
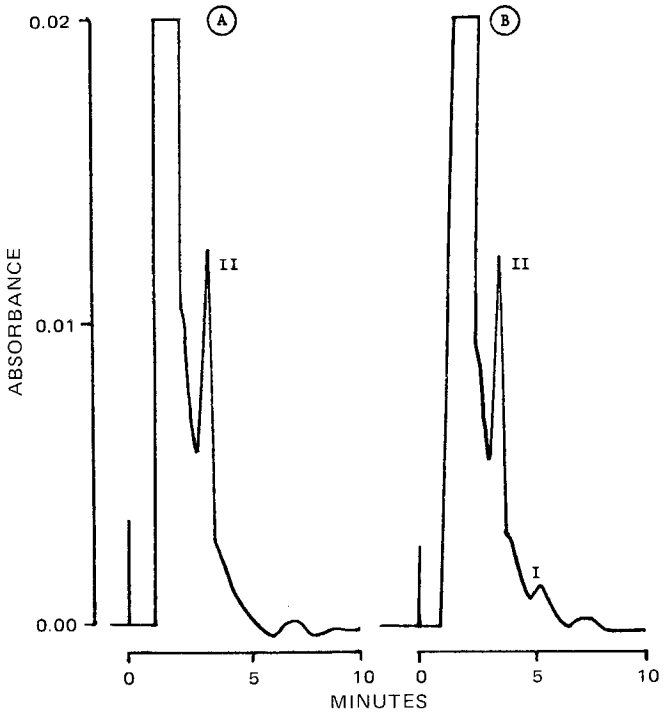

Figure 2—*Representative chromatograms of a urine extract containing 0.98 μg of II (A) and of a urine extract containing 0.125 μg of I plus 0.98 μg of II (B) after chromatography on a bonded reversed-phase column using methanol–0.1 M NaH_2PO_4 (3:2 v/v) as the mobile phase.*

titation was achieved by measuring the peak areas of II and relating them to the least-squares linear regression curve (n = 15) of the peak area of II *versus* the amount of II injected. Peak areas were measured as described previously.

Precision Determination for Mefloquine Assay—Aliquots (25 ml) of human whole blood and plasma were spiked with a methanol solution of mefloquine (250 μg/ml) to give drug concentrations of 5.00, 1.00, 0.50, and 0.05 μg/ml. Urine aliquots (25 ml) were spiked at 5.00, 1.00, 0.50, and 0.25 μg/ml. The samples were thoroughly mixed for 30 min and treated as described under *General Assay Procedure*.

Clinical Study—An adult male was given two 250-mg tablets of mefloquine hydrochloride. Whole blood and plasma samples were obtained at 0, 1, 2, 4, 8, and 12 hr and at 2, 3, 4, 7, 9, 14, 21, 31, and 57 days. A random urine sample was obtained on Days 1 and 2. All specimens were stored in glass tubes with polytef-lined screw caps at −10° until analyzed.

RESULTS AND DISCUSSION

Mefloquine and its analog II have similar physicochemical properties. Both compounds are extensively bound to plasma proteins and are concentrated in the erythrocytes (5, 6); they have nearly identical molar absorptivity at 280 nm, pKa's, solvent partition coefficients, and low aqueous solubility. Both compounds were well resolved from each other and from extracts of blood and urine under appropriate chromatographic conditions. For these reasons, II was chosen as the internal standard for the mefloquine assay.

The establishment of HPLC conditions was accomplished by examining the retention characteristics of mefloquine and II on polar bonded phase and bonded reversed-phase partitioning columns. Comparative retention volumes for mefloquine and II are presented in Table I. Optimal resolution of both compounds from each other and from ethyl acetate extracts of blood and plasma was accomplished using a polar bonded phase partitioning column with a mobile phase of isopropyl ether–dioxane–acetic acid (3:2 v/v + 0.5%). These conditions did not adequately resolve mefloquine and II from the urine extract peaks. Resolution of mefloquine and II from urine extracts was achieved on a bonded reversed-phase column utilizing a mobile phase of methanol–0.1 M NaH_2PO_4 (3:2 v/v). Representative chromatograms are presented in Figs. 1 and 2. No interfering peaks from blood, plasma, or urine extract components were detected in control samples.

Mean percent recovery ± *RSD*	102.9 ± 6.7	99.5 ± 9.5	97.1 ± 9.4

[a] Chromatographic conditions are described under *Experimental*. [b] The concentration of internal standard was 1.96 μg/ml. [c] Mean ± *SD* for four replicates at each level.

Recovery percentages for the individual extraction of mefloquine and II from whole blood using ethyl acetate as solvent are presented in Table II. The recoveries were greater than 95% for both compounds over the range studied with standard deviations less than 10%.

Linear calibration curves of the peak area ratio for I/II *versus* the amount of I were constructed each day utilizing 15 points at five concentration ratios. The data were analyzed using least-squares regression analysis. A family of curves over a 6-month period had a mean slope of 1.013 with a relative standard deviation of 3.9% and a correlation coefficient (r) of 0.9997.

Precision data utilizing optimal conditions for the assay of blood, plasma, and urine specimens spiked with known concentrations of mefloquine are presented in Table III. The relative accuracy was ±3% of the amount added with relative standard deviations less than 10% over the 0.05–5.00-μg/ml range for blood and plasma and over the 0.25–5.00-μg/ml range for urine. The lower limit of sensitivity for the assay was 0.05 μg/ml for blood and plasma samples and 0.25 μg/ml for urine samples.

Based on the results of these experiments, an adult male was given 500 mg of mefloquine hydrochloride, and serial blood and plasma specimens were assayed for 2 months for mefloquine concentrations (Figs. 3 and 4). Blood and plasma levels of mefloquine were readily quantitated 57 days after drug ingestion. Random urine specimens obtained on Days 1 and 2 were assayed for free mefloquine content (Table IV) and contained low, but quantifiable, levels of mefloquine.

The mefloquine blood and plasma level data from a single subject after oral administration indicated relatively rapid absorption, extensive distribution, and prolonged elimination phases. Partitioning of mefloquine into the erythrocytes in competition with extensive binding to

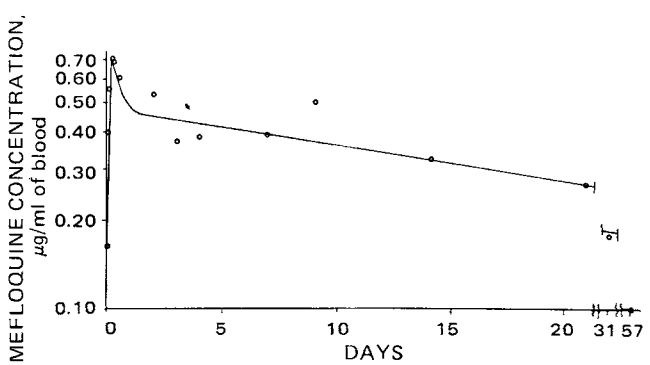

Figure 3—*Whole blood I concentrations in a male subject following a single oral dose of 500 mg of I.*

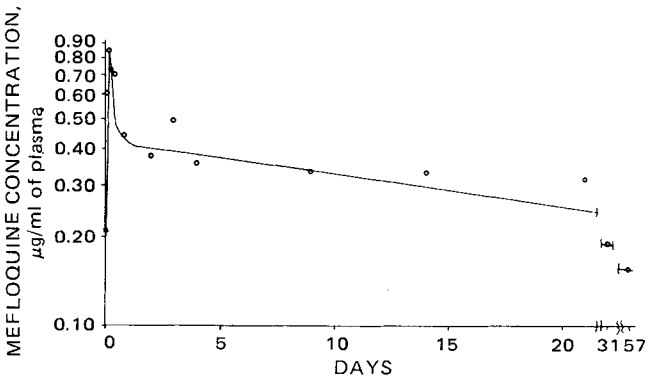

Figure 4—*Plasma I concentrations in a male subject following a single oral dose of 500 mg of I.*

plasma proteins probably caused the apparent disparities in the blood and plasma level data. Further data interpretation will be performed in conjunction with ongoing pharmacokinetic studies. The ability of the assay to follow blood and plasma levels of mefloquine for at least 57 days after a single oral administration of the drug established its utility for studying mefloquine's pharmacokinetic parameters in humans.

Cytolysis of Neuroblastoma Cells *In Vitro* and Treatment of Neuronal Tumors *In Vivo* with Bromoacetylcholine

C. Y. CHIOU

Abstract □ The effect of bromoacetylcholine on mouse neuroblastoma C-1300 was investigated in cell culture as well as in A/J mice. *In vitro,* bromoacetylcholine (1×10^{-5} *M*) was a potent cytolytic agent and produced an additive effect in combination with vincristine (3×10^{-9} *M*). Since the choline acetyltransferase inhibitor, dimethylaminoethyl chloroacetate, does not inhibit neuroblastoma efficiently *in vitro,* the potent cytolytic action of bromoacetylcholine is probably not due to its choline acetyltransferase inhibitory action. Furthermore, the neuroblastoma inhibitory effect of bromoacetylcholine was not affected by atropine. Therefore, the inhibitory action is not related to the interaction of bromoacetylcholine with muscarinic receptors either. In *in vivo* experiments, 1, 10, or 30 mg/kg of bromoacetylcholine was injected directly into the tumors three times daily for 6 weeks. Bromoacetylcholine at 10 and 30 mg/kg gave significant protection of A/J mice from the death induced by neuroblastoma inoculation, and the lifespan was prolonged significantly with these bromoacetylcholine treatments.

Keyphrases □ Bromoacetylcholine—*in vitro* cytotoxic and *in vivo* antitumor activity, mice □ Cytotoxic activity—bromoacetylcholine evaluated, mouse neuroblastoma cell culture □ Antitumor activity—bromoacetylcholine evaluated, mouse neuroblastoma □ Cholinergic agents—bromoacetylcholine, *in vitro* cytotoxic and *in vivo* antitumor activity, mice

Many attempts have been made to treat the highly malignant neuroblastoma in children (1). However, no drug tested, including cyclophosphamide and vincristine, is satisfactory, mainly because the remission rate in neuroblastoma patients is quite low and the duration of drug effectiveness is fairly short (2–4).

The nature of neuroblastoma cells can be cholinergic, adrenergic, or inactive (5–8). Acetylcholinesterase is always present, and these cells possess membranes that respond to acetylcholine and are excitable electrically. These data indicate the existence of cholinergic receptors at the membrane site (7, 9). Attempts were made to destroy these

neuronal tumors with an irreversible sympatholytic agent, 6-hydroxydopamine (10), resulting in a brief tumor regression only in the 1st week of treatment. The effectiveness of this treatment then decreased rapidly.

The ineffectiveness of 6-hydroxydopamine to maintain cytolysis of neuroblastoma was confirmed further by Finklestein *et al.* (11). Therefore, instead of an adrenolytic agent, an irreversible cholinolytic agent, bromoacetylcholine (12), was evaluated and is the subject of this report.

EXPERIMENTAL

Materials—Vincristine sulfate, 6-hydroxydopamine hydrochloride, and atropine sulfate were obtained commercially. Bromoacetylcholine perchlorate and dimethylaminoethyl chloroacetate were synthesized using previously published methods (13, 14).

Culture Medium—Mouse neuroblastoma C-1300 was cultivated in Dulbecco modified Eagle medium[1] supplemented with 10% fetal calf serum[2], 200 m*M* L-glutamine, 30 m*M* $NaHCO_3$, 50 units of penicillin/ml, and 50 μg of streptomycin/ml (7). The cells were grown at 37° under 95% air–5% CO_2 with 100% humidity.

For the culture experiments, 1×10^6 cells were placed in a tissue culture flask[3] (75 cm^2) for 3–5 days until the cells were in the logarithmic growth phase. They were then removed from the surface by a 15-min exposure to 0.25% trypsin in modified D_1 solution[4] (7, 15). The cells were then tapped off in fresh medium containing 10% fetal calf serum. Aliquots of the cell suspension were incubated for 5 min with 0.4% trypan blue, and the number of viable and nonviable cells was counted with a hemocytometer.

Appropriate dilution was made, and the cell suspension was plated at

[4] Modified D_1 solution contained 1.2 mg of phenolsulfonphthalein, 8 g of sodium chloride, 0.4 g of potassium chloride, 45 mg of dibasic sodium phosphate heptahydrate, 30 mg of monobasic potassium phosphate, 2 g of glucose, 20.2 g of sucrose, 5×10^4 units of penicillin, and 50 mg of streptomycin in 1 liter of double-distilled water.

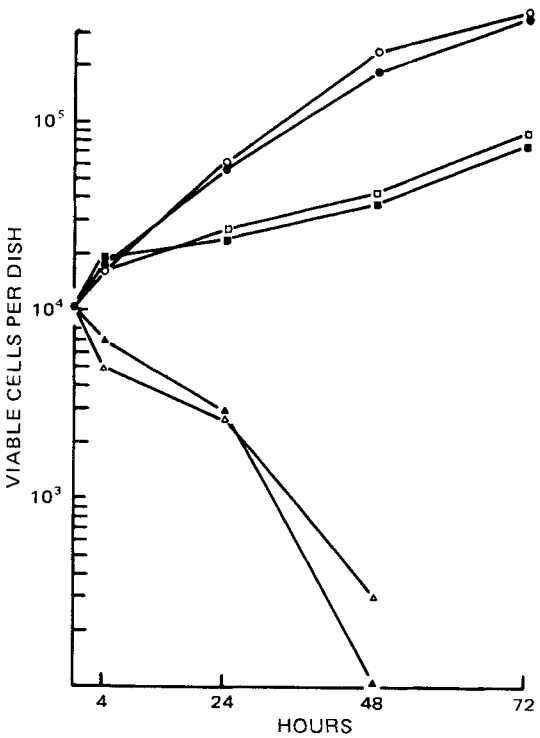

Figure 4—*Effect of atropine (1×10^{-7} M) on the control growth of neuroblastoma and inhibitory action of bromoacetylcholine* in vitro. *Key: ●, control; ○, 1×10^{-7} M atropine; ■, 1×10^{-5} M bromoacetylcholine; □, 1×10^{-5} M bromoacetylcholine plus 1×10^{-7} M atropine; ▲, 3×10^{-5} M bromoacetylcholine; and △, 3×10^{-5} M bromoacetylcholine plus 1×10^{-7} M atropine. Each point is a mean of four experiments.*

5×10^4 cells/dish (tissue culture dishes[3] of 35-mm diameter) and grown for 24 hr. Various concentrations of drugs were added to the medium, and these cultures were incubated further for 72 hr. The cultures were removed at intervals (4, 24, 48, and 72 hr) for cell count.

Inhibition of Neuroblastoma *In Vitro*—Various concentrations of bromoacetylcholine, dimethylaminoethyl chloroacetate, 6-hydroxydopamine, and vincristine were added to the cell culture to determine the potency of these drugs and drug combinations to inhibit neuroblastoma. Drug concentrations required to reduce the initial control viable cells (at zero time) by 50% after 72 hr of incubation were termed CD_{50} (50% cytolytic dose). Bromoacetylcholine (3×10^{-5} *M*) also was added to the culture medium after various incubation times (0, 4, 24, and 48 hr) to study its inhibitory ability at various stages of neuroblastoma culture.

To determine whether the inhibitory action of bromoacetylcholine is mediated through its interaction with the muscarinic site, atropine was added to the medium.

Treatment of Neuroblastoma *In Vivo*—The cell suspension of mouse neuroblastoma C-1300 was injected (1×10^6 cells/mouse) subcutaneously to the interscapular area of A/J mice[5], 16–18 g (11, 16). Ten days later, the animals were divided into tumor-control and tumor-treated groups. The control group was injected three times daily, except Saturdays and Sundays, with saline; the treated groups were injected similarly with bromoacetylcholine at 1, 10, or 30 mg/kg. Injections were made directly into the tumors. The size and body weight were recorded every other day.

Figure 5—*Control A/J mouse inoculated with 10^6 cells of neuroblastoma for 5 weeks.*

[5] Jackson Lab., Bar Harbor, Me.

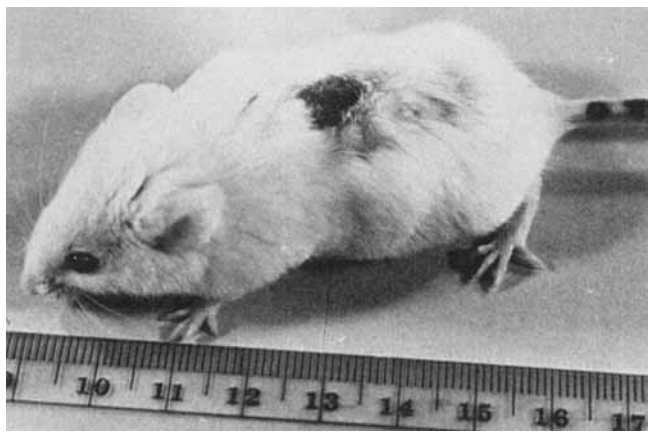

Figure 6—*Treatment of neuroblastoma-inoculated A/J mouse with 30 mg of bromoacetylcholine/kg three times daily for 6 weeks.*

RESULTS

Figure 1 shows a potent cytolytic effect of bromoacetylcholine on neuroblastoma cells at a concentration of 1×10^{-5} *M*. The neuroblastoma cells could be inhibited by bromoacetylcholine (3×10^{-5} *M*) at any stage of the incubation period (0, 4, 24, and 48 hr) (Fig. 2). The CD_{50} of bromoacetylcholine was 5.8×10^{-6} *M*.

Bromoacetylcholine is a potent inhibitor of choline acetyltransferase in cell-free choline acetyltransferase preparations (17). Although bromoacetylcholine does not cross the cell membrane efficiently because of its positive charge in the molecule, it is possible to accumulate enough bromoacetylcholine in the intracellular site to inhibit choline acetyltransferase after prolonged incubation. To determine whether the cytolytic action of bromoacetylcholine is related to its inhibition of choline acetyltransferase in the intracellular site, dimethylaminoethyl chloroacetate was used because it can get into the intracellular site efficiently. Although dimethylaminoethyl chloroacetate inhibited choline acetyltransferase in the intact cellular preparation with an I_{50} of 1.29×10^{-4} *M* (14), it took 1.3×10^{-3} *M* to inhibit the growth of neuroblastoma, indicating that the cytolytic action of dimethylaminoethyl chloroacetate

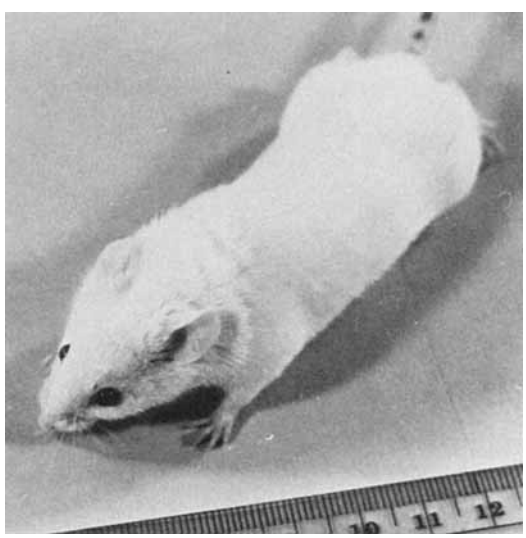

Figure 7—*Complete recovery of neuroblastoma-inoculated A/J mouse. The mouse was treated with 30 mg of bromoacetylcholine/kg three times daily for 6 weeks. Drug treatment was stopped thereafter, and the picture was taken 7 weeks after the drug treatment was stopped.*

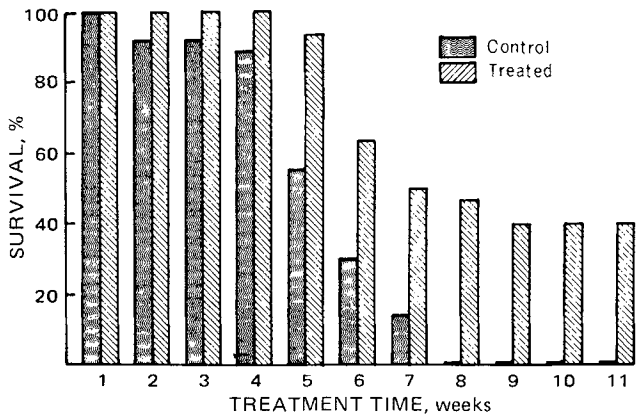

Figure 8—*Comparison of survival rate between treated (bromoacetylcholine, 30 mg/kg) and untreated (control) neuroblastoma-inoculated A/J mice.*

on neuroblastoma is either unrelated to the inhibition of choline acetyltransferase or due to a rise in concentration needed in cancer cells to inhibit choline acetyltransferase.

The sympatholytic, 6-hydroxydopamine, had a CD_{50} of 2.0×10^{-5} *M*. Vincristine, a cellular mitotic arresting agent used clinically to treat neuroblastoma, was very potent, inhibiting neuroblastoma *in vitro* with a CD_{50} of 8.5×10^{-9} *M*. Combined use of bromoacetylcholine (1×10^{-5} *M*) and vincristine (3×10^{-9} *M*) produced an additive effect, which was equivalent to the higher concentration of bromoacetylcholine or vincristine given individually (Fig. 3).

Atropine (1×10^{-7}–1×10^{-5} *M*) did not affect the cytolytic action of bromoacetylcholine on neuroblastoma (Fig. 4), indicating that bromoacetylcholine does not act *via* muscarinic sites to inhibit neuroblastoma. The CD_{50} of atropine was greater than 1.0×10^{-4} *M*.

In *in vivo* experiments, a dramatic difference between control and treated neuroblastoma mice was noted (Figs. 5–8). Marked tumor regression was noted 3 weeks after bromoacetylcholine treatment at doses of 10 and 30 mg/kg (Figs. 5 and 6). The area of tumor became hard, flattened, and necrotic after 6 weeks of treatment. Finally, the fur grew back and looked healthy 3 months after the treatment was initiated (Fig. 7). Treatments were stopped after 6 weeks.

The survival time increased significantly with mice treated with 10 and 30 mg/kg of bromoacetylcholine (Table I and Fig. 8). Although the body weight of the control group was only slightly lower than that of treated ones (Fig. 9), subtraction of tumor weight from the total body weight would make the net body weight of control mice be even lighter than the treated ones.

DISCUSSION

Bromoacetylcholine is promising as a cancer chemotherapeutic agent for metastatic neuroblastoma, because it inhibits effectively the growth

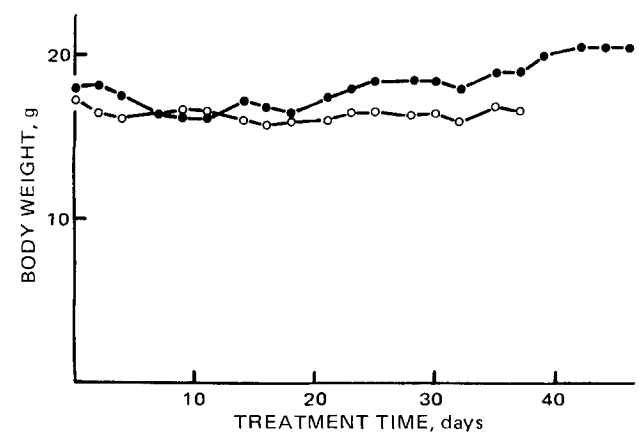

Figure 9—*Comparison of body weights of treated (bromoacetylcholine, 30 mg/kg) and untreated (control) neuroblastoma-inoculated A/J mice. Key: ●, treated; and ○, control.*

Table I—Treatment of Neuroblastoma with Bromoacetylcholine in Adult A/J Mice on Subcutaneously Inoculated Tumors

Treatment	*n*	Survival Time: Range, days	Survival Time: Mean, days	CLS[a], %
Control	12	10–47	34.3 ± 2.9	—
Bromoacetylcholine, 1 mg/kg[b]	7	27–39	33.4 ± 1.7	−2.6
Bromoacetylcholine, 10 mg/kg[b]	7	31–120[c]	56.9 ± 11.7[d]	+65.8
Bromoacetylcholine, 30 mg/kg[b]	10	30–120[c]	64.3 ± 12.6[d]	+87.5

[a] Percent change in lifespan (CLS) of treated over control mice. [b] These doses were administered three times daily, except Saturday and Sunday, for 6 weeks (40 days). [c] The 120 days is not the upper range of survival time, because some mice survived longer; 120 days was chosen arbitrarily as a cutoff date for the purpose of statistical analysis. [d] Statistically different from control ($p < 0.05$).

of neuroblastoma at 5.8×10^{-6} *M* or higher *in vitro* (12).

One major obstacle of using anticancer drugs is toxicity. The main side effect anticipated with the use of bromoacetylcholine is the muscarinic (parasympathomimetic) action, which can be eliminated with atropine and its analogs. Bromoacetylcholine is a cholinergic agonist and stimulates both nicotinic and muscarinic receptors directly (18–20). However, when it is incubated with cells for 15 min or longer, it binds irreversibly to the cholinergic receptor at the nicotinic site but not at the muscarinic site (18, 21).

Atropine (up to 1×10^{-5} *M*) did not affect the cytolytic actions of bromoacetylcholine on neuroblastoma. Therefore, it is possible that bromoacetylcholine can be used along with muscarinic blocking agents as a safe and potent drug to treat neuronal tumors.

Alternatively, reduced doses of more than one cancer chemotherapeutic agent with different action mechanisms can be used in combination. In this way, the chemotherapeutic actions of these drugs can be enhanced while their side effects can be minimized.

Among several agents tested, vincristine was the most potent neuroblastoma inhibitor. When combined with bromoacetylcholine, it showed additive effects, indicating that reduced quantities of bromoacetylcholine (1×10^{-5} *M*) and vincristine (3×10^{-9} *M*) can be used together to get an effect that requires higher concentrations of bromoacetylcholine (3×10^{-5} *M*) or vincristine (1×10^{-8} *M*) when given individually.

Results obtained from *in vivo* experiments are very encouraging, because 50% of the neuronal tumor mice that were treated with bromoacetylcholine at the 30-mg/kg dose injected three times daily for 6 weeks survived after all untreated control mice were dead. Certainly, the dose regimens and the administration route in this study are not ideal, and the combined use of bromoacetylcholine with atropine and/or vincristine should be tried[6].

Since the murine neuroblastoma system used is reported to be a model of human disease (16), the effectiveness of bromoacetylcholine for treating neuroblastoma *in vivo* in this study makes it promising for treating neuroblastoma in children.

Determination of Triprolidine in Human Plasma by Quantitative TLC

R. L. DeANGELIS, M. F. KEARNEY, and R. M. WELCH ˣ

Abstract □ A chromatographic thin-layer fluorescence procedure, with a sensitivity limit of 0.8 ng/ml, is described for the quantitative analysis of triprolidine in human and rat plasma. Following the intravenous administration of 1 mg/kg of triprolidine to rats, the drug distributed rapidly into tissues and was eliminated from plasma with a half-life of 53 min. The method was used to determine the plasma triprolidine levels in 16 normal human volunteers following oral administration of 3.75 mg of triprolidine hydrochloride in 15 ml of a syrup. The drug obtained a mean peak plasma level of 8.2 ng/ml in 2 hr and was eliminated from the plasma with a half-life of 5 hr. Considerable individual variation was observed in the area under the plasma triprolidine level–time curve; values ranged from 19 to 163 ng hr/ml with a mean value of 75 ng hr/ml.

Keyphrases □ Triprolidine—TLC analysis, human and rat plasma, pharmacokinetic profile □ TLC—analysis, triprolidine, human and rat plasma □ Pharmacokinetics—triprolidine, humans and rats □ Antihistamines—triprolidine, TLC analysis, human and rat plasma, pharmacokinetic profile

Triprolidine hydrochloride [(*E*)-2-[3-(1-pyrrolidinyl)-1-*p*-tolylpropenyl]pyridine hydrochloride] is an unusually potent antihistaminic agent used for the treatment of various allergic conditions. Although animal data (1–3) and several clinical reports (4–8) substantiate the efficacy of triprolidine, its disposition is unknown. One report indicated that triprolidine had a duration of action of approximately 4–6 hr (5), but no confirming plasma level data were given.

In another study on the *in vitro* metabolism of ^{14}C-triprolidine by guinea pig liver, the drug was extensively metabolized (9). Other reports described the TLC (10) and GC (11) properties of triprolidine, but no attempt was made to quantitate the drug in tissues. Considering the extensive clinical use of this antihistamine, alone and in combination with other drugs, a sensitive quantitative analysis in biological fluids is needed.

This report describes a sensitive analytical method for quantitating triprolidine in plasma following oral administration of a therapeutic dose to human subjects. The method was used to determine the pharmacokinetic profile of the drug in animals and humans.

EXPERIMENTAL

Materials—The organic solvents utilized to develop the thin-layer plates were reagent grade and were used as received; the solvents employed for the extraction of triprolidine from plasma were glass distilled[1]. A 0.01% stock solution of triprolidine hydrochloride was prepared by dissolving the drug in 1–2 ml of methanol and then adding an appropriate volume of chloroform. From this solution, a working standard of 1 μg/ml was prepared in chloroform. A spray reagent of 2 *M* ammonium bisulfate, prepared every 2 weeks, was employed to induce the fluorescence of the drug on the TLC plate.

Analytical Procedure—Plasma, 1 ml, and 6 ml of dichloroethane were added to a 15-ml conical glass centrifuge tube, mechanically shaken for 15 min, and centrifuged (1000×*g*). Five milliliters of the organic phase was placed in a disposable glass culture tube, the tube was immersed in a water bath at 45°, and the solvent was evaporated to dryness under a nitrogen stream. The residue was redissolved in 0.1 ml of chloroform, and a suitable aliquot (50–80 μl) was spotted on a prescored silica gel plate[2]. Samples were applied to a thin-layer plate with an automatic spotter[3], while the standards (1–5 ng) were spotted by hand using a 10-μl syringe.

Prior to use, each TLC plate was channeled (scored) into 20 units 1 cm wide. The plate was developed to a height of 15 cm in methanol–ammonium hydroxide–chloroform (10:1:89). The solvent system was prepared fresh each day and allowed to equilibrate for 30 min prior to use. After development, the plate was allowed to air dry for 15 min and then sprayed with a 2 *M* aqueous solution of ammonium bisulfate until shiny. After the plate was air dried for about 1 hr, each channel was scanned, and the fluorescent spot representing triprolidine was quantitated.

Instrumentation—Fluorescence measurements were determined by scanning the TLC plate with a spectrodensitometer[4] in the reflectance mode, utilizing only the sample beam that had been passed through a secondary cutoff filter of 405 nm. The fluorophore was excited at 300 nm, and the total emission above 405 nm was read using a density computer[5].

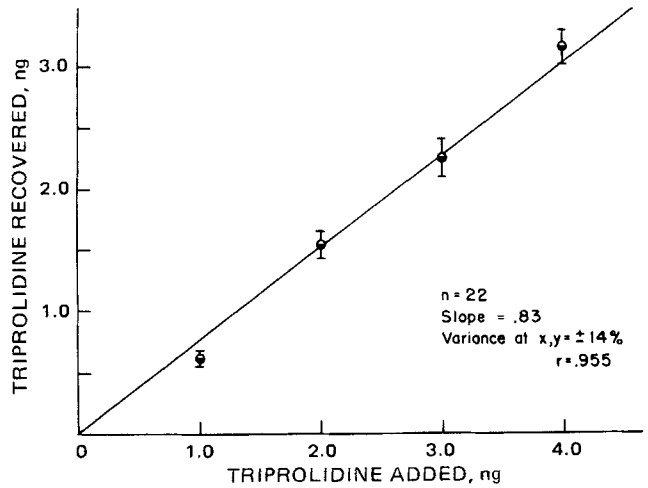

Figure 1—*Recovery of triprolidine from human plasma.*

The area of each peak was simultaneously integrated[6] while recorded on a strip-chart recorder.

Subjects and Protocol—Sixteen male volunteers, with an average age of 23 years and an average weight of 72.5 kg (160 lb), were studied. A complete medical history was taken to eliminate individuals with a history of kidney, liver, or cardiovascular disease. All subjects were fasted 12 hr before and 2 hr after dosing and were free of other medication for 2 weeks prior to triprolidine administration.

Each subject received 15 ml of a syrup[7] containing 3.75 mg of triprolidine hydrochloride followed by 240 ml of water. The syrup was given orally by syringe to ensure complete drug delivery. Seven milliliters of blood was drawn at 0, 0.5, 1, 2, 4, 6, 12, and 24 hr and placed into a Vacutainer containing edetate disodium as the anticoagulant. These samples were centrifuged, and the resulting plasmas were stored in a refrigerator for no more than 24–36 hr before analysis.

RESULTS AND DISCUSSION

Since the pKa of triprolidine is approximately 6.5, it can be extracted quantitatively from plasma into dichloroethane at a physiological pH of 7.4. As shown in Fig. 1, the recovery of 1–4 ng of triprolidine from human plasma was 83% with a variance of 14% at the mean of the linear regression based on 22 determinations. A similar recovery was obtained (n = 29) when higher amounts (5–35 ng) of triprolidine were added to plasma and extracted. The stability of triprolidine was reduced considerably in the presence of a strong base, and the recovery data indicate

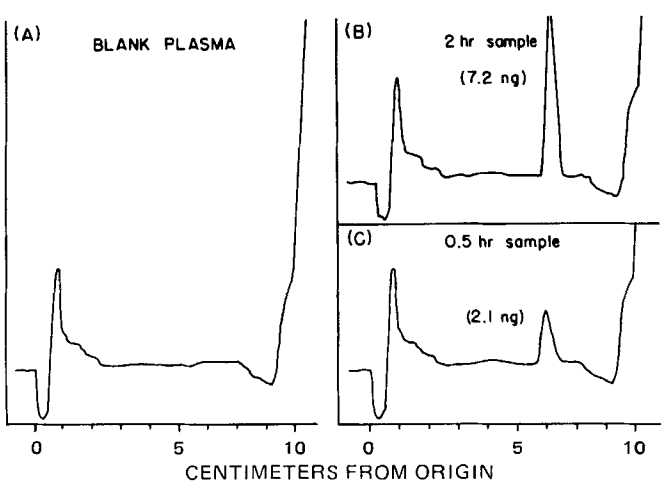

Figure 2—*TLC scan of triprolidine extracted from human plasma. Key: A, control plasma; B, 2.0-hr plasma sample; and C, 0.5-hr plasma sample.*

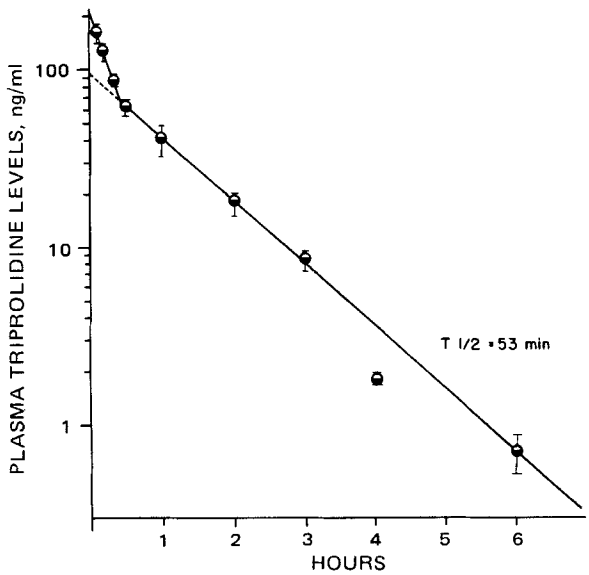

Figure 3—*Disappearance of triprolidine from plasma following intravenous administration of 1 mg of triprolidine hydrochloride/kg to male Sprague–Dawley rats. Results represent the mean ±SE from four rats at each time interval.*

that increasing the pH of plasma above the physiological range is not necessary for good recovery.

Although the exact chemical nature of the fluorophore formed on the plate after spraying triprolidine with ammonium bisulfate is unknown, it is relatively stable to UV irradiation; repeated scans over several hours or direct exposure to irradiation for several minutes did not change the intensity of the fluorescence. However, after 2–3 days of exposure to air, the fluorophore changed its original excitation (300 nm) and emission (>405 nm) wavelengths to 285 and 350 nm, respectively.

A chromatogram of plasma from a human subject prior to and after an oral dose of triprolidine hydrochloride is shown in Fig. 2. Since there was no interfering material in normal human plasma in the region of triprolidine, it was possible to quantitate as little as 0.4 ng of triprolidine spotted on the plate or as little as 0.8 ng of triprolidine/ml of human plasma.

The described procedure was used to determine plasma triprolidine levels in male Sprague–Dawley rats at various times after the administration of 1 mg/kg iv of triprolidine hydrochloride (Fig. 3). The observed plasma concentration (C_p) *versus* time (t) data were fitted to the biexponential equation $C_p = Ae^{-\alpha t} + Be^{-\beta t}$ by least-squares regression analysis, as shown by the solid line. The parameters A and B are zero time intercepts, and α and β are disposition slope constants. The apparent volume of distribution (V_d) of triprolidine was calculated by dividing the

[a] Not detectable; value was considered below the sensitivity of the method and recorded as zero.

intravenous dose by $(AUC)(\beta)$, and the areas under the plasma triprolidine–time curve (AUC) were calculated by applying the trapezoidal rule.

The calculated pharmacokinetic parameters for the rat are: A, 132 ng/ml; α, 0.1 min^{-1}; B, 95 ng/ml; β, 0.0131 min^{-1}; V_d, 9.6 liters/kg; area, 133.5 ng hr/ml; and $T_{1/2}$, 53 min. Following a rapid distribution phase, triprolidine was eliminated from rat plasma with a half-life of 53 min. The large volume of distribution (9.6 liters/kg) indicates the extensive diffusion of this antihistamine into tissues, which is similar to the distribution reported for other antihistamines (12, 13).

Plasma Levels of Triprolidine in Humans—Although triprolidine is used extensively for the treatment of various congestive diseases associated with the release of histamine, plasma drug levels following a therapeutic dose to humans are unknown. Therefore, plasma triprolidine levels were determined in 16 healthy male volunteers following oral administration of 15 ml of a syrup containing 3.75 mg of triprolidine hydrochloride. Individual plasma triprolidine levels at various intervals over 24 hr and the area under the triprolidine plasma–time curve for each subject are shown in Table I. In addition, an average plasma curve for all subjects is shown in Fig. 4.

Plasma triprolidine levels less than 0.8 ng/ml were considered below the sensitivity of the method and were included as zero in calculating the areas under the curves. Of the 16 subjects studied, five individuals had peak plasma levels exceeding 10 ng/ml and only one subject had a peak plasma level below 5 ng/ml. The low plasma levels of this antihistamine in humans are not only related to the low dose administered but are consistent with the data showing a large volume of tissue distribution in rats.

The area under the triprolidine plasma–time curve ranged between 19 and 182 ng hr/ml with a mean value of 75 ng hr/ml. Although triprolidine was detected in plasma within 30 min after its oral administration, the average time required to achieve peak plasma levels was 2 hr. Also, the mean oral plasma half-life of triprolidine was 5.0 hr, but the between-subject variation ranged from 1.5 (Subject J.H.) to 20 (Subject R.J.) hr. Similarly, the mean peak plasma triprolidine level was 8.2 ng/ml but varied from 3 to 17.4 ng/ml. These variations may reflect genetic and environmental factors that influence drug metabolism in humans (14). Also to be considered are individual differences in absorption rates, which are always a problem in an oral study with humans. However, the plasma triprolidine levels obtained following a therapeutic dose of the drug are the lowest reported in humans for any antihistamine.

Probiotics: Antistaphylococcal Activity of 4-Aminocyclohexanecarboxylic Acid, Aminobenzoic Acid, and Their Derivatives and Structure–Activity Relationships

AKIRA FUJII *, JAMES H. BUSH ‡§, KENNETH E. SHORES ‡¶, ROBERT G. JOHNSON ‡, RICHARD J. GARASCIA ‡, and ELTON S. COOK *x

Abstract □ Derivatives of 4-aminocyclohexanecarboxylic acid and aminobenzoic acid were prepared and tested against experimentally induced *Staphylococcus aureus* infections in mice. *cis*- and *trans*-Guanidinocyclohexanecarboxylic acid, *trans*-4-aminomethylcyclohexanecarboxylic acid, *trans*-4-guanidinomethylcyclohexanecarboxylic acid, 4-aminomethylbenzoic acid, 4-guanidinomethylbenzoic acid, 4-(2-aminoethyl)benzoic acid, 4-(2-guanidinoethyl)benzoic acid, and most of the ω-aminoacyl-4-aminobenzoic acids possessed antistaphylococcal activity. The R_m values of these compounds were determined by a reversed-phase TLC system. Experimental R_m values of several additional series of probiotics (ω-amino acids, ω-aminoacyl-L-histidines, ω-guanidino acids, ω-guanidinoacyl-L-histidines, and ω-aminoalkanesulfonic acids) were also obtained. A regular relationship was observed between the constitution of the mobile phases and the R_m values; the optimal mobile phase was 70% acetone in water on silica gel G TLC plates. In all series, relationships were obtained between the biological response (antistaphylococcal activity per millimole) and the R_m values, with an increased R_m value paralleling an increased antistaphylococcal activity.

Keyphrases □ 4-Aminocyclohexanecarboxylic acid and derivatives—synthesized, evaluated for antistaphylococcal activity *in vivo*, mice □ Aminobenzoic acid and derivatives—synthesized, evaluated for antistaphylococcal activity *in vivo*, mice □ Structure–activity relationships—4-aminocyclohexanecarboxylic acid, aminobenzoic acid, and various derivatives evaluated for antistaphylococcal activity □ Antistaphylococcal activity—4-aminocyclohexanecarboxylic acid, aminobenzoic acid, and various derivatives evaluated

The term probiotics was proposed to designate compounds that build resistance to infection in the host but do not inhibit the growth of microorganisms *in vitro* (1). Investigations of probiotics (1–5) provided several series of compounds active against experimentally induced *Staphylococcus aureus* infections in mice. A relationship was indicated between the degree of protection afforded by the compounds against staphylococcal infections and the distance separating the functional groups, *i.e.*, between the ω-amino and carboxyl groups of ω-amino acids (2) and their dipeptides (2–4), between ω-guanidino and carboxyl groups of ω-guanidino acids and their dipeptides (1), and between ω-amino, ω-guanidino, and sulfonyl groups of ω-amino- and ω-guanidinoalkanesulfonic acids (5). The relationship between antifibrinolytic activity and the distance separating functional groups of ω-amino acids and related compounds was demonstrated (6–13). A possible relationship between the biological response and R_m values of probiotics also was reported (5).

The present report describes the synthesis and antistaphylococcal activity of derivatives of 4-aminocyclohexanecarboxylic acid (I*a*), aminobenzoic acid (II*a*), and ω-aminoacyl-4-aminobenzoic acids (III*a*–III*e*) and discusses the relationship between biological response of probiotics and R_m values.

BACKGROUND

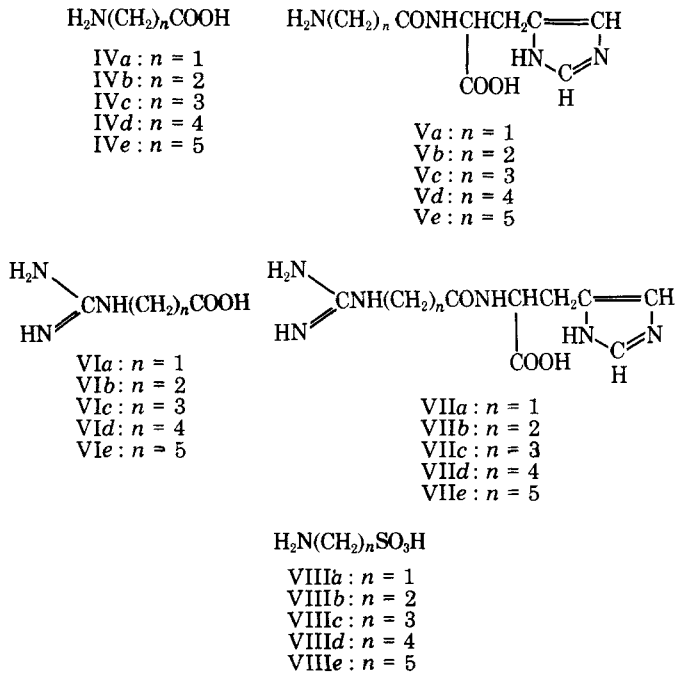
Compound I*a* was prepared by a modification of the method described by Pearlman (14) by hydrogenation of II*a* with hydrogen in the presence of 10% rhodium–0.1% palladium-on-carbon. Compound I*a* was also prepared by the method of Takagi *et al.* (15–18), using platinum dioxide in the presence of hydrogen gas. Compounds I*b*, I*d*, II*d*, and II*f* were prepared from I*a*, I*c*, II*c*, and II*e*, respectively, by a modification of the method reported by Morrison *et al.* (19). Compound II*b* was prepared from II*a* by a method described by Beyerman and Bontekoe (20). Compounds II*c* and II*e* were prepared from 4-bromomethylbenzoic acid and 4-(2-bromoethyl)benzoic acid, respectively, by treatment with concentrated ammonium hydroxide. Compounds III*a*–III*e* were prepared from the appropriate benzyloxycarbonyl-ω-amino acid by a reported method (2) that was modified using several literature methods (21–23).

To investigate a possible relationship between biological response and physicochemical character, R_m values of probiotics also were determined. The lipophilic–hydrophilic balance of a compound, which can be expressed by a partition coefficient, is critical for drug transport. The theoretical relationship between the partition coefficient, P, and R_f values was deduced (24–26) for liquid–liquid partition chromatography, and this relationship was simplified (27) to:

$$R_m = \log\left(\frac{1}{R_f} - 1\right) \qquad \text{(Eq. 1)}$$

Since R_m values are free-energy-based constants related to the π values of the Hansch approach, it is possible in principle to correlate the biological action of a drug with R_m values (28–32).

The optimal mobile phase constitution was first determined using silica gel G plates impregnated with paraffin oil white for ω-amino acids (IV*a*–IV*e*) and ω-aminoacyl-L-histidines (V*a*–V*e*), which possess antistaphylococcal activity (2). The optimal mobile phase was 70% acetone in water. The R_m values of derivatives of I*a* and II*a*, III*a*–III*e*, and additional series of probiotics, ω-guanidino acids (VI*a*–VI*e*), ω-guanidinoacyl-L-histidines (VII*a*–VII*e*), and ω-aminoalkanesulfonic acids (VIII*a*–VIII*e*), were then determined, using the optimal mobile phase, to investigate structure–activity relationships.



EXPERIMENTAL[1]

10% Rhodium–0.1% Palladium-on-Carbon—This catalyst was prepared by the method of Pearlman (14), using a mixture of 40 g of rhodium chloride trihydrate[2], 0.26 g of palladium chloride[2], 13.7 g of carbon[3], and 200 ml of water. The yield was 15.8 g.

***cis*- and *trans*-4-Aminocyclohexanecarboxylic Acid (Ia)**—*Method A*—A mixture of 27.4 g (0.200 mole) of IIa[4], 200 ml of water, and 4 g of 10% rhodium–0.1% palladium-on-carbon was placed in an autoclave[5] and hydrogenated at 3.52 kg/cm^2. When 0.26 mole of hydrogen gas was absorbed, the mixture was filtered and concentrated *in vacuo* until crystals started to form. Then the mixture was diluted with 200 ml of dimethylformamide and cooled to 5°. The precipitate was filtered, washed first with dimethylformamide and then cold methanol, and dried. The yield was 5.3 g (18.5%) [lit. (14) yield 68–71%], mp 271–275° dec. [lit. (14) mp 292–296°].

Method B—The compound was also prepared by the method of Takagi *et al.* (15–18) by pressure hydrogenation for 6 days in an autoclave[5] of a mixture of 20.0 g (0.146 mole) of IIa, 300 ml of water, and 2.0 g (0.085 mole) of platinum dioxide[3]. The yield was 6.6 g (32.0%), mp 269–270° dec. [lit. (14) mp 292–296°].

***cis*- and *trans*-4-Guanidinocyclohexanecarboxylic Acid (Ib)**—A mixture of 2.9 g (0.021 mole) of Ia and 4.5 g (0.053 mole) of *S*-methylisothiourea hemisulfate[6] in 30 ml of concentrated ammonium hydroxide was refluxed until all reactants were dissolved. After filtration, the solution was concentrated *in vacuo*.

The resulting syrup was diluted with pH 2.2 pyridine–formic acid buffer for purification by ion-exchange chromatography[7]. The sample was eluted with 250 ml of water, 250 ml of 0.5 *M* pyridine, 450 ml of 2 *M* pyridine, and then 200 ml of 2 *M* pyridine–2 *N* NH_4OH (50:50 v/v). Fractions containing Ib were pooled and concentrated *in vacuo* and crystallized from hot water. The yield was 0.6 g (20.0%), mp > 370°.

Anal.—Calc. for $C_8H_{15}N_3O_2$: C, 51.88; H, 8.16; N, 22.69. Found: C, 51.76; H, 8.10; N, 22.55.

***trans*-4-Guanidinomethylcyclohexanecarboxylic Acid (Id)**—A mixture of 2.0 g (0.013 mole) of Ic[8], 2.36 g (0.017 mole) of *S*-methylisothiourea hemisulfate[6], and 10 ml of concentrated ammonium hydroxide was treated in the same way as for Ib. The yield was 2.0 g (78.5%), mp 353–354° dec. [lit. (33) mp 349° dec.].

4-Guanidinomethylbenzoic Acid (IId)—A mixture of 1.43 g (0.0095 mole) of IIc, 2.1 g (0.0145 mole) of *S*-methylisothiourea hemisulfate[6], and 25 ml of concentrated ammonium hydroxide was allowed to react in the same way as already described. The yield was 1.32 g (72.0%), mp 303–304° dec.

Anal.—Calc. for $C_9H_{11}N_3O_2 \cdot H_2O$: C, 51.18; H, 6.20; N, 19.89. Found: C, 51.66; H, 6.10; N, 19.89.

4-(2-Guanidinoethyl)benzoic Acid (IIf)—A mixture of 5.0 g (0.030 mole) of IIe, 5.95 g (0.046 mole) of *S*-methylisothiourea hemisulfate[6], and 40 ml of concentrated ammonium hydroxide was allowed to react in the same way as for IId. The yield was 5.7 g (91.0%), mp 328–330° dec.

Anal.—Calc. for $C_{10}H_{13}N_3O_2$: C, 57.95; H, 6.32; N, 20.28. Found: C, 57.80; H, 6.20; N, 20.15.

4-Guanidinobenzoic Acid (IIb)—By using the method of Beyerman and Bontekoe (20), thioureidobenzoic acid was prepared from 15.8 g (0.115 mole) of IIa and 12.1 g (0.160 mole) of ammonium thiocyanate in 42 ml of concentrated hydrochloric acid and 75 ml of water. Thioureidobenzoic acid (10.65 g, 0.057 mole) and 8.1 g (0.057 mole) of methyl iodide in 82 ml of absolute ethanol[9] gave *S*-methylisoureidobenzoic acid. Compound IIb was obtained by refluxing 10.0 g (0.030 mole) of *S*-methylisoureidobenzoic acid with concentrated ammonium hydroxide. The yield was 4.26 g (62.0%), mp 300–302° dec. [lit. (20) mp ~310° for the free base and 268° dec. for the hydrochloride].

4-Aminomethylbenzoic Acid (IIc)—4-Bromomethylbenzoic acid[10] (14.0 g, 0.070 mole) was dissolved in 2100 ml of concentrated ammonium hydroxide and allowed to stand at room temperature for 2 weeks. The solution was concentrated to dryness *in vacuo*, and the residue was crystallized from water after the addition of absolute ethanol[9]–ether. The crystals were then filtered and subjected to ion-exchange chromatography using a 3 × 35-cm column[7] and the same eluents as in the preparation of Ib.

The elution of IIc was detected by the ninhydrin reaction and appeared in 500–700 ml of the effluent. These fractions were concentrated to dryness *in vacuo*. The residue was crystallized from water after the addition of absolute ethanol[9]–ether; yield, 6.92 g (70.7%); mp 351–353° dec. [lit. (34) mp 346–348° dec.].

4-(2-Aminoethyl)benzoic Acid (IIe)—4-(2-Bromoethyl)benzoic acid[10] (5.0 g, 0.0218 mole) and 675 ml of concentrated ammonium hydroxide were treated in the same way as for IIc, except that the ion-exchange purification was omitted. The residue, after concentration and the addition of absolute ethanol[9]–ether, was crystallized from water. The yield was 1.65 g (46.0%), mp >370°.

Anal.—Calc. for $C_9H_{11}NO_2$: C, 65.44; H, 6.71; N, 8.48. Found: C, 65.32; H, 6.60; N, 8.49.

4-(Glycylamino)benzoic Acid (IIIa)—To a solution of 10.5 g (0.050 mole) of benzyloxycarbonylglycine[11] in 250 ml of dichloromethane was added 7.0 ml of triethylamine. After the resulting solution had been chilled to −5°, 4.8 ml of ethyl chloroformate was added and the mixture was kept at this temperature for 10 min. To this solution was added rapidly a solution of ethyl 4-aminobenzoate[12] (8.3 g, 0.050 mole) in 100 ml of dichloromethane, which had been chilled to 0°.

The resulting mixture was stored at room temperature for 3 days. It was then washed with 200 ml of water and 200 ml of 1 *N* $NaHCO_3$, dried over sodium sulfate, and concentrated to a syrup. The concentrate was dissolved in 100 ml of methanol, and insoluble material (unreacted benzyloxycarbonylglycine) was filtered off. To the filtrate was added 50 ml of 1 *N* NaOH, and the mixture was kept at room temperature for 3 hr. The reaction mixture was adjusted to pH 5 with 4 *N* H_2SO_4 and concentrated to dryness *in vacuo*. The residue was extracted with two portions of 50 ml each of hot absolute ethanol[9], and 50 ml of water was added to the extract.

After the addition of 1.0 g of 10% palladium-on-carbon, the mixture was hydrogenated in an autoclave at atmospheric pressure and room temperature for 6 hr. The reaction mixture was then filtered and concentrated *in vacuo*. Ion-exchange chromatography, with a 2.0 × 30-cm column[7], was used to purify the product. The fractions containing IIIa were pooled, concentrated *in vacuo*, and then treated with absolute ethanol[9] to obtain white needle crystals. The yield was 1.55 g (15.0%), mp 237–238° dec.

---

[1] IR spectra (potassium bromide) were taken of all compounds with a Perkin-Elmer IR spectrophotometer, model 337, and were in accord with the assigned structures. Elemental analyses were made of all compounds by Galbraith Laboratories, Inc., Knoxville, Tenn., but analyses and melting points are reported only for new compounds. Solvents and chemicals, except where indicated, were purchased from Fisher Scientific Co. and Matheson, Coleman and Bell.

Anal.—Calc. for $C_9H_{10}N_2O_3 \cdot H_2O$: C, 50.94; H, 5.70; N, 13.20. Found: C, 50.72; H, 5.48; N, 13.20.

After hydrolysis (6 *N* HCl, 105° for 24 hr), III*a* gave glycine and II*a* as confirmed on TLC.

4-(β-Alanylamino)benzoic Acid (III*b*)—Benzyloxycarbonyl-β-alanine[13] (4.4 g, 0.020 mole) and 3.3 g (0.020 mole) of ethyl 4-aminobenzoate[12] were treated in the same way as for III*a*. The yield was 2.1 g (47.4%), mp 256–257° dec.

Anal.—Calc. for $C_{10}H_{12}N_2O_3 \cdot \frac{1}{2}H_2O$: C, 55.29; H, 6.03; N, 12.90. Found: C, 55.04; H, 6.17; N, 12.80.

Acid hydrolysis gave β-alanine and II*a*.

4-(4-Aminobutyrylamino)benzoic Acid (III*c*)—4-(Benzyloxycarbonylamino)butyric acid[14] (12.0 g, 0.050 mole) and 8.3 g (0.050 mole) of ethyl 4-aminobenzoate[12] were treated in the same manner as for III*a*. The yield was 5.2 g (44.2%), mp 214–215° dec.

Anal.—Calc. for $C_{11}H_{14}N_2O_3$: C, 59.45; H, 6.35; N, 12.61. Found: C, 59.20; H, 6.50; N, 12.43.

Acid hydrolysis gave 4-aminobutyric acid and II*a*.

4-(5-Aminovalerylamino)benzoic Acid (III*d*)—5-(Benzyloxycarbonylamino)valeric acid[15] (12.5 g, 0.050 mole) and 8.3 g (0.050 mole) of ethyl 4-aminobenzoate[12] were treated in the same manner as for III*a*. The yield was 5.0 g (40.0%), mp 203–204°.

Anal.—Calc. for $C_{12}H_{16}N_2O_3$: C, 61.00; H, 6.83; N, 11.86. Found: C, 60.82; H, 6.96; N, 11.73.

Acid hydrolysis gave 5-aminovaleric acid and II*a*.

4-(6-Aminohexanoylamino)benzoic Acid (III*e*)—6-(Benzyloxycarbonylamino)hexanoic acid[16] (2.65 g, 0.010 mole) and 1.65 g (0.010 mole) of ethyl 4-aminobenzoate were treated in the same way as for III*a*. The yield was 1.20 g (45.4%), mp 258–259° dec.

Anal.—Calc. for $C_{13}H_{18}N_2O_3$: C, 62.38; H, 7.25; N, 11.19. Found: C, 62.19; H, 7.32; N, 11.05.

Acid hydrolysis gave 6-aminohexanoic acid and II*a*.

Reversed-Phase TLC—The R_m values were obtained by the method described by Boyce and Milborrow (28) using silica gel G TLC plates. Chromatography was carried out on glass plates[17] (10 × 20 cm) coated with a 250-μm layer of silica gel G. After activation at 105° for 10 min, the plates were impregnated by allowing a 5% (v/v) solution of paraffin oil white in hexane to cover the plate; the solvent was evaporated at 40°.

Optimal Solvent—The optimal mobile phase composition was determined using the mobile phases of 80, 70, 60, 50, 40, and 20% (v/v) acetone in water. Solutions that contained 1% of IV*a*–IV*e*, V*a*–V*e*, and L-alanine dissolved in 10% (w/v) 2-propanol were spotted and then developed[18] with each different mobile phase. The spots were located by the ninhydrin reaction. The relationship between R_m values of series IV and V and the composition of the mobile phases is shown in Figs. 1 and 2. The optimal solvent ratio, which produced maximum increments of R_m values (28, 29), was obtained from the most linear region of the curves: 70% (v/v) acetone in water.

Determination of R_m Values with Optimal Solvent System—With the optimal composition of the mobile phase, TLC plates were developed after spotting with series I–VIII; L-alanine and L-arginine were used as standards. The spots were located by the ninhydrin reaction, the Sakaguchi reaction, or iodine treatment. Figure 3 summarizes the relationship between biological response and R_m values of series IV–VIII.

Biological Testing Procedure—*In vivo* antistaphylococcal activity was determined by the method described previously (1–5), except that BDF mice, 9–13 weeks old and weighing 12–19 (male) and 18–24 (female) g, were used instead of Swiss albino mice. Because of the low solubility of some compounds, 1 mg of each sample (I*a*–I*d*, II*a*–II*f*, and III*a*–III*e*) was given in equally divided doses subcutaneously 2 hr before and 4 hr after the injection of *S. aureus*[19]. 5-Aminovaleryl-L-histidine (V*d*) was

Table I—R_f Values of Derivatives of Ia and IIa and of ω-Aminoacyl-4-aminobenzoic Acids on TLC [a] ($R_f \times 100$)

Compound	Solvent 1	Solvent 2	Solvent 3	Solvent 4	Solvent 5
Ia	66	87	86	—	92
Ib	45	62	79	33	61
Ic	41	65	76	63	91
Id	47	64	80	28	62
IIa	48	67	75	49	49
IIb	52	68	81	37	54
IIc	43	55	69	32	65
IId	52	67	81	32	55
IIe	37	59	71	31	68
IIf	55	66	80	34	60
IIIa	38	73	64	70	82
IIIb	38	69	61	40	79
IIIc	43	70	60	24	77
IIId	46	70	59	19	74
IIIe	49	72	61	14	77
L-Alanine [b]	35	40	52	47	71
L-Arginine [c]	13	22	36	4	25

[a] The plates were silica gel G (Merck), 250 μm, from Analtech, Inc. Solvent 1 = phenol–water (75:25 w/v), pH 2.0. Solvent 2 = 1-butanol–acetic acid–water (60:20:20), pH 2.4. Solvent 3 = 2-propanol–formic acid–water (77:4:19), pH 2.7. Solvent 4 = 1-methylpropanol–methyl ethyl ketone–dicyclohexylamine–water (55:15:10:20), pH 10.0. Solvent 5 = chloroform–methanol–17% NH_4OH (40:40:20), pH 11.4. [b] Spots were identified by ninhydrin reaction for Ia, Ic, IIa, IIc, IIe, and IIIa–IIIe, and L-alanine was the standard. [c] Spots were identified by Sakaguchi reaction for Ib, Id, IIb, IId, and IIf, and L-arginine was the standard.

used as the positive control. Compounds Ia, Ic, IIa, IIc, and IIe also were tested at 5 mg with a positive control of 4-aminobutyryl-L-histidine (Vc). Guanidino derivatives Ib, Id, IIb, IId, and IIf were poorly soluble in water. To provide a high dose of a compound of low water solubility, a fine suspension of IIf in cottonseed oil (20 mg/ml, dose of 0.25 ml) was also investigated.

Antistaphylococcal activity *in vivo* (ASA) is expressed as:

$$\text{ASA} = [(M_c - M_e)/M_c]/C \qquad \text{(Eq. 2)}$$

where M_c is the mortality of untreated negative control, M_e is the mortality of the experimental (treated), and C is the dose (millimoles). Previously (1–5), percent protection, $(M_c - M_e)100/M_c$, was used for comparison of activity. The relationship between antistaphylococcal activity and the R_m value of series I–III is summarized in Fig. 4. Antistaphylococcal activity *in vitro* was determined in the same manner as before (1).

RESULTS AND DISCUSSION

Compounds Ia–Id, IIa–IIe, and IIIa–IIIe were homogeneous on TLC with five different solvent systems (Table I). Single spots were given with the ninhydrin reaction, iodine treatment, and potassium dichromate–sulfuric acid. Compounds Ia, Ic, IIa, IIc, IIe, and IIIa–IIIe were positive to the phenol–calcium hypochlorite color reaction (2).

[a] L-Alanine was used as a positive control with an average R_m value of −0.30 ± 0.06 for ninhydrin-positive compounds Ia, Ic, IIa, IIc, IIe, and series III–VIII. L-Arginine was used as a positive control with an average R_m value of 1.32 ± 0.37 for Sakaguchi-reaction-positive compounds Ib, Id, IIb, IId, IIf, and series VI and VII. [b] ASA is defined by Eq. 2. [c] Silica gel G (Merck), 250-μm plates (Analtech, Inc.), were used. The stationary and mobile phases were 5% paraffin oil white in hexane (v/v) and 70% acetone in water (v/v), respectively.

The effectiveness of protection was calculated using the χ^2-test. All series I–III compounds, except Ia, IIa, IIb, and IIIa, were significantly effective as compared with the untreated negative control (>95% confidence level) at 1 mg. All of the compounds tested at 5 mg (Ia, Ic, IIa, IIc, and IIe) were significantly more effective than the untreated negative control (>95% confidence level). With a 5-mg dose as an oil suspension, IIf provided significant effectiveness at greater than the 99.5% confidence level. Antistaphylococcal activities *in vivo* obtained with two different dosages, 1 and 5 mg, were essentially identical (percent deviation <5.0), except for Ia which gave 31.1% deviation. None of the compounds had antistaphylococcal activity *in vitro*, as was true of the previously reported probiotics.

A regular relationship was obtained between the composition of the mobile phases and the R_m values (Figs. 1 and 2). The optimal mobile phase was determined to be 70% acetone in water, and it was used in the study of the correlation between structure and biological response. Antistaphylococcal activity *in vivo* and R_m values of series I–VIII compounds are summarized in Table II. In general, increased R_m values paralleled a corresponding increase in biological response to experimentally induced *S. aureus* infections in mice for each group of compounds investigated (Figs. 3 and 4). The histidine dipeptides of both ω-amino acids (series V) and ω-guanidino acids (series VII) showed higher R_m values and also higher antistaphylococcal activity than the corresponding parent acids.

The ω-amino acids have partition coefficients in 1-octanol–water of

the order of 10^{-3} [20]. The partition coefficient of IIa in the same system was reported as 4.8 (uncorrected) (36) or 2.9 (corrected) (37). It was hoped that the lipophilicity of the ω-amino acids would be enhanced by forming the ω-aminoacyl-4-aminobenzoic acids. The results on reversed-phase TLC indicate that no increase in lipophilicity of ω-amino acids resulted from forming IIa derivatives.

While there was a significant relationship between biological response and R_m values in each series of compounds, this was not true when all series I–VIII compounds were considered together. This finding suggests that the modifications of functions from amino (NH_2) to guanidino [$NCH(=NH)NH_2$], from carboxylic acid (COOH) to sulfonic acid (SO_3H), and from straight-chain polymethylene [$-(CH_2)_n-$] to ring (C_6H_6 or C_6H_{10}) gave a considerable change in partitioning. Therefore, each of the groups (series I–VIII) should be viewed independently.

Potential Antitumor Agents: Procarbazine Analogs and Other Methylhydrazine Derivatives

JOHN A. BEISLER ˣ, GEOFFREY W. PENG *, and JOHN S. DRISCOLL

Abstract □ With the objective of developing new antitumor agents, two groups of hydrazine compounds, having structural features in common with the antitumor agents procarbazine and 1-acetyl-2-picolinoylhydrazine, were synthesized. The L-1210 leukemia system was used to evaluate compounds of both groups. The aliphatic procarbazines also were screened for antitumor activity as bis(benzyloxycarbonyl) derivatives and as derivatives having a phthalazine nucleus. No L-1210 antitumor activity was exhibited by these compounds.

Keyphrases □ Hydrazines, substituted—synthesized, antitumor activity evaluated □ Procarbazine analogs—synthesized, antitumor activity evaluated □ Phthalazines, substituted—synthesized, antitumor activity evaluated □ Antitumor activity—evaluated in substituted hydrazines and phthalazines □ Structure-activity relationships—substituted hydrazines and phthalazines evaluated for antitumor activity

Hydrazine derivatives interact with biological systems to produce a wide range of responses. For example, isoniazid is a well-established tuberculostatic agent (1), and isocarboxazid finds clinical utility as a monoamine oxidase inhibitor (2). A recent survey (3) listed 19 hydrazine derivatives that are tumorigenic in animals, although hydrazine sulfate inhibited tumor growth in rats (4).

Procarbazine (I), a methylhydrazine derivative, displayed antitumor effects in a spectrum of animal neoplasms and is used clinically in the treatment of Hodgkin's disease (5). Although hydrazine and benzylhydrazine have considerable toxicity, they selectively inhibited Ehrlich ascites carcinoma in mice (6). The corresponding methyl derivatives (methylhydrazine and 1-methyl-2-benzylhydrazine) retained toxicity but exhibited an increased antitumor effect, apparently because the *N*-methyl groups metabolized to formaldehyde, which contributed an added cytotoxic effect. Thus, the *N*-normethyl analog of procarbazine was much less effective against Ehrlich ascites than procarbazine itself; however, both showed a diminished toxicity with respect to 1-methyl-2-benzylhydrazine.

A series of acylhydrazines and 1,2-diacylhydrazines showed activity in the Walker 256 carcinosarcoma test system with moderate toxicities in some instances, giving favorable therapeutic indexes (7). One member of the series, 1-acetyl-2-picolinoylhydrazine (II), was selected for clinical trials (8–10).

As part of a continuing interest in the development of new antitumor agents (11), a study was initiated to synthesize methylhydrazine derivatives for potential antitumor activity. Two groups of compounds were selected for

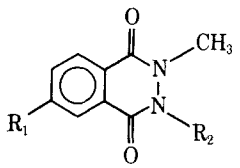
VI: $R_1 = R_2 = C_6H_5CH_2OCO$, $R_3 = H$
VII: $R_1 = R_2 = C_6H_5CO$, $R_3 = H$



VIII: $R_1 = R_2 = H$
IX: $R_1 = CO_2H$, $R_2 = CH_3$

synthesis and antitumor evaluation against L-1210 leukemia. The first group consisted of simple methylhydrazines (III–IX), having structural attributes of both I and II. Accordingly, these hydrazines were provided with *N*-methyl groups in the hope of augmenting any emergent antitumor activity and acyl functions to moderate toxicity. In the second group, the structural importance of the phenylene group of I for antitumor activity was explored by replacing it with straight-chain aliphatic moieties. As in the first group, the methylhydrazine substructure was incorporated into the aliphatic procarbazine derivatives (Scheme I, XVI–XVIII), and provisions were made in the synthetic scheme to prepare acylated derivatives for antitumor testing.

RESULTS AND DISCUSSION

Chemistry—Compound III was synthesized using a modification of a literature procedure (12). Compounds IV–VIII were made according to established procedures (13–16, Table I).

The synthetic route to the aliphatic procarbazine derivatives (XVI–XVIII) utilized the approach developed by Zeller *et al.* (17), wherein the doubly blocked methylhydrazine (VI) served as a starting material. Thus, condensation of VI with the requisite bromo ester (Scheme I) gave the fully substituted hydrazines (X–XII). These compounds were converted to the *N*-isopropyl-substituted amides (XIII–XV) using a standard three-step synthetic sequence. As an inadvertant result, the lower homolog in the series (XIII) quantitatively lost a benzyloxycarbonyl substituent. The loss was probably due to the presence of the terminal carboxyl function, which is favorably disposed toward participation in a six-membered cyclic intermediate with the carbonyl of the near benzyloxycarbonyl group. Based on this reasoning, Structure XIII was assigned to this compound.

Hydrogenolysis smoothly removed the benzyloxycarbonyl-protecting groups to provide the substituted methylhydrazines, which were isolated as the semicrystalline hygroscopic dihydrochloride salts. Water solutions of the latter, when passed through an anion-exchange column (oxalate form), yielded oxalate salts after lyophilization as analytically pure, white solids (XVI–XVIII), which were not hygroscopic. Attempted recrystallization of the oxalates led to decomposition.

Reaction of the hydrazines, either as the oxalate or dihydrochloride salts, formed phthalazine derivatives (XIX–XXI). The three phthalazine

[a] NMR and IR spectra were consistent with structure assignments. [b] The temperature indicated is that of the heating block of a short path distillation apparatus. The recorded temperatures are not corrected. [c] The analytical sample was prepared by condensing the necessary amount on a cold finger under high vacuum. [d] Percentage yield over three synthetic steps. [e] One benzyloxycarbonyl blocking group was lost (NMR) using the general synthetic procedure. [f] The melting points of the lyophilized oxalates were broad and variable, although the compounds were spectrally and analytically pure.

homologs gave mass spectra (Table II) characterized by three common ions at m/e 189 $[C_6H_4(CON)_2CH_3(CH_2)]^+$, 162 $[C_6H_4(CO)_2NHCH_3]^+$, and 89 $[CONHC_3H_7]^+$. The balance of the fragmentation patterns for each phthalazine could be readily interpreted in terms of stepwise scissions of the respective side-chain elements.

Biology—The synthesized compounds, including synthetic intermediates, were evaluated for antitumor activity in the mouse L-1210 leukemia system according to established protocols (18). Compounds III–XXI showed no significant activity (Table III), as indicated by the ratio of the mean survival time of the test animals over that of the control animals expressed as a percentage (%T/C). A %T/C value greater than 125 is considered indicative of activity in this test system.

The murine tumor systems used to evaluate I and II, as well as their respective analogs, were Ehrlich carcinoma, Sarcoma 180, and Walker carcinosarcoma 256 (6, 7). However, the L-1210 system was chosen for screening the present series of compounds because of its greater predictive value for clinically useful drugs (19).

The nonacylated methylhydrazine, 1-ethyl-2-methylhydrazine (III), exerted a general toxicity on L-1210 tumor-bearing mice (Table III). Addition of acyl groups to methylhydrazine (IV–VII) neither ameliorated toxicity nor elicited antitumor activity. Compounds VIII and IX were both nontoxic and inactive.

The more fully elaborated methylhydrazines (XVI–XVIII) patterned after procarbazine demonstrated a nonselective toxicity, which was

Table II—Mass Spectral Data for the Phthalazines[a]

Compound	M+	M − 28	M − 29	M − 58	M − 100	189	Base	M − 175	89
XIX	289 (7.8)	261 (20.3)	260 (16.6)	231 (4.4)	189 (6.9)		162 (100)	114 (19)	89 (9.4)

XXI	317 (7.1)	289 (6.9)	288 (7.5)	259 (14)	217 (0.7)	189 (10.7)	162 (100)	142 (63)	89 (15.7)

[a] The tabulated values are mass-charge ratios *(m/e)* followed by the relative intensities (indicated in parentheses) as percentages of the base peak.

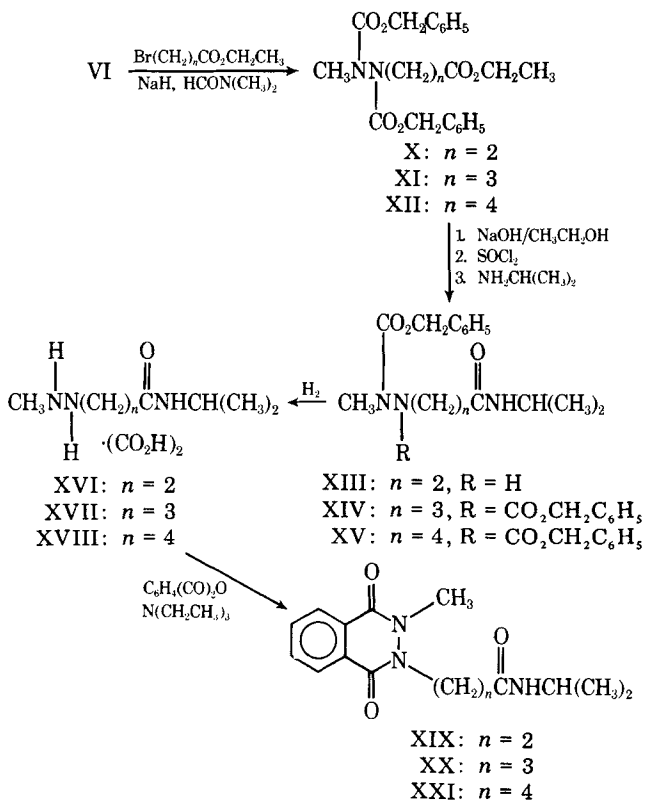
eliminated when they were tested as bis(benzyloxycarbonyl) derivatives (XIV and XV) but without a concomitant appearance of antitumor effects. Methylhydrazine XVIII has a calculated partition coefficient that is nearly identical to the measured value (20) of procarbazine (log P = 0.06, octanol). The lack of activity shown by XVIII and its derivatives (XV and XXI) was, therefore, particularly disappointing.

Derivatizing the aliphatic procarbazine analogs with phthalic anhydride gave water-soluble phthalazines (XIX–XXI), which were nontoxic and inactive.

EXPERIMENTAL[1]

1-Ethyl-2-methylhydrazine Dihydrochloride (III)—A procedure (12) for the synthesis of 1,2-dimethylhydrazine dihydrochloride was modified for the preparation of III. Accordingly, a twofold excess of ethyl bromide was reacted with 7.6 g (0.03 mole) of VII in ethanolic potassium hydroxide solution.

6-Carboxy-2,3-dihydro-2-methyl-1,4-phthalazinedione (IX)—1,2,4-Benzenetricarboxylic anhydride (9.6 g, 0.05 mole) and 1,2-dimethylhydrazine dihydrochloride (6.6 g, 0.05 mole) were refluxed in a mixture of 100 ml each of triethylamine and dimethylformamide for 18 hr. After solvent evaporation, the residue was treated with dilute hydrochloric acid and the product was extracted with ether–ethyl acetate (1:1). Evaporation of the dried extracts gave 6.1 g of IX after recrystallization.



Scheme I

Bis(phenylmethyl) 1-(5-Ethoxy-5-oxopentyl)-2-methyl-1,2-hydrazinedicarboxylate (XII): General Preparation for X and XI—To a stirring suspension of 0.72 g (30 mmoles) of sodium hydride in 70 ml of dry dimethylformamide was added, in parts, 9.42 g (30 mmoles) of VI. The reaction mixture was protected with a calcium sulfate drying tube and stirred for 30 min after the addition. A solution of 6.27 g (30 mmoles) of ethyl 5-bromovalerate in 20 ml of dry dimethylformamide was added dropwise to the reaction solution over 10 min, producing a mild exothermicity. After the reaction solution was stirred for 20 hr, it was poured into 500 ml of saline and the product was removed by extraction with ether. The dried extracts were evaporated, and the residual oil was vacuum distilled in a short path apparatus to give 11.46 g of XII.

Bis(phenylmethyl) 1-Methyl-2-[5-[(1-methylethyl)amino]-5-oxopentyl]-1,2-hydrazinedicarboxylate (XV): General Preparation for XIII and XIV—A solution of XII (11.3 g, 25.5 mmoles) in 100 ml of 95% ethanol was treated with 35 ml of 2 N sodium hydroxide solution, stirred at room temperature for 4 hr, and then poured into 500 ml of cold saline. Neutral materials were removed by extracting twice with ether. Ice chips were added to the aqueous solution, the solution was acidified with concentrated hydrochloric acid, and the acidic product was collected by three ether extractions. The combined extracts were dried and evaporated to yield quantitatively the carboxylic acid.

The carboxylic acid (10.1 g) was stirred with 50 ml of thionyl chloride for 30 min at room temperature and subsequently refluxed for 30 min. Excess thionyl chloride was removed under vacuum, and the residue was dissolved in 100 ml of dry tetrahydrofuran. While the latter solution was stirred, protected with a drying tube and cooled with an ice bath, a solution of 10 ml of isopropylamine in 100 ml of dry tetrahydrofuran was added dropwise over 20 min. The resulting solution mixed with a copious precipitate was stirred 1 hr at ice temperature and 1 hr at room temperature and was then poured into saline made basic with sodium hydroxide solution. The product was removed by three ether extractions. The combined dried extracts were concentrated to about 100 ml on a steam bath, and 150 ml of hexane was slowly added to give a saturated solution at a boil. Allowing the solution to crystallize at room temperature gave 8.02 g of XV in two crops.

Compounds XIII and XIV could not be induced to crystallize and were purified by column chromatography on alumina. After eluting with benzene, the pure product was obtained by eluting with benzene–ethyl acetate (4:1).

***N*-(1-Methylethyl)-5-(2-methylhydrazino)pentanamide Ethanedioate (1:1) (XVIII): General Preparation for XVI and XVII**—A solution of 4.56 g (10 mmoles) of XV in 50 ml of 95% ethanol was placed in a 500-ml pressure bottle containing 0.5 g of 10% palladium-on-charcoal catalyst and hydrogenated at 2.67 kg/cm^2 (38 lb/in.^{2}) pressure with shaking for 18 hr. Immediately after venting the apparatus, the reaction mixture was treated with 10 ml of 10% hydrochloric acid. The catalyst was removed by filtering through a pad of diatomaceous silica[2].

The filtrate was concentrated under vacuum, and the residue was partitioned between 140 ml of distilled water and 100 ml of ether and separated. The ether layer was washed once with 10 ml of distilled water, and the combined aqueous layers were lyophilized to give the dihydrochloride as a partially crystalline, hygroscopic glass. The glass in 10 ml of water was applied to a strongly basic, 20–50-mesh, anion-exchange column[3] (3.5 × 20 cm, oxalate form) and eluted with 400 ml of water to give 2.76 g of XVIII as a white nonhygroscopic cake after lyophilization of the fractions.

The oxalate (XVIII, XVI, and XVII) lyophilizates were analytically pure. Attempts to recrystallize them resulted in decomposition.

1-[3,4-Dihydro-3-methyl-1,4-dioxo-2(1*H*)-phthalazinyl]-*N*-(1-

[1] NMR spectra were determined with a Varian T-60 spectrometer. IR spectra were recorded with a Perkin-Elmer model 621 spectrometer in chloroform. Mass spectra were obtained by direct probe insertion with a DuPont 21-492 spectrometer with a 75-ev ionizing voltage. Combustion analyses were performed by the National Institute of Arthritis, Metabolism, and Digestive Diseases, National Institutes of Health, Bethesda, Md., and by Galbraith Laboratories, Knoxville, Tenn. All melting points are uncorrected and were determined with a Thomas-Hoover capillary melting-point apparatus. Organic extracts were dried over anhydrous sodium sulfate in all cases. The alumina for column chromatography was neutral alumina, 100–200 mesh, Brockmann Activity III.

Formulation Factors Affecting Strength and Dissolution of Uncoated Oxytetracycline Tablets

S. ESEZOBO and N. PILPEL [x]

Abstract □ The effect of various formulation and processing factors on the properties of 300-mg oxytetracycline tablets was studied. At a constant moisture level and packing fraction, an increase in gelatin concentration resulted in increased tensile strength, increased disintegration and dissolution times, and reduced capping tendency. The Wagner theory of dissolution applied satisfactorily to tablets containing up to 5% (w/w) gelatin but was less applicable at higher gelatin levels. Dissolution rate constants were calculated, and their values depended on the gelatin content and packing fraction of the tablets.

7.50	0.51	3.20

[a] Tablets weighed 325 mg and had a moisture content range of 2.4–3.2% (w/w).

serum levels also had slower *in vitro* dissolution rates.

Further investigations (3, 4) on several samples of commercial 250-mg oxytetracycline dihydrate tablets BP showed that the dissolution rate profiles varied between generic brands obtained from different manufacturers and also between and within batches from one source. More recently, Chalmers and Elworthy (5) conducted studies on a particular oxytetracycline formulation (similar in some respects to the one used in the present investigations but with povidone as the binding agent). Their work was concerned primarily with the effects of particle size, binder concentration, binder volume, and massing time on the tensile strength and disintegration and dissolution times of the resulting granules and tablets.

Preliminary work was reported (6) on the effects of moisture, gelatin binding agent, and packing fraction on the properties of certain oxytetracycline tablets prepared with a hand press. It was considered necessary to extend the work along two lines: (*a*) to see whether any correlation existed between the properties of tablets made in a hand press and in high speed tableting machines, and (*b*) to analyze in detail the dissolution results obtained on all of the tablets to arrive at a better understanding of the mechanisms of dissolution in typical oxytetracycline tablet formulations.

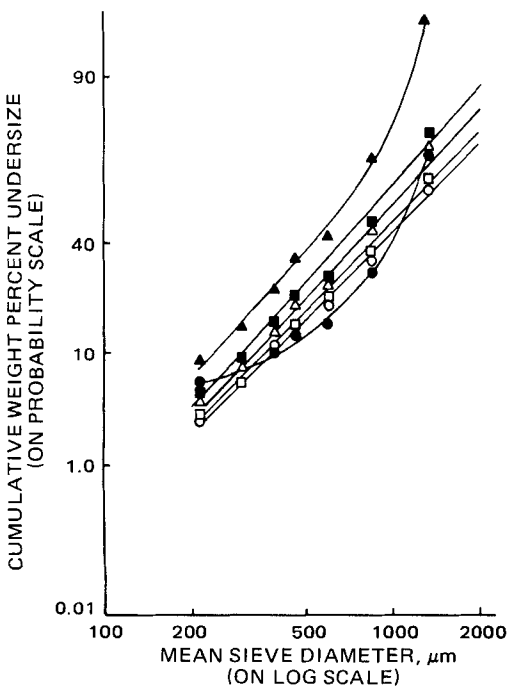

Figure 1—*Sieve analysis of granules on a log probability plot. Key (% w/w gelatin): ●, 0; ▲, 2.50; ■, 3.75; △, 5.00; □, 6.25; and ○, 7.50.*

Table II—Effect of Gelatin Concentration on the Capping Pressure of 300-mg Deep Biconvex Tablets Using a Hand-Operated Hydraulic Press

Gelatin Concentration, % (w/w)	Capping Pressure, MNm^{-2}	Packing Fraction (ρ_f)
0	29.8	0.74
2.50	59.5	0.81
3.75	89.3	0.83
5.00	119.1	0.85
6.25	119.1	0.87
7.50	148.9	0.88

Two methods of analysis were employed. The first involved using the equation of Wagner (7):

$$\text{\% dissolved by time } t = \frac{W}{W^\infty} \times 100 = \frac{\int_0^t s(t)\,dt}{\int_0^\infty s(t)\,dt}$$

$$\times 100 = \text{\% surface area generated by time } t \text{ of total surface generated} \quad \text{(Eq. 1)}$$

in which it is assumed that the surface area of the drug available for dissolution is initially zero, then increases to a maximum as disintegration occurs, and then falls off progressively to zero when dissolution is complete. The W and W^∞ are the amounts of drug dissolved at time t and at infinite time, respectively; the integrals represent the cumulative surface areas, S, that have been made available for dissolution from time zero to the particular time t and infinity, respectively.

The applicability of Eq. 1 can be tested by plotting values of cumulative percent drug dissolved on a probability scale (ordinate) *versus* the corresponding time values on a logarithmic scale (abscissa) and seeing whether straight-line graphs are obtained.

The second method of analysis was the equation proposed by Kitazawa *et al.* (8):

$$\ln \frac{C_s}{C_s - C} = kt \quad \text{(Eq. 2)}$$

where k is the dissolution rate constant, C_s is the concentration of the solute at saturation, and C is the actual solute concentration in solution at time t. Equation 2 was derived from a study of the dissolution of uncoated caffeine tablets and showed that a change in the dissolution rate at a cer-

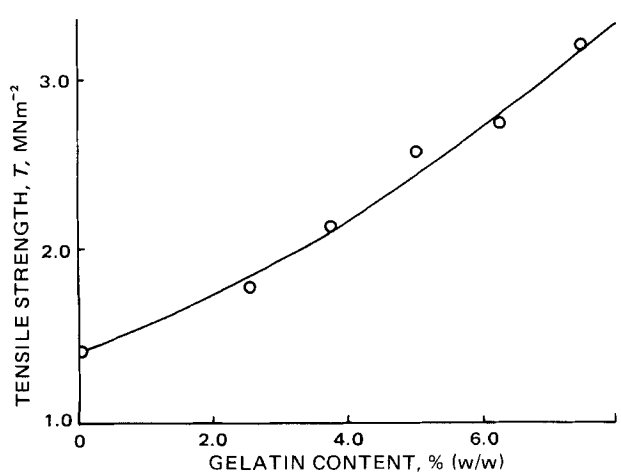

Figure 2—*Tensile strength* versus *gelatin content of flat-faced tablets prepared with a single-punch machine. The range of ρ_f was 0.85–0.87, and the range of moisture content was 2.4–3.2% (w/w).*

[a] Mean of four tablets. [b] Mean of 20 tablets. [c] Sixty-one percent released after 180 min.

tain time, t, represented a change in the surface area of the tablet due to it breaking into small particles.

EXPERIMENTAL

Materials—The basic formulation employed was 90.2% (w/w) oxytetracycline dihydrate[1] EP, 7.2% (w/w) microcrystalline cellulose BPC[2], and 3.6% (w/w) alginic acid HED[3] BPC.

Granule Preparation—Granules were prepared using gelatin[4] as previously reported (6).

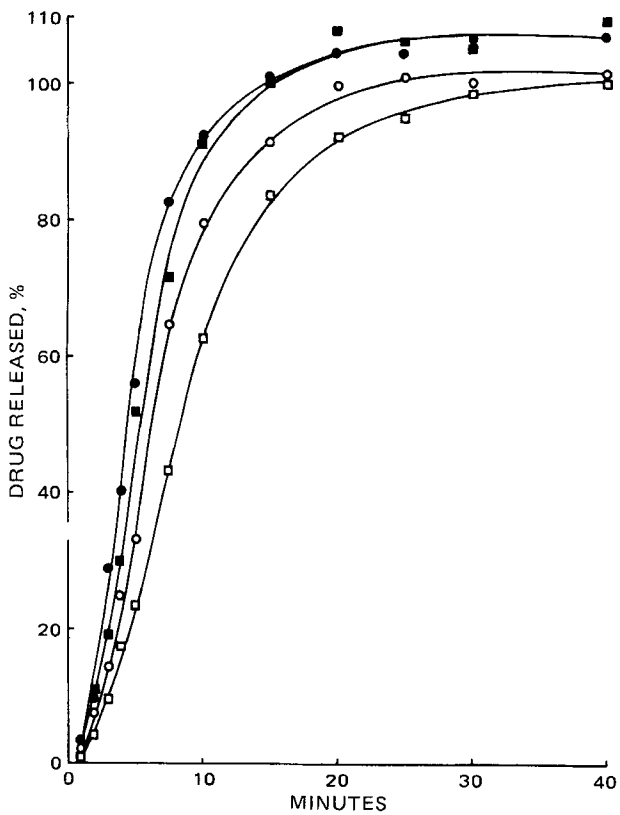

Figure 3—*Drug release* versus *time for tablets containing 3.75% (w/w) gelatin prepared with a single-punch machine of a constant pressure setting. Key (packing fraction, ρ_f): ●, 0.79; ■, 0.80; ○, 0.81; and □, 0.82.*

Tableting Procedure—A hand-operated hydraulic press[5] (6) and single-punch[6] and rotary-punch[7] tableting machines equipped with flat-faced or deep concave punches, 1.03 cm in diameter, were used to compress the granules. The granules had been lubricated with 1% (w/w) magnesium stearate. The compression speed of the single-punch machine was adjusted to 70 strokes/min. The multipunch machine was modified by blocking off 14 stations so that only two compression stations, fitted with deep concave punches on opposite sides of the revolving turret, were used. It was operated at 30 rpm.

The setting on each machine was adjusted to produce tablets (about 400–500) from each batch of granules with predetermined weights and packing fractions. The following tablets were prepared (all contained approximately 250 mg of oxytetracycline):

type of machine	shape	total weight, mg	tablets packing fraction (ρ_f)
hand press	deep biconvex	300 ± 10	0.69–0.90
single punch	flat faced	325 ± 10	0.85 ± 0.05
	deep biconvex	300 ± 10	0.80 ± 0.05
rotary punch	deep biconvex	300 ± 10	0.80 ± 0.05

Tests on Tablets—*Tensile Strength*—The tensile strengths of 325-mg flat-faced tablets were determined using the diametral compression test (6, 9, 10) on 20 tablets of each batch, and the means were calculated. The measurements were made in a room having a relative humidity of 50%.

Capping Pressure—Capping pressure was determined by subjecting the 300-mg biconvex tablets, which had been compressed to different packing fractions with the hand press, to the diametral test. The packing fraction at which each batch of tablets capped was noted, and the corresponding pressure employed to achieve tablets of this packing fraction was regarded as the capping pressure. The determination was made on at least 20 tablets per packing fraction in each batch, and capping was said to occur at a particular packing fraction when at least 50% of tablets tested capped.

Disintegration—The disintegration times of the 300-mg deep biconvex tablets were measured individually on 20 tablets by the BP method in a disintegration apparatus[8], and a mean time was calculated. Distilled water was used as the disintegration fluid (6).

Dissolution—The dissolution times of the 300-mg deep biconvex tablets were measured in an apparatus similar in principle to the "beaker method" of Levy and Hayes (6, 11). Individual tablets were placed in a pH 2 dissolution buffer solution and stirred at 100 rpm. Samples were removed at known time intervals and assayed in a spectrophotometer[9] for oxytetracycline content. The mean of four tablets was calculated at each gelatin concentration and packing fraction.

RESULTS

The size distributions of the granules used for preparing the tablets are shown in Fig. 1 as a log-probability plot.

	0.83	145.0	0.009	0.021

[a] A single straight regression line with slope = k was obtained.

The calculated values of the tensile strengths in Table I are for the 325-mg flat-faced tablets, prepared at packing fractions between 0.85 and 0.87 and containing moisture levels between 2.4 and 3.2% (w/w) with the single-punch tableting machine. The tensile strength is plotted *versus* percent (w/w) of gelatin in Fig. 2.

The information on the effects of gelatin concentration on the capping tendency of the 300-mg biconvex tablets is presented in Table II.

Table III lists the mean dissolution times for 25, 50, and 75% of drug released from the tablets (having packing fractions of approximately 0.80) prepared with both single-punch and multipunch machines. Table III also includes the mean disintegration times for these tablets.

Figure 3 shows a representative graph of the variation in dissolution profiles for tablets containing 3.75% (w/w) gelatin prepared with the single-punch machine at the same pressure settings. Similar variations were also obtained for tablets prepared with the multipunch machine at a fixed pressure setting.

The marked effect of gelatin concentration on the dissolution profiles of the tablets prepared with the single-punch machine at a packing fraction of approximately 0.80 is illustrated in Fig. 4. To test whether the data given in Table III and plotted in Fig. 4 were amenable to the Wagner (7) type of analysis, the values of percentage drug dissolved were plotted against time on a log–probability graph (Fig. 5). In general, straight lines could be drawn through the points for the tablets containing 0, 2.5, and 3.75% (w/w) gelatin. For tablets made with 5.0 and 6.25% (w/w) gelatin, curved lines were obtained.

The apparent pseudo-first-order plots corresponding to curves A and B in Fig. 5, together with similar curves obtained for tablets prepared (at the same packing fraction) with a hand-operated press and multipunch machine, are shown in Fig. 6. The Kitazawa *et al.* (8) types of plot of $\ln [C_s/(C_s - C)]$ *versus* time are shown in Figs. 7 and 8 for tablets compressed with the hand-operated press to different packing fractions and containing 0 and 5% (w/w) gelatin, respectively. Similar plots were obtained for tablets made (at approximately the 0.80 packing fraction) with the single-punch machine (Fig. 9). Depending on the packing fraction and gelatin content, either a single straight line or two intersecting straight lines were obtained for each formulation. For those with two straight lines, the time at which the lines intersect is termed t_1, the slope of the first is designated k_1, and the slope of the second is designated k_2. Additional relevant data showing the effects of both packing fraction and gelatin content on these values are listed in Tables IV and V.

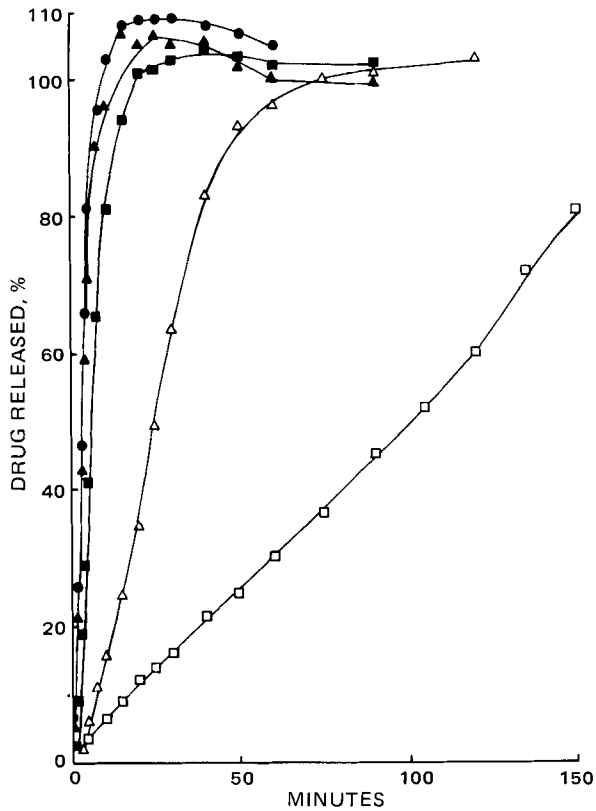

Figure 4—*Effect of gelatin content on the dissolution of tablets prepared with a single-punch machine at $\rho_f \simeq 0.80$. Key: ●, 0% (w/w) gelatin and 0.79 mean ρ_f; ▲, 2.50% (w/w) gelatin and 0.80 mean ρ_f; ■, 3.75% (w/w) gelatin and 0.80 mean ρ_f; △, 5.00% (w/w) gelatin and 0.80 mean ρ_f; and □, 6.25% (w/w) gelatin and 0.80 mean ρ_f.*

DISCUSSION

With some formulations, variations in granule size (Fig. 1) may cause significant changes in the disintegration and dissolution rates of the tablets (12, 13). However, these changes were small for two oxytetracycline formulations, one containing gelatin (14) and the other povidone (5) as the binding agent.

Increasing the gelatin concentration increased the tensile strengths of the tablets (Fig. 2). Therefore, the result was similar to that obtained on loosely packed beds (15) on tablets prepared with a hand-operated press (6) and when povidone was used as the binding agent (5). This result could be attributed to the considerable amount of heat generated during the tableting of powders or granules, producing overall temperature rises of about 5–30° and still higher rises of the contact points between the asperities on the particles (16, 17). This temperature increase could cause

melting of asperities and, in the present systems, of the gelatin binding agent; on cooling, they would solidify to form strong bonds between the particles (18). The amount of bonding that would take place and, therefore, the strength of the tablet would be expected to depend *in part* on the amount of gelatin present.

As observed previously (6), the 300-mg deep biconvex tablets spontaneously capped when subjected to the diametral compression test, presumably because of their very thin edges. These tablets are known to be subject to capping in production. However, the higher the gelatin concentration in the formulations, the higher was the packing fraction to which the tablets could be compressed before capping occurred (Table II). Therefore, to overcome the tendency of the 300-mg biconvex oxytetracycline tablets to cap during production, a reasonably high concentration of gelatin should be incorporated into the formulation.

Small changes in the packing fraction of oxytetracycline tablets containing the same gelatin concentration and prepared at the same nominal pressure setting of the machine produced wide variations in their dissolution profiles (Fig. 3). This effect could also account for the reported variations in the dissolution rates of oxytetracycline tablets from different manufacturers and between or within batches obtained from one manufacturer (3, 4).

Besides bond formation, another mechanism that might contribute to the observed increases in both the disintegration and dissolution times of the tablets with an increase in gelatin content (Table III and Fig. 4) might be the formation of a thin film of gelatin around the powder particles or granules; its thickness would depend on the quantity of gelatin employed. This thin film could subsequently be converted into a mucilaginous viscous barrier when the tablets and breakup fragments contacted the test media (19), which would increase their disintegration and dissolution times. The greater rate of disintegration than of dissolution (Table III) was as expected, since the disintegration tests only measured the time for the tablets to break into granules or particles that could pass through a No. 10 mesh screen while dissolution tests measured the time for the oxytetracycline particles to dissolve from the intact tablets, fragments, granules, or aggregates.

Analysis of the dissolution results showed that the oxytetracycline tablets containing less than 5% (w/w) gelatin conformed satisfactorily to Wagner's (7) concept of a log-normal distribution plot, since linear graphs were obtained for these samples (Fig. 5). [Wagner (7) obtained linear plots on results obtained by various other workers using, for example, tablets of buffered aspirin, griseofulvin, and potassium chloride.] When more than 5% (w/w) gelatin was present, the graphs became curved and exhibited kinks when linearized by the first-order method of plotting (Fig. 6).

The value of a Wagner plot (Fig. 5) (7) is that it enables a dissolution rate to be described in terms of two parameters: the medium $t_{50\%}$ and the standard deviation. One can also obtain values of $t_{20\%}$, $t_{90\%}$, *etc.*, from these plots. Under theoretically ideal circumstances, when a tablet disintegrates and liberates the primary particles of drug, the dissolution rate is limited by the effective surface area of the particles. On this basis, Wagner (7) suggested that both the $t_{50\%}$ and standard deviation values might provide information on the likely behavior of tablets in *in vivo* tests, but this suggestion has not yet been confirmed.

Analysis by the Kitazawa *et al.* (8) method showed that tablets compressed to a packing fraction of approximately 0.80 and containing less than 5% (w/w) gelatin yielded straight lines, with one dissolution rate constant, k, in each case (Fig. 9). These tablets broke up rapidly into small particles as soon as they were in contact with the dissolution medium, resulting in a sudden increase in surface area and a subsequent constant decrease as the granules dissolved.

However, for tablets containing 5 and 6.25% (w/w) gelatin, the dissolution rate constants changed from k_1 to k_2 at certain times, t_1, at all packing fractions (Figs. 8 and 9). Similar observations were obtained with tablets containing less than 5% (w/w) gelatin when their packing fractions were either below 0.75 or above 0.85 (Fig. 7). This change in the dissolution rate constant is ascribed to an increase in surface area due to break-up of the tablets into large and small fragments at time t_1. The changes in the dissolution rate profile with packing fraction (Fig. 7 and Table IV) showed that the dissolution rate was a maximum (6) at packing

altered. The times corresponding to the kinks in Fig. 6 were identical with the t_1 values obtained from Figs. 8 and 9 because Eqs. 1 and 2 were both derived from the same basic equation of Noyes and Whitney (20):

$$\frac{dC}{dt} = k(C_s - C) \qquad \text{(Eq. 3)}$$

where the symbols are as defined for Eq. 2.

Visual observations during the tests confirmed that in the first sections (*i.e.*, up to times t_1) in graphs A–C in Figs. 6 and 9 and in graphs E and F in Fig. 8, dissolution was occurring from intact tablets; the second sections (*i.e.*, after times t_1) represented dissolution from broken fragments of the tablets. The tablets whose results are shown in graph D of Fig. 6 and in graphs G–J of Figs. 7 and 8 initially broke up quite rapidly into fairly large fragments, and these fragments then broke up into smaller fragments very slowly. Similar conclusions were reached by Kitazawa *et al.* (8).

In contrast to their results (8) on caffeine tablets, no good correlation was obtained between the values of t_1 and disintegration time or between k_1 and k_2 for the oxytetracycline tablets investigated. The disintegration times of these tablets were less than the t_1 values, possibly because in the present work [in contrast to that of Kitazawa *et al.* (8)] more vigorous agitation was employed in the disintegration test than in the dissolution test.

Irrespective of the tableting equipment employed, the values of k for

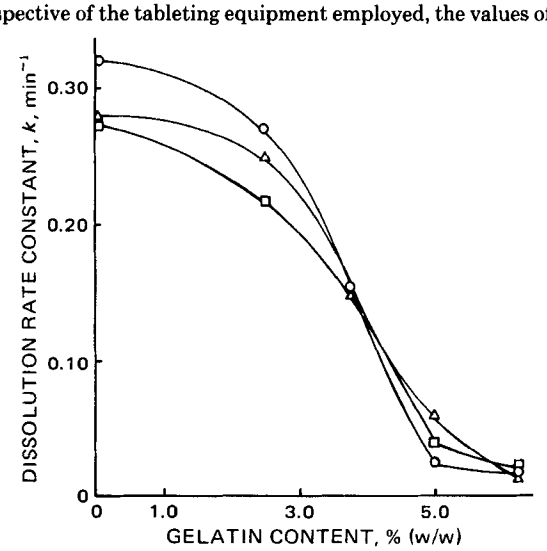

Figure 10—*Effect of gelatin content on the k values calculated using Eq. 2 for tablets prepared with the three types of machines at $\rho_f \simeq 0.80$. Key: ○, hydraulic press; □, single punch; and △, multipunch.*

all tablets decreased with their binding agent content (Fig. 10). Although this finding is similar to a previous one where povidone was substituted for gelatin (5), it is also clear that the nature of the binding agent has a profound effect on the dissolution characteristics of a formulation.

Micellar Distribution Equilibria: Ultracentrifugal Study of Apparent Partition Coefficients

JUNG Y. PARK * and EDWARD G. RIPPIE *

Abstract □ Ultracentrifugation was used for the partial isolation of polysorbate 80 micelles in aqueous media to determine the apparent partition coefficients of various drug species between water and the micellar pseudophase. The ratio of solute concentration in the micelles to that in water was measured for procaine, salicylic acid, sulfapyridine, sulfisoxazole, and sodium 2-naphthalenesulfonate over ranges of pH, surfactant concentration, drug concentration, and micelle sedimentation. Apparent partition coefficients for the systems investigated were independent of both drug concentration and surfactant concentration, indicating that the mode(s) of surfactant–drug interaction are essentially invariant over the ranges of systematic variables studied. The method provides a relatively simple and rapid means of quantitatively evaluating drug–surfactant interactions above the CMC, when surfactant and solute can be assayed in mixtures without interference.

Keyphrases □ Micellar distribution—ultracentrifugal study of apparent partition coefficients of various drugs between water and micellar pseudophase □ Partition coefficients, apparent—various drugs between water and micellar pseudophase, ultracentrifugal study □ Ultracentrifugation—determination of apparent partition coefficients of various drugs between water and micellar pseudophase □ Solute–micelle interactions—ultracentrifugal study of apparent partition coefficients of various drugs between water and micellar pseudophase

Much experimental evidence relating to the mechanisms of interactions between secondary solutes and surfactant micelles is obtained from measurements of the magnitude of solute–micelle interactions and their dependence on variables such as concentration, ionic strength, temperature, and pH. Experimental techniques often introduce inherent systematic errors. Methods such as dialysis, gel filtration, and ultrafiltration, which are based on the mechanical or physicochemical isolation of the micellar pseudophase from the aqueous phase (1, 2), require the use of semipermeable membranes, selectively permeable gels, or other materials that may interact with various components and perturb the system beyond the desired separation.

The micellar isolation or separation process also may result in the destruction of the micellar structure of the surfactant system by concentrating the surfactant until it separates as a true second phase. Solute–micelle interactions also were studied extensively through the solubilization resulting from such interactions (3–6). While this latter method overcomes the problems previously mentioned, it is limited to a single thermodynamic activity for a given solute.

The analytical ultracentrifuge was used to determine the molecular weight, size, and molecular interactions of micelles (7, 8) and to determine the partition coefficients of drugs between liquid and liquid crystalline phases (9) that have been caused to separate. Ultracentrifugation offers the capability of either complete or partial micellar isolation without membranes or other added components within a reasonably short experiment time. The present paper investigates the feasibility of determining solute–micelle interactions, over a range of both solute and surfactant concentrations, using a moderate partial micelle separation by ultracentrifugation. Previously studied systems of aqueous polysorbate 80 solutions containing

all tablets decreased with their binding agent content (Fig. 10). Although this finding is similar to a previous one where povidone was substituted for gelatin (5), it is also clear that the nature of the binding agent has a profound effect on the dissolution characteristics of a formulation.

procaine, salicylic acid, sulfapyridine, sulfisoxazole, and sodium 2-naphthalenesulfonate were selected.

DATA TREATMENT

Various separate and distinct modes of solute–micelle interaction occur, including adsorption onto the micelle surface, penetration into the palisade layer of nonionic micelles, and dissolution in the fluid hydrocarbon central core. No attempt is made here to imply or otherwise define the particular mechanisms operating, but the solute–micelle association is treated as a partition phenomenon having an associated apparent partition coefficient. The appropriateness of this simple pseudophase model was discussed (1), and it serves as a useful approximation if contributions to micellar free energy from changes in solvent are small and if the micelles are essentially noninteracting. That these conditions are met is evidenced by the independence of the apparent partition coefficients on surfactant concentration. Further assumptions and approximations implicit in the pseudophase model were discussed by Mukerjee (10).

Consider an aqueous micellar solution of a nonionic surfactant containing a second solute partitioned between the water and the micellar pseudophase. After a suitable period of ultracentrifugation, a higher concentration of the more dense micelles exists in the lower (outer) portion of the centrifuge tube as opposed to the upper portion. By assuming that there is no change in the system other than the induced micellar concentration gradient, a resultant concentration gradient of the associated partitioning solute can be predicted.

If, following centrifugation, the contents of the centrifuge tube are separated into upper and lower portions, which are subsequently mixed individually to ensure their homogeneity, the following expressions can be written for X and Y, which are solute concentrations in grams per milliliter in the upper and lower portions, respectively:

$$X = (U/\rho)[(HA) + (A^-)] + (1 - U/\rho)[[HA] + [A^-]] \quad \text{(Eq. 1)}$$

$$Y = (L/\rho)[(HA) + (A^-)] + (1 - L/\rho)[[HA] + [A^-]] \quad \text{(Eq. 2)}$$

where U and L represent surfactant concentrations in grams per milliliter in the upper and lower portions, respectively, and ρ is the micellar density in grams per milliliter. The equations are derived for weakly acidic solutes whose free acid, HA, and conjugate base, A^-, concentrations in grams per milliliter are denoted by ( ) and [ ] in the micellar and aqueous pseudophases, respectively. The first terms on the right in Eqs. 1 and 2 represent the micelle associated solute in 1 ml of aqueous micellar solution, whereas the second terms represent the aqueous solute in the same 1 ml of solution. These expressions can be written in terms of the apparent acid dissociation constant of the solute, K_a, and the solute's apparent partition coefficients, $K_1 = (HA)/[HA]$ and $K_2 = (A^-)/[A^-]$, in its free acid and conjugate base forms:

$$[H^+]\rho X = U[HA][K_1[H^+] + K_2K_a] + (\rho - U)[HA][[H^+] + K_a] \quad \text{(Eq. 3)}$$

$$[H^+]\rho Y = L[HA][K_1[H^+] + K_2K_a] + (\rho - L)[HA][[H^+] + K_a] \quad \text{(Eq. 4)}$$

Combining Eqs. 3 and 4 to eliminate [HA] yields the following expression relating K_1 and K_2 to experimentally measurable quantities:

$$[H^+]K_1 + K_2K_a = ([H^+] + K_a)\left[1 - \frac{\rho(X - Y)}{(XL - YU)}\right] \quad \text{(Eq. 5)}$$

A plot of the expression on the right of Eq. 5 *versus* $[H^+]$ yields a straight line with slope K_1 and intercept K_2K_a. For weakly basic drugs, the following definitions apply to Eq. 5: $K_a = K_w/K_b$, $K_1 = (BH^+)/[BH^+]$, and $K_2 = (B)/[B]$.

Application of Eq. 5 requires that the stoichiometric concentrations of both the surfactant and the partitioning solute be determined. The concentration of micellar surfactant was taken to be equal to its stoichiometric concentration since the critical micelle concentration (CMC) of polysorbate 80 is approximately $1.0–6.2 \times 10^{-3}$% (w/v) (3, 11–14) and can be neglected at the surfactant concentrations studied. The density, ρ, of the polysorbate 80 micelles was taken as 1.11 (11), and the K_a values (moles per liter) employed are: procaine, 1.40×10^{-9}; salicylic acid, 1.06×10^{-3}; sulfapyridine, 3.60×10^{-9}; and sulfisoxazole, 7.60×10^{-6}. Slopes and intercepts of data plotted in accordance with Eq. 5 were obtained by the method of least squares, and their standard deviations were estimated from an analysis of variance of the experimental data points.

EXPERIMENTAL

Centrifugation—Aliquots, 10 ml, of aqueous solutions containing the desired concentrations of polysorbate 80[1] and the secondary solutes were centrifuged at 25° for 10 hr in an ultracentrifuge[2] at 40,000 rpm in cellulose nitrate tubes. The tubes were then cut in half with a tube slicer, and the upper and lower samples were assayed to determine the polysorbate 80 and partitioning solute concentrations. The period of centrifugation was selected to give an approximately 40% separation of micelles and was a fraction of the time required to reach sedimentation equilibrium. This degree of separation was sufficient to provide suitable sensitivity for the method and yet not great enough to alter micellar properties significantly.

The solutes investigated were procaine hydrochloride[3], salicylic acid[4], sulfapyridine[5], sulfisoxazole[5], and sodium 2-naphthalenesulfonate[6]. All other chemicals were reagent grade and were used as received without further purification. Solutions were prepared by dissolving measured quantities of polysorbate 80 and the various drugs in double-distilled water, diluting to 90% of volume, adjusting the pH to the desired values with either hydrochloric acid or sodium hydroxide solutions, and diluting to volume. The pH's were checked in all cases following centrifugation and did not change.

Polysorbate 80 Assay—Polysorbate 80 was assayed in the presence of the solubilized drugs by the method of Cucakovich (15), based on the formation of a complex between the amylose fraction of potato starch and polysorbate 80. That portion of the starch added in excess and not complexed with polysorbate combined quantitatively with iodine to form a blue amylose–iodine complex. The blue color was determined spectrophotometrically[7] at 680 nm, and the procedure gave good results without interference by the solubilized drugs present.

Secondary Solute Assays—Following centrifugation of the micellar polysorbate 80–drug solutions, samples of the upper and lower fractions were diluted with 95% ethyl alcohol to appropriate concentrations of drug and assayed spectrophotometrically[7] for drug content. The presence of polysorbate 80 did not interfere with the assays conducted at the following wavelength maxima: procaine, 288 nm; salicylic acid, 298 nm; and sulfapyridine and sulfisoxazole, 260 nm.

The assay for sodium 2-naphthalenesulfonate was performed fluorometrically[8] at an excitation wavelength of 280 nm and an emission wavelength of 340 nm following dilution of the centrifuged samples with water to a concentration of approximately 1 μg/ml at pH 7. No interference by polysorbate 80 was observed, and the same calibration curve was used with all surfactant concentrations.

RESULTS AND DISCUSSION

Distribution measurements were made at several concentrations of the surfactant and of the various drugs at a number of pH values. Table I summarizes the scope of these experimental variables. The good linearity of data plotted in accordance with Eq. 5 is apparent from Fig. 1, for 0.01% solutions of procaine and sulfapyridine in 1% polysorbate 80, and is typical of all systems studied.

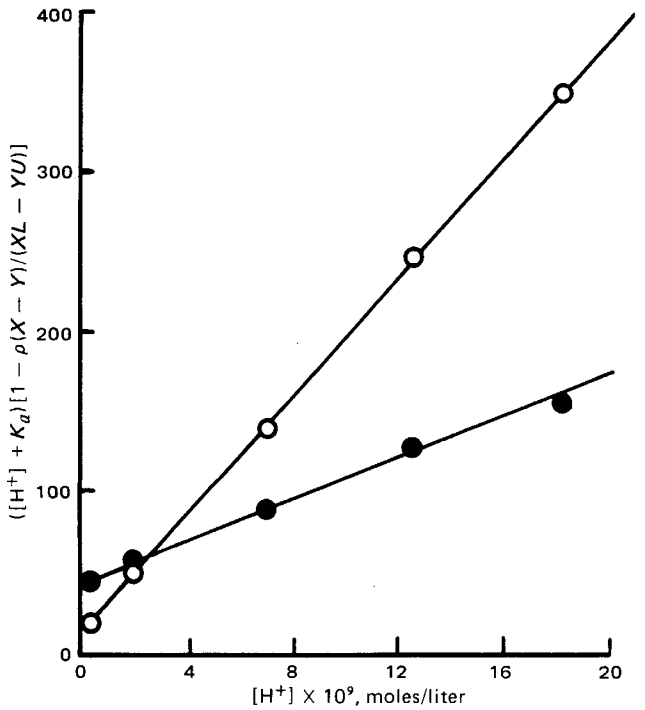

Figure 1—*Relationship of solute distribution data to hydrogen-ion concentration for 0.01% (w/w) procaine and sulfapyridine in 1% (w/w) polysorbate 80 plotted according to Eq. 5. Key: ●, procaine; and ○, sulfapyridine.*

Apparent partition coefficients for the weakly acidic and basic drugs and their conjugate forms are listed in Table II together with their estimated standard deviations and the corresponding linear correlation coefficients, r, of the various plots. No significant difference was found between the apparent partition coefficients of any given drug or its conjugate acid or base over the range of drug or surfactant concentrations studied. This observation is consistent with the assumption, made in deriving Eq. 5, that the nature of the micelles would not be measurably altered by the concentration differences induced by centrifugation.

Apparent partition coefficients of the free drugs reported here are approximately 50–60% of those previously reported or estimated from the literature (5, 6, 16). Also, micellar association with procaine ion (5) and with salicylate ion (2, 6) occurred, in contrast to previous reports. However, these findings should be considered in light of the rather large drug concentration differences and temperature and ionic strength differences used in these methods.

Implicit in the present method is the assumption that ultracentrifugation does not significantly alter the chemical potential of molecular solutes at various levels within the centrifuge tube. For incompressible solutions of neutral molecules, the chemical potential at equilibrium, u_i, is given as a function of angular velocity, ω, radial distance, r, and molecular weight, M_i (17), as:

$$d\bar{u}_i/dr = du_i/dr - M_i\omega^2 r = 0 \qquad \text{(Eq. 6)}$$

The magnitude of centrifugal effects is small for low molecular weight solutes. Furthermore, the apparent average molecular weight of association colloids can be assumed to be a function only of the monomer activity; therefore, the apparent average molecular weight *versus* monomer concentration curve is independent of the rotor speeds and solution depths at which various monomer concentrations occur.

A Donnan effect may occur when a concentration gradient is induced in a charged species in a solution where no such gradient is induced in other diffusible ions. While this effect is commonly observed when a polyelectrolyte in solution is excluded from a second solution by a semipermeable membrane, it also results from the centrifugal induction of a concentration gradient of micelles containing associated charged species. The expression:

$$K_2 = \frac{\rho([A^-]_u^2 - [A^-]_l^2)}{L[A^-]_u^2 - U[A^-]_l^2} \qquad \text{(Eq. 7)}$$

holds for the apparent partition coefficient of a negatively charged species, A^-, between water and nonionic surfactant micelles where subscripts u and l denote upper and lower fractions of the centrifuged solution. Equation 7 requires that $[A^-]_u < [A^-]_l$, a condition not assumed in the derivation of Eq. 5. Neglect of the Donnan effect will diminish the magnitude of the calculated value of K_2.

The effect of a swamping electrolyte on the apparent partition coefficient, K, of sodium 2-naphthalenesulfonate between water and polysorbate 80 micelles was determined by the addition of potassium chloride to the micellar solutions prior to centrifugation. Results of measurements at several concentration combinations of polysorbate and naphthalenesulfonate are presented in Table III. Calculations of K were made with the use of:

$$K = 1 - \frac{\rho(X - Y)}{(XL - YU)} \qquad \text{(Eq. 8)}$$

which is a limiting form of Eq. 5 and applies where only charged solute species exist. Results compare favorably with those reported using dialysis (2). No attempts were made to adjust K_2 values for Donnan effects, since such calculations would require an exact knowledge of the micellar concentration profile within the centrifuge tube.

SUMMARY

The study of micelle–solute interactions by means of partial ultracentrifugal separations of the micellar components offers some possible advantages over other procedures. It permits relatively rapid separations, which are advantageous when solutes are unstable chemically, and avoids the use of membranes or other added materials for the purpose of micelle isolation. Moreover, flexibility in the choice of systems is essentially limited only by the need to assay both the micellar and secondary solute components. While the data were treated in terms of a nonspecific partitioning model in the present paper, the general approach is equally compatible with various adsorption, specific site, or other models of micelle–solute interactions.

Physicochemical Properties of β-Lactam Antibacterials: Deuterium Solvent Isotope Effect on Penicillin G Degradation Rate

TSUKINAKA YAMANA [x], AKIRA TSUJI, EMI KIYA, and ETSUKO MIYAMOTO

Abstract □ To obtain kinetic evidence on the degradation mechanism of penicillin in aqueous solution, degradation rates of penicillin G in water and deuterium oxide were measured in the pH (pD) range of 4–10. The solvent isotope effect (k^{H_2O}/k^{D_2O}) of 1.53 below pH (pD) 6 supports the mechanism of water-catalyzed rearrangement of undissociated penicillin G to benzylpenicillenic acid. The spontaneous degradation at neutral pH (pD) and the hydroxide-ion-catalyzed degradation in the alkaline pH (pD) range progress with a deuterium solvent isotope effect (k^{H_2O}/k^{D_2O}) of 4.5 and 0.59, respectively. This finding indicates the mechanisms of general base-catalyzed hydrolysis by water in the neutral pH range and of nucleophilic attack of the hydroxide ion on the β-lactam in the alkaline pH range. No significant side-chain dependency was observed in the reaction of penicillins with bases. The solvent isotope studies led to the conclusion that penicillin degradation is catalyzed by a series of bases *via* general base-catalyzed and nucleophilic mechanisms, depending on their basicity.

Keyphrases □ Penicillin G—degradation in aqueous solution, deuterium solvent isotope effect, pH 4–10 □ Degradation—penicillin G in aqueous solution, deuterium solvent isotope effect, pH 4–10 □ Deuterium oxide—solvent isotope effect on penicillin G degradation in aqueous solution, pH 4–10 □ Antibacterials—penicillin G, degradation in aqueous solution, deuterium solvent isotope effect, pH 4–10

Although the stability of penicillins in aqueous solution has been studied (1–14), little work has been done on their mechanism of degradation.

Interest in the degradation of penicillin in acid and neutral solutions has been stimulated by the suggestion that its degradative product, penicillenic acid, rather than penicillin itself, may be responsible for allergic reactions[1]. During the degradation of penicillin G at a physiological pH of 7.5, the solution slowly gave rise to both benzylpenicilloic acid and benzylpenicillenic acid (15, 16). Levine (15, 16) suggested that the formation of benzylpenicilloic acid proceeded by way of benzylpenicillenic acid as an intermediate, because the latter compound was converted rapidly into the former with a half-life of 6.5 min at pH 7.5 and 37° (17).

Furthermore, some investigators (18, 19) assumed that higher sensitivity of the β-lactam ring in penicillin molecules relative to that of simple β-lactams to hydroxide-ion-catalyzed degradation can be attributed in part to the intramolecular attack of the side-chain amide on the β-lactam moiety. These two hypotheses (15–19) recently were criticized (13, 20) on the basis of kinetic observations, although the mechanism of degradation in neutral and alkaline solutions is not completely understood.

The present study was undertaken to obtain kinetic

Table I—Rate Constants [a] and pKa Values Determined for the Degradation of Penicillin G in Water and Deuterium Oxide at 0.5 Ionic Strength

Solvent	Temperature	k_0, hr^{-1}	$10^3 k_0'$, hr^{-1}	$10^{-3} k'_{OH}$ [b], $M^{-1} hr^{-1}$	pKa
Water	35°	3.41	0.90	1.19	2.80[c]
Water	60°	37.4	7.20	5.39	2.78[d]
Deuterium oxide	60°	24.5	1.60	9.12	3.24[c]

[a] Based on the kinetic expression of Eq. 1. [b] Calculated using the autoprotolytic constant: $K_w = 2.09 \times 10^{-14}$ at 35° and $K_w = 9.61 \times 10^{-14}$ at 60° (31); $K_{D2O} = 1.36 \times 10^{-14}$ at 60°, which was extrapolated from the data of Corington *et al.* (32) by the least-squares curve-fitting method. [c] Determined potentiometrically. [d] Reference 7.

evidence on the degradation mechanism of penicillin and to consider possible ways of stabilizing penicillins in aqueous solution. The rates of degradation of penicillin G as a model penicillin were measured in buffered and unbuffered deuterium oxide solutions.

EXPERIMENTAL

Materials—Penicillin G potassium[2], cloxacillin sodium[2], ampicillin sodium[3], and cyclacillin[3] were used as supplied. All other chemicals were the highest commercial grades available. Double-distilled water was used.

Kinetic Procedures—Degradation was initiated by the addition of a known weight of penicillin to a buffer solution preheated to the desired temperature. Aliquots of the solution were withdrawn at suitable time intervals. Unless otherwise stated, the residual penicillin concentration was analyzed by the modified iodometric method (7). In most cases, the initial concentration of penicillin was 5×10^{-3} *M*. The pseudo-first-order rate constants, k_{obs}, were calculated by linear regression analysis of a plot of the logarithm of the penicillin concentration against time.

The rate constants of penicillin G corresponding to those in unbuffered solution of water (k_{pH}) and deuterium oxide (k_{pD}) were determined by the two methods: (*a*) by extrapolation of a plot of k_{obs} *versus* buffer total concentration to zero concentration at constant pH (pD) or by direct determination from analysis of the solution whose pH was maintained constant with the aid of a pH-stat[4], and (*b*) by following the rate of acid formation on a pH-stat. The rate constants were calculated from Guggenheim plots of recorded curves of the volume of titrant [standard 0.01–0.1 *N* NaOH (NaOD) solution whose ionic strength was adjusted to 0.5 with potassium chloride] as a function of time.

In the pH-stat experiments, edetate disodium was added to a final concentration of 5×10^{-4} *M* to avoid occasional erratic results, apparently due to heavy metal-catalyzed decomposition. The concentration of penicillin G was in the range of $5–10 \times 10^{-3}$ *M*.

Unless otherwise stated, kinetic experiments were conducted at 35 or 60° and at a constant ionic strength of 0.5 adjusted with potassium chloride. The pH (pD) of a kinetic solution was measured[5] both before and at the end of the experiments. Where the buffer capacity was too low, constant pH was maintained by a pH-stat. When using deuterium oxide as a solvent, the pD values were taken as the pH meter reading plus the electrode correction of 0.25 at 60° (21).

pKa Determination—The pKa of penicillin G in deuterium oxide at 60° and $\mu = 0.5$ was determined in the manner described by Finholt *et al.* (7). The pKa values of conjugated acids of oxygen bases and amines were determined by the method of half-neutralization.

RESULTS AND DISCUSSION

Degradation Pathway and Mechanism—Figure 1 shows the rate constants, k_{pH}, of penicillin G degradation at 35 and 60° as a function of pH in water. Above pH 4, this degradation is known to obey the following rate law (5, 7, 13):

$$k_{pH} = k_0 \frac{a_{H^+}}{K_a + a_{H^+}} + (k_0' + k'_{OH}\text{-}K_w/a_{H^+}) \frac{K_a}{K_a + a_{H^+}} \quad \text{(Eq. 1)}$$

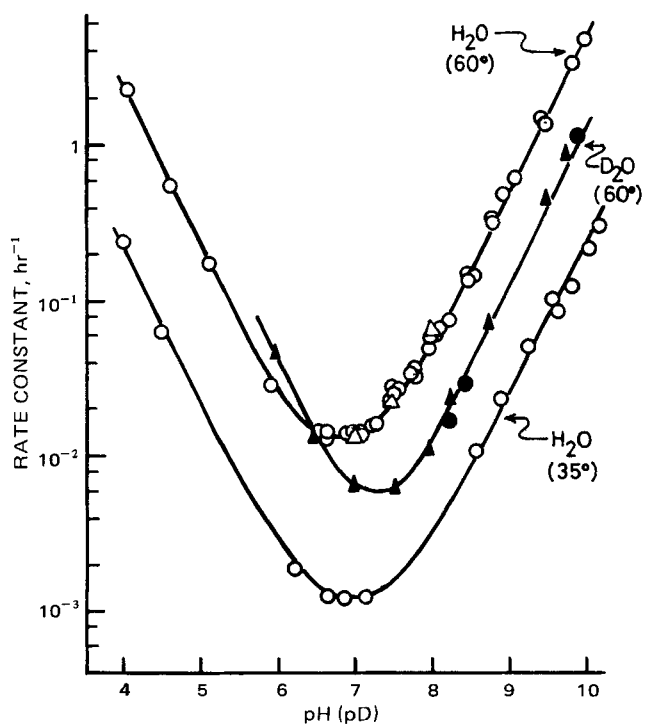

Figure 1—*Log k–pH (pD) profiles for the degradation of penicillin G in water (○, △) and in deuterium oxide (●, ▲) at 35 and 60° and 0.5 ionic strength. Triangles and circles refer to the data determined by the pH-stat alkalimetric titration and iodometric methods, respectively.*

where K_a is the dissociation constant of penicillin G; K_w is the autoprotolysis constant for water; a_{H^+} is the hydrogen-ion activity as determined by the glass electrode; k_0 and k_0' represent the spontaneous or water-catalyzed degradation rate of undissociated and ionized penicillin G, respectively; and k'_{OH^-} is the second-order rate constant for the hydroxide-ion-catalyzed degradation of ionized penicillin G. In the experimental pH region, acid-catalyzed degradation of undissociated penicillin G can be neglected, since such a reaction is only significant below pH 2 (1, 5). The specific rate constants and the dissociation constant are listed in Table I. These values at 60° are in good agreement with those reported by Finholt *et al.* (7).

The rates in deuterium oxide were also determined in the same way as in water. The log k_{pD}–pD profile at 60° is shown in Fig. 1, and the various specific rate constants corresponding to those in water and the pKa value are given in Table I. Above pH (pD) 7, the rates in water were about five times faster than those in deuterium oxide; below pH (pD) 6, the rates in deuterium oxide were about twice those in water.

The k'_{OH^-}/k'_{OD^-} ratio (Table I) was 0.59, consistent with the expected kinetic isotope effect for the reaction involving nucleophilic attack of OH^- and OD^- on the carbonyl carbon of carboxylic acid derivatives (22). The lack of a significant side-chain dependency on k'_{OH^-} (13, 23–25) and the present results led to the conclusion that the 10^4-fold higher reactivity of penicillins toward hydroxide-ion attack compared with that of monocyclic β-lactam and ordinary amides is not primarily due to an intramolecular participation effect as suggested (18, 19) but exclusively due to the strained fused-ring β-lactam and/or to a suppression of the usual amide resonance resulting from the nonplanarity of the β-lactam nitrogen atom.

The reaction below pH 6 is attributed to the spontaneous degradation of unionized penicillin G or the kinetically equivalent hydrogen-ion-

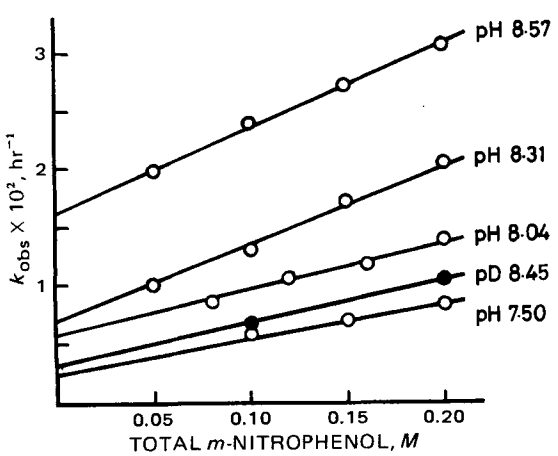

Figure 4—*Plots of pseudo-first-order rate constants* versus *total m-nitrophenol concentration for the degradation of penicillin G in water (○) and deuterium oxide (●, 50% free base) at 60° and 0.5 ionic strength.*

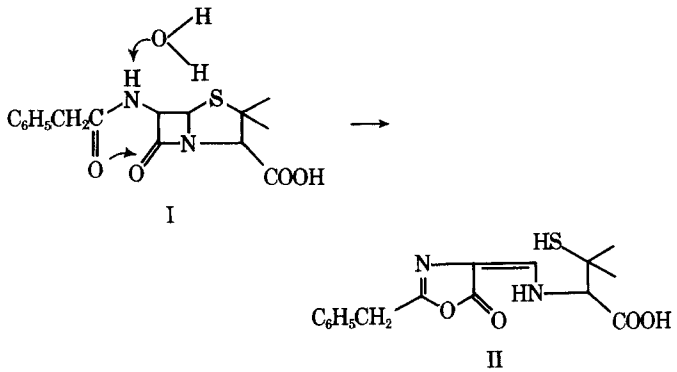
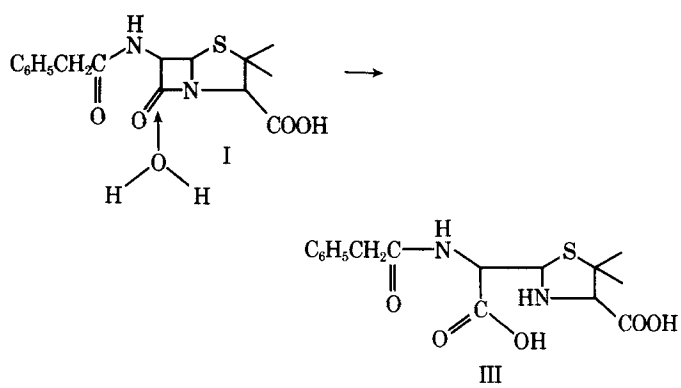


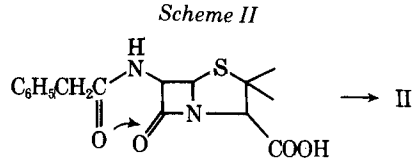
Scheme I

catalyzed degradation of its ionized form. The observed solvent isotope effect of 1.53 for $k_0^{H_2O}/k_0^{D_2O}$ is consistent with the former reaction mechanism favored by Finholt *et al.* (7) and Yamana *et al.* (13) on the basis of the kinetic observation of little ionic strength effect in the pH 4–6 region. However, a more plausible mechanism would be water-catalyzed rearrangement of undissociated penicillin G (I) to benzylpenicillenic acid (II) (Scheme I).

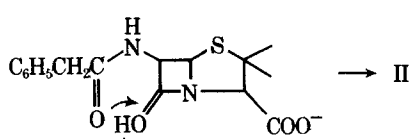
The proposed mechanism should give the expected solvent isotope effect of $1 < k^{H_2O}/k^{D_2O} < 2.5$. A value of 1.53 is not totally consistent with water attack on the β-lactam ring to afford the penicilloic acid (III) (Scheme II, k^{H_2O}/k^{D_2O} expected to be >2.2) or with direct attack of the neighboring acylamide oxygen on the β-lactam ring to produce the penicillenic acid (II) (Scheme III, expected isotope effect of 1.0). The other two kinetically undistinguishable mechanisms, hydrogen-ion-catalyzed rearrangement of ionized penicillin G to benzylpenicillenic acid (Scheme IV) and attack of water on the protonated β-lactam moiety (Scheme V),



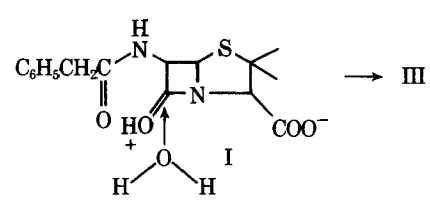
Scheme II



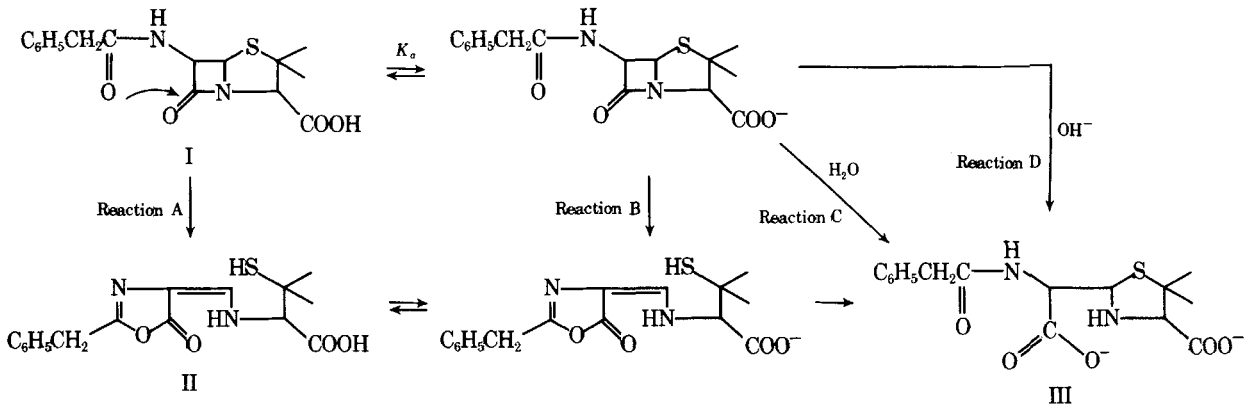
Scheme III



Scheme IV



Scheme V



Scheme VI

can probably both be excluded because k^{H_2O}/k^{D_2O} should be[6] <1.

The production of unstable benzylpenicillenic acid as the reaction intermediate under the conditions below pH (pD) 6 was confirmed by the increase in absorbance at 325 nm of the reaction solution in both water and deuterium oxide. Based on these facts, Scheme I would be the most reasonable to account for the k_0 reaction.

The unique feature of the pH–rate profile for the degradation of penicillin G is the plateau in the neutral pH region. Remarkably broad plateaus have been observed in the degradation of penicillins such as ampicillin (9), cyclacillin (13), phenethicillin (4), and cloxacillin (10), which have characteristically lower k_0 values than penicillin G. The spontaneous rate, k_0', may be due to (*a*) intramolecular attack of the side-chain amide carbonyl on the β-lactam of ionized penicillin (Scheme VI) to produce the penicillenic acid (II) (Reaction B) and/or (*b*) a water-catalyzed β-lactam cleavage to give the penicilloic acid (III) (Reaction C).

Levine (15, 16) postulated that the degradation of penicillin G at pH 7.5 proceeds through benzylpenicillenic acid (II) (*via* Reaction B, Scheme VI), which can be rapidly converted to benzylpenicilloic acid (III) (17). The intramolecularly catalyzed mechanism is an unlikely explanation for the plateau rates, since the large deuterium solvent isotope effect on k_0' ($k_0'^{H_2O}/k_0'^{D_2O}$ = 4.5, Table I) and largely negative entropies of activation ($\Delta S^{\ddagger}$ = −30 eu)[7] are inconsistent with Reaction B (Scheme VI). The most logical possibility for the pH-independent degradation (k_0' reaction) of penicillin G at neutral pH is spontaneous hydrolysis involving nucleophilic attack at the β-lactam ring by a water molecule facilitated (general base) by neighboring water molecules to produce benzylpenicilloic acid (III) directly (Reaction C, Scheme VI). Two possible transition states (I*a* and I*b*) for Reaction C might explain the extremely large solvent isotope effect of 4.5.

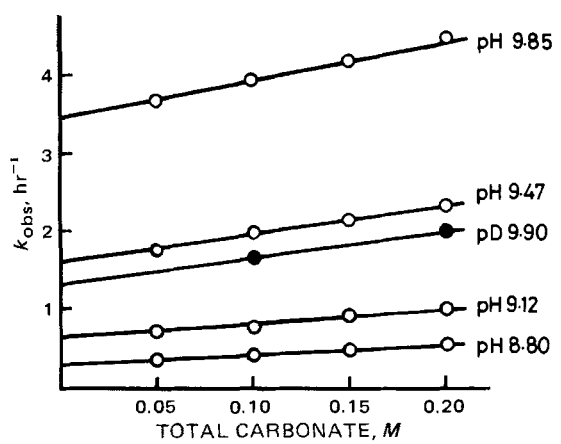


Figure 5—*Plots of pseudo-first-order rate constants* versus *total carbonate concentration for the degradation of penicillin G in water* (○) *and deuterium oxide* (●, *50% free base) at 60° and 0.5 ionic strength.*

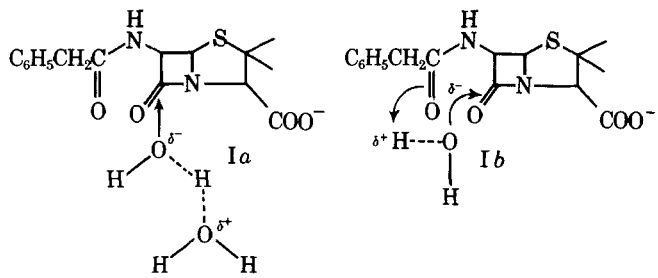

Although Reaction C rather than Reaction B has widely been believed to proceed in neutral degradation of penicillins, no reliable evidence sufficiently supports Reaction C and differentiates these reactions. Yamana *et al.* (13) and Butler *et al.* (20) reached the same conclusion from the absence of significant side-chain dependency on k_0' values and by following the benzylpenicillenic acid formation rate, respectively.

Reaction Mechanism with General Base—Previous work on penicillin aminolysis (26, 27) showed that the reaction of penicillin G with various primary and secondary amines proceeds exclusively through a nucleophilic attack pathway to produce the corresponding benzylpenicilloylamides. In the present work, the reactions of penicillin G with oxygen bases were studied. A linear relationship between k_{obs} and total oxygen-compound concentration was observed (Figs. 2–5).

The second-order rate constants, k_B, thus determined at 35 and 60° from the relationship between ($k_{obs} - k_{pH}$) values and base concentrations are recorded in Table II, together with values reported by Finholt *et al.* (7).

Figure 6 shows a plot of log k_B against pKa of the conjugated acid of an oxygen base. The solid line corresponds to the Brønsted equation, log k_B = 0.56pKa − 4.41, for the unassisted nucleophilic reaction of an amine with penicillin G at 60° and μ = 0.5 (26).

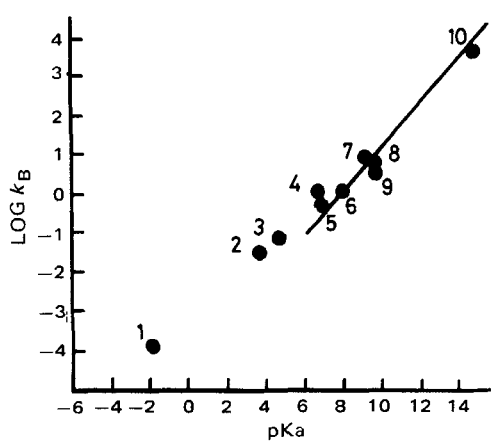

Figure 6—*Brønsted plots for the reaction of penicillin G with oxygen bases in aqueous solution at 60° and 0.5 ionic strength. The numbers refer to the bases in Table II. The solid line corresponds to the Brønsted equation, log* k_B = 0.56pKa − 4.41, *for the unassisted nucleophilic reaction of amines with penicillin G at 60° and 0.5 ionic strength (26).*

[a] All rates were determined by the iodometric titration method. Each reaction was carried out at three or more different buffer concentrations at each of three or more different pH values. [b] Determined by the half-neutralization method. [c] $k_0'/55.5$. [d] Reference 10. [e] Reference 9. [f] The reactions were carried out at pH 7.0 and 7.5. The pH of the reaction solution was maintained by means of a pH-stat. [g] Reference 7. [h] Reference 26.

The reactions of penicillin G with oxygen bases, except acetate, formate, and water, appear to represent a nucleophilic displacement reaction rather than a general base-catalyzed degradation, because the rate constants, k_B, for m-nitrophenol (Fig. 4) and carbonate (Fig. 5) showed only a small deuterium solvent isotope effect, with a $k_B^{H_2O}/k_B^{D_2O}$ ratio of approximately 1.0 in both cases. Nucleophilic reaction did not lead to a deuterium solvent isotope effect appreciably greater than unity (28). Water, however, probably acts as a general base catalyst as discussed on the basis of a large solvent isotope effect. The formate and acetate ions, having relatively low pKa values, also probably participate as general bases in the degradation of penicillin G, in view of the general principle (28) that a change in the mechanism from a general base-catalyzed path to a nucleophilic reaction may occur as the pKa value of the reacting base becomes greater than that for the leaving group (imino group in β-lactam in this case), as was found for an ester (29) and an amide (30).

Table II also includes k_B values from the literature (7, 9, 10, 13) and from the present study for the reaction of other penicillins with some bases. Figure 7 shows a plot of log k_B of penicillin G *versus* log k_B of other penicillins for the reaction of the same series of bases with penicillin G at 35° and $\mu = 0.5$. The solid line drawn has slope 1.0 and passes through zero. All points almost fall on this line, suggesting that alteration of the side chain of penicillins gives no significant change in the rates of their base-catalyzed degradation.

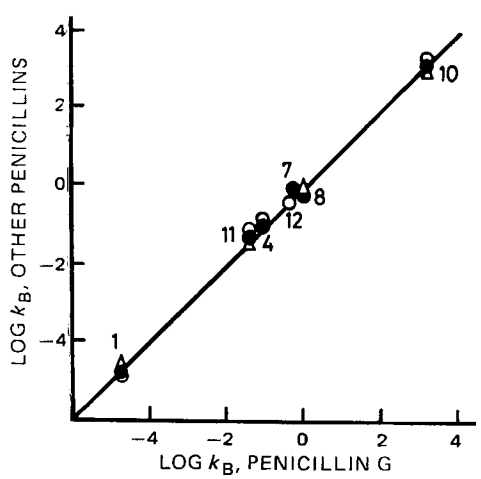

Figure 7—*Double logarithmic plots of second-order rate constants for the reaction of penicillin G with bases* versus *second-order rate constants for the reaction of other penicillins with the same bases. The numbers refer to the bases in Table II.*

Pharmacokinetics of Methylphenidate in the Rat Using Single-Ion Monitoring GLC–Mass Spectrometry

J. GAL [x], B. J. HODSHON, C. PINTAURO, B. L. FLAMM, and A. K. CHO

Abstract □ A GLC–mass spectrometric assay for methylphenidate in biological fluids was developed using the ethyl ester homolog of the drug as the internal standard. The procedure has a lower level of sensitivity of 1.2 ng/ml and is based on GLC–mass spectrometic monitoring of the *m/e* 180 ion common to the mass spectra of the *N*-trifluoroacetyl derivatives of the drug and internal standard. The brain and plasma levels of methylphenidate in rats were determined after intravenous administration of 0.5 mg/kg of the drug. The two-compartment open pharmacokinetic model fit the data.

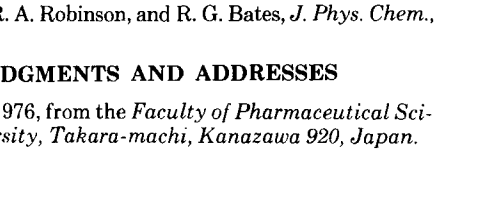
Keyphrases □ Methylphenidate—GLC–mass spectrometric analysis in biological fluids, pharmacokinetics in rats □ GLC–mass spectrometry—analysis, methylphenidate in biological fluids, pharmacokinetic study in rats □ Pharmacokinetics—methylphenidate, GLC–mass spectrometric study in rats □ Stimulants, central—methylphenidate, GLC–mass spectrometric analysis in biological fluids, pharmacokinetics in rats

Methylphenidate [(±)-*threo*-methyl α-phenyl-2-piperidineacetate, I] has pharmacological properties similar to those of dextroamphetamine (1). It is used to treat depressed states of various origins and hyperkinesis in children (2). In addition, I has become a drug of abuse in many countries (3–5).

The metabolic fate of I in humans and several other species was studied by Faraj *et al.* (6), who also reviewed previously published work. The main urinary metabolite in humans, accounting for 30% of the dose, is the hydrolysis product of I, ritalinic acid (II).

BACKGROUND

Studies on the disposition of radioactive I in the rat were reported (7), as was information on plasma I levels in humans (6, 8). While the drug appears to be essentially completely absorbed after oral administration, the concentration of I after a 20-mg oral dose of I hydrochloride was reported not to exceed 20 ng/ml of plasma (6). Plasma I levels in humans were 10–60 ng/ml 1–3 hr after a 0.4-mg/kg oral dose of I hydrochloride (8). Such low levels of I achieved after therapeutic doses may partially explain the paucity of I pharmacokinetic data.



I: $R_1 = CH_3$, $R_2 = H$
II: $R_1 = R_2 = H$
III: $R_1 = CH_2CH_3$, $R_2 = H$
IV: $R_1 = CH_3$, $R_2 = COCF_3$
V: $R_1 = CH_2CH_3$, $R_2 = COCF_3$

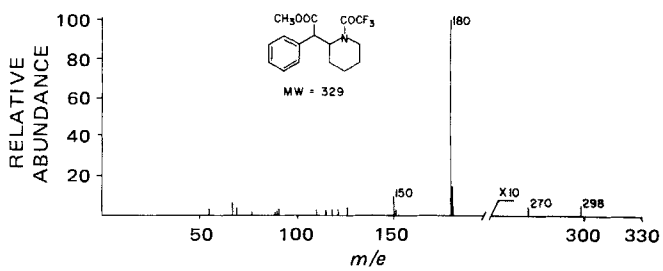


Figure 1—*Mass spectrum of IV obtained by GLC–mass spectrometry under the described conditions.*

Several analytical methods for I were reported (6–10), but none appears capable of measuring I reliably and routinely at the low levels required. *N*-Acylation of I with trichloroacetyl chloride followed by electron-capture GLC gave (9) a lower limit of detection of 9 ng/ml in plasma. Another procedure (10), also using electron-capture GLC, involved reduction of the methoxycarbonyl function of I to $-CH_2OH$ using lithium aluminum hydride, followed by derivatization with pentafluoropropionic anhydride. The sensitivity of the assay was 2 ng of I/ml of plasma. Recently, an analytical procedure for I based on GLC–mass spectrometry, with a sensitivity limit of 1.5 ng/ml in plasma, was described (8).

None of these methods (8–10) included an internal standard. A further difficulty with the published (8) GLC–mass spectrometric assay is that the procedure involved the GLC of underivatized I. Underivatized I may undergo extensive and variable decomposition in the injection port of the gas chromatograph, making quantitative determination difficult at best (11).

A new GLC–mass spectrometric assay for I in biological fluids and tissues is now described. The procedure involves the addition of the ethyl ester homolog of I, Compound III (12), to the biological medium, extraction of the drug and internal standard under mildly basic conditions, concentration of the extract, and derivatization with trifluoroacetic anhydride. GLC–mass spectrometric analysis was then performed with the mass spectrometer focused on an ion common to the spectra of both I and the internal standard. The lower limit of sensitivity of the assay is 1.2 ng of I/ml of plasma. The procedure was applied to the study of the pharmacokinetics of I in the rat, and the data obtained were examined in terms of classical pharmacokinetic models.

EXPERIMENTAL

Materials—Internal standard III was prepared *via* two different methods. A solution of II[1] (0.5 g) in 55 ml of absolute ethanol containing

Underivatized I may undergo extensive and variable decomposition in the injection port of the gas chromatograph, making quantitative determination difficult at best (11).

A new GLC–mass spectrometric assay for I in biological fluids and tissues is now described. The procedure involves the addition of the ethyl ester homolog of I, Compound III (12), to the biological medium, extraction of the drug and internal standard under mildly basic conditions, concentration of the extract, and derivatization with trifluoroacetic anhydride. GLC–mass spectrometric analysis was then performed with the mass spectrometer focused on an ion common to the spectra of both I and the internal standard. The lower limit of sensitivity of the assay is 1.2 ng of I/ml of plasma. The procedure was applied to the study of the pharmacokinetics of I in the rat, and the data obtained were examined in terms of classical pharmacokinetic models.

EXPERIMENTAL

Materials—Internal standard III was prepared *via* two different methods. A solution of II[1] (0.5 g) in 55 ml of absolute ethanol containing

[1] Ciba-Geigy Corp.

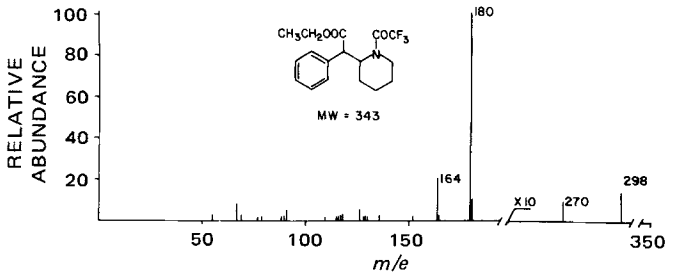

Figure 2—*Mass spectrum of V obtained by GLC–mass spectrometry under the described conditions.*

dry 10% (w/w) HCl was refluxed overnight. The solvent was then evaporated, and the residue was recrystallized from ethanol–ether to give III hydrochloride, mp 171–173° [lit. (12) mp 172–173°]. In the second method, I hydrochloride[1] (0.2 g) was treated in the same way, but the reflux time was 3 weeks. Stock solutions of I hydrochloride in methanol and III hydrochloride in ethanol were used in the described analytical procedures.

Animal Procedures—Male Sprague–Dawley rats, 200–250 g, were given an intravenous injection of I hydrochloride in normal saline equivalent to 0.5 mg of free base/kg; 0.5 ml of solution/100 g of animal weight was used. At the appropriate times, the animals were lightly anesthetized with ether, and blood was collected by cardiac puncture with a heparinized syringe. The brains were removed and immediately frozen. The whole blood was centrifuged (3000×*g*), and aliquots of plasma were taken for analysis.

Extraction and Sample Preparation—The brain was homogenized in twice the volume of saturated ammonium carbonate solution containing 500 pmoles of internal standard, and the homogenate was extracted as described for the plasma samples. To a 2-ml aliquot of plasma were added 500 pmoles of the internal standard and 0.6 g of ammonium carbonate, and the mixture was extracted with 6 ml of hexane by shaking[2] for 15 min. The mixture was then centrifuged for 10 min, 4.5 ml of the organic layer was transferred to a 5-ml microcentrifuge tube[3], and the solvent was evaporated in a nitrogen stream.

The residue in each tube was treated with 50 μl of acetonitrile and 50 μl of trifluoroacetic anhydride, and the solution was swirled on a mixer and then heated at 70° for 15 min. The solvent and excess derivatizing agent were evaporated in a nitrogen stream. The residue was treated with 50 μl of acetonitrile and swirled[4]. Analysis by GLC–mass spectrometry was then performed.

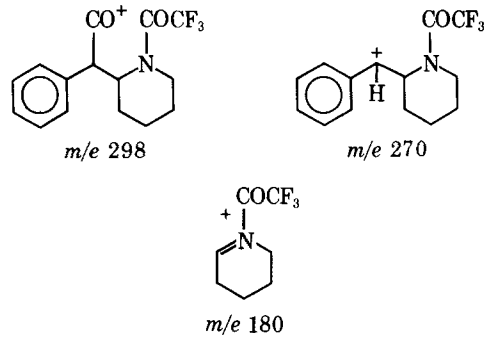
A standard curve was routinely obtained by adding 0–2000 pmoles of I to a series of extraction tubes containing 2 ml of a solution of plasma proteins[5] and 500 pmoles of the internal standard. These tubes were then carried through the assay procedure.

GLC–Mass Spectrometry—A quadrupole GLC–mass spectrometry system[6] was used under the following conditions: helium carrier gas, 35 ml/min; injector temperature, 250°; and column temperature, 170°. The 0.9-m × 2-mm i.d. glass column was packed with 3% phenyl methyl silicone[7] coated on acid-washed dimethylchlorosilane-treated diatomite[8] support. The temperature of the membrane separator was 170°, and that of the transfer line was 250°. The ionizing energy was 70 ev.

A digital selected-ion monitor (13) was used to monitor the ion current at *m/e* 180. The retention times of the *N*-trifluoroacetyl derivatives IV and V were 2.8 and 3.4 min, respectively. No interfering peaks were observed when brain and plasma samples from animals not given the drug were analyzed without adding the internal standard.

RESULTS AND DISCUSSION

Since I may decompose when injected directly into a gas chromatograph (11), the assay developed involved the derivatization of I with trifluoroacetic anhydride before GLC. The mass spectrum of the *N*-trifluoroacetyl derivative IV of I is shown in Fig. 1. The molecular ion is not discernible. Weak ions are seen at *m/e* 298 and 270 with relative intensities of 0.5 and 0.4%, respectively.



The *m/e* 298 ion likely results from the loss of the methoxyl radical from the molecular ion, while the *m/e* 270 ion arises from the loss of the entire methoxycarbonyl group. The ion of *m/e* 150 (8%) appears to be formed *via* the McLafferty rearrangement, frequently occurring during the fragmentation of carbonyl-containing compounds (Scheme I). The base peak in the spectrum is the *m/e* 180 ion, arising *via* β-cleavage to nitrogen. All other ions in the spectrum are weak, <5%.

The mass spectrum of the *N*-trifluoroacetyl derivative V of the ethyl ester homolog III is shown in Fig. 2. The spectrum is similar to that of IV (Fig. 1). The molecular ion is not seen, the base peak is at *m/e* 180, and the ions of *m/e* 270 and 298 are present. The ion arising *via* the McLafferty rearrangement appears, as expected, at *m/e* 164.

The ethyl ester III was selected to serve as the internal standard in the assay for I. This homolog is readily obtained by esterification of amino acid II or by transesterification of I in ethanolic hydrochloric acid. Homologs, rather than stable-isotope-labeled analogs, were used as internal standards in some selected-ion monitoring GLC–mass spectrometric assays (14, 15), and the two approaches were critically compared (16). In the present case, III proved highly suitable as an internal standard due to its chemical similarity to I and the similarity of the mass spectrum of its *N*-trifluoroacetyl derivative (V) (Fig. 2) to that of IV (Fig. 1). The ion of *m/e* 180 is the base peak in the spectra of both compounds and was chosen for selected-ion monitoring. The mass spectrometer could thus be used in the *single*-ion monitoring mode, serving as a sensitive and selective GLC detector. The two trifluoroacetyl derivatives are sufficiently resolved under the GLC conditions used (Fig. 3).

Compounds I and III were extracted with hexane from plasma or rat brain homogenate after saturation with ammonium carbonate (pH 8.8–9.0) (17) since these esters rapidly hydrolyze (18) under the strongly basic conditions often used to extract basic drugs (19). The overall recovery of I from plasma was 96% at 117 ng/ml and 101% at 23 ng/ml. The relative standard deviation of the slopes of three calibration curves was 4.2%. The coefficient of variation in the determination of five 2-ml plasma samples containing 1.2 ng of I/ml was 14%. This concentration is considered to be the lower limit of sensitivity of the assay; attempted determination of three samples of 0.6 ng of I/ml gave an average value of 0.3 ng/ml with a coefficient of variation of 100%.

Concentrations of I in rat plasma and brain are plotted in Fig. 4. The concentration in plasma (C_p) declined biexponentially, and the two-compartment open model (20) (Scheme II) fit the data. In Scheme II, V_1

and V_2 are the volumes of the central and second compartments, respectively, and the k's are the rate constants for the movement of the drug as indicated by the arrows. A desk calculator[9] using a nonlinear regression program was employed to determine the four parameters A, B, α, and β of the equation $C_p = Ae^{-\alpha t} + Be^{-\beta t}$ that best fits the experimentally determined plasma I concentrations.

Analysis of the plasma data in terms of this model gave the results shown in Table I. The initial decline in plasma concentration is rapid and the β-phase is reached within a few minutes. Thus, transfer of I from plasma to tissues is rapid and distribution is extensive, as indicated by the ratio $C_p{}^0/B$, which was as high as 3.5. The volume of the central compartment (1.18 liters/kg) is about twice the volume of body water.

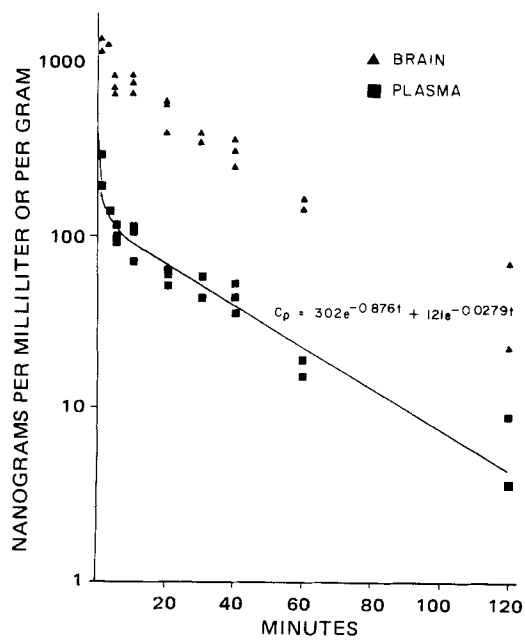

Figure 4—*Plasma and brain I levels. The line superimposed on the plasma data points was obtained by nonlinear regression analysis as described. The correlation coefficient for the plasma data on the calculated curve was 0.959.*

[9] Wang 600, Wang Laboratories, Tewksbury, Mass.

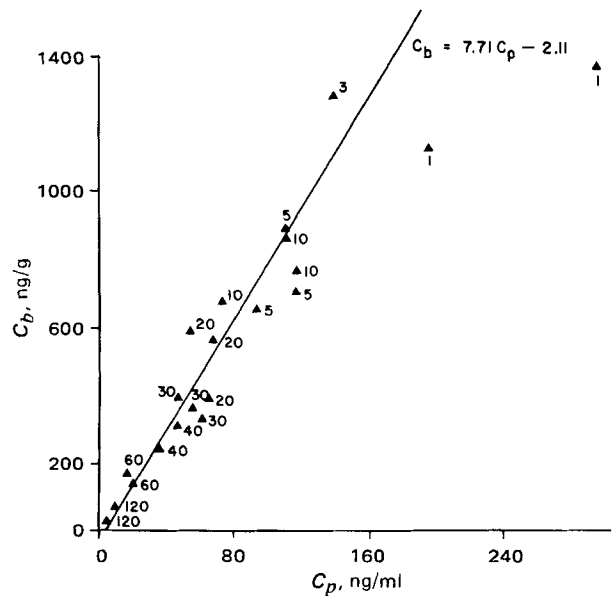

Figure 5—*Relationship of brain and plasma I concentrations* (C_b *and* C_p, *respectively). The number next to each data point is the time of sampling in minutes. The equation of the line was determined by least-squares linear regression analysis without the 1-min time points. (See text for explanation.) The correlation coefficient is 0.947.*

Compound I is metabolized extensively in the rat; less than 1% unchanged I was found in the 48-hr urine (6). The major route of metabolism in this species appears to be initial *para*-hydroxylation, and the resulting metabolite may undergo further transformations. In humans, the predominant route is hydrolysis of the ester portion of the molecule without *para*-hydroxylation (6). This difference between humans and rats in the metabolism of I is similar to the differences in the metabolism of amphetamine by the two species. The major route of *in vivo* biotransformation of amphetamine in the rat is *para*-hydroxylation; this pathway is minor in humans, however, with deamination and side-chain degradation being the predominant transformations (22). It was suggested (6) that metabolism of I is very rapid, in agreement with the rapid clearance of the drug from rat plasma (Table I). Compound I has been found to be poorly bound to human plasma proteins (6).

The concentration of I in rat brain was higher than the plasma concentration and declined parallel with the plasma concentration after the 1-min sampling point (Fig. 5), with a brain/plasma ratio of 7.7. The rapid entry of I into the brain is in agreement with its rapid and extensive tissue distribution and with its organic–aqueous partitioning characteristics (6). The brain appears to be part of the central compartment. The deviation in the 1-min sampling points (Fig. 5) may be the result of the delay caused by the mixing time of the bolus with the blood or of inaccurate measurement at the early time point when the change in concentration is very rapid.

Segal *et al.* (7) recently published a study on the disposition of ^{14}C-I in the rat, with emphasis on the time course of entry and distribution of the drug in the brain. In agreement with the present report, the concentration of I in rat plasma declined biexponentially. However, a detailed pharmacokinetic analysis in terms of an appropriate model was not described. The biological half-life (β-phase) was given (7) as 105 min, a value considerably larger than the finding (24.8 min) of the present report. The origin of this discrepancy is not clear. The assay of ^{14}C-labeled I used (7) was based on extraction of the biological medium with methylene chloride, and no further purification was performed. A metabolite could interfere in such determinations, since at least one lipid-soluble metabolite of I has been found in the rat (6). The rapid entry of I into rat brain after intravenous administration of the drug reported by Segal *et al.* (7) is in qualitative agreement with the findings of the present report, although significant quantitative differences in the half-life of I in the brain between the two studies exist.

The half-life of I in the rat is 24.8 min (Table I), while that of dextroamphetamine is 86.7 min (23), reflecting the faster metabolism of I.

Table I—Pharmacokinetic Analysis of Plasma Methylphenidate Concentrations[a]

Parameter	Value
C_p^0, ng/ml	424
V_1, liters/kg	1.18
V_2, liters/kg	2.35
$V_{d_{ss}}$, liters/kg	3.53
k_{12}, min^{-1}	0.542
k_{21}, min^{-1}	0.272
k_{el}, min^{-1}	0.090
Total body clearance, ml/min/kg	107.2
$t_{1/2}$, min	24.8

[a] The plasma levels were analyzed by nonlinear regression to the two-exponential function describing the two-compartment model (20). The volume of distribution at steady state, $V_{d_{ss}}$, is that defined by Riegelman *et al.* (21).

The volume of distribution of dextroamphetamine is 6.04 liters/kg (23), considerably larger than the value obtained for I, 3.53 liters/kg (Table I). The pKa values of I and dextroamphetamine are 8.8 (24) and 9.9 (25), respectively. The apparent heptane–water partition coefficient of I at pH 7.4 was determined (6) to be 0.63, while that of dextroamphetamine may be computed from published data (25) as 0.00593. Thus, I is ionized at physiological pH to a lesser extent than dextroamphetamine and is considerably more lipid soluble. The larger volume of distribution of amphetamine may be a reflection of the greater concentration of this compound, a stronger base than I, in the intracellular water of tissues, the pH of which is lower than that of extracellular water (26).

Stannous-Ion Quantitation in Pyrophosphate and Polyphosphate Radiopharmaceutical Kits Using Differential Pulse Polarography

MARTIN H. D. McBRIDE, ROBERT E. GEORGE, WAYNE V. KESSLER, and STANLEY M. SHAW ˣ

Abstract □ Stannous salts are used as reducing agents in many radiopharmaceutical kits. Differential pulse polarography, with 1 *M* sulfuric acid as the supporting electrolyte, is a relatively simple and effective technique for stannous quantitation and can be used in the quality assurance testing of pyrophosphate and polyphosphate radiopharmaceutical kits.

Keyphrases □ Stannous ion—differential pulse polarographic analysis in pyrophosphate and polyphosphate radiopharmaceutical kits □ Polarography, differential pulse—analysis, stannous ion in pyrophosphate and polyphosphate radiopharmaceutical kits □ Radiopharmaceutical kits—pyrophosphate and polyphosphate types, differential pulse polarographic analysis of stannous content □ Tin—stannous ion, differential pulse polarographic analysis in pyrophosphate and polyphosphate radiopharmaceutical kits

Stannous ion, Sn(II), is the most effective and widely used reducing agent in radiopharmaceutical kits. However, Sn(II) is unstable in the presence of oxygen. Even in the crystalline state, stannous chloride can react with oxygen to form insoluble oxychlorides (1) and stannic, Sn(IV), "material" (2). In aqueous solution, Sn(II) can be precipitated as an insoluble basic chloride (3) or oxidized to Sn(IV) (4) by dissolved oxygen.

A quantitative test for Sn(II) content during the manufacture and storage of various radiopharmaceutical kits would be a very desirable quality assurance procedure. This Sn(II) test must be highly sensitive, because many kits contain much less than 1 mg of stannous salt. Furthermore, the test must be accurate in the presence of Sn(IV) contamination.

Differential pulse polarography was studied as a method for measuring the Sn(II) content of pyrophosphate and polyphosphate kits. Measured Sn(II) levels, 10^{-3}–10^{-4} *M*, were in the range of those found in many reconstituted commercial kits.

EXPERIMENTAL

The relationship between polarographic peak height and Sn(II) content of pyrophosphate and polyphosphate kits was studied by assaying a series of each kit type. The total tin concentration of each pyrophosphate kit was 8.3×10^{-4} *M* (equivalent to the tin supplied by 0.49 mg of stannous chloride dihydrate in a kit). The total tin concentration in each polyphosphate kit was 2.8×10^{-3} *M* (equivalent to 1.3 mg of stannous chloride dihydrate). The fraction of total tin as Sn(II) was varied among the kits from 0 to 1.0 in steps of 0.1 to illustrate the sensitivity range of differential pulse polarographic Sn(II) analysis and to demonstrate any polarographic interference produced by the presence of Sn(IV).

Tin Solutions—Sn(II) stock solutions were prepared by dissolving stannous chloride dihydrate[1] in concentrated reagent grade hydrochloric acid and diluting to volume with distilled water. The Sn(IV) stock solutions were prepared in a similar manner with anhydrous stannic chloride[2]. Tin concentrations in these stock solutions were 1.4×10^{-3} *M* for use with pyrophosphate kits and 5.5×10^{-3} *M* for use with the polyphosphate kits. The hydrochloric acid concentration in all tin stock solutions was 2 *M*. To reduce the chance of Sn(II) deterioration, Sn(II) stock solutions were placed in 20-ml multiple-dose vials, purged with nitrogen, and stored under 2.4 atm of nitrogen.

Radiopharmaceutical Kits—Pyrophosphate kits were prepared in 10-ml vials by combining 1.1 ml of an aqueous solution containing 17 mg of tetrasodium pyrophosphate[3] with an appropriate aliquot of Sn(IV) stock solution. Polyphosphate kits were prepared in 10-ml vials by combining 1.0 ml of an aqueous solution containing 67 mg of polyphosphate, prepared by the method of Subramanian *et al.* (5), with an appropriate aliquot of Sn(IV) stock solution. All vials were sealed, nitrogen purged, and stored under a positive nitrogen pressure for a maximum of 8 hr.

An appropriate amount of Sn(II) stock solution was added to the kits just prior to the polarographic analysis (*i.e.*, during the sulfuric acid outgassing in the cell). The combined volume of Sn(II) and Sn(IV) stock solutions added to each pyrophosphate kit was 1.5 ml. The combined volume of tin stock solutions added to each polyphosphate kit was 1.0 ml.

Instrumentation and Analyses—An unmodified, commercially available polarographic analyzer[4] was used for the differential pulse polarographic analysis as follows. Nine milliliters of 1 *M* H_2SO_4 was placed in the polarographic cell, and the cell was outgassed with nitrogen (prepurified grade, scrubbed with vanadous chloride) for 1 min. A 1-ml portion of the kit was then added through the cell top with a 1-ml disposable syringe, and the cell solution was outgassed for 1 additional min. The nitrogen was then diverted over the solution, and a differential pulse polarographic scan was made from −0.30 to −1.00 v with a saturated calomel electrode (SCE) as reference. The following parameters were used: drop time, 0.5 sec; modulation amplitude, 25 mv/pulse; and scan rate, 5 mv/sec.

The peak heights and peak potentials of the scans were calculated and recorded. Peak heights were measured from the baseline of the peak. Each kit analysis required approximately 3.5 min.

RESULTS

Differential pulse polarographic peaks corresponding to Sn(II) reduction were found at peak potentials of −0.44 v for pyrophosphate kits (Fig. 1) and −0.48 v for polyphosphate kits. Standard curves of peak height *versus* Sn(II) concentration were prepared and were linear. The slope of the curves was 0.14 μamp/10^{-4} *M* for polyphosphate kits (correlation coefficient of 0.9962) and 0.17 μamp/10^{-4} *M* for pyrophosphate kits (correlation coefficient of 0.9994). Peak heights for individual kits, especially those with low Sn(II) concentrations, varied with maximum standard deviations of 7% for pyrophosphate and 17% for polyphosphate over four calibration runs.

The polyphosphate Sn(II) peaks were somewhat asymmetric, suggesting the presence of maxima. Ordinary pulse polarography scans confirmed the maxima. The larger standard deviation for the polyphosphate kits as well as the shift in peak potential may be attributed

[1] Analytical reagent grade, Fisher Scientific Co.

[2] Baker analyzed reagent.

[3] Sigma Chemical Co.

[4] Princeton Applied Research polarographic analyzer model 174 with cell and drop timer.

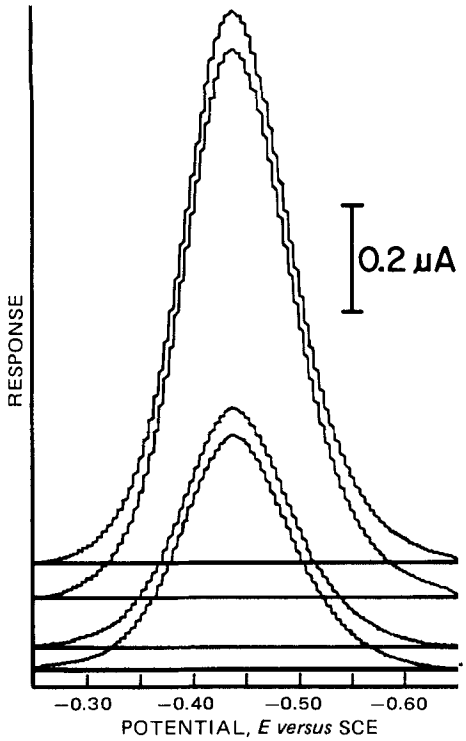

Figure 1—*Differential pulse polarographic scans of two pyrophosphate kits (8.3 × 10⁻⁴ M total tin). The top two scans are of a kit containing 70% of the tin as Sn(II) and 30% as Sn(IV). The lower two scans are of a kit containing 30% Sn(II) and 70% Sn(IV). The peaks occurred at −0.44 v. The vertical positioning of the scans is unimportant, since peak height was measured from the baseline of each peak.*

to the maxima. However, the potential shift could also be an indication of the differences between the Sn(II)–pyrophosphate and Sn(II)–polyphosphate complexes. Nothing was done to suppress the maxima because the polyphosphate variability was not so great to warrant an added step, namely the addition of a surfactant to the supporting electrolyte prior to each analysis.

Several supporting electrolytes were used, but only 1 *M* H_2SO_4 was satisfactory. Since Sn(IV) is not soluble in this electrolyte (6), it does not produce a reduction peak that could interfere with the Sn(II) peak.

Sn(II) solutions in 0.12 *M* HCl were tested by the differential pulse polarographic technique. The method was effective in quantitating Sn(II) at concentrations as low as 8×10^{-6} *M* (2 μg of stannous chloride dihydrate in 1 ml). Sn(IV) interference was not examined at these low Sn(II) concentrations.

DISCUSSION

Classical dc polarography, electrolysis on a microscale in which the magnitude of current flow is proportional to the sample concentration, is useful in tin analysis (6). Differential pulse polarography is a relatively new, highly sensitive version of this technique (7) and is a convenient and effective method for the quantitation of Sn(II) in pyrophosphate and polyphosphate radiopharmaceutical kits. One should not assume that simple Sn(II)–hydrochloric acid solutions can be used as standards, since different peak potentials and slopes can be expected for different kit types as the result of different matrixes. This Sn(II) analytical technique is currently being studied for its value in the qualitative control testing of other radiopharmaceutical products.

GI Absorption of Niacin in Humans

HELLE BECHGAARD [x] and S. JESPERSEN

Abstract □ By using the GI tube technique, niacin was shown to be equally well absorbed from the stomach and the upper small intestine. The maximum plasma niacin concentrations occurred 10–20 and 5–10 min, respectively, after instillation. Thus, the physiological prerequisites for a physically retarded niacin preparation were established.

Keyphrases □ Absorption, GI—niacin, stomach and small intestine compared, humans □ Niacin—absorption from stomach and small intestine compared, humans □ Vitamins—niacin, absorption from stomach and small intestine compared, humans

It is generally accepted that weak organic acids or bases are absorbed primarily by penetration of the unionized form of the drug through a lipoidal barrier (1). Niacin (nicotinic acid) (pKa 4.8) should theoretically be better absorbed from the stomach than from the small intestine. However, salicylic acid (pKa 3.0) is reportedly well absorbed even at pH values where it is predominantly ionized (2).

Limited data are available concerning the GI absorption of niacin in humans. In a steady-state situation, about 85% of an orally administered dose (3 g/day) of niacin was recovered from the urine, and it was concluded that absorption was nearly complete (3).

