Meyer (1) and Overton (2) showed a correlation between anesthetic drug activity and the partition coefficient, *i.e.*, the ratio of drug solubility in a lipoid phase to its solubility in a water phase. For the lipoid phase, olive oil, corn oil, chloroform, and a spectrum of nonpolar organic solvents have been used. Water can act as a nonpolar solvent when it is bound to various molecules (proteins, surface-active agents, *etc.*) to form a liquid that is insoluble in a regular or bulk liquid water. This nonpolar structured water complex is referred to as a coacervate. Coacervates have been suggested as models for cytoplasm since cytoplasm is also essentially an aqueous phase of water–protein–colloid complexes (3, 4).

This report considers the use of a coacervate system as the nonpolar phase in equilibrium with a normal water phase.

BACKGROUND

The partition coefficients of four barbiturates were obtained, and the values were compared to those reported in the literature using an organic nonpolar medium (5). Schanker (5) studied the absorption of barbiturates from the rat colon and compared the percent absorption with the partition coefficients of the free acids in chloroform–water systems. The reported percent absorption values are compared here with the partition coefficient values of the barbiturate salts in a coacervate–water system.

The partition coefficients of theobromine and theophylline in gelatin–benzalkonium chloride coacervate systems were obtained and compared to those reported for heptane–water and chloroform–water systems (6). Comparisons were also made to percent drug absorption in the rat colon as reported in the literature (6).

The rationale for attempting to correlate partition coefficients of compounds with reported values for percent absorption is as follows. Since coacervates, regardless of their composition and pH, are complex aqueous colloidal systems, it is expected that they bear more resemblance in overall properties to protoplasm than do lipids and lipid-like solvents such as chloroform and heptane. Any correlation between interactions of compounds with coacervates, as evidenced by preferential uptake or exclusion, and absorption profiles of these compounds can be considered to support the hypothesis that complex coacervates systems (not necessarily the systems considered in this work) can be considered as models for protoplasm. It is obvious that barbiturates are not appreciably ionized at physiological pH. However, since the properties and interactions of the salts reflect, in some ways, the properties of the parent compounds, it is not unreasonable to attempt correlation of salt–coacervate interactions with absorption characteristics.

EXPERIMENTAL

Preparations of Coacervate System—In 15-ml graduated tubes, 3.0 ml of a 10% gelatin solution, 2.0 ml of a 5% benzalkonium chloride solution, and sufficient 0.1 *N* sodium hydroxide were added to give a pH above 9. This solution was diluted to 15 ml with distilled water. The tubes were stoppered, mixed vigorously, and left undisturbed for 24 hr at 37°. Complete separation of two aqueous phases occurred. The bottom layer was the coacervate and contained most of the colloidal material.

Assay of Drug by Difference—The concentration of the barbiturates used in this study was determined spectrophotometrically. The concentration of the compound in the coacervate was determined from the difference between the total amount in the system and the amount spectrophotometrically found in the equilibrium liquid. The sodium salts of barbital, phenobarbital, pentobarbital, and secobarbital were studied at 37°. The concentration of the salts in equilibrium liquid was determined at 240 nm, using a 0.2 *M* borate buffer (pH 9.6) as the diluting solvent and a total system concentration of 200 mg %.

Partitioning of theophylline and theobromine was studied at 37°. Theophylline dilutions were prepared in a potassium chloride–sodium hydroxide buffer of pH 12 and measured at 275 nm. The same solvent was used for theobromine, which was measured at 274 nm. The partition coefficients (P.C.) were obtained at 50 and 100 mg %, and the average values are reported in Table I.

RESULTS AND DISCUSSION

The partitioning patterns of barbiturate salts are shown in Fig. 1. Barbital sodium showed the least uptake in coacervates. At concentrations higher than 100 mg %, it exerted a suppressive action on coacervation as evidenced by a decrease in the volume of the coacervate layer. At a concentration of 200 mg %, the compound was distributed equally between the two phases.

Barbital sodium did not show a precipitation–resolubilization interaction with benzalkonium chloride, which explains its weak affinity for coacervates. The partitioning isotherms for the sodium salts of phenobarbital, pentobarbital, and secobarbital showed a strong affinity of these salts toward coacervates and the dependence of this affinity on the concentration of the salt.

Schanker (5) studied the absorption of barbiturates from the rat colon and compared the percent absorption with the partition coefficient of the free acids in chloroform–water systems. Figure 2 shows the correlation between the percent absorption and the partition coefficient of the barbiturate salts in gelatin–benzalkonium chloride systems. The averages of the partition coefficients at the four highest concentrations studied

Table I—Partition Coefficient Studies of Theophylline and Theobromine[a]

Compound	Percent Absorbed	Partition Coefficients: Heptane–Water	Chloroform–Water	Coacervates
Theophylline	30	0.02	0.3	3.32
Theobromine	22	0.002	0.4	2.37

[a] The data, with the exception of the partition coefficients in coacervates, are from Ref. 6.

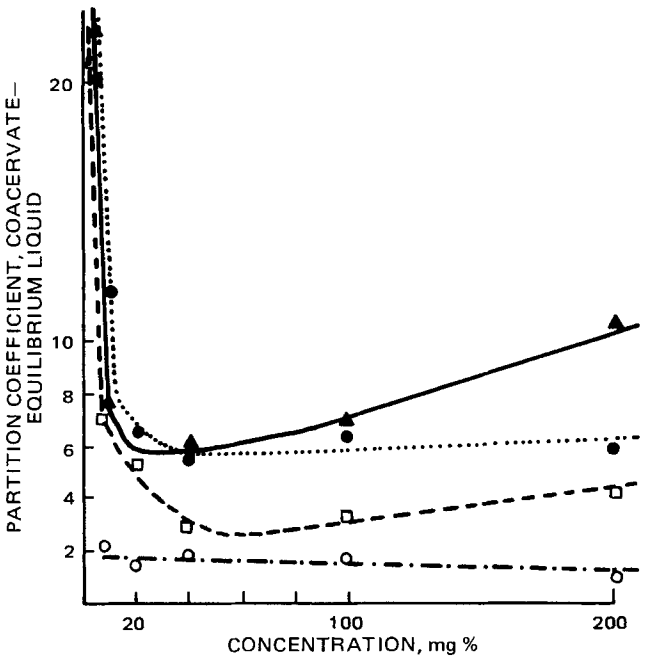

Figure 1—*Partitioning of barbiturate salts in gelatin–benzalkonium chloride system at 37°. Key: ▲—▲, secobarbital sodium; ●·····●, pentobarbital sodium; □- - -□, phenobarbital sodium; and O----O, barbital sodium.*

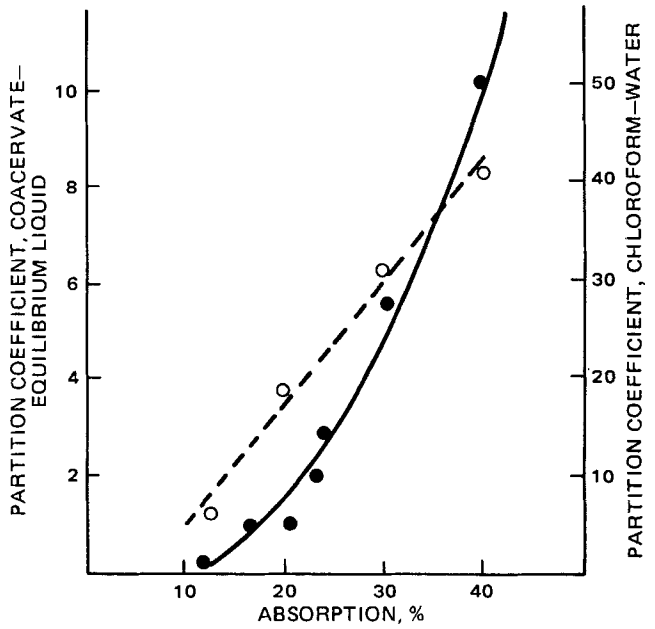

Figure 2—*Correlation of the partition coefficients of barbiturate salts with percent absorption from the rat colon. Data for percent absorption and chloroform–water partition coefficients are from Schanker (5). Key: O- - -O, partition coefficient, coacervate–equilibrium liquid, of barbiturate salts; and ●—●, partition coefficient, chloroform–water, of free acids.*

(20–200 mg %) were plotted *versus* the percent absorption as reported by Schanker. The choice of these average values was arbitrary and based on the assumption that the average partition coefficient over a wide concentration range was more representative of the intrinsic affinity between the coacervate and the barbiturate salt and tended to cancel the effects of any secondary interactions between the compound and the components of the coacervate.

Table I shows the intestinal absorption of theobromine and theophylline in relation to their partition coefficients in heptane–water, chloroform–water, and gelatin–benzalkonium chloride systems. It is obvious that there exists a better correlation between the percent absorption and the partitioning in coacervates than between the absorption and the partitioning in nonpolar organic solvents.

These coacervates are particularly useful for studying partitioning of water-soluble salts of insoluble weak acids between coacervates and their equilibrium liquids. The hypothesis underlying these studies is that the differences between the "hydrophobicity" of these anions will be manifested in their affinity (*i.e.*, partitioning) for structured water in the coacervate phase.

There is a clear correlation between variables in the experiments using barbiturates and xanthines, suggesting that coacervates of this type might serve as biological models for studying and predicting the absorption characteristics of drugs.

The purpose of benzalkonium chloride is to act as a coacervating agent in the system. The gelatin used has an isoelectric point of 8.2. Above this pH, gelatin is negatively charged and, under the proper conditions, forms true complex coacervates with benzalkonium chloride. Most of the studies on coacervation of gelatin with, for example, acacia involved gelatin of a lower isoelectric point and the pH of coacervates was, generally, on the acid side. At the time of these studies, true complex coacervation between a high isoelectric point gelatin and other ingredients, particularly surface-active agents, had not been reported in the literature.

Chemistry and Pharmacology of Homologs of 6-Acetyl- and 3,6-Diacetylmorphine

EVERETTE L. MAY and ARTHUR E. JACOBSON ˣ

Abstract □ 3,6-Diformyl- and 3,6-dipropanoylmorphine and 6-formyl- and 6-propanoylmorphine were prepared to obtain longer acting, heroin-like compounds. The 6-acylated compounds were more potent than heroin subcutaneously and were orally effective, and their duration of action was at least two to three times greater than that of heroin in monkey species.

Keyphrases □ Morphine derivatives, various—synthesized, analgesic activity evaluated, monkeys □ Analgesic activity—various morphine derivatives, monkeys □ Structure–activity relationships—various morphine derivatives, analgesic activity evaluated, monkeys

For some time, there has been an interest in heroin-like compounds whose duration of action would be greater than that of heroin (3,6-diacetylmorphine, I). Goldstein (1), for example, recently suggested a provocative procedure for rehabilitating "hard-core" addicts who resist contemporary methods of treatment. One early step that might lead to the complete withdrawal of narcotics would entail the use of a longer acting heroin. As potential agents for this phase of treatment, higher and lower homologs of I, the 3,6-diformyl (II), 3,6-dipropanoyl (III), 6-formyl (V), and 6-propanoyl (VI) derivatives were prepared. The chemistry and pharmacology of I–VI and 3-acetylmorphine (VII) are described here and some stability data are presented.

3,6-Diformylmorphine (II) was prepared from morphine hydrate and excess formic–acetic anhydride (2) at 15–25°. If pyridine was used as a solvent, 6-formylmorphine (V) resulted. Excess propanoic anhydride and morphine at 100° gave 3,6-dipropanoylmorphine (III) (3). Anhydrous morphine, potassium carbonate, and 1.2 *M* equivalents of propanoic anhydride (reflux temperature) produced 6-propanoylmorphine (VI). Finally, 3-acetylmorphine (VII) was synthesized by the method of Welsh (4) for pharmacology and stability comparisons.

