as a monoclinic crystal. This reviewer believes that the method developed by Busetta *et al.*, although tedious, is the ultimate method for establishing whether a polymorph exists and should be used whenever the polymorphism of a compound is in question.

The search for different polymorphs of pharmaceuticals has now spread all over the world, with sulfonamides being extensively studied (40–43).

The p-amino group, the acidic N^1-hydrogen atom, and the oxygens of the sulfonamide group were implicated in the various hydrogen bonding arrangements that distinguish one polymorphic form from another (43). It was postulated that electron-withdrawing and electron-donating groups at the N^1-position influence the strength of the hydrogen bonds formed, hence the tendency of compounds to exist in more than one crystalline form.

The thermal behavior of four crystalline phases of sulfanilamide and of sulfanilamide-d_4 were compared; the deuterated modifications exhibited smaller heats of transition and heats of fusion than the corresponding undeuterated forms (44). Further work was done on the different crystal forms of sulfathiazole (45–47).