In a comparative study of plain and enteric-coated niacin tablets (4), niacin was absorbed from the small intestine to only a small extent. Based on this finding, in-

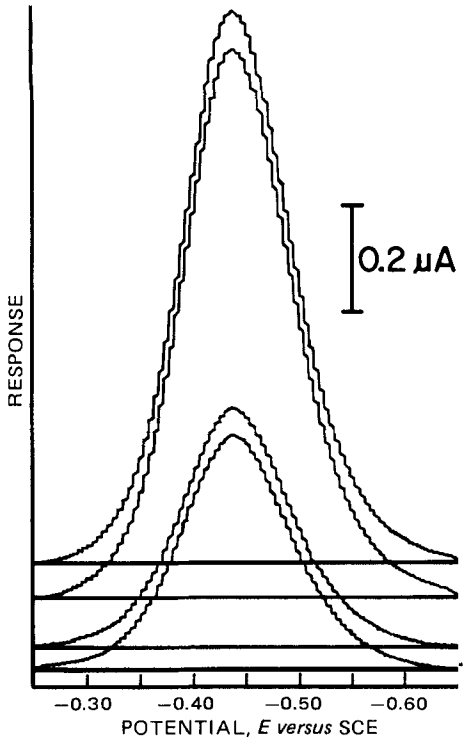

Figure 1—*Differential pulse polarographic scans of two pyrophosphate kits (8.3 × 10⁻⁴ M total tin). The top two scans are of a kit containing 70% of the tin as Sn(II) and 30% as Sn(IV). [a] Thirty minutes after ingestion of a standard meal. [b] Without ingestion of a standard meal.

vestigators suggested that the physiological prerequisites for a sustained-release niacin preparation are absent (4, 5). In general, however, absorption from enteric-coated tablets is known to be unreliable and often incomplete.

In the present study, absorption of niacin from the human stomach and the upper intestinal tract was compared by means of the GI tube technique.

EXPERIMENTAL

Three healthy, young, male volunteers with normal GI function were the test subjects. No medicine or alcohol consumption was allowed during the 24 hr preceding the tests, and only water was allowed during the 12 hr preceding the tests. In each subject, niacin absorption was studied after instillation of the drug under the following three conditions: (*a*) in the empty stomach, (*b*) in the stomach 30 min after a standard meal, and (*c*) in the small intestine 30 min after a standard meal. An interval of at least 2 weeks was allowed between two consecutive tests.

When niacin absorption from the small intestine was studied, the subjects were admitted to a hospital ward on the day before the test and the stomach tube (weighted with lead shot at the distal opening) was applied. During the night, peristalsis moved the tube into the intestinal tract. The localization of the tube was estimated by an X-ray check and by the measured distance from the nose. In all cases, the distal opening of the tube was located 1–1.5 m from the pylorus.

Niacin (200 mg) dissolved in water (25 ml) was instilled over 15–30 sec, immediately followed by two rinses with water (totaling 50 ml). Venous blood samples were drawn from the supine experimental subject before the test and at fixed time intervals after drug instillation. Blood pressure and pulse rate were registered simultaneously.

Free niacin in plasma was analyzed by the colorimetric technique of Carlson (6). Considering the high levels of niacin involved and the fact that each individual's basal values for König-positive substances before instillation of the drug were used for correction, the well-known relative unspecificity of the analytical method did not compromise the significance of the results obtained (7–9). The coefficient of variation for the analytical procedure was 5%.

RESULTS AND DISCUSSION

The highest level of niacin in plasma was found 5–10 min after instillation into the upper small intestine (Table I). During instillation into the stomach, the maximum plasma niacin concentration occurred 10–20 min after drug administration. Evidently, food did not influence niacin absorption, as evidenced by the peak plasma concentrations with and without a standard meal (Table I).

Immediately after drug instillation, an increase in pulse rate (maximum 45%) and blood pressure (maximum 20%) appeared, indicating rapid absorption. The pulse rate was normalized after 20 min. The increase in blood pressure, however, was ultimately followed by a decrease and normalized after 20–50 min.

CONCLUSION

After instillation into the small intestine of an aqueous niacin solution, the drug appears faster in the plasma and reaches higher levels than after instillation into the stomach. This finding indicates that the compound is absorbed at least as readily from the small intestine as from the stomach. Thus, the physiological basis for the development of a sustained-release niacin preparation is established.

Alkaloids of *Glaucium flavum* Grantz, Populations Isfahan and Kazerun

A. SHAFIEE [x], I. LALEZARI, S. LAJEVARDI, and F. KHALAFI

Abstract □ *Glaucium flavum* Grantz, population Isfahan, contained four major alkaloids: dicentrine (0.8%), bulbocapnine (0.42%), protopine (0.35%), and salutaridine (0.2%). *G. flavum* Grantz, population Kazerun, contained four major alkaloids: dicentrine (1.4%), bulbocapnine (0.5%), *O*-methylflavinantine (0.5%), and salutaridine (0.3%); it also contained two minor alkaloids, protopine and α-allocryptonine. *O*-Methylflavinantine was found for the first time in the Papaveraceae.

Keyphrases □ *Glaucium flavum* Grantz—populations Isfahan and Kazerun, major alkaloids identified □ Alkaloids—identified in *Glaucium flavum* Grantz, populations Isfahan and Kazerun

Recently, in a continuation of a research program dealing with the chemotaxonomic studies of Iranian wild Papaveraceae (1–4), the major alkaloids of *Glaucium flavum* Grantz, population Ghom, were reported (5). In this work, the alkaloids of *G. flavum* Grantz, populations Isfahan (south) and Kazerun[1] (southwest of Iran), are reported. Although *Glaucium* species growing in Ghom, Isfahan, and Kazerun are morphologically similar and were identified as *G. flavum* Grantz, careful chemical studies revealed that they are independent chemotypes.

EXPERIMENTAL[2]

Plant Material—The whole aerial parts were collected during May, air dried in the shade, further dried at 60° to a constant weight, and powdered so that all material passed a mesh not greater than 0.5 mm.

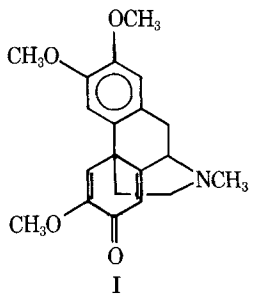
Extraction—Powdered plant material, 200 g, was moistened with 200 ml of 15% ammonium hydroxide solution, stirred with 600 ml of chloroform at room temperature for 1 hr, and filtered. The extraction was repeated four times. After the evaporation of the solvent, the residue was extracted with 100 ml of 5% sulfuric acid. The solution was filtered and extracted with petroleum ether (3 × 20 ml) to remove the colored material. The aqueous layer was made alkaline with 15% ammonium hydroxide solution and extracted with chloroform (4 × 50 ml).

Evaporation of the solvent gave a residue of crude alkaloids. The crude extract was subjected to preparative TLC (silica gel $HF_{254+366}$, thickness 1 mm, plate size 20 × 20 cm). Two solvent systems were used for the separation of alkaloids: A, ethyl acetate–methanol–ammonia (85:10:5); and B, petroleum ether–chloroform–diethylamine (70:20:10). Resolved components were detected under 254-nm UV light. Appropriate zones were removed from the plates, and the components were extracted with chloroform–methanol (80:20). The solvent was evaporated under reduced pressure, and the alkaloids were crystallized from an appropriate solvent and characterized.

RESULTS AND DISCUSSION

The following alkaloids were isolated from *G. flavum* population Isfahan:

1. Dicentrine, R_f 0.6 (Solvent System A) and 0.44 (Solvent System B); yield 1.6 g (0.8%); mp 166–169° [lit. (5) mp 166–169°].



I

2. Bulbocapnine, R_f 0.65 (Solvent System A) and 0.32 (Solvent System B); yield 0.8 g (0.4%); mp 199–200° [lit. (5) mp 199–200°].

3. Salutaridine, R_f 0.42 (Solvent System A) and 0.15 (Solvent System B); yield 0.4 g (0.2%); mp 197–199° [lit. (5) mp 197–199°].

[The melting points, mixed melting points, IR, UV, NMR, and mass spectral data of these alkaloids were identical with those reported (5).]

4. Protopine, R_f 0.71 (Solvent System A) and 0.5 (Solvent System B); yield 0.7 g (0.35%), mp 205–207° [lit. (6) mp 207°]; mixed melting point with an authentic sample 205–207°. Its NMR spectrum was identical with that reported previously (7).

From *G. flavum* population Kazerun, in addition to dicentrine (1.5%), bulbocapnine (0.5%), salutaridine (0.3%), and protopine (minor alkaloid), the following alkaloid was also isolated:

α-Allocryptonine, R_f 0.59 (Solvent System A) and 0.47 (Solvent System B); mp 160–161° [lit. (8) mp 160–161°]; mixed melting point with an authentic sample 160–161°. Its spectral data were similar to those reported previously (9, 10).

In addition, another alkaloid was also isolated [R_f 0.35 (Solvent System A) and 0.15 (Solvent System B)]. This alkaloid was an oil; UV: λ_{max} (ethanol) 282 and 238 nm; IR ($CHCl_3$): 1666 (C=O), 1642, and 1621 cm^{-1}; NMR ($CDCl_3$): δ 1.93 (m, 2H), 2.44 (s, 3H, NCH_3), 2.49–3.66 (m, 5H), 3.82 (s, 3H, OCH_3), 3.87 (s, 3H, OCH_3), 3.90 (s, 3H, OCH_3), 6.30 (s, 1H), 6.53 (s, 1H), 6.70 (s, 1H), and 6.95 (s, 1H); mass spectrum: *m/e* 341 (M^+), 326 ($M^+ - 15$), 313 ($M^+ - 28$), 298 ($M^+ - 43$), 282, and 149.

Anal.—Calc. for $C_{20}H_{23}NO_4$: C, 70.38; H, 6.74; N, 4.11. Found: C, 70.45; H, 6.83; N, 4.26.

The hydrochloride had a melting point of 195–196° (ethanol). The methiodide had a melting point of 223–225° (methanol) [lit. (11) mp 223–225°].

The spectral data (UV, IR, NMR, and mass) as well as the TLC data of this alkaloid (I) were identical with an authentic sample of *O*-methylflavinantine.

The alkaloid profiles of *G. flavum* Grantz, populations Ghom, Isfahan, and Kazerun, indicate that they are independent chemotypes. The major alkaloids of Ghom are dicentrine, bulbocapnine, and salutaridine. *G. flavum* population Isfahan also has protopine as a major alkaloid. Protopine could not be detected in *G. flavum* population Ghom. Finally, *G. flavum* population Kazerun also has *O*-methylflavinantine, which was not present in the other populations. A literature survey revealed that *O*-methylflavinantine was found in *Nemuaron vieillardii* (Monimiaceae) (12) and *Rhigiocarja racemifera* Miers (Menispermaceae) (13).

Rapid Determination of Procainamide and Its *N*-Acetyl Derivative in Human Plasma by High-Pressure Liquid Chromatography

ORVILLE H. WEDDLE and WILLIAM D. MASON [x]

Abstract □ A rapid, specific, high-pressure liquid chromatographic method for the determination of procainamide and its *N*-acetyl derivative in plasma was developed. The procedure is fast enough (15 min from receipt of blood to reporting value) to be used for emergency determinations. The sensitivity, precision, and accuracy are sufficient for routine monitoring of therapeutic levels in patients. The assay is specific enough to be valid in the presence of a number of drugs and dietary substances present in clinical samples.

Keyphrases □ Procainamide and *N*-acetyl derivative—high-pressure liquid chromatographic analyses, human plasma □ High-pressure liquid chromatography—analyses, procainamide and *N*-acetyl derivative, human plasma □ Cardiac depressants—procainamide and *N*-acetyl derivative, high-pressure liquid chromatographic analyses, human plasma

Procainamide (I) is an antiarrhythmic compound which demonstrates marked intersubject variability in absorption and elimination (1). Its *N*-acetyl metabolite (II) in humans (2) has antiarrhythmic activity comparable to that of I (3) but demonstrates an even greater variability in plasma concentration with a given I dosage schedule. Methods of monitoring plasma I concentrations that do not also determine II are not adequate.

Recently, several methods for the simultaneous determination of I and II were reported. A fluorometric method required more than 4 ml of blood for a duplicate determination and involved reextraction into acid, addition of alkali, and two fluorescence measurements (4). No mention was made of the possible interference of the fluorescent base quinidine, which would be extracted under these conditions and might be present in patients receiving procainamide.

A GLC method was reported for I and II determinations in urine samples (5), but no mention was made of its application to blood samples. Another GLC method for the determination of both I and II in blood, urine, and saliva samples was reported (6). However, each duplicate analysis probably required 1 hr or more because of a three-stage acid–base extraction, evaporation, and the 23.5-min retention time for II.

A quantitative TLC approach to the problem was developed (2). The reported standard deviations of 9% for I and 11% for II reflect a well-known difficulty of quantitative TLC.

None of the reported methods claimed the combination of small sample size, rapidity, specificity, and precision desirable for routine patient monitoring. This paper describes a method for performing a duplicate analysis in 16 min on as little as 300 μl of whole blood with sufficient accuracy, precision, and specificity for clinical samples.

EXPERIMENTAL

Materials—UV grade hexane, 2-propanol, methanol, 1-butanol, and chloroform[1] and reagent grade concentrated ammonium hydroxide[2] were used as obtained. High purity samples of I and II[3] were used in the preparation of standards.

Apparatus—A high-pressure liquid chromatograph[4] was equipped with a septumless injection port[5] and a fixed wavelength (280 nm) UV absorption detector[6]. The detector was operated at 0.005 and 0.01 absorbance unit full scale.

Chromatographic Parameters—The mobile phase was prepared by diluting concentrated ammonium hydroxide 10:1 with distilled water. One milliliter of this solution was added to 1 liter of 2-propanol and 1 liter of hexane, and the solution was diluted to 5 liters with methanol. The mobile phase was pumped at 5.0 ml/min (3500 psi) through a stainless steel column (4 mm i.d. × 30 cm) packed with a high efficiency bonded-phase absorption packing[7].

Analytical Procedure—Two 50-μl aliquots of each plasma sample were placed in 1.5-ml disposable centrifuge tubes[8]. To each tube was added 10 μl of 5 *N* NaOH solution and 600 μl of an organic extraction solution containing 20% 1-butanol, 20% chloroform, and 60% hexane by volume. The two tubes, together with any other samples being run at the same time, were shaken for 30 sec at 1350 oscillations/sec[9] and then centrifuged for 30 sec at 15,000 rpm[10].

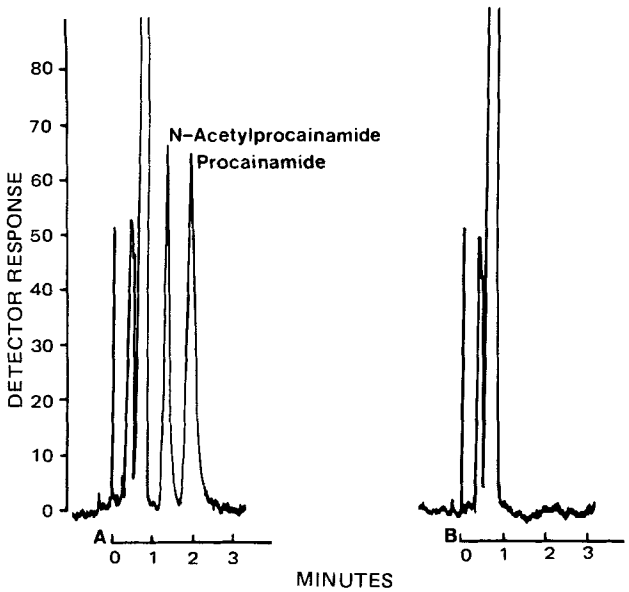

Figure 1—*High-pressure liquid chromatograms of human plasma extracts. Key: A, plasma containing 5 μg of I/ml and 5 μg of II/ml; amd B, control plasma.*

After centrifugation, exactly 100 μl of the supernate from the first tube was measured accurately with a syringe[11] and injected into the chromatograph. Three minutes after the first injection, 100 μl from the second tube was injected. Three minutes after the second injection, the chromatogram was removed and the peak heights were measured in millimeters. The peak heights were converted to plasma I and II concentrations by comparison to a standard curve.

Standard Curve—Stock solutions of 0.10 mg of I/ml and 0.10 mg of II/ml were prepared by dissolving weighed drug samples in methanol. Appropriate aliquots of these standards were added to conical centrifuge tubes and evaporated under nitrogen. Sufficient pooled human plasma was added to each tube to produce final concentrations of 2, 4, 6, 8, 10, 15, and 20 μg/ml. The tubes were vortexed to dissolve the drugs, and then 100-μl aliquots were removed for analysis by the described procedure.

Eight analyses were done at each concentration. The heights of the chromatographic peaks were measured in millimeters. A straight-line fit of the data was made by linear regression analysis, and the correlation coefficient was determined.

Accuracy and Precision—The accuracy and precision of the method were evaluated by performing 48 duplicate analyses on spiked samples of human plasma. Twelve duplicate analyses were performed at each of the following concentrations: 2, 4, 6, and 8 μg/ml. The spiked samples were prepared by adding appropriate aliquots of the 0.10-mg/ml stock solution to centrifuge tubes, evaporating the methanol in a nitrogen stream, and then dissolving I and II in 100-μl aliquots from selected plasma samples.

The 48 plasma samples used were left over from blood samples originally drawn for analyses of other drugs from patients known not to be receiving I or II. After preparation, the spiked samples were analyzed as described; the mean and standard deviation of the measured values were determined.

Evaluation of Interferences—Samples of caffeine, theobromine, theophylline, 3-methylxanthine, quinidine, and propranolol were dissolved in the extraction solution. Aliquots (100 μl) of these solutions were injected into the chromatograph, and the retention times of the drugs were determined. The possibility of interferences also was tested by performing the analysis on a series of plasma samples from patients receiving drugs other than procainamide. Any interferences from quinidine, primidone, phenobarbital, phenytoin, and their metabolites were detected in this way.

RESULTS AND DISCUSSION

Figure 1A shows the chromatogram obtained by injecting 100 μl of the extract of the plasma sample spiked with 5 μg of I/ml and 5 μg of II/ml. The method of analysis described under *Analytical Procedure* was used.

[11] Precision Sampling Corp.

Table I—Accuracy and Precision of HPLC Assay for I and II

I Added, μg/ml	II Added, μg/ml	I Found, μg/ml	*SD* of I Found, %	II Found, μg/ml	*SD* of II Found, %
4	4	3.95	3.0	3.93	2.4
6	6	5.94	2.2	5.96	2.2
8	8	8.04	2.1	7.92	1.4
10	10	10.13	1.2	10.06	1.4

Figure 1B shows the chromatogram of a 100-μl injection of a plasma sample extracted in exactly the same way but with no added I or II. Figure 1B shows that all significant artifact peaks and baseline variations due to the injection of 100 μl of extraction solvent plus components extracted from plasma were complete within about 1 min after injection. Figure 1A shows that the I and II peaks were well separated from each other and from the artifact peaks.

The I and II peak heights (in millimeters) measured on the chromatograms were plotted against the concentrations (in micrograms per milliliter) of I and II in the plasma standard solutions to prepare a standard curve. Twelve plasma samples were assayed at each concentration: 2, 4, 6, 8, 10, 15, and 20 μg/ml of both I and II. The curves obtained by linear regression analyses of these data were $y = 22.8x - 4.76$ for I and $y = 22.5x - 4.6$ for II. The regression coefficients were 0.9999 for I and 0.9996 for II.

The method is sufficiently accurate and precise for routine analysis of clinical samples (Table I). The time required for a duplicate analysis, from centrifugation of the blood to final calculations, is only 16 min. In this laboratory, all routine I and II analyses are run once a day along with external standards. The stat samples are run as soon as received and are checked by external standards, which are run after the values are reported. It has never proven necessary to recall a stat value.

Several drugs that might be taken by patients also taking procainamide were tested for interference with the procainamide assay. Plasma samples from patients having therapeutic levels of quinidine, primidone, phenobarbital, and phenytoin but no procainamide were analyzed. The samples were extracted and chromatographed in exactly the same way as for a I and II analysis. In none of these cases was there a peak giving a false I or II level. In some cases, this result was probably due to the fact that the drug or its metabolites did not extract under the assay conditions. Injection of solutions of caffeine, theobromine, theophylline, 3-methylxanthine, quinidine, and propranolol made up in the extraction solvent failed to reveal any interferences. Only quinidine gave a peak, with a retention time of about 1 min, and it was well resolved from II.

A total of 37 clinical samples have been run by this method. In all of these samples as well as in all controls, no significant peaks with retention times longer than the procainamide have been observed. This result is perhaps due partly to the fact that substances more polar than procainamide tend to be left behind in the aqueous phase during extraction. An important conclusion is that the extractions into less polar solvents followed by normal phase liquid chromatography can lead to short chromatographic runs and short analysis times.

Lipid–Protein Interactions: Detergent Binding to L-Glutamic Acid Dehydrogenase

DAVID H. KEMPNER and BRIAN J. JOHNSON ˣ

Abstract □ A nonionic detergent was found to bind to the enzyme L-glutamic acid dehydrogenase [L-glutamate:nicotinamide adenine dinucleotide phosphate oxidoreductase (deaminating) EC1.4.1.3]. The amount bound was 17 moles of detergent/mole of enzyme, which, however, was not sufficient for the enzyme to be included in a detergent micelle.

Keyphrases □ L-Glutamic acid dehydrogenase—binding of nonionic detergent □ Detergents, nonionic—binding to L-glutamic acid dehydrogenase □ Binding—L-glutamic acid dehydrogenase to nonionic detergent □ Enzymes—L-glutamic acid dehydrogenase, binding to nonionic detergent

It has been reported (1) that the enzyme activity of L-glutamic acid dehydrogenase [L-glutamate:nicotinamide adenine dinucleotide phosphate oxidoreductase (deaminating) EC 1.4.1.3] changes in the presence of nonionic detergents. It was suggested that this change was due to some conformational event being produced in the enzyme by the detergent. Such a supposition implies that the detergent is bound to the enzyme. This paper reports an investigation of this hypothesis.

EXPERIMENTAL

The concentration of L-glutamic acid dehydrogenase solutions was determined using an $E^{1\%}_{280}$ of 10.0 (2). Quantitation of the enzyme in detergent solution and of ovalbumin was determined by fluorescamine (3).

Synthesis of ^{125}I-L-Glutamic Acid Dehydrogenase—The labeled compound was prepared by the method of Marchalonis (4) as modified by David and Reisfeld (5). To 600 μl of a 0.5% solution of enzyme in phosphate-buffered saline (1×10^{-4} *M* ethylenediaminetetraacetic acid, 0.1 *M* NaCl, and 0.04 *M* sodium phosphate, pH 7.4) were added 11 μg of lactoperoxidase coupled to 40 mg of wet Sepharose 4B[1] and 1 mCi of carrier-free ^{125}I-labeled sodium iodide. The reaction was initiated by addition of 20 μl of a 1×10^{-2} *M* solution of hydrogen peroxide in water.

The reaction mixture was shaken for a total of 10 min, but the shaking was stopped at 2-min intervals so that additional 20-μl aliquots of the hydrogen peroxide solution could be added. At the completion of the reaction, the radioiodinated enzyme was collected by centrifugation at 6000×*g* for 2 min. The supernate containing the enzyme was decanted off, and the beads were washed once with 0.5 ml of phosphate Buffer A (1×10^{-4} *M* ethylenediaminetetraacetic acid and 0.04 *M* sodium phosphate, pH 7.4) and centrifuged to extract any residual iodinated enzyme. The combined solutions were dialyzed overnight at 4° against 2 × 300-ml changes of phosphate Buffer A.

An equal volume of 2 *M* ammonium sulfate was added to the dialysate, and the solution was allowed to stand overnight at 4°. The precipitated protein was collected by centrifugation at 5000×*g* for 10 min, and the pellet was washed once with approximately 2 ml of chilled 2 *M* ammonium sulfate and recentrifuged. The pellet was dissolved in approximately 1 ml of phosphate Buffer A and dialyzed overnight at 4° against 2 × 300-ml changes of the same phosphate buffer.

The final traces of unbound iodine were removed by gel filtration on a column (2.3 × 9 cm) of Sephadex G-200. Fractions of 1 ml were collected and counted for radioactivity. Alternate fractions were assayed for protein by fluorescamine. Appropriate fractions, as determined by the ratio of radioactive counts to fluorescence, were pooled such that the specific activity of a preparation was typically 34,000 cpm/μg of enzyme.

Synthesis of ^{125}I-Nonionic Detergent—To 600 μl of a 10% solution of the detergent[2] in phosphate Buffer A were added 11 μg of lactoperoxidase coupled to 40 mg of wet Sepharose 4B and 1 mCi of carrier-free ^{125}I-labeled sodium iodide[3]. The reaction was initiated by addition of a 20-μl aliquot of a 1×10^{-2} *M* solution of hydrogen peroxide in deionized water. The reaction mixture was shaken for a total of 10 min, but shaking was interrupted at 2-min intervals so that additional 20-μl aliquots of the hydrogen peroxide solution could be added. A control was performed in an identical manner, except that 0.1 mCi of ^{125}I-labeled sodium iodide was used without lactoperoxidase or hydrogen peroxide.

After the iodination of the nonionic detergent, the entire reaction mixture was passed through a column (2.3 × 9 cm) of Sephadex G-15 to remove the unbound iodine. Fractions of 0.8 ml were collected and counted for radioactivity. The absorbance at 275 nm of alternate fractions was obtained; those fractions, as determined by the ratio of radioactive counts to absorption at 275 nm, were pooled such that a typical preparation with a specific activity of 8×10^9 cpm/mmole was obtained.

Micelle Formation and Binding of Nonionic Detergent to L-Glutamic Acid Dehydrogenase—*Sephadex G-75 Chromatography*—Samples (3.5–0.35%) of enzyme in phosphate Buffer A were mixed with equal volumes of radioiodinated nonionic detergent. The mixtures were incubated at 4° overnight and then passed through a column (0.9 × 14 cm) of Sephadex G-75 at 4°. The sample was eluted from the column using the phosphate buffer as eluant at a flow rate of 7 ml/hr. Each fraction of 0.3 ml was counted for radioactivity. A control consisting of only radioiodinated detergent was also run.

Bio-Gel A-15m Chromatography—A 50-μl aliquot of a 100-μg/ml solution of ^{125}I-labeled enzyme (specific activity of 7000 cpm/μg) was added to 100 μl of a 7% solution of enzyme in phosphate Buffer A. To this mixture was added 50 μl of detergent. A control was prepared in the same way, except that 50 μl of deionized water was substituted for the detergent.

The samples were then incubated at 37° for 15 min and then at 4° overnight. All samples were layered onto a column (0.9 × 14 cm) and eluted with phosphate Buffer B (0.2 *M* NaCl, 1×10^{-4} *M* ethylenediaminetetraacetic acid, and 0.04 *M* sodium phosphate, pH 7.4), which also contained 1% by volume of the nonionic detergent. Fractions of 0.2 ml were collected and counted for radioactivity.

Sephadex G-200 Chromatography—The molecular weight markers, L-glutamic acid dehydrogenase, and ovalbumin, each dissolved in Buffer B, were run through their respective columns (0.9 × 29 cm) to determine their elution volumes. The void volume of the columns also was determined with Blue Dextran 2000 with every column run. A 50-μl aliquot of a 60-μg/ml solution of ^{125}I-labeled enzyme (specific activity of 3.7×10^4 cpm/μg) in phosphate Buffer B was added to 100 μl of a 7% solution of enzyme in phosphate Buffer A. To this mixture was added 50 μl of the nonionic detergent. For the control, run under identical conditions, 50 μl of deionized water was added to the enzyme sample. For samples of radioiodinated enzyme containing the nonionic detergent, the eluting buffer also contained 1% by volume of the detergent. Fractions of 0.4 ml were collected and counted for radioactivity. Each peak was pooled and assayed for protein by the use of fluorescamine.

RESULTS AND DISCUSSION

The binding of a nonionic detergent to the enzyme L-glutamic acid dehydrogenase was investigated because such detergents previously enhanced the activity of the enzyme to an appreciable extent (1). This investigation necessitated the preparation of the radioiodinated detergent and the enzyme. Enzyme synthesis was achieved by the use of insolubilized lactoperoxidase (4, 5).

The interaction of the enzyme and detergent was studied using gel

[1] Worthington Biochemical Corp., Freehold, N.J.

[2] Triton X-102, Sigma Chemical Co., St. Louis, Mo. This detergent possessed a hydrophilic portion in the form of a polyoxyethylene moiety and a lipophilic portion consisting of octylphenyl. These data were obtained from Rohm and Haas Surfactants Technical Bulletin, Rohm and Haas Co., Philadelphia, Pa.

[3] New England Nuclear Corp., Boston, Mass.

filtration. The results of this procedure have been shown to be in good agreement with those obtained by equilibrium dialysis (6). However, this technique will not determine accurately the binding parameters of any rapidly equilibrating system; under such circumstances, an overestimation of binding is observed.

In the present studies, it was possible to separate the detergent bound to the enzyme from that unbound and to estimate the amount of interaction between the two moieties. The enzyme, at a 4–5% concentration dissolved in a 0.9% solution of radioiodinated detergent, was chromatographed on Sephadex G-75. It was found that 1.4×10^{-5} mmole (mol. wt. 744) of the detergent was associated with 825 μg of the enzyme. This result indicates that 17 moles of detergent bound per mole of enzyme, calculated on the latter having a molecular weight of 1×10^6. This ratio of detergent to enzyme nearly corresponds to one binding site per 55,000 molecular weight subunit of the enzyme (7). This calculation presupposes detergent that is bound rather than in the micellar form. Such binding has occurred when ligand and protein were present in relatively low concentrations (8–10).

One interesting aspect of the interactions between proteins and detergents is the inclusion of several protein molecules in one detergent micelle (11). To test whether the enzyme could be included in detergent micelles, solutions of the radioiodinated enzyme in detergent were prepared and passed through a column of Bio-Gel A-15m. The results indicated that the enzyme could not be aggregated in detergent micelles, because no sample of L-glutamic acid dehydrogenase in detergent had an elution volume less than the native enzyme, even when the eluting buffer contained 1% by volume of the detergent.

While this experiment on agarose showed that the enzyme was not measurably aggregated in detergent micelles, it was not clear whether the enzyme was dissociating into its 55,000 subunits (7). Therefore, gel filtration on Sephadex G-200 was performed. The enzyme buffer only eluted as a single peak, whereas the enzyme in detergent gave a chromatograph of two peaks. In this latter case, the first peak eluted with the void volume whereas the position of the second peak indicated a molecular weight of 55,000. However, the amount of dissociation into these small subunits was never more than 5% of the total amount applied to the column.

The results indicate that the nonionic detergent can bind to the enzyme L-glutamic acid dehydrogenase. This binding is only in the order of approximately 17 moles of detergent/mole of enzyme, hardly sufficient to allow the enzyme to be included in a detergent micelle. However, it obviously is sufficient to cause enhancement of the activity of this enzyme (1).

These results suggest a possible avenue for enhancement of the biological activities of other proteins and drugs.

Separation and Quantitative Determination of 2,4-Disulfamyl-5-trifluoromethylaniline in Hydroflumethiazide Using High-Pressure Liquid Chromatography

B. J. OWEN [x] and S. V. WILKIE

Abstract □ A high-pressure liquid chromatographic method was developed to quantify 2,4-disulfamyl-5-trifluoromethylaniline in hydroflumethiazide using a bonded pellicular packing. An internal standard was added to the samples to ensure reproducibility. The results were compared with methods currently in use.

Keyphrases □ 2,4-Disulfamyl-5-trifluoromethylaniline—high-pressure liquid chromatographic analysis in hydroflumethiazide samples and tablets □ Hydroflumethiazide—prepared samples and tablets, high-pressure liquid chromatographic analysis of its precursor 2,4-disulfamyl-5-trifluoromethylaniline □ High-pressure liquid chromatography—analysis, 2,4-disulfamyl-5-trifluoromethylaniline in hydroflumethiazide prepared samples and tablets □ Antihypertensives—hydroflumethiazide prepared samples and tablets, high-pressure liquid chromatographic analysis of its precursor 2,4-disulfamyl-5-trifluoromethylaniline

The hydroflumethiazide monographs in the National Formulary (1) and the British Pharmacopoeia (2) include assays for free amine in the form of its precursor 2,4-disulfamyl-5-trifluoromethylaniline (I) (3–6). In the BP method, the free amine in the sample is compared visually with a standard of I using TLC for the separation. A diazotization is performed in the NF method, and the solution absorbance is read spectrophotometrically and compared with a standard preparation.

This paper describes a high-pressure liquid chromatographic (HPLC) method for the separation of I from hydroflumethiazide, and the results are compared with those from the compendial methods.

EXPERIMENTAL

Materials—Standard solutions containing 0.02, 0.04, 0.06, and 0.08 mg of I[1]/ml of reagent grade methanol were prepared. Hydroflumethia-

zide samples were diluted to 4 mg/ml in methanol. Hydroflumethiazide tablets were made up to the same concentration; the solutions were filtered before injection. Sulfathiazole, 0.4 mg/ml, was added to both standard and sample solutions as an internal standard.

Apparatus—A high-pressure liquid chromatograph[2] with a double-beam UV detector operating at 254 nm was used in conjunction with a 10-mv recorder. The columns were 0.5 m long stainless steel (2.6 mm i.d.) packed with an octadecyl hydrocarbon bonded to a deactivated silica[3].

Separation Conditions—The eluting solvent was 5% methanol (reagent grade) in distilled water flowing at 1.5 ml/min, and the temperature of the column oven was 35°. Three microliters of each solution was chromatographed, and the time for complete elution of the sample was approximately 15 min. Each sample was run once, and the calculations were based on peak height. The response for I in the sample was compared with that of the standard solutions. The separation is shown in Fig. 1.

0.032	0.8	1.304	0.809

RESULTS AND DISCUSSION

The primary goal in developing this assay was to provide a fast precise method for the estimation of I in hydroflumethiazide and hydroflumethiazide tablets. The assay described met these criteria. This HPLC assay gave better precision than TLC and similar results to the diazotizable substance assay (Table I). The linearity of the detector response for 0.02, 0.04, 0.06, and 0.08 mg of I/ml of methanol was satisfactory. From one sample of hydroflumethiazide, 10 weighings produced assays giving a mean result for free amine content of 0.971 ± 0.0281% (*SD*). The recovery of free amine added to a sample of hydroflumethiazide was also checked (Table II).

Enhancement of Intestinal Glucose Transport following Chronic Parathion Poisoning

CASEY P. ROBINSON ˣ, JUNGJA J. CHOI, and J. THOMAS PENTO

Abstract □ Chronic administration of parathion to male rats stimulated glucose ($p < 0.05$) but not calcium ($p > 0.05$) transport in the everted duodenal gut sac preparation. Chronic parathion stimulation was not reduced by concurrent administration of atropine. Acutely applied parathion or paraoxon, its active metabolite, did not increase glucose transport in this preparation.

Keyphrases □ Parathion—chronic administration, effect on intestinal glucose and calcium transport, rats □ Paraoxon—chronic administration, effect on intestinal glucose and calcium transport, rats □ Glucose transport, intestinal—effect of chronic administration of parathion or paraoxon, rats □ Calcium transport, intestinal—effect of chronic administration of parathion or paraoxon, rats □ Insecticides—parathion and paraoxon, chronic administration, effect on intestinal glucose and calcium transport, rats

Parathion (*O,O*-diethyl *O*-*p*-nitrophenyl phosphorothioate), a widely used insecticide, is toxic to both insects and mammals only after conversion to the active metabolite paraoxon (*O,O*-diethyl *O*-*p*-nitrophenyl phosphate), which is a potent inhibitor of cholinesterases. The toxicity observed after parathion poisoning results from an accumulation of acetylcholine at certain critical sites subsequent to cholinesterase inhibition. Other effects not clearly associated with cholinesterase inhibition also have been reported for organophosphates. Two organophosphate cholinesterase-inhibiting insecticides (azinphosmethyl and dimethoate) reduced glucose penetration across the isolated mouse intestine (1). Dimethoate resembles parathion in that it requires activation to an active metabolite before becoming a cholinesterase inhibitor; azinphosmethyl does not require activation. The reduction of glucose penetration observed (1) in the presence of parathion was not significant ($p > 0.05$).

It is unlikely that a large portion of an organophosphate that requires activation would be activated in the isolated intestine. Thus, any change in intestinal glucose transport occurring after the addition of such an organophosphate would probably result from a direct effect of the unactivated organophosphate or from an effect of a very small quantity of active metabolite. Therefore, it was of interest to determine the effects of acute exposure to parathion and its active metabolite paraoxon and of chronic parathion poisoning on intestinal glucose transport. The mechanism and specificity of these effects on glucose transport were also examined.

EXPERIMENTAL

Two experiments were undertaken to examine the effects of parathion or paraoxon on intestinal transport of glucose and calcium. One experiment concerned the effects of the acute addition of the insecticides *in vitro*. Male Holtzman rats were initially placed on a diet of ground rat chow[1] and tap water for 7 days and then on a ground, low calcium diet[2] (0.02% calcium) and distilled water for 7 days. Each animal was given vitamin D (200 units po) every 3rd day. The mean weight of the rats at the time of sacrifice was 81 ± 10 g. The low calcium diet and vitamin D were used to optimize calcium transport.

Rats were fasted overnight before the intestinal segments were removed. Upon removal of the segments, they were placed into one of three types of incubation media: with parathion (0.1 m*M*), with paraoxon (0.1 m*M*), or with no insecticide. Each of the three solutions contained polysorbate 80[3] (0.03%), used to solubilize the insecticides. The organophosphate was in the media both inside and outside the gut sacs.

In the other experiment, the effects of chronic parathion poisoning on intestinal transport were investigated. Rats, 60–80 g (mean of 69 g), were randomly divided into four groups. One group received rat chow containing 20 ppm of parathion, a second group received rat chow containing 20 ppm each of parathion and atropine, and a third group was fed rat chow containing no parathion as a control. Each group was allowed free access to food. In another control group, rats were pair-fed with the parathion-poisoned rats.

Rats were poisoned for 14 days. Vitamin D was administered to these rats as described in the previous experiment; during the last 7 days of the poisoning period, the poisons were administered in the low calcium diet previously described. Animals were fasted overnight before removal of the intestinal segments. Thus, poisoning was discontinued 15–18 hr before removal of the intestinal segments. The mean weight of the control rats at the time of sacrifice was 108 ± 10 g.

Glucose and calcium transport were measured by a modification of the everted gut sac technique of Wiseman (2). The animals were lightly anesthetized with ether, bled by cardiac puncture, and killed by cervical fracture. Blood was collected in heparinized syringes, and the plasma was separated immediately. The upper intestine was quickly removed, everted, and washed in saline. Duodenal segments, 5 cm in length, were filled with 0.5 ml of an oxygenated phosphate buffer and placed into 25-ml erlenmeyer flasks containing 3 ml of the same solution, which was sufficient to cover the gut sac.

The phosphate buffer contained 2.4 m*M* dibasic sodium phosphate, 1.6 m*M* monobasic sodium phosphate, 150 m*M* sodium chloride, 5.6 m*M* glucose, and 0.045 μCi/ml of calcium-45. The buffer pH was adjusted to 7.4. The duodenal segments were incubated under an atmosphere of 95% O_2–5% CO_2 for 1 hr at 37° on a gyrorotary metabolic shaker[4]. The ratio of the final concentration of glucose and calcium-45 in the serosal medium (solution inside the gut sac) to the concentration in the mucosal medium (solution bathing the gut sac) was used as an index of transport.

Calcium-45 in the mucosal and serosal media was measured by counting 0.1-ml aliquots of the media on a liquid scintillation counter[5]. Plasma calcium was determined by the method of Baginski *et al.* (3). Plasma and incubation medium glucose was measured by the method of Feteris (4).

In the parathion and control groups of the chronic study, a 2-cm section of intestine immediately adjacent to that used in each transport study was removed, washed, blotted dry, weighed, and frozen for the later determination of cholinesterase activity. This assay was accomplished by the automated colorimetric method of Fowler and McKenzie (5).

Statistical comparisons were made using the Student *t* test for unpaired data.

RESULTS

Both glucose and calcium were actively transported in the rat everted duodenal sac from calcium-deprived rats (Table I). Neither parathion nor paraoxon affected ($p > 0.05$) the transport of either of these substances when the toxins were added to the incubation media.

Rats chronically poisoned with parathion had diarrhea and other signs of parasympathetic stimulation. These signs tended to become less severe

Table I—Effects of Acute Exposure to Parathion or Paraoxon on Glucose and Calcium Transport in Duodenal Segments

Treatment	Transport, Serosal/Mucosal[a]	
	Glucose	Calcium
Control	3.9 ± 0.80	4.2 ± 0.42
Parathion, 0.1 m*M*	3.4 ± 0.48	4.2 ± 0.44
Paraoxon, 0.1 m*M*	4.2 ± 1.02	4.8 ± 0.88

[a] After 60-min incubation. Each value is the mean ± *SEM* of one segment from each of five or six rats.

with time and, in some cases, disappeared toward the end of the 14-day poisoning period. Rats receiving atropine and parathion exhibited few, if any, signs of parasympathetic stimulation.

Cholinesterase activities were lower ($p < 0.05$) in segments from parathion-poisoned rats (7.16 ± 0.95 m*M* of acetylcholine hydrolyzed/min/g of tissue) than in segments from control rats (10.49 ± 0.89).

Chronic parathion poisoning enhanced intestinal glucose transport ($p < 0.05$) without affecting calcium transport in calcium-deprived rats (Table II). Glucose and calcium transport in the control group was lower than in the acute experiment. At the time of sacrifice, these rats averaged 27 g more than those in the acute experiment. A decreasing rate of active intestinal transport with maturing may have accounted for some, or perhaps all, of the differences in control transport rates between the two experiments. Rats weighing less than 100 g have a faster rate of intestinal glucose transport than heavier rats (6), and the rate of intestinal transport of calcium in rats decreases with maturing (7). However, treatment-induced changes in transport should not be influenced by differences in baseline values in the control groups.

Addition of the muscarinic blocking drug atropine did not decrease the parathion-induced enhancement of glucose transport. Thus, if increased glucose transport results from acetylcholine accumulation following cholinesterase inhibition, it is unlikely that it is mediated through stimulation of muscarinic receptors.

Reduction in food intake by parathion-poisoned rats apparently was not involved in the enhanced glucose absorption, judging from the glucose transport values observed in intestinal segments from control rats pair-fed with poisoned rats and from control rats allowed to eat *ad libitum* (Table II).

Neither plasma glucose nor plasma calcium levels were different ($p > 0.05$) in chronically parathion-poisoned rats (glucose, 125.4 ± 17.2 mg %; calcium, 11.7 ± 0.5 mg %) than in control rats (glucose, 128.3 ± 11.4 mg %; calcium, 11.3 ± 0.4 mg %).

DISCUSSION

Although acute *in vitro* exposure of duodenal segments to parathion or its active metabolite paraoxon did not alter glucose transport, chronic poisoning with parathion enhanced it. Concurrent administration of atropine did not alter the parathion effect. However, since both atropine and parathion were discontinued 15 or more hr prior to obtaining the duodenal segments, neither atropine, free paraoxon, nor parathion should have been present in the duodenum at the time of the transport study. However, partial inhibition of cholinesterase (30%) was still observable at this time. Thus, if the enhancemnt of glucose transport results from the accumulation of acetylcholine, either it does not involve chronic stimulation of muscarinic receptors or the period of time after the bioremoval of atropine was sufficient to allow this effect to develop.

One model of glucose transport across the intestinal epithelial cell has glucose transferred across the brush border coupled with a sodium ion (8, 9) by a membrane carrier system allowing coupled facilitated diffusion. The model requires that the sodium concentration be lower inside the cell than in the lumen. This concentration gradient is maintained by a sodium pump (10). Thus, stimulation of movement of sodium ions into the cells should increase the rate of glucose transport. One means of accomplishing this is by stimulating the extrusion of sodium from epithelial cells. Phenytoin stimulated extrusion of sodium ions in brain (11) and muscle (12) cells and also enhanced intestinal glucose absorption in the rat isolated jejunal loop (13). Sodium transport by the acetylcholine receptor in cultured muscle cells has been observed (14). If acetylcholine stimulates a receptor to enhance coupled sodium and glucose transport, it should probably also do so on acute exposure. However, enhanced glucose transport on acute exposure to cholinesterase inhibitors was not observed. Also, acute applications of acetylcholine in isolated human ileal strips did not affect sodium transport (15).

This effect may be unrelated to cholinesterase inhibition. Whatever the mechanism, the results of this study indicate that sublethal chronic exposure to parathion stimulates glucose transport in the rat duodenum. Furthermore, this enhancement shows some specificity, since the rate of calcium transport was not significantly altered.

Table II—Effects of Chronic Poisoning with Parathion or Parathion and Atropine on Glucose and Calcium Transport in Duodenal Segments

Treatment[a]	Transport, Serosal/Mucosal[b]	
	Glucose	Calcium
Control	2.6 ± 0.69	2.4 ± 0.50
Control (paired with parathion)	2.6 ± 0.57	2.1 ± 0.37
Parathion, 20 ppm	4.4[c] ± 0.38	3.1 ± 0.37
Parathion, 20 ppm, and atropine, 20 ppm	4.5 ± 0.97	3.2 ± 0.60

[a] In rat chow for 14 days. [b] After 60-min incubation. Each value is the mean ± *SEM* of one segment from each of four or five rats. [c] Significantly different from control-paired ($p < 0.05$) and control ($p = 0.05$).

Metabolic Studies with the Nonnutritive Sweetener Cycloheptylsulfamate

G. ANTHONY BENSON and WILLIAM J. SPILLANE ˣ

Abstract □ The nonnutritive sweetener cycloheptylsulfamate was administered orally to rabbits and rats. The urine of each species was separately collected for 3 days and examined for the metabolites cycloheptylamine, cycloheptanone, and cycloheptanol and for cycloheptylsulfamate. A previously tested GLC method was adapted for the determination of the metabolites. Cycloheptylsulfamate was assayed by hydrolysis and subsequent measurement of the absorbance of the product formed (λ_{max} = 489 nm) by the liberated amine with *p*-benzoquinone. The conversions to the metabolites were 0.276, 0.390, and 0.170%, respectively, in rabbits and 0.064, 0.022, and 0.017%, respectively, in rats.

Keyphrases □ Cycloheptylsulfamate—metabolism, rabbits and rats □ Metabolism—cycloheptylsulfamate, rabbits and rats □ Excretion, urinary—cycloheptylsulfamate and metabolites, rabbits and rats □ Sweeteners—cycloheptylsulfamate, metabolism, rabbits and rats

Cyclamates (sodium and calcium salts of cyclohexylsulfamic acid) have been the subject of considerable investigation over the past few years. This research involved metabolic studies in humans (1–5) and other species (6–12) to determine the metabolites and toxicity of the cyclamates. Further work involved the search for the metabolic site of cyclamate breakdown and the possible microorganisms involved (13–19).

It also seemed worthwhile to evaluate other sulfamates that have a reduced ring and are sweet. Since enzymatic action has been implicated in the breakdown of cyclamate, other sweet sulfamates might be resistant to enzyme action and not be metabolized. Metabolic experiments involving cyclopentylsulfamate were carried out previously (20). Since cycloheptylsulfamate is also sweet (21, 22), in fact, almost as sweet as cyclamate sodium (23), it was tested in rabbits and rats. The results of these metabolic experiments are presented in this paper.

EXPERIMENTAL

Reagents and Chemicals—Sodium cycloheptylsulfamate was synthesized by the reaction of cycloheptylamine in dry chloroform with chlorosulfonic acid (24) and recrystallized twice from ethanol. It was administered orally as an approximately 1% aqueous solution to rats and as an approximately 1.7% aqueous solution to rabbits at doses of 1250 and 349 mg/kg, respectively.

Anal.—Calc. for $C_7H_{14}NNaO_3S$: C, 39.07; H, 6.51; N, 6.51. Found: C, 38.89; H, 6.43; N, 6.56.

Cycloheptylamide[1], cycloheptanone[1], cycloheptanol[1], and dichloromethane[2] were redistilled before use. *p*-Benzoquinone was sublimed. *n*-Dodecane[3], sulfosalicylic acid[2] (Analar), chloroform, ethanol, and 1,4-dioxane (reagent grade) were used as obtained.

Metabolism Experiments—Female New Zealand White rabbits, 3.1–3.6 kg, were kept on solid food and water in metabolism cages[4]. Female Wistar albino rats, approximately 400 g, were kept on solid food and water in smaller metabolism cages[5].

GLC and Visible Spectrophotometry—Cycloheptylamine, cycloheptanol, and cycloheptanone excreted in the urine of both rats and rabbits receiving cycloheptylsulfamate were determined by the GLC method described previously (20) except for the following changes. The column temperature was 130° and the gas flow rates were: nitrogen (carrier), 75 ml/min; hydrogen, 60 ml/min; and overall, 500 ml/min. Under these conditions, the retention times of *n*-dodecane, cycloheptylamine, cycloheptanone, and cycloheptanol were 4.6, 6.3, 8.4, and 13 min, respectively (Fig. 1).

For the purpose of estimating the percent recovery, varying amounts of amine, ketone, and alcohol were determined (Table I). The unmetabolized cycloheptylsulfamate excreted in the urine was determined by visible spectrophotometry (20). Samples of control urine of both species were monitored using both detection methods.

RESULTS AND DISCUSSION

The results from the analysis of the urine of rabbits and rats for unchanged cycloheptylsulfamate and various metabolites are given in Tables II and III, respectively. The average percentage for unchanged cycloheptylsulfamate excreted in the urine for rats was 35%; for rabbits, it was 66%. In metabolic studies with cyclopentylsulfamate (20), rats excreted 15% unchanged cyclopentylsulfamate in the urine and rabbits excreted 56%. U-^{14}C-Cyclamate sodium also was extensively excreted in the urine by rabbits, whereas the average level of excretion for rats was 40% in the urine (2). In rats that had received a level of cyclamate similar to that used in the present study, about 17% cyclamate was excreted in the urine and about 70% in the feces (25). Thus, the main excretory pathways for these administered sulfamates apparently are the urine for rabbits and the feces for rats.

The average conversion of cycloheptylsulfamate by rabbits to cycloheptylamine, cycloheptanone, and cycloheptanol was 0.276, 0.390, and 0.170%, respectively (Table II). Comparison of these results with those for cyclopentylsulfamate (20) showed that they were slightly higher. The conversion results of Ichibagase *et al.* (14) and Suenaga *et al.* (16) for cyclamate also were lower than the present results for cycloheptylsulfamate in rabbits. Renwick and Williams (2) also found a lower conversion in rabbits for cyclamate.

In the five rats studied, the level of cycloheptylamine found (Table III) was similar to the level of cyclopentylamine found (20) and higher than the level of cyclohexylamine obtained (14, 16) in metabolic studies with cyclopentylsulfamate and cyclamate, respectively. Only one rat excreted cycloheptanol in urine, and only two rats excreted cycloheptanone (Table III).

It appears that cycloheptyl- and cyclopentylsulfamates are cleaved to the same extent in rats, but in rabbits the conversion of cycloheptylsulfamate is higher. Metabolic studies with other sweet sulfamates are necessary to assess the breakdown pattern, if any, and the effect of prolonged administration on metabolite levels.

Cytotoxic Agents from *Michelia champaca* and *Talauma ovata*: Parthenolide and Costunolide

JOSEPH J. HOFFMANN, STERLING J. TORRANCE, RICHARD M. WIEDHOPF, and JACK R. COLE [x]

Abstract □ The ethanol extract of *Michelia champaca* and the petroleum ether extract of *Talauma ovata* showed activity toward the human epidermoid carcinoma of the nasopharynx test system. The active constituents were sesquiterpene lactones, identified as parthenolide ($C_{15}H_{20}O_3$) and costunolide ($C_{15}H_{20}O_2$). Their identities were proven by elemental analyses, PMR, IR, and mass spectral data, melting-point and mixed melting-point determinations, and comparisons with authentic samples and spectra.

Keyphrases □ Parthenolide—isolated from ethanol extract of bark of *Michelia champaca*, cytotoxic activity evaluated □ Costunolide—isolated from ethanol extract of bark of *Michelia champaca* and petroleum ether extract of roots of *Talauma ovata*, cytotoxic activity evaluated □ *Michelia champaca*—parthenolide and costunolide isolated from ethanol extract of bark, cytotoxic activity evaluated □ *Talauma ovata*—costunolide isolated from petroleum ether extract of roots, cytotoxic activity evaluated □ Cytotoxic activity—plant constituents parthenolide and costunolide evaluated

As a result of the continuing search for plants having tumor inhibitory constituents, it was found that the ethanol extract of the stem bark of *Michelia champaca* L.[1] (Magnoliaceae) and the petroleum ether extract of the roots of *Talauma ovata* A. St. Hil.[2] (Magnoliaceae) showed cytotoxic activity toward the human epidermoid carcinoma of the nasopharynx test system[3] (KB).

DISCUSSION

The cytotoxic agents were found to be parthenolide (from *M. champaca*) and costunolide (from *M. champaca* and *T. ovata*). Parthenolide previously was isolated from several Magnoliaceae plants, including *Magnolia grandiflora* (1) and *M. champaca* (2), and also from *Chrysanthemum parthenium* (Asteraceae) (3). Costunolide has been found mainly in Asteraceae plants, *e.g.*, the "costus root," *Saussurea lappa* (4). Identification of parthenolide and costunolide was achieved by IR, PMR, and mass spectral data and by comparison with authentic spectra and samples.

Parthenolide demonstrated an activity of 2.3 μg/ml, and costunolide showed an activity of 2.8 μg/ml. Activity in the KB test system is defined as $ED_{50} \leq 20$ μg/ml (5).

EXPERIMENTAL[4]

Isolation Procedure—The ground stem of *M. champaca* (7 kg) was extracted exhaustively with ethanol in a Lloyd-type extractor. The air-dried residue was partitioned between chloroform and water. The air-dried chloroform phase (11.8 g) was extracted twice with benzene (500 ml), and the benzene-soluble fraction (8 g) was subjected to silica gel 60 (200 g) column (4 × 46 cm) chromatography. The column was eluted with benzene (1000 ml), chloroform (1000 ml), chloroform–methanol [(95:5) six fractions, 500 ml each], acetone, and methanol.

The dried and ground roots of *T. ovata* (1.0 kg) were extracted by maceration with 3 liters of petroleum ether (bp 30–60°) overnight. After filtration and removal of the solvent from the extract, crude crystals of costunolide formed.

Isolation of Parthenolide—Parthenolide was isolated from the first chloroform–methanol (95:5) fraction by preparative TLC using benzene–dichloromethane–ethyl acetate (3:6:1). Crystallization from ether resulted in colorless plates, mp 115° [lit. (2) mp 115°]. The PMR spectrum was identical to the previously reported spectrum (2). The IR

NMR Solvent Shift Data for Methoxylated Xanthones

R. A. FINNEGAN [x] and K. E. MERKEL

Abstract □ The NMR spectra of 1-, 2-, 3-, and 4-hydroxyxanthones, 1,3-, 1,5-, 1,6-, 1,7-, 1,8-, 2,5-, 3,4-, 3,5-, 3,6-, and 4,5-dihydroxyxanthones, 1,3,6- and 1,3,8-trihydroxyxanthones, and 1,3,6,8-tetrahydroxyxanthone, as well as those of the corresponding methyl ethers and acetates, were recorded. The spectra of the methyl ethers were measured in deuterochloroform, benzene, trifluoroacetic acid, and 3% trifluoroacetic acid in benzene. The solvent shift parameters for the methoxyl resonances are tabulated and discussed.

Keyphrases □ Methoxyxanthones, various—NMR spectra and solvent shift data □ NMR—spectra and solvent shift data, various methoxyxanthones □ Xanthones, methoxy substituted—NMR spectra and solvent shift data

Recently, the isolation of four simple hydroxylated xanthones from seed extracts of *Mammea americana* L. was reported (1). They were identified as the 2- and 4-monohydroxy derivatives and the 1,7- and 1,5-dihydroxy derivatives by a combination of spectroscopic studies and syntheses of authentic materials (1). The last substance, in fact, was prepared for the first time. The 2,5- and 4,5-dihydroxy isomers were also prepared (2). During this work, other hydroxylated xanthones (3, 4) were prepared, not only for comparison purposes but also for inclusion in a preliminary antitumor screen (5).

The chemical shifts of methoxy resonances in some methoxyxanthone derivatives were dependent on the position of substitution (3). The magnitude of the benzene-induced solvent shift for the methyl group in substituted anisoles was dependent on the nature and orientation of the substituents (6). These facts suggested that benzene-induced shifts of methoxyl resonances in methoxyxanthones also might be position dependent and, therefore, might be helpful in elucidating the structures of naturally occurring hydroxyxanthones and methoxyxanthones.

While this work was in progress, benzene-induced shifts of methoxyl resonances in flavonoids (7–11) and substituted xanthones (12, 13) were reported and, indeed, found to be of use in structure determination. Useful solvent shift correlations were previously derived for steroidal ketones (14, 15) and substituted coumarins (16). In addition, trifluoroacetic acid (I) was found to be a useful adjunct to the

use of benzene (II) and deuterochloroform (III) as shift-inducing solvents (9, 10, 17) and was included in the present study.

EXPERIMENTAL

The preparation of the compounds used (1–4) and their complete NMR, IR, and UV data and those of their related phenols and corresponding acetates were presented previously (4). All spectra were determined using a 60-mHz spectrometer. Tetramethylsilane (2%) was employed as the internal reference in all solvents. The concentration of the solute was not greater than 3% (w/v), and the benzene–trifluoroacetic acid solvent contained 3% (v/v) of the latter. The chemical shifts for the methyl groups in the various methoxyxanthones are listed in Table I.

RESULTS AND DISCUSSION

Table II lists the Δ values ($\Delta = \delta_{\text{Solvent 1}} - \delta_{\text{Solvent 2}}$) for the four monomethoxyxanthones and for eight (of the 10 possible) dimethoxyxanthones that do not have the methoxyl groups in the same ring. For Table III, the data from Table II were retabulated and averaged according to the methoxyl positions on the xanthone nucleus. (For the purposes of averaging, the symmetrical xanthones were counted twice. The range of values found is also included in the table.)

Since the 3(6)-position is *para* to the electron-withdrawing carbonyl group, it showed the largest benzene-induced shift, Δ (III–II), in line with the indications of Bowie *et al.* (6) for simple anisole derivatives. The magnitude of Δ (III–II) decreased in the order of C-3(6) > C-4(5) > C-2(7) > C-1(8), and the differences in magnitudes were large enough to distinguish among the closely related isomeric pairs listed in Table II. The introduction of the second methoxyl group into the unsubstituted ring of monomethoxyxanthone seemed to have little effect on the Δ (III–II) value for the first methoxyl. A possible exception was seen for 3,5-dimethoxyxanthone, where the shift for the 3-methoxyl group was somewhat enhanced. This exception could have been a reflection of the fact that the 5-methoxyl group, being *meta* to the carbonyl group, increased its electron-withdrawing power.

Methoxyl resonances appeared at relatively low field in trifluoroacetic acid, so relatively large solvent shifts were obtained in combination with benzene. These shifts again showed a dependence on the position of substitution; their magnitude decreased in the order C-1(8) ≅ C-3(6) > C-4(5) > C-2(7). The 1(8)- and 3(6)-positions (*ortho* and *para* to the

Table IV—Solvent Shift Data for Some Methoxyxanthones Having More than One Methoxyl Group on the Same Ring

carbonyl group) were those from which the electron pairs on the methoxyl groups were most efficiently delocalized and, therefore, were the least basic positions. The fact that they showed enhanced rather than reduced values for Δ (I–II) suggests that protonation occurred on the carbonyl oxygen rather than on the ether oxygens.

Tables II and III also list the Δ (I–III) values, which also showed positional dependence, in this case mainly for the 1(8)-position where the shift was about twice that for the other three positions. This pattern was similar to that found (9) for methoxyflavones, where the shift for the 5-methoxyl (*ortho* to the carbonyl) was larger and easily distinguished from those for methoxyls at the 6-, 7-, or 8-position. Values of 0.37 and 0.15 ppm were reported (10) for the 1- and 7-methoxyls of 1,7-dimethoxyxanthone, and the deviations from the presently reported measurements of 0.44 and 0.21 ppm probably resulted from the slightly different experimental conditions.

Table IV gives shift data for a few xanthones having two methoxyls in the same ring. The abnormally low value of Δ (III–II) for the 4-methoxyl in 3,4-dimethoxyxanthone is consistent with values reported for similarly situated methoxyls flanked by two *ortho*-substituents (6, 12, 13, 16, 18). This apparent decrease in the ability of the benzene solvent to shield the methoxyl group in question has been ascribed to steric hindrance. This effect is also apparent in the corresponding value of Δ (I–II) for the 4-methoxyl in this compound. The Δ (I–III) value (0.19 ppm), however, is quite normal for a methoxyl in this position (*cf.*, the value 0.20 ppm in Table III), although it was suggested (9, 17) that such a methoxyl ought to show an enhanced shift because of its increased basicity.

Although the data in Table IV are limited, they suggest that polyoxygenation tends to increase the Δ values by a small amount. This decrease can also be noted in the values reported (12, 13) for a series of 1,3,5,6- and 1,3,6,7-tetraoxygenated xanthones (further substituted by saturated or unsaturated alkyl groups), which are included (as average values) in Table IV.

Finally, the trifluoroacetic acid addition shifts, Δ (II–II/I), were extremely small (*cf.*, Table I), mostly within the experimental error of 1–2 Hz. Therefore, they are of little help in distinguishing the positions of methoxylation, at least in these simple xanthones. This finding is in contrast to their potential usefulness in the methoxyflavone series (9).

Synthesis of 5-Substituted 2-Oxazolidinethiones and Their Antagonism to Uterotropic Effect of Diethylstilbestrol

A. K. AGRAWAL *, S. S. PARMAR *, C. DWIVEDI ‡§, and R. D. HARBISON ‡x

Abstract □ 5-(4-Aminophenoxymethyl)-2-oxazolidinethiones were synthesized by the cyclization of 1-(4-aminophenoxy)-3-amino-2-propanol in the presence of potassium hydroxide and carbon disulfide. This oxazolidinethione, on reaction with suitable isothiocyanates, yielded 5-[4-(substituted thiocarbamido)phenoxymethyl]-2-oxazolidinethiones. These compounds antagonized the uterotropic effects of diethylstilbestrol in female rats and possessed approximate LD_{50} values of 400–>800 mg/kg.

Keyphrases □ 2-Oxazolidinethiones, 5-substituted—synthesized, evaluated for antagonism to diethylstilbestrol effects, rats □ Diethylstilbestrol effects—antagonism by 5-substituted 2-oxazolidinethiones evaluated, rats □ Structure–activity relationships—5-substituted 2-oxazolidinethiones evaluated for antagonism to diethylstilbestrol effects, rats

Significant anti-implantation effects in rats after oral or subcutaneous administration of oxazolidinethiones suggested an antifertility property for these compounds (1). Oxazolidinethiones also lack androgenic and antigonadotropic activity (2). These observations led to the synthesis of substituted 2-oxazolidinethiones and the evaluation of their ability to antagonize the uterotropic effects of diethylstilbestrol in female rats. The various oxazolidinethiones were synthesized according to Scheme I.

EXPERIMENTAL

Melting points were taken in open capillary tubes with a partial immersion thermometer. The compounds were characterized by their sharp melting points and elemental analyses. All compounds were analyzed for carbon, hydrogen, and nitrogen.

Chemistry—*p*-Acetylaminophenol, on reaction with epichlorohydrin, gave 1-(4-acetylaminophenoxy)-2,3-epoxypropane (I). On treatment with succinimide, I yielded 1-(4-acetylaminophenoxy)-2-hydroxypropylsuccinimide (II). Compound II, on hydrolysis, yielded 1-(4-aminophenoxy)-3-amino-2-propanol (III), which cyclized in the presence of carbon disulfide and potassium hydroxide to 5-(4-aminophenoxymethyl)-2-oxazolidinethione (IV). This oxazolidinethione, on reaction with appropriate isothiocyanates, yielded corresponding thiocarbamide derivatives (V–XIII).

1-(4-Acetylaminophenoxy)-2,3-epoxypropane (I)—A mixture of *p*-acetylaminophenol (0.2 mole), epichlorohydrin (0.6 mole), and pyridine (3 ml) was stirred at 100° for 17 hr. The excess epichlorohydrin was distilled off under reduced pressure. The residue was added to a solution of 23 g of sodium hydroxide in 150 ml of water, and the mixture was stirred at room temperature for 24 hr and then extracted with ether. The ethereal extract was washed with water (200 ml), dried over anhydrous calcium chloride, and filtered. Excess ether from the filtrate was removed by distillation under reduced pressure. The solid mass thus obtained was recrystallized from ethanol (70% yield), mp 103–104°.

Anal.—Calc. for $C_{11}H_{13}NO_3$: C, 63.76; H, 6.28; N, 6.76. Found: C, 63.97; H, 6.01; N, 6.58.

1-(4-Acetylaminophenoxy)-2-hydroxypropylsuccinimide (II)—A mixture of I (0.1 mole), succinimide (0.1 mole), 100 ml of ethanol, and 4 drops of pyridine was refluxed on a steam bath for 20 hr and then poured over 500 ml of cold water. The separated solid mass was filtered, washed with water, and recrystallized from methanol (80% yield), mp 152–153°.

Anal.—Calc. for $C_{15}H_{18}N_2O_5$: C, 58.82; H, 5.88; N, 9.15. Found: C, 59.12; H, 5.68; N, 8.92.

1-(4-Aminophenoxy)-3-amino-2-propanol (III)—A mixture of II (0.1 mole), 33 g of sodium hydroxide, and 120 ml of ethanol was refluxed on a steam bath for 20 hr. Excess ethanol was distilled off under reduced pressure, and 90 ml of cold water was added to the residue. The separated solid mass was collected by filtration, washed thoroughly with water, and recrystallized from ethanol (75% yield), mp 184°.

Anal.—Calc. for $C_9H_{14}N_2O_2$: C, 59.39; H, 7.63; N, 15.38. Found: C, 59.67; H, 7.53; N, 15.00.

5-(4-Aminophenoxymethyl)-2-oxazolidinethione (IV)—A cold solution of potassium hydroxide (0.2 mole) in 30 ml of water containing 20 ml of ethanol was added to a mixture of III (0.1 mole) and carbon disulfide (0.1 mole). The mixture was refluxed on a steam bath for 4 hr. Excess ethanol was distilled off under reduced pressure. The residue was diluted with 300 ml of water, cooled in an ice bath, and acidified with 6 *N* hydrochloric acid. The separated solid mass was filtered, washed with water, and recrystallized from acetone (60% yield), mp 230°.

Anal.—Calc. for $C_{10}H_{11}N_2O_2S$: C, 53.57; H, 5.35; N, 12.28. Found: C, 53.89; H, 5.45; N, 12.55.

5-[4-(Substituted Thiocarbamido)phenoxymethyl]-2-oxazolidinethiones (V–XIII)—A mixture of IV (0.01 mole) and the appropriate alkyl or aryl isothiocyanate (0.01 mole) in 40 ml of absolute ethanol was refluxed on a steam bath for 5 hr. Excess ethanol was removed by distillation. The solid mass thus obtained was filtered, washed thoroughly with water and ether, and recrystallized from ethanol. The various substituted 2-oxazolidinethiones (Table I) gave characteristic bands of C=S at 1051–1100 cm^{-1} and >NH at 3300–3340 cm^{-1} in their IR spectra.

Biological Methods—The ability of V–XIII to antagonize the uterotropic effect of diethylstilbestrol was determined using immature healthy female rats (3). The compounds were dissolved in propylene glycol (100%) and administered to 10 rats at a dose of 80 mg/kg ip every 24 hr for 3 days. The control group received an equivalent amount of propylene glycol. Diethylstilbestrol, 2 mg/kg sc, was administered on the 3rd day 6 hr after the last dose of the test compound or propylene glycol.

The decrease in the dry weight of the uterus caused by the test compounds in diethylstilbestrol-treated rats was recorded to evaluate the antiestrogenic activity of the oxazolidinethiones. The results were analyzed statistically using the Student *t* test. The approximate LD_{50} values were determined in mice by intraperitoneal administration of substituted oxazolidinethiones (4).

RESULTS AND DISCUSSION

The ability of V–XIII to antagonize the uterotropic effect of diethylstilbestrol at a dose of 80 mg/kg is recorded in Table II. Diethylstilbestrol treatment significantly increased the dry weight of the uterus to 22.9 ± 2.61 mg as compared to 8.4 ± 1.62 mg in the control rats ($p < 0.001$). All compounds reduced the diethylstilbestrol-induced increase in the dry weight of the uterus of rats. Most of these compounds produced statistically significant reductions in the dry weight of the uterus increased by diethylstilbestrol treatment; maximum reduction was observed with VIII and IX ($p < 0.05$), which possess a methyl or methoxy substituent at the 4-position of the phenyl moiety. Compounds with a 2-methylphenyl (VI) or alkyl (XIII) group showed considerably lower reduction. The introduction of an aromatic nucleus (V and VII–XII) in place of an alkyl substituent (XIII) increased the effectiveness, with the exception of VI where a decrease was observed.

These results failed to provide a definite structure–activity relationship of substituted 2-oxazolidinethiones. The decrease in the uterotropic effects of diethylstilbestrol provided evidence for the greater affinity of substituted 2-oxazolidinethiones without appreciable intrinsic activity toward estrogen receptors in the rat uterus. However, the ability of these compounds to alter the estrogen and progesterone balance, which may lead to the termination of pregnancy, could presumably permit their use as postcoital antifertility agents. Because of the low toxicity, as reflected by their approximate LD_{50} values of 400–>800 mg/kg, further study to

Table II—Antagonism to the Uterotropic Effect of Diethylstilbestrol by 5-Substituted 2-Oxazolidinethiones

Cytotoxic Agents from *Bursera klugii* (Burseraceae) I: Isolation of Sapelins A and B

S. D. JOLAD, R. M. WIEDHOPF, and J. R. COLE ˣ

Abstract □ A crude chloroform-soluble fraction of the ethanol extract of the leaves of *Bursera klugii* showed activity against two test systems, the P-388 lymphocytic leukemia (3PS) and the human epidermoid carcinoma of the nasopharynx (9KB). The PS activity was due to two constituents, sapelins A and B.

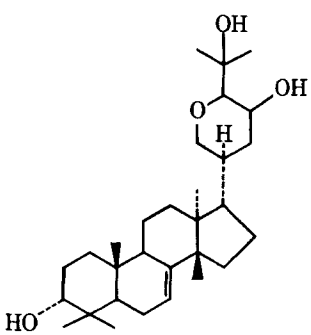
Keyphrases □ Sapelins A and B—isolated from ethanol extract of leaves of *Bursera klugii*, cytotoxic activity evaluated □ *Bursera klugii*—sapelins A and B isolated from ethanol extract of leaves, cytotoxic activity evaluated □ Cytotoxic activity—sapelins A and B evaluated

During a continuing search for plants having tumor inhibitory constituents, the chloroform-soluble fraction of the ethanol extract of the leaves of *Bursera klugii* Macbr (Burseraceae[1]) was shown to be active against the P-388 lymphocytic leukemia test system (3PS) and the human epidermoid carcinoma of the nasopharynx test system[2] (9KB). The activity against the PS test system was due to two constituents of the crude chloroform-soluble fraction.

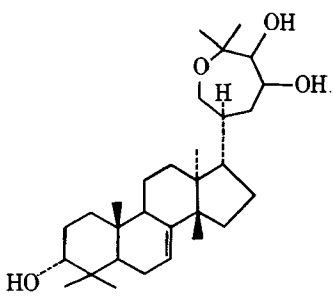
DISCUSSION

The two major constituents of the chloroform-soluble fraction were triterpenes, sapelin A (I) and sapelin B (II). These compounds were isolated previously from commercial sapele, *Entandrophragma cylindricum* Sprague (1). Isolation of these triterpenes was effected by solvent extraction followed by column chromatography and crystallization. Identification was made by elemental analysis; IR, NMR, and mass spectral data; and direct comparison with an authentic specimen.

Sapelin A demonstrated activities of 130, 136, 127, and 130% test/control (T/C) at 10.0, 5.0, 2.5, and 1.25 mg/kg, respectively. Sapelin B demonstrated activities of 136, 136, 130, and 138% T/C at the same doses, respectively. Activity in the PS system is defined as an increase in the survival of treated animals over that of control animals resulting in a T/C ≥ 125% (2).



I



II

EXPERIMENTAL[3]

The leaves of *B. klugii*, collected in Peru during August 1975, were ground and stored at −10° prior to extraction.

The ground material (7.72 kg) was extracted exhaustively in a Lloyd-type extractor with petroleum ether followed by 95% ethanol. The air-dried ethanol extract was subjected to partitioning between chloroform and water. The chloroform phase was first air dried and then vacuum dried. A 300-g portion of the residue was extracted with 5 liters of *n*-hexane in three portions by mechanical stirring. The hexane-insoluble residue was then extracted with 5 liters of ether in three portions using a magnetic stirrer.

The combined ether-soluble fraction, on concentration under vacuum followed by cooling in a freezer overnight, yielded a residue. TLC of this residue showed two spots as major constituents, one corresponding to sapelin A and the other to sapelin B. A 4-g portion of this residue was subjected to alumina (grade III, 160 g) dry column chromatography. Elution with ethyl acetate–benzene (1:1) afforded nearly pure sapelins

[1] Identification was confirmed by Dr. Robert E. Perdue, Medicinal Plant Resources Laboratory, Plant Genetics and Germ Plasm Institute, Beltsville, Md. A reference specimen was deposited in that herbarium.

[2] Division of Cancer Treatment, National Cancer Institute, National Institutes of Health, Bethesda, Md.

[3] Carbon and hydrogen analyses were carried out by Chemalytics, Inc., Tempe, Ariz. Melting points were determined on a Kofler hot-stage apparatus and are uncorrected. IR spectra were run on a Beckman IR-33. NMR and mass spectra were run using a Varian T-60 spectrometer and a Hewlett-Packard quadrupole spectrometer (model 5930), respectively.

determine the antifertility effects of 5-[4-(substituted thiocarbamido)-phenoxymethyl]-2-oxazolidinethiones is warranted.

Cytotoxic Agents from *Bursera klugii* (Burseraceae) I: Isolation of Sapelins A and B

S. D. JOLAD, R. M. WIEDHOPF, and J. R. COLE ˣ

Abstract □ A crude chloroform-soluble fraction of the ethanol extract of the leaves of *Bursera klugii* showed activity against two test systems, the P-388 lymphocytic leukemia (3PS) and the human epidermoid carcinoma of the nasopharynx (9KB). The PS activity was due to two constituents, sapelins A and B.

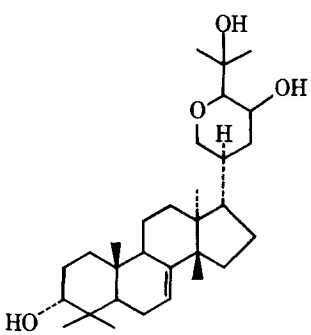
Keyphrases □ Sapelins A and B—isolated from ethanol extract of leaves of *Bursera klugii*, cytotoxic activity evaluated □ *Bursera klugii*—sapelins A and B isolated from ethanol extract of leaves, cytotoxic activity evaluated □ Cytotoxic activity—sapelins A and B evaluated

During a continuing search for plants having tumor inhibitory constituents, the chloroform-soluble fraction of the ethanol extract of the leaves of *Bursera klugii* Macbr (Burseraceae[1]) was shown to be active against the P-388 lymphocytic leukemia test system (3PS) and the human epidermoid carcinoma of the nasopharynx test system[2] (9KB). The activity against the PS test system was due to two constituents of the crude chloroform-soluble fraction.

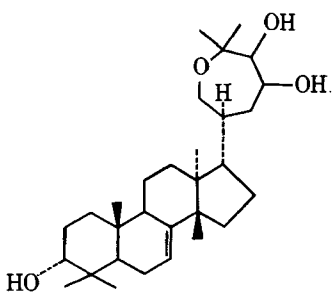
DISCUSSION

The two major constituents of the chloroform-soluble fraction were triterpenes, sapelin A (I) and sapelin B (II). These compounds were isolated previously from commercial sapele, *Entandrophragma cylindricum* Sprague (1). Isolation of these triterpenes was effected by solvent extraction followed by column chromatography and crystallization. Identification was made by elemental analysis; IR, NMR, and mass spectral data; and direct comparison with an authentic specimen.

Sapelin A demonstrated activities of 130, 136, 127, and 130% test/control (T/C) at 10.0, 5.0, 2.5, and 1.25 mg/kg, respectively. Sapelin B demonstrated activities of 136, 136, 130, and 138% T/C at the same doses, respectively. Activity in the PS system is defined as an increase in the survival of treated animals over that of control animals resulting in a T/C ≥ 125% (2).



I



II

EXPERIMENTAL[3]

The leaves of *B. klugii*, collected in Peru during August 1975, were ground and stored at −10° prior to extraction.

The ground material (7.72 kg) was extracted exhaustively in a Lloyd-type extractor with petroleum ether followed by 95% ethanol. The air-dried ethanol extract was subjected to partitioning between chloroform and water. The chloroform phase was first air dried and then vacuum dried. A 300-g portion of the residue was extracted with 5 liters of *n*-hexane in three portions by mechanical stirring. The hexane-insoluble residue was then extracted with 5 liters of ether in three portions using a magnetic stirrer.

The combined ether-soluble fraction, on concentration under vacuum followed by cooling in a freezer overnight, yielded a residue. TLC of this residue showed two spots as major constituents, one corresponding to sapelin A and the other to sapelin B. A 4-g portion of this residue was subjected to alumina (grade III, 160 g) dry column chromatography. Elution with ethyl acetate–benzene (1:1) afforded nearly pure sapelins

[1] Identification was confirmed by Dr. Robert E. Perdue, Medicinal Plant Resources Laboratory, Plant Genetics and Germ Plasm Institute, Beltsville, Md. A reference specimen was deposited in that herbarium.

[2] Division of Cancer Treatment, National Cancer Institute, National Institutes of Health, Bethesda, Md.

[3] Carbon and hydrogen analyses were carried out by Chemalytics, Inc., Tempe, Ariz. Melting points were determined on a Kofler hot-stage apparatus and are uncorrected. IR spectra were run on a Beckman IR-33. NMR and mass spectra were run using a Varian T-60 spectrometer and a Hewlett-Packard quadrupole spectrometer (model 5930), respectively.

A and B, which were further purified by decolorization followed by crystallization.

Sapelin A was obtained as long colorless thick needles from methanol, mp 219–220° with initial sweating. It was identical in all respects with the authentic specimen[3].

Anal.—Calc. for $C_{30}H_{50}O_4$: C, 75.9; H, 10.6; mol. wt. 474. Found: C, 75.31; H, 10.10; *m/e* 474 (M^+).

Sapelin B was obtained as tiny colorless needles from ethyl acetate–petroleum ether, mp 174–176° with initial sweating. It was identical in all respects with the authentic specimen.

Anal.—Calc. for $C_{30}H_{50}O_4$: C, 75.9; H, 10.6; mol. wt. 474. Found: C, 75.32; H, 10.13; *m/e* 474 (M^+).

Quinuclidine Chemistry: Autocondensation Reactions of 3-Quinuclidinone

R. A. SANDMANN [x] and W. C. McHUGH, Jr.

Abstract □ During the synthesis of 3-hydroxy-3-ethinylquinuclidine (I), two additional products were isolated and identified as (*E*)-3-[2-(3-oxoquinuclidine)]quinuclidylidene (III) and (*E*)-3-[2-(3-hydroxy-3-ethinylquinuclidine)]quinuclidylidene (V). The base-catalyzed autocondensation of 3-quinuclidinone resulted in the α,β-unsaturated ketone dimer (III) as a single isomer. The geometric configuration was deduced by examination of the NMR spectra of the methyl iodide salt. Compound V was thus the result of attack on the carbonyl carbon of III by the acetylide anion. The isolation and identification of these compounds clarified the reported differences in the physical properties of I and its analogs.

Keyphrases □ Quinuclidines, substituted—synthesized, structures, stereoisomers, and physical properties identified □ Autocondensation—3-quinuclidinone, products identified

It was necessary to synthesize significant quantities of 3-hydroxy-3-ethinylquinuclidine (I) as an intermediate in preparing a series of potential antidepressant agents. However, there was a disparity in the physical properties of I prepared by two different methods (1, 2). The synthetic method employed by Ernest (2) gave a compound melting at 192°, and that of Clemo and Hoggarth (1) gave a compound melting at 159°.

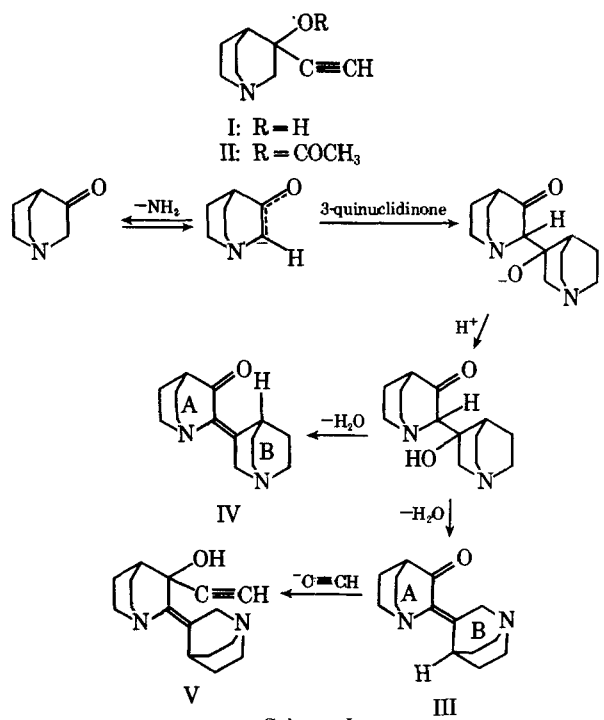
A clarification of these discrepancies by the synthesis of I and (*E*)-3-[2-(3-oxoquinuclidine)]quinuclidylidene (III) (mp 159°) is now reported.

DISCUSSION

The preparation of I involved dispersing acetylene gas through a tetrahydrofuran solution of 3-quinuclidinone and sodium amide. Three products were isolated, the major compound being I and having the same characteristics as demonstrated by Ernest (2). Mass spectra of the remaining two compounds indicated masses of 258 and 232. The difference in masses was 26, the molecular weight of acetylene. IR analysis of the 258 compound indicated a terminal acetylene (ν_{max} at 3240 and 2095 cm^{-1}). The IR spectrum for the 232 compound showed an α,β-unsaturated ketone (ν_{max} 1685 and 1615 cm^{-1}).

3-Quinuclidinone condenses with aldehydes under basic conditions (3–5); autocondensation under similar conditions and by the same aldol-type mechanism can now be demonstrated (Scheme I). A base such as sodium amide generates the enolate, which condenses by nucleophilic attack with another molecule of 3-quinuclidinone. The resultant dimer alkoxide is protonated, and dehydration of the ketol should result in a mixture of α,β-unsaturated ketone isomers, III and IV, its (*Z*)-isomer.

Conventional synthesis of III employed the use of potassium *tert*-butoxide in *tert*-butyl alcohol as the condensing agent for 3-quinuclidinone. The product (mol. wt. 232) proved to be identical with the one isolated from the acetylene–sodium amide reaction. Thus, the reaction between III and the acetylide ion gave (*E*)-3-[2-(3-hydroxy-3-ethinylquinuclidine)]quinuclidylidene (V, mol. wt. 258).



Scheme I

A and B, which were further purified by decolorization followed by crystallization.

Sapelin A was obtained as long colorless thick needles from methanol, mp 219–220° with initial sweating. It was identical in all respects with the authentic specimen[3].

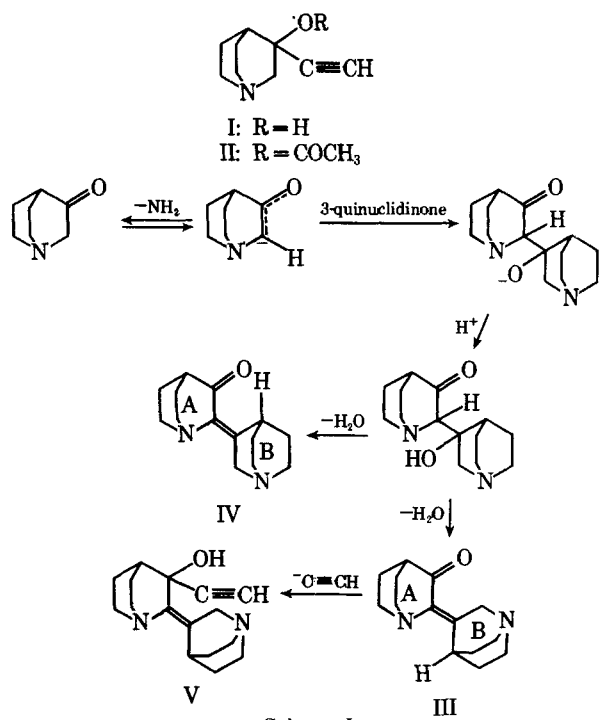
A clarification of these discrepancies by the synthesis of I and (*E*)-3-[2-(3-oxoquinuclidine)]quinuclidylidene (III) (mp 159°) is now reported.

DISCUSSION

The preparation of I involved dispersing acetylene gas through a tetrahydrofuran solution of 3-quinuclidinone and sodium amide. Three products were isolated, the major compound being I and having the same characteristics as demonstrated by Ernest (2). Mass spectra of the remaining two compounds indicated masses of 258 and 232. The difference in masses was 26, the molecular weight of acetylene. IR analysis of the 258 compound indicated a terminal acetylene (ν_{max} at 3240 and 2095 cm^{-1}). The IR spectrum for the 232 compound showed an α,β-unsaturated ketone (ν_{max} 1685 and 1615 cm^{-1}).

3-Quinuclidinone condenses with aldehydes under basic conditions (3–5); autocondensation under similar conditions and by the same aldol-type mechanism can now be demonstrated (Scheme I). A base such as sodium amide generates the enolate, which condenses by nucleophilic attack with another molecule of 3-quinuclidinone. The resultant dimer alkoxide is protonated, and dehydration of the ketol should result in a mixture of α,β-unsaturated ketone isomers, III and IV, its (*Z*)-isomer.

Conventional synthesis of III employed the use of potassium *tert*-butoxide in *tert*-butyl alcohol as the condensing agent for 3-quinuclidinone. The product (mol. wt. 232) proved to be identical with the one isolated from the acetylene–sodium amide reaction. Thus, the reaction between III and the acetylide ion gave (*E*)-3-[2-(3-hydroxy-3-ethinylquinuclidine)]quinuclidylidene (V, mol. wt. 258).



Scheme I

Basic conditions need not necessarily be employed in obtaining III. While attempting to make a dioxolone quinuclidine by reacting 3-quinuclidinone with glycolic acid and a catalytic amount of *p*-toluenesulfonic acid, a small amount of III was isolated.

Since only one isomer (III) was isolated, comparative spectral data between the (*E*)- and (*Z*)-configurations were not available to substantiate their geometry. However, inspection of molecular models of the two isomers indicated that the nitrogen in ring A (the ring containing the carbonyl) was sterically hindered by the bridgehead proton in ring B for the (*E*)-isomer. If this configuration was correct for the (*E*)-isomer, only the monomethyl iodide salt could be formed, since the formation of the dimethyl iodide salt would be impeded. NMR and elemental analysis confirmed that just one methyl iodide added, indicating the (*E*)-isomer.

Thermal and chemical techniques were employed to induce isomerization of the (*E*)-form. These attempts failed, as indicated by no significant changes in the NMR spectra. Again, models help to explain why the (*E*)-isomer would be favored over the (*Z*)-form. The model of the (*Z*)-isomer indicates very unfavorable steric interactions between the carbonyl oxygen in ring A and the bridgehead hydrogen on ring B. The space-filling models actually show that the valence orbitals of the bridgehead hydrogen and the oxygen overlap and that considerable twisting of the carbonyl is necessary to prevent this interaction. The rigidity of the quinuclidine cage maintains the bridgehead hydrogen in a fixed position. Thus, the carbonyl is forced out of its normal plane, increasing strain in the quinuclidine ring and causing a loss of conjugation with the exocyclic double bond. The (*Z*)-isomer is definitely the thermodynamically less stable configuration.

The rate of dimer formation is fairly rapid. Clemo and Hoggarth (1) used potassium metal in *tert*-amyl alcohol to generate the acetylide anion *in situ*. The result was the condensation product III, incorrectly identified as I. Ernest (2) generated the acetylide anion in liquid ammonia and then added 3-quinuclidinone, obtaining the expected product I. The formation of the (*E*)-isomer is stereoselective, and its formation should be considered in reactions using 3-quinuclidinone and base, especially in solvents that enhance aldol condensations.

The hydrochloride salt of 3-acetoxy-3-ethinylquinuclidine (II) was previously reported (6). Since the method of Clemo and Hoggarth (1) was used in obtaining I, the values are suspect. The results of Grob *et al.* (6) would not be corroborated, since they did not report the free base. Also, their melting points for the hydrochloride (234–240°) and the picrate (181–183°) were dissimilar to those found.

EXPERIMENTAL

3-Hydroxy-3-ethinylquinuclidine (I)—Sodium amide (10.5 g, 0.26 mole) was suspended in 90 ml of tetrahydrofuran, which had been dried over potassium hydroxide pellets and distilled. Dry acetylene gas was bubbled into the suspension; positive pressure was maintained using a mercury trap. 3-Quinuclidinone (32.3 g, 0.26 mole), which had been recrystallized from petroleum ether, was dissolved in 90 ml of dry tetrahydrofuran and dropped into the mixture over 4 hr. The reaction was allowed to continue for another 19 hr. After that time, most solvent was removed *in vacuo*. Ice and then ice water were added to the residue. The precipitate that resulted was filtered and dried, giving 25.47 g. It was recrystallized from ethanol–water, giving 13.52 g (34.76%), mp 191–193°; IR (KBr): 3225 (≡C—H) and 2090 (C≡C) cm^{-1}.

Anal.—Calc. for $C_9H_{13}NO$: C, 71.52; H, 8.60; N, 9.27. Found: C, 71.49; H, 8.86; N, 9.23.

The hydrochloride salt, recrystallized from 2-propanol, gave a melting point of 198–199°.

(*E*)-3-[2-(3-Oxoquinuclidine)]quinuclidylidene (III)—*Method A: Dihydrochloride*—The basic solution from which I was filtered was extracted with methylene chloride, decolorized with activated charcoal, and dried over magnesium sulfate. Hydrogen chloride gas was bubbled into the methylene chloride, and the solvent was removed *in vacuo*. The residue was recrystallized from water–methanol–2-propanol, yielding 2 g of white needle crystals, mp 275–276°. The IR spectrum indicated a hydrate, as was confirmed by Karl Fischer titration.

Anal.—Calc. for $C_{14}H_{22}Cl_2N_2O{\cdot}H_2O$: C, 52.05; H, 7.49; N, 8.67. Found: C, 51.99; H, 7.58; N, 8.37.

Method A: Free Base—The dihydrochloride was dissolved in water and made basic with 10% NaOH solution. This solution was extracted with methylene chloride and dried over magnesium sulfate. The solvent was removed *in vacuo*, and the residue was recrystallized from absolute ether (mp 159–160°).

Method B—3-Quinuclidinone (50 g, 0.4 mole) was dissolved in 200 ml of *tert*-butyl alcohol containing 23 g (0.205 mole) of potassium *tert*-butoxide. This mixture was stirred under a nitrogen atmosphere for 4 hr, giving a red-brown solution. After that time, the solvent was removed *in vacuo*. Water was added to the residue, this solution was extracted with hot benzene, and the benzene was dried over magnesium sulfate. The solvent was removed *in vacuo*, giving 42.7 g (92%) of a light-yellow powder, mp 148–157°, soften 138°. Recrystallization in absolute ether gave prism crystals having a green tint, mp 159–160°; IR (KBr): 1685 (C=O) and 1615 (conjugated C=C) cm^{-1}; NMR ($CDCl_3$): δ 1.90 [m, 8H, $(CH_2)_2C$], 2.5 (quintet, 1H, bridgehead hydrogen, ring A), 2.87 [t, 8H, $(CH_2)_2N$], 3.33 (quintet, 1H, bridgehead hydrogen, ring B), and 3.83 (s, 2H, $=CCH_2N$) ppm.

Anal.—Calc. for $C_{14}H_{20}N_2O$: C, 72.38; H, 8.68; N, 12.06. Found: C, 72.45; H, 8.96; N, 11.87.

The methyl iodide salt was recrystallized from methanol–acetone–absolute ether, mp 225–226°.

Anal.—Calc. for $C_{15}H_{23}IN_2O$: C, 48.14; H, 6.19; N, 7.48. Found: C, 47.20; H, 6.29; N, 7.48.

The picrate was recrystallized from ethanol, mp 207–208°.

(*E*)-3-[2-(3-Hydroxy-3-ethinylquinuclidine)]quinuclidylidene (V)—From the ethanol–water solution from which I was recrystallized, V was isolated by a number of selective recrystallizations using methanol until TLC indicated one component [silica gel developed with chloroform–methanol–ammonium hydroxide (85:15:1)]. The yield was 550 mg, mp 245–247°; IR (KBr): 3240 (≡CH) and 2090 (C≡C) cm^{-1}. Preparation of the hydrochloride salt of V was accomplished by preparing a solution in hot tetrahydrofuran and treating with hydrogen chloride gas. The solvent was removed *in vacuo*, and the solid was recrystallized from methanol–2-propanol, mp 259–260°.

Anal.—Calc. for $C_{16}H_{24}Cl_2N_2O$: C, 58.04; H, 7.25; N, 8.46. Found: C, 57.82; H, 7.35; N, 8.12.

3-Acetoxy-3-ethinylquinuclidine (II)—To 7.85 g (0.52 mole) of I was added 85 ml of acetic anhydride and 550 mg of zinc chloride. This mixture was refluxed for 2 hr. After that time, the excess acetic anhydride was distilled off under reduced pressure to a volume of approximately 15 ml. Ice was then added. The pH was adjusted to 12 with cold saturated potassium carbonate, and the solution was extracted with chloroform. The chloroform was dried over magnesium sulfate, and the solvent was removed *in vacuo*. An oil resulted and then crystallized upon scratching. Absolute ether–acetone was used for recrystallization. Large colorless prisms resulted, 4.61 g (46%), mp 89–91°; IR (KBr): 3250 (≡CH), 2100 (C≡C), and 1730 (C=O) cm^{-1}.

Anal.—Calc. for $C_{11}H_{15}NO_2$: C, 68.39; H, 7.77; N, 7.25. Found: C, 68.49; H, 7.99; N, 7.10.

The hydrochloride had a melting point of 217–219° dec., and the picrate had a melting point of 149°.

Cytotoxic Agents from *Bursera morelensis* (Burseraceae): Deoxypodophyllotoxin and a New Lignan, 5′-Desmethoxydeoxypodophyllotoxin

S. D. JOLAD, R. M. WIEDHOPF, and J. R. COLE ˣ

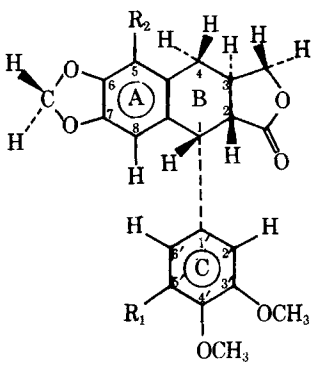
Abstract □ The isolation and identification of deoxypodophyllotoxin and a new lignan, 5′-desmethoxydeoxypodophyllotoxin, from the dried exudate of *Bursera morelensis* (Burseraceae) are reported. Deoxypodophyllotoxin showed high activity in the KB and PS test systems; the new lignan, although highly active against the KB test system, demonstrated only marginal activity against the PS test system. A structure is suggested for the new lignan, which was named morelensin.

Keyphrases □ Deoxypodophyllotoxin—and 5′-desmethoxy derivative, isolated from dried exudate of *Bursera morelensis*, cytotoxic activity evaluated □ *Bursera morelensis*—deoxypodophyllotoxin and 5′-desmethoxy derivative isolated from dried exudate, cytotoxic activity evaluated □ Cytotoxic activity—deoxypodophyllotoxin and 5′-desmethoxy derivative evaluated

During a continuing search for plants having tumor-inhibitory constituents, the ethanol extract of the dried exudate of the Mexican plant *Bursera morelensis* (Burseraceae[1]) demonstrated biological activity against two test systems, the P-388 lymphocytic leukemia (PS) and the human epidermoid carcinoma of the nasopharynx[2] (KB). The activity against these two test systems was due to two constituents, deoxypodophyllotoxin (I) and a new lignan, 5′-desmethoxydeoxypodophyllotoxin (II), which was named morelensin.

RESULTS AND DISCUSSION

Exhaustive extraction of the dried exudate of *B. morelensis* with ethanol, followed by partition of the ethanol extract between chloroform and water, yielded a chloroform-soluble syrup. The syrup was separated into methanol-soluble and methanol-insoluble fractions. The methanol-insoluble fraction was dissolved in ether, and precipitation with isopropyl ether yielded a gum. Extraction of the gum with ether afforded almost a single-component residue. On crystallization, this residue yielded a known lignan, I, mp 167°. Compound I [$C_{22}H_{22}O_7$, *m/e* 398 (M^+)] was identified by its IR, NMR, and mass spectral properties and by direct comparison with an authentic specimen.



I: $R_1 = OCH_3, R_2 = H$ III: $R_1 = H, R_2 = OCH_3$
II: $R_1 = R_2 = H$

The ether-soluble fraction was essentially a mixture of two components. Separation of these two components by silica gel column chromatography and subsequent crystallization yielded, in addition to I, a new lignan, II, mp 181°. This new compound was 1-(3′,4′-dimethoxyphenyl)-3-hydroxymethyl-6,7-methylenedioxy-1,2,3,4-tetrahydronaphthalene-2-carboxylic acid lactone.

The molecular formula of II ($C_{21}H_{20}O_6$) was established by carbon and hydrogen analysis and mass spectrometry. The intense molecular ion peak (*m/e* 368) in the mass spectrum of II immediately suggested that the new lignan was desmethoxy-I. Biogenetically, the 5′-desmethoxy compound (*i.e.*, Structure II) is most favorable. Support of this hypothesis was found in the spectra of this new lignan. The IR spectrum indicated the absence of hydroxyl groups and the presence of methoxy (2840 cm^{-1}), methylenedioxy (2780 cm^{-1}), and γ-lactone (1775 cm^{-1}) groups. The NMR spectrum supported these findings, exhibiting signals for two methoxy groups (δ 3.79 and 3.86, both three-proton singlets) and one methelenedioxy group (δ 5.90, two-proton singlet). A comparison of the NMR signals contributed by the tetrahydronaphthalene-γ-lactone moiety of Compounds I and II indicated that the A, B, and lactone rings of both compounds were identical.

The proposed substitution pattern in ring C of II is identical to the pattern of 5′-desmethoxy-β-peltatin-A methyl ether (III), previously isolated from *B. fagaroides* (Burseraceae) (1). Indeed, a comparison of the aromatic region of the NMR spectra of II and III (subtracting A-ring signals) showed nearly identical signals for C-ring protons. This proposed C-ring substitution in II was supported by its mass spectrum. The significant peak at *m/e* 77 can be visualized as having arisen from the dimethoxybenzene ion (*m/e* 138) *via* the protonated oxepin ion (*m/e* 95) followed by the expulsion of a molecule of water. Among the three isomeric dimethoxybenzenes, only the *o*-isomer displays a mass spectrum with this fragmentation pattern (2). Morelensin (II) was optically active, $[\alpha]_D^{24}$ −125°, indicating one A-type isomer (*cis*, 1/2; *trans*, 2/3). Since the absolute configuration of III was established previously by X-ray crystallography (3), the stereochemistry of II was assumed to be identical to that of III.

Compound I demonstrated activities of 194 (one cure) and 161% test/control (T/C) at 12.50 and 6.25 mg/kg, respectively. Compound II demonstrated activity of 127% test/control (T/C) at 50 mg/kg. Activity in the PS test system is defined as an increase in the survival of treated animals over that of control animals resulting in a T/C ≥ 125% (4).

In the KB test system, I and II demonstrated activities of 2.48×10^{-4} and 3.99×10^{-4} μg/ml, respectively. Activity in the KB test system is defined as $ED_{50} \leq 20$ μg/ml (5).

EXPERIMENTAL[3]

The dried exudate of *B. morelensis*, collected in Mexico during October 1974, was stored at −10° prior to extraction.

The exudate (0.68 kg) was extracted exhaustively with 95% ethanol. The air-dried chloroform-soluble fraction (syrup) was dried further as much as possible under vacuum to a total of 80 g and then dissolved in a minimum amount of methanol. The solution was left in a freezer for 2 days, and the resulting residue was separated by decanting the supernate. The residue was then dissolved in a minimum amount of ether, and isopropyl ether was added until the solution was slightly turbid. The mixture was left in a freezer overnight, and the gummy residue that separated was removed by decantation. Trituration of the residue with ether followed by stirring with a magnetic stirrer gave a colorless residue, which was filtered. The residue (2.13 g), which on TLC showed essentially

[1] Identification was confirmed by Dr. Robert E. Purdue, Medicinal Plant Resources Laboratory, Plant Genetics and Germ Plasma Institute, Beltsville, Md. A reference specimen was deposited in that herbarium.

Modified Electron-Capture GLC Assay for Salsolinol in Brain Tissue

PATRICK J. O'NEILL [*] and RALF G. RAHWAN [x]

Abstract □ A modified assay for a neuroamine-derived tetrahydroisoquinoline, salsolinol, is presented. It combines the ease and rapidity of solvent extraction from brain tissue with the sensitivity of electron-capture GLC. Detection of salsolinol (1,2,3,4-tetrahydro-1-methyl-6,7-isoquinolinediol), the alkaloid derived from condensation of dopamine and acetaldehyde, at levels of 5–10 ng/g of brain tissue is possible. The advantages afforded by the modifications are discussed in relation to existing procedures.

Keyphrases □ Salsolinol—electron-capture GLC analysis, mouse brain tissue □ GLC, electron capture—analysis, salsolinol in mouse brain tissue □ Tetrahydroisoquinolines, substituted—salsolinol, electron-capture GLC analysis in mouse brain tissue □ Alkaloids—salsolinol, electron-capture GLC analysis in mouse brain tissue

The *in vivo* formation of tetrahydroisoquinoline alkaloids from aldehydes and endogenous biogenic amines has been suggested to mediate some effects of alcohol (1, 2). These alkaloids possess a variety of pharmacological actions *in vitro* and *in vivo* (3). Tetrahydropapaveroline (the condensation product of dopamine with dopaldehyde) and salsolinol (1,2,3,4-tetrahydro-1-methyl-6,7-isoquinolinediol) (the condensation product of acetaldehyde with dopamine) were detected in the urine of humans (4) and in rat brain (5, 6). Likewise, tetrahydroprotoberberines (the cyclization derivatives of tetrahydropapaveroline) were recovered from human urine (7).

The analyses used in some of these studies (4, 5, 7) involved costly mass fragmentography. Recently, a sensitive electron-capture GLC assay was reported for salsolinol in rat brain (8). However, the tissue extraction method was time consuming (adsorption onto and elution from alumina, followed by overnight lyophilization) and presented additional problems such as inadequate buffering of the extract prior to alumina adsorption and incomplete removal of the derivatizing reagent prior to injection into the chromatograph. Even with appropriate modifications to eliminate the latter problems, the long extraction procedure still proved undesirable.

The present report describes a more rapid and convenient method for the detection of salsolinol in mouse brain using a simplified solvent extraction and electron-capture GLC system. Detection of salsolinol at levels of 5–10 ng/g of brain tissue [approximately 1% of the endogenous dopamine level (9)] is possible with this method.

EXPERIMENTAL

Extraction—The extraction method from tissue is essentially that of Maruyama and Takemori (9) with some modifications. A single mouse brain was added to an all-glass grinding vessel[1] containing 1 ml of 0.05 *N* oxalic acid, saturated with sodium chloride, and 3.5 ml of 25% 1-butanol in 2-propanol and was homogenized. Standards were added at this point and mixed by passing the pestle through the homogenate.

The homogenate was transferred to a conical test tube and centrifuged at 3000×*g* for 5 min in a clinical centrifuge. The lower phase was discarded, and a 3-ml aliquot of the upper solvent phase was removed. Hexane, 3 ml, and 0.5 ml of 0.5 *M* sodium phosphate buffer (pH 6.5) were added to this aliquot, and the mixture was shaken for 5 min, followed by a 5-min centrifugation. The upper phase was discarded, and a 0.5-ml

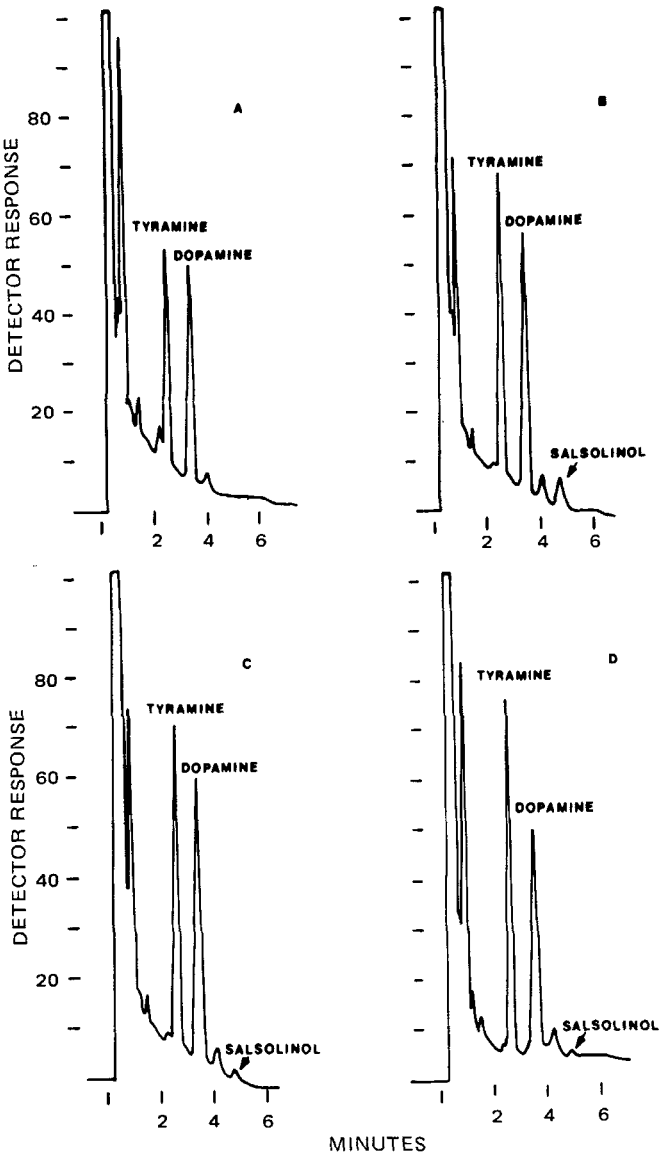

Figure 1—*Chromatograms of mouse brain extracts. Key: A, single mouse brain with 500 ng of tyramine added; B, single mouse brain with 500 ng of tyramine and 40 ng of salsolinol added; C, single mouse brain with 500 ng of tyramine and 10 ng of salsolinol added; and D, single mouse brain with 500 ng of tyramine and 4 ng of salsolinol added. Samples of 5 μl were injected at attenuation 512; attenuation was changed to 256 after tyramine appeared. See text for conditions. The peak immediately preceding tyramine corresponds to norepinephrine.*

aliquot of the aqueous lower phase was saturated with sodium chloride and reextracted with 0.5 ml of 25% 1-butanol in 2-propanol. The lower phase was discarded, and 0.5 ml of the upper solvent phase was transferred to another tube and evaporated to dryness under nitrogen; the residue was used for derivatization.

Derivatization—Derivatization of the compounds was carried out using a modification of the method of Bigdeli and Collins (8). Acetonitrile, 0.2 ml, and 0.05 ml of heptafluorobutyric anhydride[2] were added to the nitrogen-dried residue and allowed to react at room temperature for 30 min. The samples were evaporated to dryness under nitrogen, and the residue was dissolved in 1 ml of benzene. Immediately prior to assay, each sample was washed with 5 ml of a saturated solution of sodium borate (10) by shaking, followed by a brief centrifugation to separate the aqueous and organic phases. A portion (2–5 μl) of the upper benzene layer was injected into the chromatograph.

Table I—Retention Times and Recoveries for Tyramine, Dopamine, and Salsolinol

Compound	Retention Time, min	Recovery[a], % ± *SEM*
Tyramine	2.6	38.8 ± 1.13[b]
Dopamine	3.5	68.5 ± 5.07[c]
Salsolinol	4.8	62.3 ± 2.14[d]

[a] Mean of six to 16 determinations. [b] Recovery was calculated from 500 ng of added tyramine. [c] Dopamine recovery was estimated on the basis of an average whole brain content of 350 ng (9). [d] Recovery was calculated from 10–100 ng of added salsolinol. Recovery was linear over the range of 4–400 ng of added salsolinol.

Instrumentation—A gas chromatograph[3] with a ^{63}Ni-electron-capture detector was used for the analyses. A 1.83-m (6-ft) glass column (2 mm i.d.) packed with 3% OV-17 on 100–120-mesh Gas Chrom Q[4] was used. Temperatures were: injector, 250°; oven, 150°; and detector, 300°. The mobile phase was argon–methane (95:5) at a flow rate of 20 ml/min.

Quantitation—The peak height ratio method (11) was employed to estimate quantities of salsolinol. Tyramine[2] (500 ng) was added to each homogenate as the internal standard; various amounts of authentic salsolinol[5] (4–400 ng) were also added. A standard curve was constructed by plotting the ratio of the relative peak height of salsolinol to the relative peak height of tyramine *versus* the quantity of authentic salsolinol in the sample. Regression lines were fitted by computer analysis using the method of least squares.

RESULTS AND DISCUSSION

Chromatograms obtained are shown in Fig. 1. Figure 1A represents a brain extracted as described under *Experimental* but with no salsolinol added. Figures 1B, 1C, and 1D represent single brains with 40, 10, and 4 ng of salsolinol added, respectively. The on-column lower limit of detection sensitivity for salsolinol under the conditions of the assay (attenuation = 256) was approximately 10 pg. Identity of the peaks was confirmed by comparison of retention times of derivatized authentic standards or by addition of derivatized authentic standards to the injection solution.

Recoveries and retention times for tyramine, dopamine, and salsolinol are shown in Table I; recoveries were slightly higher than those reported by Bigdeli and Collins (8) for dopamine and salsolinol. Regression analysis indicated that the method was linear over the tested range of 4–400 ng of added salsolinol. Norepinephrine was neither well extracted nor sensitive to detection by this method.

The assay described in this report differs in several respects from the extraction and assay procedures previously reported (8, 9). Maruyama and Takemori (9) suggested adjusting the aqueous phase (after separation from hexane) to pH 2 with hydrochloric acid prior to saturation with sodium chloride and extraction with 25% 1-butanol in 2-propanol. However, preliminary experiments using this method gave low recoveries. Furthermore, adding no acid gave the maximum recovery for salsolinol and dopamine, the compounds of major interest for *in vivo* studies conducted in this laboratory (12). The entire extraction procedure described here takes approximately 3 hr to bring as many as 16 samples to the derivatizing step; the alumina adsorption method of Bigdeli and Collins (8) involves an extensive time period, even including overnight lyophilization to reach this point.

Bigdeli and Collins (8) suggested a ratio of 0.2 ml of acetonitrile to 0.4 ml of heptafluorobutyric anhydride during derivatization. In the present method, the quantity of heptafluorobutyric anhydride can be reduced to 0.05 ml without any decrease in efficiency while derivatizing as much as 1 mg of any of the amines. Therefore, a significant saving of an expensive reagent is realized, and the amount of unreacted heptafluorobutyric anhydride that must be removed prior to the electron-capture GLC assay is substantially reduced.

In this respect, the use of benzene as a solvent [rather than ethyl acetate (8)] allows a significant improvement. Any traces of unreacted heptafluorobutyric anhydride left in the GLC injection solution make it virtually impossible to obtain meaningful results. "Washing" the sample with a saturated solution of sodium borate (see *Experimental*) removes

[3] Model 5713A, Hewlett-Packard, Palo Alto, Calif.
[4] Applied Science Laboratories, State College, Pa.
[5] Aldrich Chemical Co., Milwaukee, Wis.

any traces of the derivatizing reagent (10), thus removing the interfering contaminant; however, this washing is not possible with ethyl acetate as the injection solvent (8), since the latter is miscible with the sodium borate solution. Therefore, benzene was selected since the derivatized compounds are freely soluble in it, it is not miscible with aqueous solutions, and no significant loss occurs from this organic layer by washing with the saturated solution of sodium borate.

The sensitivity achieved for salsolinol in the present method is comparable to that for tetrahydropapaveroline using GC–mass spectrometry (5). Sandler *et al.* (4) also used a GC–mass spectrometric method for salsolinol, but they did not report the absolute sensitivity of their method.

Preliminary *in vivo* experiments utilizing this method to investigate the role of salsolinol in the effects of alcohol were reported elsewhere (12).

Quantitative Determinations of Codeine Phosphate, Guaifenesin, Pheniramine Maleate, Phenylpropanolamine Hydrochloride, and Pyrilamine Maleate in an Expectorant by High-Pressure Liquid Chromatography

V. DAS GUPTA ˣ and A. G. GHANEKAR

Abstract □ The quantitative determinations of codeine phosphate, guaifenesin, pheniramine maleate, phenylpropanolamine hydrochloride, and pyrilamine maleate in a liquid dosage form are described. All active and inactive ingredients (sodium benzoate and FD&C Yellow No. 5 dye) can be separated with high-pressure liquid chromatography except the two antihistamines, pheniramine maleate and pyrilamine maleate. Pheniramine maleate is determined colorimetrically, and pyrilamine maleate is determined either by difference or spectrophotometrically. The methods are simple, short, accurate, and precise. The standard deviations are reported.

Keyphrases □ Codeine phosphate—high-pressure liquid chromatographic analysis, cough syrup □ Guaifenesin—high-pressure liquid chromatographic analysis, cough syrup □ Phenylpropanolamine hydrochloride—high-pressure liquid chromatographic analysis, cough syrup □ Pheniramine maleate—colorimetric analysis, cough syrup □ Pyrilamine maleate—spectrophotometric analysis, cough syrup □ High-pressure liquid chromatography—analyses, codeine phosphate, guaifenesin, and phenylpropanolamine hydrochloride, cough syrup □ Colorimetry—analysis, pheniramine maleate, cough syrup □ Spectrophotometry—analysis, pyrilamine maleate, cough syrup □ Antitussives—cough syrup ingredients analyzed by high-pressure liquid chromatography, colorimetry, and spectrophotometry

A commonly used cough syrup contains an antitussive agent, codeine phosphate, an expectorant, guaifenesin, two antihistamines, pheniramine maleate and pyrilamine maleate, and a decongestant, phenylpropanolamine hydrochloride. In addition to active ingredients, most cough syrups contain dye(s), preservative(s), flavor(s), and sweetening agent(s). Due to interferences, no easy methods are available for the quantitative determinations of various ingredients in such a cough syrup. The purpose of these investigations was to develop easy, simple, short, and accurate methods for the quantitative determinations of various ingredients in such a cough syrup by high-pressure liquid chromatography (HPLC).

EXPERIMENTAL

Chemicals and Reagents—All chemicals and reagents including codeine phosphate (I), guaifenesin (II), pheniramine maleate (III), phenylpropanolamine hydrochloride (IV), and pyrilamine maleate (V) were ACS, USP, or NF grade and were used without further purification.

Apparatus—A high-pressure liquid chromatograph[1] equipped with a fixed wavelength (254 nm) detector and recorder[2] was used.

Column—A nonpolar column[3] consisting of a monomolecular layer of octadecyltrichlorosilane permanently bonded to Si–C (30 cm long and 4 mm i.d.) was used.

Chromatographic Conditions—The chromatographic solvent was 0.05 *M* KH_2PO_4 in water containing 13% (v/v) methanol. The temperature was ambient, and the solvent flow rate was 2.0 ml/min (at an inlet

[1] Waters ALC 202 equipped with a U6K universal injector.

[3] Waters μ-Bondapak/C_{18}, Catalog No. 27324 (prepacked column).

any traces of the derivatizing reagent (10), thus removing the interfering contaminant; however, this washing is not possible with ethyl acetate as the injection solvent (8), since the latter is miscible with the sodium borate solution. Therefore, benzene was selected since the derivatized compounds are freely soluble in it, it is not miscible with aqueous solutions, and no significant loss occurs from this organic layer by washing with the saturated solution of sodium borate.

The sensitivity achieved for salsolinol in the present method is comparable to that for tetrahydropapaveroline using GC–mass spectrometry (5). Sandler *et al.* (4) also used a GC–mass spectrometric method for salsolinol, but they did not report the absolute sensitivity of their method.

Preliminary *in vivo* experiments utilizing this method to investigate the role of salsolinol in the effects of alcohol were reported elsewhere (12).

Quantitative Determinations of Codeine Phosphate, Guaifenesin, Pheniramine Maleate, Phenylpropanolamine Hydrochloride, and Pyrilamine Maleate in an Expectorant by High-Pressure Liquid Chromatography

V. DAS GUPTA ˣ and A. G. GHANEKAR

Abstract □ The quantitative determinations of codeine phosphate, guaifenesin, pheniramine maleate, phenylpropanolamine hydrochloride, and pyrilamine maleate in a liquid dosage form are described. All active and inactive ingredients (sodium benzoate and FD&C Yellow No. 5 dye) can be separated with high-pressure liquid chromatography except the two antihistamines, pheniramine maleate and pyrilamine maleate. Pheniramine maleate is determined colorimetrically, and pyrilamine maleate is determined either by difference or spectrophotometrically. The methods are simple, short, accurate, and precise. The standard deviations are reported.

Keyphrases □ Codeine phosphate—high-pressure liquid chromatographic analysis, cough syrup □ Guaifenesin—high-pressure liquid chromatographic analysis, cough syrup □ Phenylpropanolamine hydrochloride—high-pressure liquid chromatographic analysis, cough syrup □ Pheniramine maleate—colorimetric analysis, cough syrup □ Pyrilamine maleate—spectrophotometric analysis, cough syrup □ High-pressure liquid chromatography—analyses, codeine phosphate, guaifenesin, and phenylpropanolamine hydrochloride, cough syrup □ Colorimetry—analysis, pheniramine maleate, cough syrup □ Spectrophotometry—analysis, pyrilamine maleate, cough syrup □ Antitussives—cough syrup ingredients analyzed by high-pressure liquid chromatography, colorimetry, and spectrophotometry

A commonly used cough syrup contains an antitussive agent, codeine phosphate, an expectorant, guaifenesin, two antihistamines, pheniramine maleate and pyrilamine maleate, and a decongestant, phenylpropanolamine hydrochloride. In addition to active ingredients, most cough syrups contain dye(s), preservative(s), flavor(s), and sweetening agent(s). Due to interferences, no easy methods are available for the quantitative determinations of various ingredients in such a cough syrup. The purpose of these investigations was to develop easy, simple, short, and accurate methods for the quantitative determinations of various ingredients in such a cough syrup by high-pressure liquid chromatography (HPLC).

EXPERIMENTAL

Chemicals and Reagents—All chemicals and reagents including codeine phosphate (I), guaifenesin (II), pheniramine maleate (III), phenylpropanolamine hydrochloride (IV), and pyrilamine maleate (V) were ACS, USP, or NF grade and were used without further purification.

Apparatus—A high-pressure liquid chromatograph[1] equipped with a fixed wavelength (254 nm) detector and recorder[2] was used.

Column—A nonpolar column[3] consisting of a monomolecular layer of octadecyltrichlorosilane permanently bonded to Si–C (30 cm long and 4 mm i.d.) was used.

Chromatographic Conditions—The chromatographic solvent was 0.05 *M* KH_2PO_4 in water containing 13% (v/v) methanol. The temperature was ambient, and the solvent flow rate was 2.0 ml/min (at an inlet

[1] Waters ALC 202 equipped with a U6K universal injector.

[3] Waters μ-Bondapak/C_{18}, Catalog No. 27324 (prepacked column).

Table I—Assay Results on Various Ingredients Using High-Pressure Liquid Chromatography

Syrup	Percent of Label Claim Found			
	I	II	III + V Combination	IV
Lot A	99.8	101.3	99.2	100.8
SD^a	1.96	1.08	1.24	2.32
Commercial sample	—[b]	106.9	104.3	55.3

[a] Based on four readings. [b] Had no codeine; *i.e.*, the manufacturer did not claim any on the label.

pressure of approximately 2000 psig). The chart speed was 30.5 cm/hr; the attenuation unit for full scale deflection was 0.04, which was changed to 0.08 after 10 min.

Solutions for HPLC—A standard solution containing 20 mg of I, 200 mg of II, 12.5 mg each of III and V, and 25 mg of IV/100 ml of chromatographic solvent was prepared using a simple solution method. Solutions of sodium benzoate (50 μg/ml) and FD&C No. 5 (4 μg/ml) in the chromatographic solvent also were prepared.

Solutions for Colorimetric Analysis of Pheniramine Maleate—A standard solution containing 50 μg/ml of pheniramine maleate in approximately 0.25 *N* HCl was prepared. Cyanogen bromide, 4 g/100 ml of water, also was prepared. A buffer was prepared according to a reported procedure (1).

Solution for Spectrophotometric Analysis of Pyrilamine Maleate—A standard solution containing 20 μg/ml of pyrilamine maleate in approximately 0.1 *N* HCl was prepared. Other solutions were prepared as needed.

Cough Syrup—Lot A cough syrup was prepared containing the following: 200 mg of codeine phosphate, 2 g of guaifenesin, 125 mg of pheniramine maleate, 250 mg of phenylpropanolamine hydrochloride, 125 mg of pyrilamine maleate, 1 ml of dye solution (0.8% FD&C Yellow No. 5 in water), 1 drop of flavor[4], 50 g of sugar, 5 mg of methylparaben, 2 mg of propylparaben, and 5 ml of alcohol.

The flavor was dissolved in alcohol. In 40 ml of water, sugar and guaifenesin were dissolved with the aid of heat and then cooled to room temperature. Then the remaining ingredients were added. The aqueous and alcoholic solutions were mixed and diluted to 100 ml with water.

Two additional lots, B (without pheniramine maleate) and C (without pyrilamine maleate), were prepared.

Assay Procedure for Cough Syrup—First 10.0 ml of the cough syrup (Lot A) was diluted to 100 ml with the chromatographic solvent, and then 10 μl was injected. For purposes of comparison, an identical volume of the standard solution was injected after the assay was eluted.

Since preliminary investigations indicated that the peak area of each ingredient was directly related to the concentration (range for I was 1.4–4 μg, range for II was 10–30 μg, range for III and V in combination was 1.25–5 μg, and range for IV was 1.25–5 μg), the results were calculated by direct comparison of the peak areas as follows:

$$\frac{A_a}{A_s} = \text{percent of label claim found} \qquad \text{(Eq. 1)}$$

where A_a = peak area of the assay sample, and A_s = peak area of the standard solution. The detector's response is presented in Fig. 1, and the results are presented in Table I.

A commercial sample was assayed according to the described procedure. The detector's response is presented in Fig. 2, and the results are presented in Table I.

To identify the additional peaks in the commercial sample, 10 μl each of the dye solution and of the sodium benzoate solution was injected. The detector's response is presented in Fig. 3.

Colorimetric Assay Procedure for Pheniramine Maleate—First 4.0 ml of the cough syrup (Lot A) was diluted to 100 ml with 0.25 *N* HCl and then to 1.0 ml of this dilution were added 7.0 ml of the buffer and 3.0 ml of the cyanogen bromide solution. Immediately after 13 min[5], the absorbance value of the color developed at 480 nm was measured against a blank prepared by substituting 3.0 ml of water for the cyanogen bromide solution. Concurrently, the absorbance value of the standard solution of pheniramine maleate (50 μg/ml) was determined.

Since preliminary investigations indicated that Beer's law was followed

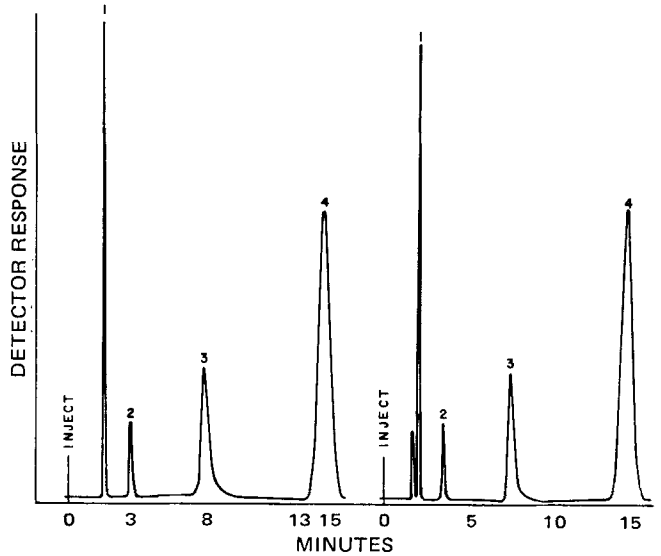

Figure 1—*HPLC analysis of Lot A cough syrup (for chromatographic conditions, see text). Peaks 1, 2, 3, and 4 are two antihistamines in combination (pheniramine maleate and pyrilamine maleate), phenylpropanolamine hydrochloride, codeine phosphate, and guaifenesin, respectively, from a standard solution (first injection) and cough syrup Lot A (second injection).*

(range of 30–80 μg/ml of the standard solution) and that there was no interference from other active and inactive ingredients, the results were calculated by a direct comparison of the absorbance values:

$$\frac{(A_{480})_a}{(A_{480})_s} = \text{percent of label claim} \qquad \text{(Eq. 2)}$$

where $(A_{480})_a$ = absorbance value of the assay sample, and $(A_{480})_s$ = absorbance value of the standard solution.

A commercial sample was also assayed according to the procedure reported (Table II).

Assay Procedure for Pyrilamine Maleate—First 2.0 ml of the syrup (Lot A) was diluted to 100 ml with approximately 0.1 *N* HCl solution and then the absorbance value at 315 nm was determined against 0.1 *N* HCl as the blank. A small interference from the dye may be corrected by either: (*a*) using Lot C syrup (2.0 ml diluted to 100.0 ml with 0.1 *N* HCl solution) as the blank or (*b*) measuring the absorbance values of the diluted Lot C syrup at 315 and 365 nm against 0.1 *N* HCl solution as the blank and determining the correction factor using:

$$\text{factor} = \frac{A_{315}}{A_{365}} \qquad \text{(Eq. 3)}$$

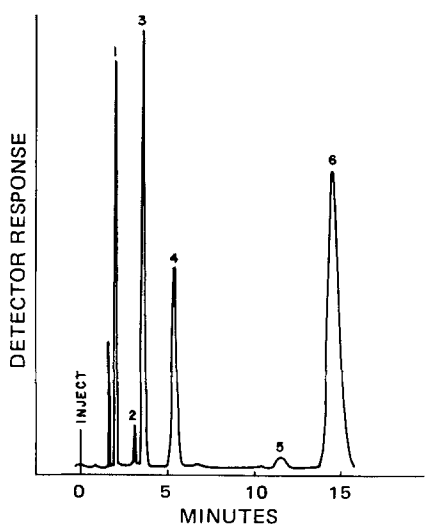

Figure 2—*HPLC analysis of a commercial cough syrup. Peaks 1, 2, and 6 are two antihistamines in combination, phenylpropanolamine hydrochloride, and guaifenesin, respectively. Peak 4 is sodium benzoate, and other peaks are unidentified.*

[4] Dolco Cherry, No. 5225, Dodge & Olcott, Inc., New York, N.Y.

[5] Time required for the maximum sensitivity in the assay procedure as determined in this laboratory.

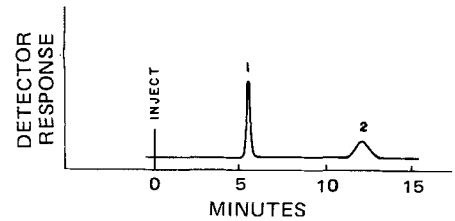

Figure 3—*HPLC analysis of some inactive ingredients used in cough syrups. Peaks 1 and 2 are sodium benzoate and FD&C Yellow No. 5, respectively.*

and:

$$\text{corrected } A_{315} = A_{315} - A_{365} \times \text{factor} \qquad \text{(Eq. 4)}$$

Since preliminary investigations indicated that Beer's law was followed, the results were calculated by direct comparison of the absorbance values at 315 nm:

$$\frac{\text{corrected } A_{315}}{(A_{315})_s} = \text{percent of label claim} \qquad \text{(Eq. 5)}$$

where corrected A_{315} is the absorbance value of the assay sample from Eq. 4, and $(A_{315})_s$ is the absorbance value of the standard solution containing 20 μg/ml of pyrilamine maleate in 0.1 *N* HCl solution against 0.1 *N* HCl as the blank. The results are presented in Table II.

DISCUSSION

The results (Tables I and II) indicate that a complex mixture of five active ingredients and two inactive ingredients (Figs. 2 and 3) can be separated and assayed quantitatively using HPLC. HPLC always has additional advantages such as the identification of the compounds from their retention times and separation of some inactive ingredients. In these investigations, it was possible to separate the preservative (sodium benzoate) and to identify it in the commercial sample (Figs. 2 and 3). Moreover, HPLC is usually short and often stability indicating.

The developed method is easy, accurate, and precise (for standard deviations, see Table I). It was not possible to separate pheniramine maleate from pyrilamine maleate, even by using many other solvents such as: (*a*) 0.05 *M* KH_2PO_4 in water containing 10% (v/v) methanol with the pH adjusted to 3.5 using acetic acid; (*b*) 0.05 *M* KH_2PO_4 in water containing 10, 15, 17, 20, and 45% (v/v) methanol; (*c*) 0.05 *M* KH_2PO_4 in water containing 13% (v/v) methanol with the pH adjusted to 6.5 using 0.2 *N* NaOH; (*d*) 0.05 *M* KH_2PO_4 in water containing 20% (v/v) acetonitrile; (*e*) 0.05 *M* NH_4HCO_3 in water containing 10% (v/v) methanol; and (*f*) 1-heptanesulfonic acid for paired-ion chromatography (2) in water containing 1% (v/v) acetic acid and 13% (v/v) methanol and filtered through a 0.45-μm filter.

Table II—Assay Results on Pheniramine Maleate and Pyrilamine Maleate by Spectrophotometric Methods

	Percent of Label Claim Found		
Syrup	III	V (by Difference)[a]	V (by Spectrophotometry)
Lot A	98.6	99.8	99.5
Commercial sample	105.2	103.4	—[b]

[a] Since preliminary investigations indicated that the combined peak area of III and V was equal to the sum of the separate peak areas of III and V and that, after determining the exact concentration of III by the cyanogen bromide method, it was possible to determine the peak area due to III, the peak area due to V could be determined by difference. This area was directly compared with the peak area of the standard solution of V (125.0 μg/ml in the chromatographic solvent). [b] Not determined since the authors did not know what dyes were used in the commercial sample.

Due to problems in separating III and V, spectrophotometric methods were used to determine the two antihistamines separately (Table II). However, if the concentration of one is known, the concentration of the other may be determined by difference (Table II, footnote *a*).

In these studies, it was possible to determine the concentration of pyrilamine maleate by difference after the quantitative analysis of pheniramine maleate with cyanogen bromide, which opens the pyridine ring (1) and imparts color to the solution. Whenever new prepacked columns are purchased, the percent of methanol in the chromatographic solvent may have to be changed slightly to accomplish the same separation.

Quantitative Determinations of Antipyrine and Benzocaine in Ear Drops by High-Pressure Liquid Chromatography

V. DAS GUPTA [x] and S. SACHANANDANI

Abstract □ Antipyrine and benzocaine were determined quantitatively in ear drops by high-pressure liquid chromatography on an octadecyltrichlorosilane permanently bonded to a Si–C column, using 0.02 *M* KH_2PO_4 in methanol–water as the mobile phase. Both compounds can be assayed in combination directly without interference from each other or from oxyquinoline sulfate (the preservative). The method is accurate, precise (estimated universe standard deviations of 0.68% for antipyrine and 1.18% for benzocaine), simple, and short (requires 30 min *versus* 2–3 hr by the NF method). The method was tried on a commercial product with excellent results and can be used in the presence of decomposition products.

Keyphrases □ Antipyrine—high-pressure liquid chromatographic analysis, commercial combination with benzocaine □ Benzocaine—high-pressure liquid chromatographic analysis, commercial combination with antipyrine □ High-pressure liquid chromatography—analyses, antipyrine and benzocaine in commercial combination

An antipyrine and benzocaine mixture is used extensively for earache. The NF methods (1) for the quantitative determinations of antipyrine and benzocaine are lengthy and tedious. The purpose of these investigations was to develop a simple, short, accurate, precise, and stability-indicating assay method for the quantitative determina-

Peaks 5, 6, and 7 are from the decomposed standard solution.*

tions of antipyrine and benzocaine in combination in the NF solution (1) using high-pressure liquid chromatography (HPLC).

EXPERIMENTAL

Chemicals and Reagents—All chemicals and reagents were ACS, USP, or NF grade and were used without further purification.

Apparatus—A high-pressure liquid chromatograph[1] equipped with a fixed wavelength (254 nm) detector and recorder[2] was used.

Column—A nonpolar column[3] consisting of a monomolecular layer of octadecyltrichlorosilane permanently bonded to Si–C (30 cm long and 4 mm i.d.) was used.

Chromatographic Conditions—The chromatographic solvent was 0.02 *M* KH_2PO_4 in water containing 40% (v/v) methanol. The temperature was ambient, and the solvent flow rate was 1.6 ml/min (at an inlet pressure of approximately 2200 psig). The chart speed was 30.5 cm/hr, and the absorbance units for full scale deflection were 0.08 for benzocaine and 0.64 for antipyrine.

Standard Solutions—The following standard solutions were prepared in water containing 0.5% (v/v) glycerin: A, 0.027% antipyrine alone; B, 0.007% benzocaine alone; C, 0.027% antipyrine plus 0.007% benzocaine in combination; and D, 0.027% antipyrine, 0.007% benzocaine, and 0.002% oxyquinoline sulfate in combination. Solutions E–G were the same as Solutions A–C, respectively, except that pH 9 borate buffer USP (2) was substituted for water.

[1] Waters ALC 202 equipped with a U6K universal injector.

[3] Waters μ-Bondapak/C_{18}, Catalog No. 27324.

Table I—Assay Results on Antipyrine and Benzocaine

Solution	Assay Results, % of Claim	
	Antipyrine	Benzocaine
Prepared NF solution	99.52[a]	99.43[a]
Universe standard deviation (estimated)	0.68	1.18
Commercial sample	99.23[b]	99.13[b]
NF solution after decomposition	99.42[c]	52.86

[a] Average of four. The statistical data are based on four results. [b] The assay results by the NF method (1) as supplied by the manufacturer were 98.52% for antipyrine and 99.29% for benzocaine. [c] A small difference in the assay result from the undecomposed sample may be an experimental error.

Assay Procedure for NF Solution or Commercial Product—First 0.5 ml of the solution is diluted to 100.0 ml with water and then 10 μl is injected. For comparison, an identical volume of the appropriate standard solution is injected after the assay sample is eluted.

Calculations—Since preliminary investigations indicated that the peak area of each ingredient was directly related to the concentration (range of 1.35–4.05 μg for antipyrine and of 0.35–1.40 μg for benzocaine), the results were calculated by direct comparison of the peak areas:

$$\frac{A_a}{A_s} = \text{percent of label claim} \qquad \text{(Eq. 1)}$$

where A_a = peak area of the assay sample, and A_s = peak area of the standard solution. The detector's response is presented in Fig. 1, and the assay results are presented in Table I.

Procedure for Decomposition of Solution—For decomposition studies, 25.0 ml of the standard solution containing both antipyrine and benzocaine in pH 9 borate buffer [with 0.5% (v/v) glycerin] was heated on a hot plate until the volume was reduced to approximately 5 ml. The solution was cooled and brought to the original volume (25.0 ml) with water. A 10-μl aliquot of this solution was injected for quantitative determinations of antipyrine and benzocaine as described. Since preliminary investigations indicated that borate buffer does not interfere with the quantitative determinations of the active ingredients, the results were calculated using Eq. 1. The detector's response is presented in Fig. 1, and the results are presented in Table I.

DISCUSSION

The results (Table I) indicate that antipyrine and benzocaine can be easily separated (Fig. 1) and assayed by HPLC. The method developed is simple, accurate, precise, and short (requires only about 30 min *versus* 2–3 hr by the NF method). However, the developed method requires a high-pressure liquid chromatograph, costing about three times more than the equipment required for NF methods. Since the proposed method appears to be stability indicating (Fig. 1), it may be preferred by those who already have a high-pressure liquid chromatograph available.

In the decomposed sample, the assay results on benzocaine were 52.86 *versus* 99.43% in the undecomposed sample. In the process used for the decomposition, benzocaine appears to have hydrolyzed. The hydrolyzed sample showed an additional peak (Fig. 1, peak 5). There was no interference from the preservative, oxyquinoline sulfate.

GI Pharmacology of Polyethyleneimine I: Effects on Gastric Emptying in Rats

SIDNEY MELAMED *, GLENN R. CARLSON *, JACK N. MOSS *, ERNEST J. BELAIR *, and MARTIN F. TANSY ‡x

Abstract □ Experiments were conducted to determine the effect of ingested polyethyleneimine upon gastric emptying of the fasted rat. Emptying was evaluated by the phenolsulfonphthalein and resin bead methods. The two techniques gave comparable results; both showed that this agent inhibited gastric emptying. A delay in gastric emptying could be detected within 15 min of intubation. The effect was dose related, quite long lasting (~4 hr), and reversible. Commercially available, branched polyethyleneimines were highly active, but the linear polyethyleneimine was without observable effect. A branched polyethyleneimine derivative with all primary amine sites selectively acetylated also was inactive.

Keyphrases □ Polyethyleneimines, various—effect on gastric emptying, phenolsulfonphthalein and resin bead methods compared, rats □ Gastric emptying—effect of various polyethyleneimines, phenolsulfonphthalein and resin bead methods compared, rats □ Polyamines—various polyethyleneimines, effect on gastric emptying, phenolsulfonphthalein and resin bead methods compared, rats

Commercial polyethyleneimines are used as fungicides in shampoo (1), as bactericides (2), as antiviral and antitumor agents (3), and as mucolytic agents in mouthwash (4). They are extensively used in industry as wet strength paper additives, flocculants, and modifiers for adhesives and coatings (5).

Polyethyleneimine is a water-soluble polyamine formed by the acid-catalyzed polymerization of ethyleneimine (6). Polyethyleneimine prepared in this manner contains primary, secondary, and tertiary amine nitrogens in a 1:2:1 ratio (5). The result is a highly branched spheroid-shaped molecule such as Structures I and II. A linear polymer (IV) of polyethyleneimine is also available *via* a two-step synthesis (7) and contains essentially only the secondary amine functionality if n is large. This linear polymer is crystalline and essentially insoluble in water at 25°.

In view of the therapeutic and hygienic usefulness of the commercial polyethyleneimines and the lack of literature

reports concerning their effects on the gut, a study was conducted to determine the effects of ingestion of these polymers upon GI motor activity.

EXPERIMENTAL

Methods—Three hundred and twenty-four female Wistar rats, 144–155 g, were used. The first series of experiments was designed to determine the influence of polyethyleneimine mol. wt. 40,000–60,000[1] (I) upon gastric emptying; the phenolsulfonphthalein method (8) was used. Essentially, overnight fasted rats were intubated in groups of six with a predetermined dosage of I (adjusted to pH 7.0 with dilute hydrochloric acid) for each group along with 3 mg of phenolsulfonphthalein, a nontoxic, nonabsorbable dye.

Compound I and the dye were given in 1.5 ml of aqueous solution. At fixed time intervals, the animals were sacrificed and the residual phenolsulfonphthalein stomach content was determined by spectrophotometry. Control groups of animals received only dye and were sacrificed

[1] PEI 600, Dow Chemical Co., Midland, Mich.

Table III—Evaluation of the Rate of Onset of the Gastric Emptying Inhibitory Effect of I

Treatment	Time of Sacrifice after Phenol-sulfonphthalein Dosing, min	Gastric Dye Content in Milligrams at Time of Sacrifice; Dye Dosed at Indicated Times after Water (Control) or I (Treatment)[a]		
		0 min	15 min	30 min
Control (water)	0	5.8	7.75	7.05
	60	0.90	1.55	1.30
% Retention (60 min)	$= \frac{\text{mg (60)}}{\text{mg (0)}} = A$	15.5 ± 4.3	20.0 ± 1.0	18.4 ± 3.9
I (125 mg/kg)	0	7.65	8.40	8.40
	60	6.15	6.70	5.30
% Retention	$= \frac{\text{mg (60)}}{\text{mg (0)}} = B$	80.4 ± 7.2[b]	79.8 ± 1.2[c]	63.1 ± 3.6[b]
% Inhibition	= % retention with drug − % retention with water = B − A	64.9 ± 8.4	59.8 ± 1.5	44.7 ± 5.3

[a] Values are expressed as the mean for two groups of three animals. Retention and inhibition values are expressed as the mean ± *SE* of the mean. [b] $p < 0.025$ when compared to control group. [c] $p < 0.005$ when compared to control group.

similarly. Each group of six rats, including the control group, was divided into two sets of three rats each. The milligrams of dye was determined for each pooled set of three rats, and the group average was determined from the two sets of three rats in each group. Thus, group means were compared.

Zero-time controls also received only dye but were sacrificed immediately after dosing (t_0). This number is important since some dye is forced mechanically past the pyloric sphincter on dosing. Therefore, the actual dye at zero time must be determined. This phenomenon was confirmed by injecting laparotomized, anesthetized rats and observing the dye passage. Animals should be dosed gently. Stomach retention and percent inhibition of stomach emptying were calculated as follows:

$$\% \text{ retention } (t_1) = \frac{\text{mg of dye at } t_1 \text{ (treated)}}{\text{mg of dye at } t_0 \text{ (zero-time control)}} \times 100 \quad \text{(Eq. 1)}$$

$$\% \text{ inhibition } (t_1) = \% \text{ retention } (t_1) - \frac{\text{mg of dye at } t_1 \text{ (control)}}{\text{mg of dye at } t_0 \text{ (zero-time control)}} \times 100 \quad \text{(Eq. 2)}$$

The percent inhibition is the percent retention corrected for the percent of dye that remains at time t_1 in untreated, control animals. Table I provides the actual amount of dye determined at each dosage level, including zero-time and timed controls. These data show the reproducibility of the data and provide a basis for calculating the retention and inhibition values reported in Table II.

In the second series of experiments, designed to compare the phenolsulfonphthalein method with a bead method (9), 1.0 ml of the polyamine solution, again adjusted to pH 7.0, was administered to rats by intubation. This time, however, the polymer dose was immediately followed by a second solution (0.5 ml) containing a suspension of 30 very small resin beads of uniform diameter (0.5 mm) and shape. Each dosage group consisted of six animals. For the bead studies, the bead content was determined for each animal and was averaged for each group of six. The phenolsulfonphthalein comparison groups were analyzed as described.

The animals were sacrificed after fixed time periods (t_1), and the locations of the beads were noted. The number of beads leaving the stomach in a specified time was assumed to be a measure of stomach emptying. The percent retention and inhibition were calculated after referring to the appropriate control groups in a manner similar to that used in the phenolsulfonphthalein method:

$$\% \text{ retention } (t_1) = \frac{\text{number of beads at } t_1 \text{ (treated)}}{\text{number of beads at } t_0 \text{ (zero-time control)}} \times 100 \quad \text{(Eq. 3)}$$

$$\% \text{ inhibition } (t_1) = \% \text{ retention } (t_1) - \frac{\text{number of beads at } t_1 \text{ (control)}}{\text{number of beads at } t_0 \text{ (zero-time control)}} \times 100 \quad \text{(Eq. 4)}$$

Table IV—Comparison of Phenolsulfonphthalein and Bead Methods of Estimating the Effect of Various Doses of I on Gastric Emptying at 4 hr Posttreatment

Dose, mg/kg	Inhibition (Phenol-sulfonphthalein), %	Inhibition (Beads)[a], %
250	60.7 ± 5.0[b]	93.2 ± 4.8[c]
125	17.0 ± 1.1[c]	45.2 ± 12.2[b]
62.5	12.4 ± 1.9	29.3 ± 12.9
31.2	5.4 ± 1.9	15.8 ± 11.3
15.7	4.6 ± 1.6	22.0 ± 7.0[b]
0	0.0 ± 0.0	0.0 ± 0.0

[a] The samples consisted of six rats in each instance. Phenolsulfonphthalein samples were pooled as before, $n = 2$. Values are expressed as the mean ± *SE* of the mean. [b] $p < 0.025$ when compared to control groups. [c] $p < 0.005$ when compared to control groups.

In the next series of experiments, designed to determine the rate of onset of gastroinhibitory effects, 12 sets of three female rats were fasted for 24 hr. Zero-time (treated) animals were given 1.5 ml of a solution containing 125 mg of I/kg (pH 7) plus 3 mg of phenolsulfonphthalein. Fifteen- and thirty-minute animals were first given I at time zero in 0.75 ml of water and then, after the appropriate time, were given an additional 0.75 ml of a second solution containing 3 mg of the dye. Control groups of animals at 0, 15, and 30 min were treated in the same way except that they received pure water instead of the polymer solution.

All animals in this experiment were sacrificed 1 hr after dye administration, and the dye content of the stomachs was determined. The stomach contents of each group of three rats were pooled; that is, each group of three rats received a total of 9 mg of phenolsulfonphthalein. The results in Table III indicate the milligrams of dye remaining for each pooled set of three rats.

The next series of experiments was designed to evaluate the duration of the effect of I. Sets of six rats were each dosed with 125 mg/kg of the polymer and the dye marker. The same analytical techniques as already described were used; the groups were sacrificed at various time periods up to 6 hr after dosing.

Materials—Compound I was dialyzed for 30 hr in regenerated cellulose tubing[2] (molecular weight cutoff of 12,000) prior to use. A change of tubing was made after approximately 15 hr. Polyethyleneimine mol. wt. 600[3] (II) was used without dialysis. $\text{Acetyl}_{0.25}$ polyethyleneimine (III) was prepared from I and acetic anhydride (0.33 equivalent) in water at 35° according to literature procedures (6). It was dialyzed for 48 hr prior to use. Analysis by NMR spectroscopy in deuterium oxide indicated only primary amine acetylation: a broad singlet at 1.9 ppm ($NHCOCH_3$) and no signal at 2.1 ppm ($NRCOCH_3$). Linear polyethyleneimine mol. wt. 10,000[4] (IV) was used without dialysis.

RESULTS AND DISCUSSION

Dosages of 15–250 mg of I/kg to fasted rats gave dose-related, long lasting, but reversible, inhibition of stomach emptying. The effect of I on gastric emptying performance was defined by the time-dependent percentage loss of either inert beads or phenolsulfonphthalein from the stomachs of rats dosed orally with the polyamine (Tables II and IV).

These data indicate that the two techniques gave qualitatively com-

Table V—Duration of the Delay of Gastric Emptying by I

Dosage	Retention[a] of Phenolsulfonphthalein in Rat Stomachs at Predetermined Posttreatment Times, %			
	1 hr	2 hr	4 hr	6 hr
Control	17.2 ± 0.7	4.1 ± 0.7	2.0 ± 1.1	0.1 ± 0.1
125 mg/kg	99.0 ± 1.5[b]	67.6 ± 1.9[b]	22.3 ± 3.4[c]	9.5 ± 3.0

[a] Calculations: (mg of dye remaining in stomach × 100)/(mg of dye initially administered). Samples consisted of two groups of three rats. Values are expressed as the mean ± *SE* of the mean. [b] $p < 0.005$ when compared with control groups. [c] $p < 0.05$ when compared with control groups.

parable results. The phenolsulfonphthalein method was quicker, easier, and more reproducible, and it gave lower values than the bead method. With the phenolsulfonphthalein method of estimating gastric emptying, an experiment was done to determine the onset of gastric inhibition, as indicated under *Experimental* (Table III).

In addition to the actual amounts of dye remaining at each of the three dosing times, Table III shows the percent retention and inhibition. Within the limits of the method, the percent inhibition at zero time after dosing was as great as at 15 min. At 30 min, the effect of the drug began to decrease. Thus, the data indicate that the onset of the effect of I must occur fairly rapidly following oral administration. The results in Table V indicate the duration of action of I at a dosage level of 125 mg/kg. Some effect was still observable 6 hr after dosing.

The LD_{50} for oral administration of I (pH 7) to the rat is approximately 2 g/kg[5]. At the dosages used for stomach retention, no signs of overt toxicity or pathology were observed over a pH range of 2–12.

In a recent article (10), it was reported that chemical trauma to the small intestinal mucosa prevents gastric emptying. Histopathological examination of the small intestine of rats treated with I showed normal tissue.

Preliminary retention experiments with a lower molecular weight branched polymer (II) suggest that the activity of this agent in producing a delay in gastric emptying may depend on molecular weight. A 250-mg/kg dose of II produced an inhibition of 82 ± 0.7% at 2 hr, in contrast with the value of 68.6 ± 1.0% observed for I.

Compound III did not inhibit gastric emptying in the rat as measured by the phenolsulfonphthalein method (inhibition of 2.0 ± 0.9%, 250 mg/kg, 4-hr evaluation). Likewise, IV had no observable effect when administered in the range of dosages that proved to be effective for I. These results suggest that large numbers of primary amine sites per molecule are required for optimum activity.

In summary, these results indicate that orally administered branched-chain polyethyleneimine is associated with delayed gastric emptying in fasted rats. With the method used, a dosage of 125 mg of I/kg produced this effect as early as 15 min following administration, and the effect could be detected up to 6 hr later.

GI Pharmacology of Polyethyleneimine II: Motor Activity in Anesthetized Dogs

MARTIN F. TANSY *x, JOHN S. MARTIN *, DAVID L. INNES *, FRANK M. KENDALL *, SIDNEY MELAMED ‡, and JACK N. MOSS ‡

Abstract □ The effects of orally and intravenously administered doses of polyethyleneimine were observed in 18 chloralose–urethan-anesthetized dogs. Polyethyleneimine produced an initial augmentation of rhythmic segmenting gastric antral contractions, a copious flow of gastric mucus, increased segmenting and propulsive activities of the small and large intestines, and occasional micturition and defecation. The gastric corpus and fundic regions became relaxed and enlarged. These events were associated with the prompt appearance of retching. The retching response to oral administration could only be abolished by bilateral vagotomy or bilateral sympathectomy. The skeletal muscle component of retching was blocked by tubocurarine. Intravenous administration of chlorpromazine blocked the retching response and gastric corporal atonia to either intravenous or oral doses of polyethyleneimine. Either oral or intravenous administration of polyethyleneimine produced no detectable changes in the lead II ECG but was associated with marked transient reductions in both mean and pulsatile arterial blood pressures. These depressor effects showed clear tachyphylaxis. In all cases where GI effects were noted, respiration was augmented and erratic in a manner associated with the retching responses.

Keyphrases □ Polyethyleneimine—GI and cardiopulmonary effects, oral and intravenous administrations compared, dogs □ GI effects—polyethyleneimine, oral and intravenous administrations compared, dogs □ Cardiopulmonary effects—polyethyleneimine, oral and intravenous administrations compared, dogs □ Polyamines—polyethyleneimine, GI and cardiopulmonary effects, oral and intravenous administrations compared, dogs

The naturally occurring polyamines putrescine, spermidine, and spermine have attracted considerable attention with regard to their biological functions (1). However, there have been no studies to determine the effects of either the naturally occurring or synthetic polyethyleneimines on GI functions.

Recent experimental data indicated that a high molecular weight polyethyleneimine polymer produced delayed gastric emptying when orally administered to fasted rats (2). It might be possible to utilize this effect to prolong orally administered drug action or as an appetite suppressant (3). The objective of the present experiments was to determine those GI secreto-motor effects associated with the oral administration of the polyamine as well as any cardiopulmonary effects.

EXPERIMENTAL

Methods—Eighteen mongrel dogs of both sexes were used. Following an overnight fast with water *ad libitum*, all animals were anesthetized with a mixture of 5% α-chloralose dissolved in polyethylene glycol 200 and 50% urethan in 0.9% saline. Each animal was individually titrated to a surgical plane of anesthesia using this mixture. Anesthesia was maintained by individual subsequent administration of the same mixture.

In all cases, the following procedures were used. A tracheal cannula was inserted to ensure patency of the airway and to permit monitoring of respiratory frequency. The femoral artery was cannulated for the purpose of recording blood pressure. The ipsilateral vein was cannulated to permit either bolus or infusion administration of drugs. The standard lead II ECG was continuously monitored throughout each experiment.

The following specific procedures were employed depending on the design of the particular experiment. Motor activities of the small and large intestines were monitored by surgically placed intraluminal water-filled balloons. Gastric motor activity was monitored by oral intubation with a water-filled balloon. Gastric secretion was collected by continuous drainage from a Thomas cannula surgically placed into the corpus of the stomach, as previously described (4).

Biliary and pancreatic flows were monitored by drop counters connected *via* polyethylene cannulas to the extramural pancreatic and common bile ducts. Portal venous pressure was monitored *via* a cannula placed in a splenic vein. The vagus nerves were exposed cervically, and either the splanchnic nerves or the sympathetic chains were exposed at the T-9–T-10 level.

In some experiments, the vagi were sectioned and the peripheral ends were electrically stimulated using bipolar electrodes. Square-wave stimuli ranged from 12 to 30 v at 30 Hz with a 2-msec duration. Monitored parameters were recorded on a strip-chart recorder. Increases in GI motor activities were directly visualized and photographed so that the resulting pressure wave forms could be interpreted in terms of the type of activity represented.

Materials—The test agent employed was the high molecular weight (40,000–60,000) branched polyethyleneimine[1] (I) in saline, 10–200 mg/kg iv depending on the experiment. Tubocurarine (1.0 mg/kg) and 2.0 mg of chlorpromazine hydrochloride[2]/kg were also used.

RESULTS AND DISCUSSION

In all 18 dogs, the intravenous administration of I was immediately associated with a marked reduction in arterial blood pressure (Fig. 1). This response showed marked tachyphylaxis to an extent that it had disappeared completely by the beginning of the third trial in each dog (Fig. 1). Other than reflex changes in heart rate, the morphology of the ECG showed no suggestive changes. Respiratory rate was augmented with substantially complete tachyphylaxis by the beginning of the third dose.

Portal venous pressure promptly and consistently rose following intravenous administration of I (Fig. 1). These responses also showed tachyphylaxis (Fig. 1). All doses were consistently associated with transient decreases in extrahepatic bile flow. Pancreatic flow was not influenced by any dose employed. The entire small and large intestines exhibited increased motor activities. Gastric motor activity took the form of an initial augmentation followed by a marked depression within 2–3 min of I administration. In all 18 animals, exaggerated respiratory movements were noted; in some cases, they progressed to violent cyclic retching (Fig. 1), frequently accompanied by micturition and defecation. Fatalities in six dogs occurred at total cumulative intravenous dosages of 25–31 mg/kg.

The described effects also were noted in eight dogs when doses of 200 mg/kg were administered by gastric or duodenal intubation. The only differences were the latencies of the responses, which were uniformly longer (Fig. 2).

The fatal total oral dose in three dogs was estimated by average to be about 1.8 g/kg. The retching observed subsequent to oral administration could be abolished by bilateral cervical vagotomy. This procedure did not abolish the retching responses to intravenous administration.

The first task resulting from the previous observations was to determine the exact changes of gastric motor activity that resulted from I administration. In these four experiments, the intravenous dosage was 1 mg/kg and the intragastric dosage was reduced to 50 mg/kg.

Direct visualization of the stomach following I administration revealed that the gastric antrum, defined as the region below the incisura angularis, exhibited protracted, rhythmic, propulsive contractile activity, which

[1] PEI 600, Dow Chemical Co., Midland, Mich.

[2] Thorazine Injectable, Smith Kline and French Laboratories, Philadelphia, Pa.

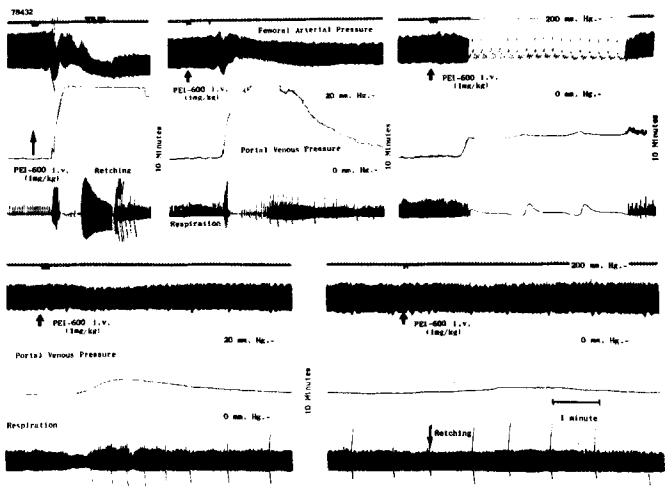

Figure 1—*Polygrams depicting the time course of femoral arterial pressure (top trace), portal venous pressure (center trace), and respiratory movements (bottom trace). The panels are ordered sequentially. This figure shows that tachyphylaxis was noticeably present with respect to all parameters upon the third intravenous administration of I (PEI-600). Tachyphylaxis was essentially complete following the fifth dose. The sharp spikes on the respiration trace show that retching movements were present during the entire period depicted.*

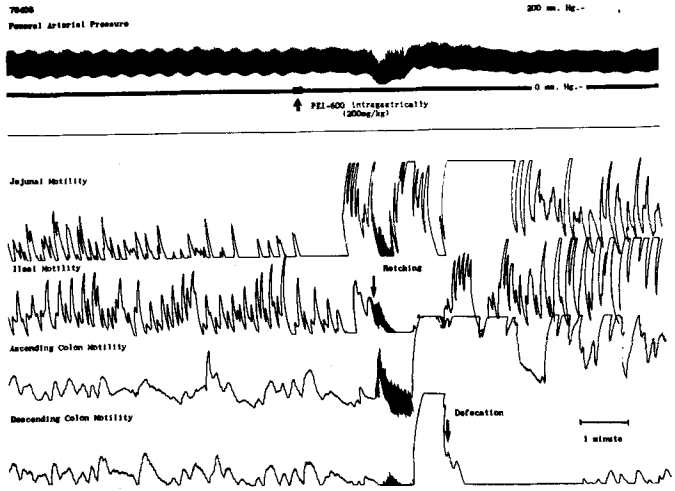

Figure 2—*Polygram depicting the time course of arterial blood pressure and jejunal, ileal, ascending colon, and descending colon motilities following the intragastric administration of 200 mg/kg of I (PEI-600). The latency of the responses was about 1.5 min. Arterial blood pressure was transiently affected. Jejunal, ileal, and ascending colonic movements underwent protracted augmentation. In this particular recording, the abrupt decrease in activity of the descending colon was associated with spontaneous defecation. The blurring of the motility traces was an artifact associated with gross retching movements.*

was coincident with increased propulsive activity of the small intestine. As additional drug was administered, a progressive enlargement of the corpus and fundic regions occurred to an extent that the total volume occupied by the stomach became greatly enlarged. During repeated administrations, exaggerated respiratory movements and retching appeared. Electrical stimulation of the peripheral vagi augmented the propulsive movements of both the gastric antrum and the small intestine.

A gastric pH electrode was introduced orally into the stomachs of three dogs. The gastric pH rose continuously during 2 hr of intravenous I administration. At the end of 2 hr, the gastric pH was 8.0. A single gastric fistula dog was then prepared to determine the effect of intravenous I administration on gastric acid secretion following an overnight fast. The repeated intravenous administration of 1.0 mg/kg markedly increased the amount of gastric mucus produced during the 15-min collection periods. Tachyphylaxis was not noted.

The latter observations suggested that a sympathetic component might be responsible for the motor effects and the secretion of gastric mucus (4). Accordingly, in another series of four dogs, the sympathetic chains were surgically interrupted prior to intravenous I administration. Gastric enlargement was not seen in these animals, but they all had cyclic bouts of retching. One dog retched continuously. Retching was abolished in the four dogs by intravenous tubocurarine administration.

A final experimental series utilized two dogs and was designed to determine whether the prior intravenous administration of 2 mg/kg of chlorpromazine could modify the observed GI effects of oral or intravenous I. Oral dosages ranged from 50 to 200 mg/kg, and intravenous dosages ranged from 1.0 to 5.0 mg/kg. In no case was either retching or gastric enlargement observed.

During the first canine experiments, it was immediately noted that the classic physiological responses (5) included in the description of retching were produced by I. The 1.0-mg/kg iv dose appears to be near the threshold for this response because the responses were variable. One animal retched each time the drug was administered, while another dog retched unpredictably with no apparent relationship between total accumulated dosage and prediction of the response.

The responses themselves were of unpredictable duration. One dog might retch continuously during the entire experiment following the initial dosage while another retched for a short time following a dosage that happened to produce the response. At the higher intragastric and intravenous dosages, retching was more predictable and of longer duration.

An analysis of the retching responses indicates the following. The skeletal muscle component was blocked by curare, indicating that the classical voluntary skeletal muscle component of the response was present. The gastric response consisted of increased secretion of mucus, relaxation of the corpus and fundus, and marked antral contractions. Interruption of the sympathetic chains and sectioning of the splanchnic nerves abolished relaxation and increased mucus secretion. This response indicates that a characteristic sympathetic component of the retch reflex was present.

The immediate sympathetic and parasympathetic responses to gastric or duodenal administration could be blocked by bilateral vagotomy (Fig. 3), indicating that the reflex can be subserved by vagal afferent pathways (6). Furthermore, the observation that retching produced by intravenous administration of I could be blocked by prior treatment with chlorpromazine (7) indicates that the agent or one or more of its metabolites can directly stimulate the chemoreceptor trigger zone. Thus, the emetic action of I (emesis did occur in the nonfasted dog) appears to be similar to that of ipecac (7).

The most pronounced effects of I upon systems other than the GI are upon the circulation. The marked decreases in arterial pressure were

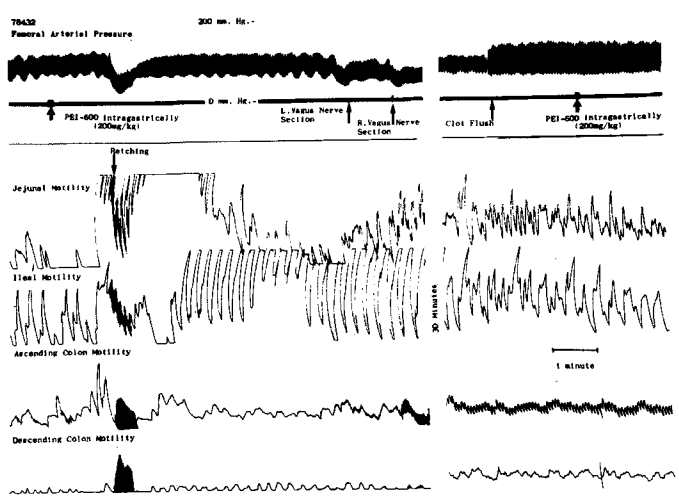

Figure 3—*Polygram depicting the time course of femoral arterial pressure and motor activities of the jejunum, ileum, and ascending and descending colons of a dog subsequent to the intragastric administrations of 200 mg/kg of I (PEI-600) prior to and following bilateral cervical vagotomy. The pressure artifacts produced by gross retching movements were absent following vagotomy.*

associated with reductions in pulse pressures and rises in portal venous pressures. These changes appeared to exhibit rapid and complete tachyphylaxis. The lack of apparent changes in the morphology of the lead II ECG indicates that the effects of the agent did not produce arrhythmias or ectopic foci of excitation. A determination of whether minor local changes in excitation occurred secondary to such effects as regional changes in myocardial circulation cannot be inferred from these limited data.

Experiments with lower dosages or apparently ineffective 1.0-mg/kg iv and 50-mg/kg intragastric dosages indicated that the individual components of the retch response (increased frequency of respiration, gastric mucus secretion, antral contractions, and corporal-fundal atonia) were invariably present but of such small intensity that the composite response was decidedly less than that constituting frank retching.

A similar set of sequelae is also present in humans who report feelings of nausea but who do not visibly retch. It is impossible to make this judgment with dogs, particularly anesthetized dogs. But these observations furnish an adequate physiological basis to suspect that the gastric or intravenous administration of dosages that are insufficient to produce frank retching might be accompanied by sensations of nausea.

It is concluded that the high molecular weight, branched polyethyleneimine, whether administered to dogs by gastric intubation or intravenously, produces an emetic response similar to ipecac in that it can act reflexly or by direct stimulation of the chemoreceptor trigger zone.

New Compounds: Potential Antituberculous Agents I: Alkylaryl 4-Arylformamidinothiosemicarbazones

P. K. SRIVASTAVA ˣ and J. S. UPADHYAYA

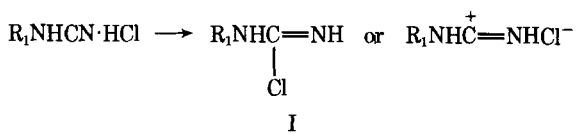
Abstract □ A series of alkylaryl 4-arylformamidinothiosemicarbazones was synthesized for evaluation as antituberculous agents. The synthesis was effected by the condensation of different arylcyanamides with various thiosemicarbazones. The required intermediates also are described.

Keyphrases □ Thiosemicarbazones, various—synthesized for evaluation as antituberculous agents □ Antituberculous agents, potential—various thiosemicarbazones synthesized

Interest in the synthesis and biological evaluation of thiosemicarbazone derivatives was renewed by the fact that tibione (*p*-acetylaminobenzaldehyde thiosemicarbazone) (1–3) possesses antituberculous activity. Many reports (4–13) discussed the change of activity due to variations in the structure of the parent compound.

DISCUSSION

The present report deals with the synthesis of acetophenone 4-arylformamidinothiosemicarbazones (V*a*–V*m*, Table I) and 1-acetonaphthone 4-arylformamidinothiosemicarbazones (VI*a*–VI*m*, Table II) by the condensation of corresponding arylcyanamide hydrochlorides (I, Scheme I) with the appropriate thiosemicarbazones (II or III, Scheme II). Although the monosulfides (IV) could not be isolated, this intermediate stage was confirmed previously in analogous reactions (14–17).



Scheme I

Precursors (I) were obtained by the desulfurization of related thioureas by lead hydroxide and conversion to related hydrochlorides (18). The synthesized thiosemicarbazones (Tables I and II) are white crystalline compounds soluble in polar solvents. Since these compounds could not be crystallized without decomposition, purification was achieved by repeated washings with several solvents. It was hoped that these potential antituberculous agents would have low toxicity to normal cells and have a good chemotherapeutic index[1].

EXPERIMENTAL[2]

Phenylcyanamide (18)—A mixture of phenylthiourea (15.2 g, 0.1 mole) dissolved in sodium hydroxide (3 g in 200 ml of water) and freshly prepared lead hydroxide (24.12 g, 0.1 mole) was heated on a water bath for 4 hr. It then was cooled and filtered, and the filtrate was acidified with acetic acid. The fluffy precipitate of phenylcyanamide was dissolved in ether and dried by adding anhydrous sodium sulfate. The hydrochloride of phenylcyanamide was prepared by passing dry hydrogen chloride gas through the ethereal solution.

By adopting a similar procedure, the following cyanamides were prepared: 2-methylphenyl, 3-methylphenyl, 4-methylphenyl, 2-methoxyphenyl, 4-methoxyphenyl, 4-ethoxyphenyl, 2-chlorophenyl, 3-chlorophenyl, 4-chlorophenyl, 4-bromophenyl, 2,5-dimethylphenyl, and 1-naphthyl.

Acetophenone Thiosemicarbazone (II) (12, 13)—Acetophenone (12.0 g, 0.1 mole) was dissolved in ethanol (50%, 100 ml) and acetic acid (2.0 ml), and thiosemicarbazide (9.10 g, 0.1 mole) was added. The solution was warmed with occasional swirling until the thiosemicarbazide dissolved, and then the solution was refluxed for 1 hr. After cooling, crys-

[2] Melting points were determined with a Kofler hot-stage apparatus and are uncorrected.

associated with reductions in pulse pressures and rises in portal venous pressures. These changes appeared to exhibit rapid and complete tachyphylaxis. The lack of apparent changes in the morphology of the lead II ECG indicates that the effects of the agent did not produce arrhythmias or ectopic foci of excitation. A determination of whether minor local changes in excitation occurred secondary to such effects as regional changes in myocardial circulation cannot be inferred from these limited data.

Experiments with lower dosages or apparently ineffective 1.0-mg/kg iv and 50-mg/kg intragastric dosages indicated that the individual components of the retch response (increased frequency of respiration, gastric mucus secretion, antral contractions, and corporal-fundal atonia) were invariably present but of such small intensity that the composite response was decidedly less than that constituting frank retching.

A similar set of sequelae is also present in humans who report feelings of nausea but who do not visibly retch. It is impossible to make this judgment with dogs, particularly anesthetized dogs. But these observations furnish an adequate physiological basis to suspect that the gastric or intravenous administration of dosages that are insufficient to produce frank retching might be accompanied by sensations of nausea.

It is concluded that the high molecular weight, branched polyethyleneimine, whether administered to dogs by gastric intubation or intravenously, produces an emetic response similar to ipecac in that it can act reflexly or by direct stimulation of the chemoreceptor trigger zone.

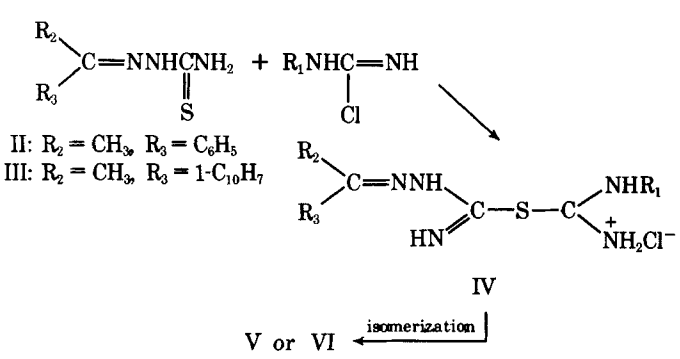
talline II was collected and recrystallized from 50% ethanol as white needles, 18.9 g (90%), mp 116–117° [lit. (19) mp 118–119°].

1-Acetonaphthone thiosemicarbazone (III) was prepared similarly.

Acetophenone 4-Phenylformamidinothiosemicarbazone Hydrochloride (V*a*)—Compound II (3.0 g, 0.015 mole) was dissolved in acetone (20.0 ml), and the solution was cooled in a freezing mixture. To this cooled solution, phenylcyanamide hydrochloride (2.4 g, 0.015 mole) dissolved in acetone (10.0 ml) was gradually added with constant shaking. After this solution was in the freezing mixture for 1 hr, crystalline pure V*a* was separated, filtered, and washed with acetone and petroleum ether to remove any unreacted material, 4.15 g (18%), mp 208–209°.



Scheme II

Anal.—Calc. for $C_{16}H_{18}ClN_5S$: C, 55.25; H, 5.18; N, 20.14; S, 9.20. Found: C, 55.08; H, 5.06; N, 20.06; S, 9.15.

Compounds V*b*–V*m* (Table I) were prepared by condensing II with the appropriate I.

With a similar procedure, VI*a*–VI*m* (Table II) were obtained.

These thiosemicarbazone hydrochlorides were characterized by elemental analyses and the presence of characteristic bands at 1520 (N=C=S), 1625 (C=N), and 3400 (NH) cm^{-1} and a substituted benzene ring (760 cm^{-1}) in their IR spectra.

Perfluorooctyl Bromide: A Potential Antiobesity Compound

Keyphrases □ Perfluorooctyl bromide—coated on GI tract, effect on food absorption and weight gain, rats □ Absorption, food—effect of perfluorooctyl bromide coated on GI tract, rats □ GI absorption—effect of coating with perfluorooctyl bromide, rats □ Antiobesity agents, potential—perfluorooctyl bromide, coated on GI tract, effect on food absorption and weight gain, rats

To the Editor:

Perfluorooctyl bromide (I) is a chemically and biologically inert, high molecular weight fluorocarbon used as a radiopaque contrast medium (1, 2). Although this compound is immiscible with water, its low surface tension renders it easily spreadable over mucous membranes. This property led to our investigation of its possible use in retarding food absorption and, therefore, as an agent for the treatment of obesity.

The radiopaque nature of I allowed direct observation of its transit through the GI tract using whole body X-ray imaging (Fig. 1). After administration of 2 ml of I[1] *via* an oral intubation needle to a rat weighing about 450 g, an instantaneous coating of the stomach was obtained. It took about 1.5 hr to clear the GI tract of the fluorocarbon, which uniformly coated the walls of the stomach and intestine. Since I serves as a poor solvent for most chemical structures (3), the coating of the stomach and intestines forms a temporary barrier to the absorption of ingested food.

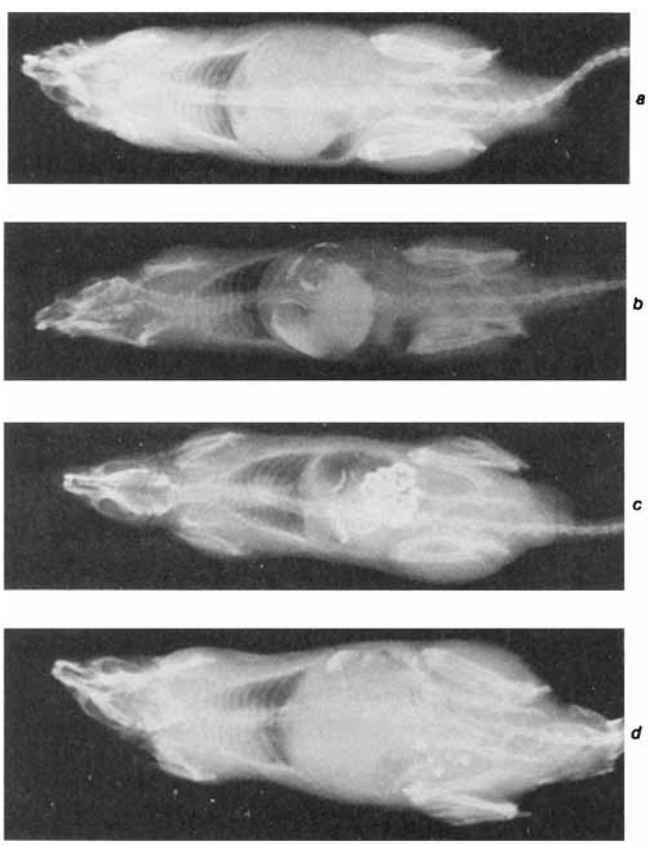

Figure 1—*Whole body X-ray images of rat before* (a) *and 7* (b), *30* (c), *and 75* (d) *min following administration of 2 ml of I.*

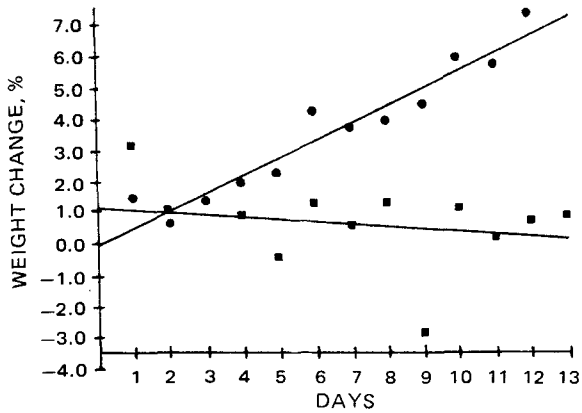

Figure 2—*Comparison of rate of growth of rats given I* (■) *and water* (●) *during their feeding cycle* (n = *19*).