EXPERIMENTAL[1]

3,6-Diformylmorphine (II)—To 60 ml of acetic anhydride (ice cooled and stirred) was added dropwise (5–10 min) 25 ml of 97% formic acid (5). The mixture was warmed slowly to 50–55°, where it was kept for 15–20 min. To 25 ml of this solution was added (ice cooling) 5.0 g of morphine monohydrate so that the temperature did not rise above 15°. The solution was then treated with an additional 5 ml of the acetic anhydride–acetic acid mixture.

Stirring was continued at room temperature (21–24°) for 24 hr, after which another 25-ml portion of the formylating mixture was added during 5 min. The solution was left at 21–24° for an additional 70 hr and then evaporated to dryness *in vacuo*. The residue was dissolved in ice water; after 20 min, methylene chloride and then 10% Na_2CO_3 were added to pH 9 (at 10–12°). The dried (sodium sulfate) methylene chloride layer was evaporated to dryness *in vacuo*. The residue was dissolved in 50–70 ml of boiling acetone, from which II crystallized on cooling to 0°, yielding 4.5 g, mp 170° (gas evolution) and 212–215° dec.

Anal.—Calc. for $C_{19}H_{19}NO_5$: C, 66.84; H, 5.61; N, 4.00. Found: C, 66.64; H, 5.58; N, 4.10.

The hydrochloride salt (from acetone–hydrogen chloride gas) was dried at 65°, mp 210–211° (froth).

Anal.—Calc. for $C_{19}H_{20}ClNO_4 \cdot 0.5H_2O$: C, 58.98; H, 5.47; Cl, 9.16; N, 3.62. Found: C, 58.93; H, 5.53; Cl, 9.04; N, 3.40.

6-Formylmorphine (V)—Formic acid (90 ml) and 40 ml of acetic anhydride (5) were mixed at 0° and then kept at 50–55° for 15 min. The solution was cooled to 0° (stirring) and treated dropwise (at 0°) with 7.4 g of morphine monohydrate in 50 ml of pyridine. The mixture was kept at 25° for 65–70 hr, poured into ice water, and treated with 100 ml of methylene chloride and 20% Na_2CO_3 to pH 9. The organic layer and one methylene chloride extract of the aqueous layer were combined, dried (magnesium sulfate), and evaporated to dryness *in vacuo*. Trituration of the 9.1 g of residue in acetone gave, after cooling to 0°, 5.4 g of V, mp 208–215° dec.

Anal.—Calc. for $C_{18}H_{19}NO_4$: C, 68.99; H, 6.11; N, 4.47. Found: C, 69.03; H, 6.07; N, 4.29.

The hydrochloride salt (from acetone–hydrogen chloride gas) melted at 265–267° dec.

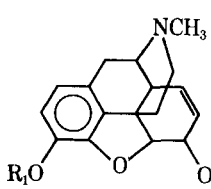
Anal.—Calc. for $C_{18}H_{20}ClNO_4$: C, 61.80; H, 5.76; Cl, 10.14; N, 4.00. Found: C, 61.44; H, 5.93; Cl, 10.05; N, 3.84.

3,6-Dipropanoylmorphine (III)—Morphine (2.0 g) and 5.0 ml of propanoic anhydride were kept on the steam bath for 4 hr, cooled to room temperature, and treated with water. After 1 hr, the clear solution was partitioned between ether and 10% KOH (ice cooling). The ether was washed once with water, dried over sodium sulfate, and evaporated. The hydrochloride salt (3) (from ether–hydrogen chloride gas) weighed 2.6 g (87%). After a recrystallization from ethyl acetate, it melted at 150–155° (froth).

In another run, 0.25 g of crude III, obtained as described, was dissolved in acetone and treated with 0.08 g of sulfamic acid in 0.5 ml of water. Further dilution with acetone gave 0.3 g of the sulfamate salt of III, mp 190–191° if the capillary tube was inserted in a bath preheated to 185–188°. Otherwise, the sample became brown at 175° and did not melt even at 200°.

Anal.—Calc. for $C_{23}H_{30}N_2O_8$: C, 55.85; H, 6.11; N, 5.67. Found: C, 56.13; H, 5.91; N, 5.78.

6-Propanoylmorphine (VI) Hydrochloride—Morphine (2.9 g of anhydrous base) and 50 ml of acetone (dried over molecular sieve) were stirred and refluxed together while 1.6 ml (1.2 equivalents) of propanoic anhydride in 10 ml of dry acetone was added during 1 hr. The mixture was refluxed for 4–5 hr and evaporated to dryness *in vacuo*. The residue was treated with cold water, ether, and excess potassium carbonate. The ether was dried (sodium sulfate) to give 3.3 g of base which, as determined by TLC analysis [chloroform–methanol–ammonium hydroxide (85:14:1)] on silica gel, consisted of about 97% of VI and 2–3% of III. It was dissolved in acetone–ether (3:1) and treated (to pH 4–5) with hydrogen chloride gas to give (ice cooling) 2.2 g of VI hydrochloride, which was dissolved in 140 ml of boiling acetone. The solution was concentrated to 45–50 ml



I: $R_1 = R_2 = COCH_3$
II: $R_1 = R_2 = CHO$
III: $R_1 = R_2 = COC_2H_5$

(to the appearance of crystals) and cooled finally to 0° for 1 hr to give 1.8 g, mp 155–165°.

Anal.—Calc. for $C_{20}H_{24}ClNO_4 \cdot 0.5H_2O$: C, 62.07; H, 6.47; Cl, 9.16; N, 3.62. Found: C, 61.70; H, 6.43; Cl, 9.18; N, 3.29.

RESULTS AND DISCUSSION

As seen in Table I, the 3,6-diformyl (II), 3,6-dipropanoyl (III), and 6-propanoyl (VI) derivatives were comparable to heroin (I) and 6-acetylmorphine (IV) in analgesic potency and were three to four times as potent as morphine (6, 7). 3-Acetylmorphine (VII) sulfamate (4) was nearly identical in potency to morphine. As expected, all had good capacity to sustain morphine dependence in monkeys (8, 9) with a wide variation in duration of action. Superiority in this respect was shown by V (12 hr) and VI (>6 hr), both longer acting than morphine, heroin, or 6-acetylmorphine[2].

The mode of action of the 6-acylated compounds, V and VI, is not known. Like 6-acetylmorphine, they are probably metabolized to morphine (10), albeit less rapidly. Their duration of action for analgesia (mice) was much longer than that for heroin but similar to morphine. Their considerably longer action than heroin and even morphine in higher animals (monkeys) may be more indicative of their behavior in humans.

The oral activity of V and VI (in mice) was relatively good (ED_{50} 11.6 and 7.4 mg/kg, respectively). Thus, V and VI would appear to be the most interesting compounds of this group for further study as possible maintenance drugs or in detoxification therapy. The diformyl compound (II) was too unstable to be tested in monkeys.

Qualitatively, the order of stability of these compounds in the salt form noted in Table I appeared to be: 3,6-diacetyl ≅ 3,6-dipropanoyl > 6-propanoyl ≅ 6-acetyl ≅ 3-acetyl > 6-formyl > 3,6-diformyl derivatives at 25°. This order seems to be at variance with the durations of action in supporting morphine dependence in monkeys. The impression is given by these qualitative studies that the acylmorphines (as salts), except II, are more stable in aqueous solution than is generally believed.

Liquid Chromatography in Pharmaceutical Analysis VI: Determination of Dantrolene Sodium in a Dosage Form

S. J. SAXENA, I. L. HONIGBERG [x], J. T. STEWART, G. R. KEENE, and J. J. VALLNER

Abstract □ Operating conditions are described for the qualitative and quantitative determination of dantrolene sodium by high-pressure liquid chromatography. A 10-μm porous silica column was employed, using carbon tetrachloride–dimethylformamide (90:10) as the mobile phase. The flow rate was 2.0 ml/min (1800 psig), and the peaks were detected at 375 nm. The analysis of a dosage form can be carried out within 30 min with an accuracy of 3.1%. The results agree favorably with those obtained with a modified spectrophotofluorometric method.

Keyphrases □ Dantrolene sodium—high-pressure liquid chromatographic analysis, commercial dosage forms □ High-pressure liquid chromatography—analysis, dantrolene sodium, commercial dosage forms □ Relaxants, skeletal muscle—dantrolene sodium, high-pressure liquid chromatographic analysis, commercial dosage forms

Dantrolene sodium, 1-[[5-(*p*-nitrophenyl)furfurylidene]amino]hydantoin sodium salt hydrate, was first reported by Snyder *et al.* (1) as a representative of a new class of muscle relaxants which apparently acts directly on the skeletal muscle.

Previous reported analyses of dantrolene sodium include spectrophotofluorometry (2, 3), differential pulse polarography (4), and a colorimetric procedure for qualitative

Liquid Chromatography in Pharmaceutical Analysis VI: Determination of Dantrolene Sodium in a Dosage Form

S. J. SAXENA, I. L. HONIGBERG [x], J. T. STEWART, G. R. KEENE, and J. J. VALLNER

Abstract □ Operating conditions are described for the qualitative and quantitative determination of dantrolene sodium by high-pressure liquid chromatography. A 10-μm porous silica column was employed, using carbon tetrachloride–dimethylformamide (90:10) as the mobile phase. The flow rate was 2.0 ml/min (1800 psig), and the peaks were detected at 375 nm. The analysis of a dosage form can be carried out within 30 min with an accuracy of 3.1%. The results agree favorably with those obtained with a modified spectrophotofluorometric method.

Keyphrases □ Dantrolene sodium—high-pressure liquid chromatographic analysis, commercial dosage forms □ High-pressure liquid chromatography—analysis, dantrolene sodium, commercial dosage forms □ Relaxants, skeletal muscle—dantrolene sodium, high-pressure liquid chromatographic analysis, commercial dosage forms

Dantrolene sodium, 1-[[5-(*p*-nitrophenyl)furfurylidene]amino]hydantoin sodium salt hydrate, was first reported by Snyder *et al.* (1) as a representative of a new class of muscle relaxants which apparently acts directly on the skeletal muscle.

Previous reported analyses of dantrolene sodium include spectrophotofluorometry (2, 3), differential pulse polarography (4), and a colorimetric procedure for qualitative

Table I—Calibration Data for Standard Drug Solutions

Analytical Method	Initial Concentration of Dantrolene Sodium, mg/ml	Observed Results	Slope	Intercept	$r \pm s_{yx}$[a]
HPLC	0.2	1.1192 ± 0.0010[b]			
	0.5	2.8129 ± 0.0100	0.5362	0.0795	0.9997 ± 0.0369

[a] r is the correlation coefficient determined from linear regression analysis, and s_{yx} is the sample standard deviation, also from regression analysis. [b] The D/IS ratio is based on four replicate injections of standard solution. The table value is the mean ± *SD*. The D/IS is the ratio of the integrated area of the drug at some concentration to the integrated area of furil at a concentration of 4 mg/ml. [c] Arbitrary fluorescence units.

determination (5). Although the use of liquid chromatography *via* a reversed-phase process has been successful with various drugs (6–8), the limited solubility of dantrolene sodium in polar mobile phases has precluded use of this technique. This paper reports the conversion of the drug to its free acid followed by extraction, chromatographic separation, and quantification using adsorption chromatography. The analysis of dosage forms can be performed within 30 min. The results of the high-pressure liquid chromatographic (HPLC) procedure are compared to those of a spectrophotofluorometric method, modified from that reported by Hollifield and Conklin (3).

EXPERIMENTAL

Reagents and Chemicals—A powdered sample of dantrolene sodium[1] was used; chemicals and reagent grade solvents were obtained commercially and used as received. The chromatographic solvents, carbon tetrachloride and dimethylformamide, were filtered through a 0.5-μm filter[2] prior to use. The pH of a 0.5 *M* aqueous solution of dimethylformamide was consistently 6.8 ± 0.1.