To test this hypothesis, Sprague–Dawley male rats, 400–500 g, were conditioned for 2 weeks by allowing food[2] for only 3 hr/day and water for 14 hr/day, commencing with the food intake cycle. All rats were weighed before the feeding cycle. A crossover study was performed where the test group was given 1 ml of I at 1.5 and 2.0 hr of their 3-hr food intake cycle. The control group was given water instead, and the study was continued for 14 days. The control group showed a net increase in weight whereas the treated group showed a slight decrease (Fig. 2). The weight gain difference between the groups was statistically significant at the 95% confidence level, proving the definite effect of I on food absorption in rats.

The schedule of I administration was chosen to allow at least 1 hr for the coating of the stomach and almost 2 hr of residence time in the GI tract. Variations in this schedule may result in greater or lesser effects of the fluorocarbon on food absorption, and studies in this area are in progress.

The suitability of I for reducing food absorption is due to its complete inertness, lack of absorption from the GI tract, and physical properties that allow its uniform distribution throughout the GI tract. Also, the small quantity of fluorocarbon administered does not result in any apparent change in the bowel movement (diarrhea).

At present, we are designing dosage forms of I that can be tested in humans, and these findings will be reported soon.

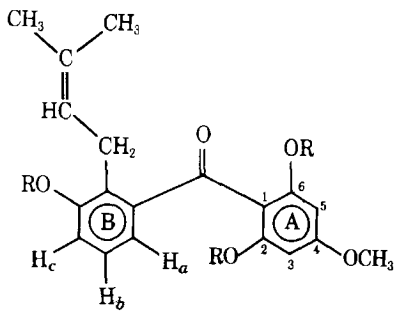
Keyphrases □ Cudranone—isolated and identified from stems and roots of *Cudrania chochinchinensis*, antimicrobial activity evaluated □ Benzophenone derivative—cudranone isolated and identified from stems and roots of *Cudrania chochinchinensis*, antimicrobial activity evaluated □ Antimicrobial agents, potential—cudranone, isolated and identified from stems and roots of *Cudrania chochinchinensis*

To the Editor:

In a largescale program for screening higher plants for antimicrobial activity, an ethanolic extract of the stems and roots of the Chinese plant[1] *Cudrania chochinchinensis* (Lour.) Kudo & Masam. var. *gerontogea* (Sieb. & Zucc.) Kudo & Masam. (Moraceae) exhibited strong activity against a wide range of microorganisms. Partitioning the alcohol extract between water and chloroform concentrated the antimicrobial activity in the chloroform phase. This fraction was then chromatographed over silica gel, using increasing amounts of ether (4–40%) in benzene as the solvent system. Several known crystalline compounds[2] were isolated from the column fractions.

The 4% ether in benzene fraction yielded, upon crystallization from *n*-hexane–ethyl acetate, a novel crystalline substance which was named cudranone (I). This new compound occurred in the form of bright-yellow needles, mp 172–173°, and had a molecular formula of $C_{19}H_{20}O_5$, as supported by elemental analysis and high-resolution mass spectral data.

The 60-MHz ^{1}H-NMR spectrum (taken in acetone-d_6 with tetramethylsilane as the internal standard) provided information on most functional groups of this compound. It revealed the presence of a β,β-dimethylallyl group (two vinylic three-proton singlets at δ 1.53 and 1.50; a broad one-proton triplet at δ 5.23, J = 8 Hz; and a two-proton doublet at δ 3.37, J = 8 Hz). It also exhibited a methoxy singlet at δ 3.83 and three exchangeable phenolic protons as a broad signal at δ 10.17. The aromatic region of the



I: R = H
II: R = CH_3
III: R = CCH_3 (=O)

NMR spectrum showed a two-proton singlet at δ 6.00 and a three-proton group of signals forming a complex *ABC* system centered at δ 6.91. The IR spectrum confirmed the phenolic nature of the compound and showed a carbonyl absorption band at λ_{max} (potassium bromide) 6.06 μm, assigned to a hydrogen-bonded ketonic carbonyl function. Thus, by assuming that the compound had two aromatic rings, it was concluded that it must have a benzophenone skeleton rather than a xanthone skeleton like some reported constituents of the *Cudrania* species (1, 2).

The nature of ring A was revealed when the compound gave, in low yields, phloroglucinol monomethyl ether[3] by heating with solid potassium hydroxide at 245–250°. This finding indicated that the rest of the benzophenone moiety must be substituting ring A at C-1 rather than at C-3 or C-5 to account for the equivalency of the two aromatic protons of ring A appearing in the NMR spectrum as a sharp singlet at δ 6.00. This finding also indicated that the β,β-dimethylallyl group and the remaining hydroxyl group should be substituting ring B.

Compound I yielded the trimethyl ether (II) as white needles, mp 126–127°, by treatment with dimethyl sulfate and aqueous sodium hydroxide. The NMR spectrum of II taken in deuterochloroform still showed the complex *ABC* three-proton system in the aromatic region. However, this system was simplified and showed first-order splitting when benzene-d_6 (100%) was used as the solvent. It showed a one-proton doublet[4] at δ 7.23, J = 8 Hz; a one-proton triplet at δ 6.80, J = 8 Hz; and another one-proton doublet[4]

[1] The plant material was collected in Chia-Yi, Taiwan, in 1974. Its identity was confirmed by Dr. Ping C. Cheng, Taipei Medical College. A voucher specimen is deposited in the herbarium of the Department of Pharmacognosy, School of Pharmacy, University of Mississippi.
[2] To be reported later.
[3] Characterized by direct comparison with an authentic sample (superimposable IR, NMR, and mass spectra and identical R_f values on TLC and retention times on GLC).
[4] The doublets due to H_a and H_c were slightly split (J = 2 Hz) due to *meta*-coupling to each other.

at δ 6.42, J = 8 Hz. This pattern indicated that the three remaining aromatic protons in I must be located on three successive carbon atoms in ring B with the one most downfield (H_a) *ortho* to the ketone group, the one most upfield (H_c) *ortho* to the phenolic hydroxyl group, and the one in between (H_b) on the middle of these three carbons. This finding was further confirmed by the presence in the mass spectrum of the base peak IV, derived by acyl cleavage associated by hydrogen migration to ring A (3) (Scheme I). The highly conjugated nature of this fragment accounts for its abundance in the mass spectrum. The formation of fragment IV is favorable only if the β,β-dimethylallyl group is located *ortho* to the ketone group.

Although the evidence that I is the structure of cudranone was convincing, it was uncertain why the NMR signal of H_a was never as far downfield as expected for a proton *ortho* to a carbonyl group. This position was found not only for the H_a signal in I but also its trimethyl ether (II) and triacetate[5] (III) when taken in acetone-d_6 or deuterochloroform. A possible explanation for the shielding of H_a can be provided by assuming that I adopts a conformation that leads to the placing of H_a in the shielding zone of ring A. The assigned structure was confirmed by X-ray crystallographic analysis[6].

The structure of cudranone proves that biogenetic isoprenylation of xanthones does not take place after the cyclization of the corresponding benzophenones as suggested previously (4).

Cudranone exhibited significant activity against *Staphylococcus aureus* (MIC 25 μg/ml) and *Bacillus subtilis* (MIC 12.5 μg/ml) and even greater activity against *Mycobacterium smegmatis* (MIC 1.6 μg/ml)[7]. Further evaluation of antimicrobial activity of I is in progress.

Marihuana: An Annotated Bibliography. By COY W. WALLER, JACQUELINE J. JOHNSON, JUDY BUELKE, and CARLTON E. TURNER. Macmillan, 866 Third Ave., New York, NY 10022, 1976. 560 pp. 18.5 × 25.5 cm. Price $13.95.

This handbook will be most appreciated by those interested in the world literature on any aspect of marihuana (*Cannabis* species), its constituents, pharmacology, metabolism, toxicology, chemistry, synthesis, botany, *etc.* Every conceivable type of citation is found, ranging from reviews and books to original research reports, notes, communications, letters to the editor, rebuttals, book reviews, patents, dissertations, UN documents, introductory remarks to symposia, and the like.

The compilation was assembled by the Waller–Turner group, who have been actively engaged in *Cannabis* research for several years at the Research Institute of Pharmaceutical Sciences, University of Mississippi, under sponsorship of the National Institute of Mental Health. Literature coverage is stated to be from the beginning of 1964 through 1974, and "3045 entries covering the international scientific publications" are included (all entries are definitely not "scientific"). In all cases, the full citation of each entry is given, *i.e.*, all author names, journal title, volume, issue number, full pagination (in most, but not all, cases), and year of publication. Foreign language titles are given with parenthetical English translations in some cases.

Articles are entered alphabetically by senior author name. Most citations are followed by a brief abstract prepared by the editors. Author and subject indexes are included, as well as a summary table, the Biological Actions of Marihuana in Various Animals. The structure, molecular formula, and molecular weight of each known "natural" cannabinoid are given. Also, all of the names and structures of the metabolities of Δ^9-tetrahydrocannabinol, Δ^8-tetrahydrocannabinol, cannabinol, and cannabidiol are given, with an indication of those that are "active," although the term "active" is undefined.

Although this useful handbook represents a monumental effort on the part of the Mississippi group and was apparently prepared without governmental support (no acknowledgment was found to this effect), a number of minor deficiencies, as judged by this reviewer, and errors should be pointed out so that the user may be forewarned.

There is no statement concerning where the citations were obtained and how systematic the literature coverage may have been. For example, were "Chemical Abstracts" and "Biological Abstracts" covered completely for the stated time period? Were the brief abstracts derived from abstracts or from reading the original papers or books? Since the entries covered range from citations of introductory remarks to *Cannabis* symposia through entries in "Encyclopedia Britannica," one must wonder where the literature coverage started and ceased. For example, the authoritative book by H. Wagner, "Rauschgift-Drogen" (Springer-Verlag, Berlin, Germany, 1969), most surely should have been included in the handbook.

A useful addition to each citation would have been either the mailing address of the senior author and/or the secondary source, since the articles in some obscure journals would have to be verified before obtaining an interlibrary loan of the journal.

To this reviewer, the subject index was difficult to use. For example, no major heading concerning Isolation of Constituents was found. A major heading "Trigonelline (isolation from *Cannabis*)" was found, but no major headings for "Friedelin," "Epifriedelanol," "Sitosterol," "Stigmasterol," "Campesterol," and most other noncannabinoids isolated from *Cannabis* were entered. The major subject heading "Biochemistry" lists

at δ 6.42, J = 8 Hz. This pattern indicated that the three remaining aromatic protons in I must be located on three successive carbon atoms in ring B with the one most downfield (H_a) *ortho* to the ketone group, the one most upfield (H_c) *ortho* to the phenolic hydroxyl group, and the one in between (H_b) on the middle of these three carbons. This finding was further confirmed by the presence in the mass spectrum of the base peak IV, derived by acyl cleavage associated by hydrogen migration to ring A (3) (Scheme I). The highly conjugated nature of this fragment accounts for its abundance in the mass spectrum. The formation of fragment IV is favorable only if the β,β-dimethylallyl group is located *ortho* to the ketone group.

Marihuana: An Annotated Bibliography. By COY W. WALLER, JACQUELINE J. JOHNSON, JUDY BUELKE, and CARLTON E. TURNER. Macmillan, 866 Third Ave., New York, NY 10022, 1976. 560 pp. 18.5 × 25.5 cm. Price $13.95.

This handbook will be most appreciated by those interested in the world literature on any aspect of marihuana (*Cannabis* species), its constituents, pharmacology, metabolism, toxicology, chemistry, synthesis, botany, *etc.* Every conceivable type of citation is found, ranging from reviews and books to original research reports, notes, communications, letters to the editor, rebuttals, book reviews, patents, dissertations, UN documents, introductory remarks to symposia, and the like.

The compilation was assembled by the Waller–Turner group, who have been actively engaged in *Cannabis* research for several years at the Research Institute of Pharmaceutical Sciences, University of Mississippi, under sponsorship of the National Institute of Mental Health. Literature coverage is stated to be from the beginning of 1964 through 1974, and "3045 entries covering the international scientific publications" are included (all entries are definitely not "scientific"). In all cases, the full citation of each entry is given, *i.e.*, all author names, journal title, volume, issue number, full pagination (in most, but not all, cases), and year of publication. Foreign language titles are given with parenthetical English translations in some cases.

Articles are entered alphabetically by senior author name. Most citations are followed by a brief abstract prepared by the editors. Author and subject indexes are included, as well as a summary table, the Biological Actions of Marihuana in Various Animals. The structure, molecular formula, and molecular weight of each known "natural" cannabinoid are given. Also, all of the names and structures of the metabolities of Δ^9-tetrahydrocannabinol, Δ^8-tetrahydrocannabinol, cannabinol, and cannabidiol are given, with an indication of those that are "active," although the term "active" is undefined.

Although this useful handbook represents a monumental effort on the part of the Mississippi group and was apparently prepared without governmental support (no acknowledgment was found to this effect), a number of minor deficiencies, as judged by this reviewer, and errors should be pointed out so that the user may be forewarned.

There is no statement concerning where the citations were obtained and how systematic the literature coverage may have been. For example, were "Chemical Abstracts" and "Biological Abstracts" covered completely for the stated time period? Were the brief abstracts derived from abstracts or from reading the original papers or books? Since the entries covered range from citations of introductory remarks to *Cannabis* symposia through entries in "Encyclopedia Britannica," one must wonder where the literature coverage started and ceased. For example, the authoritative book by H. Wagner, "Rauschgift-Drogen" (Springer-Verlag, Berlin, Germany, 1969), most surely should have been included in the handbook.

A useful addition to each citation would have been either the mailing address of the senior author and/or the secondary source, since the articles in some obscure journals would have to be verified before obtaining an interlibrary loan of the journal.

To this reviewer, the subject index was difficult to use. For example, no major heading concerning Isolation of Constituents was found. A major heading "Trigonelline (isolation from *Cannabis*)" was found, but no major headings for "Friedelin," "Epifriedelanol," "Sitosterol," "Stigmasterol," "Campesterol," and most other noncannabinoids isolated from *Cannabis* were entered. The major subject heading "Biochemistry" lists

under it "Edestin from hemp seed," "Edestinase from hemp seed," and "Quaternary bases in *Cannabis*" only. For the amount of biochemical studies published on the cannabinoids, the biochemists will be disturbed with this type of index coverage.

A large number of incorrect spellings of common and technical words are found in the abstracts. These errors are self-evident for the most part but confusing in cases such as, for example, citation 2914 where "Cannabidivarian" appears in the title of the article and "Cannabidivarin" in the abstract, the latter presumably correct. In a few cases, words and/or phrases are apparently missing in titles of articles or in the abstracts. These omissions are usually not too much of a problem as in citations 368, 431, 474, 740, 1290, 1321, 1679, 1905, 1927, 2058, 2480, 2493, 2708, 2722, and 2914. The journal citation in 301 is confusing, and citation 2212 does not refer to the journal cited.

When abstracts are given, there is a great degree of inconsistency regarding content. Also, the summary table on p. XXII hardly can be considered complete.

However, even though these minor problems were found, the book at a very reasonable price of $13.95 is a bargain. It will be an indispensable, and much used addition to the personal library of anyone having even a remote interest in *Cannabis*. It will be of special interest to researchers in the field of *Cannabis*, to students in the medical professions and social sciences, to the pharmaceutical industry, and to reporters in the media and should be available in every library.

Reviewed by Norman R. Farnsworth
Department of Pharmacognosy and Pharmacology
College of Pharmacy
University of Illinois at the Medical Center
Chicago, IL 60612

Essentials of Medicinal Chemistry. By ANDREJUS KOROLKOVAS and JOSEPH H. BURCKHALTER. Wiley, 605 Third Ave., New York, N Y 10016, 1976. 697 pp. 16 × 23.5 cm. Price $22.50.

The book is designed as an undergraduate text in medicinal chemistry as well as a resource work for the chemist and biologist interested in several aspects of drugs. The composition of the book is built around succinctly stated facts and theories, which the authors hope are presented in a palatable, yet useful, form for the student. The authors have in mind the role of the pharmacist as an information source helping the physician and patient.

The book is in eight parts and generally follows pharmacological or therapeutic categories. These are Introduction: Basics, Drug Development and Theories; CNS Drugs; Drugs Acting at the Peripheral Nervous System; Cardiovascular, Blood and Renal Systems; Chemotherapeutics; Vitamins; Hormones; and Miscellaneous Agents including Diagnostics. The appendix lists drugs in the USP and NF.

Each part consists of several chapters dealing with discrete topics. They are concisely written along the lines of precis or compendia. The highlights of drug structure and action, as well as side effects and dosage, are recorded. Structural formulas and tables are utilized to illustrate structure–activity relationships in some cases. Useful references are appended to each chapter and are divided into general background and specific citations by class of agents.

The book should prove useful as a compendium of information in medicinal chemistry. This book plus a text organized in depth over the same topics should provide the student with a good background in course work, for board exams, and for professional practice.

Reviewed by Lemont B. Kier
Massachusetts College of Pharmacy
Boston, MA 02115

Manual of Clinical Immunology. Edited by NOEL R. ROSE and HERMAN FRIEDMAN. American Society for Microbiology, 1913 I St. N.W., Washington, DC, 20006, 1976. 932 pp. 17.5 × 26 cm. Price $16.00, flexible binding; $20.00, cloth binding.

This much needed volume, written by 180 authorities in various aspects of the rapidly expanding field of immunology, presents the latest information. The book is directed mainly to laboratory directors and technologists but should prove extremely useful to graduate students, medical students, postdoctoral fellows, residents, and clinicians. The greatest value of this book is the presentation of methodologies, allowing a stepwise approach to various procedures currently used in both clinical and research immunology. Of particular importance is the discussion of the pros and cons of each procedure with emphasis on the pitfalls encountered. Suggestions as to sources of materials and equipment required for each test can save time when setting up a new method.

The arrangement of the book in sections covering different aspects of the components involved in immunological responses and the cross-referencing between chapters allow the investigator to understand not only his or her own area but also the influence of cellular *versus* humoral aspects of immunology. Of particular importance are the chapters covering delayed hypersensitivity, lymphocyte subpopulations, and lymphocyte transformation.

The principles of radioimmunoassay are well presented, and the methods for determining various hormones in body fluids have general applicability not only in the clinic but also in the research laboratory.

Coverage of the immunological aspects of bacterial, mycotic, parasitic, viral, rickettsial, and chlamydial diseases will assist the clinician in more accurate diagnosis. The disadvantages of immunofluorescence and radioimmunoassays in immunodiagnosis of viral diseases are discussed, and suggestions for the use of microplate enzyme methods are given. The main advantages of the latter are a long shelflife, cheap simple equipment, and the same degree of sensitivity as the other procedures.

In the immunohematology section, the chapters on autoimmune and drug immune hemolytic anemia and the immunology of clotting factors point out the importance of modern immulogical methods in the diagnosis of often fatal diseases. Allergic disease testing is well covered, but the importance of testing for drug hypersensitivity is not adequate, being confined almost entirely to penicillin. The subject of autoimmune diseases receives full treatment, including tests for antibodies to tissue-specific antigens. The section on tumor immunology covers the present state of the art and indicates the necessity for further research to improve early tumor diagnosis. The section on transplantation immunology presents the immunological aspects of tissue transplantation, particularly the rejection phenomenon. The last section is of importance to clinical laboratories because it covers legal requirements, quality control, standardization of materials and methods, and proficiency testing of laboratory personnel.

This volume should be available to clinical and research workers in immunology and, because the field is expanding so rapidly, it should be updated more often than most such manuals.

Aliphatic Chemistry. Vol. 4. A Specialist Periodical Report. Edited by A. McKILLOP *et al.* The Chemical Society, Burlington House, London, W1V 0BN, England, 1976. 281 pp. 14 × 22.5 cm. Price $49.50.

The fourth volume of the Specialist Periodical Reports on aliphatic chemistry is comprised of four chapters which summarize developments reported during 1974 in each of the chosen areas. Chapter 1, on the chemistry of acetylenes, alkanes, allenes, and alkenes, was contributed by D. W. Dunwell, J. C. Saunders, and B. P. Swann. The second chapter, which deals with aliphatic compounds having other functional groups (carboxylic acids and their derivatives, amino acids, aldehydes and ketones, alcohols, amines, alkyl halides, ethers, sulfur compounds, and miscellaneous aliphatic compounds) was prepared by E. W. Colvin, who also contributed the analogous reviews in all of the preceding volumes of this series.

The remainder of the volume is devoted to surveys of the literature dealing with naturally occurring polyolefinic and polyacetylenic compounds (Chapter 3) and with the chemistry of prostaglandins (Chapter 4). Both of these chapters were written by G. Pattenden, as were the corresponding chapters of Volumes 2 and 3. The reviews of Chapter 3 include, in addition to other topics, summaries of new work on polyolefinic antibiotics (*e.g.*, ansamycins) and other microbial metabolites, a variety of plant-product structures, polyolefins and polyacetylenes of marine origin, and insect pheromones. The fact that the chapter on prostaglandins is less than one-third of the length of the same chapter in Volume 3 is cogent testimony to the author's opening assertion of the

Essentials of Medicinal Chemistry. By ANDREJUS KOROLKOVAS and JOSEPH H. BURCKHALTER. Wiley, 605 Third Ave., New York, N Y 10016, 1976. 697 pp. 16 × 23.5 cm. Price $22.50.

The book is designed as an undergraduate text in medicinal chemistry as well as a resource work for the chemist and biologist interested in several aspects of drugs. The composition of the book is built around succinctly stated facts and theories, which the authors hope are presented in a palatable, yet useful, form for the student. The authors have in mind the role of the pharmacist as an information source helping the physician and patient.

The book is in eight parts and generally follows pharmacological or therapeutic categories. These are Introduction: Basics, Drug Development and Theories; CNS Drugs; Drugs Acting at the Peripheral Nervous System; Cardiovascular, Blood and Renal Systems; Chemotherapeutics; Vitamins; Hormones; and Miscellaneous Agents including Diagnostics. The appendix lists drugs in the USP and NF.

Each part consists of several chapters dealing with discrete topics. They are concisely written along the lines of precis or compendia. The highlights of drug structure and action, as well as side effects and dosage, are recorded. Structural formulas and tables are utilized to illustrate structure–activity relationships in some cases. Useful references are appended to each chapter and are divided into general background and specific citations by class of agents.

The book should prove useful as a compendium of information in medicinal chemistry. This book plus a text organized in depth over the same topics should provide the student with a good background in course work, for board exams, and for professional practice.

Manual of Clinical Immunology. Edited by NOEL R. ROSE and HERMAN FRIEDMAN. American Society for Microbiology, 1913 I St. N.W., Washington, DC, 20006, 1976. 932 pp. 17.5 × 26 cm. Price $16.00, flexible binding; $20.00, cloth binding.

This much needed volume, written by 180 authorities in various aspects of the rapidly expanding field of immunology, presents the latest information. The book is directed mainly to laboratory directors and technologists but should prove extremely useful to graduate students, medical students, postdoctoral fellows, residents, and clinicians. The greatest value of this book is the presentation of methodologies, allowing a stepwise approach to various procedures currently used in both clinical and research immunology. Of particular importance is the discussion of the pros and cons of each procedure with emphasis on the pitfalls encountered. Suggestions as to sources of materials and equipment required for each test can save time when setting up a new method.

The arrangement of the book in sections covering different aspects of the components involved in immunological responses and the cross-referencing between chapters allow the investigator to understand not only his or her own area but also the influence of cellular *versus* humoral aspects of immunology. Of particular importance are the chapters covering delayed hypersensitivity, lymphocyte subpopulations, and lymphocyte transformation.

The principles of radioimmunoassay are well presented, and the methods for determining various hormones in body fluids have general applicability not only in the clinic but also in the research laboratory.

Coverage of the immunological aspects of bacterial, mycotic, parasitic, viral, rickettsial, and chlamydial diseases will assist the clinician in more accurate diagnosis. The disadvantages of immunofluorescence and radioimmunoassays in immunodiagnosis of viral diseases are discussed, and suggestions for the use of microplate enzyme methods are given. The main advantages of the latter are a long shelflife, cheap simple equipment, and the same degree of sensitivity as the other procedures.

In the immunohematology section, the chapters on autoimmune and drug immune hemolytic anemia and the immunology of clotting factors point out the importance of modern immulogical methods in the diagnosis of often fatal diseases. Allergic disease testing is well covered, but the importance of testing for drug hypersensitivity is not adequate, being confined almost entirely to penicillin. The subject of autoimmune diseases receives full treatment, including tests for antibodies to tissue-specific antigens. The section on tumor immunology covers the present state of the art and indicates the necessity for further research to improve early tumor diagnosis. The section on transplantation immunology presents the immunological aspects of tissue transplantation, particularly the rejection phenomenon. The last section is of importance to clinical laboratories because it covers legal requirements, quality control, standardization of materials and methods, and proficiency testing of laboratory personnel.

This volume should be available to clinical and research workers in immunology and, because the field is expanding so rapidly, it should be updated more often than most such manuals.

Aliphatic Chemistry. Vol. 4. A Specialist Periodical Report. Edited by A. McKILLOP *et al.* The Chemical Society, Burlington House, London, W1V 0BN, England, 1976. 281 pp. 14 × 22.5 cm. Price $49.50.

The fourth volume of the Specialist Periodical Reports on aliphatic chemistry is comprised of four chapters which summarize developments reported during 1974 in each of the chosen areas. Chapter 1, on the chemistry of acetylenes, alkanes, allenes, and alkenes, was contributed by D. W. Dunwell, J. C. Saunders, and B. P. Swann. The second chapter, which deals with aliphatic compounds having other functional groups (carboxylic acids and their derivatives, amino acids, aldehydes and ketones, alcohols, amines, alkyl halides, ethers, sulfur compounds, and miscellaneous aliphatic compounds) was prepared by E. W. Colvin, who also contributed the analogous reviews in all of the preceding volumes of this series.

The remainder of the volume is devoted to surveys of the literature dealing with naturally occurring polyolefinic and polyacetylenic compounds (Chapter 3) and with the chemistry of prostaglandins (Chapter 4). Both of these chapters were written by G. Pattenden, as were the corresponding chapters of Volumes 2 and 3. The reviews of Chapter 3 include, in addition to other topics, summaries of new work on polyolefinic antibiotics (*e.g.*, ansamycins) and other microbial metabolites, a variety of plant-product structures, polyolefins and polyacetylenes of marine origin, and insect pheromones. The fact that the chapter on prostaglandins is less than one-third of the length of the same chapter in Volume 3 is cogent testimony to the author's opening assertion of the

under it "Edestin from hemp seed," "Edestinase from hemp seed," and "Quaternary bases in *Cannabis*" only. For the amount of biochemical studies published on the cannabinoids, the biochemists will be disturbed with this type of index coverage.

A large number of incorrect spellings of common and technical words are found in the abstracts. These errors are self-evident for the most part but confusing in cases such as, for example, citation 2914 where "Cannabidivarian" appears in the title of the article and "Cannabidivarin" in the abstract, the latter presumably correct. In a few cases, words and/or phrases are apparently missing in titles of articles or in the abstracts. These omissions are usually not too much of a problem as in citations 368, 431, 474, 740, 1290, 1321, 1679, 1905, 1927, 2058, 2480, 2493, 2708, 2722, and 2914. The journal citation in 301 is confusing, and citation 2212 does not refer to the journal cited.

When abstracts are given, there is a great degree of inconsistency regarding content. Also, the summary table on p. XXII hardly can be considered complete.

However, even though these minor problems were found, the book at a very reasonable price of $13.95 is a bargain. It will be an indispensable, and much used addition to the personal library of anyone having even a remote interest in *Cannabis*. It will be of special interest to researchers in the field of *Cannabis*, to students in the medical professions and social sciences, to the pharmaceutical industry, and to reporters in the media and should be available in every library.

Physiologic Disposition of Drugs of Abuse. By LOUIS LEMBERGER and ALAN RUBIN. Halsted, 605 Third Ave., New York, NY 10016, 1976. 401 pp. 16 × 23.5 cm. Price $29.50.

This book contains 10 chapters. The first chapter describes the fundamental principles of drug disposition. The absorption, distribution, and *in vivo* and *in vitro* metabolism of drugs of abuse are described in Chapters 2–9. The 10th chapter deals with the phenomenon and mechanism of tolerance.

The drugs of abuse discussed include amphetamine, mescaline and related phenylalkylamines, LSD and related indolealkylamines, morphine, morphine substitutes, barbiturates, methaqualone, caffeine, nicotine, alcohol, the cannabinoids, cocaine, and miscellaneous drugs including volatile solvents.

Numerous scattered papers and reviews concerning the physiologic disposition of drugs of abuse are summarized in the book. Chemical structural illustrations are used to demonstrate the metabolic pathways of drugs. These illustrations help readers to understand the process of biotransformation of the drug. There is no doubt in the reviewer's mind that this book will be of value and benefit to pharmacologists, psychiatrists, psychologists, and those in basic and clinical fields, especially graduate students and research associates beginning research in fields related to drugs of abuse. The extensive, up-to-date bibliography is very helpful.

It would be nice if a chapter on tranquilizers, especially benzodiazepams, was incorporated in this book.

Drug Regulation and Innovation: Empirical Evidence and Policy Options. By HENRY G. GRABOWSKI. American Enterprise Institute for Public Policy Research, 1150 17th Street, N. W., Washington, DC 20036, 1976. 82 pp. 15 × 23 cm. Price $3.00.

This book sets out to prove that there is a drug lag in the United States due to governmental regulation of the pharmaceutical industry. It must be seen as an attempt to convince readers of this lag by citing portions of several economic studies. The first five chapters examine various aspects of the effects of regulation on the pharmaceutical industry, and the final chapter presents some suggested policy modifications to rectify the supposed "drug lag."

The book, which is very one-sided, failed to convince the reviewer of the seriousness, or even existence, of the problem. There is a citation that U.S. doctors sent patients abroad for treatment in order to use a drug not available here. This statement is supported by a single citation indicating TWO such examples,

The tone of the work is evident in a quotation from the forward, written by Professor Yale Brozen: "A small step in this direction would be to eliminate the FDA's power to require substantial evidence of effectiveness" (p. 7). Essentially, the argument is made that the United States is falling behind in the number of new chemical entities first developed and/or introduced in this country and that this problem is related to the 1962 amendments to the Federal, Food, Drug, and Cosmetics Act. Arguments for the value of some drugs include their sales and market share abroad. The market test is hardly a valid indicator of the value of a product, and it is perplexing that economists choose to use this argument. No one would deny that each of 80 different penicillin derivatives could be useful individually, but more subject to controversy is whether we have a "drug lag" at all if analogs of existing products are not on the U.S. market.

It is argued that the 1962 amendments will decrease U.S. prestige, harm our foreign balance of payments, and decrease support of academic pharmacology. Yet these arguments are unsupported. Surely the author must have considered factors encouraging foreign research such as the corporate tax structure, foreign profit repatriation rules, and relative labor costs. We come across the statement that the pharmaceutical industry is of above-average riskiness (p. 40). While this may be so for individual products, Barges and Hickey and others have refuted this argument. Easing of FDA regulation and earlier releasing of drugs with greater surveillance after marketing are proposed.

It is no great shock to this reviewer to see that researchers and investors in foreign lands have had successes as we have had. Also, one might argue that the availability of fewer new products is less potentially confusing to prescribers and that competition from products having expired patent protection should help to reduce prices. It seems that in this book conclusions are made repeatedly that are far broader than merited by the findings. The author dismisses arguments about decreases in the number of new product introductions in other countries and points made by government officials if they do not coincide with his hypothesis. This reviewer was expecting a much more even-handed treatment of the subject than he found.

Antibiotics. A Critical Review. Edited by W. KURYLOWICZ. Polish Medical Publishers, Warsaw, Poland. Distributed by the American Society for Microbiology, 1913 I St., N.W., Washington, DC 20006, 1976. 204 pp. 17 × 24.5 cm. Price $6.00.

This book by four Polish authorities in the field attempts to compress the subject of antibiotics into about 200 pages. There is a short introduction as well as a brief section on classification, but the bulk of the book is devoted to two sections. Antibiotics in Microbial Metabolism deals with the biosynthesis and mode of action of antibiotics, and Antibiotics as Therapeutic Agents discusses the pharmacology and therapeutics. A great deal of condensed information is included in this book, which is both its strength and its weakness.

The section Antibiotics in Microbial Metabolism is the most useful. Structural formulas and diagrams are plentifully used in a valuable overview of this complex area. The section Antibiotics as Therapeutic Agents is less successful. Here the abridgement combined with the desire to be comprehensive, even to the point of presenting the principles of drug–protein binding and pharmacokinetics, each in a few pages, creates significant problems. A large number of drugs, some of only minor clinical interest in the United States, are dealt with summarily and important omissions occur. There is no mention, for instance, of colitis as a toxic side effect of clindamycin or of cardiomyopathy as a toxicity of the anthracycline antibiotics.

The book contains a substantial number of misprints, most of which are trivial, but some are more problematic; for instance, on page 97 there is a reference to Table 1 which, I think, though I cannot be sure, is a reference to Table 4–3.

In summary, I feel that these authors have made an admirable attempt to review an enormous amount of information in a small book. The result is a valuable introduction to the subject of antibiotics and a useful adjunct to other texts, but it would be unwise to rely on it as a sole source of information about these compounds.

There is a citation that U.S. doctors sent patients abroad for treatment in order to use a drug not available here. This statement is supported by a single citation indicating TWO such examples,

The tone of the work is evident in a quotation from the forward, written by Professor Yale Brozen: "A small step in this direction would be to eliminate the FDA's power to require substantial evidence of effectiveness" (p. 7). Essentially, the argument is made that the United States is falling behind in the number of new chemical entities first developed and/or introduced in this country and that this problem is related to the 1962 amendments to the Federal, Food, Drug, and Cosmetics Act. Arguments for the value of some drugs include their sales and market share abroad. The market test is hardly a valid indicator of the value of a product, and it is perplexing that economists choose to use this argument. No one would deny that each of 80 different penicillin derivatives could be useful individually, but more subject to controversy is whether we have a "drug lag" at all if analogs of existing products are not on the U.S. market.

It is argued that the 1962 amendments will decrease U.S. prestige, harm our foreign balance of payments, and decrease support of academic pharmacology. Yet these arguments are unsupported. Surely the author must have considered factors encouraging foreign research such as the corporate tax structure, foreign profit repatriation rules, and relative labor costs. We come across the statement that the pharmaceutical industry is of above-average riskiness (p. 40). While this may be so for individual products, Barges and Hickey and others have refuted this argument. Easing of FDA regulation and earlier releasing of drugs with greater surveillance after marketing are proposed.

It is no great shock to this reviewer to see that researchers and investors in foreign lands have had successes as we have had. Also, one might argue that the availability of fewer new products is less potentially confusing to prescribers and that competition from products having expired patent protection should help to reduce prices. It seems that in this book conclusions are made repeatedly that are far broader than merited by the findings. The author dismisses arguments about decreases in the number of new product introductions in other countries and points made by government officials if they do not coincide with his hypothesis. This reviewer was expecting a much more even-handed treatment of the subject than he found.

Antibiotics. A Critical Review. Edited by W. KURYLOWICZ. Polish Medical Publishers, Warsaw, Poland. Distributed by the American Society for Microbiology, 1913 I St., N.W., Washington, DC 20006, 1976. 204 pp. 17 × 24.5 cm. Price $6.00.

This book by four Polish authorities in the field attempts to compress the subject of antibiotics into about 200 pages. There is a short introduction as well as a brief section on classification, but the bulk of the book is devoted to two sections. Antibiotics in Microbial Metabolism deals with the biosynthesis and mode of action of antibiotics, and Antibiotics as Therapeutic Agents discusses the pharmacology and therapeutics. A great deal of condensed information is included in this book, which is both its strength and its weakness.

The section Antibiotics in Microbial Metabolism is the most useful. Structural formulas and diagrams are plentifully used in a valuable overview of this complex area. The section Antibiotics as Therapeutic Agents is less successful. Here the abridgement combined with the desire to be comprehensive, even to the point of presenting the principles of drug–protein binding and pharmacokinetics, each in a few pages, creates significant problems. A large number of drugs, some of only minor clinical interest in the United States, are dealt with summarily and important omissions occur. There is no mention, for instance, of colitis as a toxic side effect of clindamycin or of cardiomyopathy as a toxicity of the anthracycline antibiotics.

The book contains a substantial number of misprints, most of which are trivial, but some are more problematic; for instance, on page 97 there is a reference to Table 1 which, I think, though I cannot be sure, is a reference to Table 4–3.

In summary, I feel that these authors have made an admirable attempt to review an enormous amount of information in a small book. The result is a valuable introduction to the subject of antibiotics and a useful adjunct to other texts, but it would be unwise to rely on it as a sole source of information about these compounds.

Lipid Chromatographic Analysis. Vol. 2. Edited by GUIDO V. MARINETTI. Dekker, 270 Madison Avenue, New York, NY 10016, 1976. 400 pp. 15 × 23.5 cm. Price $34.50.

This text contains five chapters covering compounds that, in the broadest sense, can be considered as lipids. The chapters cover TLC of sterols and steroids, GLC of bile acids, chromatography of prostaglandins,

decrease in the chemical literature in this area.

As in the preceding volumes, the emphasis is on syntheses and reactions of the various classes of compounds. The liberal use of structural formulas and reaction schemes is an invaluable aid to the user of these volumes. Like its predecessors, this volume serves as a well-organized source of much valuable information on general aliphatic chemistry and on aliphatic natural products.

Physiologic Disposition of Drugs of Abuse. By LOUIS LEMBERGER and ALAN RUBIN. Halsted, 605 Third Ave., New York, NY 10016, 1976. 401 pp. 16 × 23.5 cm. Price $29.50.

This book contains 10 chapters. The first chapter describes the fundamental principles of drug disposition. The absorption, distribution, and *in vivo* and *in vitro* metabolism of drugs of abuse are described in Chapters 2–9. The 10th chapter deals with the phenomenon and mechanism of tolerance.

The drugs of abuse discussed include amphetamine, mescaline and related phenylalkylamines, LSD and related indolealkylamines, morphine, morphine substitutes, barbiturates, methaqualone, caffeine, nicotine, alcohol, the cannabinoids, cocaine, and miscellaneous drugs including volatile solvents.

Numerous scattered papers and reviews concerning the physiologic disposition of drugs of abuse are summarized in the book. Chemical structural illustrations are used to demonstrate the metabolic pathways of drugs. These illustrations help readers to understand the process of biotransformation of the drug. There is no doubt in the reviewer's mind that this book will be of value and benefit to pharmacologists, psychiatrists, psychologists, and those in basic and clinical fields, especially graduate students and research associates beginning research in fields related to drugs of abuse. The extensive, up-to-date bibliography is very helpful.

It would be nice if a chapter on tranquilizers, especially benzodiazepams, was incorporated in this book.

Drug Regulation and Innovation: Empirical Evidence and Policy Options. By HENRY G. GRABOWSKI. American Enterprise Institute for Public Policy Research, 1150 17th Street, N. W., Washington, DC 20036, 1976. 82 pp. 15 × 23 cm. Price $3.00.

This book sets out to prove that there is a drug lag in the United States due to governmental regulation of the pharmaceutical industry. It must be seen as an attempt to convince readers of this lag by citing portions of several economic studies. The first five chapters examine various aspects of the effects of regulation on the pharmaceutical industry, and the final chapter presents some suggested policy modifications to rectify the supposed "drug lag."

The book, which is very one-sided, failed to convince the reviewer of the seriousness, or even existence, of the problem. There is a citation that U.S. doctors sent patients abroad for treatment in order to use a drug not available here. This statement is supported by a single citation indicating TWO such examples,

This text contains five chapters covering compounds that, in the broadest sense, can be considered as lipids. The chapters cover TLC of sterols and steroids, GLC of bile acids, chromatography of prostaglandins,

GLC of carbohydrate glycolipids, and GLC of long chain nitrogen bases.

The chapter on sterols and steroids (139 pages) deals primarily with TLC, and data are presented clearly in tabular form for a most comprehensive list including many steroids currently on the market. The chapter on bile acids (130 pages) provides a highly detailed description of GLC methodology including experimental methodology for "Filling of Columns" and "Formation of Derivatives." The chapter on prostaglandins (51 pages) succinctly covers all chromatographic methods with emphasis on metabolites and extraction. The section on carbohydrate glycolipid GLC (37 pages) includes many common sugars as well as detailed methodology for synthesizing derivatives. The section on long chain nitrogen bases (11 pages) provides detailed procedures for cleavage, derivative formation, and GLC.

Knowledge of chromatographic methodology is often critical in many pharmaceutical, biological, and synthetic research projects. The detailed information and experimental methodology presented in this book should provide a most useful source to the pharmaceutical scientist. It is highly recommended to those involved in research as well as development of compounds in the classes covered.

Pharmacology of Marihuana. Vols. 1 and 2. Edited by MONIQUE C. BRAUDE and STEPHEN SZARA. Raven, 1140 Avenue of the Americas, New York, NY 10036, 1976. 458 pp. 16.5 × 24.5 cm. Price $50.00 (two volumes).

This two-volume set represents the proceedings of the International Conference sponsored by the National Institute on Drug Abuse in Savannah, Ga., December 3–6, 1974.

These books contain a total of nine parts. The first part offers general background information, and the last part deals with the therapeutic potential. In the remaining seven parts, comprehensive research data are presented, including chemical and metabolic aspects; cellular, immunological, hormonal, autonomic, and neuropharmacological effects; behavioral pharmacology; related drug interactions; effects on genetics and reproduction; and the long-term effects of marihuana.

The data from both preclinical and clinical research are presented. Respiratory and cardiovascular effects are discussed in Part IV under Autonomic Effects. It is rather surprising that only a small portion of the text is devoted to these aspects, considering the complex effects of Δ^9-tetrahydrocannabinol on the cardiovascular and respiratory systems, including interference with the reflexogenic mechanisms. The discussion on p. 287, Cardiovascular Effects, has very little to do with the cardiovascular system and deals mostly with bronchodilator effects.

The primary means of self-administration of marihuana is by inhalation, but little information is presented in these texts concerning its acute and/or chronic effects on pulmonary hemodynamics. Such information would have been useful, especially since therapeutic value has been implicated for marihuana in bronchial asthma. These limitations perhaps emphasize the urgent need for further research in these areas. In this respect, these books serve a useful purpose in documenting what is known and what is not.

Marihuana and its constituents are highly complex and possess numerous pharmacological properties; the National Institute on Drug Abuse performed an extremely useful service in comprehensively presenting this material. Dr. Braude and Dr. Szara should be commended for excellence in designing the symposium and editing the proceedings. These books will be extremely useful for researchers and clinicians concerned with research on marihuana.

Kremers and Urdang's History of Pharmacy. Fourth Ed. Revised by GLENN SONNEDECKER. J. B. Lippincott, East Washington Square, Philadelphia, PA 19105, 1976. 571 pp. 19.5 × 24 cm. Price $24.00.

Methods in Receptor Research. Part 1. Edited by MELVIN BLECHER. Dekker, 270 Madison Ave., New York, NY 10016, 1976. 383 pp. 15.5 × 23.5 cm. Price $36.50.

Drugs and Therapy. A Psychotherapist's Handbook of Psychotropic Drugs. By ALVIN K. SWONGER and LARRY L. CONSTANTINE. Little, Brown, 34 Beacon St., Boston, MA 02106, 1976. 292 pp. 14.5 × 22 cm. Price $8.95.

Fluorocarbon and Related Chemistry. Vol. 3. Edited by R. E. BANKS, M.G. BARLOW, *et al.* The Chemical Society, Burlington House, London W1V OBN, England, 1976. 491 pp. 14.5 × 22.5 cm. Price £35.00.

Stylebook/Editorial Manual of the AMA. 6th Ed. By the Scientific Publications Division, American Medical Assn. Publishing Sciences Group, 162 Great Rd., Acton, MA 01720, 1976. 161 pp. 13.5 × 21.5 cm. Price $6.50.

Handbook of Basic Pharmacokinetics. By W. A. RITSCHEL. Drug Intelligence Publications, Hamilton, IL 62341, 1976. 370 pp. 11.5 × 19.5 cm. Price $16.00.

Aminergic Hypotheses of Behavior: Reality or Cliche? National Institute on Drug Abuse Research Monograph Series 3. Edited by BRUCE K. BERNARD. National Institute on Drug Abuse, 11400 Rockville Pike, Rockville, MD 20852, 1975. 148 pp. 20.5 × 27 cm. Price $6.75.

Handbook of Intermediary Metabolism of Aromatic Compounds. By B. L. GOODWIN. Halsted, 605 Third Ave., New York, NY 10016, 1976. 25.5 × 20 cm. Price $75.00.

Frontiers of Pharmacology. Journal of Pharmacy and Pharmacology: Special Supplement. Edited by B. A. CALLINGHAM, M. A. SIMMONDS, and D. W. STRAUGHAN. The Pharmaceutical Press, 17 Bloomsbury Square, London, WC1A 2NN, England, 1976. 405 pp. 18 × 25.5 cm. Price £2.50.

Dimethyl Sulphoxide. By DIETER MARTIN and HERMANN G. HAUTHAL. Halsted, 605 Third Ave., New York, NY 10016, 1975. 500 pp. 16 × 25 cm.

Organic Chemistry, Series Two. Vol. 3: Aromatic Compounds. Edited by H. ZOLLINGER. Butterworth, Borough Green, NR Sevenoaks, Kent, England, 1976. 350 pp. 16 × 24 cm. Price £13.45.

Organic Chemistry, Series Two. Vol. 4: Heterocyclic Compounds. Edited by K. SCHOFIELD. Butterworth, Borough Green, NR Sevenoaks, Kent, England, 1976. 392 pp. 16 × 24 cm. Price £13.45.

Lung Liquids. Ciba Foundation Symposium 38 (new series). CIBA Pharmaceutical Co. Elsevier, 52 Vanderbilt Ave., New York, NY 10017, 1976. 330 pp. 17 × 24.5 cm.

Narcolepsy. (Advances in Sleep Research. Vol. 3) Edited by C. GUILLEMINAULT, C. DEMENT, and P. PASSOUANT. Halsted, 605 Third Ave., New York, NY 10016, 1976. 689 pp. 16 × 23.5 cm. Price $40.00.

Organophosphorus Chemistry. Vol. 7. Edited by S. TRIPPETT *et al.* The Chemical Society, Burlington House, London, W1V OBN, England, 1976. 285 pp. 14.5 × 22.5 cm. Price $55.00.

Pharmacology of Behavior and Memory. By R. YU. Il'YUCHENOK. Halsted, 605 Third Ave., New York, NY 10016, 1976. 216 pp. 16 × 23.5 cm. Price $22.50.

Photochemistry. Vol. 7. Edited by D. BRYCE-SMITH *et al.* The Chemical Society, Burlington House, London, W1V OBN, England, 1976. 617 pp. 14.5 × 22.5 cm. Price £32.00.

Psychotropic Action of Hormones. Edited by T. M. ITIL, G. LAUDAHN, and W. M. HERRMANN. Halsted, 605 Third Ave., New York, NY 10016, 1976. 248 pp. 16 × 23.5 cm. Price $25.00.

Separation and Purification Methods. Vol. 4. Edited by E. S. PERRY, C. J. van OSS, and E. GRUSHKA. Dekker, 270 Madison Ave., New York, NY 10016, 1976. 413 pp. 16 × 23.5 cm. Price $32.50.

Drug Misuse . . . Human Abuse. By HELEN I. GREEN and MICHAEL H. LEVY. Dekker, 270 Madison Ave., New York, NY 10016, 1976. 566 pp. 18.5 × 26 cm. Price $19.75.

Basic Neurochemistry. Second Ed. Edited by GEORGE J. SIEGEL *et al.* Little, Brown, 34 Beacon St., Boston, MA 02106, 1976. 825 pp. 15.5 × 23.5 cm. Price $15.00.

Genetic and Biochemical Aspects of the Development of Datura. Monographs in Developmental Biology. Vol. 12. By MARIE E. CONKLIN. S. Karger AG., Arnold-Bocklin-Strasse 25, CH-4011 Basel, Switzerland, 1976. 170 pp. 15.5 × 22.5 cm. Price $30.50.

GLC of carbohydrate glycolipids, and GLC of long chain nitrogen bases.

The chapter on sterols and steroids (139 pages) deals primarily with TLC, and data are presented clearly in tabular form for a most comprehensive list including many steroids currently on the market. The chapter on bile acids (130 pages) provides a highly detailed description of GLC methodology including experimental methodology for "Filling of Columns" and "Formation of Derivatives." The chapter on prostaglandins (51 pages) succinctly covers all chromatographic methods with emphasis on metabolites and extraction. The section on carbohydrate glycolipid GLC (37 pages) includes many common sugars as well as detailed methodology for synthesizing derivatives. The section on long chain nitrogen bases (11 pages) provides detailed procedures for cleavage, derivative formation, and GLC.

Knowledge of chromatographic methodology is often critical in many pharmaceutical, biological, and synthetic research projects. The detailed information and experimental methodology presented in this book should provide a most useful source to the pharmaceutical scientist. It is highly recommended to those involved in research as well as development of compounds in the classes covered.

Pharmacology of Marihuana. Vols. 1 and 2. Edited by MONIQUE C. BRAUDE and STEPHEN SZARA. Raven, 1140 Avenue of the Americas, New York, NY 10036, 1976. 458 pp. 16.5 × 24.5 cm. Price $50.00 (two volumes).

This two-volume set represents the proceedings of the International Conference sponsored by the National Institute on Drug Abuse in Savannah, Ga., December 3–6, 1974.

These books contain a total of nine parts. The first part offers general background information, and the last part deals with the therapeutic potential. In the remaining seven parts, comprehensive research data are presented, including chemical and metabolic aspects; cellular, immunological, hormonal, autonomic, and neuropharmacological effects; behavioral pharmacology; related drug interactions; effects on genetics and reproduction; and the long-term effects of marihuana.

The data from both preclinical and clinical research are presented. Respiratory and cardiovascular effects are discussed in Part IV under Autonomic Effects. It is rather surprising that only a small portion of the text is devoted to these aspects, considering the complex effects of Δ^9-tetrahydrocannabinol on the cardiovascular and respiratory systems, including interference with the reflexogenic mechanisms. The discussion on p. 287, Cardiovascular Effects, has very little to do with the cardiovascular system and deals mostly with bronchodilator effects.

The primary means of self-administration of marihuana is by inhalation, but little information is presented in these texts concerning its acute and/or chronic effects on pulmonary hemodynamics. Such information would have been useful, especially since therapeutic value has been implicated for marihuana in bronchial asthma. These limitations perhaps emphasize the urgent need for further research in these areas. In this respect, these books serve a useful purpose in documenting what is known and what is not.

Marihuana and its constituents are highly complex and possess numerous pharmacological properties; the National Institute on Drug Abuse performed an extremely useful service in comprehensively presenting this material. Dr. Braude and Dr. Szara should be commended for excellence in designing the symposium and editing the proceedings. These books will be extremely useful for researchers and clinicians concerned with research on marihuana.

A NEW KIND OF "DRUG LAG"

Much has been said and written about the purported "drug lag" in the United States. Although we are certain that most of our readers are quite familiar with this issue, for the sake of those who are not, a brief description would be in order.

Basically, the present drug laws in this country require a demonstration of both safety and effectiveness before the marketing of a new drug is permitted. Moreover, the implementing regulations spell out in more precise terms and in greater detail the types of testing and test data that must be compiled in support of the claims made in the application submitted for approval. For example, controlled, double-blind clinical studies generally are considered essential in the effort to document the effectiveness claimed for a new drug.

The documentation required, both in a qualitative and a quantitative sense, coupled with the administrative procedures utilized generally results in new drugs appearing on the U.S. market at a later date than in most countries abroad. Depending upon the interests and politics of the person commenting, this situation is depicted as ranging from a very serious problem in which desperate patients are denied lifesaving therapy for years on end, to a blessing in which the public is guarded and shielded from inadequately tested, dangerous agents that are promiscuously marketed in other countries.

The drugs involved are new chemical entities which are patentable and, therefore, the firm submitting the New Drug Application would retain exclusive property rights—except, of course, for possible licensing and royalty agreements—to that agent for the life of the patent. Hence, there is a strong profit motive which greatly encourages the interested company to actively pursue its efforts toward obtaining government approval for marketing the new drug discovery.

Indeed, various allegations have been made that certain firms and certain drug industry representatives have pursued this objective too vigorously to the point of bringing improper pressures to bear upon the government agency's medical scientists in a zealous effort to win such approval for their new drugs.

The purpose of this editorial, however, is not to enter this familiar "drug lag" controversy. Rather, it is to call attention to the neglected compounds that have great potential as useful drugs, but which are shunned by drug companies simply because they are unpatentable. For all its benefits and advantages, the free enterprise and patent system discourages private industry from investigating the potential therapeutic value of such unpatentable compounds.

Consequently, a "research lag" exists because research and development relating to these compounds—which happen to be in this category of known compounds or naturally occurring substances—simply are not conducted. A rather dramatic illustration is the drug lithium carbonate. The value of lithium in treating manic-depression was suggested many years ago; indeed, reports of its effectiveness appeared in the late 1940's. However, as recent as 1965, no commercial firm was sufficiently interested in pursuing these leads because lithium and its common salts are naturally occurring substances which are not patentable.

Eventually, we understand that the American College of Neuropsychopharmacology, in a move that would have been without precedent, seriously considered submitting a New Drug Application in its own name in order to win government approval for the agent as a drug. What abruptly changed this situation and prompted industry interest in the mid-1960's was a recognition that the clinical usefulness of lithium is dependent upon its formulation as a slow-release dosage form and that such timed-release products are patentable.

We are not suggesting that the drug industry was negligent or derelict in failing to devote research dollars to study lithium or any other such unprofitable entity. But we are suggesting that a void exists in our present system, which results in potentially useful drugs being neglected.

Various possible remedies are available to fill this research gap, including private foundations, academic institutions, and various public facilities such as hospitals operated by the Public Health Service or Veterans Administration. However, it would appear that the most logical central facility to assume this role is the National Institutes of Health and, specifically, the National Institute of General Medical Sciences. Moreover, it strikes us that federal research dollars—which often are spent in such questionable pursuits as to merit U.S. Senator William Proxmire's celebrated "Golden Fleece Award"—would be well utilized if expended for this purpose.

REVIEW ARTICLE

Electrophysiological and Pharmacological Properties of Skeletal Muscle in Culture

A. L. HARVEY and W. F. DRYDEN ˣ

Keyphrases □ Skeletal muscle in culture—electrophysiological and pharmacological properties, chemosensitivity, review □ Tissue culture—skeletal muscle, electrophysiological and pharmacological properties, chemosensitivity, review □ Electrophysiology—skeletal muscle in culture, review □ Chemosensitivity—skeletal muscle in culture, review

Tissue culture is the maintenance or growth of biological tissues in an artificial medium. Techniques in use include: (*a*) organ culture, which uses a complete organ in isolation from the body; (*b*) explant culture, in which a small portion of tissue is excised and maintained as a discrete piece; (*c*) cell culture, which involves dissociation of the explant to a suspension of separate cells; and (*d*) continuous cell lines, which can be maintained in culture conditions by continuous multiplication.

Tissue culture has several advantages over conventional *in vivo* or *in vitro* experimental systems. Blood flow, hormones, nerve trophic factors, and other body influences no longer affect the functions of the tissue; the cultures are in a controlled environment which is easy to alter for experimental purposes. The amount of tissue disintegration can be selected by the choice of technique, for example, by using explants or cell lines. Monolayer cultures of dissociated cells are usually more accessible than tissues *in situ*, thus enabling cells to be studied throughout development and allowing prolonged experiments. In addition, human tissue from biopsies or embryos can be readily studied using culture techniques.

Many cell types have been grown in tissue culture, but skeletal muscle appears to be particularly suitable. It remains remarkably similar in physiology and biochemistry to skeletal muscle *in situ* (1). Skeletal muscle from various species, including chick, rat, mouse, and human, has been grown as explants, cell cultures, or cell lines (2–7).

Skeletal muscle in culture is especially useful in pharmacological studies, because it provides a simple system of only muscle fibers without nerves. The effects of neurons on muscle function can, however, be studied in culture (8, 9).

Early studies on skeletal muscle in culture used organ culture or explants of muscle from embryos or adult animals. Often such tissue suffered from "dedifferentiation"—loss of characteristic structures of the tissue and reappearence of cytological features typical of an earlier state of differentiation. Advances were made rapidly after studies that led to a method of growing consistent cell cultures of skeletal muscle fibers (2, 10).

For cell cultures, tissue is ideally obtained from embryos or neonates. Muscle is dissected and broken down to a suspension of individual cells, either mechanically or by using enzymes such as trypsin or collagenase. The cell suspension contains myoblasts, the mononuclear precursors of muscle fibers, and connective tissue cells, the fibroblasts.

Cultures can easily be grown in plastic petri dishes that have been coated with collagen; collagen appears to be a necessary substrate during the early stages of muscle differentiation (10). The cells are maintained at 37° in a standard tissue culture medium supplemented with serum and embryo extract.

The sequence of events during differentiation of skeletal muscle in culture has been studied in some detail. After trypsin dissociation, the cultures consist of spherical mononuclear cells. These cells settle onto the surface of the culture dish, and different types can be distinguished after a few hours. Some cells appear extremely flattened and have an irregular multipolar shape; these cells are usually regarded as fibroblasts. Other cells have a marked bipolar

shape with a prominent central nucleus and scanty cytoplasm; these cells, thought to be myogenic in origin, are termed "myoblasts" (11).

The mononuclear cell population goes through a period of replication. After a time, some cells stop dividing, line up in parallel arrays, and fuse to form multinucleated cells called "myotubes." This fusion, taking 4–8 hr, occurs sooner in cultures with a higher initial cell density (12). The multinuclear myotubes are often highly branched (especially chick muscle), and the cell nuclei are in a central position. These myotube cells continue to grow and develop in culture, forming mature cross-striated muscle fibers with nuclei aligned along the cell membrane.

The fibroblasts continually divide in culture and eventually can overgrow the muscle fibers, thus making experiments difficult. After the formation of myotubes, the cultures can be treated with a DNA synthesis inhibitor, such as cytarabine (cytosine arabinoside), to remove the actively replicating fibroblasts. Since DNA synthesis in muscle ceases after cell fusion, this treatment does not hinder the development of the muscle fibers (13, 14).

The studies on skeletal muscle in culture that are dealt with in detail in this review are grouped for convenience into three separate areas: electrophysiological properties, development of chemosensitivity, and pharmacological properties. Nevertheless, there is considerable overlap among these sections.

ELECTROPHYSIOLOGY

Passive Electrophysiological Properties—In directing the techniques of conventional electrophysiology toward recording from cells in culture, a few refinements are necessary. While normal electronic amplification and glass microelectrodes of resistance 5–50 megohms may be used with ease, the nature of the test material requires a microscope, preferably of the inverted type, with phase contrast or Nomarski interference optics. Furthermore, the scale of the work dictates that the utmost stability in micromanipulators and worktop be sought.

Embryonic chick skeletal muscle fibers explanted into tissue culture retained a resting membrane potential between −60 and −75 mv (15), although Harris *et al.* (5) noted a drop from −63.8 (mean) to a mean of −51.0 mv over a 10-day culture period. No difference was noted between explants from chick anterior latissimus dorsi (slow muscle) and posterior latissimus dorsi (fast muscle) (16).

In muscle fibers developed from the fusion of disaggregated primary myoblasts obtained from chick embryos or neonatal rodents, the resting membrane potential changed from a value around −10 mv before fusion and immediately afterward, rising steadily as fiber length and diameter increased to about −50 or −60 mv (4, 6, 14, 17–20). Thereafter, little change in the resting membrane potential was observed. Higher values, between −70 and −95 mv, were reported by some workers but were less common (21–23).

The increase in membrane potential was correlated with numbers of nuclei in the fiber (4), with fiber thickness (14), and with fiber length (6, 18). Fibers of 1000 μm in length usually have attained their maximum resting membrane potential, although the morphology of multiply branched myotubes in culture presents formidable difficulties in measuring fiber length. However, Hooisma *et al.* (23) were unable to note any correlation between the resting membrane potential and the fiber age or size in their cultures.

With respect to membrane potential, the development of muscle in culture resembled closely the development followed by embryonic muscle *in situ* (24); the highest membrane potentials recorded were similar to the values reported for isolated chicken muscle (25) and rodent muscle (26–28). Human muscle, developing in culture from fetal myoblasts, showed a similar increase in membrane potential[1]. The progressive increase in the resting membrane potential was apparently achieved by changes in the ratio of the permeabilities of the principal cations, sodium and potassium. Intracellular potassium remained constant at about 140 m*M* throughout muscle development in culture. In chick muscle, intracellular sodium fell from 56 to 22 m*M* over a period when the resting membrane potential rose from −10 to −21 mv (14). Catterall (29) estimated the internal sodium concentration of 5–9-day chick myotubes to be 13 m*M*; Ritchie and Fambrough (20) reported the same value for rat myotubes, although no change during development was observed.

Both chick and rat myoblasts and myotubes of low resting membrane potential are relatively insensitive to alterations in external potassium. As the resting membrane potential increases, however, the sensitivity to changes in $[K]_0$ increases until there is a virtual linear relationship between log $[K]_0$ and membrane potential (14, 20, 30). The curves obtained with rat myotubes closely followed the theoretical line derived from the Goldman equation and derived values for the internal ion concentrations (20). This correlation was interpreted as an increase in membrane potassium permeability during development, while sodium permeability remained low. However, since the resting membrane potential never attained the level of the potassium equilibrium potential, it must be assumed that sodium permeability remains a significant factor in determining the final resting membrane potential.

Chloride distribution across the cell membrane is such that the Nernst equilibrium potential (E_{Cl}) is the same as the resting membrane potential[2]. Chloride permeability, however, appears to be low, since changes in external chloride concentration caused no alteration in membrane potential or input resistance (20). The ionic composition of the cell is maintained by a ouabain-sensitive ion pump. Electrogenic pumping is not a significant contribution to the maintenance of membrane potential, at least in chick myotubes, although it can be identified during recovery from prolonged exposure to low temperature or acetylcholine. Presumably, the increased sodium within the myotube acts as the stimulus to such electrogenic pumping.

The input resistance of muscle fibers in culture was shown to fall from relatively high values of 30–40 megohms to about 1 megohm or less as the cells increased in size (5, 18). This change in input resistance was not apparently caused by changes in the specific resistance of the membrane, which remained constant. Fischbach *et al.* (18) were

Table I—Physical Constants of Muscle Fibers in Culture

	Specific Resistance of Membrane (R_m), ohm cm^2	Resistance of Cytoplasm (R_i), ohm cm	Membrane Time Constant (T_m), msec	Membrane Capacitance (C_m), μF/cm^2	Length Constant (λ), μm
		Steady-State Analysis			
Chick (Ref. 5)	720	—	5	—	—
Mouse (Ref. 6)	694 ± 75	109 ± 19	5.4 ± 0.9	8.4 ± 1.2	609 ± 50
Rat (5 day) (Ref. 20)	1000 ± 94	—	3.1 ± 0.1	3.0 ± 0.3	—
		Transient Analysis			
Chick (Ref. 18)	2639 ± 1166	220 ± 190	9.95 ± 5.45	3.9 ± 1.45	639 ± 299
Mouse (Ref. 6)	2089 ± 343	132 ± 41	6.9 ± 1.6	4.6 ± 2	912 ± 158

unable to demonstrate any correlation between the specific resistance of the myotube membrane and the resting membrane potential. The values obtained for the membrane constants depended on the method of analysis after passing a current of known intensity through the membrane and recording the change in electrotonic potential.

Powell and Fambrough (6), using cultures of mouse muscle where the myotubes were relatively unbranched, preferred to base their calculations on the steady state of the electrotonic potential rather than on an analysis of transient potentials, since the inconstancy of potassium conductance and possible low resistance coupling between myotubes and other cells introduced indeterminate variables. The values reported (Table I) for mouse and chick showed no significant difference, whereas there was an appreciable difference in the results obtained by each method. The values showed similarities to values quoted for adult muscle preparations, but they appeared to occupy a position intermediate between the values quoted for innervated and denervated muscle, suggesting that they can be further modified after the establishment of neural control at innervation.

In contrast to muscle fibers developing from primary myoblasts, the myogenic cell line L6 shows little developmental change in passive electrical properties during the formation of myotubes. Line L6 was first reported by Richter and Yaffe (31), and a number of reports have appeared on its electrophysiological properties. The individual myoblasts, prior to fusion, showed an unusually high resting membrane potential of between −60 and −80 mv (32–34). After fusion, no significant change in the resting membrane potential was detectable. A linear relationship existed between membrane potential and the logarithm of the external potassium concentration, suggesting that the membranes of both myoblasts and myotubes were permeable to K^+ ions. Little Na^+ or Cl^- permeability, however, was measurable.

The specific membrane resistance and capacitance for L6 myoblasts were 8 kilohms cm^2 and 1 μF/cm^2; for myotubes, the values were 12 kilohms cm^2 and 5 μF/cm^2. These values differed significantly from those reported in Table I and probably reflected the altered ion permeability found in this cell line. Myoblasts did not show delayed rectification, which was demonstrable in myotubes. Clearly, therefore, a change in the nature of ionic channels in the membrane did occur at fusion of the L6 myoblast.

Active Electrophysiological Properties—Active changes in membrane potential of muscle fibers in culture have been observed. In general, they can be classified as either action potentials or as oscillations of membrane potential, often associated with twitching or fibrillation of the fibers. The latter activity was first detected by Li *et al.* (15), who noted that a discharge of an action potential ensued in fibers developing from explants when the oscillations in membrane potential caused it to fall below a threshold of about −50 mv. The origins of these fibrillation potentials were suggested to be metabolic (35).

Although action potentials do occur spontaneously in muscle in culture (6, 18), they are seen most frequently after extraneous stimulation. A much slower depolarization, described as a plateau, sometimes with a train of spike discharges superimposed, may also be observed (15, 22). Mainly, the response of a cell to a rapid depolarization from around −70 to below −50 mv is the discharge of an action potential with overshoot. Where the resting potential of the myotubes is less than −50 mv, it is usually necessary first to hyperpolarize the cell by passing an inward current (5, 6, 18).

Unlike the passive properties, the active responses of myotubes of both primary cultures and myogenic clones differ little. Catterall and Nirenberg (36) demonstrated that in both primary chick myotubes and a cloned line of muscle, the sodium channels which open transiently during the action potential, can be activated by veratridine. This activation was antagonized by tetrodotoxin. The fast spike potentials seen in discharging cultured muscle cells can be abolished by removing external sodium or by adding tetrodotoxin to the medium (5, 22, 37). Therefore, the fast spike component is caused by an inward sodium current and resembles that found in normal vertebrate muscle and nerve. The threshold potential necessary to initiate the fast sodium spike was about −45 mv (37).

A study of the currents flowing during voltage clamp suggested that the depolarization necessary to evoke the sodium spike was greater than that necessary to initiate a sodium current. This condition was also true of the peak or reversal potential at which the sodium current ceased to be inward. These differences were ascribed to the cable properties of myotubes, which permitted membrane currents to flow in restricted areas of the membrane during voltage clamp but necessitated a greater depolarization of the membrane for a propagated action potential in an unclamped fiber. To overcome such problems, the cable properties of myotubes of indeterminate length were eliminated by exposing the cultures of 10^{-8} *M* colchicine after 3–4 days of development (38). The destruction of microtubules that this procedure caused resulted in the formation of "myosacs," nearly spherical structures rather than the normal cylindrical shape. Contractile elements were present in such structures, and membrane potentials (−48 mv), action potentials, depolarization in response to acetylcholine, and contractions induced by various agents suggested that the properties of myosacs were comparable

with those of myotubes. An extensive t-tubular system was considered as a possible cause of slight deviations from the predicted response during the initial stages of constant current hyperpolarization. The cytoplasm of these cells was at the isopotential with respect to ground, so good membrane clamping could be achieved. Under these conditions, threshold and peak potentials for both current depolarization and current flow during clamping were in close agreement.

The slow potential was more difficult to characterize. It could be absent, present alone, or present in combination with a fast tetrodotoxin-sensitive spike. Where it occurred, the slow potential was insensitive to tetrodotoxin (37, 39), its amplitude and duration were increased by elevating the concentration of calcium in the bathing medium (40), and it could be abolished by the addition of 2 m*M* manganese chloride (39) or lanthanum chloride (41) to the bath. Removal of the external sodium from the medium also abolished the slow potential (33). Barium was apparently able to substitute for calcium in the bathing solution. The conclusion was that the slow potential was attributable to an inward current of both sodium and calcium. The time course of the tetrodotoxin-resistant slow potential resembled that found in neonatal muscle and denervated muscle (42); the slow channel may be a feature of incomplete development, which is eliminated once full tropic control is established after innervation.

A third type of depolarizing response was noted by Fukuda *et al.* (37, 43), when the membrane potential of the cells was hyperpolarized by passing an appropriate current through electrodes. After the fast spike and the slow potential had been elicited by a short depolarizing pulse superimposed on the hyperpolarizing current, a prolonged depolarization was seen and lasted for several seconds. The amount of depolarization was increased when the external chloride was reduced in concentration, and substitution of potassium chloride in the current passing electrode with the more impermeant potassium acetate resulted in a decrease in amplitude and duration. It appeared, therefore, that the prolonged depolarization of the fibers was attributable to an outward flow of chloride ions supplied to the cytoplasm from the hyperpolarizing electrode, which followed a post spike increase in chloride conductance.

In myosacs (44), prolonged depolarizations of up to 10 sec were associated with a late inward current, attributed to an outflow of chloride ions. This late current and the late chloride spike previously reported were attributed to the same mechanism, which operated in response to changes in membrane potential; chloride redistributed itself during a change in conductance, which was at a maximum around −50 mv. Under normal conditions, such a change in chloride conductance would not be manifested, since active fluctuations and action potentials have a much more rapid time course.

DEVELOPMENT OF CHEMOSENSITIVITY

Acetylcholine Receptor—Much of the relevance of skeletal muscle as a pharmacological preparation hinges on the presence and properties of specialized structures associated with chemosensitivity in the intact fiber, the acetylcholine receptor, and acetylcholinesterase. A detailed review of the developmental biology of membrane cholinoceptors is contained in a recent series of publications (30, 45, 46).

The presence of sensitivity to acetylcholine in muscle in culture was confirmed by Dryden (47) by direct application of acetylcholine from a micropipet to individual fibers in culture. The response was simple contractions of the fiber, but this response was dependent on the possession by the fiber of an intact contractile mechanism. Noncontractile cells and myoblasts cannot be expected to respond mechanically, and intracellular electrophysiological methods are required to investigate fully the properties of the acetylcholine receptor in cultured muscle. The receptor was found in myoblasts insofar as an electrophysiological response could be evoked from myoblasts, especially more developed ones (4, 14), but not in myoblasts of the L6 clone (48). Instead, a slow hyperpolarization of some L6 myoblasts from −25 to −60 mv was observed after acetylcholine iontophoresis. This response was not susceptible to α-neurotoxin or tubocurarine blockade and was not comparable with the rapid hyperpolarization to the reversal potential seen in primary chick myoblasts of low membrane potential exposed to acetylcholine (14). It probably represents an interaction with a membrane component other than the conventionally recognized nicotinic receptor and serves to distinguish clone L6 myoblasts from primary cells.

The rapid rate of acetylcholine receptor formation that occurs at fusion is not apparently dependent on fusion itself, since it also occurs when fusion is prevented by lowering the calcium content of the bathing medium. Indeed, fusion appears to be incidental to the acquisition of differentiated characteristics, since myofilaments, acetylcholinesterase activity, and adenylate cyclase activity all were greatly increased at the time of normal fusion (4, 49). A functioning receptor was not apparently required for fusion of myotubes, since this process proceeded in the presence of tubocurarine, acetylcholine (4), or α-bungarotoxin (50).

The use of ^{125}I-labeled α-bungarotoxin has greatly aided research into receptor distribution and incorporation in view of the virtual irreversibility of the reaction between the two. Autoradiographic investigation of cells and fibers thus labeled confirmed the presence of receptors on the occasional myoblast; on young myotubes, the label appeared to be uniformly distributed over the surface (51, 52), corresponding to a receptor density between 1500 and 2000/μm^2 (53). The uniformity of receptor distribution was a feature only of young myotubes; as development proceeded, clusters of greater receptor density were noted with increasing frequency. The average cluster was 125 μm^2 in area and ovoid and occurred predominantly at the fiber margin. No correlation between the occurrence of clusters and cytological features of the fibers could be found (52, 53).

Electrophysiological confirmation of nonuniform sensitivity along the muscle fibers was provided by a number of reports. Initially, fibers when formed exhibited uniform sensitivity to the transmitter along their length (5, 14, 54). The iontophoretic sensitivities were between 4 and 400 mv/nC. Close application of acetylcholine from an iontophoretic pipet revealed variations in sensitivity ranging from 10 to 1000 mv/nC (55). The areas of greatest sensitivity coincided with the areas of greatest density of

^{125}I-labeled α-bungarotoxin. Furthermore, the areas of greatest sensitivity were thought to be associated with prominent muscle nuclei, although no great significance has been attached to this observation. Such "hot spots" of acetylcholine sensitivity also were noted in myosacs (38). Fetal skeletal muscle prior to innervation, denervated muscle, and adult muscle maintained in organ culture were all sensitive to acetylcholine over the whole muscle surface (56–58), although the sensitivity was not necessarily uniform. The original end-plate membrane retained a much higher receptor density than surrounding areas (59, 60). The muscle in cell culture, therefore, had properties similar to other muscle preparations devoid of nervous control.

The accumulation of receptors, at least at points of innervation in nerve–clonal muscle cultures, was not inhibited by blockade of muscle activity by long-term depolarization in a high K^+ growth medium (61) or by exposure to cobra α-neurotoxin (62). However, the overall sensitivity of muscle fibers was lower if they were repeatedly stimulated by field current depolarization during development (63). The mechanism relating electrical properties of the membrane and receptor incorporation remains to be demonstrated.

The dynamic aspects of receptor biosynthesis and degradation have been studied. Work with fluorescent labeled antimuscle antibody revealed a fair degree of mobility in the surface molecules of membranes of cells in culture (64). It was supposed that the acetylcholine receptor in the absence of innervation was no exception and that a fluid to rigid transformation occurred at synaptogenesis to provide the lattice of receptors found in normal adult end-plates (30).

The binding of ^{125}I-α-bungarotoxin to myotubes was biphasic with a rapid and a slow component (53). The slow component was attributed to the appearance of new receptors, since it could be abolished by inhibitors of RNA synthesis such as cycloheximide and dactinomycin. There was, however, a delay in the reduction in the appearance of new receptors after inhibitor treatment, which suggested that there existed within the myotube a pool of newly synthesized receptors available for incorporation into the membrane. The rate of new receptor incorporation was 90 receptors/μm^2/hr, although the increase in density was only 35/μm^2/hr. This difference was explained by the fact that the surface area in the developing myotubes was also increasing by about 4–5%/hr.

Further work (65) revealed a proteolytic degradation of receptors which required energy and was not affected by prior binding of ^{125}I-α-bungarotoxin. The degradation of the receptors followed first-order kinetics and was, therefore, presumably random. The half-life of receptors in both chick and rat myotubes was about 22 hr. Proteolysis was apparently a cytoplasmic event requiring prior internalization of the receptor. Whether this sequence of events occurs in innervated muscle, which is susceptible to the trophic regulation of the neuron, is a question of considerable interest.

The interactions of receptors with both agonist and antagonist drugs are considered in the following section, but the ionic parameters associated with the activation of the receptor in cultured muscle are discussed here. In myotubes, including clone L6 myotubes (48), exposure of the cell to cholinomimetic agonists resulted in a rapid depolarization of the cell membrane as in "normal" muscle. The action of carbachol was associated with a substantial increase in the rate of sodium entry into a fiber (29). The time course of this entry was not constant throughout equilibration in the presence of carbachol but fell after an initial rapid influx. The fall in influx was attributed to desensitization of the receptors by the agonist. By reducing the temperature to 2°, the rapid initial sodium influx could be studied. The maximum influx (V_{max}) under these conditions was 2×10^7 min^{-1} ions/ionophore. This value compared well with the value of $4–12 \times 10^8$ min^{-1} at 35° computed from the membrane noise measurements of Sachs and Lecar (66) in cultured muscle. Their value for the elementary conductance of a single channel was 0.8×10^{-10} mho which was close to values obtained in frog sartorius muscle (67, 68).

When activated by a cholinomimetic agonist drug, the acetylcholine receptor in cultured muscle fibers apparently opens a sodium permeable ionophore in a manner similar, if not identical, to that taking place in the normal muscle end-plate. Within the ion channel, there is apparently a sodium binding site or energy barrier, possibly analogous to those proposed for the transient tetrodotoxin-sensitive sodium channels of nerve (69).

More recent work (70) on acetylcholine current noise in cultured muscle cells that had fused but had been prevented from elongating (myosacs or "myoballs") showed reasonable agreement with Sachs and Lecar (single-channel conductance = 0.3×10^{-10} mho) and provided evidence that the conformational freedom of the acetylcholine channel is limited by the fluidity of membrane lipids. Since these membrane lipids undergo a phase transition to a more rigid state at about 20° in homeothermic animals, the degree of channel opening is restricted below this temperature. The channel is not apparently specific for sodium, since potassium permeability too is increased on activation (and also trivalent ions, if present) but chloride remains impermeant (71). The behavior of the two permeant ions is interesting in that potential changes attributable to potassium can be predicted from the Goldman equation, *i.e.*, ion flow is through channels of fixed conductance and dependent on ion concentration on each side of the membrane. Sodium-dependent potential changes are described by:

$$E_r = E_K + \frac{(\Delta g_{Na}/\Delta g_K)E_{Na}}{1 + \Delta g_{Na}/\Delta g_K} \qquad \text{(Eq. 1)}$$

where the conductance of the channels is variable. The precise mechanism of ion transfer through the ionophore is clearly complex and awaits further work.

The reversal potential of the activated receptor was described as from 0 to +10 mv for chick embryo muscle explants (5), between −20 and +10 mv (55) and −7 mv (14) in dissociated chick embryo muscle cultures, from +5 to +10 mv in dissociated rat muscle cultures (4), and −2.5 mv in clone L6 myotubes (48). Ritchie and Fambrough (71) reported a mean reversal potential of −2.6 mv, which remained constant despite the increase in the resting membrane potential (30). This result was obtained using rat tissue, which the same authors had shown to retain an unchanged internal ion composition during this period (20). Where the internal sodium concentration fell, a change in reversal potential was expected. The reversal

potential of L6 myoblasts was the same at 22° as at 35° (48). Reduction in $[K]_0$ or $[Na]_0$ caused the reversal potential to be more negative, reversing at between −30 and −40 mv in sodium-free solution. Chloride movement was not apparently involved in determining this value, so suspicion fell on Ca^{2+} as a possible participant in the receptor activated current. No experimental evidence was available, however, to substantiate this view.

Acetylcholinesterase—The enzyme responsible for the hydrolysis of acetylcholine is found in close association with the cholinoceptor in intact muscle, and similar activity was found in muscle in culture (72, 73). Choline acetyltransferase activity was predictably absent in cultures of muscle cells (74). Although acetylcholinesterase was present in myoblasts, a substantial increase in enzymic activity occurred at the time of fusion (75–77). This association of activity and myoblast fusion was also noted for a number of other enzymes (78). The cholinesterase was specific for acetylcholine, since butyrylcholinesterase activity remained at a low level throughout the culture period (76, 77). However, a number of different isozymic forms were present, comparable with those found in embryonic muscle *in situ*.

Harvey and Dryden (77) identified soluble and membrane-bound fractions of total activity and showed that the soluble activity reached a plateau after 4 days of culture while the membrane-bound fraction continued to increase. Little of the enzyme activity was found at the cell surface, most being associated with intracellular membranes (79). The distribution of the enzyme in the myotube showed developmental changes reminiscent of those noted with the cholinoceptor. Enzyme could be histochemically demonstrated in a uniform distribution in the cytoplasm of young myotubes; but, as the cultures aged, the enzyme was apparently localized into areas of greater activity than the surrounding cytoplasm. No correlation between the distribution of receptors and enzyme activity has been shown, and the factors that influence this development remain a matter of speculation.

The sequence of enzyme synthesis in 14-day myotubes was studied by Wilson and Walker (80) after inhibition of existing enzyme with isoflurophate (diisopropyl fluorophosphate). Within 4 hr, 78% of the original activity was restored. The newly synthesized enzyme was of low molecular weight and was not stained by traditional cytochemical methods. The low molecular weight isozymes were readily released from the cell and could be detected in the medium after 4 hr. About this time, the first cytochemically identifiable enzyme appeared around the myotube nuclei. This enzyme was associated with the polymerization of the low molecular weight isozymes and their incorporation into membranous structures. The process continued with a reduction in the proportion of the low molecular weight form present.

The physiological function of acetylcholinesterase in cultured muscle is not obvious. Pharmacological studies, discussed in the following section, suggest that the developmental process in cultures of muscle alone is incomplete.

PHARMACOLOGICAL PROPERTIES

Receptor Specificity—The close similarity of some physiological properties of skeletal muscle in culture to muscle *in vivo* led to the assumption that the pharmacological characteristics would also be similar. Indeed, the response of cultured muscle to acetylcholine was blocked by tubocurarine (4, 47, 54). In the last few years, more detailed studies have shown the faith of muscle physiologists to be justified.

Obata (81), Steinbach (48), and Harvey and Dryden (82) considered the possibility that the development of muscle in the artificial environment of culture may cause the appearance of unusual receptor types. Obata tested cell cultures prepared from the diaphragms of 1-day-old rats. Depolarization responses were obtained with acetylcholine added iontophoretically or directly to the bath, but levarterenol, γ-aminobutyric acid, and glutamic acid had no effect on membrane potential. Steinbach applied methacholine, choline, and levarterenol iontophoretically to L6 myotubes without success. Harvey and Dryden tested a series of compounds (epinephrine, levarterenol, histamine, 5-hydroxytryptamine, dopamine, and γ-aminobutyric acid) for agonist and antagonist activities on cultured chick embryonic muscle. None of these substances produced a significant change in membrane potential. However, epinephrine (but not levarterenol) and 5-hydroxytryptamine reduced responses to the test agonist, carbachol; the mechanism of this depressant activity is unknown and requires further investigation.

Three muscarinic receptor stimulants, methacholine, bethanechol, and pilocarpine, were tested on cultures of chick embryo leg muscle (14, 80). Since no response could be obtained, it is likely that skeletal muscle in culture does not have muscarinic receptor sites.

All nicotinic cholinoceptor stimulant drugs that have been tested on skeletal muscle in culture produced a response. The drugs used included acetylcholine, carbachol (83), decamethonium, tetramethylammonium, nicotine, succinylcholine, and dimethylphenylpiperazinium (82).

From the results of such studies, it is concluded that skeletal muscle in culture responds to agonists that normally activate nicotinic cholinoceptors at the neuromuscular junction but not to agonists that do not normally act on skeletal muscle.

The reversal potential of the acetylcholine response in cultured muscle is between +10 and −20 mv. Feltz and Mallart (84) reported that the reversal potential in junctional areas of frog skeletal muscle was −16 mv, whereas it was −42 mv in extrajunctional areas. This finding suggested that the receptors in muscle in culture behave in a manner more closely resembling junctional rather than extrajunctional cholinoceptors.

The specificity of receptors on cultured skeletal muscle was examined using antagonist drugs. Muscarinic receptor antagonists in high concentrations blocked the response to acetylcholine of normal rat and frog skeletal muscle preparations (85, 86). Similar results were found with cultured muscle. A low concentration of atropine was without effect on responses of cultured skeletal muscle to acetylcholine (81), but responses were inhibited by concentrations of 10^{-4}–10^{-2} *M* atropine (5, 29, 55, 82) and hyoscine (82). Similarly, high concentrations of atropine inhibited end-plate potentials in combined chick muscle–ciliary ganglia cultures (23). Acetylcholine responses of primary mouse cultures and of rat cell line cultures were blocked by both tubocurarine and atropine (40).

All of these studies indicated that the concentrations of atropine have to be 100–1000 times greater than the effective concentrations of tubocurarine. A similar ratio was seen in other skeletal muscle preparations (85, 86).

The reduction of acetylcholine-induced responses by the nicotinic antagonist tubocurarine was demonstrated in several culture systems (13, 47, 48, 53, 81, 83). The concentration–effect curves to carbachol were shifted in a parallel fashion to the right by increasing concentrations of tubocurarine. Similar results were obtained with other nicotinic antagonists, *e.g.*, gallamine (82) and chandonium iodide (87). Affinity constants were calculated to be around 10^7 for tubocurarine, about $2–5 \times 10^6$ for gallamine, and between 10^7 and 10^8 for chandonium iodide. From the half-blocking concentrations of tubocurarine on miniature end-plate potentials in combined spinal cord–rat muscle cell line cultures, the affinity constant would be 0.25×10^7 (88). These values were of the same order as reported from experiments on other more conventional skeletal muscle preparations.

Acetylcholine-induced depolarization can be antagonized by neurotoxins from snake venoms. Such toxins were reported to be highly specific for nicotinic receptors in skeletal muscle preparations (89). Cobra neurotoxin blocked responses in a rat cell line (90) and in explants of chick embryo skeletal muscle (5); α-bungarotoxin blocked responses in primary cultures of rat (53, 81) and chick muscle (55, 91, 92). Dose–response curves to carbachol in the presence of increasing concentrations of α-bungarotoxin showed a reduction in maximal response, as would be expected with a noncompetitive antagonist. Blockade with α-bungarotoxin was essentially irreversible (53, 91). Moreover, β-type bungarotoxins that are selective prejunctional antagonists (93) were without effect on skeletal muscle fibers in nerve-free cultures (92).

The results of experiments with antagonists further substantiated the postulate that cultured skeletal muscle fibers possess one main receptor type that resembles the nicotinic cholinoceptor. There is evidence that the receptor in denervated skeletal muscle has different affinities for antagonists from those of the receptor at the normal motor end-plate (85, 94). While it was suggested (40) that the receptors on cultured muscle resembled more closely those of denervated muscle, available evidence does not support this proposal.

The nicotinic cholinoceptor was suggested to be a protein with an easily reducible disulfide bond near the acetylcholine binding site, and reduction of the disulfide bond was thought to alter the conformation of the receptor protein and its specificity (95). Treatment of electroplax with the disulfide bond reducing agent, 1,4-dithiothreitol, decreased the effects of carbachol and acetylcholine and converted the action of hexamethonium from that of an antagonist to that of an agonist; these changes could be reversed by oxidation (96, 97). Similar results were obtained with several skeletal muscle preparations including frog rectus abdominis (98) and sartorius muscles (99–101), denervated rat skeletal muscle (102), chick biventer cervicis muscle (103), and leech dorsal muscle (104). Despite some species variation (101, 104), 1,4-dithiothreitol appeared to affect the properties of the nicotinic receptor in skeletal muscle.

Harvey and Dryden (105) examined the effects of 1,4-dithiothreitol treatment on chick embryo skeletal muscle grown in cell culture and compared the behavior of the receptors present in cultured muscle to that of the receptors in adult muscle. The receptors on cultured chick embryonic skeletal muscle underwent the characteristic changes in properties following disulfide bond reduction. The concentrations of 1,4-dithiothreitol and exposure times required to produce these effects were similar to the conditions employed in other studies. The changes after 1,4-dithiothreitol (decrease in response to carbachol and conversion of the action of hexamethonium from antagonist to agonist) were as readily reversed by oxidation in cultured muscle as in other systems (96, 97, 103). Membrane depolarization by K^+ ions was not affected by 1,4-dithiothreitol treatment, suggesting that the action of 1,4-dithiothreitol is related to the receptor itself rather than to a nonspecific membrane effect. The actions of 1,4-dithiothreitol were also distinguished from receptor desensitization effects. Harvey and Dryden (105) concluded that the receptors in cultured aneural muscle and in normal muscle were affected similarly by disulfide bond reduction.

Effects of Anticholinesterase Drugs—At the adult neuromuscular junction, the transmitter action of acetylcholine is terminated by hydrolysis by the enzyme acetylcholinesterase. The activity of this enzyme can be affected by anticholinesterase drugs (106). The actions of acetylcholine are generally potentiated and prolonged after administration of an anticholinesterase. The actions of anticholinesterases have been tested on responses to acetylcholine applied directly to cultured muscle cells and on cholinergic end-plate potentials found in combined cultures of nerve and muscle. Physostigmine or neostigmine in concentrations between 0.1 and 100 μg/ml did not affect the size or time course of end-plate potentials in cultures of chick embryo muscle and spinal cord (13, 21). Physostigmine (5–20 μg/ml) did not increase the duration of end-plate potentials in combined cultures of chick embryo muscle and ciliary ganglia; however, 20 μg of physostigmine/ml decreased the amplitude of the end-plate potentials (23). Edrophonium (3.8×10^{-6}–10^{-4} M) did not increase amplitude, time to peak, or half decay time of miniature end-plate potentials recorded in cultures of the muscle cell line L6 and fetal rat spinal cord (88).

Physostigmine and edrophonium did not potentiate the response of cultured chick embryo muscle to iontophoretically applied acetylcholine, and high concentrations of both anticholinesterase drugs inhibited the response to acetylcholine (5, 79). The response of cultured chick embryo muscle to bath application of 10^{-6} M acetylcholine was not increased in the presence of 0.5 μg of neostigmine or physostigmine/ml; the responses to 10^{-3} M acetylcholine and carbachol were inhibited slightly (83). Higher concentrations of anticholinesterase produced depolarization and reduced subsequent acetylcholine responses.

An extension of this study showed that concentration–effect curves to acetylcholine were not altered by 10^{-8}–10^{-7} M physostigmine or neostigmine or by pretreatment of the cultures with 5.4×10^{-6} M of the irreversible anticholinesterase isoflurophate (107).

Although anticholinesterase treatment potentiates the action of acetylcholine in normal muscle, it has little effect on chronically denervated muscle (57). In this respect,

muscle in culture is similar to denervated muscle. A recent electron microscope study of the subcellular distribution of cholinesterase in cultured muscle indicated that little enzyme is on the surface membrane, most being located in the cytoplasm, over myofilaments, or associated with internal membranes (79). The localization of acetylcholinesterase on the external surface of the muscle and the assumption of its physiological function probably occur later in development and are regulated by a "trophic" influence from nerves. Presumably, the lack of effect of anticholinesterases on end-plate potentials in combined nerve and muscle cultures is due to the immaturity of the functional contacts.

Direct effects of the anticholinesterases on membrane potential have also been tested. At concentrations above 10^{-7} *M*, both neostigmine and physostigmine produced a concentration-dependent depolarization of myotubes (107). The depolarization induced by neostigmine, but not that by physostigmine, was inhibited by tubocurarine (107). Isoflurophate at 5.4×10^{-6} *M* had no effect on membrane potential but reduced responses to both acetylcholine and carbachol (107). It was postulated that the antagonism by isoflurophate and the inhibitory actions of high concentrations of other anticholinesterases on acetylcholine responses in culture (5, 79, 83) may be caused by receptor desensitization induced by the anticholinesterase.

Owing to its lack of physiologically functional acetylcholinesterase, nerve-free muscle cultures were the preparation of choice in a study of the site of action of nicotinic agonists (108). It had been postulated that certain agonists other than acetylcholine act at the neuromuscular junction by releasing endogenous acetylcholine (109). This postulate was based on the findings that triethylcholine, tetraethylammonium, and hexamethonium, drugs assumed to block choline and cholinomimetic uptake by the nerve terminal, inhibited responses to carbachol, nicotine, tetramethylammonium, decamethonium, and dimethylphenylpiperazinium but not to acetylcholine (109, 110). However, these effects may result from a combination of two postjunctional actions of these drugs: a curare-like blocking action and an anticholinesterase action (111).

When tested in cultured skeletal muscle at concentrations used previously to eliminate neural acetylcholine release (109, 110, 112), hemicholinium, triethylcholine, tetraethylammonium, and hexamethonium blocked responses to all agonists, and acetylcholine responses were affected as much as those of other cholinomimetics (108). This finding confirms previous work (111, 113) and lends support to the belief that the lack of effect of these blocking drugs on acetylcholine responses in whole muscle was because of their anticholinesterase activity. The results obtained with cultured muscle support the classical theory that nicotinic agonists act directly on receptors on the muscle itself and not by releasing endogenous acetylcholine.

Receptor Desensitization—In many skeletal muscle preparations, cholinomimetic-induced depolarization is not maintained despite a constant drug concentration. This phenomenon, termed "desensitization" (114), is equivalent to a progressive decrease of the response during prolonged contact with cholinomimetics. Desensitization in skeletal muscle has several characteristic features: it is specific for cholinoceptors, it increases with agonist concentration and contact time, and it is reversible.

In explant cultures of chick embryo muscle, the response to iontophoretic pulses of acetylcholine declined if the frequency of stimulation was above 6/min (5). Since the responses did not recover fully after rest, the decline in sensitivity may have represented desensitization or a gradual deterioration of the preparation. Desensitization was, however, evident in rat muscle cultures when acetylcholine pulses were given during a maintained acetylcholine-induced depolarization (81). A similar phenomenon occurred with repeated or prolonged application of acetylcholine or carbachol to L6 myotubes (48). The responses to the brief acetylcholine pulses recovered to control level after the desensitizing exposure was stopped.

The response of cultured chick embryo muscle to prolonged exposure to acetylcholine and carbachol was not maintained, and the membrane gradually repolarized (83). This fading response was suggested to reflect desensitization, and evidence was presented that the desensitization affected cholinoceptors specifically and depended on the concentration of the agonist. Cross-desensitization between acetylcholine and carbachol was also reported. Desensitization in cultured chick embryo muscle was reversible, although the recovery rate was much slower than the recovery rate of other muscle preparations (83). Recovery of cultured muscle appeared to be a two-component process, with an initial phase of rapid recovery followed by a very slow recovery rate (115).

Ritchie and Fambrough (20) found a marked difference in the response of rat and chick myotubes to prolonged application of acetylcholine. Chick myotubes repolarized rapidly in the presence of 10^{-5} *M* acetylcholine, but the depolarization of rat myotubes could be maintained for as long as 100 min. The reason for this difference is unknown.

Desensitization was reported to be more pronounced in older cultures (115). Catterall (29) thought that desensitization increased with the morphological maturity of the myotubes, being more rapid in myotubes possessing cross-striations and hypolemmal nuclei. However, it is possible that the increased rate of desensitization reflects the increased resting membrane potential of the more developed cells (116).

Different agonists have differing abilities to produce desensitization in cultured chick embryo muscle. Concentrations of drugs that produced the same depolarization had markedly different rates of repolarization (117). Succinylcholine produced rapid desensitization, while nicotine caused slow desensitization; acetylcholine and carbachol were intermediate in activity.

Certain drugs increased the rate of repolarization in the presence of a cholinomimetic. Isoflurophate (107), atropine, and hyoscine (115) produced this effect, which is equivalent to an increase in rate of desensitization. Isoflurophate increased the rate of decay of the end-plate current of frog sciatic nerve–sartorius muscle preparations (118). Isoflurophate was thought to be affecting the receptor–ionic conductance modulator complex. Atropine shortened the time that an acetylcholine molecule opened the ionic channels in the muscle membrane (119). This action seems to indicate an enhancement by atropine of desensitization by acetylcholine. The results obtained with

cultured muscle suggest that these drugs (isoflurophate, atropine, and hyoscine) may operate similar mechanisms in cultured muscle fibers.

Desensitization protected cholinoceptors of frog sartorius muscle preparations from binding of snake venom neurotoxins (120, 121). In a similar study with cultured chick embryo muscle, α-bungarotoxin was ineffective in blocking agonist responses after receptor desensitization (122). These results provide further evidence that the nicotinic receptors present in cultured skeletal muscle are similar in properties to the receptors of normal muscle. The finding that desensitization prevents α-bungarotoxin from blocking receptors suggests that desensitization involves a change in the conformation of the receptor so that the toxin-binding sites are no longer operational.

Recent studies showed that binding of labeled snake venom toxins to cultured muscle was reduced in the presence of cholinomimetics (51, 90, 123). Desensitization, rather than physical occlusion, of receptor sites may account for some part of this protective effect.

CONCLUSION

Much has been written on the suitability of some cells in culture for pharmacological investigation. The evidence presented in this review supports the inclusion of skeletal muscle in this category. Most of the pharmacology so far investigated involved electrophysiological changes occurring at the sarcolemma. T-Tubule and sarcoplasmic reticulum sensitivities have not yet been investigated, nor have phenomena involving the contractile element itself. There are formidable technical problems in measuring tension generated by single muscle fibers, and little additional information would be added to existing information achieved using conventional methods.

Yet the increasing availability of sophisticated techniques involving ion-sensitive electrodes, fluorescent probes, and other physical and physicochemical tools will undoubtedly add cell culture to the list of preparations available for the study of all aspects of pharmacology in muscle. The development of membrane noise analysis together with the easy availability of receptor sites gives promise of answers to some fundamental questions concerning the reaction of a drug molecule with a single receptor.

Sulfur-Containing Derivatives of Amphetamine: Thioureas, Methanesulfonamides, and Trifluoromethanesulfonamides

WILLIAM O. FOYE ˣ and JAYANT N. SANE

Abstract □ *N*-Methylthiourea, methanesulfonamide, and trifluoromethanesulfonamide derivatives of amphetamine, 4-nitroamphetamine, and 4-aminoamphetamine were synthesized. The *N*-methylthiourea derivative of amphetamine, as well as the triethylammonium salt of the dithiocarbamate, produced significant depressor effects in normotensive dogs. *N,N'*-Bis(methanesulfonyl)-1-methyl-2-(4-aminophenyl)ethylamine and *N*-trifluoromethanesulfonyl-1-methyl-2-phenylethylamine, but not *N*-methanesulfonyl-1-methyl-2-phenylethylamine and *N*-trifluoroacetyl-1-methyl-2-(4-trifluoromethanesulfonamidophenyl)ethylamine, showed significant antiobesity effects in rats.

Keyphrases □ Amphetamine analogs—various sulfur-containing derivatives synthesized, evaluated for central stimulant and anorexic effects, rats □ 2-Phenylethylamines, substituted—various sulfur-containing amphetamine derivatives synthesized, evaluated for central stimulant and anorexic effects, rats □ Stimulant activity—various sulfur-containing amphetamine derivatives evaluated □ Anorexic activity—various sulfur-containing amphetamine derivatives evaluated □ Structure–activity relationships—various sulfur-containing amphetamine derivatives evaluated for central stimulant and anorexic activity

Conversion of the amino group of the 2-phenylethylamine structure to dithiocarbamate and thiourea groups, with the intention of providing copper-binding ligands to inhibit dopamine β-hydroxylase, resulted in compounds with blood pressure lowering effects (1). Similarly, conversion of the 2-phenylethylamine structure to methanesulfonamides, both of the aliphatic nitrogen and in the *para*-position of the ring, also gave compounds that lowered blood pressure in hypertensive rats and dogs (2). The methanesulfonamide of dextroamphetamine produced a similar result (2). Previously, inclusion of the alkanesulfonamide group in the aromatic ring of phenylethanolamines was shown to confer either adrenergic stimulant or blocking activity, the latter generally in conjunction with an isopropyl or larger group on the aliphatic nitrogen (3, 4).

To investigate further the effect of converting the aliphatic amino group of 2-phenylethylamines, particularly the amphetamine structure, to an acidic function, methanesulfonamido, trifluoromethanesulfonamido, and trifluoroacetyl derivatives of amphetamine, 4-nitroamphetamine, and 4-aminoamphetamine were prepared. Thiourea derivatives also were prepared, since a number of thiourea derivatives have shown inhibitory activity against dopamine β-hydroxylase (5) and the aliphatic amino is converted to an acidic function. Several corresponding derivatives of 2-phenylethylamine also were obtained.

Since both tyramine and the 4-hydroxy derivative of amphetamine are better substrates for dopamine β-hydroxylase than the nonhydroxylated compounds (6), the inclusion of the *para*-substituents in the amphetamine structure should provide compounds with potential for activity as inhibitors of dopamine β-hydroxylase. Larsen and Lish (7) pointed out that methanesulfonamides may be considered bioisosteres of the phenolic function.

The possibility exists that by conversion of the basic nitrogen of the amphetamine structure to an acidic function or by introduction of an essentially acidic function into the *para*-position of amphetamine, some of the characteristic pharmacological effects of amphetamine might be lost and others retained. Some ring substitutions in 2-phenylethylamine dithiocarbamates resulted in a loss of behavioral effects (8). Several pharmacological activities to be expected from amphetamine, including blood pressure effects, central nervous system (CNS) stimulation, behavioral effects, and antiobesity effects, have been observed in animals on treatment with these compounds.

DISCUSSION

Chemistry—Ammonium (+)-1-methyl-2-phenylethyldithiocarbamate was prepared previously and showed behavioral effects somewhat different from those of amphetamine (8). Since the compound was rather unstable, the triethylammonium salt was obtained to provide a product of greater stability. Nitration of amphetamine was carried out by the procedure of Holland *et al.* (9), in which the *para*-isomer was separated by fractional crystallization of the trifluoroacetyl derivative. Hydrogenation of the *para*-nitro group was achieved with either the *N*-trifluoroacetyl derivative (9) or 4-nitroamphetamine obtained by hydrolysis of the *N*-trifluoroacetyl derivative, using platinum oxide as the catalyst.

The methanesulfonamide and trifluoroacetamide derivatives were readily obtained from methanesulfonyl chloride and trifluoroacetic anhydride. Preparation of the trifluoromethanesulfonamides proved to be more difficult, but they were obtained by use of trifluoromethanesulfonic anhydride in dry ether. Vacuum distillation of the resulting liquids generally gave low melting solids. Methylthiourea derivatives were obtained from methyl isothiocyanate; many of these products were extremely hygroscopic and had to be stored under dry nitrogen and *in vacuo*.

Attempts also were made to obtain 4-trifluoroacetamido-2-phenylethylamine, 4-trifluoromethanesulfonamido-2-phenylethylamine, and 4-methanesulfonamido-2-phenylethylamine from the respective benzyl cyanide derivatives; catalytic hydrogenation with various catalysts and such reducing agents as lithium aluminum hydride, diborane, and sodium borohydride failed to provide pure products. The compounds prepared are listed in Table I.

Biological Results[1]—Behavioral effects in rats were observed continuously for 6 hr and daily for 7 days after dosing with *N,N'*-bis(methanesulfonyl)-1-methyl-2-(4-aminophenyl)ethylamine (XI). An oral dose of 25 mg/kg in three rats caused low body posture (2/3), moderately decreased spontaneous motor activity (2/3), and slight (1/3) or moderate

[1] The behavioral observations and antiobesity tests were carried out at Smith Kline & French Laboratories. Results were made available through the courtesy of Dr. J. W. Wilson.

(1/3) hypothermia. The bis(trifluoroacetyl) derivative (VIII), however, showed most of the behavioral effects of amphetamine, whereas IX had no overt effects at the same dose level.

In antiobesity tests, oral administration of 25 mg/kg of the same compound to rats daily for 5 days significantly reduced 1-hr food consumption as well as 5-hr food consumption over the 5-day period. There was also a significant change in body weight gain compared to controls during the 5-day test period.

Oral administration of 25 mg/kg of III to rats in the antiobesity test significantly reduced both 1- and 5-hr food consumptions over the 5-day period. There was also a significant change in body weight gain compared to controls during this period. However, oral administration of 25 mg/kg of *N*-methanesulfonyl-1-methyl-2-phenylethylamine, previously prepared (2), to rats significantly reduced 1-hr food consumption only on Day 4 and failed to reduce 5-hr food consumption significantly. There was no significant change in body weight gain for this compound compared to controls over the 5-day period. Oral administration of 25 mg/kg of *N*-trifluoroacetyl-1-methyl-2-(4-trifluoromethanesulfonamidophenyl)ethylamine (IX) to rats failed to produce a significant reduction in either 1- or 5-hr food consumption. There was, however, a significant reduction in body weight compared to controls over the 5-day test period.

The following cardiovascular effects were observed[2]. The triethylammonium salt of the dithiocarbamate of amphetamine (I) and the *N*-methylthiourea of amphetamine (II) both produced significant depressor effects at doses of 4 mg/kg in normotensive dogs anesthetized with urethan–chloralose, with I being the most potent (10). Both compounds caused CNS stimulation, significantly reduced the effects of ephedrine in rats, and reduced hexobarbital sleeping time in mice. In addition, the typical stereotyped behavior of amphetamine was observed in mice, along with increased motor activity and mydriasis.

Whereas the dithiocarbamate and methylthiourea of amphetamine retained much of the behavioral pattern of amphetamine, the more negatively *N*-substituted bis(methanesulfonyl) derivative (XI) lost most of these behavioral effects while retaining the ability to suppress appetite. Conversion of the nitrogen of amphetamine to a negatively substituted amide was not the sole requirement for this combination of effects, however, since the *N*-methanesulfonyl derivative of amphetamine (2) and IX showed no significant appetite suppressant effects.

EXPERIMENTAL[3]

The following procedures are representative.

Triethylammonium (+)-1-Methyl-2-phenylethyldithiocarbamate (I)—To a cooled solution of 5.44 g (0.04 mole) of dextroamphetamine in 25 ml of absolute ethanol was added, with stirring, 6.06 g (0.06 mole) of triethylamine. To this solution was added dropwise 4.56 g (0.06 mole) of carbon disulfide. Stirring was continued for 24 hr, and the dark-yellow liquid was evaporated in a rotary evaporator, leaving a sticky, yellow residue. This residue was washed with dry ether and dried *in vacuo*, giving 5.8 g (46%) of yellow oil; IR (film): 3220 (NH), 2620 (NH^+), 1300 (C=S), and 970 (C=S) cm^{-1}; $[\alpha]_D^{29}$ +32.1° (c = 1, ethyl acetate); n_D^{22} 1.6011.

Anal.—Calc. for $C_{16}H_{28}N_2S_2$: C, 61.54; H, 8.97; N, 8.97; S, 20.51. Found: C, 61.3; H, 9.0; N, 8.5; S, 20.2.

(±)-1-Methyl-3-(1-methyl-2-phenylethyl)thiourea (II)—To a solution of 2.72 g (0.02 mole) of dextroamphetamine in 25 ml of absolute ethanol was added dropwise, with stirring, 1.125 g (0.025 mole) of methyl isothiocyanate in 10 ml of absolute ethanol. The mixture was refluxed for 12 hr and was allowed to cool, and the solvent was removed in a rotary evaporator. The sticky residue was washed with petroleum ether and dried *in vacuo*. A 65% yield of brown oil was obtained; IR (film): 3220 (NH), 1250 (C=S), and 970 (C=S) cm^{-1}; n_D^{22} 1.6042.

Anal.—Calc. for $C_{11}H_{16}N_2S$: C, 63.46; H, 7.69; N, 13.46. Found: C, 63.7; H, 7.8; N, 13.4.

(+) - *N* - Trifluoromethanesulfonyl-1-methyl-2-phenylethylamine (III)—To a cooled solution of 2.72 g (0.02 mole) of dextroamphetamine in 25 ml of ether was added, with stirring, 7.05 g (0.025 mole) of trifluoromethanesulfonic anhydride (8) in 25 ml of ether. The mixture was stirred for 3 hr, refrigerated overnight, and filtered; the solvent was removed in a rotary evaporator. The white solid was recrystallized from petroleum ether (bp 30–60°), giving 2.1 g (40%), mp 75–78°; IR (potassium bromide): 3300 (NH), 1600 (NH), and 1175–1225 (SO_2) cm^{-1}; $[\alpha]_D^{29}$ +21.0° (c = 1, ethyl acetate).

Anal.—Calc. for $C_{10}H_{12}F_3NO_2S$: C, 44.94; H, 4.49; N, 5.24; S, 11.98. Found: C, 44.8; H, 4.46; N, 5.22; S, 12.36.

(+)-1-Methyl-2-(4-nitrophenyl)ethylamine—A mixture of 11.0 g (0.04 mole) of (+)-*N*-trifluoroacetyl-1-methyl-2-(4-nitrophenyl)ethylamine (9) and 120 ml of 1 *N* sodium hydroxide in 180 ml of dimethoxyethane was stirred at 25° for 3 hr under nitrogen. The dimethoxyethane was removed *in vacuo*, and the aqueous portion was extracted three times with 70-ml portions of methylene chloride. The combined extracts were washed three times with 50-ml portions of water and dried over anhydrous sodium sulfate. The solvent was removed in a rotary evaporator, leaving 5 g (95%) of residual oil. This oil was converted to the hydrochloride, mp 195–199° [lit. (11) mp 197–199°]; $[\alpha]_D^{29}$ +30.0° (c = 4, ethyl acetate).

(+) - *N* - Methanesulfonyl-1-methyl-2-(4-nitrophenyl)ethylamine (VI)—To a cooled solution of 9.0 g (0.05 mole) of (+)-1-methyl-2-(4-nitrophenyl)ethylamine in 50 ml of methylene chloride were added dropwise, with stirring, 5.92 g (0.052 mole) of methanesulfonyl chloride in 40 ml of methylene chloride and 5.25 g (0.052 mole) of triethylamine in 40 ml of methylene chloride. The mixture was then allowed to reach room temperature and was stirred for 12 hr. The resulting solution was washed with 1 *N* hydrochloric acid and water, dried over anhydrous sodium sulfate, and evaporated in a rotary evaporator. The brown residue was dissolved in hot benzene, treated with charcoal, and filtered. The cooled filtrate gave 10 g (79%) of the desired product, mp 95–98°; IR (potassium bromide): 3270 (NH), 1500 (NO_2), and 1145 (SO_2) cm^{-1}; $[\alpha]_D^{29}$ +30.0° (c = 1, ethyl acetate).

Anal.—Calc. for $C_{10}H_{14}N_2O_4S$: C, 46.51; H, 5.43; N, 10.81; S, 12.40. Found: C, 46.53; H, 5.41; N, 10.65; S, 12.32.

(+)-1-Methyl-2-(4-aminophenyl)ethylamine—(+)-1-Methyl-2-(4-nitrophenyl)ethylamine (18 g, 0.1 mole) in 200 ml of tetrahydrofuran with 0.3 g of platinum dioxide was hydrogenated at 4 atm. After the theoretical amount of hydrogen had been taken up, the catalyst was filtered and the solvent was removed in a rotary evaporator. A yield of 14.2 g (95%) of compound was obtained; the dihydrochloride melted at 255–260° [lit. (12) mp 258–260°]; $[\alpha]_D^{29}$ +15.8° (c = 1, ethyl acetate).

(±)-*N,N'*-Bis(trifluoroacetyl)-1-methyl-2 - (4 - aminophenyl)ethylamine (VIII)—To a cooled solution of 2.46 g (0.01 mole) of (±)-1-methyl-2-(4-aminophenyl)ethyltrifluoroacetamide (9) in 50 ml of benzene was added 2.94 g (0.014 mole) of trifluoroacetic anhydride dropwise over 10 min. The mixture was brought to room temperature and refluxed for 3 hr. It was refrigerated overnight, and the white solid was filtered, washed with dilute hydrochloric acid and water, and dried in a vacuum desiccator. The product was recrystallized from chloroform, giving 2.6 g (76%) of white solid, mp 173–176°; IR (potassium bromide): 3300 (NH), 1700 (C=O), 1550 (amide), and 1150 (CF_3) cm^{-1}.

Anal.—Calc. for $C_{13}H_{12}F_6N_2O_2$: C, 45.61; H, 3.51; F, 33.33; N, 8.19. Found: C, 45.34; H, 3.72; F, 32.9; N, 7.98.

(±)-*N*-Methanesulfonyl-1-methyl-2-(4 - trifluoroacetylaminophenyl)ethylamine (XII)—A solution of 2.28 g (0.01 mole) of VI in 200 ml of absolute ethanol with 0.65 g of 5% platinum-on-charcoal was hydrogenated at 3 atm. After 48 hr, the mixture was filtered and the solvent was removed *in vacuo*. The residual viscous liquid was dissolved in 250 ml of benzene, and trifluoroacetic anhydride (2.1 g, 0.015 mole) was added with stirring. The mixture was refluxed for 3 hr, allowed to cool, and refrigerated overnight. The resulting solid was filtered, washed with water, and dried *in vacuo*. It was recrystallized from ethanol–water, giving 0.5 g, mp 157–160°; IR (potassium bromide): 3270 (NH) and 1700 (C=O) cm^{-1}.

Anal.—Calc. for $C_{12}H_{15}F_3N_2O_3S$: C, 44.44; H, 4.63; N, 8.64. Found: C, 44.7; H, 4.7; N, 8.8.

(±)-1-Methyl-3-[1-methyl-2-(4-methanesulfonamidophenyl)ethyl]thiourea (XIII)—A solution of 2.28 g (0.01 mole) of VI in 200 ml of absolute ethanol with 0.65 g of 5% platinum-on-charcoal was hydrogenated at 3 atm. After 48 hr, the mixture was filtered and the solvent was removed *in vacuo*. The residual viscous liquid was dissolved in 50 ml of absolute ethanol, and 0.85 g (0.008 mole) of methyl isothiocyanate was added. The mixture was refluxed for 3 hr, the solvent was removed *in vacuo*, and the residue was washed with dry ether and dried *in vacuo*, mp 45–50°; IR (film): 3350 (NH), 1300–1335 (SO_2), and 1135–1165 (SO_2) cm^{-1}.

Anal.—Calc. for $C_{12}H_{19}N_3O_2S_2$: C, 47.84; H, 6.31; N, 13.95. Found: C, 48.2; H, 6.4; N, 13.6.

(+)-*N*-Trifluoromethanesulfonyl-1-methyl-2 - (4 - nitrophenyl)ethylamine (V)—To a cooled solution of 9.0 g (0.05 mole) of (+)-1-methyl-2-(4-nitrophenyl)ethylamine in 30 ml of anhydrous ether was added, with stirring, 14.6 g (0.052 mole) of trifluoromethanesulfonic anhydride in 20 ml of anhydrous ether. The resulting mixture was stirred

[3] Melting points were determined in capillaries with a Mel-Temp melting-point block and are uncorrected. IR absorption spectra were obtained with a Perkin-Elmer model 137B spectrophotometer. Optical rotations were obtained with a Carl Zeiss polarimeter. NMR spectra were determined with a Varian T60 spectrometer using tetramethylsilane as the internal standard. Elemental analyses were performed by Dr. F. B. Strauss, Oxford, England, or by Dr. Carol K. Fitz of Carlisle, Mass. TLC was carried out using silica gel, and products were detected by exposure to iodine vapor. Dextroamphetamine, 4-aminobenzyl cyanide, 4-amino-2-phenylethylamine, trifluoroacetic anhydride, methyl isothiocyanate, and methanesulfonyl chloride were obtained from Aldrich Chemical Co. Trifluoromethanesulfonic acid was obtained from the 3M Co.

for 12 hr and refrigerated overnight. The precipitate was filtered and washed with dry ether, and the filtrate was evaporated *in vacuo*, leaving an oil. This oil was distilled at 165–170°/0.2 mm, giving 3.8 g (25%) of a solid, mp 42–45°; IR (potassium bromide): 3300 (NH), 1520 (NO_2), 1335–1375, and 1125–1150 (SO_2) cm^{-1}; $[\alpha]_D^{30}$ +37.0° (c = 1, ethyl acetate).

Anal.—Calc. for $C_{10}H_{11}F_3N_2O_4S$: C, 38.46; H, 3.53; N, 8.97; S, 10.26. Found: C, 38.7; H, 3.8; N, 9.2; S, 10.3.

(+)-*N*-Trifluoromethanesulfonyl-1-methyl-2 - (4 - trifluoroacetylaminophenyl)ethylamine (XIV)—A solution of 3.12 g (0.01 mole) of V in 150 ml of tetrahydrofuran with 0.4 g of platinum dioxide was hydrogenated at 3 atm. After 48 hr, the solution was filtered and the solvent was removed *in vacuo*. The residual viscous liquid was dissolved in 250 ml of benzene; to this solution was added, with stirring, 2.1 g (0.015 mole) of trifluoroacetic anhydride. The mixture was refluxed for 3 hr, allowed to cool, and refrigerated overnight. The resulting solid was filtered, washed with water, and dried *in vacuo*. Recrystallization from aqueous ethanol gave 0.8 g, mp 143–145°; IR (potassium bromide): 3350, 3230 (NH), 1700 (C=O), 1200, and 1150 (SO_2) cm^{-1}; $[\alpha]_D^{29}$ +20° (c = 1, ethyl acetate).

Anal.—Calc. for $C_{12}H_{12}F_6N_2O_3S$: C, 38.10; H, 3.17; N, 7.41; S, 8.47. Found: C, 38.2; H, 3.2; N, 7.7; S, 8.1.

Antiobesity Test—Rats were trained over 2 weeks to eat their daily food ration[4] in only 5 hr. After training, either vehicle (controls) or drug was administered orally by gastric intubation daily for 5 days. One hour after drug, tared food cups containing the food ration were presented. The cups were weighed after 1 hr of feeding and again after 5 hr of feeding. Water was available *ad libitum*. Rats were weighed daily before drug administration.

Release of Drugs from Ointment Bases II: *In Vitro* Release of Benzocaine from Suspension-Type Aqueous Gels

F. BOTTARI, G. DI COLO [x], E. NANNIPIERI, M. F. SAETTONE, and M. F. SERAFINI

Abstract □ The *in vitro* release of benzocaine, suspended in an aqueous gel, through silicone rubber membranes was studied to test an extension of existing mathematical models. The theoretical treatment proposed is intended for experimental systems involving release, through a nonporous membrane, of a drug whose concentration is a few times (≥3) greater than its solubility in the vehicle. For either micronized (2 μm) or macrosize (125 μm) drug, the Q (amount released) *versus* $t^{1/2}$ (time$^{1/2}$) plots were not linear until substantial time had elapsed. Excellent agreement was found between the experimental points and theoretical plots, generated by a computer fit to experimental data of an equation derived from a reported vehicle-boundary diffusion layer model. The values of the solubility and of the diffusion coefficient of benzocaine in the gel, calculated by the present mathematical treatment from release data, were in agreement with literature data. The particle size of released benzocaine did not influence the release pattern, thus confirming release in the present conditions to be diffusion rather than dissolution controlled. The present method is applicable for determining the solubility and diffusion coefficient of drugs in vehicles in cases not contemplated in current release theories.

The *in vitro* release of drugs from topical vehicles, in spite of its limited correlations with *in vivo* absorption, may offer useful information on some physicochemical factors involved in the latter process. Such important parameters as the diffusion coefficient and the solubility of a drug in a vehicle can be calculated by relatively simple equations, derived from mathematical models describing the process of *in vitro* release of drugs dissolved (1–3) or

for 12 hr and refrigerated overnight. The precipitate was filtered and washed with dry ether, and the filtrate was evaporated *in vacuo*, leaving an oil. This oil was distilled at 165–170°/0.2 mm, giving 3.8 g (25%) of a solid, mp 42–45°; IR (potassium bromide): 3300 (NH), 1520 (NO_2), 1335–1375, and 1125–1150 (SO_2) cm^{-1}; $[\alpha]_D^{30}$ +37.0° (c = 1, ethyl acetate).

Anal.—Calc. for $C_{10}H_{11}F_3N_2O_4S$: C, 38.46; H, 3.53; N, 8.97; S, 10.26. Found: C, 38.7; H, 3.8; N, 9.2; S, 10.3.

(+)-*N*-Trifluoromethanesulfonyl-1-methyl-2 - (4 - trifluoroacetylaminophenyl)ethylamine (XIV)—A solution of 3.12 g (0.01 mole) of V in 150 ml of tetrahydrofuran with 0.4 g of platinum dioxide was hydrogenated at 3 atm. After 48 hr, the solution was filtered and the solvent was removed *in vacuo*. The residual viscous liquid was dissolved in 250 ml of benzene; to this solution was added, with stirring, 2.1 g (0.015 mole) of trifluoroacetic anhydride. The mixture was refluxed for 3 hr, allowed to cool, and refrigerated overnight. The resulting solid was filtered, washed with water, and dried *in vacuo*. Recrystallization from aqueous ethanol gave 0.8 g, mp 143–145°; IR (potassium bromide): 3350, 3230 (NH), 1700 (C=O), 1200, and 1150 (SO_2) cm^{-1}; $[\alpha]_D^{29}$ +20° (c = 1, ethyl acetate).

Anal.—Calc. for $C_{12}H_{12}F_6N_2O_3S$: C, 38.10; H, 3.17; N, 7.41; S, 8.47. Found: C, 38.2; H, 3.2; N, 7.7; S, 8.1.

Antiobesity Test—Rats were trained over 2 weeks to eat their daily food ration[4] in only 5 hr. After training, either vehicle (controls) or drug was administered orally by gastric intubation daily for 5 days. One hour after drug, tared food cups containing the food ration were presented. The cups were weighed after 1 hr of feeding and again after 5 hr of feeding. Water was available *ad libitum*. Rats were weighed daily before drug administration.

Release of Drugs from Ointment Bases II: *In Vitro* Release of Benzocaine from Suspension-Type Aqueous Gels

F. BOTTARI, G. DI COLO [x], E. NANNIPIERI, M. F. SAETTONE, and M. F. SERAFINI

Abstract □ The *in vitro* release of benzocaine, suspended in an aqueous gel, through silicone rubber membranes was studied to test an extension of existing mathematical models. The theoretical treatment proposed is intended for experimental systems involving release, through a nonporous membrane, of a drug whose concentration is a few times (≥3) greater than its solubility in the vehicle. For either micronized (2 μm) or macrosize (125 μm) drug, the Q (amount released) *versus* $t^{1/2}$ (time$^{1/2}$) plots were not linear until substantial time had elapsed. Excellent agreement was found between the experimental points and theoretical plots, generated by a computer fit to experimental data of an equation derived from a reported vehicle-boundary diffusion layer model. The values of the solubility and of the diffusion coefficient of benzocaine in the gel, calculated by the present mathematical treatment from release data, were in agreement with literature data. The particle size of released benzocaine did not influence the release pattern, thus confirming release in the present conditions to be diffusion rather than dissolution controlled. The present method is applicable for determining the solubility and diffusion coefficient of drugs in vehicles in cases not contemplated in current release theories.

The *in vitro* release of drugs from topical vehicles, in spite of its limited correlations with *in vivo* absorption, may offer useful information on some physicochemical factors involved in the latter process. Such important parameters as the diffusion coefficient and the solubility of a drug in a vehicle can be calculated by relatively simple equations, derived from mathematical models describing the process of *in vitro* release of drugs dissolved (1–3) or

suspended (1, 4–7) in ointment bases. In practice, these equations are used rarely, since their use is restricted by theoretical requirements whose fulfillment is difficult to realize and to verify in most experimental systems (3, 8–10).

For suspended systems, zero concentration of the drug at the interface separating the donor and the receiving phase is required in the vehicle-controlled model proposed by Higuchi (4), while Roseman and Higuchi's (6) vehicle–interfacial barrier-controlled model applies only to systems where the solubility of the drug is negligible with respect to the concentration in the vehicle. Neither model adequately fits some common experimental systems such as those involving release through a nonporous membrane of a drug whose concentration is only a few times greater than its solubility in an ointment.

The purposes of the present work are to describe and to assess an extension of the existing quantitative treatments that might be useful in similar cases. As a practical test of the theory, the release of benzocaine from suspension-type aqueous gels through silicone rubber membranes was investigated.

THEORETICAL

The matrix–boundary layer model proposed by Roseman and Higuchi (6) for the release of drugs suspended in planar matrixes may be extended to any homogeneous solid or semisolid vehicle separated from a receptor sink by a planar diffusional barrier. Accordingly, the following equation describing the pattern of the amount of drug released *versus* time can be derived:

$$Q^2 + 2D_vRAQ = 2D_vAC_st \qquad \text{(Eq. 1)}$$

where Q is the amount of drug released per unit area; D_v is the effective diffusivity of drug in the vehicle; A and C_s are the total concentration and the solubility, respectively, of drug in the vehicle; and R is the diffusional resistance of the barrier interposed between the vehicle and the receiving phase[1].

The following assumptions were made in the derivation of Eq. 1: (*a*) a quasi-steady state (11) exists, (*b*) the drug particles are small when compared to the average distance of diffusion, (*c*) the concentration of drug in the vehicle is much greater than its solubility in the vehicle ($A \gg C_s$), (*d*) the diffusion coefficients in the vehicle and in the barrier are constant, (*e*) diffusion rather than dissolution is the rate-controlling step, (*f*) the diffusion process occurs through the continuous phase rather than through pores or channels within the medium, and (*g*) the receiving solution is a perfect sink.

Equation 1 is essentially valid for all times in which the suspended phase is present, less than the initial lag time, corresponding to the time necessary for establishment of a quasi-stationary state and for the average distance of diffusion to overwhelm particle dimension [see conditions (*a*) and (*b*)].

When $Q^2 \gg 2D_vRAQ$, *i.e.*, when $Q/A \gg 2D_vR$, Eq. 1 reduces to Eq. 2, previously derived by Higuchi (4) for the entirely vehicle-controlled process:

$$Q = \sqrt{2AC_sD_vt} \qquad \text{(Eq. 2)}$$

Under these conditions, any appreciable resistance to diffusion at the vehicle-receiving phase interface, where the drug concentration drops to negligible values, no longer exists.

Where C_s is not negligible with respect to A, the vehicle-controlled model is described by (3):

$$Q = \sqrt{(2A - C_s)C_sD_vt} \qquad \text{(Eq. 3)}$$

The conditions for validity of Eq. 3 are the same as for Eq. 2, except that the total drug concentration (A) is only a few (3–4) times greater than the solubility in the vehicle (C_s). The application of Eq. 3 to the determination of the diffusivity and solubility of drugs in solid or semisolid vehicles was reported previously (12). However, Eq. 3 is only applicable when zero concentration exists at the vehicle-receiving phase interface. This condition is well approximated only in cases of very little diffusional resistance of the interfacial barrier compared with that of the vehicle. The more general Eq. 1, although not limited by this condition, is only valid when C_s is negligible with respect to A [condition (*c*)], so its use for the determination of D_v and C_s is limited in cases of high C_s values due to considerable experimental difficulties in attaining the $A \gg C_s$ condition.

The applicability of Eq. 1 can be extended to experimental systems in which A is but a few times (≥ 3) greater than C_s if it is modified as follows:

$$Q^2 + 2D_vRA^*Q = 2D_vA^*C_st \qquad \text{(Eq. 4)}$$

where:

$$A^* = A - \frac{(C_s + C_v)}{2} \qquad \text{(Eq. 5)}$$

and C_v represents the concentration of drug in the vehicle at the interface with the barrier. According to the assumptions made in the *Appendix*, where details of the derivation of Eq. 4 are discussed, A^* seems to be comparatively little influenced by the variation of C_v with time and may be considered as constant. For small values of R and/or large values of time, Eq. 5 reduces to $A^* = A - C_s/2$ (*cf.*, Eq. 8) and Eq. 4 reduces to Eq. 3.

Equation 4 should lend itself to the determination of the solubility and diffusivity of drugs in ointments through release data when either Eq. 1 or 3 is inapplicable. Therefore, it is convenient to put Eq. 4 in the form:

$$Q = -a + \sqrt{a^2 + b(t - q)} \qquad \text{(Eq. 6)}$$

where $a = D_vRA^*$, $b = 2D_vC_sA^*$, and q is a correction term which depends on the lag time.

The values of a, b, and q can be obtained through a least-squares fit of Eq. 6 to experimental release data. By recalling Eq. 5, the following relationship between the parameter b and $(A - C_v/2)$ can be written:

$$b = 2D_vC_s\left(A - \frac{C_v}{2}\right) - D_vC_s^2 \qquad \text{(Eq. 7)}$$

For the same reasons indicated for Eqs. 4 and 5, Eq. 7 is supposed to hold with sufficient approximation for any value assumed by C_v in the time interval under study. Since linear concentration gradients are assumed, the value of C_v at any point of this interval can be obtained, once the diffusional resistance, R, is experimentally determined (*e.g.*, by steady- or quasi-steady-state permeation experiments), from the relationship (11):

$$C_v = R\frac{dQ}{dt} \qquad \text{(Eq. 8)}$$

where dQ/dt, the instantaneous release rate, can be obtained from Eq. 6 by differentiation. According to Eq. 7, it should be possible to construct a linear plot of b *versus* $(A - C_v/2)$ by carrying out experiments with varying drug concentrations ($A \geq 3C_s$) and calculating a single C_v value for each A at any time in the interval studied. The value of C_s equals twice the abscissa intercept of this plot.

Alternatively, C_s can be obtained from the averaged ratio of parameter b to parameter a (Eq. 6) once R is known:

$$C_s = (R/2)\overline{(b/a)} \qquad \text{(Eq. 9)}$$

Following the calculation of C_s, D_v can be calculated from the slope of the b *versus* $(A - C_v/2)$ plot utilizing Eq. 7. The accuracy of the results and its dependence on the C_v values used in the calculations will be evaluated later.

EXPERIMENTAL

Materials—Carbomer 934P, a carboxyvinyl polymer[2], was used as received; its sodium salt was prepared as described in the literature (13). Benzocaine[3] was crystallized to a constant melting point of 91.5°. Particles with an average diameter of 125 μm (geometric) were obtained using 100–140-mesh ASTM sieves. A sample was micronized[4], and the average diameter of the particles (microscopic analysis) was 2.0 μm (geometric).

[1] When more than one barrier is involved (*e.g.*, a membrane and the adjacent hydrodynamic layer), the resistance is the sum of the resistances of the individual barriers.

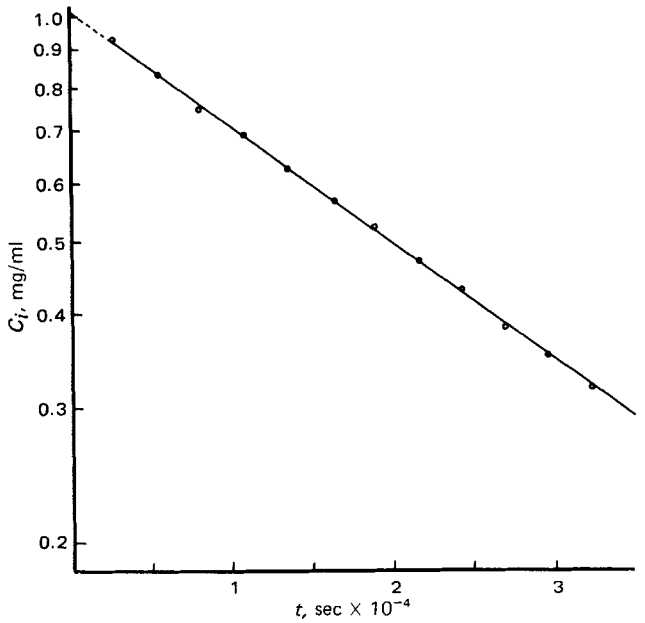

Figure 1—*Quasi-steady-state permeation plot of benzocaine through a silicone rubber membrane from an aqueous solution. Initial concentration* C_{i0} = *1.0 mg/ml.*

Silicone rubber[5] sheeting, labeled thickness of approximately 127 μm, was used as the membrane material.

Solubility Determinations—The water solubility of benzocaine at 30°, determined spectrophotometrically[6] (286 nm) on a sample equilibrated for 3 days, was 1.31 g/liter. The solubility in the gel was presumed to be the same, since gels containing 1.31 mg of benzocaine/ml were perfectly clear on microscopic[7] examination while suspended particles were visible in the gel kept at 30° several days after addition of 5% excess drug over the water solubility value.

Gel Preparation—The following procedure allowed preparation of homogeneous, air-free, suspension-type gels. To 100 ml of a saturated solution of benzocaine (0.13% w/v) in distilled water at 30° was added portionwise, while stirring, the sodium salt of the carboxyvinyl polymer (1.0 g, or 2.0 g in one case) together with the appropriate amount of either micronized or macrosize benzocaine. After the addition, the vessel was connected to a water pump; thorough stirring was continued until a bubble-free, clear gel formed.

After preparation, all gels were stored at 30° for future use. The benzocaine contents of the gels used, determined spectrophotometrically after appropriate dilution with water, were 2.59, 3.03, 3.70, 4.60, 5.10, and 10.90 mg/ml for micronized drug and 3.05, 4.12, and 4.92 mg/ml for macrosize drug.

Release Experiments—The release of benzocaine from the gels through silicone rubber membranes was investigated using a previously described apparatus (14) with minor modifications. A new cell, made entirely of polymethyl methacrylate[8], was used in place of the metal cell. The metal cell released, to the acidic (0.1 *N* HCl) receiving solution, substances interfering with the spectrophotometric assays. The only metal parts were the screw shanks (*cf.*, Ref. 14, Fig. 1), whose contact with the external solution was prevented by polymethyl methacrylate cap nuts and silicone rubber gaskets. The transparent material also allowed inspection of the cell contents, so the development of a sharply defined depletion zone in the gels could be observed during the experiments.

The capacity of the cell was 19.60 ml, and the diameter of the available area for diffusion was 5.0 cm. The cell was filled with the gel, the excess was removed with a spatula to produce an even surface, and the membrane, which had been presoaked in water for at least 24 hr, was carefully placed and pressed on the gel. The upper part of the cell was then assembled. All of these operations were performed in a conditioned atmosphere (30° and 100% relative humidity). The cell was then placed into a jacketed beaker (full capacity of 1.5 liters) connected to a constant-temperature bath (30 ± 0.1°) and circulator.

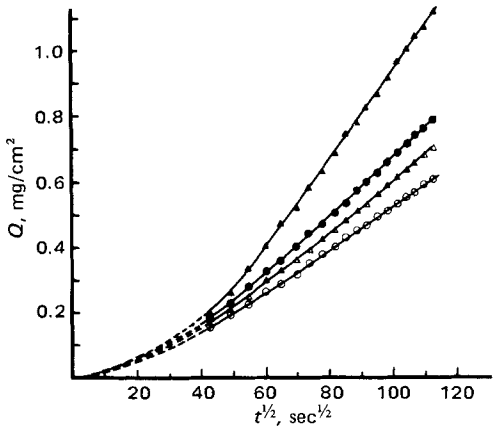

Figure 2—*Amount of benzocaine released from suspension-type gels prepared with micronized drug as a function of the square root of time. Key:* ▲, *10.9 mg/ml;* ●, *4.6 mg/ml;* △, *3.7 mg/ml; and* ○, *2.59 mg/ml. Two plots (5.10 and 3.03 mg/ml) were omitted for clarity.*

At t = 0, prewarmed 0.1 *N* HCl (0.5–1.0 liter, depending on the gel concentration) was introduced into the beaker, and stirring was immediately initiated using a two-blade propeller connected to a 300-rpm synchronous motor[9]. At appropriate intervals, measured volumes of the receiving phase were removed, diluted, if necessary, with 0.1 *N* HCl, and analyzed spectrophotometrically for benzocaine hydrochloride (227 nm). Blank runs demonstrated the absence in the external solution of materials that might interfere with the measurements.

Diffusional Resistance of Membrane—This value was determined by allowing benzocaine to permeate through the membrane under quasi-steady-state conditions. The experimental technique was described previously (15, 16). The permeation cell used had polymethyl methacrylate parts, instead of the stainless steel parts of the original cell, in contact with the external solution. The membranes were of the same type as in the release experiments and were presoaked in water for at least 24 hr. Both the internal and external stirring was performed by 300-rpm synchronous motors[9].

The available area for diffusion was 7.55 cm^2; the volume of the internal solution (benzocaine in distilled water, 0.1% w/v) was 25.0 ml. The experiments were carried out at 30°. Aqueous 0.1 *N* HCl (500 ml) was used as the external solution; the permeant content of this solution was determined at appropriate intervals, as in the release experiments. The concentration of the internal solution (C_i) at different times was calculated from the final drug concentration inside the cell and the amount that had appeared in the external solution. Blank runs demonstrated the absence, in the external solution, of materials that might interfere with the measurements.

Data Treatment—Each release and permeation experiment was performed at least four times, and the averaged data were used to draw the individual plots. With the linear plots, the data were fed to a desk electronic computer[10] fitted with a program for the computation of regression parameters and statistics. All linear regressions were highly significant ($p < 0.005$). Least-squares fits of Eq. 6 to release data were done with the aid of a digital computer, using an appropriate program[11].

RESULTS AND DISCUSSION

Diffusional Resistance of Membrane—In the present system, the diffusional resistance of the interfacial barrier, R, was only due to the silicone rubber membrane, since the diffusant was completely converted to a different species (its salt form) immediately after crossing the membrane. To obtain a more realistic value, R was determined by quasi-steady-state rather than by steady-state experiments. The conditions were thought to reproduce more closely those existing during release experiments, *i.e.*, a varying drug concentration at the membrane–donor phase interface.

If sink conditions are assured, the permeation of a drug from a stirred

solution across a membrane under quasi-steady-state conditions is described by (11):

$$\ln C_i/C_{i0} = \frac{S}{R'V_i}t \qquad \text{(Eq. 10)}$$

where C_i and C_{i0} are the concentrations of the donor solution at finite time t and at $t = 0$, respectively; V_i is the volume of the donor solution; S is the area of the membrane; and R' is the diffusional resistance of the membrane if contributions from nonstirred liquid layers adjacent to both sides of the membrane are insignificant, as assumed for the present experimental system.

The value of R (in release experiments) is related to R' (calculated from permeation experiments) through the following equation, which takes into account the difference existing between the donor phases in release and permeation experiments:

$$R = \frac{K_{m/w}}{K_{m/g}}R' \qquad \text{(Eq. 11)}$$

where $K_{m/w}$ and $K_{m/g}$ are the membrane–water and membrane–gel partition coefficients, respectively. In the present case, the drug solubility

Symbols represent experimental data; curves are based on theoretical calculations. Key: ■, 10.9 mg/ml; □, 5.1 mg/ml; ▲, 4.6 mg/ml; △, 3.7 mg/ml; ●, 3.03 mg/ml; and ○, 2.59 mg/ml.*

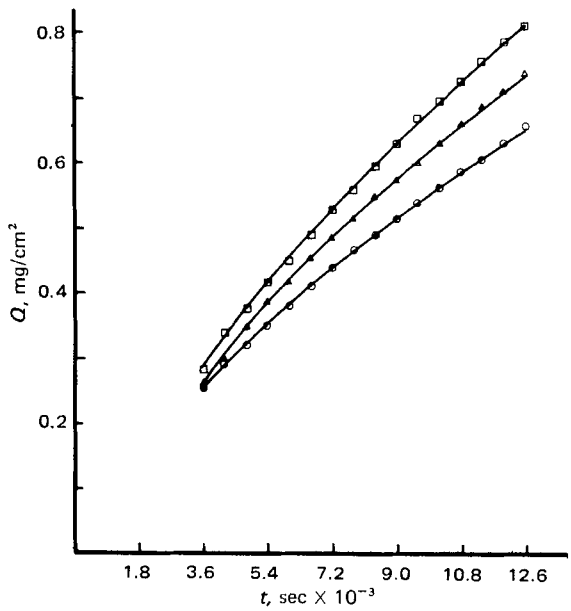

Figure 5—*Amount of benzocaine released from suspension-type gels containing different concentrations of macrosize drug as a function of time. Symbols represent experimental data; curves are based on theoretical calculations. Key: □, 4.92 mg/ml; △, 4.12 mg/ml; and ○, 3.05 mg/ml.*

in the gel was the same as in water. Therefore, $K_{m/w} = K_{m/g}$, and R could be calculated directly from the slope of the permeation plot according to Eq. 10. Figure 1 illustrates a typical permeation (log C_i/C_{i0} *versus* t) plot, whose linearity demonstrates the adherence of the experimental system to Eq. 10. An average value of 8.3×10^3 sec/cm resulted for R from the permeation experiments.

Release Experiments—Figures 2 and 3 illustrate the results of release experiments with micronized and macrosize benzocaine, respectively. The experiments were carried out over 3.5 hr at concentrations ranging from 2.59 to 10.9 mg/ml for micronized drug and from 3.05 to 4.92 mg/ml for macrosize drug. In no case was a linear relationship between Q and $t^{1/2}$ observed, at least until a substantial amount of time elapsed. Thus, the nonlinearity of the graphs appears to rule out the vehicle-controlled model described by Eq. 3. Since Eqs. 1 and 4 predict the presence of a nonlinear region during early release times, it is reasonable to assume that the vehicle–membrane-controlled model was operative in this case.

This assumption is confirmed by the graphs in Figs. 4 and 5, in which the experimental release plots of benzocaine (micronized and macrosize, respectively) are compared with theoretical plots, generated by a least-squares fit of Eq. 6 to experimental data, obtained with the aid of a digital computer. Since, as pointed out in the theoretical section, Eq. 6 is valid after the lag time, all data used for the interpretation were taken 30 min after the beginning of release experiments with micronized drug (60 min with macrosize drug). After these lapses of time, the thickness of the depletion zone, l, approximately estimated for each concentration from the amount of released drug ($l = Q/A$), was sufficiently great with respect to particle size and interparticulate distance for micronized and macrosize particles. The time required for establishment of a linear concentration gradient in the membrane should be negligible, as shown by the quasi-steady-state permeation graph in Fig. 1, whose ordinate intercept closely approaches the theoretical value, 1.00 mg/ml. Thus, it can be safely assumed that conditions (*a*) and (*b*) for the validity of Eq. 1 (and 6) were attained. The excellent agreement between calculated and experimental points indicates that Eq. 6 is well suited for describing the release pattern of micronized and macrosize drug.

The values of a, b, and q, estimated for each release experiment by the computer fit of Eq. 6 to release data, and the corresponding values of the concentration at the gel–membrane interface, calculated by Eqs. 6 and 8, at the lower (C_v^i) and the upper (C_v^f) ends of each time interval, are listed in Table I. The values of C_v^i and C_v^f are approximately 47–80 and 18–40%, respectively, of C_s, the solubility of benzocaine in the gel (1.31 mg/ml, see *Experimental*). These comparatively high values possibly account for the curvature of the Q *versus* $t^{1/2}$ plots (Figs. 2 and 3) and further support the application of Eq. 4, rather than of Eq. 3, to the present experimental system.

Table I—Values of Parameters *a*, *b*, and *q* (Eq. 6) and of C_v (Eq. 8) Calculated at the Lower ($C_v{}^i$) and Upper ($C_v{}^f$) Ends of the Time Interval for Each Release Experiment

Particle Size, μm	*A*, mg/ml	*a*	$b \times 10^4$	*q*	$C_v{}^i$, mg/ml	$C_v{}^f$, mg/ml
2.0	2.59	0.140	0.441	297	0.62	0.24
2.0	3.03	0.170	0.485	163	0.61	0.25
125.0	3.05	0.173	0.550	990	0.55	0.28
2.0	3.70	0.208	0.640	396	0.73	0.29
125.0	4.12	0.254	0.797	1170	0.65	0.33
2.0	4.60	0.260	0.852	378	0.81	0.34
125.0	4.92	0.325	0.995	945	0.68	0.37
2.0	5.10	0.330	1.005	360	0.83	0.36
2.0	10.90	0.720	2.330	405	1.05	0.53

Determination of Diffusion Coefficient and Solubility—In Fig. 6, *b* was plotted *versus* $(A - C_v{}^i/2)$ and $(A - C_v{}^f/2)$ (*cf.*, Eq. 7 and Table I). Since all points fell, within the range of experimental error, on the same line, all data were grouped to build up the regression line. The nonperfect alignment of the points in the line is due to wide variations of the parameter *b* with experimental error. However, the high value of the correlation coefficient (0.998) points to a significant linear relationship between *b* and $(A - C_v/2)$ as predicted by Eq. 7.

The value for the solubility of benzocaine in the gel, C_s, calculated from the abscissa intercept of the plot in Fig. 6, was 1.18 mg/ml; the value of C_s calculated by Eq. 9 was 1.29 mg/ml. Both values are in satisfactory agreement with the directly determined solubility value at 30°, 1.31 mg/ml. The values of the diffusion coefficient of benzocaine in the gel, calculated from the slope of the plot reported in Fig. 5 according to Eq. 7, are 1.00×10^{-5} and 9.14×10^{-6} cm²/sec, assuming $C_s = 1.18$ and 1.29 mg/ml, respectively. The agreement with the literature (17) value for the diffusion coefficient of benzocaine in water at 30° (9.9×10^{-6} cm²/sec) is satisfactory. This finding is indicative of the absence of interactions, mechanical and/or chemical, between diffusant and gel. Indeed, the pores in the gel network should be much larger than the molecular diameter of the diffusing drug, as indicated also by the observation that the rate of release of benzocaine was unaffected when the concentration of carboxyvinyl polymer in the gels was doubled. The occurrence of chemical interactions appears unlikely in view of the chemical nature of benzocaine and the carboxyvinyl polymer and because the solubility of benzocaine in the gel was the same as in water.

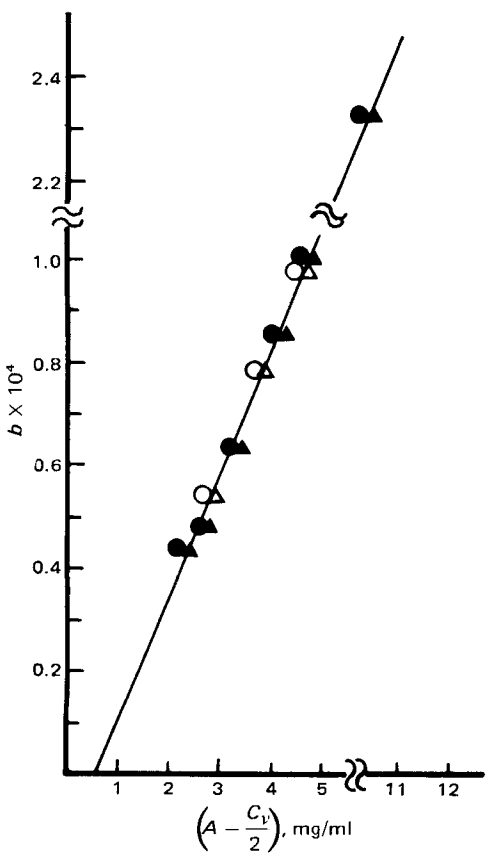

Figure 6—*Relationship between parameter* b *and* $(A - C_v/2)$. *Key:* ●, $(A - C_v{}^i/2)$, *micronized;* ○, $(A - C_v{}^i/2)$, *macrosize;* ▲, $(A - C_v{}^f/2)$, *micronized; and* △, $(A - C_v{}^f/2)$, *macrosize. See text for details.*

Influence of Particle Size—As stated earlier, the release pattern of benzocaine was unaffected by particle size; both micronized and macrosize drug were released according to Eq. 4 after a finite time from the beginning of the experiments. Indeed, the surface area of undissolved drug should not influence the release rate beyond the lag time, since Eq. 4 requires release to be diffusion rather than dissolution controlled. However, the lag time itself should be highly influenced by particle size insofar as it depends on the time necessary for the thickness of the depletion zone to overwhelm particle diameter. In effect, the correction factor *q* (Eq. 6), which is directly related to the lag time, was greater for macrosize than for micronized drug (Table I).

The observations do not disagree with the assumptions of Haleblian *et al.* (10), who found that the surface area greatly influenced the release rate of chlormadinone acetate from silicone elastomer matrixes. They attributed this effect to a dissolution-influenced release. Indeed, the thickness of the depletion zone of their experimental system, estimated (as the Q/A ratio) from the reported data, was at most about 100 μm, while the diameters of the macrocrystals used were in the 100–300-μm range.

CONCLUSIONS

Equation 1, applied previously to the release of drugs from solid matrixes at concentrations largely exceeding solubility, is valid in a modified form (Eq. 4) for the release of benzocaine from an aqueous gel at drug concentrations only a few times greater than solubility. Equation 4 lends itself to the determination of the solubility as well as of the diffusion coefficient of drug in a vehicle. The determined values are satisfactorily accurate, at least for practical purposes.

The present results are indicative of a method of potential utility for the study of the above parameters, particularly where the application of Eq. 3 is ruled out by the influence on release of the diffusional resistance of the barrier separating the donor and receiving phase and where the use of Eq. 1 is prevented by the practical impossibility of attaining the $A \gg C_s$ condition because of a high drug solubility in the ointment.

The size of suspended particles is particularly important. Since the time necessary for attainment of the conditions of applicability of Eq. 4 is remarkably dependent on particle dimension, the use of macrosize powder might waste both time and materials.

APPENDIX

Equation 1 was derived by equating the rate of release and the rate of quasi-steady-state diffusion through the vehicle and the interfacial barrier. For the $A \gg C_s$ condition, the first parameter is directly proportional to the rate of increase of the thickness of the depletion zone, *l* (6):

$$dQ/dt = A\, dl/dt \qquad \text{(Eq. A1)}$$

When C_s is not negligible with respect to *A*, the proportionality fails as long as the time-dependent concentration at the interface with the barrier, C_v, must also be taken into account in the expression of the released amount per unit area and of the release rate:

$$Q = [A - (C_s + C_v)/2]l \qquad \text{(Eq. A2)}$$

$$dQ/dt = [A - (C_s + C_v)/2]\, dl/dt - 1/2l\, dC_v/dt \qquad \text{(Eq. A3)}$$

However, if the second term in the rate expression is negligible when compared with the first, the factor within brackets in Eq. A3 can be as-

sumed by approximation to be constant (*cf.*, Eq. 5). The consequent proportionality between dQ/dt and dl/dt should enable derivation of Eq. 4 in complete analogy with Eq. 1. That the condition for proportionality is generally satisfied also for values of A as little as $3C_s$ can be verified by expressing this condition through the ratio of the first to the second term in the expression of the release rate (Eq. A3):

$$\left|\frac{2A - C_s - C_v}{l} dl/dC_v\right| \gg 1 \qquad \text{(Eq. A4)}$$

and further substituting into this relationship the following expressions of C_v, dC_v, l, and dl:

$$C_v = R\, dQ/dt \qquad \text{(Eq. A5)}$$

$$dC_v = (R\, d^2Q/dt^2)\, dt \qquad \text{(Eq. A6)}$$

$$l = Q/(n - 1/2)C_s \qquad \text{(Eq. A7)}$$

$$dl = [1/(n - 1/2)C_s]\, dQ \qquad \text{(Eq. A8)}$$

where $n = A/C_s$. Equation 1, where $(n - 1/2)C_s$ is used in place of A, can be employed to obtain approximate expressions of Q, dQ, and d^2Q/dt^2.

Following calculation, the condition for proportionality between the release rate and the rate of increase of the thickness of the depletion zone can be written as follows:

$$\frac{2x^2(n - 1/2) - x}{x - 1} \gg 1 \qquad \text{(Eq. A9)}$$

where $x = \sqrt{1 + [2/(n - 1/2)D_vR^2]t}$.

It can be readily verified that the minimum value of the ratio is 18 for $n = 3$, while it increases with increasing n.

Metabolism of *N*-Ethyl-3-piperidyl Benzilate in Rats

CHING-HSIU CHEN [*], MAHMOUD M. ABDEL-MONEM [*x], and THOMAS P. KRICK [‡]

Abstract □ The metabolic fate of *N*-ethyl-3-piperidyl benzilate (I) and its potential metabolites 3-piperidyl benzilate (II), *N*-ethyl-3-hydroxypiperidine (III), and 3-hydroxypiperidine (IV) was studied. Incubation of I with rat liver homogenates resulted in the formation of II and III. Only a trace of unchanged drug appeared in urine after intraperitoneal injection of I. Approximately 9% of the injected dose of I was excreted in urine as III and 2% in the form of metabolites that produced III after acid hydrolysis. After intraperitoneal injection of II in rats, 18% of the dose was excreted in urine as IV. Approximately 26% of the injected dose of III was present in urine as the unchanged drug, and 63% of the dose was excreted in the urine in the form of conjugates that produced III on acid hydrolysis. Urine of rats injected with IV contained approximately 50% of the injected dose as the unchanged drug and 50% of the dose in the form of a conjugate that produced IV on acid hydrolysis. The identity of the metabolites in extracts from urine was established by GLC–mass spectrometry. It is concluded that hydrolysis was one metabolic pathway for I and II. The major routes of elimination of these compounds are not yet known and may include excretion in feces or metabolic transformations resulting in the degradation of the piperidine ring.

During studies to develop potent and selectively acting atropine substituents for the treatment of GI disturbances, numerous compounds were synthesized that were superior to atropine with respect to anticholinergic potency, antisecretory effects, and reduced incidence of side effects (1). Most of these compounds are glycolate esters of heterocyclic imino alcohols. In experimental animals, these drugs produced potent central nervous system (CNS) stimulation, as indicated by hyperactivity and other behavioral disturbance tests (2). In humans, they were potent and long-lasting hallucinogenic and psychotomimetic agents (3).

Some human subjects manifested a marked change in their basic mood and drive 1 or 2 days following a single

sumed by approximation to be constant (*cf.*, Eq. 5). The consequent proportionality between dQ/dt and dl/dt should enable derivation of Eq. 4 in complete analogy with Eq. 1. That the condition for proportionality is generally satisfied also for values of A as little as $3C_s$ can be verified by expressing this condition through the ratio of the first to the second term in the expression of the release rate (Eq. A3):

$$\left|\frac{2A - C_s - C_v}{l} dl/dC_v\right| \gg 1 \qquad \text{(Eq. A4)}$$

and further substituting into this relationship the following expressions of C_v, dC_v, l, and dl:

$$C_v = R\, dQ/dt \qquad \text{(Eq. A5)}$$

$$dC_v = (R\, d^2Q/dt^2)\, dt \qquad \text{(Eq. A6)}$$

$$l = Q/(n - 1/2)C_s \qquad \text{(Eq. A7)}$$

$$dl = [1/(n - 1/2)C_s]\, dQ \qquad \text{(Eq. A8)}$$

where $n = A/C_s$. Equation 1, where $(n - 1/2)C_s$ is used in place of A, can be employed to obtain approximate expressions of Q, dQ, and d^2Q/dt^2.

Following calculation, the condition for proportionality between the release rate and the rate of increase of the thickness of the depletion zone can be written as follows:

$$\frac{2x^2(n - 1/2) - x}{x - 1} \gg 1 \qquad \text{(Eq. A9)}$$

where $x = \sqrt{1 + [2/(n - 1/2)D_vR^2]t}$.

It can be readily verified that the minimum value of the ratio is 18 for $n = 3$, while it increases with increasing n.

During studies to develop potent and selectively acting atropine substituents for the treatment of GI disturbances, numerous compounds were synthesized that were superior to atropine with respect to anticholinergic potency, antisecretory effects, and reduced incidence of side effects (1). Most of these compounds are glycolate esters of heterocyclic imino alcohols. In experimental animals, these drugs produced potent central nervous system (CNS) stimulation, as indicated by hyperactivity and other behavioral disturbance tests (2). In humans, they were potent and long-lasting hallucinogenic and psychotomimetic agents (3).

Some human subjects manifested a marked change in their basic mood and drive 1 or 2 days following a single

dose of these drugs (4). Clinical trials of one compound[1] in psychiatric patients revealed that it was a safe and effective antidepressant agent (5). The delayed onset of the mood enhancement effects of the glycolate esters in humans might be attributed to the formation of active metabolites. Therefore, the metabolic fate of these compounds in rats was studied as a prelude to metabolic studies in humans.

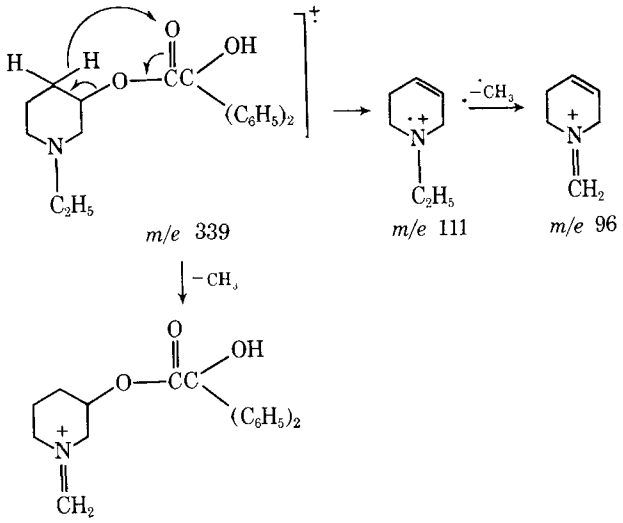
The metabolic fate of glycolate esters has received little attention, and the few reported studies provide somewhat contradictory results. The metabolism of ^{3}H-*N*-ethyl-3-piperidyl benzilate (I) was studied in rats; 75% of the injected dose was present in urine as the unchanged drug at 2 hr after intraperitoneal injection, and 96% was excreted after 12 hr (6). However, the unchanged drug was not detected in urine of rats during 48 hr after intraperitoneal injection of I and the only metabolites detected were benzilic acid, *N*-ethyl-3-hydroxypiperidine (III), and a small amount of conjugate(s) that produced III after acid hydrolysis (7). Another study (8) found that I produced acetaldehyde when incubated *in vitro* with microsomes from rat liver. The present paper reports the identification of the metabolites produced from the incubation of I with rat liver homogenate *in vitro* and the urinary metabolites of I after intraperitoneal injection in rats.

RESULTS AND DISCUSSION

Synthesis and Identification of Potential Metabolites—The hydrochloride of I was synthesized from III and methyl benzilate as described by Biel *et al.* (1). 3-Piperidyl benzilate (II) hydrochloride was obtained by catalytic hydrogenolysis of *N*-benzyl-3-piperidyl benzilate. The latter was obtained by reacting *N*-benzyl-3-chloropiperidine with benzilic acid. The hydrochlorides of III and 3-hydroxypiperidine (IV) were obtained from commercially available III and IV.

***In Vitro* Studies**—Compound I hydrochloride was incubated with rat liver homogenate. The metabolites were extracted from the incubation mixture and examined by two-dimensional TLC on silica gel plates. Spots with chromatographic mobilities similar to authentic samples of I–III were observed on the TLC plates. No spot corresponding in position to IV was observed.

To confirm the identity of the metabolites produced, areas of the TLC plates corresponding to the positions of I–III were scraped and the adsorbent was extracted with methanol. The methanol extracts were evaporated to dryness, and the residues were submitted for mass spectral analysis. The mass spectrum of an authentic sample of I and that of the substance recovered from the incubation mixture were virtually identical, confirming the identity of the latter. The mass spectrum for I showed the molecular ion at *m/e* 339. The base peak appeared at *m/e* 111 and was tentatively assigned to the $C_7H_{13}N^+$ fragment. A plausible fragmentation pathway accounting for the major fragments in the mass spectrum of I is shown in Scheme I.



Scheme I

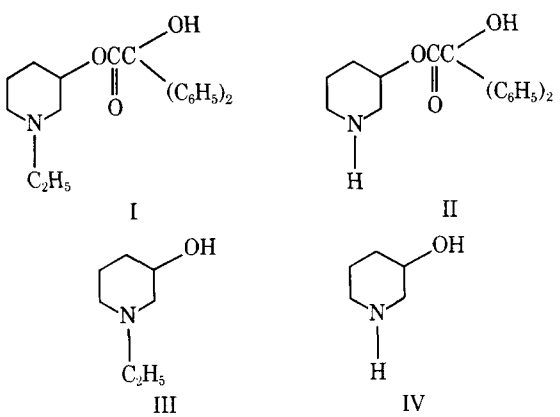
The mass spectrum of authentic II was not identical to that of the metabolite believed to be II. Evidently, the fragmentation pattern of II by electron impact was dependent on the concentration of the compound and/or the temperature in the ionization chamber, since recording consecutive spectra after the introduction of the sample in the ionization chamber of the mass spectrometer resulted in vastly different spectra. To confirm the identity of the metabolite, the IR spectrum of the residue eluted from the TLC plate was recorded and was identical to that of an authentic sample of II.

The crude extract from the incubation mixture was examined by GLC–mass spectrometry to detect the presence of III and IV. The chromatographic separation was performed on a 12% Carbowax 20M column, and the mass spectrum for the peaks eluted with the same retention time as III and IV were recorded. No peak with the same retention time and mass spectrum as IV was detected in the crude extract of the incubation mixture. A peak with the same retention time as III was present in this extract, and the mass spectrum of this peak was virtually identical to that obtained for an authentic sample of III. The mass spectrum of III showed the molecular ion at *m/e* 129 and the base peak at *m/e* 114 and was similar to the spectrum previously reported for this compound (9).

The possibility that III was produced by the nonenzymatic hydrolysis of I also was explored. Incubation of I under the same conditions as for the enzymatic studies, except for the absence of liver homogenate, resulted in the formation of only a trace of III, if at all. This result indicated that the hydrolysis of I to III in the previous studies was indeed enzyme catalyzed, undoubtedly by esterases present in liver homogenates. It was of interest to determine the site of these esterases in the different fractions of liver homogenates and whether these esterases were present in rat blood.

Compound I was incubated with the microsomal and the supernatant fractions of the rat liver homogenate and with rat blood. The incubation conditions and the workup of the incubation mixture were the same as described for the experiments using liver homogenates. Incubation of I with the microsomal fraction of the rat liver homogenates resulted in a metabolite profile qualitatively and quantitatively (as determined by comparison of the relative intensities of the spots on the TLC plate) similar to that obtained with the rat liver homogenates. On the other hand, incubation of I with the 105,000×*g* supernate of rat liver homogenates resulted only in the formation of traces of III. The formation of III by incubation with the 105,000×*g* supernate may be attributed to the presence of residual microsomes or the presence of esterase enzymes in this fraction. Incubation of I with rat blood resulted in the formation of traces of III. These results indicated that the enzymes responsible for the metabolism of I *in vitro* were mainly localized in the microsomal fraction of the liver homogenates. The blood showed only a very low esterase activity for this compound.

The absence of IV in the products of the metabolism of I was not expected, since the incubation conditions resulted in the accumulation of II and III in the incubation mixture. The latter two metabolites would be expected to be substrates for the liver enzymes and would be further metabolized to IV. Therefore, II and III were investigated as substrates



[1] Ditran.

for the rat liver homogenate enzymes. Compounds II and III were incubated with the rat liver homogenates using the same incubation conditions and workup procedures described for I. These studies indicated that II was not hydrolyzed to IV by the microsomal esterases. Likewise, III was not *N*-deethylated to IV.

Urinary Metabolites of I in Rats—The urinary excretion of I and its potential metabolites after intraperitoneal injection in rats also was studied. Several methods for the isolation of the metabolites from urine were investigated, including extraction of urine with solvents, adsorption of the metabolites on activated charcoal (10), use of cation-exchange resins to retain the basic metabolites, and partition column chromatography as described by Egli (7). The use of activated charcoal for the adsorption of the metabolites from urine was most satisfactory. The recovery of metabolites from urine was high, and there was minimum interference from other urinary constituents.

Extracts from urine of rats injected with I hydrochloride were examined by GLC–mass spectrometry using a 3% OV-1 column and monitoring *m/e* 339 and 129. A peak of *m/e* 339, at a column temperature of 220°, with the same retention time as I was observed in the urine extracts, indicating the urinary excretion of unchanged drug. The identity of this substance was further established by recording the spectrum of this peak between *m/e* 400 and 10. This spectrum was virtually identical to that obtained for an authentic sample of I treated in the same way as the metabolite sample. The amount of unchanged drug in urine was very small, and quantitation was not practical. This finding indicated that only a trace amount of the unchanged drug was excreted in urine after intraperitoneal injection in rats.

The extracts from urine also showed a peak with *m/e* 129, at a column temperature of 120°, with a retention time equal to that of an authentic sample of III. The identity of this substance was further established by recording its mass spectrum between *m/e* 200 and 10. The mass spectrum obtained was virtually identical to that of an authentic sample of this compound. Compound III was present in a considerably larger amount than the unchanged drug.

The chromatographic separation of IV using the described conditions was not satisfactory. However, the separation of the silyl derivatives of III and IV was acceptable. Extracts from urine were silylated with *N,O*-bis(trimethylsilyl)acetamide to form the monosilyl derivative of III (mol. wt. 201) and the disilyl derivative of IV (mol. wt. 245). The silylated extract was examined by GLC–mass spectrometry using a 3% OV-1 column at 65° and monitoring *m/e* 201 (monosilyl derivative of III) and at 80° and monitoring *m/e* 245 (disilyl derivative of IV).

A peak of *m/e* 201 was observed, confirming the presence of III in urine. The quantitation of III in urine was achieved by comparing the absolute intensity of *m/e* 201 at the peak maximum with the intensities obtained by adding different known concentrations of the standard compound to rat urine and subjecting these samples to exactly the same processes as the experimental samples. Estimation of III in urine indicated that approximately 9% of the injected dose was excreted as this metabolite. No peak of *m/e* 245 (the disilylated derivative of IV) was detected in urine.

Since it was not possible to develop a GLC procedure for the detection and quantitation of II in urine, it was imperative to use an indirect method for its determination. This method involved the acid hydrolysis of urine and measurement of the increase in the amount of IV. Conjugated metabolites that may be excreted in urine after the intraperitoneal injection of I would produce III and IV on acid hydrolysis. Urine was subjected to acid hydrolysis and extracted in the same way as previously described. The GLC–mass spectrometric examination of these extracts directly and after silylation indicated the presence of only III. The amount of III in urine after acid hydrolysis was 11% of the injected dose, indicating that 2% of the injected dose was excreted in urine in the form of a conjugate of I or III and/or unchanged I. The absence of IV in the hydrolyzed urine indicated that neither II nor conjugates of II and IV were excreted in urine.

These findings are in agreement with those of Egli (7), who reported that approximately 9% of injected I was recovered in the 48-hr urine of rats as III and that 2% was recovered as conjugates that produced III on acid hydrolysis. Egli (7) was not able to detect the presence of the unchanged drug in urine.

However, these findings are in contradiction with the findings of Abood and Rinaldi (6), who reported that 96% of the injected dose of I was excreted unchanged in rat urine within 48 hr after intraperitoneal injection in rats. These investigators used tritium-labeled I with no provision to establish the position of the label in the molecule. The radioactivity they measured in rat urine may have been due to some metabolite not detected with the present analytical methods.

The absence of II and its hydrolysis product IV from urine was unexpected since II was a major metabolite of I *in vitro*. Also, it was disturbing that about 90% of the injected dose was not accounted for. Consequently, the metabolism of the potential metabolites, II–IV, was studied to determine whether they are terminal metabolites or may be further metabolized to other products.

Extracts from urine of rats injected with II hydrochloride contained the disilyl derivative of IV in an amount approximately 18% of the injected dose. The amount of IV in urine after hydrolysis was approximately the same as before hydrolysis, indicating that no unchanged II or a conjugate that produced IV on acid hydrolysis was present.

These findings indicated that hydrolysis was one metabolic pathway for II. However, the major route of elimination of this compound as well as I is not as yet known. The presence of IV in urine of rats injected with II and its absence in the urine of rats injected with I indicated that II is probably not a major metabolite of I.

Approximately 26% of the injected dose of III hydrochloride was present in urine as the unchanged drug. The amount of III in urine after acid hydrolysis was 89% of the injected dose, indicating that 63% of the injected dose was excreted in urine in the form of conjugates that produced III on acid hydrolysis. The extracts from urine did not contain the potential metabolite IV.

Extracts from urine of rats injected with IV hydrochloride contained approximately 50% of the injected dose as the unchanged drug. The amount of IV in urine after acid hydrolysis was approximately 100% of the injected dose, indicating that 50% of the injected dose was excreted in urine in the form of conjugates that produced IV on acid hydrolysis.

EXPERIMENTAL[2]

Compound I Hydrochloride—The title compound was obtained in 72% yield from III and methyl benzilate as described by Biel *et al.* (1). Recrystallization from absolute ethanol gave pure I hydrochloride, mp 190–192° [lit. (1) mp 191–192°].

Anal.—Calc. for $C_{21}H_{25}ClNO_3$: C, 67.11; H, 6.92; Cl, 9.45; N, 3.72. Found: C, 66.89; H, 7.16; Cl, 9.84; N, 3.54.

Compound II Hydrochloride—*N*-Benzyl-3-chloropiperidine (6.7 g, 30 mmoles) was dissolved in dry isopropyl alcohol (30 ml). To this solution was added benzilic acid (10.29 g, 45 mmoles) in dry isopropyl alcohol (90 ml), and the mixture was heated under reflux for 24 hr. Isopropyl alcohol was then removed by evaporation under reduced pressure. The precipitate was partitioned between 5% potassium carbonate aqueous solution and ether (60 ml). The ether layer was evaporated to dryness, and the residue was dissolved in a minimum volume of isopropyl alcohol; hydrogen chloride-saturated ether was added to precipitate the hydrochloride salt.

The resulting *N*-benzyl-3-piperidyl benzilate hydrochloride was filtered and recrystallized from absolute ethanol. It weighed 5.3 g (40.4% yield), mp 204.5° dec. *N*-Benzyl-3-piperidyl benzilate (4.6 mmoles) was dissolved in methanol (60 ml) containing acetic acid (0.4 ml), and 5% palladium-on-charcoal (900 mg) was added. The mixture was shaken under 46.5 psi of hydrogen for 90 min and filtered. The filtrate was concentrated to about one-third of its volume under reduced pressure. Hydrogen chloride-saturated ether (40 ml) was added and evaporated to dryness.

The residue was dissolved in methanol, and sufficient ether was added to effect complete precipitation. The precipitate was filtered, washed with ether, and dried *in vacuo* to provide 1.435 g (90% yield). Recrystallization from absolute ethanol gave 1.435 g of II hydrochloride (71% yield), mp 179.5–182°; NMR ($CDCl_3$): δ 7.25 (m, 10H), 4.8 (m, 1H), 3.4 (m, 2H), 2.5 (m, 4H), and 1.5 (m, 4H); mass spectrum: *m/e* (relative intensity), 312 (0.2), 212 (0.3), 183 (42.4), 105 (68.1), 84 (20.8), 83 (100), and 76 (1.7).

Compound III Hydrochloride—The hydrochloride was prepared by dissolving III[3] in methanol and adding hydrogen chloride-saturated ether. The precipitate was collected and recrystallized from isopropyl alcohol–ether, mp 159–162°; NMR (free base in $CDCl_3$): δ 3.0 (s, 1H), 3.6 (m, 1H), 1.1 (t, 3H, J = 7 Hz), 2.35 (q, 2H, J = 7 Hz), 2.35 (m, 4H), and

[2] Melting points were determined in open capillary tubes and are *uncorrected*. IR spectra were obtained with a Perkin-Elmer 237B spectrophotometer in potassium bromide disks. NMR spectra were obtained in deuterochloroform with a Varian A-60D spectrometer, using tetramethylsilane as the internal standard. Microanalyses were performed by M-H-W Laboratories, Garden City, Mich. Mass spectra were obtained with an AEI MS-30 mass spectrometer. GLC analyses were carried out on a Perkin-Elmer 900 instrument equipped with a flame-ionization detector. GLC–mass spectral analyses were performed on an LKB 9000 instrument equipped with a PDP 8E data processing system.

[3] Aldrich Chemical Co., Milwaukee, Wis.

1.68 (m, 4H); mass spectrum: *m/e* (relative intensity) 129 (17.39), 114 (100), 199 (6.77), 84 (9.16), 72 (32.71), 58 (14.91), 57 (40.37), 44 (21.74), 43 (20.91), 42 (58.18), and 41 (18.63).

Compound IV Hydrochloride—Compound IV[3] was dissolved in methanol and treated with hydrogen chloride-saturated ether until complete precipitation of the hydrochloride salt was observed. The precipitate was recrystallized from isopropyl alcohol–ether, mp 193–196°; NMR (free base in $CDCl_3$): δ 3.7 (m, H), 3.45 (s, H), 2.96 (m, H), 2.75 (m, 4H), and 1.65 (m, 4H); mass spectrum: *m/e* (relative intensity) 101 (42.61), 83 (2.20), 57 (65.25), 56 (35.85), 55 (12.74), 44 (100), 43 (32.23), 42 (24.06), and 41 (16.35).

***In Vitro* Studies**—*Tissue Preparations*—Livers from male Sprague–Dawley rats, 150–200 g, were used as the source of liver homogenates and microsomal preparations. Blood from the same rats was used for measurement of blood esterase activity. The animals were allowed food and water *ad libitum*. They were stunned by a blow on the head and decapitated, and the blood was collected in heparinized beakers.

The livers were removed rapidly and placed in ice-cold 1.15% KCl solution. All further preparations were conducted at 0–4°. The livers were mixed with three times their weight of 1.15% KCl and homogenized[4], and the homogenate was centrifuged in a refrigerated centrifuge[5] at 10,000×*g* for 30 min. The supernate was withdrawn, and half of it was used in studies with liver homogenates. The other half was centrifuged[6] at 105,000×*g* for 60 min. The high-speed supernatant layer was used as the "supernatant fraction of liver homogenate," and the precipitate, the microsomal pellet, was resuspended in 1.15% KCl solution.

Incubation Conditions—All solutions for enzyme preparation and incubation mixtures were prepared in water double distilled from glass. The incubation mixture contained 10 ml of 10 m*M* substrate (I, II, or III), 10 ml of enzyme preparation (liver homogenate, microsomal fraction, supernate of liver homogenate, or blood), 5 ml of cofactors solution (2.25 μmoles of NADP and 25 μmoles of glucose 6-phosphate in 1.15% KCl), 20 ml of buffer (prepared from 10 μmoles of nicotinamide, 5 μmoles of magnesium chloride, 1.63 g of dibasic sodium phosphate/100 ml, and 0.53 g of monobasic potassium phosphate/100 ml and adjusted to pH 7.4 with sodium hydroxide), and 5 ml of 1.15% KCl solution. The total volume was 50 ml.

Incubations were conducted at 37° in an open atmosphere for 2 hr in 250-ml conical flasks placed in a water bath shaker[7]. The reactions were terminated by the addition of 10 ml of 0.6 *N* perchloric acid. The incubation mixtures used in the zero-time studies were identical to the described mixtures without the enzyme preparation. Addition of the enzyme preparation was carried out in the last step, after the addition of perchloric acid. The mixtures were centrifuged, and the supernate was used for the identification of metabolites.