Mobile Phase—The mobile phase consisted of carbon tetrachloride–dimethylformamide (90:10) and was used after degassing.

Internal Standard Solution—The stock internal standard solution (20 mg/ml) was prepared by dissolving powdered furil[3] in water-saturated 1-butanol–chloroform (30:70). It was filtered through a 5.0-μm filter[4] before use.

Standard Solution for Calibration Curve—A stock solution of dantrolene sodium was prepared by dissolving 25 mg of dantrolene sodium powder in 5 ml of dimethylformamide in a 25-ml volumetric flask. The solution was then diluted to 25 ml with distilled water to yield a solution of 1 mg/ml.

Determination of Calibration Curve—Accurately pipetted volumes of 2.0, 5.0, and 10.0 ml of the dantrolene sodium stock solution were each placed in a 60-ml separator. Where necessary, the volume of each solution was adjusted to 10 ml with distilled water. Then 5.0 ml of 2 *N* HCl solution was added to each separator to precipitate dantrolene. The aqueous solutions were extracted with 2 × 10-ml portions of 1-butanol–chloroform (30:70), and the organic layer from each separator was separated and transferred to 25-ml volumetric flasks.

The volume of each flask was then adjusted to 25 ml with additional organic solvent, and the organic extract was filtered through a 5.0-μm filter[4]. Four milliliters of the filtered extract was pipetted into a 5-ml volumetric flask followed by the addition of 1 ml of the internal standard stock solution. Twenty microliters of each solution was injected into the chromatograph.

Determination of Percent Extraction of Dantrolene Sodium—A solution of dantrolene[5] (0.0522 mg/ml) was prepared in 1-butanol–chloroform (30:70). Four milliliters was pipetted into a 5-ml volumetric flask, 1 ml of internal standard solution was added, and the solution was chromatographed. The ratio of the dantrolene peak area to the area of the internal standard (D/IS) was compared with the D/IS ratio obtained by a theoretically equivalent amount of dantrolene free acid, extracted from dantrolene sodium, which was prepared as follows. Two milligrams of dantrolene sodium was dissolved in 10 ml of water, converted to dantrolene, and extracted into 3 × 10-ml portions of 1-butanol–chloroform (30:70) to give a solution with a theoretical dantrolene concentration of 0.0522 mg/ml. Four milliliters of this solution was pipetted into a 5-ml volumetric flask, 1 ml of internal standard solution was added, and the solution was chromatographed.

Determination of Dantrolene Sodium in Dosage Form—The contents of two 25-mg capsules[6] were quantitatively transferred to separate 50-ml volumetric flasks with the aid of a small amount of distilled water. The contents were dissolved in 10 ml of dimethylformamide and

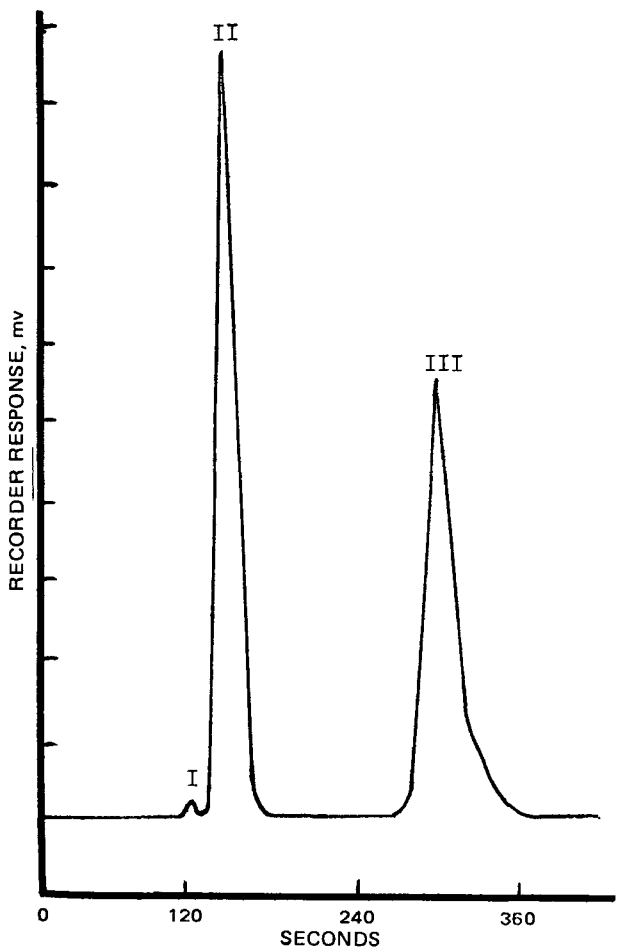

Figure 1—*Typical chromatogram of dantrolene sodium using a porous silica column (room temperature) at a flow rate of 2.0 ml/min. Mobile phase was carbon tetrachloride–dimethylformamide (90:10). Key: I, solvent front; II, furil (internal standard); and III, dantrolene.*

diluted to volume with distilled water. The solutions were then filtered[7]. Ten milliliters of the filtrate was transferred to a 60-ml separator, acidified, extracted, and analyzed as described under *Determination of Calibration Curve*.

Conditions for Chromatographic Quantification—The liquid chromatograph was equipped with a pump[8], a variable wavelength detector[9], an integrator with digital printout[10], and a column containing a porous silica packing[11]. The degassed mobile phase was pumped through the column at a flow rate of 2.0 ml/min (1800 psig) at room temperature (23 ± 2°) until a stable baseline was obtained. Replicate 20-μl injections of sample and standard solutions were made using a 25-μl syringe[12]. The chart recorder provided a record of drug elution from the column as peaks on a chromatogram. The peaks were detected at 375 nm. In all cases, the solute was measured by digital integration of the peak area.

Determination of Dantrolene Sodium by Fluorescence—One milliliter of the 1-butanol–chloroform extract from both the calibration curve and the dosage form was added to a 100-ml volumetric flask and diluted to volume with 1-butanol–chloroform (30:70). The fluorescence was measured in a spectrophotofluorometer[13] with the following operating parameters: slit width for excitation and emission, 5 nm; sensitivity, 3.0; excitation wavelength, 395 nm; and emission wavelength, 575 nm. By using the fine sensitivity control, the recorder was set to read full scale (100 units) for the 1-butanol–chloroform solution containing the highest concentration of dantrolene. Measurements for the standard and dosage form were made respective to this arbitrary setting.

RESULTS AND DISCUSSION

Studies on the dosage form of dantrolene sodium showed that dantrolene free acid could be precipitated in acidic media between pH 2.5 and 4.0 using 2 *N* HCl. The free acid was then extracted into 1-butanol–chloroform with a percent extraction of 90.97 ± 0.14 as compared to the theoretical amount of known dantrolene free acid. When injected into the chromatograph, dantrolene was eluted within 6 min (Fig. 1). Furil was found to be a suitable internal standard. Although furil and dantrolene have absorption maxima at 305 and 395 nm, respectively, an intermediate wavelength of 375 nm was selected to obtain the sensitivity necessary to detect both components.

Standard solutions of dantrolene sodium were chromatographed using the microsilica column. The area under the curve for each peak on the chromatogram was digitally integrated. The ratio of the dantrolene peak area to the area of the internal standard was calculated for each chromatogram. A linear regression analysis of the data at three concentrations of dantrolene sodium gave the results shown in Table I. The calibration data for the fluorometric method are also listed.

Dantrolene sodium in a commercial dosage form was dissolved, extracted, and chromatographed in a manner analogous to the standard solutions, and the D/IS ratio was calculated. The constants (slope and intercept) from the linear regression equation shown in Table II were used to solve for drug concentration [D/IS = (slope × concentration) + intercept]; a programmable calculator[14] was used. The same extraction solutions were analyzed fluorometrically after appropriate dilutions.

The data in Table II demonstrate the quantitative results obtained for the dosage form. The utility of HPLC in the analysis of dantrolene sodium is clearly indicated, and the results agree favorably with those obtained with the spectrophotofluorometric method.

With various concentrations of dantrolene sodium as unknowns, the accuracy of the overall chromatographic procedure was shown to be 3.1%.

Effect of Chloroquine Adsorption on Acid Reactivity of Magnesium Trisilicate

SALEH A. H. KHALIL

Abstract □ Due to the adsorption of chloroquine by magnesium trisilicate, both the BP acid absorption test and the rate of hydrochloric acid uptake, as monitored by pH measurements, were significantly reduced. This reduction was dependent on the amount of chloroquine adsorbed, since multilayer adsorption produced relatively more suppressive effects than did monolayer adsorption. The presence of adsorbed chloroquine also decreased the amounts of magnesium released in an acid medium. The inhibition of the antacid property due to chloroquine adsorption may be attributed to the occupation of the reactive sites of the antacid surface by chloroquine and to a reduction of the surface area of the antacid due to flocculation of the particles.

Keyphrases □ Chloroquine—adsorption by magnesium trisilicate, effect on acid reactivity □ Magnesium trisilicate—adsorption of chloroquine, effect on acid reactivity □ Adsorption, drug—chloroquine by magnesium trisilicate, effect on acid reactivity □ Acid reactivity—magnesium trisilicate, effect of adsorption of chloroquine □ Antacids—magnesium trisilicate, adsorption of chloroquine, effect on acid reactivity □ Antimalarial agents—chloroquine, adsorption by magnesium trisilicate, effect on acid reactivity

Few reports have appeared on the effects of drug adsorption on the surface properties of the adsorbents. However, protective colloids and surfactants adsorbed at liquid–solid interfaces are known to inhibit crystal growth (1, 2) and polymorphic conversion of drugs (3). The adsorption of some certified dyes resulted in the inhibition of single crystal dissolution of a number of pharmaceuticals (4, 5). In recent years, the adsorption of some drugs by magnesium trisilicate was reported (6, 7), but no detailed studies appear to have been made concerning the effect of drug adsorption on the antacid efficacy.

The present work examines the influence of chloroquine adsorption on the acid reactivity of magnesium trisilicate as measured by both the BP acid absorption test and the rate of hydrochloric acid uptake. Measurements of flocculation and determination of the amounts of magnesium released were also made before and after chloroquine adsorption by magnesium trisilicate.

EXPERIMENTAL

Materials—Magnesium trisilicate powder BP[1] of 11.2-nm mean surface–volume diameter and chloroquine phosphate powder BP[2] were used.

Methods—*Adsorption Experiments*—These experiments were carried out at 37 ± 0.2° by adding aqueous solutions of chloroquine phosphate (100 ml) of appropriate concentrations to a series of weighed quantities (1 g) of magnesium trisilicate. The glass-stoppered flasks were shaken in an oscillating water bath (25 ± 2 strokes/min) until completely equilibrated (6 hr). After centrifugation at 2000 rpm for 3 min, the supernate was suitably diluted with 0.01 *N* HCl and the chloroquine concentration was determined spectrophotometrically[3] at 329 nm.

Acid Absorption Test—The BP procedure (8) was adopted using magnesium trisilicate before and after chloroquine adsorption. The results were expressed as the volume of 0.05 *N* HCl absorbed by 1 g of magnesium trisilicate. To study the effect of chloroquine adsorption on the acid absorption test, the antacid after the adsorption experiment was centrifuged and the residue, equivalent to 0.3 g of magnesium trisilicate, was tested.

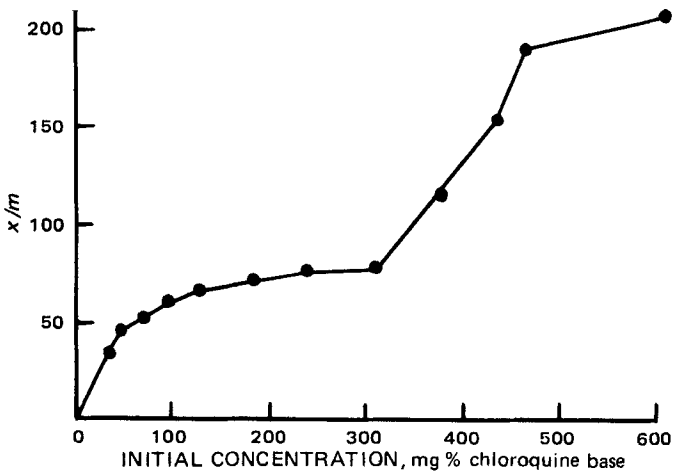

Figure 1—*Adsorption of chloroquine by 1% (w/v) magnesium trisilicate at 37 ± 0.2° (pH of the medium was 9.6).*

Rate of Hydrochloric Acid Uptake—The rate was determined at 37 ± 0.2° by monitoring the pH changes produced after the addition of 340 ml of 0.02 *N* HCl to 1 g of magnesium trisilicate. The apparatus and procedure adopted were as reported previously (9). To study the effect of chloroquine adsorption on the rate of hydrochloric acid uptake, the residue, equivalent to 1 g of the antacid remaining after the adsorption run, was used.

Determination of Magnesium Release—The amounts of magnesium

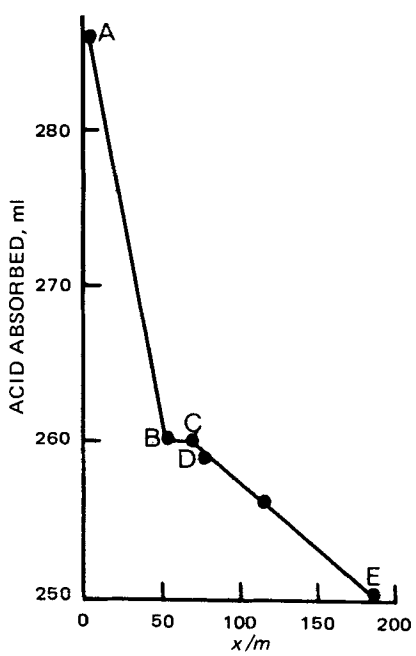

Figure 2—*Effect of amount of chloroquine adsorbed on the volume of 0.05 N HCl absorbed by 1 g of magnesium trisilicate (x/m) as measured by the BP acid absorption test.*

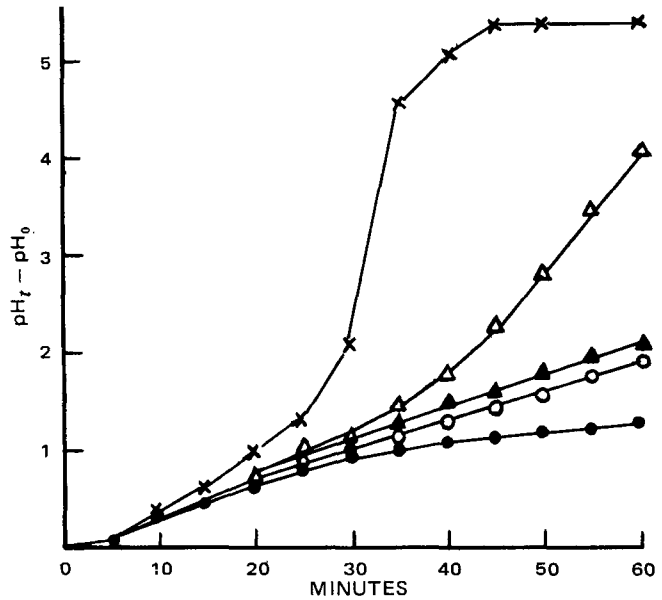

Figure 3—*The pH change* versus *time curves for magnesium trisilicate before chloroquine adsorption* (×) *and after adsorption of the following amounts of chloroquine (in milligrams per gram):* △, *68.2;* ▲, *75.9;* ○, *112.0; and* ●, *183.5.*

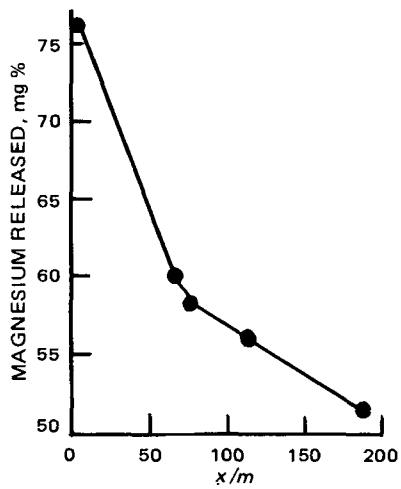

Figure 4—*Effect of amount of chloroquine adsorbed on the amount of magnesium released after 1 hr under the conditions of the BP acid absorption test.*

released after 1 hr under the conditions of the rate of hydrochloric acid uptake were determined by titrating an aliquot of the supernate with 0.05 *M* disodium ethylenediaminetetraacetate. A mordant black mixture was used as the indicator. Interference due to the released chloroquine was negligible.

Turbidity Measurements—A nephelometer[4] was used to measure, at 25°, the turbidity of the supernate sampled from the suspension after 10 min from a depth of 5 cm. The suspension was prepared by dispersing the residue (equivalent to 0.3 g of magnesium trisilicate) obtained after the adsorption experiment in 100 ml of water in a stoppered glass measure.

RESULTS AND DISCUSSION

Figure 1 shows the adsorption plot of chloroquine (where *x/m* is milligrams of chloroquine adsorbed per gram) on magnesium trisilicate (1% w/v) at pH 9.6[5]. At initial chloroquine concentrations below 300 mg %, the adsorption data fitted a Langmuir plot within the monolayer adsorption region; at higher drug concentrations, multilayer adsorption occurred. In the present study, the acid reactivity of magnesium trisilicate was tested before and after adsorbing varying amounts of chloroquine. Figure 2 shows the results of the BP acid absorption test. The adsorption of chloroquine on magnesium trisilicate resulted in a reduction of the volume of 0.05 *N* HCl absorbed by 1 g of the antacid. After an initial decrease from 282.2 to 260.1 ml (line AB, Fig. 2), an increase in the amount of chloroquine adsorbed within the region of monolayer adsorption (BCD) did not produce any significant reduction in the volume of the acid. Multilayer adsorption of chloroquine, however, produced a further decrease (line DE).

Measurements of the rate of hydrochloric acid uptake were made by monitoring the pH changes over 1 hr. The results shown in Fig. 3 illustrate a gradual suppression of the rate of acid uptake as the amount of chloroquine adsorbed was increased. At an *x/m* value of 183.5 mg/g, the acid reactivity decreased to 24.1%, calculated by comparing the pH changes 1 hr before and after adsorption. Determinations of the amounts of magnesium released under acidic conditions showed a gradual decrease due to chloroquine adsorption (Fig. 4). As a result of the adsorption, the antacid particles flocculated. Consequently, the turbidity percentages of the supernate decreased to 53.1, 41.6, and 40.3 for *x/m* values of 68.2, 75.9, and 112.0 mg/g, respectively.

The results suggest that the acid reactivity of magnesium trisilicate was suppressed due to chloroquine adsorption. This finding was evidenced by the acid absorption test where the volume of 0.05 *N* HCl consumed by 1 g of the antacid decreased from 282.2 ml to between 260.1 and 250.3 ml (Fig. 2). The suppressive effect of chloroquine adsorption of the acid reactivity was also reflected in the rate of hydrochloric acid uptake (Fig. 3). In the absence of adsorption, the pH change recorded after 1 hr was 5.4 units. Due to the adsorption of 183.5 mg of chloroquine, however, the pH value did not change by more than 1.3 units.

Since chloroquine has pKa values of 8.4 and 10.8, the ionization percentages at pH 9.6 (of the adsorption medium) would be 5.9 and 94.1, respectively. Therefore, the monoprotonated form probably is mainly involved in the adsorption. The mechanism suggested is probably electrostatic attraction between the negatively charged silicate surface and the monoprotonated form of chloroquine. As a result, neutralization of the charges occurred, as evidenced by the flocculation of the system. Since the reactive sites on the antacid were occupied by chloroquine, both the volume of the acid absorbed by 1 g of the antacid and the rate of acid uptake were reduced. Also, the amounts of magnesium released decreased as the amount of chloroquine adsorbed was increased, probably due to the "blocking" of the dissolution sites on the surface. The suppression of the acid reactivity may have been due to the decreased surface area of the flocculated antacid. The latter was, however, a direct effect of chloroquine adsorption.

In conclusion, the interaction between chloroquine and magnesium trisilicate not only resulted in the adsorption of the antimalarial drug (possibly altering its bioavailability) but also reduced the acid reactivity of magnesium trisilicate.

[4] Corning EEL, Evans Electroselenium Ltd., Essex, England.

[5] At this pH, no precipitation of chloroquine occurs since it is monoprotonated (pKa values of 8.4 and 10.8).

Hydrazones of Isoniazid for Colorimetric Analysis

P. R. SHAH and R. R. RAJE ˣ

Abstract □ Two sensitive color reactions of isoniazid are described. They are based on the formation of hydrazone Schiff bases when isoniazid is reacted with 4-nitrobenzaldehyde or pyridoxal. Linear curves were obtained with both reagents when absorbance values were plotted against concentrations.

Keyphrases □ Isoniazid—colorimetric analysis, hydrazones formed with 4-nitrobenzaldehyde or pyridoxal, prepared samples □ Colorimetry—analysis, isoniazid, hydrazones formed with 4-nitrobenzaldehyde or pyridoxal, prepared samples □ Antitubercular agents—isoniazid, colorimetric analysis, hydrazones formed with 4-nitrobenzaldehyde or pyridoxal, prepared samples □ Hydrazones—formed by reaction of isoniazid and 4-nitrobenzaldehyde or pyridoxal, colorimetric analysis

The USP XVIII (1) assay for isoniazid is based on iodometry. Some earlier reported spectrophotometric estimation methods involving color reactions due to Schiff base formation entailed reactions of isoniazid with benzaldehyde (2), vanillin (3), and 4-(dimethylamino)benzaldehyde (4). This report describes two color reactions based on the formation of yellow hydrazone Schiff bases when isoniazid is treated with 4-nitrobenzaldehyde or pyridoxal. Linear curves are obtained with both reagents by measuring the color intensities and plotting the absorbance values against graded concentrations of isoniazid.

EXPERIMENTAL

Reagents and Chemicals—The following were used: 4-nitrobenzaldehyde solution, 0.4% (w/v), prepared by dissolving 4-nitrobenzaldehyde[1] (analytical reagent) in ethyl alcohol; pyridoxal hydrochloride solution, 0.25% (w/v), prepared by dissolving pyridoxal hydrochloride[2] (analytical reagent) in distilled water; and 1 *N* sodium hydroxide solution, prepared by dissolving sodium hydroxide[3] (analytical reagent) in distilled water.

Standard Solution of Isoniazid—Isoniazid[4] was dissolved in distilled water to give a 1-mg/ml solution.

Determination of Wavelength of Maximum Absorption—*Method A*—A 2.0-ml quantity of the standard solution of isoniazid (1 mg/ml) and 1.0 ml of 4-nitrobenzaldehyde solution (0.4% w/v) were mixed; after 10 min, the mixture was brought to volume (25 ml) with 1 *N* sodium hydroxide solution. After shaking the mixture well and allowing it to stand for 75 min, the yellow solution was scanned in the visible range using a spectrophotometer[5]. A broad peak was recorded between 409 and 430 nm. A blue filter (range of 400–530 nm) and a photoelectric colorimeter[6] were used for further analyses.