Identification of Metabolites—The supernate was extracted with an equal volume of benzene to remove lipids. The aqueous phase was adjusted to pH >10 with dilute ammonium hydroxide and extracted first with methylene chloride (75 ml) and then with 75 ml of chloroform–isopropyl alcohol (3:1). The extracts were combined and evaporated to dryness in a nitrogen stream, and the residues were dissolved in 0.1-ml portions of methylene chloride.

The residues obtained from each incubation were applied onto 10 silica gel GF TLC plates[8] (20 × 20 cm, 250 μm). The plates were developed in acetonitrile–chloroform–methanol–ammonium hydroxide (50:40:29:1) in one dimension and then in ethyl acetate–methanol–ammonium hydroxide (100:100:1) in a second dimension. The dry plates were examined under a UV lamp for the detection of I and II, and one plate was sprayed with 0.5% $KMnO_4$ to locate the metabolites. Areas of the plates corresponding to the positions of the authentic samples were scraped off the remaining nine plates.

The adsorbent fractions obtained from the same area on different plates were combined and extracted with methanol. The methanol extracts were dried in a nitrogen stream, and the residues were submitted for mass spectral analysis. The residue obtained from the area on the TLC plates corresponding in position to that of an authentic sample of II was dissolved in 0.1 ml of chloroform and mixed with 200 mg of potassium bromide (IR grade). The dried mixture was used for the preparation of a pellet for IR spectroscopy.

The residues obtained by evaporation of the extracts from the incubation mixtures (before application to the TLC plates) also were examined by GLC–mass spectrometry, using a 12% Carbowax 20M column at 120° to detect metabolites III and IV. The mass spectrum of the peak eluted with the same retention time as authentic III was recorded. No chromatographic peaks with the same retention times as authentic IV were observed in any extract.

***In Vivo* Studies**—Three male Sprague–Dawley rats, 500 g, were used for each experiment. The rats were placed individually in metabolism cages and allowed food and water *ad libitum;* urine (control) was collected for 24 hr. The rats were injected intraperitoneally with solutions of the hydrochloride salts of I, II, III, or IV in normal saline at 80 mg/kg in four equal injections for I, III, and IV or at 60 mg/kg in five equal injections for II. The urine was collected under toluene for 72 hr after injection. Urine samples were removed from the metabolism cage periodically and stored at −25° until analyzed.

Preparation of Correlation Curves—A 30-, 20-, 10-, or 7.5-mg portion of authentic III hydrochloride was added to separate 10-ml aliquots of control urine. The solutions were made alkaline (pH 8.0) by the addition of dilute ammonium hydroxide. A 20-ml aliquot of 0.2 *M* carbonate buffer (pH 11) and 5 ml of the basic charcoal suspension were added to each urine sample. The basic charcoal suspension was prepared by adding 15 g of charcoal[9] to 400 ml of carbonate buffer (sodium carbonate–sodium bicarbonate, pH 11) and mixing thoroughly, allowing the charcoal to settle overnight, and then aspirating as much as possible of the supernatant buffer.

The mixtures were mixed thoroughly by repeated gentle shaking for 30 min and then centrifuged at 4000×*g* for 15 min. The clear supernatant layers were discarded, and the charcoal precipitates were shaken with 150 ml of methanol. The methanol extracts were filtered and evaporated to dryness in a nitrogen stream. The residues were each treated with 235 mg of *N,O*-bis(trimethylsilyl)acetamide to form the monosilyl derivative of III. The mixtures were examined by computer-equipped GLC–mass spectrometry on 3% OV-1 at 65°, using the mass spectrometer as a specific ion detector. A correlation curve was obtained by plotting the concentration of authentic III *versus* the absolute intensity of the ions of *m/e* 201 at the peak maximum for the monosilyl derivative of III. Regression analysis[10] was used to determine the line of the best fit for the data points.

A 7.5-mg portion of authentic IV hydrochloride was added to a 10-ml aliquot of urine. The standard sample was then extracted as described. The residue after silylation was examined by computer-equipped GLC–mass spectrometry using a 3% OV-1 column at 80°.

Examination of Urine for I, III, and IV—An aliquot of urine (one-third to one-fourth the urine sample) was adjusted to pH 11.0 and treated with a suspension of charcoal, and the charcoal was extracted with methanol as previously described. The methanol extract was evaporated in a nitrogen stream, and the residue was dissolved in methylene chloride. The detection of I in urine was achieved by examining the solution by computer-equipped GLC–mass spectrometry using a 3% OV-1 column at 220°. The mass spectrometer was used in the specific ion detector mode to monitor the peaks with *m/e* 339.

The methylene chloride solution was evaporated to dryness in a nitrogen stream, and the residue was treated with 609 mg of *N,O*-bis(trimethylsilyl)acetamide. The solution was examined again by computer-equipped GLC–mass spectrometry using a 3% OV-1 column at 65° and monitoring the ions with *m/e* 201 for the monosilyl derivative of III. The column temperature was raised to 80°, and the sample was reinjected; the mass spectrometer was set to monitor ions with *m/e* 245 for the detection and quantitation of the disilyl derivative of IV.

Examination of Urine for Compounds that Produce III or IV after Acid Hydrolysis—An aliquot of the urine sample was mixed with an equal volume of 12 *N* HCl and heated at 118° for 16 hr. The mixture was adjusted to pH 11.0 and treated with a suspension of charcoal, and the charcoal was extracted with methanol as previously described. The methanol extract was evaporated in a nitrogen stream, and the residue was treated with 609 mg of *N,O*-bis(trimethylsilyl)acetamide. The solution was examined for the presence of the monosilyl derivative of III and the disilyl derivative of IV by computer-equipped GLC–mass spectrometry as previously described.

Effects of Agitation on Size Distribution of Particulate Matter in Large-Volume Parenterals

JAMES BLANCHARD ˣ, JOHN A. SCHWARTZ, and DALE M. BYRNE *

Abstract □ The particle-size distributions of six types of large-volume parenterals subjected to different degrees of agitation were determined using an automatic particle counter. Data acquired from each solution, which had been maintained in a stored condition, subjected to agitation by inverting 20 times, and then mechanically shaken for 30 min, produced a linear relationship between log $N_{>D}$ and log D. Both the slope (K) and the number of particles per milliliter exceeding 1 μm in diameter ($N_{>1}$) exhibited a dependence on the degree of agitation. Their combined effect indicates that agitation by 20 hand inversions removed particulate matter from the surface of the container, which increased the total number of particles in solution (>1 μm) but did not significantly alter the relative size distribution. Agitation for 30 min, however, disintegrated agglomerates and produced a particle-size distribution with a greatly increased number of particles whose diameters were less than 1 μm and a corresponding decrease in the number of particles exceeding 1 μm in diameter. The particle-size distribution of a parenteral solution determined by this *in situ* instrumental method was, therefore, dependent upon the degree of agitation to which the parenteral was subjected prior to examination.

Keyphrases □ Particle-size distribution—various large-volume parenterals, effect of different degrees of agitation □ Parenterals, large volume—particle-size distribution, effect of different degrees of agitation □ Dosage forms—various large-volume parenterals, particle-size distribution, effect of different degrees of agitation □ Agitation—effect on particle-size distribution of various large-volume parenterals

Particulate matter was defined as "extraneous, mobile, undissolved substances, other than gas bubbles, unintentionally present in parenteral solutions" (1). In a previous report, efforts to compare and contrast the ability of five methods to monitor the levels of particulate matter were described (2). During this investigation, it became apparent that the automatic particle counter was suitable for the rapid determination and sizing of particulate matter. This instrument's ability to provide a reasonably accurate determination of the particle-size distributions present in large-volume parenterals was comparable[1] to the membrane filtration and microscopic examination technique utilized in the recently adopted USP–NF standard (1).

Some difficulties previously were noted in determining the actual levels of particulate matter of a given size present in parenterals. Ernerot *et al.* (3), who utilized a destructive counting procedure, reported that the particle-size distribution in a parenteral solution at a given time was largely dependent upon the degree of agitation the solution had previously received. By its very nature, a destructive counting technique introduces a certain amount of shear force upon the particles in the solution, thereby altering the initial distribution of particles. This shear force introduced by the measuring technique itself would be eliminated by a nondestructive technique, since it would not be necessary to remove the solution from its container. Therefore, a nondestructive *in situ* technique that does not impose any additional shear force on the particles in a solution would be ideally suited for characterizing the effects of agitation on particle-size distributions in parenteral solutions.

Some recent reports gave conflicting accounts of the importance of the effects of agitation. Groves (4) attributed the increase in particle counts observed (3) to the presence of air bubbles generated during the agitation procedure. Ernerot (5) refuted this argument and identified the disintegration and flocculation of particles as the true sources of the variation in particle counts following agitation. Blaug and Sarabia (6) noted that the particle counts recorded using an electronic particle counter were the same for samples taken from intravenous bottles at rest or from the same bottles shaken immediately prior to sampling. Since destructive particle counting techniques were used in these investigations, it is difficult to draw definitive conclusions regarding the actual effects of agitation. Therefore, a major goal of this study was to examine more definitively the effects of agitation on the particle-size distribution in large-volume parenterals utilizing a nondestructive instrumental technique.

EXPERIMENTAL

Large-volume parenteral solutions[2] (1000 ml) were inspected using an automatic particle counter[3]. The six types of commercially available solutions examined were chosen on the basis of their extensive use in clinical practice (Table I).

The particle counter utilized is capable of detecting particles as small as 1 μm in diameter. Solutions were examined by the automatic particle counter in the manner previously described (2). The number of particles per milliliter exceeding the following diameters was determined: 1.000, 1.259, 1.585, 1.995, 2.512, 3.162, 3.981, 5.012, and 6.310 μm. These diameters were chosen to facilitate data analysis since their logarithms are equally spaced. Starting at 1 μm, particle counts were recorded at successively increasing threshold settings until a given setting produced 10 readings whose average was less than 10 particles/ml. This value was chosen to ensure statistical accuracy and to limit the instrumental error resulting from the fact that this instrument displays the truncated, rather than the rounded, version of the number of particles counted (2).

Triplicate samples of each of the six types of large-volume parenterals, stored in an undisturbed condition for 65 days, were gently placed in position on the instrument for counting. After completion of the readings on the stored solutions, each bottle was agitated by being inverted, end-over-end, 20 times. This degree of agitation was chosen to conform with the degree of agitation used in the recently instituted compendial standard technique (1). These inversions were performed by the same individual to obtain a uniform degree of agitation from bottle to bottle.

Upon completion of this set of readings, each bottle was then shaken for 30 min at 140 excursions/min on a mechanical agitator[4]. After each agitation procedure, the bottles sat undisturbed on the measuring platform of the instrument for a *minimum* of 45–60 sec before any readings were recorded. This time period was reported to be adequate to ensure that air bubbles introduced even under "severe" agitation conditions would not be counted by this instrument (7, 8). The present data support these observations.

RESULTS AND DISCUSSION

The particle-size distributions in parenteral solutions often can be described[1] by a straight-line equation of the form:

$$\log N_{>D} = K \log D + \log N_{>1} \qquad \text{(Eq. 1)}$$

where $N_{>D}$ is the number of particles per milliliter with a diameter larger than D, $N_{>1}$ is the number of particles per milliliter with a diameter larger than 1 μm, D is the particle diameter in micrometers, and K is equal to the slope of a plot of log $N_{>D}$ *versus* log D. This equation was used to characterize the particle-size distributions of the parenteral solutions to determine the effects of agitation on particle-size distributions.

The effects of different degrees of agitation on the measured particle counts in a typical solution are shown in Table II; only the particle counts with diameters greater than 1.000, 1.585, and 2.512 μm are represented. Values for K, $N_{>1}$, and correlation coefficients were calculated from *all* results, provided that at least 10 particles/ml exceeding a given diameter were counted.

The data in Table II for the stored solutions illustrate how the particle-size distribution characteristics varied considerably among individual samples, as previously noted[1]. In addition, the effects of agitation on the measured particle-size distributions varied from sample to sample. For example, 20 inversions of a stored solution caused the particles counted, exceeding 1 μm in diameter, to *decrease* in Solutions C and K and to *increase* in Solution G relative to the stored condition. When these same solutions were subsequently shaken for 30 min, $N_{>1}$ *decreased* for Solutions C and G and *increased* for Solution K relative to the condition in these same solutions following 20 hand inversions.

The effects of these different degrees of agitation on the slopes of the log–log plots also varied between individual samples. For example, 20 inversions of a stored solution *increased* the absolute magnitude of the slopes for Solutions C and K relative to the stored condition, but that for Solution G *decreased*. When these same solutions were subjected to 30 min of shaking, the slopes for Solutions G and K *increased* (*i.e.*, became steeper) while the slope for Solution C *decreased* relative to the condition in these same solutions following 20 hand inversions. A close adherence to Eq. 1 (indicative of a linear relationship between log $N_{>D}$ and log D) is apparent for all three individual solutions shown in Table II regardless of the degree of agitation since the poorest correlation coefficient is −0.9815.

Due to the variable effects of agitation on particle-size distributions among individual solutions (Table II), the data for each solution type were averaged. The averaging of triplicate samples of a given type of solution facilitated the discrimination of the effects of agitation on their particle-size distributions. The data in Table I clearly indicate certain trends. First, the average number of particles per milliliter exceeding 1.000 μm in diameter *increased* upon 20 inversions of a stored solution and then *decreased* when the solution was subsequently shaken for 30 min. Only the 5% dextrose in normal saline solution deviated from this trend. However, individual samples of 5% dextrose in normal saline exhibited some of these trends (Table II). Second, the average slopes of the log–log plots varied throughout the six solution types. Upon 20 inversions of the stored solutions, the slopes for three solution types *increased* while three decreased. However, the subsequent 30 min of shaking resulted in an *increase* in all slopes of the log–log plots.

Finally, the correlation coefficients between log $N_{>D}$ and log D for any type of solution were very high, regardless of the degree of agitation, and ranged from −0.9257 to −0.9998. These high correlation coefficients show that neither the type of solution nor the degree of agitation had any significant effect upon the linearity of the log–log plots. These observations differ from those of Ernerot (5) who reported a bend in the log–log plots of the particle-size distributions of stored parenterals.

Since these results and those in another study[1] indicated that the effects of agitation upon the particle-size distributions and the particle-size distributions themselves were independent of the type of solution, the data were analyzed without regard to solution type. When the 18 stored

samples were inverted 20 times, the slopes of the log–log plots of nine of the samples *increased* while the other nine *decreased*. The values of the individual slopes were analyzed by the Student t-test, and no significant difference ($p > 0.5$) was observed between the slopes corresponding to these two degrees of agitation. When these bottles that had been inverted 20 times were subjected to an additional 30 min of shaking, 13 of the 18 individual slopes *increased*. This increase was significant ($p < 0.01$) by the Student t-test.

A similar analysis of the number of particles exceeding 1 μm in diameter indicated that, when a stored solution was inverted 20 times, 15 of the 18 individual intercepts (log $N_{>1}$) *increased;* the subsequent 30 min of shaking caused 12 of the 18 individual intercepts to *decrease*. A Student t-test revealed that these trends were significant at the $p < 0.005$ and $p < 0.05$ levels, respectively.

Figure 1 illustrates the effects of agitation on K and $N_{>1}$. Since the particle-size distribution was independent of the type of solution, the data in Fig. 1 represent the average values of these two parameters for the 18 solutions.

When a stored solution was inverted 20 times, two effects were evident (Fig. 1). As previously noted, there was no statistically significant change in the slope of the log–log plot whereas the intercept *increased* significantly. These simultaneous effects can be interpreted to mean that there is an increase in the number of particles at all size ranges measured. The origin of these additional particles is most likely particles that are dislodged from the inner surface of the container (9) by the relatively mild agitation produced by 20 inversions (10).

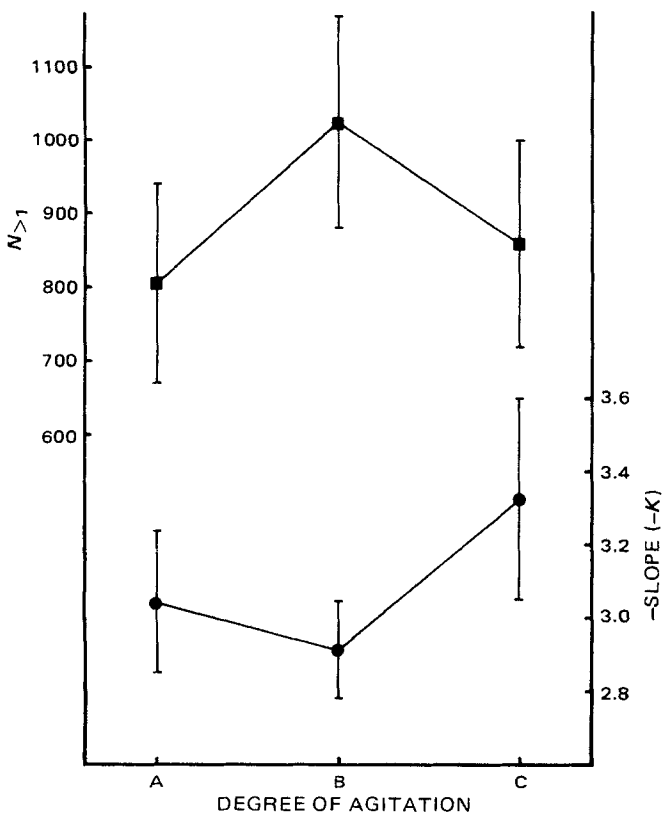

Figure 1—*Effects of degree of agitation on the slopes and intercepts of the log–log plots. Key: A, storage for 65 days; B, 20 hand inversions; and C, 30-min shake.*

However, Ernerot *et al.* (3) previously noted that one effect of agitation on a parenteral solution was a disintegration of large agglomerates into smaller sized particles. This effect would result in an increase in the intercept and a steeper slope. Since no significant increase in the slope was observed at this degree of agitation, the predominant effect appeared to be the dislodging of particles from the surface of the container whose size distribution was similar to those already present in solution. An alternative possibility is that only the larger particles were resuspended by the 20 hand inversions and that the process, in addition to resuspending these particles, also supplied sufficient shear force to disintegrate them into smaller particles whose resulting distribution was similar to the existing distribution.

When the solutions previously subjected to 20 inversions were subsequently shaken for 30 min, there was a significant *increase* in the slope of the log–log plot coupled with a significant *decrease* in the intercept. This decrease in the intercept is obviously indicative of the reduction of the total number of particles greater than 1 μm in diameter. The increased slope of the log–log plot represents a greater reduction in the number of larger sized, relative to smaller sized, particles following 30 min of shaking. A logical explanation for these concurrent effects is that the reduction in the number of larger sized particles is due to their disintegration caused by the high degree of agitation. This agitation, in turn, reduces these smaller particles to a size less than 1 μm in diameter, which is below the minimum size detectable by the automatic particle counter, causing a reduction in the observed intercept value. Since the disintegration of particles is the predominant event at this degree of agitation, the slope increases and the intercept decreases concurrently.

The health-related implications of these observations are difficult to state unequivocally, since the clinical significance of the very presence of particulate matter in a parenteral solution has not been proven conclusively. There is some controversy as to the most harmful size of particles (9), although one would intuitively suspect that a given number of larger sized particles would be potentially more harmful than a like number of smaller particles. The comment by Groves (11) that a container of parenteral fluid should not be subjected to violent shaking prior to injection is therefore somewhat difficult to reconcile. One point that is clear is that particle counting procedures should be carried out under well-controlled and reproducible conditions utilizing measuring techniques that do not impose a shear force upon the particles.

Actions of Mescaline on Isolated Rat Atria

PETER K. S. SIEGL and RAYMOND F. ORZECHOWSKI ˣ

Abstract □ Mescaline, in concentrations of 5×10^{-4} and 1×10^{-3} *M*, produced negative chronotropic and positive inotropic responses in isolated, spontaneously beating rat atria. In tissues driven at a constant rate, the inotropic response was diminished greatly, indicating that the increment in the force of contraction was secondary to the reduction in rate. These chronotropic and inotropic responses were not altered consistently by pretreatment with the histamine antagonists chlorpheniramine and metiamide.

Keyphrases □ Mescaline—chronotropic and inotropic effects on isolated rat atria □ Chronotropic effects—mescaline on isolated rat atria □ Inotropic effects—mescaline on isolated rat atria □ Phenethylamines—mescaline, chronotropic and inotropic effects on isolated rat atria □ Cardiovascular effects—mescaline on isolated rat atria □ Psychotomimetics—mescaline, chronotropic and inotropic effects on isolated rat atria

In this study, the effects of mescaline (3,4,5-trimethoxyphenethylamine) on isolated rat atria were examined to reveal its possible actions directly on the pacemaker and atrial tissue. By the use of histamine antagonists, the involvement of histamine receptors (both H_1 and H_2) was examined as a possible mechanism of the *in vitro* cardiac action of mescaline.

BACKGROUND

The cardiovascular actions of the psychotomimetic amine mescaline were reported previously (1–8). Mescaline consistently evoked bradycardia in several species of animals. Mescaline-induced slowing of the frog heart was first observed by Dixon (1); others confirmed this action in the dog (2), rabbit, and cat (3). The bradycardia was inhibited by vagotomy or pretreatment with atropine (3); however, other published data (1, 2, 4) challenged these findings. Most evidence favors the conclusion that mescaline does not produce an effect on the heart by a vagal reflex or cholinergic stimulation.

Competition for epinephrine receptors by mescaline was proposed (5) because both mescaline-induced bradycardia and hypoglycemia in rats were reduced upon pretreatment with epinephrine. In another study (6), mescaline showed no propranolol-like antagonism of isoproterenol-induced relaxation of spontaneously contracting rat uterus. Mescaline failed to antagonize isoproterenol-induced positive chronotropism and hypotension (4) or to reverse an ethylnorepinephrine depressor response (6) in anesthetized dogs. From these data, β-adrenergic receptor blockade by mescaline or one of its metabolites was an unlikely explanation.

Histamine release or direct stimulation of histamine receptors by mescaline might account for the observed bradycardia. Potentiation of the hypotensive response to histamine in rats (7) was attributed to inhibition of the histaminolytic action of diamine oxidase by mescaline. Dogs receiving an intravenous infusion of mescaline showed (4) increased plasma histamine levels and a hypotensive response similar to that produced by compound 48/80, a known histamine-liberating substance (9). Alteration of respiratory dynamics and elevated right ventricular pressure, resembling responses to histamine, were observed in the guinea pig (8). Attempts to block these effects of mescaline with the antihistamine diphenhydramine were unsuccessful (4, 8).

More recent evidence suggested that histamine produced bradycardia by a stimulation of histamine receptor subtypes (H_2-receptors), which were not blocked by conventional antihistaminic agents such as diphenhydramine (10). The possible interaction of mescaline or mescaline-released histamine with H_2-receptors in the myocardium could be evaluated with an H_2-blocker, such as metiamide, in an attempt to confirm or refute this hypothesis.

EXPERIMENTAL

Sprague–Dawley rats of both sexes, 250–400 g, were sacrificed by cervical fracture and the hearts were rapidly removed. Paired atria were sectioned from the ventricles with a bridge of tissue joining the two atria. For examination of inotropic responses, left atria were electrically driven by paired platinum electrodes. Monophasic square wave pulses of 1-msec duration were delivered by a stimulator[1]. Tissues were suspended in a 10-ml glass tissue bath filled with Krebs–Henseleit solution (11) at a constant temperature of 35° and equilibrated with 95% O_2–5% CO_2. The solution pH was adjusted to 7.3.

A constant resting tension of 1.0 g was maintained throughout each experiment. All preparations were allowed to equilibrate for a minimum of 50 min with washes at 10-min intervals prior to drug challenge. Isometric contractions were measured with a force-displacement transducer[2] and recorded on a polygraph[3]. A linear tachometer[4] was used to record changes in heart rate. All drug solutions were prepared daily in Krebs–Henseleit solution and expressed as molar concentration of base.

Dose–Response Curves with Mescaline—To observe chronotropic and inotropic responses to mescaline, concentrations of 1×10^{-4}, 5×10^{-4}, and 1×10^{-3} *M* mescaline base were generated in a tissue bath containing spontaneously beating, paired atria. Heart rate and developed tension were recorded as maximum responses within 5 min. To minimize possible tachyphylaxis, only two drug challenges per preparation were employed. The challenges were separated by three washes and a 15-min reequilibration period. Sixteen atrial preparations were tested in this manner. All data were reported as the percent change from the pretreatment period and analyzed by Duncan's New Multiple Range Test (12).

The effects of mescaline were studied on separated left and right atria of the same heart to determine differences in inotropic responses in both the presence and absence of chronotropic responses. Right atria were allowed to contract spontaneously, while left atria were electrically driven (150% threshold voltage). After a 1-hr equilibration period, the rate of electrical stimulation was adjusted to equal the heart rate of the spontaneously contracting right atrium. At 5 min after the addition of mescaline to the tissue bath, changes in the developed tension for both atria

Actions of Mescaline on Isolated Rat Atria

PETER K. S. SIEGL and RAYMOND F. ORZECHOWSKI ˣ

Abstract □ Mescaline, in concentrations of 5×10^{-4} and 1×10^{-3} *M*, produced negative chronotropic and positive inotropic responses in isolated, spontaneously beating rat atria. In tissues driven at a constant rate, the inotropic response was diminished greatly, indicating that the increment in the force of contraction was secondary to the reduction in rate. These chronotropic and inotropic responses were not altered consistently by pretreatment with the histamine antagonists chlorpheniramine and metiamide.

Keyphrases □ Mescaline—chronotropic and inotropic effects on isolated rat atria □ Chronotropic effects—mescaline on isolated rat atria □ Inotropic effects—mescaline on isolated rat atria □ Phenethylamines—mescaline, chronotropic and inotropic effects on isolated rat atria □ Cardiovascular effects—mescaline on isolated rat atria □ Psychotomimetics—mescaline, chronotropic and inotropic effects on isolated rat atria

In this study, the effects of mescaline (3,4,5-trimethoxyphenethylamine) on isolated rat atria were examined to reveal its possible actions directly on the pacemaker and atrial tissue. By the use of histamine antagonists, the involvement of histamine receptors (both H_1 and H_2) was examined as a possible mechanism of the *in vitro* cardiac action of mescaline.

BACKGROUND

The cardiovascular actions of the psychotomimetic amine mescaline were reported previously (1–8). Mescaline consistently evoked bradycardia in several species of animals. Mescaline-induced slowing of the frog heart was first observed by Dixon (1); others confirmed this action in the dog (2), rabbit, and cat (3). The bradycardia was inhibited by vagotomy or pretreatment with atropine (3); however, other published data (1, 2, 4) challenged these findings. Most evidence favors the conclusion that mescaline does not produce an effect on the heart by a vagal reflex or cholinergic stimulation.

Competition for epinephrine receptors by mescaline was proposed (5) because both mescaline-induced bradycardia and hypoglycemia in rats were reduced upon pretreatment with epinephrine. In another study (6), mescaline showed no propranolol-like antagonism of isoproterenol-induced relaxation of spontaneously contracting rat uterus. Mescaline failed to antagonize isoproterenol-induced positive chronotropism and hypotension (4) or to reverse an ethylnorepinephrine depressor response (6) in anesthetized dogs. From these data, β-adrenergic receptor blockade by mescaline or one of its metabolites was an unlikely explanation.

Histamine release or direct stimulation of histamine receptors by mescaline might account for the observed bradycardia. Potentiation of the hypotensive response to histamine in rats (7) was attributed to inhibition of the histaminolytic action of diamine oxidase by mescaline. Dogs receiving an intravenous infusion of mescaline showed (4) increased plasma histamine levels and a hypotensive response similar to that produced by compound 48/80, a known histamine-liberating substance (9). Alteration of respiratory dynamics and elevated right ventricular pressure, resembling responses to histamine, were observed in the guinea pig (8). Attempts to block these effects of mescaline with the antihistamine diphenhydramine were unsuccessful (4, 8).

More recent evidence suggested that histamine produced bradycardia by a stimulation of histamine receptor subtypes (H_2-receptors), which were not blocked by conventional antihistaminic agents such as diphenhydramine (10). The possible interaction of mescaline or mescaline-released histamine with H_2-receptors in the myocardium could be evaluated with an H_2-blocker, such as metiamide, in an attempt to confirm or refute this hypothesis.

EXPERIMENTAL

Sprague–Dawley rats of both sexes, 250–400 g, were sacrificed by cervical fracture and the hearts were rapidly removed. Paired atria were sectioned from the ventricles with a bridge of tissue joining the two atria. For examination of inotropic responses, left atria were electrically driven by paired platinum electrodes. Monophasic square wave pulses of 1-msec duration were delivered by a stimulator[1]. Tissues were suspended in a 10-ml glass tissue bath filled with Krebs–Henseleit solution (11) at a constant temperature of 35° and equilibrated with 95% O_2–5% CO_2. The solution pH was adjusted to 7.3.

A constant resting tension of 1.0 g was maintained throughout each experiment. All preparations were allowed to equilibrate for a minimum of 50 min with washes at 10-min intervals prior to drug challenge. Isometric contractions were measured with a force-displacement transducer[2] and recorded on a polygraph[3]. A linear tachometer[4] was used to record changes in heart rate. All drug solutions were prepared daily in Krebs–Henseleit solution and expressed as molar concentration of base.

Dose–Response Curves with Mescaline—To observe chronotropic and inotropic responses to mescaline, concentrations of 1×10^{-4}, 5×10^{-4}, and 1×10^{-3} *M* mescaline base were generated in a tissue bath containing spontaneously beating, paired atria. Heart rate and developed tension were recorded as maximum responses within 5 min. To minimize possible tachyphylaxis, only two drug challenges per preparation were employed. The challenges were separated by three washes and a 15-min reequilibration period. Sixteen atrial preparations were tested in this manner. All data were reported as the percent change from the pretreatment period and analyzed by Duncan's New Multiple Range Test (12).

The effects of mescaline were studied on separated left and right atria of the same heart to determine differences in inotropic responses in both the presence and absence of chronotropic responses. Right atria were allowed to contract spontaneously, while left atria were electrically driven (150% threshold voltage). After a 1-hr equilibration period, the rate of electrical stimulation was adjusted to equal the heart rate of the spontaneously contracting right atrium. At 5 min after the addition of mescaline to the tissue bath, changes in the developed tension for both atria

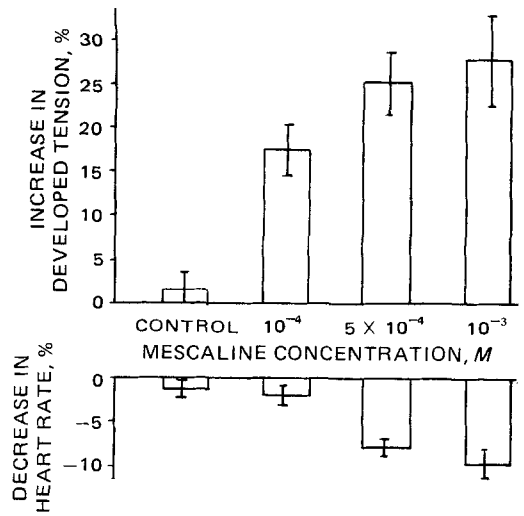

Figure 1—*Responses to mescaline challenge in spontaneously contracting paired rat atria. All bars indicate mean* ± SEM; n = *8.*

and the heart rate for the right atria were recorded. Twelve preparations were studied (*i.e.*, six hearts), each challenged with 1×10^{-4}, 5×10^{-4}, and 1×10^{-3} *M* mescaline base. Inotropic responses of left *versus* right atria were treated as paired data and tested by the Student *t* test (13).

To establish the relationship between rate and tension for rat atria and to allow interpretation of the effects obtained with mescaline, a Bowditch or rate–tension curve was constructed. Four left atria were electrically driven at 150% of threshold voltage and at various rates of stimulation. The maximum developed tension was recorded 5 min after the rate was altered. Results were graphed as the average developed tension (grams) *versus* the rate of stimulation (Hertz and beats per minute).

Histaminic Mechanism Study: Pretreatment with Antihistamines—Two concentrations of an H_1-antagonist (chlorpheniramine maleate, 1×10^{-6} and 1×10^{-5} *M*) and an H_2-antagonist (metiamide, 3×10^{-6} and 3×10^{-5} *M*) were each employed to pretreat six spontaneously contracting, paired atria 8 min prior to challenge with mescaline. Twelve control preparations were pretreated with 0.1 ml of Krebs–Henseleit solution. Pretreatments were randomized by the use of a table of random numbers.

Concentrations of mescaline were log spaced, and each challenge was separated by three washes and 8 min of incubation with the antagonist. Chronotropic and inotropic responses were measured before and 5 min after the addition of mescaline. Results were reported as the percent change from pretreatment values. Tukey's multiple range procedure for

unequal subclass numbers[5] was used to test for statistical significance.

RESULTS

Dose–Response Curves with Mescaline—Dose-related positive inotropic and negative chronotropic responses were observed when spontaneously beating, paired rat atria were challenged with 1×10^{-4}, 5×10^{-4}, and 1×10^{-3} *M* mescaline (Fig. 1). All inotropic responses were significantly different from the control; however, only the two highest concentrations of mescaline produced a chronotropic response significantly different ($p < 0.05$) from the control.

Positive inotropic responses in electrically driven left atria challenged with 5×10^{-4} and 1×10^{-3} *M* mescaline were significantly less in the absence of a negative chronotropic response (Fig. 2). Since 10^{-4} *M* mescaline produced no significant change in heart rate, a difference in inotropic responses between spontaneously beating and electrically driven preparations was neither anticipated nor seen. Responses of spontaneously beating right atria were similar to those of spontaneously beating paired atria.

Since data from electrically driven atria suggested that a major component of the positive inotropic response was related to the negative chronotropic effect of mescaline, it was important to examine the effects of heart rate upon the developed tension in the control atria. A Bowditch or rate–tension curve for the electrically stimulated left rat atrium (Fig. 3) indicated that a positive inotropic response accompanied a decrease in heart rate. This relationship between rate and tension also was reported for rat papillary muscle (14, 15) and rat arterially perfused septal (16) preparations.

Histaminic Mechanism Study: Effects of Pretreatment with Antihistaminic Agents—Negative chronotropic responses to mescaline

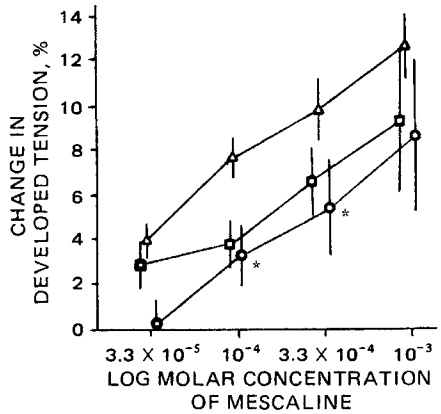

Figure 5—*Effect of pretreatment with chlorpheniramine upon the positive inotropic response to mescaline challenge. Key: same as Fig. 4; and *, p < 0.05.*

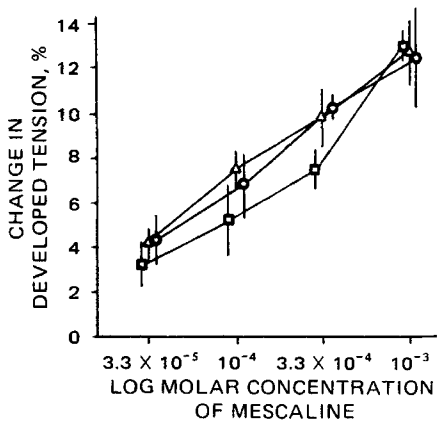

Figure 7—*Effect of pretreatment with metiamide upon the positive inotropic response to mescaline challenge. Key: same as Fig. 6.*

were unaltered by pretreatment with 1×10^{-5} or 1×10^{-6} *M* chlorpheniramine (Fig. 4). Both concentrations of chlorpheniramine produced a dose-related shift of the percent change in developed tension *versus* the log concentration of mescaline (Fig. 5); however, only responses to 1×10^{-4} and 3.3×10^{-4} *M* mescaline were reduced significantly by 1×10^{-5} *M* chlorpheniramine.

Metiamide, 3×10^{-5} and 3×10^{-6} *M*, failed to show a significant blockade of the negative chronotropic response, except at 1×10^{-3} *M* mescaline with 3×10^{-5} *M* metiamide (Fig. 6). Positive inotropic responses also were unchanged following pretreatment with metiamide (Fig. 7).

DISCUSSION

A significant role of endogenous histamine in the regulation of cardiac dynamics was proposed previously (17–19). The presence of histamine in rat atrial tissue (17) and evidence of the histamine-releasing activity of mescaline in vascular tissue (4) suggested that the cardiac actions of mescaline might involve activation of a histaminergic mechanism. Recent studies (10, 20, 21) indicated that separate receptors may mediate the chronotropic and inotropic responses to histamine in guinea pig atria. Positive chronotropic responses blocked by metiamide or burimamide, but not by promethazine or tripelennamine, suggested involvement of histamine H_2-receptor subtypes, whereas positive inotropic responses were altered only by promethazine and tripelennamine, histamine H_1-receptor blocking agents.

Exogenous histamine effects a negative chronotropic response in the isolated rat heart (17, 22). Based on the situation in the guinea pig heart, stimulation of H_2-receptors in rat atria by mescaline, either directly or *via* a release of endogenous histamine, could be responsible for the observed bradycardia (10, 20). That direct stimulation of histamine receptors could not account for the cardiac effects of mescaline was indicated by failure of histamine receptor blockers of the H_1 and H_2 type to obtund the response to mescaline. This explanation of mescaline-induced bradycardia in species other than the rat is untenable, since exogenous histamine evokes positive chronotropic responses in most species (22–27).

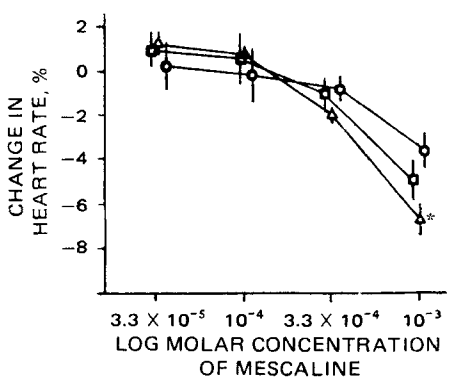

Figure 6—*Effect of pretreatment with metiamide upon the negative chronotropic response to mescaline challenge. Key: △, control,* n = *12;* □, *3 × 10⁻⁶* M *metiamide,* n = *6; and* ○, *3 × 10⁻⁵* M *metiamide,* n = *6.*

An inverse relationship existed between atrial rate and peak muscle tension in control rat atria; *i.e.*, the Bowditch curve showed that a decrease in atrial rate was associated with an increase in peak tension development (Fig. 3). Thus, it was of interest to determine whether the positive inotropic effect of mescaline would persist in atrial preparations electrically driven at a constant rate. The data indicated that a major component of the observed increase in tension development following mescaline was directly attributable to the slowing effect of the drug on atrial rate, since only slight increases in contractile force were seen in electrically driven tissues when the rate was held constant (Fig. 2).

A central action of mescaline might account for the bradycardia reported to occur in *in vivo* preparations. α-Adrenergic agonists injected into certain brain sites produced bradycardia and hypotension, due apparently to a reduction in sympathetic nervous tone (28). Mescaline penetrated into the central nervous system (29) and also evidenced α-adrenergic agonist properties in *in vitro* systems (30). Bradycardia was observed 1 min following injections of mescaline into the lateral brain ventricle of the mouse (31). Further investigation into the central mechanism appears to be warranted.

Finally, the concentrations of mescaline required to evoke alterations in myocardial rate in this study were relatively high (3.3×10^{-5}–1×10^{-3} *M*). Such concentrations, if extrapolated to the *in vivo* situation, would probably represent toxic concentrations of the drug (5).

Comparative Pharmacokinetics of Coumarin Anticoagulants XXIV: Effect of Treatment with Phenobarbital on Serum Protein Binding of Warfarin and Dicumarol in Rats

AVRAHAM YACOBI, JOHN T. SLATTERY, and GERHARD LEVY [x]

Abstract □ Rats were treated with the enzyme inducer phenobarbital to determine if it would affect the serum protein binding of warfarin and dicumarol, possibly by changing the rate of formation or elimination of endogenous inhibitor(s). Daily administration of phenobarbital, 75 mg/kg, for 4 days increased relative liver size (a concomitant of enzyme induction) but had no apparent effect on the serum protein binding of warfarin and dicumarol.

Keyphrases □ Phenobarbital—effects on serum protein binding of warfarin and dicumarol, rats □ Protein binding, serum—warfarin and dicumarol, effect of phenobarbital, rats □ Binding, serum protein—warfarin and dicumarol, effect of phenobarbital, rats □ Warfarin—serum protein binding, effect of phenobarbital, rats □ Dicumarol—serum protein binding, effect of phenobarbital, rats □ Anticoagulants—warfarin and dicumarol, serum protein binding, effect of phenobarbital, rats □ Enzyme inducers—phenobarbital, effect on serum protein binding of warfarin and dicumarol, rats

The total clearance of warfarin by the body is directly proportional to the free fraction of this drug in serum of rats (1, 2) and humans (3). There are pronounced interindividual differences in free fraction values of warfarin (4) and corresponding differences in the total clearance of this drug by the body (2, 3). Ongoing studies in rats[1] indicate that this is true also for the other major coumarin anticoagulant, dicumarol. There is no relationship between the free fraction values of either warfarin (2) or dicumarol (data in this report) and the concentration of albumin in serum.

Recent studies showed that endogenous inhibitors in uremic as well as in normal human serum cause a decrease in the protein binding of warfarin and other drugs (5). Therefore, interindividual differences in the serum protein binding of warfarin and dicumarol may be caused by corresponding differences in the serum concentration of such inhibitors. Treatment with an enzyme inducer such as phenobarbital may change the serum protein binding of warfarin, dicumarol, and other drugs by changing the concentration of endogenous inhibitors in serum. This situation could result from a change in the formation or elimination kinetics of the inhibitors due to increased activity of certain enzyme systems. Accordingly, a study was initiated to determine the effect of treatment with phenobarbital on the protein binding of warfarin and dicumarol in the serum of rats.

EXPERIMENTAL

Forty-eight adult male Sprague–Dawley rats, ~350 g, were used for an initial screening study. About 3 ml of blood was obtained from the tail artery of each animal, and serum was separated. The free fraction of racemic warfarin in these serum samples was determined by equilibrium dialysis as described previously (2). Based on the results of this screening study, 20 rats were selected and classified into 10 pairs with very small intrapair and large interpair differences in the warfarin free fraction value.

Four days later, one member of each pair received phenobarbital, 75 mg/kg/day ip, for 4 days while the other member received injections of normal saline solution. One day later, the animals were sacrificed by removing all blood from the aorta under ether anesthesia. The liver was also removed, compressed slightly between paper tissue to remove remaining blood, and weighed. Serum was separated and used to determine the free fraction values for warfarin (2) and dicumarol (6) by equilibrium dialysis. The concentration of total protein in serum was determined by the method of Gornall *et al.* (7) with crystalline rat albumin as the standard, and the fraction of albumin was determined by electrophoresis using a commercial[2] serum protein electrophoresis system.

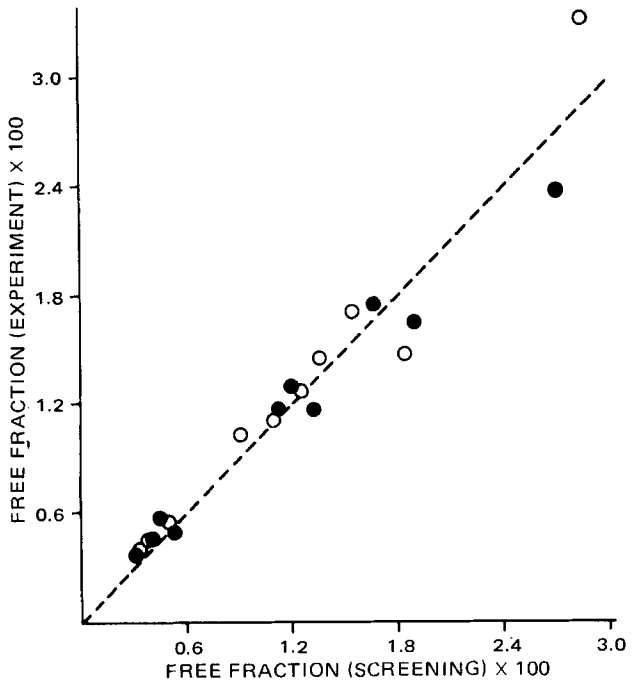

Figure 1—*Effect of phenobarbital treatment (75 mg/kg/day for 4 days) on the free fraction of warfarin in the serum of individual rats. Shown is a plot of free fraction values determined in a screening study preceding the experiment against the free fraction values in the same animals 1 day after the treatment period. Key: ●, animals treated with phenobarbital; and ○, control animals that received only saline solution. The stippled line has a slope of unity.*

RESULTS AND DISCUSSION

The warfarin free fraction value in the serum of the 20 selected rats ranged from 0.00344 to 0.0286 in the screening experiment. The percentage difference in the free fraction value within the 10 matched pairs was 3.9 ± 2.5 (mean ± *SD*). The correlation of free fraction values between the members of the 10 pairs was strong and highly statistically

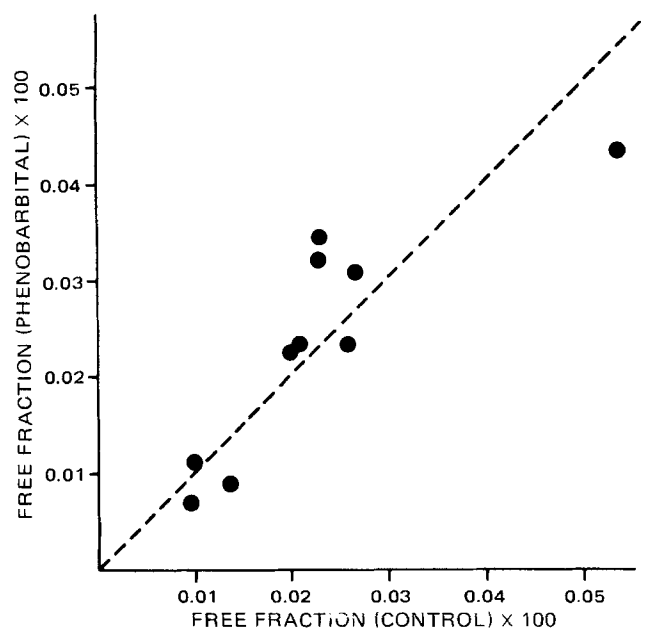

Figure 2—*Effect of phenobarbital treatment on the free fraction of dicumarol in the serum of rats. Plotted are the free fraction values in 10 control rats against the free fraction values in 10 phenobarbital-treated rats (r = 0.863, p < 0.001). The 10 pairs of rats were matched on the basis of nearly identical warfarin free fraction values in a preceding screening experiment. The stippled line has a slope of unity.*

Table I—Effect of Treatment with Phenobarbital on the Serum Protein Binding of Racemic Warfarin in Male Sprague–Dawley Rats

Group	Free Fraction × 100[a] Before	After	Ratio, After/Before[b]
Control	1.22 (0.344–2.86)	1.28 (0.389–3.34)	1.06 ± 0.107
Phenobarbital treated	1.17 (0.315–2.72)	1.14 (0.350–2.38)	1.03 ± 0.122[c]

[a] Mean (range) for 10 animals per group, 4 days before and 1 day after daily injections of phenobarbital (75 mg/kg) for 4 days. [b] Mean ± *SD*. [c] Not statistically significantly different from control ratio values.

significant ($r = 0.997$, $p < 0.001$). The group treated with phenobarbital had a significantly higher relative liver weight than the control group (37.0 ± 3.5 *versus* 30.9 ± 1.6 g/kg, $p < 0.001$), but there was no significant difference in serum albumin concentration (3.30 ± 0.20 *versus* 3.49 ± 0.20 g/100 ml, $p > 0.1$).

Treatment with phenobarbital had no apparent effect on the serum protein binding of warfarin (Table I). There was a strong correlation between the pretreatment and posttreatment free fraction values for individual animals (Fig. 1). The correlation coefficients for the data from control and phenobarbital-treated animals were 0.957 ($p < 0.001$) and 0.906 ($p < 0.001$), respectively.

It was not possible to obtain enough blood in the screening study to determine the free fraction values for dicumarol in addition to those for warfarin. However, in view of the previously documented strong correlation between the free fraction values for warfarin and dicumarol in individual rats (6), the warfarin free fraction values serve also to characterize and classify the animals with respect to serum protein binding of dicumarol. Therefore, it is possible to compare the posttreatment free fraction values for dicumarol in serum of phenobarbital-treated rats with the free fraction values of control animals. These values were 0.000238 (range of 0.000070–0.000432) for the phenobarbital group and 0.000225 (range of 0.000099–0.000540) for the control group and did not differ

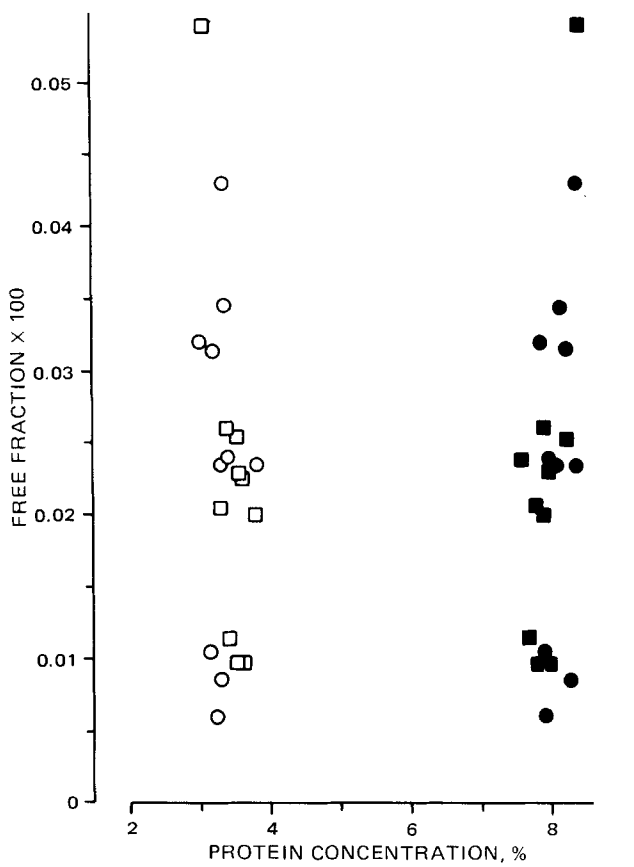

Figure 3—*Relationship between free fraction of dicumarol and the concentrations of albumin (open symbols) or total protein (closed symbols) in the serum of control rats (squares) and phenobarbital-treated rats (circles).*

significantly from one another. The ratio of free fraction values (treated/control) for the 10 matched pairs was 1.06 ± 0.27 (mean ± *SD*), and the correlation of these values between members of each pair was strong (Fig. 2).

Figure 3 is a plot of dicumarol free fraction values in serum against the serum concentration of albumin or total protein. The pronounced interindividual differences in serum protein binding of dicumarol were not related to corresponding differences in the concentration of serum proteins. Similar results were obtained previously for warfarin (2). Also consistent with previous observations (6) was the strong correlation between the free fraction values for dicumarol and warfarin in individual animals ($r = 0.937$, $p < 0.001$, $n = 20$ in this study).

The phenobarbital treatment regimen used is sufficient to cause pronounced enzyme induction, as reflected by the increased total clearance of warfarin[1] and dicumarol (8) and by the increase in relative liver weight. This treatment had no significant effect on the serum protein binding of warfarin and dicumarol. This result could mean that the concentrations of endogenous inhibitors in serum were not affected by enzyme induction or that the interindividual differences in serum protein binding of the coumarin anticoagulants are due to conformational differences of albumin, with enzyme induction having no effect on the steady-state concentration of that particular protein.

Comparative Pharmacokinetics of Coumarin Anticoagulants XXV: Warfarin–Ibuprofen Interaction in Rats

JOHN T. SLATTERY, AVRAHAM YACOBI, and GERHARD LEVY [x]

Abstract □ The effect of ibuprofen on the pharmacokinetics and anticoagulant action of racemic warfarin was determined in a crossover study on male Sprague–Dawley rats. At average plasma concentrations of 24–83 mg/liter, ibuprofen decreased the biological half-life and increased the total clearance of warfarin. It also increased the anticoagulant effect produced by a given plasma concentration of total (free and protein-bound) warfarin. These effects of ibuprofen appear to be a consequence of its displacing effect on warfarin in plasma.

Keyphrases □ Ibuprofen—effect on pharmacokinetics and anticoagulant action of warfarin, rats □ Pharmacokinetics—warfarin, effect of ibuprofen, rats □ Anticoagulant action—warfarin, effect of ibuprofen, rats □ Warfarin—pharmacokinetics and anticoagulant action, effect of ibuprofen, rats □ Anti-inflammatory agents—ibuprofen, effect on pharmacokinetics and anticoagulant action of warfarin, rats

The widely used nonsteroidal anti-inflammatory agent ibuprofen is a weak acid extensively bound to plasma proteins (1). As such, it may be expected to displace coumarin anticoagulants such as warfarin from plasma protein binding sites. This type of drug interaction can modify the distribution and elimination kinetics of warfarin and produce transient potentiation of its anticoagulant effect (2–4). Nevertheless, several clinical investigations failed to detect any effect of ibuprofen, in doses of up to 2.4 g/day, on the anticoagulant action of the coumarin drugs phenprocoumon and warfarin (5–8).

In view of the recent tendency to use doses of ibuprofen larger than 2.4 g/day for the treatment of inflammatory disease, it is important to determine *in principle* if ibuprofen interacts with warfarin under appropriate conditions (*i.e.*, at plasma ibuprofen concentrations sufficient to displace warfarin from protein binding sites). Such an investigation was carried out on rats dosed with ibuprofen at a rate producing ibuprofen concentrations moderately higher than those commonly encountered clinically.

EXPERIMENTAL

Male Sprague–Dawley rats[1], 250–300 g at screening time and 350–450 g during the interaction study, were maintained on a standard diet[2] with unrestricted access to water.

To determine the *in vitro* effect of ibuprofen on warfarin binding to rat serum protein, blood was obtained from the abdominal aorta of 11 ether-anesthetized rats and the serum was separated. To serum samples from individual rats were added 0.7–0.8 μg/ml of racemic ^{14}C-warfarin[3], 76 μCi/mg, and 0–150 μg/ml of racemic ibuprofen[4]. The free fraction of warfarin in serum (free/total warfarin concentration) was determined by equilibrium dialysis (9).

Sixty-three rats were screened for the *in vivo* interaction study by collecting 3 ml of blood from the tail artery under light ether anesthesia, separating the serum, and determining the free fraction of warfarin by equilibrium dialysis. Fourteen rats with widely differing warfarin free fraction values (0.0023–0.0157) were selected from this group for the

significantly from one another. The ratio of free fraction values (treated/control) for the 10 matched pairs was 1.06 ± 0.27 (mean ± *SD*), and the correlation of these values between members of each pair was strong (Fig. 2).

Figure 3 is a plot of dicumarol free fraction values in serum against the serum concentration of albumin or total protein. The pronounced interindividual differences in serum protein binding of dicumarol were not related to corresponding differences in the concentration of serum proteins. Similar results were obtained previously for warfarin (2). Also consistent with previous observations (6) was the strong correlation between the free fraction values for dicumarol and warfarin in individual animals ($r = 0.937$, $p < 0.001$, $n = 20$ in this study).

The phenobarbital treatment regimen used is sufficient to cause pronounced enzyme induction, as reflected by the increased total clearance of warfarin[1] and dicumarol (8) and by the increase in relative liver weight. This treatment had no significant effect on the serum protein binding of warfarin and dicumarol. This result could mean that the concentrations of endogenous inhibitors in serum were not affected by enzyme induction or that the interindividual differences in serum protein binding of the coumarin anticoagulants are due to conformational differences of albumin, with enzyme induction having no effect on the steady-state concentration of that particular protein.

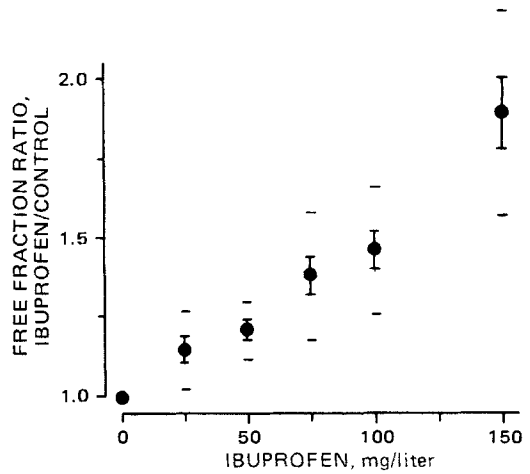

Figure 1—*Effect of ibuprofen on protein binding of warfarin in rat serum. Shown is the relationship between the warfarin free fraction ratio (with ibuprofen/control) and the ibuprofen concentration. Each point is the mean of the free fraction values in individual serum samples from 11 animals. Bars = ±1 SE; dashes = ±1 SD. The concentration of racemic warfarin was 0.718 ± 0.095 mg/liter, and the control free fraction value ranged from 0.00482 to 0.0149.*

interaction study, which was initiated 30 days after the screening experiment.

All animals received racemic ^{14}C-warfarin, 0.45 mg/kg iv. Some animals also received ibuprofen, 40 mg/kg ip at −1 hr and 20 mg/kg ip every 3 hr thereafter; the others received injections of normal saline solution at the same intervals. A crossover experiment was carried out 3 weeks later. The warfarin and ibuprofen injection solutions were freshly prepared by dissolving the drugs in a small amount of sodium hydroxide solution and diluting to the desired volume with isotonic pH 7.4 phosphate buffer.

Blood samples (0.20–0.45 ml) were obtained at frequent intervals from the tail artery (10). Plasma was separated and used for determination of prothrombin complex activity (10), warfarin concentration (11), and ibuprofen concentration (12). Ibuprofen was separated from the plasma extract during TLC separation of warfarin. Ibuprofen reference spots were located on the TLC plate after development by spraying the appropriate region with 0.1% bromocresol purple in water (13). A band of silica coating corresponding to the R_f of ibuprofen[5] was then scraped off,

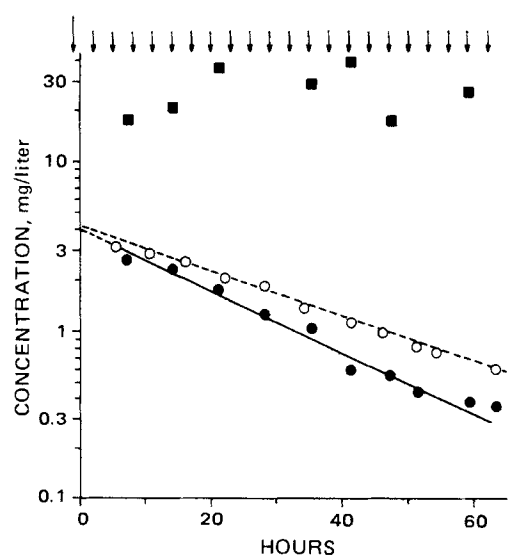

Figure 2—*Effect of ibuprofen administration on the elimination of warfarin in Rat 11. Shown are the warfarin concentrations in serum during the control experiment (○) and during ibuprofen administration (●) 3 weeks later. The ibuprofen concentrations in serum (■) were produced by an initial injection of 40 mg/kg at −1 hr (long arrow) followed by 20 mg/kg every 3 hr (short arrows).*

[5] The R_f of ibuprofen in this system is about 0.35; that of warfarin is about 0.7.

Table I—Concentrations of Ibuprofen in Plasma of Rats Used in the Warfarin Interaction Study[a]

Rat Number	Average Concentration (± *SD*), mg/liter	Number of Determinations
1	71.6 (±32.9)	7
2	68.1 (±27.8)	7
3	33.6 (±26.0)	12
4	38.7 (±31.9)	10
5	78.4 (±43.7)	5
6	71.6 (±27.2)	3
7	60.5 (±31.7)	6
8	48.8 (±28.6)	8
9	47.4 (±38.8)	9
10	82.7 (±40.3)	10
11	23.8 (±9.69)	7
12	42.9 (±32.9)	11
13	39.2 (±26.2)	8
14	54.8 (±28.3)	8
Mean	54.4	

[a] The rats received an initial ibuprofen dose of 40 mg/kg and 20 mg/kg every 3 hr thereafter.

placed in a glass centrifuge tube with 2.5 ml of 0.1 *N* sodium hydroxide, shaken for 20 min, and centrifuged. A 2-ml aliquot of the supernate was acidified with 0.5 ml of 6 *N* hydrochloric acid and extracted (20 min of shaking) into 5 ml of benzene, which was then separated by centrifugation; 4 ml of the benzene phase was used for GLC analysis (12). The recovery of ibuprofen was 90 ± 7.5% (mean ± *SD*, n = 14) and was independent of concentration in the 2–120-μg/ml range.

The effect of ibuprofen on the prothrombin complex activity (PCA) in the serum of otherwise untreated rats was determined by administering ibuprofen, 25 mg/kg ip, every 4 hr to six rats and obtaining blood samples at 12, 24, and 36 hr. The effect of ibuprofen on the rate constant for degradation of prothrombin complex activity, k_{deg}, was determined by administering a prothrombin complex activity synthesis blocking dose (12 mg/kg) of warfarin to 12 rats. Six received ibuprofen, 25 mg/kg ip, every 4 hr from −36 hr to the end of the experiment while the other six received normal saline injections at the same intervals. Blood samples for prothrombin complex activity determination were obtained every 3 hr for 9–12 hr after warfarin administration.

RESULTS

Ibuprofen, at concentrations of 25 mg/liter and above, significantly ($p < 0.001$) decreased the protein binding of warfarin in the serum of rats (Fig. 1). There was a statistically significant ($p < 0.001$) correlation between the control free fraction value and the free fraction value of warfarin at each ibuprofen concentration in individual animals.

Figure 2 shows the effect of ibuprofen administration on the pharmacokinetics of warfarin in a rat. The average plasma ibuprofen con-

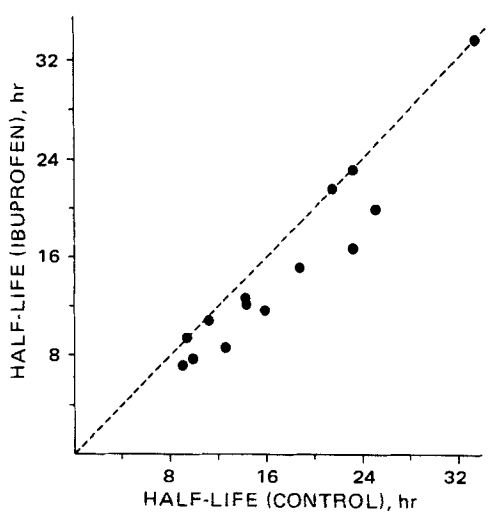

Figure 3—*Relationship between half-life of warfarin in the same animals in a control experiment and during ibuprofen administration in a crossover study. The stippled line has a slope of unity.*

Table II—Effect of Ibuprofen Administration on the Pharmacokinetics of Warfarin in Rats

Parameter	Control Experiment (C)	With Ibuprofen (I)	Ratio, C:I
Half-life, hr	17.3 (9.13–33.5)[a]	15.0 (7.17–33.5)[b]	1.19 (1.00–1.47)
Apparent volume of distribution, ml/kg	155 (98–212)	154 (118–197)[c]	1.01 (0.824–1.21)
Body clearance, ml/hr/kg	7.62 (2.36–13.4)	8.99 (2.56–16.2)[b]	0.851 (0.592–1.00)

[a] Mean (n = 14) and range of individual values. [b] Significantly different from control value by paired t-test ($p < 0.01$). [c] Not significantly different from control value.

centrations observed during the study ranged from 23.8 to 82.7 mg/liter in the 14 animals (Table I). Preliminary studies on six other rats yielded ibuprofen total clearance values from 139 to 220 ml/hr/kg and a half-life of 1.5–3.6 hr after a single 75-mg/kg iv dose. The effect of ibuprofen on the pharmacokinetics of warfarin in all 14 rats is summarized in Table II. Ibuprofen caused a small but statistically significant ($p < 0.01$) decrease in the biological half-life and increase in total body clearance ($p < 0.001$) of warfarin but had no apparent effect on the volume of distribution of the anticoagulant. There was a highly statistically significant correlation between the control and ibuprofen treatment values of half-life ($r = 0.957$, $p < 0.001$; Fig. 3), the apparent volume of distribution ($r = 0.980$, $p < 0.001$; Fig. 4), and the total body clearance ($r = 0.980$, $p < 0.001$; Fig. 5) for warfarin in individual animals.

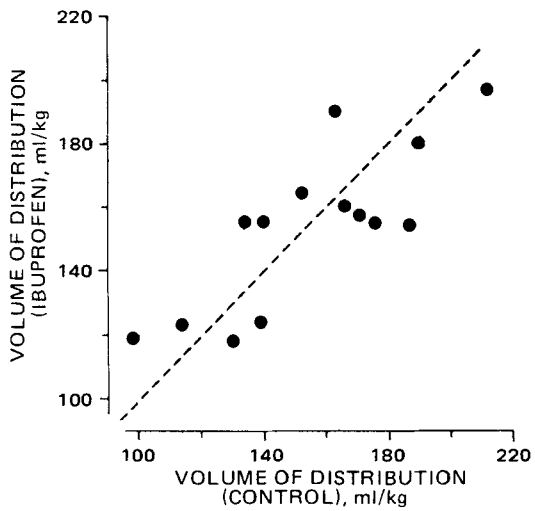

Figure 4—*Relationship between apparent volume of distribution of warfarin in a control experiment and during ibuprofen administration to the same animals in a crossover study. The stippled line has a slope of unity.*

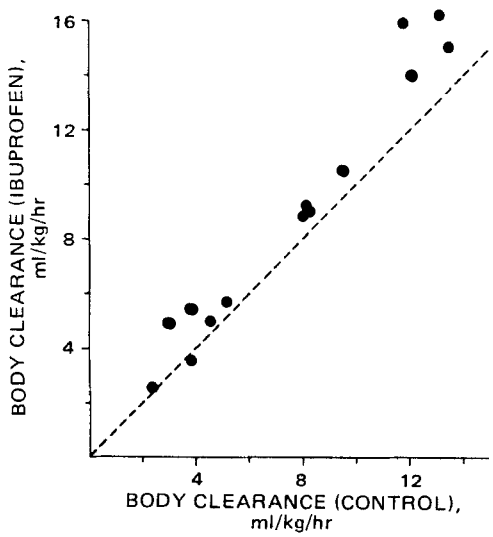

Figure 5—*Relationship between body clearance of warfarin in a control experiment and during ibuprofen administration to the same animals in a crossover study. The stippled line has a slope of unity.*

Table III—Effect of Ibuprofen Treatment[a] on Clotting Time of Plasma in Rats

Duration of Treatment, hr	Clotting Time, sec[b]
0	28.9 ± 0.88
0[c]	28.6 ± 0.66
12	29.3 ± 0.84[d]
24	29.6 ± 1.7[d]
36	28.9 ± 2.3[d]

[a] 25 mg/kg ip every 4 hr. [b] Mean ± SD, n = 8, except at 36 hr when n = 5 (three animals died). [c] Ibuprofen, 0.1 mg/ml, added *in vitro*. [d] Not statistically significantly different from zero-time value.

Ibuprofen, when added to plasma *in vitro* or when administered to the rats, had no apparent effect on the prothrombin complex activity, as reflected by a lack of significant change in the clotting time of plasma (Table III). Ibuprofen administration also had no statistically significant effect on the degradation kinetics of prothrombin complex activity (k_{deg} = 5.48 ± 0.42 days^{-1} in control animals and 5.99 ± 0.63 days^{-1} in ibuprofen-treated animals).

Figure 6 shows the effect of ibuprofen treatment on the relationship between the relative synthesis rate of prothrombin complex activity and the plasma warfarin concentration in one rat. The linear logarithmic regression line can be characterized by its slope and by the concentration required to decrease the relative synthesis rate to one-half of normal (designated as the "effective concentration"). The results obtained in all animals are summarized in Table IV. Ibuprofen caused a significant decrease in the effective concentration and increase in the absolute slope value. There was a statistically significant correlation ($r = 0.974$, $p < 0.001$) between the effective concentrations of warfarin for individual animals in the control experiment and during ibuprofen administration (Fig. 7).

DISCUSSION

Ibuprofen can displace warfarin from serum protein binding sites. Since the total clearance of warfarin by the body is proportional to the free fraction of the drug in serum or plasma (14, 15) and since the anticoagulant action of warfarin is a function of the concentration of free drug

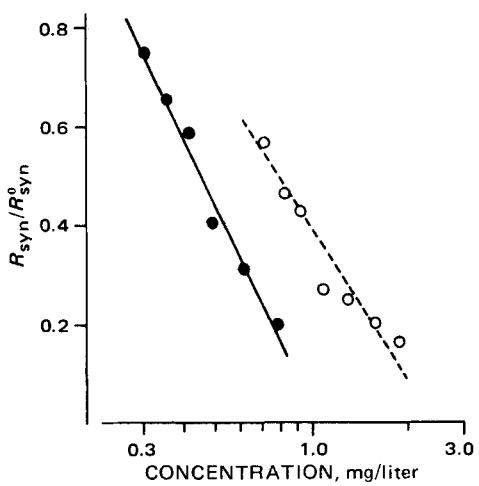

Figure 6—*Effect of ibuprofen administration on the relationship between the relative synthesis rate of prothrombin complex activity (R_{syn}/R^0_{syn}) and warfarin concentration in plasma. Data are from Rat 11 during a control experiment (○) and during ibuprofen administration (●).*

Table IV—Effect of Ibuprofen Treatment on the Relationship between Anticoagulant Effect and Plasma Concentration of Warfarin in Rats[a]

Parameter	Control (C)	Ibuprofen (I)	Ratio, C:I
Effective concentration (concentration when $R_{syn} = 0.5\ R^0_{syn}$), mg/liter	0.598 (0.146–2.03)[b]	0.414 (0.042–1.38)[c]	1.65 (0.730–3.48)
Slope of regression line for R_{syn}/R^0_{syn} *versus* log concentration	−1.01 (−0.455 to −1.69)	−1.31 (−0.851 to −2.06)[d]	0.830 (0.452–1.70)

[a] Crossover study on 13 rats (data on the 14th animal could not be obtained for technical reasons). [b] Mean (range). [c] $p < 0.005$ *versus* control (paired t-test). [d] $p < 0.05$ *versus* control (paired t-test).

(16), it follows that, all else being equal, displacement of warfarin from plasma proteins by ibuprofen should increase the total clearance of the anticoagulant and decrease the plasma concentration required to produce a given degree of anticoagulation. The results of this investigation are consistent with these considerations; ibuprofen treatment caused an increase in the total clearance of warfarin and a decrease in its effective concentration. Since ibuprofen has no apparent inductive effect on drug-metabolizing enzyme systems (1, 17), it is unlikely that the increased total clearance of warfarin was due to enzyme induction.

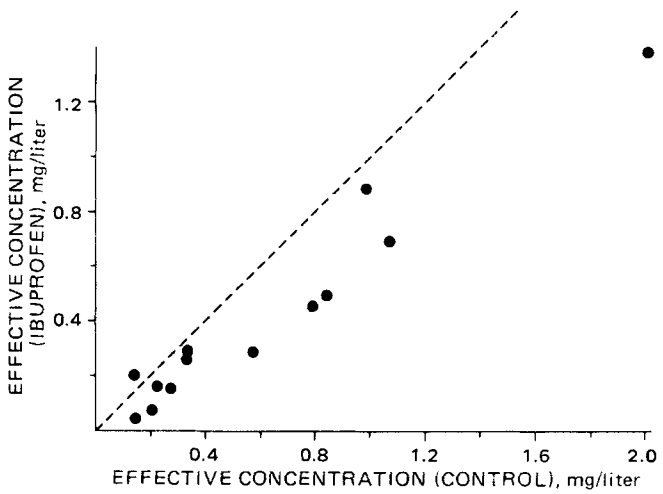

Figure 7—*Relationship between the effective plasma warfarin concentration in rats in a control experiment and during ibuprofen administration to the same animals in a crossover study. The effective concentration is the concentration of total (free and protein-bound) warfarin required to decrease* R_{syn} *to one-half of normal* (i.e., $R_{syn}/R^0_{syn} = 0.5$). *The stippled line has a slope of unity.*

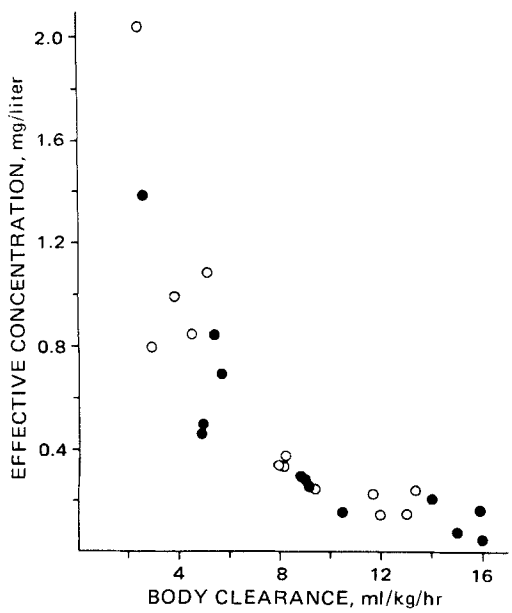

Figure 8—*Relationship between the effective plasma warfarin concentration and the body clearance of warfarin in individual rats in a crossover study. Key:* ○, *control experiment; and* ●, *during ibuprofen administration.*

Due to the short half-life of ibuprofen in rats, the concentrations of this drug fluctuated significantly during the 3-hr interval between injections. The timing of blood sample withdrawals was dictated primarily by the need to characterize the pharmacokinetics and time course of the anticoagulant effect of warfarin. Consequently, blood samples were not obtained at constant times after ibuprofen injection, and this magnified the intra- and intersubject variations in the observed plasma ibuprofen concentrations. For the same reason, the free fraction value of warfarin fluctuated within ibuprofen dosing intervals. These complexities and the need to keep the animals in good condition for the crossover experiment made it impossible to determine the time course of concentrations of free (not protein-bound) warfarin in serum during the *in vivo* interaction study.

It is feasible, however, to determine indirectly if displacement of warfarin from serum proteins is the sole or predominant mechanism of the observed warfarin–ibuprofen interaction or if additional factors contribute significantly to the interaction. Since both the body clearance and anticoagulant effect of warfarin are functions of the free fraction of drug in plasma, the relationship between body clearance and effective concentration should be the same in control and ibuprofen experiments if the interaction is due only to displacement of the protein-bound anticoagulant. As evident in Fig. 8, this appears to be the case. In support of this conclusion are the observations that ibuprofen has no apparent effect on the synthesis and degradation of prothrombin complex activity and that the average increase in total clearance of warfarin (Table II) is of similar magnitude as the increase in warfarin free fraction produced by the observed average ibuprofen concentrations (Table I and Fig. 1).

Based on pharmacokinetic data from humans (12), the steady-state plasma concentration of ibuprofen produced by a daily dose of 2.4 g is estimated to be 30–40 mg/liter. Peak concentrations of ibuprofen during a dosing interval will be appreciably higher, and an increase in the dosing rate will produce a corresponding increase in the steady-state concentration. It was estimated that the binding capacity of albumin in human plasma for ibuprofen is only 120 mg/liter (1). Inflammatory disease is often associated with hypoalbuminemia (18), resulting in a decreased binding capacity of plasma. For these reasons, it is desirable to determine the effect of various concentrations of ibuprofen on warfarin binding in normal and hypoalbuminemic human plasma.

This investigation showed that ibuprofen can, in principle, modify the elimination kinetics and anticoagulant activity of warfarin. These effects appear to be the consequence of decreased serum protein binding of warfarin in the presence of ibuprofen. Since this displacing effect of ibuprofen is concentration dependent, the clinical significance of these findings can only be assessed by determining the effect of therapeutic concentrations of the agent on the plasma protein binding of warfarin (19). Such determinations are in order also for other nonsteroidal anti-inflammatory agents that have recently come into clinical use (20).

Interrelation between Two Anticomplement Cobra Venom Factors Isolated from Crude *Naja naja* Cobra Venom

BRIAN J. JOHNSON [x] and UMBERTO N. KUCICH [x]

Abstract □ Two moieties occurring in crude *Naja naja* cobra venom were found to possess anticomplement activity. Both materials possessed similar molecular weights and specific activities but dissimilar elution profiles upon ion-exchange chromatography. The anticomplement activities of these materials were maintained upon digestion with neuraminidase, and their elution profiles from cation-exchange chromatography became identical after this treatment. It was concluded that the differences between the two anticomplement materials were due to their different sialic acid contents.

Keyphrases □ Cobra venom—two anticomplement factors isolated by ion-exchange chromatography, effect of neuraminidase digestion □ Ion-exchange chromatography—isolation, two anticomplement factors from cobra venom □ Anticomplement activity—two factors isolated by ion-exchange chromatography from cobra venom, effect of neuraminidase digestion

Purified cobra venom factor is probably the single most valuable substance for lowering complement levels *in vivo*. The mechanism of action of cobra venom factor *via* one pathway was described previously (1). When the factor is administered in small doses to minimize the lysis of red blood cells, complement activity is depressed; this depression can be maintained for 3–4 days (1). However, an antibody eventually develops against the cobra venom factor, inhibiting its anticomplement activity.

The possible clinical usefulness of cobra venom factor in reducing the amount of infarcted tissue following coronary occlusion was reported previously (2). In experimental animals, the myocardium that can be salvaged is substantial, and the treatment may be started a number of hours following the occlusion and still be effective. Since acute myocardial infarction constitutes the most common cause of death in this country, any procedure that can salvage substantial quantities of the patient's myocardium after the patient's arrival at the hospital should be investigated. Animal studies showed that cobra venom factor diminishes the inflammatory response following ischemic damage and thus reduces the size of myocardial infarcts after coronary occlusion (3, 4). These conclusions were reached using various electrophysiological, biochemical, histological, histochemical, and electron microscope techniques.

During an investigation on the purification of cobra venom factor from crude *Naja naja* cobra venom, two anticomplement factors were obtained. This report concerns the identification of these materials and their interrelationship.

EXPERIMENTAL

All buffers were prepared from reagent grade materials according to American Chemical Society standards. Gel filtration media were equilibrated with starting buffer for 2 days or heated to 80° for 6 hr prior to column preparation. All absorbance measurements were made at 280 nm. Freshly drawn human blood was allowed to clot, and the resulting serum served as the complement source.

Anticomplement Activity—*Qualitative Assay*—The assay was based on previously reported methods (5–7). For scanning column runs, sensitized sheep erythrocytes, EA (8), were labeled by incubation with ^{51}Cr-labeled sodium chromate in barbital buffer, pH 7.4 (50 μCi/1 × 10^9 cells), at 37° for 45 min with constant agitation. The cells were washed (5 × 10 ml of barbital buffer at 4°), resuspended in buffer, and then standardized to a concentration of 1 × 10^9 cells/ml.

To a series of wells in a microtiter test plate was added 20 μl of human complement, C. To each well was added 20 μl of cobra venom factor or column sample, and the plate was incubated at 37° for 1 hr. Another 100 μl of buffer was added to each well, followed by 20 μl of the ^{51}Cr-primed sensitized sheep erythrocytes, EA, with constant agitation. The samples were incubated at 37° for 1 hr and centrifuged, and aliquots of 50 μl were removed from each well.

The amount of lysis was obtained by measuring the amount of ^{51}Cr-label released with a γ-counter. Controls consisting of sensitized cells alone, sensitized cells plus complement, and cells plus water were run concurrently with the described assay. The percentage of inhibition (I) of lysis was calculated from:

$$\%I = 100\left[1 - \frac{\text{cpm released by EA, sample, and C} - \text{cpm released by EA alone}}{\text{cpm released by EA and C} - \text{cpm released by EA alone}}\right] \quad \text{(Eq. 1)}$$

Interrelation between Two Anticomplement Cobra Venom Factors Isolated from Crude *Naja naja* Cobra Venom

BRIAN J. JOHNSON [x] and UMBERTO N. KUCICH [x]

Abstract □ Two moieties occurring in crude *Naja naja* cobra venom were found to possess anticomplement activity. Both materials possessed similar molecular weights and specific activities but dissimilar elution profiles upon ion-exchange chromatography. The anticomplement activities of these materials were maintained upon digestion with neuraminidase, and their elution profiles from cation-exchange chromatography became identical after this treatment. It was concluded that the differences between the two anticomplement materials were due to their different sialic acid contents.

Keyphrases □ Cobra venom—two anticomplement factors isolated by ion-exchange chromatography, effect of neuraminidase digestion □ Ion-exchange chromatography—isolation, two anticomplement factors from cobra venom □ Anticomplement activity—two factors isolated by ion-exchange chromatography from cobra venom, effect of neuraminidase digestion

Purified cobra venom factor is probably the single most valuable substance for lowering complement levels *in vivo*. The mechanism of action of cobra venom factor *via* one pathway was described previously (1). When the factor is administered in small doses to minimize the lysis of red blood cells, complement activity is depressed; this depression can be maintained for 3–4 days (1). However, an antibody eventually develops against the cobra venom factor, inhibiting its anticomplement activity.

The possible clinical usefulness of cobra venom factor in reducing the amount of infarcted tissue following coronary occlusion was reported previously (2). In experimental animals, the myocardium that can be salvaged is substantial, and the treatment may be started a number of hours following the occlusion and still be effective. Since acute myocardial infarction constitutes the most common cause of death in this country, any procedure that can salvage substantial quantities of the patient's myocardium after the patient's arrival at the hospital should be investigated. Animal studies showed that cobra venom factor diminishes the inflammatory response following ischemic damage and thus reduces the size of myocardial infarcts after coronary occlusion (3, 4). These conclusions were reached using various electrophysiological, biochemical, histological, histochemical, and electron microscope techniques.

During an investigation on the purification of cobra venom factor from crude *Naja naja* cobra venom, two anticomplement factors were obtained. This report concerns the identification of these materials and their interrelationship.

EXPERIMENTAL

All buffers were prepared from reagent grade materials according to American Chemical Society standards. Gel filtration media were equilibrated with starting buffer for 2 days or heated to 80° for 6 hr prior to column preparation. All absorbance measurements were made at 280 nm. Freshly drawn human blood was allowed to clot, and the resulting serum served as the complement source.

Anticomplement Activity—*Qualitative Assay*—The assay was based on previously reported methods (5–7). For scanning column runs, sensitized sheep erythrocytes, EA (8), were labeled by incubation with ^{51}Cr-labeled sodium chromate in barbital buffer, pH 7.4 (50 μCi/1 × 10^9 cells), at 37° for 45 min with constant agitation. The cells were washed (5 × 10 ml of barbital buffer at 4°), resuspended in buffer, and then standardized to a concentration of 1 × 10^9 cells/ml.

To a series of wells in a microtiter test plate was added 20 μl of human complement, C. To each well was added 20 μl of cobra venom factor or column sample, and the plate was incubated at 37° for 1 hr. Another 100 μl of buffer was added to each well, followed by 20 μl of the ^{51}Cr-primed sensitized sheep erythrocytes, EA, with constant agitation. The samples were incubated at 37° for 1 hr and centrifuged, and aliquots of 50 μl were removed from each well.

The amount of lysis was obtained by measuring the amount of ^{51}Cr-label released with a γ-counter. Controls consisting of sensitized cells alone, sensitized cells plus complement, and cells plus water were run concurrently with the described assay. The percentage of inhibition (I) of lysis was calculated from:

$$\%I = 100\left[1 - \frac{\text{cpm released by EA, sample, and C} - \text{cpm released by EA alone}}{\text{cpm released by EA and C} - \text{cpm released by EA alone}}\right] \quad \text{(Eq. 1)}$$

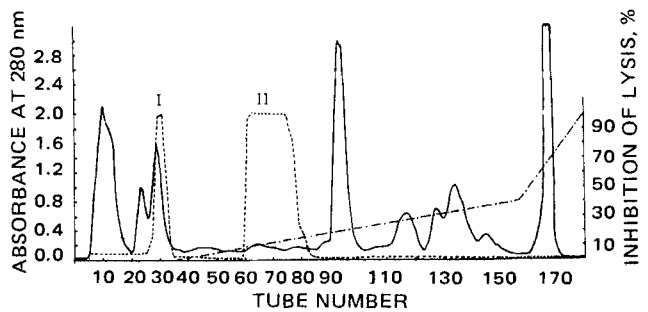

Figure 1—*Carboxymethylcellulose cation-exchange chromatography of dialyzed crude* N. naja *cobra venom. Key: —, optical density; - - -, anticomplement activity; and — · —, sodium chloride gradient (0.0 → 0.2 → 0.5 M).*

Quantitative Assay—The method was essentially the same as the qualitative one, except that serial dilutions of the anticomplement samples were assayed. To a series of wells in a microtiter plate was added 20 μl of human complement, to each of these was added the serially diluted sample, and the plate was incubated at 37° for 1 hr. Each well was diluted with 100 μl of buffer, and the microtiter plate was agitated during these additions. After incubation at 37° for 1 hr, the samples were centrifuged, aliquots of 50 μl were removed from each well, and the amount of lysis was ascertained by the ^{51}Cr-label released. Identical controls to those described were run concurrently.

The percentage of inhibition of lysis was calculated from Eq. 1 and was plotted against the dilution of the complement-consuming material. The dilution of material that produced 50% inhibition of lysis was considered equal to the number of cobra venom factor units in the original 20-μl aliquot of material. By this means, comparison could be made of the purification and activity of the various complement-consuming materials.

Isolation of Cobra Venom Factor—*Carboxymethylcellulose Chromatography*—One gram of lyophilized cobra venom[1] was suspended in 15 ml of 0.05 *M* sodium acetate buffer, pH 5.5, containing 0.02% sodium azide and then dialyzed overnight against two changes of 1 liter each of the same buffer. A column (1.5 × 25.0 cm) of CM-52 carboxymethylcellulose[2] was equilibrated with 0.05 *M* sodium acetate buffer, pH 5.5. The crude dialyzed cobra venom mixture, typically containing 560–760 absorbance units, was applied to the column; elution was performed using 0.05 *M* sodium acetate, pH 5.5.

When no further material was eluted from the column, as shown by absorbance measurements, a sodium chloride gradient was applied. The flow rate of the column was 20 ml/hr, and 4-ml fractions were collected. Each tube was assayed for anticomplement activity. The elution profile and the peaks of activity, I and II, are shown in Fig. 1.

Gel Filtration Chromatography—Lyophilized peak II, obtained from carboxymethylcellulose chromatography, was suspended in 3.5 ml of 0.015 *M* tris(hydroxymethyl)aminomethane–0.15 *M* sodium chloride buffer, pH 8.5, containing 0.02% sodium azide. This sample, containing 28 absorbance units, was applied to a column (1.5 × 85 cm) of Sephadex G-200 equilibrated in the same buffer.

The flow rate was adjusted to 15 ml/hr, and 2.5-ml fractions were collected. Three well-defined protein peaks were obtained (Fig. 2A). The major peak, containing all of the anticomplement activity eluted, possessed a molecular weight slightly less than 150,000, as shown by using human IgG1 as a molecular weight marker. The fraction containing the biological activity was pooled and then lyophilized.

Peak I, obtained from carboxymethylcellulose chromatography was treated in an identical manner as peak II. The elution and anticomplement activity profiles are shown in Fig. 2B.

Diethylaminoethylcellulose Chromatography—One gram of lyophilized cobra venom was suspended in 10.6 ml of 0.05 *M* barbital sodium buffer, pH 8.6, containing 0.05% sodium azide. This solution, containing 967 absorbance units, was filtered through a filtration membrane[3], 1 × 10^5 mol. wt. exclusion limit, and washed thoroughly with 0.05 *M* barbital sodium buffer, pH 8.6. The solution was then concentrated to 15.5 ml, and it possessed 688 absorbance units.

The material was charged on a column (2.5 × 40 cm) of DE-52 diethylaminoethylcellulose[2] equilibrated with 0.05 *M* barbital sodium buffer, pH 8.6. The flow rate of the column was 35 ml/hr, and 5-ml fractions were collected. After the initial protein was eluted from the column, a sodium chloride gradient was applied. The elution and anticomplement activity profiles are shown in Fig. 3.

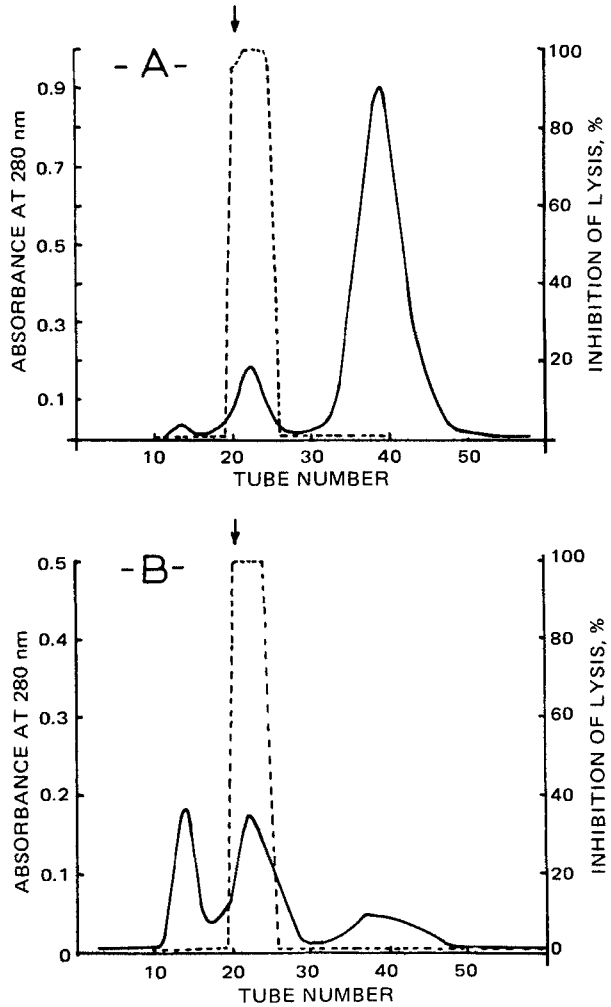

Figure 2—*Sephadex G-200 chromatography of peaks I and II obtained from cation-exchange chromatography (Fig. 1). Figure 2A corresponds to peak I and Fig. 2B to peak II. The molecular weight marker, human IgG1, is indicated by an arrow. Key: —, optical density; and - - -, anticomplement activity.*

Neuraminidase Digestion A—In separate but concurrent experiments, 4.2 ml of anticomplement active peak I, 5.46 absorbance units, and 4.4 ml of anticomplement active peak II, 2.66 absorbance units, obtained from the procedure described under *Carboxymethylcellulose Chromatography* were digested with insolubilized neuraminidase. To each sample in 0.05 *M* sodium acetate–0.02% sodium azide, pH 5.5, was added 1.7 units of insolubilized neuraminidase. Each mixture was incubated at 37° for 1 hr with shaking. At the end of the digestion, the solutions were cleared by centrifugation and the supernates were removed by decantation. Control samples of peaks I and II were treated identically except that buffer was substituted for neuraminidase.

Quantitative anticomplement assays of each peak after neuraminidase treatment and its appropriate control were performed. Peak I possessed 680 cobra venom factor units per absorbance unit without neuraminidase digestion and 640 after digestion. Peak II possessed 695 cobra venom factor units per absorbance unit without neuraminidase digestion and 642 after digestion. A further control to investigate the activity of the insolubilized neuraminidase was also performed. To 0.4 ml of a 4% solution of bovine mucin in 0.05 *M* sodium acetate–0.02% sodium azide buffer, pH 5.5, was added 1.7 units of insolubilized neuraminidase. The digestion was conducted for 1 hr at 37° with mixing and was arrested by removal of the insolubilized enzyme by centrifugation. The presence of sialic acid was determined using 2-thiobarbituric acid as reported by Warren (9) and modified by Aminoff (10).

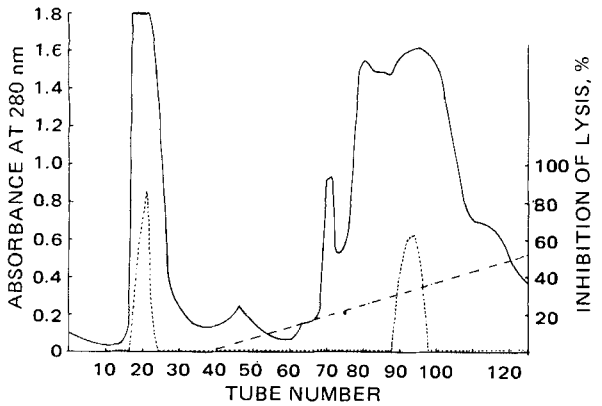

Figure 3—*Diethylaminoethylcellulose anion chromatography of crude* N. naja *cobra venom. Key: —, optical density; - - - , anticomplement activity; and — · —, sodium chloride gradient (0.0 → 0.25* M*).*

Neuraminidase Digestion B—Peaks I and II obtained from the carboxymethylcellulose ion-exchange chromatography were combined. The solution was concentrated using a filtration membrane[3], 30,000 mol. wt. exclusion limit, and then was dialyzed overnight against 1000 ml of 0.05 *M* sodium acetate–0.05% sodium azide buffer, pH 5.5. The solution was centrifuged to give 13.5 ml containing 13.5 absorbance units of material. This material was incubated with 3.4 units of previously calibrated insolubilized neuraminidase for 1 hr at 37° with agitation.

After this digestion period, the enzyme was removed by centrifugation. The supernate, 14.0 ml, 10.4 absorbance units, was chromatographed on a column (2.0 × 37.5 cm) of CM-52 carboxymethylcellulose. The flow rate of the column was 40 ml/hr, and 5.5-ml fractions were collected. Each fraction was assayed for anticomplement activity. Only one peak of anticomplement activity was detected, and it eluted from the column in an identical position to that of peak II before neuraminidase digestion.

RESULTS AND DISCUSSION

The complement fixation assays utilized the quantitation of ^{51}Cr-release by the action of complement on sensitized erythrocytes (5–7). The anticomplement activity of a pertinent sample was ascertained by its prior incubation with human serum and then quantitation of the unconsumed complement (8).

Dialysis of crude *N. naja* venom usually removed up to 25% of the available optical density. Chromatography of the dialyzed cobra venom through a carboxymethylcellulose column gave two peaks, I and II (Fig. 1), of anticomplement activity. Similarly, chromatography of crude *N. naja* cobra venom on diethylaminoethylcellulose gave two peaks of anticomplement activity. Other investigators reported the presence of only a single material with anticomplement activity (11, 12), mol. wt. 144,000 (12).

Each anticomplement material from cation-exchange chromatography (Fig. 1) was subjected to gel filtration chromatography on Sephadex G-200. Both materials eluted in identical positions (Fig. 2), and both had apparent molecular weights of slightly under 150,000. Furthermore, the specific anticomplement activities of each peak were very similar. The interrelationship between peaks I and II (Fig. 1) was shown using neuraminidase digestion.

In separate experiments, peaks I and II were digested with insolubilized neuraminidase (Digestion A); within experimental error, there was no change in the specific activity of either peak. In another experiment (Digestion B), fresh samples of peaks I and II were combined and then treated with insolubilized neuraminidase. Only one peak of anticomplement activity was detected when this digest was subjected to cation-exchange chromatography.

Neuraminidase cleaves sialic acid (*N*-acetyl- and *O*-acetylneuraminic acids) from suitable substrates. However, sterically hindered sialic acids are resistant (13). Neuraminidase did not cause either cobra venom factor I or II to lose anticomplement activity. However, it did change the elution profile of peak I on cation-exchange chromatography such that it eluted in an identical position to that of peak II. These results indicate that these anticomplement materials, peaks I and II, probably differ in their sialic acid compositions.

Functional Modification of Indole Binding Site with Indomethacin Congeners

E. M. K. LUI *, P. S. FARMER ˣ, and C. R. DEAN *

Abstract □ Indomethacin and four congeners were shown by equilibrium dialysis to interfere with the binding of L-tryptophan at the primary indole binding site on defatted human serum albumin. Incubation of albumin with 1-(*p*-bromoacetamidobenzoyl)- and 1-(*m*-bromoacetamidobenzoyl)-5-methoxy-2-methyl-3-indolylacetic acids functionally modified this site, decreasing the availability of the site for the binding of L-tryptophan. Incubation in the presence of a large excess of L-tryptophan resulted in the partial protection of the site from modification by 1-(*m*-bromoacetamidobenzoyl)-5-methoxy-2-methyl-3-indolylacetic acid.

Keyphrases □ Indomethacin and congeners—effect on binding of L-tryptophan by defatted human serum albumin □ L-Tryptophan—binding by defatted human serum albumin, effect of indomethacin and congeners □ Binding, protein—L-tryptophan binding by defatted human serum albumin, effect of indomethacin and congeners □ Protein binding—L-tryptophan binding by defatted human serum albumin, effect of indomethacin and congeners □ Indole binding site—on defatted human serum albumin, functional modification with indomethacin and congeners □ Anti-inflammatory agents—indomethacin and congeners, effect on binding of L-tryptophan by defatted human serum albumin

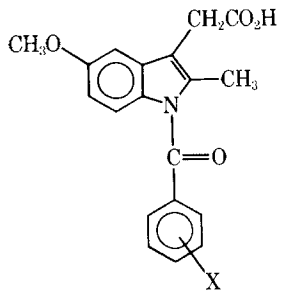
The nonsteroidal anti-inflammatory agents exert various pharmacological effects. There are several currently prevailing theories regarding their mode(s) of action, and a single biochemical mechanism for the anti-inflammatory and antirheumatic actions of these drugs has not yet been identified. Furthermore, the mechanisms so far proposed are not necessarily mutually exclusive. These agents are bound strongly with serum proteins, and at various concentrations they inhibit numerous enzyme systems implicated in the inflammatory process. The clinical effects of these drugs may possibly result from action at several sites rather than from a specific action on a single enzyme system.

Nevertheless, it is desirable to determine the extent to which any one enzyme or other protein is involved in inflammation and to evaluate the importance of inhibiting or interfering with that involvement. One approach is to design agents to bind selectively and irreversibly with one protein of interest. Functional modification of an implicated protein *in vivo* by such an agent and the evaluation of the anti-inflammatory effect achieved by such modification would provide a measure of the significance of interference with that protein by the drug.

In the present investigation, the object was to obtain a chemical agent that selectively alkylates the serum albumin binding sites of the anti-inflammatory agent indomethacin (I) while leaving its other receptors intact.

BACKGROUND

Indomethacin and other nonsteroidal anti-inflammatory agents are strongly bound by human serum albumin. The protein-bound rather than the unbound forms of these drugs may be responsible for their chronic antirheumatic effects (1). The drugs compete with endogenous biologically active small molecules for their binding sites on albumin. Among those substances displaced by these drugs are L-tryptophan (1–4) and certain dipeptides (1–3). Measurement of the displacement of tryptophan from human serum albumin was proposed as a new assay for screening drugs for potential anti-inflammatory activity (5).



I: X = *p*-Cl
II: X = *p*-NHCOCH$_2$Br
III: X = *p*-NHCOCH$_3$
IV: X = *m*-NHCOCH$_2$Br
V: X = *m*-NHCOCH$_3$

Several forms of human serum albumin are believed to exist and to have different affinities and binding capacities for L-tryptophan and other small molecules (6–8). Rheumatoid arthritis patients may have an abnormal ratio of one form of albumin to another (8). Thus, rheumatoid arthritis and related diseases may be due to an abnormal serum protein binding of certain endogenous anti-inflammatory peptide-like small molecules, leading to a decrease in the free concentration of these substances for protection against chronic inflammatory insult (1, 8–10). Anti-inflammatory agents may act by displacing these endogenous factors from their binding sites on albumin, thereby redressing the bound–free ratio to that found in normal subjects.

The binding of L-tryptophan and its displacement may parallel those of the postulated protective peptides; thus, L-tryptophan could be used as an indicator of the extent of binding of the peptides. L-Tryptophan and some other indole derivatives combine tightly with albumin at a specific primary binding site (11–14) but are displaced by anti-inflammatory agents. L-Tryptophan is not displaced from albumin by other drugs that resemble the commonly used antirheumatic drugs in being administered over long periods and being equivalently bound to plasma proteins (3).

These observations and hypotheses lend themselves quite conveniently to examination by an affinity labeling technique. The proteins under scrutiny, namely serum albumins from humans and other species, are

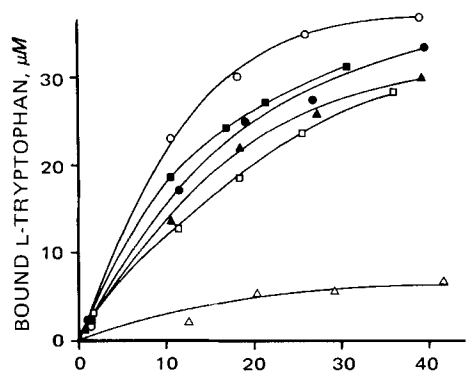


Figure 1—*Binding of L-tryptophan by defatted human serum albumin (0.4%) in 67 mM phosphate buffer at pH 7.4 and 3° and effect of competitors. Key: ○, no competitor (control); △, in presence of I (40 μM); □, in presence of II (40 μM); ●, in presence of III (40 μM); ▲, in presence of IV (40 μM); and ■, in presence of V (40 μM). In this and subsequent figures, each data point represents a single determination.*

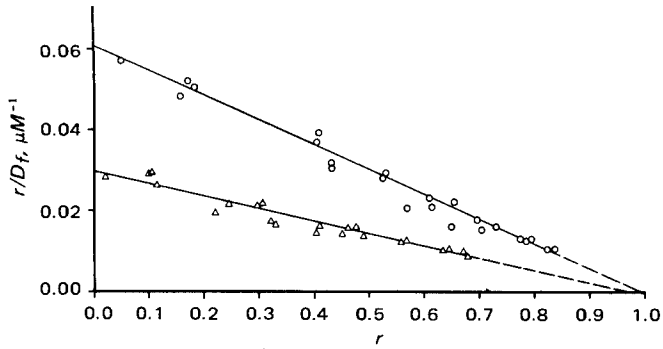

Figure 2—*Scatchard plots for the binding of* L-*tryptophan by defatted human serum albumin (0.4%) in 67 mM phosphate buffer at pH 7.4 and 3°. Key:* O, *control; and* Δ, *presence of II (40 μM).*

readily isolated for *in vitro* screening. More importantly, serum albumin is accessible in the intact animal. *In vivo* affinity labeling and active-site-directed irreversible enzyme inhibition usually require the reagent to reach the target site by a random-walk process, avoiding premature reaction with a bewildering array of tissue constituents (15). In contrast, for the present proposal, the reagent is required to alkylate specifically a major constituent of the compartment into which it is administered—albumin of the serum. Thus, the danger of alkylating other tissue components is mainly circumvented.

Gambhir and McMenamy (16) demonstrated site-specific covalent binding at the indole binding site by *N*-bromoacetyl-L-tryptophan and by two other reagents. They used these affinity labels to locate the site in the albumin molecule. Their results, however, cannot be extrapolated to nonsteroidal anti-inflammatory agents.

Therefore, it was decided to investigate the influence of indomethacin and four congeners (II–V) on L-tryptophan binding by human serum albumin. Compounds II and IV are potential affinity-labeling reagents for indomethacin receptors, since these compounds bear the electrophilic bromoacetamido moiety. Indomethacin was chosen as the pharmacophoric structure from which to design an irreversible protein binder, because it has a high displacement potency of L-tryptophan from its binding site and the indole ring and general similarity of the indomethacin structure to that of L-tryptophan may increase the specificity of its binding to albumin. (It is not certain whether indomethacin and L-tryptophan share the same binding site on albumin or whether the indole moiety of both compounds has a similar orientation in the binding site.)

The indolic nature of I suggests the possibility of displacement of active molecules from albumin as a major mode of action for I, with inhibition of various enzymes such as the prostaglandin synthetase system playing more minor roles in its action; other drugs may act predominantly by the latter mechanisms, with specific albumin binding being secondary. Such differences in the relative importance of their component actions could account for the different spectra of pharmacological activities of these drugs.

The alkylating function required placement in such a position that it would not interfere with the initial reversible binding of the agents to the protein site. Since the benzoyl group of I constitutes a considerable change in gross dimensions from those of L-tryptophan, it was selected as the most logical area on which to substitute the bromoacetamido

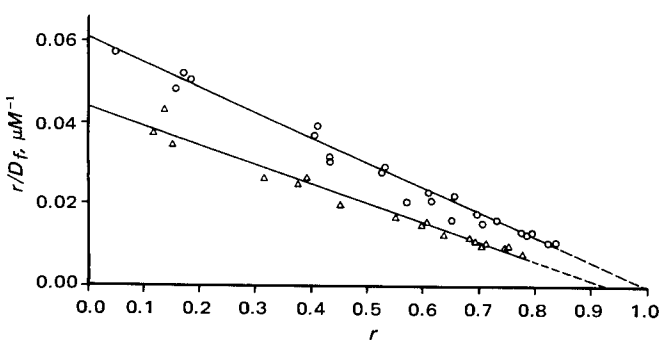

Figure 3—*Scatchard plots for the binding of* L-*tryptophan by defatted human serum albumin (0.4%) in 67 mM phosphate buffer at pH 7.4 and 3°. Key:* O, *control; and* Δ, *presence of III (40 μM).*

moiety. Furthermore, the benzoyl group may act as a "bridge" between the site-directing group and the covalent bond-forming group, thereby enhancing the probability of alkylation of the indomethacin-binding site by the exo mechanism (17).

RESULTS AND DISCUSSION

L-Tryptophan was extensively bound by its primary binding site on albumin. The maximum number of binding sites, n, was 0.98, in good agreement with previous reports (10–12); the association constant, K_d, was $6.11 \times 10^4\ M^{-1}$. As reported previously (1–4), this binding of L-tryptophan was greatly inhibited in the presence of indomethacin; apparent n and K_d values could not be estimated.

The new indole compounds also inhibited the binding of L-tryptophan by albumin (Fig. 1). The order of decreasing L-tryptophan-displacement potency was: I ≫ II > IV > III > V. Scatchard plots for the binding of L-tryptophan in the presence of each indomethacin congener are illustrated in Figs. 2–5, and apparent binding parameters for L-tryptophan are listed in Table I. That these compounds probably inhibit albumin binding of L-tryptophan by a competitive mechanism at 3° is indicated by the constant value of n ($p < 0.01$)[1] while K_d changes significantly ($p > 0.01$)[1]. These findings are significant, since they show that the L-tryptophan binding site on human serum albumin has the bulk tolerance necessary to accommodate an acetamido or bromoacetamido group in the 3′- or 4′-position of the 1-benzoylindole system.

Once it was established that the indomethacin congeners did compete with L-tryptophan for its albumin binding site, a series of experiments was carried out to determine their ability to block or modify the binding site irreversibly at physiological temperature. The increased temperature was expected to promote covalent bond formation. An analogous situation was reported wherein acetylation of a lysine residue of albumin occurred readily at 37° but not at 0° (18). Thus, L-tryptophan binding was measured after incubation of the albumin at 37° for 24 hr in the presence of the respective competitors (Table II).

Defatted human serum albumin, incubated as a control in the absence of an indole compound, exhibited a slightly enhanced affinity for L-tryptophan. Incubation of albumin alone at 37° similarly increased its affinity for phenylbutazone, flufenamic acid, and dicumarol (19).

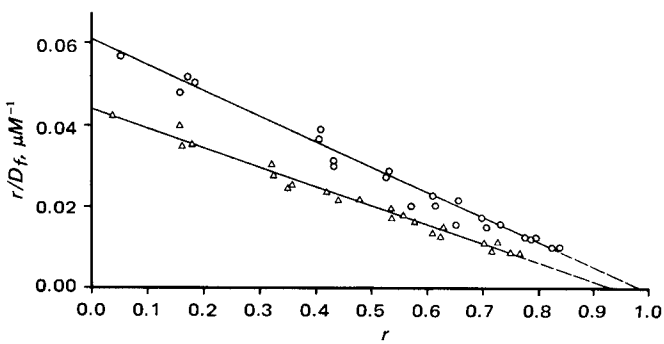

Figure 5—*Scatchard plots for the binding of* L-*tryptophan by defatted human serum albumin (0.4%) in 67 mM phosphate buffer at pH 7.4 and 3°. Key:* O, *control; and* Δ, *presence of V (40 μM).*

[1] Significance tested at 1% level with a Fortran analysis of variance program.

Table I—Binding of L-Tryptophan by 0.4% Defatted Human Serum Albumin and Effect of Competitors[a]

Competitor	$K_d \times 10^{-4}$, M^{-1}	n	Linear Correlation Coefficient
None (control)	6.11	0.98	−0.988
I	—[b]	—[b]	—
II	3.07[c]	0.95[d]	−0.967
III	4.64[c]	0.94[d]	−0.981
IV	3.52[c]	0.96[d]	−0.960
V	4.73[c]	0.93[d]	−0.990

[a] Determined in 67 m*M* phosphate buffer at pH 7.4 and 3°; L-tryptophan concentration was varied from 5 to 100 μ*M*; competitors were used with single initial concentration of 40 μ*M*. [b] Not measurable; no correlation was found between r and r/D_f. [c] Significantly different from control value at $p > 0.01$. [d] No significant difference from control value at $p < 0.01$.

Incubation with II decreased the availability of the primary L-tryptophan-binding site by about 26% and also decreased the affinity slightly (Fig. 6). That is, functional modification of the primary L-tryptophan-binding site was observed. The slight decrease in K_d was probably due to competitive binding of residual noncovalently bound II, in spite of dialysis against four changes of sodium chloride. The presence of L-tryptophan during incubation with II in another experiment did not protect significantly against the modification (Fig. 6). The K_d was returned to the control value, however, indicating that L-tryptophan successfully competed with II for the site under these conditions. [L-Tryptophan is more effectively removed than II by sodium chloride. Chloride ion is an acknowledged competitive inhibitor of tryptophan binding (13).] These observations suggest that the functional modification by II is not dependent on the initial formation of a reversible complex with the primary indole-binding site.

Figure 7 shows the effects of incubation with IV. When incubated without L-tryptophan, the indole-binding site is more extensively modified by IV than by II, with only about 30% of the original site left unblocked. Unlike the observations with II, the presence of L-tryptophan during incubation of albumin with IV provided approximately 60% protection to the site, allowing modification of only about 28%. Protection at secondary sites would not be expected since, at a total concentration of 250 μ*M*, L-tryptophan is not bound appreciably by secondary sites on human serum albumin[2].

That the protection achieved was by competition and not by chemical inactivation of IV was evidenced by the lack of reaction between IV and L-tryptophan in the absence of albumin (*cf., Experimental*). These experiments provide evidence for site specificity in the functional modification by IV of the L-tryptophan primary binding site on albumin. They do not preclude additional *nonselective* reaction of IV at other sites on the protein molecule.

A second feature obvious from Fig. 7 is the generation or exposure by

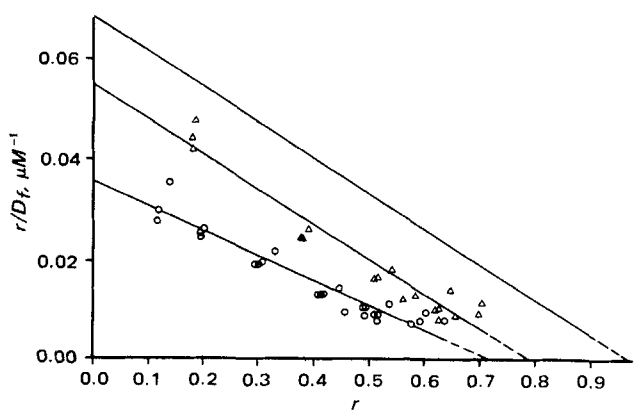

Figure 6—*Scatchard plots for the binding of L-tryptophan by defatted human serum albumin (0.4%) in 67 m*M *phosphate buffer at pH 7.4 and 3° after incubation at 37° for 24 hr. Key: top line without data points, albumin incubated in buffer alone (control); ○, albumin incubated in presence of II (290 μ*M*); and △, albumin incubated in presence of both II (290 μ*M*) and L-tryptophan (250 μ*M*).*

[2] This laboratory, unpublished data.

Table II—Binding of L-Tryptophan by 0.4% Defatted Human Serum Albumin after Incubation with Indole Compounds

Compound Incubated with	$K_d \times 10^{-4}$, M^{-1}	n	Linear Correlation Coefficient
None (control)	7.20	0.96	−0.987
I	4.22[a]	0.91[b]	−0.967
II	4.96[a]	0.71[a,c]	−1.002
II + 250 μ*M* L-tryptophan	6.91[b]	0.77[c]	−0.990
III	5.93[a]	0.89[b]	−0.995
IV	5.21[a,d]	0.29[a,d,e]	−0.982
IV + 250 μ*M* L-tryptophan	7.19[b]	0.69[e]	−0.993
V	4.86[a]	0.98[b]	−0.996

[a] Significantly different from control value at $p > 0.01$. [b] No significant difference from control value at $p < 0.01$. [c] No significant difference between the two values at $p < 0.01$. [d] Estimates for the first class of binding sites; insufficient data were available for determination of parameters for the second class by nonlinear least-squares fit. [e] These two values are significantly different at $p > 0.01$.

IV of a second class of L-tryptophan-binding sites. Visual inspection of the Scatchard plot of the "tryptophan-protection" experiment (Fig. 7) similarly reveals a possible break in the curve at higher r values, although a linear regression line was obtained with a correlation coefficient of −0.993 (*cf.*, Table II). Two possible explanations for this phenomenon were considered: (*a*) additional sites on the albumin molecule may be modified by IV, generating by an allosteric effect a new L-tryptophan-binding site; and (*b*) partial blocking or modification of the primary site on some albumin molecules may result in decreased, but measurable, affinity (K_d) at those sites. The unconvincing protection by L-tryptophan against the formation of the new class of sites discredits the latter explanation.

To establish that site modification was a function of the electrophilic bromoacetyl moieties of II and IV, albumin was incubated under the same conditions with I and with the nonalkylating congeners III and V separately. These compounds had no significant effect on r, the availability of the primary indole-binding site (Fig. 8). These compounds, like II and IV, decreased the association constant slightly.

Acetylation of albumin by aspirin modified binding of phenylbutazone and flufenamic acid, while acylation by other reagents had no measurable effect (19). Site protection experiments were not carried out, however, and the investigators were unable to state that all three drugs were bound at the same or proximal sites on the albumin.

EXPERIMENTAL

Biological—*Measurement of L-Tryptophan Binding by Albumin*—Protein binding was measured by equilibrium dialysis at 3°, using Visking dialysis bags[3]. Essentially fatty acid-free human serum albumin[4] (0.4%) in 2.0 ml of 67 m*M* phosphate buffer (pH 7.4) was used after dialysis overnight against the buffer at 3°. Diffusate solutions contained 15 ml of 3-^{14}C-L-tryptophan with initial concentrations of 5–100 μ*M* and activities of at least 4000 cpm.

3-^{14}C-L-Tryptophan was assayed as free (diffusate) and total (retentate) L-tryptophan by single-channel liquid scintillation counting[5] at 6–8°, with a counting time of 10 min and a counting efficiency of 97.36%. The scintillation fluid consisted of a commercial fluor[6]–toluene–ethylene glycol monomethyl ether (1:175:75) and was used to dilute 0.2 ml of dialysate to 10 ml. The protein concentration of the retentate after equilibrium dialysis was determined by the method of Lowry *et al.* (20).

The extent of binding was computed by the Scatchard method (21):

$$r/D_f = nK_d - rK_d \qquad \text{(Eq. 1)}$$

where r is the number of moles of L-tryptophan bound per mole of human serum albumin, D_f is the molar concentration of free L-tryptophan at equilibrium, n is the maximum number of binding sites of a single class, and K_d is the association constant for the binding of L-tryptophan by sites in that class.

A regression line for each set of experiments was generated using the

[3] Dialysis tubing, 0.63-cm (0.1251-in.) diameter (Union Carbide Corp.), was prepared for use as described by Gambhir and McMenamy (16).

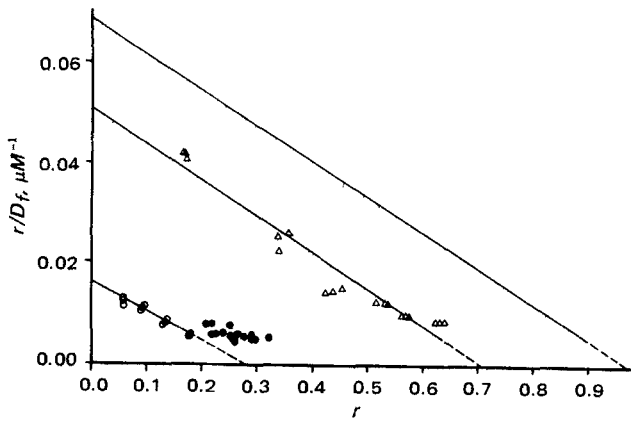

Figure 7—*Scatchard plots for the binding of L-tryptophan by defatted human serum albumin (0.4%) in 67 mM phosphate buffer at pH 7.4 and 3° after incubation at 37° for 24 hr. Key: top line without data points, albumin incubated in buffer alone (control); ○, albumin incubated in presence of IV (290 μM), data points used for estimation of regression line and binding parameters; ●, albumin incubated in presence of IV (290 μM), data points excluded for estimation of binding parameters; and △, albumin incubated in presence of both IV (290 μM) and L-tryptophan (250 μM).*

program BMDO3R[7] with a digital computer[8]. The slopes and elevations of replicated lines were compared ($p = 0.01$), using a Fortran analysis of covariance program (22). The homogeneous data were pooled for the estimation of a single regression line. Where the correlations between r/D_f and r were nonlinear, indicating binding at secondary binding sites, a second Fortran program[9] was used to compute binding parameters for both classes of binding sites.

Estimation of Competition by Indomethacin and Congeners—L-Tryptophan binding by 0.4% defatted human serum albumin in the presence of I–V was similarly measured. The diffusate solutions initially contained 5–100 μ*M* L-tryptophan and one test compound (I–V) in a single concentration of 40 μ*M*. Preliminary experiments showed I–V to have no appreciable quenching effect.

Affinity Labeling—Essentially fatty acid-free human serum albumin (0.4%) was incubated at 37° for 24 hr with each test compound (I–V) (290 μ*M*) in 67 m*M* phosphate buffer (pH 7.4). The incubated albumin solutions were then dialyzed at 3° for 48 hr against four changes of 0.15 *M* NaCl solution and finally against four changes of distilled water (19). A control experiment was run in which the albumin was incubated without an indole compound. L-Tryptophan binding by the albumin was measured as already described.

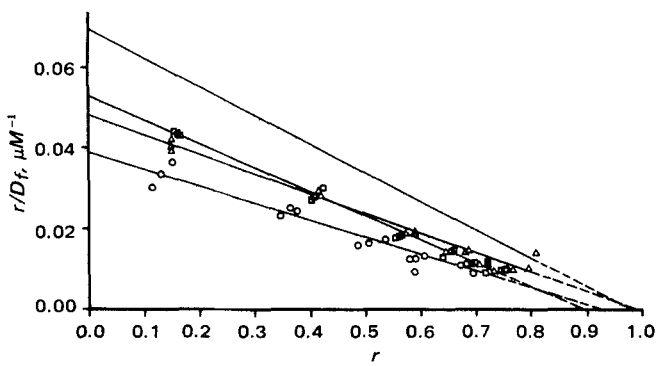

Figure 8—*Scatchard plots for the binding of L-tryptophan by defatted human serum albumin (0.4%) in 67 mM phosphate buffer at pH 7.4 and 3° after incubation at 37° for 24 hr. Key: top line without data points, albumin incubated in buffer alone (control); ○, albumin incubated in presence of I (290 μM); △, albumin incubated in presence of III (290 μM); and □, albumin incubated in presence of V (290 μM).*

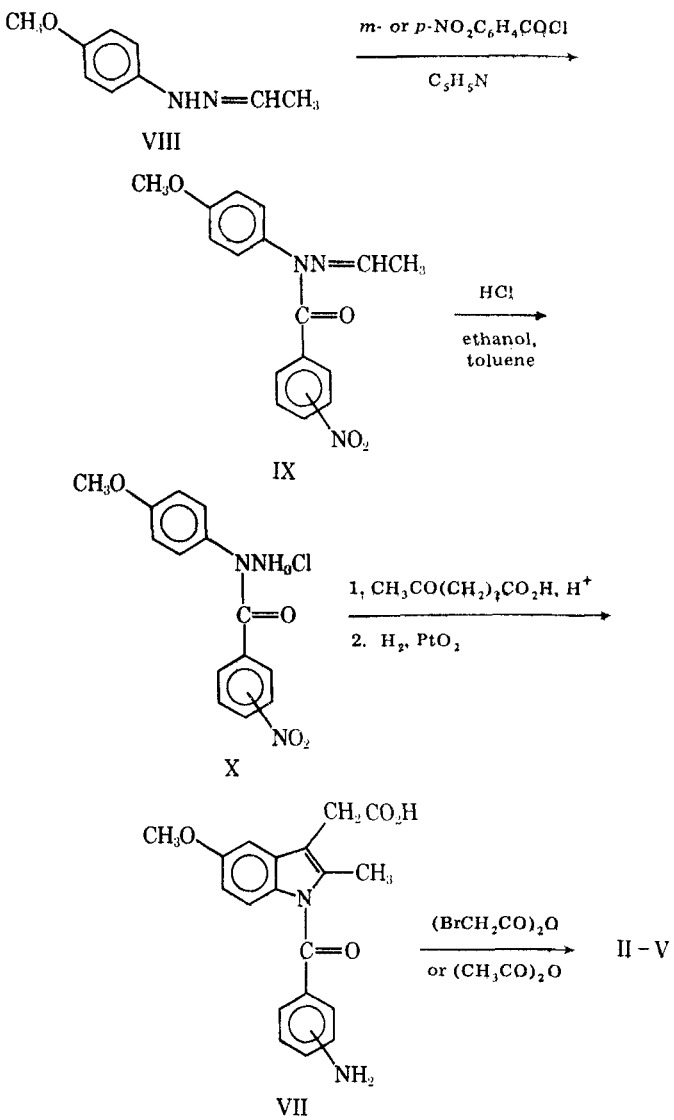
Site Protection—Solutions of essentially fatty acid-free human serum albumin (0.4%), which had been equilibrated at 37° with 250 μ*M* L-tryptophan, were incubated with II or IV and subsequently treated as described. The L-tryptophan solution used for the preliminary equilibration carried the same specific activity (3-^{14}C) as the stock solution used in the binding studies.

Determination of Ionization Constants[10]—A spectrophotometric method (23) was used for the determination of pKa values for I and III. The absorbance of 1×10^{-4} *M* solutions of I was measured at 259 nm in 1.0 *M* HCl, 0.1 *M* NaOH, and seven formate buffers (0.01 *M*, pH 3.55–4.36), giving pKa 3.96 ± 0.03. When 3.85×10^{-5} *M* solutions of III were measured at 244 and 272 nm, they had a pKa of 4.11 ± 0.07. No suitable wavelength was found for differentiating between the acid and anion forms of V; their absorbances did not differ by greater than 10% in any part of the spectrum. The pKa of V was not determined.

The compounds are too insoluble in water or even in 50% methanol for potentiometric determination of their ionization constants.

Chemistry[11]—A modified Fischer indole synthesis, such as that de-



Scheme I

[7] One of the BMD series of programs available from the health sciences computing facility of the University of California at Los Angeles.

[8] Model 6400, Control Data Corp.

[9] This program for nonlinear least-squares fit was made available by Dr. R. F. Mais, Midwest Research Support Center, Veterans Administration Hospital, Hines, Ill.

[10] For the determination of acid dissociation constants, a Fisher Accumet model 220 pH meter was used with a standard combination electrode; spectra were obtained with a Zeiss model PMQ II spectrophotometer, using matched 1.0-cm quartz cells.

[11] Melting points were determined with a Thomas–Hoover capillary melting-point apparatus and are uncorrected. IR spectra were recorded with a Perkin-Elmer model 237B spectrophotometer. NMR spectra were recorded, using tetramethylsilane as the internal reference, with a Varian model T-60 spectrometer and, where indicated, with a Varian model HR-220 spectrometer, the latter at the 220 MHz NMR Center, Ontario Research Foundation, Sheridan Park, Ontario. Microanalyses were carried out by Dr. G. I. Robertson, Jr., Robertson Laboratory, Florham Park, N.J., and by Dr. H. Bieler, Organisch-Chemisches Institut, Vienna, Austria.

scribed for I (24, 25) and for certain 1-heteroaroyl analogs (25, 26), was used (Scheme I). The nitrobenzoylindoles (VI) so obtained were easily hydrogenated in the presence of platinum dioxide in tetrahydrofuran, giving the corresponding amines (VII). Hydrogenation did not proceed in anhydrous ether or dimethyl formamide. The amines were acylated in anhydrous acetone by bromoacetic anhydride or acetic anhydride to yield II–V.

Acetaldehyde p-*Methoxyphenylhydrazone* (*VIII*)—Compound VIII was prepared from *p*-methoxyphenylhydrazine hydrochloride (14 g, 80 moles) and acetaldehyde (6.6 g, 150 mmoles) by the method of Yamamoto (27). The yield was 10.1 g (76%), bp 120–124°/0.2 mm [lit. (27) bp 119–125°/0.2 mm]; IR (film): 3300, 1500, 1235, 1030, and 820 cm^{-1}.

Acetaldehyde N^1-p-*Nitrobenzoyl*-N^1-p-*methoxyphenylhydrazone* (*IX*a)—Powdered *p*-nitrobenzoyl chloride (9.6 g, 50 mmoles) was added in portions to a solution of VIII (7 g, 45 mmoles) in 60 ml of pyridine at 0–5° for 1.5 hr. After being stirred at ice-bath temperature for an additional 2.5 hr, the reaction mixture was poured into 500 ml of cold water. On standing overnight at 2–5°, precipitation occurred. The orange precipitate was isolated, washed with 100 ml of cold water, and dried *in vacuo* overnight. The product was obtained from ethylene glycol monomethyl ether as yellow crystals (12 g, 91%), mp 126–127.5°; IR (KBr): 1650 (C=O, tertiary amide), 1520, and 1340 (NO_2, aromatic) cm^{-1}; NMR (60 MHz) (dimethyl sulfoxide-d_6): δ 1.70 (d, 3, J = 5 Hz, CH_3CH), 3.75 (s, 3, CH_3O), 6.73 (q, 1, J = 5 Hz, CH_3CH), 7.18 (*AB*q, 4, J = 9 Hz, ArH), and 8.08 (*AB*q, 4, J = 9 Hz, benzoyl ArH) ppm.

Anal.—Calc. for $C_{16}H_{15}N_3O_4$: C, 61.34; H, 4.83; N, 13.41. Found: C, 61.37; H, 5.00; N, 13.29.

Acetaldehyde N^1-m-*Nitrobenzoyl*-N^1-p-*methoxyphenylhydrazone* (*IX*b)—Compound IX*b* was prepared in 90% yield by the method described for IX*a*. Recrystallized from 95% ethanol, the product had a melting point of 106°; IR (KBr): 1650 (C=O, tertiary amide), 1520, and 1340 (NO_2, aromatic) cm^{-1}; NMR (60 MHz) (dimethyl sulfoxide-d_6): δ 1.70 (d, 3, J = 5 Hz, CH_3CH), 3.76 (s, 3, CH_3O), 6.76 (q, 1, J = 5 Hz, CH_3CH), 7.20 (*AB*q, 4, J = 9 Hz, ArH), and 7.7–8.52 (m, 4, benzoyl ArH) ppm.

Anal.—Calc. for $C_{16}H_{15}N_3O_4$: C, 61.34; H, 4.83; N, 13.41. Found: C, 61.50; H, 5.00; N, 13.29.

N^1-p-*Nitrobenzoyl*-N^1-p-*methoxyphenylhydrazine Hydrochloride* (*X*a)—Gaseous hydrogen chloride was bubbled through a solution of IX*a* (5 g, 16 mmoles) in 99% ethanol (2 ml) and 27 ml of toluene below 5° for 15 min with stirring. Stirring was continued for an additional 2 hr at 0–5°. The precipitate was collected by filtration, washed with ether, and dried *in vacuo* overnight. The product was obtained from absolute ethanol as white needles (4.8 g, 92.8%), mp 183.5°; IR (KBr): 3000–2250 (NH^+), 1665 (tertiary amide), 1520, and 1340 (NO_2, aromatic) cm^{-1}; NMR (60 MHz) (dimethyl sulfoxide-d_6): δ 3.75 (s, 3, CH_3O), 7.22 (*AB*q, 4, J = 9 Hz, ArH), 7.92 (*AB*q, 4, J = 9 Hz, benzoyl ArH), and 9.77 (s, 3, NH_3^+) ppm.

Anal.—Calc. for $C_{14}H_{14}ClN_3O_4$: C, 51.94; H, 4.36; Cl, 10.95; N, 12.98. Found: C, 51.98; H, 4.50; Cl, 10.88; N, 13.01.

N^1-m-*Nitrobenzoyl*-N^1-p-*methoxyphenylhydrazine Hydrochloride* (*X*b)—Compound X*b* was prepared in 99% yield by the method described for X*a*. Recrystallized from absolute ethanol, the product had a melting point of 178–178.4°; IR (KBr): 3000–2250 (NH^+), 1665 (tertiary amide), 1520, and 1340 (NO_2, aromatic) cm^{-1}; NMR (60 MHz) (dimethyl sulfoxide-d_6): δ 3.80 (s, 3, CH_3O), 5.25 (H_2O), 7.26 (q, 4, J = 9 Hz, ArH), and 7.63–8.37 (m, 4, benzoyl ArH) ppm.

Anal.—Calc. for $C_{14}H_{14}ClN_3O_4$: C, 51.94; H, 4.36; Cl, 10.95; N, 12.98. Found: C, 52.19; H, 4.54; Cl, 10.79; N, 13.02.

5-Methoxy-2-methyl-1-(p-*nitrobenzoyl*)-*3-indolylacetic Acid* (*VI*a)—Compound X*a* (9.4 g, 29 mmoles) and levulinic acid (4.3 g, 37 mmoles) were stirred in 17 ml of acetic acid at 65° for 2 hr. The reaction mixture was allowed to stand at room temperature overnight, and the precipitate was collected by filtration. Then the precipitate was washed with 100 ml of water in three portions and dried *in vacuo* overnight. It was recrystallized from a solution of acetone and water. The greenish-yellow powder (8.1 g, 77%) had a melting point of 180–181°; IR (KBr): 1700 (CO_2H), 1670 (C=O, tertiary amide), 1520, and 1350 (NO_2, aromatic) cm^{-1}; NMR (60 MHz) (dimethyl sulfoxide-d_6): δ 2.13 (s, 3, indole-CH_3), 3.60 (s, 2, CH_2CO_2H), 3.73 (s, 3, CH_3O), 6.63 (split d, *ABC*, 1, J = 2.5, 9.0 Hz, indole-6-H), 6.95–7.15 (m, *ABC*, 2, indole-4, 7-H), and 8.11 (*AB*q, 4, J = 9 Hz, benzoyl ArH) ppm.

Anal.—Calc. for $C_{19}H_{16}N_2O_6$: C, 61.95; H, 4.38; N, 7.61. Found: C, 62.04; H, 4.61; N, 7.57.

5-Methoxy-2-methyl-1-(m-*nitrobenzoyl*)-*3-indolylacetic Acid* (*VI*b)—Compound VI*b* was prepared in 76% yield by the method described for VI*a*. The product was recrystallized from acetone in the form of a greenish-yellow powder, mp 191–191.7°; IR (KBr): 1700 (CO_2H), 1670 (C=O, tertiary amide), 1520, and 1350 (NO_2, aromatic) cm^{-1}; NMR (60 MHz) (dimethyl sulfoxide-d_6): 2.23 (s, 3, indole-CH_3), 3.70 (s, 2, CH_2CO_2H), 3.78 (s, 3, CH_3O), 6.72 (split d, *ABC*, 1, J = 2.5, 9.0 Hz, indole-6H), 7.07 (d, *ABC*, 1, J = 9.0 Hz, indole-7H), 7.10 (d, *ABC*, 1, J = 2.5 Hz, indole-4-H), and 7.70–8.67 (m, 4, benzoyl ArH) ppm.

Anal.—Calc. for $C_{19}H_{16}N_2O_6$: C, 61.95; H, 4.38; N, 7.61. Found: C, 62.15; H, 4.65; N, 7.50.

1-(p-*Aminobenzoyl*)-*5-methoxy-2-methyl-3-indolylacetic Acid* (*VII*a)—By means of a Parr hydrogenator, VI*a* (15.0 g, 41 mmoles) in 100 ml of tetrahydrofuran was hydrogenated in the presence of platinum oxide (0.28 g) at 25° for 24 hr. The reaction mixture was filtered with the use of a filtering aid[12], and the solvent was removed by evaporation under reduced pressure. A light-yellow powder was obtained and recrystallized from 95% ethanol. The product was in the form of a milky-colored powder (14.0 g, 94.1%), mp 193.5–194.5°; IR (KBr): 3420, 3340 (NH stretching), 1700 (CO_2H), 1670 (C=O, tertiary amide), and 1650 (NH bending) cm^{-1}; NMR (220 MHz) (dimethyl sulfoxide-d_6): δ 2.28 (s, 3, indole-CH_3), 3.66 (s, 2, CH_2CO_2H), 3.75 (s, 3, CH_3O), 6.3 (s, 2, NH_2), 6.36 (d, 2, J = 9 Hz, benzoyl-*m*-H), 6.43 (split d, *ABC*, 1, J = 2.5, 9.0 Hz, indole-6-H), 6.85 (d, *ABC*, 1, J = 9 Hz, indole-7-H), 6.98 (d, *ABC*, 1, J = 2.5 Hz, indole-4H), and 7.36 (d, 2, J = 9 Hz, benzoyl-*o*-H) ppm.

Anal.—Calc. for $C_{19}H_{18}N_2O_4$: C, 67.44; H, 5.36; N, 8.28. Found: C, 67.32; H, 4.95; N, 8.02.

1-(m-*Aminobenzoyl*)-*5-methoxy-2-methyl-3-indolylacetic Acid* (*VII*b)—Compound VII*b* was obtained in 92.0% yield by the method described for VII*a*. The product was recrystallized from benzene–chloroform in the form of yellowish-white crystals, mp 164–165°; IR (KBr): 3430, 3330 (NH stretching), 1705 (CO_2H), 1665 (C=O, tertiary amide), and 1650 (NH bending) cm^{-1}; NMR (60 MHz) (dimethyl sulfoxide-d_6): δ 2.30 (s, 3, indole-CH_3), 3.66 (s, 2, CH_2CO_2H), 3.78 (s, CH_3O), and 6.60–7.38 (m, 9, NH_2, ArH) ppm.

Anal.—Calc. for $C_{19}H_{18}N_2O_4$: C, 67.44; H, 5.36; N, 8.28. Found: C, 67.05; H, 5.36; N, 7.93.

1-(p-*Bromoacetamidobenzoyl*)-*5-methoxy-2-methyl-3-indolylacetic Acid* (*II*) (*Method A*)—Bromoacetic anhydride (0.80 g, 2.9 mmoles) in 20 ml of anhydrous acetone was added all at once to a solution of VII*a* (1.0 g, 2.9 mmoles) in 80 ml of anhydrous acetone. The reaction mixture was stirred at room temperature for 20 hr. On evaporating the solvent under reduced pressure, a milky-colored solid was collected. The product was obtained from aqueous ethanol as a white powder (1.2 g, 90%), mp 208°; IR (KBr): 3440 (NH), 1710 (CO_2H), 1680 (C=O, secondary amide), and 1670 (C=O, tertiary amide) cm^{-1}; NMR (220 MHz) (dimethyl sulfoxide-d_6): δ 2.25 (s, 3, indole-CH_3), 3.66 (s, 2, CH_2CO_2H), 3.75 (s, 3, CH_3O), 4.08 (s, 2, $COCH_2Br$), 6.70 (split d, *ABC*, 1, J = 2.5, 9.0 Hz, indole-6-H), 6.85 (d, *ABC*, 1, J = 9.0 Hz, indole-7-H), 7.01 (d, *ABC*, 1, J = 2.5 Hz, indole-4-H), and 7.70 (*AB*q, 4, J = 9.0 Hz, benzoyl ArH) ppm.

Anal.—Calc. for $C_{21}H_{19}BrN_2O_5$: C, 54.91; H, 4.17; Br, 17.40; N, 6.10. Found: C, 54.78; H, 4.36; Br, 17.00; N, 5.87.

1-(p-*Bromoacetamidobenzoyl*)-*5-methoxy-2-methyl-3-indolylacetic Acid* (*II*) (*Method B*)—Bromoacetyl bromide was used in place of the anhydride, giving II identical with that obtained by Method A but in lower yield. A considerable quantity of the hydrobromide salt of VII*a* formed, from which VII*a* was recovered on treatment with potassium bicarbonate followed by extraction with chloroform. Attempts to protect VII*a* from salt formation by carrying out the reaction in the presence of triethylamine failed to yield any II.

1-(m-*Bromoacetamidobenzoyl*)-*5-methoxy-2-methyl-3-indolylacetic Acid* (*IV*)—Compound IV was prepared in 77.6% yield from VII*b* by Method A. The product was recrystallized from benzene–chloroform in the form of a milky-colored powder, mp 130°; IR (KBr): 3440 (NH), 1710 (CO_2H), 1680 (C=O, secondary amide), and 1670 (C=O, tertiary amide) cm^{-1}; NMR (60 MHz) (dimethyl sulfoxide-d_6): δ 2.25 (s, 3, indole-CH_3), 3.67 (s, 2, CH_2CO_2H), 3.78 (s, 3, CH_3O), 4.05 (s, 2, $COCH_2Br$), 6.77–7.13 (m, 3, indole-H), and 7.40–7.95 (m, 4, benzoyl ArH) ppm.

Anal.—Calc. for $C_{21}H_{19}BrN_2O_5$: C, 54.91; H, 4.17; N, 6.10. Found: C, 54.73; H, 4.37; N, 5.93.

1-(p-*Acetamidobenzoyl*)-*5-methoxy-2-methyl-3-indolylacetic Acid* (*III*)—Compound III was prepared in 87.5% yield from VII*a* and acetic anhydride by Method A. Recrystallized from benzene–chloroform, the product had a melting point of 210°; IR (KBr): 3440 (NH), 1710 (CO_2H), 1670 (C=O, secondary amide), and 1650 (C=O, tertiary amide) cm^{-1}; NMR (60 MHz) (dimethyl sulfoxide-d_6): δ 2.05 (s, 3, $COCH_3$), 2.20 (s, 3, indole-CH_3), 3.64 (s, 2, CH_2CO_2H), 3.75 (s, 3, CH_3O), 6.67 (m, 1, indole-

[12] Hyflo Super Cel, Fisher Scientific Co., Fair Lawn, N.J.

6-H), 6.77 (m, 1, indole-7-H), 6.93 (m, 1, indole-4-H), and 7.65 (*AB*q, 4, benzoyl ArH) ppm; pKa 4.11.

Anal.—Calc. for $C_{21}H_{20}N_2O_5$: C, 66.30; H, 5.30; N, 7.37. Found: C, 66.25; H, 5.38; N, 7.31.

1-(m-Acetamidobenzoyl)-5-methoxy-2-methyl-3-indolylacetic Acid (V)—Compound V was prepared in 77.8% yield from VII*b* and acetic anhydride by Method A. Recrystallized from benzene–chloroform, the product had a melting point of 135°; IR (KBr): 3440 (NH), 1710 (CO_2H), 1670 (C=O, secondary amide), and 1650 (C=O, tertiary amide) cm^{-1}; NMR (60 MHz) (dimethyl sulfoxide-d_6): δ 2.07 (s, 3, $COCH_3$), 2.25 (s, 3, indole-CH_3), 3.67 (s, 2, CH_2CO_2H), 3.80 (s, 3, CH_3O), 6.63–7.13 (m, 3, indole-H), and 7.33–7.97 (m, 4, benzoyl ArH) ppm.

Anal.—Calc. for $C_{21}H_{20}N_2O_5$: C, 66.30; H, 5.30; N, 7.37. Found: C, 65.80; H, 5.34; N, 7.29.

Reactivity of II and IV toward L-Tryptophan—L-Tryptophan was shaken at 37° for 24 hr with an equimolar quantity of II or IV in 67 m*M* phosphate buffer (pH 7.4). TLC revealed no products of reaction between either II or IV and L-tryptophan.

Rectal Absorption of Nitrofurantoin

EUGENE L. PARROTT ˣ and LLOYD E. MATHESON, Jr.

Abstract □ The absorption in humans of nitrofurantoin from seven suppository bases was studied using urinary excretion measurements. Rectal absorption was poorer than GI absorption. The administration of 400 mg of nitrofurantoin in a polyethylene glycol–polysorbate 80 suppository base and in a polyethylene glycol–silica suppository base provided an adequate urinary concentration of nitrofurantoin. Persons who cannot tolerate orally administered nitrofurantoin due to gastric upset could receive nitrofurantoin therapy rectally.

Keyphrases □ Nitrofurantoin—rectal absorption, effect of various suppository bases, humans □ Absorption, rectal—nitrofurantoin, effect of various suppository bases, humans □ Antibacterials, urinary—nitrofurantoin, rectal absorption, effect of various suppository bases, humans

Nitrofurantoin is an antibacterial agent used widely in the treatment of urinary tract infections (1). Between 30 and 50% of an oral or intravenous dose can be recovered intact from the urine (2). The efficacy of nitrofurantoin depends on attaining an adequate concentration of drug in the urine.

Patients receiving nitrofurantoin may exhibit emesis and be deprived of an effective medication. Macrocrystals of nitrofurantoin improved GI tolerance without interfering with clinical efficacy (3). An optimal average crystal size of 150 mesh (80–200-mesh size fraction) reduced the incidence of emesis while still permitting ample urinary excretion for efficacy (4). The larger crystals dissolved more slowly than the smaller crystals and, since dissolution is the rate-limiting step for slightly soluble drugs, nitrofurantoin absorption was slower.

The purpose of this study was to investigate the rectal absorption of nitrofurantoin and to determine if nitrofurantoin could be administered in a suppository to per-

6-H), 6.77 (m, 1, indole-7-H), 6.93 (m, 1, indole-4-H), and 7.65 (*AB*q, 4, benzoyl ArH) ppm; pKa 4.11.

Anal.—Calc. for $C_{21}H_{20}N_2O_5$: C, 66.30; H, 5.30; N, 7.37. Found: C, 66.25; H, 5.38; N, 7.31.

1-(m-Acetamidobenzoyl)-5-methoxy-2-methyl-3-indolylacetic Acid (V)—Compound V was prepared in 77.8% yield from VII*b* and acetic anhydride by Method A. Recrystallized from benzene–chloroform, the product had a melting point of 135°; IR (KBr): 3440 (NH), 1710 (CO_2H), 1670 (C=O, secondary amide), and 1650 (C=O, tertiary amide) cm^{-1}; NMR (60 MHz) (dimethyl sulfoxide-d_6): δ 2.07 (s, 3, $COCH_3$), 2.25 (s, 3, indole-CH_3), 3.67 (s, 2, CH_2CO_2H), 3.80 (s, 3, CH_3O), 6.63–7.13 (m, 3, indole-H), and 7.33–7.97 (m, 4, benzoyl ArH) ppm.

Anal.—Calc. for $C_{21}H_{20}N_2O_5$: C, 66.30; H, 5.30; N, 7.37. Found: C, 65.80; H, 5.34; N, 7.29.

Reactivity of II and IV toward L-Tryptophan—L-Tryptophan was shaken at 37° for 24 hr with an equimolar quantity of II or IV in 67 m*M* phosphate buffer (pH 7.4). TLC revealed no products of reaction between either II or IV and L-tryptophan.

Rectal Absorption of Nitrofurantoin

EUGENE L. PARROTT ˣ and LLOYD E. MATHESON, Jr.

Abstract □ The absorption in humans of nitrofurantoin from seven suppository bases was studied using urinary excretion measurements. Rectal absorption was poorer than GI absorption. The administration of 400 mg of nitrofurantoin in a polyethylene glycol–polysorbate 80 suppository base and in a polyethylene glycol–silica suppository base provided an adequate urinary concentration of nitrofurantoin. Persons who cannot tolerate orally administered nitrofurantoin due to gastric upset could receive nitrofurantoin therapy rectally.

Keyphrases □ Nitrofurantoin—rectal absorption, effect of various suppository bases, humans □ Absorption, rectal—nitrofurantoin, effect of various suppository bases, humans □ Antibacterials, urinary—nitrofurantoin, rectal absorption, effect of various suppository bases, humans

Nitrofurantoin is an antibacterial agent used widely in the treatment of urinary tract infections (1). Between 30 and 50% of an oral or intravenous dose can be recovered intact from the urine (2). The efficacy of nitrofurantoin depends on attaining an adequate concentration of drug in the urine.

Patients receiving nitrofurantoin may exhibit emesis and be deprived of an effective medication. Macrocrystals of nitrofurantoin improved GI tolerance without interfering with clinical efficacy (3). An optimal average crystal size of 150 mesh (80–200-mesh size fraction) reduced the incidence of emesis while still permitting ample urinary excretion for efficacy (4). The larger crystals dissolved more slowly than the smaller crystals and, since dissolution is the rate-limiting step for slightly soluble drugs, nitrofurantoin absorption was slower.

The purpose of this study was to investigate the rectal absorption of nitrofurantoin and to determine if nitrofurantoin could be administered in a suppository to per-

sons who otherwise would be deprived of nitrofurantoin therapy because of GI intolerance.

EXPERIMENTAL

Dosage Forms—Nitrofurantoin[1] was classified by a sonic sifter[2], and the 230–325-mesh size fraction (53 μm) was used throughout the experiment. Two hundred milligrams of nitrofurantoin without excipients was placed in a No. 2 gelatin capsule.

The formulations for the suppositories are given in Table I. The suppositories were prepared by the cold compress method[3] when feasible; suppositories containing polyethylene glycols were prepared by the fusion method. For Formula L, the powder to be incorporated into the suppository base was prepared by dissolving the nitrofurantoin in alcohol, suspending the silica in the liquid, and evaporating the solvent in a stream of air. The solid, which consisted of 20% silica and 80% nitrofurantoin, was then passed through a 100-mesh screen (5).

The percent of nitrofurantoin dissolved from the dosage form was determined using the USP disintegration apparatus. The dosage form was placed in the apparatus and held in a single glass cylinder by means of plastic tubing bent in the upper end of the cylinder to prevent the escape of the dosage form. The disintegration apparatus operated in 16 liters of distilled water at 37° contained in a 30 × 30-cm cylindrical jar. Samples were removed by a pipet fitted with a sintered-glass filter. The samples were analyzed, and the percent dissolved at each interval of time was calculated (Fig. 1).

Table II—Dosage Forms Administered to Subjects

Subject	Dosage
EP	400 mg po; 400 mg in five suppository bases (T, L, C, B, and D); 65 mg po
RW	400 mg po; 400 mg in two suppository bases (T and B-7)
SB	400 mg po; 400 mg in two suppository bases (T and B-7)
MS	400 mg po; 400 mg in two suppository bases (T and B)
SK	400 mg po; 400 mg in two suppository bases (K and B)
KS	400 mg po; 400 mg in two suppository bases (L and B-7)
TI	400 mg po; 400 mg in two suppository bases (L and B)

Analytical Method—The analysis of the urine samples was carried out by the method of Conklin and Hollifield (6) on the day of collection. To protect the nitrofurantoin from light, amber glassware was used.

Protocol—Seven healthy male human subjects, 25–51 years old and 62–77 kg, were studied. Four hundred milligrams of nitrofurantoin in gelatin capsules was administered orally after arising and voiding the bladder. Subjects were ambulatory and ingested food as desired. It was recommended that a minimum of 150 ml of water be ingested hourly.

Urine samples were collected at 1-hr intervals for 14 hr. Volumes were measured, and aliquots were retained in amber vials for analysis. The pH of the urine was determined at the time of each sample collection and ranged from 5 to 7.5. No attempt was made to control the urinary pH.

After 1 week, a suppository containing the same dose of nitrofurantoin was administered rectally, and the urine samples were collected according to the protocol. All suppositories were identified by code, and the drug was not identified for the subjects. After another week, a suppository containing the same dose of nitrofurantoin in a different suppository base was administered rectally, and the urine samples were collected according to the protocol. Each subject served as his control in the comparison of the urinary excretion of the drug from the oral and rectal administrations. Subjects received nitrofurantoin according to the schedule of dosage forms given in Table II.

RESULTS AND DISCUSSION

For the seven subjects, the fraction of the 400-mg oral dose of nitrofurantoin recovered in the urine in 24 hr ranged from 0.22 to 0.54, with

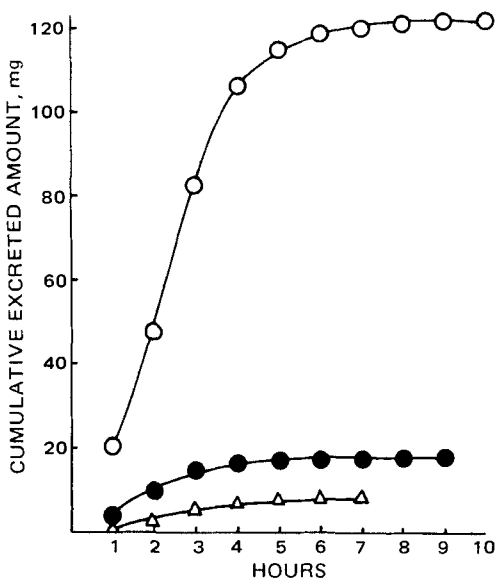

Figure 2—*Cumulative amount of nitrofurantoin excreted in the urine after oral and rectal administrations as a function of time. Key: ○, 400 mg po in a capsule; ●, 65 mg po in a capsule; and △, 400 mg rectally in theobroma oil.*

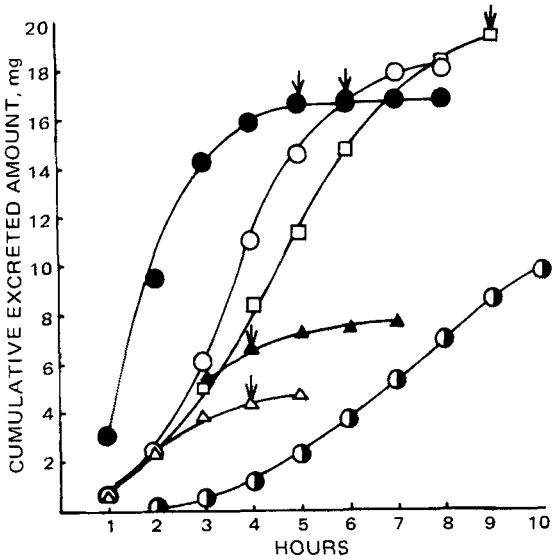

Figure 3—*Cumulative amount of nitrofurantoin excreted in the urine of Subject EP after oral and rectal administrations as a function of time. Key: ↓, latest urine sample having a concentration exceeding 1:100,000; ●, 65 mg po in a capsule; ○, polyethylene glycol–polysorbate 80; □, polyethylene glycol–silica; △, polyethylene glycol–sodium bicarbonate; ▲, theobroma oil; and ◑, sorbitan monostearate–glyceryl monolaurate.*

an average of 0.39. Nitrofurantoin is bacteriostatic in concentrations as low as 1:100,000–1:200,000 (7). A nitrofurantoin concentration of approximately 30 μg/ml (1:40,000) reportedly will eradicate at least 90% of the strains of *Escherichia coli* (8). In the seven subjects studied, the concentration of nitrofurantoin exceeded 1:40,000 for 7–9 hr, with an average of 8.6 hr, after a single oral administration of 400 mg of nitrofurantoin.

Nitrofurantoin frequently causes nausea and/or emesis. In this study, the administration of a single oral 400-mg dose of nitrofurantoin caused gastric upset in four of eight subjects (one subject withdrew). Rectal administration of 400 mg of nitrofurantoin provided poor absorption (Fig. 2); however, even though the fraction of the dose recovered in the urine was 0.02, the concentration of the nitrofurantoin in the urine exceeded 1:100,000 for 4 hr after insertion of the suppository. This result suggested that the administration of a large dose (400 mg) in a suitable suppository base might provide an adequate bacteriostatic concentration in the urine without gastric upset from three or four daily insertions.

In the preliminary stage, five suppository bases were used to administer 400 mg of nitrofurantoin rectally to Subject EP. The cumulative amount excreted and the concentration in the urine were compared to the amount

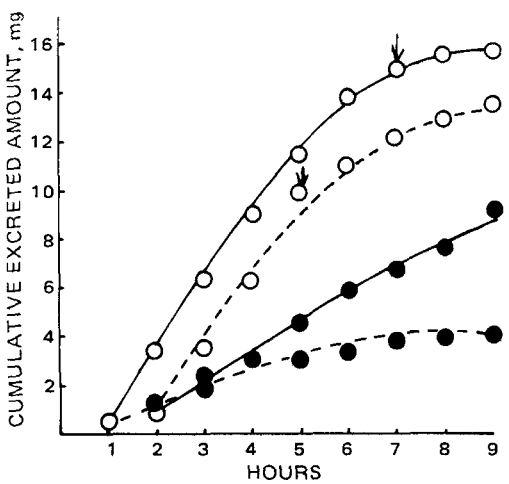

Figure 4—*Comparison of effect of suppository formulation on cumulative amount of nitrofurantoin excreted. Key: ↓, latest urine sample having a concentration exceeding 1:100,000; ○, polyethylene glycol–polysorbate 80; ●, polyethylene glycol; —, Subject RW; and - - -, Subject SB.*

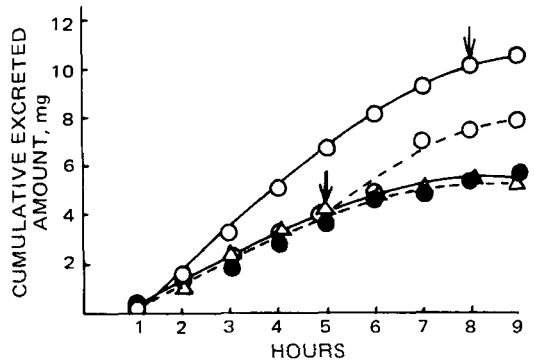

Figure 5—*Comparison of effect of suppository formulation on cumulative amount of nitrofurantoin excreted. Key: ↓, latest urine sample having a concentration exceeding 1:100,000; ○, polyethylene glycol–silica; ●, polyethylene glycol; △, theobroma oil; —, Subject KS; and - - -, Subject TI.*

and concentration after the administration of 65 mg of nitrofurantoin orally (Fig. 3). Formulas B, C, and D were unsatisfactory. Formulas L and T provided approximately 5% recovery of the administered dose in the urine, with the maximum amount released in the 4th hr of urine collection. The concentration of nitrofurantoin in the urine was 1:32,000 in the 6-hr collection with the polyethylene glycol–polysorbate 80 base (Formula T) and 1:34,000 in the 9-hr collection with the polyethylene glycol–silica base (Formula L).

For Subjects RW and SB 9 hr after administration, 1.7 and 3.3 times as much nitrofurantoin were eliminated in the urine from Formula T as from the polyethylene glycol base (Formula B-7) (Fig. 4), respectively. The amount of nitrofurantoin absorbed from the polyethylene glycol base was not sufficient to provide a bacteriostatic concentration. The amount of nitrofurantoin absorbed from the polyethylene glycol–polysorbate 80 base provided a concentration exceeding 1:100,000 until at least the 5th hr after insertion in Subjects EP, RW, and SB.

The volume of fluid in the rectum is only several milliliters. As a consequence of the limited fluid and the very slight solubility of nitrofurantoin, only a small part of the 400 mg administered rectally is dissolved. Thus, the apparently poor rectal absorption of nitrofurantoin is probably due to the severe restrictions on dissolution of the drug from the suppository base. The addition of a surface-active agent to a dosage form containing a hydrophobic drug often increases dissolution (9–12). With Formula T, polysorbate 80 reduced interfacial tension and thereby promoted wetting and/or deaggregation of nitrofurantoin.

For Subject KS 9 hr after administration, 1.8 times as much nitrofurantoin was eliminated in the urine from the polyethylene glycol–silica base (Formula L) as from the polyethylene glycol base (Formula B-7) (Fig. 5). With the latter, the concentration of nitrofurantoin in the urine exceeded 1:40,000 for only 1 hr. The concentration exceeded 1:40,000 for 6 hr after the insertion of a polyethylene glycol–silica base suppository. A similar elimination pattern is shown in Fig. 3. For Subject TI 9 hr after administration, 1.5 times as much nitrofurantoin was eliminated in the urine from Formula L as from the theobroma oil base (Formula B) suppository (Fig. 5).

If a hydrophobic drug is dispersed by means of a volatile organic solvent onto the surface of fumed silicon dioxide and then the mixture is dried, the resulting small size of the drug and the concomitant increase in surface area greatly increase the surface available for contact with the dissolution medium. Thus, adsorbents facilitate the dissolution process of relatively insoluble drugs (5).

In Subject MS, the amount of nitrofurantoin eliminated in the urine

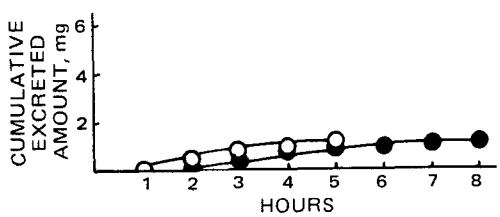

Figure 6—*Comparison of effect of suppository formulation on cumulative amount of nitrofurantoin excreted in Subject MS. Key: ○, polyethylene glycol–polysorbate 80; and ●, theobroma oil.*

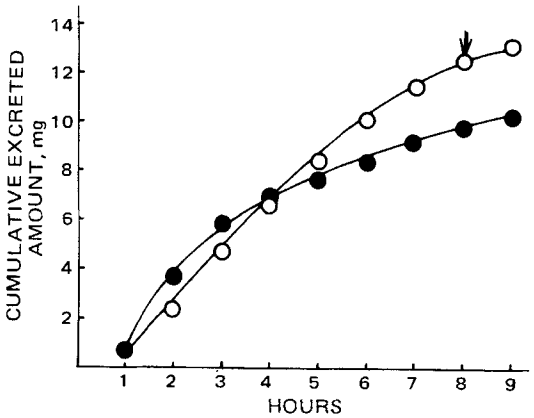

Figure 7—*Comparison of effect of suppository formulation of cumulative amount of nitrofurantoin excreted in Subject SK. Key: ○, lecithin and dried whey product; and ●, theobroma oil.*

from Formula T was greater than that from Formula B (Fig. 6); however, in this subject, both bases provided an adequate bacteriostatic concentration in the urine.

The amount of nitrofurantoin released from Formula D (Fig. 3) was so small that further investigation was not attempted.

Formula K provided a slightly greater amount of nitrofurantoin in the urine than the theobroma oil base suppository (Fig. 7). The dissolution profile of the theobroma oil base suppository suggested poor bioavailability, which was confirmed by *in vivo* data. In water at body temperature, the nitrofurantoin–theobroma oil suppository melted and formed a tacky mass from which the nitrofurantoin was slowly dissolved. With the limited fluid in the rectum, dissolution of the nitrofurantoin from the tacky mass was a very slow process. By mixing a lecithin and dried whey product with theobroma oil, it was hoped that the surface activity of the lecithin and the water solubility of the whey might enhance nitrofurantoin release. In measuring the dissolution profile, it was noticed that the mass was not tacky and that the release was slightly faster. Similarly, in the *in vivo* test, the amount of nitrofurantoin eliminated in the urine was slightly greater than that from the theobroma oil base.

SUMMARY

The usual adult dose of nitrofurantoin is 50–100 mg four times a day. If doses of nitrofurantoin several times the usual oral dose are administered with the same frequency rectally, adequate concentration of nitrofurantoin in the urine is attained. In this preliminary investigation, 400 mg of nitrofurantoin administered in a polyethylene glycol–polysorbate 80 suppository base and in a polyethylene glycol–silica suppository base provided an adequate concentration in the urine. Persons who exhibit nausea and emesis after oral administration of nitrofurantoin possibly could receive nitrofurantoin therapy by the rectal route.

Electronic Absorption Spectra and Protolytic Equilibria of Doxorubicin: Direct Spectrophotometric Determination of Microconstants

ROY J. STURGEON [*] and STEPHEN G. SCHULMAN [*x]

Abstract □ The ground- and excited-state dissociation constants and the electronic absorption and fluorescence spectra of doxorubicin were investigated by spectrophotometry. A general method for the direct calculation of individual microscopic dissociation constants was derived using the spectrophotometric data obtained. It was concluded that the protonated amino sugar group is slightly more acidic than the phenolic group. The spectrophotometric data were analyzed, and the macro- and microconstants for the various equilibria are reported.

Keyphrases □ Doxorubicin—electronic absorption and fluorescence spectrophotometric determination of dissociation constants and protolytic equilibria □ Spectrophotometry, electronic absorption and fluorescence—determination, doxorubicin dissociation constants and protolytic equilibria □ Dissociation constants—doxorubicin, electronic absorption and fluorescence spectrophotometric determination □ Protolytic equilibria—doxorubicin, electronic absorption and fluorescence spectrophotometric determination □ Antineoplastic agents—doxorubicin, electronic absorption and fluorescence spectrophotometric determination of dissociation constants and protolytic equilibria

Molecules containing a quinone moiety have been widely employed in trace analysis, dye manufacturing, and metal–ligand binding. In pharmaceutical applications, molecules such as the naphthoquinones (1) and the anthraquinones have shown promise as antifungal and antibacterial agents. Of more recent importance is the use of

anthracycline antibiotics to treat carcinomas (2–4). The anthracyclines contain the anthraquinone nucleus linearly fused to a saturated six-membered ring.

Several fluorometric procedures for the analysis of doxorubicin have been reported (5–7), but little information is available about its acid–base properties and electronic absorption spectra. To obtain information of analytical, biological, and photochemical interest, it is desirable to know accurately in what prototropic form doxorubicin occurs in various media. Such studies are a necessary prerequisite to the spectrometric interpretation of the interactions of doxorubicin with biologically significant macromolecules such as proteins and nucleic acids.

EXPERIMENTAL

Reagents—Doxorubicin[1] was used without further purification.

Analytical reagent grade sulfuric acid[2] was diluted with distilled, deionized water for the solutions used to study the Hammett acidity region (8). Solutions in the pH range were citrate and phosphate buffers and sodium hydroxide solutions in distilled, deionized water.

Each sulfuric acid or buffer solution, in a 10-ml volumetric flask, was injected with 100 μl of a 4.4×10^{-4} *M* stock solution of doxorubicin in a mixed solvent of 10% (v/v) ethanol and 90% distilled, deionized water immediately prior to the taking of spectra to minimize decomposition errors. The tendency of doxorubicin to self-aggregate at higher concentrations dictated the low concentrations ($\sim 4 \times 10^{-6}$ *M*) employed.

Apparatus—Absorption spectra were taken on a spectrophotometer[3]. Fluorescence spectra were taken on a fluorescence spectrophotometer[4] whose monochromators were calibrated against the emission spectrum from a low-pressure mercury lamp and whose output was uncorrected for wavelength variable instrumental response. The pH measurements were made on a pH meter[5] employing a silver–silver chloride–glass combination electrode[6].

pK_{NA}	10.10
$\frac{[N]}{[Z]}$	6.27 ± 0.02
pK_4	13.2 ± 0.2

Calculations of macro- and microconstants were made employing three analytical wavelengths in the 465–495-nm region, where the molar absorptivity of the phenolate form is minimal compared to the undissociated phenolic form. Within experimental error, the results reported are independent of the wavelength selected.

RESULTS AND DISCUSSION

The electronic absorption and fluorescence spectra of doxorubicin and its various prototropic forms are shown in Figs. 1 and 2, respectively. The maxima along with the corresponding molar absorptivities (log ϵ) of the various species are presented in Table I.

To establish the optimal pH region for the analysis of aqueous solutions of doxorubicin, the ground-state dissociation constants (pKa) for the various prototropic species must be known. The pKa values (Table II) were determined for the dissociation in concentrated sulfuric acid of a proton from a protonated carbonyl group and for the dissociations in alkaline media of a protonated alkyl amino group and two phenolic groups, as shown in Scheme I. The pK_{CN} corresponds to the equilibrium between the singly charged cation and the neutral species; pK_{CZ} corresponds to the equilibrium between the singly charged cation and the zwitterionic species; pK_{AZ} corresponds to the equilibrium between the zwitterion and the singly charged anion, and pK_{NA} corresponds to the equilibrium between the neutral species and the singly charged anion.

In concentrated sulfuric acid, one of the three carbonyl groups of doxorubicin is protonated, the molecule existing as a dication (D). Dissociation of the protonated carbonyl group results in a blue shift of the long wavelength absorption maximum, from which the pKa of −5.9 may be calculated. The only species significantly present in the region between Hammett acidity −4.0 and pH 7.0 is the singly charged species with the positive charge at the amino sugar group. However, at a pH greater than 7.0, this monocation (C) can lose a proton either from a phenolic group to form a zwitterion (Z) or from the amino sugar group to form the neutral species (N). Either may then lose a proton to form the singly charged anion (A^-).

Doxorubicin, like numerous other drugs, contains several ionizable functions, including some of similar acidity. Therefore, overlapping

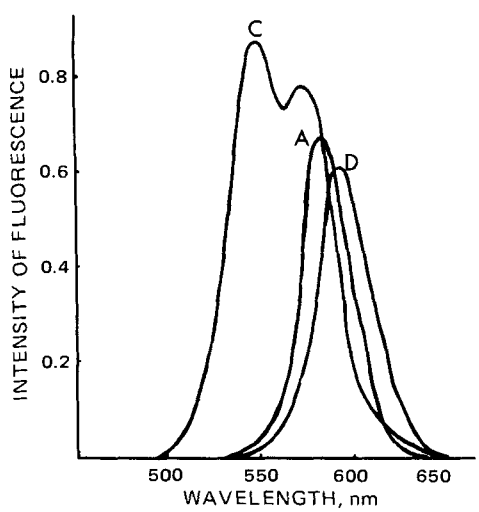

Figure 2—*Fluorescence spectra of doxorubicin as the monocation (C), doubly charged cation (D), and singly charged anion (A).*

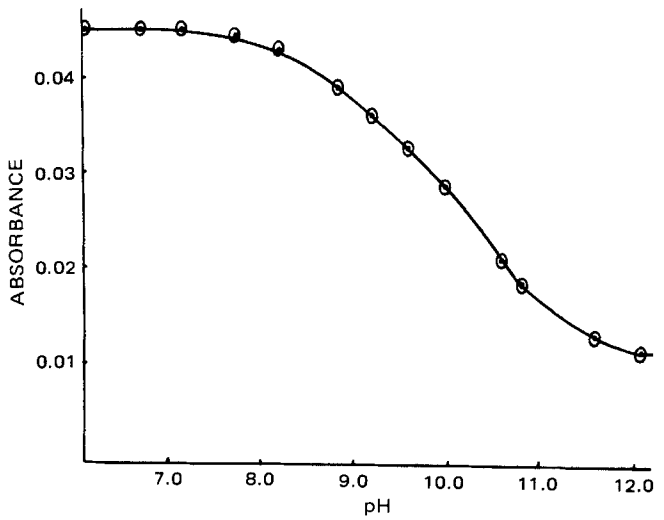

Figure 3—*Plot of absorbance at 495 nm* versus *pH for* 4.4×10^{-6} M *doxorubicin in the pH 7–12 range.*

protolytic equilibria are possible. In doxorubicin, the amino sugar group and a phenolic group both ionized in the pH region from 8 to 13. To calculate accurately the corresponding dissociation constants, the effects of the dissociations on the electronic absorption spectra must be followed carefully. Because the amino group of the amino sugar moiety is several atoms removed from the aromatic chromophore of doxorubicin, electrometric or inductive influences, due to the free or protonated amino group, upon the electronic spectrum of doxorubicin are negligible. Thus, only the dissociation of the phenolic group affects the spectrometric properties of the molecule in alkaline solutions. However, the competing protolytic equilibria involving the amino sugar group affect the rate of appearance of the various spectrometric species of doxorubicin during the pH titration.

While following the spectrometric changes resulting from variations in pH of solutions of doxorubicin in the pH 7–12 region, no distinct isosbestic point was observed. The lack of an isosbestic point is indicative of three or more absorbing species present in the solutions. The overlapping successive protolytic equilibria also result in a wider titration interval than would normally be expected if no competition was observed. Figure 3 shows a plot of absorbance *versus* pH for the titration of doxorubicin in the pH 6.0–12.5 range.

Since dissociation of the zwitterion to form the singly charged anion is spectrometrically undetectable, the molar absorptivities (ϵ_λ) of the monocation and neutral species are equal and those of the zwitterion and anion are equal at the analytical wavelength. The total absorbance (A_T) at the analytical wavelength may be written as the sum of the absorbances of the various species present:

$$A_T = A_C + A_Z + A_N + A_{A^-} = \epsilon_C[C]1 + \epsilon_Z[Z]1 + \epsilon_N[N]1 + \epsilon_{A^-}[A^-]1 \quad \text{(Eq. 1)}$$

The individual stages of ionization have microscopic dissociation constants, denoted as K_{CN}, K_{CZ}, K_{ZA^-}, and K_{NA^-} in Scheme I. The macroscopic constants, K_2 and K_3, have the following relation to the microscopic constants:

$$K_2 = K_{CN} + K_{CZ} \quad \text{(Eq. 2)}$$

$$K_3^{-1} = K_{ZA}^{-1} + K_{NA}^{-1} \quad \text{(Eq. 3)}$$

and since the free energy change in going from C to A^- is the same regardless of whether path C → N → A^- or C → Z → A^- is taken:

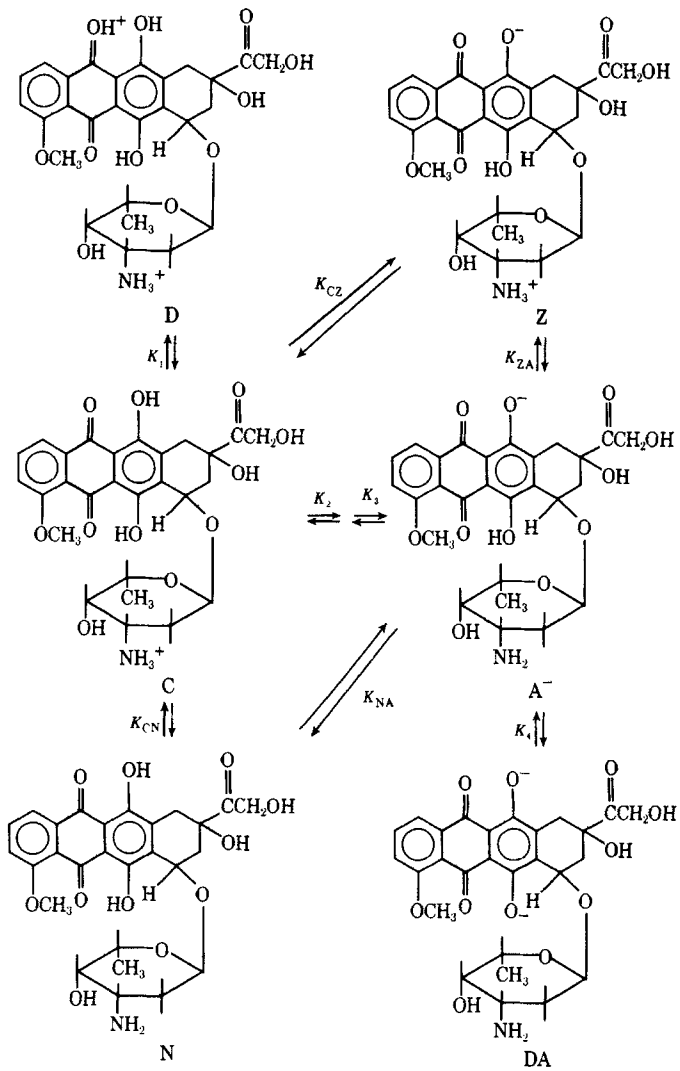
$$K_2K_3 = K_{CN}K_{NA} = K_{CZ}K_{ZA} \quad \text{(Eq. 4)}$$

By letting the sum of the concentrations of the neutral species and zwitterion equal [N′], Eqs. 2–4 may be written as:

$$K_2 = \frac{[H^+][N']}{[C]} \quad \text{(Eq. 5)}$$

$$K_3 = \frac{[A^-][H^+]}{[N']} \quad \text{(Eq. 6)}$$

$$K_2K_3 = \frac{[H^+]^2[A^-]}{[C]} \quad \text{(Eq. 7)}$$



Scheme I

At equilibrium, the mass balance equation states that the sum of the concentrations of all species must equal the total analytical concentration of doxorubicin (C_T):

$$C_T = [C] + [N'] + [A^-] \quad \text{(Eq. 8)}$$

By combining the mass balance equations and the equilibrium expressions, the concentrations of the cation, [C], zwitterion, [Z], neutral, [N], and anion, [A^-], may be written as:

$$[C] = \frac{C_T[H^+]^2}{[H^+]^2 + K_2[H^+] + K_2K_3} \quad \text{(Eq. 9)}$$

$$[N'] = \frac{C_TK_2[H^+]}{[H^+]^2 + K_2[H^+] + K_2K_3} \quad \text{(Eq. 10)}$$

$$[A^-] = \frac{C_TK_2K_3}{[H^+]^2 + K_2[H^+] + K_2K_3} \quad \text{(Eq. 11)}$$

Equation 1 can be rewritten as:

$$A_T = \epsilon_C[C]1 + \epsilon_{N'}[N']1 + \epsilon_{A^-}[A^-]1 \quad \text{(Eq. 12)}$$

Since [N′] is the sum of the concentrations of the neutral and zwitterionic species, $\epsilon_{N'}$ is the expedient molar absorptivity of N′. This ϵ value is essentially a weighted sum of the neutral and zwitterionic molar absorptivities with respect to the fraction of each uncharged species present.