Method B—A 2.0-ml quantity of the standard solution of isoniazid (1 mg/ml), 6.0 ml of distilled water, and 2.0 ml of pyridoxal hydrochloride solution (0.25% w/v) were mixed in a glass-stoppered cylinder. After allowing the mixture to stand for 90 min, the yellow solution was scanned in the visible range using a spectrophotometer[5]. Although a well-defined peak could not be recorded, the maximum absorption was observed at 400 nm. The same blue filter and photoelectric colorimeter used in Method A were used for further analyses.

Colorimetric Analysis with Graded Concentrations of Isoniazid—4-Nitrobenzaldehyde solution, 1.0 ml (0.4% w/v), was added to each of seven volumetric flasks (25 ml) containing the standard solution of isoniazid as shown in Table I and treated as described for Method A. Similarly, 2.0 ml of pyridoxal hydrochloride solution (0.25% w/v) was added to each of five glass-stoppered cylinders (10 ml) containing the standard solution of isoniazid, diluted to volume with distilled water, and treated as described for Method B (Table II).

[5] Beckman model DB.
[6] Systronix, type 101, Serial No. 149.

DISCUSSION

The results given in Tables I and II indicate that the color reactions were sensitive at low concentrations of isoniazid and gave linear absorbance *versus* concentration curves with both chromogenic reagents. Color development in the isoniazid and 4-nitrobenzaldehyde system requires an alkaline medium.

Table I—Concentration *versus* Absorbance for Isoniazid–4-Nitrobenzaldehyde Solutions

Number	Quantity of Standard Solution of Isoniazid, ml	Concentration of Isoniazid, mg/ml	Absorbance
1	1.5	0.06	0.190
2	1.75	0.07	0.210
3	2.0	0.08	0.230
4	2.25	0.09	0.250
5	2.5	0.10	0.270
6	2.75	0.11	0.290
7	3.0	0.12	0.310

Table II—Concentration *versus* Absorbance for Isoniazid–Pyridoxal Solutions

Number	Quantity of Standard Solution of Isoniazid, ml	Final Concentration of Isoniazid, mg/ml	Absorbance
1	1.0	0.10	0.110
2	1.5	0.15	0.140
3	2.0	0.20	0.170
4	2.5	0.25	0.200
5	3.0	0.30	0.230

Both color reactions can be used for the estimation of isoniazid in pharmaceutical formulations. Examination of one commercial tablet preparation of isoniazid using both procedures afforded results comparable to those obtained by the USP XVIII procedure.

The hydrazone formed in the case of pyridoxal hydrochloride might conceivably be of therapeutic value in that it might not cause vitamin B_6 deficiency. In addition, it might possess lower toxicity and enhanced antituberculous activity when compared with isoniazid, as was reported for similar hydrazone compounds (5–7). The conversion of hydrazide to hydrazone apparently effectuates no loss in antituberculous activity.

Rapid Near IR Spectrophotometric Determination of Meprobamate in Pharmaceutical Preparations

ALFRED F. ZAPPALA [x] and ALEX POST

Abstract □ A rapid near IR spectrophotometric method was developed for determining meprobamate in tablets, sustained-release capsules, suspensions, and injectables. The absorbance of a chloroform solution of the drug is obtained at about 1.96 μm for quantitation. Assay of nine commercial products from four different manufacturers gave results ranging from 97 to 104% of label claim. Coefficients of variation of 0.7 and 1.3% were obtained on the tablets and a sustained-release product, respectively.

Keyphrases □ Meprobamate—IR spectrophotometric analysis, commercial dosage forms □ IR spectrophotometry—analysis, meprobamate, commercial dosage forms □ Sedatives—meprobamate, IR spectrophotometric analysis, commercial dosage forms

Since the USP XVIII (1) titrimetric procedure for determining meprobamate in tablets is lengthy and somewhat cumbersome, a rapid and easy-to-handle method is needed. A significant step toward this goal was taken by Sherken (2), who spectrophotometrically scanned chloroform solutions of the drug from 3.00 to 2.80 μm and utilized the absorbance at 2.91 μm to obtain the meprobamate concentration. This wavelength is characteristic of the symmetric stretching band of the primary amine group of meprobamate. However, for this procedure to be applicable, it was of paramount importance that the chloroform be freed of the stabilizer, alcohol. Therefore, extraction of the chloroform with water, followed by column chromatography through two tandem columns of activated alumina, was necessary.

Since the commencement of this work, USP XIX (3) adopted a colorimetric method for the assay of meprobamate in tablets. This method is sensitive and fairly rapid. However, the pH of the reagents must be carefully controlled and the acidified phenol reagent must be added carefully to decompose completely any chlorinating solution retained on the neck of the volumetric flask.

Because of the difficulties with these methods, a more rapid and facile procedure was desired that would be applicable to tablets and other dosage forms. The described near IR method is more rapid and does not suffer from the critical requirements of the other methods. Purification of the chloroform solution is not required since the alcohol does not interfere with the absorbance at 1.958 μm used to quantitate meprobamate. This band is subject to fewer interferences than the one at 2.91 μm (4). That the primary amine combination band at 1.958 μm is significantly weaker than the one at 2.91 μm also does not present any detection problem. High sensitivity is not of concern, because the levels of meprobamate in pharmaceutical preparations are generally high.

Table I—Comparison of Results Obtained on Commercial Products[a]

[a] Values reported are the average of duplicate assays. [b] Film-coated tablet. [c] Intramuscular injectable. [d] Sustained-release capsule. [e] Sustained-release capsule containing 15 mg of dextroamphetamine sulfate. [f] Samples 1–9. [g] Samples 1–7.

EXPERIMENTAL

Apparatus—A recording spectrophotometer equipped with an IR source[1] and matching 5-cm silica cells were used.

Reagents—Chloroform (reagent grade) and a standard solution of meprobamate (NF XIV), 3.0–4.0 mg/ml in chloroform, were used.

Sample Preparation—*Tablets*—Determine the average tablet weight of not less than 20 tablets. Reduce the tablets to a fine powder and accurately weigh a portion, equivalent to 300–400 mg of meprobamate, into a 100-ml volumetric flask. Add about 70 ml of chloroform to the flask and shake for 15–20 min. Dilute to volume with chloroform and filter through paper[2], discarding the first 15–20 ml.

Sustained-Release Capsules—Determine the average net fill of not less than 20 capsules. Shake the contents to obtain a representative sample. Triturate an accurately weighed sample, equivalent to 300–400 mg of meprobamate; transfer it to a 100-ml volumetric flask with the aid of about 70 ml of chloroform and shake for 15–20 min. Dilute to volume with chloroform and filter as described for tablets.

Suspensions—Shake the sample for several minutes so that a representative sample aliquot can be removed. With a "to contain" pipet, transfer an aliquot equivalent to about 400 mg of meprobamate to a separator. Rinse the pipet thoroughly with distilled water into the separator and add water, if necessary, to obtain a volume of about 30 ml.

Table II—Results of Precision Study on Sample 5

Determination	Amount Found, mg	
	Near IR	USP XIX
1	415	395
2	415	396
3	413	408
4	413	404
5	416	399
6	422	401
7	416	403
8	410	405
9	415	412
10	415	414
Mean	415	404
SD	3.1	6.3
CV	0.7	1.5

Extract with three 30-ml portions of chloroform, collecting the chloroform extracts in a 100-ml volumetric flask after filtering through a small amount of anhydrous sodium sulfate. Then dilute to volume with chloroform and mix well. Accurately weigh about 400 mg of meprobamate standard material into a separator, suspend the material in about 30 ml of water, and similarly extract with chloroform.

Injectables—Combine the contents of several ampuls and transfer an aliquot, equivalent to about 400 mg of meprobamate, to a separator. Add about 25 ml of distilled water and extract with chloroform as described for suspensions. Prepare a placebo solution containing the same amount of polyethylene glycol 400 as is found in the commercial ampul preparation. In addition, accurately prepare a standard of about 400 mg of meprobamate dissolved in the placebo solution and then extract as described for suspensions.

Assay Procedure—*Tablets, Sustained-Release Capsules, and Suspensions*—Balance the instrument at 2.00 μm with chloroform in both cells and then scan to 1.93 μm to establish the baseline. Record the spectra of the prepared samples and standard solutions *versus* chloroform over the same range (Fig. 1). Draw a line connecting the points on the curve at 1.945 and 1.980 μm. Obtain the absorbance difference (ΔA) between the absorbance maximum at about 1.958 μm and at the same point on the line drawn.

Injectables—Balance the instrument at 2.00 μm with the extracted placebo in both cells and then scan to 1.93 μm to establish the baseline. Record the spectra of the standard and ampul extracts *versus* the placebo extract over the same range.

Calculations—Calculate the quantity of meprobamate using:

$$\frac{\Delta A \times f \times d \times c}{s} = \text{mg meprobamate/capsule or tablet} \quad \text{(Eq. 1)}$$

or:

$$\frac{\Delta A \times f \times d}{v} = \text{mg meprobamate/ml of suspension or injectable} \quad \text{(Eq. 2)}$$

where ΔA = absorbance difference at 1.958 μm, f = standard factor in milligrams of meprobamate per milliliter per ΔA, d = dilution volume, c = average capsule fill or tablet weight in grams, s = sample weight in grams, and v = sample aliquot in milliliters.

RESULTS AND DISCUSSION

A series of standard solutions ranging from 2.0 to 7.0 mg/ml was analyzed, and adherence to Beer's law was observed. Nine commercial samples of meprobamate products from four different manufacturers were assayed by the near IR method and the USP XIX method (Table I). The near IR method can be successfully applied to various dosage forms including a combination product. A precision study, based on 10 separate determinations of a tablet preparation, was performed using both the near IR method and the USP XIX method (Table II).

When a suspension was assayed by the USP XIX colorimetric method, very low and widely scattered results were obtained. Similarly, when the same suspension was assayed by the USP XVIII titrimetric method, low results were obtained. During the hydrolysis step in the latter procedure, the suspension darkened to such an extent that the detection of the colorimetric end-point of the subsequent titration became extremely difficult.

When an intramuscular injectable was first assayed by the near IR method used to assay suspensions, it was immediately apparent that the spectra were distorted. The gross distortion was due to the large amount of polyethylene glycol 400 in the formulation (400 mg of meprobamate/5 ml of a 65% solution of polyethylene glycol 400). This problem was circumvented by "blanking out" this interference as already described. However, since the amount of polyethylene glycol 400 might vary by as much as ±10% of the label declaration, an experiment was performed to determine the effect of such a variation on the assay. The meprobamate extracted from a 65% polyethylene glycol 400 solution, when assayed against extracted placebos containing 58 and 72% polyethylene glycol 400, yielded recoveries of 99.7 and 101.0%, respectively. Thus, the proposed method is unaffected by variable amounts of polyethylene glycol 400. The results of the near IR method compare favorably with those obtained by the USP XIX method (Table I).

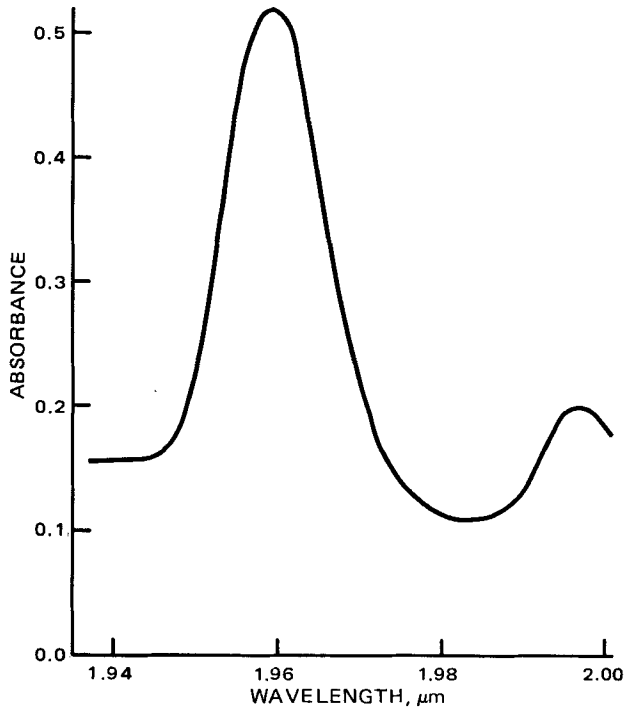

Figure 1—*Near IR absorption spectrum of meprobamate (4.17 mg/ml) in chloroform (5-cm cells).*

The product containing meprobamate in combination with dextroamphetamine gave a high result when assayed by the USP XIX procedure (Table I). This high value was partially due to dextroamphetamine reacting with the reagents. The dye used in the capsule also contributed to the high result. In contrast, dextroamphetamine and the dye did not cause any interference with the determination of meprobamate in this combination product by the near IR method.

pH Partition Behavior of Ampicillin

Keyphrases □ Partition coefficients—ampicillin in aqueous buffer–octanol systems, effect of pH □ Ampicillin—partition coefficients in aqueous buffer–octanol systems, effect of pH □ pH—effect on partition coefficients of ampicillin in aqueous buffer–octanol systems □ Antibacterials—ampicillin, partition coefficients in aqueous buffer–octanol systems, effect of pH

To the Editor:

The pH partition behavior of the ampholytic β-lactam antibiotics ampicillin, cephalexin, and cephaloglycin was previously studied in aqueous buffer–1-octanol and aqueous buffer–1-butanol systems (1). The results obtained for ampicillin in both systems appeared to indicate that the anion was the partitioning species. Over the pH 4.9–7.9 range, apparent partition coefficients increased with pH. Apparent partition coefficient values for ampicillin in aqueous octanol were calculated after spectrophotometric analysis of only the aqueous phase and ranged from 0.18 to 0.31. These values were nearly an order of magnitude greater than the apparent partition coefficient values reported for ampicillin in water–ethyl acetate (2). In contrast, the partition coefficient values for penicillin G in water–octanol or water–ethyl acetate only differed by a factor of about 1.5 (3). The purpose of this study was to obtain reproducible partition coefficient values for ampicillin based on analyses of both the aqueous and organic phases.

Buffered solutions of ampicillin were prepared at 2 mg/ml. Twenty milliliters of both the buffer and octanol were pipetted into a container suitable for shaking. In some cases, each phase was presaturated with the other. The samples were shaken[1] mechanically for 20 min at 200–300 cpm and then centrifuged.

The octanol phase was withdrawn and transferred to a separator, where any carried-over aqueous phase was separated and discarded. Then the octanol was extracted with one 20-ml and two 10-ml portions of pH 5.2 buffer containing copper sulfate (4). These buffer portions were combined and diluted to volume in a 50-ml volumetric flask using the prepared pH 5.2 buffer. This solution was analyzed to determine the organic phase concentrations.

The aqueous phase was analyzed after dilution of a 0.3-ml aliquot with pH 5.2 buffer containing copper sulfate to 25 ml in a volumetric flask.

Analysis was by a copper catalyst procedure (4) in which the absorbance difference between the maximum near 320 nm and the baseline at 390 nm was determined from a spectrophotometric[2] recording. The concentration of each solution was calculated using a calibration curve obtained with standard solutions. Total recovered ampicillin was calculated by summing the amounts found in each solvent phase. Recovery was 100 ± 5% for the samples handled by one chemist. A slightly broader variation was noted for samples handled by another chemist.

Table I—Aqueous Buffer–Octanol Apparent Partition Coefficient Values for Ampicillin at 25°

pH	Apparent Partition Coefficient × 10^3	n
3.0	8.3	2
5.0	7.4	2
	6.2[a]	2
7.0	7.4[a]	2
	8.2	10
7.2	8.0	3
7.9	8.2	2
	6.4	2

[a] Determinations made by a second chemist.

The apparent partition coefficient was calculated by dividing the organic phase concentration by the aqueous phase concentration:

$$\text{partition coefficient} = \frac{[\text{ampicillin}]_{\text{octanol}}}{[\text{ampicillin}]_{\text{water}}} \qquad \text{(Eq. 1)}$$

The results obtained in the pH 3.0–7.9 range at 25° are shown in Table I. Contrary to previous reports, no change in the apparent partition coefficient with pH was observed.

Temperature may affect the observed partition coefficient values. However, for ampicillin in aqueous buffer–octanol systems at 25 and 37°, differences were insignificant. At pH 5.1 and 7.0 at 37°, the apparent partition coefficients were 8.3×10^{-3} and 7.3×10^{-3}, respectively, based on two determinations at each pH.

The precision and accuracy of the analytical procedure for each phase were determined, and the apparent partition coefficients were calculated. First, a spiked octanol solution, extracted with buffer as previously described, gave a mean total recovery (n = 6) of 95.5% with a range of 92.8–97.6% and a coefficient of variation of 2.0%. After partitioning, the coefficient of variation values of 0.97 and 21% were obtained for aqueous phase and organic phase concentrations, respectively. Thus, determination of the apparent partition coefficient values gave a coefficient of variation of 21% too. These values were calculated for duplicate determinations on 5 consecutive days. The poor precision probably resulted from poor phase separation, which has the greatest effect on the determination of the organic phase concentration. Therefore, a significant variation in the apparent partition coefficient value resulted.

Other factors evaluated included the time of mixing and presaturation of each phase with the other. Neither mixing time in the 10–160-min range nor presaturation of phases appeared to affect the results.

The results indicate that the extent of ampicillin partitioning in aqueous buffer–octanol systems is significantly less than had been reported earlier and is apparently unaffected by pH in the 3.0–7.9 range.

BOOKS

REVIEWS

The *Catharanthus* Alkaloids. Edited by W. I. TAYLOR and N. R. FARNSWORTH. Dekker, 270 Madison Ave., New York, NY 10016, 1975. 323 pp. 16 × 32.5 cm. Price $29.50.

This valuable book for students, teachers, researchers, and clinicians interested in the pharmacognosy of the *Catharanthus* alkaloids opens with a concise and significant introduction by Gordon H. Svoboda, in which he outlines the history and discovery of the outstanding alkaloid pair, vinblastine and vincristine. Dr. Svoboda, responsible for much of this research, reviews the scientific and medical aspects of these and other *Catharanthus* alkaloids in terms of their biological specificity and their relative clinical merit.

The book includes chapters dealing with the following topics: a Synopsis of the Genus *Catharanthus* (William T. Stearn, British Museum), the Photochemistry and Pharmacology of *Catharanthus roseus* (G. H. Svoboda and D. A. Blake), the Phytochemistry of the Minor *Catharanthus* Species (M. Tin-Wa and N. R. Farnsworth), Structure Elucidation and Chemistry of the Bis *Catharanthus* Alkaloids (D. J. Abrahams), the Biosynthesis of *Catharanthus* Alkaloids (R. J. Parry), and Tissue Culture Studies of *Catharanthus roseus* (David P. Carew). The final chapters, dealing with Biochemistry (William A. Creasey) and the Clinical Aspects of the Dimeric *Catharanthus* Alkaloids (R. C. DeConti and W. A. Creasey), comprehensively and thoroughly review these important topics.

The book is well organized; tables, figures, and text are of professional quality; and, in spite of the many botanical terms used, the number of misprints is remarkably small, a rare exception being a twice misspelled catharanthine (I) (p. 128).

The total amount of multidisciplinary information contained in this monograph is considerable. The book, therefore, constitutes a valuable reference work for diverse professionals needing reliable information. The authors all have worked extensively in their various specialties, thus endowing the book with an authoritative quality. In particular, the chapter on clinical effects of vinblastine and vincristine as well as other alkaloids of lesser efficacy summarizes the relative and specific clinical activity in a clear and comprehensive manner. For researchers not having easy access to detailed medical literature in this area, this chapter by DeConti and Creasey constitutes a good source for reliable information on clinical usages of currently available oncolytic *Catharanthus* alkaloids.

The only regret felt during the reading of various chapters, especially those dealing with topics presently in an active state of investigation, is in the time lag during writing and publication. Few references beyond 1972 are included in most chapters. Much excellent work during the following years thus remains unmentioned through no fault of authors or publishers.

In summary, the editors have made an excellent selection of topics and authors. The resulting book summarizes available information on this important class of alkaloids in a most readable and reliable manner. The book is heartily recommended for readers wanting to become acquainted or reacquainted with the chemistry or biology of these complex herbal products of outstanding medicinal value.

Pro-drugs as Novel Drug Delivery Systems. Edited by T. HIGUCHI and V. STELLA. American Chemical Society, 1155 16th Street, N.W., Washington, DC 20036, 1975. 245 pp. 16 × 24 cm. Price $13.50.

This volume is a collection of papers presented during a symposium on prodrugs held in Atlantic City, September 10, 1974, under the sponsorship of the ACS Division of Medicinal Chemistry. The book consists of six sections. The first section, which constitutes approximately half of the volume, is a review of the basic concepts and approaches to the design of prodrugs. The second section covers applications of the prodrug approach to antibiotics. The remainder of the volume describes, in the form of research papers, chemical and biological studies on prodrug candidates performed in the laboratories of the authors. These chapters deal with prodrugs of phenytoin (diphenylhydantoin) and epinephrine and with the use of prodrugs in the formulation of cytotoxic agents for parenteral administration.

Although the enzymatic and some biological aspects, which are important in the design of new prodrugs, are not discussed, this book represents an excellent compilation of data on the subject. The extensive bibliography, particularly of the first two sections, and the excellent examples selected to illustrate the chemical approaches to the problem of drug delivery should make this volume a valuable addition to the library of every researcher in this field.

The book is easily readable and is recommended to graduate students and faculty of both chemistry and pharmacy. The material described in this book by the authors, who are experts in this field, ought to stimulate greatly the thinking of those who are seeking new ideas in the application of chemistry to biology and pharmacy.

The Effect of Disease States on Drug Pharmacokinetics. Edited by LESLIE Z. BENET. American Pharmaceutical Association, 2215 Constitution Ave. N.W., Washington, DC 20037, 1976. 252 pp. 15.5 × 23 cm. Price $9.25 (APhA Member Rate, $6.50).

"The Effect of Disease States on Drug Pharmacokinetics" is a collection of the papers presented at the April 1976 symposium sponsored by the Academy of Pharmaceutical Sciences of the American Pharmaceutical Association. The 29 contributors to this symposium are among the most prominent researchers in the field of clinical pharmacokinetics.

The introduction is a general orientation to the subject and a brief discussion of various possible approaches to the investigation of potential pharmacokinetic changes. The book is divided into four parts, each of which contains one chapter that discusses the subtopic in general and one or more chapters that deal with specific examples.

In the first section, Body Perfusion, Chapter 2 presents an overview of pharmacokinetics in disease states that modify blood flow and organ perfusion. Chapter 3 deals specifically with the effects of cardiac failure on GI absorption.

BOOKS

REVIEWS

The *Catharanthus* Alkaloids. Edited by W. I. TAYLOR and N. R. FARNSWORTH. Dekker, 270 Madison Ave., New York, NY 10016, 1975. 323 pp. 16 × 32.5 cm. Price $29.50.

This valuable book for students, teachers, researchers, and clinicians interested in the pharmacognosy of the *Catharanthus* alkaloids opens with a concise and significant introduction by Gordon H. Svoboda, in which he outlines the history and discovery of the outstanding alkaloid pair, vinblastine and vincristine. Dr. Svoboda, responsible for much of this research, reviews the scientific and medical aspects of these and other *Catharanthus* alkaloids in terms of their biological specificity and their relative clinical merit.