By substituting Eqs. 9–11 into Eq. 12, the following equation results:

$$(A_T - \epsilon_CC_T)[H^+]^2 + (A_T - \epsilon_{N'}C_T)K_2[H^+] + (A_T - \epsilon_{A^-}C_T)K_2K_3 = 0 \quad \text{(Eq. 13)}$$

Equation 13 may now be solved at three different points in the titration

for the values of $\epsilon_{N'}$, K_2, and K_3 (9). With these values (Table II), the microconstants may then be determined. The K_{NZ}, the ratio of the concentration of the neutral species to that of the zwitterionic species, is a constant independent of pH. Since:

$$\epsilon_C[N] + \epsilon_A[Z] = \epsilon_{N'}[N'] \qquad \text{(Eq. 14)}$$

and at 495 nm $\epsilon_{N'}$ is equal to 9.10×10^3 cm^{-1} M^{-1}, the following equation can be used to evaluate K_{NZ}:

$$K_{NZ} = \frac{[N]}{[Z]} = \frac{\epsilon_{N'} - \epsilon_A}{\epsilon_C - \epsilon_{N'}} \qquad \text{(Eq. 15)}$$

Since [N] = 6.27 [Z], Eq. 2 may be solved for K_{CZ} and K_{CN} as follows:

$$K_2 = \frac{6.27[H^+][Z]}{[C]} + \frac{[H^+][Z]}{[C]} = 7.27\,K_{CZ} \qquad \text{(Eq. 16)}$$

Similar substitution into Eq. 3 allows both K_{NA} and K_{ZA} to be calculated.

A similar method for the spectrophotometric evaluation of microconstants involving overlapping equilibria, in which the dissociation of one group affects the absorption spectrum and the other does not, was developed by Edsall *et al.* (10) in studies of the dissociations of tyrosine. This method was applied to the dissociation equilibria of alkanolamines (11). However, the latter approach is somewhat more complicated algebraically than the present one. Moreover, the macroconstants in Edsall's method are calculated from the microconstants. In the present approach, the preliminary evaluation of macroconstants from spectrophotometric data can be checked independently by potentiometry if solubility permits.

The fluorescence spectrum of doxorubicin in the pH region follows the same changes observed in the pH dependence of the absorption spectrum, indicating that protolytic reaction in the excited state is too slow to compete with fluorescence. However, in the Hammett acidity region the fluorescence spectrum of doxorubicin red shifts with increasing acidity in acid solutions more dilute than those in which the corresponding absorption spectral changes occur. This shift is indicative of protonation in the lowest excited singlet state, with the inflection point in the fluorometric titration representing the excited-state dissociation constant (pK*) of −3.1. Doxorubicin becomes more basic in the excited state due to the transfer of charge to a carbonyl group upon excitation.

The method allows the direct calculation of microconstants when overlapping dissociation equilibria are present in a system under spectrometric study. This method is general for any molecule with overlapping equilibria in which dissociation of only one functional group affects the electronic spectral properties of the molecule. The values of the microconstants show that the protonated amino sugar group is slightly more acidic than the phenolic group.

In developing or using any method of analysis for doxorubicin, careful choice of the pH and the analytical wavelength is necessary. The prevalence of only one absorbing species having intense, long wavelength absorption in the pH 4–7 region and one emitting species having intense fluorescence in the pH 1–7 region suggests that the spectrometric analysis of doxorubicin in aqueous solutions be carried out in dilute acidic solutions.

Determination of Energy Change Associated with Dissolution of a Solid

DAVID C. HSIA *, CHONG-KOOK KIM, and DANE O. KILDSIG ˣ

Abstract □ The dissolution of a solid immersed in a solvent was considered as a consecutive process, consisting of a primary surface interaction leading to the production of a new surface at the solid–liquid interface, solvation of the solid at the interface, and transfer of the solvated solid into the bulk of the solution. The energy changes involved in each step were studied for the dissolution of *m*-tolylacetamide in hexane and heptane. An energy diagram was constructed according to the proposed dissolution mechanism. The heats of dissolution determined from the energy diagram agreed well with those obtained experimentally.

Keyphrases □ Solids—dissolution in a solvent, energy changes determined □ Dissolution—solid in a solvent, energy changes determined □ Energy changes—determined for dissolution of a solid in a solvent

Several recent investigations concerned the energy changes involved in the dissolution process. Wadke and Reier (1) presented a rate equation, based on previously published results (2–4), involving both the heat of solution of the solid and the activation energy for diffusion. Szinai and coworkers (5, 6), after reviewing several articles on dissolution, proposed a rate equation incorporating an energy term comprised of the energy required to remove a solute molecule from the solid surface, the energy of solvation, and the activation energy for diffusion. A numerical study of the three energy terms was not reported.

The purpose of this study was to quantify the energy associated with initial solvent–solid interaction, the solvation of the solute, and the mass transfer steps of the dissolution process.

for the values of $\epsilon_{N'}$, K_2, and K_3 (9). With these values (Table II), the microconstants may then be determined. The K_{NZ}, the ratio of the concentration of the neutral species to that of the zwitterionic species, is a constant independent of pH. Since:

$$\epsilon_C[N] + \epsilon_A[Z] = \epsilon_{N'}[N'] \quad \text{(Eq. 14)}$$

and at 495 nm $\epsilon_{N'}$ is equal to 9.10×10^3 cm^{-1} M^{-1}, the following equation can be used to evaluate K_{NZ}:

$$K_{NZ} = \frac{[N]}{[Z]} = \frac{\epsilon_{N'} - \epsilon_A}{\epsilon_C - \epsilon_{N'}} \quad \text{(Eq. 15)}$$

Since [N] = 6.27 [Z], Eq. 2 may be solved for K_{CZ} and K_{CN} as follows:

$$K_2 = \frac{6.27[H^+][Z]}{[C]} + \frac{[H^+][Z]}{[C]} = 7.27\,K_{CZ} \quad \text{(Eq. 16)}$$

Similar substitution into Eq. 3 allows both K_{NA} and K_{ZA} to be calculated.

A similar method for the spectrophotometric evaluation of microconstants involving overlapping equilibria, in which the dissociation of one group affects the absorption spectrum and the other does not, was developed by Edsall *et al.* (10) in studies of the dissociations of tyrosine. Keyphrases □ Solids—dissolution in a solvent, energy changes determined □ Dissolution—solid in a solvent, energy changes determined □ Energy changes—determined for dissolution of a solid in a solvent

Several recent investigations concerned the energy changes involved in the dissolution process. Wadke and Reier (1) presented a rate equation, based on previously published results (2–4), involving both the heat of solution of the solid and the activation energy for diffusion. Szinai and coworkers (5, 6), after reviewing several articles on dissolution, proposed a rate equation incorporating an energy term comprised of the energy required to remove a solute molecule from the solid surface, the energy of solvation, and the activation energy for diffusion. A numerical study of the three energy terms was not reported.

The purpose of this study was to quantify the energy associated with initial solvent–solid interaction, the solvation of the solute, and the mass transfer steps of the dissolution process.

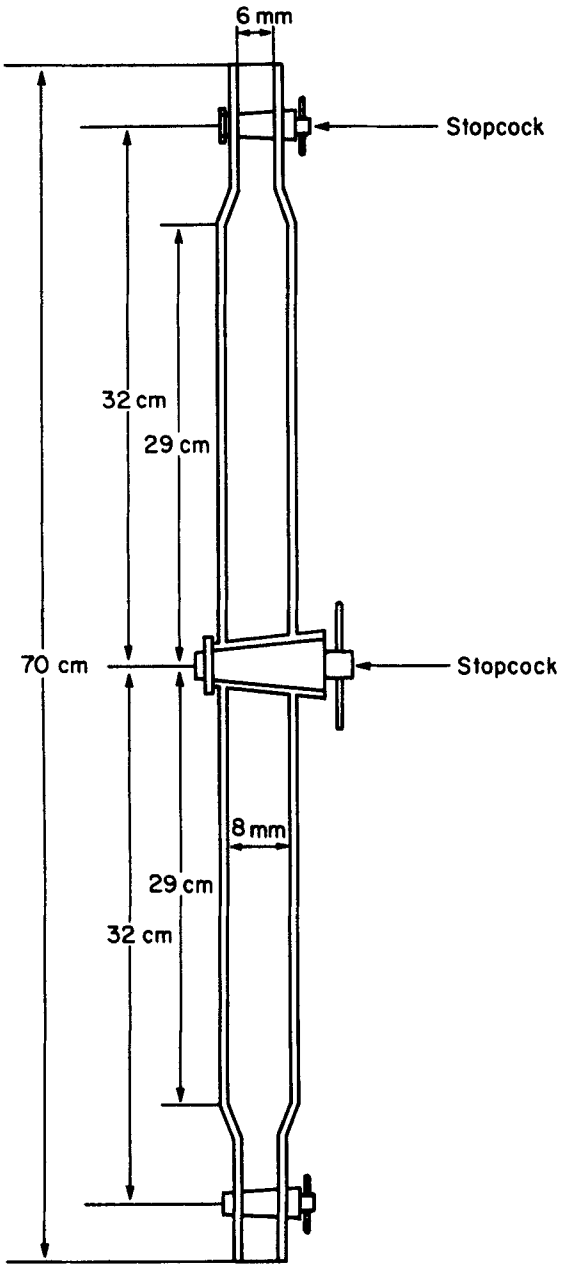

Figure 1—*Diagram of glass dispersion column.*

EXPERIMENTAL

Materials—The solid was *m*-tolylacetamide[1] (I). The solvents used were spectral quality.

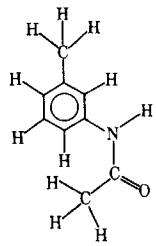
Temperature Dependence of Solubility of I—The solubility of I in hexane and heptane was determined at 14.3–39.9 ± 0.01°. A 300-ml, three-necked, round-bottom flask, containing approximately 20 g of I powder, was put in a constant-temperature water bath at 14.3 ± 0.01°. A stirrer was mounted in the flask, 200 ml of hexane or heptane was added, and the stirring speed was set at 150 rpm.

After 24 hr, a 10-ml sample was taken from the flask and quickly filtered through a 0.45-μm filter. Five milliliters of the filtered solution was diluted in a 250-ml volumetric flask with anhydrous methanol. Duplicate samples were taken each time. The temperature of the water bath was then increased about 5°. After temperature equilibrium was reached in the water bath for 24 hr, another sample was removed, filtered, and diluted as previously described.

The absorbance of each sample was determined at 242 nm with a 1:50 dilution of hexane or heptane in methanol as the reference. A blank was run each time to ensure that the baseline was straight. The absorbance at 242 nm was recorded and converted into concentration through an appropriate calibration curve. The solubility of I in hexane and heptane at the different temperatures was then calculated.

[1] Eastman Kodak Co., Rochester, NY 14605.

Table I—Molecular Structure of *m*-Tolylacetamide



Bond	Bond Length	Group	Geometry	Angle
C=O	1.162	Carbonyl	Planar	120°
C—H	1.09	Methyl	Tetrahedral	109°
C—C	1.54	Alkane	Tetrahedral	109°
N—H	1.038	Amide	Tetrahedral	109°
C=C in benzene	1.39	Benzene	Planar	120°
C—N	1.329	Amide	Tetrahedral	109°

Temperature Dependence of Dissolution Rate of I—The dissolution rate of I in hexane and heptane was determined at 25.0, 29.9, 33.1, and 35.5 ± 0.05° in a constant-temperature chamber (7).

Glass tubes, 45 cm long × 1.65 cm i.d., were flat sealed on one end and employed as dissolution vessels. A stainless steel tablet holder was constructed to fit easily into the dissolution tube without causing bubble formation.

A small amount of I was placed in a casserole, which was then warmed in a water bath at 75°. After the compound was melted, it was poured into a 1.11-cm (7/16-in.) tablet die with a polished, flat-faced punch in place. The cast tablets were removed after solidification, and mottled or chipped tablets were discarded. The punch face was cleaned with anhydrous methanol.

A mixture containing 40% polyethylene glycol 4000 and 60% polyethylene glycol 400 was prepared and carefully applied to the cylindrical surface of the tablet. Care was taken to prevent any of the mixture from contacting the flat surface of the tablet. Solvent, 85 ml, was placed in the dissolution tube and allowed to equilibrate for 8 hr in the controlled temperature chamber. The dissolution tubes were held in a perfect vertical position using a suitable supporting device (8). The tablet was wrapped with aluminum foil and pushed into the tablet holder, which was put through the center of a stopper that sealed the open end of the dissolution tube.

A dissolution run was begun by gently immersing the tablet surface just below the solvent surface. Dissolution was timed for 3 min. The run was stopped by gently removing the tablet holder from the dissolution tube, and the amount dissolved was then determined. Dissolution rate determination was made in triplicate, using a new tablet for each determination. The temperature of the chamber was then increased by 5°, and the dissolution rate was determined at this temperature in the same manner.

Determination of Dispersion Rate—A Pyrex glass column (70 cm long × 8 mm i.d.) was used to measure the dispersion rate of solutions of I in hexane and heptane into the pure solvent (Fig. 1). The column had stopcocks of 2-mm bore at each end and a stopcock with a straight 8-mm bore in the middle.

Dispersion experiments were conducted at 30° in the constant-temperature chamber. The solvent, solution, and column were placed inside the chamber and allowed to equilibrate. The lower stopcock was then closed, and the lower half of the column was filled with solvent to a point above the middle stopcock. Suction was then applied to remove any entrapped air bubbles in the lower column. The middle stopcock was then closed, and the solvent remaining in the upper column was removed. The upper column was then dried with a stream of air.

A series of I solutions in hexane and in heptane were prepared ranging in concentration from 30 to 300 mg/liter. A solution of I was transferred into the upper column while the middle stopcock was still in a closed position. The upper stopcock was then closed, and the entire column was inspected to be certain that no air bubbles were present. Two hours after

Table II—Temperature Dependence of the Solubility of *m*-Tolylacetamide in Hexane and Heptane

Temperature	Solubility in Hexane, mg/liter	Solubility in Heptane, mg/liter
14.3°	294.8	—
19.8°	449.5	—
24.5°	562.4	—
25.7°	—	527.5
29.8°	666.1	—
30.3°	—	688.4
33.8°	758.1	—
35.2°	—	901.0
39.9°	—	1066.9

the column was filled, the middle stopcock was turned to the open position for 3 min and then closed. The upper column was first drained and rinsed with 10 ml of solvent five times. After the upper column was air dried, the middle stopcock was opened to let the liquid inside the stopcock mix with the liquid in the lower column. The solution in the lower column was then removed for assay.

The volumes of the upper and lower (including the stopcock) columns were calibrated with a 50-ml buret and found to be 19.1 ± 0.05 and 20.25 ± 0.05 ml, respectively. From the volume and the final solution concentration in the lower column, the amount of I transferred from the upper column to the lower column and the dispersion rate of I in hexane and heptane were calculated.

Temperature Dependence of Dispersion Rate—The dispersion rates of solutions of I in hexane and heptane into their respective pure solvents were determined at four different temperatures using the same dispersion column and the described method. The concentration of I used in the upper column was that concentration which, during dispersion, transferred to the lower column approximately the same amount of solute as was dissolved from the solid I during the same time period. This concentration was 44.2 mg/liter in hexane and 32.6 mg/liter in heptane. A second concentration, 240 mg/liter in hexane and 265 mg/liter in heptane, was also used to determine if the temperature dependence of the dispersion rate was a function of concentration.

The temperature dependence of the dispersion rate was independent of concentration for the concentrations used. The rates of dispersion, expressed as the amount of solute transferred per minute, were determined by assaying for the amount of I transferred to the lower section of the column.

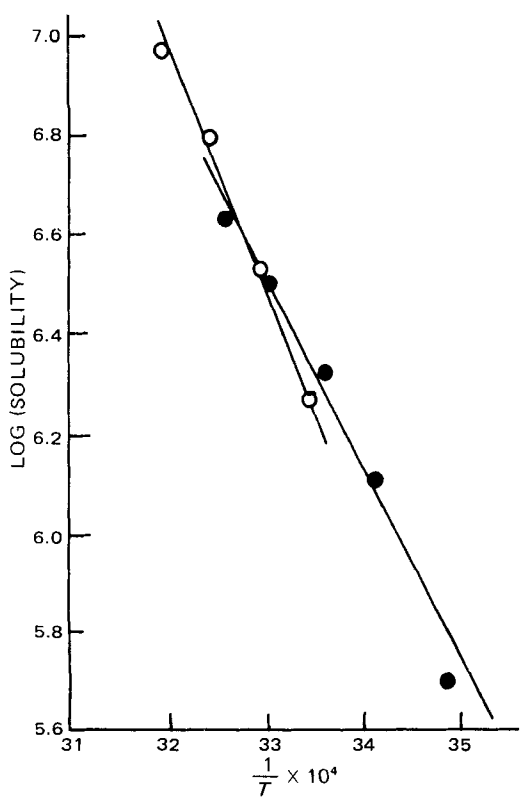


Figure 2—*Temperature dependence of the solubility of I in hexane* (●) *and heptane* (○).

Table III—Temperature Dependence of the Dispersion Rate of *m*-Tolylacetamide in Hexane and Heptane

Temperature	Dispersion Rate in Hexane, μg/min	Dispersion Rate in Heptane, μg/min
27.9°	34.2	23.6
30.0°	36.2	26.4
33.1°	37.9	28.0
35.4°	41.1	29.5

Heat of Fusion—The heat of fusion of I was determined in a differential scanning calorimeter[2] with indium as the standard. Approximately 3 mg of I was weighed to the nearest 0.01 mg on a microbalance[3] into each of five sample holders, which were then sealed. Empty sample holders were used as reference. An indium sample weighing 6.22 mg was used as a standard. The temperature was scanned from 416 to 430 °K for indium and from 316 to 338 °K for I at a rate of 2.5 °C/min. Sharp and symmetric peaks were obtained in each case. The area under the curves was measured with a planimeter.

The calculation of the heat of fusion of I was based on the following equation:

$$\Delta H_1 = \frac{\Delta H_2 A_1 W_2}{A_2 W_1} \qquad \text{(Eq. 1)}$$

where ΔH_1 is the heat of fusion of I, ΔH_2 is the heat of fusion of indium, A_1 is the area under the curve of the sample, A_2 is the area under the curve of indium, W_1 is the weight of the sample, and W_2 is the weight of indium.

RESULTS AND DISCUSSION

Determination of Energy Involved in Each Dissolution Step—Three fundamental processes contribute to the dissolution of a solid immersed in a solvent, regardless of the mechanism by which dissolution is thought to occur (Scheme I). The three processes are: (*a*) the primary surface interaction leading to the continual production of a new surface at the solid–liquid interface, (*b*) solvation of the solid at the solid surface or solid–liquid interface, and (*c*) mass transfer of the dissolved solid into the bulk of the solution. The slowest process determines the dissolution mechanism. The first two steps are interfacial interactions between the solid and the solvent, which are related to interfacial energy and the solid lattice energy. In Step 3, the mass transfer process, solvated solid is brought into the bulk of the solution by diffusion and/or convection.

$$\text{solid} \xrightarrow[\Delta E_1]{\text{surface interaction}} \text{solvent} \cdots \text{solid} \xrightarrow[\Delta E_2]{\text{solvation}} \text{solvated solid at solid surface} \xrightarrow[\Delta E_4]{\text{mass transfer}} \text{solution}$$

Scheme I

The energy required to produce a new surface or to remove a molecule from the surface of a solid, ΔE_1, is equal to the product of the interfacial tension between the solid and the solvent and the surface area of the solid or:

$$\Delta E_1 = \gamma_{SL}\, \Delta A \qquad \text{(Eq. 2)}$$

where ΔA represents the exposed surface area of a mole of solid, and γ_{SL} is the interfacial tension. The literature values of γ_{SL} for I in hexane and heptane are 3.9 and 7.6 dynes/cm, respectively. The value of ΔA for I can be calculated from its molecular structure. The calculation is made possible through a knowledge of the bond lengths and bond angles (Table I), the fact that the benzene ring and acetyl group are planar, and the assumption that the methyl group is spherical. The surface area of I calculated from the molecular structure, based on a two-dimensional planar projection and the assumption that both sides of the molecule interact with the solvent, is 47.08 A^2 or 2.83 × 10^9 cm^2/mole. The ΔE_1 values for I in hexane and heptane calculated from Eq. 2 are 0.26 and 0.51 kcal/mole, respectively.

The heat of solvation consists of two energy terms. The first, ΔE_2, is the energy required to break the solid lattice energy and is equal to the

Table IV—Energy Terms Involved in Each Step of the Dissolution of *m*-Tolylacetamide in Hexane and Heptane

Solvent	ΔE_1 ($\Delta E_{wetting}$), kcal/mole	ΔE_2 (ΔE_{fusion}), kcal/mole	ΔE_3 ($\Delta E_{solvation}$), kcal/mole	ΔE_4 ($\Delta E_{disperson}$), kcal/mole	ΔH_S ($\Delta H_{solution}$), kcal/mole	ΔE_d ($\Delta E_{dissolution}$), kcal/mole (exp)	ΔE_d ($E_{dissolution}$), kcal/mole (calc. from Eq. 7)
Hexane	0.26	4.15	5.61	4.17	10.0	15.9	14.2
Heptane	0.51	4.15	4.63	5.25	9.30	15.3	14.6

heat of fusion of the solid, ΔH_f. The heat of fusion for I determined by differential scanning calorimetry was 4.15 kcal/mole.

The second energy term, ΔE_3, is the energy released or required during solvation. If the interaction energy between the solid and solvent is larger than that between solid molecules, energy is released; if the interaction energy is less than that existing between solid molecules, energy is required. Although ΔE_3 cannot be determined experimentally, it can be calculated from ΔE_1, ΔE_2, and the heat of solution, ΔH_S.

Since the amount of I in the saturated solution in hexane and heptane is relatively small, 602 and 646 mg/liter, respectively, at 30°, the volume change during dissolution may be considered negligible. From the equation:

$$\Delta H_S = \Delta E_S + P\,\Delta V \qquad \text{(Eq. 3)}$$

it can be seen that at constant pressure the heat of solution, ΔH_S, is equal to the energy change in solution, ΔE_S. Then:

$$\Delta H_S = \Delta E_S = \Delta E_1 + \Delta E_2 + \Delta E_3 \qquad \text{(Eq. 4)}$$

The heat of solution, ΔH_S, is the energy difference between two equilibrium states, *i.e.*, the energy of the system before and after the solid is dissolved. This energy term can be obtained from a Van't Hoff plot of the I solubility data (Table II). Figure 2 shows a plot of log (I solubility) as a function of the reciprocal of temperature. From the slope of the line, values of 10.0 and 9.30 kcal/mole were calculated for the heat of solution of I in hexane and heptane, respectively.

From the experimental results of ΔH_S, ΔE_1, and ΔE_2 and Eq. 4, the term ΔE_3 can be obtained such that:

$$\Delta E_3 = \Delta H_S - \Delta E_1 - \Delta E_2 \qquad \text{(Eq. 5)}$$

which yields ΔE_3 = 5.60 kcal/mole for I in hexane and 4.63 kcal/mole for I in heptane. The fact that ΔE_3 has a positive sign shows that energy is required for the solvation step in addition to the heat of fusion.

The activation energy for mass transfer or dispersion is the energy required to transfer the solvated solid from the interfacial region to the bulk of the solution. This energy, ΔE_4, can be determined from the temperature dependence of the liquid–liquid dispersion rate of the I solution into pure solvent (Table III). If it is assumed that the dispersion coefficient is related to temperature in the same manner as the diffusion coefficient, then:

$$D = D_0 e^{-\Delta E_4/RT} \qquad \text{(Eq. 6)}$$

where D is the dispersion coefficient, D_0 is a constant related to the molecular dimensions of the solute, ΔE_4 is the activation energy for dispersion, R is the gas constant, and T is the absolute temperature. Since the dispersion rate is proportional to the dispersion coefficient, an Arrhenius plot may be made of the dispersion rate data as a function of the reciprocal of temperature. Arrhenius-type plots are shown in Fig. 3. From the slope of the lines, values of 4.17 and 5.25 kcal/mole were calculated for ΔE_4 for the systems of I in hexane and heptane, respectively.

The heat of dissolution, ΔE_d, is the energy of activation associated with solid dissolution. This term may also be determined from an Arrhenius plot using the dissolution rate in place of the dispersion rate constant. Figure 4 shows a plot of log (dissolution rate) *versus* the reciprocal of absolute temperature for the dissolution of I in both hexane and heptane. The energies of activation determined from the slope of the lines in Fig. 4, along with the energy terms discussed, are listed in Table IV.

Based on these energy terms, an energy diagram (Fig. 5) can be constructed. From the energy diagram, it can be seen that:

$$\Delta E_d = \Delta E_1 + \Delta E_2 + \Delta E_3 + \Delta E_4 \qquad \text{(Eq. 7)}$$

The activation energy of dissolution, ΔE_d, can then be calculated from Eq. 7 and compared with the value of ΔE_d determined experimentally. This comparison is shown in Table IV.

The comparison between the experimental value of ΔE_d and the value

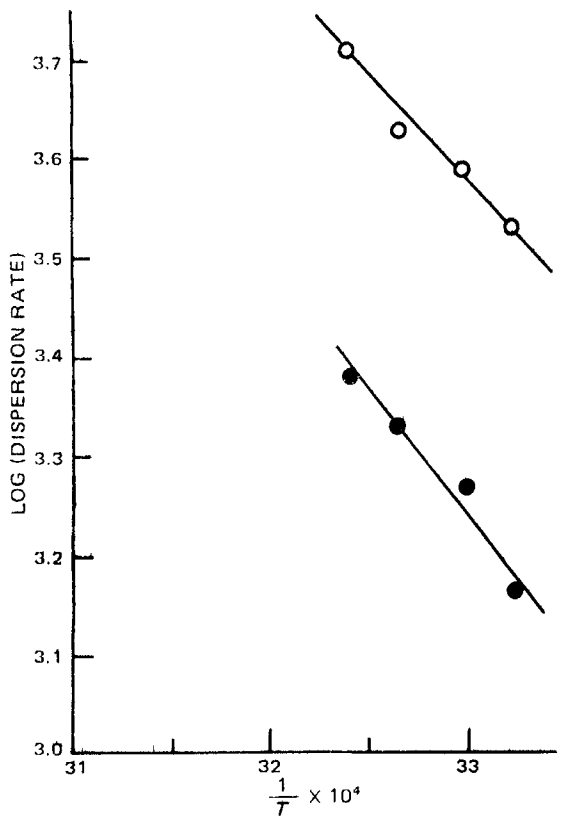

Figure 3—*Temperature dependence of the dispersion rate of I in hexane* (○) *and heptane* (●).

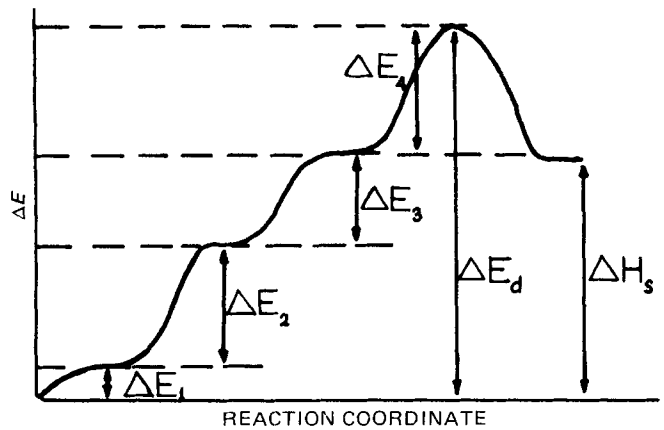

Figure 5—*Energy diagram for the dissolution of I.*

of ΔE_d based on the proposed energy diagram is quite good, considering the errors inherent in the graphical determination of energy values. This finding indicates that the proposed scheme of dissolution should reflect accurately the overall mechanism of the dissolution process. The sum of the energy terms of ΔE_1, ΔE_2, and ΔE_3, all of which are related to the process at the interface between the solid and solvent, is larger than ΔE_4, which is related to the dispersion process. This finding may also indicate that the energy barrier for dissolution of I is the interaction between the solvent and solid at the interface and not the mass transfer of solute into the bulk solution.

Effect of Laboratory Light on Tetrazolium Reaction and on Stability of Formazans in Various Solvents

ROBERT E. GRAHAM *ˣ, EDWARD R. BIEHL ‡, and CHARLES T. KENNER ‡

Abstract □ Studies on purified formazans of blue tetrazolium and triphenyltetrazolium showed that ordinary laboratory fluorescent light of about 52-foot-candle intensity provided sufficient energy for phototransformation in certain nonpolar solvents. Slow reoxidation of formazan to tetrazolium was observed in all solvents tested in the presence or absence of light. Water greatly inhibited the oxidation of the red formazan of blue tetrazolium. The blue formazan of blue tetrazolium isomerized to the red formazan in protic solvents in the presence and absence of light. The photochromic phenomena for the blue formazan of blue tetrazolium and the formazan of triphenyltetrazolium in cyclohexane were completely reversible when exposed to alternate periods of intense light and darkness. Under irradiation, the formazans of blue tetrazolium and triphenyltetrazolium in chloroform solution formed their respective photoformazans; darkness reversed the process, and continued exposure of the same solutions for extended times or at a higher light intensity created a solution whose spectrum was no longer reversibly affected by the presence or absence of light. When alcohol USP is used as the solvent for the quantitative determination of corticosteroids, no light precautions need be observed, although reagent blanks have higher absorbances than light-protected solutions. Exact compensation is made by running samples and standards *versus* the reagent blank as recommended by the USP. When other solvents and/or tetrazolium reagents are used, special precautions may be required to keep the reagents, developing solutions, and final formazans protected from light to ensure a quantitative reaction.

Keyphrases □ Tetrazolium reagents—effect of laboratory light, various solvents □ Formazans—of blue tetrazolium and triphenyltetrazolium, stability, effect of laboratory light, various solvents □ Phototransformation—formazans of blue tetrazolium and triphenyltetrazolium, effect of various solvents □ Stability—formazans of blue tetrazolium and triphenyltetrazolium, effect of laboratory light, various solvents

The blue tetrazolium reaction is widely used for the analysis of corticosteroids. USP XIX (1) and NF XIV (2) indicate a slightly modified Mader and Bück procedure (3) for corticosteroid analysis. Blue tetrazolium (I) [3,3′-(3,3′-dimethoxy -4,4′- biphenylylene)bis(2,5-diphenyl-2*H*-tetrazolium chloride)] and triphenyltetrazolium (II) (2,3,5-triphenyl-2*H*-tetrazolium chloride) oxidize the α-keto moiety of the C_{17} side chain in strongly alkaline solution and are reduced quantitatively to highly colored formazans, which are measured spectrophotometrically.

The analytical procedure is subject to several variables such as temperature (4–6), solvent (1–3, 7–13), and concentrations of base (14), water (6, 14), and tetrazolium (6), as well as the steric configuration of the corticosteroid molecule (15). The effect of these variables is minimized by analyzing reagent blanks, standards, and samples concurrently.

Light may or may not influence the tetrazolium reaction. For example, both II (16, 17) and II formazan (10, 12, 16–19) were reported to be light sensitive. Photochemical reoxidation of II formazan to the tetrazolium salt in the presence of intermittent UV irradiation was observed (20). The I formazan was reported (21) to be photosensitive in chloroform solution, and the sensitivity of I to light in 60% chloroform was observed (11) to present problems in the assay. The use of actinic glassware was recommended in

a study of the effect of light and other parameters on the reaction of II with corticosteroids (12). In contrast, several studies (6, 22) found that the reaction of I with corticosteroids was not sensitive to light.

This paper reports the effect of laboratory fluorescent lighting on the compendial (1, 2) reaction of I with corticosteroids. The effect of fluorescent and incandescent light on I and II formazans in various solvents also is discussed.

EXPERIMENTAL

Apparatus—The following were used: UV–visible recording spectrophotometers[1] with 1-cm stoppered quartz matched cells, an electrobalance[2], a TLC apparatus[3], a light meter[4], an IR instrument[5], and a microscope light[6] equipped with a transformer.

Materials—The following solvents were used: distilled-in-glass acetone, acetonitrile, absolute methanol, chloroform, and cyclohexane; analytical reagent grade absolute ethanol, cyclohexanol, cyclohexene, carbon tetrachloride, dimethylformamide, dimethyl sulfoxide, *n*-hexane, and methylene chloride; alcohol USP; sodium borohydride[7], 0.8-cm (0.3-in.) pellets; blue tetrazolium[8]; triphenyltetrazolium[9]; 10% aqueous tetramethylammonium hydroxide[9]; and USP reference standard hydrocortisone and prednisone.

Reagents—Tetramethylammonium hydroxide (1%) was prepared by diluting 5.00 ml of 10% aqueous reagent to 50.0 ml with alcohol USP. Blue tetrazolium (5 mg/ml) was prepared by dissolving 250.0 mg of I in 50.0 ml of alcohol USP. A standard solution containing 0.010 mg of hydrocortisone/ml of alcohol USP was prepared.

General Procedure—All studies were performed in 25-ml glass-stoppered flasks, which were placed on white paper during irradiation. Unless otherwise indicated, the solutions were irradiated with laboratory fluorescent light of 52-foot-candle (ft-c) intensity. Spectrophotometric scans were made from 720 to 250 nm *versus* the same solvent as the blank unless otherwise noted.

Formazan Isolation—Actinic glassware and aluminum foil-wrapped columns were used to protect the formazans from light during the isolation procedures.

I Blue Formazan—One pellet of sodium borohydride was added to a solution containing 53 mg of I in 100 ml of absolute ethanol, and this mixture was placed in the dark for several days. The precipitate was filtered, washed with absolute ethanol, dissolved in chloroform, and evaporated to dryness to obtain the blue formazan.

I Red Formazan—Three milliliters of 10% tetramethylammonium hydroxide was added to a solution containing 75 mg of prednisone and 1.53 g of I in 300 ml of alcohol USP. The mixture was placed in the dark for 30 min and then transferred to a separator containing 600 ml of water and 100 ml of chloroform. This solution was shaken vigorously for 1 min, the layers were allowed to separate, and the chloroform layer was filtered through a 12-cm length of sodium sulfate. An additional 50-ml portion of chloroform was used to complete the extraction and to wash the formazan from the sodium sulfate column. The chloroform extracts were combined and evaporated to obtain the red formazan.

II Formazan—One pellet of sodium borohydride was added to a solution of 100 mg of II in 20 ml of absolute ethanol. The solution was kept in the dark for 24 hr; it was then transferred to a separator containing 80 ml of water and extracted repeatedly with chloroform until the aqueous phase became colorless. The combined chloroform extracts were filtered through chloroform-washed cotton and evaporated to dryness to obtain a pure crystalline formazan.

Effect of Light on I–Hydrocortisone Reaction—Ten 20.0-ml aliquots, each containing 0.200 mg of USP reference standard hydrocortisone in alcohol USP plus a reagent blank, were treated in accordance with the official procedure (1). Each of the 10 hydrocortisone standard solutions was scanned *versus* the reagent blank from 720 to 490 nm exactly 90 min after addition of the tetramethylammonium hydroxide reagent. The reagent blank was scanned *versus* alcohol USP exactly 90 and 130 min after addition of the tetramethylammonium hydroxide. All reagents and solutions were protected from light at all times. The experiment was repeated with the exception that all reagents and solutions were exposed to laboratory fluorescent lighting during the entire study.

Photochemical Effect of Laboratory Lighting on Tetrazolium Formazans—For each experiment involving formazans, aliquots of chloroform stock solutions were taken to dryness carefully, and these residues were dissolved in an appropriate volume of solvent. Care was taken to protect all solutions from light before the experiment was initiated.

Solutions of I blue formazan (0.0086 mg/ml), I red formazan (0.0647 mg/ml), and II formazan (0.0103 mg/ml) in each of several different solvents were exposed to laboratory lighting for 1 hr and to office lighting (78 candle power) for 19 hr, with spectra being obtained after 0, 20, and 60 min and 20 hr. These solutions were then exposed to intense incandescent light of approximately 1×10^4-ft-c intensity for 90 min and rescanned. Certain red formazan solutions were exposed to laboratory lighting for an additional 11 days. These solutions were then scanned and evaporated to dryness. Each residue was dissolved in alcohol USP, a pellet of sodium borohydride was added, and the absorption spectrum of the resulting solution was obtained.

Reversibility of Photoeffect on I and II Formazans—*I Blue Formazan in Chloroform*—Duplicate solutions containing 0.0687 mg of I blue formazan in 10.0 ml of chloroform were prepared; one solution was placed in the light and the other was kept in the dark for 24 hr. During this period, absorption spectra were determined periodically on each solution. Both solutions were subsequently exposed to alternating periods of laboratory lighting and darkness, and their visible absorption spectra were obtained periodically for an additional 976 hr. The solutions were then evaporated to dryness; each residue was dissolved in alcohol USP, a pellet of sodium borohydride was added, and the absorption spectrum of the resulting solution was obtained.

I Blue Formazan in Cyclohexane—A solution containing 0.0687 mg of I blue formazan in 10.0 ml of cyclohexane was exposed alternately to light and darkness for 960 hr, and absorption spectra were obtained during this time.

I Red Formazan in Chloroform—A solution containing 0.496 mg of

[a] The amount of I blue formazan taken was not completely dissolved in the volume of solvent used. [b] Values are the λ_{max}, nanometers, with the absorbance in parentheses.

I red formazan in 10.0 ml of chloroform was exposed to laboratory light and scanned periodically for 485 min. It was then treated as follows, with the absorption spectrum taken at the end of each step: dark, 88 hr; light, 24 hr; dark, 168 hr; light days and dark nights, 5 days; 78-ft-c light, 24 hr; dark, 48 hr; and the same light intensity, 18 hr.

Two additional solutions containing 0.496 mg of I red formazan in 8.0 and 10.0 ml of chloroform were prepared. The former solution was scanned, exposed to incandescent light of approximately 1×10^4 ft-c for 65 min, and scanned immediately after being exposed to light. The volume was adjusted to 8.0 ml after light exposure before scanning. The latter solution was kept in the dark for 23 days, and absorption spectra were obtained periodically during this time.

II Formazan in Chloroform—Ten milliliters of chloroform containing 0.161 mg of II formazan was exposed for 34 days to several cycles of laboratory light and darkness, and the absorption spectrum was obtained after each cycle. The experiment was repeated with a duplicate aliquot irradiated with approximately 1×10^4 ft-c of light intensity.

II Formazan in Cyclohexane—Ten milliliters of cyclohexane was pipetted into each of two flasks containing 0.161 mg of II formazan. One solution was exposed to laboratory lighting continuously for 53 hr; the other was wrapped in aluminum foil for the first 5 hr before exposure to light for 48 hr. Nine absorption spectra were made of these samples during this time. These solutions were then exposed to a light of approximately 1×10^4-ft-c intensity for short periods, scanned, placed in the dark overnight, and rescanned. This latter procedure was repeated through several cycles of light and darkness.

Rate Studies—*Light Effect*—A 10.0-ml chloroform solution containing 0.496 mg of I red formazan was exposed to laboratory light, and absorption spectra were obtained periodically during 485 min to follow the conversion of I red formazan to its photoformazan.

Dark Effect—A 4.0-ml chloroform solution containing 0.496 mg of I red formazan was exposed to laboratory fluorescent light of 78 ft-c intensity until the maximum amount of its yellow photoform was generated. The solution was placed in a stoppered spectrophotometric cell in the dark, and absorption spectra were made every 15 min for 8 hr.

Correlation of Phototransformation of Formazans to Photoformazans—Chloroform solutions of I red, I blue, and II formazans were scanned, irradiated with light to complete the conversion to their respective photoformazans, and then rescanned. The wavelength of the absorption maximum for each species was determined.

Photochemical Effect of Laboratory Lighting on Tetrazoliums—*Blue Tetrazolium*—A saturated solution of I in absolute ethanol and a concentration of 5 mg of I/ml of alcohol USP were exposed to laboratory fluorescent lighting for 4 days, after which time the absorption spectrum of each solution was taken.

Triphenyltetrazolium—A colorless solution of II in absolute ethanol and another in alcohol USP (both 5 mg/ml) were exposed for 24 hr to laboratory lighting and then scanned. The absolute ethanol solution was then divided into two parts; one part was used as a control, and enough water was added to the other to change it to the equivalent of alcohol USP. These solutions were exposed to light for 1 additional week and rescanned.

RESULTS AND DISCUSSION

The effect of laboratory fluorescent light upon the reaction of I with hydrocortisone is shown in Table I. The average net absorbance (0.578 ± 0.001 *SD*) of 10 determinations of hydrocortisone not exposed to light by the USP XIX (1) method was essentially the same as that (0.579 ± 0.001 *SD*) obtained for the same number of hydrocortisone determinations exposed to laboratory lighting. These results indicate that the net absorbance of this reaction is not affected by ordinary laboratory light. The reagent blank of I was found previously (10, 21) to be affected by light. This study found that the absorbance of the light-exposed blanks was approximately 1.5 times as great as the blank protected from light at 90 and 130 min from the start of the reaction. However, the procedure of running sample *versus* blank compensated for any deviation in the reagent blank caused by light.

The influence of light on the stability of I and II formazans in various solvents is listed in Tables II–IV. In general, the formazans were converted to photoderivatives in nonpolar solvents such as cyclohexane, *n*-hexane, and chloroform. Exposure of these solutions to laboratory lighting resulted in hypsochromic shifts of the absorption maxima. Figures 1 and 2 show typical absorption spectra of I blue and red formazans

Table III—Effect of Extent of Exposure on the λ_{max} and Absorbance Values of I Red Formazan to Light

[a] Values are the λ_{max}, nanometers, with the absorbance in parentheses. [b] A second λ_{max} was observed in these solvents. [c] The yellow photosolution reverted completely to orange before the spectrum could be obtained.

and their corresponding yellow derivatives. The conversion of II formazan to its photoderivative was accompanied by a change in the color of the solution from orange to yellow. Small amounts of the three formazans were converted to the corresponding photoformazans in acetonitrile. The insolubility of I red formazan in cyclohexane and *n*-hexane prevented the investigation of the effect of light in these systems.

In the protic solvents, absolute methanol, absolute ethanol, and alcohol USP, I blue formazan was partially converted to I red formazan in the presence or absence of light. During this process, a gradual diminution in the absorption maxima at about 585 nm and a corresponding increase at approximately 525 nm were observed. The amount of conversion of the blue form to the red form decreased as the solvent was varied from absolute methanol to alcohol USP to absolute ethanol. These results are consistent with the conclusion of Graham *et al.* (13) that water and methanol stabilize the *trans-anti*-configuration of I red formazan to a larger extent than ethanol due to the smaller size and greater hydrogen-bonding ability of methanol and water.

Of all solvents studied, I red formazan was the most stable in absolute methanol in the presence of light, even though methanol inhibits the formation of I formazan in the reaction of I with corticosteroids. By using the procedure described previously (13), the formazans were reoxidized to tetrazolium in varying degrees in all solvents listed in Tables II–IV.

To study the influence of water on the stability of I red formazan toward light, selected solutions of this formazan were exposed to laboratory light for 12 days. After this time, the absorbance of the absolute ethanol solution was reduced to 47% of its original value; the absorbance of the alcohol USP solution was reduced to only 93%. Construction of Dreiding models revealed that the *trans-syn*-configuration, III, of I blue formazan would be more readily reoxidized to I than the *trans-anti*-configuration, IV, of I red formazan. Water stabilizes I red formazan (13) and thus acts to prevent the rearrangement of IV to III and the subsequent oxidation of III to I.

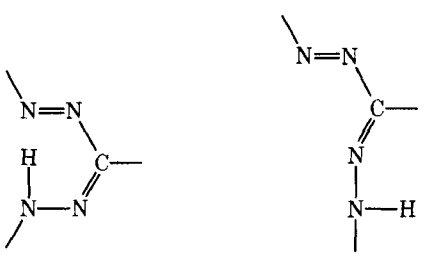
The reversibility of the photoeffect observed in solutions of I and II formazans was studied by exposing these solutions to alternating periods of light and darkness and obtaining spectra at appropriate times during each cycle. In cyclohexane, I blue formazan (λ_{max} 595 nm) and its photoderivative (λ_{max} 487 nm) were completely interconverted by the action of light and darkness during 960 hr. During this time, a small portion (21%) of I blue formazan was reoxidized to tetrazolium, as shown by a decrease in absorbance.

An immediate scan of II formazan in cyclohexane yielded an absorption spectrum of typical shape with a maximum at 486 nm. Further scans of the solution during light exposure produced time-related curves in which an absorption maximum of the photoderivative appeared at about 400 nm. The absorbance of this wavelength increased with time and reached a maximum after 30 min of light exposure. However, further scans during 53 hr of continued light exposure produced curves in which the photoderivative absorption maximum gradually disappeared to yield a spectrum similar to that of the original II formazan. The absorption spectrum of II formazan in a duplicate cyclohexane solution that was not exposed to light exhibited no change during 5 hr; however, when this solution was exposed to light for an additional 48 hr, periodic scans yielded spectra similar to those observed for the first solution. Figure 3 shows spectra typical of those obtained for II formazan in cyclohexane when irradiated with laboratory light.

Irradiation of a solution of II formazan in cyclohexane with approximately 1×10^4 ft-c of light intensity produced a light-stable yellow photoderivative (λ_{max} 400 nm), which could be converted to the original II formazan by darkness. These two species were readily interconvertible over several cycles of alternating intense light and darkness.

Five alternate periods of exposure of I blue formazan in chloroform to laboratory light and darkness during 1000 hr showed partial reversibility of the photoformazan. The wavelength and absorbance at the maximum returned to the starting value after each period of darkness, but there was less conversion to the photoform with each period of light exposure, as shown by decreased absorbance at 487 nm. This result indicates that two forms of I blue formazan exist and have similar absorbance maxima in chloroform. One form apparently is photolabile and converts gradually to the other, which is not further affected by light.

Spectra of the aliquot exposed to light in the initial 24 hr revealed that I blue formazan was converted mainly to its yellow photoform. A dupli-



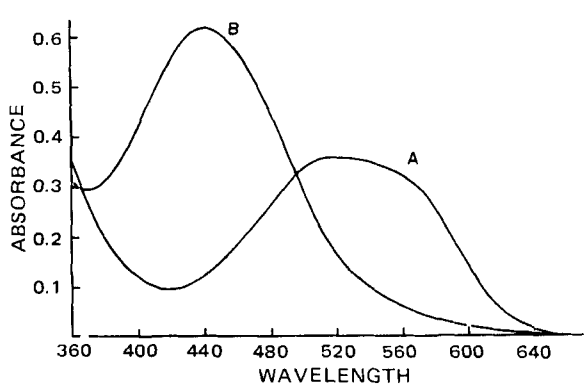


Figure 2—*Spectra of I red formazan (A) and its photoformazan (B) in chloroform.*

cate aliquot kept in the dark during the same period showed no spectral changes. However, when the latter solution was exposed to light, a similar photoeffect was observed. During the observation period, the absorbances of both solutions gradually decreased until they were free of color and contained only I. The addition of a sodium borohydride pellet to an alcoholic solution of the final tetrazolium residue yielded a mixture of I red and blue formazans (λ_{max} 555 nm). TLC confirmed the presence of both colored formazans in these solutions.

Exposure of a chloroform solution of I red formazan (λ_{max} 525 nm) to ordinary laboratory fluorescent lighting of approximately 52-ft-c intensity produced the corresponding yellow photoform (λ_{max} 440 nm). This photoform readily interconverted to I red formazan by exposure to alternating periods of light and darkness. Evaporation of the yellow photoform solution afforded the crystalline I red formazan, as determined by TLC, IR, and its reconversion to the yellow photoform derivative upon being redissolved in chloroform and exposed to laboratory light. During the evaporation process, the color of the solution changed from yellow to red immediately before dryness.

Exposure of a chloroform solution of the yellow photoform of I red

Table V—Change of Absorbance at 525 nm of I Red Formazan when Exposed to Laboratory Lighting

Minutes	Observed Absorbance[a]	Absorbance of Yellow Photoformazan[b]	Net Absorbance of Red Photoformazan

485	0.136	0.136	0.000

[a] Includes the absorbance of I red formazan plus its photoformazan. [b] Absorbance due to the yellow photoformazan of I red formazan calculated from maximum absorbance (0.136), assuming that the rate of formation of the photoformazan is constant. [c] Complete conversion to photoformazan occurs by this time.

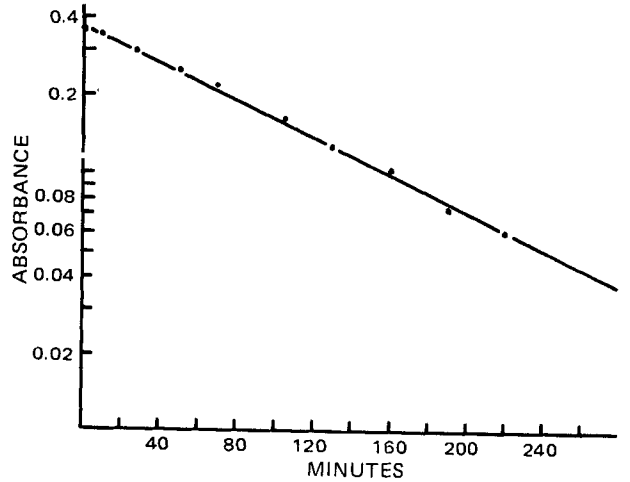

Figure 4—*Rate of change of I red formazan to its yellow photoform in chloroform when exposed to laboratory lighting.*

formazan to ordinary office light of approximately 72 ft-c for about 16 hr converted it to a red color with a spectrum like the original. This spectrum does not change upon further exposure to alternate periods of light and darkness. Exposure of a chloroform solution of I red formazan to intense incandescent light of approximately 1×10^4 ft-c produced a yellow color within 2 min, which remained unchanged for 1 hr under continuous irradiation and then quickly turned (5 min) to red. The spectrum of the final red solution was similar to the original, but the absorbance was 44% higher in the final solution as compared to the original. The higher absorbances and the lack of response of this photoform to successive periods of light and darkness indicate that it may be a different high energy conformer than the original I red formazan. A chloroform solution of the I red formazan that was kept in the dark and scanned periodically showed no change in the spectrum during 23 days.

The II formazan in chloroform demonstrated a photoeffect during the first 2 hr of exposure to laboratory fluorescent lighting, as shown by a change in color from orange to yellow and by a hypsochromic shift of the maximum from 487 to 406 nm. Within the next 5 hr of exposure, the solution returned to an orange color with a spectrum similar to the original and a bathochromic shift of the maximum back to 487 nm. No change was observed in the spectra following successive exposures of the solution to light and dark during the next 33 days, except for a gradual reduction in the intensity of the color due to the oxidation of the orange photoformazan back to II. A chloroform solution of II formazan, when irradiated with approximately 1×10^4 ft-c, changed to a yellow color within 1 min and back to orange within 5 min. The spectrum of the latter color was similar in absorbance and shape to the original formazan but was not reversible when exposed to additional periods of light and dark.

Table V lists the spectral data obtained from the rate study of the conversion of I red formazan to its photoderivative in chloroform in the presence of laboratory light. The observed absorbance values at 525 nm had to be corrected for a small amount of overlap of the absorption maximum of the yellow photoform of I red formazan (Fig. 2). From the graph of the corrected absorbance *versus* time (Fig. 4), the rate of conversion of I red formazan to its photoderivative in chloroform was found to be 1.4×10^{-3} absorbance unit/min.

A sequence of spectrophotometric scans of the regeneration of I red formazan from its yellow photoformazan in chloroform in the dark was taken at 15-min intervals over 8 hr. These scans revealed isosbestic points at 370 and 490 nm, indicating that these two species were in equilibrium with each other. The rate for the regeneration process calculated either from the decrease in absorbance of the yellow form or from the increase in absorbance of the red form corrected for overlap by the yellow form yielded the same value, 2.5×10^{-3} absorbance unit/min.

The difference in energy of the transformation of a formazan to its photoderivative may be calculated from:

$$\Delta E = \frac{hc(\lambda_2 - \lambda_1)}{\lambda_2 \lambda_1} \qquad \text{(Eq. 1)}$$

where ΔE is the difference in energy in ergs at the longer wavelength (λ_2) of absorption of the formazan and the shorter wavelength (λ_1) of the photoform, h is Planck's constant, and c is the speed of light. By using

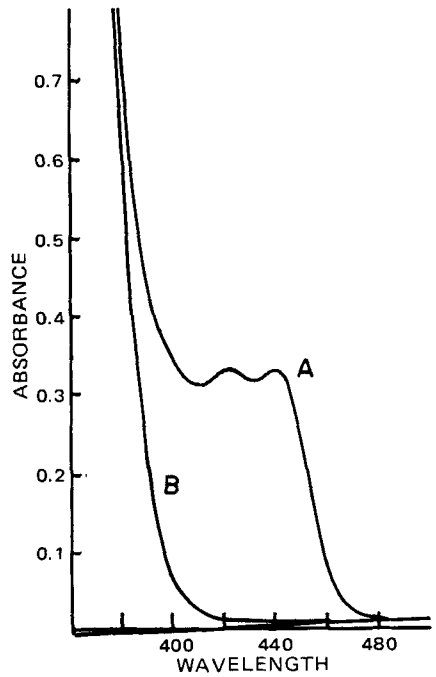

Figure 5—*Spectra of II (B) and its photoderivative (A) in absolute ethanol.*

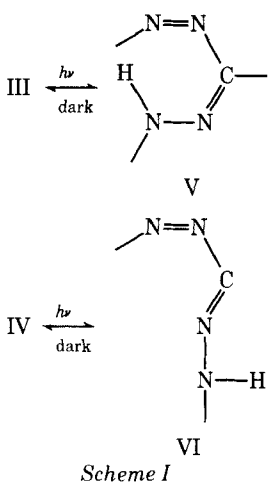
the maximum absorption values for the hypsochromic shifts observed in chloroform solutions of 595–487 nm for I blue formazan, 525–440 nm for I red formazan, and 487–407 nm for II formazan, the following ΔE values were calculated: 7.31×10^{-13} erg for the I blue formazan transformation, 7.40×10^{-13} erg for the I red formazan transformation, and 8.02×10^{-13} erg for the II formazan transformation. These calculated values indicate that the transformation process is similar for all three formazans.

A possible mechanism for the phototransformation of I blue and red formazans is suggested in Scheme I. The *trans–syn*-configuration, III, of I blue formazan is isomerized to the *cis–syn*-configuration, V, and the *trans–anti*-configuration, IV, of I red formazan is isomerized to the *cis–anti*-configuration, VI, by absorption of light by the N=N moiety. Construction of Dreiding models revealed that steric effects prevent coplanarity of the conjugated π electronic system in the photoderivatives, V and VI, which would account for the hypsochromic shifts observed in these phototransformations.



Scheme I

Finally, the stability of I and II in the presence of light was studied. Solutions of I in absolute ethanol and alcohol USP showed no apparent change in their absorption spectra after extended exposure to laboratory light. However, when II reagent in absolute alcohol was exposed to laboratory lighting, the solution changed from colorless to yellow within a few hours. The absorption spectrum of this solution (Fig. 5) shows the presence of two additional peaks with maxima at 420 and 440 nm. Addition of water to a portion of the yellow photosolution of II sufficient to make a 95% ethanol–water mixture (USP) caused the solution to become colorless within 1 week of continuous light exposure. The other portion of the absolute ethanol solution remained yellow. A control solution of II in absolute ethanol kept in the dark as well as a similar concentration of II in alcohol USP exposed to laboratory light for the same period remained colorless.

These experiments showed that ordinary laboratory fluorescent lighting of approximately 52–74 ft-c provided sufficient energy for phototransformations of the formazans studied to take place in certain nonpolar solvents. Alcohol USP, recommended by the compendia (1, 2), is the solvent of choice for both the tetrazolium reagent and the I reaction with corticosteroids since no special light precautions need be observed, although reagent blanks have higher absorbances than light-protected ones. Exact compensation is made by running samples and standards *versus* the blanks in accordance with the official procedure. If other solvents and/or tetrazolium reagents are used, special precautions may be required to keep the reagents, developing solutions, and final formazans protected from light to ensure a quantitative reaction.

Anticonvulsant Activity and Selective Inhibition of NAD-Dependent Oxidations in Rat Brain Homogenates by Newer Mercaptotriazoles

SURENDRA S. PARMAR *‡ˣ, MAHIMA CHAUDHARY *, SUNIL K. CHAUDHARY *, SUSHIL KUMAR *, and HERZL R. SPIRO ‡

Abstract □ Eight 1-(2,6-dimethylphenoxyacetyl)-4-(substituted phenyl)thiosemicarbazides were cyclized to the corresponding 5-(2,6-dimethylphenoxymethyl)-4-(substituted phenyl)-3-mercapto-1,2,-4(4*H*)-triazoles and 5-(2,6-dimethylphenoxymethyl)-4-(substituted phenyl)-3-[1,2,4(4*H*)-triazolethioglycolic] acids. These compounds were characterized by their sharp melting points, elemental analyses, and IR spectra and were evaluated for anticonvulsant activity. The degree of protection (range) provided by these thiosemicarbazides, triazoles, and triazolethioglycolic acids at a dose of 100 mg/kg ip against pentylenetetrazol (90 mg/kg sc)-induced convulsions in mice was 10–50, 20–80, and 10–70%, respectively, where cyclization to triazoles increased anticonvulsant activity of the precursor thiosemicarbazides. Increased protection by these compounds against convulsions was generally associated with decreased 24-hr pentylenetetrazol-induced mortality. These compounds exhibited selective *in vitro* inhibition of nicotinamide adenine dinucleotide (NAD)-dependent oxidation of pyruvate, α-ketoglutarate, and NADH by rat brain homogenates while NAD-independent oxidation of succinate remained unaltered. The presence of added NAD to the reaction mixture during *in vitro* oxidation of pyruvic acid not only increased the respiratory activity of rat brain homogenates but also decreased the inhibitory effectiveness of thiosemicarbazides, triazoles, and triazolethioglycolic acids. The degree of selective inhibition of NAD-dependent oxidations was unrelated to their anticonvulsant activity.

Keyphrases □ Thiosemicarbazides, various—synthesized, evaluated for anticonvulsant activity and effect on NAD-dependent oxidations, rats □ Mercaptotriazoles, various—synthesized, evaluated for anticonvulsant activity and effect on NAD-dependent oxidations, rats □ Triazolethioglycolic acids, various—synthesized, evaluated for anticonvulsant activity and effect on NAD-dependent oxidations, rats □ Anticonvulsant activity—evaluated in various thiosemicarbazides, mercaptotriazoles, and triazolethioglycolic acids, rats □ NAD-dependent oxidations—effect of various thiosemicarbazides, mercaptotriazoles, and triazolethioglycolic acids, rat brain homogenates □ Oxidations, NAD dependent—effect of various thiosemicarbazides, mercaptotriazoles, and triazolethioglycolic acids, rat brain homogenates □ Structure–activity relationships—various thiosemicarbazides, mercaptotriazoles, and triazolethioglycolic acids evaluated for anticonvulsant activity and effect on NAD-dependent oxidations, rats

Interest has been focused on the pharmacology of 1-phenyl-1,2,4-triazoles and 4-phenyl-1,2,4-triazoles (1). Earlier studies indicated central nervous system depressant (2), analgesic (3), and anti-inflammatory (4, 5) properties of 1,2,4(4*H*)-triazoles. Furthermore, 1,4-disubstituted thiosemicarbazides, the precursors for the synthesis of cyclized triazoles, possess a broad spectrum of biological activities (6, 7). Anticonvulsant compounds also cause selective inhibition of nicotinamide adenine dinucleotide (NAD)-dependent oxidations (8).

These observations prompted synthesis of eight 1-(2,6-dimethylphenoxyacetyl)-4-(substituted phenyl)-thiosemicarbazides and their corresponding cyclized 5-(2,6-dimethylphenoxymethyl)-4-(substituted phenyl)-3-mercapto-1,2,4(4*H*)-triazoles. The substituted triazoles were further converted into 5-(2,6-dimethylphenoxymethyl)-4-(substituted phenyl)-3-[1,2,4(4*H*)-triazolethioglycolic] acids. The effects of all compounds were determined on the respiratory activity of rat brain homogenates in an attempt to elucidate the biochemical basis for their anticonvulsant activity.

CHEMISTRY

The various substituted 1,2,4(4*H*)-triazoles were synthesized by following the reactions outlined in Scheme I. Conversion of 2,6-dimethylphenol (I) to ethyl 2,6-dimethylphenoxyacetate (II) was carried out to synthesize 2,6-dimethylphenoxyacetohydrazide (III) through refluxing in ethanol with 99–100% hydrazine hydrate. Substituted thiosemicarbazides (IV–XI, Table I), prepared by the reaction of III with the appropriate aryl isothiocyanate, were cyclized to the corresponding mercaptotriazoles (XII–XIX, Table II) in 2 *N* NaOH. Condensation of the substituted triazoles with monochloroacetic acid resulted in the formation of substituted 3-triazolethioglycolic acids (XX–XXVII, Table III). All compounds were characterized by their sharp melting points, elemental analyses, and IR spectra.

EXPERIMENTAL[1]

Ethyl 2,6-Dimethylphenoxyacetate (II)—Equimolar quantities of I (0.2 mole), ethyl chloroacetate (0.2 mole), and potassium carbonate (0.25 mole) in dry acetone (60 ml) were refluxed under anhydrous conditions for 12 hr. The reaction mixture was filtered, and the filtrate was poured over 100 ml of ice-cold water. The separated ester was extracted with ether and dried over anhydrous magnesium sulfate. Excess ether was removed by distillation, the remaining liquid fraction was subjected to fractional distillation, and the fraction boiling at 270° was collected, yield 33.3 g (80%).

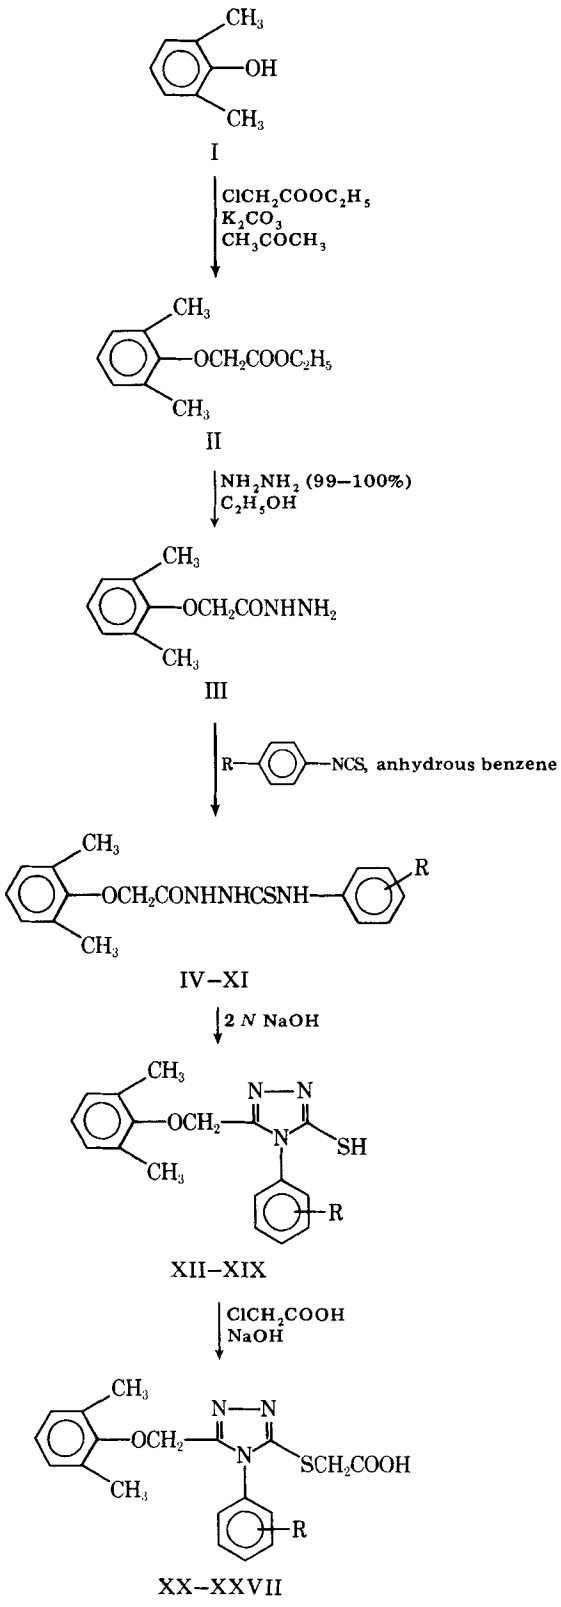
2,6-Dimethylphenoxyacetohydrazide (III)—To a solution of 0.15 mole (31.2 g) of II in absolute ethanol (50 ml) was added 10 g of 99–100% hydrazine hydrate, and the mixture was refluxed under anhydrous conditions on a water bath for 4 hr. A white solid mass, which separated on cooling, was collected by filtration and recrystallized from ethanol into white crystalline solid, mp 92°, yield 17.4 g (60%).

Anal.—Calc. for $C_{10}H_{14}N_2O_2$: C, 61.85; H, 7.21; N, 14.63. Found: C, 61.40; H, 7.36; N, 14.98.

1-(2,6-Dimethylphenoxyacetyl)-4-(substituted Phenyl)-thiosemicarbazides (IV–XI)—Equimolar quantities of III (0.02 mole) and the appropriate aryl isothiocyanate (0.02 mole) were mixed in dry benzene, and the mixture was refluxed on a steam bath for 2 hr. Excess benzene was removed by distillation. The separated solid was collected by filtration, washed with a cold ethanol–water mixture, dried, and recrystallized from ethanol. The various substituted thiosemicarbazides (Table I) were characterized by their sharp melting points and elemental analyses.

5-(2,6-Dimethylphenoxymethyl)-4-(substituted Phenyl)-3-mercapto-1,2,4(4*H*)-triazole (XII–XIX)—A solution of 1-(2,6-dimethylphenoxyacetyl)-4-(substituted phenyl)thiosemicarbazide (0.01 mole) in 2 *N* NaOH was refluxed over a free flame for 2–3 hr. After cooling, the mixture was filtered; the filtrate was acidified with dilute hydrochloric acid until complete precipitation occurred (9, 10). The separated solid was collected by filtration, washed with water, dried, and recrystallized from ethanol. Various substituted mercaptotriazoles were characterized by their sharp melting points and elemental analyses (Table II).

[1] All compounds were analyzed for their carbon, hydrogen, and nitrogen content. Melting points were taken in open capillary tubes with a partial immersion thermometer and are corrected. IR spectra provided support for the structures of these compounds.



Scheme I

5-(2,6-Dimethylphenoxymethyl)-4-(substituted Phenyl)-3-[1,2,4(4*H*)-triazolethioglycolic] Acids (XX–XXVII)—A mixture of the appropriate substituted mercaptotriazole (0.005 mole), chloroacetic acid (0.005 mole), and sodium hydroxide (0.01 mole) was refluxed for 3 hr. The mixture was cooled and acidified with dilute hydrochloric acid. The solid mass, which separated slowly from the acid solution, was collected by filtration and recrystallized from ethanol (11) (Table III).

Determination of Respiratory Activity of Rat Brain Homogenates[2]—Male albino rats, 100–150 g, were kept on an *ad libitum* diet until they were sacrificed by decapitation. The brains were removed immediately and homogenized[3] in ice-cold 0.25 *M* sucrose in a ratio of 1:9 (w/v). All incubations were carried out at 37° in the conventional Warburg manometric apparatus, using air as the gas phase (12). The oxygen uptake was measured at 10-min intervals.

Fresh brain homogenate (1 ml) equivalent to 100 mg wet brain weight was added to the chilled Warburg vessels containing 6.7 m*M* magnesium sulfate, 20 m*M* dibasic sodium phosphate buffer solution (pH 7.4), 1 m*M* adenosine monophosphate (sodium salt), 33 m*M* potassium chloride, and 500 μg of cytochrome c in a final volume of 3 ml unless otherwise stated. The central well contained 0.2 ml of 20% KOH solution. Pyruvate, α-ketoglutarate, and succinate were used at a final concentration of 10 m*M*; NAD and NADH were used at 0.5 m*M*. It was presumed that the endogenous NAD, present in brain homogenates, was sufficient for the cellular respiratory activity of rat brain homogenates.

All test compounds were dissolved in propylene glycol (100%) and were used at a final concentration of 2 m*M*. An equal volume of propylene glycol was added to the control vessels.

Determination of Anticonvulsant Activity—Anticonvulsant activity was determined (13) in mice of both sexes weighing 25–30 g. The mice were divided into groups of 10, keeping the group weights as near the same as possible. The test compounds were suspended in 5% aqueous gum acacia (1% w/v) and injected in a group of 10 mice each at a dose of 100 mg/kg ip. Four hours after the administration of the test compound, the mice were injected with 90 mg/kg sc of pentylenetetrazol. This dose of pentylenetetrazol not only produced convulsions in almost all untreated mice but also caused 100% mortality during the 24-hr period. No mortality was found in mice treated with 100 mg/kg alone of the test compounds, and the animals were devoid of any behavioral effects.

The occurrence of seizures was observed for 60 min. An episode of clonic spasm that persisted for a minimum of 5 sec after administration of pentylenetetrazol was considered a threshold convulsion. Transient intermittent jerks and tremulousness were not counted. Animals devoid of threshold convulsions during 60 min were considered protected. The number of animals protected in each group was recorded, and the anticonvulsant activity of the test compounds was represented as the percent protection. The mice were then observed for 24 hr, and their mortality was recorded.

RESULTS AND DISCUSSION

In the present study, the anticonvulsant activity possessed by thiosemicarbazides, triazoles, and triazolethioglycolic acids was reflected by their ability to provide 10–50% (Table I), 20–80% (Table II), and 10–70% (Table III) protection, respectively, against pentylenetetrazol (90 mg/kg sc)-induced convulsions in mice at a dose of 100 mg/kg ip. Compounds V, X, and XXII were devoid of anticonvulsant activity, since no protection was observed at 100 mg/kg. These results indicated an increase in anticonvulsant activity by cyclization of the precursor thiosemicarbazides into the corresponding triazoles. Further conversion of the triazoles into the corresponding triazolethioglycolic acids in most cases caused a decrease in their anticonvulsant activity; however, XXIV and XXV provided greater protection than their precursors (XVI and XVII).

These results did not provide any specific requirements in the molecular structure of these compounds to warrant structure–activity relationships with respect to the anticonvulsant activity. In addition, the anticonvulsant activity of some substituted mercaptotriazoles alone was comparable to that of methaqualone and meprobamate, which provided 60 and 80% protection, respectively, at 100 mg/kg ip against pentylenetetrazol-induced convulsions in mice under similar experimental conditions (14).

All thiosemicarbazides, triazoles, and triazolethioglycolic acids selectivity inhibited NAD-dependent oxidation of pyruvate, α-ketoglutarate, and NADH by rat brain homogenates at 2 m*M* (Table IV). The degree of inhibition of pyruvic acid oxidation ranged from 35.4 to 93.7, from 18.5 to 62.3, and from 30.5 to 90.8% with thiosemicarbazides, triazoles, and triazolethioglycolic acids, respectively. Similar inhibition of the oxidation of α-ketoglutarate was 30.5–54.2, 14.4–46, and 37.2–64.7%, respectively. Of NADH, it was 36.2–60.2, 14.1–89.2, and 45.6–67.5% by thiosemicarbazides, triazoles, and triazolethioglycolic acids, respectively. Oxidation of succinate remained unaltered in the presence of these compounds.

[2] Commercial chemicals were used. Sodium pyruvate, sodium α-ketoglutarate, NADH, sodium succinate, adenosine monophosphate (sodium salt), and cytochrome c were obtained from Sigma Chemical Co., St. Louis, Mo.

[a] Anticonvulsant activity was determined at 100 mg/kg ip as described under *Experimental*. [b] Represents mortality over 24 hr in each group of animals administered pentylenetetrazol (90 mg/kg sc). [c] The presence of characteristic bands of C=O (attached to nitrogen), C=S (flanked by nitrogen), and NH groups at 1695, 1538, and 3344 cm^{-1}, respectively, in the IR spectrum of VI provided further support for the structure of substituted thiosemicarbazides.

Addition of NAD during the oxidation of pyruvate not only increased the respiratory activity of rat brain homogenates but also decreased the ability of these compounds to inhibit pyruvate oxidation, as reported earlier with quinazolones (15), β-aminoketones (12), and thiazolidones (16). The degree of inhibition of 35.4–93.7, 18.5–62.3, and 30.5–90.8% observed during the oxidation of pyruvate by thiosemicarbazides, triazoles, and triazolethioglycolic acids was reduced to 26.2–82.3, 10.7–52.7, and 25.5–79.3%, respectively, in the presence of added NAD. These results provided evidence for a possible competition between thiosemicarbazides, triazoles, and triazolethioglycolic acids and NAD for the active site(s) on the enzyme molecule. Cyclization to triazoles caused a significant decrease in the ability of triazoles to inhibit NAD-dependent oxidations as compared to precursor thiosemicarbazides. Further conversion of triazoles into triazolethioglycolic acids increased the inhibitory effectiveness of the latter compounds to inhibit respiratory activity of rat brain homogenates with pyruvate, α-ketoglutarate, and NADH as the substrates.

As was observed with the anticonvulsant activity possessed by these compounds, their selective inhibition of NAD-dependent oxidations was unrelated to their structure; a definite structure–activity relationship was not exhibited (Table IV). The ability of these thiosemicarbazides, triazoles, and triazolethioglycolic acids to inhibit oxidation of pyruvate, α-ketoglutarate, and NADH provides evidence regarding the possible inactivation of the electron-transfer process in the electron-transport chain by their actions presumably at the site of transfer of electrons from NADH to flavine adenine dinucleotide.

Contrary to the increase in the anticonvulsant activity observed after cyclization of thiosemicarbazides into triazoles, the results indicated a decrease in the ability of triazoles to inhibit NAD-dependent oxidations by rat brain homogenates. Thus, selective inhibition of the respiratory

[a] Vessel contents and assay procedures were as described in the test. All values are the mean of three duplicate experiments. The percent inhibition and standard errors (*SE*) were calculated from the decrease in the oxygen uptake per 100 mg of wet brain weight per hour. The final concentration of pyruvate, α-ketoglutarate, and succinate was 10 m*M*; the final concentration of NAD and NADH was 0.5 m*M*. All thiosemicarbazides, triazoles, and triazolethioglycolic acids were used at 2 m*M*. The values of oxygen uptake in the control experiments during oxidation of pyruvate, pyruvate plus NAD, α-ketoglutarate, NADH, and succinate were 71.6 ± 1.3, 83 ± 2.2, 96 ± 1.8, 63.3 ± 1.1, and 163 ± 2.8 μl, respectively. The inhibition of the oxidation of succinate by these compounds was nil.

activity cannot account for the biochemical basis of the anticonvulsant activity of thiosemicarbazides, triazoles, and triazolethioglycolic acids.

Interaction of Hydrocortisone with Model Membranes Containing Phospholipid and Cholesterol

GARY W. CLEARY * and JOEL L. ZATZ ˣ

Abstract □ Pure and mixed monolayers of lecithin and cholesterol were spread on substrates of dissolved hydrocortisone at 25 and 37°. The presence of hydrocortisone increased the surface pressure of dipalmitoyl and egg lecithin films that were in head contact. The increase in surface pressure was dependent on steroid concentration. There were no significant interactions with coherent cholesterol monolayers. Penetration of hydrocortisone was decreased by the addition of cholesterol to the monolayer system. These model membrane systems indicate that hydrocortisone interacts with the hydrated polar head group of the phospholipid and not with films whose molecules are in hydrocarbon tail contact.

Keyphrases □ Hydrocortisone—interaction with pure and mixed monolayers of lecithin and cholesterol □ Monolayers—lecithin and cholesterol, pure and mixed, interaction with hydrocortisone □ Lecithin—monolayers, pure and mixed with cholesterol, interaction with hydrocortisone □ Cholesterol—monolayers, pure and mixed with lecithin, interaction with hydrocortisone □ Membranes, model—pure and mixed monolayers of lecithin and cholesterol, interaction with hydrocortisone

Several literature reports have drawn attention to the possibility that the biological activity of certain steroids is due to an interaction with biological membranes (1–5). In a review of steroids and cell surfaces, Willmer (1) proposed a mechanism of steroid activity based on the penetration of steroid molecules between the hydrocarbon tails of membrane phospholipids. Erythrocytes were more resistant to lysis in hypotonic solution when steroids were present in low concentration (2). In high concentration, the steroids themselves caused lysis or precipitation. Another study (3) showed that the corticosteroids tended to stabilize lysosomes at pharmacological concentration (10^{-4}–10^{-6} *M*) but to lyse them at higher concentrations. Cortisone and hydrocortisone exerted a protective effect on the membranes of erythrocytes (4) and rat liver cells (5).

BACKGROUND

One approach to an understanding of steroid–membrane interactions is through model membrane systems. Monomolecular films provide an organized interfacial structure believed to be similar to that found in biological membranes. Studies of drug penetration into monolayers containing components of natural membranes have been useful in explaining the mode of action of many drugs (6, 7).

Current concepts of cellular membranes suggest the existence of a fluid mosaic structure of globular proteins embedded in, and partially protruding from, an organized but discontinuous lipid layer (8). The site of attachment for membrane-active steroids might be protein or lipid. But membrane proteins have not been well characterized. Because of the availability of pure lipid substances known to be components of biological membranes and in view of Willmer's hypothesis (1), it was decided to use monolayers containing lecithins and cholesterol as membrane models.

Few studies on the effect of steroids on monolayers have been reported. Progesterone penetrated monolayers of cholesterol and dipalmitoyl lecithin to some extent (9). Cortisone had little effect on monolayers of stearic acid or cholesterol (10), and the properties of stearyl alcohol monolayers were not affected by the presence of dissolved steroids (11).

Progesterone, testosterone, etiocholanolone, and androsterone had little effect on the surface pressure of lipid monolayers in the condensed state (12), but the surface potential of every monolayer was lowered by the same amount in the presence of a given steroid regardless of the nature of the polar group. This finding was attributed to alteration of the structure of water beneath the monolayers by the steroids. Similar changes in surface potential were caused by hydrocortisone in the presence of lecithin and cholesterol monolayers (13). However, the observed changes were an artifact of the experimental procedure and not a result of changes in water structure.

This report describes the effect of hydrocortisone (I) on model membranes composed of monolayers containing dipalmitoyl (II) and egg (III) lecithins and cholesterol (IV). The molecular weights (in daltons) used

EXPERIMENTAL

Hydrocortisone[1] was used as received. Its identity and purity were checked by melting point, optical rotation, paper chromatography, TLC, and IR spectroscopy. Cholesterol[2], dipalmitoyl lecithin[2], and egg lecithin[3] were reported as 99% pure by the suppliers. Organic solvents, spectrograde, were free of surface-active impurities (14). Sodium chloride was reagent grade. Water was double distilled with the final distillation in an all-glass still.

Surface pressure, π, measurements were made by the Wilhelmy plate method using a thin platinum plate suspended from a torsion balance[4] (15). The polytef[5] surface balance was similar to one described previously (16).

The hydrocortisone was dissolved in the subphase consisting of 0.9% sodium chloride solution prior to spreading the monolayer. Hexane was the spreading solvent for cholesterol. The lecithins and all mixed lipid systems were spread from solution in hexane–ethanol (4:1). The lipid solutions were spread on the subphase with a micrometer syringe[6]. Subphase temperature was controlled to within 0.1° with a thermostat[7]. The reproducibility of each π reading in replicate experiments at the 95% confidence interval was ±0.5 mN m^{-1} at all areas.

RESULTS AND DISCUSSION

Single-Component Monolayers—The properties of dipalmitoyl lecithin monolayers were described previously (17). Surface pressure–surface area (π–A) curves for dipalmitoyl lecithin monolayers on a subphase containing dissolved hydrocortisone at 25° are shown in Fig. 1. The surface pressure of the monolayer was increased in the presence of hydrocortisone if the area per molecule of dipalmitoyl lecithin was greater than about 0.5 nm^2. Under these conditions, the lecithin molecules had their hydrated polar groups in close contact while the hydrocarbon "tails" were not tightly packed (17).

The increase in surface pressure that occurred when hydrocortisone was in the subphase was indicative of surface penetration by hydrocortisone molecules. The magnitude of the change in surface pressure was a function of hydrocortisone concentration. As the monolayers were compressed to surface areas smaller than 0.50 nm^2/molecule of dipalmitoyl lecithin, the π–A curves for the systems containing hydrocortisone approached the curve obtained in the absence of the steroid. This finding was interpreted as an expulsion of steroid molecules from the monolayers. The removal of hydrocortisone from the surface coincided with a change in monolayer structure in which the lecithin polar groups underwent a change in hydration and the vertically oriented hydrocarbon tails became closely associated (17). The presence of hydrocortisone did not prevent this transition or alter the surface area at which it took place.

At a subphase temperature of 37°, the transition from an arrangement involving head contact to one of tail contact in dipalmitoyl lecithin monolayers (Fig. 2) took place at a much higher surface pressure than at 25° (17). Penetration of the monolayers by hydrocortisone was, again, a function of subphase concentration of the steroid. As the monolayers were compressed to smaller values of surface area available to the lecithin, the π–A curves obtained with hydrocortisone present (Fig. 2) were shifted closer to the curve for lecithin alone, suggesting that hydrocortisone molecules were being forced from the surface in response to the change to a state of tail contact in the monolayer.

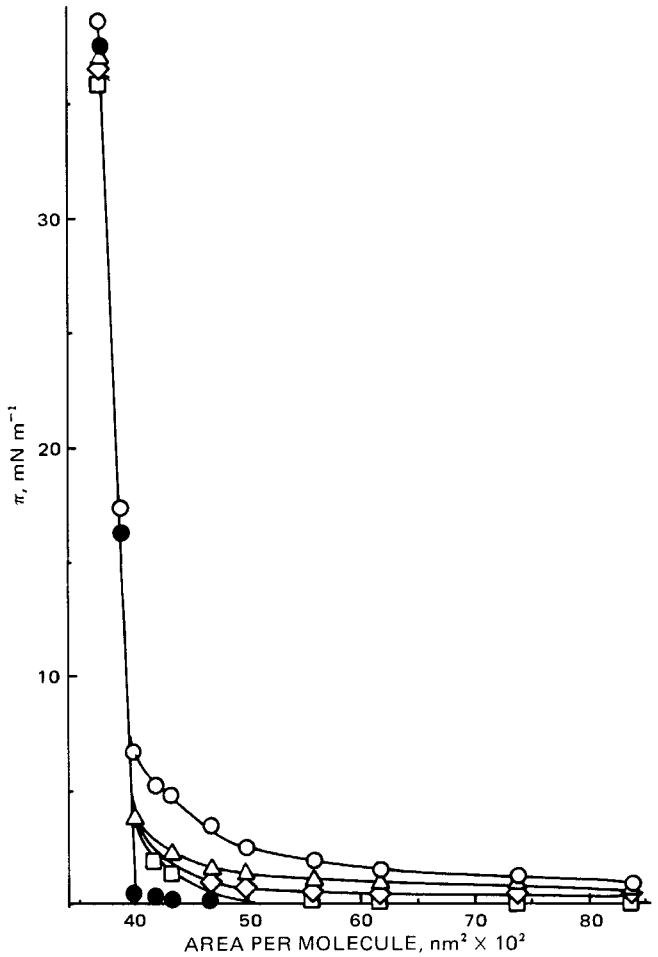

Figure 5—*The π–A curves of cholesterol monolayers spread on a subphase containing dissolved hydrocortisone at 37°. Key: ●, no hydrocortisone; □, 2.98 × 10⁻⁵ M hydrocortisone; ◇, 8.20 × 10⁻⁵ M hydrocortisone; △, 13.7 × 10⁻⁵ M hydrocortisone; and ○, 19.7 × 10⁻⁵ M hydrocortisone.*

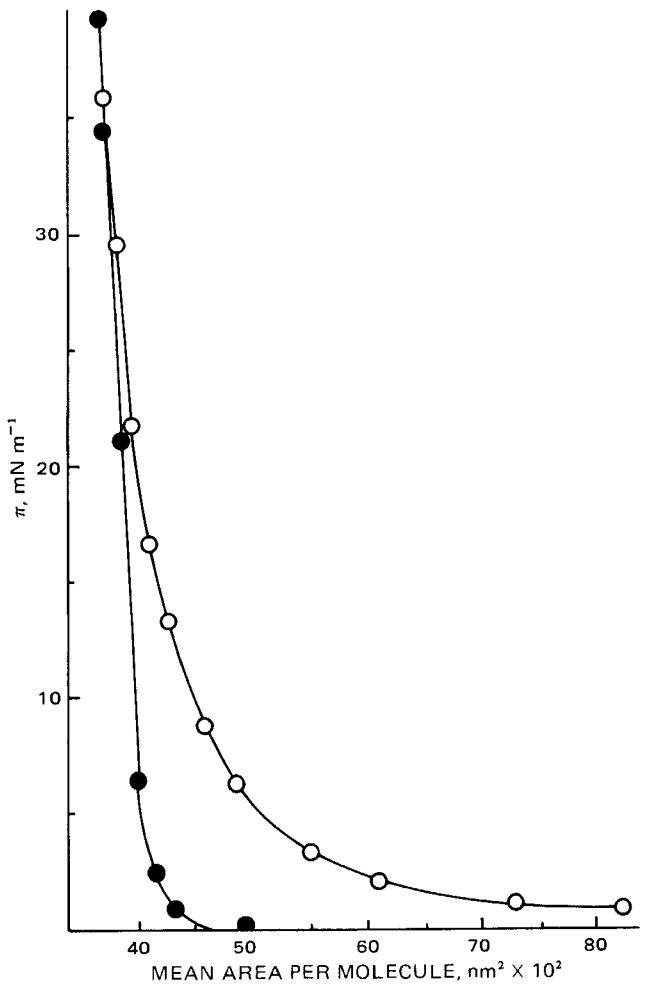

Figure 6—*The π–A curves of monolayers of dipalmitoyl lecithin and cholesterol in a 1:2 molar ratio on a subphase containing dissolved hydrocortisone at 25°. Key: ●, no hydrocortisone; and ○, 19.7 × 10⁻⁵ M hydrocortisone.*

Egg lecithin contains a mixture of phosphatidyl cholines. Approximately 53% of the fatty tails are unsaturated (18). The *π–A* curve (Fig. 3) was of the expanded type, and compression of the monolayer did not force the hydrocarbon groups together until near the collapse point (19). As with dipalmitoyl lecithin, the extent of monolayer penetration by hydrocortisone depended on subphase concentration. Compression caused the *π–A* curves for the systems containing steroid to approach the curve for egg lecithin alone, and all curves merged just before the collapse pressure was reached.

Figure 4 demonstrates the effect of hydrocortisone on cholesterol monolayers at 25°. At the lower concentrations, hydrocortisone caused little change in the *π–A* curve; but at a subphase concentration of 19.7 × 10^{-5} *M* hydrocortisone, the surface pressure of the cholesterol monolayer increased significantly. However, this effect may have been due to physical entrapment of hydrocortisone molecules during compression of the cholesterol surface films. Surface potential work showed that some adsorption of hydrocortisone takes place at the air–water interface (13). If desorption were slow relative to compression, some hydrocortisone might remain at the surface even in the absence of an appreciable interaction with the monolayer. The cholesterol monolayers were unstable in the sense that when the surface area per cholesterol molecule was held constant, surface pressure readings dropped with time. In contrast, the surface pressure measurements made on the lecithin monolayers remained stable for at least 20 min whether or not hydrocortisone was present.

At a subphase temperature of 37°, hydrocortisone caused a small increase in surface pressure when the area per cholesterol molecule exceeded 0.40 nm^2 (Fig. 5). The condensed portion of the *π–A* curve was unaffected, indicating that hydrocortisone was not retained in the monolayer. These results are in agreement with the report of Gershfeld and Heftmann (10). When the molecular area of cholesterol is greater than 0.40 nm^2, the cholesterol molecules exist as individual units or clusters, leaving some aqueous surface available for adsorption of hydrocortisone. Compression forces the cholesterol molecules together (the monolayer becomes coherent) and causes desorption of hydrocortisone.

The incorporation of hydrocortisone into monolayers can be thought of as a distribution phenomenon in which the surface concentration depends on the characteristics of the surface film as well as the bulk concentration of steroid. With a monolayer in a condensed state (with close packed vertical hydrophobic groups), hydrocortisone cannot penetrate between the fatty tails. Hydrophobic interactions between hydrocortisone and the film molecules cannot compete successfully with the interactions between film molecules.

In earlier work on monolayers in which no penetration by steroids was observed (10, 11), the surface films studied were condensed. With expanded monolayers, hydrocortisone can enter the surface under two sets of conditions. First, adsorption occurs at monolayer-free aqueous interfaces so it should also take place when monolayer molecules are widely separated at the surface. Such simple adsorption does not require any interaction with film molecules but can occur only when the monolayer is gaseous, *i.e.*, at surface areas where the monolayer without hydrocortisone is less than 1–2 mN m^{-1}. This mechanism appears to be operative in cholesterol monolayers.

The second condition involves penetration of a monolayer in which the film molecules are in contact without tight packing of hydrocarbon tails. The effective molecular area of film molecules is determined by the size of the hydrated polar group. With this arrangement, steroid molecules might displace water of hydration and associate with film molecules. This mechanism appears to be operative in the penetration of lecithin monolayers by hydrocortisone.

Mixed Monolayers—Cholesterol causes changes in the molecular organization of dipalmitoyl lecithin monolayers (17). Since the pene-

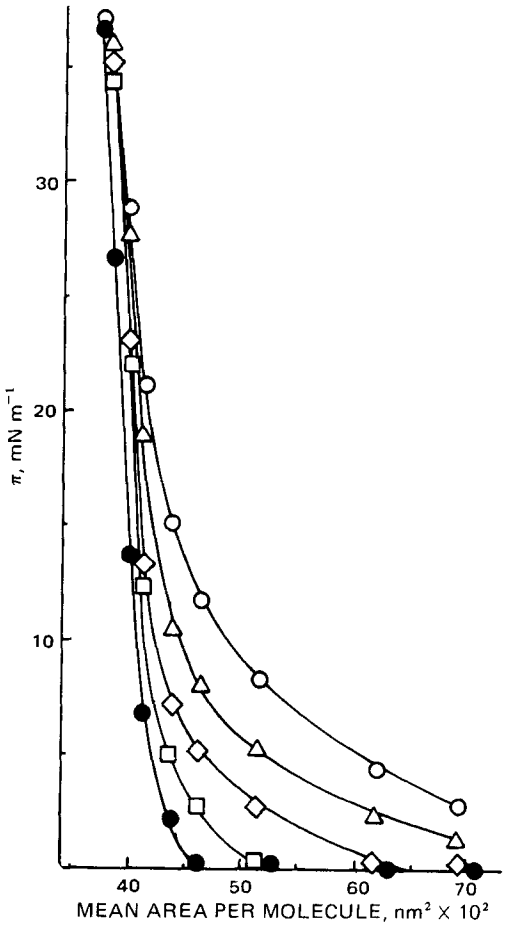

Figure 8—*The π–A curves of monolayers of dipalmitoyl lecithin and cholesterol in a 1:1 molar ratio on a subphase containing dissolved hydrocortisone at 25°. Key: ●, no hydrocortisone; □, 2.98 × 10^{-5} M hydrocortisone; ◇, 8.20 × 10^{-5} M hydrocortisone; △, 13.7 × 10^{-5} M hydrocortisone; and ○, 19.7 × 10^{-5} M hydrocortisone.*

tration of monolayers by hydrocortisone depends on the monolayer state, it was of interest to see whether the inclusion of cholesterol in surface films of lecithin influences interactions of the model system with hydrocortisone. Accordingly, some experiments were conducted in which mixed dipalmitoyl lecithin–cholesterol monolayers were spread on subphases containing hydrocortisone (Figs. 6–9). Only one subphase concentration was used with the dipalmitoyl lecithin–cholesterol mixed monolayer in a 1:2 molar ratio (Fig. 6). The *π–A* curve obtained with hydrocortisone present was the same as the one produced when the monolayer contained only cholesterol. The influence of the lecithin seemed to be completely swamped.

A single subphase concentration of hydrocortisone was used with the dipalmitoyl lecithin–cholesterol mixed monolayer in a 2:1 molar ratio (Fig. 7). The change in surface pressure due to hydrocortisone was smaller than with a monolayer of pure dipalmitoyl lecithin. The equimolar mixed systems at 25° (Fig. 8) and 37° (Fig. 9) were similar in structure (17). At 25° (Fig. 8), hydrocortisone increased the surface pressure only at mean molecular areas corresponding to a gaseous monolayer, one in which the film molecules are separated from one another. In a coherent system, such as a membrane, no space would be available to steroid molecules. At 37° (Fig. 9), the situation was quite similar, although there was a small region of head contact in the *π–A* curves. All curves met at about 15 mN m^{-1}.

Comparison of these results for mixed monolayers with the experiments on single-component lecithin monolayers shows that monolayer penetration by hydrocortisone was diminished effectively in the presence of cholesterol. Previously (20), the addition of cholesterol to lipid dispersions decreased the uptake of hydrocortisone and other steroids by the membranes.

Application of the heads-or-tails model (17, 19) provides an explanation for the effect of cholesterol. In mixed monolayers containing cholesterol and dipalmitoyl lecithin, cholesterol molecules change the packing in the monolayer under conditions where the cholesterol molecules become interspersed among the hydrocarbon tails of the dipalmitoyl lecithin molecules. The molecular assembly is more compact, and the molecular area is determined by the cross-sectional area of the hydrocarbon portion.

The extent of this change in packing depends on the cholesterol content. When cholesterol is the principal component of the mixed systems, all molecules are in tail contact. In the 1:1 mixed system, all molecules are in tail contact over most of the surface pressure range. When dipalmitoyl lecithin is the principal component, some lecithin molecules are in tail contact while a portion are in the same state as they would be in a monolayer of pure dipalmitoyl lecithin at the same surface pressure. Conversion of lecithin molecules from a head contact situation to one of tail contact blocks possible sites of hydrocortisone penetration, making it more difficult for hydrocortisone to enter the monolayer.

Extrapolation to Biological Membranes—Although extrapolation from a simple model system to a complex biological system is always hazardous, some general statements seem justified. The ability of hydrocortisone to penetrate lecithin monolayers at 37° that are coherent (but in head contact) suggests that hydrocortisone can associate with lecithin molecules in biological membranes. The uptake by membranes is expected to be dependent on the bulk concentration. Cholesterol monolayers must be in the gaseous state to interact with hydrocortisone. This is not likely in membranes. In mixed monolayers, cholesterol reduces monolayer penetration by hydrocortisone. Membranes containing cholesterol should admit fewer hydrocortisone molecules into the plane of the membrane than those that are free of cholesterol.

Orientation of Hydrocortisone in Penetrated Monolayers—The inability of hydrocortisone to be accommodated between hydrocarbon chains in lecithin monolayers whose molecules are in a state of tail contact

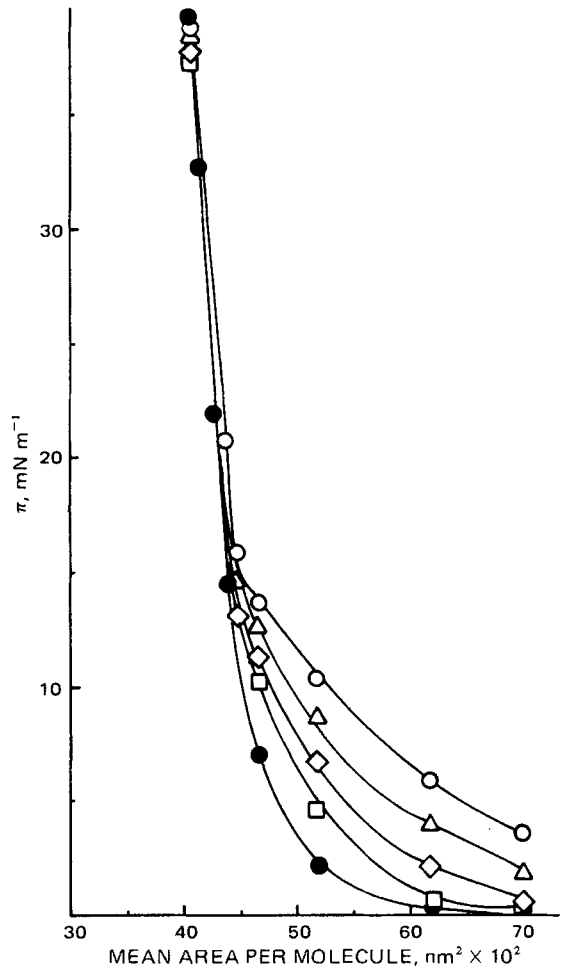

Figure 9—*The π–A curves of monolayers of dipalmitoyl lecithin and cholesterol in a 1:1 molar ratio on a subphase containing dissolved hydrocortisone at 37°. Key: ●, no hydrocortisone; □, 2.98 × 10⁻⁵ M hydrocortisone; ◇, 8.20 × 10⁻⁵ M hydrocortisone; △, 13.7 × 10⁻⁵ M hydrocortisone; and ○, 19.7 × 10⁻⁵ M hydrocortisone.*

is in marked contrast to the behavior of cholesterol, which is completely miscible (17). The difference is most likely due to the location of polar groups on the hydrocortisone molecule. Cholesterol has a single polar group at one end of the molecule, allowing orientation at the interface so that the polar group is in contact with water while the hydrophobic portion of the molecule protrudes from the surface. Hydrocortisone has polar groups at both ends of the molecule, thus favoring a horizontal orientation so that all polar groups can remain hydrated. Support for this orientation comes from spin label studies showing that corticosteroids do not orient in the hydrocarbon tail region of lipid bilayers (21). Willmer's theory of steroid hormone activity (1) was based on the notion that steroid molecules would be retained between the phospholipid fatty chains so that the long axis of the steroid molecule would be normal to the surface. The results of this study, therefore, contradict Willmer's hypothesis.

Absorption Kinetics of Procainamide in Humans

CARL V. MANION ×, DAVID LALKA *,
DENISE T. BAER, and MELVIN B. MEYER

Abstract □ Plasma procainamide concentrations following the administration of 500 mg of procainamide hydrochloride *via* intravenous infusion, conventional capsules, and sustained-release tablets were compared in 11 healthy male volunteers. Two-compartment open modeling of the plasma levels from the intravenous infusion experiments yielded mean K_{el}, k_{12}, and k_{21} values of 0.0162, 0.0542, and 0.0233 min^{-1}, respectively. The bioavailability of the oral preparations (*versus* intravenous) averaged 83% for the capsule and 79% for the sustained-release tablet. Calculations using a previously reported method suggested that absorption was a first-order process with mean k_a's of 0.0336 and 0.0039 min^{-1} for the capsule and sustained-release tablet, respectively. The sustained-release formulation exhibited delayed release and adequate bioavailability.

Keyphrases □ Procainamide—bioavailability of intravenous infusion, capsules, and sustained-release tablets, absorption of oral forms compared, humans □ Bioavailability—procainamide, intravenous infusion, capsules, and sustained-release tablets compared, humans □ Absorption, GI—procainamide, capsules and sustained-release tablets compared, humans □ Antiarrhythmic agents—procainamide, bioavailability of intravenous infusion, capsules, and sustained-release tablets, absorption of oral forms compared, humans

Procainamide, a widely used antiarrhythmic agent, has a log-linear phase plasma disappearance half-life of about 3 hr (1). This short half-life can lead to subtherapeutic plasma levels 4 hr after oral administration of conventional formulations. Therefore, a 3-hr dosing interval was recommended for maintenance of a therapeutic plasma concentration (2).

More recently, several attempts to prolong the apparent half-life of plasma procainamide utilized formulation techniques to produce sustained release (3–5). Studies with these formulations generally suggested some advantages. The present study was undertaken to measure the absorption rate and bioavailability of an experimental sustained-release tablet and to document its plasma concentration–time curve.

EXPERIMENTAL

Subjects and Dosing—Eleven male subjects participated after giving written informed consent. They were healthy as judged by history, physical examination, and laboratory tests. Their ages ranged between 21 and 28 years with a mean of 21.8, and their weights ranged between 73.6 and 94 kg (Table I).

Procainamide hydrochloride for intravenous use[1] was administered by intravenous infusion over 16 min at a constant rate of 27.1 mg of base/min. Each of the other two dosage forms, the capsule[2] or sustained-release tablet[3], was given with 100 ml of water after an overnight fast. The schedule of administration of dosage forms was randomly determined for each volunteer. Each dosage form was administered at intervals of 1 week or more.

Sample Collection—Blood specimens were collected at −0.25, 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4, 5, 6, 8, 12, and 24 hr for both oral preparations. Blood specimens were collected during and after the intravenous infusion at −5, 3.5, 7, 10.5, 14, 17.5, 20, 24, 28, 32, 38, 44, 50, and 60 min and 1.5, 2, 3, 4, 5, 6, 8, 12, and 24 hr. A pretreatment urine sample as well as 0–8- and 8–24-hr specimens was collected for drug determination. For the first eight single studies, 24–48-hr urine specimens were collected.

Analysis of Procainamide and Apparent *N*-Acetylprocainamide in Plasma and Urine—Plasma procainamide levels were measured spectrophotometrically by the method of Mark *et al.* (6) as modified by Sitar *et al.* (7). In some studies, conjugates of procainamide (presumably *N*-acetylprocainamide) were approximated by the same method after acid hydrolysis of the methylene chloride extract (evaporated to dryness, dissolved in 1 *N* hydrochloric acid, and heated to 100° for 1 hr) of the plasma specimen. Urine samples were assayed as described but were also analyzed by a modification of a reported GLC procedure (8), again with and without hydrolysis.

The sensitivity of the spectrophotometric method was approximately 0.10 μg/ml with a concentration-independent recovery of 98% during this study; the sensitivity of the GLC method was 1–5 μg/ml with a recovery of 97% over a similar concentration range (urine contained an interfering peak). The coefficient of variation for the spectrophotometric method throughout this study was 3% as measured by quality control specimens run daily. The GLC method yielded an 8% coefficient of variation measured from deviation of slopes of the standard curves. These measurements were similar to previous estimates of precision, sensitivity, and recovery (1, 6–9).

Plasma specimens were frozen to −20° and stored at that temperature until the analysis was performed, except as noted below. Since artifactual procainamide could be generated from *N*-acetylprocainamide (a known metabolite) by hydrolysis, a blank plasma sample to which *N*-acetylprocainamide (10 μg/ml) had been added was also carried through the assay procedure. Furthermore, several sets of samples were assayed within 48 hr or less of the time they were drawn or received and were reanalyzed 6–8 weeks later. These studies were all performed in an effort to ensure that the procainamide plasma and urine levels were not artifactual.

Pharmacokinetics—Plasma concentrations, C_p, following intravenous infusion declined biexponentially in accordance with:

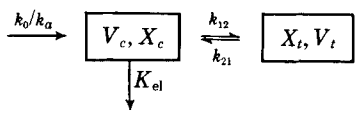
$$C_p = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 1)}$$

The values of A and B were corrected by the method of Loo and Riegelman (10) for the infusion time of 16 min using:

$$A_i = \frac{k_i \tau}{(1 - e^{-k_i \tau})} A_i' \qquad \text{(Eq. 2)}$$

where τ is the duration of the constant-rate infusion, the A_i's are the $t = \tau$ intercepts of the two exponential phases, and the k_i's are the disposition slope constants (*i.e.*, α and β). The data were fitted to a two-compartment open model (Scheme I), and the values for K_{el}, k_{12}, k_{21}, and V_c were estimated by utilizing the nonlinear least-squares regression analysis program NONLIN (11) on a time-share computer. Each plasma concentration was weighted as its reciprocal.

The computer fit values for K_{el}, k_{12}, k_{21}, and V_c from each individual were then further utilized for the calculation of the apparent absorption rate constant, k_a, by the method of Loo and Riegelman (12). Percent unabsorbed estimations were made at various times, and least-squares



Scheme I—Representation of transfer and elimination in a two-compartment open model; k_{12} *and* k_{21} *are first-order transfer rate constants between the central and peripheral compartments as indicated;* K_{el} *is the first-order elimination rate constant from the central compartment;* k_0 *is a zero-order infusion rate constant;* k_a *is the first-order rate constant for drug absorption;* V_c *and* V_t *are the apparent volumes of the central and tissue compartments, respectively; and* X_c *and* X_t *are the masses of drug contained in these compartments.*

Mean ± *SD*	21.8	80.1 ± 6.5	6.27 ± .48

fits were performed to estimate k_a. Plasma level simulations from mean data were performed by the method of superposition as described by Westlake (13). Individual curves were described by:

$$C_p = \frac{k_a DF}{V_c}\left[\frac{(\alpha - k_{21})}{(\alpha - \beta)(k_a - \alpha)}e^{-\alpha t} + \frac{(k_{21} - \beta)}{(\alpha - \beta)(k_a - \beta)}e^{-\beta t} - \frac{(k_a - k_{21})}{(k_a - \alpha)(k_a - \beta)}e^{-k_a t}\right] \quad \text{(Eq. 3)}$$

RESULTS

Intravenous Infusion Experiments—After a brief infusion of procainamide, the plasma concentration declined biexponentially with a $t_{1/2\alpha}$ = 8.8 ± 1.2 min and a $t_{1/2\beta}$ = 204 ± 14 min (Table II). Fitting of these data to a two-compartment open model (Scheme I) yielded mean K_{el}, k_{12}, and k_{21} values of 0.0162, 0.0542, and 0.0233 min^{-1}, respectively (Table III). The apparent volume of the immediately equilibrating space, V_c, was 0.79 liter/kg, and $V_{d\beta}$ was 2.74 liters/kg. Renal clearance, Cl_R, and total body clearance, Cl_B, averaged 400 and 749 ml/min, respectively.

[a] All ratios ×100. [b] This value was excluded from bioavailability calculations because it is believed that the volunteer lost some urine containing drug following his intravenous dose.

administration of the two oral preparations are shown in Fig. 1. The plasma procainamide levels following the conventional capsule were higher during the first 3 hr of the experiment; at later time points, the sustained-release tablet yielded higher levels.

Bioavailability was estimated by two methods: the ratio of the areas under the plasma concentration–time curves ($AUC_{po}^{24hr}/AUC_{iv}^{24hr}$) and the ratio of the total urinary excretion of procainamide ($PA_{u,po}^{24hr}/PA_{u,iv}^{24hr}$). The *AUC* estimates suggest that the two preparations (conventional capsule and sustained-release tablet) possess nearly equal bioavailability, while the urinary excretion data indicate that procainamide is absorbed more completely from the conventional capsule (86.0 *versus* 71.0%, Table IV).

The plasma levels from each subject were further analyzed by the method of Loo and Riegelman (12) to estimate the apparent absorption rate constant from each formulation (Fig. 2). The results of these estimations for all subjects (assuming first-order absorption) as well as the Loo–Riegelman approximation of the known intravenous infusion rate are shown in Table V. The k_a for the sustained-release tablet averaged almost an order of magnitude slower than the k_a of procainamide from the conventional capsule.

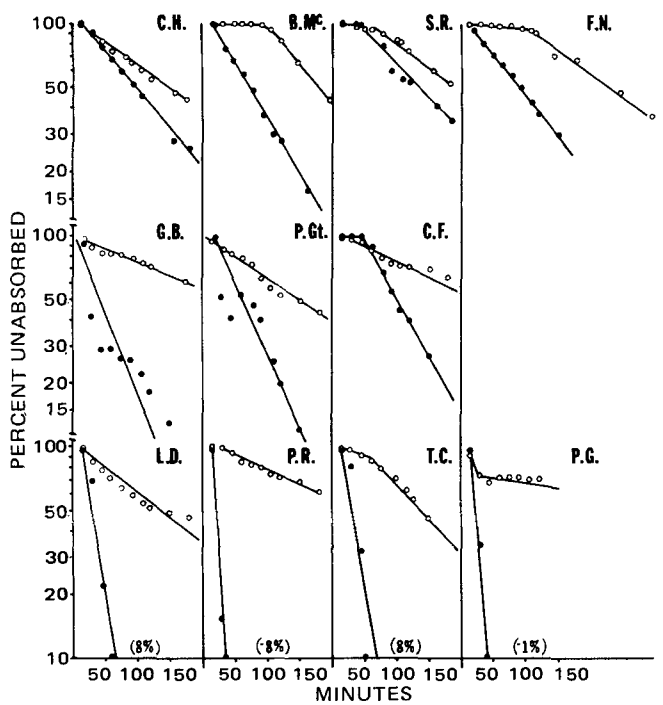

Figure 2—*Loo–Riegelman plots of percent unabsorbed* versus *time following the administration of 500 mg of procainamide hydrochloride as a sustained-release tablet (○) and a conventional capsule (●) for volunteers.*

DISCUSSION

Intravenous Studies—A two-compartment open model adequately described the plasma levels following intravenous infusion of procainamide. The value of V_c was 0.79 ± 0.11 liter/kg, substantially greater than a previously reported value (5). That report (5), however, contained a fixed recording error of elapsed time for the intravenous procainamide doses, which, if corrected, yields a V_c of 0.48 liter/kg[4]. The V_{dB} (2.74 liters/kg) was approximately equal to the previous literature value (5). Other differences in pharmacokinetic constants are, therefore, explained by this correction in V_c.

Concern in this study regarding the potential hydrolysis of *N*-acetylprocainamide to procainamide as a general source of error appears answered by the small coefficient of variation observed for the assay, the absence of hydrolysis as measured under the assay conditions utilized, and the relative agreement of infusion rate prediction (Loo–Riegelman) with the known infusion rate. These observations are supported by a recent report suggesting that the various procainamide assay procedures yield similar results (13). If any method is subject to interference from *N*-acetylprocainamide, it appears to be the fluorometric procedure (14).

Bioavailability—The sustained-release preparation, whose characteristics this study was to determine, appears to have satisfactory bioavailability. First-pass metabolic effect considerations (15) suggest that the bioavailability of both oral preparations approaches the maximum possible for procainamide in humans if nonrenal clearance ($Cl_{NR} = Cl_B - Cl_R$) is presumed to represent hepatic clearance. The difference in the ($PA_{u,po}^{24hr}/PA_{u,iv}^{24hr}$) bioavailability calculation suggests that the sustained-release tablet is less available than the conventional capsule. However, the urinary procainamide excretion from any administration is subject to the problem of the completeness of urine collection, and the urinary recovery ratio method may be less reliable (footnote *a*, Table IV). Indeed, incomplete urinary recovery from Subject B.M. following his intravenous dose is perhaps the most plausible explanation for his high bioavailability when calculated from urinary excretion data. The overall variability in the urinary excretion data is sufficiently great to limit the capacity to suggest a bioavailability difference.

Absorption Rate—A principal objective of this study was to compare the absorption rate of procainamide from a sustained-release tablet to that from a conventional capsule. The calculation of an absorption rate constant further requires that the individual percent unabsorbed *versus* time data points be fitted to an equation. This approach assumes that oral absorption can be adequately described as a simple function of time (which is not necessarily accurate). Since the Loo–Riegelman plots did show good linearity on semilogarithmic coordinates when the initial "lag time" and the postabsorptive phase were ignored, it seems that apparent first-order kinetics were operative. Furthermore, the relative agreement of the known intravenous infusion rate with that calculated by the method of Loo and Riegelman supports this approach for the approximation of the k_a's (at least for the study of procainamide in humans). Based on these data, a substantial alteration has been achieved in k_a that may be clinically meaningful (16).

[a] This value was not used in the calculation of the mean k_0 since when it was deleted it fell more than 5 *SD* above the mean.

CONCLUSIONS

1. It seems to be possible to delay the *in vivo* absorption rate of procainamide in humans at least an order of magnitude and still achieve satisfactory bioavailability.
2. The method of Loo and Riegelman seems to be satisfactory for the estimation of absorption rate constants for procainamide in humans.
3. Plasma procainamide levels following a brief intravenous infusion were well described by a biexponential equation.
4. Therapeutic blood levels may be achieved with the sustained-release tablet with doses of approximately 1–2 g (four tablets) every 6–8 hr.

Liposomal Entrapment of Floxuridine

STEPHEN P. SIMMONS and PAUL A. KRAMER [x]

Abstract □ Floxuridine was found to have an apparent initial entrapment within negatively charged sphingomyelin liposomes about three times higher than its parent, fluorouracil. The drug also diffused out of the liposomes at a much lower rate than fluorouracil. Substitution of lecithin for sphingomyelin destroyed the effect. Liposomal entrapment may provide enhanced stability and decreased toxicity of floxuridine, permitting wider therapeutic utilization of pyrimidine nucleosides.

Keyphrases □ Floxuridine—entrapment within sphingomyelin and lecithin liposomes, compared to fluorouracil □ Liposomes, sphingomyelin and lecithin—entrapment of floxuridine, compared to fluorouracil □ Antitumor agents—floxuridine, entrapment within sphingomyelin and lecithin liposomes, compared to fluorouracil

The actual inhibitor of thymidylate synthetase and, hence, DNA biosynthesis in tumor growth inhibition by fluorouracil (I) is 2′-deoxy-5-fluorouridine 5′-monophosphate (II) (1). Floxuridine (2′-deoxy-5-fluorouridine) (III) is a better precursor of II than I, as evidenced by the fact that it is 10^3 times as effective in inhibiting DNA thymine synthesis in Ehrlich ascites cells *in vitro* (2) and is a more effective carcinostatic agent against both Ehrlich ascites and Sarcoma-180 *in vivo* (3). This increased intrinsic activity is not translated into increased effectiveness in humans, because III is degraded to its constituent pyrimidine and sugar moieties by nucleoside phosphorylases in serum and tissues (4). Attempts at stabilization have included chemical modification of the drug itself as well as the addition of deoxyribose donors and enzyme inhibitors to suppress the degradation reaction (5, 6).

One might expect the encapsulation of III within the aqueous compartments of phospholipid vesicles (liposomes) to be of utility in this regard. The protective lipid sheath might prevent enzymatic degradation in serum and reduce the toxicity of the drug by excluding it from regions such as the GI tract. Previous workers reported difficulty

Liposomal Entrapment of Floxuridine

STEPHEN P. SIMMONS and PAUL A. KRAMER [x]

Abstract □ Floxuridine was found to have an apparent initial entrapment within negatively charged sphingomyelin liposomes about three times higher than its parent, fluorouracil. The drug also diffused out of the liposomes at a much lower rate than fluorouracil. Substitution of lecithin for sphingomyelin destroyed the effect. Liposomal entrapment may provide enhanced stability and decreased toxicity of floxuridine, permitting wider therapeutic utilization of pyrimidine nucleosides.

Keyphrases □ Floxuridine—entrapment within sphingomyelin and lecithin liposomes, compared to fluorouracil □ Liposomes, sphingomyelin and lecithin—entrapment of floxuridine, compared to fluorouracil □ Antitumor agents—floxuridine, entrapment within sphingomyelin and lecithin liposomes, compared to fluorouracil

The actual inhibitor of thymidylate synthetase and, hence, DNA biosynthesis in tumor growth inhibition by fluorouracil (I) is 2′-deoxy-5-fluorouridine 5′-monophosphate (II) (1). Floxuridine (2′-deoxy-5-fluorouridine) (III) is a better precursor of II than I, as evidenced by the fact that it is 10^3 times as effective in inhibiting DNA thymine synthesis in Ehrlich ascites cells *in vitro* (2) and is a more effective carcinostatic agent against both Ehrlich ascites and Sarcoma-180 *in vivo* (3). This increased intrinsic activity is not translated into increased effectiveness in humans, because III is degraded to its constituent pyrimidine and sugar moieties by nucleoside phosphorylases in serum and tissues (4). Attempts at stabilization have included chemical modification of the drug itself as well as the addition of deoxyribose donors and enzyme inhibitors to suppress the degradation reaction (5, 6).

One might expect the encapsulation of III within the aqueous compartments of phospholipid vesicles (liposomes) to be of utility in this regard. The protective lipid sheath might prevent enzymatic degradation in serum and reduce the toxicity of the drug by excluding it from regions such as the GI tract. Previous workers reported difficulty

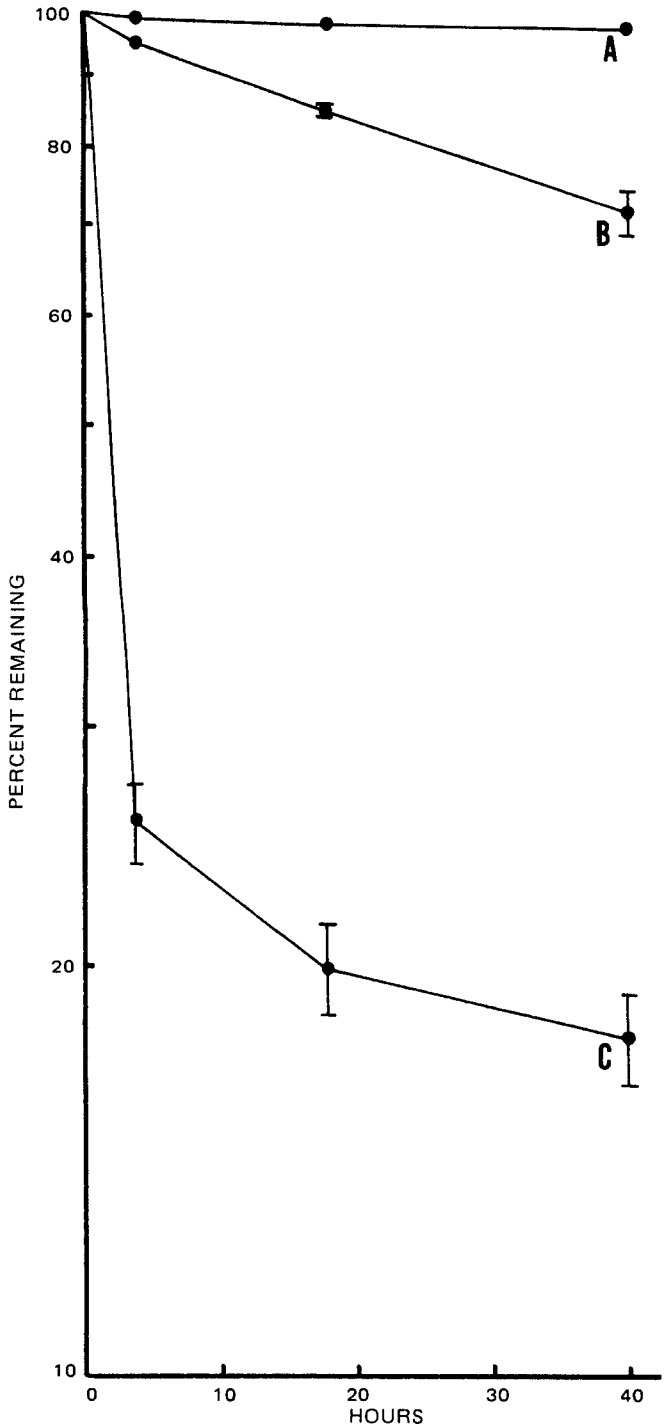

Figure 1—*Diffusion of sucrose (A), floxuridine (B), and fluorouracil (C) from sphingomyelin liposomes. The sphingomyelin–cholesterol–dicetyl phosphate ratio was 4.8:2.8:1.0, and the lipid–aqueous phase ratio was 70:1. The zero-time value of 100% represents initial entrapment after 4 hr of swelling at 25° plus 15 min of sonication. All other values are percentages of this initial quantity that remained entrapped after incubation of the liposomes for various times at 25°. Plotted points are mean ±SEM for three determinations.*

retaining I within liposomes (7, 8). The distribution of I in the rat was favorably altered toward exclusion of the drug from GI tissues, even though there was pronounced diffusion of drug from liposomes to plasma (8). The present studies were undertaken to determine if the more hydrophilic deoxyribose derivative might be a better candidate for liposomal delivery.

EXPERIMENTAL

Materials—Sphingomyelin[1] (bovine brain), egg lecithin[2], and dicetyl phosphate[3] were used as received. Fluorouracil[4], floxuridine[5], sucrose[6], and cholesterol[5] were mixed with 6-^{3}H-fluorouracil[7] (26 Ci/mmole), 6-^{3}H-floxuridine[7] (2.3 Ci/mmole), 6,6′(*n*)-^{3}H-sucrose[7] (3.6 Ci/mmole), and 4-^{14}C-cholesterol[7] (47.2 mCi/mmole) (5 μCi/ml), respectively, prior to use. Spectral grade chloroform was used to dissolve the lipids, and all water was double distilled in an all-glass system.

Liposome Preparation—Liposomes were prepared from chloroform solutions of phospholipid (egg lecithin or sphingomyelin), cholesterol (sometimes 4-^{14}C-labeled), and dicetyl phosphate in molar ratios of 7:2:1 or 4.8:2.8:1. The lipids were evaporated under vacuum to a thin film on a 10-ml pear-shaped flask, and an isotonic, buffered (pH 6.0, 0.01 *M* phosphate) solution of tritiated sucrose, fluorouracil, or floxuridine (0.077 *M*) was added. The lipid–aqueous phase ratios used were 50 and 70 μmoles of lipid/ml of buffer.

A small number of 0.5-mm glass beads was added, and the lipids were dispersed by vortexing[8] for 2 min. After a 2-hr "swelling period" at 25°, the vesicles were sonicated in a bath sonicator[9] for 15 min at 15°. They were held at 25° for an additional 2 hr and then separated from unentrapped drug by chromatography on a 1.5 × 16-cm column[10]. The liposomal eluate was pooled, and the drug content was taken as a measure of "initial" entrapment. The liposomes obtained had a diameter range of 0.5–5.0 μm.

Quantitative determination of drugs and liposomal cholesterol was accomplished by liquid scintillation counting[11]. Drug release kinetics were determined by removing aliquots of liposomes from the pool at various sampling times, rechromatographing to remove released drug, and counting the liposome fractions upon elution from the column.

RESULTS AND DISCUSSION

Table I shows the initial entrapment percentages as a function of drug and lipid composition of the liposome. These percentages depend upon lipid–aqueous phase ratios and molar ratios of constituents of the vesicle as expected. Sucrose was used as a nearly nondiffusable marker to indicate liposome integrity. Increasing the total lipid content and the relative quantity of cholesterol enhanced entrapment of both floxuridine and sucrose. These materials were entrapped to about the same extent when sphingomyelin was the phospholipid, but the entrapment of floxuridine relative to sucrose decreased dramatically when lecithin was substituted.

Increased unsaturation and melting of the acyl side chains were reported to increase the rate of diffusion of both charged and uncharged solutes through phospholipid membranes (9). The fact that sphingomyelin has a gel–liquid crystalline phase transition temperature of 40° (10) while egg lecithin vesicles "melt" at −15° (11) may account for the observed results. Fluorouracil was apparently entrapped within sphingomyelin liposomes about three times less extensively than floxuridine, but this finding could be an anomalous result produced by the arbitrary definition of "initial" entrapment.

Figure 1 depicts the release of sucrose, floxuridine, and fluorouracil from sphingomyelin liposomes at 25° over nearly 2 days. The liposomal preparation used was that providing the best initial entrapment (Table I). Sucrose was nearly completely retained, as expected. Fluorouracil diffused out with a very high initial rate, high enough to perhaps account for the apparently lower initial entrapment which was actually measured more than 4 hr after swelling began. At least for sphingomyelin liposomes, the hydrogen-bonding hydroxyl groups on the deoxyribose moiety of floxuridine prevent its rapid diffusional loss, as evidenced by the improved retention of floxuridine within sphingomyelin liposomes. This effect is in accord with previous observations by Cohen (12), who concluded that retention of materials within the aqueous interstices of liposomes was directly related to the ability of the material to hydrogen bond. The kinetics of diffusion of drug from these multiconcentric spheres

[a] Measured after 2 min of vortexing, 2 hr of swelling at 25°, 15 min of sonication, and a second 2 hr of swelling at 25°. [b] Seventy micromoles of lipid/ml of aqueous phase. [c] Mean ± *SEM* (three determinations). [d] Fifty micromoles of lipid/ml of aqueous phase. [e] Average of two determinations.

are complex and not first order. The data are plotted on a semilogarithmic plot only as a convenient method for visualizing the relative differences observed.

There is considerable rationale for the entrapment of fluorouracil within liposomes and, as mentioned, retention has been a problem. The present results indicate that floxuridine is retained far better when sphingomyelin liposomes are used, and several other benefits, such as higher intrinsic activity against some cancers, favor the nucleoside. Preliminary results in these laboratories indicate that, after intraperitoneal administration to mice bearing L-1210 leukemia in the ascites form, the liposomes and their floxuridine content are avidly engulfed by the L-1210 cells, with large quantities of floxuridine concentrating in the cells. Further studies are in progress to ascertain the effect of such administrations on the survival times of tumor-bearing mice.

Inhibition of Catechol *O*-Methyltransferase and Transfer RNA Methyltransferases by Coralyne, Nitidine, and Related Compounds

JOHN W. LEE, JOHN O. MacFARLANE, ROBERT K. Y. ZEE-CHENG, and C. C. CHENG [x]

Abstract □ Inhibitory activity against both catechol *O*-methyltransferase and transfer RNA methyltransferases was observed among the antileukemic alkaloids coralyne, nitidine, and related synthetic alkoxy analogs. Inhibition of both classes of enzymes seems to have a similar profile. The role of water solubility of these compounds with regard to their enzyme inhibitory activity was noted.

Keyphrases □ Catechol *O*-methyltransferase—activity, effect of coralyne, nitidine, and related compounds, rat liver homogenate □ tRNA methyltransferase—activity, effect of coralyne, nitidine, and related compounds, rat liver homogenate □ Enzyme activity—catechol *O*-methyltransferase and tRNA methyltransferase, effect of coralyne, nitidine, and related compounds, rat liver homogenate □ Coralyne—effect on catechol *O*-methyltransferase and tRNA methyltransferase activity, rat liver homogenate □ Nitidine—effect on catechol *O*-methyltransferase and tRNA methyltransferase activity, rat liver homogenate □ Alkaloids, antileukemic—coralyne, nitidine, and related compounds, effect on catechol *O*-methyltransferase and tRNA methyltransferase activity, rat liver homogenate □ Structure–activity relationships—effect of coralyne, nitidine, and related compounds on catechol *O*-methyltransferase and tRNA methyltransferase activity, rat liver homogenate

Experimental evidence (1–9) has substantiated the observation of higher transfer RNA (tRNA) methyltransferase activity in fetal or malignant tumor tissue than in normal or benign tumor tissue. Also, certain chemical carcinogens increased tRNA methyltransferase activity (10, 11). These aberrant methylating enzymes may differ qualitatively from the regular tRNA methyltransferase in their specificity of action (12, 13). Certain oxygen-containing compounds possessing antileukemic activity may be tRNA 2′-*O*-methyltransferase inhibitors, and this

methylating enzyme may act *via* a complex analogous to that known for catechol *O*-methyltransferase (COMT) (14).

Therefore, preliminary enzyme inhibitory activity tests of the antileukemic alkaloids coralyne, nitidine, and related compounds (15–19) against catechol *O*-methyltransferase and tRNA methyltransferases were conducted. A number of antitumor purine nucleosides (20), the tubercidin analog of *S*-adenosylhomocysteine (21), and polyinosinate (22) have already been reported as inhibitors of tRNA (and rRNA) methyltransferases.

EXPERIMENTAL

Assay of Catechol *O*-Methyltransferase—The colorimetric assay method used was based on that reported by Herblin (23). The catechol *O*-methyltransferase enzyme extract was prepared according to the method of Axelrod and Tomchick (24) with some modification (all procedures performed at 0–5°). Male adult rat liver, 100 g, was homogenized in 400 ml of 0.15 *M* isotonic potassium chloride. The solution was centrifuged at 41,000×*g* for 30 min. The supernate was drained through cheesecloth, adjusted to pH 5.3 with 1 *N* acetic acid, and centrifuged at 800×*g* for 10 min. The precipitate was discarded, and ammonium sulfate was added to achieve 30% saturation.

This solution was again centrifuged (800×*g* for 10 min), and ammonium sulfate was added to the supernate to achieve 50% saturation. The resulting solution was centrifuged at 6600×*g* for 15 min. The precipitate was collected and dissolved in 40 ml of water and dialyzed against 0.001 *M* phosphate buffer at pH 7 for 4 hr. The enzyme preparation was then dispensed into small (1–5-ml) aliquots and frozen at −60°. The partially purified enzyme preparations used for these tests contained approximately 40–50 mg of protein/ml and 0.05–0.1 unit of enzyme/mg of protein, or approximately 0.75–1.5 units of enzyme per test.

Based upon a series of preliminary titrations and experimental studies, the following procedure was used. Reagents were added to the reaction tubes at 0–5° (ice bath) in the following quantities and order: 0.25 μmole of pH 7 tris(hydroxymethyl)aminomethane buffer, 2.5 μmoles of magnesium chloride hexahydrate, 0.5 ml of the prepared catechol *O*-methyltransferase enzyme extract, 0.1 μmole of *S*-adenosylmethionine (SAM), and 0.13 μmole of 2.68×10^{-4} *M* 4-nitrocatechol as the methyl acceptor. Distilled water was added to tubes as needed to give a final total volume of 2.5 ml.

For the inhibition test, 0.5 ml of the inhibitor solution was allowed to react with 0.5 ml of the enzyme preparation at 0–5° for 5 min and then was added to the reaction mixture. This solution was allowed to remain in a 37° water bath for 45 min, followed by the addition of 2 ml of 6 *N* NaOH to terminate the enzyme reaction. Tubes containing the reaction mixture were centrifuged at 800×*g* at 5° for 10 min. The absorbance of the supernate was measured at 520 nm in a UV spectrophotometer (cell had 10-mm light path). Since at pH ≥ 9, 4-nitrocatechol exhibits a red color whereas its methylated product does not, methylation of catechol *O*-methyltransferase activity can be measured as a decrease in absorbance at 520 nm.

To determine enzyme activity, a reaction mixture was run as a control against the mixture with enzyme. The difference in the absorbance of these two mixtures was then the measure of enzyme activity. Inhibitors were generally tested at three different concentrations. The concentration of an inhibitor was calculated as the final concentration after dilution of the reaction mixture (0.5 ml in 2.5 ml or 1:5). The level of inhibition was determined by measuring the absorbance of a reaction mixture with the inhibitor and subtracting that of a reaction mixture with both the inhibitor and the enzyme.

The percent of enzyme inhibition was then calculated as:

$$\% \text{ inhibition} = \frac{\Delta \text{ absorbance (reflecting enzyme activity with inhibitor)}}{\Delta \text{ absorbance (reflecting enzyme activity without inhibitor)}} \times 100 \quad \text{(Eq. 1)}$$

As a control of the entire procedure, a known inhibitor of catechol *O*-methyltransferase, pyrogallol, was run to achieve a "standard" curve of inhibition (100, 45, and 12% inhibition at 10^{-3}, 10^{-4}, and 10^{-5} *M*, respectively). Pyrogallol was run periodically to check that the assay was producing consistent results.

Assay of tRNA Methyltransferases—The activity of tRNA methyltransferases was measured by the amount of ^{14}C-methyl groups incorporated into the tRNA using the procedure of Waalkes *et al.* (25) with slight modification. The tRNA methyltransferase enzyme extraction was prepared according to the method of Kerr (26) with some modification. Male adult rat liver, 50 g, was homogenized in 200 ml of isotonic potassium chloride, and the mixture was centrifuged at 60,000×*g* for 60 min.

The supernate was drained through cheesecloth, adjusted to pH 5.3 with 1 *N* acetic acid, and centrifuged for 10 min at 6600×*g*. The precipitate was collected and dissolved in 20 ml of 0.1 *M* tris(hydroxymethyl)aminomethane hydrochloride buffer (pH 8). This solution was then stored in small aliquots at −60° and used as the source of inhibitor-free enzyme. Since this extract contained some catechol *O*-methyltransferase activity, pyrogallol was added to the reaction mixture to suppress this activity.

The following procedure was used as the basis of a series of titrations and experimental studies. Reagents were added to the reaction tubes at 0–5° in the following order and quantities: 70 μmoles of ammonium acetate, 0.3 μmole of dithiothreitol[1], 0.3 μmole of tetrasodium ethylenediaminetetraacetate, 25 μmoles of pH 9 tris(hydroxymethyl)aminomethane hydrochloride, 0.5 μmole of magnesium chloride, 0.5 μmole of pyrogallol, enzyme extract (200 μg of protein), 100 μg of undermethylated *Escherichia coli* B tRNA[2], and 5 pmoles of ^{14}C-*S*-adenosyl-L-methionine (58 mCi/mole). The final volume of each tube was 0.5 ml.

For the inhibition test, 0.05 ml of the inhibitor solution was mixed with the enzyme extract in an ice bath (0–5°) for 5 min and then added to the reaction mixture, which was placed in a 37° water bath for 30 min. The reaction was terminated by placing the tube in an ice bath and adding 2.5 ml of 10% trichloroacetic acid. After 20 min, the reaction mixture was

[a] Values in parentheses denote those obtained by graph extrapolation. [b] Insoluble.

filtered through a type HA individual filter (0.45-μm pore size) and washed with 20 ml of 5% trichloroacetic acid. The residue was then air dried and placed into vials with 10 ml of a mixture of 91% of 2,5-diphenyloxazole and 9% of 1,4-bis[2-(4-methyl-5-phenyloxazolyl)]benzene. Radioactivity was measured in a liquid scintillation counter.

To determine enzyme activity, a reaction mixture without tRNA was run as a control against a reaction mixture with tRNA. The difference in ^{14}C-incorporation, measured in counts per minute between these two mixtures, is a measure of enzyme activity (*A*).

Inhibitors were generally tested at three different concentrations. The concentration of an inhibitor was calculated as the final concentration after dilution of the reaction mixture. The level of inhibition was determined by subtracting the counts per minute of a reaction mixture with the inhibitor only from that of a reaction mixture with both the inhibitor and the enzyme (*B*). The percent of inhibition was then calculated as $[(A - B)/A] \times 100$.

An ideal standard for inhibition of tRNA methyltransferases is yet to be found. Nicotinamide (27, 28) and ascorbic acid (40 and 51% inhibition, respectively, at 10^{-3} *M*) were used as controls throughout the tRNA methyltransferase inhibitory tests.

RESULTS AND DISCUSSION

Preliminary enzyme inhibitory results are given in Table I. The first nine compounds (I–IX) were active against leukemias P-388 and L-1210 (15–19), whereas the last five compounds (X–XIV) were inactive. Although no definite conclusion should be drawn at this stage, the results suggest that there is a parallel correlation between the antileukemic activity of these alkoxy compounds and their inhibitory activity against both classes of enzyme. In addition, inhibition against both enzymes seems to have a similar profile.

Solubility characteristics of these compounds in water play an important role in enzyme inhibition. Compound IV (stracoralyne acetosulfate), for example, is quite insoluble in water. Thus, the observed activity may not reflect the true value.

Although X showed high inhibitory activity against both enzymes, it was without effect against leukemias P-388 and L-1210. This finding is probably due to the relative ease of hydrolysis of the acetoxy groups *in vivo;* the resulting phenolic compounds may not be readily transported to the proper biological site to achieve the desired antineoplastic action. (The fact that the tetrahydroxy compound, XI, possessed enzyme inhibitory activity but was inactive against leukemias P-388 and L-1210 further substantiates the proposition.) The corresponding uncharged compound, XII, which is much less soluble in water, was inactive against both enzyme and leukemia systems.

Since the presently studied tRNA methyltransferases are composed of a mixture of methylating enzymes and since purified enzymes such as tRNA *O*-methyltransferase and tRNA *N*-methyltransferase could not be realized, a definite relationship could not be drawn as to whether the inhibitory action against tRNA methylating enzymes is directed to any specific portion of the macromolecule. The original tRNA 2′-*O*-methylation hypothesis (14) thus remains to be examined. Therefore, single tRNA methyltransferases that specifically methylate oxygen, nitrogen, or other atoms should be isolated and purified before further study.

Pharmaceutical Applications of Solid Dispersion Systems: X-Ray Diffraction and Aqueous Solubility Studies on Griseofulvin–Polyethylene Glycol 6000 Systems

WIN L. CHIOU

Abstract □ The X-ray diffraction method was used to characterize physicochemical properties of griseofulvin dispersed in polyethylene glycol 4000 and 6000. Results indicate a negligible or very limited solid solubility of griseofulvin in the pulverized solid dispersions. Pulverization and aging had pronounced effects on the X-ray diffraction spectrum. Results from aqueous solubility studies of griseofulvin in various concentrations of polyethylene glycol 6000 further indicate weak or insignificant interactions between the drug and the carrier. Mechanisms are postulated to account for the reported marked enhancement of dissolution rates and oral absorption of griseofulvin dispersed in these carriers.

Keyphrases □ Griseofulvin—dispersed in polyethylene glycol 6000, X-ray diffraction study, aqueous solubility, effects of pulverization and aging □ Polyethylene glycol 6000—dispersions with griseofulvin, X-ray diffraction study, aqueous solubility, effects of pulverization and aging □ Solid dispersions—griseofulvin–polyethylene glycol 6000, X-ray diffraction study, aqueous solubility, effects of pulverization and aging □ Dispersions, solid—griseofulvin–polyethylene glycol 6000, X-ray diffraction study, aqueous solubility, effects of pulverization and aging □ Solubility, aqueous—griseofulvin–polyethylene glycol 6000 dispersions, X-ray diffraction study □ X-ray diffraction—study, griseofulvin–polyethylene glycol 6000 dispersion, effects of pulverization and aging □ Antifungal agents—griseofulvin dispersed in polyethylene glycol 6000, X-ray diffraction study, aqueous solubility

The *in vitro* dissolution and oral absorption of griseofulvin in dogs and humans were markedly enhanced by the formation of solid dispersions in polyethylene glycol 6000 (1–3). Recently, these results were confirmed with a newly introduced commercial product[1] in single- (4) and multiple- (5) dose studies using larger numbers of test subjects. The new product requires only half of the dose recommended for conventional micronized products. Furthermore, the incidence of side effects decreased with this new formulation (5).

Although it was proposed that the enhancement of dissolution and absorption of griseofulvin dispersed in the polymer was primarily due to the molecular and colloidal dispersion of the drug in the highly water-soluble carrier (1–3), no extensive experimental data regarding physicochemical properties of such a dispersed system have been reported.

This paper reports the detailed results of X-ray diffraction and aqueous solubility studies on such a system. The X-ray diffraction data do not support the previous postulate regarding the extensive formation of a solid solution of griseofulvin in polyethylene glycol polymers. The aqueous solubility study was performed to investigate the possible interaction between the drug and the polymer in an aqueous medium. Findings from the present study should be valuable to the development of solid dispersion dosage forms of other poorly water-soluble drugs utilizing the same type of carriers. Some preliminary results were discussed in a review article (6).

Although different average molecular weights of polyethylene glycol polymers can be used as dispersion carriers (1–3), only polymer 6000 was studied in detail in the present investigation. This polymer has much less absorption in the UV and visible region than polymer 20,000 and thus interferes less with the direct spectrophotometric analysis of drugs (1). Furthermore, based on the author's experience, the solid dispersions prepared with this polymer were generally much easier to pulverize than those prepared with other molecular weights of the polymer.

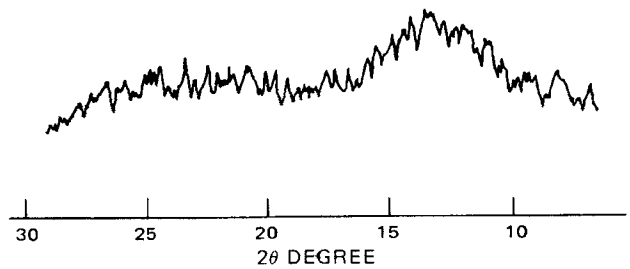

Figure 1—*X-ray diffraction spectrum of the unpulverized resolidified melt of griseofulvin.*

EXPERIMENTAL

Solid Dispersions—Griseofulvin[2]–polyethylene glycol 6000[3] solid dispersions containing 5, 10, 25, and 50% (w/w) griseofulvin were prepared by the melting method (1). After hardening, the melt was pulverized to a fine powder with a mortar and pestle. To study the effect of powdering on the X-ray diffraction pattern of the sample, some melts were poured directly into the sample holder used for the X-ray diffraction studies.

X-Ray Diffraction Studies—The procedure used was described previously (7, 8). The samples studied included the pure and resolidified griseofulvin and the polymers, solid dispersions and their physical mixtures.

Solubility Studies—Micronized griseofulvin, 10 mg, was evenly suspended in 15 ml of 0–10% (w/v) aqueous solutions of polyethylene glycol 6000 in screw-topped extraction tubes and equilibrated by shaking for 48 hr (a preliminary study indicated essentially a constant solubility value after 48 hr) in a constant-temperature water bath maintained at 22 ± 0.5°. The suspensions were then filtered through a 0.22-μm filter[4]. The first 10 ml of the filtrate was discarded to saturate the adsorption sites for griseofulvin on the filter (9); the last 5 ml of the filtrate was analyzed for the concentration of griseofulvin at 295 nm[5]. All experiments were performed at least in duplicate. The UV absorption, due to the presence of the polymer, was corrected in griseofulvin concentration determinations.

RESULTS AND DISCUSSION

X-ray diffraction spectra of the untreated griseofulvin and polyethylene glycol 6000 were previously reported (6). In the present study, essentially identical spectra were also obtained after they were melted, solidified, and pulverized. This, however, was not the case for the unpulverized resolidified griseofulvin melt (Fig. 1). The absence of major griseofulvin diffraction peaks indicates that an amorphous form existed in the unpulverized melt; this amorphous form is thought to convert to the crystalline form after pulverization. The observed glassy and brittle property of the melt and the appearance of an exothermic transition peak below the melting point when the melt was rerun in a differential thermal analyzer[6] are also in accordance with the postulate of the amorphous state of the melt sample. This effect of pulverization on the crystallinity was not observed for polyethylene glycol 4000 and 6000.

Major X-ray diffraction peaks of griseofulvin, particularly at 10.8, 13.3, and 16.6° (8), were all present in the pulverized dispersion samples containing 5–50% griseofulvin. A typical spectrum is shown in Fig. 2. The diffraction spectra of the 5% griseofulvin system were previously reported (6). The similarity of heights of the major diffraction peaks of griseofulvin in the physical mixture and dispersion samples with the same composition indicates the limited or negligible solid solubility of griseofulvin in the polymer. This result is obviously different from the previous postulation of the extensive solid solution formulation (1). Similar findings were also obtained for the griseofulvin–polyethylene 4000 system. Based on these findings and analyses, the (pulverized) dispersed systems of griseofulvin in polyethylene glycol 4000 or 6000 should be classified as simple eutectic mixtures with negligible or limited solid solubility. This result is similar to the findings with chloramphenicol–urea (10) and griseofulvin–succinic acid (8) binary systems and different from the finding on sulfathiazole–urea binary system (7).

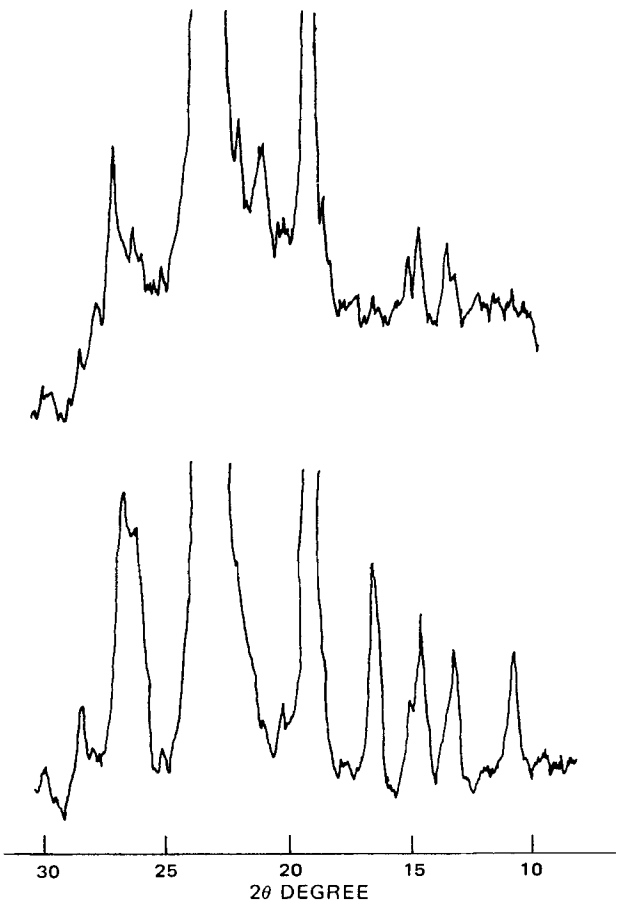

Figure 2—*X-ray diffraction spectra of 20% griseofulvin solid dispersion in polyethylene glycol 6000. Key: top spectrum, unpulverized sample; and bottom spectrum, pulverized sample.*

X-ray diffraction spectra of the freshly prepared (within 2 hr) unpulverized solid dispersions were quite different from those of freshly prepared or aged pulverized samples (Figs. 2 and 3). All major diffraction peaks of griseofulvin were absent. The most logical explanation is that the amorphous form of griseofulvin was precipitated from the melt after cooling, which is consistent with the observed formation of the amorphous form after resolidification of the pure griseofulvin melt, as discussed. The viscous property of the melt of the polymer also might retard the orderly crystallization of griseofulvin during the resolidification process.

The absence of those diffraction peaks, particularly in samples con-

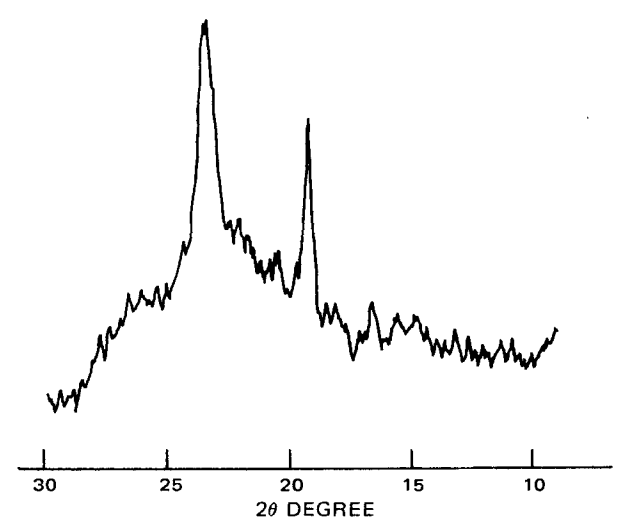

Figure 3—*X-ray diffraction spectrum of the freshly prepared unpulverized sample of 50% griseofulvin solid dispersion in polyethylene glycol 6000.*

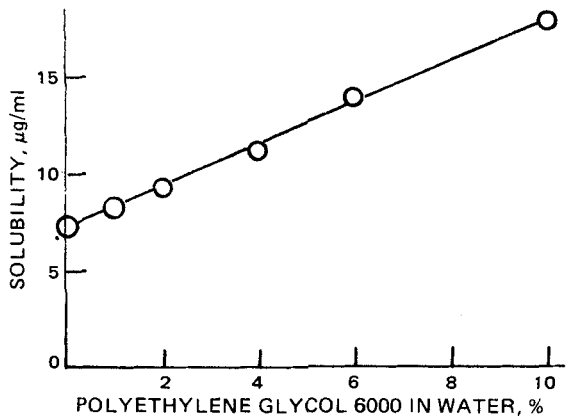

Figure 4—*Solubilities of griseofulvin in the presence of polyethylene glycol 6000.*

taining smaller fractions of griseofulvin, may also be attributed to the supersaturation of griseofulvin in the polymer caused by the retardation of the viscous polymer on the precipitation of griseofulvin (1, 6) and/or the colloidal or ultrafine crystallization. When X-ray diffraction studies were repeated several days later, major diffraction peaks of griseofulvin appeared in all samples except for the 5% griseofulvin system. Identical results for the latter system were obtained even after 3 months of storage at room temperature.

Intensive diffraction peaks of polyethylene glycol 6000 were present in all unpulverized, freshly prepared solid dispersions except for the 50% griseofulvin sample. It was soft and somewhat sticky 1 hr after preparation, and the hardness increased with time. The hardness of freshly solidified melts increased with the increase in griseofulvin concentration. This phenomenon is somewhat similar to that observed in the eutectic mixture of the sulfathiazole–urea system (7).

The effects of pulverization and aging on the X-ray diffraction pattern and hardness of the solid dispersions reported in this paper may also have some pronounced effect on their dissolution and absorption characteristics. The dissolution rate of sulfathiazole dispersed in urea with the eutectic composition decreased after storage (7). However, it is possible that no further changes in physical properties may occur after initial pulverization or a short period of storage. Identical dissolution profiles of griseofulvin were obtained for the pulverized samples of the 10% griseofulvin–90% succinic acid system and from its 10–20% dispersion in polyethylene glycol 4000 and 6000 even after 1 year of storage at ambient temperature. These original dissolution studies (not on samples aged for 1 year) were reported previously (1).

The absence of any X-ray diffraction peaks, other than those attributed to pure griseofulvin and the polymers in all solid dispersion samples, also indicates a lack of definite chemical complexation between the drug and the carrier polymer in their solid state. However, some interaction could be detected in their aqueous solutions, as shown by a moderate increase in the aqueous glycol 6000 (Fig. 4). Based on these data, the ratio for the number of molecules of the polymer required to solubilize one molecule of griseofulvin is 555. Since the ratio is so high, it is difficult to visualize the existence of any strong complexation between the two components. The high ratio can, however, be rationalized by the formation of a very weak complex with a high dissociation constant. The slight enhancement in the polymer solution can be equally well explained by the cosolvent effect of the polymer rather than by invoking complexation theory.

Based on the results of the X-ray diffraction and aqueous solubility studies, the previously reported marked enhancement of dissolution and absorption rates of griseofulvin dispersed in the polyethylene glycol polymers was primarily due to the reduction of the size of griseofulvin crystals rather than to the formation of solid solution, complexation, or metastable polymorphic forms. The generally observed decrease in the dissolution rate as the fraction of griseofulvin in solid dispersions increased (1) can be rationalized by the formation of larger crystals of griseofulvin due to the presence of relatively less carrier. This approach is in analogy to the griseofulvin–succinic acid solid dispersion system (11).

Other factors (6, 7, 11) such as increased wettability, reduction or absence of aggregation, and agglomeration and solubilization of the drug by the carrier at the diffusion layer of particles may also partially contribute to the enhancement of dissolution and absorption rates of griseofulvin dispersed in the polyethylene glycol polymers.

GLC Determination of Ethinamate and Its Hydroxy Derivative in Biological Fluids

J. W. KLEBER [x], L. D. BECHTOL, M. K. BRUNSON, and S. M. CHERNISH

Abstract □ A sensitive, specific GLC assay was developed for the determination of ethinamate in plasma and its major metabolite, *trans*-4-hydroxyethinamate, in urine. The assay uses a mass internal standard of dimethylethinamate. Ethinamate is extracted from alkalinized plasma with dichloromethane. Urine samples require β-glucuronidase hydrolysis prior to extraction of hydroxyethinamate. The dichloromethane is removed by evaporation, and the compounds are measured by GLC using a flame-ionization detector. By using GLC–chemical-ionization mass spectrometry, the compounds measured were identified as the intact ethinamates. Plasma and urine data are presented from a bioavailability study to demonstrate the utility of this method. From these data, the ethinamate plasma half-life was calculated as 1.9 ± 0.3 hr.

Keyphrases □ Ethinamate and hydroxy derivative—GLC analysis in biological fluids, bioavailability from tablets and capsules, humans □ GLC—analysis, ethinamate and hydroxy derivative in biological fluids □ Sedatives—ethinamate and hydroxy derivative, GLC analysis in biological fluids, bioavailability from tablets and capsules, humans

GLC of acetylenic hypnotic agents was first described in 1960 (1) and later applied to biological samples (2). A method also was developed[1] for the determination of ethinamate[2] in human plasma by GLC. This method was improved (3) by using benzene instead of carbon disulfide as the extracting solvent. None of the foregoing methods utilized a mass internal standard.

This paper describes a method for the assay of ethinamate (I) in plasma and of *trans*-4-hydroxyethinamate (III) (4) in urine; it employs a mass internal standard.

EXPERIMENTAL

Reagents—Ethinamate and dimethylethinamate (II) were synthesized[3]. Compound II was used as the internal standard for GLC analysis. Compound III was obtained from the urine of human subjects given ethinamate. All solvents were spectroquality. The GLC packing material was 2% OV-17 on 80–100-mesh Chromosorb G[4].

Apparatus—The gas–liquid chromatograph[5] was equipped with a flame-ionization detector and 1-mv recorder[6]. Disposable 15-ml centrifuge tubes[7] were used for the extractions. Tapered 15-ml glass centrifuge tubes[8], previously silanized, were used for evaporating dichloromethane (IV).

Chromatographic Conditions—The recorder was operated at a chart speed of 0.63 cm/min. Helium carrier gas (flow rate of 60 ml/min) was filtered through a sieve, which had been preconditioned overnight at 200° with dry nitrogen. A glass column (0.61 m × 3 mm i.d.) containing the packing material was heated isothermally at 140° for 4 min followed by 16°/min programming to 240° during the analysis to clear the column of late emerging peaks. The detector temperature was maintained at 250°. The oxygen and hydrogen flow rates were 240 and 60 ml/min, respectively.

Under these conditions, the following retention times were observed: I, 170 sec; II, 240 sec; and III, 420 sec (Fig. 1). The chromatogram obtained when a urinary extract was evaluated by GLC looked similar but was devoid of the ethinamate peak.

Table I—Precision and Accuracy in Measurement of Ethinamate Added to Plasma and *trans*-4-Hydroxyethinamate Added to Urine

Added, μg/ml	Measured μg/ml	*RSD*, %	*RE*, %

[a] Mean of eight replicate samples with range. [b] Mean of four replicate samples with range.

Procedure—The 15-ml tapered centrifuge tubes were washed with chromic acid cleaning solution, rinsed with water, dried, and then silanized using a 1% solution of dimethyldichlorosilane in toluene[9]. A standard solution of ethinamate in chloroform was added to 2 ml of blank plasma to give calibration concentrations of 0, 0.5, 2, 4, and 8 μg of drug/ml. To each tube was added 30 μl (6 μg) of the internal standard solution and 1 ml of 0.1 *N* NaOH. The mixture was then vortexed to ensure uniform distribution of the compounds in the plasma.

With a pipet[10], 10 ml of IV was added to each tube. The samples were shaken for 2 min and then centrifuged at 2000 rpm for 4 min. The upper aqueous phase was aspirated and discarded. The IV phase was transferred to a 15-ml silanized, tapered centrifuge tube and was evaporated to dryness at room temperature under a gentle stream of dry nitrogen. The residue was dissolved in 20 μl of carbon disulfide–chloroform (1:1) with the aid of a vortex mixer, and 2 μl of each sample solution was injected onto the GLC column.

Urine was assayed for III by the following procedure. A standard solution of III in chloroform was added to 0.1 ml of blank urine to give calibration concentrations of 100, 200, 400, and 800 μg of drug/ml. This solution was buffered with 1 ml of 0.2 *N* sodium acetate buffer (pH 5.5)

and incubated overnight at 37° with 50 μl of β-glucuronidase solution[11]. The next day, 30 μl (6 μg) of the internal standard solution was added, and the procedure used for plasma was followed.

Following chromatography of the calibration standards, peak height ratios[12] of I and III to the internal standard were calculated. These ratios, plotted against concentrations in the 0.50–8.0-μg/ml range for I in plasma and in the 200–800-μg/ml range for III in urine, gave straight lines passing through the origin ($r = 1.0$). Mean slope values of 0.39 ± 0.02 and 0.012 ± 0.0007 were obtained for I and III, respectively.

A bioavailability study of different dosage forms of ethinamate dem-

[12] Results were virtually unaffected when relative peak areas were used instead of relative peak heights.

Table II—Dissolution Profiles of Ethinamate Tablets and Capsules[a]

Minutes	Ethinamate in Solution, $\bar{X}$% (Range, *RSD*) Tablet	Capsule
5	58.6 (9.3, 6.2)	41.9 (21.4, 18.8)
15	78.0 (11.6, 5.7)	74.3 (29.2, 14.2)
20	84.7 (6.2, 3.4)	89.4 (26.4, 19.4)
60	94.1 (9.5, 3.6)	101.9 (15.4, 5.6)

[a] Mean of six tablets or capsules.

Table III—Ethinamate in Plasma Data

Data Set	Mean ± *SE* Tablets	Capsules	Mean Difference[a]
Area under curves, 0–24 hr, μg hr/ml	23.63 ± 12.57	25.24 ± 12.84	−1.61
Mean peak plasma concentrations, μg/ml	9.60 ± 4.17	9.12 ± 4.60	+0.48
Mean peak times, hr	0.60 ± 0.38	0.75 ± 0.57	−0.15

[a] Not significant at $p < 0.05$.

onstrated the utility of this method. Ethinamate tablets and capsules[13], 500 mg each, were administered to 12 subjects in a two-way crossover study. Each subject fasted for 8 hr before receiving a therapeutic dose of two ethinamate tablets or capsules. Blood samples were drawn at 0, 0.25, 0.5, 1, 1.5, 2, 4, 6, 8, 10, 12, and 24 hr. Urine was collected for 24 hr.

Dissolution characteristics of the ethinamate tablets and capsules were determined using the USP–NF apparatus. Tablets or capsules were placed in 500 ml of pH 1.2 buffer at 37° and stirred at 50 rpm. The ethinamate content of the buffer solution was assayed colorimetrically[14] using an automated analysis system.

RESULTS AND DISCUSSION

To estimate the precision and accuracy of the assay, plasma samples with known amounts of I and urine samples with known amounts of III were assayed. The results are summarized in Table I.

Chemical-ionization mass spectra[15] of I–III were obtained after GLC (Figs. 2*a*–2*c*). These spectra verify that these compounds pass through the chromatographic column intact and are the compounds measured by the detector.

The dissolution profiles (Table II) show that I is rapidly made available for absorption from both the tablet and capsule formulations.

The mean plasma ethinamate concentrations after administration of tablets and capsules are shown in Fig. 3. These plasma data were evaluated by an analysis of variance on the basis of the area under the plasma concentration–time curves, peak times, and the peak plasma concentrations (Table III). All parameters showed the tablets and capsules to be similar. The mean recoveries of the metabolite in the 24-hr urines were 359.6 ± 119.1 mg (32.8% recovery) for the tablets and 490.4 ± 193.5 mg

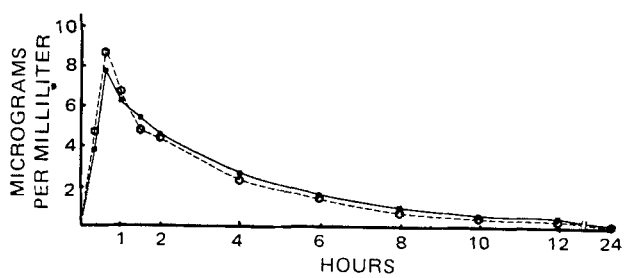

Figure 3—*Plasma ethinamate concentrations after administration of two 500-mg tablets (○) or two 500-mg capsules (■) of ethinamate to 12 subjects.*

[13] Valmid (ethinamate, Dista), Pulvules 399, 500 mg.

[14] Sulfuric acid is used to hydrolyze the amide portion of the molecule. The liberated ammonia is complexed with sodium phenolate. This complex is oxidized with sodium hypochlorite to yield a chromophore absorbing at 590 nm.

[15] A Finnigan model 3100 Quadrupole mass spectrometer (Sunnyvale, Calif.) was used with the column and conditions used in this procedure. Methane was the reagent gas.

(44.6% recovery) for the capsules. The mean difference of 130.8 mg of hydroxyethinamate in the 24-hr urine from the tablets and capsules was significant. However, this significant difference can be explained largely by the unusually low recovery of 77 mg of III from one subject. Without this subject, the average 24-hr urine recovery of III was 385 mg for the other 11 subjects. The mean difference of 105 mg of III recovered in the 24-hr urine from the two dosage forms was not significant.

The half-life of ethinamate in plasma was determined from a semilogarithmic regression analysis. The $t_{1/2}$ of ethinamate in plasma from these products was 1.9 ± 0.3 hr.

Solubility and Ionization Characteristics of Phenytoin

PETER A. SCHWARTZ [*], C. T. RHODES [*x], and J. W. COOPER, Jr.[‡]

Abstract □ The solubility of phenytoin was determined in pH 7.4 and 5.4 phosphate buffers at five temperatures; in hydroalcoholic solutions, 0–4% methanol; and in pH 4.8–8.4 buffer solutions. From the temperature data, the enthalpy and entropy of solution of this nonideal system were calculated and were similar at both pH values. The data obtained from the buffer solutions were used to calculate the apparent dissociation constant, pKa′, of phenytoin as 8.06. A GLC method with on-column methylation was used to quantitate phenytoin with 5-(*p*-methylphenyl)-5-phenylhydantoin as an internal standard. The assay uses chloroform for extraction of the drug from aqueous solutions. The ratio of peak heights was adjusted for weights of aqueous and organic layers, and results were calculated in micrograms per gram of sample and mole fraction of phenytoin. Although hydroalcoholic solutions enhanced drug solubility, there is a potentially significant disadvantage in using alcohol for clinical studies.

Keyphrases □ Phenytoin—solubility and ionization characteristics in various buffers and hydroalcoholic solutions □ Solubility—phenytoin in various buffers and hydroalcoholic solutions □ Ionization characteristics—phenytoin in various buffers and hydroalcoholic solutions □ Anticonvulsants—phenytoin, solubility and ionization characteristics in various buffers and hydroalcoholic solutions

Because of its regulating effect on the bioelectric activity of the nervous system, phenytoin is used widely as an anticonvulsant and cardiac antiarrhythmic (1). The therapeutic activity of the drug appears to be related to the concentration of free unbound drug in the plasma (2, 3). The present paper reports some fundamental physicochemical properties of the drug which have considerable relevance for pharmacokinetic studies. A GLC method was devised to achieve acceptable sensitivity (<5% error) from 0.5 to 100 μg of phenytoin/ml.

The apparent dissociation constant, pKa′, was 8.31 when determined by UV spectrophotometry and 8.33 when determined by potentiometric titration in hydroalcoholic solutions (4). A graph of pKa′ values as a function of the ethanol concentrations yields the apparent pKa′ value in water (0% alcohol). A pKa′ of 9.2 was determined by titration in 50% methanol (5), in good agreement with that for 50% ethanol (4).

Phenytoin is very slightly soluble in alkali at 26° (5), *e.g.*, 165 μg/ml at pH 9.1 (borate buffer) and 1.52 mg/ml at pH 10, but it is practically insoluble in water, *e.g.*, 14 μg/ml at pH 7 and 20 μg/ml at pH 7.4 at 24° (6). However, it is sparingly soluble in alcohol, 19.4 mg/g (7) or 1 g in about 60 ml, and about one part in 30 ml of acetone (8). It is only slightly soluble in ether and chloroform (9).

Shortly after the introduction of phenytoin as an anticonvulsant in 1937 (10), the first analytical method, a titrimetric procedure, was developed for the determination of quantitative plasma phenytoin levels (11, 12), but this method lacked sensitivity in the clinical microgram range. Several spectrophotometric procedures (13–18) had considerably improved sensitivity.

The most recent development in phenytoin assay procedures involves the application of GLC, a highly specific and sensitive analytical technique (19, 20). A procedure using trimethylsilyl derivatives of phenytoin and its metabolic products is sensitive, but these products are unstable in the presence of moisture (21, 22). The quaternary ammonium base, trimethylanilinium hydroxide (I), was used successfully as a methylating agent (23) to convert the hydantoins to nonpolar, volatile derivatives, using the injection port of a gas chromatograph as the reaction chamber. This flash-heater methylation reaction is complete; the 1,3-dimethylhydantoin products are stable (24) and were identified by mass spectrometry as the sole products of this reaction (25).

EXPERIMENTAL

Materials—Phenytoin (5,5-diphenylhydantoin) and 5-(*p*-methylphenyl)-5-phenylhydantoin (II) were used as obtained (99+%)[1]. The melting point and IR spectrum of phenytoin were determined as an index of purity (9). Chloroform[2] and all other chemicals employed were reagent grade.

Table I—Average Solubility for Six Samples of Phenytoin in Buffers at 25°

pH	Solubility, μg/ml (SD)	S/S^0
8.3	56.8 (2.8)	3.08
8.2	44.7 (2.2)	2.43
8.0	32.4 (2.0)	1.76
7.8	27.6 (1.8)	1.50
7.5	21.9 (1.4)	1.19
7.1	20.3 (0.9)	1.10
4.9	18.4 (0.8)	—

Phenytoin Extraction—Phenytoin and II, as an internal standard, were extracted from aqueous samples in chloroform and measured by a modification of several methods using flash-heater methylation (24, 26, 27). To 1 ml of an aqueous sample in a 50-ml glass-stoppered centrifuge tube was added 5 ml of chloroform containing 2 μg of II/ml. The mixture was shaken[3] for 15 min and centrifuged[4] at 1000 rpm for 6 min to break any emulsion. As much of the organic (lower) phase as possible was removed by pipet and placed in a 15-ml ground-glass-stoppered centrifuge tube.

This mixture was dried under a nitrogen stream on a 60° water bath. Twenty-five microliters[5] of a solution of I, 0.5 *M* in methanol[6], was added to the dry residue, and 1 μl of the extract was injected into the gas chromatograph. The centrifuge tubes and aqueous and organic solvents were weighed[7] to permit calculation of mole fractions from the microgram per gram concentrations.

Phenytoin Analysis—A gas chromatograph[8] fitted with dual hydrogen flame-ionization detectors was used. Each U-shaped borosilicate glass column (183 cm × 2 mm i.d.) was packed with 3% phenyl methyl silicone[9] coated on acid-washed, dimethyldichlorosilane-treated, high performance flux-calcined diatomite support[10], 100–200 mesh. Small silanized glass wool plugs were inserted in both ends of the columns after packing by the vibrator method.

Heat conditioning was accomplished by connecting the columns to the injector inlet only with a nitrogen purge of about 20 ml/min and maintaining a temperature of 325° for at least 24 hr (the recommended maximum is 350° for the packing). During periods of inactivity, the column oven was set at 160° with a small nitrogen flow of about 5–10 ml/min.

For routine analysis of phenytoin, the on-column injectors were sealed with high temperature septa[11] and maintained at 250°. The same temperature was chosen for the detectors. The column was operated isothermally at 230° using a nitrogen carrier gas flow rate of about 30 ml/min (65 psi) and a hydrogen and air flame, 30 ml/min (20 psi) and 300 ml/min (40 psi), respectively. The electrometer output was monitored with a 1-mv recorder[12] with a chart speed of 0.254 cm (0.1 in.)/min at a range of 10^{-11} amp/mv, and the signal was usually attenuated by a factor of 2–64.

Under these operating conditions, a 1-μl injection[5] of an extracted standard solution of 10 μg/ml each of phenytoin and II produced peak height responses of about one-half to three-fourths full scale. Retention times of the methylated phenytoin and II were 8 and 12 min, respectively. There was no trap for any trimethylamine eluted from the GLC column since the entire effluent passed through the flame detector.

Calibration—Standard solutions were prepared from dry chemicals without further purification. The melting point and IR spectra[13] were determined for phenytoin and were acceptable evidence of purity. Stock solutions of phenytoin, 1 mg/ml, and II, 250 μg/ml, were prepared in anhydrous methanol and maintained in a freezer at −15° for no more than 6 months. No apparent loss of activity was noted over this time.

Standard solutions of phenytoin were freshly prepared from aliquots of the stock solution and were evaporated to dryness under nitrogen at room temperature. These samples were redissolved in 1% (w/v) methanol in pH 7.4 aqueous buffer, so that the ionic strength of the final solution was 0.16. Multiple samples were extracted in less than 1 hr. A 2-μg/ml solution of II in chloroform, the extracting solvent for phenytoin, was maintained at −15°; unused portions were discarded after 30 days.

Table II—Average Solubility[a] for Six Samples of Phenytoin in Buffered (pH 7.4) Methanol at 25 and 37°

Temperature	Methanol, % (w/v)				
	0	0.5	1.0	2.0	4.0
25°	20.6 (1.3)	21.2 (1.0)	21.8 (0.8)	24.2 (0.5)	27.7 (0.3)
37°	30.6 (0.9)	32.2 (0.8)	34.2 (0.6)	36.4 (0.3)	38.6 (0.3)

[a] Values are micrograms per milliliter with the standard deviation given in parentheses.

A series of standard solutions, 1–50 μg/ml, were extracted, completely dried, and kept in stoppered centrifuge tubes at room temperature for up to 6 months without any apparent loss of sample activity. These dried standards permitted ready calibration of the gas chromatograph. Several sets of standard solutions were analyzed; the chromatograms were linear with respect to peak height ratios of phenytoin to II up to 100 μg/ml, with reproducibility of less than 5% error. A single 5-ml extraction of a 100-μg/ml phenytoin solution was examined for completeness of the extraction procedure. Samples of the separate aqueous and chloroform layers were evaporated to dryness, and direct comparison demonstrated a >99% extraction.

Solubility—Methanolic solutions for the determination of phenytoin solubility were prepared using pH 7.4 phosphate buffer with an ionic strength of 0.16. Determination of the apparent pH values[14] for these 0.5, 1, 2, and 4% methanol solutions demonstrated no significant pH shifts from the pH measured in the buffer alone.

A series of pH 5.6–8.4 phosphate buffers with an ionic strength of 0.16 were prepared for the determination of the solubility and the dissociation constant of phenytoin at 25°. Similarly prepared solutions at pH 5.4 and 7.4 were used to determine the change in phenytoin solubility with temperature over 25–50°.

The saturated solubility of phenytoin in alcohols and buffers was attained using a previously described procedure (28). The solute, in an amount in excess of its solubility (about 100 mg), was placed in polytef[15]-lined screw-capped glass vials with each solvent system. The vials were closed tightly and rotated at 28 rpm in a large constant-temperature (±0.2°) water bath[16] maintained successively at 50, 44, 37, 30, and 25°. After at least 24 hr of continuous rotation, a time sufficient to obtain saturated solutions at 25°, each sample vial was removed in succession for assay.

The exterior of the vial was quickly dried, and the cap was unscrewed carefully to prevent water contamination. A 2-ml sample of the saturated solution was drawn into a glass syringe and filtered into a small glass vial through a cellulose acetate filter with a pore size of 0.22 μm[17]. A 1-ml sample of this filtrate was placed in a tared 50-ml centrifuge tube, the total weight was recorded, and the filtrate was extracted. All glass syringes, pipets, and filter apparatus was prewarmed to prevent drug precipitation.

Calculations—Peak height ratios were calculated by dividing the height of the peak due to phenytoin by the height of the peak due to II. A peak height adjustment was made using the weights of the aqueous and chloroform layers. Calibration curves were constructed from the results of extracted standards by plotting the concentration of phenytoin in micrograms per gram against the respective adjusted peak height ratios.

RESULTS AND DISCUSSION

Phenytoin is more soluble in alkaline solutions (Table I). The total solubility, S, can be expressed as a function of the hydrogen-ion concentration, solubility of the unionized form, S^0, and the dissociation constant, K_a:

$$S = S^0 + P^- = S^0 + K_a S^0/[H^+] \quad \text{(Eq. 1)}$$

Krebs and Speakman (29, 30) transformed this equation into the more customary pH and pKa notation:

$$\log(S/S^0 - 1) = \text{pH} - \text{pKa} \quad \text{(Eq. 2)}$$

so that a plot of pH against the logarithmic term gives a straight line intersecting the pH axis at the pKa. The value of the pKa is described by this method as an apparent dissociation constant, pKa′, since the activity coefficients are unknown. From the data plotted in Fig. 1, a value of 8.06 for the pKa′ was obtained. This pKa′ differs slightly (8.3) from that reported by Agarwal and Blake (4), but their methods and materials differed and the temperature was not specified.

Table II contains the data for the solubility of phenytoin in methanolic solutions at 25 and 37° and shows the increase in phenytoin solubility with increasing alcohol concentration. The data also show the expected increase in solubility with temperature for all concentrations in methanol. The phenytoin could not be redissolved easily or quickly after extraction without using methanol. The reasons for this finding are not fully apparent, but one possible mechanism is solvate formation by phenytoin and methanol. A 1% (w/v) methanol solution in buffer was chosen for all studies to ensure a phenytoin concentration in the range of up to 20 μg/ml.

The solubility of phenytoin is quite low in aqueous buffered solutions ($\mu = 0.16$), and the results at 25° (Table I) agree with those of Glazko and Chang (6). Several studies with phenytoin, *e.g.*, protein binding, reported concentrations of the drug exceeding the aqueous solubility and, in fact, used hydroalcoholic solutions of the drug without considering the effects of the alcohol on the binding process (31–33).

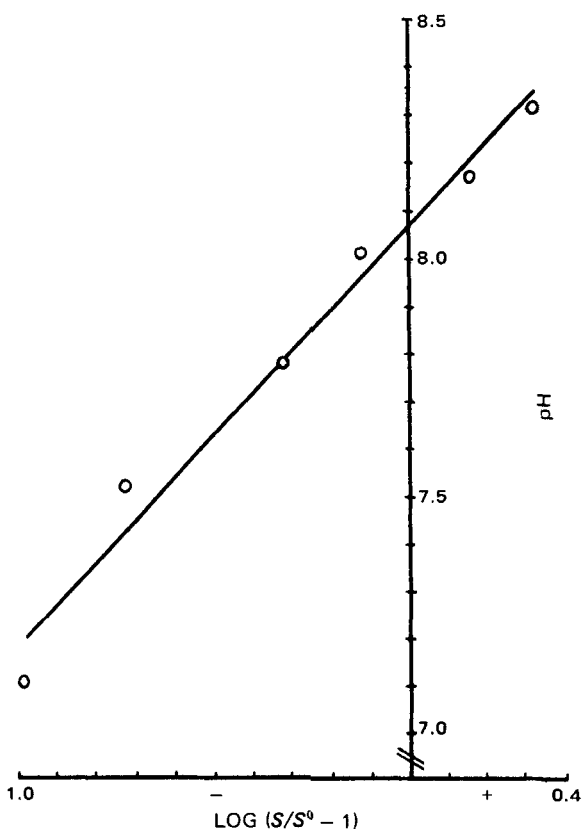

Figure 1—*Plot of log(S/S⁰ − 1) for phenytoin as a function of pH, r = 0.977. The intercept on the pH axis is the apparent pKa.*

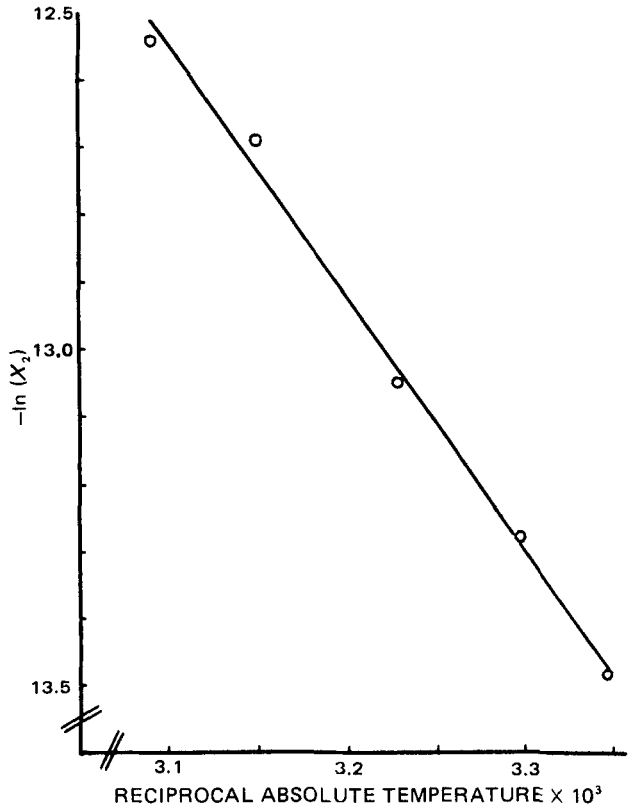

Figure 2—*Van't Hoff plot for solubility of phenytoin at pH 5.4, r = 0.995.*

The data for the phenytoin solubilities at pH 5.4 and 7.4 at five temperatures (Table III) are expressed as micrograms per gram and were converted to mole fractions from the appropriate specific gravity of the solutions. Specific gravities were determined by a pycnometer; in all cases, the difference in weight per milliliter between samples and reference was less than 1%. This procedure allowed for the determination of thermodynamic relationships that do not require corrections for the cratic effect, *i.e.*, volume changes on mixing (34). Values for the enthalpy and entropy of solution were determined from the slope and intercept of the plot of log mole fraction solubility against the reciprocal absolute temperature, as shown in Fig. 2 for pH 5.4 (35).

The literature does not apparently contain any previous reports on the thermodynamic functions for phenytoin. The enthalpy of fusion was determined[18], using samples of phenytoin from this laboratory, to be approximately 47.5 kjoules/mole (11.3 kcal/mole) by differential scanning calorimetry. The entropy of fusion was calculated as 84 joules/kelvin (20 cal/mole kelvin) using the melting point of 294° found for this sample.

The enthalpy of solution is positive, as would be expected for nonelectrolytes with low aqueous solubility. The entropy of solution is negative, since the highly ordered crystal is dispensed into smaller (disordered) units in solution, a process accompanied by an entropy increase. However, the nonpolar phenyl groups of the drug may change the structure of water surrounding these groups (36) into a more ordered arrangement, accounting for a negative entropic effect that outweighs the positive entropy associated with the breakdown of the crystal lattice. Thermodynamic functions derived from the system at pH 5.4 and 7.4 are: enthalpy, 31.3 (7.5) and 33.6 (9.0) kjoules/mole (kcal/mole), respectively; and entropy, −7.1 (−1.7) and −1.4 (−0.3) joules/mole kelvin (cal/mole kelvin), respectively. The acid was essentially unionized (>99%) at pH 5.4, while the data at pH 7.4 (>80% unionized) represent both ionized and unionized species.

Investigators must have a clear understanding of the physicochemical characteristics of phenytoin. Because of its limited solubility, hydroalcoholic solutions have been used in the past to broaden the experimental range of concentrations. Alcohol would affect *in vitro* binding experiments; studies intended to be of clinical relevance should be conducted at physiologic temperature, pH, and ionic strength in aqueous buffer.

Determination of Acenocoumarol in Plasma and Urine by Double Radioisotope Derivative Analysis

Y. Le ROUX ˣ and J. RICHARD

Abstract □ Acenocoumarol, to which a ^{14}C-labeled internal standard has been added, is extracted at pH 4 into ethyl acetate–heptane (20:80 v/v), back-extracted into aqueous sodium hydroxide solution after solvent washing with a pH 7 buffer, and reextracted after acidification in the solvent mixture. It is then acetylated with ^{3}H-acetic anhydride. The acenocoumarol acetyl derivative is separated from the metabolite derivatives by TLC, and its radioactivity is measured. The method is specific and sensitive to a concentration of 8 ng/ml.

Keyphrases □ Acenocoumarol—double radioisotope derivative analysis, plasma and urine □ Radiochemistry—double radioisotope derivative analysis of acenocoumarol in plasma and urine □ Anticoagulants—acenocoumarol, double radioisotope derivative analysis in plasma and urine

Acenocoumarol (I) is an oral coumarin anticoagulant[1]. It is analyzed in biological fluids using the O'Reilly *et al.* (1) method. This technique was originally developed for the determination of another coumarin anticoagulant, warfarin, which was then administered in much higher doses than acenocoumarol. It is a simple UV absorption assay, performed after solvent extraction; its sensitivity is limited to 1 μg/ml, and its specificity has not been verified. Nevertheless, it has been used for the determination of acenocoumarol (2). Two other methods, neither of which is more sensitive, also were reported (3, 4). Recently, a fluorometric assay after TLC was reported that is more sensitive (0.2 μg/ml) (5).

The metabolism of acenocoumarol was only recently elucidated[2]. Several metabolites were found: 3-[α-(4′-aminophenyl)-β-acetylethyl]-4-hydroxycoumarin (III), 3-[α-(4′-acetamidophenyl) -β- acetylethyl] -4- hydroxycoumarin (IV), two diastereoisomers of the alcohol 3-[α-(4′-nitrophenyl)-γ-hydroxybutyl]-4-hydroxycoumarin (V), 3-[α-(4′-nitrophenyl)-β-acetylethyl] -4,7- dihydroxycoumarin (VI), and 3-[α-(4′-nitrophenyl)-β-acetylethyl]-4,6-dihydroxycoumarin (VII).

All attempts to elaborate a GLC procedure for aceno-

Determination of Acenocoumarol in Plasma and Urine by Double Radioisotope Derivative Analysis

Y. Le ROUX ˣ and J. RICHARD

Abstract □ Acenocoumarol, to which a ^{14}C-labeled internal standard has been added, is extracted at pH 4 into ethyl acetate–heptane (20:80 v/v), back-extracted into aqueous sodium hydroxide solution after solvent washing with a pH 7 buffer, and reextracted after acidification in the solvent mixture. It is then acetylated with ^{3}H-acetic anhydride. The acenocoumarol acetyl derivative is separated from the metabolite derivatives by TLC, and its radioactivity is measured. The method is specific and sensitive to a concentration of 8 ng/ml.

Keyphrases □ Acenocoumarol—double radioisotope derivative analysis, plasma and urine □ Radiochemistry—double radioisotope derivative analysis of acenocoumarol in plasma and urine □ Anticoagulants—acenocoumarol, double radioisotope derivative analysis in plasma and urine

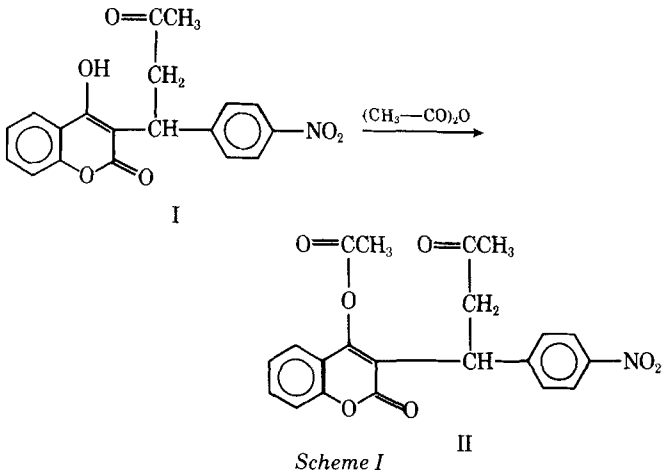
Acenocoumarol (I) is an oral coumarin anticoagulant[1]. It is analyzed in biological fluids using the O'Reilly *et al.* (1) method. This technique was originally developed for the determination of another coumarin anticoagulant, warfarin, which was then administered in much higher doses than acenocoumarol. It is a simple UV absorption assay, performed after solvent extraction; its sensitivity is limited to 1 μg/ml, and its specificity has not been verified. Nevertheless, it has been used for the determination of acenocoumarol (2). Two other methods, neither of which is more sensitive, also were reported (3, 4). Recently, a fluorometric assay after TLC was reported that is more sensitive (0.2 μg/ml) (5).

The metabolism of acenocoumarol was only recently elucidated[2]. Several metabolites were found: 3-[α-(4′-aminophenyl)-β-acetylethyl]-4-hydroxycoumarin (III), 3-[α-(4′-acetamidophenyl) -β- acetylethyl] -4- hydroxycoumarin (IV), two diastereoisomers of the alcohol 3-[α-(4′-nitrophenyl)-γ-hydroxybutyl]-4-hydroxycoumarin (V), 3-[α-(4′-nitrophenyl)-β-acetylethyl] -4,7- dihydroxycoumarin (VI), and 3-[α-(4′-nitrophenyl)-β-acetylethyl]-4,6-dihydroxycoumarin (VII).

All attempts to elaborate a GLC procedure for aceno-

[1] Sintrom, Ciba-Geigy.

[2] W. Dieterle *et al.*, to be published.



Scheme I

coumarol were unsuccessful; one of the two alcohol metabolites (V) could never be separated from the unchanged drug. Therefore, a specific method of determination was developed based on the principle of double radioisotope derivative analysis (6). After the addition of ^{14}C-labeled internal standard, acenocoumarol was extracted and then acetylated with ^{3}H-acetic anhydride (Scheme I). The acetyl derivative (II) was separated from the acetyl derivatives of the metabolites by TLC, and its radioactivity was measured.

EXPERIMENTAL

Reagents—Sodium hydroxide (2×10^{-3} *N*, 11.76 μg/ml) and a methanolic solution of ^{14}C-acenocoumarol[3] (20 μCi/mg) were used. ^{3}H-Acetic anhydride[4] (100 mCi/mmole) was diluted in freshly dried heptane to give a concentration of 1 μmole/50 μl.

This solution was stored in 2-ml portions in sealed glass ampuls at 4°. ^{3}H-Maprotiline[3] (65 μCi/mg) methanolic solution (944 ng/ml) was used to determine the ^{3}H-channel ratio.

Dioxane was distilled over lithium aluminum hydride and stored in glass ampuls sealed under nitrogen at 4°.

All other reagents were analytical grade[5,6]. Buffers, pH 4 and 7[6], were used in fourfold concentrations.

Materials—Radiochemical measurement was performed by means of a liquid scintillation spectrometer[7]; the scintillator used was 2-(4-*tert*-butylphenyl)-5-(4-biphenyl)-1,3,4-oxadiazole[3] (0.8% toluene solution).

Extraction—Plasma or urine (2 ml), 1 ml of aqueous ^{14}C-acenocoumarol (58.8 ng/ml), 2 ml of pH 4[8] citrate buffer, and 10 ml of solvent mixture [ethyl acetate–heptane (20:80 v/v)] were introduced into conical polypropylene tubes with screw caps. These tubes were vigorously shaken for 15 min and then centrifuged at 3500 rpm for 10 min. The organic phase was transferred with a Pasteur pipet into 10-ml glass ampuls containing 1 ml of pH 7[8] phosphate buffer. Each ampul was closed with a polyethylene cap, shaken for 15 min, and centrifuged at 2000 rpm for 10 min.

The organic phase was transferred into 10-ml glass ampuls containing 0.5 ml of 1 *N* NaOH; these ampuls were then closed, shaken, and centrifuged. The organic phase was discarded, and 0.7 ml of 1 *N* H_2SO_4 and 5 ml of solvent mixture were added to the basic phase. Again the ampuls were closed, shaken, and centrifuged. The organic phase was then transferred into 5-ml glass ampuls, which were closed with polyethylene caps and stored overnight at 4°. On the following day, the ampuls were placed in a thermostat bath at 40°, and the solvent was removed with a nitrogen flow. Thereafter, they were kept in a vacuum desiccator for 1 hr.

Acetylation—Dioxane (100 μl) and 50 μl of ^{3}H-acetic anhydride (1 μmole or 100 μCi) in heptane solution were added to the evaporation residue. The ampuls were closed with polyethylene caps, heated at 60° for 1 hr, and then opened. The acetic anhydride, dioxane, and heptane were evaporated by heating at 50° for 10 min and sucking off the vapors with a water aspirator (the aspirated air was passed through two wash bottles containing concentrated sodium hydroxide). Then 2 ml of heptane–ethyl acetate (80:20 v/v) and 1 ml of pH 4 buffer were added, and the ampuls were shaken for 15 min and then centrifuged at 2000 rpm for 10 min. The organic phase was transferred into 2-ml glass ampuls, and the solvent was removed at 40° with a nitrogen flow. The ampuls were kept in a vacuum desiccator overnight.

TLC Purification—A diluted solution (50 μl) of unlabeled acenocoumarol acetyl derivative and unlabeled V acetyl derivatives in chloroform were added to the residue and spotted on a silica gel F254[6] thin-

Table I—Assay of Unknown Solutions

Acenocoumarol Introduced, ng/ml		Concentration Found, ng/ml	*SD*	95% Confidence Interval	*SE*, %

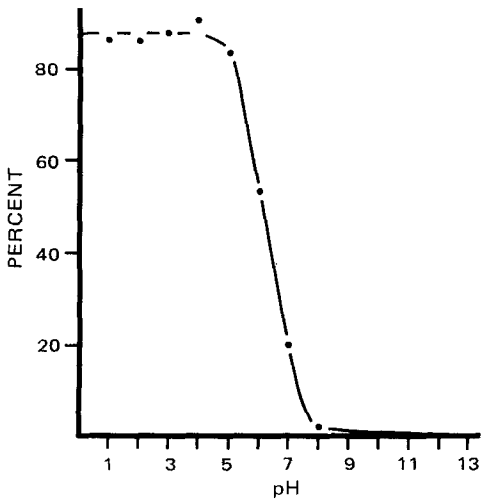

Figure 1—*Extraction of acenocoumarol from 2 ml of its plasma solution (117.6 ng/ml) into 10 ml of heptane–ethyl acetate (80:20) at different pH's.*

layer plate. Each ampul was rinsed with 50 μl of chloroform, which also was spotted on the plate. The chromatogram was developed in the first dimension with petroleum ether–acetone (140:60 v/v) and then in the second dimension with benzene–ethyl acetate (140:60 v/v) to about 2 cm from the edge of the plate.

Radiochemistry—Each plate was examined under a UV lamp (254 nm), and the spots were outlined with a pencil. The plate was cut close to the spot of acetylated acenocoumarol, which was scraped into a counting vial. Then 200 μl of methanol and 20 ml of scintillator solution were added. Four "blank" counting samples, four ^{3}H-standard samples (125.9 ng of ^{3}H-maprotiline in methanol), and four ^{14}C-standard samples (58.8 ng of ^{14}C-acenocoumarol in methanol) were counted together in a liquid scintillator spectrometer with a discriminator setting for simultaneous counting of tritium and carbon-14.

Data Processing—The calculation program subtracted the plasma or urine blanks from the ^{3}H-counts and then calculated a linear regression from the known concentrations and g (^{3}H − 100% cpm/ml of plasma or urine) (6, 7) before calculating the unknown concentrations from the linear regression.

The linear regression must be checked for each series of analyses from several concentrations (4 × 4) in the range expected for the study.

RESULTS AND DISCUSSION

Extraction—Acenocoumarol (I) was extracted only at acid pH (Fig. 1). After extraction, the solvent was washed to remove some plasma impurities extracted from the acid solution. It was then very important to have 1 ml of pH 7 buffer and 10 ml of organic phase (volume of organic phase/total volume = 10/11 = 0.9), because at pH 7 the solubility of I in the organic phase depended on the relative volumes of the organic and aqueous phases. When the ratio decreased, the solubility of I in the organic phase also decreased.

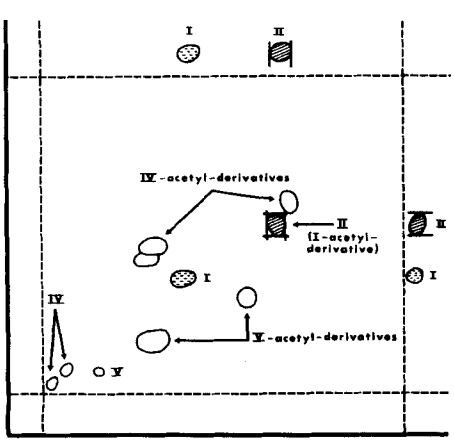

Figure 2—*TLC purification of II.*

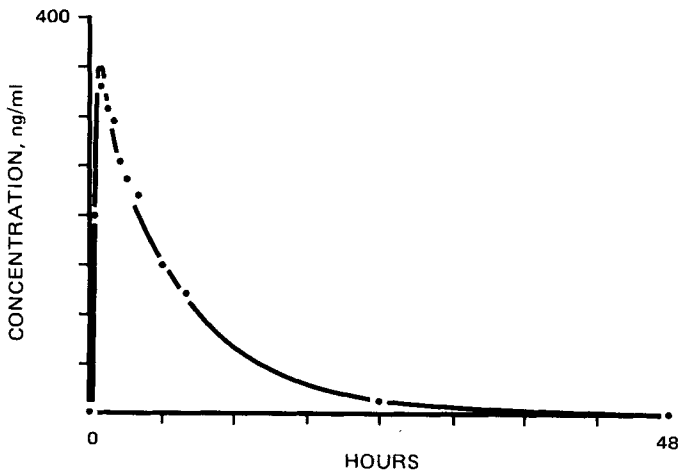

Figure 3—*Plasma concentrations of acenocoumarol as a function of time after the oral administration of a single dose of 8 mg to humans.*

Under the described conditions, I was satisfactorily extracted from plasma over a large range of concentrations (70–75% extraction).

Acetylation—Acenocoumarol was acetylated under the same experimental conditions as maprotiline (6). The overall yield (≃ 20–30% after thin-layer purification) was not improved by the addition of pyridine. The elemental analysis and mass spectrum of II corresponded to those of the monoacetylated compound.

Calibration Curves—Several known concentrations of I were prepared in plasma, urine, or water. After extraction and derivatization, the values of g (^{3}H − 100% cpm/ml) were calculated, and a linear regression was obtained from known concentrations and g. For plasma:

$$^3\text{H} - 100\%\ \text{cpm/ml} = 107.72 \times \text{concentration (ng/ml)} + 2{,}871.4 \qquad r = 0.999 \qquad \text{(Eq. 1)}$$

For urine:

$$^3\text{H} - 100\%\ \text{cpm/ml} = 83.33 \times \text{concentration (ng/ml)} + 2{,}662.6 \qquad r = 0.997 \qquad \text{(Eq. 2)}$$

For the aqueous solution:

$$^3\text{H} - 100\%\ \text{cpm/ml} = 88.43 \times \text{concentration (ng/ml)} + 2{,}024.6 \qquad r = 0.997 \qquad \text{(Eq. 3)}$$

The slopes of the calibration curves were different because the ^{3}H-acetic anhydride solutions were not the same for plasma as for urine and the aqueous solution.

Sensitivity and Accuracy—Good determinations could be obtained in plasma to 8 ng/ml with a 95% confidence interval from 7.5 to 9.4 (± 11%) and a standard error percent of 4.45 for n = 7 (Table I).

Specificity—TLC purification of II was elaborated to avoid any interference of metabolites and their acetyl derivatives. Figure 2 shows that a satisfactory separation was achieved. The described method was verified in the presence of each metabolite except VII, which was not available. None of these metabolites interfered. Owing to their close structural relationship, VII should behave similarly to VI and should also not interfere with II. Therefore, the method can be considered specific for the analysis of plasma samples.

It also can be considered specific for urine, after verification for VII, but practically no further acenocoumarol was found in urine after administration of a 12-mg dose[2].

Application in Pharmacokinetic Study[9]—Acenocoumarol (8 mg) was administered to one healthy volunteer. Before administration and at specified times after administration (0.5, 1, 1.5, 2, 2.5, 3, 4, 6, 8, 24, and 48 hr), 10-ml blood samples were collected in heparinized tubes. After centrifugation, the plasma was immediately deep frozen and kept at −20° until analysis. The determinations were made in duplicate (Fig. 3).

Effect of Sleep on Bioavailability of Tetracycline

JOSEPH ADIR [x] and WILLIAM H. BARR [*]

Abstract □ The effect of sleep on the bioavailability of tetracycline was studied using 250-mg tetracycline hydrochloride capsules from two commercial sources. One capsule of each brand was given to each of 12 healthy volunteers on two separate occasions. On one occasion, the subject ingested the drug upon arising in the morning and remained ambulatory (ambulatory trial). On the other, the subject awakened during the night, ingested the capsule, and resumed sleep (sleep trial). Bioavailability was assessed from the cumulative amount of drug excreted in the urine during the 96 hr following drug intake. While there was no significant difference in the bioavailability of one brand between the ambulatory and sleep trials, the bioavailability of the other decreased an average 27% ($p < 0.01$) in the sleep trial. Also, the difference between the bioavailability of the two preparations was not discernible in ambulatory subjects, but it was statistically significant ($p < 0.05$) in the sleep trial. The impaired bioavailability appears to result from decreased dissolution of one brand in the high gastric pH occurring at night. These findings raise questions as to the predictability of bioavailability studies in ambulatory subjects relative to the actual use of drug products, which are frequently administered during conditions of bed rest or sleep.

Keyphrases □ Tetracycline—bioavailability, different commercial capsules, effect of sleep, humans □ Bioavailability—tetracycline, different commercial capsules, effect of sleep, humans □ Sleep—effect on bioavailability of tetracycline, different commercial capsules, humans □ Antibacterials—tetracycline, bioavailability, different commercial capsules, effect of sleep, humans

The pharmacokinetics and pharmacodynamics of several drugs including sulfonamides, penicillin, streptomycin, griseofulvin, minocycline, indomethacin, and levodopa (1–8) may be subject to diurnal variations and may display considerable dependency on changes in the posture and state of wakefulness. Observed changes in blood drug levels, urinary excretion, and pharmacological effects generally were attributed to changes in distribution or elimination. However, decreased systemic availability would also provide a reasonable explanation for some observed results.

Gastric pH increases at night (9), and body position may greatly affect gastric emptying (10). These changes might significantly affect the absorption of some drugs, such as tetracycline, whose dissolution is pH dependent. Absorption of tetracycline from solid dosage forms is dependent upon rapid dissolution in acidic gastric fluids and subsequent gastric emptying of dissolved drug into the upper small intestine where absorption occurs (11–15).

The solubility and dissolution rate of tetracycline are much smaller at duodenal pH (4–5) than gastric pH (1–3), which would result in the decreased absorption of products that are incompletely dissolved in gastric fluids when emptying occurs (14, 15). Furthermore, decreased absorption of tetracycline from solid dosage forms occurs when gastric pH is increased. Concomitant administration of sufficient sodium bicarbonate to increase the gastric pH to 4–5 resulted in a 50% decrease in the bioavailability of tetracycline (14). In this study, tetracycline absorption in one individual who returned to sleep after drug ingestion was dramatically less than in all other subjects (14).

These considerations prompted this study on the bioavailability of two tetracycline products in ambulatory and sleeping individuals.

EXPERIMENTAL

Twelve apparently healthy volunteers (11 males and one female) participated. Each subject was administered one capsule containing 250 mg (labeled amount) of tetracycline hydrochloride with 200 ml of water either upon arising in the morning (ambulatory trial) or during the night (sleep trial). Two preparations, Brands A[1] and B[2], containing the same labeled amount of the drug[3], were used in each ambulatory and sleep trial, so that each subject participated in four separate trials. Brand A was tested first, and the trial condition was assigned randomly to the subjects by drawing lots. Then Brand B was ingested by all subjects in the sleep trial, followed by its administration to the subjects while ambulatory. At least 2 weeks separated each trial.

In the ambulatory trial, the drug was ingested in the morning between 8:00 and 9:00 am following an overnight fast. No food was allowed for at least the next 4 hr, and the subjects remained ambulatory for the rest of the day. In the sleep trial, the subjects were instructed to awaken at about the midpoint of their sleeping time, ingest the capsule, and directly resume sleep. Breakfast was taken upon arising in the morning, after which the subjects remained ambulatory. The average sleeping time was 6–8 hr, and the drug was ingested at about 4:00 am. Therefore, in both trials, food was withheld for at least 4 hr before and after drug ingestion.

No attempt was made to control the composition of the meal of the evening before or the day after drug administration, except that milk and dairy products were strictly forbidden on the 1st day of the study. No other medication was allowed for at least 7 days before and throughout the study. Immediately before taking the drug, the subjects voided completely, and this sample was saved and used as the urine blank sample. Urine was collected every hour for the first 8 hr after drug ingestion in the ambulatory trial or upon arising in the sleep trial and then

Effect of Sleep on Bioavailability of Tetracycline

JOSEPH ADIR [x] and WILLIAM H. BARR [*]

Abstract □ The effect of sleep on the bioavailability of tetracycline was studied using 250-mg tetracycline hydrochloride capsules from two commercial sources. One capsule of each brand was given to each of 12 healthy volunteers on two separate occasions. On one occasion, the subject ingested the drug upon arising in the morning and remained ambulatory (ambulatory trial). On the other, the subject awakened during the night, ingested the capsule, and resumed sleep (sleep trial). Bioavailability was assessed from the cumulative amount of drug excreted in the urine during the 96 hr following drug intake. While there was no significant difference in the bioavailability of one brand between the ambulatory and sleep trials, the bioavailability of the other decreased an average 27% ($p < 0.01$) in the sleep trial. Also, the difference between the bioavailability of the two preparations was not discernible in ambulatory subjects, but it was statistically significant ($p < 0.05$) in the sleep trial. The impaired bioavailability appears to result from decreased dissolution of one brand in the high gastric pH occurring at night. These findings raise questions as to the predictability of bioavailability studies in ambulatory subjects relative to the actual use of drug products, which are frequently administered during conditions of bed rest or sleep.

Keyphrases □ Tetracycline—bioavailability, different commercial capsules, effect of sleep, humans □ Bioavailability—tetracycline, different commercial capsules, effect of sleep, humans □ Sleep—effect on bioavailability of tetracycline, different commercial capsules, humans □ Antibacterials—tetracycline, bioavailability, different commercial capsules, effect of sleep, humans

The pharmacokinetics and pharmacodynamics of several drugs including sulfonamides, penicillin, streptomycin, griseofulvin, minocycline, indomethacin, and levodopa (1–8) may be subject to diurnal variations and may display considerable dependency on changes in the posture and state of wakefulness. Observed changes in blood drug levels, urinary excretion, and pharmacological effects generally were attributed to changes in distribution or elimination. However, decreased systemic availability would also provide a reasonable explanation for some observed results.

Gastric pH increases at night (9), and body position may greatly affect gastric emptying (10). These changes might significantly affect the absorption of some drugs, such as tetracycline, whose dissolution is pH dependent. Absorption of tetracycline from solid dosage forms is dependent upon rapid dissolution in acidic gastric fluids and subsequent gastric emptying of dissolved drug into the upper small intestine where absorption occurs (11–15).

The solubility and dissolution rate of tetracycline are much smaller at duodenal pH (4–5) than gastric pH (1–3), which would result in the decreased absorption of products that are incompletely dissolved in gastric fluids when emptying occurs (14, 15). Furthermore, decreased absorption of tetracycline from solid dosage forms occurs when gastric pH is increased. Concomitant administration of sufficient sodium bicarbonate to increase the gastric pH to 4–5 resulted in a 50% decrease in the bioavailability of tetracycline (14). In this study, tetracycline absorption in one individual who returned to sleep after drug ingestion was dramatically less than in all other subjects (14).

These considerations prompted this study on the bioavailability of two tetracycline products in ambulatory and sleeping individuals.

EXPERIMENTAL

Twelve apparently healthy volunteers (11 males and one female) participated. Each subject was administered one capsule containing 250 mg (labeled amount) of tetracycline hydrochloride with 200 ml of water either upon arising in the morning (ambulatory trial) or during the night (sleep trial). Two preparations, Brands A[1] and B[2], containing the same labeled amount of the drug[3], were used in each ambulatory and sleep trial, so that each subject participated in four separate trials. Brand A was tested first, and the trial condition was assigned randomly to the subjects by drawing lots. Then Brand B was ingested by all subjects in the sleep trial, followed by its administration to the subjects while ambulatory. At least 2 weeks separated each trial.

In the ambulatory trial, the drug was ingested in the morning between 8:00 and 9:00 am following an overnight fast. No food was allowed for at least the next 4 hr, and the subjects remained ambulatory for the rest of the day. In the sleep trial, the subjects were instructed to awaken at about the midpoint of their sleeping time, ingest the capsule, and directly resume sleep. Breakfast was taken upon arising in the morning, after which the subjects remained ambulatory. The average sleeping time was 6–8 hr, and the drug was ingested at about 4:00 am. Therefore, in both trials, food was withheld for at least 4 hr before and after drug ingestion.

No attempt was made to control the composition of the meal of the evening before or the day after drug administration, except that milk and dairy products were strictly forbidden on the 1st day of the study. No other medication was allowed for at least 7 days before and throughout the study. Immediately before taking the drug, the subjects voided completely, and this sample was saved and used as the urine blank sample. Urine was collected every hour for the first 8 hr after drug ingestion in the ambulatory trial or upon arising in the sleep trial and then

ad libitum for a total of 96 hr. The volume of each sample was measured and an aliquot was frozen until analyzed.

The amount of tetracycline in the two preparations and the unchanged drug excreted in urine were assayed spectrophotofluorometrically[4] by the method of Kohn (16). This assay is specific for tetracycline and has a high degree of precision, as indicated by the 3–6% variations in replicate determinations of biological samples (16).

The results were analyzed according to the analysis of variance of split-plot in time design (17). Differences between the means of the four trials were tested for significance by Duncan's new multiple-range analysis (18).

RESULTS

The cumulative amounts of intact tetracycline excreted in urine in 96 hr (Qu^{∞}) in the four trials are reported in Table I. Large inter- and intrasubject variations were seen in the urinary recoveries. Six subjects (A, B, D, F, H, and J) of the 12 ingesting Brand A in the sleep trial had between an 11 and 74% decrease in Qu^{∞} compared with the ambulatory trial of the same brand. However, in four other subjects (C, I, K, and L), a 22–36% increase in Qu^{∞} in the sleep trial was observed. Subjects E and G excreted essentially the same amount of tetracycline in the sleep and ambulatory trials.

When Brand B was taken in the sleep trial, eight subjects (A, D, F, H, I, J, K, and L) showed a 10–77% decrease in Qu^{∞} compared with drug ingestion while ambulatory. The other four subjects excreted virtually the same amount of tetracycline in the sleep and ambulatory trials. Unlike with Brand A, no increase in Qu^{∞} was observed when Brand B was taken in the sleep trial.

The overall mean and standard deviation of the Qu^{∞} obtained with Brand A in the ambulatory and sleep trials were 144.6 ± 33.7 and 116.8 ± 31.5 mg, respectively. The mean Qu^{∞} and standard deviation of Brand B were 122.5 ± 42.9 mg in ambulatory subjects compared to 89.0 ± 42.8 mg in the same subjects taking the drug in the sleep trial, representing a decrease of about 27%.

Analysis of variance of these data and the multiple-range comparison between means are shown in Table II. Sleep had a differential effect on the two brands of tetracycline. Whereas no statistically significant difference in the mean Qu^{∞} was observed between the sleep and ambulatory trials of Brand A, the average urinary recovery of Brand B in the sleep trial was significantly reduced ($p < 0.01$) compared with its mean Qu^{∞} in the ambulatory subjects. Most importantly, in spite of the lack of significant difference between the two preparations in the ambulatory subjects, the difference between their mean Qu^{∞} in the sleep trials was statistically significant ($p < 0.05$).

If urinary recovery from Brand A during the ambulatory trial is taken as a standard, then Brand B administered at night during sleep showed a highly significant ($p < 0.01$), almost 39% decrease in the cumulative amount of tetracycline excreted in urine (Fig. 1).

Figure 2 shows a representative plot (Subject J) of urinary excretion rates of tetracycline as a function of time in the sleep and ambulatory trials. The inset figure indicates that the elimination kinetics of the drugs in the postabsorptive-distributive phase were essentially identical for both brands in these trials. Similar results were observed in all other subjects.

DISCUSSION

Generally, a decrease in urinary recovery of a drug under different experimental conditions may result from changes in several events involved in its absorption and/or disposition[5] including: (*a*) decreased renal excretion, (*b*) increased extrarenal elimination from the systemic circulation such as hepatic metabolism and biliary or other clearances, and (*c*) a decrease in the amount of drug reaching the systemic circulation (bioavailability).

A decrease in bioavailability may be characterized further as resulting from a decrease in the fraction of drug available for absorption from the luminal contents or an increase in the fraction of drug metabolized, stored in intestinal tissue, or cleared by biliary secretion during the initial transit through the hepatoportal system (first-pass effect).

Decrease in Elimination—The parallel slopes of the urinary excretion rate–time plots (Fig. 2) rule out the occurrence of changes in elimination kinetics during the postabsorptive-distributive phase (~8–10 hr after drug administration). However, this finding does not rule out the possibility of changes occurring in the elimination of tetracycline from the systemic circulation during the first few hours following its administration when the subjects were either sleeping or ambulatory. Since urinary excretion parameters were employed in the present study, it is logical to consider the possibility of decreased renal elimination at night during sleep as a result of alteration in urine pH or renal function.

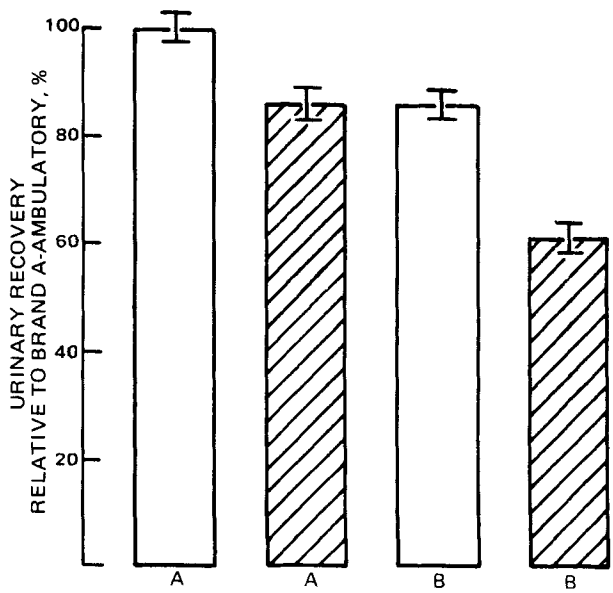

Figure 1—*Percent mean urinary recovery relative to Brand A administered to ambulatory subject when Brands A and B were administered to ambulatory subjects (open bars) and during sleep (hatched bars). The standard errors of the mean are indicated by the horizontal lines.*

[a] Split-plot in time design (17). [b] Refers to ambulatory and sleep conditions. [c] Duncan's new multiple-range test (18).

Elliot *et al.* (19) observed a 0.77–2.48 unit rise in urinary pH in 12 of 18 normal subjects after awakening in the morning compared with urinary pH at night. This rise in pH, termed the morning tide, lasted 2–3 hr after arising (19), occurred irrespective of food intake (20), and was part of the diurnal variation in urinary pH, which appeared to follow a pattern characteristic for a given individual (21). A similar increase in urinary pH was observed in humans upon assuming a recumbent posture (22).

Alkalinization of urine pH (~7.5) over 48 hr significantly increased the cumulative amount of tetracycline excreted in urine (23). Based on this study and the presumed occurrence of high urinary pH in the morning, subjects who ingest the tetracycline capsules at 4:00 am should show an *increase* in urinary recovery of the drug compared with the ambulatory trials in which the drug is taken at 8:00–9:00 am. This assumption is made because the sleep trial drug absorption, which lasts between 3 and 4 hr (24), is essentially complete upon awakening and the presumably high urinary pH enhances tetracycline excretion in urine; the ambulatory subjects, who take the drug upon arising, cannot absorb significant amounts during the time their urinary pH remains alkaline.

The results shown in Table I do not support this logical corollary. Only four subjects (C, I, K, and L) displayed an increase in Qu^{∞} in the sleep trial of Brand A that was not manifested in the sleep trial of Brand B as would be expected from the consistency of the urinary pH profile of individuals (21). In fact, three of these subjects (I, K, and L) had a 20–77% decrease in the urinary recovery of Brand B and the fourth showed a meager 3% reduction. In addition, comparison between the means of the four trials indicates that sleep caused a significant differential reduction in Qu^{∞} of Brand B (Table II). These facts are difficult to reconcile with the notion that the observed decreases in urinary recovery of the drug in the sleep trials are due to its reduced renal excretion as a result of changes occurring in urinary pH.

The other factor that would account for the decreased urinary excretion of tetracycline in the sleep trial is the physiological alterations of kidney function. Little information is available on the effect of sleep, bed rest, or recumbent posture on the function of this organ. In a recent study employing seven catheterized sleeping patients, within 2 min of the onset of rapid eye movement (REM) epochs, there was a marked decrease in the urine flow rate; however, the glomerular filtration rate in these patients remained unaffected (25). At the termination of the REM state, the urine flow rate increased even beyond the baseline value.

In a study of renal function in 18 normal male subjects at 4-hr intervals over 24 hr (26), there was no change in renal plasma flow during sleep at night as compared to bed rest during the day. There was a slight, but statistically significant, drop in the glomerular filtration rates during the REM sleep between 12:00 midnight and 4:00 am, after which the glomerular filtration rate achieved a normal value. The urine flow rate, however, was diminished significantly during sleep, with the greatest drop occurring during the REM periods. This drop in the urine flow rate was attributed to increased tubular reabsorption of water (26). In another study, prolonged bed rest had no effect on the urine flow rate or kidney function (27).

These findings indicate that while the glomerular filtration rate of the subjects ingesting tetracycline at about 4:00 am could be considered reasonably similar to that of the ambulatory subjects, a comparison between their urine flow rates is difficult to make. It is particularly difficult to conjecture the effect of arising to ingest the drug and then resuming sleep on the urine flow rate. Nevertheless, other investigators found that changes in the urine flow rate had no effect on the renal clearance of tetracycline and three other analogs (28, 29). Although no information is available on the effect of this parameter on the fraction of tetracycline ultimately excreted in urine, it is inconceivable that such an effect would be demonstrated in the sleep trial of only one brand of the drug and not the other.

Increase in Extrarenal Elimination—The tetracyclines are not appreciably metabolized (30). In addition, biliary excretion of tetracycline in the rat does not constitute a major route of elimination, since 95% of the amount excreted *via* the bile is absorbed from the small intestine (31). Rather, excretion in the lower part of the small intestine and colon is believed to account for the extrarenal elimination, as stipulated for another analog of this antibiotic (32). If this is also the other extrarenal route of elimination of tetracycline in humans, then, to account for the observed decrease in Qu^{∞}, a compensatory increase in its elimination *via* this route must be expected. Although this possibility cannot be ruled out, some physiological modalities of sleep provide no support for its occurrence. For instance, blood pressure, which may affect organ perfusion, drops and intestinal function proceeds normally during sleep (33).

On the other hand, if extrarenal elimination of tetracycline in humans occurs *via* biliary excretion, this route of elimination may actually be diminished at night. Bile collected through a fistula in humans was lower at night, with a minimum between 1:00 and 5:00 am (34); the same was true for rabbits which are more active at night (35).

An increase in any other extrarenal route of elimination of tetracycline during sleep is unlikely because of the difficulty to explain its differential occurrence with two preparations of the same drug.

Decrease in Bioavailability—Previously (15) in ambulatory subjects, urinary excretion rates of tetracycline were proportional to serum concentrations, and the cumulative amount excreted in urine, Qu^{∞}, was proportional to the total amount absorbed as assessed by the area under the serum concentration–time curve (AUC). In both of these relationships, the proportionality constant, as predicted by theory, was equal to the renal clearance of the drug, namely 80–90 ml/min. Since changes in the glomerular filtration rate, urine pH, and renal and extrarenal elimination have been ruled out implicitly, the observed decrease in Qu^{∞} when tetracycline capsules are taken during sleep more likely represents a decrease in the bioavailability of the drug relative to its administration to ambulatory subjects.

Sleep reportedly causes a decrease in gastric, salivary, and lacrimal secretion, but it has no effect on intestinal function (33). The decrease in gastric acidity is likely to affect the dissolution of a drug such as tetracycline (14), which is favored by low pH, thereby causing a decrease in the extent of its bioavailability during sleep[6]. No information is available on the effect of sleep on gastric emptying, and its contribution to the decreased bioavailability at night cannot be ruled out. However, an increase in the fraction eliminated during the first pass through the hepatoportal system may be rejected on the basis of a lack of evidence

[6] Because of the inherent limitations of urinary excretion studies, alteration in the absorption rate of tetracycline at sleep cannot be established.

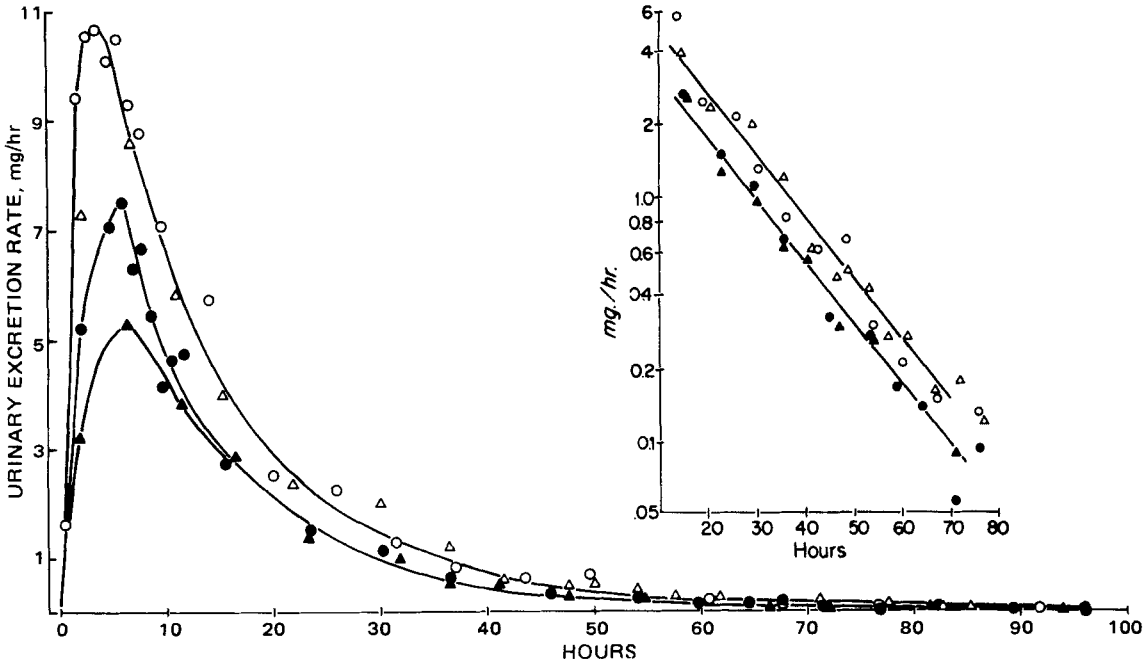

Figure 2—*Representative urinary excretion rates* versus *time plots for Subject J ingesting a tetracycline hydrochloride capsule while ambulatory (open symbols) and during sleep (closed symbols). Data for Brand A are designated by circles; Brand B by triangles. The excretion rates of the two brands in the ambulatory phase (open symbols) are superimposable.*

for the hepatic or biliary clearances of tetracycline (30–32).

In addition to dissolution, other important considerations suggest and possibly contribute to the decreased bioavailability of tetracycline during sleep. While the difference in the mean Qu^{∞} between the two brands in the 12 ambulatory subjects was not large enough to be statistically significant, the difference between them in the sleep trials was significant (Table II). In other words, differences between the bioavailability of the two brands conceivably could have been demonstrated in a larger number of *ambulatory* subjects, but only 12 *sleeping* subjects were needed to detect these bioavailability differences.

In addition, the bioavailability of Brand A in the ambulatory subjects was statistically similar to its bioavailability in the sleep trial, but it was almost 39% greater ($p < 0.01$) than the bioavailability of Brand B in the sleep trial (Fig. 1). Poor formulation, coupled with the sleep effect, could have produced the marked impairment in the bioavailability of Brand B. This situation is implied also by the lack of interaction between brands and conditions (Table II), which may characterize an additive effect between two factors (36).

The difference in formulation is illustrated also by the intersubject variability of the two brands. In general, this variability was smaller in Brand A than B. The coefficients of variation for A in the ambulatory and sleep trials were 23.3 and 27%, respectively; the coefficient of variation of B in ambulatory subjects was 35%, compared with 48% in the same subjects ingesting the drug during sleep. This increased variability is characteristic of products with low bioavailability (37).

CONCLUSIONS

The results of the present study involving two brands of tetracycline under the specific conditions of the trials indicate that the ingestion of one brand of tetracycline hydrochloride capsule during sleep resulted in a decrease in the bioavailability of the drug compared with its administration to ambulatory subjects. Obviously, these results cannot be extrapolated to other drugs or even other brands or lots of the same drug. In addition, although it was previously shown that differences between tetracycline products observed in single-dose studies are quantitatively predictive of multiple-dose plasma levels in ambulatory subjects (15), further studies are needed to determine whether the effect of sleep also is observed upon multiple-dose administration.

These findings, however, provide one example of an interaction between physiological and formulation variables which must be considered in the design and interpretation of bioavailability studies. Questions are raised as to the predictability of ambulatory studies relative to the actual clinical use of drug products frequently administered during conditions of bed rest or sleep. Most important is the fact that differences in products that were not statistically demonstrable in the usual ambulatory subjects were evident in the more clinically realistic situation involving sleep.

Hydrolysis and Epimerization Kinetics of Hetacillin in Aqueous Solution

AKIRA TSUJI, YOSHITAKA ITATANI, and TSUKINAKA YAMANA [x]

Abstract □ Methods were developed for quantitating epimerization to epihetacillin and hydrolysis to ampicillin in the alkaline degradation of hetacillin, and both rates in deuterium oxide at 35° and in water at various temperatures were determined. In each case, plots of log k for the epimerization against pH or pD yielded straight lines with a positive slope, which verified the first-order dependence on the hydroxide ion or deuteroxide ion. The activation energy of the epimerization process was 21.2 kcal/mole. In aqueous solution at high pH, epimerization rather than conversion to ampicillin represents a major pathway of hetacillin degradation, although the β-lactam ring of the hetacillin molecule is highly resistant to attack by the hydroxide ion.

Keyphrases □ Hetacillin—epimerization and hydrolysis in aqueous solution, effect of pH and temperature □ Epimerization—hetacillin in aqueous solution, effect of pH and temperature □ Hydrolysis—hetacillin in aqueous solution, effect of pH and temperature □ Antibacterials—hetacillin, epimerization and hydrolysis in aqueous solution, effect of pH and temperature

Hetacillin, which was developed to improve the aqueous stability of concentrated ampicillin solutions and to increase oral absorption of ampicillin, is a condensation product of ampicillin and acetone (1) and is often used instead of ampicillin.

In the degradation of hetacillin (I) in aqueous solution, at least two reactions are possible: hydrolytic interconversion to ampicillin (II) (2, 3) and epimerization to 6-epihetacillin (III) (4), which produces inactive 6-epiampicillin (5). The rates of both hydrolysis (2, 3, 6) and epimerization (7) depend on pH and occur simultaneously (Scheme I). Although detailed kinetics of the hydrolysis of hetacillin to ampicillin were reported (2, 3, 6, 8–10), much less is known about the kinetic behavior of the C-6 epimerization reaction.

The present investigation was undertaken to develop methods for quantitating epimerization of hetacillin and to determine the rates of hydrolysis and epimerization of hetacillin in aqueous basic solution by utilizing NMR and optical rotatory dispersion spectroscopy. The preliminary NMR observations were reported previously (7).

EXPERIMENTAL

Materials—Hetacillin potassium[1] and ampicillin sodium[2] were used as supplied.

Epihetacillin was synthesized by a reported procedure (4). Two grams of hetacillin potassium was placed in 20 ml of distilled water, and the

solution pH was maintained at 11.50 for 90 min at 25° with the aid of a pH-stat. The reaction solution was acidified to pH 4.5 with 1 N HCl at 0° to precipitate epihetacillin as a white powder. The collected crystals were washed exhaustively with cold water and dried over phosphorus pentoxide, mp 163° [lit. (4) mp 164–165°]. The identity was confirmed by elemental analysis, IR and NMR spectroscopy, and TLC.

Deuterium oxide (99.75%)[3], deuterium chloride (20% in deuterium oxide)[3], and sodium deuteroxide (40% in deuterium oxide)[3] were used for the preparation of the deuterium solvent buffer. All other chemicals were analytical reagent grade.

Apparatus—NMR spectra were recorded on a 100-MHz spectrometer[4] operating in a field sweep mode. Optical rotatory dispersion measurements were made on a recording spectropolarimeter[5], using thermostated 1-cm cells. The apparent pH values of the reaction solution were measured using microelectrodes and a pH meter[6], both before and at the end of the reaction. When no buffer or a low buffer capacity was used, a constant pH was maintained during the reaction by a pH-stat[7]. The pD values in deuterium solvent were obtained by proper correction (11) to the pH meter reading.

Kinetic Procedure—*NMR Study*—Hetacillin potassium (80 mg) was dissolved in 2 ml of deuterium oxide buffer at 35°. The time was recorded when the pH of the reaction buffer was corrected to the desired pD values by addition of 1 N NaOD by a pH-stat. As soon as possible after the pH adjustment, 1 ml of the reaction solution was placed in the NMR sample tube and left in the probe of the instrument[4].

The spectra were recorded at suitable time intervals, with sodium 2,2,3,3-tetradeutero-3-(trimethylsilyl)propionate as the internal reference. The temperature was maintained at 35 ± 0.5° by a variable-temperature probe unit[4]. The NMR spectra of the phenyl groups and C-3 protons were recorded with a twofold-scale expansion, and their signals were integrated on a spectrometer. The same procedure was used for epihetacillin and ampicillin sodium.

Optical Rotatory Dispersion Study—The reaction was initiated by dissolving exactly weighed hetacillin potassium or epihetacillin into a buffer preheated to a suitable temperature (±0.05°) to give a final concentration of 6×10^{-4} M. The 3 ml was replaced in a cell, which was thermally equilibrated (±0.05°) in the thermostated compartment of the spectrometer, and the optical rotatory dispersion change at 240 nm as the function of time was recorded. The reactions in deuterium solvent were also carried out in a similar manner as in water.

The buffers used in NMR and optical rotatory dispersion studies were NaD_2PO_4–Na_2DPO_4, $NaDCO_3$–Na_2CO_3, Na_2DPO_4–Na_3PO_4, H_3BO_3–$Na_2B_2O_7$, $NaHCO_3$–Na_2CO_3, and Na_2HPO_4–Na_3PO_4. The ionic strength of each solution was adjusted to 0.5 by the addition of potassium chloride. The pH and pD drifts during the reaction were within ±0.02 and ±0.05 unit for optical rotatory dispersion and NMR studies, respectively.

TLC Study—TLC was also employed to identify the degradation products and to verify the NMR and optical rotatory dispersion results. Aliquots, 10 μl, of the degradation solution ($\sim 1 \times 10^{-2}$ M) were applied to silica gel G precoated glass plates[3] (5 × 20 cm) of 250-μm thickness. Chromatograms were run for 15 cm in acetone–acetic acid (95:5). Spots were visualized by spraying 0.5% aqueous permanganate reagent or by exposure of the plates to iodine vapor.

Hetacillin, epihetacillin, ampicillin, and epiampicillin showed R_f values of 0.32, 0.45, 0.13, and 0.25, respectively. TLC of the standard solutions of the penicilloic acids of ampicillin and epihetacillin, synthesized by the method similar to that described by Schwartz and Delduce (12) for benzylpenicilloic acid, revealed virtually single spots with R_f values of 0.05 and 0.17, respectively. All spots, except for epiampicillin, were detected by TLC of the degradation solution of hetacillin at high pH.

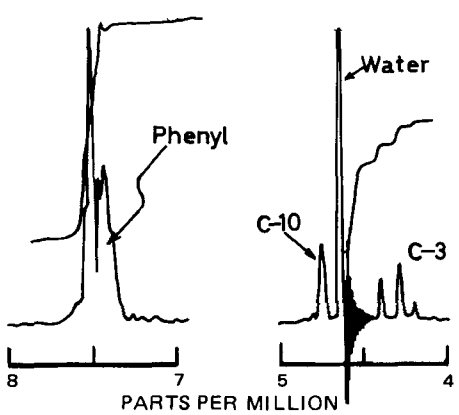

Figure 1—*NMR spectrum (100 MHz) of a synthetic mixture of hetacillin (50%), epihetacillin (40%), and ampicillin (10%) in 0.2* M *$NaDCO_3$–Na_2CO_3 buffer at pD 10.6.*

RESULTS AND DISCUSSION

Kinetic Study by NMR Spectroscopy—Table I summarizes the 100-MHz spectral data of hetacillin, epihetacillin, and ampicillin in deuterium oxide and dimethyl sulfoxide-d_6. Assignments were made on the basis of previous results (4, 13). Although the principal differences in the spectra of the two epimers were due to the characteristic protons at C-5 and C-6 (J = 4.0 Hz in hetacillin and J = 2.0 Hz in epihetacillin), these signal areas were unsuitable for monitoring the kinetics of hetacillin degradation because of considerable interference of other proton signals.

The chemical shifts for the C-3 methine groups differed by 0.1 ppm

[a] Calculated using Eq. 1.

among these β-lactam compounds and their β-lactam cleavage products and provided the best means for quantifying epimerization and also hydrolysis of hetacillin. A typical NMR spectrum of a synthetic mixture of hetacillin (50%), epihetacillin (40%), and ampicillin (10%) in 0.2 *M* carbonate buffer at pD 10.6 is depicted in Fig. 1. Signals due to the phenyl groups in these compounds all fell in the area of 7.40–7.50 ppm. If the total integration values for the range represent 100% of the phenyl groups present, then the amount of the three compounds may be calculated from each integrated value of the respective C-3 proton as follows:

$$\text{percent compound} = (5I/I_T) \times 100 \qquad \text{(Eq. 1)}$$

where I_T = total integral value of the phenyl groups in the area of 7.40–7.50 ppm, and I = integral value of the C-3 methine proton for hetacillin, epihetacillin, or ampicillin.

The recovery of known synthetic mixtures of the three compounds at lower pD than 10.6 was satisfactory, with standard deviation of less than ±2% (Table II). Although such tests at a more alkaline pD gave relatively poor recovery for hetacillin and epihetacillin because of rapid epimerization and for ampicillin because of facile β-lactam cleavage, each concentration in the kinetic solutions at the desired time after hetacillin dissolution in such a high alkaline buffer at the kinetic temperature might be determined reasonably by this analytical method.

NMR spectra of the degradation solution of hetacillin in alkaline deuterium oxide solution showed that each proton for hetacillin at 4.30 (C-3), 5.08 (C-6), and 4.76 (C-10) ppm decreased in intensity, accompanied by an increase and then a decrease in intensity of proton resonance at 4.39 ppm due to the C-3 proton and at 4.85 ppm due to the C-10 proton of epihetacillin and at 4.19 ppm due to the C-3 proton of ampicillin. Two signals also appeared at 3.30 and 3.52 ppm, assigned to the C-3 protons of the β-lactam ring opening products, probably the penicilloic acids, of ampicillin and epiampicillin. However, there were no detectable signals corresponding to intact epiampicillin. During the reaction processes studied, the total integrated values for the phenyl proton area were constant and gave an I_T value corresponding to five protons. The typical NMR spectrum for the degradation after 40 min in 0.2 *M* carbonate buffer at pD 10.6 and 35° is illustrated in Fig. 2.

Figures 3, 4, and 5 give typical plots of the mole percents for hetacillin, epihetacillin, and ampicillin, calculated from the integral value of the C-3 proton for each compound using Eq. 1, as a function of time for the degradation of hetacillin at pD 9.8, 10.6, and 11.4, respectively. The completed curves were generated from an analog computer[8] according to Scheme I. The kinetic parameters used are listed in Table III; the rate constants, k_4 and k_5, were determined directly from the degradation of epihetacillin and ampicillin under the same conditions, and the k_3 value was assumed to be zero. In all cases, reasonably good agreement was found between the experimental values for each species and the computer-drawn curves (Figs. 3–5). These results indicate that the present NMR method is sufficiently accurate for simultaneous determination of hetacillin, epihetacillin, and ampicillin from a kinetic solution.

The reaction of epihetacillin at pD 9.8, 10.6, and 11.4 gave no detectable amount of hetacillin. This result is consistent with the previous report (5) of the irreversible conversion of hetacillin into epihetacillin. The degradation products from hetacillin in deuterium oxide at high pD were also confirmed by TLC studies to be in accordance with the NMR observations. These results strongly support the assumption that the degradation of hetacillin, in the pD ranges examined, follows the reaction route illustrated in Scheme I. The reversible reaction of ampicillin and acetone to form hetacillin gave only a negligible contribution under the present experimental conditions.

Kinetic Study by Optical Rotatory Dispersion Spectroscopy—By utilizing the large difference in optical rotatory dispersion maxima near 240 nm between hetacillin ($[\Phi]_{240\,nm} = 3.40 \times 10^3$) and epihetacillin ($[\Phi]_{238\,nm} = 2.12 \times 10^3$), Mitscher *et al.* (14) proposed a useful method for monitoring the kinetics of epimerization of hetacillin in aqueous solution. Loss of the 238-nm optical rotatory dispersion peak with time in glycine buffer at pH 11 and 23.8° followed a biexponential process in accordance with the following general equation (14):

$$\text{rotation} = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 2)}$$

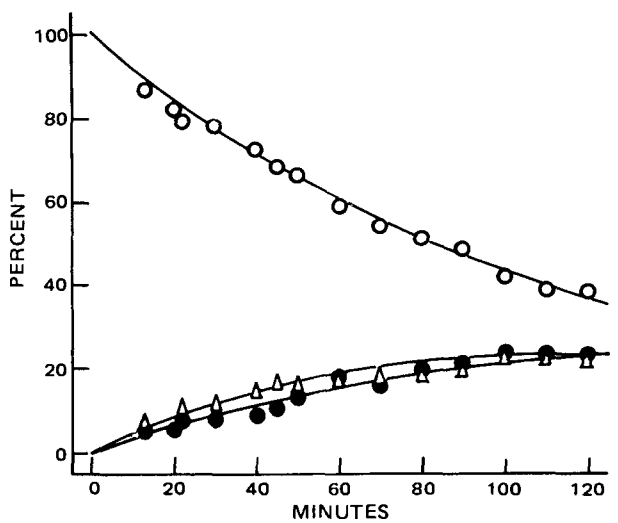

Figure 3—*Time course for hetacillin (○), epihetacillin (●), and ampicillin (△) determined by NMR spectroscopy during the degradation of hetacillin in 0.1 M $NaDCO_3$–Na_2CO_3 buffer at pD 9.8 and 35°. Curves were generated by the analog computer simulation according to Scheme I and the kinetic parameters listed in Table III.*

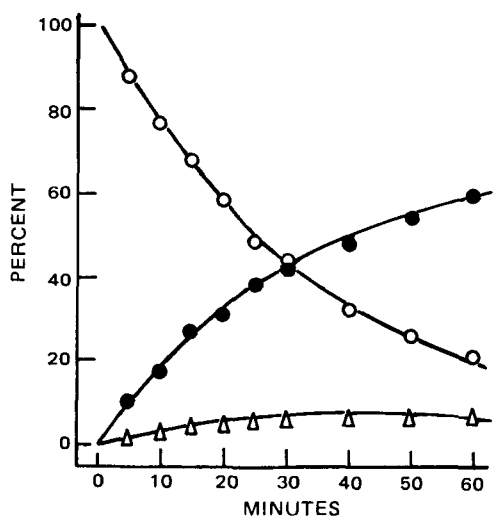

Figure 4—*Time course for hetacillin (○), epihetacillin (●), and ampicillin (△) determined by NMR spectroscopy during the degradation of hetacillin in 0.2 M $NaDCO_3$–Na_2CO_3 buffer at pD 10.6 and 35°. Curves were generated by the analog computer simulation according to Scheme I and the kinetic parameters listed in Table III.*

[a] Rate constants are defined in Scheme I. [b] The value was obtained from the assumption that ($k_1 + k_2$) values determined by the optical rotatory dispersion method would be almost equal to k_1 values (see text).

where A, B, α, and β are constants. Although Mitscher *et al.* (14) suggested that the results of rotation change reflect epimerization followed by hydrolysis, theoretical implications of Eq. 2 or detailed kinetics of epimerization of hetacillin by means of the optical rotatory dispersion method have not been reported.

The rotation at any time during the reaction of hetacillin, R_t, may be the sum of the rotation of the individual species of hetacillin (I), ampicillin (II), epihetacillin (III), epiampicillin (IV), and penicilloic acids of the last three compounds, V–VII, as follows:

$$R_t = \Phi_I[I] + \Phi_{II}[II] + \Phi_{III}[III] + \Phi_{IV}[IV] + \Phi_V[V] + \Phi_{VI}[VI] + \Phi_{VII}[VII] \quad \text{(Eq. 3)}$$

where Φ_i refers to the molar rotation coefficient of the ith species. In aqueous solution at pH >10, the amount of intact β-lactam compounds II and IV may be negligible because of their slow formation rate and the fast degradation rate of the β-lactam rings. These speculations were confirmed using TLC for the degradation of hetacillin at pH >10 and 35°. Equation 3 can be reduced to:

$$R_t = \Phi_I[I] + \Phi_{III}[III] + \Phi_V[V] + \Phi_{VI}[VI] + \Phi_{VII}[VII] \quad \text{(Eq. 4)}$$

and the following approximate relationship can be derived:

$$[V] + [VI] + [VII] = C_0 - ([I] + [III]) \quad \text{(Eq. 5)}$$

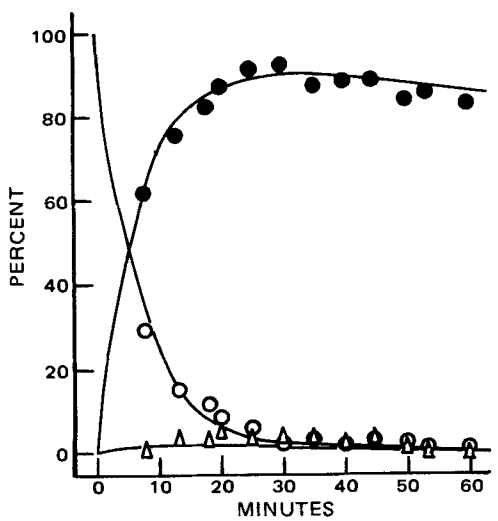

Figure 5—*Time course for hetacillin (○), epihetacillin (●), and ampicillin (△) determined by NMR spectroscopy during the degradation of hetacillin in 0.1 M Na_2DPO_4–Na_3PO_4 buffer at pD 11.4 and 35°. Curves were generated by the analog computer simulation according to Scheme I and the kinetic parameters listed in Table III.*

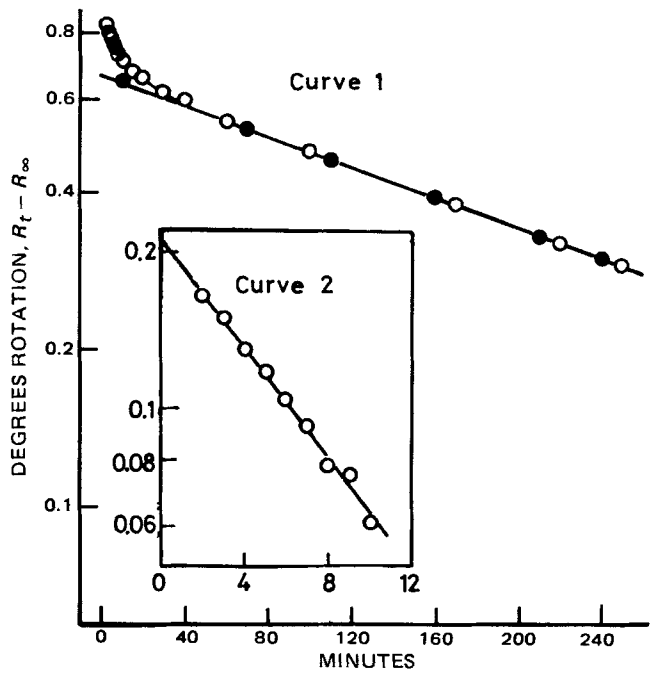

Figure 6—*First-order plot for the decrease in optical rotatory dispersion at 240 nm for the degradation of hetacillin (○, 6×10^{-4} M) and epihetacillin (●, 6×10^{-4} M) in 0.1 M Na_2HPO_4–Na_3PO_4 buffer at pH 11.1 and 35°. Curve 2 is a first-order plot for epimerization and hydrolysis.*

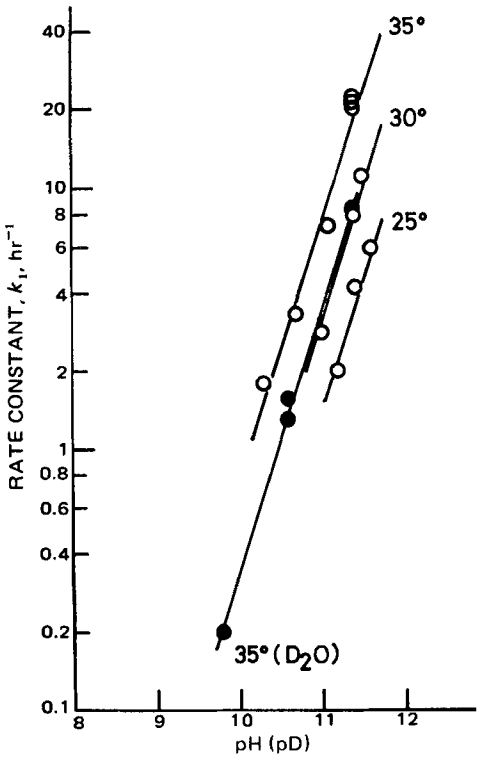

Figure 7—*Log* k-*pH (pD) profiles for the epimerization of hetacillin in water (○) at various temperatures and in deuterium oxide (●) at 35°.*

where C_0 represents the initial concentration of hetacillin. Results from the degradation of epihetacillin and ampicillin at pH >10 gave, within the experimental error, an approximate and simple relationship at 240 nm:

$$\Phi_V C_0 = \Phi_{VI} C_0 = \Phi_{VII} C_0 = R_\infty \qquad \text{(Eq. 6)}$$

Since the reversed reaction from ampicillin and acetone to hetacillin may be negligible in a sufficiently dilute solution of hetacillin, the time dependence of [I] and [III] can be given by the following equations from Scheme I:

$$[I] = C_0 e^{-(k_1+k_2)t} \qquad \text{(Eq. 7)}$$

$$[III] = \frac{k_1}{(k_1+k_2)-k_4} C_0 [e^{-k_4 t} - e^{-(k_1+k_2)t}] \qquad \text{(Eq. 8)}$$

These specific situations in a highly basic solution can lead to Eq. 9 for the R_t change at 240 nm:

$$R_t - R_\infty = A e^{-(k_1+k_2)t} + B e^{-k_4 t} \qquad \text{(Eq. 9)}$$

where:

$$A = (\Phi_I C_0 - R_\infty) - (\Phi_{III} C_0 - R_\infty) \frac{k_1}{(k_1+k_2)-k_4} \qquad \text{(Eq. 10)}$$

$$B = (\Phi_{III} C_0 - R_\infty) \frac{k_1}{(k_1+k_2)-k_4} \qquad \text{(Eq. 11)}$$

Equation 9 is essentially in agreement with that found by Mitscher *et al.* (14).

Figure 6 shows a typical plot of log $(R_t - R_\infty)$ *versus* time for the degradation of hetacillin and epihetacillin in 0.1 *M* phosphate buffer (μ = 0.5) at pH 11.1 and 35°. Since $k_1 + k_2$ is faster than k_4, $e^{-(k_1+k_2)t}$ approaches zero at some time point. There will remain a term in $e^{-k_4 t}$, and the plot of log $(R_t - R_\infty)$ *versus* time will be linear with a slope of $-k_4/2.303$. This linear portion of the curve may be extrapolated to zero time, and the value of $(R_t - R_\infty)$ along this portion of the line represents the contribution of the term in $e^{-k_4 t}$ to the overall value. Thus, subtraction of this term from the observed $(R_t - R_\infty)$ leaves only the term $e^{-(k_1+k_2)t}$. Then a plot of the logarithm of these residuals against time should be linear with a slope of $-(k_1 + k_2)/2.303$ (curve 2 in Fig. 6). The linear portions corresponding to $Be^{-k_4 t}$ were essentially identical at pH > 10 to the portion for epihetacillin itself, obtained from independent measurements at the same concentration under the same conditions as shown in Fig. 6, indicating the validity of Eq. 9 and suggesting the relation of $k_1 \gg k_2, k_4$.

Table IV—Epimerization Rate Constants of Hetacillin at Various Temperatures and μ = 0.5

Solvent	Temperature	k_{ep}, M^{-1} hr^{-1}
Water	25°	1.29×10^3
Water	30°	2.05×10^3
Water	35°	3.84×10^3
Deuterium oxide	35°	1.04×10^4

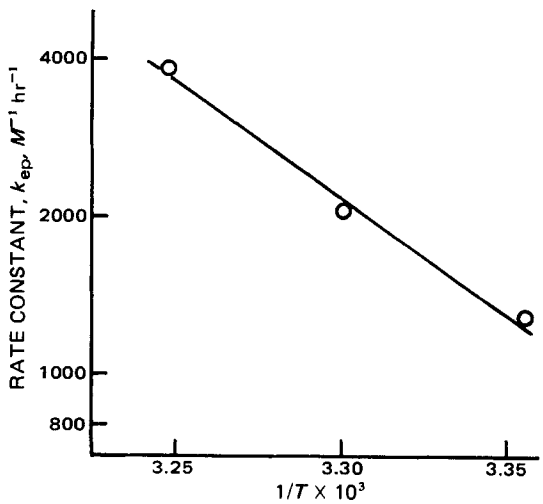

Figure 8—*Arrhenius plot of the second-order epimerization rate constant,* k_{ep}, *of hetacillin.*

Calculation of each value of k_1 and k_2 is theoretically possible from the intercept value of A or B. However, when taking into account the experimental error and large contribution of k_1 in the $(k_1 + k_2)$ value, it seems reasonable to assume for the data at pH > 10 that the $(k_1 + k_2)$ values thus determined are approximately equal to the epimerization rate constant, k_1. These rate constants are summarized in Table III. The k_1 and k_4 values determined at pD 10.6 and 11.4 by optical rotatory dispersion spectroscopy are in satisfactory agreement with those determined by NMR spectroscopy.

The results in phosphate buffer and sodium hydroxide solution at pH 11.4 (Table III) revealed that the apparent epimerization rate constants, k_1, were almost independent of the buffer concentration used. Since the C-6 epimerization of penicillin is known to proceed by general base catalysis (15, 16), the present results indicate that the general base-catalyzed epimerization rate of hetacillin may be negligible compared with the hydroxide-ion-catalyzed process in the experimental pH range.

pH–Rate Profile and Temperature Dependence for Epimerization of Hetacillin—Plots of log k_1 against pH (pH > 10) or pD for various temperatures in water and in deuterium oxide are illustrated in Fig. 7 and yielded straight lines with a slope of unity in each case, verifying a first-order dependence on the hydroxide ion. The rate law may be written as:

$$k_1 = k_{ep} a_{OH^-} \qquad \text{(Eq. 12)}$$

$$k_1 = k_{ep}(a_{H^+}/K_w) \qquad \text{(Eq. 13)}$$

where k_{ep} represents the second-order rate constant for hydroxide-ion-catalyzed epimerization; and a_{OH^-} and a_{H^+} refer to the activity of the hydroxide ion and hydrogen ion, respectively, which were calculated from pH measurements and the autoprotolytic constant in water (17) and deuterium oxide (18). The rate constants, k_{ep}, consistent with the experimental results in water and deuterium oxide are shown in Table IV.

Since the epimerization of hetacillin was suggested (5, 15) to occur through a rate-limiting formation of an enolate intermediate resulting from the proton subtraction of the acidic C-6 proton by a hydroxide ion, the ratio $k_{ep}^{D_2O}/k_{ep}^{H_2O}$ = 2.7 may be attributed to the difference in base strength between deuteroxide and hydroxide ions. Subsequent reprotonation gives the thermodynamically more stable epihetacillin; then epimerization proceeds irreversibly, as noted previously (5).

An Arrhenius plot for k_{ep} is illustrated in Fig. 8. By applying the method of least squares to the plots, the energy of activation for epimerization to epihetacillin was 21.2 kcal/mole.

In plots of log k_1 *versus* pH at 35° in water, slight positive deviation from the first-order dependence on the hydroxide ion was observed at alkaline pH < 10 (not presented in Fig. 7). This result may have been due to the considerable contribution of the hydrolysis rate, k_2, to the k_1 value estimated from the optical rotatory dispersion method. This result would occur because of the pH-dependent degradation behavior of hetacillin in which the epimerization process is a major pathway in a highly basic solution, whereas hydrolysis to ampicillin becomes increasingly significant in medium basic and neutral solutions (2, 3, 6).

No significant β-lactam cleavage reaction probably would take place in hetacillin itself, since the disappearance of hetacillin was virtually accompanied, even in highly basic solutions, with two competing reactions, the formation of epihetacillin (k_1 reaction) and the conversion to ampicillin (k_2 reaction), as verified by quantitative NMR studies (Figs. 3–5). The extreme stability of the β-lactam in the hetacillin molecule was also revealed in epihetacillin degradation. The k_4 reaction concerned with the disappearance of epihetacillin is controlled by hydrolysis of the β-lactam ring and conversion to epiampicillin. The pH dependency of k_4 at 35° (Table III) indicates that the hydroxide-ion-catalyzed hydrolysis of the β-lactam moiety of epihetacillin is predominant above pH 11.5, and conversion to epiampicillin seems to be significant below this pH.

The second-order rate constant for the β-lactam hydrolysis of epihetacillin was calculated to be 65.8 M^{-1} hr^{-1} at 35°, one-twentieth of the value for the hydrolysis of ampicillin β-lactam (19). The remarkable stability of both β-lactam rings of hetacillin and its epimer may be attributed to the steric hindrance of *gem*-dimethyl groups of the imidazolidine rings toward the attack by a hydroxide ion.

Reactions of Benzenesulfonohydrazides and Benzenesulfonamides with Hydrogen Chloride or Hydrogen Bromide in Acetic Acid

D. K. YUNG [*x], T. P. FORREST [‡], A. R. MANZER [*], and M. L. GILROY [*]

Abstract □ Benzenesulfonohydrazides capable of yielding a sulfinic acid intermediate by virtue of a basic nitrogen atom in the second position of the hydrazide moiety produced thiosulfonates when treated with 1 *N* hydrogen chloride in acetic acid and produced disulfides when treated with 1 *N* hydrogen bromide in the same solvent. In two cases, a crystalline mixture of *p*-nitrophenyl *p*-nitrobenzenethiosulfonate and bis(*p*-nitrophenyl) disulfide was isolated from the hydrogen chloride reactions. No reaction product was obtained from either the hydrogen chloride or hydrogen bromide reaction with benzenesulfonohydrazides that were unable to form a sulfinic acid intermediate. Reduction of benzenesulfonamides to disulfides appeared to be possible only with hydrogen bromide in acetic acid. No thiosulfonate was isolated from the treatments of benzenesulfonamides with 1 *N* hydrogen chloride in acetic acid. *p*-Nitrophenyl *p*-nitrobenzenethiosulfonate and *p*-bromophenyl *p*-bromobenzenethiosulfonate exhibited some antimicrobial activities against Gram-positive bacteria. The latter compound also showed analgesic properties in the phenylquinone test.

Keyphrases □ Benzenesulfonohydrazides and benzenesulfonamides—reaction with hydrogen chloride or bromide in acetic acid, pharmacological activity of thiosulfonates formed □ Thiosulfonates—formed by reaction of benzenesulfonohydrazides and benzenesulfonamides with hydrogen chloride in acetic acid, pharmacological activity screened □ Antimicrobial activity—screened in thiosulfonates formed by reaction of benzenesulfonohydrazides and benzenesulfonamides with hydrogen chloride in acetic acid

While preparing some potential antimicrobial unsymmetrical piperazine compounds, it was necessary to synthesize 1-(*p*-acetamidobenzenesulfonamido)piperazine from 1-(*p*-acetamidobenzenesulfonamido)-4-ethoxycarbonylpiperazine (Ia, Table I). Removal of ethoxycarbonyl groups of piperazine derivatives is usually accomplished by either acidic or alkaline hydrolysis (1, 2).

A nonhydrolytic method utilizing dry hydrogen bromide

An Arrhenius plot for k_{ep} is illustrated in Fig. 8. By applying the method of least squares to the plots, the energy of activation for epimerization to epihetacillin was 21.2 kcal/mole.

In plots of log k_1 *versus* pH at 35° in water, slight positive deviation from the first-order dependence on the hydroxide ion was observed at alkaline pH < 10 (not presented in Fig. 7). This result may have been due to the considerable contribution of the hydrolysis rate, k_2, to the k_1 value estimated from the optical rotatory dispersion method. This result would occur because of the pH-dependent degradation behavior of hetacillin in which the epimerization process is a major pathway in a highly basic solution, whereas hydrolysis to ampicillin becomes increasingly significant in medium basic and neutral solutions (2, 3, 6).

No significant β-lactam cleavage reaction probably would take place in hetacillin itself, since the disappearance of hetacillin was virtually accompanied, even in highly basic solutions, with two competing reactions, the formation of epihetacillin (k_1 reaction) and the conversion to ampicillin (k_2 reaction), as verified by quantitative NMR studies (Figs. 3–5). The extreme stability of the β-lactam in the hetacillin molecule was also revealed in epihetacillin degradation. The k_4 reaction concerned with the disappearance of epihetacillin is controlled by hydrolysis of the β-lactam ring and conversion to epiampicillin. The pH dependency of k_4 at 35° (Table III) indicates that the hydroxide-ion-catalyzed hydrolysis of the β-lactam moiety of epihetacillin is predominant above pH 11.5, and conversion to epiampicillin seems to be significant below this pH.

The second-order rate constant for the β-lactam hydrolysis of epihetacillin was calculated to be 65.8 M^{-1} hr^{-1} at 35°, one-twentieth of the value for the hydrolysis of ampicillin β-lactam (19). The remarkable stability of both β-lactam rings of hetacillin and its epimer may be attributed to the steric hindrance of *gem*-dimethyl groups of the imidazolidine rings toward the attack by a hydroxide ion.

in acetic acid for 1-alkyl-4-ethoxycarbonylpiperazines and 1-ethylsulfonyl-4-ethoxycarbonylpiperazine was reported (3). Similarly, other studies (4, 5) used dry hydrogen bromide or dry hydrogen chloride in acetic acid to remove benzoxycarbonyl groups from the nitrogen atoms in peptides. This paper describes the products isolated from the reactions of Ia and other structurally related compounds with dry hydrogen chloride in acetic acid and with dry hydrogen bromide in acetic acid.

RESULTS AND DISCUSSION

In the original attempt to remove the ethoxycarbonyl group of Ia, two problems were envisioned. First, the generally useful hydrolytic methods were considered unsuitable because of another vulnerable acetamido substituent in the molecule. Second, treatment of Ia with dry hydrogen bromide in acetic acid could result in the cleavage of the sulfonamide linkage, giving bis(*p*-acetamidophenyl) disulfide (XIIa) (6, 7) instead of the desired product.

However, in view of reported success with 1-ethylsulfonyl-4-ethoxycarbonylpiperazine (3), Ia was treated with 1 *N* hydrogen bromide in acetic acid. The desired product was not obtained; only XIIa in a 48% yield was isolated. Since it was reported that cleavage of sulfonamide with hydrogen bromide in acetic acid was a reduction process (8), it was decided to replace the dry hydrogen bromide with hydrogen chloride, a less active reducing agent. The reaction of Ia with 1 *N* hydrogen chloride in acetic acid produced a product characterized by IR, NMR, and elemental analysis to be the thiosulfonate XIa in about an 80% yield. No other products could be isolated from the reaction mixture.

In view of these results, two other piperazine compounds (Ib and Ic) were examined. In each instance, the corresponding thiosulfonates (XIb and XIc) were obtained in good yield on reaction with hydrogen chloride in acetic acid. However, treatment of Ib and Ic with 1 *N* hydrogen bromide in acetic acid resulted in the formation of disulfides (XIIb and XIIc).

[a] Yield is calculated on the basis of unrecovered starting compound.

To determine the scope of the reaction involving 1 *N* hydrogen chloride in acetic acid, 10 other benzenesulfonohydrazides without the piperazine ring (Table I) were investigated. As indicated in Table II, thiosulfonates were obtained from II*a*, III*a*, III*b*, and IV*a*. The hydrazides II*b* and IV*b*, however, produced the disulfide (XII*c*) in addition to the thiosulfonate (XI*c*). The two products were isolated as a crystalline solid (mp 157–158°), which consisted of an equimolar mixture of the two, as indicated by the proton NMR spectrum. Recrystallizations from common organic solvents failed to separate the two compounds; however, they could be separated by TLC (silica gel) using carbon tetrachloride–benzene (4:1) as the eluant. The melting point and IR spectrum of the mixture were identical to those of the authentic mixture (1:1) of XI*c* and XII*c*.

The other four benzenesulfonohydrazides (V*a*, V*b*, VI*a*, and VI*b*) do not have a basic nitrogen in the second position and did not yield any isolatable products in the reaction with hydrogen chloride in acetic acid. A significant amount of unreacted starting compound was recovered in each instance when the acid was removed *in vacuo*. Thus, the formation of thiosulfonates in the reactions with hydrogen chloride in acetic acid apparently depends on the availability of a basic nitrogen atom in the second position of the benzenesulfonohydrazides. Such a postulation is supported by the fact that none of the benzenesulfonamides (Table III) produced any thiosulfonates under similar conditions.

Thiosulfonates and sulfonic acids are known to result from disproportionation of sulfinic acids. In the acid-catalyzed hydrolysis of toluenesulfonohydrazides, sulfinic acids were formed as intermediates (9). Kice and coworkers (10, 11) proposed that the mechanism for the disproportionation of sulfinic acids involved an initial equilibrium between benzenesulfinic acid (XIII) and a sulfinyl sulfone intermediate (XIV), followed by the rearrangement of XIV to a sulfenyl sulfonate (XV). Reaction of XV with an additional molecule of XIII led to thiosulfonate and sulfonic acid as final products. Sulfonohydrazides are also reported to undergo a pyrolytic disproportionation, presumably *via* sulfinic acids, to yield a mixture of disulfide and thiosulfonate (12).

In the present study, all those benzenesulfonohydrazides that yielded thiosulfonates when treated with hydrogen chloride in acetic acid are capable of forming a sulfinic acid by electron shift from the basic nitrogen atom in the second position to the SO_2 group (Scheme I). Thus, the formation of thiosulfonates from these hydrazides probably proceeds *via* a sulfinic acid intermediate. When the same benzenesulfonohydrazides were allowed to react with 1 *N* hydrogen bromide in acetic acid, only the

XIII XIV XV

disulfides were formed. This finding is in contrast to reported results for the reactions of toluenesulfonohydrazides and aqueous hydrobromic acid, in which the thiosulfonates were the major products (9). A plausible explanation for the exclusive disulfide formation could be that the bromide ions attack the sulfinyl sulfur in XIV to give sulfinyl bromide (XVI) and XIII before the sulfenyl sulfonate (XV) is formed. In dioxane–water (60:40), the bromide ion was about five times more active a nucleophile than chloride ion toward the sulfinyl sulfur atom in XIV (13). Reduction of XVI by hydrogen bromide would yield the sulfenyl bromide (XVII), which has been suggested to be an intermediate for disulfide formation in the cleavage of sulfonamide with aqueous hydrogen bromide (7).

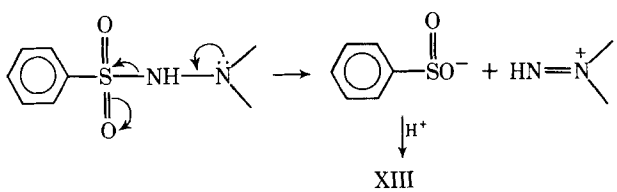
The fact that the sulfonamides (VII*a*, VIII*b*, and IX*a*) are not capable of producing the sulfinic acid intermediate and are still reduced to the disulfides suggests that the benzenesulfonohydrazides might react in a similar manner with hydrogen bromide to form the disulfides. However, the almost quantitative recovery of VI*a* and VI*b* from the reactions with hydrogen bromide in acetic acid does not support this suggestion.

Although thiosulfonates are not novel compounds, information on their biological properties is lacking. For this reason, a general screening of the pharmacological activities was performed on XI*b* and XI*c*. Preliminary results indicated that none of the compounds showed any significant antidepressant, cardiovascular, anti-inflammatory, antidiabetic, antihistaminic, or antiallergic activities. However, both compounds did exhibit some antimicrobial activities against Gram-positive bacteria such as *Bacillus subtilis* (ATCC 6633), *Staphylococcus aureus* (ATCC 8030), *Streptococcus pyogenes* (ATCC 6538), *Streptococcus faecalis* (a clinical isolate), and *Diplococcus pneumoniae* (ATCC 6303) but not against Gram-negative bacteria. In addition, XI*b* showed some analgesic activity in the phenylquinone test[1].

EXPERIMENTAL[2]

The benzenesulfonohydrazides and benzenesulfonamides were prepared from the amine and the corresponding benzenesulfonyl chloride in pyridine and were purified by recrystallization from ethanol or aqueous ethanol. With the exception of 1-amino-4-ethoxycarbonylpiperazine, all amines and benzenesulfonyl chlorides were obtained commercially. 1-Amino-4-ethoxycarbonylpiperazine was prepared by a previously reported method (14). The physical data of the benzenesulfonohydrazides and benzenesulfonamides are listed in Tables I and III, respectively.

p-Acetamidophenyl p-Acetamidobenzenethiosulfonate (XI*a*)—In a flask fitted with a gas-absorption trap were placed 0.8 g (0.0022 mole) of I*a* and 70 ml of 1 *N* hydrogen chloride in acetic acid, prepared by adding acetic acid to 10–15% hydrogen chloride in acetic acid. The mixture was warmed in a steam bath for 25 min and at 60° for 3 hr. The solution was allowed to stand at room temperature overnight and then filtered. About 0.2 g of crystalline XI*a* was collected and washed with ether. The filtrate was concentrated *in vacuo* to give a residue which, upon mixing with a small amount of ethanol, yielded an additional 0.12 g of XI*a*. Removal of the ethanol gave an unmanageable tar-like material. The total yield of XI*a* was 82%, mp 227–228°, after recrystallization from aqueous ethanol.



XIII

Scheme I

[1] The preliminary biological data were supplied by the Bio-Research Laboratories Ltd., Montreal, Quebec, Canada.

[2] Melting points were determined on a Thomas-Hoover capillary melting-point apparatus and are uncorrected. Elemental analyses were performed by Robertson Laboratory, Florham Park, N.J. IR spectra were recorded on a Perkin-Elmer model 237B spectrophotometer in potassium bromide. A Varian model T-60 spectrometer was used to record the NMR spectra, with deuterochloroform as the solvent and tetramethylsilane as the internal reference.

Mechanism of Methacholine-Induced Rise in Intraocular Pressure in the Dog

EUGENE R. BAIZMAN and HOWARD J. JENKINS ˣ

Abstract □ The mechanism of the methacholine-induced rise in intraocular pressure in the dog was studied to determine the basis of the relationship, if any, between lens thickness and intraocular pressure. The results rule out a vasodilator component in methacholine intraocular pressure elevation, and the tonometric recording of the elevation makes unlikely the involvement of methacholine stimulation of the rectus muscles of the eye. Thus, indirect evidence points to methacholine stimulation of ciliary muscle contraction with consequent thickening of the lens as responsible for its intraocular pressure-elevating effect and, hence, the ability of the response under investigation to specify the cycloplegic liability of a neurotropic antispasmodic agent.

Keyphrases □ Methacholine—mechanism of induced rise in intraocular pressure, effect of phenylephrine, dogs □ Intraocular pressure—mechanism of methacholine-induced rise, effect of phenylephrine, dogs □ Phenylephrine—effect on methacholine-induced rise in intraocular pressure, dogs □ Cholinergic agents—methacholine, mechanism of induced rise in intraocular pressure, effect of phenylephrine, dogs □ Adrenergic agents—phenylephrine, effect on methacholine-induced rise in intraocular pressure, dogs

During studies to determine the relative response of a number of parameters to intravenously administered methacholine chloride, intraocular pressure, as measured with an applanation tonometer, increased during a brief postinjection period and then decreased to normal (1). In contrast, parasympathomimetic agents in general, when applied topically to the cornea, were reported (2, 3) to lower intraocular pressure. It became apparent that the increase in intraocular pressure in response to methacholine is dose dependent and that it can be offset by the prior administration of an anticholinergic compound such as atropine if the dose of the latter is adequate. Moreover, if the dose of the anticholinergic be such as to effect a partial block of established extent of the cholinergic receptors, the magnitude of the dose of methacholine that will elicit a 50% increase (half of the maximal response) in intraocular pressure (Me_{50}) is an index of the affinity of the anticholinergic agent for cholinergic receptors associated with the response.

EXPERIMENTAL

Mongrel, male dogs, 12–17 kg, were fed once a day at approximately the same time each day and allowed water *ad libitum*. Each dog was anesthetized with 10 mg of thiopental sodium/kg and 90 mg of α-chloralose/kg iv, mixed in the calculated amounts and heated in an aqueous solution to 40–45° to increase solubility just prior to injection.

Blood pressure was recorded directly by femoral artery puncture and pressure transducer. Changes in intraocular pressure during a determination were transmitted to a pressure preamplifier by an applanation pressure transducer, the pressure-sensitive metallic core of which was positioned directly over the pupil on the corneal surface. A short piece of glass tubing, flanged at its point of contact with the eyeball, was used to support the base of the tonometer so that the core of the tapered end made unobstructed contact with the corneal surface.

The dosage regimen employed in the initial portion of this study was identical with that used previously (1). The first standard dose of 5.55 μg of methacholine/kg iv was injected and subsequently flushed into the circulatory system of the animal with 3 ml of saline. Intraocular pressure responses to methacholine were read at their respective peaks. Blood pressure responses were read twice for each dose of methacholine administered. The first reading was made just prior to drug administration, and the second was made at the nadir of the depressor response.

The second standard dose of methacholine (5.55 μg/kg) was administered in the same manner as the first. If the response to either of these two drug administrations differed by much more than 10% from the average of the two, a third standard dose of methacholine was given. Then the three responses were averaged for use in subsequent calculations to determine the degree of inhibition of the response occasioned by the anticholinergic agent.

When the effect of the last preanticholinergic dose of methacholine had terminated, a 6.5-μg/kg iv dose of the anticholinergic agent, glycopyrrolate bromide, was administered. During the following 30 min, the anticholinergic compound was allowed to exert its full effect. Then the preanticholinergic dose of methacholine (5.55 μg/kg) was repeated, and the responses of the two parameters to this dose were read in the same manner as described previously. After ensuring that all records had returned to their respective baselines, a second dose of methacholine was administered 15 min after the administration of the initial postanticholinergic dose; similarly, a third dose of this drug was administered 15 min following the second dose.

In all determinations, the quantities of the postanticholinergic doses of methacholine were equivalent to: (*a*) the preanticholinergic dose, (*b*) twice the preanticholinergic dose, and (*c*) three times the preanticholinergic dose. This series was chosen in an attempt to elicit responses such that one would be approximately 50% of the (average) preanticholinergic response, one would be greater than 50% of this (average) response, and one would be less than 50%.

Each postanticholinergic response to methacholine was expressed as the percent inhibition of the (average) preanticholinergic response. An Me_{50} was then obtained for each parameter whose responses lent themselves to quantitative treatment (intraocular pressure and arterial blood pressure) by plotting dose–response data on logarithmic–probability paper, with the percent inhibition as the ordinate and the dose of methacholine as the abscissa (single dose of anticholinergic per determination). The fit of the line to the plotted points was determined both by visual inspection and by the method of least squares. The Me_{50}'s so obtained were averaged, and their standard deviations were determined.

The first modification of the described drug dosage regimen was the substitution of an intravenous dose of phenylephrine hydrochloride for glycopyrrolate. Doses of 10, 20, and 30 μg/kg of the latter were administered 15 min apart, beginning 15 min after the last prephenylephrine dose of methacholine had been injected. Responses were recorded in the usual manner.

Exactly 60 sec after the injection of the first dose of phenylephrine, at the peak of the response to this pressor agent, a dose of methacholine equivalent to the prephenylephrine dose (5.55 μg/kg) was administered and the responses were recorded. After both intraocular pressure and blood pressure parameters had again returned to their respective baselines, the second phenylephrine dose was administered, followed 1 min later by a dose of methacholine identical to the one previously administered. The third and largest dose of phenylephrine was then given, again followed precisely 1 min later by 5.55 μg/kg of methacholine. By means of the prior systemic administration of phenylephrine, a potent vasoconstrictor and pressor agent, it was possible to obtain pharmacological opposition to the depressor and vasodilator effects of methacholine which might be involved in the intraocular pressure rise.

RESULTS AND DISCUSSION

Variations in such physiological phenomena as respiration and arterial blood pressure can affect intraocular pressure (4), and intraocular pressure elevated as a result of such variations has been reported. Carballo (4) stated that acetylcholine and anticholinesterases elevate ocular tension by producing vasodilation in the eye and by stimulating the contraction of the external rectus muscles. This finding was substantiated

Table I—Methacholine-Induced Responses of Intraocular Pressure and Arterial Blood Pressure after Injection of Phenylephrine Hydrochloride in a 16.0-kg Dog

by Colle *et al.* (5), who observed that administration of large doses of acetylcholine produced a rapid rise in intraocular pressure of the perfused dog head, with a rise in systemic blood pressure. Here also vasodilation of intraocular vessels and contraction of the rectus muscle were implicated in the response. Methacholine, certain anticholinesterases, and pilocarpine have all caused a vasodilation of the conjunctival and intraocular vessels as well as increased permeability of their walls (6). The volume of blood contained in the vessels of the choroid and of the ciliary body constitutes a large part of the total volume of the eye. Hence, any agent affecting the filling of these vessels may affect intraocular pressure (7).

Cholinergic agents, especially echothiophate iodide and pilocarpine, may produce a shallowing of the anterior chamber, which could result from an anterior displacement of the lens with relaxation of the suspensory ligaments following contraction of the ciliary muscle (8). The thrust of the anterior lenticular displacement may cause a bowing of the iris in the direction of the cornea, narrowing the chamber angle and increasing resistance to drainage. As the thickening lens pushes anteriorly against the iris, its more spherical anterior surface may achieve a pupil block, which prevents dissipation of a pressure rise through this avenue of escape.

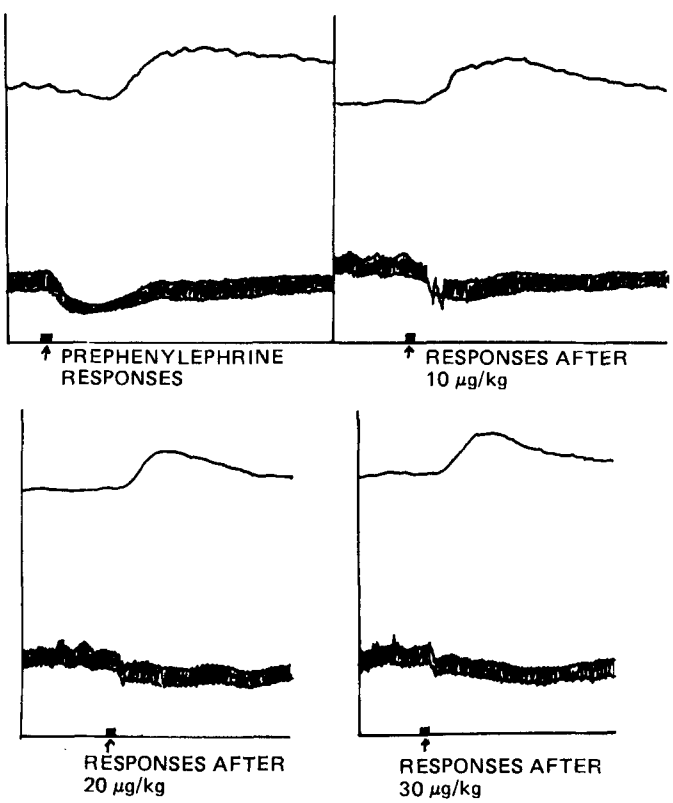

Figure 1—*Intraocular and arterial blood pressure responses to methacholine chloride (5.55 μg/kg) in an anesthetized dog before and after injection of 10, 20, and 30 μg of phenylephrine hydrochloride/kg iv. (Time: 1 mm = 1 sec; arterial blood pressure: 1 mm = 10 mm Hg; intraocular pressure: 1 mm = 1 mm Hg.)*

Thus, there are three (chief) mechanisms by which parasympathetic stimulation and parasympathomimetic agents may increase intraocular pressure such as is obtained in the intravenous administration of methacholine chloride in the dog:

1. Increased aqueous humor production through vasodilation and increased permeability of ciliary vessels.
2. Anterior thickening of the crystalline lens pushing the iris toward the rigid cornea, thereby decreasing the drainage angle of the anterior chamber and the chamber volume. (A combination of 1 and 2 is possible.)
3. Contraction of the external rectus muscle with consequent reduction in intrachamber volume.

In light of results obtained when phenylephrine was injected intravenously, vasodilation probably does not play a significant role in the methacholine-induced rise in intraocular pressure in the intact dog (Table I and Fig. 1). Little, if any, change occurred in the elevation of intraocular pressure after methacholine injection when phenylephrine was administered intravenously beforehand and was acting systemically to constrict intraocular vessels or was applied topically, directly upon the corneal surface (not shown). Phenylephrine was used to eliminate the possibility that intraocular vessel changes elicited by methacholine are responsible for the rise in intraocular pressure. This sympathomimetic mydriatic agent is reported to lower significantly an elevated intraocular pressure by decreasing aqueous humor formation through constriction of the intraocular vessels of the ciliary body and the choroid coat. Furthermore, it induces no significant changes in the aqueous humor outflow, the ciliary muscle, or the crystalline lens (9–11).

A comparison of the mean and standard deviation of the mean blood pressure Me_{50} values with the mean and standard deviation of the intraocular pressure Me_{50} values for glycopyrrolate shows a significant difference ($p = 0.005$) between the affinities of vascular and ciliary cholinergic receptors for this anticholinergic agent (Table II). This difference indicates that the rise in intraocular pressure elicited by methacholine is not secondary to the fall in arterial blood pressure, *i.e.*, to vasodilation and the subsequent increase in aqueous humor production. Thus, the two responses do not appear to represent the same basic phenomenon and might be separable on an experimental basis. Moreover, the rapidity of the rise of intraocular pressure in response to methacholine makes increased aqueous humor production an unlikely etiologic factor. Besides, the contraction of ciliary muscle in response to methacholine reduces muscle volume, with a resultant constriction of ciliary blood vessels, each of which tends to lower intraocular pressure. On the other hand, the reduction in the diameter of the ciliary circle, which attends contraction of the ciliary muscle, itself reduces the size of the anterior chamber and favors a pressure rise. In the early work of Armaly (8), the latter effect predominated in the cat eye after parasympathetic stimulation.

Because of the nature of the intraocular pressure determination (employing an applanation tonometer), any contraction of the external rectus muscle would manifest itself as a decrease in intraocular pressure and would be thus detectable.

By deduction, then, it appears that a thickening of the crystalline lens

Table II—Determination of Me_{50} Values for Glycopyrrolate (6.5 μg/kg iv)

	Intraocular Pressure, mm Hg	Inhibition, %	Arterial Blood Pressure, mm Hg	Inhibition, %
Mean preantispasmodic	12.0		85.00

t = 5.489				

with a resultant thrust of the iris in the direction of the cornea, decreasing the chamber volume and drainage angle, together with a (possible) block of the pupillary opening preventing the dissipation of increasing chamber pressure is responsible for the methacholine-induced rise in intraocular pressure. This rise probably occurs only after intravenous injection of methacholine when the rapid forward thrust of the iris by the thickening of the lens, which appears responsible for it, is able to overcome for a time the tendency of the drainage system to offset it, a tendency soon realized in the speedy return of pressure to baseline following the postinjection rise. Subsequent investigation might involve another route of methacholine administration in an effort to determine the influence of the administration route on the response. It should also attempt to determine whether a dose of methacholine that is threshold for blood pressure reduction has any effect on intraocular pressure or, conversely, the extent to which methacholine might reduce blood pressure before it effects an increase in intraocular pressure.

The significance of this study involves the use of the parameter of intraocular pressure to determine the liability of a neurotropic antispasmodic (parasympatholytic) agent to induce cycloplegia. If a direct relationship exists between intraocular pressure and lens thickness, as this study indicates, then the extent to which the neurotropic antispasmodic interferes with a cholinergic-induced rise in intraocular pressure is a measure of its tendency to produce cycloplegia or blurring of vision. Hence, neurotropic antispasmodic compounds with relatively high intraocular pressure Me_{50}'s (in relation to their antimotility or antisecretory Me_{50}'s) should have a high liability with respect to the side effect of cycloplegia.

The study reported is a facet of a comprehensive investigation conducted over years. Numerous determinations of the effect of neurotropic antispasmodic agents on the intraocular pressure response to methacholine in the dog were made, and the data reported here are representative.

Impurities in Drugs I: Imipramine, Desipramine, and Their Formulations

K. M. McERLANE [x], N. M. CURRAN, and E. G. LOVERING

Abstract □ Nineteen lots of imipramine tablets and four lots of desipramine tablets were examined for impurities by TLC. Iminodibenzyl, desipramine, and 10,11-dihydro-5-[3-(methylamino-3′-dimethylaminopropyl)propyl]-5*H*-dibenz[*b,f*]azepine dihydrobromide (I) were found in some imipramine tablets, and iminodibenzyl and imipramine were found in some desipramine tablets, all at levels of less than 0.3% of label claim of the drug. Except for I, the identity of the impurities was established by comparison with known standards; I was synthesized and its composition was established by elemental analysis. All impurities, including I, were characterized by TLC, GLC, and mass spectrometry.

Keyphrases □ Imipramine tablets—impurities, TLC, GLC, and mass spectral analysis □ Desipramine tablets—impurities, TLC, GLC, and mass spectral analysis □ Impurities—in imipramine and desipramine tablets, TLC, GLC, and mass spectral analysis □ Tablets—imipramine and desipramine, TLC, GLC, and mass spectral analysis of impurities □ Dosage forms—tablets, imipramine and desipramine, TLC, GLC, and mass spectral analysis of impurities □ Antidepressants—imipramine and desipramine tablets, TLC, GLC, and mass spectral analysis of impurities

Organic compounds found as impurities in drugs and drug formulations may be intermediates or by-products of the drug synthesis, products of drug or excipient degradation, products of drug–excipient interaction, or the result of contamination. The nature of the impurities in a drug may depend on the synthetic process and the source of materials used in manufacture or the nature and source of the excipients. Impurities may be toxic, and their

presence may be indicative of inadequately controlled manufacturing or storage conditions.

To obtain a broadly based perspective of impurity levels and the potential problems associated with them, drug products and formulations from many different sources should be examined. This paper, the first of a series reporting the occurrence of impurities in drugs, describes a study of imipramine and desipramine formulations.

Imipramine hydrochloride is official in USP XIX (1) and BP 1973 (2, 3). Limits for iminodibenzyl, one of the starting materials, are set at 0.1% by the USP and at 0.2% by the BP. Tablets and injections are described in the USP, and tablets are described in the BP, but only the latter specifies a limit for iminodibenzyl (0.3%) in tablet formulations.

Desipramine hydrochloride is official in NF XIV (4) and in BP 1973 (2). The limits specified for iminodibenzyl are 0.1 and 0.2%, respectively. Tablets and capsules are described in the NF, and tablets are described in the BP. The latter sets a limit of 0.3% for the content of iminodibenzyl in tablets.

EXPERIMENTAL

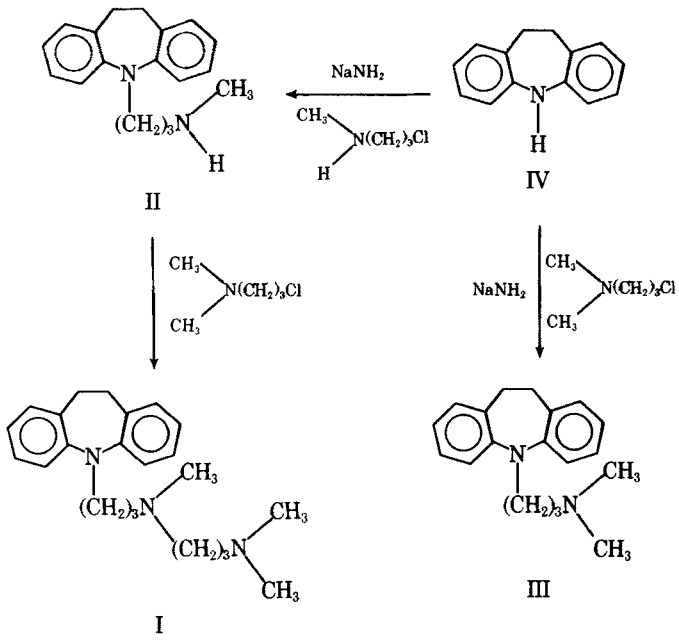
Materials—Imipramine hydrochloride and desipramine hydrochloride were the respective USP and NF reference standard materials. Nineteen lots of seven brands of imipramine tablets and four lots of two brands of desipramine tablets were obtained from the manufacturers. The other reagents used were redistilled chloroform[1], benzene[1], ethyl acetate[1], absolute ethanol[2], and dimethylaminopropyl chloride[3]. Macherey–Nagel TLC plates[4] were precoated with 0.25-mm silica gel G containing a 254-nm fluorescent indicator.

Standard Solutions—For imipramine studies, 56.5 mg of imipramine hydrochloride was dissolved in 2.0 ml of 0.1 *N* hydrochloric acid, made basic with 0.1 ml of concentrated ammonium hydroxide, and extracted by shaking into 5.0 ml of chloroform containing 0.15 mg of iminodibenzyl, 0.17 mg of desipramine hydrochloride, and 0.22 mg of 10,11-dihydro-5-[3-(methylamino-3′-dimethylaminopropyl)propyl] - 5*H* - dibenz[*b,f*]-azepine dihydrobromide (I, Scheme I). The standard solution in chloroform was separated from the aqueous layer. The desipramine standard solution was prepared in a similar way by extracting 57.9 mg of desipramine hydrochloride into 5 ml of chloroform containing 0.15 mg of iminodibenzyl and 0.17 mg of imipramine hydrochloride.

Both reference standard drugs were shown, by the TLC system described in this paper, to be free of detectable impurities. Each standard solution contained 10 mg/ml of the free base form of the drug with the remaining compounds, also as the free bases, at 0.3% with respect to the drug.

TLC Solvent Systems—For imipramine, a system of benzene–ethyl acetate–absolute ethanol–concentrated ammonium hydroxide (50:50:15:3) was used. For desipramine, the proportions were 50:50:20:3, respectively. Both solutions were placed in filter paper-lined chromatographic tanks and allowed to equilibrate for 1 hr prior to use.

Tablet Extraction—Twenty tablets were weighed and finely powdered. An amount of drug equivalent to 50 mg of the free base was weighed into a 10-ml polytef-lined, screw-capped centrifuge tube. Then 2 ml of 0.1 *N* hydrochloric acid was added, and the tube was shaken vigorously for 15 min on a horizontal shaker. Concentrated ammonium hydroxide, 0.1 ml, and 5 ml of redistilled chloroform were added, and the tube was shaken for 20 min. A portion of the chloroform layer, containing the drug and impurities, was removed for analysis.



Scheme I

Screening for Impurities—The R_f of each drug and impurity in chloroform solution was determined in the appropriate TLC system. To check for possible decomposition, each compound was scraped from the plate and subjected to GLC and mass spectrometry. A portion of the eluate recovered from the gas chromatograph was rerun in the TLC system. The lower detection limit of each impurity was established by spotting serial dilutions of the appropriate stock solution.

Aliquots of 10 and 20 μl (100 and 200 μg) of the tablet extract in chloroform for each formulation were spotted beside 10- and 20-μl (100- and 200-μg) aliquots of the appropriate standard solution. Plates were developed, and the compounds were visualized using UV light at 254 nm and subsequently spraying with 0.5% (w/v) potassium dichromate in 20% (v/v) sulfuric acid. The concentration of impurities was approximated by comparison of the spot diameters and intensities with the corresponding spots due to the standard solutions.

Isolation of Impurities—A tablet extract containing 40 mg of drug as the hydrochloride in 1.0 ml of chloroform was applied in a narrow band to a 0.25-mm TLC plate, 20 × 20 cm, and developed in the appropriate solvent system. Four such plates were prepared. Impurities were visualized by UV light at 254 nm and by spraying a 1-cm band along each side of the plate with 0.5% (w/v) potassium dichromate in 20% (v/v) sulfuric acid.

To reduce the possibility of decomposition during manipulation, the impurities were converted to the more stable hydrochloride form by spraying lightly with ethanolic hydrochloric acid, and the bands were scraped from the TLC plates. The scrapings were stirred with 25 ml of absolute ethanol for 60 min and then filtered, and the ethanol solution was evaporated to dryness on a rotary evaporator at room temperature. The purity of the isolated compounds was checked by TLC and GLC.

Samples of impurities for mass spectral analysis were isolated by GLC using a column of 5% OV-25 on 100–120-mesh Chromosorb W (HP). The injection port, detector block, and column temperatures were 250, 250, and 240°, respectively. The flow rates of nitrogen, hydrogen, and air were 40, 50, and 400 ml/min, respectively. Approximately 50 μg of drug from the TLC plate extract was injected into the chromatographic column.

Fractions were collected in dry ice-cooled capillary tubes held over the flame tip of the chromatograph. The hydrogen flame was extinguished just prior to elution of the required fraction and reignited after collection to burn off material condensed on the flame tip. TLC showed that each fraction consisted of a single component, was free from decomposition products, and was identical to the material originally removed from the TLC plate.

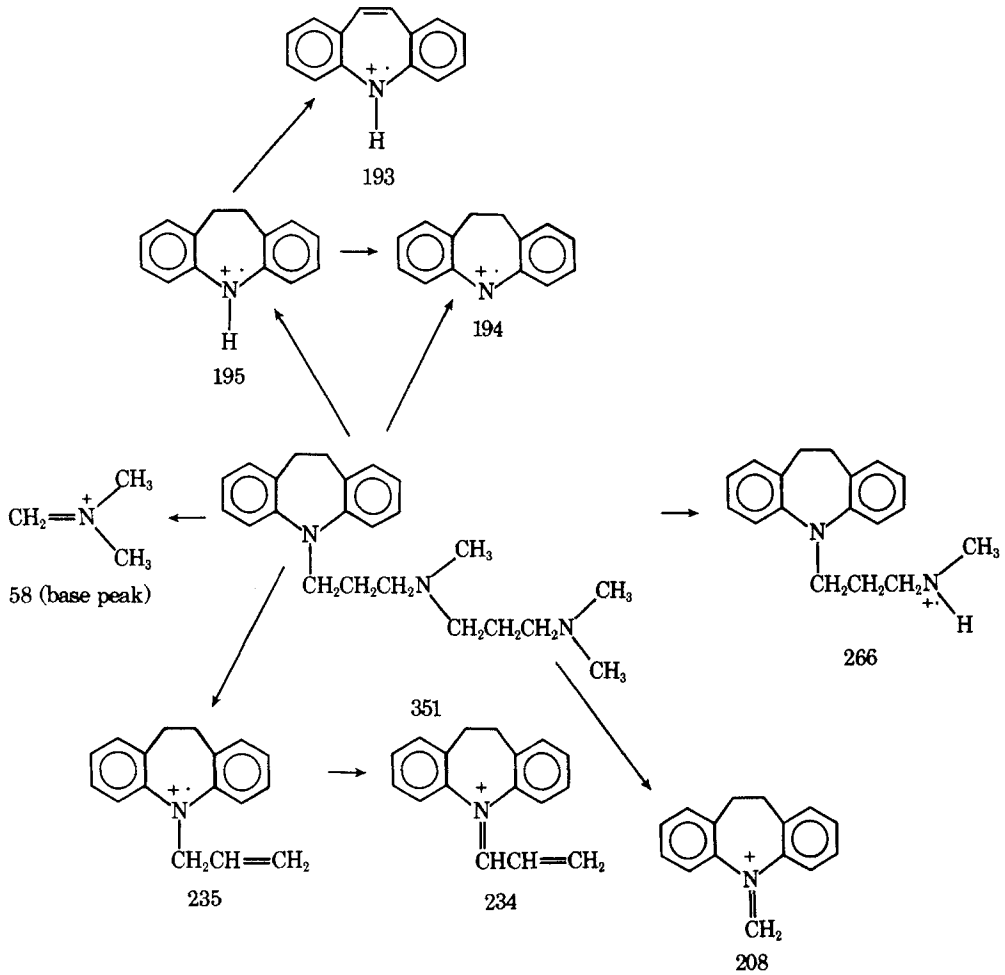

Scheme II

Synthesis—Dimethylaminopropyl chloride was obtained from its hydrochloride salt by triturating 16.0 g of the latter with 8.0 g of flaked sodium hydroxide (5). The free amine was decanted from the solid phase and distilled at 124–128°/160 mm Hg through a 5-cm vigreaux column.

Compound I was prepared by refluxing a mixture of 7.5 g of freshly distilled dimethylaminopropyl chloride and 0.83 g of desipramine (II) in 20.0 ml of dry acetone for 18 hr (Scheme I). The acetone and excess dimethylaminopropyl chloride were removed on a rotary evaporator. The residue was taken up in 10 ml of 0.1 *N* hydrochloric acid, washed twice with 50 ml of ether, made basic with 1.0 ml of concentrated ammonium hydroxide, and extracted with two 50-ml portions of chloroform. The chloroform was removed on a rotary evaporator at room temperature, and ethanolic hydrogen bromide was added to the residue. The resulting salt was crystallized by the addition of ether and dried at 56°/1 mm Hg. The crystalline melting point[5] was 218–221° (uncorrected).

Anal.—Calc. for $C_{23}H_{33}N_3 \cdot 2HBr$: C, 53.81; H, 6.87; N, 8.19. Found: C, 53.95; H, 6.97; N, 8.05.

The PMR[6] spectrum (1% in deuterochloroform, 40°) exhibited distinctive signals downfield from trimethylsilane at 131 Hz due to the three-proton *N*-methyl singlet and at 138 Hz due to the six-proton *N,N*-dimethyl singlet, but the signal at 73.5 Hz due to the NH proton in desipramine was not observed. The mass spectrum[7] was obtained by direct probe in the electron-impact mode at 70 ev and 160°. Attempts to prepare the crystalline hydrochloride salt were unsuccessful.

RESULTS AND DISCUSSION

A single chloroform extraction was sufficient for complete removal of imipramine and desipramine from aqueous tablet powder mixtures. No drug was found in the chloroform fraction following a second extraction of the aqueous tablet powder mixture. In addition, the diameters and intensities of the TLC spots from tablet extracts were identical to those from standard solutions of the hydrochlorides at corresponding concentrations. No degradation of the drug or its impurities was observed when the free bases were applied at 0.5-hr intervals over 3 hr. The TLC solvent system was chosen to maximize separation of the impurities. The toluene–methanol (95:5) system described in BP 1973 (2) is adequate only for iminodibenzyl.

The identity of iminodibenzyl, imipramine, and desipramine found in tablet formulations was established by comparison of the TLC R_f values, GLC retention times, and mass spectral fragmentation patterns with those of known samples. Tablet impurities for GLC were recovered from TLC plates, and GLC eluates were collected for mass spectrometry and TLC, as previously described. The purity of the standard compounds was authenticated by subjecting them to the TLC, GLC, and mass spectral treatment.

The structure postulated for I is in agreement with the elemental analysis and the PMR spectrum. It is further supported by the mass spectral results, which conformed to the fragmentation scheme presented

in Scheme II. Detectability limits and R_f values by TLC and retention times by GLC for imipramine, desipramine, iminodibenzyl, and I are given in Table I.

Nineteen lots of imipramine tablets from seven manufacturers were tested for impurities (Table II). All lots contained desipramine at levels from 0.1 to 0.3%, and all but two contained iminodibenzyl at levels from 0.05 to 0.2%. Compound I was found in 14 lots in amounts to 0.3%. The occurrence of desipramine (II) and I in imipramine (III) formulations may be due to the presence of monomethylaminopropyl chloride in the dimethylaminopropyl chloride used as a starting material in at least one synthetic process (6) (Scheme I). Iminodibenzyl (IV) is used as a starting material, but its presence may also result from decomposition of the drug (7).

An impurity at R_f 0.30 was observed in five lots at levels from trace to 0.3%, on the basis of the sensitivity established for imipramine. This impurity may be the 10-hydroxy analog of imipramine suggested by Adank and Hammerschmidt (7), but attempts to isolate and identify the compound were unsuccessful. Trace amounts of an impurity at R_f 0.15 were observed in two lots, but no attempt at isolation and identification was made.

Each of four lots of two brands of desipramine contained iminodibenzyl, and three of the four contained imipramine, all at levels below 0.15% (Table III). Iminodibenzyl is a synthetic precursor (8) (Scheme III) and may also result from breakdown of the drug (9); the source of imipramine may be due to the residual material remaining if imipramine is demethylated *via* the chloroformate ester to produce desipramine (10). The level of iminodibenzyl in all formulations tested was below the limit of 0.3% specified for tablets in BP 1973, even though some formulations were manufactured to specifications other than those of the BP.

Chemical and Spectroscopic Analysis of a Phenobarbital–Ephedrine Complex

MARSHA B. MRTEK ˣ, JAMES E. GEARIEN, and MARTIN I. BLAKE

Abstract □ A complex of phenobarbital and ephedrine was prepared and characterized. The complex was differentiated from physical mixtures of the two drugs by TLC and IR spectroscopy. NMR spectroscopy was used to verify the proportion of each drug in the complex and to confirm the existence of intermolecular binding. Mass spectrometry was employed to establish that all fragments characteristic of the individual drug entities could be isolated from the complex. Elemental analysis confirmed the chemical composition of the complex. A possible chemical structure for the complex was hypothesized on the basis of the chemical and spectroscopic data.

Keyphrases □ Phenobarbital—complex with ephedrine prepared, chemical and spectroscopic analysis □ Ephedrine—complex with phenobarbital prepared, chemical and spectroscopic analysis □ Complexes—phenobarbital with ephedrine, preparation, chemical and spectroscopic analysis

One widely used method to measure complexation has been to monitor a change in the curve produced for some additive property such as spectrophotometric absorbance. Titration techniques have been used whenever a change in pH accompanied the complexation reaction. The change in absolute solubility in a given solvent was used to measure quantitatively the production of caffeine complexes (1), and a phase solubility technique was used to study the formation of complex salts of triamterene with several acids (2).

The color reaction of local anesthetics with 1,3,5-trinitrobenzene was utilized to study the stoichiometry of complex formation (3). NMR spectroscopy was used (4) to study the structure of the caffeine–sodium benzoate complex, and differential thermal analysis was used (5) to follow the interaction of aminopyrine and barbital. A combination of NMR and IR spectroscopy was employed to investigate the extent of hydrogen bonding resulting in increased solubility of paraben combinations (6).

A number of molecular phenobarbital complexes were investigated. Phase solubility studies of phenobarbital and polyethylene glycol complexes (7), an IR study of phenobarbital association with purines (8), and IR studies of phenobarbital complexes with quinine, quinidine, and hydroquinidine (9) were reported. The isolation of a 1:1 phenobarbital–ephedrine complex formed by acid–base neutralization in ether also was reported (10).

The objective of this study was to apply chemical and spectroscopic analytical techniques to determine the nature and structure of a phenobarbital–ephedrine complex.

EXPERIMENTAL

Phenobarbital was recrystallized from boiling water, and the melting point of the recrystallized and dried product was determined by differential thermal analysis to be 174–176°. Ephedrine hemihydrate was made anhydrous by azeotroping with benzene, and the resulting solid was dried and stored under vacuum. The melting point determined by differential thermal analysis was 33–36°. Spectral grade chloroform was used for the IR analysis. All other reagents were analytical grade. The recrystallized complex was subjected to elemental analysis[1].

Table I—R_f Values for Ephedrine, Phenobarbital, and Complex

Solvent System	Plates	R_f Ephedrine	R_f Phenobarbital	R_f Complex
50% Ethanol	Alumina	0.38	0.75	0.70
Anhydrous methanol	Alumina	0.57	0.31	0.23
50% Ethanol	Silica	0.10	0.80	0.80
				0.03
Anhydrous methanol	Silica	0.18	0.71	0.71
				0.11

Synthesis of Complex—Exactly 1.65 g (10 mmoles) of anhydrous ephedrine was added to 2.70 g (12 mmoles) of phenobarbital. The mixture was dissolved in approximately 15 ml of anhydrous ether, which had been stored over metallic sodium. Any excess phenobarbital was removed by filtration. The resulting solution was crystallized by chilling in an acetone–dry ice bath. The sides of the flask were scratched with a sharp glass rod to induce crystallization.

A "dry box" was prepared from an air-tight glove box containing phosphorus pentoxide under an atmosphere of nitrogen and was fitted with a suction hose for filtration. A specially prepared funnel was made by cutting a hole for a 9-cm büchner funnel in a 15-cm polyethylene büchner funnel. The holes in the outer funnel were sealed with a resin, and the space between the two funnels was filled with crushed dry ice. The funnel and filter paper were allowed to equilibrate in the dry box for at least 0.5 hr prior to filtration.

The crystals were collected in the central filter, and the ether was removed as rapidly as possible by vigorous suction aided by a positive pressure from nitrogen gas being introduced into the box. The filter system, including the dry ice and the crystalline material, was rapidly removed to a vacuum desiccator containing sulfuric acid and phosphorus pentoxide. The desiccator was immediately evacuated, and the crystals were left to dry for not less than 24 hr.

TLC—TLC was performed on both silica[2] and alumina[3] fluorescent plates for phenobarbital, ephedrine, and the complex. The plates were spotted with an ether solution of each compound, and spots were visualized with a UV lamp and iodine vapors. The following solvents were used: anhydrous methanol, 95% ethanol, 70% ethanol, anhydrous ether, 75% benzene–25% ethyl acetate, and 50% benzene–50% ethyl acetate.

IR Spectroscopy—IR spectra were obtained[4] for ephedrine, phenobarbital, and the complex using approximately 10% (w/v) samples dissolved in spectral grade chloroform.

NMR Spectroscopy—NMR spectroscopy[5] was used to examine the proton resonance structures of ephedrine, phenobarbital, the complex, ephedrine acetate, and phenobarbital triethylamine solutions in deuterochloroform (approximately 5% w/v). The spectra were determined in the field-sweep mode using an internal tetramethylsilane standard.

Mass Spectrometry—Mass spectrograms for ephedrine, phenobarbital, and the complex were obtained[6].

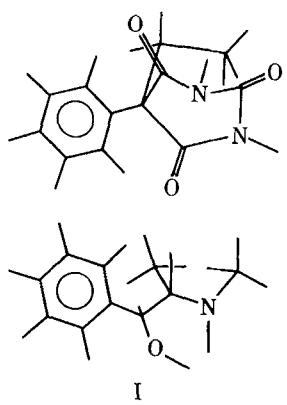
RESULTS AND DISCUSSION

The results of Babin and Coustou (10) for the preparation of the complex by titration could not be duplicated in this laboratory. Only by removing all sources of water from the reagents and from the atmosphere surrounding them could a crystalline substance be isolated. It was then necessary to dry the crystals in a chilled, evacuated vessel to prevent further absorption of water and subsequent liquefaction. Once the crystals were completely free of solvent, they exhibited no further hygroscopic tendency. Differential thermal analysis showed the complex to have a wide melting range, centering at approximately 70°.

The results of TLC studies performed on the complex are summarized in Table I. Since the manufacturer's plates were used without subsequent activation, hydration of the silica plates cannot be ruled out as a cause of the decomposition of the complex that occurred on the silica plates but not on the alumina plates.

IR spectroscopy of phenobarbital in spectral grade chloroform yielded values of 3690 and 3630 cm^{-1} for NH and of 1750 and 1730 cm^{-1} for CO (Fig. 1). Ephedrine yielded peaks at 3670 and 3620 cm^{-1} for the phenolic hydrogen and a broad peak between 3500 and 3300 cm^{-1} for the hydrogen-bonded COH group (Fig. 2). The IR spectrum of the complex differed greatly from spectra of the individual compounds. An NH peak was found at approximately 3375 cm^{-1} with broad and ill-defined peaks surrounding it, indicating that hydrogen bonding existed in this area of the molecular complex (Fig. 3). The 3600–2600-cm^{-1} region for the complex more closely resembled that of the salts of ephedrine than of the alkaloid itself. A CO peak was found at 1750 cm^{-1}, as in the spectrum of phenobarbital.

To gain further evidence of complex formation, the NMR spectra of ephedrine, phenobarbital, and the product of their reaction were examined. The formation of a complex (Structure I) might be expected to affect the magnetic environment of the hydrogens of the aromatic rings of both compounds and the protons on the carbon atom of ephedrine adjacent to the methylamino group. It is assumed that the reaction proceeds first with salt formation, followed by the formation of a hydrogen bond between phenobarbital and the hydroxyl group of ephedrine and an alignment of the phenyl groups one on top of the other.



I

The NMR spectra of phenobarbital and ephedrine are shown in Figs. 4 and 5, respectively. The spectrum of the product of the reaction between phenobarbital and ephedrine (Fig. 6) appears to exist as a superimposition of one spectrum on another. A closer examination indicates an appreciable change in the chemical shift of the protons of the aromatic ring of phenobarbital, the benzylic proton of ephedrine, and the methine proton adjacent to the methylamino group of ephedrine (Table II). Since these shifts might result from the protonation of ephedrine by phenobarbital or the formation of the anion of phenobarbital, the spectra of these species were examined. The anion was formed by treating a solution of phenobarbital in deuterochloroform with excess triethylamine (Fig. 7). The spectrum of the protonated species of ephedrine (Fig. 8) was obtained by treating a deuterochloroform solution of ephedrine with excess acetic acid. The significant chemical shifts of these species are summarized in Table II.

In the complex, the aromatic protons of ephedrine and phenobarbital overlapped, representing an upfield shift of the aromatic protons of phenobarbital to 7.28 ppm. Formation of the anion of phenobarbital caused a downfield shift of the aromatic protons to 7.41 ppm. Protonation of ephedrine caused a downfield shift of the aromatic protons. The benzylic proton of ephedrine appeared as a doublet at 4.65 ppm. When protonated with excess acetic acid, it was slightly shifted downfield to 4.83 ppm. In the complex, this proton gave a doublet at 5.14 ppm. Protonation of the hydrogen adjacent to the methylamino group of ephedrine caused a downfield shift from 2.69 to 3.15 ppm. In the complex, this multiplet was found at 2.78 ppm.

The chemical shifts reported in Table II represent several spectral examinations and did not result from concentration differences. The findings indicate that the product of the reaction of phenobarbital and ephedrine is held together by weak intermolecular forces as well as an ionic bond. The changes in chemical shifts of aliphatic protons between ephedrine, the complex, and the protonated species were all to a lower magnetic field, and the complex was shifted the most. In the case of the aromatic protons of phenobarbital, however, the aromatic protons of the anion were shifted downfield from phenobarbital while those of the complex were shifted upfield. Integration of the NMR signal as well as

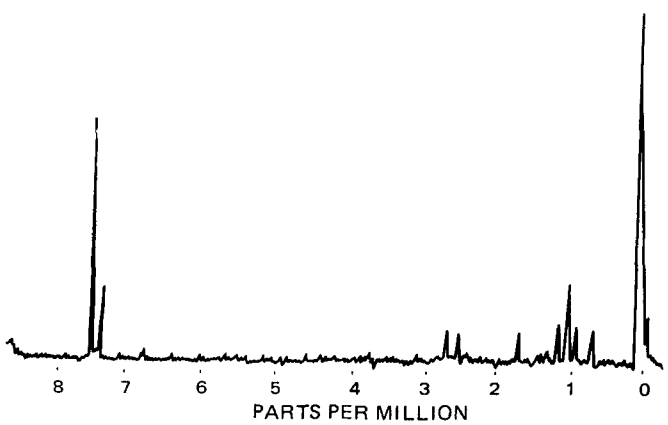


Figure 4—*NMR spectrum of phenobarbital.*

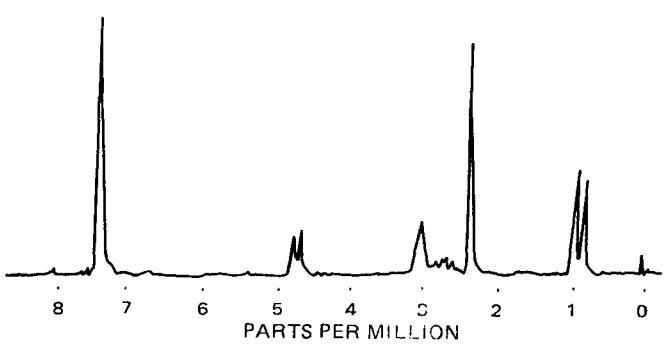

Figure 5—*NMR spectrum of ephedrine.*

[6] Hitachi Perkin-Elmer RMU-60 spectrometer.

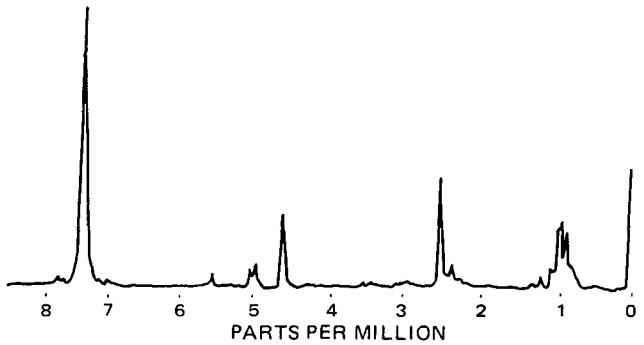

Figure 6—*NMR spectrum of complex.*

elemental analysis suggests that the complex is composed of equimolecular quantities of phenobarbital and ephedrine.

While it is not possible to elucidate completely the structure of the complex, the spectral data suggest the protonation of ephedrine by phenobarbital followed by the formation of a hydrogen bond between the alcoholic hydroxyl of ephedrine and a suitable group of phenobarbital. A structure resembling I would place the phenyl groups of one molecule above the other and provide an opportunity for hydrophobic bonding. Such an arrangement might provide a conformational change in phenobarbital, which would account for the change in chemical shift of the aromatic protons.

The observed fragmentation pattern for phenobarbital as determined by mass spectrometry yielded two different primary fragments: one from the loss of an NH group, which had an *m/e* ratio of 217, and another from the loss of a CO group with an *m/e* of 204. Both gave rise to a secondary fragment of *m/e* 189 in which both a CO and an NH were missing. This fragment was broken down further by loss of a second CO to give an ion with *m/e* 161. A second NH was then lost to produce a fragment of *m/e* 146. The mass spectrometry data show that ephedrine broke down into four primary fragments with *m/e* ratios of 132, 105, 91, and 58. Furthermore, the fragment at 105 split to produce an ion with an *m/e* ratio of 77. The fragmentation pattern observed from the mass spectrometry of the complex was the combination of the two patterns for phenobarbital and ephedrine.

CONCLUSIONS

A complex of phenobarbital and ephedrine was isolated and demonstrated to have different physical and chemical properties from the individual drugs or from simple admixtures of the drugs. It is postulated that the phenobarbital–ephedrine complex forms through a combination of bonding types rather than simply being a salt formed as the product of a neutralization reaction between an acid and a base. The complex does, however, exhibit some characteristics of a salt, and salt formation is proposed as one bonding mechanism involved.

Other types of bonds are proposed as an explanation for some of its unique properties. Face-to-face stacking of the aromatic rings may occur and allow π forces to interact between the rings. Hydrogen bonding may also occur at several sites. In addition to dimer formation, it is also possible that trimers, tetramers, and higher aggregates such as base-stacked tetramers, spirals, and indefinite linear aggregates may occur.

Synthesis and Cytotoxic Activity of Latentiated Derivatives of 3-Methyleneoxindole

M. J. KORNET ˣ, A. P. THIO, and J. H. THORSTENSON

Abstract □ Several latentiated derivatives of 3-methyleneoxindole were synthesized and examined for cytotoxic activity. The latentiated forms are represented by three general types which differ in leaving and cleaved groups. All are expected to be converted into 3-methyleneoxindole by bioactivation processes normally occurring in the cell. Two compounds were tested against L-1210 lymphoid leukemia, and six were tested against P-388 lymphocytic leukemia; all were inactive.

Keyphrases □ 3-Methyleneoxindole—latentiated derivatives synthesized and evaluated for cytotoxic activity □ Oxindoles, substituted—latentiated derivatives synthesized and evaluated for cytotoxic activity □ Cytotoxic activity—evaluated in latentiated derivatives of 3-methyleneoxindole □ Structure–activity relationships—latentiated derivatives of 3-methyleneoxindole evaluated for cytotoxic activity

Beneficial effects were reported when several cancer patients were treated with 3-indoleacetic acid for extended periods (1). Other studies found that certain esters of 3-indoleacetic acid prolonged the survival time of white mice (2) implanted with Ehrlich ascites carcinoma. The similarity of the effect on cell growth of 3-indoleacetic acid and 3-methyleneoxindole (I) (3) and the demonstrated oxidative conversion of 3-indoleacetic acid into I (4) strongly suggest that I may be the actual pharmacological agent in the action of 3-indoleacetic acid on cancer growth.

BACKGROUND

Compound I was first synthesized in 1964 (5) and is unstable. It possesses an activated ethylenic double bond and is very reactive toward the sulfhydryl group. It reacts smoothly with thiophenol (5), glutathione, and other biologically important thiol compounds (6) to give stable adducts. A sulfhydryl reagent such as I may exhibit selective cytotoxicity toward cancer cells, not only because rapidly proliferating cells reportedly expose more sulfhydryl groups (7) but also because I–sulfhydryl adducts should be more resistant toward dissociation (6) in the more acidic tumor cells (8), resulting in a slower rate of detoxification of I (9).

Finally, I bears a marked similarity to a number of anticancer substances including the antibiotic enzyme inhibitor sarkomycin (II) (10–12) and the antiascites substance primocarcin (III) (13, 14).

The pronounced instability and reactivity of this compound and the marked concentration dependency of its biological action (3, 15) make it impractical to apply I itself as a drug. This report is concerned with the synthesis and evaluation of latentiated forms of I, which can be converted into the active I by processes known to occur *in vivo*, *e.g.*, hydrolysis, oxidation, and reduction (16).

Immediate precursors of I that may be expected to undergo spontaneous conversion into the active compound can be represented by the three general types, A, B, and C (17), illustrated in Structures I*a*, I*b*, and I*c*, respectively. In these structures, X represents leaving groups (*e.g.*, halogens, hydroxyl, acyloxy, and amino), while Y stands for cleaved groups capable of being cleaved off from the electron pair that binds them to the rest of the molecule (*e.g.*, carboxylate and immomium). In most cases, these immediate precursors are too unstable to be useful as drugs and need to be latentiated.

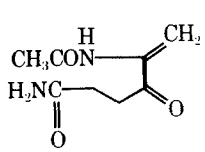
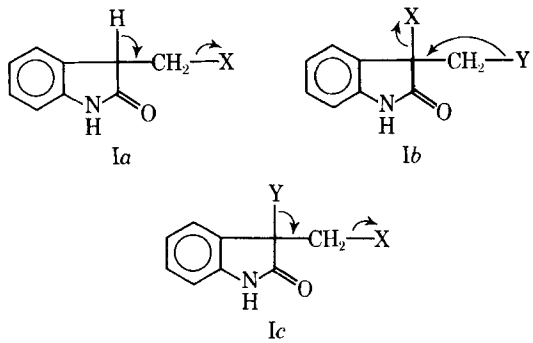
II



III



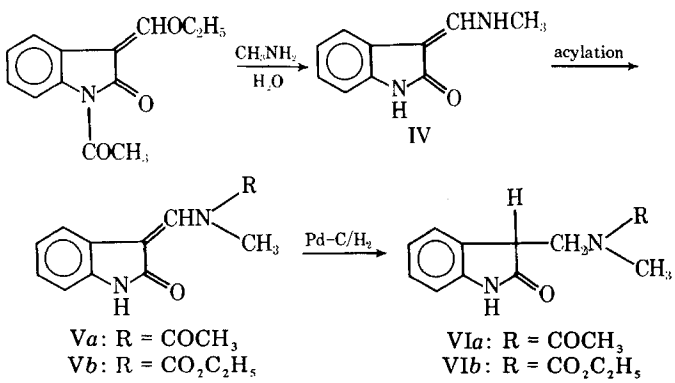
Ia Ib Ic

RESULTS AND DISCUSSION

Synthesis—Two examples of compounds of Type A were prepared (VI*a* and VI*b*, Scheme I). Compound VI*a* was obtained in four steps from oxindole (18, 19). Compound VI*b* was analogously prepared, except that acylation in the next to the last step involved ethyl chloroformate.

Three latentiated 3-methyleneoxindole derivatives of Type B were prepared. Ethyl 2,3-dioxindolyl-3-acetate (VII) (20) was synthesized from isatin and ethyl bromoacetate. Compound VII is a close relative of 3-bromo-3-oxindoleacetic acid (VIII); the latter is transformed into I almost immediately by dissolving it in water (5). For this reason, VIII (21) also was prepared for biological evaluation.

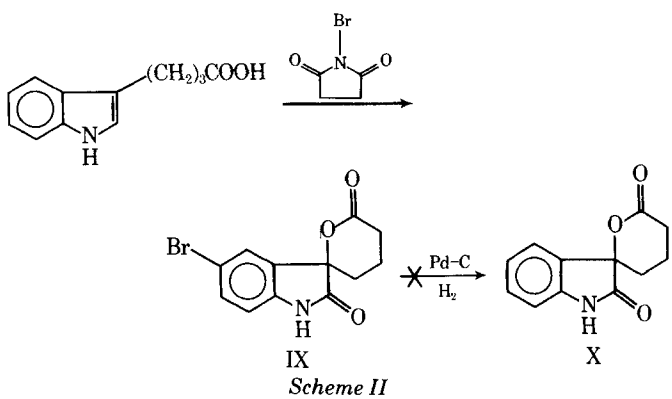
In addition, the preparation of the spirolactone X (Scheme II), which represents a third Type B compound, was attempted. 5-Bromo-2,3-dioxindole-3-butyric lactone (IX) was obtained by the *N*-bromosuccinimide oxidation of 4-indolebutyric acid according to a previous method



Va: R = $COCH_3$
Vb: R = $CO_2C_2H_5$

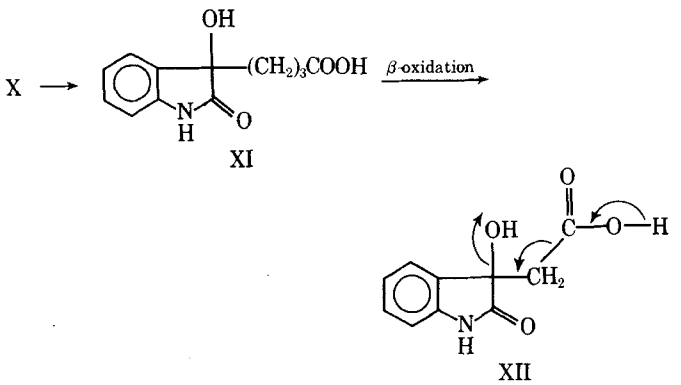
VI*a*: R = $COCH_3$
VI*b*: R = $CO_2C_2H_5$

Scheme I



IX X

Scheme II



Scheme III

(22) for the corresponding propionic lactone. However, debromination of IX failed to give X. Bioactivation of X would necessitate lactone hydrolysis followed by β-oxidation (Scheme III). 2,3-Dioxindole-3-acetic acid (XII) has been proposed as the intermediate in the enzymatic oxidation of the plant growth hormone 3-indoleacetic acid to I (23).

Compounds of Type C include XIV–XVI (Scheme IV). Treatment of oxindole with diethyl carbonate in the presence of sodium ethoxide provided 3-ethoxycarbonyloxindole (XIII). The latter readily added formaldehyde and gave the adduct XIV. Tosylation of XIV afforded the corresponding tosyl derivative XV. Compound XVI was synthesized in good yield from XIII and *N*-chloromethylphthalimide (Scheme IV).

Biological Activity—Compounds VI*a*, VI*b*, VII–IX, and XIV–XVI[1] were screened according to standard protocols[2] (24). Compounds VI*b* and VIII were evaluated against L-1210 lymphoid leukemia and were inactive at doses of 100, 200, and 400 mg/kg. The remaining six compounds were tested against P-388 lymphocytic leukemia and were inactive at 50, 100, and 200 mg/kg.

One interpretation of the data is that I is devoid of antitumor activity. Other possible explanations include: (*a*) unfavorable distribution of the latentiated forms chosen, (*b*) inappropriate biological test systems, and (*c*) bioactivation before reaching the tumor site. Further investigation is required to determine which, if any, of these explanations is correct.

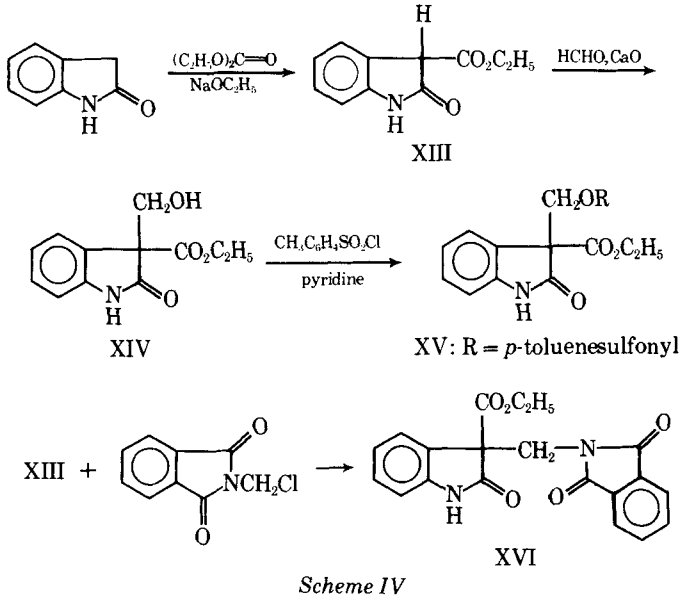
EXPERIMENTAL[3]

3-Bromo-3-oxindoleacetic Acid (VIII)—This compound was prepared according to Hinman and Bauman (21) and recrystallized from acetonitrile, mp 153.5–155.5° [lit. (21) mp 152–153°].

3-Methylaminomethyleneoxindole (IV)—A mixture of 1.0 g (4.34 mmoles) of 1-acetyl-3-ethoxymethyleneoxindole (18) in 20 ml of 30% aqueous methylamine was stirred at ambient temperature for 2.5 hr (Scheme I). The resulting precipitate was filtered and dried and amounted to 690 mg of solid, mp 230–232° [lit. (19) mp 235°]. Its IR and UV spectra agreed with the reported (19) spectra.

3-[(*N*-Methylacetamido)methyl]oxindole (VI*a*)—This compound was obtained by hydrogenation of V*a* (Scheme I) according to the recorded procedure (19), mp 134–136° [lit. (19) mp 135°]; NMR ($CDCl_3$): δ 1.92, 2.09 (2 s, 3H, CH_3C=O), 3.02, 3.05 (2 s, 3H, NCH_3), 3.58–4.17 (m, 3H, CH_2 and aliphatic CH), 6.75–7.50 (m, 4H, ArH), 9.36, and 9.67 (2 broad s, 1H, NH) ppm.

3-[(*N*-Ethoxycarbonyl-*N*-methylamino)methylene]oxindole (V*b*)—To a stirred, cooled solution of 4.0 g (0.023 mole) of IV in 32 ml of dry pyridine was added dropwise 12 ml of ethyl chloroformate (Scheme I). The solution was then warmed on the steam bath for 15 min and poured onto ice. The pale-yellow solid was filtered and washed well with cold water. The dried product, 5.24 g (93%), was recrystallized from 95% ethanol, mp 201–203°; IR ($CHCl_3$): 1710 (C=O) cm^{-1}; NMR (dimethyl sulfoxide-d_6): δ 1.28 (t, 3H, CCH_3), 3.43 (s, 3H, NCH_3), 4.30 (q, 2H, OCH_2), 6.73–7.68 (m, 4H, ArH), 7.90 (s, 1H, =CHN), and 10.47 (broad s, 1H, NH) ppm.



Scheme IV

Anal.—Calc. for $C_{13}H_{14}N_2O_3$: C, 63.40; H, 5.73; N, 11.38. Found: C, 63.14; H, 5.84; N, 11.20.

3 - [(*N* - Ethoxycarbonyl - *N* - methylamino)methyl]oxindole (VI*b*)—A slurry of 2.5 g (0.0102 mole) of V*b* in 200 ml of 95% ethanol containing 250 mg of 10% palladium-on-carbon catalyst was hydrogenated in a Parr apparatus (Scheme I). Hydrogen uptake stopped after 30 min, and the solution was filtered and evaporated under reduced pressure to give a colorless oil in quantitative yield. The oil was dried over phosphorus pentoxide in a drying pistol at 0.1 mm Hg for 2 hr. TLC on silica gel (ethyl acetate) exhibited a single spot, R_f 0.52; IR ($CHCl_3$): 1700 (C=O) cm^{-1}; NMR ($CDCl_3$): δ 1.18, 1.23 (overlapping t, 3H, CCH_3), 3.0 (s, 3H, NCH_3), 3.50–4.35 (m, 5H, OCH_2, CCH_2, and CH), 6.78–7.44 (m, 4H, ArH), and 9.70 (broad s, 1H, NH) ppm.

Anal.—Calc. for $C_{13}H_{16}N_2O_3$: C, 62.89; H, 6.50; N, 11.28. Found: C, 62.93; H, 6.54; N, 11.34.

Ethyl 2,3-Dioxindolyl-3-acetate (VII)—Compound VII was obtained *via* a Reformatsky reaction between isatin and ethyl bromoacetate by the method of Hallmann (20). The product was recrystallized from benzene and yielded colorless crystals, mp 111–111.5° [lit. (20) mp 102°]; mass spectrum: *m/e* 235 (M^+); NMR ($CDCl_3$): δ 1.13 (t, 3H, CCH_3), 2.98 (s, 2H, CH_2C=O), 4.08 (q, 2H, OCH_2), 4.82 (s, 1H, OH), 6.76–7.56 (m, 4H, ArH), and 9.02 (broad s, 1H, NH) ppm.

5-Bromo-2,3-dioxindole-3-butyric Lactone (IX)—This compound was prepared according to a previous procedure (22) (Scheme II) for the preparation of the propionic lactone analog. The pale-yellow solid obtained from filtration was air dried overnight and amounted to 2.15 g, mp 198–203°. From the ether extraction, an additional 0.33 g was obtained, mp 204–208°, giving a total of 2.48 g (79%). Recrystallization from aqueous methanol afforded white crystals, mp 208–211°; IR (KBr): 1720 and 1750 (C=O) cm^{-1}; NMR (dimethyl sulfoxide-d_6): δ 1.42–2.94 (m, 6H, $CH_2CH_2CH_2$) and 6.75–7.92 (m, 3H, ArH) ppm.

Anal.—Calc. for $C_{12}H_{10}BrNO_3$: C, 48.67; H, 3.40; N, 4.73. Found: C, 48.48; H, 3.60; N, 4.66.

Attempted Debromination of IX—A mixture of 1.0 g (3.37 mmoles) of IX, 350 mg of 5% palladium-on-charcoal catalyst, 4 ml of dry triethylamine, and 75 ml of absolute ethanol was hydrogenated in a Parr apparatus for 2 hr (Scheme II). Workup gave 100 mg of crystals, mp 160.5–163.5°. A second crop of 65 mg, mp 164.5–168°, was also obtained. Spectroscopic evidence indicated that this compound was a carboxylic acid and it was not investigated further.

3-Ethoxycarbonyloxindole (XIII)—To a hot solution containing 10.5 g (0.079 mole) of oxindole, 40 ml of diethyl carbonate (~0.32 mole), and 50 ml of dry toluene was added dropwise an ethanolic solution of sodium ethoxide [from 1.97 g (0.085 g-atom) of sodium in 30 ml of absolute ethanol] (Scheme IV). The flask contained a mechanical stirrer and was equipped for distillation. Moisture was excluded by means of a drying tube. The rate of addition was controlled to allow a smooth rate of distillation of the ethanol–toluene azeotrope (bp 76.7°).

Near the end of the addition, a heavy precipitate appeared and an additional 75 ml of toluene was added. Heating was continued until the boiling point of the distillate fell below 76°. The resulting solid was fil-

[1] NSC 246030–246037, respectively.

[2] National Cancer Institute.

[3] Melting points were determined with a Fisher-Johns melting-point apparatus and are uncorrected. The structures of the products were confirmed by their IR and NMR spectra. IR spectra were obtained on a Beckman IR-8 spectrophotometer. NMR spectra were determined on a Varian A-60A spectrometer, using tetramethylsilane as the internal reference. Microanalysis were performed by Dr. Kurt Eder, Geneva, Switzerland.

tered, washed with toluene, slurried in water, and acidified in the cold to pH 3–4. The mixture was extracted three times with 100-ml portions of ether, and the combined extract was dried over magnesium sulfate. Concentration of the solution gave 11.5 g (71%) of an oil that slowly solidified.

Trituration with ligroin and recrystallization from cyclohexane–benzene gave crystals, mp 91–93°. A second recrystallization from the same solvent system afforded the analytically pure product, mp 93–94°; IR ($CHCl_3$): 1725 (C=O) cm^{-1}; NMR ($CDCl_3$ containing D_2O and Na_2CO_3): δ 1.27 (t, 3H, CH_3), 4.25 (q, 2H, OCH_2), and 6.75–7.60 (m, 4H, ArH) ppm. Both the NH and 3-H exchange under these conditions.

Anal.—Calc. for $C_{11}H_{11}NO_3$: C, 64.38; H, 5.40; N, 6.83. Found: C, 64.50; H, 5.44; N, 6.87.

3-Ethoxycarbonyl-3-hydroxymethyloxindole (XIV)—To a cooled solution containing 5.7 g (0.0278 mole) of 3-ethoxycarbonyloxindole and 100 mg of calcium oxide in 150 ml of 70% aqueous ethanol was added dropwise a mixture of 2.26 ml of 40% aqueous formaldehyde in 5 ml of water (Scheme IV). The resulting solution was kept at room temperature overnight. The mixture was acidified with 6.5 ml of 5% aqueous hydrochloric acid, followed by addition of 50 ml of 95% ethanol. The solution was filtered and evaporated under reduced pressure at 35° to give a solid. Recrystallization from acetonitrile afforded 2.5 g (38%) of crystals, mp 149–152° dec. (with evolution of formaldehyde); IR (KBr): 1720 (C=O) cm^{-1}; mass spectrum: *m/e* 235 (M^+); NMR (dimethyl sulfoxide-d_6): δ 1.08 (t, 3H, CH_3), 3.74 (m, 4H, 2 CH_2), 5.05 (t, 1H, OH), and 6.85–7.53 (m, 4H, ArH) ppm.

Anal.—Calc. for $C_{12}H_{13}NO_4$: C, 61.27; H, 5.57; N, 5.95. Found: C, 61.15; H, 5.65; N, 6.00.

3 - Ethoxycarbonyl - 3 - *p* - toluenesulfonyloxymethyloxindole (XV)—A mixture of 2.11 g (0.00897 mole) of XIV and 3.43 g (0.018 mole) of *p*-toluenesulfonyl chloride in 75 ml of pyridine was stored at 0° for 46 hr. The rose-colored solution was poured onto 100 g of ice and stirred; a pink solid was collected by filtration. After drying *in vacuo*, 1.65 g (47%) of the tosylate was obtained, mp 155–157°. Recrystallization from 95% ethanol gave colorless crystals, mp 163–164.5°; IR ($CHCl_3$): 1730 (C=O) cm^{-1}; NMR ($CDCl_3$): δ 1.14 (t, 3H, $OCCH_3$), 2.42 (s, 3H, $ArCH_3$), 4.18 (q, 2H, O=$COCH_2$), 4.58 (d, 1H, J = 10 Hz, SO_2OCH_2), 4.83 (d, 1H, J = 10 Hz, SO_2OCH_2), 6.78–7.85 (m, 8H, ArH), and 8.93 (broad s, 1H, NH) ppm.

Anal.—Calc. for $C_{19}H_{19}NO_6S$: C, 58.61; H, 4.92; N, 3.60. Found: C, 58.74; H, 4.99; N, 3.61.

3-Ethoxycarbonyl-3-phthalimidomethyloxindole (XVI)—To a slurry of 368 mg (7.68 mmoles) of a 50% sodium hydride dispersion in mineral oil in 40 ml of dimethylformamide was added 1.28 g (6.25 mmoles) of XII portionwise at room temperature (Scheme IV). After stirring for 15 min, 1.22 g (6.26 mmoles) of *N*-chloromethylphthalimide (25) was added. The dark-red color of the mixture was slowly discharged upon stirring at room temperature overnight. Then the solution was poured onto 100 g of ice, and the precipitate was filtered. After drying, 1.95 g (85%) of solid was obtained, which was recrystallized from benzene–carbon tetrachloride, mp 202–203°; IR ($CHCl_3$): 1720 and 1770 (C=O) cm^{-1}; mass spectrum: *m/e* 364 (M^+); NMR ($CDCl_3$): δ 1.19 (t, 3H, CH_3), 4.25 (q, 2H, OCH_2), 4.50 (d, 1H, J = 14.5 Hz, NCH_2), 4.83 (d, 1H, J = 14.5 Hz, NCH_2), 6.75–7.93 (m, 8H, ArH), and 8.72 (broad s, 1H, NH) ppm.

Anal.—Calc. for $C_{20}H_{16}N_2O_5$: C, 65.93; H, 4.43; N, 7.69. Found: C, 65.95; H, 4.39; N, 7.82.

Relationship between Protein Binding of Bilirubin, Salicylic Acid, and Sulfisoxazole in Serum of Unmedicated and Phenobarbital-Treated Rats

AVRAHAM YACOBI, SVEIN ØIE, and GERHARD LEVY ˣ

Abstract □ The relationship between the protein binding of bilirubin, salicylic acid, and sulfisoxazole in the serum of phenobarbital-treated and untreated rats was studied. The free fraction of bilirubin in serum varied about threefold between animals but was not related to the albumin concentration, the free fraction of salicylate, or the free fraction of sulfisoxazole. However, there was a strong positive correlation between the free fraction values of salicylate and sulfisoxazole. The free fraction value for each of these drugs showed a significant negative correlation with the serum albumin concentration. Treatment of the animals with phenobarbital had no apparent effect on the serum protein binding of bilirubin, salicylic acid, and sulfisoxazole.

Keyphrases □ Bilirubin—protein binding, relationship to binding of salicylic acid and sulfisoxazole, effect of phenobarbital, rat serum □ Salicylic acid—protein binding, relationship to binding of bilirubin and sulfisoxazole, effect of phenobarbital, rat serum □ Sulfisoxazole—protein binding, relationship to binding of salicylic acid and bilirubin, effect of phenobarbital, rat serum □ Protein binding—bilirubin, salicylic acid, and sulfisoxazole, effect of phenobarbital, rat serum □ Binding, protein—bilirubin, salicylic acid, and sulfisoxazole, effect of phenobarbital, rat serum □ Phenobarbital—effect on protein binding of bilirubin, salicylic acid and sulfisoxazole, rat serum

Drugs that displace bilirubin from plasma protein binding sites can cause brain damage and death in premature infants with neonatal jaundice (1–3). Classical bilirubin displacing agents, in terms of clinical experience and experimental interest, are sulfisoxazole and salicylic acid. Administration of these drugs to humans and animals during hyperbilirubinemia causes a redistribution of bilirubin from plasma to extravascular tissues, including the brain (4–9).

The rat has been used in this laboratory as a model for investigating the pharmacokinetics of the interaction of salicylic acid and sulfisoxazole with bilirubin. As an extension of this research, the relationship between the protein binding of bilirubin, salicylic acid, and sulfisoxazole in the serum of individual rats has been determined. A previous study revealed that there are pronounced interindividual differences in the serum protein binding of bilirubin in rats (10).

Neonatal unconjugated hyperbilirubinemia is treated sometimes with the enzyme inducer phenobarbital (11, 12). *In vitro* addition of phenobarbital to hyperbilirubinemic serum does not change the total binding capacity of albumin (13), but it remains to be determined if enzyme induction *per se* affects the serum protein binding of bilirubin, perhaps by changing the formation and/or elimination kinetics of endogenous inhibitors of bilirubin binding. Accordingly, protein binding studies were carried out with serum from unmedicated and phenobarbital-pretreated rats.

EXPERIMENTAL

Twenty adult male Sprague–Dawley rats, ~350 g, were divided into two groups. One group received daily injections of phenobarbital, 75 mg/kg ip, for 4 days; the other group received daily injections of normal saline solution. On the 5th day, all blood was removed from the aorta under light ether anesthesia and the liver was excised and weighed. Serum was separated and assayed for total protein (14), using crystalline rat albumin as the standard. The fraction of albumin was determined by electrophoresis[1].

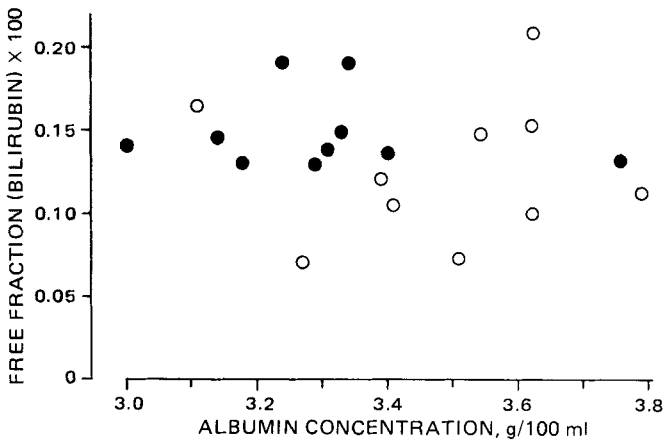

Figure 1—*Relationship between free fraction of bilirubin and albumin concentration in serum of phenobarbital-treated (●) and control (○) rats. Correlation coefficient = 0.36 (not significant) for combined data.*

The protein binding of salicylic acid and sulfisoxazole was determined by equilibrium dialysis at 37° as previously described (15). The buffer solution contained an initial concentration of 30 mg of salicylic acid or 10 mg of sulfisoxazole/100 ml. The protein binding of bilirubin was determined by measuring the rate of the peroxidase-catalyzed degradation of the pigment by peroxide (16). Since only unbound bilirubin reacts with peroxide, the reaction rate is proportional to the free bilirubin concentration.

Bilirubin solution[2], 10 μl, was added to 0.5 ml of serum from a rat to

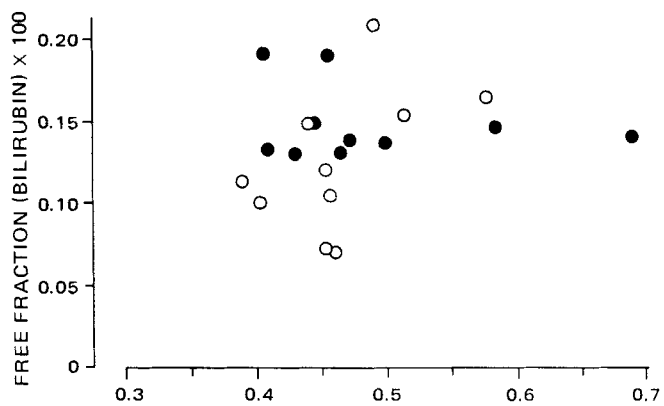

Figure 2—*Relationship between free fraction values of bilirubin and salicylic acid in serum of phenobarbital-treated (●) and control (○) rats. Correlation coefficient is 0.185 (not significant) for combined data and 0.518 (not significant) for control data.*

Table I—Effect of Treatment with Phenobarbital on Total Protein and Albumin Concentrations[a] in Serum of Rats

	Before Treatment		After Treatment	
	Control	Phenobarbital	Control	Phenobarbital
Total protein, g/100 ml	8.10 ± 0.24	8.01 ± 0.35	7.94 ± 0.26	8.13 ± 0.20
Albumin, g/100 ml	3.96 ± 0.22	3.77 ± 0.21	3.49 ± 0.20	3.30 ± 0.20
	N.S.		N.S.	
	$p < 0.001$			
		$p < 0.001$		

[a] Mean ± *SD*, $n = 10$.

obtain a serum bilirubin concentration of 8.7–9.5 mg/100 ml. A 0.1-ml aliquot of 0.1 *M* phosphate buffer, pH 7.4, containing 0.01 *M* edetate disodium was evaporated to dryness in a 10-ml centrifuge tube. Plasma, 0.1 ml, was added, and the dried buffer was dissolved in it by vortexing. Peroxidase solution, 10 μl (8 purpurogallin units of horseradish peroxidase[3]/ml of 0.1 *M* phosphate buffer, pH 7.4), was then added.

The reaction was started by adding 5 μl of peroxide solution (0.2% ethyl hydrogen peroxide in 0.1 *M* phosphate buffer, pH 7.4) and stopped after 1–2 min by addition of 1 ml of 6% ascorbic acid in 0.2 *M* phosphate buffer, pH 8.2. The entire reaction was carried out in a water bath at 37°. The concentration of total unconjugated bilirubin before and after the reaction was determined spectrophotometrically after chloroform extraction (17), using a commercial bilirubin control[4] as the standard.

All protein binding data are expressed as free fraction values, *i.e.*, the concentration of free (unbound) divided by the concentration of total (free and protein bound) drug or bilirubin in serum.

RESULTS

Treatment with phenobarbital caused a significant increase in liver weight (3.70 ± 0.35 *versus* 3.09 ± 0.16 g/100 g of body weight, $p < 0.001$) but had no apparent effect on the concentrations of total protein and albumin in serum (Table I). There was a small but statistically significant decrease in the serum albumin concentration in both the control and phenobarbital-treated groups during the treatment period. Treatment with phenobarbital had no statistically significant effect on the serum protein binding of bilirubin, sulfisoxazole, and salicylic acid (Table II).

There were appreciable intersubject differences in the binding of bilirubin and the concentration of albumin in serum but no apparent correlation between the free fraction values of bilirubin and the albumin concentration in serum (Fig. 1). There was also no apparent correlation between the free fraction values of bilirubin and those of salicylic acid (Fig. 2) or sulfisoxazole (Fig. 3). On the other hand, a strong and statistically highly significant correlation existed between the free fraction values of salicylic acid and sulfisoxazole in individual animals (Fig. 4). There was also a statistically significant negative correlation between

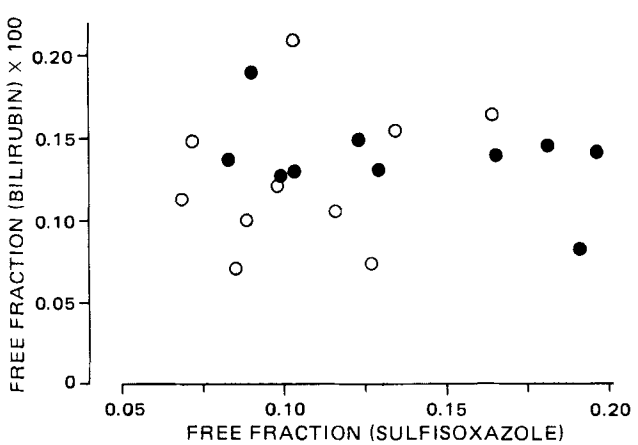

Figure 3—*Relationship between free fraction values of bilirubin and sulfisoxazole in serum of phenobarbital-treated (●) and control (○) rats. Correlation coefficient is 0.074 (not significant) for combined data.*

the serum albumin concentration and the free fraction of salicylic acid ($r = -0.635$, $p < 0.005$) and sulfisoxazole ($r = -0.600$, $p < 0.005$).

DISCUSSION

Binding of bilirubin to albumin in serum, which is technically difficult to determine because it is so extensive (>99%), cannot be predicted by the extent of serum protein binding of two other weak acids, salicylic acid and sulfisoxazole, at least in the rat. There are significant intersubject differences in the protein binding of bilirubin, salicylic acid, sulfisoxazole, and other drugs in the rat and also in humans (10, 15, 18, 19, and unpublished data). This fact must be considered in the design and interpretation of studies on species differences in serum protein binding of drugs.

No apparent relationship between the concentration of albumin and the free fraction of bilirubin in serum of rats was found. A similar lack of correlation was observed previously with two other extensively albumin-bound compounds, warfarin (18) and dicumarol (20). However, the

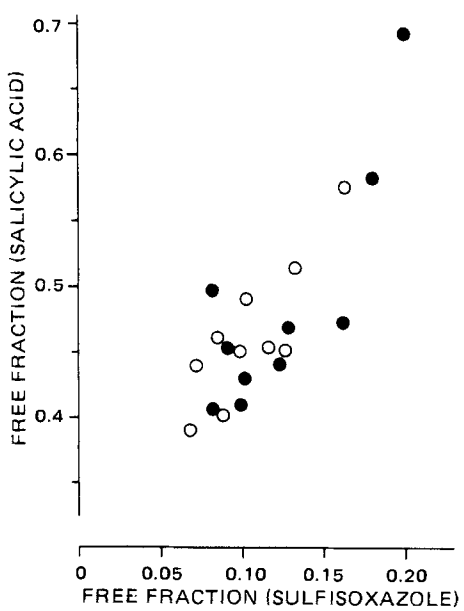

Figure 4—*Relationship between free fraction values of salicylic acid and sulfisoxazole in serum of phenobarbital-treated (●) and control (○) rats. Correlation coefficient is 0.818, p < 0.001, for combined data.*

free fraction values of salicylic acid and sulfisoxazole, which are much less extensively protein bound, exhibited a statistically significant negative correlation with the concentration of albumin in rat serum.

Phenobarbital treatment, which is an effective means of lowering the serum bilirubin concentration in certain types of unconjugated hyperbilirubinemia (11, 12), has no apparent effect on the serum protein binding of bilirubin in rats. This information will facilitate the interpretation of results of phenobarbital–bilirubin interaction studies in normal rats. It remains to be determined if phenobarbital treatment affects bilirubin binding in the Gunn rat, the most important animal model of physiological unconjugated hyperbilirubinemia.

Rapid GLC Determination of Therapeutic Plasma Glycerin Levels

THOMAS J. GOEHL [x], WILLIAM H. PITLICK, GERALD K. SHIU, and PICHAI PIRAKITIKULR

Abstract □ A new rapid and inexpensive method for the determination of therapeutic plasma glycerin concentrations is described. In this method, acetic anhydride and pyridine are added to 15 μl of plasma. After brief incubation and centrifugation, an aliquot of the supernate is injected directly onto the 3% OV-1 column. A linear calibration curve was found in the 0.05–3-mg/ml range, with the precision of the assay estimated to be ±5.5% (*RSD*). The method was used in determining preliminary pharmacokinetic data in the rabbit.

Keyphrases □ Glycerin—GLC analysis, plasma □ GLC—analysis, glycerin in plasma □ Hyperosmolar dehydrating agents—glycerin, GLC analysis in plasma

Cerebral edema, or swelling of brain tissue, increases intracranial pressure, which, if not medically corrected, leads to herniation of brain tissue with irreversible brain damage and subsequent death. Deterioration of brain function and progressive deepening of coma in acute neurologic emergencies are often results of increased intracranial pressure due to cerebral edema. Medical management is a triad composed of hypothermia, hypocapnea, and hyperosmolar dehydration of cerebral tissues (1). Glycerin has been particularly useful for the treatment of cerebral edema by hyperosmolar dehydration because of its physical properties, but a lack of clinical knowledge has hindered its maximum use (2, 3).

At present, empirical relationships govern the use of glycerin in life-threatening situations. The efficacy of treatment with glycerin probably could be improved with quantitative assessment of glycerin therapy, including monitoring of plasma levels. It is now possible, and preferable, to individualize the dosage regimen for each patient based on a desired therapeutic plasma concentration range known to produce a desired response. In life-threatening situations, such as increased intracranial pressure, it is imperative to have rapid assessment of plasma glycerin levels for effective therapy.

Currently, the most commonly used methods for the determination of plasma glycerin levels are enzymatic (4–11). The first such method (4) was developed for determining endogenous glycerin levels, normally in the 5–17-μg/ml range. For assaying therapeutic plasma glycerin levels (milligram per milliliter range) with enzymatic methods, it is necessary to find the proper dilution factor for each sample, which is both time consuming and expensive. Thus, another method was needed that would be

free fraction values of salicylic acid and sulfisoxazole, which are much less extensively protein bound, exhibited a statistically significant negative correlation with the concentration of albumin in rat serum.

Phenobarbital treatment, which is an effective means of lowering the serum bilirubin concentration in certain types of unconjugated hyperbilirubinemia (11, 12), has no apparent effect on the serum protein binding of bilirubin in rats. This information will facilitate the interpretation of results of phenobarbital–bilirubin interaction studies in normal rats. It remains to be determined if phenobarbital treatment affects bilirubin binding in the Gunn rat, the most important animal model of physiological unconjugated hyperbilirubinemia.

Rapid GLC Determination of Therapeutic Plasma Glycerin Levels

THOMAS J. GOEHL [x], WILLIAM H. PITLICK, GERALD K. SHIU, and PICHAI PIRAKITIKULR

Abstract □ A new rapid and inexpensive method for the determination of therapeutic plasma glycerin concentrations is described. In this method, acetic anhydride and pyridine are added to 15 μl of plasma. After brief incubation and centrifugation, an aliquot of the supernate is injected directly onto the 3% OV-1 column. A linear calibration curve was found in the 0.05–3-mg/ml range, with the precision of the assay estimated to be ±5.5% (*RSD*). The method was used in determining preliminary pharmacokinetic data in the rabbit.

Keyphrases □ Glycerin—GLC analysis, plasma □ GLC—analysis, glycerin in plasma □ Hyperosmolar dehydrating agents—glycerin, GLC analysis in plasma

Cerebral edema, or swelling of brain tissue, increases intracranial pressure, which, if not medically corrected, leads to herniation of brain tissue with irreversible brain damage and subsequent death. Deterioration of brain function and progressive deepening of coma in acute neurologic emergencies are often results of increased intracranial pressure due to cerebral edema. Medical management is a triad composed of hypothermia, hypocapnea, and hyperosmolar dehydration of cerebral tissues (1). Glycerin has been particularly useful for the treatment of cerebral edema by hyperosmolar dehydration because of its physical properties, but a lack of clinical knowledge has hindered its maximum use (2, 3).

At present, empirical relationships govern the use of glycerin in life-threatening situations. The efficacy of treatment with glycerin probably could be improved with quantitative assessment of glycerin therapy, including monitoring of plasma levels. It is now possible, and preferable, to individualize the dosage regimen for each patient based on a desired therapeutic plasma concentration range known to produce a desired response. In life-threatening situations, such as increased intracranial pressure, it is imperative to have rapid assessment of plasma glycerin levels for effective therapy.

Currently, the most commonly used methods for the determination of plasma glycerin levels are enzymatic (4–11). The first such method (4) was developed for determining endogenous glycerin levels, normally in the 5–17-μg/ml range. For assaying therapeutic plasma glycerin levels (milligram per milliliter range) with enzymatic methods, it is necessary to find the proper dilution factor for each sample, which is both time consuming and expensive. Thus, another method was needed that would be

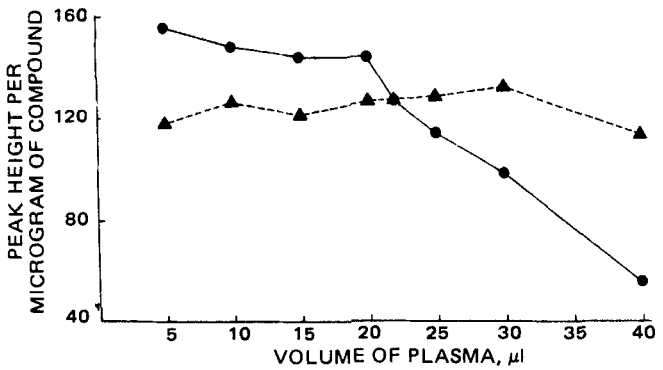

Figure 1—*Effect of plasma volume on acetylation of glycerin* (●) *and 1,6-hexanediol* (▲).

applicable over a wide range of plasma glycerin concentrations. In addition, it was highly desirable to reduce the cost of each assay by eliminating the use of relatively expensive enzymes. Consequently, a rapid, specific, and inexpensive method for the determination of glycerin in microliter volumes of plasma was developed.

EXPERIMENTAL

Apparatus—A gas chromatograph, equipped with a flame-ionization detector[1] and a 2-mm i.d. × 180-cm coiled glass column packed with 3% OV-1 on 80–100-mesh Supelcoport[2], was used. Prior to packing, the column was thoroughly rinsed with methanol and acetone, dried, and conditioned for 1 hr with 5% dimethyldichlorosilane[3] in toluene. Then the column was rinsed with toluene and acetone and dried. A silane-treated glass wool[3] plug was placed in the exit end of the column, but none was used in the injection port side. Prior to use, the column was conditioned by injecting 30 μl of a trimethylsilylating mixture[4].

Chromatographic Conditions—The column oven, injection port, and detector were maintained at 120, 250, and 250°, respectively. Nitrogen, the carrier gas, was maintained at 60 ml/min, with hydrogen and air at 20 and 240 ml/min, respectively.

Reagents—Glycerin[5], the internal standard 1,6-hexanediol[6], pyridine[7], and acetic anhydride[5] were of reagent grade and were used without further purification. Stock solutions containing 1 and 2 mg of 1,6-hexanediol/ml of pyridine were prepared. Small aliquots of stock aqueous solutions of glycerin were added to control citrated plasma to prepare plasma standards.

GLC Assay Procedure—To 15 μl of plasma in a 12-ml Pyrex glass-stoppered centrifuge tube were added 100 μl of acetic anhydride and 10 μl of the stock pyridine solution of 1,6-hexanediol. The glass stoppers were then inserted, and the test tubes were mixed well and heated for 15 min at 80°. After centrifugation at about 3000 rpm for 5 min, 4 μl of the supernate was injected onto the GLC column.

Enzymatic Assay Procedure—This newly developed GLC method was compared to an established enzymatic method. A commercial glycerin assay kit[8], which had been developed based on the Bucolo and David method (10), was used.

Calculations—Peak height ratios were calculated by dividing the peak height corresponding to the acetylated glycerin by the peak height corresponding to the acetylated 1,6-hexanediol. Calibration curves were constructed daily from results of spiked control plasma samples by plotting peak height ratios *versus* concentrations of glycerin.

RESULTS AND DISCUSSION

Quantification of glycerin in lipids by GLC was reported previously (12–14); glycerin was methylated (12), silylated (13), or acetylated (14) prior to chromatography. However, these methods do not lend themselves to an easy direct adaptation to the assay of glycerin in plasma.