The book includes chapters dealing with the following topics: a Synopsis of the Genus *Catharanthus* (William T. Stearn, British Museum), the Photochemistry and Pharmacology of *Catharanthus roseus* (G. H. Svoboda and D. A. Blake), the Phytochemistry of the Minor *Catharanthus* Species (M. Tin-Wa and N. R. Farnsworth), Structure Elucidation and Chemistry of the Bis *Catharanthus* Alkaloids (D. J. Abrahams), the Biosynthesis of *Catharanthus* Alkaloids (R. J. Parry), and Tissue Culture Studies of *Catharanthus roseus* (David P. Carew). The final chapters, dealing with Biochemistry (William A. Creasey) and the Clinical Aspects of the Dimeric *Catharanthus* Alkaloids (R. C. DeConti and W. A. Creasey), comprehensively and thoroughly review these important topics.

The book is well organized; tables, figures, and text are of professional quality; and, in spite of the many botanical terms used, the number of misprints is remarkably small, a rare exception being a twice misspelled catharanthine (I) (p. 128).

The total amount of multidisciplinary information contained in this monograph is considerable. The book, therefore, constitutes a valuable reference work for diverse professionals needing reliable information. The authors all have worked extensively in their various specialties, thus endowing the book with an authoritative quality. In particular, the chapter on clinical effects of vinblastine and vincristine as well as other alkaloids of lesser efficacy summarizes the relative and specific clinical activity in a clear and comprehensive manner. For researchers not having easy access to detailed medical literature in this area, this chapter by DeConti and Creasey constitutes a good source for reliable information on clinical usages of currently available oncolytic *Catharanthus* alkaloids.

The only regret felt during the reading of various chapters, especially those dealing with topics presently in an active state of investigation, is in the time lag during writing and publication. Few references beyond 1972 are included in most chapters. Much excellent work during the following years thus remains unmentioned through no fault of authors or publishers.

In summary, the editors have made an excellent selection of topics and authors. The resulting book summarizes available information on this important class of alkaloids in a most readable and reliable manner. The book is heartily recommended for readers wanting to become acquainted or reacquainted with the chemistry or biology of these complex herbal products of outstanding medicinal value.

Pro-drugs as Novel Drug Delivery Systems. Edited by T. HIGUCHI and V. STELLA. American Chemical Society, 1155 16th Street, N.W., Washington, DC 20036, 1975. 245 pp. 16 × 24 cm. Price $13.50.

This volume is a collection of papers presented during a symposium on prodrugs held in Atlantic City, September 10, 1974, under the sponsorship of the ACS Division of Medicinal Chemistry. The book consists of six sections. The first section, which constitutes approximately half of the volume, is a review of the basic concepts and approaches to the design of prodrugs. The second section covers applications of the prodrug approach to antibiotics. The remainder of the volume describes, in the form of research papers, chemical and biological studies on prodrug candidates performed in the laboratories of the authors. These chapters deal with prodrugs of phenytoin (diphenylhydantoin) and epinephrine and with the use of prodrugs in the formulation of cytotoxic agents for parenteral administration.

Although the enzymatic and some biological aspects, which are important in the design of new prodrugs, are not discussed, this book represents an excellent compilation of data on the subject. The extensive bibliography, particularly of the first two sections, and the excellent examples selected to illustrate the chemical approaches to the problem of drug delivery should make this volume a valuable addition to the library of every researcher in this field.

The book is easily readable and is recommended to graduate students and faculty of both chemistry and pharmacy. The material described in this book by the authors, who are experts in this field, ought to stimulate greatly the thinking of those who are seeking new ideas in the application of chemistry to biology and pharmacy.

The Effect of Disease States on Drug Pharmacokinetics. Edited by LESLIE Z. BENET. American Pharmaceutical Association, 2215 Constitution Ave. N.W., Washington, DC 20037, 1976. 252 pp. 15.5 × 23 cm. Price $9.25 (APhA Member Rate, $6.50).

"The Effect of Disease States on Drug Pharmacokinetics" is a collection of the papers presented at the April 1976 symposium sponsored by the Academy of Pharmaceutical Sciences of the American Pharmaceutical Association. The 29 contributors to this symposium are among the most prominent researchers in the field of clinical pharmacokinetics.

The introduction is a general orientation to the subject and a brief discussion of various possible approaches to the investigation of potential pharmacokinetic changes. The book is divided into four parts, each of which contains one chapter that discusses the subtopic in general and one or more chapters that deal with specific examples.

In the first section, Body Perfusion, Chapter 2 presents an overview of pharmacokinetics in disease states that modify blood flow and organ perfusion. Chapter 3 deals specifically with the effects of cardiac failure on GI absorption.

The Effect of Disease States on Drug Pharmacokinetics. Edited by LESLIE Z. BENET. American Pharmaceutical Association, 2215 Constitution Ave. N.W., Washington, DC 20037, 1976. 252 pp. 15.5 × 23 cm. Price $9.25 (APhA Member Rate, $6.50).

"The Effect of Disease States on Drug Pharmacokinetics" is a collection of the papers presented at the April 1976 symposium sponsored by the Academy of Pharmaceutical Sciences of the American Pharmaceutical Association. The 29 contributors to this symposium are among the most prominent researchers in the field of clinical pharmacokinetics.

The introduction is a general orientation to the subject and a brief discussion of various possible approaches to the investigation of potential pharmacokinetic changes. The book is divided into four parts, each of which contains one chapter that discusses the subtopic in general and one or more chapters that deal with specific examples.

In the first section, Body Perfusion, Chapter 2 presents an overview of pharmacokinetics in disease states that modify blood flow and organ perfusion. Chapter 3 deals specifically with the effects of cardiac failure on GI absorption.

Hepatic and Metabolic Function is the subject of the second section, which includes Chapters 4–6. A comprehensive review of drug kinetics in patients with hepatic dysfunction is presented in Chapter 4. The effect of chronic liver disease on hepatic clearance is examined in Chapter 5, and Chapter 6 is a description of the kinetics of a single drug, carbamazepine, in a particular disease state, epilepsy.

The third section, Protein Binding, contains, in Chapter 7, a survey of disease-induced changes in drug-binding components and factors that alter drug–protein binding. Chapter 8 reviews the effects of uremia, bacterial infections, and cardiopulmonary bypass on serum protein binding. The clinical implications of interindividual differences of plasma protein binding, specifically for warfarin, phenytoin, and bilirubin, are discussed in Chapter 9.

Renal Function, the final section, is the area in which the most progress has been made in evaluating effects of disease states on drug kinetics. Chapter 10 presents a broad consideration of the field and a tabular compilation that may be used in adjusting drug dosage for compounds influenced by changes in renal function. The influence of renal disease on the elimination of procainamide and the accumulation of *N*-acetylprocainamide is described in Chapter 11. Finally, in Chapter 12, the effect of changes in renal function on gentamicin kinetics is discussed.

This book should be of particular value to students and researchers in the field of clinical pharmacokinetics, as well as practitioners and professionals in allied fields.

Staff Review

Practical Pharmaceutical Chemistry. Third Edition–Part Two. By A. H. BECKETT and J. B. STENLAKE. Humanities Press, Atlantic Highlands, NJ 07716, 1976. 552 pp. 16 × 24 cm. Price $37.50.

The present volume is an attempt to provide to students the benefit of numerous developments in practical pharmaceutical chemistry since the book was first written (1970). This resulted in an increase in the length of the volume by 127 pages, a figure that gives some idea of the new matter incorporated in the present edition.

This edition again opens with a chapter on "General Physical Methods," which covers some of the general topics in physics including molecular weight, refractometry, optical activity, and viscosity. These topics, systematically presented in concise form, lay the groundwork for subsequent chapters. It would be invidious to single out any chapter for special mention because the book covers such a wide variety of topics. These topics include analysis of drugs, measurement of electromotive force and pH, conductometric titrations, polarography, chromatography, spectrophotometry, flame photometry, and atomic absorption spectroscopy, spectrofluorometry, IR, NMR, mass spectrometry, and radiochemical techniques. These topics provide a sound basic knowledge to chemistry and pharmacy students.

The organization of this edition is identical to the previous edition. In addition to the material covered in the previous edition, this edition has given more detailed coverage to flame photometry, atomic absorption, and GC–mass spectrometric systems and has incorporated excellent introductions to, and practical applications of, circular dichroism spectra, thermal methods of analysis, coulometry, and high pressure liquid chromatography. The sections on NMR have been extended to include lanthanide shift reagents, ^{13}C-NMR spectroscopy, fourier transform NMR, and an introduction to internuclear double resonance and nuclear overhauser effect. The chapter on radiochemical techniques includes additional practical experiments with radionuclide generators and the use of radioimmunoassay techniques. All chapters of the book are sufficiently illustrated with diagrams, experiments (none in chapters on NMR and mass spectrometry), cognate experiments, and references. At the end of certain chapters, the authors provide a list of recommended books for additional study.

Overall, this is a lucid book presented in the style employed by Arthur I. Vogel, the author of "Practical Organic Chemistry." It is the opinion of this reviewer and his associates that this edition will not only stimulate the interest of chemistry and pharmacy students but will also assist in enhancing their knowledge.

Handbook of Ocular Toxicity. By MARVIN B. SMITH. Publishing Sciences Group Inc., 162 Great Rd., Acton, MA 01720, 1976. 525 pp. 16 × 24 cm. Price $20.00.

British National Formulary 1976–78. The British Medical Association, Tavistock Square, London, WC1H 9JP and The Pharmaceutical Press, 17 Bloomsbury Square, London WC1A 2NN, England, 1976. 422 pp. 16.5 × 10.5 cm. Price £ 1.55.

Thiamine. Edited by CLARK J. GUBLER, MOTONORI FUJIWARA, and PIERRE M. DREYFUSS. Wiley, 605 Third Ave., New York, NY 10016, 1976. 393 pp. 16 × 23.5 cm. Price $27.00.

Contemporary Organic Chemistry. By MARION H. O'LEARY. McGraw-Hill Book Co., 1221 Avenue of the Americas, New York, NY 10020, 1975. 396 pp. 16.5 × 24 cm. Price $13.95.

Visceral Muscle. Its Structure and Function. By HENRY HUDDART and STEPHEN HUNT. Halsted, 605 Third Ave., New York, NY 10016, 1976. 181 pp. 15 × 21 cm. Price $13.95.

Biochemical Fluorescence: Concepts. Vol. 2. Edited by RAYMOND F. CHEN and HAROLD EDELHOCH. Dekker, 270 Madison Ave., New York, NY 10016, 1976. 944 pp. 16 × 24 cm. Price $38.00.

The Heroin Epidemics. A Study of Heroin Use in the United States, 1965–1975. By LEON GIBSON HUNT and CARL D. CHAMBERS. Halsted, 605 Third Ave., New York, NY 10016, 1976. 145 pp. 16 × 23.5 cm. Price $12.95.

Immunopharmacology. Edited by MARVIN E. ROSENTHALE and HERBERT C. MANSMANN, Jr. Halsted, 605 Third Ave., New York, NY 10016, 1976. 332 pp. 15.5 × 23.5 cm. Price $25.00.

Hormones, Behavior and Psychopathology. Edited by EDWARD J. SACHAR. Raven, 1140 Avenue of the Americas, New York, NY 10036, 1976. 307 pp. 16 × 24.5 cm. Price $24.00.

Hepatic and Metabolic Function is the subject of the second section, which includes Chapters 4–6. A comprehensive review of drug kinetics in patients with hepatic dysfunction is presented in Chapter 4. The effect of chronic liver disease on hepatic clearance is examined in Chapter 5, and Chapter 6 is a description of the kinetics of a single drug, carbamazepine, in a particular disease state, epilepsy.