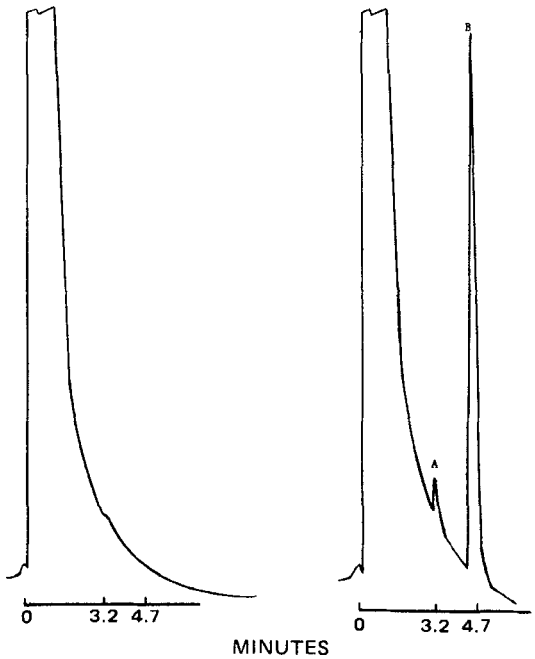

Figure 2—*Chromatograms showing peaks from glycerin analysis. Key: left, control plasma; and right, plasma containing 0.09 mg of glycerin/ml and 2.0 mg of 1,6-hexanediol/ml.*

Since removal of the glycerin from its aqueous environment in plasma proved to be difficult without a lengthy procedure, an attempt was made to derivatize the glycerin in plasma directly. A major factor that would seem to make this approach feasible was the high plasma glycerin concentrations found when glycerin was used to produce hyperosmolar dehydration of cerebral tissue. With such high concentrations, only small volumes of plasma are needed.

Acetylation of glycerin and 1,6-hexanediol, the internal standard, was accomplished with acetic anhydride in the presence of pyridine. Within 15 min at 80°, the reaction was complete. The effect of plasma volume on the acetylation was then studied. Various aliquots (5–40 μl) of plasma spiked with 1.15 mg of glycerin/ml were transferred to glass-stoppered test tubes. To each test tube were added 100 μl of acetic anhydride and 10 μl of a pyridine solution of the internal standard. Then these test tubes were incubated at 80° for 15 min.

After GLC analysis, the peak heights were measured and divided by the absolute amount of compound injected onto the column. A plot of peak height (millimeters) per microgram of compound *versus* plasma volume (microliters) was constructed (Fig. 1). The reaction with glycerin was minimally affected with up to 20 μl of plasma; with 1,6-hexanediol, up to 30 μl of plasma was tolerated. As a precaution, it is recommended that 15 μl of plasma be used. Acetic anhydride serves as an acetylating agent for the glycerin and 1,6-hexanediol and also as a precipitating agent of the plasma protein.

The recovery of glycerin and 1,6-hexanediol in this direct derivatization method was virtually 100%. In a stability study, glycerin was added to control plasma; aliquots were frozen and assayed periodically. Glycerin was stable in frozen plasma for at least 1 month.

Chromatograms of control human plasma and human plasma containing 0.09 mg of glycerin/ml are shown in Fig. 2. The chromatogram of control plasma shows no interfering peaks. In the other chromatogram, two peaks with retention times of 3.2 and 4.7 min correspond to the derivatives of glycerin and 1,6-hexanediol, respectively.

Since glycerin is often given in a glucose solution, the effect of high concentration of glucose in plasma was studied. Blood glucose levels as high as 500 mg % did not interfere with the glycerin determination.

The standard curve for the assay of glycerin in human plasma was linear and showed good reproducibility.

Table I shows a comparison of the precision and accuracy of the GLC and enzymatic assays. The enzymatic assay includes a series of reactions. First, glycerin in the sample solution is phosphorylated by adenosine triphosphate in a reaction catalyzed by glycerin kinase forming adenosine diphosphate and glycerin phosphate. Second, adenosine diphosphate reacts with phosphoenol pyruvate in a reaction mediated by pyruvate

[a] Not detectable. [b] Values of 0.0009 and 0.0005 mg/ml were obtained in the low and high range validation runs, respectively.

kinase, forming pyruvate and regenerating adenosine triphosphate. Third, pyruvate is reduced to lactate by lactate dehydrogenase. The concomitant oxidation of NADH to NAD^+ results in an absorbance change at 340 nm proportional to the glycerin content of the sample.

Two validation runs were made; one covered the 0.05–0.20-mg/ml range, and the other covered the 0.2–3.5-mg/ml range. The amount of internal standard used for the higher concentration range was twice that of the lower range. With the GLC assay, a mean percent *RSD* of 5.5 was found with a mean percent error of 2.9. These results compared favorably with the mean percent *RSD* of 0.6 and mean percent error of 7.1 for the enzyme assay.

A problem of sample carryover was encountered in the chromatography of these samples. This carryover could not be eliminated by on-column silylation or by increasing the injection port temperature, but it could be eliminated by removing the glass wool from the injection end of the column. In practice, a very small plug of silane-treated glass wool was used, and 5 μl of solvent was injected between samples to flush the system.

The method was used to monitor glycerin in clinical situations and to study glycerin pharmacokinetics in the rabbit. Glycerin, 10% (w/v), in normal saline solution was infused intravenously into the marginal ear vein of three rabbits (1 g/kg). Blood samples were withdrawn from the opposite marginal ear vein into small heparinized capillary tubes. After centrifugation, 15 μl of plasma was transferred into a glass-stoppered test tube and derivatized by the direct acetylation method.

A standard curve was prepared by assaying control plasma to which had been added known amounts of glycerin. A linear plot of peak height ratio *versus* concentration was prepared and used to determine the concentration of glycerin in the rabbit plasma. A semilogarithmic plot of the plasma concentration–time profile for three rabbits is shown in Fig. 3. From the mean concentration values, the half-life of glycerin in the rabbit was about 41 min with a volume of distribution of about 0.6 liter/kg, corresponding to a clearance ($K_E V_d$) of about 9 ml/kg/min.

Pharmacokinetics of the Anti-Inflammatory Tiaprofenic Acid in Humans, Mice, Rats, Rabbits, and Dogs

J. POTTIER ˣ, D. BERLIN, and J. P. RAYNAUD

Abstract □ The pharmacokinetics of tiaprofenic acid were studied in rats, dogs, mice, and rabbits using the ^{14}C-labeled compound and in humans using the radioinert compound. Its absorption was partially gastric but mainly intestinal and was total in all species. Its apparent volume of distribution was small; it was bound markedly to albumin, and its plasma clearance was high in all species. Absence of retention was confirmed in rats by the very low tissue radioactivity levels 24 hr after oral dosing. In humans, identical maximum plasma concentrations and elimination rates were recorded after the first and 40th dose during a 2-week treatment with 200 mg three times daily. During this period, constant residual levels were recorded before the first dose of the day. These results indicate that, for a dose in the therapeutic range, a steady state was reached as early as the end of the 1st day of treatment and that tiaprofenic acid did not inhibit or induce its own biotransformation. Urinary excretion accounted for one-half of the dose in rats and from 0.6 to 0.9 in humans, dogs, mice, and rabbits. Two metabolites were formed, one resulting from the reduction of the ketone group to an alcohol and the other from oxidation generating a phenol in the benzene ring in the *para*-position to the ketone group. These two metabolites were common to all species, but the latter was present in minute amounts only in dogs. Tiaprofenic acid was conjugated as an amide in dogs and as an acylglucuronide in the other species. In rats, phenobarbital induced the oxidative, but not the reductive, pathway.

Keyphrases □ Tiaprofenic acid—pharmacokinetics in humans, rats, dogs, mice, and rabbits □ Pharmacokinetics—tiaprofenic acid in humans, rats, dogs, mice, and rabbits □ Anti-inflammatory agents—tiaprofenic acid, pharmacokinetics in humans, rats, dogs, mice, and rabbits

Tiaprofenic acid[1], 5-benzoyl-α-methyl-2-thiopheneacetic acid (I) (Table I), is a highly potent anti-inflammatory and nonnarcotic analgesic agent as demonstrated both in animal (1) and in human (2–4) studies. In the present study, its animal pharmacokinetics were studied in rats and dogs—the species used to evaluate its pharmacological activity and tolerance—and, in less detail, in rabbits and mice—the species used to establish the absence of teratogenicity[2]. The absorption, distribution, excretion, and biotransformations of tiaprofenic acid were compared in these species and in humans after oral and parenteral administrations.

EXPERIMENTAL

Radiolabeled Compound—Tiaprofenic acid was labeled[3] with carbon-14 in the carbonyl group (Table I) with a specific activity of 54 mCi/mmole and a radiochemical purity of 95% as checked by TLC.

Animal and Human Studies—Male adult animals were used: Swiss mice (22 g), Sprague-Dawley rats (200 g), "Normandy" rabbits (2.4 kg), and beagle dogs (15 kg). Clinical pharmacology studies were carried out in adult subjects of both sexes. Prior to oral administration, animals and humans were fasted overnight. Unless otherwise indicated, the pharmacological dose of 5 mg/kg was administered to animals. In humans, the dosage varied from 1.5 to 3.0 mg/kg in a single administration. For the steady-state study, a daily dose of 600 mg (8.5 mg/kg), divided into three equal doses to be taken at 9:00 am, 2:00 pm, and 8:00 pm was administered for 13 days. A 40th dose of 200 mg was administered on the morning of the 14th day.

The drug was administered either as a suspension in 0.25% carboxymethylcellulose with 0.2% polysorbate 80, a solution after addition of lysine or tromethamine, capsules, or tablets. The stability of formulations containing ^{14}C-I was checked by TLC and scanning.

Blood samples were collected in dry heparin sodium in animals and with or without an anticoagulant in humans. Tissue samples were deposited on dry ice and stored at −25°. Bile was collected by catheterization of the common bile duct under prolonged anesthesia with urethan (1 g/kg ip). For intraduodenal administration, the pylorus was ligatured to avoid gastric reflux. Gastric absorption was studied in rats treated 1 hr after recovery from ligation of the pylorus under mild ether anesthesia. Pulmonary carbon dioxide was trapped in an aqueous solution of 4 *N* ethanolamine. Enzymatic induction was obtained with daily subcutaneous injections of 100 mg of phenobarbital sodium/kg for 3 days.

Hydrolysis of Conjugates—Biliary and urinary conjugates were hydrolyzed either enzymatically by leaving the material for 24 hr at 37° in a buffered acetate medium (pH 5.2) containing *Helix pomatia* juice[4] or at alkaline pH by slowly adding 0.2 *N* NaOH at 0°, away from light and under argon. In some excreta, polar products persisting after hydrolysis at alkaline pH were separated by TLC and, after elution, hydrolyzed with 1 or 6 *N* HCl for 1 hr at 100°.

Extraction and Chromatography—Plasma samples were acidified to pH ≃ 5 with 1 *M* KH_2PO_4. Urine and bile samples were acidified to pH 5 (extraction of I and II) or 2 (extraction of III) with 1 *N* HCl and then extracted twice with ethyl acetate. Extracts were chromatographed on silica gel plates[5] in various solvent systems (Table I). When ^{14}C-tiaprofenic acid was administered, the radioinert reference compounds were added before TLC to enable detection at 254 nm. Relevant areas were eluted either with methanol–acetic acid (1:1) (radiochemical assay) or with acetone or ethyl acetate–acetic acid (98:2) (spectrophotometric assay).

Radiochemical Assay—A solution of either scintillator[6] alone (0.4% w/v) in toluene or of scintillator (0.4% w/v) and naphthalene (8% w/v) in methoxyethanol–toluene (2:3) was added to the samples. Carbon dioxide formed after combustion of tissues[7] was trapped in a solution of scintillator (0.7% w/v) in toluene–phenylethylamine–methanol–water (40:33:22:5). Radioactivity was measured in a liquid scintillation spectrometer[8]. Quenching was corrected by the channel ratio method. Certain measurements were obtained by integration of the chromatographic curves with a scanner[9].

Spectrophotometric Assay—Chromatographic eluates were taken up by aqueous 1 *M* sodium acetate–ethanol (1:9). Absorbances were determined at 313 nm for I (ϵ = 15,400 M^{-1} cm^{-1}), at 248 nm for II (ϵ = 10,300 M^{-1} cm^{-1}), and at 319 nm for III (ϵ = 19,400 M^{-1} cm^{-1}). Optical interferences were eliminated by assaying control samples obtained before treatment or from untreated subjects.

For the determination of I, corrections for losses were made by the addition of labeled compound to the samples prior to analysis. Because the absorption of II is negligible above 280 nm, the determination of I is possible after chromatography in System B (Table I) even though this system does not separate I from II. This approach was checked on dog plasma, which contained relatively large quantities of II. The coefficient of correlation between radiochemical and spectrophotometric determinations of I was 0.997 (12 pairs of plasma concentrations from 3 to 100 mg/liter).

The method for the determination of I and its two metabolites in human urine after separation in System C (Table I) was checked by the analysis of control samples with compounds added *in vitro* (10 mg/liter

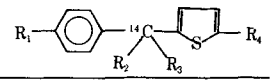
Table I—Structures and R_f Values of Tiaprofenic Acid and Its Derivatives Found in Biological Media



Compound	Substituent R_1	R_2	R_3	R_4	R_f of System: Solvent System A[a]	Solvent System B[b]	Solvent System C[c]
I	H	=O		$CH(CH_3)CO_2H$	0.35	0.50	0.70
II[d]	H	H	OH	$CH(CH_3)CO_2H$	0.25	0.50	0.60
III[e]	OH	=O		$CH(CH_3)CO_2H$	0.05	0.40	0.30
IV[f]	H	=O		$COCH_3$	0.45	0.60	0.80
V[g]	H	=O		CH_2CH_3	0.70	0.80	0.85

[a] Toluene–acetic acid (88:12). [b] Benzene–dioxane–acetic acid (10:5:1). [c] Benzene–dioxane–acetic acid (9:1:1); two migrations. [d] 5-(α-Hydroxybenzyl)-α-methyl-2-thiopheneacetic acid. [e] 5-(4-Hydroxybenzoyl)-α-methyl-2-thiopheneacetic acid. [f] (2-Acetyl-5-thienyl)phenylmethanone. [g] (2-Ethyl-5-thienyl)phenylmethanone.

of each). The recovery of I [88.2 ± 2.6% (mean ± *SD*, $n = 8$)] was total when radiochemical corrections were applied (100.2 ± 2.6%). Recoveries of II and III were 94.5 ± 3.7 and 95.3 ± 1.7% ($n = 8$), respectively, and no correction was applied in these cases.

For a 5-ml sample, the limits of sensitivity were 0.1 mg/liter for I, whatever the mode of separation, 0.1 mg/liter for III, and 0.3 mg/liter for II.

Plasma Protein Binding—Binding to nondiluted plasma or to human albumin[10] in 0.1 *M* phosphate buffer (pH 7.4) was determined by ultrafiltration[11] to avoid the degradations occurring during long contact (equilibrium dialysis). Protein solutions were ultrafiltered at room temperature under a nitrogen pressure of 0.5 kg/cm^2 and magnetic stirring. In 5 min, 10% of the total volume was collected.

RESULTS

Structures of Free Compounds Found in Biological Media—The ^{14}C-label was stable; during 24 hr after intravenous administration, less than 0.01% of the radioactivity in the rat and less than 0.1% in the mouse were excreted by the lungs as ^{14}C-carbon dioxide.

Apart from tiaprofenic acid, which was found in all media studied and which was characterized by the similarity between its chromatographic properties, UV spectrum, and mass spectrum and those of a reference sample, four products were identified (II–V, Table I). Their presence was established both in humans and in the four animal species.

Compound II arises from the reduction of the ketone group of I to an alcohol. Absence of absorption in the UV spectrum around 300 nm indicated the loss of the ketone group. Its mass spectrum with a molecular peak at 262 corresponded to the introduction of two hydrogen atoms, and the fragmentation pattern was in agreement with the proposed formula.

Compound III results from an oxidation process introducing a phenol function in the benzene ring in a *para*-position to the ketone group. The maximum of absorption at 319 nm in its UV spectrum established the presence of the ketone group. Its mass spectrum revealed the introduction of an oxygen atom (molecular peak at 276) in the benzene ring (fragmentation pattern). The position of the phenol group was established by the NMR spectrum, which indicated that the proton in the *para*-position to the ketone group was absent.

Compounds II and III were identified conclusively by comparison with reference substances (1).

Compounds IV and V result from substitution of the methylacetic radical by acetyl and ethyl radicals, respectively, with the loss of one carbon atom. They were first isolated from an aqueous solution of I as degradation products; their structures were established by mass spectrometry (molecular peaks at 230 and 216, respectively, and fragmentation patterns in agreement). They were also found in small quantities *in vivo*.

In the plasma of the four animal species studied, IV and V accounted for about 5% of the total radioactivity measured after treatment with ^{14}C-I, and this proportion did not change significantly with time. Likewise, they accounted for 2–5% of the excreted radioactivity, the amount depending on the conditions of hydrolysis. Too strong alkalinization considerably increased the quantities of IV at the expense of free and conjugated I. Unlike II and III, which exist only *in vivo*, IV and V result from degradation and not from enzymatic biotransformations. Therefore, they cannot be considered as metabolites.

Animal Plasma Kinetics—Total radioactivity kinetic curves after oral and intravenous administrations of ^{14}C-I (Fig. 1) showed that absorption was rapid in the rat for the oral route and slightly slower in the dog; plasma clearance of I and its metabolites, 24 hr after administration, was almost complete in the rat but not in the dog. Tiaprofenic acid was the major constituent. Compound II was present in small quantities in rat plasma (not shown) but in appreciable quantities in dog plasma. In the plasma of both species, III was not detectable.

The kinetics of I after intravenous administration can be depicted according to a two-compartment open model. The apparent initial volumes of distribution, V_c, were calculated from biexponential plasma curves ($C = Ae^{-\alpha t} + Be^{-\beta t}$). The value of V_c is given by $V_c = \chi_0/C_0$, where χ_0 is the intravenous dose and C_0 is the plasma concentration at time $t = 0$ ($C_0 = A + B$) (5). The V_c was 17% of body weight in the rat and

8% in the dog. The extravascular diffusion space was thus smaller in the dog. The plasma clearance of I [$Cl_p = \chi_0/\int_0^\infty C\,dt = \chi_0\alpha\beta/(A\beta + B\alpha)$] per kilogram was 27 ml/hr in the dog and 96 ml/hr in the rat.

Absorption was estimated (6) from the ratio of areas under plasma curves after oral and intravenous administrations. In the rat and dog, the area ratios based on total radioactivity were 0.78 and 1.01; based on tiaprofenic acid, they were 0.87 and 1.12, indicating both a good rate of absorption and no first-pass effect.

Total plasma radioactivity and the radioactivities due to the different compounds were determined 0.25 and 6 hr after intravenous administration of ^{14}C-I in all four animal species (Fig. 2). The decrease in total radioactivity was much faster in the rabbit and mouse than in the rat and, particularly, the dog. Six hours after the injection, tiaprofenic acid represented the major fraction in all species except the rabbit. Metabolite II concentrations were very low in the rat, a little higher in the mouse, and considerably higher in the dog and rabbit. Metabolite III was detected in the rabbit only—in limited quantities and only 0.25 hr after the injection.

On the basis of a simplified one-compartment open model, $C = Ae^{-\alpha t}$, defined by the concentrations at 0.25 and 6 hr, the clearance of I ($Cl_p = \chi_0\alpha/A$) was 91 ml/hr/kg in the rat and 25 ml/hr/kg in the dog. These values are similar to those calculated in the preceding assay. Its clearance was 140 ml/hr/kg in the rabbit and 196 ml/hr/kg in the mouse. The V_c values were calculated according to this same model and enabled the classification of the animal species into two groups with V_c values equivalent to 12 and 13% (dog and rabbit, respectively) and to 24 and 26% (rat and mouse, respectively) of body weight.

Human Serum or Plasma Kinetics—The concentrations of I were assayed spectrophotometrically. Although the UV absorption of II was detected in some samples, this metabolite was present only in weak concentrations and was not measured. The presence of III could not be confirmed in serum, since a meaningful UV spectrum could not be obtained after elution.

After a single oral dose of 100 or 200 mg, peak concentrations were achieved in 0.5–1 hr. Within 4 hr of administration, the level had dropped to one-fifth of the peak value, indicating both rapid absorption and disappearance of the compound (Fig. 3). After a single intramuscular injection of the same dosages (Fig. 3), a rapid decrease in plasma levels established satisfactory diffusion from the injection site and confirmed the fast elimination rate. The V_c of I, calculated according to a one-compartment open model, was about 10% of body weight, and its clearance was 6 liters/hr.

In the steady-state study, the plasma kinetics of tiaprofenic acid after the first dose on Day 1 and after the 40th and last dose on Day 14 were similar (Fig. 4), with mean peaks of 17 mg/liter and equal elimination rate constants (0.50 and 0.46 hr^{-1}, respectively). The areas under individual curves, calculated from 0 to 5 hr by the trapezoidal rule, were not significantly different (paired t test). From Days 2 to 11, mean plasma concentrations fluctuated from 0.6 to 0.8 mg/liter. After the end of treatment (Day 14), from Days 15 to 18, concentrations were equal to or below the limit of sensitivity of the method (0.1 mg/liter).

Absorption by Stomach—The importance of gastric absorption was evaluated in rats by comparing the plasma radioactivity of a group of animals with a ligated pylorus to that of a sham group 0.5 hr after oral administration of ^{14}C-I. Plasma concentrations in control animals were close to those found previously at 0.5 hr (11.7 *versus* 13.9% of dose/10 ml). Therefore, anesthesia and laparotomy did not influence absorption. After ligature of the pylorus, the plasma concentration was only halved, 5.07 ± 0.82 (n = 10) *versus* 11.7 ± 1.08 (n = 7), indicating that the gastric mucosa absorbs tiaprofenic acid.

Tissue Distribution in Rats—Figure 5 represents plasma and tissue concentrations of total radioactivity in the rat 24 hr after ingestion of ^{14}C-I. Tissue levels were all very low and generally lower than plasma levels. Levels in central nervous system tissues were particularly low. The only tissues with concentrations higher than in the plasma were those involved in metabolism and excretion (liver and kidney) or in contact with excreta (bladder). On the basis of the tissue composition of the rat (7), the total concentrations in the whole animal, excluding the GI tract, accounted for about 2% of the dose. This very low residual fraction indicated that I and its metabolites were almost totally eliminated 24 hr after ingestion.

Excretion Routes in Animals—Renal excretion of I and its metabolites was high in all of the animal species (Table II). The total radioactivity excreted in 24 hr accounted for one-half of the dose in the rat and two-thirds of the dose in the dog after ingestion of 5 mg/kg. It accounted for three-fourths of the dose in the mouse and about nine-tenths in the rabbit after ingestion of 50 mg/kg. These high excretion levels recorded after administration of such a suprapharmacological dose are indicative of excellent absorption.

Recovery of about one-half of the dose in rat feces implies significant biliary excretion, since absorption is good in this species. This biliary excretion was measured in anesthetized rats after intravenous administration of ^{14}C-I (Fig. 6). Under conditions where bile collection prevented enterohepatic recirculation, 70% of the dose was excreted in 6 hr and 80% in 24 hr. These results confirmed the importance of biliary excretion of I and/or its metabolites.

Reabsorption of products excreted in the bile was evaluated by comparing the quantity absorbed after administration of bile of control rats

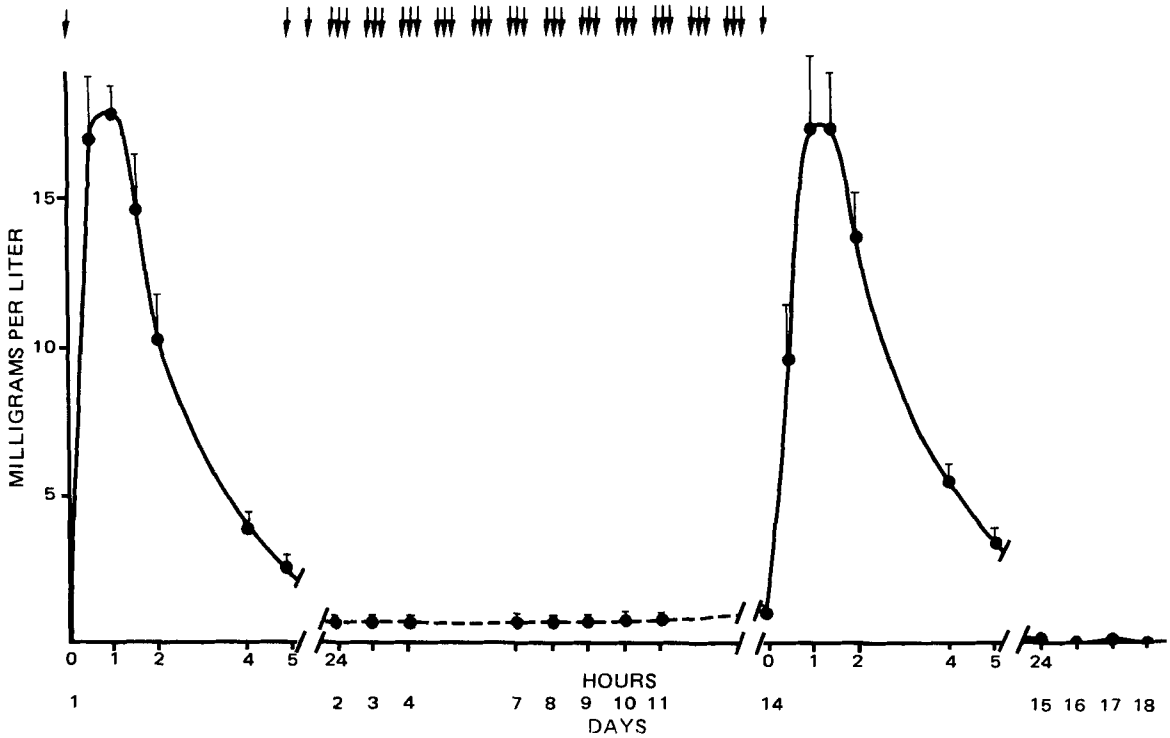

Figure 4—*Plasma concentrations of tiaprofenic acid during and after a chronic treatment with 600 mg/day. Key: ↓: dose of 200 mg (mean ± SE, n = 12).*

with ^{14}C-I added *in vitro* or of bile collected after intravenous injection of ^{14}C-I. These two types of bile samples were administered either orally to conscious rats or intraduodenally to anesthetized rats after catheterization of the common bile duct. Reabsorption, when given by the ratio of the areas under plasma radioactivity curves, was 32% (Fig. 7, top); when given by the ratio of the excreted radioactivity in the collected bile samples, it was 56% (Fig. 7, bottom). Thus, in the rat, there is a significant enterohepatic cycle.

Tiaprofenic acid was much more rapidly absorbed than its biliary metabolites, as indicated by a comparison of plasma kinetics in the first assay and of biliary excretion kinetics in the second assay.

Nature of Excreted Radioactivity in Animals—In the rat, after intravenous administration of ^{14}C-I, the percentage of radioactivity excreted within 6 hr was 29.0 ± 1.1 (n = 5) in urine (conscious animals) and 74.1 ± 2.5 (n = 4) in bile (anesthetized animals). Compounds I and II were mainly free in urine, whereas almost nine-tenths was conjugated in bile. In both fluids, the yields obtained after hydrolysis at alkaline pH were greater than those liberated by enzymatic lysis. Conjugates of I and II were consequently acylglucuronides. Their hydrolysis during collection due to their instability explains the presence of a larger free fraction in urine than in bile under the experimental conditions used.

Compound III was mainly conjugated in urine and bile. Since significant quantities of free III were liberated after enzymatic hydrolysis only, it was conjugated as an ether glucuronide or sulfate ester of the phenol group, although, in addition, an acylglucuronide with the carboxyl group could not be excluded. Tiaprofenic acid and its two metabolites represented three-fourths of the urinary radioactivity and two-thirds of the biliary radioactivity, I being the major fraction in both cases (Fig. 8). The two metabolites were excreted mainly *via* the urine. The remaining ra-

dioactivity was due to the noncarboxylic degradation products IV and V and primarily to polar products(s), possibly nonhydrolyzed conjugate(s). More vigorous hydrolytic methods yielded no further information because of degradation.

In the dog, the percentage of the dose excreted in the urine 6 hr after an intravenous injection of ^{14}C-I was 42.8 ± 9.4 (n = 3). Free II accounted for one-third of the total excretion (15.1 ± 6.2%, n = 3). A small quantity of free tiaprofenic acid (0.5% of dose) was unchanged after hydrolysis by enzymes or by alkaline pH. On the other hand, the residual polar fraction, after isolation by chromatography and hydrolysis by hot 6 N HCl, released a significant quantity of I (7.3 ± 1.3%, n = 3). Considering the easy degradation of I under these severe conditions, this quantity was only a minimum. The conjugate of I excreted in the urine of the dog was consequently not an acylglucuronide. Its characteristics suggest that it was an amide conjugate. Compound III was identified by its mass spectrum after hydrochloric acid hydrolysis of this same polar fraction from the urine of dogs treated orally by 100 mg of ^{14}C-I/kg. It was present in very small quantities.

In rabbit and mouse urine, collected for 24 hr after oral administration of 50 mg of ^{14}C-I/kg, tiaprofenic acid was excreted partially conjugated and accounted for most of the radioactivity, *i.e.*, 60% in rabbits and 57% in mice. Its conjugate, because it was hydrolyzed by β-glucuronidase and with a better yield at an alkaline pH, was an acylglucuronide. Compounds II and III occurred mainly in free form and accounted for 5% each of total excretion in the rabbit and 5 and 10%, respectively, in the mouse.

Urinary Excretion in Humans—Tiaprofenic acid was assayed spectrophotometrically in 24-hr urine samples. Its free form and the acylglucuronide, which was the main form, accounted for 45.2 ± 4.9 (n = 17) and 51.4 ± 3.5% (n = 5) of the dose 24 hr after oral administration of 100 and 200 mg, respectively. They accounted for 50.3 ± 3.4 (n = 5) and 39.7 ± 7.9% (n = 3) after intramuscular administration of the same doses, respectively. Metabolites II and III were also excreted partly as acylglucuronides, but the presence of an ether glucuronide or sulfate ester of the alcoholic or phenol groups cannot be excluded completely. Tiaprofenic acid and its two metabolites accounted for 60% of an oral 100-mg dose (Table III); I accounted for nine-tenths of the total excretion. The excretion of II was about double that of III.

Biotransformations of tiaprofenic acid in humans and in the four animal species studied are summarized in Scheme I.

Induction with Phenobarbital—Enzymatic induction was studied by comparing the plasma levels of I and its metabolites and their urinary excretions after intravenous injection of ^{14}C-I in rats, with or without phenobarbital pretreatment.

Compound I and its metabolites were cleared more rapidly from plasma in phenobarbital-induced rats, since plasma radioactivity was about the same 0.25 hr after the injection but was reduced by nearly 50% compared

to controls 6 hr after the injection (Fig. 9, top). Plasma levels of I also were reduced; its plasma clearance, calculated with a one-compartment open model, was increased by 58% (139 compared to 88 ml/hr/kg in control animals). There were no significant changes in the quantities of II and III, which remained very low.

After induction by phenobarbital, the urinary excretion of radioactivity 6 hr after injection was slightly increased: 30.1 ± 1.5 *versus* 27.5 ± 2.5% (n = 5). However, the quantities of I and II were lowered, whereas the quantity of III was increased (Fig. 9, bottom). The radioactivity from other origins, mainly composed of polar products, was increased ($0.05 > p > 0.02$).

The enzymes that hydroxylate I and probably those that conjugate I and its metabolites are induced by phenobarbital. On the contrary, the enzymes that reduce I are not induced by phenobarbital, leading to a decrease in the excretion of II.

Protein Binding—The amount of radioactivity bound from a nondiluted plasma pool from rats 0.5 hr after oral administration of ^{14}C-I was 98.2 ± 0.2% (n = 5). As shown previously, 85% of the plasma radioactivity was due to I under these conditions. A similar result, 97.6 ± 0.1% (n = 3), was obtained from a plasma pool taken from control animals with identical concentrations of ^{14}C-I added *in vitro*. Similarly, 97.9 ± 0.3% (n = 3) of radioactivity was bound when I was added to a solution of human albumin (0.5 m*M*). This concentration was close to that of albumin in normal plasma.

DISCUSSION

The absorption of tiaprofenic acid was very good in all species studied, as shown by a comparison of its plasma kinetics after oral administration and after intravenous or intramuscular injection in rats, dogs, and humans, as well as by its very high urinary excretion after oral administration of a large dose in rabbits and mice.

The gastric mucosa plays a role in this absorption. In the rat, gastric absorption occurs by passive diffusion of undissociated compounds (8), and I is certainly weakly dissociated at gastric pH. Plasma radioactivity in rats with a ligated pylorus 0.5 hr after ingestion was 43% of that observed in controls, a percentage close to that obtained, under identical conditions after ingestion of ^{3}H-water, ^{14}C-ethanol, or ^{14}C-sodium acetate (50–70%). Acetic acid, like I, is only weakly dissociated at gastric pH. For

a highly dissociated product, such as floctafenine (9), a very low (1%) percentage was recorded. Human gastric mucosa probably also absorbs I since the absorption mechanisms are qualitatively and quantitatively identical in both humans and rats (10). Absorption speed and capacity were considerable in the rat duodenum after *in situ* administration. The duodenum is certainly the main site of absorption, since, under normal conditions, residence time and the area of contact are higher in it than in the stomach.

The very high plasma concentrations recorded shortly after injection indicated that the extravascular diffusion space of tiaprofenic acid was small in all species. The V_c varied, however, according to species. In rats and mice, it was about twice that in dogs, rabbits, and humans. Like other anionic molecules such as indomethacin (11), fenoprofen (12), and tolmetin (13), tiaprofenic acid was extensively bound to the many available sites of plasma albumin.

Radioactivity was almost entirely cleared from the plasma 24 hr after administration in all species studied, including the dog where disappearance was slowest. The clearance of tiaprofenic acid in humans, 6 liters/hr, was close to that of indomethacin, 7.8 liters/hr (14). These values are relatively high, about twice those obtained for fenoprofen (15) and ketoprofen (calculated from Ref. 16) and much higher than the clearance of naproxen, 0.4 liter/hr (calculated from Ref. 17), and phenylbutazone, 0.1 liter/hr (calculated from Ref. 18). In relation to body weight, human clearance of tiaprofenic acid was of the same order as in the rat and rabbit, half that in the mouse, and four times that in the dog.

The chronic study in humans confirmed rapid elimination, since the steady state was reached as early as the end of the 1st treatment day and the concentrations were down to zero 24 hr after the last ingestion. The maximum concentrations, the areas under curves, and the elimination rate constants, which were identical after the first and 40th ingestion, showed that tiaprofenic acid cannot inhibit or induce its own biotransformations.

Renal excretion, which in rats was equal to fecal excretion, was preponderant in humans and in the other species studied. A significant en-

terohepatic cycle was demonstrated in the rat. Biliary metabolites were absorbed slower than I, since most of them were conjugated, with polarities unfavorable to intestinal absorption (19). Progressive hydrolysis of acylglucuronides by the weakly alkaline pH in the distal part of the duodenum and of all types of conjugates by bacterial enzymes (20) accounts for this difference.

Metabolites II and III were common to all species. In the dog, however, II was present in large quantities and III was present in very small quantities. They are pharmacologically less active than I (1).

In the rat, the clearance of I was greatly increased by phenobarbital, partly because of enzymatic induction of hydroxylation. This result is in agreement with the location of hydroxylase(s) in the hepatic endoplasmic reticulum, which is stimulated by phenobarbital (21). The approximately 50% increase in biliary flow induced by phenobarbital (22) increases the importance of this route of excretion and, together with enzymatic induction, accounts for the large increase in plasma clearance as opposed to the small increase in urinary radioactivity excretion. On the other hand, the enzymes that reduce the ketone group were not induced, in agreement with the location of several keto reductases in the soluble fraction from rabbit (23), rat, and human (24) liver and kidney.

No reduction of the ketone group was observed for two compounds whose structures, like I, are formed by a ring with a carboxylic radical linked to another ring by a carbonyl group: tolmetin [1-methyl-5-(4-methylbenzoyl)-2-[1*H*]-pyrroleacetic acid] (25) and ketoprofen [2-(3-benzoylphenyl)propanoic acid] (16).

For tolmetin, the only metabolite identified in rats, monkeys, and humans was the diacid formed by oxidation of the 4-methyl group. For ketoprofen, the two metabolites partially identified in rats, dogs, rabbits, and humans resulted from hydroxylation in different positions of the benzene ring not substituted by a propanoic radical.

On the other hand, Lan *et al.* (26) found that, after administration of a similar structure, 4-cyclopropylcarbonylbenzeneacetic acid[12] (VI), the alcohol derivative was excreted in low quantities in the urine of rats and monkeys but in much higher quantities in the urine of dogs. This result is parallel to the present observation of a higher urinary excretion of II in the dog than in the rat.

Regarding secondary biotransformations, a ketoprofen acylglucuronide was found in all species, including the dog (16), whereas VI was excreted in this species conjugated with taurine (26). Like VI, tiaprofenic acid was also excreted as an amide conjugate in the dog but as an acylglucuronide in the other species.

Colorimetric Assay of Benzocaine and Some Dosage Forms

HENRY S. I. TAN ˣ, GARY A. BRUEMMER, and DAVID SHELTON *

Abstract □ A colorimetric procedure for benzocaine and a number of its dosage forms was developed; it offers improvement in ease, speed, and sensitivity over the official method. The method is based on the formation of a red Schiff base between benzocaine and *p*-dimethylaminocinnamaldehyde in a nonaqueous acidic medium. At the maximum absorption of 544 nm, the Beer–Lambert law was adhered to over the 0.025–2.5-μg/ml range. Best accuracy can be obtained for solutions containing 0.25–1.25 μg/ml. The color was stable for at least 2 hr. Analysis of benzocaine in the dosage forms studied can be directly performed without prior drug extraction.

Keyphrases □ Benzocaine—colorimetric analysis, bulk drug and commercial dosage forms □ Colorimetry—analysis, benzocaine bulk drug and commercial dosage forms □ Anesthetics, topical—benzocaine, colorimetric analysis, bulk drug and commercial dosage forms

Benzocaine (ethyl *p*-aminobenzoate) is an extensively used local anesthetic in various products for the relief of pain and pruritis. A significantly large number of products are readily available as nonprescription drugs, varying in benzocaine concentration from 0.5 to 20.0%.

The NF XIV (1) method for benzocaine is based on the known diazotization or nitritometric titration (2–7). This tedious and time-consuming titration utilizes standard sodium nitrite at low temperatures with starch iodide paper as an external indicator. The official assay procedures (1) for benzocaine creams and ointments also are based on the same diazotization titration where the endpoint is determined potentiometrically. In ointments having water-insoluble bases, the drug must be isolated by solvent extraction prior to the diazotization titration. Furthermore, in formulations with antipyrine in glycerin or propylene glycol bases, the benzocaine is analyzed by UV spectrophotometry after it is separated from antipyrine by column partition chromatography using three different columns assembled serially (8, 9).

Colorimetric methods for the analysis of benzocaine based on the formation of Schiff bases were performed using *p*-dimethylaminobenzaldehyde (10) and vanillin (11) in acidic hydroalcoholic solutions, and the products obtained were yellow. *p*-Dimethylaminocinnamaldehyde was utilized as a colorimetric agent for primary aromatic amines (12–14). This reagent is advantageously employed in place of *p*-dimethylaminobenzaldehyde and vanillin, since the resulting Schiff bases are red. This paper presents a simple, sensitive, and accurate method for the analysis of benzocaine and some of its dosage forms.

EXPERIMENTAL

Instruments—A UV–visible double-beam spectrophotometer[1] with 1-cm cells and a dynode voltage of 500 v (slit width 0.35–0.55 mm) and an analytical balance[2] were used.

Materials and Reagents—The following were used: benzocaine[3], acetone-free absolute methanol containing 0.05% water[4], a 0.1% (w/v) solution of *p*-dimethylaminocinnamaldehyde[5] (mp 137–139°) in methanol (stable for at least 3 weeks if refrigerated), and a 50% (w/v) solution of trichloroacetic acid (ACS grade) in methanol.

Standard Curve—A stock solution of benzocaine was prepared by dissolving 50.0 mg of the drug in methanol. Further dilutions were made to prepare standard solutions containing 0.25–25.0 μg of benzocaine/ml. One milliliter of each solution was utilized for color development as described under *Assay Procedure for Benzocaine*. The stock and standard solutions were freshly prepared.

Assay Procedure for Benzocaine—Pipet 1.0 ml of a methanolic solution containing 2.5–12.5 μg of benzocaine into a 10-ml volumetric flask. To this solution, add exactly 2.00 ml of *p*-dimethylaminocinnamaldehyde reagent followed by 1.0 ml of trichloroacetic acid reagent and wait for 10 min. Dilute to volume with methanol, and measure the absorbance at 544 nm against a blank prepared similarly but omitting the benzocaine.

Assay Procedure for Benzocaine Dosage Forms—*Creams, Ointments with Water-Soluble Bases, and Otic Drops*—Weigh or pipet accurately an amount equivalent to 15–50 mg of benzocaine, transfer into a 100-ml volumetric flask, and dissolve or suspend in methanol. Dilute to volume with methanol. Filter through dry filter paper, if necessary, and discard the first 5 ml of filtrate. Pipet 1.0 ml of the filtrate into a 50-ml volumetric flask, and dilute to volume with methanol. Pipet 1.0 ml of the resulting solution into a 10-ml volumetric flask and proceed as described under *Assay Procedure for Benzocaine*, beginning with: "To this solution, add exactly . . . ."

Ointments and Suppositories with Water-Insoluble Bases—Weigh accurately an amount equivalent to 15–50 mg of benzocaine in a beaker, dissolve in 14 ml of cyclohexane, and transfer quantitatively into a 100-ml volumetric flask. Rinse the beaker three times with 2-ml portions of cyclohexane, and combine the washings with the cyclohexane solution in the volumetric flask. Shake the solution vigorously, and slowly add methanol to the mark. Proceed as described for creams, beginning with: "Filter through dry filter paper . . . ."

Lozenges—Weigh and grind 20 lozenges to a very fine powder. Add slowly an accurately weighed amount of the powder, equivalent to 15–50 mg of benzocaine, to about 75 ml of methanol in a 100-ml volumetric flask with shaking. Place the stoppered volumetric flask in an ultrasonic bath for 30 min to enhance dissolution of the benzocaine, and dilute to volume with methanol. Proceed as described for creams, beginning with: "Filter through dry filter paper . . . ."

RESULTS AND DISCUSSION

The red Schiff base produced by the interaction of benzocaine and *p*-dimethylaminocinnamaldehyde in an acidic anhydrous medium exhibited a maximum absorption at 544 nm (Fig. 1). This reaction resulted in a more sensitive and deep coloration than the yellow color obtained

from the reaction of benzocaine with the commonly used aldehydes such as *p*-dimethylaminobenzaldehyde (10) and vanillin (11). This bathochromic shift was expected since the structure of the Schiff base (I) formed with *p*-dimethylaminocinnamaldehyde showed greater conjugation than, for example, II, that formed with *p*-dimethylaminobenzaldehyde. The red color of the product was stable for at least 120 min (Table I).

The effect of reagents on color development was investigated by adding varying volumes of 0.1% *p*-dimethylaminocinnamaldehyde in methanol to 10-ml volumetric flasks, each containing 1.0 ml of 16 μg of benzocaine/ml and 1.0 ml of 50% trichloroacetic acid in methanol. The absorbance of each solution was measured at 544 nm against a blank[6] after each solution was diluted to volume with methanol. The absorbance readings increased with increasing amounts of *p*-dimethylaminocinnamaldehyde up to a concentration of about 250 μg/ml in the final solution.

However, blank solutions containing more than 200 μg of *p*-dimethylaminocinnamaldehyde/ml were dark colored. This condition limits the range of usable concentrations and makes the method less sensitive, because wider slit widths must be used to maintain the dynode voltage on the spectrophotometer at 500 v. Based on these considerations, exactly 2.0 ml of the 0.1% *p*-dimethylaminocinnamaldehyde reagent was used for color development. Changing the volumes of 50% trichloroacetic acid did not appreciably affect absorbance readings; 1.0 ml of this acid reagent was used for the assay.

As in a previous study (14), the color formed was instable in the presence of water. Therefore, the methanol used must be as anhydrous as possible. The use of methanol containing 0.05% water appeared to be satisfactory for the benzocaine assay.

Under the proposed experimental conditions, a linear response between absorbance and concentration was demonstrated over the concentration range of 0.025–2.5 μg/ml (r = 0.9997). The linear regression line[7] was $A_{544} = 0.5974C - 0.0059$, where A_{544} is the absorbance at 544 nm and C is the concentration expressed in micrograms per milliliter in the final test solution. The standard deviations of the slope and y intercept were 0.0121 and 0.0076, respectively (n = 4). The calculated molar absorptivity, ϵ, was 9.87×10^4 liter mole^{-1} cm^{-1}.

Determination of the concentration range for maximum accuracy was done by constructing the Ringbom plot (15, 16). The plot (Fig. 2) indicates an optimum range for solutions containing 0.25–1.25 μg of benzocaine/ml in the final test solution. The curve also shows an inflection at 37% transmittance, indicating that the system follows the Beer–Lambert law.

The limit of detection, as determined on 20 samples by the procedure of Kaiser (17), at the 95% confidence level is 5.5×10^{-7} M or 0.090 μg of benzocaine/ml in the test solution.

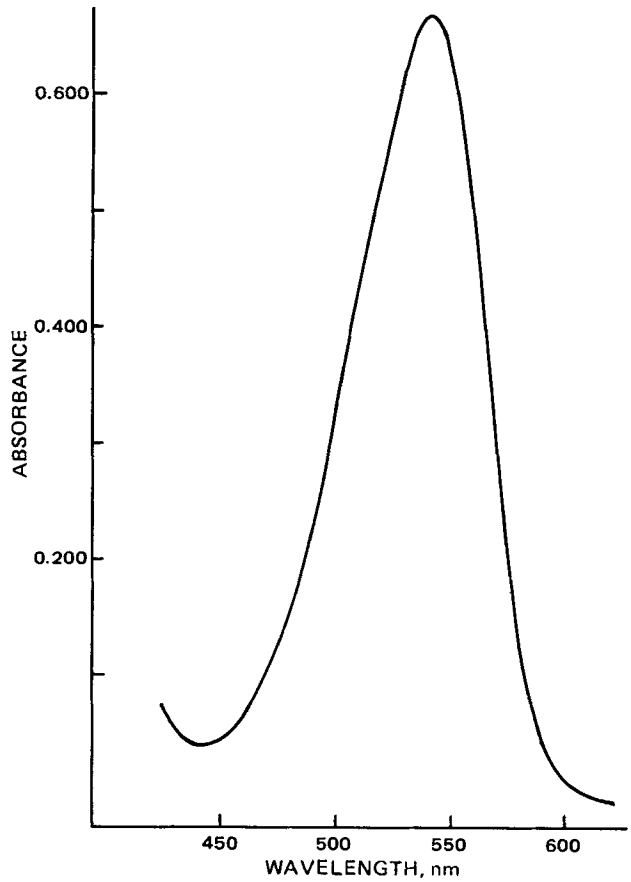

Figure 1—*Absorption spectrum of the benzocaine–*p*-dimethylaminocinnamaldehyde reaction product.*

The reproducibility of the proposed color development was determined by analyzing nine replicate samples of benzocaine solutions in methanol, each containing 0.5 μg/ml. The precision at this concentration level showed a relative standard deviation of 0.0103 (Table II).

The data in Table III show the accuracy of the procedure. These studies were performed on four different, but accurately known, amounts of benzocaine. Each sample was dissolved in 100.0 ml of methanol. Appropriate dilutions were then made to give different concentration levels (Table III), which were analyzed by the proposed method. The results

were in agreement with those obtained by the compendial method. An average of 99.6% of the original amount weighed was found. In comparison, an average of 100.6% was obtained for two benzocaine samples analyzed by the NF XIV method.

Results of analyses of different benzocaine dosage forms by the proposed method are presented in Table IV. The recovery data showed good correlation with those of the NF XIV procedure. The results also indicated that benzocaine in ointments or suppositories with water-insoluble bases need not be isolated by solvent extraction prior to analysis as required by the official method. This difference shortens the analysis time considerably.

The concentration of cyclohexane used to dissolve the ointment or suppository in the final test solution was 0.04% (w/v). Increasing the cyclohexane concentration to 0.06% (w/v), which corresponded to an initial volume of 30 ml, did not affect color intensity or stability. Furthermore, active ingredients normally present in the benzocaine formulations studied, such as antipyrine, menthol, camphor, triclosan, benzethonium chloride, and oxyquinoline sulfate, do not interfere with the reaction and do not have to be removed; these compounds lack the primary aromatic amino functional group necessary for the reaction with *p*-dimethylaminocinnamaldehyde to form a red Schiff base. On the other hand, *p*-aminobenzoic acid, a degradation product of benzocaine, reacts under the proposed experimental conditions, producing a red color with λ_{max} of 541 nm.

In the analysis of lozenges, the lozenges must be ground to a very fine powder, and care must be taken when suspending the powder in methanol. The powder must be added slowly with frequent shaking to prevent the formation of lumps. The undissolved particles must flow freely upon shaking. The use of an ultrasonic bath facilitates the disintegration of lumps and enhances the dissolution of benzocaine. The pink dye present in the lozenges did not interfere with the analysis.

Solvent-Dependent Conformational System of Hydroxyureas in Octanol–Water and in Inhibition of Ribonucleotide Reductase

GEORGE R. PARKER ˣ and E. COLLEEN MOORE *

Abstract □ The carbonyl nitrogen IR absorption region of selected hydroxyureas was examined in octanol. The spectra indicated appreciably different absorptions prior to and after equilibration with water. Stability studies on the hydroxyureas indicated that the absorption differences were not due to chemical decomposition in the equilibration process but were due to solvent conformational and/or tautomeric dependency of the system. Preliminary *in vitro* inhibition of the enzyme ribonucleoside diphosphate reductase by selected hydroxyureas also indicated an apparent solvent dependency, which may involve the conformational and/or tautomeric properties of these agents. The implications of the solvent-dependent conformational–tautomeric system observed are discussed in relation to this property in the biological action of these agents.

Keyphrases □ Hydroxyureas, various—solvent-dependent conformation in octanol–water, effect on ribonucleotide reductase activity *in vitro* □ Conformation—various hydroxyureas in octanol–water, effect of solvent equilibration □ Ribonucleotide reductase—activity, effect of various hydroxyureas *in vitro* □ Enzymes—ribonucleotide reductase, effect of various hydroxyureas on activity *in vitro* □ Structure–activity relationships—various hydroxyureas, solvent-dependent conformation in octanol–water, effect on ribonucleotide reductase activity *in vitro*

A solvent-dependent conformational system in substituted hydroxyureas was reported (1) utilizing solvents such as acetone, pyridine, and tetrachloroethane in the presence and absence of water. The conformational aspects of hydroxyureas were investigated, since this property may influence their transport, stability *in vivo*, and mechanism of action. Since there is no accepted explanation for the low anticancer activity of substituted hydroxyurea analogs compared to the parent antileukemia agent hydroxyurea, the conformational properties of hydroxyureas were examined.

In this study, the properties of the carbonyl–nitrogen system of substituted hydroxyureas were examined in the solvent 1-octanol before and after equilibration with water (pH 7.4); this system closely simulates the environment of *in vitro* and *in vivo* systems. The findings further substantiate conformational properties of hydroxyureas as detected by IR spectroscopy in 1-octanol. Initial biological data on the action of hydroxyureas on the enzyme ribonucleoside diphosphate reductase, the proposed site of anticancer action, indicate that the solvent plays a role in the *in vitro* inhibition of the enzyme, which may be due to the solvent-dependent conformation of certain hydroxyureas.

EXPERIMENTAL

Compounds—The 3-substituted analogs were synthesized according to a literature method (2) with modifications (3, 4). Hydroxyurea and the 1-substituted analogs were used as received[1].

IR Spectra—The IR spectra were obtained[2] using liquid cells. The solvent was 1-octanol[3] dried over anhydrous sodium sulfate. Spectra were taken immediately after dissolution, after equilibration with glass-distilled water (adjusted to pH 7.4) for 24 hr, and after 2 weeks.

After equilibration, the solvents were separated; the octanol layer was dried over sodium sulfate prior to recording the IR spectra. All spectra were taken with the following instrument settings: gain, 2; period, 1 sec; balance, 0; chart expansion, 1×; sensitivity, 3; ordinate scale, 100%; scan speed, 600 (8 min); and baseline transmission, 90%. All spectra were taken with dry octanol as the blank.

Stability Studies—The stability and decomposition of hydroxyureas in aqueous solutions were examined *via* the method of Harmon *et al.* (3). The solution of the hydroxyurea in a reaction vessel was connected to a gas dispersion tube immersed in anhydrous ether. Any gas evolved in the hydroxyurea decomposition was observed visually or in the IR spectrum of the ether solution after bubbling through the ether. IR spectra of the ether solutions after standing in water (pH 7.4), in acidic solutions at pH 1.5, and with ferric chloride added (in a ratio of 2 moles of hydroxyurea to 1 mole of ferric chloride) were recorded at intervals (up to 1 week for water at pH 7.4) using a double-beam instrument[4] and liquid cells with ether as the blank. The pH values were determined on a standard pH meter[5]. The pH of the aqueous layers in the equilibration experiments was also checked after 24 hr and 2 weeks and was in all cases 7.4 ± 0.2, indicating that no appreciable pH change occurred in the equilibration process. Water layers were removed by freeze drying[6] (at 20 mm Hg) to afford solids identical to starting materials, as verified by melting points and IR spectra.

Ribonucleotide Reductase Assay—The enzyme ribonucleoside diphosphate reductase was isolated from Novikoff ascites hepatoma of rats and purified according to the method of Moore (5). The assay included 8.3 m*M* phosphate buffer (pH 7), 2.1 m*M* adenosine triphosphate, 4.2 m*M* magnesium acetate, 0.04 m*M* $Fe(NH_4)_2(SO_4)_2$, 0.17 m*M* cytidine ^{32}P-diphosphate, 6.3 m*M* dithiothreitol, 1.0 μl of thioredoxin, and approximately 0.2 mg of partially purified ribonucleotide reductase in a total volume of 0.12 ml. Inhibitors were present in the reaction mixture (in an ice bath) when the enzyme was added; the mixture was then moved to a water bath at 37° and incubated for 30 min. The reaction was stopped with perchloric acid (1 *M*), and the products were hydrolyzed, separated on a cation-exchange resin[7], and analyzed according to the method of Reichard (6).

The hydroxyureas were tested five times over 6 months; each compound was evaluated at four different concentrations with two tests at each concentration. The enzyme activity was plotted *versus* the inhibitor concentration and extrapolated to determine the concentration required to inhibit 50% of the enzyme activity (ID_{50}). The control activities for the enzyme system in the five determinations were 2.28, 0.75, 4.16, 2.20, and 1.50 nmoles/30 min/tube.

RESULTS

The IR spectra of the carbonyl nitrogen region of the hydroxyureas in 1-octanol (with 1-octanol as blank) are shown in Fig. 1. The spectra labeled A were taken immediately after dissolving each compound in dried solvent; those labeled B and C were taken after equilibration with water (pH 7.4) for 24 hr and 2 weeks, respectively. In each case, octanol was separated from the water layer and dried over sodium sulfate, and the IR spectra were taken in the same manner as A.

Since B and C spectra were appreciably different from A spectra in every case except hydroxyurea, the stability of the compounds was examined using the method of Harmon *et al.* (3) to determine if chemical decomposition had occurred in the pH 7.4 water layer compared to so-

lutions of pH 1.5 or in solution with ferric chloride (pH 1.5) (Table I). All compounds were stable in pH 7.4 water, whereas only I was stable in pH 1.5 water, with gas evolution observed for the other compounds.

The relative inhibitory concentrations of selected substituted hydroxyureas compared to hydroxyurea are shown in Table II. By using the method of Moore (5) for the purification of the enzyme and the method of Reichard (6) for the evaluation of the inhibitory concentration of the hydroxyureas, the concentration required for 50% enzyme inhibition was

Table I—Stability[a] of Hydroxyureas in Ferric Chloride Solution (pH 1.5)

$$R_1NHC(=O)NOH\text{-}R_2$$

Compound	R_1	R_2	Stability in Ferric Chloride Solution
I	H	H	Gas[b] plus blue color
II	H	CH_3	Gas plus blue color
III	H	C_2H_5	Gas plus blue color
IV	C_2H_5	H	Gas plus blue color
V	n-C_3H_7	H	Gas plus blue color
VI	iso-C_3H_7	H	Gas plus black color
VII	n-C_4H_9	H	Gas plus blue color
VIII	$tert$-C_4H_9	H	Gas plus brown color
IX	p-ClC_6H_4	H	Gas and no color change

[a] All compounds were stable in pH 7.4 solutions; only I was stable in pH 1.5 solutions, with gas evolution observed for the other compounds. Reaction vessels were connected to gas dispersion tube in ether; no signals were detected in IR spectra of ether solutions after 1 week. [b] Gas was detected according to method of Harmon *et al.* (3); signals were observed in the 2350–2200- and 600–700-cm^{-1} regions for all compounds where gas was observed. In most cases, gas was evolved immediately.

determined. Hydroxyurea and the 1-substituted analogs were dissolved in distilled water for all determinations. The 3-*n*-propyl analog (V) was dissolved in water and the 3-*n*-butyl analog (VII) was dissolved in 1 ml of 95% ethanol and diluted with water to 1% for the first determination. For the second, third, and fourth determinations, V and VII were dissolved in 6 and 10% dimethyl sulfoxide, respectively, and diluted to 1% with water. Ethanol and dimethyl sulfoxide were not inhibitory to the enzyme system at 1% concentrations.

A general trend in relative inhibitory activity was observed in all but the first determination (especially for V) where a different solvent was used. A fifth determination was performed with water as the solvent, and again a higher relative concentration was required for V to produce 50% enzyme inhibition compared to the concentration required when the solvent was 1% dimethyl sulfoxide.

DISCUSSION

For a drug molecule to exhibit its biological action at its molecular site of action in an *in vivo* system, it must first be transported from its original entry site to its target site. To simplify the dynamics of drugs in biological fluids (the biophase), various model systems attempt to approximate the biophase (an aqueous system with a nonpolar component present similar to a colloidal suspension) with, for example, the octanol–water system (7–9). The octanol–water system used in determining drug dynamics in complex *in vivo* biophases is a simplification of the actual occurrences but has been accepted as suitable for determining relative membrane *versus* water solubilities. It is the most extensively studied system depicting *in vitro* partitioning between polar and nonpolar biological components (10, 11).

The octanol–water system was selected as a model to evaluate the effect of lipophilicity or hydrophobicity in the biological action of substituted hydroxyureas. Surprisingly, the properties of the substituted hydroxyureas, as observed by their IR carbonyl nitrogen absorption (1720–1550 cm^{-1}), were different in octanol after equilibration with pH 7.4 water compared to spectra taken immediately after dissolving the substituted hydroxyurea in octanol (Fig. 1). This spectral change (C spectra compared to A spectra) after extended equilibration with water (2–4 weeks) occurred after 24 hr of equilibration with water (B spectra), and this process proceeded without a change of pH in the aqueous system. In spectra of all hydroxyureas except hydroxyurea itself, a change occurred in the carbonyl nitrogen region after water equilibration from two distinct peaks at around 1550–1580 and 1650–1690 cm^{-1} [1720 and 1780 cm^{-1} for the isopropyl analog (VI) and 1660 and 1710 cm^{-1} for the *tert*-butyl analog (VIII)] to a broad band centered around 1650 cm^{-1}. The spectra of VI–VIII also had additional shoulders in the broad band at 1650 cm^{-1}.

To determine if a chemical reaction occurred in the aqueous solvents during water equilibration, the compounds were allowed to stand in water (pH 7.4 at room temperature) in sealed flasks. These flasks were attached *via* polyethylene tubing to a gas dispersion apparatus in anhydrous ether. With this method, a gas could be detected immediately after the solution was acidified to pH 1.5 or after ferric chloride was added (with a corresponding color change to blue) for most hydroxyureas (Table I). IR spectra of the ether solutions (using a double-beam instrument with ether as the blank) also indicated the presence of decomposition gases after treatment with acid or ferric chloride. For the hydroxyureas in pH 7.4 water at room temperature, no decomposition gases were observed over 4 weeks, and no absorption could be detected in the ether solution spectra (taken at intervals) in which the gas dispersion tube had been immersed.

Table II—Relative Concentrations Required to Inhibit 50% Enzyme Activity (ID_{50}) of Ribonucleoside Diphosphate Reductase

Compound	Determination 1	2	3	4	5	Inhibitor Concentration Range, m*M*	Average Concentration
I	1.0	1.0	1.0	1.0	1.0	0.055–0.27	0.12

VII	9.1	6.4	5.8	7.0	7.5	0.35–2.0	0.84
VI	—		—	—	19.0	0.80	—
VIII	—		—	—	9.5	0.40	—

The solutes (hydroxyureas) also were examined for possible decomposition during the equilibration process. Attempts to remove octanol by evaporation under vacuum were unsuccessful (hydroxyurea slowly decomposed) due to the high boiling point of 1-octanol (194–195°), but the water layer could be removed by freeze drying under vacuum. The solids obtained from solutions treated by freeze drying (I and IV–VIII) were identical to starting material (melting points) and showed IR spectra in dry octanol identical to those obtained for the initial solution (*i.e.*, A spectra in Fig. 1). Identical solid materials also could be obtained when the octanol layer was washed with water and the water was removed by freeze drying under vacuum, indicating that chemical decomposition was not the cause of the IR spectral changes in octanol after water equilibration.

Various reactions of the hydroxyureas with water could account for the IR spectra, and the function of water in each reaction is different (Scheme I). Scheme I depicts the conformational system of hydroxyureas (I*e*, I*f*, I*j*, and I*k*) produced by interconversion through canonical forms I*g* and I*h*. Water could: (*a*) catalyze the tautomerization (as could the solvent) of the N-1 or N-3 proton to form tautomers I*a*–I*d* and I*l*–I*o*; (*b*) react with a form similar to canonical form I*h* to produce a diol (I*i*) by addition to the carbonyl function; or (*c*) react with a form that is not internally hydrogen bonded, such as conformer I*k*, *via* hydrogen bonding to form a solvated form of the hydroxyurea (I*p*).

In B and C spectras (Fig. 1) for all substituted hydroxyureas, there is an absence of absorption similar to that observed in A spectra, indicating that the chemical process that caused the new signals had proceeded to 100% completion. The presence of water in the original samples of hydroxyureas could account for different spectra after equilibration and drying due to the removal of all water. This possibility was eliminated when spectra taken after initial solution and those taken after drying over anhydrous sodium sulfate (for 1 and 24 hr) were identical (Fig. 2).

Of the three possible products that can form with water in octanol, the diol (I*i*) is the least likely and would be the most unstable. For diol formation to occur, the carbonyl carbon would have to possess a strong $\delta+$ charge ($\delta+CO^{\delta-}$); therefore, the canonical form I*h* would represent the form of hydroxyurea present. This form would require minimal double bond character between N^1C and N^2C bonds, which is unlikely since any positive charge that forms at the carbonyl carbon causes electron flow

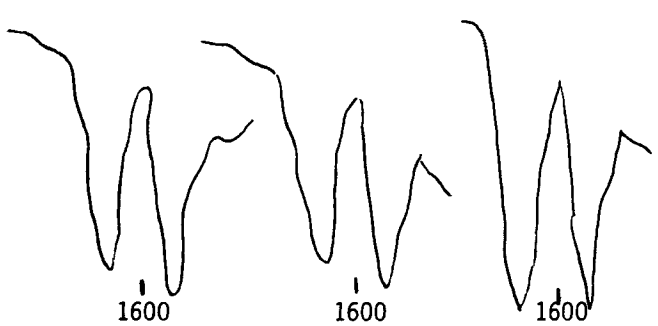

Figure 2—*Carbonyl nitrogen region of IR spectra of VII after dissolution in dry octanol (left) and after drying over anhydrous sodium sulfate for 1 (middle) and 24 (right) hr.*

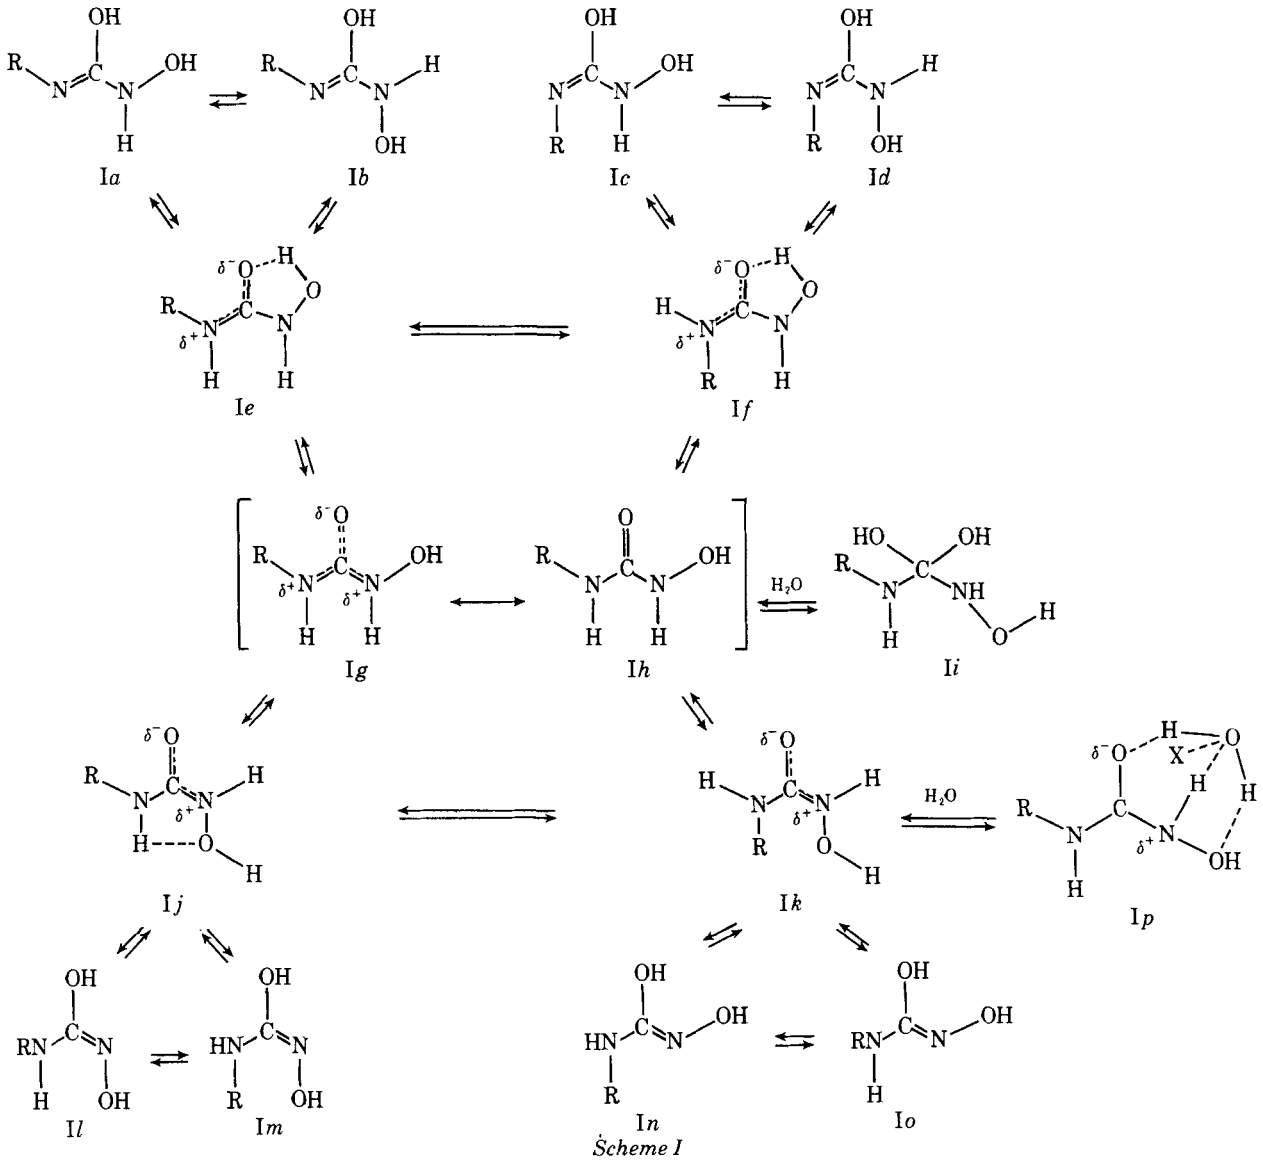

Scheme I

from the nitrogens toward the δ+C=O to stabilize the carbonyl group. Since the carbonyl absorption completely disappears, it is highly unlikely that it is due to a 100% conversion to diol I*i*, which could not have a C=N system, and it would be hard to rationalize the strong absorption at 1650 cm^{-1}, which is probably due to C=N in the molecules.

The reaction of the hydroxyurea with water in the other two cases involves tautomerization catalyzed by water or the solvent to form tautomers I*a*–I*d* and I*l*–I*o* and the solvate formation with water to form I*p* (Scheme I). In tautomerization, water does not add to the molecule, but rather bond breaking and bond making are promoted by water or by the solvent. The spectral phenomenon observed in octanol also occurred in ether. Upon initial solution, two signals were observed; after water equilibration and drying, a single signal (also around 1650 cm^{-1}) was detected. Attempts to reproduce the spectral changes in a solvent without the addition of water were performed by allowing VII to stand for 3 days in dry solvents with proton affinity closer to water [proton affinities in kilocalories per mole (12) are: water, 164; 1-octanol, 202; and ether and tetrahydrofuran, 187]. Tests with tetrahydrofuran and ether were unsuccessful, indicating that the process observed when water was present did not occur in the dry solvent and that the molecular species in the dry solvents were probably the same.

Therefore, the spectral changes observed in octanol after equilibration with water are due to conformational and/or tautomeric changes similar to those reported in other solvents (1). The conformational and/or tautomeric changes are the result of the stabilization or destabilization of conformational isomers in each solvent system (Scheme I). This type of conformational system would be sensitive to the presence of water or other polar solvents or molecules (allowing hydrogen bonding to water or other polar groups rather than internal hydrogen bonding). The IR spectra of the hydroxyureas taken in dry solvents immediately after solution most likely depict conformers I*e* and I*f*, which are stabilized by OH···O=C hydrogen bonding, and conformer I*j*, which is stabilized by weaker NH···OH hydrogen bonds (Scheme I). All conformers (I*e*, I*f*, I*j*, and I*k*) are formed by interconversion through some intermediate. This intermediate may be similar to canonical form I*g*, where rotation around the NC bonds is restricted due to the C=N character, or the canonical form I*h*, which allows rapid rotation and interconversion.

In dry octanol, the internal hydrogen bonding may exist in preference to hydrogen bonding with the solvent. This effect would be observed in the IR spectra as complex signals due to conformers I*e*, I*f*, and I*j* and the canonical form present during interconversion. Conformer I*k* should not be an important contributor in the IR absorption, since it is not stabilized by internal hydrogen bonding and it would be quickly interconverted to the other conformers through canonical forms I*g* and I*h*. After equilibration with water, a form similar to I*k* is present. This form is stabilized by solvate formation with water, which does not allow it to interconvert back to the other forms due to hydrogen bonding with water. Since I*k* or its solvate form would be stabilized, it would not be able to interconvert into a canonical form, which would have a carbonyl absorption and would primarily possess a C=N absorption observed as strong absorptions at 1650 cm^{-1}.

The implications of these data are relevant to drug action if different forms of the hydroxyurea conformational system are present in preference to others, depending on whether the system is in a polar or a non-

polar environment and whether internal hydrogen bonding is stabilized or whether hydrogen bonding to a solvent or to other biochemical entities has occurred. Hydroxyurea appears to possess the same type of carbonyl nitrogen character before and after equilibration with water. Therefore, no conformational preference may exist in hydroxyurea in solutions where conformational preference may be conferred to substituted hydroxyureas by their bulk or steric hindrance or to some electronic stabilization factor. The crystal structure of hydroxyurea indicates that intermolecular hydrogen bonding exists between the hydroxyl group of one molecule and the carbonyl oxygen of another molecule rather than intramolecular hydrogen bonding (13), and internal hydrogen bonding may not be preferred in solution.

The *in vitro* inhibition of ribonucleotide reductase by selected hydroxyureas (Table II) relative to hydroxyurea seems to indicate a solvent dependency. Although the enzyme system is quite complex and its activity is dependent on many variables (14), its inhibition by hydroxyureas followed a general trend, except for the 3-*n*-propyl analog (V) in the first determination. The solvent for hydroxyurea and the 1-analogs (II and III) was water for all determinations, and water was used for V in the first determination. The solvent for all other determinations for V and VII was 1% dimethyl sulfoxide.

The inhibitory concentration required to obtain 50% enzyme activity with V was much higher in the first determination than in the other determinations (2–4 in Table II), and this result was due to some error in the enzyme determination or to the different solvent. To verify which factor was the determinant in the inhibition study, another analysis was performed (5 in Table II) in which water was the solvent for all compounds. Again the concentration required for 50% enzyme inhibition for V was appreciably higher than in determinations where dimethyl sulfoxide was the solvent. This result implicates the solvent as a potential variable in the ability of hydroxyureas to function in the *in vitro* inhibition of ribonucleoside diphosphate reductase, and this property should be considered in the elucidation of the biodynamics of drugs in the hydroxyurea class.

Although it is not possible to determine whether the solvent-dependent conformational system observed in substituted hydroxyureas is the actual cause of the poor inhibition of the enzyme, with V the conformation and solvent have an interdependence that may affect the biological action of the drug. The transport and partitioning properties of hydroxyureas in octanol–water are currently being investigated to determine whether predicted and actual partition coefficients support the solvent-dependent conformation and the importance of this property in drug transport *in vivo*.

NOTES

Improved Recovery of Morphine from Biological Tissues Using Siliconized Glassware

HEMENDRA N. BHARGAVA

Abstract □ The adsorption of morphine onto glassware during analysis in aqueous solutions and biological tissues is a common problem, resulting in lower recoveries than expected. The problem can be remedied by siliconization of all glassware involved. The same glassware cannot be used repeatedly without incurring a significant loss of morphine.

Keyphrases □ Morphine—adsorption onto glassware during fluorometric analysis, effect of siliconization □ Adsorption—morphine onto glassware during fluorometric analysis, effect of siliconization □ Siliconization—of glassware, effect on adsorption of morphine during fluorometric analysis □ Narcotic analgesics—morphine, adsorption onto glassware during fluorometric analysis, effect of siliconization

Several methods including fluorometric (1, 2), flame-ionization (3) and electron-capture (4) GLC, and radioimmunoassay (5) have been used to measure morphine levels in biological tissues. The fluorometric procedure is still the most widely used method because of its simplicity and rapidity.

A major problem in the extraction of morphine from aqueous solutions and biological tissues has been adsorption of the drug onto detergent-cleaned glassware. Wilkinson and Way (3) were unsuccessful in circumventing this problem since they siliconized only the centrifuge tubes. The present paper reports that siliconization of all glassware that comes in contact with aqueous solutions of morphine reduces the loss of morphine by adsorption and thus significantly increases its recovery from aqueous solutions and from biological tissues.

EXPERIMENTAL

Chemicals—1-Butanol[1], chloroform[2], sodium bicarbonate[3], monobasic sodium phosphate[3], dibasic sodium phosphate[3], potassium ferricyanide[3], and potassium ferrocyanide[3] were the highest quality commercially available.

Siliconization of Glassware—The glassware was siliconized by using a water-soluble silicone concentrate[4] and was dried at 100° for 10 min according to the directions on the container.

Procedures—*Recovery of Morphine from Rat Brain*—The procedure of Kupferberg *et al.* (2), slightly modified, was used. Individual rat brain samples were homogenized[5] for 30 sec with 1.5 ml of isotonic saline in a 50-ml polyethylene tube. The shaft of the homogenizer was then washed with 0.5 ml of saline into the centrifuge tube. Different amounts (0.125–0.5 μg) of morphine sulfate contained in equal volumes (50 μl) were added to the homogenate. Each concentration was run in duplicate.

Sodium bicarbonate (0.5 g) and 10% 1-butanol in chloroform (10 ml) were added to the homogenate. The mixture was shaken on a mechanical shaker for 10 min at 200 oscillations/min and then centrifuged at 28,000×*g* for 30 min at 4°. The aqueous layer was aspirated, and the matted tissue was removed with a spatula. A 7-ml aliquot of the organic phase (butanol–chloroform) was transferred to a 15-ml glass-stoppered centrifuge tube containing 1.2 ml of 0.01 *M* hydrochloric acid; the tube was gently inverted 30 times and then centrifuged for 10 min at 2000 rpm at 4°.

One milliliter of the acid phase was removed and added to 1 ml of phosphate buffer (pH 8.5), and this mixture was oxidized with 0.1 ml of potassium ferricyanide–ferrocyanide reagent (2). The fluorescence of the solution was measured at 440 nm after excitation at 250 nm on a spectrophotofluorometer[6].

Recovery of Morphine from Aqueous Solution—The assay procedure used for the brain tissue was also used to determine recovery of morphine sulfate (0.125–0.5 μg) from aqueous solutions.

RESULTS AND DISCUSSION

A linear relationship existed between the amount (0.125–0.5 μg in the original sample) of morphine sulfate used and the relative fluorescence intensity. A similar relationship existed after morphine was extracted from aqueous solutions or rat brain homogenates to which morphine sulfate had been added. When all glassware was siliconized, the average recoveries of morphine from the water standards and brain tissues, excluding aliquot losses, were 52.6 ± 1.9 (n = 5) and 46.5 ± 2.0% (SE) (n = 4), respectively (Table I). Similarly, the recoveries of morphine, including aliquot losses, were 90.0 and 79.4%, respectively. When none of the glassware was siliconized, the recovery from the rat brain, including aliquot losses, was only 26.3%.

The major loss of morphine occurred when the volumetric flasks used to prepare stock solutions and dilutions of morphine were not siliconized.

Table I—Effect of Siliconization on Recovery of Morphine[a]

Number of Times Glassware Was Used	Fluorescence Intensity for 0.5 μg of Morphine		Recovery from Water, %	Recovery from Rat Brain, %
	Absolute	%		
1	140	100.0	47.0	39.5
2	125	89.2	47.3	38.6
3	110	78.4	46.2	36.5
4	82	58.4	46.9	32.9
0[b]	225	—	52.6	46.5

[a] All glassware was siliconized except for the volumetric flasks used for making stock solutions of morphine. [b] Represents values when all glassware was siliconized.

The absolute fluorescence units for 0.5 μg of morphine fell from 225 to 140, a decrease of 38% (Table I).

Repeated use of glassware also decreased the absolute fluorescence intensity of morphine. The silicone coating is probably lost during the cleaning procedure, resulting in a loss of morphine due to its adsorption to the glass. Table I shows the fluorescence intensities for morphine recovered from aqueous solutions and from brain homogenates when glassware was used four consecutive times after siliconization. The glassware was cleaned with laboratory detergents and deionized water prior to each experimental run.

The recovery of morphine from the water standard or aqueous solution was not affected significantly by repeated use of glassware, but it was lower than when all glassware was siliconized before use. The recovery of morphine from rat brain samples decreased with each successive use of the glassware. Thus, both the absolute recovery and the extraction recovery were reduced when all glassware was not siliconized. This result could be seen by the decrease in the slope of the calibration curves (Table I). A net loss of 10, 20, and 40% of morphine was observed during the second, third, and fourth use, respectively, of the same glassware. No loss of morphine was observed when nonsiliconized pipets were used to transfer butanol–chloroform extract containing morphine, indicating that adsorption losses occurred only when morphine was present in the aqueous solution.

In conclusion, the present study shows that significant loss of morphine onto glassware can occur. This adsorption loss can be minimized by siliconization of all glassware that comes in contact with aqueous solutions of morphine. Since the slope of the calibration curve declines with successive use of the glassware, the sensitivity of the method decreases. Therefore, to minimize adsorption losses, all glassware should be siliconized each time morphine is to be analyzed in aqueous solutions and tissue samples.

Binding of Pyridine Derivatives to Cytochrome P-450

JERRY L. BORN ˣ and DAVID VAUGHN *

Abstract □ The spectral binding constants, K_s, of pyridine, methylpyridine, and dimethylpyridines were determined. The K_s values of the compounds were discussed in terms of mechanisms of possible bonding to cytochrome P-450.

Keyphrases □ Pyridine and derivatives—spectral binding to cytochrome P-450, constants determined □ Spectral binding—pyridine and derivatives to cytochrome P-450, constants determined □ Binding, spectral—pyridine and derivatives to cytochrome P-450, constants determined □ Cytochrome P-450—spectral binding to pyridine and derivatives, constants determined

Cytochrome P-450, a terminal oxidase responsible for the hydroxylation of many drugs and organic compounds (1, 2), exhibits two distinct types of spectral binding curves when the difference spectra are recorded in the presence of "substrates." Type I binding curves are thought to result from the interaction of a substrate with the enzyme at a site associated with hydroxylation (3), resulting in a perturbation of the enzyme that produces a difference spectrum with a peak in the 390-nm region and a trough in the 420-nm region (4). The binding of type II substrates involves the interaction of nonbonding electrons with the heme site (5–8), producing difference spectra with a peak in the 420-nm region and a trough at approximately 390 nm (4).

Many type II binding compounds have been identified including aliphatic alcohols, primary aliphatic and aromatic amines, pyridine, and metyrapone[1], the potent inhibitor of cytochrome P-450 (2). Water recently was proposed as the sixth ligand of the heme site with four ligands from the porphyrin ring and the other ligand from a sulfhydryl group (5). The nonbonding electrons of pyridine are thought to result in the displacement of water from the heme site, resulting in a pyridine-coordinated cytochrome P-450. This work describes the determination of the spectral binding constants for a series of methylpyridines.

EXPERIMENTAL

Adult male rats were injected with 80 mg/kg ip of phenobarbital sodium for 3 consecutive days, fasted for 24 hr, and then sacrificed by decapitation. The liver was removed, washed with 0.25 *M* sucrose, and then homogenized in 10 volumes of 0.25 *M* sucrose using a Potter–Elvehjem glass tube and a polytef [2] pestle. The homogenized material was centrifuged for 15 min at 10,000×*g*, and the supernate was removed and centrifuged at 100,000×*g* for 1 hr to produce a microsomal pellet. The microsomal pellet was resuspended in 0.15 *M* KCl and recentrifuged at 100,000×*g*. This microsomal pellet was then resuspended in 0.05 *M* tromethamine buffer (pH 7.4), and the protein was adjusted to 1 mg/ml by the method of Lowry (9).

Difference spectra were recorded by placing 3 ml of the protein solution in both the sample and reference cells and then recording the baseline using a double-beam spectrophotometer[3] equipped with a scattered transmission accessory. After the baseline was established, 3-μl portions of substrate dissolved in tromethamine buffer were added to the sample cell and successive spectra were recorded. When the solubility of the substrate in tromethamine buffer was low, spectroanalyzed methanol was utilized to dissolve the compounds in the buffer.

The spectral binding constant, K_s, was determined by substituting the difference between the maximum and minimum absorbance in the spectrum for initial velocity in the classical enzyme substrate models (10).

The pyridine compounds were distilled prior to use, and their purity was checked by GLC.

Table I—Comparison of Spectral Binding Constants (K_s) for Pyridine and Methylpyridines

Compound	K_s	Relative Activities	pKa of Conjugate Acid[a]
Pyridine	1.46×10^{-3}	1	5.3
2-Methylpyridine	6.15×10^{-3}	0.24	5.95
3-Methylpyridine	0.353×10^{-3}	4.14	5.85
4-Methylpyridine	0.166×10^{-3}	8.8	6.10
2,6-Dimethylpyridine	1.95×10^{-3}	0.75	6.72
2,4-Dimethylpyridine	0.945×10^{-3}	1.54	6.8
2,5-Dimethylpyridine	3.7×10^{-3}	0.39	6.55
3,4-Dimethylpyridine	0.089×10^{-3}	16.4	6.61
3,5-Dimethylpyridine	0.16×10^{-3}	9.13	6.34

[a] N. Ikekana, Y. Sato, and T. Maeda, *Pharm. Bull.*, 2, 205 (1954).

RESULTS AND DISCUSSION

Three distinct factors should influence the binding of methylpyridines to the heme site: the basicity of the compound, the steric factors involved with the approach of the methylpyridines to the heme site, and the hydrophobic bonding of the methyl groups to the site as proposed by Jefcoate *et al.* (7). The instability of 2-methylpyridine and 2,6-dimethylpyridine complexes with formyl-substituted hemins (11) was attributed to steric inhibition of bonding, as was the instability of the boron trifluoride–2-methylpyridine complex (12). If the nonbonding electrons of pyridine are involved with coordination with the heme site of cytochrome P-450, introduction of a methyl group on the 2-position of pyridine should result in less binding of the compound to the heme site.

Table I shows the spectral binding constants for some methyl-substituted pyridines, the relative activities of the compounds as binders to cytochrome P-450, and the pKa values. The results support the concept of the nonbonding electrons of pyridine interacting with the heme site. In each case investigated, the activity of 2-methylpyridines was uniformly low. 2-Methylpyridine was approximately one-fourth as active as pyridine, and the activities of 2,4-dimethylpyridine and 2,5-dimethylpyridine were significantly lower than those of their parent compounds, 4-methylpyridine and 3-methylpyridine, respectively, indicating the importance of having an unsubstituted 2-position on the pyridine ring for maximal binding.

The discovery that 2,6-dimethylpyridine had a greater activity than 2-methylpyridine was unexpected and may be due to its basicity (pKa 6.72). The activity of 2,6-dimethylpyridine cannot be explained by a direct interaction between the nonbonding electrons and the heme site and may result from the transfer of electrons from the nitrogen to the heme site through a molecule of water.

A plot of log K_s for the 3- and 4-substituted pyridines against the pKa for the compounds shows a linear relationship between pKa and the binding activity ($r = 0.9817$). While this information cannot preclude the possibility of hydrophobic bonding, it strongly suggests that the basicity of the nitrogen is the dominant binding force in this series of compounds.

The consistently high activities of 4-methylpyridines suggests that appropriately substituted 4-pyridines may be potent binders of cytochrome P-450, a possibility now under investigation in these laboratories.

Determination of Dextrorphan in Plasma and Evaluation of Bioavailability of Dextromethorphan Hydrobromide in Humans

GOLLAMUDI RAMACHANDER [x], FLORENCE D. WILLIAMS, and JANE FRANCES EMELE

Abstract □ A method is described for the estimation of dextrorphan, a metabolite of dextromethorphan, in plasma. The bioavailability of dextromethorphan hydrobromide after 30 mg po, as measured by the concentration of total (free and conjugated) dextrorphan in the plasma, was determined in six human volunteers with this procedure.

Keyphrases □ Dextrorphan—fluorometric analysis, human plasma □ Dextromethorphan hydrobromide—bioavailability evaluated using fluorometric analysis of dextrorphan in human plasma □ Fluorometry—analysis, dextrorphan in human plasma □ Bioavailability—dextromethorphan hydrobromide evaluated using fluorometric analysis of dextrorphan in human plasma □ Antitussives—dextromethorphan hydrobromide, bioavailability evaluated using fluorometric analysis of dextrorphan in human plasma

Dextromethorphan hydrobromide, a widely accepted, nonnarcotic antitussive agent, is a common ingredient in many cough–cold preparations. Despite its clinical use for over two decades, a method for estimating its plasma levels in humans has not been published. Presently available analytical methods lack the sensitivity needed to determine its plasma levels after oral administration of the maximum permissible over-the-counter dose of 30 mg[1] (1).

The metabolism of dextromethorphan has been studied in several species (2–6). Following oral administration, this drug is rapidly metabolized; the principal metabolites are the *O*-demethylated product dextrorphan and its glucuronide and sulfate ester conjugates. In humans, dextrorphan [(+)-3-hydroxy-*N*-methylmorphinan], (+)-3-hydroxymorphinan, and traces of the unmetabolized drug were found in urine after oral administration of the drug (6). Enzymatic hydrolysis of urines from patients administered dextromethorphan yielded 40–50% of the drug and metabolites, mostly in the form of glucuronide and sulfate conjugates[1].

Because the blood levels of unmetabolized dextromethorphan were low, another approach was to measure the levels of the major metabolites. Dextrorphan was estimated in plasma and urine by paper chromatography (7), colorimetric determination of the methyl orange complex (8), and radiotracer techniques (9). These methods suffer from inherent disadvantages such as a lack of sensitivity and cumbersome operation. This report describes a sensitive and more convenient method for the determination of plasma levels of dextrorphan and its conjugates. Its applicability to bioavailability studies in humans also is demonstrated.

EXPERIMENTAL

Plasma Levels of Dextrorphan and Its Conjugates—Plasma (3.0 ml) was transferred into a glass-stoppered erlenmeyer flask (25 ml). The pH was adjusted to 5.5 with 3.0 *N* acetic acid, and an enzyme solution[2] (0.2 ml) containing 30,000 units of β-glucuronidase and 10,000 units of arylsulfatase was added. The flask was stoppered and incubated at 37° for 2 hr. The incubate was brought to room temperature, and the pH of the contents was adjusted to 9.5 by the addition of a saturated solution of sodium carbonate (0.6 ml).

Spectroscopically pure ethyl acetate (15 ml) was then pipetted into the flask, and the contents were shaken for 20 min on a mechanical shaker. The mixture was transferred quantitatively into a 30-ml centrifuge tube, and the extract was separated by centrifuging at 3000 rpm for 15 min. Then an aliquot (12 ml) of the supernate was transferred into a stoppered 50-ml erlenmeyer flask containing 3.0 ml of 1.0 *N* HCl, and

Determination of Dextrorphan in Plasma and Evaluation of Bioavailability of Dextromethorphan Hydrobromide in Humans

GOLLAMUDI RAMACHANDER [x], FLORENCE D. WILLIAMS, and JANE FRANCES EMELE

Abstract □ A method is described for the estimation of dextrorphan, a metabolite of dextromethorphan, in plasma. The bioavailability of dextromethorphan hydrobromide after 30 mg po, as measured by the concentration of total (free and conjugated) dextrorphan in the plasma, was determined in six human volunteers with this procedure.

Keyphrases □ Dextrorphan—fluorometric analysis, human plasma □ Dextromethorphan hydrobromide—bioavailability evaluated using fluorometric analysis of dextrorphan in human plasma □ Fluorometry—analysis, dextrorphan in human plasma □ Bioavailability—dextromethorphan hydrobromide evaluated using fluorometric analysis of dextrorphan in human plasma □ Antitussives—dextromethorphan hydrobromide, bioavailability evaluated using fluorometric analysis of dextrorphan in human plasma

Dextromethorphan hydrobromide, a widely accepted, nonnarcotic antitussive agent, is a common ingredient in many cough–cold preparations. Despite its clinical use for over two decades, a method for estimating its plasma levels in humans has not been published. Presently available analytical methods lack the sensitivity needed to determine its plasma levels after oral administration of the maximum permissible over-the-counter dose of 30 mg[1] (1).

The metabolism of dextromethorphan has been studied in several species (2–6). Following oral administration, this drug is rapidly metabolized; the principal metabolites are the *O*-demethylated product dextrorphan and its glucuronide and sulfate ester conjugates. In humans, dextrorphan [(+)-3-hydroxy-*N*-methylmorphinan], (+)-3-hydroxymorphinan, and traces of the unmetabolized drug were found in urine after oral administration of the drug (6). Enzymatic hydrolysis of urines from patients administered dextromethorphan yielded 40–50% of the drug and metabolites, mostly in the form of glucuronide and sulfate conjugates[1].

Because the blood levels of unmetabolized dextromethorphan were low, another approach was to measure the levels of the major metabolites. Dextrorphan was estimated in plasma and urine by paper chromatography (7), colorimetric determination of the methyl orange complex (8), and radiotracer techniques (9). These methods suffer from inherent disadvantages such as a lack of sensitivity and cumbersome operation. This report describes a sensitive and more convenient method for the determination of plasma levels of dextrorphan and its conjugates. Its applicability to bioavailability studies in humans also is demonstrated.

EXPERIMENTAL

Plasma Levels of Dextrorphan and Its Conjugates—Plasma (3.0 ml) was transferred into a glass-stoppered erlenmeyer flask (25 ml). The pH was adjusted to 5.5 with 3.0 *N* acetic acid, and an enzyme solution[2] (0.2 ml) containing 30,000 units of β-glucuronidase and 10,000 units of arylsulfatase was added. The flask was stoppered and incubated at 37° for 2 hr. The incubate was brought to room temperature, and the pH of the contents was adjusted to 9.5 by the addition of a saturated solution of sodium carbonate (0.6 ml).

Spectroscopically pure ethyl acetate (15 ml) was then pipetted into the flask, and the contents were shaken for 20 min on a mechanical shaker. The mixture was transferred quantitatively into a 30-ml centrifuge tube, and the extract was separated by centrifuging at 3000 rpm for 15 min. Then an aliquot (12 ml) of the supernate was transferred into a stoppered 50-ml erlenmeyer flask containing 3.0 ml of 1.0 *N* HCl, and

[1] B. A. Koechlin and F. Rubio, work cited in Ref. 1.

[2] Glusulase, Endo Laboratories, Garden City, NY 11530.

the drug and its metabolites were extracted into the acid by shaking the mixture for 20 min.

The aqueous layer was separated using a 50-ml separator, and its fluorescence was measured in a fluorescence spectrophotometer[3]. The fluorescence and excitation wavelengths were 310 and 280 nm, respectively, and the slit dials were set to give a bandpass of 8 nm for excitation and of 5 nm for fluorescence. The concentrations of the drug and its metabolites in the sample were read from a calibration curve whose validity was determined by including three or four known concentrations of dextrorphan added to normal human plasma with each series of unknowns.

Bioavailability Studies in Humans—Six healthy male volunteers, 27–32 years old, received 30 mg po of dextromethorphan hydrobromide in a syrup (10 ml) after an overnight fast. Blood samples were drawn from the antecubetal vein into heparinized tubes immediately prior to and at 15 and 30 min and 1, 2, and 4 hr after drug administration. Plasma was separated by centrifuging at 3000 rpm for 20 min, and an aliquot was assayed by the described procedure.

RESULTS AND DISCUSSION

A calibration curve was constructed by plotting the fluorescence intensity against the concentration of dextrorphan added to drug-free plasma. Regression analysis of the least-squares line fitting the data points provided an equation for the curve as $y = 0.2658x + 3.728$ ($r = 0.9956$), where y represents fluorescence units and x is nanograms of dextrorphan per milliliter of plasma. The recovery of known amounts of dextrorphan added to human plasma was 70%. To determine the precision of the method, eight plasma samples spiked with 400 ng of dextrorphan/ml and four samples containing 600 ng of dextrorphan/ml were analyzed in duplicate over 6 months. The coefficients of variation at these two concentrations were 8 and 4%, respectively.

The fluorescence characteristics of dextrorphan and dextromethorphan in 1.0 *N* hydrochloric acid are rather similar. The fluorescence and excitation wavelengths of dextrorphan are 310 and 280 nm, respectively; for dextromethorphan, they are 305 and 270 nm, respectively.

The fluorescence spectrum of dextrorphan extracted from plasma was identical with that of dextrorphan in 1.0 *N* HCl. Some interference by the unmetabolized drug and possibly other minor metabolites could be expected in the measurement of dextrorphan levels. However, the contribution to fluorescence by the unmetabolized drug would be negligible in this method because extracts from plasma of humans administered dextromethorphan hydrobromide exhibited fluorescence spectra characteristic of dextrorphan but not dextromethorphan. Furthermore, since dextromethorphan is metabolized rapidly and extensively upon oral administration, the amount present in the extracts would be very low.

Plasma Levels in Humans—The average plasma levels ($\pm SE$) of dextrorphan and its conjugates following 30 mg po of dextromethorphan hydrobromide to six volunteers at 15, 30, and 60 min were 21.3 ± 6.7, 107.3 ± 44.6, and 368.0 ± 71.2 ng/ml, respectively. The peak level was 381.3 ± 56.9 ng/ml at 2 hr and it declined thereafter, reaching 262.7 ± 43.3 ng/ml at 4 hr. Almost all of the dextrorphan was present in the form of conjugates. This finding was confirmed by analyzing the plasma samples from one of the six volunteers, with and without enzymatic hydrolysis. Whereas hydrolysis gave rise to concentrations ranging from 26 to 380 ng/ml, none of the unhydrolyzed samples contained measurable levels of the unconjugated drug or metabolites.

It may be concluded that this method is applicable to the determination of the bioavailability of dextromethorphan hydrobromide in humans.

Effects of 3,4-Dimethoxyphenethylamine Derivatives on Monoamine Oxidase

WILLIAM J. KELLER [x] and GARY G. FERGUSON

Abstract □ The cactus alkaloid 3,4-dimethoxyphenethylamine and its naturally occurring *N*-methylated homologs inhibited the deamination of tyramine and tryptamine by rat brain monoamine oxidase. In contrast, the β-hydroxylated derivatives of this series failed to inhibit the action of monoamine oxidase on both tyramine and tryptamine.

Keyphrases □ 3,4-Dimethoxyphenethylamine and *N*-methyl homologs—effect on monoamine oxidase-catalyzed deamination of tyramine and tryptamine □ Monoamine oxidase—deamination of tyramine and tryptamine, effect of 3,4-dimethoxyphenethylamine and *N*-methyl homologs □ Tyramine—monoamine oxidase-catalyzed oxidative deamination, effect of 3,4-dimethoxyphenethylamine and *N*-methyl homologs □ Tryptamine—monoamine oxidase-catalyzed deamination, effect of 3,4-dimethoxyphenethylamine and *N*-methyl homologs □ Enzymes—monoamine oxidase, deamination of tyramine and tryptamine, effect of 3,4-dimethoxyphenethylamine and *N*-methyl homologs □ Structure–activity relationships—3,4-dimethoxyphenethylamine and *N*-methyl homologs, effect on monoamine oxidase-catalyzed deamination of tyramine and tryptamine

The present study was directed at observing the effects of 3,4-dimethoxyphenethylamine (I) and its *N*-methyl homologs on rat brain monoamine oxidase, using both tyramine and tryptamine as substrates. The results of these experiments were contrasted with those obtained with the β-hydroxy derivatives of the same series. The al-

the drug and its metabolites were extracted into the acid by shaking the mixture for 20 min.

leged mind-altering effects produced by ingesting cacti containing one or more of the test compounds could be partially explained by data generated from this investigation.

BACKGROUND

Many members of the Cactaceae produce and accumulate various derivatives of I. Compound I was detected in several species of *Trichocereus* (1–3), *Echinocereus merkeri* Hildm. (4), *Pelecyphora aselliformis* Ehrenberg (5), *Stetsonia coryne* (SD.)-Br. and R. (3), and *Lophophora williamsii* (Lem.) Coult. (6). *N*-Methyl-3,4-dimethoxyphenethylamine (II) was identified as a natural product (2) and was isolated from numerous cacti (4, 5, 7–15). The *N,N*-dimethyl derivative of I has a more restricted distribution in nature, having been originally isolated from extracts of *E. merkeri* (4) and subsequently found to be present in *Coryphantha greenwoodii* H. Bravo (14) and *Ariocarpus scapharostrus* Bodeker (15).

N-Methylated homologs of 3,4-dimethoxy-β-hydroxyphenethylamine are particularly abundant in the cactus genus *Coryphantha*. Macromerine [2-hydroxy-2-(3,4-dimethoxyphenyl)-*N,N*-dimethylethylamine] occurs naturally in *C. macromeris* (Engelm.) Lem. (16) and several other *Coryphantha* species (10, 11, 17).

Normacromerine [2-hydroxy-2-(3,4-dimethoxyphenyl)-*N*-methylethylamine] was isolated from *C. macromeris* (Engelm.) Br. and R. var. *runyonii* L. Benson (18) and two other *Coryphantha* species (13, 14), *Dolichothele longimamma* (DC.) Br. and R. (19), and a legume, *Desmodium tiliaefolium* G. Don. (20). The parent compound of this series is not a natural product.

L. williamsii and the various *Trichocereus* species are hallucinogenic because of their mescaline content. The other previously mentioned cacti are suspected of containing psychoactive substances because of various folkloric tales. Recently, the monoamine oxidase inhibitory activity of 4-methoxylated phenethylamines was used in an attempt to explain the purported pharmacological activity of cactus plants containing these compounds (21). The hypothesis was expanded when a series of β-hydroxylated 4-methoxyphenethylamines was observed to inhibit selectively enzymatic oxidative deamination of tyramine but not tryptamine (22).

EXPERIMENTAL

Synthesis—Compound I hydrochloride[1] was available commercially and served as the starting point for the *N*-methylation reactions that yielded the other two members of this series. Compound II hydrochloride, mp 132–134° [lit. (4) mp 134–136°], was synthesized by reacting I with 36% formaldehyde[2] followed by a sodium borohydride reduction of the Schiff-base intermediate. Refluxing equimolar quantities of II, 36% formaldehyde, and 88% formic acid[3] gave *N,N*-dimethyl-3,4-dimethoxyphenethylamine (III) hydrochloride, mp 193–194° [lit. (4) mp 193–196°].

Racemic 3,4-dimethoxy-β-hydroxyphenethylamine (IV) hydrochloride, mp 170–171° [lit. (23) mp 170–171°], *N*-methyl-3,4-dimethoxy-β-hydroxyphenethylamine (V) hydrochloride, mp 115–116° [lit. (18) mp 115–117°], and *N,N*-dimethyl-3,4-dimethoxy-β-hydroxyphenethylamine (VI) hydrochloride, mp 161–162° [lit. (23) mp 161–162°], were produced by a Houben–Hoesch condensation of veratrole[3] with aminoacetonitrile hydrochloride[4], *N*-methylaminoacetonitrile hydrochloride[4], and *N,N*-dimethylaminoacetonitrile hydrochloride[4], respectively, followed by a reduction of the ketone intermediate with sodium borohydride.

Warburg Studies—As an evaluation of possible monoamine oxidase inhibition, the effects of the compounds on the oxidation of tyramine and tryptamine hydrochlorides by rat brain mitochondria were investigated. Brain mitochondria (containing monoamine oxidase) were prepared from albino Wistar female rats, 150–200 g, according to the method of Brody and Bain (24). Monoamine oxidase activity was determined in the presence and absence of the respective compounds by conventional manometric techniques (25)[5].

In the manometric determinations, the main compartment of the Warburg flasks contained 0.8 ml of a 0.1 *M* buffered solution of the compound studied (or buffer), 1 ml of mitochondrial suspension (representing 500 mg wet weight of original brain tissue), and sufficient 0.01 *M* phosphate buffer (pH 7.4) to make a total volume of 2.7 ml. All aliquots for a given run were taken from the same mitochondrial preparation. The side arm of each flask contained 0.3 ml of 0.1 *M* tyramine or tryptamine hydrochloride. After the flasks were allowed to equilibrate for 15 min at 37°, the manometer valves were closed and the side arm contents of each were tipped in.

Manometers were set at 150 mm, and readings were taken at 15-min intervals for 90 min. Values for the 90-min reaction period were obtained for each flask and were multiplied by the respective flask constants after adjusting for changes in the thermobarometer. The total microliters of oxygen uptake for each flask was thus obtained.

Reference flasks, using 0.05 *M* isocarboxazid (0.8 ml) as the monoamine oxidase inhibitor, were employed as already described and were used for comparison.

Statistical Analysis—The mean and standard error were determined for each control or treated group. Values thus obtained were compared, using the difference between the means and the standard error of the difference between the means for the respective control-treated pairs of groups. The Student *t* test was applied to the results, and the probability was determined (p values of less than 0.05 were considered significant).

RESULTS AND DISCUSSION

Data from Warburg studies revealed that I–III produced significant ($p < 0.05$) inhibition of rat brain monoamine oxidase when tyramine and tryptamine were used as substrates. Conversely, the β-hydroxylated derivatives of this series (IV–VI) had little effect on the enzymatic oxidative deamination of tyramine and tryptamine. These results were validated by the activity exhibited by reference isocarboxazid (Table I).

Substrate selectivity was observed with an *N*-methylated series of 4-methoxy-β-hydroxyphenethylamines, with each member inhibiting the action of monoamine oxidase on tyramine but not on tryptamine (22). The same series of compounds without the β-hydroxy group inhibited monoamine oxidase with respect to both tyramine and tryptamine. Johnston (26) found that there are at least two forms of monoamine oxidase in rat brain, while Tabakoff *et al.* (27) suggested that separate interacting sites exist in brain monoamine oxidase for the binding of phenethylamines and for compounds possessing an indole nucleus. With this information, it was proposed that the presence of a β-hydroxy group in the 4-methoxyphenethylamine moiety interferes with the binding of

[5] Precision Warburg apparatus, Precision Scientific Co.

these derivatives with the active site and/or isozyme responsible for the oxidation of tryptamine (22). From these suppositions, it appears that a 3,4-dimethoxyphenethylamine nucleus with a β-hydroxy group cannot properly bind with the active site and/or isozyme associated with both tyramine and tryptamine oxidation.

The monoamine oxidase inhibitory activity of 4-methoxyphenethylamine derivatives has been used to explain the folkloric uses of *D. longimamma* as a psychoactive "peyote" cactus (19). Macromerine and normacromerine are the major alkaloids in *C. macromeris* var. *runyonii* (11), and this cactus was reported to be psychoactive (16, 28). Vogel *et al.* (29) concluded that macromerine and normacromerine were not responsible for the psychoactivity, since they produced no effects on the conditioned avoidance response in rats. Since macromerine and normacromerine are devoid of monoamine oxidase inhibitory activity, there appears to be no correlation between the presence of these compounds and the purported psychoactivity of *C. macromeris* var. *runyonii*.

Harley-Mason (30) predicted that an abnormal methylation of dopamine and/or norepinephrine *in vivo* could produce I or IV. Of these compounds, I received wide attention because of its detection in the urine of schizophrenics (31). Later studies revealed that urinary excretion of I is not unique to schizophrenia (32) and that administration of this compound to humans produces no psychological changes (33, 34). However, the ingestion of cacti containing I and/or its *N*-methyl derivatives together with indirectly acting amines such as synephrine could alter behavior by inhibiting monoamine oxidase and thus potentiating the effects of the indirectly acting amines. This may be the case with the supposedly psychoactive *C. macromeris* var. *runyonii*. Although the major alkaloids do not inhibit monoamine oxidase, this cactus does contain two known monoamine oxidase inhibitors, *N*-methyl-4-methoxyphenethylamine and II, together with several indirectly acting amines (11). This situation may also contribute to the well-documented hallucinogenic activity of the mescaline-containing cacti.

[a] The percentages of the alkaloids were based on the dried seedless capsules.

quantitative results on the alkaloid content of *P. orientale* L.[1] are reported.

BACKGROUND

P. orientale L. is a perennial wild poppy growing in the north and northwest of Iran at 2000–2500 m above sea level. The height of the plant is 30–70 cm (occasionally 1 m), bearing one to four flowering stems and usually four, rarely six, pale-orange petals with no marking above the base. The petals distinguish *P. orientale* L. from *P. bracteatum* Lindl. and *P. pseudo-orientale* Fedde. In addition, *P. orientale* L. lacks bracts while the other two species have bracts.

P. orientale L. is the only species in section oxytona that can be regarded as truly alpine, though it also grows at low altitudes with *P. pseudo-orientale* Fedde. in moist, sheltered areas. It blooms in late June at low elevations, but flowering continues until early September at high altitudes and on open slopes.

Three species of section oxytona were classified according to their haploid chromosome numbers: *P. bracteatum* Lindl., $n = 7$; *P. orientale* L., $n = 14$; and *P. pseudo-orientale* Fedde., $n = 21$ (6).

Extensive chemical studies in section oxytona revealed that *P. bracteatum* Lindl. contained thebaine (1, 3) or thebaine along with alpinigenine (2, 7, 8). *P. pseudo-orientale* Fedde. contained isothebaine as a major alkaloid and orientalidine, bracteolin, salutaridine, Or_1, Or_2, PO-4, alborine (PO-5), and aryapavine as minor alkaloids (4). Some workers found oripavine in *P. orientale* L. (9, 10), while others reported the same alkaloid in *P. bracteatum* Lindl. (11). These results suggest that the previous alkaloid accounts are unreliable with respect to species determination (6).

To clarify present uncertainties, the alkaloid contents of the capsules of *P. orientale* L., collected from Shuran, Zinjinab, Siah Cheshmeh, Khalkhal, and Guleh Khaneh, were isolated and studied.

EXPERIMENTAL[2]

A small portion (about 100 mg) of individual capsules collected from each region was ground, moistened with ammonia, and extracted exhaustively with chloroform (5 × 5 ml) at room temperature. The solvent was evaporated, and the residue was chromatographed [TLC, silica gel, ethyl acetate–methanol–ammonia (85:10:5)]. The spots were detected first under the UV lamp and then were developed with Dragendorf reagent.

For semiquantitative analysis, the remaining individual capsules, which were chemically similar by TLC and were collected from the same geographical source, were mixed to obtain about 50 g of dried material. These capsules were powdered so that all of the material possessed a mesh size not greater than 0.5 mm. The powder was moistened with ammonia, macerated with 200 ml of chloroform overnight at room temperature, and filtered. This procedure was repeated three more times. The chloroform was evaporated under reduced pressure, and the residue was treated with dilute acetic acid (20%, 20 ml) and filtered. The residue was then washed with water (20 ml).

The combined aqueous solutions were made alkaline with ammonia and extracted with chloroform (4 × 25 ml). The organic layer was dried (sodium sulfate), filtered, and evaporated to give the crude total alkaloids. The crude extract was subjected to preparative TLC [silica gel, ethyl acetate–methanol–ammonia (85:10:5)], and each alkaloid was eluted with chloroform–methanol (80:20). The solvent was evaporated and weighed to determine the percentage of alkaloid. The residue was crystallized from an appropriate solvent and characterized (see *Results and Discussion* and Table I).

RESULTS AND DISCUSSION

The following alkaloids were isolated by TLC and characterized.

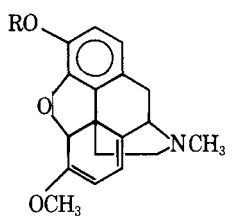
1. Oripavine (I): R_f 0.36, mp 201–203° (ethanol) [lit. (4, 9) mp 201–203°], mixed melting point with an authentic sample 201–203°; NMR (deuterochloroform): δ 6.50 (broad s, 2H, aromatic), 5.90–5.63 (broad s, 1H, OH), 5.50 (d, 1H, H-7 or 8), 5.23 (s, 1H, H-5), 5.0 (d, 1H, H-8 or 7), 3.56 (s, 3H, CH_3O), and 2.43 (s, 3H, NCH_3) ppm; $[\alpha]_D^{20}$ −216.9° (c = 3.44, $CHCl_3$) [lit. (9) $[\alpha]_D^{20}$ −211.8°]; UV_{max} (ethanol): 283 (log ε 3.90) nm; *m/e*: 297 (M^+).

Anal.—Calc. for $C_{18}H_{19}NO_3$: C, 72.73; H, 6.39; N, 4.71. Found: C, 72.85; H, 6.41; N, 4.65.

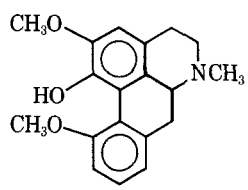
The reaction of oripavine with diazomethane in methanol–ether afforded, in quantitative yield, thebaine (II), mp 193° (ethanol), mixed melting point with an authentic sample 193° (1). The spectral data (IR, UV, NMR, and mass) were identical with an authentic sample.

2. Thebaine (II): R_f 0.36, mp 193° (ethanol) [lit. (1) mp 193°], mixed melting point with an authentic sample 193°. The spectral data (IR, UV, NMR, and mass) were identical with an authentic sample.

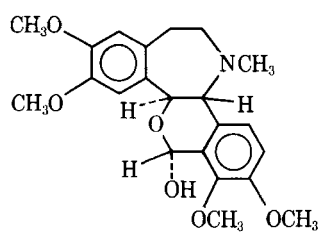
3. Isothebaine: R_f 0.43, mp 203–204° [lit. (4, 12) mp 203–204°], mixed melting point with an authentic sample 203–204°; NMR ($CDCl_3$): δ 7.63 (broad s, 1H, OH), 7.30–6.70 (m, 3H, aromatic), 6.53 (s, 1H, H-3), 3.88 (s, 3H, OCH_3), 3.82 (s, 3H, OCH_3), and 2.47 (s, 3H, NCH_3) ppm (13); $[\alpha]_D^{20}$ +275° (c = 1.47, $CHCl_3$) [lit. (14) $[\alpha]_D^{21}$ 281 ± 10°]; UV_{max} (methanol): 270



I: R = H
II: R = CH_3



III



IV

[1] The plant was identified by P. Goldblatt, Missouri Botanical Garden, St. Louis, Mo. Herbarium samples were deposited in the Missouri Botanical Garden. (Also see Ref. 6.)

[2] Melting points were taken with a Koffler hot-stage microscope and are uncorrected. UV spectra were recorded on a Varian Techtron 635 instrument. NMR spectra were taken with a Varian A60A instrument. Mass spectra were recorded on a CH5 spectrometer at Aryamehr Technical University. IR spectra were obtained with a Leitz Model III spectrograph. The optical rotation was measured with a Perkin-Elmer polarimeter model 241 instrument. For qualitative detection of alkaloids, the silica gel was DC-Karten SI F from Riedel (West Germany).

(log ϵ 4.16) nm; *m/e*: 311 (M^+).

Anal.—Calc. for $C_{19}H_{21}NO_3$: C, 73.31; H, 6.75; N, 4.50. Found: C, 73.21; H, 6.81; N, 4.58.

4. Alpinigenine: R_f 0.68, mp 185–186° [lit. (2) mp 185–186°], mixed melting point with an authentic sample 185–186°; $[\alpha]_D^{20}$ +230.2° (c = 1.59, $CHCl_3$) [lit. (15) $[\alpha]_D^{20}$ +286°]. The spectral data (IR, UV, NMR, and mass) were identical with an authentic sample (2).

The alkaloid profiles of *P. orientale* L. from different geographical areas suggested classification according to five different chemotypes (Table I). Oripavine was either a sole alkaloid of the poppy (chemotype A) or a single major alkaloid (chemotypes B, C, D, and E).

A literature survey (16) revealed that alpinigenine was not found previously in *P. orientale* L.

Physiologically Active Substances from Marine Sponges IV: Heterocyclic Compounds

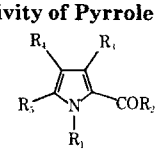
JOGINDER S. CHIB [x], MARTIN F. STEMPIEN, Jr., JACK T. CECIL, GEORGE D. RUGGIERI, and ROSS F. NIGRELLI

Abstract □ Several guanidine compounds were synthesized by the reaction of acid chlorides of thiophene and furan with guanidines. Some of these compounds showed antibiotic and cytotoxic activities. Series of pyrrole compounds were synthesized and found to have significant antibiotic activity.

Keyphrases □ Pyrroles, various—synthesized, evaluated for antibacterial activity □ Furans, various—synthesized, evaluated for antibacterial and cytotoxic activity □ Thiophenes, various—synthesized, evaluated for antibacterial and cytotoxic activity □ Heterocycles—various pyrroles, furans, and thiophenes synthesized, evaluated for antibacterial and cytotoxic activity □ Antibacterial activity—various pyrroles, furans, and thiophenes evaluated □ Cytotoxic activity—various furans and thiophenes evaluated □ Structure–activity relationships—various pyrroles, furans, and thiophenes evaluated for antibacterial and cytotoxic activity

Several biologically significant pyrrole (1) and indole (2, 3) derivatives have been isolated from marine sources. Most of these compounds show pronounced antibiotic activity. During the present investigation of the sponge *Agelas* sp. (JC-6), a new brominated pyrrole derivative incorporating the guanidine moiety was isolated and showed significant activity against *Escherichia coli* (4). This natural product also showed cytotoxicity against KB carcinoma cells (5). This report describes the synthesis of several pyrrole, furan, and thiophene analogs and their physiological activities.

Table I—Antibiotic Activity of Pyrrole Derivatives



Compound	R_1	R_2	R_3	R_4	R_5	Activity against *E. coli*[a]
XII*a*	H	OCH_3	H	H	H	+++
XII*b*	H	NH_2	H	H	H	++++
XII*c*	CH_3	OCH_3	H	H	H	+++
XII*d*	CH_3	NH_2	H	H	H	++++
XII*e*	H	H	H	Br	H	++++
XII*f*	H	OCH_3	H	Br	H	++++
XII*g*	H	OCH_3	H	Br	Br	++
XII*h*	H	OCH_3	Br	Br	Br	+

[a] After paper disk incubation, zones of bacterial inhibition were measured: +, <15 mm; ++, 15–18 mm; +++, 18–22 mm; and ++++, >22 mm.

EXPERIMENTAL[1]

Chemistry—Since 2-aminopyrimidine (I*a*) and guanidine (II*a*) have a common structural unit, it was considered desirable to synthesize furan, thiophene, and pyrrole derivatives incorporating this structural feature.

[1] All melting points are uncorrected. Microanalyses were performed by Schwarzkopf Microanalytical Laboratories, Woodside, N.Y. IR spectra were recorded on a Perkin-Elmer 421 grating IR spectrometer, NMR spectra were recorded on a Varian A-60A spectrometer, and mass spectra were recorded on a Hitachi Perkin-Elmer spectrometer 107.

(log ϵ 4.16) nm; *m/e*: 311 (M^+).

Anal.—Calc. for $C_{19}H_{21}NO_3$: C, 73.31; H, 6.75; N, 4.50. Found: C, 73.21; H, 6.81; N, 4.58.

4. Alpinigenine: R_f 0.68, mp 185–186° [lit. (2) mp 185–186°], mixed melting point with an authentic sample 185–186°; $[\alpha]_D^{20}$ +230.2° (c = 1.59, $CHCl_3$) [lit. (15) $[\alpha]_D^{20}$ +286°]. The spectral data (IR, UV, NMR, and mass) were identical with an authentic sample (2).

The alkaloid profiles of *P. orientale* L. from different geographical areas suggested classification according to five different chemotypes (Table I). Oripavine was either a sole alkaloid of the poppy (chemotype A) or a single major alkaloid (chemotypes B, C, D, and E).

A literature survey (16) revealed that alpinigenine was not found previously in *P. orientale* L.

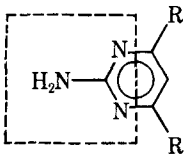
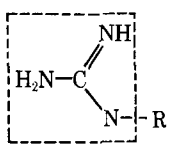
The reaction of guanidine (II*a*) with 2-furoyl chloride (III) and 2-thiophenecarbonyl chloride (IV) afforded intractable mixtures. However, the reaction of *N,N*-dimethylguanidine (II*b*) with these two carbonyl chlorides yielded crystalline derivatives V and VI.

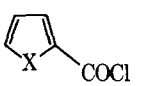
2-Aminopyrimidine (I*a*) and 2-amino 4,6-dimethylpyrimidine (I*b*), on similar treatment with these acid chlorides, resulted in products VII–X. The 5-acylated derivative (XI) was also isolated as a minor component from the reaction of 2-aminopyrimidine (I*a*) and thiophene carbonyl chloride (IV). This product resulted from the nucleophilic substitution at C-5 of the pyrimidine ring. Attempts to synthesize similar derivatives from pyrrole were unsuccessful.



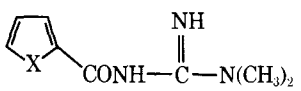
I*a*: R = H
I*b*: R = CH_3



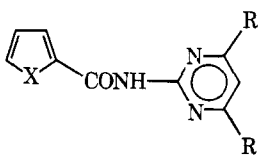
II*a*: R = H_2
II*b*: R = $(CH_3)_2$



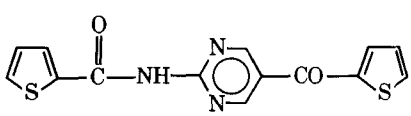
III: X = O
IV: X = S



V: X = O
VI: X = S



VII: X = O, R = H
VIII: X = O, R = CH_3
IX: X = S, R = H
X: X = S, R = CH_3



XI

Biological Activity—The thiophene and furan derivatives were tested for antibacterial (4) and cytotoxic activities (6).

In testing the activity against *Escherichia coli*[2] (ATCC 4157), 0.005 g of the compound was applied to a paper disk and incubated for 18 hr at 35°. Zones of bacterial inhibition were measured. Compounds IX and X showed 15–18-mm inhibition zones; VI showed an 18–22-mm zone.

Cytotoxic activity was tested against human oral epidermoid carcinoma KB cells (ATCC CCL 17) by adding 25–50 μg/ml of the test compound to the growth medium. Compounds V and VI showed 50% cytotoxicity.

Furan derivatives V, VII, and VIII were inactive against *E. coli*, but V was fairly cytotoxic. Thiophene derivatives VI, IX, and X showed moderate activity against *E. coli.*, but only VI exhibited cytotoxic activity.

Several pyrrole derivatives were also examined for antibacterial activity (Table I) and were considerably more potent as antibacterial agents than the corresponding thiophene and furan compounds. Although it is difficult to establish rigorously any structure–activity relationship, the introduction of halogen progressively decreased the antibiotic activity in this series.

General Method for Synthesis of Furan and Thiophene Derivatives—A solution of 2-furoyl chloride (III) (3.92 g, 0.03 mole) was added dropwise, at room temperature over 2 hr, to a suspension of 2-amino-4,6-dimethylpyrimidine (I*b*) (3.69 g, 0.03 mole) and triethylamine (3.03 g, 0.03 mole) in 150 ml of acetonitrile. The reaction mixture was heated to 65° for 0.5 hr and then kept overnight at room temperature. The precipitated triethylamine hydrochloride was filtered off, and the filtrate was evaporated under reduced pressure.

The residue was dissolved in chloroform (150 ml), washed with sodium bicarbonate solution (50 ml, 1 *N*) and water (2 × 100 ml), and dried over magnesium sulfate. Removal of the solvent afforded a dark viscous material. Repeated crystallization from ethyl acetate gave VIII.

Analytical and spectral data for these compounds are given in Table II.

Pyrrole derivatives were synthesized by literature methods (7–9).

Preparation of Spin-Labeled Opiates: Morphine and Codeine

JAMES A. CELLA [x] and JAMES A. KELLEY

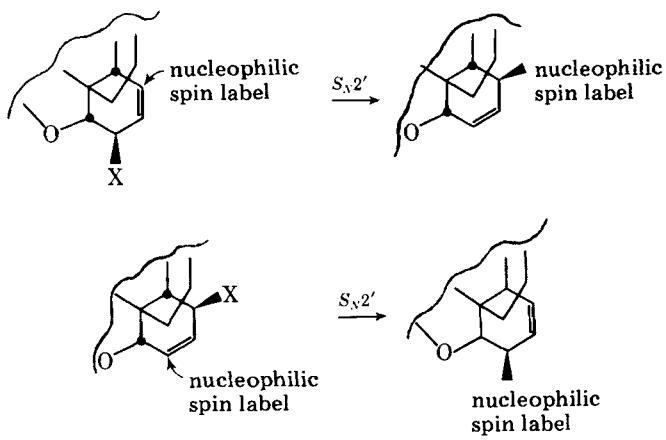
Abstract □ The preparation of 6-spin-labeled codeine and morphine is described. Treatment of either 6-chlorocodide or 8-bromocodide with 4-amino-2,2,6,6-tetramethylpiperidino-1-oxyl free radical in dimethylformamide afforded 6-spin-labeled codeine. Similar treatment of 6-chloromorphide afforded 6-spin-labeled morphine. Exclusive formation of the 6-isomer in these reactions is explained by halide-ion-catalyzed isomerization of the 6-halo opiate to the 8-halo isomer followed by a normal S_N2' displacement of the halogen. Both spin-labeled compounds displayed weak *in vivo* analgesic activity and did not bind appreciably to receptors in brain homogenate.

Keyphrases □ Spin-labeled opiates—morphine and codeine labeled in 6-position, effect on binding to brain receptors and analgesic activity □ Morphine—spin labeled in 6-position, effect on binding to brain receptors and analgesic activity □ Codeine—spin labeled in 6-position, effect on binding to brain receptors and analgesic activity □ Opiates—morphine and codeine, spin labeled in 6-position, effect on binding to brain receptors and analgesic activity □ Analgesics, narcotic—morphine and codeine, spin labeled in 6-position, effect on binding to brain receptors and analgesic activity

In numerous attempts to identify and characterize the opiate receptor (1–4), the binding characteristics of pharmacologically active and inactive isomers were compared or the reduced agonist binding in the presence of antagonists was noted using radiolabeled opiates with high specific activity. The spin label method (5, 6) is an attractive alternative to the radioisotope method for studying this drug–receptor interaction *in vitro*, since it obviates the need for separating bound from unbound drug. A preliminary report demonstrated the feasibility of this method (7).

DISCUSSION

Essential to the success of this approach is the requirement that the nitroxide label not constitute a significant perturbation to the interaction of the drug with its receptor. As such, the label should be attached to a pharmacologically unimportant position in the drug molecule. For purposes of stability, the label should be covalently attached to the drug *via* a linkage resistant to hydrolytic enzymes and inert to aqueous media at physiological pH. Finally, it is desirable, although not essential, that the labeled drug possess biological activity similar to that of the parent drug.



Scheme I

With these requirements in mind, the preparation of spin-labeled derivatives of morphine and codeine suitable for the *in vitro* study of the interaction of these drugs with possible receptors was attempted.

The hydroxyl group at the 6-position of morphine and codeine appeared to offer a suitable point for attachment for the spin label, particularly in view of the relative unimportance of this position in the pharmacological activity of these drugs (8, 9). However, the steric inaccessibility of this alcohol (10, 11) precluded all attempts to alkylate at this position[1]. Consequently, the mode of reaction was reversed by using a nucleophilic spin label to displace halogen from a 6- or 8-halo opiate (Scheme I). In the isomeric halocodides and morphides, the halogen atom has a beta configuration (*syn* to the ethylamino bridge) and is displaced by nucleophiles exclusively from the beta side in an S_N2' fashion (13). Following this precedent, the reaction of the isomeric halocodides and morphides with 4-amino-2,2,6,6-tetramethylpiperidino-1-oxyl free radical (I) as a route to spin-labeled morphine and codeine was investigated.

Reaction of I with 8-bromocodide (IIa) in dimethylformamide afforded the expected 6-spin-labeled codeine (IIIa) in 23% yield (Scheme II).

[1] A recent report (12) described the selective methylation of morphine at the 6-position *via* its dipotassium salt. A similar approach to introduce a spin label at the 6-position was attempted; however, with alkylating agents much larger than methyl, reaction occurred exclusively at the 3-position.

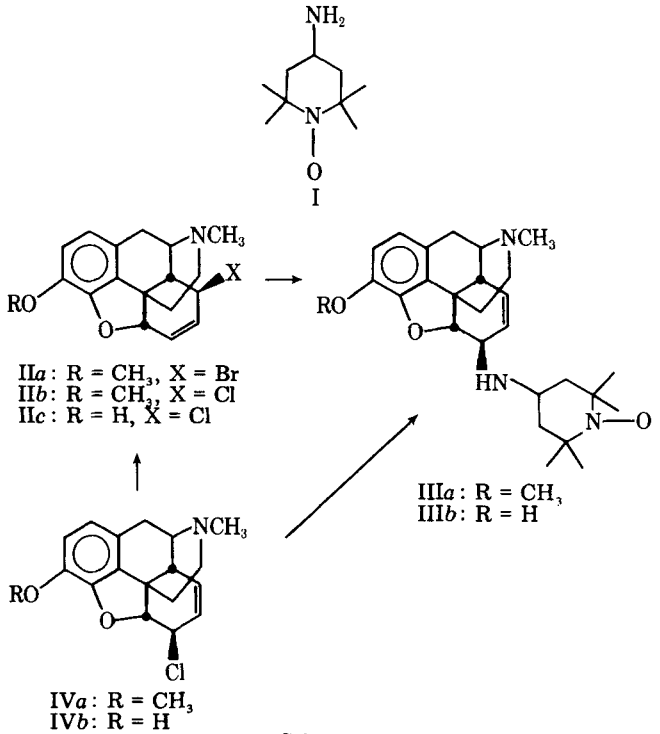
Reaction of I with 8-bromocodide (IIa) in dimethylformamide afforded the expected 6-spin-labeled codeine (IIIa) in 23% yield (Scheme II).

[1] A recent report (12) described the selective methylation of morphine at the 6-position *via* its dipotassium salt. A similar approach to introduce a spin label at the 6-position was attempted; however, with alkylating agents much larger than methyl, reaction occurred exclusively at the 3-position.



Scheme II

Similar reaction of I with 6-chlorocodide (IV*a*) produced a spin-labeled codeine in 10% yield identical in all respects to III*a* (see *Experimental*). This apparently anomalous result is accounted for by the fact that isomerization of IV*a* to the more stable 8-chlorocodide (II*b*) occurred more rapidly than did the reaction with the spin label[2]. While IV*a* did not isomerize to II*b* under the reaction conditions in the absence of added nucleophile, addition of a small amount of chloride ion to the mixture resulted in rapid conversion of IV*a* to II*b*. Thus, chloride ion generated from the initial reaction of I with IV*a* catalyzed the isomerization of the halogen to the 8-position. The 8-chlorocodide thus produced underwent a normal S_N2' reaction to produce III*a*.

In an analogous fashion, 6-chloromorphide (IV*b*) reacted with I to yield 22% of 6-spin-labeled morphine (III*b*). The structure of III*b* was confirmed by elemental and spectral analyses (see *Experimental*) and its conversion to III*a* on methylation with diazomethane. Interestingly, the chloromorphide recovered from this reaction was exclusively the 8-isomer, II*c*, verifying that halogen migration occurred during the reaction.

The low yields of spin-labeled products were due mostly to low conversions (yields based on recovered starting materials were substantially higher). An evident side reaction was the elimination of hydrogen halide from the halo opiates to produce dehydromorphine and codeine derivatives. No attempt was made to ascertain whether the dehydro derivatives were the 5,7- or 6,8-diene isomers.

The spin-labeled derivatives prepared in this study showed only marginal *in vivo* analgesic activity in the Eddy hot plate test (14, 15) and displayed weak *in vitro* binding to receptors in brain homogenate (P_2 fraction) by the method of Klee and Streaty (16). There was a small but noticeably greater potency of the labeled morphine over the labeled codeine[3]. These results, while disappointing, do not preclude the use of these compounds for studying *in vitro* binding to receptors in brain homogenate or subfractions thereof by the spin label method.

EXPERIMENTAL[4]

General—When reaction mixtures were to be separated and analyzed, a 1.9-m (6-ft), 2-mm i.d. glass column packed with 3% OV-17 on 60–80-mesh Gas Chrom Q[5] was operated in the 200–240° range with a helium carrier gas flow of 25 ml/min. The gas chromatograph was interfaced to the mass spectrometer by a permeable silicone rubber membrane separator maintained at 240°. Samples that were pure or not amenable to GLC–mass spectrometry were introduced directly into the mass spectrometer ion source *via* a direct insertion probe with a sample heater, which was varied from ambient to 250° depending on the compound.

For electron-impact ionization, the following conditions were employed: ion source, 180°; ionizing current, 0.15 mamp; and electron energy, 70 ev. Chemical-ionization mass spectra were obtained with an ion source pressure of 0.35 torr methane[6] (instrument grade, 99.7%), an ionizing current of 0.15 mamp, and an electron energy of 75 ev.

4-Amino-2,2,6,6-tetramethylpiperidino-1-oxyl (I) was obtained commercially[7]. 6-Chlorocodide, 8-bromocodide, and 6-chloromorphide were prepared as described previously (17, 18).

Preparation of 6-Spin-Labeled Codeine (III*a*)—*Reaction of I with II*a—A mixture of 2.8 g (7.8 mmoles) of II*a*, 1.5 g (9.0 mmoles) of I, and 1.1 g (8.0 mmoles) of solid potassium carbonate in dimethylformamide (20 ml) was heated in an oil bath at 90–95° for 4.5 hr. The cooled mixture was diluted with an equal volume of water, and the resulting suspension was extracted with 3 × 50 ml of ether. The combined ether extracts were washed with brine and then dried (sodium sulfate). Evaporation of solvent afforded 2.2 g of a residue, which was chromatographed on 75 g of silica gel[8] (100–200 mesh) and eluted with a chloroform–methanol gradient. Fractions were monitored by TLC [silica gel, chloroform–methanol (10:1)].

The first component eluted was a dehydrocodeine derivative; mass spectrum: *m/e* 281 (M^+, 100), 280 (67.3), 266 (45.0), 264 (11.9), 238 (14.9), 223 (11.4), 220 (11.9), 165 (17.8), 152 (19.3), and 41 (13.4). The second component eluted was III*a*, which was obtained as an oil. The oil crystallized from ether–petroleum ether as a tan solid, 970 mg (27%), mp 66–70°; mass spectrum: *m/e* 150, 453 (M + H[9], 15.3), 452 (M, 1.0), 437 (2.9), 420 (2.3), 379 (51.0), 366 (9.3), 323 (7.9), 308 (15.0), 282 (100), 266 (10.9), 192 (36.7), and 154 (25.4); methane chemical-ionization mass spectrum: *m/e* 250, 454 (M + 2H, 68.5), 453 (M + H, 100), 438 (8.3), 436 (13.4), 379 (13.2), and 282 (10.9). The electron spin resonance spectrum of III*a* exhibited the usual three-line pattern for a nitroxide derived from tetramethylpiperidine.

Anal.—Calc. for $C_{27}H_{38}N_3O_3$: C, 71.65; H, 8.46; N, 9.28. Found: C, 71.44; H, 8.51; N, 9.31.

*Reaction of I with IV*a—A mixture of 2.5 g (7.8 mmoles) of IV*a*, 1.5 g (9.0 mmoles) of I, and 1.1 g (8.0 mmoles) of potassium carbonate in dimethylformamide (20 ml) was heated in an oil bath at 110° for 8 hr. By using the same workup and chromatographic procedures described in the preceding experiment, 383 mg (10%) of III*a* was obtained as a tan solid, mp 65–68°. That this substance was indeed III*a* was ascertained by the following comparisons. The IR and mass spectra were superimposable on the spectra obtained for III*a*. TLC on silica gel using six different solvent systems demonstrated identical R_f values for this substance and III*a*. Finally, the melting point of this substance was not depressed on admixture with III*a*.

Isomerization of IV*a* to II*b*—A solution of 50 mg of IV*a* in 1 ml of dimethylformamide was heated at 90° for 1.5 hr. The IR spectrum of the recovered material was identical to that of the starting material. This experiment was repeated except that 20 mg of sodium chloride was added to the mixture. The IR spectrum of the recovered material indicated that 50% of IV*a* had isomerized to II*b*.

Preparation of 6-Spin-Labeled Morphine (III*b*)—A solution of 700 mg (2.4 mmoles) of IV*b* and 855 mg (5 mmoles) of I in dimethylformamide (10 ml) was stirred in an oil bath at 90–100° for 20 hr. The cooled solution was diluted with 25 ml of chloroform, and the resultant solution was extracted with 3 × 25 ml of 3 *N* NaOH. The combined aqueous extracts were adjusted to pH 8.5 by the slow addition of cold, concentrated hydrochloric acid, and the resultant slurry was extracted with 3 × 50 ml of chloroform. The combined chloroform extracts were dried (sodium sulfate), and the solvent was removed to afford 2.6 g of a residue containing dimethylformamide.

The residue was chromatographed on 75 g of silica gel (100–200 mesh) using a chloroform–methanol gradient. Fractions were monitored by TLC

[2] Piperidine displaces halide ion from the haloopiates much more rapidly than I (13).

[3] In the *in vitro* assay (16), III*a* was about 1/500th and III*b* about 1/350th as potent as morphine.

[4] Melting points were determined on a Thomas-Hoover melting-point apparatus. IR spectra were recorded on a Beckman IR-5A spectrophotometer using potassium chloride pellets or sodium chloride solution cells. Mass spectra were obtained on a Hewlett-Packard 5982 A gas chromatograph–mass spectrometer system. Electron spin resonance spectra were recorded on a Varian E-9 spectrometer.

[8] W. R. Grace.

[9] The much more intense than expected M + 1 peak was probably due to hydrogen radical abstraction from water adsorbed in the ion source or glass capillary sample holder by the even electron molecular ion species (19, 20).

[silica gel, chloroform–methanol (4:1)]. Compound III*b*, 960 mg (22%), was obtained as tan flakes from ether–petroleum ether, mp 212–215° dec.; mass spectrum: *m/e* >150, 439 (M + H, 18.9), 438 (M^+, 1.8), 406 (3.8), 365 (74.8), 352 (27.9), 309 (15.3), 268 (100), 266 (12.8), 178 (33.5), and 154 (27.3); methane chemical-ionization mass spectrum: *m/e* >250, 440 (M + 2H, 100), 439 (M + H, 71.1), 424 (27.1), 422 (22.6), 365 (8.3), and 268 (24.0). The electron spin resonance spectrum of III*b* exhibited the usual three-line pattern for a nitroxide derived from tetramethylpiperidine.

Anal.—Calc. for $C_{26}H_{37}N_3O_3$: C, 71.20; H, 8.27; N, 9.58. Found; C, 71.12; H, 8.11; N, 9.81.

A small portion of this material was treated with excess ethereal diazomethane. Evaporation of solvent and excess diazomethane afforded a crystalline residue identical to III*a* in all respects (melting point, IR, TLC, and mass spectral data).

Also isolated from column chromatography of this reaction mixture was a component having an R_f similar to that of IV*b*. This substance was identified as II*c* by its melting point and IR and mass spectra. No IV*b* was eluted from the column.

Radiochemical GLC Assay for Nortriptyline in Human Plasma

ARTHUR LOH, FRANCIS R. ZULESKI, and FREDERICK J. Di CARLO [x]

Abstract □ A novel method was developed for the assay of nortriptyline in plasma. After nortriptyline was extracted, it was acetylated with ^{3}H-acetic anhydride; the quantity of ^{3}H-acetylnortriptyline in the extract was determined by radiochemical GLC. The method is capable of assaying 5 ng of nortriptyline/ml of plasma. The instrumentation was assembled from commercially available components.

Keyphrases □ Nortriptyline—radiochemical GLC analysis, human plasma □ Radiochemical GLC- -analysis, nortriptyline in human plasma □ GLC, radiochemical—analysis, nortriptyline in human plasma □ Antidepressants—nortriptyline, radiochemical GLC analysis in human plasma

The assay of nortriptyline in plasma is important because its clinical activity is related to plasma levels (1, 2), which vary remarkably among individuals even at steady state (3, 4). GLC methods for nortriptyline assay (5–7), although capable of detecting 10–20 ng of compound/ml of plasma, are frequently inadequately sensitive for measuring the levels attained after a single dose. A recently published TLC assay is considerably less sensitive, having a lower limit of 50 ng/ml (8).

Zuleski *et al.* (9) developed a nortriptyline assay method which involved extracting the compound from plasma by a modification of the method of Hammer and Brodie (10), acetylating it with ^{14}C-acetic anhydride, separating acetylnortriptyline by TLC, locating this derivative by radiochromatogram scanning, removing it from the plate, and counting it by scintillation spectrometry. The present approach was more direct. Radiochemical GLC was performed directly following derivatization with ^{3}H-acetic anhydride. Thus, ^{3}H-acetylnortriptyline was resolved and counted simultaneously. Despite the wide applicability of radiochemical GLC to drug metabolism studies, this method has been developed only in a few laboratories (11–13). The present investigation shows that the method can be developed using commercially available components.

Radiochemical GLC Assay for Nortriptyline in Human Plasma

ARTHUR LOH, FRANCIS R. ZULESKI, and FREDERICK J. Di CARLO [x]

Abstract □ A novel method was developed for the assay of nortriptyline in plasma. After nortriptyline was extracted, it was acetylated with ^{3}H-acetic anhydride; the quantity of ^{3}H-acetylnortriptyline in the extract was determined by radiochemical GLC. The method is capable of assaying 5 ng of nortriptyline/ml of plasma. The instrumentation was assembled from commercially available components.

Keyphrases □ Nortriptyline—radiochemical GLC analysis, human plasma □ Radiochemical GLC- -analysis, nortriptyline in human plasma □ GLC, radiochemical—analysis, nortriptyline in human plasma □ Antidepressants—nortriptyline, radiochemical GLC analysis in human plasma

The assay of nortriptyline in plasma is important because its clinical activity is related to plasma levels (1, 2), which vary remarkably among individuals even at steady state (3, 4). GLC methods for nortriptyline assay (5–7), although capable of detecting 10–20 ng of compound/ml of plasma, are frequently inadequately sensitive for measuring the levels attained after a single dose. A recently published TLC assay is considerably less sensitive, having a lower limit of 50 ng/ml (8).

Zuleski *et al.* (9) developed a nortriptyline assay method which involved extracting the compound from plasma by a modification of the method of Hammer and Brodie (10), acetylating it with ^{14}C-acetic anhydride, separating acetylnortriptyline by TLC, locating this derivative by radiochromatogram scanning, removing it from the plate, and counting it by scintillation spectrometry. The present approach was more direct. Radiochemical GLC was performed directly following derivatization with ^{3}H-acetic anhydride. Thus, ^{3}H-acetylnortriptyline was resolved and counted simultaneously. Despite the wide applicability of radiochemical GLC to drug metabolism studies, this method has been developed only in a few laboratories (11–13). The present investigation shows that the method can be developed using commercially available components.

EXPERIMENTAL

Reagents—^{3}H-Acetic anhydride (50 mCi/4.36 mg in 5 ml of dry benzene) was received[1] in a sealed ampul. A 0.05-ml aliquot of this so-

[1] New England Nuclear, Boston, Mass.

lution was transferred quantitatively to a 50-ml volumetric flask with benzene, which had been dried over metallic sodium and then diluted to volume with the same solvent. Air in the neck of the flask was displaced gently with dry nitrogen; the flask was stoppered, sealed with tape, and stored under refrigeration in a bottle containing desiccant (calcium sulfate). The bottle and its contents were allowed to equilibrate to room temperature before opening. After using a portion of the ^{3}H-acetic anhydride solution, the flask was prepared for storage as described.

Nortriptyline hydrochloride was used as received[2]. Reagent grade solvents were used in this study.

Radiochemical GLC—An oven and proportioning temperature controller[3] were connected to a gas proportional counter[4] by a heated glass-lined metal tube. The gas chromatograph was fitted with a 1.83-m × 2-mm i.d. coiled-glass column packed with 20% SE-30 on 80–100-mesh Gas Chrom Q. Oven and injector temperatures were set at 215 and 245°, respectively.

Helium was used as carrier gas at a flow rate of 50 ml/min. The transfer line to the gas proportional counter was maintained at 237°. The hydrogen and propane (quench gas) flow rates were 10 and 2.5 ml/min, respectively. The temperature of the oxidizer and reduction furnace was 750°.

Standard Nortriptyline Solutions—Nortriptyline hydrochloride (11.35 mg) was dissolved in 10 ml of distilled water to produce a free base concentration of 1.0 mg/ml. From this solution, others were prepared in duplicate concentrations of 100, 50, 25, 12.5, and 6.25 ng/ml.

Nortriptyline Extracts and Derivatization—Twelve 2.0-ml aliquots of normal human plasma were placed into 15-ml polyethylene-stoppered conical test tubes. Duplicate standard nortriptyline solutions (1.0 ml) were added to 10 of these tubes, and water (1.0 ml) was added to the other two tubes to serve as blanks. Then 0.5 ml of 1 *N* NaOH was mixed with the contents of each tube.

Each plasma specimen was extracted twice with 5.0 ml of *n*-hexane. Any emulsion was broken by placing the tube into a dry ice–acetone mixture followed by thawing and recentrifugation. The hexane layer was transferred to another tube with an isopentyl alcohol-pretreated pipet (10). The combined hexane extracts were evaporated to dryness with nitrogen, and the residue was dissolved in 0.65 ml of dry benzene. ^{3}H-Acetic anhydride solution, 100 μl, and 0.25 ml of pyridine were added to the benzene solution, which was then mixed thoroughly and incubated at 60° for 1 hr.

After the solvent was evaporated in a water bath at 90°, 2.0 ml of 0.1 *N* NaOH was added and the tube was shaken for a few seconds. Then the solution was placed in a water bath at 95° for 15 min. The solution was cooled to room temperature, and acetylnortriptyline was extracted with two 5.0-ml aliquots of heptane. The combined heptane extracts were evaporated under nitrogen. Then the inner wall of the tube was washed down with heptane, and the solvent was evaporated to dryness. Each residue was dissolved in 50 μl of heptane.

Measurement of ^{3}H-Acetylnortriptyline—Aliquots (10 μl) of each plasma blank and ^{3}H-acetylnortriptyline solution in heptane were injected into the gas chromatograph. The area under each radioactive peak on the chromatograms was measured by planimetry. A standard curve was constructed by plotting mean areas against quantities of nortriptyline (expressed as free base) per milliliter of human plasma.

RESULTS

No peak appeared on chromatograms of "blanks" consisting of plasma and ^{3}H-acetic anhydride. Under the described operating conditions, radiochemical GLC yielded a single peak representing ^{3}H-acetylnortriptyline (Fig. 1). The retention time of this compound was 31.8 min from each plasma extract. A linear standard curve resulted from plotting peak areas against human plasma concentrations of nortriptyline ranging from 3.125 to 50.0 ng/ml. This curve passed through the intercept of the ordinate and abscissa; the peak area per nanogram of nortriptyline was 0.658 cm^2. By preparing the extracted acetylnortriptyline concentrate as described and using only one-fifth of it for assay, the radiochemical GLC method was reliable for levels of nortriptyline down to 5 ng/ml of plasma.

DISCUSSION

The radiochemical GLC assay has advantages over other methodology for nortriptyline in plasma. It is more sensitive than the TLC (8) and GLC (5–7) methods that do not employ radioactivity. Although the radiochemical GLC procedure is no more sensitive than the radiochemical TLC assay (9), it is shorter and more direct. As presently developed, both radioassays can measure nortriptyline levels as low as 5 ng/ml. However, the sensitivity of these and other radioacetylation methods probably can be increased by using acetic anhydride of higher specific activity. The major expansion of radiochemical derivatization assays probably will be in the direction of broadening their application by employing other radiolabeled reagents.

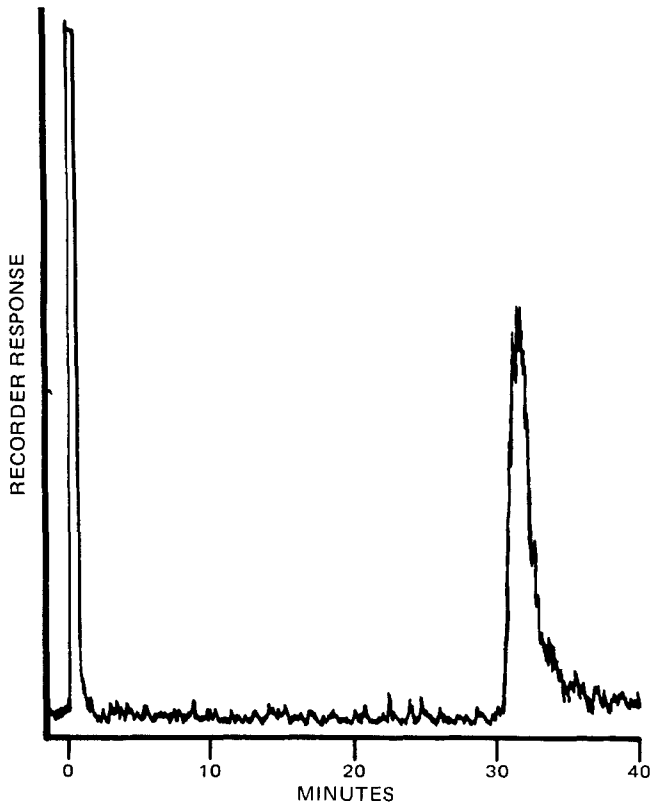

Figure 1—*Radiochemical gas chromatogram of ^{3}H-acetylnortriptyline representing 10 ng of nortriptyline extracted from human blood plasma.*

Pharmacokinetic Evidence for Improved Ophthalmic Drug Delivery by Reduction of Instilled Volume

THOMAS F. PATTON

Abstract □ The bioavailability of topically applied pilocarpine nitrate was studied as a function of instilled volume. As the instilled volume decreased, the fraction of dose absorbed increased. The relationship between fraction absorbed and instilled volume was not direct, but appropriate adjustment of instilled volume and concentration should permit substantial dosage reductions without sacrifice of drug concentration in the eye. The implications of these findings from both a therapeutic and toxicity standpoint are discussed.

Keyphrases □ Pilocarpine nitrate—bioavailability, effect of instilled volume □ Bioavailability—pilocarpine nitrate, effect of instilled volume □ Ophthalmic cholinergics—pilocarpine nitrate, bioavailability, effect of instilled volume

The drainage of an instilled drug solution away from the eye is considerable and can affect its biological activity (1). This drainage is dependent upon the volume instilled and increases linearly with instilled volume over a large range (1). This fact (2, 3) has been incorporated into experimental design. However, the concept of reducing drop size to improve ophthalmic drug delivery has not become widespread, perhaps because the pharmacokinetic advantages of such an approach have not been emphasized.

A study of the dynamics of instilled fluid drainage (1) showed that the miotic activity of pilocarpine was enhanced by administering the same amount of pilocarpine in decreasing volumes. No actual measurements of drug penetration to the interior of the eye were made. More recent studies showed that the bioavailability of ophthalmic drugs was improved by slowing the rate of drainage of instilled drug solutions (4–8). The measurement of drug concentration in the eye following the reduction of instilled volume and the resultant pharmacokinetic parameters were not reported previously.

In a recent study (9), the aqueous chamber drug distribution volume for ophthalmic drugs was calculated, thereby making it possible to define more precisely the pharmacokinetics of topically applied ophthalmic drugs. Therefore, the purpose of the present study is to show that, as the instilled volume of pilocarpine nitrate is decreased, the fraction of dose absorbed increases. As a result, the parameters of instilled volume and drug concentration can be quantitated to provide a desired level of drug in the eye.

EXPERIMENTAL

Pilocarpine Solutions—Pilocarpine nitrate was used as received[1]. Tritiated pilocarpine[2], specific activity 4.1 Ci/mmole, was purified prior to use by evaporation as recommended previously (10). The concentration of pilocarpine nitrate used was 1×10^{-2} *M* in all studies. Solutions were prepared in isotonic pH 6.24 Sorensen phosphate buffer and were filtered but not sterile. Procedures for the preparation of the tritiated solutions were described previously (10).

Methods—Male, New Zealand, albino rabbits, 60–67 days old, were used. Prior to experimentation, the animals were maintained in standard laboratory animal cages and allowed food and water *ad libitum*. During the experiments, all test animals were kept in restraining boxes in the normal upright position. The head was unencumbered so that all normal eye movements were maintained. The animals were unanesthetized in all cases.

The volumes of instilled solutions administered were 5, 10, 15, and 25 μl and were delivered accurately with a microliter syringe[3]. At various times postinstillation (5, 10, 15, 20, 30, 45, 60, 90, and 120 min), rabbits were sacrificed with an overdose of pentobarbital sodium injected into a marginal ear vein. Eyes were immediately rinsed and blotted, and aqueous humor (at least 100 μl) was aspirated from the anterior chamber.

One hundred microliters of aqueous humor was quantitatively transferred[4] to scintillation counting vials[5] containing 5 ml of prerefrigerated liquid scintillation cocktail[6]. After storage in the dark at room temperature for at least 24 hr, samples were counted[7]. These counts were converted to micrograms of pilocarpine per milliliter of aqueous humor using suitable standard and blank corrections.

RESULTS

Aqueous humor concentration–time profiles of pilocarpine for the four instilled volumes are shown in Table I. These data were plotted semilogarithmically, and the terminal slopes were calculated *via* linear regression analysis. From these slopes, the elimination rate constants were calculated. By using the trapezoidal rule with extrapolation to infinity, the areas under the aqueous humor concentration–time profiles were calculated (Table II). The apparent maximum in area under the curve with an instilled volume of 15 μl is currently unexplained. This maximum also was observed in other experiments and will be discussed in more detail later.

Using rabbits of similar size and age, Conrad and Robinson (9) calculated the aqueous humor distribution volume of pilocarpine to be 0.575

ml. When this volume was applied to the data reported here, the fraction of dose absorbed (*F*) for each volume studied, 5, 10, 15, and 25 μl, was 3.01×10^{-2}, 2.23×10^{-2}, 1.92×10^{-2}, and 1.16×10^{-2}, respectively.

DISCUSSION

The smaller the instilled volume, the greater is the fraction of applied dose absorbed. These results were implied previously (1) but were not demonstrated pharmacokinetically. Drainage rate is linear with instilled volume over a fairly wide range (1), but the relationship between fraction absorbed and volume is more complex due to other complicating factors. For example, decreases in the drainage rate (*i.e.*, increasing drug contact time) did not result in proportional increases in aqueous humor levels of drug (7, 8).

This result is true also with the fraction of dose absorbed, as seen from the calculated values. A fivefold decrease in volume results in approximately a threefold increase in fraction absorbed, possibly due to competing routes of drug absorption. For a topically applied drug to reach the aqueous humor, it must penetrate the cornea, but conjunctival or nonproductive absorption also occurs and competes with the cornea for drug uptake (8). Drug absorbed by this nonproductive route is not thought to reach the anterior chamber.

What is apparent from this study is that a considerable decrease in instilled volume coupled with a slight increase in instilled concentration should result in the same amount of drug reaching the interior of the eye as if much larger volumes were administered. A simple calculation illustrates this point. Twenty-five microliters of a 1×10^{-2} *M* pilocarpine nitrate solution resulted in an area under the curve of 60.9 μg min ml^{-1}. The dose administered was 67.82 μg, and the fraction absorbed was 1.16×10^{-2} *M*. If one wishes to match this area with a dose of 5 μl, the following equation allows the calculation to be made:

$$A = \frac{FD}{VK} \qquad \text{(Eq. 1)}$$

or, rearranged:

$$D = \frac{AVK}{F} \qquad \text{(Eq. 2)}$$

The value of *F* for the 5-μl case is 3.01×10^{-2}, and $K = 1.88 \times 10^{-2}$ min^{-1}. The area desired is 60.9 μg min ml^{-1}, and the value for *V* is 0.575 ml (9). The calculated value for *D* is 21.87 μg, which corresponds to a concentration of 1.61×10^{-2} *M*. A 5-μl dose of 1.61×10^{-2} *M* pilocarpine nitrate should result in the same area under the curve as a 25-μl dose of 1.00×10^{-2} *M* pilocarpine nitrate.

Therapeutically, it should be possible, by reducing the instilled volume by a factor of five, to reduce the dose administered by approximately a factor of three without altering drug concentration at the active site. This finding is significant and shows that the doses currently used for ophthalmic drugs are generally much larger than required. Potentially more important, however, are the implications from a toxicity standpoint. In both the 5- and 25-μl cases, only a small fraction of the dose is absorbed into the eye, the remainder being lost by various routes and potentially available to act systemically. By reducing the instilled volume and, hence, substantially decreasing the applied dose, the potential for toxic effects is reduced while drug concentration in the eye is maintained.

By using the data presented here, other combinations of volume and concentration adjustments are possible. Studies are currently in progress to confirm these findings and determine any complicating factors. Any rational approach to the development of ophthalmic dosage regimens should consider the excessive volumes currently used and the advantages from the development of better, small volume delivery systems.

Table II—Elimination Rate Constants and Areas under the Aqueous Humor Concentration–Time Profiles following Instillation of Various Volumes of 1×10^{-2} *M* Pilocarpine Nitrate in Rabbits

Volume Instilled, μl	Dose, μg	*K*, min^{-1}	Area, μg min ml^{-1}
5	13.56	1.88×10^{-2}	37.8
10	27.13	2.05×10^{-2}	51.3
15	40.69	2.13×10^{-2}	63.8
25	67.82	2.25×10^{-2}	60.9

Effect of Ibuprofen on Protein Binding of Warfarin in Human Serum

Keyphrases □ Ibuprofen—effect on protein binding of warfarin, human serum □ Binding—warfarin to serum protein, effect of ibuprofen, humans □ Warfarin—serum protein binding, effect of ibuprofen, humans □ Anti-inflammatory agents—ibuprofen, effect on protein binding of warfarin, human serum □ Anticoagulants—warfarin, serum protein binding, effect of ibuprofen, humans

To the Editor:

Ibuprofen is a widely used anti-inflammatory, which is extensively bound to plasma proteins (1). Studies in rats showed that ibuprofen can displace warfarin from serum protein binding sites and that this displacement causes an increase in the total body clearance of warfarin and in the anticoagulant effect produced by a given concentration of total (free and protein-bound) drug (2).

Theoretical considerations indicate that the displacement of a drug from protein binding sites should be associated with a transient and intermittent increase in the pharmacological effect (3, 4). However, no such potentiation was observed in humans with respect to the anticoagulant effect of warfarin when ibuprofen was administered in doses of up to 2.4 g/day (5). In view of the recent tendency to use even larger doses of ibuprofen for the treatment of inflammatory disease, it was considered advisable to determine the relationship between ibuprofen concentration and protein binding of warfarin in human serum.

Blood was obtained from five healthy adult females who were taking no drugs other than oral contraceptives. Serum was separated and pooled. Racemic ^{14}C-warfarin (1.34 μg/ml) and ibuprofen (0–200 μg/ml) were added, and the free fraction of warfarin was determined in duplicate by equilibrium dialysis (6).

The pooled serum contained 4.18% albumin and 8.46% total protein. The free fraction of warfarin in the absence of ibuprofen was 0.00978, equivalent to 99.022% protein binding. The free fraction increased continuously with the increasing ibuprofen concentration (Fig. 1). At the highest concentration of ibuprofen (about 200 μg/ml), the warfarin free fraction was 0.0198, *i.e.*, twice as large as in the absence of ibuprofen.

It is estimated that the steady-state serum concentration of ibuprofen produced by administration of 600 mg every 6 hr to adult patients is about 30–40 μg/ml (2). At this concentration, ibuprofen increases the warfarin free fraction in human serum by only about 10% so that no significant potentiation of anticoagulant effect should be apparent. However, a doubling of the dose will cause an appreciable displacement of warfarin and may be expected to produce a measurable potentiation of anticoagulant effect.

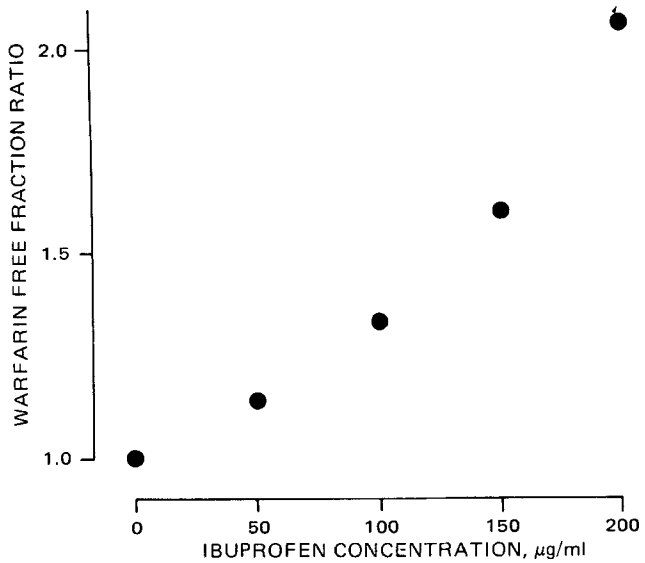

Figure 1—*Effect of ibuprofen on protein binding of warfarin in pooled human serum. Shown is the relationship between the warfarin free fraction ratio (with ibuprofen/control) and the ibuprofen concentration.*

REVIEWS

Introduction to Pharmaceutical Dosage Forms. By HOWARD C. ANSEL. Lea & Febiger, Washington Square, Philadelphia, PA 19106, 1976. 415 pp. 18.5 × 26 cm. Price $22.50.

In this second edition, the organization and content have been extensively revised. References have been updated and take into account the current literature. The purpose of the book still remains to present to "the beginning student introductory concepts of dosage form design, manufacture, and utilization" of drugs, with emphasis given to the drug entities listed in the official compendia. By selecting the route of administration as the framework, the author has succeeded admirably in meeting this purpose.

The content of the revised edition reflects accurately the changes in curricula taking place in schools of pharmacy and in the practice of pharmacy. It will enable the student to integrate easily basic scientific pharmaceutic concepts with current concepts in patient care, thus presenting a refreshing view in a basic pharmaceutics textbook. The book's value is increased by the discussion of such topics as drug standards and good manufacturing practices and by the new appendix chapter which addresses information vital to the beginning pharmacy student.

While the author extends his appreciation to many who have cooperated in this effort, one strong point of the second edition, as of the first, is its uniformity of style.

This reviewer feels somewhat disappointed in the complete exclusion of a discussion of contact lens solutions, which probably differ in dosage form design and use sufficiently from ophthalmic solutions to deserve some recognition. Also somewhat disappointing is the all too brief discussion of radiopharmaceuticals. Nevertheless, it is easy to recommend adoption of this book by those responsible for teaching basic pharmaceutics courses. Furthermore, the book can serve well as a reference source for those in industry and research.

Dispensing of Medication. 8th Ed. Edited by JOHN E. HOOVER. Mack Publishing Co., Easton, PA 18042, 1976. 654 pp. 18 × 26 cm.

This book represents a modern approach to the subject as evidenced by the omission of many chapters dealing solely with the compounding of medications on the industrial level or the type of material presented in "Preparations" courses. Most authors have presented information concerned not only with the fabrication of dosage forms but also with the anatomy and physiology of the body organ systems as well as drug absorption from the various sites. This approach is entirely in keeping with the announced intention of the editor to "aid the patient-oriented pharmacist."

Keeping this intent in mind while reading the text reveals a lapse from time to time. Thus, while an excellent review of bioavailability is presented, one wonders if the dispensing pharmacist who is deeply involved in patient care should expect to receive some direct pointers regarding bioequivalent evaluation of specific products. The chapter on dermatologicals could have presented a clearer description of the effect of ointment bases in percutaneous absorption and the extent that the clinical symptoms determine the selection of dosage form or base in the treatment of dermatologic conditions. One wonders if it is still necessary to belabor the "ideal monodisperse" suspension or to cover the subject of pills.

An excellent balanced approach makes the chapter on parenterals useful to both hospital and industrial pharmacists. If the pharmacist is to monitor parenteral therapy in a rational manner, as suggested by the authors, should not criteria for the use of intravenous administration be provided?

The last chapter, Compounding and Dispensing Information, is over 300 pages and contains a wealth of information on drug interactions and incompatibilities. Unfortunately, a portion of this chapter is not presented in a format that allows the reader to utilize this information to the best advantage. The last 170 pages of this chapter, entitled Specific Compounding and Dispensing Information, is an extremely valuable tool. It presents physical–chemical properties of drugs and drug products by nonproprietary and/or trade names and gives data including incompatibilities, stability, choice of bases, information the pharmacist must consider when dispensing the drug, and information to be given the patient. This type of information should be at every pharmacist's fingertips.

This book represents a valuable addition to the library of the practicing pharmacist, especially one who is interested in ensuring that patients receive proper and optimal pharmaceutical care. The majority of it is well written, concise, and explicit while covering the necessary subjects and should serve the student well as a text.

Pharmacognosy. 7th Ed. By VARRO E. TYLER, LYNN R. BRADY, and JAMES E. ROBBERS. Lea & Febiger, Washington Square, Philadelphia, PA 19106, 1976. 537 pp. 18.5 × 26 cm. Price $21.50.

This book is a revised and updated edition of the single standard textbook for pharmacognosy. It is the only reference suitable for general use by students in pharmacognosy in the United States. The unique position it holds attests to the usefulness of older editions over the past years but precludes comparisons with other books on the same subject.

Most of the book is unchanged from the last edition; new chapters mainly represent rearrangement of material (*e.g.*, Steroids and Peptide Hormones) taken from other sections. Other chapters have been updated, but none is totally rewritten. The drugs included are divided into chapters based upon the chemical (*e.g.*, volatile oils and alkaloids) or therapeutic category (*e.g.*, antibiotics and immunizing agents) classifications. Three chapters at the end contain introductory information on subjects difficult to find in other pharmacy books: Allergens, Poisonous Plants, and Pesticides.

The book has been revised with the expectation of making it more applicable to the "patient-oriented pharmacist." This approach can be detected in the information given regarding cardiac glycosides, in the immunization schedule, and in the list of diseases caused by various microorganisms. This aspect of the revision could have been expanded, because the use given for colchicine is simply "suppressant for gout" and the only use listed for caffeine is "central stimulant," even though the caffeine-containing prescription specialties listed are all used as analgesics. A few misleading statements have remained such as ephedrine "depressing . . . cardiac muscle action" and dextrose as a "fluid . . . replenisher."

The book is recommended as a textbook for all undergraduate pharmacognosy students.

Analytical Profiles of Drug Substances, Vol. 5. Edited by KLAUS FLOREY. Academic, 111 Fifth Ave., New York, NY 10003, 1976. xi + 560 pp. 16 × 23.5 cm. Price $22.50.

This is the fifth in a series of compilations under the sponsorship of the Pharmaceutical Analysis and Control Section of the APhA Academy of Pharmaceutical Sciences. It is the intent of these volumes to make available in a single source important information about drug substances which is scattered through the scientific literature or which may be filed

away in the laboratories of pharmaceutical scientists. Each drug profile provides useful information and data in the following general areas: description, physical properties, synthesis, stability and degradation, metabolism, analysis (for the drug substance, in its dosage forms, and in biological fluids), pharmacokinetics, and literature references. Physical properties include IR, NMR, UV, and mass spectral data, melting point, solubility data, crystal properties, and pK values where applicable. Analytical methods encompass titrimetry, chromatography, colorimetry, spectrophotometry, elemental analysis, and related techniques.

Each profile is presented in a well-organized and systematic manner. Each is introduced by a table of contents, followed in an orderly sequence by individual categories of specifications, and concluded by an extensive listing of quoted references. This compendium is printed clearly and is replete with tables and graphical presentations. Data are readily located and concisely presented with only a minimum of descriptive information. Maximum utilization is made of the available space.

This volume brings to a total of 97 the number of drugs for which profiles have thus far been prepared, including the 18 in Volume 5. These volumes serve well as companion books to the official compendia by presenting a wealth of data that supplement and are not duplicative of material found in the compendia. As noted in the Forward to Volume 1 of this series, the delegates to the 1970 meeting of the United States Pharmacopeial Convention adopted a resolution that consideration be given to the publication of just such a companion compendium. While the USPC did not undertake this project, it is worthy of note that a number of contributors to this series, including its esteemed editor, are, in fact, members of the USP Committee of Revision.

In view of the fact that fewer than 100 drug profiles have appeared in the first five volumes of this series, and with the mandate for USP XX to include all drugs currently official in USP XIX and NF XIV, all drugs added in their annual supplements, some 600 nonofficial drugs selected by the outgoing Subcommittee on Scope of the USP at its final meeting in January 1975, and new drugs marketed since that date, it is obvious that pharmaceutical scientists have their work cut out for them. It is worth repeating here the editor's invitation that: "All those who have found the profiles useful are earnestly requested to contribute a monograph of their own. The editors stand ready to receive such contributions." Hopefully, there will be an overwhelming response to this invitation.

This burgeoning library of "Analytical Profiles" is a must for all who are engaged in pharmaceutical research.

Aromatic and Heteroaromatic Chemistry. Vol. 4. A Specialist Periodical Report. Edited by C. W. BIRD, G. W. H. CHEESEMAN, *et al.* The Chemical Society, Burlington House, London W1V OBN, England, 1976. 513 pp. 14.5 × 22.5 cm. Price £28.00.

This volume comprises an in-depth review of the literature abstracted between July 1974 and June 1975 and covered by volumes 81 and 82 of "Chemical Abstracts." The organization of the report follows the established pattern of previous volumes.

There are 14 chapters written by 15 international scientists who are specialists in their fields. Most of the chapters include an introduction indicating the parameters established by the author(s) and the reviews on the subject published during the time period. A particularly helpful feature is that all literature citations are included as footnotes on the page that contains the abstract, thus eliminating the time consuming and thought-interrupting process of turning to the end of the chapter when a specific reference is desired. Another helpful feature is a complete author index.

The chapter titles include: Ring Systems of Topical Interest, Intermolecular and Intramolecular Cyclization Reactions in Ring Synthesis, Cycloaddition Reactions, Ring Transformations, Electrophilic Substitution on Carbon, Electrophilic Substitution on Heteroatoms, Nucleophilic Substitution, Aromatic Substitution by Free Radicals, Carbenes and Nitrenes, Addition Reactions, Ring Cleavage Reactions, Reactions of Substituents, Porphyrins and Related Compounds, Naturally Occurring Oxygen-ring Compounds, and Other Naturally Occurring Compounds. The volume comprises 513 pages and includes 2750 literature citations.

The book is well illustrated with many chemical structures and reaction mechanisms. These illustrations are numbered sequentially and placed in close proximity to their text reference, thus affording a free flowing continuity which contributes to the overall excellent readability of the material.

This treatise is an extremely well-organized and readable volume and should serve to stimulate fresh approaches in the ever more sophisticated areas of aromatic and heteroaromatic synthetic chemistry. It is recommended to all chemists who are actively involved in synthetic organic chemistry or who wish to be up to date and informed about research activity in aromatic and heteroaromatic chemistry.

Handbook of Analysis of Organic Solvents. By VÁCLAV ŠEDIVEC and JAN FLEK. Halsted, 605 Third Ave., New York, NY 10016, 1976. 455 pp. 16 × 23.5 cm. Price $42.50.

Within this volume the authors have compiled an extensive aggregate of information concerning the chemical and physical properties and the analysis of organic solvents. Following a brief discussion of sampling and drying techniques, procedures are described for the determination of the physical properties and quantitative identification of unknown samples. After a presentation of methods for the analysis of two- and three-component mixtures by physicochemical methods, the basics of GC are described using a general procedure. Relative retention times are given for many common solvents using six different stationary phases.

The second part of the book deals with solvents as individual classes of organic compounds. The most frequently encountered solvents are described in depth, listing synonyms, chemical properties, usual impurities, and azeotropes. Tables containing extensive physical data are included. Detection methods, derivatives, and quantitative procedures are described in detail with corresponding literature references. Three appendixes covering 80 pages include a listing of the boiling points of solvents and their azeotropic mixtures, the major physical properties, and an alphabetical listing of universally used trade names.

This handbook represents a valuable accumulation of a myriad of facts and procedures which will be of use to the analyst, the chromatographer, and the synthetic organic chemist, all of whom frequently require data or techniques to utilize or analyze organic solvents.

The National Formulary and the USP Guide to Select Drugs. Edited by W. M. HELLER, G. K. WURSTER, C. A. DICKIE, and J. W. WHEATLEY. U.S. Pharmacopeial Convention, 12601 Twinbrook Parkway, Rockville, MD 20852, 1976. 295 pp. 10 × 14.5 cm. Price $3.00.

This convenient pocket-size book is intended to be a companion to the official compendia and the USAN Dictionary and is the first compilation of its kind subsequent to the consolidation of the USP and NF. Its purpose is "to highlight those drugs that should receive attention and be used as preferred drugs."

The book contains an alphabetical list of both generic and brand names of effective and useful drugs, with the preferred drugs in boldface type. The entries also contain dosage forms and strength; indication of whether prescription, nonprescription, or DEA controlled; and the pharmacological classification. In addition, there is a cross-index by therapeutic classification.

This book should be useful as a personal prescribing and dispensing guide and as a basic list of preferred drugs for health facilities and various organizations.

REVIEWS

Introduction to Pharmaceutical Dosage Forms. By HOWARD C. ANSEL. Lea & Febiger, Washington Square, Philadelphia, PA 19106, 1976. 415 pp. 18.5 × 26 cm. Price $22.50.

In this second edition, the organization and content have been extensively revised. References have been updated and take into account the current literature. The purpose of the book still remains to present to "the beginning student introductory concepts of dosage form design, manufacture, and utilization" of drugs, with emphasis given to the drug entities listed in the official compendia. By selecting the route of administration as the framework, the author has succeeded admirably in meeting this purpose.

The content of the revised edition reflects accurately the changes in curricula taking place in schools of pharmacy and in the practice of pharmacy. It will enable the student to integrate easily basic scientific pharmaceutic concepts with current concepts in patient care, thus presenting a refreshing view in a basic pharmaceutics textbook. The book's value is increased by the discussion of such topics as drug standards and good manufacturing practices and by the new appendix chapter which addresses information vital to the beginning pharmacy student.

While the author extends his appreciation to many who have cooperated in this effort, one strong point of the second edition, as of the first, is its uniformity of style.

This reviewer feels somewhat disappointed in the complete exclusion of a discussion of contact lens solutions, which probably differ in dosage form design and use sufficiently from ophthalmic solutions to deserve some recognition. Also somewhat disappointing is the all too brief discussion of radiopharmaceuticals. Nevertheless, it is easy to recommend adoption of this book by those responsible for teaching basic pharmaceutics courses. Furthermore, the book can serve well as a reference source for those in industry and research.

Dispensing of Medication. 8th Ed. Edited by JOHN E. HOOVER. Mack Publishing Co., Easton, PA 18042, 1976. 654 pp. 18 × 26 cm.

This book represents a modern approach to the subject as evidenced by the omission of many chapters dealing solely with the compounding of medications on the industrial level or the type of material presented in "Preparations" courses. Most authors have presented information concerned not only with the fabrication of dosage forms but also with the anatomy and physiology of the body organ systems as well as drug absorption from the various sites. This approach is entirely in keeping with the announced intention of the editor to "aid the patient-oriented pharmacist."

Keeping this intent in mind while reading the text reveals a lapse from time to time. Thus, while an excellent review of bioavailability is presented, one wonders if the dispensing pharmacist who is deeply involved in patient care should expect to receive some direct pointers regarding bioequivalent evaluation of specific products. The chapter on dermatologicals could have presented a clearer description of the effect of ointment bases in percutaneous absorption and the extent that the clinical symptoms determine the selection of dosage form or base in the treatment of dermatologic conditions. One wonders if it is still necessary to belabor the "ideal monodisperse" suspension or to cover the subject of pills.

An excellent balanced approach makes the chapter on parenterals useful to both hospital and industrial pharmacists. If the pharmacist is to monitor parenteral therapy in a rational manner, as suggested by the authors, should not criteria for the use of intravenous administration be provided?

The last chapter, Compounding and Dispensing Information, is over 300 pages and contains a wealth of information on drug interactions and incompatibilities. Unfortunately, a portion of this chapter is not presented in a format that allows the reader to utilize this information to the best advantage. The last 170 pages of this chapter, entitled Specific Compounding and Dispensing Information, is an extremely valuable tool. It presents physical–chemical properties of drugs and drug products by nonproprietary and/or trade names and gives data including incompatibilities, stability, choice of bases, information the pharmacist must consider when dispensing the drug, and information to be given the patient. This type of information should be at every pharmacist's fingertips.

This book represents a valuable addition to the library of the practicing pharmacist, especially one who is interested in ensuring that patients receive proper and optimal pharmaceutical care. The majority of it is well written, concise, and explicit while covering the necessary subjects and should serve the student well as a text.

Pharmacognosy. 7th Ed. By VARRO E. TYLER, LYNN R. BRADY, and JAMES E. ROBBERS. Lea & Febiger, Washington Square, Philadelphia, PA 19106, 1976. 537 pp. 18.5 × 26 cm. Price $21.50.

This book is a revised and updated edition of the single standard textbook for pharmacognosy. It is the only reference suitable for general use by students in pharmacognosy in the United States. The unique position it holds attests to the usefulness of older editions over the past years but precludes comparisons with other books on the same subject.

Most of the book is unchanged from the last edition; new chapters mainly represent rearrangement of material (*e.g.*, Steroids and Peptide Hormones) taken from other sections. Other chapters have been updated, but none is totally rewritten. The drugs included are divided into chapters based upon the chemical (*e.g.*, volatile oils and alkaloids) or therapeutic category (*e.g.*, antibiotics and immunizing agents) classifications. Three chapters at the end contain introductory information on subjects difficult to find in other pharmacy books: Allergens, Poisonous Plants, and Pesticides.

The book has been revised with the expectation of making it more applicable to the "patient-oriented pharmacist." This approach can be detected in the information given regarding cardiac glycosides, in the immunization schedule, and in the list of diseases caused by various microorganisms. This aspect of the revision could have been expanded, because the use given for colchicine is simply "suppressant for gout" and the only use listed for caffeine is "central stimulant," even though the caffeine-containing prescription specialties listed are all used as analgesics. A few misleading statements have remained such as ephedrine "depressing . . . cardiac muscle action" and dextrose as a "fluid . . . replenisher."

The book is recommended as a textbook for all undergraduate pharmacognosy students.

Analytical Profiles of Drug Substances, Vol. 5. Edited by KLAUS FLOREY. Academic, 111 Fifth Ave., New York, NY 10003, 1976. xi + 560 pp. 16 × 23.5 cm. Price $22.50.

This is the fifth in a series of compilations under the sponsorship of the Pharmaceutical Analysis and Control Section of the APhA Academy of Pharmaceutical Sciences. It is the intent of these volumes to make available in a single source important information about drug substances which is scattered through the scientific literature or which may be filed

away in the laboratories of pharmaceutical scientists. Each drug profile provides useful information and data in the following general areas: description, physical properties, synthesis, stability and degradation, metabolism, analysis (for the drug substance, in its dosage forms, and in biological fluids), pharmacokinetics, and literature references. Physical properties include IR, NMR, UV, and mass spectral data, melting point, solubility data, crystal properties, and pK values where applicable. Analytical methods encompass titrimetry, chromatography, colorimetry, spectrophotometry, elemental analysis, and related techniques.

Each profile is presented in a well-organized and systematic manner. Each is introduced by a table of contents, followed in an orderly sequence by individual categories of specifications, and concluded by an extensive listing of quoted references. This compendium is printed clearly and is replete with tables and graphical presentations. Data are readily located and concisely presented with only a minimum of descriptive information. Maximum utilization is made of the available space.

This volume brings to a total of 97 the number of drugs for which profiles have thus far been prepared, including the 18 in Volume 5. These volumes serve well as companion books to the official compendia by presenting a wealth of data that supplement and are not duplicative of material found in the compendia. As noted in the Forward to Volume 1 of this series, the delegates to the 1970 meeting of the United States Pharmacopeial Convention adopted a resolution that consideration be given to the publication of just such a companion compendium. While the USPC did not undertake this project, it is worthy of note that a number of contributors to this series, including its esteemed editor, are, in fact, members of the USP Committee of Revision.

In view of the fact that fewer than 100 drug profiles have appeared in the first five volumes of this series, and with the mandate for USP XX to include all drugs currently official in USP XIX and NF XIV, all drugs added in their annual supplements, some 600 nonofficial drugs selected by the outgoing Subcommittee on Scope of the USP at its final meeting in January 1975, and new drugs marketed since that date, it is obvious that pharmaceutical scientists have their work cut out for them. It is worth repeating here the editor's invitation that: "All those who have found the profiles useful are earnestly requested to contribute a monograph of their own. The editors stand ready to receive such contributions." Hopefully, there will be an overwhelming response to this invitation.

This burgeoning library of "Analytical Profiles" is a must for all who are engaged in pharmaceutical research.

Aromatic and Heteroaromatic Chemistry. Vol. 4. A Specialist Periodical Report. Edited by C. W. BIRD, G. W. H. CHEESEMAN, *et al.* The Chemical Society, Burlington House, London W1V OBN, England, 1976. 513 pp. 14.5 × 22.5 cm. Price £28.00.

This volume comprises an in-depth review of the literature abstracted between July 1974 and June 1975 and covered by volumes 81 and 82 of "Chemical Abstracts." The organization of the report follows the established pattern of previous volumes.

There are 14 chapters written by 15 international scientists who are specialists in their fields. Most of the chapters include an introduction indicating the parameters established by the author(s) and the reviews on the subject published during the time period. A particularly helpful feature is that all literature citations are included as footnotes on the page that contains the abstract, thus eliminating the time consuming and thought-interrupting process of turning to the end of the chapter when a specific reference is desired. Another helpful feature is a complete author index.

The chapter titles include: Ring Systems of Topical Interest, Intermolecular and Intramolecular Cyclization Reactions in Ring Synthesis, Cycloaddition Reactions, Ring Transformations, Electrophilic Substitution on Carbon, Electrophilic Substitution on Heteroatoms, Nucleophilic Substitution, Aromatic Substitution by Free Radicals, Carbenes and Nitrenes, Addition Reactions, Ring Cleavage Reactions, Reactions of Substituents, Porphyrins and Related Compounds, Naturally Occurring Oxygen-ring Compounds, and Other Naturally Occurring Compounds. The volume comprises 513 pages and includes 2750 literature citations.

The book is well illustrated with many chemical structures and reaction mechanisms. These illustrations are numbered sequentially and placed in close proximity to their text reference, thus affording a free flowing continuity which contributes to the overall excellent readability of the material.

This treatise is an extremely well-organized and readable volume and should serve to stimulate fresh approaches in the ever more sophisticated areas of aromatic and heteroaromatic synthetic chemistry. It is recommended to all chemists who are actively involved in synthetic organic chemistry or who wish to be up to date and informed about research activity in aromatic and heteroaromatic chemistry.

Handbook of Analysis of Organic Solvents. By VÁCLAV ŠEDIVEC and JAN FLEK. Halsted, 605 Third Ave., New York, NY 10016, 1976. 455 pp. 16 × 23.5 cm. Price $42.50.

Within this volume the authors have compiled an extensive aggregate of information concerning the chemical and physical properties and the analysis of organic solvents. Following a brief discussion of sampling and drying techniques, procedures are described for the determination of the physical properties and quantitative identification of unknown samples. After a presentation of methods for the analysis of two- and three-component mixtures by physicochemical methods, the basics of GC are described using a general procedure. Relative retention times are given for many common solvents using six different stationary phases.

The second part of the book deals with solvents as individual classes of organic compounds. The most frequently encountered solvents are described in depth, listing synonyms, chemical properties, usual impurities, and azeotropes. Tables containing extensive physical data are included. Detection methods, derivatives, and quantitative procedures are described in detail with corresponding literature references. Three appendixes covering 80 pages include a listing of the boiling points of solvents and their azeotropic mixtures, the major physical properties, and an alphabetical listing of universally used trade names.

This handbook represents a valuable accumulation of a myriad of facts and procedures which will be of use to the analyst, the chromatographer, and the synthetic organic chemist, all of whom frequently require data or techniques to utilize or analyze organic solvents.

The National Formulary and the USP Guide to Select Drugs. Edited by W. M. HELLER, G. K. WURSTER, C. A. DICKIE, and J. W. WHEATLEY. U.S. Pharmacopeial Convention, 12601 Twinbrook Parkway, Rockville, MD 20852, 1976. 295 pp. 10 × 14.5 cm. Price $3.00.

This convenient pocket-size book is intended to be a companion to the official compendia and the USAN Dictionary and is the first compilation of its kind subsequent to the consolidation of the USP and NF. Its purpose is "to highlight those drugs that should receive attention and be used as preferred drugs."

The book contains an alphabetical list of both generic and brand names of effective and useful drugs, with the preferred drugs in boldface type. The entries also contain dosage forms and strength; indication of whether prescription, nonprescription, or DEA controlled; and the pharmacological classification. In addition, there is a cross-index by therapeutic classification.

This book should be useful as a personal prescribing and dispensing guide and as a basic list of preferred drugs for health facilities and various organizations.

Staff Review

away in the laboratories of pharmaceutical scientists. Each drug profile provides useful information and data in the following general areas: description, physical properties, synthesis, stability and degradation, metabolism, analysis (for the drug substance, in its dosage forms, and in biological fluids), pharmacokinetics, and literature references. Physical properties include IR, NMR, UV, and mass spectral data, melting point, solubility data, crystal properties, and pK values where applicable. Analytical methods encompass titrimetry, chromatography, colorimetry, spectrophotometry, elemental analysis, and related techniques.

Each profile is presented in a well-organized and systematic manner. Each is introduced by a table of contents, followed in an orderly sequence by individual categories of specifications, and concluded by an extensive listing of quoted references. This compendium is printed clearly and is replete with tables and graphical presentations. Data are readily located and concisely presented with only a minimum of descriptive information. Maximum utilization is made of the available space.

This volume brings to a total of 97 the number of drugs for which profiles have thus far been prepared, including the 18 in Volume 5. These volumes serve well as companion books to the official compendia by presenting a wealth of data that supplement and are not duplicative of material found in the compendia. As noted in the Forward to Volume 1 of this series, the delegates to the 1970 meeting of the United States Pharmacopeial Convention adopted a resolution that consideration be given to the publication of just such a companion compendium. While the USPC did not undertake this project, it is worthy of note that a number of contributors to this series, including its esteemed editor, are, in fact, members of the USP Committee of Revision.

In view of the fact that fewer than 100 drug profiles have appeared in the first five volumes of this series, and with the mandate for USP XX to include all drugs currently official in USP XIX and NF XIV, all drugs added in their annual supplements, some 600 nonofficial drugs selected by the outgoing Subcommittee on Scope of the USP at its final meeting in January 1975, and new drugs marketed since that date, it is obvious that pharmaceutical scientists have their work cut out for them. It is worth repeating here the editor's invitation that: "All those who have found the profiles useful are earnestly requested to contribute a monograph of their own. The editors stand ready to receive such contributions." Hopefully, there will be an overwhelming response to this invitation.

This burgeoning library of "Analytical Profiles" is a must for all who are engaged in pharmaceutical research.

Aromatic and Heteroaromatic Chemistry. Vol. 4. A Specialist Periodical Report. Edited by C. W. BIRD, G. W. H. CHEESEMAN, *et al.* The Chemical Society, Burlington House, London W1V OBN, England, 1976. 513 pp. 14.5 × 22.5 cm. Price £28.00.

This volume comprises an in-depth review of the literature abstracted between July 1974 and June 1975 and covered by volumes 81 and 82 of "Chemical Abstracts." The organization of the report follows the established pattern of previous volumes.

There are 14 chapters written by 15 international scientists who are specialists in their fields. Most of the chapters include an introduction indicating the parameters established by the author(s) and the reviews on the subject published during the time period. A particularly helpful feature is that all literature citations are included as footnotes on the page that contains the abstract, thus eliminating the time consuming and thought-interrupting process of turning to the end of the chapter when a specific reference is desired. Another helpful feature is a complete author index.

The chapter titles include: Ring Systems of Topical Interest, Intermolecular and Intramolecular Cyclization Reactions in Ring Synthesis, Cycloaddition Reactions, Ring Transformations, Electrophilic Substitution on Carbon, Electrophilic Substitution on Heteroatoms, Nucleophilic Substitution, Aromatic Substitution by Free Radicals, Carbenes and Nitrenes, Addition Reactions, Ring Cleavage Reactions, Reactions of Substituents, Porphyrins and Related Compounds, Naturally Occurring Oxygen-ring Compounds, and Other Naturally Occurring Compounds. The volume comprises 513 pages and includes 2750 literature citations.

The book is well illustrated with many chemical structures and reaction mechanisms. These illustrations are numbered sequentially and placed in close proximity to their text reference, thus affording a free flowing continuity which contributes to the overall excellent readability of the material.

This treatise is an extremely well-organized and readable volume and should serve to stimulate fresh approaches in the ever more sophisticated areas of aromatic and heteroaromatic synthetic chemistry. It is recommended to all chemists who are actively involved in synthetic organic chemistry or who wish to be up to date and informed about research activity in aromatic and heteroaromatic chemistry.

Handbook of Analysis of Organic Solvents. By VÁCLAV ŠEDIVEC and JAN FLEK. Halsted, 605 Third Ave., New York, NY 10016, 1976. 455 pp. 16 × 23.5 cm. Price $42.50.

Within this volume the authors have compiled an extensive aggregate of information concerning the chemical and physical properties and the analysis of organic solvents. Following a brief discussion of sampling and drying techniques, procedures are described for the determination of the physical properties and quantitative identification of unknown samples. After a presentation of methods for the analysis of two- and three-component mixtures by physicochemical methods, the basics of GC are described using a general procedure. Relative retention times are given for many common solvents using six different stationary phases.

The second part of the book deals with solvents as individual classes of organic compounds. The most frequently encountered solvents are described in depth, listing synonyms, chemical properties, usual impurities, and azeotropes. Tables containing extensive physical data are included. Detection methods, derivatives, and quantitative procedures are described in detail with corresponding literature references. Three appendixes covering 80 pages include a listing of the boiling points of solvents and their azeotropic mixtures, the major physical properties, and an alphabetical listing of universally used trade names.

This handbook represents a valuable accumulation of a myriad of facts and procedures which will be of use to the analyst, the chromatographer, and the synthetic organic chemist, all of whom frequently require data or techniques to utilize or analyze organic solvents.

CANCER IN THE KITCHEN?

Pundits claim that television brought violence and sensationalism into the American living room. Perhaps this is true. By analogy, we are prompted to suggest that saccharin has brought science and toxicity into the American kitchen and dining room.

The conflicting arguments concerning this chemical substance have dramatically brought home to the average citizen the harsh reality of benefit-to-risk, of informed choice, of the fallacy of absolute safety, and of a host of other scientific issues, in a way that no other controversy before it has ever done.

In recent years, the public has been generally puzzled by the apparent inability of health professionals and medical scientists to agree that this drug or that drug should or should not be permitted to be used in therapy. Similar confusion has surrounded the questions raised about food additives such as monosodium glutamate, diagnostic techniques such as X-rays and mammography, environmental pollutants such as aerosol fluorocarbons, and various other items which have come to be regarded as a part of everyday life.

But in all these cases, it seemed that the hazards were relatively remote, and the perceived reliance upon—or need for—the item involved was not critical or even very important to a great number of people. Hence, few people got very excited over these matters, except to express impatience with the apparent inability of "the experts" to agree one way or the other in terms that were clearly black or white.

Regrettably, the inability of scientists to arrive at such unequivocal answers created an attitude of suspicion and distrust on the part of much of the public. For example, sinister motives frequently have been ascribed to fluoridation of drinking water, to controls on purported health cures such as krebiozan and laetrile, to the establishment of automobile exhaust standards, and to the regulation of flights of supersonic aircraft.

At best, these issues have been publicly perceived as selfish policies by a profit hungry industry. At worst, they have been branded as subversive political plots designed to destroy the physical and mental well-being of the general population. And always there were cries of interference with personal freedom and constitutional rights. No wonder, then, that science has lost its luster and scientists are no longer accorded the hero worship so common just a generation ago.

But for all its problems, headaches, and general nuisance effect, the saccharin controversy has proven to have considerable educational value. Even the average lay person seems to have a reasonable understanding of the questions involved, the uncertainty of the hazard, and the hard choices to be made.

Moreover, saccharin is something with which the consumer readily identifies. It is in the low calorie soft drinks, the diet foods on the supermarket shelves, the packets of sweetener on restaurant tables. People of all ages are weight and calorie conscious; artificial sweeteners are felt to provide a convenient, economical, and taste-satisfying answer to this problem.

However, only one generally acceptable artificial sweetener is currently available, and fuzzy questions have now been raised as to just how safe it is. People are very unhappy with this situation; nevertheless, they are able to comprehend and understand the dilemma it poses. It is also one that, at least for the moment, they are being forced to decide for themselves—does one push the button for the diet cola in the vending machine, or the button for the sugar-sweetened version? The choice is there, and the person is thirsty now. And the answer isn't easy.

Consequently, although the pharmaceutical world is primarily taken up with what impact the proposed saccharin ban will have on drug formulations and related products such as dentifrices and mouthwash, this far-reaching proposal has brought the general public face-to-face with the type of hard decision-making common to many contemporary scientific issues. Hopefully, this experience will provide the public with a better comprehension of the difficulty involved—even for "the experts"—in making the best choice when these kinds of situations arise in the future.

And always there were cries of interference with personal freedom and constitutional rights. No wonder, then, that science has lost its luster and scientists are no longer accorded the hero worship so common just a generation ago.

But for all its problems, headaches, and general nuisance effect, the saccharin controversy has proven to have considerable educational value. Even the average lay person seems to have a reasonable understanding of the questions involved, the uncertainty of the hazard, and the hard choices to be made.

Moreover, saccharin is something with which the consumer readily identifies. It is in the low calorie soft drinks, the diet foods on the supermarket shelves, the packets of sweetener on restaurant tables. People of all ages are weight and calorie conscious; artificial sweeteners are felt to provide a convenient, economical, and taste-satisfying answer to this problem.

However, only one generally acceptable artificial sweetener is currently available, and fuzzy questions have now been raised as to just how safe it is. People are very unhappy with this situation; nevertheless, they are able to comprehend and understand the dilemma it poses. It is also one that, at least for the moment, they are being forced to decide for themselves—does one push the button for the diet cola in the vending machine, or the button for the sugar-sweetened version? The choice is there, and the person is thirsty now. And the answer isn't easy.

Consequently, although the pharmaceutical world is primarily taken up with what impact the proposed saccharin ban will have on drug formulations and related products such as dentifrices and mouthwash, this far-reaching proposal has brought the general public face-to-face with the type of hard decision-making common to many contemporary scientific issues. Hopefully, this experience will provide the public with a better comprehension of the difficulty involved—even for "the experts"—in making the best choice when these kinds of situations arise in the future.

Kinetics of Drug–Drug Interactions in Sheep: Tolbutamide and Sulfadimethoxine

J. J. THIESSEN *x and M. ROWLAND ‡

Abstract □ The interaction between sulfadimethoxine and tolbutamide in sheep involving displacement from protein binding sites was investigated quantitatively. A 52% increase in the unbound plasma concentration of tolbutamide was observed *in vitro* at 37° after the addition of sulfadimethoxine (100 μg/ml) to sheep plasma containing tolbutamide (50 μg/ml). Transient changes in tolbutamide's unbound and total plasma concentrations were noted after acute intravenous administration of sulfadimethoxine to sheep receiving a constant intravenous infusion of tolbutamide. These observations were consistent with displacement of tolbutamide from plasma and tissue binding sites and redistribution of the displaced tolbutamide into body water spaces. The steady state of both agents featured little change in the total plasma tolbutamide concentration, a 150% increase in the unbound plasma tolbutamide concentration, and an inhibition of tolbutamide oxidation by sulfadimethoxine. A model is presented and mathematical relationships are derived that permit a quantitation of the interaction and that indicate that sulfadimethoxine's constant of metabolic inhibition (K_I) for tolbutamide metabolism is 65 μg/ml.

Keyphrases □ Tolbutamide—interaction with sulfadimethoxine, kinetic analysis, sheep □ Sulfadimethoxine—interaction with tolbutamide, kinetic analysis, sheep □ Drug interactions—tolbutamide and sulfadimethoxine, kinetic analysis, sheep □ Interactions, drug—tolbutamide and sulfadimethoxine, kinetic analysis, sheep □ Kinetics—analysis of tolbutamide–sulfadimethoxine interaction, sheep □ Antidiabetic agents—tolbutamide, interaction with sulfadimethoxine, kinetic analysis, sheep □ Antibacterials—sulfadimethoxine, interaction with tolbutamide, kinetic analysis, sheep

The coadministration of two or more drugs may produce ineffective therapy, exaggerated therapeutic responses, or even toxic responses. While numerous reports on such drug interactions have appeared in review articles (1–7) and books (8–10), they generally provide little more than a compilation of observed events. In one publication (11), attempts were made to discuss and relate the molecular events underlying various drug interactions.

The application of pharmacokinetic principles to the quantitation of drug–drug interactions has been limited but successful in the interpretation of the data. Kinetic analysis of the metabolic interaction of tolbutamide and sulfaphenazole explained observed clinical adverse effects and permitted a prediction of plasma levels of both agents when coadministered (12). Kinetic evaluation of the interaction between warfarin and phenylbutazone demonstrated the complexities that may be involved in metabolic interactions (13, 14). By using a perfusion-limited pharmacokinetic model (15), it was possible to assess contributions of enzyme induction and increased hepatic blood flow in mixed enzymatic–hemodynamic drug interactions (16).

Displacement of one drug by another from protein binding sites has frequently been suggested as the cause of an enhanced pharmacological response, but no reports exist quantitating the kinetics of these displacement interactions. The purpose of this investigation was to examine critically the pharmacokinetic aspects of an interaction between two agents, tolbutamide and sulfadimethoxine, that exhibit a displacement phenomenon *in vitro* (17). This report, describing experiments with sheep, demonstrates the involved complexities and the approaches that can be taken to quantitate drug interactions.

EXPERIMENTAL

Animal Preparation—Vascular catheters, 2.3-mm o.d. Tygon flexible tubing[1], were inserted into either the saphenous vein and the femoral artery or the jugular vein and the carotid artery of 40–50-kg sheep. Between experiments, the catheters were kept patent by filling with heparin[2] and flushing with normal saline periodically. A foley 20 FR catheter[3] was

[1] Type S-54-HL, Port Plastics Inc.
[2] Lipo-Hepin, 1000 units/ml, Riker.
[3] Bardex, 165V.

introduced into the bladder *via* its fundus after ventral midline abdominal incision. Both vascular and bladder catheters were externalized in a pocket attached to the side of the animal to permit ease of chronic sampling.

The sheep diet consisted of alfalfa pellets and water. Throughout all studies, food and water were permitted *ad libitum*.

Arterial blood samples were collected in heparinized or fluoridated Vacutainer tubes. Plasma was separated immediately by centrifugation and either used immediately for analysis or stored at −4° for subsequent analysis. All urine samples were either analyzed immediately or stored in scintillation vials at −4° for subsequent analysis.

Materials—All reagents were of analytical reagent grade. Solvents were generally redistilled prior to use. Tolbutamide[4], ^{14}C-tolbutamide[5], hydroxytolbutamide[4], ^{3}H-tolbutamide, and sulfadimethoxine[6] were administered as sodium salt solutions, diluted with normal saline where appropriate. All solutions were filtered[7] prior to intravenous administration[8].

Analytical Methods—Tolbutamide, hydroxytolbutamide, and carboxytolbutamide were determined in plasma, plasma water, or urine by the analytical method of Matin and Rowland (18).

Sulfadimethoxine and its N^4-conjugated metabolite were determined by the Bratton–Marshall method (19).

Glucose was measured[9] in plasma by the enzymatic glucose oxidase method (20).

Nonesterified (free) fatty acids were determined using the method of Dole (21).

Total plasma protein was measured, using automated equipment[10], by the biuret procedure (22) or the Lowry *et al.* method (23). Plasma electrophoresis was performed on cellulose acetate[11].

Plasma Protein Binding—All three methods were performed at 37°. Equilibrium dialysis was carried out for 6 hr using the dialyzing system[12] and the method of Weder *et al.* (24). Krebs–Henseleit buffer, pH 7.4, was used as the dialyzing fluid. Ultracentrifugation[13] was conducted at 55,000 rpm for 24 hr, after which 0.5–1.0 ml of supernate was removed for analysis. Ultrafiltration was carried out using membrane cones[14]; centrifuging[15] at 2000 rpm for 4 min provided a filtrate that was 10% of the initial plasma volume.

Radioactivity Measurements—Radioactivity was quantitated in biological fluids by scintillation counting[16] using the method of automatic external standardization and employing appropriate quench correction curves.

RESULTS AND DISCUSSION

Intravenous Tolbutamide Bolus—The intravenous bolus administration of tolbutamide in sheep served to determine its metabolic fate, characterize its disposition kinetics, and allow an appraisal of a pharmacological response, namely plasma glucose depression. In an experiment utilizing ^{3}H-tolbutamide (2.0 μCi/mg), 67.8% of the dose (100 mg, 2.9×10^7 dpm) was recovered in urine collected for 9 hr. Of this recovered radioactivity, 86.5% could be removed by exhaustive extraction of acidified urine with 0.5% isoamyl alcohol in dichloromethane. By using the separation method of Matin and Rowland (18), all extracted radioactivity was accounted for as tolbutamide, carboxytolbutamide, and hydroxytolbutamide in a ratio of 2:9:89. In subsequent experiments using unlabeled tolbutamide, 66–80% of the administered dose could be accounted for as the cumulative urinary excretion of these three compounds.

Since carboxytolbutamide represented only 10% of the detectable oxidation products excreted, it was included as part of the hydroxytolbutamide estimate in subsequent analyses of urine collected during the interaction studies. Sheep thus join rats, guinea pigs, rabbits, and humans as species that predominantly eliminate hydroxy- and carboxytolbutamide after tolbutamide administration (25–27). The tolbutamide excretion product(s) unaccounted for remain uncharacterized.

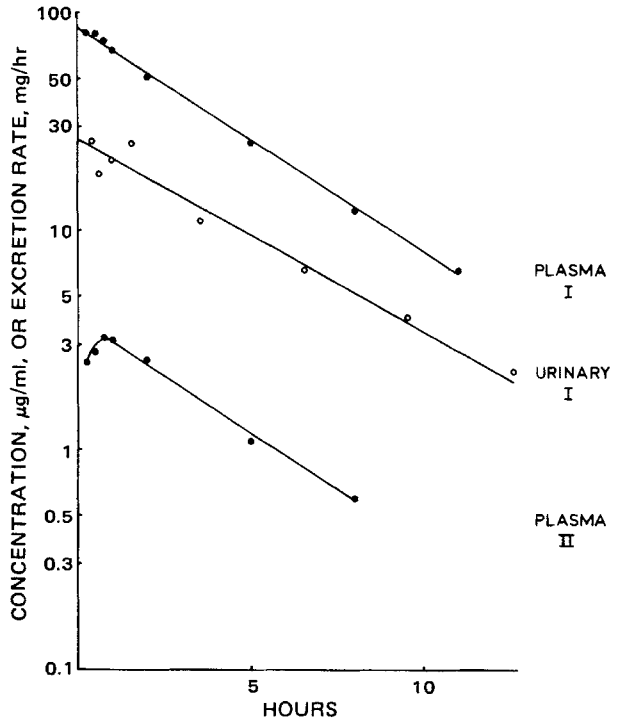

Figure 1—*Plasma concentration and urinary excretion rate of tolbutamide (I) and plasma concentration of hydroxytolbutamide (II) after an intravenous tolbutamide bolus (865 mg).*

Plasma tolbutamide and hydroxytolbutamide levels and the excretion rate of tolbutamide after an intravenous bolus dose of tolbutamide (865 mg) can be seen in Fig. 1. Tolbutamide is removed quickly from the sheep, and the data suggest that the disappearance of hydroxytolbutamide is rate limited by its formation. During some bolus experiments, a distribution phase was occasionally detected. When visible, however, its contribution was always less than 10% of the total area; therefore, less than 10% of the dose was eliminated during the distribution phase. Accordingly, as a reasonable approximation, the elimination of tolbutamide was characterized as occurring from a single compartment.

Repeated intravenous bolus administration of tolbutamide in a single sheep over 4 months provided half-lives, apparent volumes of distribution, and total body clearances (±*SD*) of 3.6 (±0.5) hr, 11.2 (±1.0) liters, and 37.5 (±2.1) ml/min, respectively. Excluded from these values are the results of an experiment that yielded a prolonged half-life of 10.6 hr, a similar apparent volume of distribution (11.7 liters), and a reduced total body clearance (12.7 ml/min). These abnormal kinetic parameters coincided with an infection. The differences could not be explained by changes in total or fractional plasma protein content or by changes in the fraction of tolbutamide bound to plasma proteins. The infectious state apparently decreased the metabolic activity of the liver.

The plasma glucose depression observed after an intravenous tolbutamide bolus (900 mg) can be seen in Fig. 2. A depression occurs shortly after administration, with a rapid return to baseline values within 2 hr. These observations made with sheep are similar to those reported for humans (28).

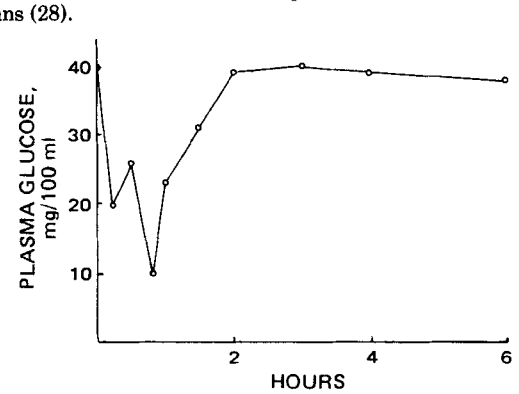

Figure 2—*Plasma glucose concentration in sheep after an intravenous tolbutamide bolus (900 mg).*

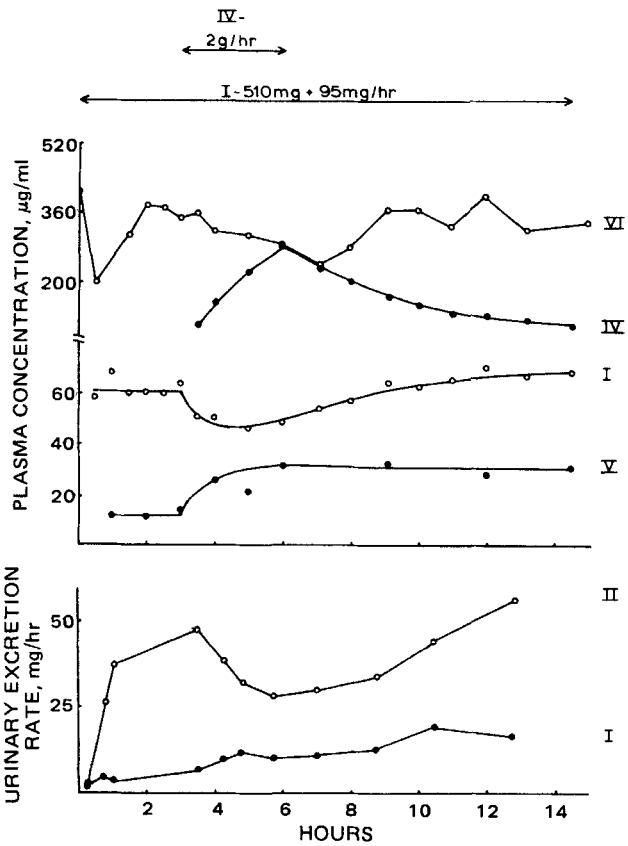

Figure 3—*Interaction Study 1 of tolbutamide and sulfadimethoxine in sheep. Tolbutamide (I) was given as a bolus (510 mg) followed by an infusion (95 mg/hr), while sulfadimethoxine (IV) was administered for 3 hr as an infusion (2 g/hr). The resultant plasma concentrations of glucose (VI), sulfadimethoxine (IV), tolbutamide (I), and unbound tolbutamide (V) and urinary excretion rates of hydroxytolbutamide (II) and tolbutamide (I) are displayed.*

Intravenous Hydroxytolbutamide Bolus—Hydroxytolbutamide is eliminated very rapidly from sheep. An intravenous bolus dose (250 mg) in two sheep provided terminal plasma half-lives of 13.5 and 26 min, apparent volumes of distribution of 15.8 and 26.5 liters, and total body clearances of 1.0 and 1.5 liters/min. These observations confirm the previous suggestion that the rate of removal of hydroxytolbutamide from the plasma after tolbutamide administration is rate limited by its formation (Fig. 1). The entire dose of hydroxytolbutamide was recovered in the urine, 90% as unchanged drug and the remainder as carboxytolbutamide. A 250-mg intravenous bolus dose failed to depress the plasma glucose level. Thus, hydroxytolbutamide appears to lack significant hypoglycemic activity.

Intravenous Sulfadimethoxine Bolus—Sulfadimethoxine exhibited biexponential kinetics, with the distribution and elimination phases having half-lives of 1 and 7.4 hr, respectively. The latter value is similar to a reported half-life of 8.4 hr in sheep (29). Further, the low total body clearance (31.8 ml/min) of sulfadimethoxine was similar to that noted for tolbutamide. However, a 4-g bolus dose failed to produce a significant hypoglycemic effect.

***In Vitro* Plasma Protein Binding**—When using ultracentrifugation, ultrafiltration, and equilibrium dialysis, tolbutamide (100 μg/ml) was bound 85.1, 85.4, and 85.6%, respectively, to sheep plasma at 37°. In light of these similar results, ultrafiltration was used almost exclusively in subsequent *in vivo* studies due to its short analysis time. While all experiments were conducted at 37°, a change to 25° resulted in a maximal mean increase in binding of only 0.7% over the tolbutamide concentration range of 10–100 μg/ml of plasma. At 100, 200, 300, and 400 μg/ml, sulfadimethoxine was bound to the extent of 88.2, 81.2, 73.4, and 66.8%, respectively, in sheep plasma.

Sulfadimethoxine displaces tolbutamide from binding sites in sheep plasma. At a tolbutamide concentration of 50 μg/ml, sulfadimethoxine concentrations of 100, 200, 300, and 400 μg/ml increased the unbound tolbutamide concentration by 52, 102, 128, and 150%, respectively. These observations confirmed the reported effectiveness of sulfadimethoxine

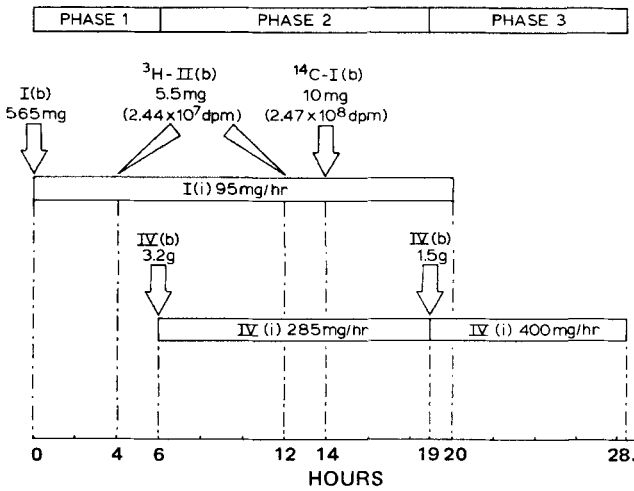

Figure 4—*Flow diagram indicating the times of administration of tolbutamide (I), hydroxytolbutamide (II), and sulfadimethoxine (IV) in Interaction Study 2. All compounds were administered in the form of an intravenous bolus (b) or infusion (i).*

as a displacer of tolbutamide from plasma proteins (17) and made this sulfonamide a logical choice for the investigation of the kinetics of drug interactions involving displacement of drugs from protein binding sites.

Tolbutamide–Sulfadimethoxine Interaction Studies—Significant displacement of tolbutamide from plasma binding sites *in vivo* was ensured by producing the same plasma concentrations of tolbutamide and sulfadimethoxine in the sheep as were used *in vitro*. By utilizing the intravenous bolus data, an infusion rate of tolbutamide was chosen to maintain its plasma concentration at approximately 50 μg/ml and a regimen of sulfadimethoxine was chosen to produce plasma concentrations up to 600 μg/ml. All interaction studies were conducted in a single animal.

In the initial experiment (Interaction Study 1), tolbutamide was administered as a bolus dose followed by a constant infusion for 14.5 hr. Sulfadimethoxine was coadministered for 3 hr by constant infusion. During its infusion, sulfadimethoxine caused a rise in the unbound concentration and a drop in the total plasma tolbutamide concentration (Fig. 3). These observations are in keeping with displacement of tolbutamide from plasma binding sites and redistribution of the unbound drug extravascularly.

At the peak plasma sulfadimethoxine concentration, the unbound tolbutamide concentration increased maximally by 160% (from 12.3 to 31.6 μg/ml). Thereafter, although the plasma sulfadimethoxine concentration fell and the total tolbutamide concentration rose eventually to exceed the presulfonamide steady-state level, the unbound tolbutamide level remained virtually unchanged for the remainder of the experiment. Meanwhile, whereas the urinary excretion rate of hydroxytolbutamide fell and rose during and after the sulfadimethoxine infusion, the tolbutamide excretion rate remained elevated despite a decrease in the plasma sulfadimethoxine concentration. Immediately after the bolus of tolbutamide, plasma glucose levels fell sharply, but they returned to the control value within 2 hr. They fell, albeit more slowly, during sulfadimethoxine administration, reaching a minimum which appeared coincident with the attainment of the maximal unbound plasma tolbutamide concentration.

The interaction study was repeated to examine the kinetics of interactions under steady-state tolbutamide levels in the absence and presence of a steady-state plasma sulfadimethoxine concentration (Interaction Study 2). Figure 4 contains a flow diagram indicating all aspects of drug administration during this study. Generally, the results in Fig. 5 confirm the observations seen during Interaction Study 1. By earlier sampling after an initial sulfadimethoxine bolus (6 hr after initiating tolbutamide administration), the early transient changes in unbound and total plasma tolbutamide concentrations were examined in greater detail. Again they reflected displacement from plasma proteins and rapid extravascular redistribution; similar events were noted in sheep (30) immediately following the displacement of sulfadoxine from binding sites by phenylbutazone.

By the end of phase 2 (19 hr), both unbound and total tolbutamide levels appeared to approach steady state. By then, the unbound tolbu-

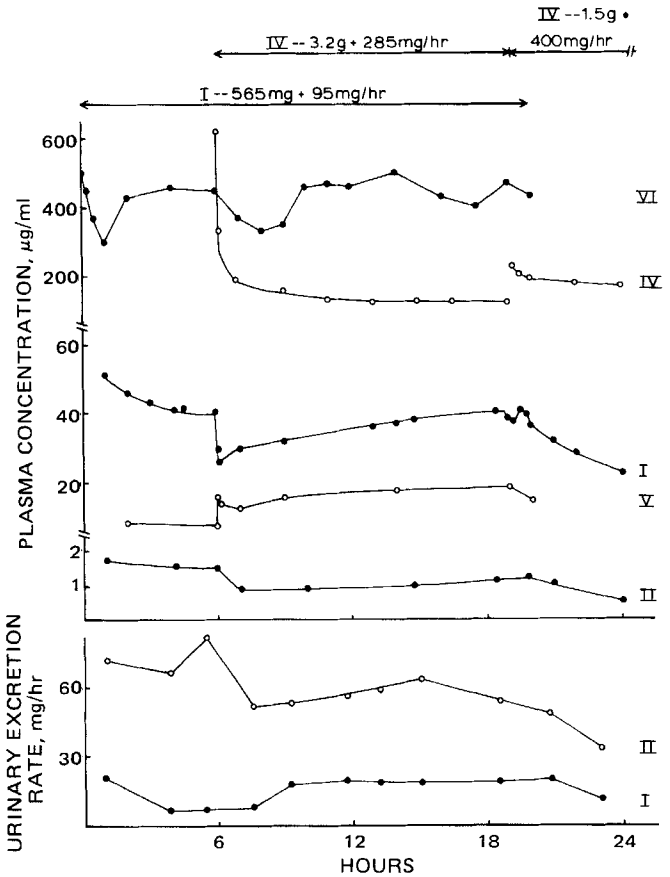

Figure 5—*Interaction Study 2 of tolbutamide and sulfadimethoxine in sheep. Tolbutamide (I) was given as a bolus (565 mg) followed by an infusion (95 mg/hr) until 20 hr. Sulfadimethoxine (IV) was coadministered as a bolus (3.2 g) at 6 hr followed by an infusion (285 mg/hr) until 19 hr, after which an additional bolus (1.5 g) was given followed by a new infusion rate (400 mg/hr) until 28.5 hr. The resultant plasma concentrations of glucose (VI), sulfadimethoxine (IV), tolbutamide (I), unbound tolbutamide (V), and hydroxytolbutamide (II), as well as the urinary excretion rates of hydroxytolbutamide (II) and tolbutamide (I), are exhibited.*

tamide level had increased twofold over the levels seen at the end of phase 1, while total tolbutamide had returned to the preexisting level. An additional bolus and increased infusion rate at the outset of phase 3 produced only minor changes in the total plasma tolbutamide concentration. The half-lives of ^{14}C-tolbutamide and nonradioactive tolbutamide during phase 3 (Figs. 6 and 5, respectively) were both 5.2 hr. This value was longer than the half-life of 3.8 hr observed following a 900-mg intravenous bolus dose of tolbutamide 2 days prior to this interaction study and longer than the ^{14}C-tolbutamide half-life (3.8 hr) observed during phase 2 of this study (Fig. 6).

Plasma hydroxytolbutamide decreased noticeably after the administration of sulfadimethoxine and then gradually increased, approaching a new steady state at 19 hr (Fig. 7). The urinary excretion rate of hydroxytolbutamide decreased temporarily and then increased, while that of tolbutamide remained notably elevated during sulfadimethoxine coadministration. The pattern of changes in plasma glucose was analogous to that seen in Fig. 3; levels were depressed after the first bolus of tolbutamide and sulfadimethoxine, but each time the glucose level returned to the control value.

Displacement of Tolbutamide by Sulfadimethoxine *In Vivo*—The magnitude of the initial changes and the subsequent levels of unbound tolbutamide as seen in Figs. 3 and 5 were greater than anticipated had only displacement from plasma protein sites occurred. By using a mean apparent volume of distribution of 11.2 liters (bolus data), a plasma volume of 1.8 liters, and 85% binding in plasma, it was calculated that only 14% of the drug in the body is bound to plasma proteins. Even if all of this plasma-bound drug had been displaced, to be redistributed throughout the rest of the body, it would fail to increase the unbound concentration to anything like the observed 110% within 1 hr following sulfadimethoxine administration. Therefore, sulfadimethoxine must also displace tolbutamide from an extensive extravascularly bound pool. The early maintenance of these elevated levels of unbound tolbutamide suggests that the distribution space of the unbound drug may, in fact, be limited. A similar explanation was suggested by Jähnchen *et al.* (31) who reported no statistically significant increase in the apparent volume of distribution of dicumarol in the rat, despite extensive displacement of this anticoagulant by phenylbutazone.

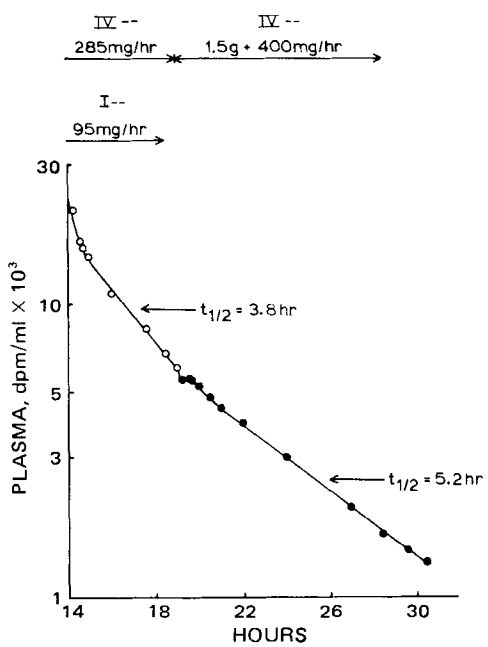

Figure 6—*Total plasma radioactivity after intravenous administration of a pulse of ^{14}C-tolbutamide (2.47×10^8 dpm) during Interaction Study 2.*

The unbound fraction of tolbutamide in plasma (α) depends on several factors, including the total plasma concentrations of the interacting drugs and binding protein(s), as well as the affinities of the binding species for the protein(s). To examine the altered binding during the interaction study, not entirely accounted for by changes in the plasma concentrations of tolbutamide and sulfadimethoxine, the following test was performed. A comparison was made between the values of α determined in samples obtained during Interaction Study 2 with those determined in samples prepared by placing the same concentrations of tolbutamide and sulfadimethoxine into control plasma collected from the animal 2 hr prior to the study.

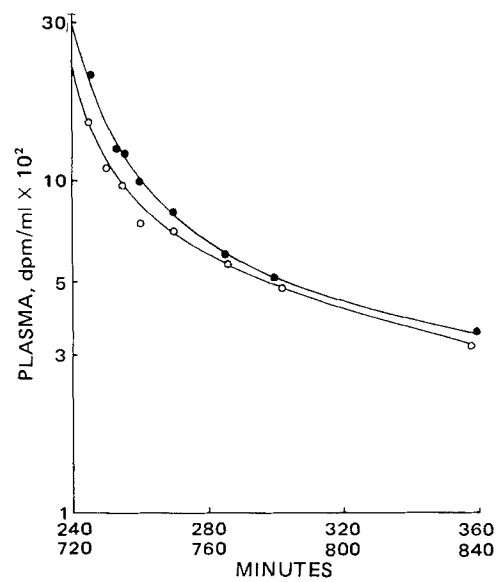

Figure 7—*Total plasma radioactivity determined after intravenous administration of a pulse of ^{3}H-hydroxytolbutamide (2.44×10^7 dpm) before (●) and after (○) sulfadimethoxine administration during Interaction Study 2.*

[a] Unbound tolbutamide fraction in plasma. [b] Sample from the infectious state during which time the tolbutamide kinetics were altered. [c] Sample from the animal 2 months prior to Interaction Study 2.

As seen in Fig. 8, major differences in the value of α between the paired samples were noted throughout most of the interaction study. Measurement of 9-, 11-, and 14-hr samples also showed a similar elevation in the α values for sulfadimethoxine. The possibility that decreases in plasma proteins [*e.g.*, albumin (32–34)] or changes in free fatty acids (35, 36) during the interaction study might have caused the exaggerated unbound fraction was excluded. No significant differences were noted between samples obtained during the study and control samples prior to the study (Table I). The possibility of additional displacement caused by the excessive accumulation of a highly bound N^4-conjugated sulfadimethoxine metabolite (37) also was excluded. No significant increase was noted in the samples between the free and total sulfonamides. The question of the differences remains unresolved.

Tolbutamide Binding and Tolbutamide Renal Clearance—By using total and unbound plasma tolbutamide concentrations, along with the urinary data of Interaction Study 2, the renal clearance of tolbutamide was evaluated. Comparing the data at the end of phases 1 and 2 resulted in renal clearances, based upon total plasma tolbutamide concentrations, of 3.0 and 7.6 ml/min, respectively; the renal clearances based upon unbound tolbutamide levels were 16.2 and 16.5 ml/min, respectively. The similarities of the latter values suggested that the unbound plasma tolbutamide concentration dictated the urinary excretion rate.

Regression analysis on all data of Interaction Study 2 was performed to evaluate the correlation between the rate of urinary tolbutamide excretion and either the total or unbound tolbutamide concentration. As seen in Fig. 9, the correlation coefficient using the unbound data ($r = 0.90$) was higher than when total tolbutamide levels were used ($r = 0.59$). Unfortunately, the unbound tolbutamide data were primarily clustered at two points so the results in Fig. 9 are not conclusive. Nevertheless, the preceding results suggest that a linear relationship exists between the urinary excretion rate of tolbutamide and the unbound plasma tolbutamide concentration. These experiments point out the usefulness of drug interactions in perturbing the normal disposition of an agent in order to evaluate its mode of elimination kinetically.

Hydroxytolbutamide Renal Clearance—The hydroxytolbutamide urinary excretion results observed in Interaction Study 1 (Fig. 3) suggested that sulfadimethoxine possibly reduced the renal clearance of hydroxytolbutamide. This potential interaction was investigated in a separate experiment. The results did not show any significant effect by sulfadimethoxine on the renal clearance of hydroxytolbutamide (738 ml/min) (Fig. 10), and this finding was confirmed in Interaction Study 2. A pulse of ^{3}H-hydroxytolbutamide (5.5 mg, 2.44×10^7 dpm) was administered in the absence (4 hr) and presence (12 hr) of sulfadimethoxine, and the plasma was monitored for radioactivity. No significant change was found in the disposition of the radioactivity (Fig. 7). Since hydroxytolbutamide is cleared almost exclusively by renal excretion, these foregoing investigations indicate that any changes in its urinary excretion rate during the tolbutamide–sulfadimethoxine interaction must have been due to changes in its formation.

Inhibition of Tolbutamide Oxidation—The total plasma clearance of tolbutamide is much lower than the combined flow to the two organs, liver and kidney, responsible for tolbutamide elimination. It is anticipated that the elimination rate of drugs like tolbutamide, which are poorly extracted by the eliminating organs, is dependent on its unbound plasma concentration (35, 38). Certainly the dependence of the renal clearance of tolbutamide on α supports this hypothesis. If this hypothesis is extended to the metabolism of tolbutamide, the sustained elevation of unbound plasma tolbutamide and changes in its total plasma concentration favor a mechanism whereby sulfadimethoxine not only displaces tolbutamide from binding sites but also inhibits its metabolism. Scheme I is the simplest model consistent with the observations. Sulfadimethoxine is depicted as displacing tolbutamide from plasma and tissue binding sites and inhibiting tolbutamide's elimination by nonrenal (metabolic) routes. The basis for these conclusions follows.

In cases where the elimination rate of a drug is proportional to its unbound concentration (Cu), the steady-state unbound concentration (Cu_{ss}) depends only on the infusion rate (R^0) and the clearance based upon the unbound drug (CLu) (35):

$$Cu_{ss} = \frac{R^0}{CLu} \qquad \text{(Eq. 1)}$$

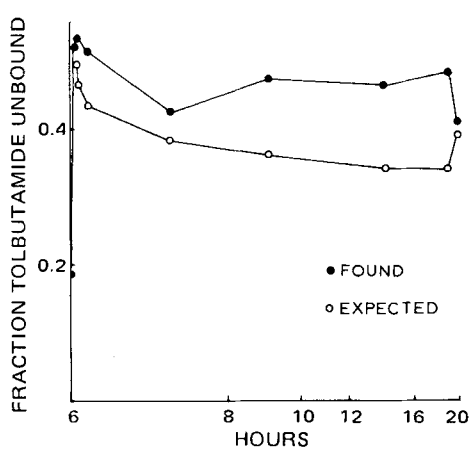

Figure 8—*Comparison of the unbound plasma tolbutamide fraction observed in Interaction Study 2, Fig. 5 (●), with the fraction anticipated (O) based upon* in vitro *displacement experiments using the same total plasma tolbutamide and sulfadimethoxine concentrations.*

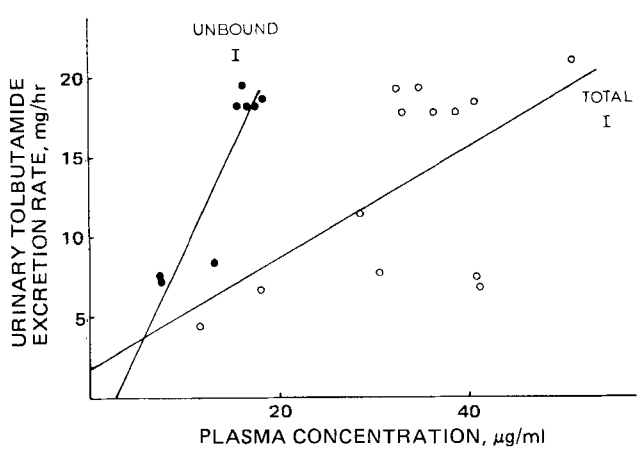

Figure 9—*Regression analysis of the rate of urinary excretion of tolbutamide on the total (O) and unbound (●) plasma tolbutamide (I) concentrations from Interaction Study 2. Correlation coefficients are 0.59 ($0.025 < p < 0.050$) and 0.90 ($p < 0.005$), respectively.*

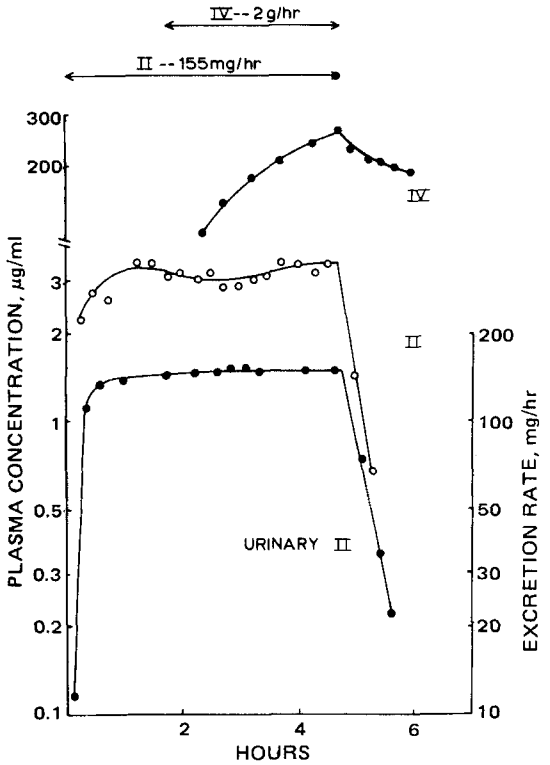

Figure 10—*Interaction of hydroxytolbutamide and sulfadimethoxine in sheep. Hydroxytolbutamide (II) was administered as an infusion (155 mg/hr) for 5 hr while sulfadimethoxine (IV) was coadministered from 2 to 5 hr as an infusion (2 g/hr). The resultant plasma concentrations of sulfadimethoxine (IV) and hydroxytolbutamide (II), as well as the urinary excretion rate of hydroxytolbutamide (II), are displayed.*

By definition, CLu is related to the clearance based on the total plasma concentration (CL) by:

$$CL = \alpha CLu \qquad \text{(Eq. 2)}$$

Thus, CLu, a measure of the inherent ability of an organ to clear a drug, may be regarded as the clearance when all drug has been displaced (α = 1). According to Eq. 1, if a compound acts only as a displacer (α increases), the steady-state unbound concentration of the displaced drug, being independent of α, remains unchanged. But, in the presence of sulfadimethoxine, the Cu_{ss} of tolbutamide rose (Fig. 5). As the infusion rate was fixed, CLu must, therefore, have decreased, with the cause being primarily the inhibition of tolbutamide metabolism.

The kinetics of competitive inhibition for a single metabolic step were described by Gillette (36):

$$\text{rate of metabolism} = \frac{V_{max}[S]}{[S] + K_m(1 + [I]/K_I)} \qquad \text{(Eq. 3)}$$

where V_{max} is the maximal velocity of the reaction, K_m is the Michaelis–Menten constant, $[S]$ is the substrate concentration, $[I]$ is the inhibitor concentration, and K_I is the concentration of inhibitor required to reduce the apparent K_m by 50%. For a compound eliminated by various routes, the rate of metabolism may alternatively be described in terms of its metabolic clearance (CLm) and when $[S] \ll K_m$:

$$\text{rate of metabolism} = \frac{CLm[S]}{1 + [I]/K_I} \qquad \text{(Eq. 4)}$$

This relationship, however, suggests that the metabolism rate is proportional to the total plasma concentration. From Eqs. 1 and 4, a general relationship is derived for the steady-state unbound plasma concentration of an agent during inhibition whose CLu takes place *via* a single metabolic step:

$$Cu_{ss} = \frac{R^0}{CLu}(1 + [I]/K_I) \qquad \text{(Eq. 5)}$$

By denoting $Cu_{ss}{}^1$ and $Cu_{ss}{}^2$ as the unbound steady-state concentration in the absence and presence of an inhibitor, respectively, Eq. 6 applies:

$$Cu_{ss}{}^2 = Cu_{ss}{}^1(1 + [I]/K_I) \qquad \text{(Eq. 6)}$$

When a compound is eliminated by various routes, the metabolic clearance based on unbound drug in the presence of inhibitor (CLu,m^2) can be predicted from the metabolic clearance in the absence of inhibitor (CLu,m^1) and the degree of inhibition:

$$CLu,m^2 = \frac{CLu,m^1}{1 + [I]/K_I} \qquad \text{(Eq. 7)}$$

Rearranging Eq. 7 yields an analytical solution for K_I:

$$K_I = \frac{[I]}{\frac{CLu,m^1}{CLu,m^2} - 1} \qquad \text{(Eq. 8)}$$

Table II—Evaluation of Tolbutamide Kinetics in Sheep 1494

Source	Parameter	Formula	Value				
Intravenous cold tolbutamide bolus data (means)	CL, ml/min	$\frac{\text{dose}}{\int_0^\infty C_p\,dt}$	37.5				
	α	—	0.18[a]				
	CLu, ml/min	CL/α	208				
	$t_{1/2}$, hr	—	3.6				
	V_d, liters	$(1.44CL)(t_{1/2})$	11.2				
			Value				
			Phase 1	Phase 2		Phase 3	
			Cold	Cold	^{14}C	Cold	^{14}C
Interaction Study 2	CL, ml/min	R^0/Ct_{ss}	40.7	38.7	45[b]	32.4[c]	34[d]
	α	Cu_{ss}/Ct_{ss}	0.19	0.45	—	0.45[c]	—
	CLu, ml/min	R^0/Cu_{ss}	214	86	—	72[c]	—
	$t_{1/2}$, hr	—	—	(3.8)	3.8	5.2	5.2
	V_d, liters	$(1.44CL)(t_{1/2})$	—	(12.7)	14.8	14.6	15.3

[a] 50 μg of tolbutamide/ml (*in vitro* determination). [b] Formula: $\text{dose}/[\int_{14}^{19} C_p\,dt + (C_p{}^{19}/K)]$. [c] Assumed or predicted values. [d] Formula:

$$\frac{\text{dose}\left[1 - \frac{\int_{14}^{19} C_p\,dt}{\int_{14}^{19} C_p\,dt + \frac{C_p{}^{19}}{K^2}}\right]}{\frac{C_p{}^{19}}{K^3}}$$

where K^2 and K^3 are the first-order rate constants for elimination during phases 2 and 3, respectively.

Table III—Results Found and Parameters Calculated from the Data of Interaction Study 2 [a]

Parameter	Formula	Phase 1	Phase 2	Phase 3
CLu, ml/min	R^0/Cu_{ss}	214	86	17 + 55 = 72[b]
CLu,r, ml/min	$\frac{\Delta Te}{\Delta t} / Cu_{ss}$	16	17	17[b]
CLu,m, ml/min	*CLu* − *CLu,r* or Eq. 7	198	70	55[b]

$t_{1/2}$ calc., hr	Eq. 9	—	—	4.9

[a] See text for explanation of abbreviations and equations. [b] Assumed or predicted values.

The elimination kinetics of tolbutamide can be characterized as occurring from a single compartment. Although the half-life in the presence of the displacer–inhibitor ($t_{1/2}^2$) is a function of the half-life in the absence of inhibitor ($t_{1/2}^1$), it also depends on the changes in overall clearance based upon the unbound drug, the apparent volumes of distribution (V_d), and the fractions of the compound in the unbound form according to:

$$t_{1/2}^2 = \frac{t_{1/2}^1 CLu^1 V_d^2 \alpha^1}{CLu^2 V_d^1 \alpha^2} \qquad \text{(Eq. 9)}$$

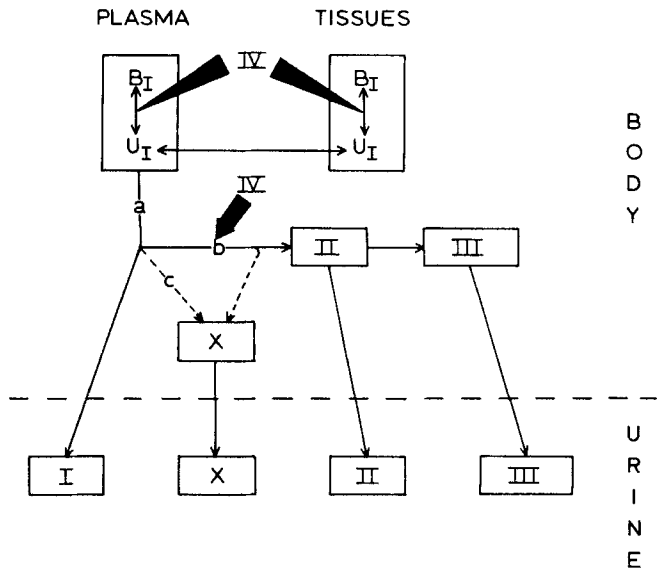
The superscripts 1 and 2 denote the situation in the absence and presence, respectively, of the displacer–inhibitor. Alternatively, they denote the situation at two levels of the displacer–inhibitor.

In Interaction Study 2, following the simplest model (Scheme I), the metabolic clearance based on unbound drug (*CLu,m*) was estimated by subtracting the renal clearance based on unbound drug (*CLu,r*), obtained by dividing the steady-state rate of renal tolbutamide excretion by its steady-state unbound plasma concentration, from the *CLu*, estimated from Eq. 1. The clearance associated with the oxidation of tolbutamide to hydroxytolbutamide, based on unbound drug, was estimated by dividing the steady-state hydroxytolbutamide excretion rate by the steady-state unbound plasma tolbutamide concentration.

Three phases were present in Interaction Study 2 (Figs. 4 and 5). A quantitative explanation for the tolbutamide–sulfadimethoxine interaction might be possible by accounting for tolbutamide's half-life during phase 3. The results of Figs. 5 and 6 revealed a prolongation in the half-life from 3.8 hr in phase 2 to 5.2 hr in phase 3. Table II summarizes the tolbutamide kinetics observed in Sheep 1494 during three nonradioactive (cold) tolbutamide intravenous bolus experiments and during Interaction Study 2. There is close agreement between the bolus results and those observed during phase 1 of Interaction Study 2. The transition from phase 1 to phases 2 and 3 was notably marked by a large reduction in the overall inherent clearance (*CLu*). The cold and ^{14}C-tolbutamide results of phases 2 and 3 are in agreement, providing mean total body clearances (*CL*), half-lives, and apparent volumes of distribution of 41.9 ml/min, 3.8 hr, and 13.8 liters, respectively, during phase 2 and of 33.2 ml/min, 5.2 hr, and 15.0 liters, respectively, during phase 3.

Table III summarizes the calculations made with the model depicted in Scheme I. From the data in phases 1 and 2, the K_I for sulfadimethoxine was calculated to be 65 μg/ml. Substituting this value of K_I and other data into the appropriate equations yielded a predicted half-life of tolbutamide in phase 3 of 4.9 hr. The close proximity between the predicted and observed half-life (5.2 hr) tends to favor the proposed interaction model. The data permitted the investigation of certain modifications in the proposed displacement–inhibition model. Inhibition by sulfadimethoxine at point a (Scheme I) or b and c independently failed to predict tolbutamide's half-life in phase 3 as well as that for the model evaluated. Consideration was also given to a model in which the renal clearance of tolbutamide was dictated by the unbound plasma concentration while the metabolic clearance was linearly related to tolbutamide's total plasma concentration. This model, however, failed to predict any change in tolbutamide's half-life in phase 3.

Tolbutamide Binding and Glucose Depression—The influence of the unbound tolbutamide concentration on glucose depression remains somewhat speculative. *In vitro* studies with pancreatic β-cells demonstrated a decreased islet uptake of tolbutamide in the presence of albumin (39). A sudden increase in unbound tolbutamide *in vivo* might, therefore, evoke an increased insulin release, resulting in a depression of plasma glucose. Indeed, the results of the interaction studies suggest such a possibility.



Scheme I—Sulfadimethoxine (IV) is depicted as altering the bound (B) to unbound (U) ratio of tolbutamide (I) in plasma and tissues. Further, it inhibits the metabolism of tolbutamide (at b) to hydroxytolbutamide (II) and an unknown metabolic product (X). A small portion of hydroxytolbutamide is oxidized to carboxytolbutamide (III).

Insulin release may involve occupancy of tolbutamide on the membrane of the β-cell (39) followed by release of part of the insulin in the labile pool (38). Maximum insulin release might follow the attainment of maximum unbound tolbutamide concentrations, leading to maximum glucose depression. After attainment of maximal unbound levels (maximum β-cell binding), no further stimulus for insulin release would exist. This hypothesis could explain the transient insulin release and glucose depression observed after an intravenous tolbutamide bolus (28).

SUMMARY

The results of the coadministration of sulfadimethoxine and tolbutamide in the sheep point to an interaction not only involving displacement of tolbutamide from proteins, which increases its renal clearance, but also inhibition of its metabolism. This explanation accounts for the changes in the total and unbound plasma tolbutamide concentrations and adequately predicts tolbutamide's half-life during phase 3 in Interaction Study 2. The observation of a simultaneous displacement–inhibition phenomenon in the interaction between tolbutamide and sulfadimethoxine is similar to that reported for the interaction between phenylbutazone and warfarin in humans (14).

This report illustrates some of the complexities of drug–drug interactions. Although gross changes in total plasma drug concentrations during the coadministration of highly plasma protein-bound agents may be absent, their absence may be due to compensative reactions. Considerable coincidental changes in unbound plasma drug concentrations may occur, however, and may provoke exaggerated therapeutic responses during chronic drug coadministration.

This report also presents a steady-state approach for investigating mechanisms of drug interactions and demonstrates that the coadministration of agents may permit investigators to scrutinize mechanisms of drug disposition. Knowledge thus obtained will help to evaluate and predict rationally the clinical significance of drug–drug interactions in humans.

Mathematical Model for Enteric Film Coating of Tablets

SALIH DINÇER *ˣ and SEZA ÖZDURMUŞ ‡

Abstract □ The enteric film coating of placebo tablets, using a methacrylic acid–methyl methacrylate copolymer as the film former in the coating solution, was studied by statistical techniques. The effects of four independent formulation and process variables on the disintegration time of the coated film in simulated intestinal fluid and on the resistance to disintegration of the coated film in simulated gastric fluid were studied. The results of a statistically designed set of experiments were used as the input data. Regression analysis of these data resulted in two first-order polynomial equations. The linear model obtained for the disintegration time of the coating in the simulated intestinal fluid was analyzed by the steepest descent method to determine the most suitable combination of the independent variables.

Keyphrases □ Tablets—enteric film coating with methacrylic acid–methyl methacrylate copolymer, disintegration time, mathematical model □ Film coating, enteric—with methacrylic acid–methyl methacrylate copolymer, tablet disintegration time, mathematical model □ Models, mathematical—disintegration time of tablets with enteric film coating of methacrylic acid–methyl methacrylate copolymer □ Disintegration time—tablets with enteric film coating of methacrylic acid–methyl methacrylate copolymer, mathematical model □ Methacrylic acid–methyl methacrylate copolymer—enteric film coating of tablets, disintegration time, mathematical model □ Dosage forms—tablets with enteric film coating of methacrylic acid–methyl methacrylate copolymer, disintegration time, mathematical model

Much research in pharmaceutics has concerned the relationship between the controllable formulation and process (independent) variables and the characteristics of the resultant system (response). An empirical relationship can be developed with data from statistically designed experiments. The relationship between the independent

Table I—Levels of Formulation and Process Variables in Physical Units

Variable	Lower Level, −1	Base Level, 0	Higher Level, +1
x_1 = film-former concentration (one experimental unit = 1%)	4.4	5.4	6.4
x_2 = plasticizer concentration (one experimental unit = 0.5%)	1.0	1.5	2.0
x_3 = total spraying time of coating solution (one experimental unit = 20 min)	40	60	80
x_4 = length of drying interval (one experimental unit = 5 sec)	10	15	20

variables can be optimized to obtain the best combination of formulation and process variables. Mathematical models for optimization of pharmaceutical formulation and processing were reported previously (1–3).

The purpose of this study was to develop a mathematical model for the enteric film coating of tablets with a widely used film former, a copolymer[1] based on methacrylic acid and methyl methacrylate, using a spray gun, a drier, and the conventional coating pan.

THEORY

Statistically designed experiments[2] were performed to derive a mathematical model for the optimization of the film-coating technique. The experimental design is dependent on the number of variables. For four independent formulation and process variables (Table I) (4), a half-factorial orthogonal design at two levels with four replicated center points requires 12 experiments (Table II).

The first eight experiments represent a half-factorial design for four factors at two levels resulting in eight (0.5×2^4) trials. The additional four trials represent the replicated center points. The two levels here are represented as +1 and −1. Level zero represents the base level. Experiments 9–12 are included to calculate the experimental error.

The type of predictor equation resulting from such a study was a first-order polynomial having the form:

$$y_j = b_0 + b_1x_1 + b_2x_2 + b_3x_3 + b_4x_4 \qquad \text{(Eq. 1)}$$

where y_j = response variable, b_i = regression coefficients for first-order polynomial, and x_i = independent variable. Such an equation can be generated for each dependent variable, relating it to the set of four independent variables.

To estimate the path of steepest descent, the gradient of the linear relation given by Eq. 1 can be written as:

$$\nabla y(x_1, x_2, \ldots, x_k) = \left(\frac{\partial y}{\partial x_1}, \frac{\partial y}{\partial x_2}, \ldots, \frac{\partial y}{\partial x_k}\right) = (b_1, b_2, \ldots, b_k) = b_i \qquad \text{(Eq. 2)}$$

where $i = 1, 2, \ldots, k$. Thus, the change in x_i in the path of steepest descent is proportional to $-b_i$, because it moves in the direction $-\nabla y(x_1, x_2, \ldots, x_k)$. In computations, one variable was selected as a standard and the changes in the other variables corresponding to a λ change in the standard variable (λ is the step size) were computed.

EXPERIMENTAL

The four independent formulation and process variables selected are defined in Table I. The length of the drying interval, x_4, was measured as the time interval the coated tablets were dried in the pan by the drier. The film former was a methacrylic acid–methyl methacrylate copolymer; the plasticizer was dibutyl phthalate[3]. Apart from the film former and the plasticizer, the coating solution consisted of isopropyl alcohol (its percentage was changed with the amounts of film former and plasticizer added), acetone (40% w/w), water (1.50% w/w), and a soluble dye (D&C Orange No. 4, 0.01% w/w).

The placebo tablets were composed of lactose, starch, gelatin solution, and magnesium stearate. The tablets were compressed on 2.65-mm deep concave punches and had an average thickness of 7.50 mm. The tablets were nonfriable with an average weight of 760 mg and an average hardness of 8.0 kg. The coating apparatus consisted of a conventional bench-type copper coating pan with 25-cm diameter and 30-rpm rotational speed.

The spraying unit consisted of a compressed air, hand-operated spray gun, but compressed nitrogen gas was used instead of compressed air. The nitrogen pressure was maintained at 0.4–0.5 atm in all experiments. The spray unit was arranged so that the spray jet met the falling cores in the upper part of the pan. It was fixed rigidly by means of clamps on a stand at the side of the pan opening approximately 20 cm from the surface of the rotating tablet bed. The drying unit consisted of a hair drier giving warm air at approximately 50°. The duration of the spraying and drying cycles was adjusted manually with the help of a stopwatch.

Since the main objective of the coating operation was to envelop the core tablets in a polymeric film, it was decided to determine the quantity of solution that would render the process inoperative. The amount of film-coating solution for a single application of the spray gun that a given weight of tablets could tolerate was determined. The amount of solution was measured as the length of spraying in seconds. The spray rate was kept constant (2.30 g/min) by adjusting the nitrogen gas pressure and

the controls of the spray gun. Coating solutions with different compositions were applied to the tablets in the rotating pan until the tablets adhered to the pan and to one another and could not be separated without breaking the deposited film. The length of the spraying interval at this point was taken as the liquid tolerance.

The results of these experiments (Table III) showed that the concentration of film former in the coating solution affected the appearance of the coated tablets greatly. Smooth coatings were obtained with a film-former concentration of 5% but not 10%; a 7% concentration was selected as the maximum. A study of the plasticization of the polymeric materials led to the selection of the 1–2% range for the dibutyl phthalate concentration (5, 6). The total spraying time of the coating solution was varied between 40 and 80 min.

During the liquid tolerance experiments, it was observed that the residual film on the tablets dried between 10 and 20 sec. The length of drying was shorter for solutions with low film-former concentrations and longer for solutions with high film-former concentrations. Therefore, the levels chosen for study were 10 and 20 sec (Table I).

In each experiment, a batch size of approximately 500 g of placebo tablets was coated. The coating solution was sprayed onto the tumbling tablets for 20 sec and then dried with warm air according to the length specified in each experiment. This spray–dry cycle was repeated several times until the total spraying time specified was reached.

Other process and formulation conditions including the spray rate, the temperature of the coating solution and tablet bed, the solvent system, and the amount of additives in the solution were the same for each trial.

After each experiment, samples of coated tablets were evaluated for disintegration in the USP disintegration apparatus (7) by placing the tablets into simulated intestinal fluid (7) and simulated gastric fluid (7). The end-point was taken when the first distinct signs of film disintegration, rupture, separation, or softening were evident.

RESULTS AND DISCUSSION

The mean values of the disintegration time in the simulated intestinal fluid and the resistance time to disintegration in the simulated gastric fluid were taken as the true values of the corresponding response at that experimental point. These values were then used in the statistical analysis to determine the regression equation for each response. The mean disintegration times and the standard deviations of the experiments are shown in Table IV.

Model for Disintegration of Film Coat in Simulated Intestinal Fluid—The fitted first-order polynomial model obtained as a result of the 0.5×2^4 fractional factorial design is:

$$y_1 = 15.000 + 3.750x_1 + 1.250x_2 + 4.750x_3 + 1.250x_4 \quad \text{(Eq. 3)}$$

where y_1 is the disintegration time of the film coat in the simulated intestinal fluid. A lack of fit test assuming a 95% F distribution led to the conclusion that the fitted model was adequate to represent the response function. The hypothesis that $b_i = 0$ for all four independent variables assuming a 95% F distribution was rejected. The ANOVA results showed that all regression coefficients were significant, assuming a 95% F distribution. The model had $R^2 = 94.64\%$, measuring the percent fit of the model.

Model for Resistance of Film Coat to Disintegration in Simulated Gastric Fluid—The fitted first-order polynomial model for this response is:

$$y_2 = 209.583 + 34.375x_1 + 39.375x_2 + 78.125x_3 + 33.125x_4 \quad \text{(Eq. 4)}$$

where y_2 is the resistance time to disintegration of the film coat in the simulated gastric fluid. A lack of fit test assuming a 95% F distribution led to the conclusion that the fitted model was adequate to represent the response function. The hypothesis that $b_i = 0$ for all four independent variables assuming a 95% F distribution was rejected. The ANOVA results showed that all regression coefficients were significant, assuming a 95% F distribution. The model had $R^2 = 89.76\%$.

Determination of Optimum Combination of Factor Levels—After obtaining the first-order regression equations for the two responses, one had to find the optimum combination of factor levels that satisfied the following constraints:

1. The film coat should disintegrate in the simulated intestinal fluid within 10 min ($y_1 < 10$ min). Past experience showed that with this choice, when the active material is inserted into the tablets, the tablets as a whole disintegrate within the desired time limit.
2. The film coat should resist disintegration in the simulated gastric fluid for at least 1 hr (7) ($y_2 > 60$ min). To satisfy these constraints, rather than selecting random values for the x's and finding the corresponding y's, the steepest descent method was employed.

When the coded base levels of the four independent variables (0, 0, 0, and 0) were inserted into the response functions, $y_1 = 15.000$ min and $y_2 = 209.583$ min. Response y_1 had to be decreased to satisfy the constraint of $y_1 < 10$ min. The value of y_2 at the base levels of the x's satisfied the constraint set on y_2.

The steepest descent procedure was applied on the regression equation of y_1. A step size of a 0.1% change in the film-former concentration, x_1, was used. Then the respective x_1, x_2, x_3, and x_4 values were obtained. By inserting the coded values of the x's into the two regression equations, corresponding y_1 and y_2 values at those points were predicted (Table V).

More than one combination of variables satisfied the restrictions set on y_1 and y_2 within the experimental region (Table V). The factor levels on the eighth trial were selected as the most suitable combination, giving the lowest predicted value for y_1 and satisfying the restriction set on y_2 within the experimental region, although the level of x_3 was negligibly below the lower limit (40 min) in the experimental design. An experiment was carried out using the selected levels in the same manner as previous experiments. The values of x_3 and x_4 were rounded to 40 min and 14 sec, respectively, since measuring the time in fractions was quite impossible. The experimental results, as the mean values for the disintegration measurements, were $y_1 = 6.375$ min and $y_2 = 80.000$ min. The predicted values for the two responses were $y_1 = 6.660$ min and $y_2 = 86.623$ min. Applying a two-tailed t test at the 5% significance level to the disintegration in the simulated intestinal fluid, with $n = 16$ and $s = 0.587$, and to the resistance to disintegration in the simulated gastric fluid, with $n = 16$ and $s = 12.712$, showed that experimental and predicted results were in good agreement.

Degradation of Carmustine in Aqueous Media

PAUL A. LASKAR * and JAMES W. AYRES

Abstract □ The degradation rate of carmustine was investigated in buffered aqueous media at several pH values. The buffering agents studied were those with potential use in parenteral formulations of this drug: acetate, citrate, and phosphate. The apparent first-order degradation rate constants were calculated using a linear regression procedure. A pH range over which minimum degradation occurred was ascertained. General acid and specific base catalysis was demonstrated for the degradation of carmustine. From the data at 5, 22, and 37°, the apparent activation energies for carmustine degradation in buffered aqueous media were computed and were strongly pH dependent.

Keyphrases □ Carmustine—degradation rate in aqueous media, effect of pH and temperature □ Degradation rate—carmustine in aqueous media, effect of pH and temperature □ Antineoplastic agents—carmustine, degradation rate in aqueous media, effect of pH and temperature □ Stability—carmustine in aqueous media, effect of pH and temperature

Drugs for the treatment of neoplastic disease have received a great deal of attention. Several thousand chemical agents are systematically screened each year for antineoplastic activity, but only a small percentage exhibit activity and are tested further for clinical utility. Carmustine [1,3-bis(2-chloroethyl)-1-nitrosourea; NSC 409962] (I) was effective in treating L-1210 leukemia, including cases where the central nervous system was involved (1–4).

Prior to the interest in I as a therapeutic agent, a study indicated that 1-methyl-1-nitrosourea (NSC 23909) (II) was unstable in aqueous solution (5), as was a nitrosamide-containing antibiotic, streptozocin, (6). The kinetics of I degradation were considered, and this compound also was unstable in aqueous media (4, 7).

Because I is often administered *via* intravenous solution (8, 9), further consideration of its stability in various aqueous media suitable for intravenous use is desirable. In addition, knowledge of the temperature dependence of the degradation of I is needed to obtain useful shelflife data and to determine desirable storage criteria. Furthermore, knowledge of acid or base catalysis also may be of value in formulating I.

The few published studies directed toward optimizing a parenteral formulation for I emphasized technological considerations such as lyophilization of drug solutions and dry filling with sterile solids (10–12). A formulation for clinical use was prepared by dry filling vials with sterile solid I and sterile, screened mannitol (11, 12). Alternatively, a solution of I in absolute ethanol was filtered through a 0.25-μm membrane and lyophilized (10, 11). These formulations should be used within 1 and 2 hr, respectively, following reconstitution with ethanol and dilution with saline (10, 12).

The purpose of this investigation was to perform accelerated stability studies on I in various aqueous media suitable for injection.

EXPERIMENTAL

Reagents—Carmustine, an investigational new drug, was obtained[1] as a lyophilized powder. All other chemicals were reagent grade.

Materials and Methods—All buffers and other solutions were prepared in volumetric flasks. Distilled water used for dissolving the basic component of the buffer systems was freshly boiled and cooled. Unless noted otherwise, solutions were stored at ambient temperature. Compound I, 0.025 g (stored at −19 ± 1°), was dissolved in sufficient cold (0°) ethanol to make 25 ml of stock solution. The stock solutions were stored at −19 ± 1° for not longer than 7 days.

Buffer solutions were prepared using published procedures (13, 14). All buffer solutions were checked for conformance to the desired pH using a pH meter calibrated at ambient temperature (20–22°) with a pH standard. When necessary, the pH was adjusted to within 0.05 pH unit of the nominal value with either the acidic or basic component of the buffer.

Degradation Experiments—All solvent systems were preequilibrated to the experiment temperature. For ambient (22 ± 1°) and physiological (37.0 ± 0.5°, forced-air oven) temperature experiments, the media were first allowed to equilibrate for at least 16 hr. For experiments at reduced temperature, the media were first chilled in a ice bath (1.0 ± 0.5°) for at least 15 min.

To a volume (~40–45 ml) of preequilibrated media was added 1.0 ml of I stock solution (1 μg/ml). Then the volume was brought rapidly to 50 ml with the appropriate medium, the mixture was shaken, and the time was recorded. A zero-time sample (0.2 ml) was taken for analysis, and the experimental solution was stored at the appropriate temperature. At designated time intervals, a sample volume (0.2, 0.5, 1.0, or 2.0 ml) was removed for analysis.

The criterion used to determine the sample size was that the apparent concentration should not fall below 1.0 μg/ml or exceed 5.0 μg/ml; the optimum range was 2–4 μg/ml to be well within the linear portion of the calibration curve. The sampling time interval depended in part on a previously observed or expected degradation rate.

Analytical Method—The colorimetric method of Loo and Dion (15) was utilized. The use of any substance that might interfere with the analytical method was scrupulously avoided.

An experimental sample volume not greater than 2.0 ml or estimated to contain between 1 and 5 μg of I/ml was added to a 17 × 150-mm Pyrex test tube. If necessary, sufficient distilled water was added to yield a total

Degradation of Carmustine in Aqueous Media

PAUL A. LASKAR * and JAMES W. AYRES

Abstract □ The degradation rate of carmustine was investigated in buffered aqueous media at several pH values. The buffering agents studied were those with potential use in parenteral formulations of this drug: acetate, citrate, and phosphate. The apparent first-order degradation rate constants were calculated using a linear regression procedure. A pH range over which minimum degradation occurred was ascertained. General acid and specific base catalysis was demonstrated for the degradation of carmustine. From the data at 5, 22, and 37°, the apparent activation energies for carmustine degradation in buffered aqueous media were computed and were strongly pH dependent.

Keyphrases □ Carmustine—degradation rate in aqueous media, effect of pH and temperature □ Degradation rate—carmustine in aqueous media, effect of pH and temperature □ Antineoplastic agents—carmustine, degradation rate in aqueous media, effect of pH and temperature □ Stability—carmustine in aqueous media, effect of pH and temperature

Drugs for the treatment of neoplastic disease have received a great deal of attention. Several thousand chemical agents are systematically screened each year for antineoplastic activity, but only a small percentage exhibit activity and are tested further for clinical utility. Carmustine [1,3-bis(2-chloroethyl)-1-nitrosourea; NSC 409962] (I) was effective in treating L-1210 leukemia, including cases where the central nervous system was involved (1–4).

Prior to the interest in I as a therapeutic agent, a study indicated that 1-methyl-1-nitrosourea (NSC 23909) (II) was unstable in aqueous solution (5), as was a nitrosamide-containing antibiotic, streptozocin, (6). The kinetics of I degradation were considered, and this compound also was unstable in aqueous media (4, 7).

Because I is often administered *via* intravenous solution (8, 9), further consideration of its stability in various aqueous media suitable for intravenous use is desirable. In addition, knowledge of the temperature dependence of the degradation of I is needed to obtain useful shelflife data and to determine desirable storage criteria. Furthermore, knowledge of acid or base catalysis also may be of value in formulating I.

The few published studies directed toward optimizing a parenteral formulation for I emphasized technological considerations such as lyophilization of drug solutions and dry filling with sterile solids (10–12). A formulation for clinical use was prepared by dry filling vials with sterile solid I and sterile, screened mannitol (11, 12). Alternatively, a solution of I in absolute ethanol was filtered through a 0.25-μm membrane and lyophilized (10, 11). These formulations should be used within 1 and 2 hr, respectively, following reconstitution with ethanol and dilution with saline (10, 12).

The purpose of this investigation was to perform accelerated stability studies on I in various aqueous media suitable for injection.

EXPERIMENTAL

Reagents—Carmustine, an investigational new drug, was obtained[1] as a lyophilized powder. All other chemicals were reagent grade.

Materials and Methods—All buffers and other solutions were prepared in volumetric flasks. Distilled water used for dissolving the basic component of the buffer systems was freshly boiled and cooled. Unless noted otherwise, solutions were stored at ambient temperature. Compound I, 0.025 g (stored at −19 ± 1°), was dissolved in sufficient cold (0°) ethanol to make 25 ml of stock solution. The stock solutions were stored at −19 ± 1° for not longer than 7 days.

Buffer solutions were prepared using published procedures (13, 14). All buffer solutions were checked for conformance to the desired pH using a pH meter calibrated at ambient temperature (20–22°) with a pH standard. When necessary, the pH was adjusted to within 0.05 pH unit of the nominal value with either the acidic or basic component of the buffer.

Degradation Experiments—All solvent systems were preequilibrated to the experiment temperature. For ambient (22 ± 1°) and physiological (37.0 ± 0.5°, forced-air oven) temperature experiments, the media were first allowed to equilibrate for at least 16 hr. For experiments at reduced temperature, the media were first chilled in a ice bath (1.0 ± 0.5°) for at least 15 min.

To a volume (~40–45 ml) of preequilibrated media was added 1.0 ml of I stock solution (1 μg/ml). Then the volume was brought rapidly to 50 ml with the appropriate medium, the mixture was shaken, and the time was recorded. A zero-time sample (0.2 ml) was taken for analysis, and the experimental solution was stored at the appropriate temperature. At designated time intervals, a sample volume (0.2, 0.5, 1.0, or 2.0 ml) was removed for analysis.

The criterion used to determine the sample size was that the apparent concentration should not fall below 1.0 μg/ml or exceed 5.0 μg/ml; the optimum range was 2–4 μg/ml to be well within the linear portion of the calibration curve. The sampling time interval depended in part on a previously observed or expected degradation rate.

Analytical Method—The colorimetric method of Loo and Dion (15) was utilized. The use of any substance that might interfere with the analytical method was scrupulously avoided.

An experimental sample volume not greater than 2.0 ml or estimated to contain between 1 and 5 μg of I/ml was added to a 17 × 150-mm Pyrex test tube. If necessary, sufficient distilled water was added to yield a total

Table I—Parameter Values for Linear Regressions of Logarithm of Apparent Degradation Rate Constants for I on pH

pH Condition	Temperature (°K)	Regression Coefficient (*SE*)	Intercept
Citrate buffer (pH 3.0, 4.0, and 5.0) and acetate buffer (pH 3.6, 4.0, and 5.0)	278	−0.106 (0.026)	0.001
Citrate buffer (pH 6.0); phosphate buffer (pH 6.0, 6.6, and 7.6); barbital buffer (pH 7.4 and 8.0)	295	1.27 (0.07)	8.86×10^{-6}
Phosphate buffer (pH 6.0, 6.6, and 7.6)	278	1.01 (0.04)	2.91×10^{-6}
	295	1.07 (0.05)	3.26×10^{-5}
	310	0.93 (0.13)	5.46×10^{-4}

volume of 2.0 ml and the contents were mixed. To this solution was added 1.0 ml of 0.5% (w/v) sulfanilamide in 2 *N* HCl, and the solution was mixed and incubated in a water bath with a shaker at 50 ± 0.01° for 45 min. The position in the water bath was randomized to minimize any position-dependent effects on the analytical results.

After 45 min, the solution in the tubes was rapidly chilled in an ice–water mixture. To the cooled solution was added 0.2 ml of 0.3% (w/v) *N*-(1-naphthyl)ethylenediamine dihydrochloride, and the mixture was agitated. The color was allowed to develop for 10 min, after which the percent transmittance was determined using a spectrophotometer[2] at 540 nm calibrated with a reagent blank. The order of percent transmittance determination of samples was randomized, and the amount of I remaining was determined with a calibration curve.

An initial experiment to determine the reliability of the standard curve used the following nominal concentrations prepared from the I stock solutions: 0, 0.01, 0.05, 0.1, 0.5, 1.0, 2.0, 5.0, 10.0, and 50.0 μg/ml. The conformance of the colorimeter as well as the reagents to the calibration curve was checked at periodic intervals throughout the study using an abbreviated set of standards.

RESULTS AND DISCUSSION

The colorimetric method of Loo and Dion (15) was utilized to quantify I, and the calibration curve generated from pooled data was linear from about 0.5 to 7 μg/ml. When subsequent batches of reagent solutions were used, neither batch- nor time-dependent variation was detectable.

The effect of solvents and other adjuvants on drug degradation under some constant conditions can often be described according to the apparent first power of the drug concentration (16). A nitroso-containing compound related to the nitrosoureas, as well as several nitrosoureas, demonstrated first-order rate dependency (4, 6, 7, 17, 18). Therefore, the apparent first-order degradation rate constants for I in several buffer systems at three temperatures were computed from a linear regression of the logarithm of I remaining on time.

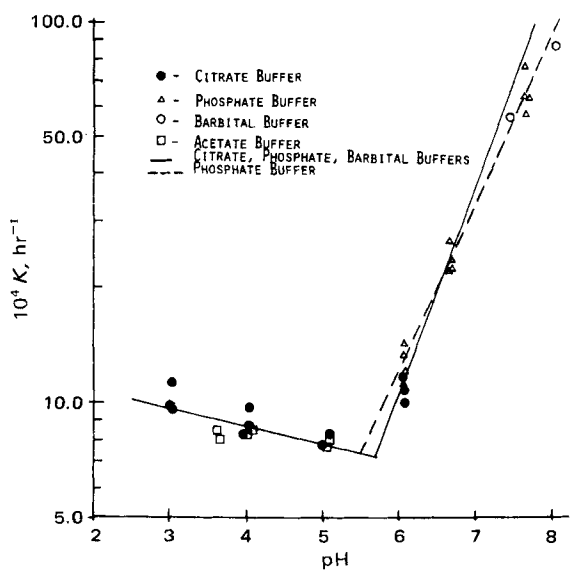

Figure 1—*Logarithm rate constant–pH profile at 278 °K.*

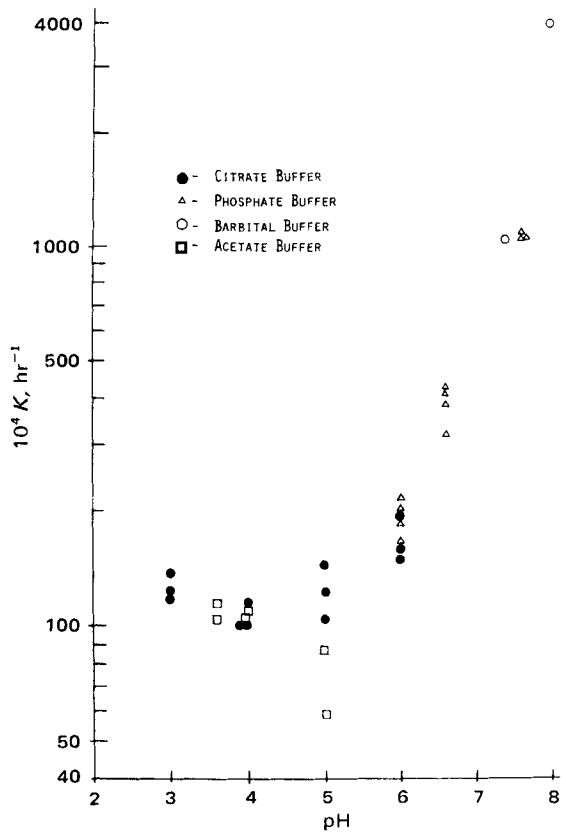

Figure 2—*Logarithm rate constant–pH profile at 295 °K.*

Examination of the linear regression lines for quadratic and cubic curvature revealed no significant departures from linearity for the data, indicating that the assumption of apparent first-order degradation is justified. When the rate constants for degradation in the various buffer solutions were plotted as the logarithm of the observed rate constants *versus* pH, the degradation rate minimum appeared between pH 5.2 and 5.5 (Fig. 1). The rate constants computed at a particular pH, regardless of the buffer system, remained similar, indicating the absence of catalytic effects by any one buffer species.

The results of regression of the logarithm of the degradation rate constants for I on pH in acetate and citrate buffers in the pH 3–5 range are summarized in Table I. The regression coefficient was nonzero and not equal to −1 at the 95% confidence level. Therefore, there is no reason to expect specific acid catalysis. Because the regression coefficient was significantly nonzero, the presence of only solvolysis was also ruled out and general acid catalysis was likely.

Determination of catalysis by base is also possible by examining Fig. 1 in the basic pH region.

The results of the regression of the logarithm of the apparent degradation rate constant for I on pH for citrate, phosphate, and barbital buffers in the pH 6–7.6 range appear in Table I and are illustrated in Figs. 1 and 2. The slope of the line was significantly nonzero but also significantly different than 1 at the 95% confidence level. This result indicates general base catalysis, which is disconcerting since the regression coefficient was nonzero and not significantly different than 1 at the 95% confidence level when only the phosphate buffers were used. The results are also shown in Table I.

The slope with combined citrate, phosphate, and barbital buffers increased with temperature, but the slope for the phosphate buffers showed no such tendency. If the degradation rate constant in a particular buffer was inordinately low at a low pH or high at a high pH, this result could be expected. The rate constants for I were lower in citrate buffer than in phosphate buffer at comparable pH values, and this difference increased with increasing temperature. While the difference at 5° was consistent but not great, the difference at 37° amounted to a factor of about 2. It is not likely that this result was anomalous, since it was consistent over all replications of both buffers.

Table II—Effect of Total Phosphate Concentration on Apparent Degradation Rate Constant of I in Phosphate Buffer at Several pH Values

Ionic Strength	pH	Rate Constant, 10^4 hr^{-1} (*SE*) 5°	22°	37°
0.2	6.0	12.6 (0.30)	197.2 (3.11)	1281.5 (83.98)
	6.6	22.8 (0.45)	353.3 (24.20)	2818.4 (85.51)
	7.6	58.9 (2.82)	1069.0 (24.34)	5428.9 (549.29)
0.05	6.0	12.9 (0.22)	179.4 (24.89)	1395.2 (31.18)
	6.6	24.5 (0.45)	397.2 (11.48)	2922.4 (81.61)
	7.6	68.2 (1.17)	1053.3 (20.98)	7431.1 (384.5)

These data indicate that at pH 6 citrate seems to have a stabilizing effect on I. While the converse, that phosphate has a catalytic effect on nitrosourea degradation, was asserted (7, 18) and denied (4), the data in this experiment do not support the hypothesis of phosphate catalysis, primarily because the degradation of I in phosphate buffers was independent of phosphate concentration (Table II). Although the monohydrogen phosphate anion is said to be the catalytic species (7, 18), degradation rate determinations for I at differing total phosphate concentrations, and thus differing monohydrogen phosphate anion concentrations, provide a measure of such an effect. Since the rate constants at any particular pH and temperature with different ionic strength of phosphate buffers were the same within replication error, evidence for phosphate catalysis is lacking.

The observation that the slope of the logarithm of the apparent degradation rate constant *versus* pH for the phosphate buffers was not significantly different than 1 supports the view of no catalytic effect by phosphate. Finally, from examination of Figs. 1 and 2, it can be seen that the degradation rate constants for I in barbital buffer at pH 7.4 and for phosphate at pH 7.6 were similar, which suggests that no catalytic effect by phosphate or barbital was taking place. These observations tend to rule out the likelihood of specific phosphate catalysis for degradation of I.

The temperature dependence of the degradation rate constants for I in the various buffer systems provides data useful in performing accelerated stability analyses. The activation energies for the degradation of I in the various buffer systems were calculated by transforming the coefficient obtained for the regression of the logarithm of the apparent degradation rate constants on the reciprocal of absolute temperature (Table III). The activation energy appears to be proportional to the pH at which the activation energy was calculated.

To examine this possibility, the hypothesis that the activation energies are the same was tested using analysis of variance techniques (19) (Table IV); results indicated that this hypothesis should be rejected. To examine the possibility that there is a relationship between the activation energy and pH, a regression of the activation energy on pH was calculated (Table IV). While the regression of activation energy on pH was highly significant, the deviations from linear regression were also highly significant (Fig. 3). This relationship, however, seems linearized using a graph of the logarithm of the activation energy *versus* pH (Table IV and Fig. 4).

This effect of pH on the activation energy and linear relationship of the logarithm of the activation energy *versus* pH might be explicable if specific base catalysis is assumed. The rate constant used in determining the activation energy is the apparent rate constant or microscopic ex-

Table III—Activation Energies of I in Buffered Aqueous Media

perimental degradation rate constant, which includes contributions of all catalytic species. Since the macroscopic rate constant for the hydroxide anion has the greatest magnitude of the catalytic constants, the apparent degradation rate constant for which the activation energy is calculated is (20):

$$K_{app} = K_0 + K_{OH}[OH^-] \qquad \text{(Eq. 1)}$$

where K_{app}, K_0, and K_{OH} are the rate constants observed for the uncatalyzed reaction and for the hydroxide-ion contribution and $[OH^-]$ is the hydroxide-ion concentration.

The apparent activation energy computed from the slope of the graph is a function of the activation energy for K_0 as well as that for K_{OH}. Aside from demonstrating that there is a marked temperature dependence of the hydroxide-anion rate constant, the results indicate that the temperature dependence of the uncatalyzed solvolytic rate constant for I is not particularly strong.

The results indicate a minimum degradation rate between about pH 5.2 and 5.5. Examination of the degradation rate constants obtained in

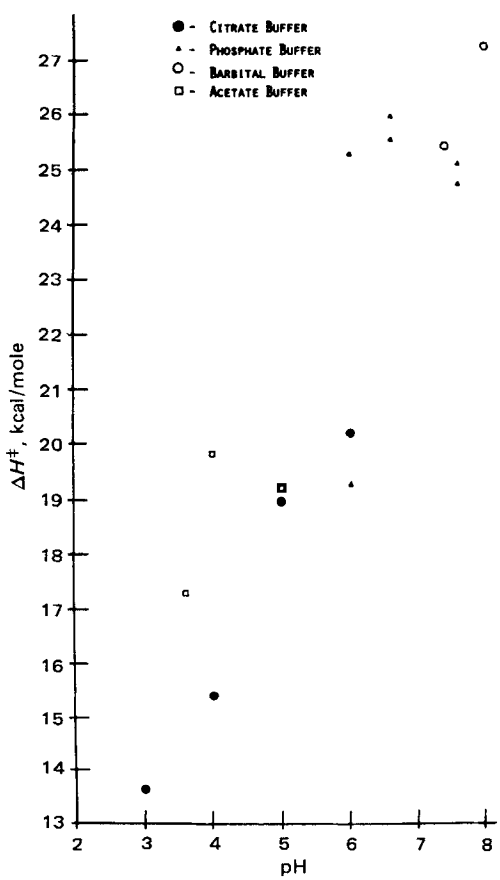

Figure 3—*Activation energy–pH profile for buffered aqueous systems.*

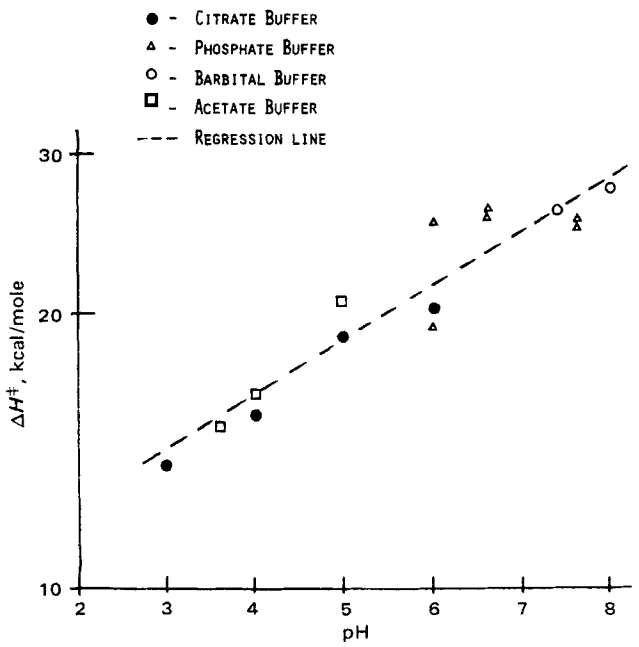

Figure 4—*Logarithm activation energy–pH profile for buffered aqueous systems.*

the accelerated stability analysis studies (Table I) indicates that I would have a short useful life at room temperature in the buffer systems studied. Ten percent degradation would occur in about 14 hr in the citrate buffer at pH 5.0. However, storage in the refrigerator (~5°) would prolong the time for 10% degradation to about 5.5 days.

These preliminary results indicate that it may be feasible to reconstitute I in some intravenous solutions at pH 5.2–5.5, to store the mixture at 5° for a few days, if necessary, and then to administer I parenterally. Further work is underway to determine the effect of certain electrolytes, commonly found in intravenous solutions, on the stability of I.

Degradation of Carmustine in Mixed Solvent and Nonaqueous Media

PAUL A. LASKAR [x] and JAMES W. AYRES

Abstract □ The degradation rate of carmustine in several solvent mixtures and in mannitol solution was investigated at 5, 22, and 37°. The solvents chosen were those utilized as parenteral diluents. The apparent first-order degradation rate constants were computed using a linear regression procedure. The most nonaqueous solvent mixtures demonstrated minimum apparent degradation rates. The apparent degradation rate constant decreased with a decrease in the macroscopic dielectric constant. From the data at several temperatures, the apparent activation energies for carmustine degradation in the several solvent mixtures were calculated. There was no evidence for a relationship between the apparent activation energy and the dielectric constant.

ubility and is quite unstable in aqueous media (1–4). Therefore, in efforts to obtain a desirable dosage form, preformulation studies with I in aqueous, mixed solvent, and nonaqueous media are appropriate. Studies with I in aqueous media were reported previously (5). The mixed solvent and nonaqueous media chosen are those generally utilized in the parenteral administration of various drug agents including nitrosoureas (3).

Little work has been reported on optimizing a parenteral dosage form of I. To date, studies have emphasized technological considerations in the delivery of I as well as other antineoplastic nitrosoureas (3, 6–8).

The present investigation was undertaken at several temperatures to obtain useful shelflife and storage data *via* accelerated stability studies.

EXPERIMENTAL

Materials and Methods—All chemicals and solvents were reagent or USP grade except where noted. Solutions of I were prepared and analyzed as described previously (5).

Degradation Experiments—For ambient (22 ± 1°) and physiological (37.0 ± 0.5°, forced-air oven) temperature experiments, the media were first allowed to equilibrate for at least 16 hr. For experiments at reduced temperature, the media were first chilled in an ice bath (1.0 ± 0.5°) for at least 15 min.

To a volume (~40–45 ml) of temperature-equilibrated media was added 1.0 ml of I stock solution (1 μg/ml). Then the volume was brought rapidly to 50 ml with the appropriate medium, the mixture was shaken, and the time was recorded. A zero-time sample (0.2 ml) was taken for analysis, and the experimental solution was stored at the appropriate temperature. At designated time intervals, a sample volume (0.2, 0.5, 1.0, or 2.0 ml) was removed for analysis.

The criterion used to determine the sample size was that the apparent concentration should not fall below 1.0 μg/ml or exceed 5.0 μg/ml; the optimum range was 2–4 μg/ml. The sampling time interval depended in part on a previously observed or expected degradation rate.

RESULTS AND DISCUSSION

The applicability of this analytical method to I was reported previously (5). Several nitrosoureas and compounds containing nitroso groups exhibit an apparent first-order degradation dependency (1, 4, 9, 10). Therefore, degradation exhibiting apparent first-order kinetics was hypothesized, and the collected data were tested for adherence to this model.

The suitability of the apparent first-order model was initially estimated visually from the graph of the logarithm of the concentration of I remaining (micrograms per milliliter) *versus* time. Since the data did not negate the assumption of apparent first-order dependence, a least-squares regression of the natural logarithm of I concentration on time was calculated and the linear parameters were estimated using a standard computer program (11). The standard error of the linear parameters, the slope, and the intercept were also calculated.

Curvilinearity was estimated qualitatively by examining residuals as well as more quantitatively by utilizing a multiple regression of the natural logarithm of I concentration on a third-degree polynomial in time (12, 13). The multiple regression was performed in a forward stepwise manner, and an analysis of variance (ANOVA) was calculated at each step to enable visualization of the individual variance contribution of the linear, quadratic, and cubic components (13). The results did not negate the assumption of an apparent first-order degradation of I in the several solvent mixtures.

The dependency of the degradation rate constant on the reciprocal dielectric constant and temperature was determined using a least-squares regression of the natural logarithm of the rate constant on the appropriate independent variable, and the regression coefficient(s) were computed. Homogeneity of the activation energy in buffered aqueous systems and solvent systems was evaluated using covariance analysis (14).

From the data calculated for I in the solvent mixtures, the apparent stability increased with an increasing nonaqueous solvent concentration (Table I). The apparent degradation rate constant in optimally buffered aqueous media was about 8×10^{-4} hr^{-1} at 5° (5). The apparent rate constants in solvent mixtures were of this magnitude or less in ethanol, propylene glycol, or dimethyl sulfoxide concentrations of 25% or greater at 5°. The solvent mixture demonstrating minimum degradation (95% ethanol at 5°) had a rate constant more than an order of magnitude less than the buffered aqueous system, thereby providing a t_{90} of about 78 days [*cf.*, about 5.5 days in the buffered aqueous media (5)].

A disadvantage of 95% ethanol as a solvent for direct parenteral administration of I is its irritation potential; this problem would necessitate dilution to a concentration at which irritation is sufficiently reduced. Propylene glycol does not have this irritation potential, although the minimum apparent degradation rate is about twice that for ethanol.

Table III—Regression of Logarithm of Apparent Rate Constant for Degradation of Carmustine on Reciprocal Dielectric Constant of Solvent

Solvent	Regression Coefficient (*SE*) 5°	22°	37°
Ethanol	−180.7 (84.8)	−193.2 (31.0)	−141.0 (2.8)
Propylene glycol	−130.6 (19.9)	−176.4 (12.4)	−101.6 (39.3)
Dimethyl sulfoxide	−355.8 (2740.3)	−350.6 (112.1)	−326.3 (115.2)
Mannitol	—	−180.2 (263.4)	—

Table IV—Activation Energies of Carmustine Degradation in Solvent Mixtures

Solvent	Concentration, %	Activation Energy, kcal/mole (*SE*)
Ethanol	2	21.43 (1.61)
	25	21.53 (3.22)
	50	22.08 (0.23)
	95	15.76 (0.94)

	50	22.21 (2.23)
	100	19.33 (0.50)
Dimethyl sulfoxide	2	26.56 (1.95)
	25	28.77 (1.59)
	50	22.97 (0.94)
	100	21.91 (——)

However, due to its high viscosity, propylene glycol presents potential difficulty for use in a syringe.

Dimethyl sulfoxide is not currently approved for use as a parenteral solvent, although it has been used in some animal studies. The results in this solvent and its mixtures were generally similar to those found for ethanol and propylene glycol. Degradation of I in 100% dimethyl sulfoxide was not followed at 5° since the mixture is solid at this temperature, presenting sampling difficulties. More important, interpretation of results might be compromised due to the "freezing out" of I, thus considerably altering the microscopic solvent environment for the degradation of I. While this occurrence has not been demonstrated for the nitrosoureas, it has been shown for other substances (15).

The results obtained for the solvent mixtures suggest that a proportionality exists between the apparent degradation rate constant and the macroscopic dielectric constant. The dielectric constants for the various solvent mixtures were obtained from the literature and adjusted for temperature (16–18) (Table II). The apparent degradation rate constant of I in a given solvent was regressed on the reciprocal dielectric constant of the solvent, and the results were tabulated (Table III). These computed data indicate a significant decrease in the rate constant with a decrease in the dielectric constant. There is likely to be disparity between the macroscopic tabulated dielectric constants and the microscopic dielectric constant existing in the immediate vicinity of the reacting species (19, 20), particularly in mixtures of solvents with disparate dielectric constants as a result of microscopic dielectric constants reflecting selective solvation (21). Therefore, these regression coefficients computed for I should be considered as qualitative rather than quantitative; they reflect the dielectric constant effect on the degradation rate constant for I.

Mannitol is used as a soluble diluent for I in dry filling vials for reconstitution. Several concentrations of mannitol were utilized to examine the effect of an altered dielectric constant on the apparent degradation rate constant of I. The effect of an increasing mannitol concentration, and thus a decreasing dielectric constant, was comparable to that for the solvent mixtures.

The temperature dependence of the apparent degradation rate constant for I in the solvent mixtures was examined using the Arrhenius equation. The activation energies were computed from the parameters estimated from the least-squares regression equation (Table IV). The regression coefficients were tested for common slope using ANOVA. The results (Table V) do not cause rejection of the hypothesis of a common slope for the temperature dependence of the degradation rate constant in the several solvent mixtures. Therefore, the activation energies may be regarded as constant and parallel. Since the degradation rate constants vary significantly for the solvent mixtures, the frequency factor term in the Arrhenius equation must vary.

Such variation in the frequency factor, and thus the degradation rates, results from the extent of solvation of the reactants and the transition state and affects the entropy of activation (20, 21). Following this reasoning, these data suggest that the differences in the degradation rate constants for I in the solvent mixtures are attributable to these factors relating to solvation.

Among regression coefficients	9	3.80	0.42
Within regression (weighted mean of deviations)	12	48.5	3.46
Common slope = 23.29 kcal/mole			

Solutions of I in concentrated ethanol or propylene glycol possessed t_{90} values at room temperature of about 2.5 and 1 week, respectively. Under refrigerated temperatures, the t_{90} values increased to about 2.5 and 1 month, respectively. The useful lifespans in these solvent mixtures permit reconstitution and refrigerated storage for reasonable time periods. Prior to parenteral administration, the reconstituted ethanol or propylene glycol solution of I would be diluted in a suitable parenteral vehicle.

Mannitol in solutions of I also stabilized I to some extent when compared to an approximately pure aqueous system. This finding may be attributable to the effect on the dielectric constant and to solvation effects. The extended timespans in solvent mixtures were significantly longer than those in buffered aqueous media, possibly attributable, at least in part, to the altered solvation of reactants and intermediates.

Application of Proton and ^{13}C-NMR Spectroscopy to Estimation of Diastereoisomer Ratio in Phenethicillin

W. L. WILSON *x, H. W. AVDOVICH *,
D. W. HUGHES *, and G. W. BUCHANAN ‡

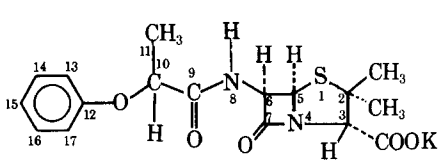
Abstract □ A procedure for the determination of the diastereoisomer ratio in phenethicillin potassium and its formulations is described. The method utilizes analyses of PMR and ^{13}C-NMR data. Assignments of ^{13}C-chemical shifts in D- and L-phenethicillin potassium also are included.

Keyphrases □ Phenethicillin—proton and ^{13}C-NMR spectral analysis of diastereoisomer ratio, bulk drug and commercial formulations □ NMR spectroscopy, proton and ^{13}C—analysis, diastereoisomer ratio of phenethicillin, bulk drug and commercial formulations □ Diastereoisomers—phenethicillin, proton and ^{13}C-NMR spectral analysis of ratio, bulk drug and commercial formulations □ Antibacterials—phenethicillin, proton and ^{13}C-NMR spectral analysis of diastereoisomer ratio, bulk drug and commercial formulations

The semisynthetic penicillin, phenethicillin potassium (I), is prepared by *N*-acylation of 6-aminopenicillanic acid with racemic α-phenoxypropionyl chloride (1). This condensation introduces another center of asymmetry into the molecule, and the resulting two diastereoisomers have different physical properties. The isomer composition of the product varies depending upon the solvent extraction and crystallization procedures. The two isomers show differences in their antibacterial spectra, thereby placing certain limitations on the interpretation of results of microbiological assay but also indicating that products from different manufacturers may vary in antibiotic effectiveness.

The L-phenethicillin potassium content of phenethicillin potassium NF is determined in the "Code of Federal Regulations" (2) by a microbiological assay. Limits of between 55 and 75% of this more active L-isomer are specified. The BP (3) allows optical rotation limits of $[\alpha]_D$ +215 to +240°, corresponding to isomer compositions of 100–34% of the L-isomer. This optical rotation measurement, however, sums the effect at all five asymmetric centers and is not as precise, although it is less tedious, than the microbiological procedure. In addition, none of the pharmacopeias specifies tests for monitoring this isomer ratio in pharmaceutical dosage forms, a control that would be useful from a regulatory standpoint.

In an earlier publication (4) on the NMR spectra of penicillins and cephalosporins, differences in the splitting patterns of the β-lactam protons in the D- and L-isomers of phenethicillin were noted. Since the area or intensity of an absorption band in an NMR spectrum is directly proportional to the number of nuclei that absorb energy at that particular frequency, an NMR assay should be possible provided that at least one resonance band from each component of a mixture is free from extensive overlap by other absorptions. Therefore, the applicability of proton (PMR) and ^{13}C- (CMR) magnetic resonance spectroscopy as a means of monitoring this isomer ratio was examined.



I

EXPERIMENTAL

Materials—Potassium 6-[L-(+)-α-phenoxypropionamido]penicillanate and potassium 6-[D-(+)-α-phenoxypropionamido]penicillinate were FDA reference standards. A sample of DL-phenethicillin potassium[1] contained 100% of the calculated amount of $C_{17}H_{19}KN_2O_5S$ with reference to the dried substance when determined by iodometric assay and had a microbiological potency of 880 μg/mg. The L-isomer content of this material as determined by the Code of Federal Regulations method (2) was 55.6%; by the BP (3) optical rotation method, it was 55.2%. A value of 55% was assigned to this material, which was used as a working standard. Phenethicillin potassium tablets were obtained locally.

Synthetic mixtures of varying L-isomer content were prepared by adding known amounts of the pure D- and L-isomers to a weighed amount of the DL-phenethicillin working standard. This approach was necessary because of the limited quantities of pure isomers available.

Sample Preparation—*Powders*—An amount of powder equivalent to about 50 mg of phenethicillin potassium was dissolved in 0.50 ml of deuterium oxide (99.8% D minimum isotopic purity) in a small glass vial. The solution was agitated for about 1 min and then transferred to a 5-mm diameter NMR tube.

Tablets—After grinding in a mortar and pestle, a weighed portion of the powder equivalent to about 250 mg of phenethicillin potassium was placed in a 15-ml centrifuge tube, and 2.5 ml of deuterium oxide was added. After mixing, the sample was centrifuged. Then 0.50 ml of the supernate was transferred to a 5-mm diameter NMR tube.

PMR—Spectra were recorded on a 60-MHz NMR spectrometer[2] at ambient probe temperature (40 ± 2°) using a sweep width of 500 Hz and a 250-sec sweep time. For quantitative purposes, the portion of the spectrum between 5 and 6 ppm (β-lactam protons) was rerecorded at a sweep width of 250 Hz and carefully integrated five times. A radio frequency power of 0.25 milligauss (normal dial setting) gave maximum integral amplitude and was used for integrations. Tetramethylsilane in deuterochloroform was the external reference. Chemical shifts were measured in parts per million downfield from tetramethylsilane.

The percent of L-phenethicillin in a sample was calculated by dividing the peak areas attributed to the *AB* quartet of L-phenethicillin by the total integral value (combination of D- and L-phenethicillins).

CMR—Spectra were recorded on a 25.2-MHz spectrometer[3].

The "standard condition" spectra were recorded using a 5000-Hz sweep width, 8192 data points, a pulse angle of 60° (20-μsec pulse duration), and a pulse interval of 1 sec. Good quality spectra were obtained from samples of 50 mg/0.50 ml with about 20,000 transients (approximately 5-hr accumulation time). To remove the effects of ^{13}C–H coupling, complete noise decoupling conditions were used. For integration, the area near δ 32 ppm was expanded to a width of 200 Hz and was electronically integrated five times.

Peak height ratios were determined from the 2-β-methyl resonances on the standard condition spectra. Probe temperature was 32°, and the deuterium of the solvent was employed for a field-frequency lock. Chemical shifts quoted are in parts per million downfield from tetramethylsilane; a methanol capillary served as an internal reference point.

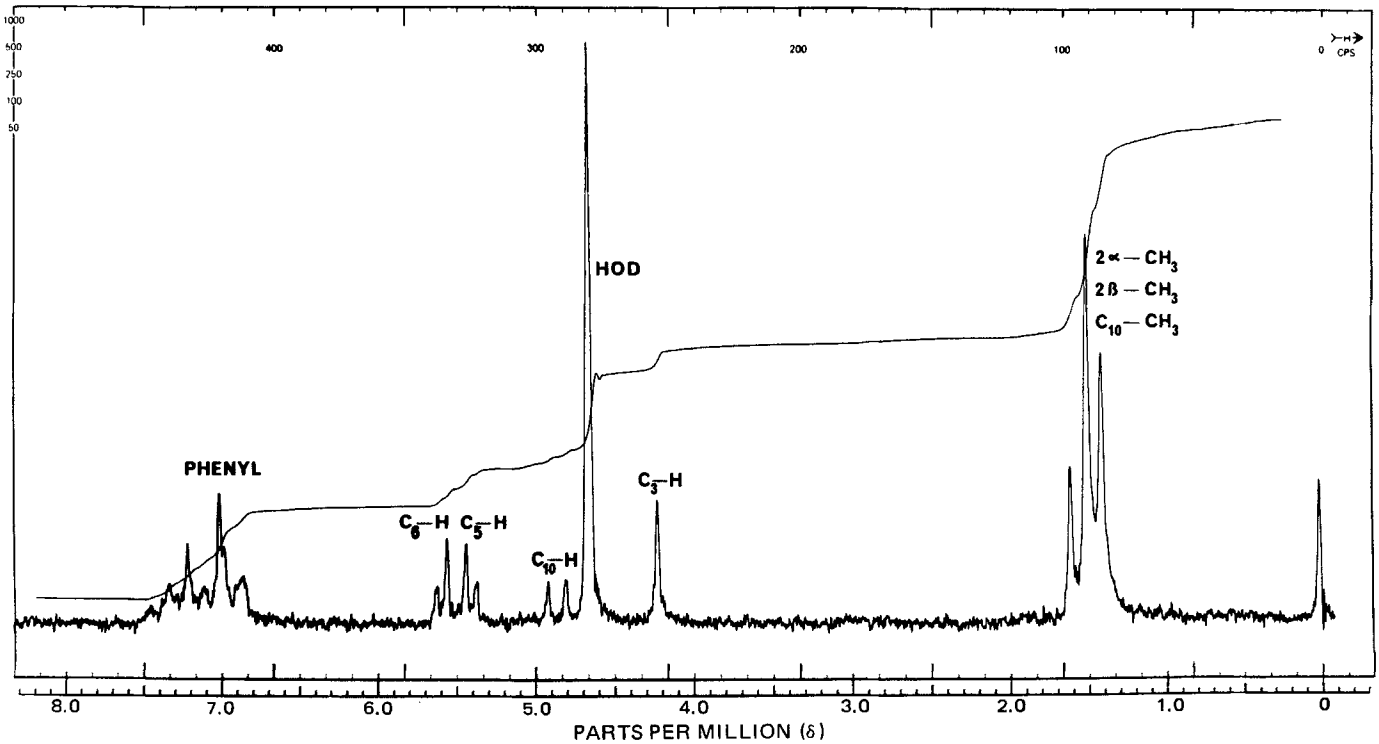

Figure 1—*PMR spectrum of* L-*phenethicillin potassium in deuterium oxide.*

The T_1 relaxation experiments, employing the kinetically inert paramagnetic metal complex tris(acetylacetonato)chromium, were conducted in the presence of 2×10^{-2} molar equivalents of the relaxation reagent. In the gated decoupling experiments, the ^{1}H-decoupler was "gated on" only during data acquisition periods, which were typically 0.5 sec. For the off-resonance decoupling experiments, the proton decoupling frequency was offset by 500 Hz from its optimum value. The selective decoupling experiments were conducted using low decoupler power in the absence of noise modulation.

RESULTS AND DISCUSSION

PMR—The PMR spectra of penicillins would be expected to have a characteristic single proton doublet arising from the C-5 hydrogen and a single proton doublet of doublets at the lower field for hydrogen at C-6. In spectra obtained from deuterium oxide solutions, these β-lactam proton signals should appear as an *AB* quartet (5).

Figure 1 illustrates the PMR spectrum of L-phenethicillin with the expected *AB* splitting pattern for the β-lactam proton signals ($J_{5,6}$ = 4 Hz; ν_5 = 5.4 and ν_6 = 5.6 ppm). The assignments of the other resonances were reported earlier (4). In the PMR spectrum of D-phenethicillin (Fig. 2), these β-lactam protons appeared as a singlet at 5.5 ppm. The β-lactam protons of ampicillin sodium also have given a two-proton singlet in deuterium oxide, possibly due to accidental equivalence of chemical shifts (6).

These spectra were recorded using a concentration of approximately 100 mg/ml. Under more dilute conditions (<60 mg/ml), broadening of the singlet in D-phenethicillin occurred, indicating that it too was splitting into an *AB* pattern.

The PMR spectrum of a typical sample of DL-phenethicillin is shown in Fig. 3. The β-lactam region was expanded and integrated (Fig. 3, inset). PMR spectra of mixtures containing varying amounts of D- and L-phenethicillins as well as commercial bulk drug powder and tablet formulations were analyzed by this method, and the percentage of the L-isomer was calculated from an average of five integrations. The results (Table I) indicated that the accuracy of this PMR quantitative method decreased as the proportion of D- and L-isomers deviated from a near equal mixture. As the relative amount of the L-isomer increased, the method led to an underestimation of its content. However, excellent correlation with calculated values was obtained in the region normally expected with commercial samples, *i.e.*, 55–75% L-isomer. Sample 9 (Table I) illustrates that results can also be obtained directly from tablets, which is particularly useful from a quality control and regulatory standpoint.

The high precision of this PMR assay method is indicated by the standard deviation and coefficient of variation of 0.6 and 1.1%, respectively, found for Sample 9 (Table I) when two separate determinations were each integrated five times. Because of broadening of the β-lactam proton signal in D-phenethicillin with dilute solutions (as mentioned previously) and the need for concentrated solutions to obtain large and,

therefore, more precise integrals, DL-phenethicillin potassium concentrations of 80–120 mg/ml were optimum for reproducible and precise quantitative results. Higher concentrations led to ill-defined separation of the *AB* quartet because of the concentration dependence of the chemical shift of protons at C-5 and C-6 (7).

CMR—The variation in carbon shieldings in neutral organic compounds is approximately 20-fold greater than that of protons, *i.e.*, approximately 200 ppm. These ^{13}C-shifts are also sensitive to steric, conformational, and electronic changes in a molecule. Because of the greater peak resolution of CMR, its application to this phenethicillin diastereoisomer study also was investigated. The CMR spectrum of DL-phenethicillin potassium is illustrated in Fig. 4. Since peaks were not assigned previously, they are listed in Table II.

Spectra of pure D- and pure L-phenethicillin potassium salts were recorded, which greatly facilitated the assignments for the diastereoisomeric mixture. To date, the only CMR data available for related systems are those for the methyl- and phenoxymethylpenicillins (8). Only assignment procedures for the L-isomer will be discussed, since completely

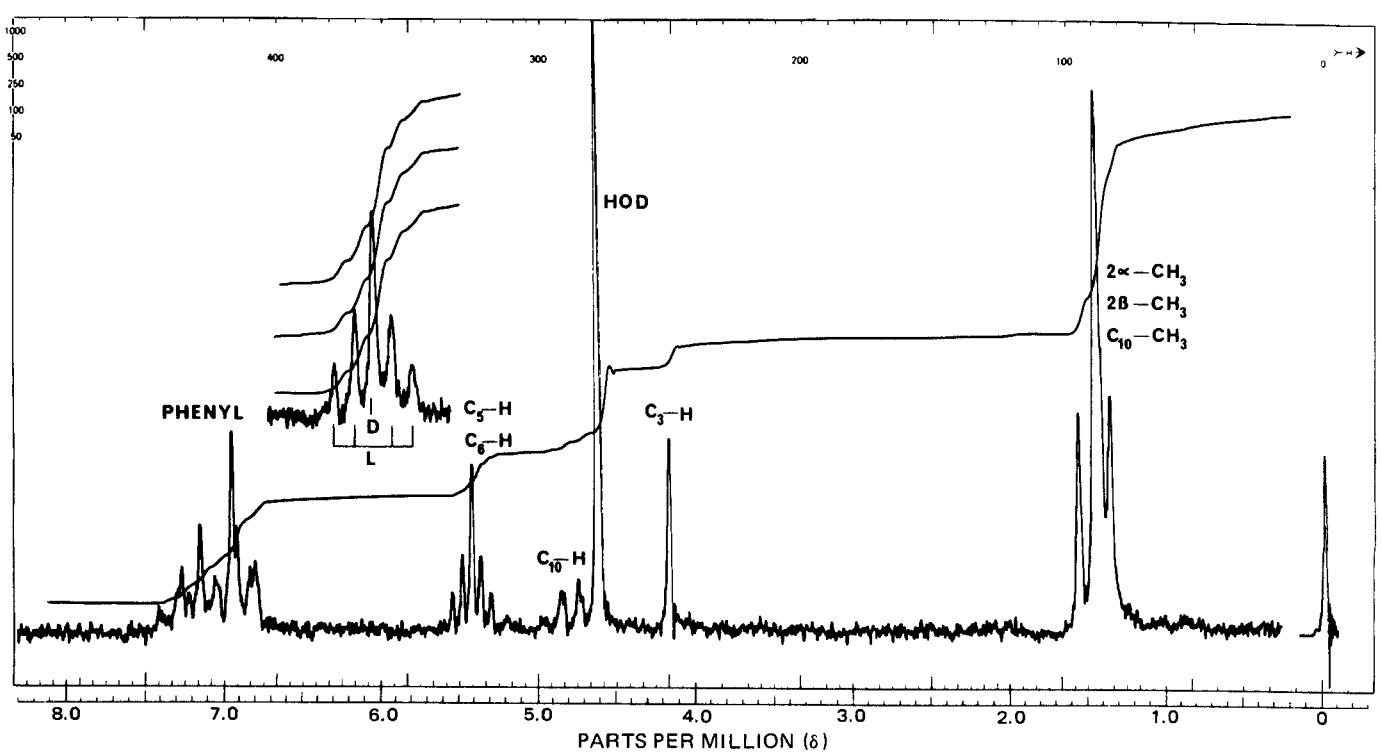

Figure 3—*PMR spectrum of commercial* DL*-phenethicillin potassium in deuterium oxide. Inset shows the β-lactam proton resonances recorded with a 250-Hz sweep width. Peaks labeled D and L refer to β-lactam protons of* D*- and* L*-phenethicillins, respectively.*

analogous techniques were used for the D-spectrum.

Initially, nonprotonated carbons were identified by their retention of singlet structure in the off-resonance decoupling experiment (9), whereas CH and CH_3 carbons yielded quartets and doublets, respectively. The three high field (lowest δ) resonances were due to the methyl groups, with that designated as C-11 being most shielded at δ 19.6 ppm. The 2-α and 2-β-methyl carbons were less shielded, which was consistent with their *gem*-dimethyl character. The 2-α group, being *cis* to the CO_2^- K^+ function, appeared 4.8 ppm upfield from its 2-β-counterpart. This shielding phenomenon at the 2-α-position presumably resulted from the γ steric interaction (10) between this function and the carboxylate moiety. The shift difference between signals from the epimeric methyls was very similar to that found in phenoxymethylpenicillin (8), although a strict comparison was not possible since the present data were recorded in deuterium oxide solutions as opposed to dimethyl sulfoxide-d_6 in the earlier work (8).

The C-2 resonance at δ 65.8 was similar to the C-2 of phenoxymethylpenicillin (δ 64.0). Distinction between the CH resonances at δ 74.3 and 75.1 was accomplished using selective ^1H-decoupling, since the corresponding proton shifts were known. Accordingly, C-3 was associated with the resonance at δ 74.3, and C-10 was associated with the δ 75.1 absorption. For the lactam ring carbons C-5 and C-6, phenoxymethylpenicillin again was a useful model compound, since the C-5 and C-6 resonances were at δ 67.4 and 58.4 ppm, respectively (8).

Assignment of the aromatic ring carbons C-12 to C-17 was straightforward, since it is well known that conjugative electron release by the ethereal oxygen shields the *ortho*- and *para*-carbons relative to the *meta*-position in anisoles and diphenyl ethers (11). Finally, the three carbonyl carbons were the most deshielded; however, unambiguous assignments were not possible.

For quantitative analysis of the diastereoisomeric mixtures, the 2-β-methyl resonances proved to be most useful since the chemical shift difference between them was the largest (0.6 ppm) and was essentially independent of the ratio of D- and L-phenethicillin potassium salts present in solution. In ^{13}C-Fourier transform NMR spectroscopy (12), great care must be taken in quantitative interpretation of data due to possible differences in spin lattice relaxation time (T_1's) and nuclear Overhauser enhancements between carbons of interest. In this study, the ratios of D- to L-forms as determined from two types of experiments were compared to verify that valid quantitative measurements were made.

Initially, the relaxation reagent tris(acetylacetonato)chromium (13) was used; no change was noted in the relative intensity of the 2-β-methyl resonances as compared to the standard condition spectrum, indicating that similar Overhauser enhancements and T_1's existed for the diastereomeric 2-β-methyl resonances. Subsequently, spectra were recorded using a gated decoupling technique (14), and again no alteration in the relative intensities of these resonances was noted. This result verified that essentially identical Overhauser enhancements operate for the diastereomeric 2-β-methyl resonances.

These experiments support the claim that the quantitative assessments are valid, and the close agreement between the CMR findings and the results from other techniques substantiates this claim. The CMR method is as accurate and as precise as the PMR assay but over a wider range of D to L ratios (Table I). Peak height measurement can be used instead without sacrificing accuracy. If more concentrated samples are used in the analysis, data accumulation time by the CMR method can be further reduced, giving reliable spectra within 2 hr.

Table II—^{13}C-Shift Assignments for D- and L-Phenethicillin Potassium in Parts per Million Downfield from Tetramethylsilane

L-Isomer	Assignment	D-Isomer
175.8	$C_{7,9,18}$	175.7
175.4	$C_{7,9,18}$	175.4 (2)
175.9	$C_{7,9,18}$	—
157.7	C_{12}	157.8

Parameter for Assessing Parenteral Cleanliness Based on Particle-Size Distributions

JAMES BLANCHARD [x], JOHN A. SCHWARTZ, and DALE M. BYRNE *

Abstract □ A new parameter for assessing the particulate matter content of large-volume parenteral solutions was developed and tested. Some problems and shortcomings associated with previously proposed standards are discussed, together with the potential advantages of employing the proposed parameter. Cleanliness factors were compared with another parameter and were less susceptible to changes resulting from the method of measurement utilized and the premeasurement conditions encountered by the solution. The use of these cleanliness factors in conjunction with an automatic particle counter is proposed as a worthwhile supplement to the USP–NF standard for monitoring the quality of large-volume parenteral solutions.

Keyphrases □ Particle-size distributions—characterized in large-volume parenteral solutions, cleanliness factor developed □ Parenterals, large volume—particle-size distributions characterized, cleanliness factor developed □ Dosage forms—large-volume parenterals, particle-size distributions characterized, cleanliness factor developed

Particulate matter is defined as "extraneous, mobile, undissolved substances other than gas bubbles, unintentionally present in parenteral solutions" (1) and has been long recognized as a problem. Recently, official standards specified the allowable levels of particulate contamination (1, 2).

To aid in the evaluation of the cleanliness[1] of a parenteral solution, an auxiliary parameter that would describe accurately the contamination level is needed. Several desirable characteristics of this parameter were described previously (3, 4); it should provide a true measurement of particulate cleanliness that is not affected by the premeasurement handling conditions, and it should indicate the correct degree of particulate cleanliness using various instrumental techniques. The method also should be rapid, nondestructive, nonsubjective, simple, inexpensive, easy to standardize, and, preferably, not require the use of a clean room.

The present study was undertaken to develop such a parameter for the objective assessment of the relative particulate cleanliness of parenteral solutions.

[1] Throughout this article, the term "cleanliness" is used to denote the level of particulate matter.

BACKGROUND

Single-Point Standards—One early standard was proposed in 1966 (5). The initial proposal was revised and formed the basis of the first provisional Australian standard (6), which stated that a parenteral solution should not contain more than 250 particles/ml exceeding 3.5 μm in diameter. In the same year, another suggested single-point standard stated that a parenteral solution should not contain more than 50 particles/ml exceeding 5 μm in diameter (7).

Single-point standards are validly subject to criticism on the basis that the particles counted exceeding a given diameter are not necessarily indicative of the number of particles exceeding another diameter. Single-point standards were based on the observation that log–log plots of $N_{>D}$ (the particle concentration exceeding the diameter, D) *versus* D (the particle diameter) were essentially linear and parallel to one another among the individual solutions examined (5). However the slopes of the log–log plots vary among individual solutions[2] (6, 8), thereby invalidating the use of single-point standards.

Multiple-Point Standards—Recent attempts to establish standards focused on multiple-point determinations. As Kendall (9) noted, a standard should ideally be based upon the determination of the particle-size distribution over a broad size range. This consideration formed the basis for an Australian standard proposed in 1966 (5), which limited the allowable levels of particles exceeding four particle diameters. This and other recently proposed multiple-point standards are shown in Table I.

Multiple-point standards (as well as single-point standards) can be criticized on the grounds that the particle-size distribution may vary with the degree of agitation to which the solution is subjected (8, 10–12). Another potential criticism is that the measurement of particle concentrations may not be obtainable using a single technique (*i.e.*, instrumental, microscopic, *etc.*). If the particle diameters specified in the standard require measurement by more than one technique, the counts provided by each technique would have to correlate extremely well with one another. Besides introducing unnecessary uncertainty, this requirement would necessitate proficiency in more than one technique.

The USP–NF standard (Table I) suggests the use of a membrane filtration and microscopic examination technique. In a practical sense, it is only suitable for counting particles larger than 10 μm in diameter (3, 6). The Australian and British Pharmacopoeia standards do not prescribe a specific measuring technique. However, an electrical resistance counter or a light-scattering or light-blocking device is required, since these standards specify the counting of particles smaller than 10 μm in diameter. A recent version of the Australian standard (Table I), soon to become effective[3], specifies the use of an instrumental particle counter operating

Parameter for Assessing Parenteral Cleanliness Based on Particle-Size Distributions

JAMES BLANCHARD [x], JOHN A. SCHWARTZ, and DALE M. BYRNE *

Abstract □ A new parameter for assessing the particulate matter content of large-volume parenteral solutions was developed and tested. Some problems and shortcomings associated with previously proposed standards are discussed, together with the potential advantages of employing the proposed parameter. Cleanliness factors were compared with another parameter and were less susceptible to changes resulting from the method of measurement utilized and the premeasurement conditions encountered by the solution. The use of these cleanliness factors in conjunction with an automatic particle counter is proposed as a worthwhile supplement to the USP–NF standard for monitoring the quality of large-volume parenteral solutions.

Keyphrases □ Particle-size distributions—characterized in large-volume parenteral solutions, cleanliness factor developed □ Parenterals, large volume—particle-size distributions characterized, cleanliness factor developed □ Dosage forms—large-volume parenterals, particle-size distributions characterized, cleanliness factor developed

Particulate matter is defined as "extraneous, mobile, undissolved substances other than gas bubbles, unintentionally present in parenteral solutions" (1) and has been long recognized as a problem. Recently, official standards specified the allowable levels of particulate contamination (1, 2).

To aid in the evaluation of the cleanliness[1] of a parenteral solution, an auxiliary parameter that would describe accurately the contamination level is needed. Several desirable characteristics of this parameter were described previously (3, 4); it should provide a true measurement of particulate cleanliness that is not affected by the premeasurement handling conditions, and it should indicate the correct degree of particulate cleanliness using various instrumental techniques. The method also should be rapid, nondestructive, nonsubjective, simple, inexpensive, easy to standardize, and, preferably, not require the use of a clean room.

The present study was undertaken to develop such a parameter for the objective assessment of the relative particulate cleanliness of parenteral solutions.

[1] Throughout this article, the term "cleanliness" is used to denote the level of particulate matter.

BACKGROUND

Single-Point Standards—One early standard was proposed in 1966 (5). The initial proposal was revised and formed the basis of the first provisional Australian standard (6), which stated that a parenteral solution should not contain more than 250 particles/ml exceeding 3.5 μm in diameter. In the same year, another suggested single-point standard stated that a parenteral solution should not contain more than 50 particles/ml exceeding 5 μm in diameter (7).

Single-point standards are validly subject to criticism on the basis that the particles counted exceeding a given diameter are not necessarily indicative of the number of particles exceeding another diameter. Single-point standards were based on the observation that log–log plots of $N_{>D}$ (the particle concentration exceeding the diameter, D) *versus* D (the particle diameter) were essentially linear and parallel to one another among the individual solutions examined (5). However the slopes of the log–log plots vary among individual solutions[2] (6, 8), thereby invalidating the use of single-point standards.

Multiple-Point Standards—Recent attempts to establish standards focused on multiple-point determinations. As Kendall (9) noted, a standard should ideally be based upon the determination of the particle-size distribution over a broad size range. This consideration formed the basis for an Australian standard proposed in 1966 (5), which limited the allowable levels of particles exceeding four particle diameters. This and other recently proposed multiple-point standards are shown in Table I.

Multiple-point standards (as well as single-point standards) can be criticized on the grounds that the particle-size distribution may vary with the degree of agitation to which the solution is subjected (8, 10–12). Another potential criticism is that the measurement of particle concentrations may not be obtainable using a single technique (*i.e.*, instrumental, microscopic, *etc.*). If the particle diameters specified in the standard require measurement by more than one technique, the counts provided by each technique would have to correlate extremely well with one another. Besides introducing unnecessary uncertainty, this requirement would necessitate proficiency in more than one technique.

The USP–NF standard (Table I) suggests the use of a membrane filtration and microscopic examination technique. In a practical sense, it is only suitable for counting particles larger than 10 μm in diameter (3, 6). The Australian and British Pharmacopoeia standards do not prescribe a specific measuring technique. However, an electrical resistance counter or a light-scattering or light-blocking device is required, since these standards specify the counting of particles smaller than 10 μm in diameter. A recent version of the Australian standard (Table I), soon to become effective[3], specifies the use of an instrumental particle counter operating

Table I—Some Standards for Particulate Contamination Levels

Standard Test	Maximum Allowable Number of Particles per Milliliter of Various Sizes					
	2.0 μm	3.5 μm	5 μm	10 μm	20 μm	25 μm
USP–NF	—	—	—	50	—	5
Australian I[a]	1000	250	100	25	—	—
Australian II[b]	—	—	100	—	2	—
BP_1[c]	2000	—	200	—	—	—
BP_5[c]	100	—	100	—	—	—

[a] See Ref. 3. [b] See footnote 2. [c] The BP_1 test refers to readings taken on one container, whereas the BP_5 test refers to the average reading of five containers.

on the light-blockage principle and the counting of particles exceeding two diameters.

Complex Standards—Ernerot (13) suggested the silting index determination as an alternative to particle counting for evaluating particulate contamination in large-volume parenterals. However, this method is not simple, either in theory or practice. While it offers certain advantages over other methods, it appears to be far from ideal because of the numerous assumptions involved. Further definitive studies might resolve some of these uncertainties.

To alleviate some shortcomings of the single- and multiple-point standards, the particle-size distribution of the contaminants should be examined over as broad a size range as practical to ascertain the correct relationship describing the particle-size distribution. In previous studies[2] (3, 12), many samples (both individually and when averaged) closely adhered to a linear equation of the form:

$$\log N_{>D} = K \log D + \log N_{>1} \qquad \text{(Eq. 1)}$$

where $N_{>D}$ is the number of particles per milliliter with a diameter larger than D, $N_{>1}$ is the number of particles per milliliter with a diameter larger than 1 μm, D is the particle diameter in micrometers, and K is equal to the slope of the plot of $\log N_{>D}$ *versus* $\log D$. This equation previously was utilized to describe the particle-size distribution of contaminants in parenterals (6). Recently (12), the effects of agitation on the particle-size distribution of particulate contamination of parenterals were determined. An unequivocal characterization of the effects of agitation on the particle-size distribution of a parenteral solution must be obtained by simultaneously examining both parameters that describe the distribution (*i.e.*, the slope *and* the intercept of the $\log N_{>D}$ *versus* $\log D$ plot). A single parameter based upon the slope and the intercept of the log–log plot would specify accurately the degree of cleanliness of a parenteral solution.

EXPERIMENTAL

The particle-size distribution data of large-volume parenteral solutions[4] (1000 ml) were obtained by two methods: a nondestructive instrumental technique, using an automatic particle counter[5], and a membrane filtration and microscopic method similar to the USP–NF technique, which is a destructive method. The exact procedures followed and the method of data analysis are described elsewhere[2] (3, 12).

The six types of parenteral solutions examined were: (*a*) 5% dextrose in 0.45% sodium chloride, (*b*) normal saline, (*c*) 5% dextrose in multiple-electrolyte solution[6], (*d*) 5% dextrose in normal saline, (*e*) 5% dextrose in water, and (*f*) 5% dextrose in lactated Ringer's solution. These solutions were chosen on the basis of their extensive clinical use.

RESULTS AND DISCUSSION

Groves (6) attempted to relate the slopes and intercepts of the $\log N_{>D}$ *versus* $\log D$ plots, which characterize the particle-size distribution of parenteral solutions, to their relative cleanliness. The form of Groves' postulated relationship is:

$$\frac{\log N_{>1} - 2.5}{-K} = \text{specific value } (S) \qquad \text{(Eq. 2)}$$

The S value was based upon the empirical observation that most parenteral solutions examined that passed a provisional Australian

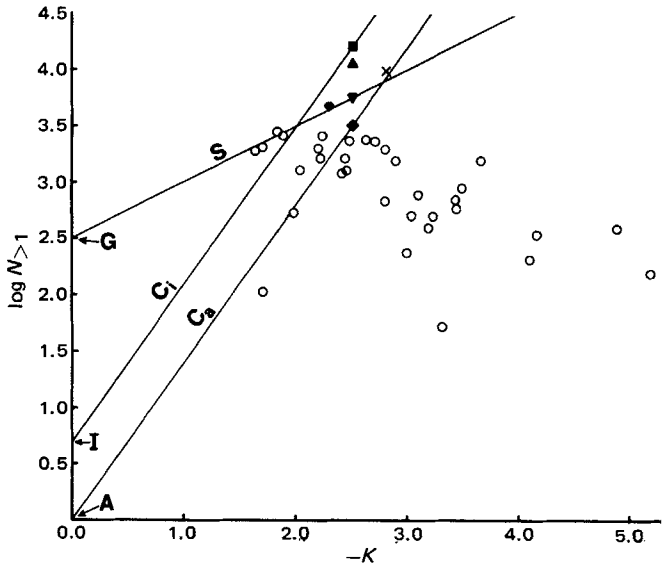

Figure 1—*Relationship between cleanliness factors and official standards. standard (≯250 particles/ml > 3.5 μm) would lie below an arbitrarily drawn line (S) having a slope of 0.5 and a y intercept (point G) of 2.5 when $\log N_{>1}$ was plotted *versus* $-K$. Conversely, most solutions that failed this standard would lie above the line. This line (S) in Fig. 1 represents a family of straight lines on the log–log plot of $N_{>D}$ *versus* D (Fig. 2), all passing through the common point S' corresponding to 316 particles/ml >3.16 μm. Due to the arbitrary manner in which Groves admittedly developed the S value and because some solutions examined in this study would have failed the Australian standard and yet passed the S value, and vice versa, the suitability of using another parameter to assess parenteral cleanliness was investigated.

The recently developed USP–NF standard (Table I) was examined in this context. If the values listed in this standard exhibit the linear relationship described by Eq. 1, then the slope and the y intercept of this line shown in Fig. 2 are −2.5126 and 16,280 ($\log N_{>1} = 4.2116$), respectively. These values are the coordinates of the point shown as the filled square (■) in Fig. 1. This point (■) was plotted and connected to point I, which represents a hypothetical particle-size distribution such that the log–log plot of $N_{>D}$ *versus* D (Fig. 2) has a slope of zero and a y intercept of 5 ($\log N_{>1} = 0.6990$). The resultant line, C_i, in Fig. 1 can be described by:

$$C_i = \frac{\log N_{>1} - 0.6990}{-K} \qquad \text{(Eq. 3)}$$

This line represents a family of straight lines on the log–log plot of $N_{>D}$ *versus* D, all passing through the common point C_i' in Fig. 2 corresponding to five particles/ml >25 μm. This point was selected since it is representative of the USP–NF standard.

Practically all commercially manufactured solutions examined would have passed a more stringent standard (3). Since the most contaminated of these solutions contained approximately one-fifth of the level of particulate matter allowed by the USP–NF standard, the possibility of using a cleanliness factor based upon a fivefold reduction of this standard was investigated. A more stringent standard for evaluating parenteral cleanliness based upon averaged data is currently used in the BP (Table I and Fig. 2). This standard specifies a twofold reduction in allowable particles when averaging data from five solutions in contrast to data from individual solutions. Increased stringency for evaluating parenteral cleanliness when averaging data is reasonable, since the mean of a set of samples exhibits much less variability than individual samples.

When this fivefold reduction of the USP–NF standard was plotted in Fig. 2, the slope and the y intercept of the line were −2.5126 and 3255 ($\log N_{>1} = 3.5126$), respectively. These values are the coordinates of the point (♦) plotted in Fig. 1 and connected to point A, which represents a hypothetical particle-size distribution in Fig. 2 with a slope of zero and a

Table II—Effect of Method of Measurement on the Cleanliness Factors

Cleanliness Factor (CF) ± SE[a]	Critical Value	Method of Measurement		Differences in Cleanliness Factor, %
		Microscope	Prototron	
$\frac{\log N_{>1}}{-K} = C_a$	1.3979	0.8905 ± 0.0456	1.1354 ± 0.0742	27.5
$\frac{\log N_{>1} - 0.6990}{-K} = C_i$	1.3979	0.5582 ± 0.0571	0.8694 ± 0.0619	55.8
$\frac{\log N_{>1} - 2.5}{-K} = S$	0.5000	−0.2978 ± 0.0913	0.1842 ± 0.0349	161.9

[a] Although the parameters C_i and S were developed to evaluate individual solutions, the data shown were based upon an average of 36 individually calculated cleanliness factors to demonstrate clearly the overall effects of the method of measurement.

y intercept of 1 ($\log N_{>1} = 0$). Line C_a in Fig. 1 can be described by:

$$C_a = \frac{\log N_{>1}}{-K} \qquad \text{(Eq. 4)}$$

This line represents a family of straight lines on the log–log plot of $N_{>D}$ *versus* D, all passing through the common point C_a' in Fig. 2 corresponding to one particle/ml >25 μm. It is proposed that this cleanliness factor, C_a, be used to evaluate the cleanliness of parenterals based upon *averaged* data for several solutions.

Equations 3 and 4 describe the two lines shown in Fig. 1 denoted by C_i and C_a, respectively, whose slopes are both numerically equal to 1.3979. This number represents the critical value, *i.e.*, the maximum allowable value of the cleanliness factors. Therefore, any individual solution whose C_i exceeds 1.3979 or a representative sample of a batch of solutions whose C_a exceeds this critical value would fail the respective standard. Effectively, this approach means that any line joining point I in Fig. 1 with a point depicting an individual parenteral solution, or point A with a point depicting the average of several parenteral solutions, whose slope exceeds that of the C_i or C_a lines would fail the respective standard. Since the relative distribution of particles is largely independent of the composition of the solution (3, 10), the cleanliness factors for the solutions were averaged without regard to solution type.

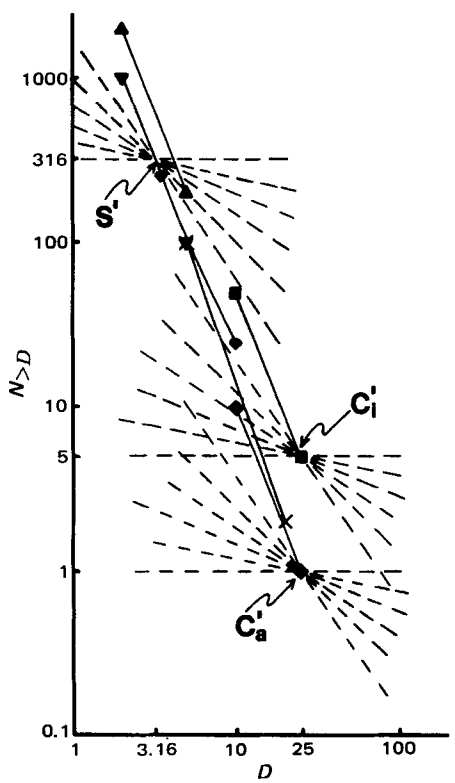

Figure 2—*Particle-size distributions of the official standards and of the critical values of the cleanliness factors. Key: -■—■-, USP–NF standard; -♦—♦-, fivefold reduction of USP–NF standard; -▲—▲-, BP_1 standard; -▼—▼-, BP_5 standard; -●—●-, Australian I standard; -×—×-, Australian II standard; and - - -, particle-size distribution of the critical value of the respective cleanliness factor.*

The cleanliness factors were calculated as follows. A particle-size distribution for a given solution was obtained by measuring the particle counts exceeding several diameters (1.000, 1.259, 1.585, 1.995, 2.512, 3.162, 3.981, 5.012, and 6.310 μm). These diameters were chosen to facilitate data analysis, since their logarithms are equally spaced. Equation 1 was fitted to the data points by means of a least-squares procedure. The slope (K) and the intercept ($\log N_{>1}$) were determined and used to calculate the cleanliness factors described by Eqs. 2–4. The cleanliness factors were then compared with the critical values of the respective standards to determine whether the solution(s) examined passed or failed.

As previously noted, one desirable feature of a parameter for assessing parenteral cleanliness is that it should be relatively independent of the method of measurement. Values for the two cleanliness factors, CF, proposed here (*i.e.*, C_i and C_a) were calculated using both microscopic and instrumental counting data based upon an average of 36 samples (Table II). The percentage differences in the CF values due to the measuring techniques employed varied considerably and were calculated as follows:

$$\% \text{ difference} = \left|\frac{\overline{CF^I} - \overline{CF^M}}{\overline{CF^M}}\right| \times 100 \qquad \text{(Eq. 5)}$$

where CF^I and CF^M refer to the CF values based upon data obtained using the instrumental and microscopic methods of measurement, respectively. This method of calculation was used since it was desirable to compare differences resulting from the method of measurement with the accepted compendial (microscopic) technique (1). Both C_i and C_a clearly exhibited much lower percentage differences resulting from a change in the method of measurement than did Groves' S value.

These observations, together with the standard error values reported in Table II, clearly indicate that the cleanliness factor utilized by Groves is much more susceptible to variations resulting from different methods of measurement than either C_i or C_a. Also, all cleanliness factors calculated for the average of 36 solutions were less than their respective critical value. Thus, the data shown in Table II are indicative of solutions whose average cleanliness factor value would have been passed by all three parameters (S, C_i, and C_a) using either microscopic or instrumental counting techniques.

Another consideration in selecting a cleanliness factor is that it should be relatively independent of the conditions to which the parenteral is subjected prior to measurement (8, 10, 12). Table III shows the effect of various degrees of agitation on the three cleanliness factors based upon averaged data for 18 parenteral solutions. The percentage change in the three CF values resulting from different degrees of agitation also varied considerably and was calculated as follows:

$$\% \text{ change} = \left|\frac{\overline{CF^A} - \overline{CF^B}}{\overline{CF^B}}\right| \times 100 \qquad \text{(Eq. 6a)}$$

or:

$$\% \text{ change} = \left|\frac{\overline{CF^C} - \overline{CF^B}}{\overline{CF^B}}\right| \times 100 \qquad \text{(Eq. 6b)}$$

where A refers to solutions stored in an undisturbed condition for 65 days, B refers to readings taken after these same solutions were inverted 20 times by hand, and C refers to the same solutions subsequently shaken for 30 min at 140 excursions/min on a mechanical agitator[7]. This method of calculation was used since it was desirable to compare the differences resulting from the effects of agitation to the degree of agitation recommended in the compendial standard technique (*i.e.*, 20 hand inversions).

Table III—Effect of Agitation on the Cleanliness Factors

Cleanliness Factor (CF) ± SE[a]	Degree of Agitation: Stored (A)	Degree of Agitation: 20 Inversions (B)	Degree of Agitation: 30-min Shake (C)	Change of Cleanliness Factor, %: Stored (A) *versus* 20 Inversions (B)	Change of Cleanliness Factor, %: 30-min Shake (C) *versus* 20 Inversions (B)
$\frac{\log N_{>1}}{-K} = C_a$	0.9829 ± 0.0715	1.0566 ± 0.0685	0.9647 ± 0.0918	7.0	8.7
$\frac{\log N_{>1} - 0.6990}{-K} = C_i$	0.7402 ± 0.0588	0.7722 ± 0.0500	0.7285 ± 0.0735	4.1	6.3
$\frac{\log N_{>1} - 2.5}{-K} = S$	0.0981 ± 0.0447	0.1635 ± 0.0295	0.1040 ± 0.0407	40.0	36.4

[a] Although the parameters C_i and S were developed to evaluate individual solutions, the data shown were based upon an average of 18 individually calculated cleanliness factors to demonstrate clearly the overall effects of agitation.

Once again, the two cleanliness factors proposed here (*i.e.*, C_i and C_a) exhibited less variability (as indicated by the standard error values shown in Table III) and significantly lower percentage changes due to agitation effects than did Groves' S value. This finding indicates that the S value is also much more affected by the degree of agitation (*i.e.*, the manner in which the solution is handled prior to measurement) than either C_i or C_a. The CF values calculated for the average of 18 solutions were all less than the critical values dictated by the respective standard, *i.e.*, 1.3979 for C_i and C_a and 0.5 for S. Thus, the values shown in Table III are indicative of solutions whose average cleanliness factor value would have been passed by all three parameters when subjected to any of the three agitation conditions. These findings indicate that the large-volume parenterals tested here contained considerably fewer particles than the USP–NF standard allows.

For the 179 tests performed on parenteral solutions, perfect agreement was observed between the ability of a fivefold reduction of the USP–NF standard and the cleanliness factor for averaged data (C_a) to pass or fail parenteral solutions correctly. A perfect agreement was also observed between the USP–NF standard and the cleanliness factor for individual solutions (C_i). In contrast, five solutions failed the provisional Australian standard from which Groves' S value was developed, whereas the S value failed only one of these solutions. Furthermore, the S value failed one solution that would have passed this standard. This apparent inadequacy of the S value was likely related to the arbitrary manner in which Groves selected it. The C_i and C_a values suggested here were based upon the USP–NF standard and a fivefold reduction of it, respectively. Thus, the correlation (observed here) between the cleanliness factors and the standard would be anticipated.

The ability to obtain nondestructive readings in a short time would be advantageous when monitoring the cleanliness of batches of parenteral solutions, since a relatively large number of individual bottles could be averaged to obtain a representative sampling of the batch. However, the appropriate number of samples that should be averaged to ensure statistical accuracy is difficult to state unequivocally, since the operational factors involved in the manufacturing process may vary from batch to batch.

SUMMARY

To characterize a particle-size distribution as accurately as possible, it is advantageous to obtain counts over a broad range of particle sizes. This method enables the particle-size distribution to be determined by statistical weighting procedures so that any unusual variation in counts at one particle diameter can be effectively "smoothed out" by using a least-squares fitting procedure of the entire particle-size distribution. When utilizing these techniques, a particle-size distribution can best be described by specifying both the slope and the intercept of the log $N_{>D}$ *versus* log D plot (12). A parameter based upon both of these particle-size distribution characteristics was developed and is referred to as the cleanliness factor. The cleanliness factor for *individual* solutions (C_i) was based upon the present USP–NF standard; the cleanliness factor for an *average* of solutions (C_a) was based upon a fivefold reduction of this standard.

An ideal cleanliness factor would not be affected by differences in the measuring technique employed or by the degree of agitation experienced by the solution prior to measurement. When the cleanliness factors developed here were compared to Groves' S value, C_i and C_a were indeed affected much less by both the degree of agitation and the measuring technique.

A parameter based upon the total distribution of the particulate matter would reflect more accurately the true nature of a parenteral solution's cleanliness than mere statements of the allowable concentration of particles exceeding certain sizes. Since C_i and C_a appear to be relatively independent of the measuring technique utilized, it is desirable that these cleanliness factors be used in conjunction with a rapid, nondestructive, and easy to operate instrument such as the one described here. The proposed cleanliness factors can be regarded as complementary, more effective, means of applying the USP–NF standard.

Factors Influencing Decomposition Rate of Amitriptyline Hydrochloride in Aqueous Solution

R. P. ENEVER ˣ, A. LI WAN PO, and E. SHOTTON

Abstract □ The degradation rate of amitriptyline hydrochloride in buffered aqueous solution containing various additives was determined. The oxidation was a free radical-mediated process, and the rate was accelerated by the presence of metal-ion contaminants. Glass ampuls, particularly amber ones, in which the solutions were stored were the major source of these contaminants. Edetate disodium stabilized the solution, but the primary antioxidants propyl gallate and hydroquinone were less effective. Sodium metabisulfite accelerated the decomposition, and it is postulated that there was direct attack by metabisulfite at the olefinic double bond in the drug molecule.

Keyphrases □ Amitriptyline hydrochloride—degradation in aqueous solution, effect of metal-ion contaminants, edetate disodium, and antioxidants □ Degradation—amitriptyline hydrochloride in aqueous solution, effect of metal-ion contaminants, edetate disodium, and antioxidants □ Metal-ion contaminants—effect on degradation of amitriptyline hydrochloride in aqueous solution □ Edetate disodium—effect on degradation of amitriptyline hydrochloride in aqueous solution □ Antioxidants, various—effect on degradation of amitriptyline hydrochloride in aqueous solution

A previous study (1) showed that amitriptyline hydrochloride decomposes in aqueous solution, with the production of dibenzocycloheptanone, 3-(propa-1,3-dienyl)-1,2:4,5-dibenzocyclohepta-1,4-diene, and 3-(2-oxoethylidene)-1,2:4,5-dibenzocyclohepta-1,4-diene. Subsequent work concerned the identification of factors influencing the rate of this oxidative process. The present report outlines this work and describes the use of chelating agents and antioxidants in stabilizing the system.

EXPERIMENTAL

Materials—The following chemicals were used: amitriptyline hydrochloride[1], citric acid[2], dibasic sodium phosphate dihydrate[2], potassium chloride[2], sodium hydroxide[2], hydroquinone[2], edetate disodium[2], ferric chloride[2], ether[2], propyl gallate[2], sodium metabisulfite[2], and chlorpromazine hydrochloride[3].

The purity of amitriptyline hydrochloride was checked by the British Pharmacopoeia (BP) method (2), and the drug was used without further purification. The pH 3.0 and 5.0 McIlvaine citric acid–phosphate buffers[4] (3) were prepared with double-distilled water and adjusted to an ionic strength of 0.5 with potassium chloride.

Assay of Amitriptyline Hydrochloride Solutions—The drug concentration was determined by GLC[5] using a 1.5-m (5-ft) × 0.6-cm (0.25-in.) i.d. glass column packed with 3% (w/w) SE-30[6] on 80–100-mesh Chromosorb W AW/DCMS[6]. The column temperature was 250° (injection port setting 6.5); the flow rates of hydrogen, air, and nitrogen were 80, 300, and 50 ml/min, respectively.

To produce a calibration curve for the assay, 1 ml of a 2-mg/ml solution of amitriptyline hydrochloride in the appropriate pH 3.0 or 5.0 buffer was pipetted into a 10-ml volumetric flask and 1 ml of a 2-mg/ml chlorpromazine hydrochloride solution (internal standard) was added. One milliliter of a 0.5-g/ml sodium hydroxide solution was added to liberate the bases, and the mixture was allowed to equilibrate with 7 ml of ether overnight in a stoppered flask previously flushed with nitrogen. Subsequently, 2 μl of the ethereal extract was injected into the chromatograph.

The procedure was repeated with amitriptyline hydrochloride solutions of 0.2, 0.4, 0.6, 0.8, 1.2, 1.4, 1.6, and 1.8 mg/ml. A linear response (slope 1.635) was obtained when the peak height ratio of amitriptyline to chlorpromazine was plotted against amitriptyline hydrochloride concentration. The test solutions of amitriptyline hydrochloride were assayed in a similar manner.

Assay of Iron in Aqueous Solution—The ferric content of the aqueous solutions was determined by atomic absorption spectroscopy[7] using an iron lamp and a wavelength of 2483 nm. A calibration curve was produced using freshly prepared solutions containing 1, 2, 3, 4, and 5 ppm of ferric ions in double-distilled water. Test solutions were assayed without further dilution.

Degradation of Amitriptyline Hydrochloride Solutions—Aliquots of 2 ml of 0.2% (w/v) solutions of amitriptyline hydrochloride in pH 3.0 or 5.0 buffer containing the appropriate additive were distributed into 10-ml clear and amber glass ampuls[8] and stored at 80° in constant-temperature water baths[9] in the dark. Samples were withdrawn at intervals up to 30 days and assayed for amitriptyline hydrochloride content.

RESULTS AND DISCUSSION

Figure 1 shows the results obtained for an amitriptyline solution sealed

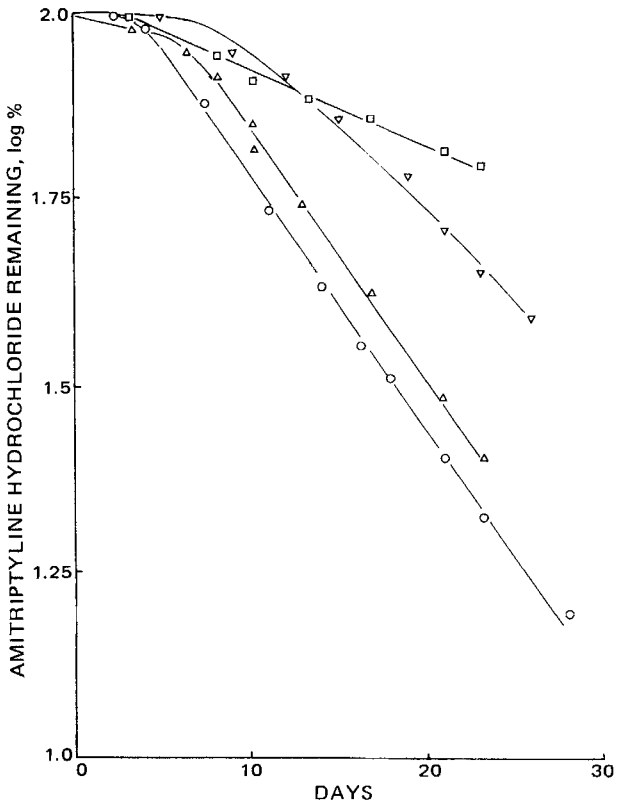

Figure 2—*Influence of glass type and batch of ampuls on decomposition of 0.2% (w/v) amitriptyline hydrochloride in pH 3.0 buffer at 80°. Key: □, clear glass ampuls (Batch 5018/10R); ○, amber glass ampuls (Batch HP65); △, amber glass ampuls (Batch HP67); and ▽, amber glass ampuls (Batch BB242).*

under air in amber ampuls. An initial slow decomposition rate was followed by a relatively faster rate ($k \sim 4.99 \times 10^{-2}$ day^{-1}). Decomposition was not measurable when a similar solution was sealed under nitrogen. Thus, the data are consistent with a free radical oxidation mechanism, since such a reaction normally exhibits an initial lag phase during which free radicals accumulate. To confirm the process, the sensitivity of the reaction to catalysts and inhibitors was investigated.

Addition of cupric acetate or ferric chloride (2×10^{-4} *M*) to amitriptyline hydrochloride solutions accelerated the decomposition rate (Fig. 1). The lag phase was removed with the ferric ions and greatly reduced with the cupric ions. The rate constants for the rapid phase of the reaction were increased to 0.0564 and 0.0854 day^{-1} with cupric and ferric ions, respectively. A reduction in the apparent activation energy of autoxidation processes by metal ions is well known (4), and such a positive catalytic effect on the decomposition of pharmaceutical compounds also was reported (5, 6).

The decomposition rate of amitriptyline hydrochloride solutions was reduced significantly by the addition of 0.1% (w/v) edetate disodium prior to storage (Fig. 1). The results obtained with this chelating agent confirm that metallic-ion impurities are a major cause of degradation. The source of impurities was at first thought to be the buffer salts, since they can contain significant amounts of metallic-ion contaminants (6). However, in the present work, metallic impurities leached from the containers were more important.

The iron content of amber glass ampuls is probably considerably greater than that of clear ampuls (7). Since amitriptyline is photolabile (8), however, such solutions probably would be stored in amber containers. The effect of different batches of such ampuls on the degradation rate is shown in Fig. 2; the rate was much greater in amber ampuls than in clear glass and there was considerable batch-to-batch variation. The amounts of iron leached from one batch[10] of amber ampuls into a 0.2% (w/v) amitriptyline hydrochloride solution in pH 3.0 buffer at 80° after 1, 8, 16, 19, 23, and 30 days were 0.8, 1.10, 1.35, 1.40, 1.58, and 1.80 ppm, respectively. There was a linear increase in iron concentration with time (rate of 0.034 ppm/day).

[10] Batch HP65.

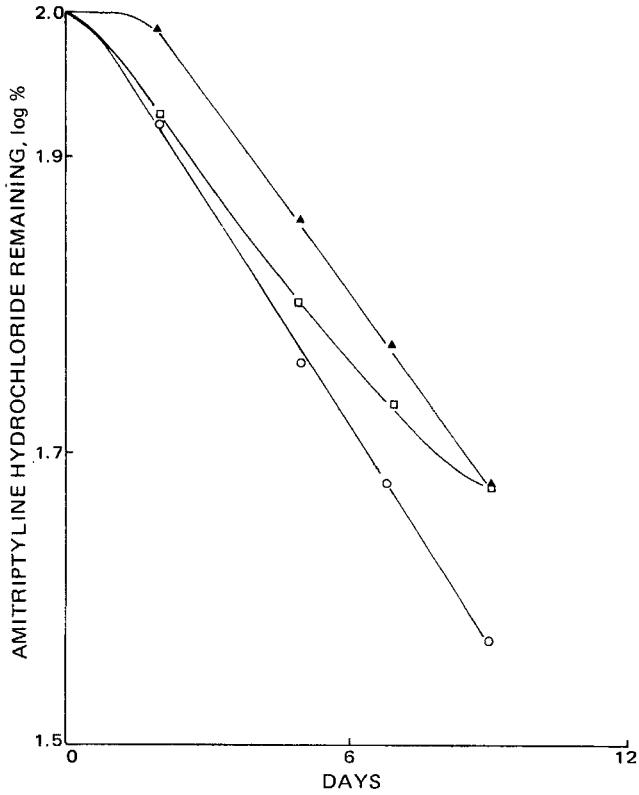

Figure 3—*Influence of addition of a decomposing solution or hydrogen peroxide to 0.2% (w/v) amitriptyline hydrochloride in pH 5.0 buffer at 80° in amber ampuls (Batch HP65). Key: ▲, 2 ml of 0.2% (w/v) amitriptyline hydrochloride solution; □, 2 ml of solution prepared by adding 1 ml of decomposing solution to 99 ml of fresh 0.2% (w/v) amitriptyline hydrochloride solution; and ○, 2 ml of solution prepared by adding 5 μl of 30% (w/w) hydrogen peroxide to 100 ml of fresh 0.2% (w/v) amitriptyline hydrochloride solution.*

Further support for the postulated free radical oxidation was obtained by adding a small volume of a partially decomposed solution to a fresh amitriptyline hydrochloride solution. Figure 3 shows that the lag phase was removed, although the chain propagation rate changed little. A similar result was obtained by adding 5 μl of a 30% (w/w) hydrogen per-

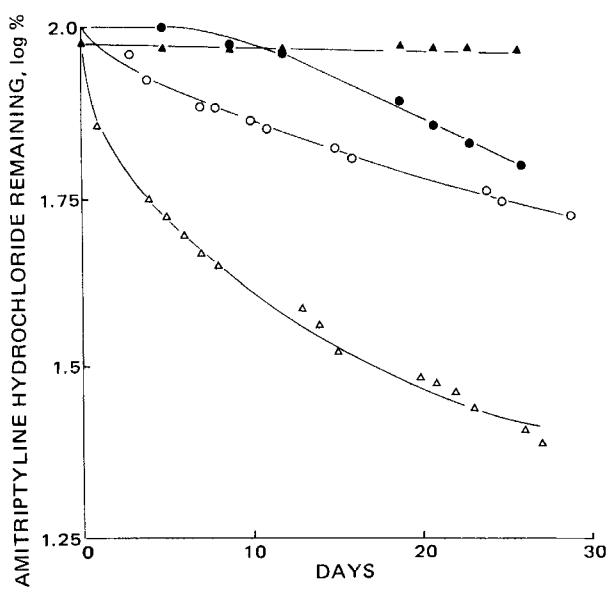

Figure 4—*Effect of antioxidants and sodium metabisulfite on the decomposition rate of 0.2% (w/v) amitriptyline hydrochloride in pH 3.0 buffer at 80°. Key: ●, control solution; ▲, containing 0.05% (w/v) propyl gallate; ○, containing 0.01% (w/v) hydroquinone; and △, containing 0.121% (w/v) sodium metabisulfite.*

oxide solution to 100 ml of fresh 0.2% (w/v) amitriptyline hydrochloride solution. The hydrogen peroxide content was insufficient to cause this marked degree of decomposition by direct oxidation.

Addition of 0.05% (w/v) of the antioxidant propyl gallate to an amitriptyline hydrochloride solution initially caused a 10% fall in drug concentration but subsequently completely stabilized the solution (Fig. 4). Hydroquinone, 0.01% (w/v), was less effective, since it abolished the lag phase and only appeared to slow the reaction after 15 days. The antioxidants appeared to break the chain reaction. With propyl gallate at least, however, there was evidence of a direct reaction with amitriptyline hydrochloride.

The reducing agent sodium metabisulfite was not effective in stabilizing the solution. Figure 4 shows that 0.121% (w/v) sodium metabisulfite produced an immediate fall in the drug concentration and a subsequent acceleration in the decomposition rate. This process did not follow first-order kinetics at any stage. The concentration of sodium metabisulfite was equimolar with amitriptyline hydrochloride (6.37×10^{-3} *M*), and the data fit a simple second-order kinetic plot.

Bisulfite-mediated reactions were reported previously (9–13), and a reaction mechanism similar to the thiamine cleavage shown previously (14, 15) is possible in the drug's side chain. However, using the isolation and identification techniques outlined previously (1), dibenzocycloheptanone was the only decomposition product present, suggesting that direct attack at the olefinic double bond in the molecule is more likely. Such an affinity for these bonds by sodium bisulfite was demonstrated and explained (16) on the basis of a free radical mechanism.

Polyamine Metabolism I: Synthesis of Dansyl Derivatives of *N*-(Monoaminoalkyl)- and *N*-(Polyaminoalkyl)acetamides and Elucidation in Urine of a Cancer Patient

MAHMOUD M. ABDEL-MONEM [x] and KOSEI OHNO

Abstract □ The dansyl derivatives of *N*-(monoaminoalkyl)- and *N*-(polyaminoalkyl)acetamides were synthesized and unequivocally characterized. TLC of the dansyl derivatives obtained from human urine indicated the presence of *N*-[3-[(4-aminobutyl)amino]propyl]acetamide (N^1-acetylspermidine), *N*-[4-[(3-aminopropyl)amino]butyl]acetamide (N^8-acetylspermidine), and *N*-(4-aminobutyl)acetamide (*N*-acetylputrescine) in appreciable amounts. The dansyl derivatives of N^1-acetylspermidine, N^8-acetylspermidine, and *N*-acetylputrescine were isolated and purified using various chromatographic methods. The mass spectra of these compounds were similar to those of authentic samples, which confirmed the identity of these compounds and established the presence of N^8-acetylspermidine as well as N^1-acetylspermidine and *N*-acetylputrescine in human urine.

Keyphrases □ Polyamines—*N*-(monoaminoalkyl)- and *N*-(polyaminoalkyl)acetamides, determined in human urine, dansyl derivatives synthesized □ *N*-(Aminoalkyl)acetamides—determined in human urine, dansyl derivatives synthesized □ Dansyl derivatives—of *N*-(monoaminoalkyl)- and *N*-(polyaminoalkyl)acetamides synthesized □ TLC—determination, dansyl derivatives of *N*-(monoaminoalkyl)- and *N*-(polyaminoalkyl)acetamides, human urine □ High-pressure liquid chromatography—determination, dansyl derivatives of *N*-(monoaminoalkyl)- and *N*-(polyaminoalkyl)acetamides, human urine

The diamine 1,4-butanediamine (putrescine) (I) and the polyamines *N*-(3-aminopropyl)-1,4-butanediamine (spermidine) (II) and *N,N'*-bis(3-aminopropyl)-1,4-butanediamine (spermine) (III) are present in all animal and plant tissues, and at least one of these is present in all microorganisms (1). Studies of both normal and neoplastic rapid growth systems indicate that the synthesis and accumulation of polyamines are elevated shortly after a stimulus inducing proliferation. Furthermore, the levels of these amines were elevated in the urine of cancer patients (2–10). These amines are excreted in human urine mainly as conjugates, which yield the free amines after hydrolysis (2).

Although several studies determined the levels of total

oxide solution to 100 ml of fresh 0.2% (w/v) amitriptyline hydrochloride solution. The hydrogen peroxide content was insufficient to cause this marked degree of decomposition by direct oxidation.

Addition of 0.05% (w/v) of the antioxidant propyl gallate to an amitriptyline hydrochloride solution initially caused a 10% fall in drug concentration but subsequently completely stabilized the solution (Fig. 4). Hydroquinone, 0.01% (w/v), was less effective, since it abolished the lag phase and only appeared to slow the reaction after 15 days. The antioxidants appeared to break the chain reaction. With propyl gallate at least, however, there was evidence of a direct reaction with amitriptyline hydrochloride.