The third section, Protein Binding, contains, in Chapter 7, a survey of disease-induced changes in drug-binding components and factors that alter drug–protein binding. Chapter 8 reviews the effects of uremia, bacterial infections, and cardiopulmonary bypass on serum protein binding. The clinical implications of interindividual differences of plasma protein binding, specifically for warfarin, phenytoin, and bilirubin, are discussed in Chapter 9.

Renal Function, the final section, is the area in which the most progress has been made in evaluating effects of disease states on drug kinetics. Chapter 10 presents a broad consideration of the field and a tabular compilation that may be used in adjusting drug dosage for compounds influenced by changes in renal function. The influence of renal disease on the elimination of procainamide and the accumulation of *N*-acetylprocainamide is described in Chapter 11. Finally, in Chapter 12, the effect of changes in renal function on gentamicin kinetics is discussed.

This book should be of particular value to students and researchers in the field of clinical pharmacokinetics, as well as practitioners and professionals in allied fields.

Staff Review

Practical Pharmaceutical Chemistry. Third Edition–Part Two. By A. H. BECKETT and J. B. STENLAKE. Humanities Press, Atlantic Highlands, NJ 07716, 1976. 552 pp. 16 × 24 cm. Price $37.50.

The present volume is an attempt to provide to students the benefit of numerous developments in practical pharmaceutical chemistry since the book was first written (1970). This resulted in an increase in the length of the volume by 127 pages, a figure that gives some idea of the new matter incorporated in the present edition.

This edition again opens with a chapter on "General Physical Methods," which covers some of the general topics in physics including molecular weight, refractometry, optical activity, and viscosity. These topics, systematically presented in concise form, lay the groundwork for subsequent chapters. It would be invidious to single out any chapter for special mention because the book covers such a wide variety of topics. These topics include analysis of drugs, measurement of electromotive force and pH, conductometric titrations, polarography, chromatography, spectrophotometry, flame photometry, and atomic absorption spectroscopy, spectrofluorometry, IR, NMR, mass spectrometry, and radiochemical techniques. These topics provide a sound basic knowledge to chemistry and pharmacy students.

The organization of this edition is identical to the previous edition. In addition to the material covered in the previous edition, this edition has given more detailed coverage to flame photometry, atomic absorption, and GC–mass spectrometric systems and has incorporated excellent introductions to, and practical applications of, circular dichroism spectra, thermal methods of analysis, coulometry, and high pressure liquid chromatography. The sections on NMR have been extended to include lanthanide shift reagents, ^{13}C-NMR spectroscopy, fourier transform NMR, and an introduction to internuclear double resonance and nuclear overhauser effect. The chapter on radiochemical techniques includes additional practical experiments with radionuclide generators and the use of radioimmunoassay techniques. All chapters of the book are sufficiently illustrated with diagrams, experiments (none in chapters on NMR and mass spectrometry), cognate experiments, and references. At the end of certain chapters, the authors provide a list of recommended books for additional study.

Overall, this is a lucid book presented in the style employed by Arthur I. Vogel, the author of "Practical Organic Chemistry." It is the opinion of this reviewer and his associates that this edition will not only stimulate the interest of chemistry and pharmacy students but will also assist in enhancing their knowledge.

HOW MUCH IS "ENOUGH"?

For the past year or two, articles, speeches, testimony, and assorted other means of communication have been rife with comment and opinion to the effect that either additional regulation is needed in the area of drug discovery and introduction or, conversely, that already drug discovery and introduction are subjected to excessive regulation.

On the one side, those who advocate additional legal controls present persuasive arguments based upon statistics showing significant toxicity, adverse reactions, and related harmful effects associated with a particular drug which often come to light only after its widespread or long-term use. On the other hand, opponents to further regulation present equally persuasive arguments that already drug innovation has been inhibited, a so-called "drug lag" has developed, and patients are presently being denied the benefit of important new drug discoveries, all due to what they regard as the excessively restrictive current regulations which delay or prevent new drug marketing approval.

It is, of course, just such differences of viewpoint which are said "to make a horse race." All of this reminds us of an anecdote which may or may not have basis in fact but certainly is pertinent. We were told that the river which ran through a small rural town was closed to swimming by the local health department on grounds that it was polluted and a menace to health. The town leaders went to extensive effort to correct the problem and to clean up their river. But when they then requested the health department to open the river to swimming, their request was again denied—this time with the explanation that the river constituted the source of the local drinking water supply and it would be unsanitary, therefore, to permit swimming!

Whether or not such an incident actually occurred, we do know for a fact that rather comparable incidents repeatedly have happened in the area of drug standards. For example, on many occasions, critics from the drug industry have alleged that official compendia specifications were insufficient to assure an aspect of drug quality whether it be potency, identity, bioavailability, stability, or some other related characteristic. Subsequently, the compendia proposed adoption of either a new or more stringent specification in order to remedy the alleged deficiency. Not uncommonly, such proposals then met with objection from the very same critics on grounds that such test requirements were excessive, or would contribute prohibitively to manufacturing costs, or even that the proposed requirements were too "severe" because their own products could not meet the new standard!

It is well to recognize that the genesis of any proposed new law or regulation generally can be traced back to some sort of abuse or problem. For example, the Good Laboratory Practice regulations which were discussed in our February editorial were the direct result of falsified test data submitted to FDA in support of certain New Drug Applications. Consequently, as a general observation, most disinterested parties would tend to feel that society and government must impose regulatory controls to avoid problems or to prevent repeated abuses.

Our view tends to concur but, at the same time, we also recognize that such regulations must be reasonable and properly tempered to avoid excessive restrictions which will unduly inhibit and discourage future research by destroying legitimate incentives. Drug regulation is particularly susceptible to "overkill," and care must be exercised to avoid a result which might be even more disastrous than the problem it is intended to control.

Predictive Conversion of *In Vitro* Drug Dissolution Data into *In Vivo* Drug Response *versus* Time Profiles Exemplified for Plasma Levels of Warfarin

VICTOR F. SMOLEN ˣ **and RANDALL J. ERB**

Abstract □ A mathematical approach to computing the *in vivo* drug response profiles (such as plasma level, pharmacological response, and urinary recovery *versus* time curves) corresponding to observed *in vitro* dissolution of drug dosage form *versus* time profiles is described. The method is exemplified for warfarin tablets, for which observed *in vivo* plasma level profiles are compared to corresponding predicted profiles computed from *in vitro* dissolution data. The potential of the method is demonstrated; approaches to its improvement, as well as its limitations, are discussed.

Keyphrases □ Drug response profiles, *in vivo*—plasma warfarin levels, predicted from *in vitro* dissolution data □ Dissolution data, *in vitro*—predictive conversion into *in vivo* drug response–time profiles, plasma warfarin levels □ Warfarin—plasma levels predicted from *in vitro* dissolution data

Even seemingly trivial changes in the formulation and manufacture of drug products can significantly alter the dynamics of a drug's release from its dosage form and, consequently, affect its therapeutic performance. The growing number of multisource drugs resulting from the expiration of patents is increasing the importance of this problem. It is not feasible to perform routinely the extensive *in vivo* bioavailability testing of drug products necessary to ensure their bioequivalency. Consequently, considerable efforts have been expended to develop and apply *in vitro* drug release tests that are rapid, convenient, and reliable in reflecting the *in vivo* behavior of drug dosage forms. Such tests have to varying degrees been successful in providing results that correlate with *in vivo* bioavailability (1).

Recently, a systematic, control engineering approach to developing drug dissolution tests that are optimally predictive of the entire time course of *in vivo* drug product performance was described (2, 3). Suggestions also were made concerning the manner in which *in vitro* tests may be improved to reflect *in vivo* behavior better (4–6). By properly adjusting the conditions under which drug product dissolution testing is performed, it is sometimes possible to achieve a linear, multiple-point relationship between the time variation of the amount of drug dissolved from dosage forms *in vitro* and analogous amounts absorbed *in vivo* (4); such relationships were successfully demonstrated (7–10). In such cases, it was shown that the time course of *in vivo* pharmacological effects can be computed from *in vitro* dissolution data under certain conditions (4).

Despite such possibilities for handling *in vitro* dissolution data, relationships between the results of *in vitro* drug product dissolution testing and *in vivo* bioavailability are most commonly reported as single-point correlations. For example, the amounts of drug dissolved *in vitro* after a given time are correlated with the amounts absorbed *in vivo* or the plasma levels of the drug observed at the same or other times after dosing (11); times for a percentage of the drug to be dissolved *in vitro* are related to time or rates at which the drug is available *in vivo* (12). It would obviously be of greater utility to correlate or predict the entirety of *in vivo* drug response profiles, *i.e.*, plasma, urinary recovery rate, and/or pharmacological response, *versus* time curves with *in vitro* results and in this manner maximize the amount of information obtainable from drug dissolution testing data.

With drugs such as warfarin, which have a long half-life and are chronically administered, the extent of the drug's bioavailability from its dosage forms is clinically more important than the rates at which it reaches the systemic circulation. However, in addition to not taking full ad-

vantage of all the *in vivo* and *in vitro* kinetic data collected in bioavailability and dissolution experiments, single-point *in vivo* to *in vitro* data correlations can be misinterpreted and misleading as tacit indicators of the extent of drug bioavailability.

For example, in a single-point correlation of average warfarin dissolved from tablets in 1 hr to *in vivo* plasma levels observed after 1 hr (11), a tablet designated A was shown to be approximately 6% dissolved *in vitro* and to elicit a plasma level of 1.11 μg/ml. A second tablet, D, was only about 3% dissolved and yielded a 1-hr plasma level of 0.58 μg/ml. The implication of such linearly correlated results is that Tablet D and other tablets having similar *in vitro* dissolution behavior are only approximately 50% as bioavailable as Tablet A in their dissolution behavior. Actually, however, the areas under the plasma curves reveal Tablet D to have an extent of bioavailability that is 1.08 times that of Tablet A.

This report presents a relatively simple mathematical approach which, under certain described conditions (3, 13, 14), allows the conversion of *in vitro* drug dissolution time curves into *in vivo* drug response *versus* time profiles. The method and its limitations are exemplified using plasma drug levels and dissolution data for warfarin reported by Wagner *et al.* (11).

THEORETICAL

Background and Assumptions—Linear systems theory (15) can be implemented to develop a mathematical relationship which, for a defined set of *in vitro* and *in vivo* experimental conditions, allows *in vitro* drug product dissolution *versus* time data to be transformed into computationally predicted or simulated *in vivo* drug response *versus* time profiles. This is feasible to accomplish provided that the dynamics of the system behavior can be presumed linear, *i.e.*, the following assumptions and conditions apply:

1. The *in vitro* and *in vivo* kinetic processes remain qualitatively the same for all of the different dosage formulations tested.

2. All kinetic processes can be described as linear, or at least approximated as linear, in the sense that the superposition principle (16) applies over an operational range of interest. *In vivo*, both the preabsorption dynamics of the drug's release from its dosage forms and the subsequent systemic absorption into the blood, as well as its disposition and elimination from the body, are required to be dose independent and nonsaturable, *i.e.*, linear. In practice, it may be sufficient that the *in vivo* system approximates linearity over the range of difference seen between the dosage forms tested. However, as commonly heard, it is not necessary that the *in vivo* bioavailability of the drug be rate limited only by its dissolution from its dosage forms. However, the *in vivo* absorption, as well as any presystemic metabolism of the drug in the gut lumen, wall, or liver, must be linear and describable by proportional rate constants that are time invariant. In other words, drug absorption occurring by site specific, facilitated, or active transport, as well as the involvement of saturable metabolic processes, could vitiate the approach, depending upon the magnitude of the effects.

It is emphasized, however, that the *in vitro* time course of dissolution rates or extents of release of the drug from its dosage form can theoretically have any type of kinetic behavior provided that the apparatus and conditions of the *in vitro* dissolution test are such that the experimentally recorded drug dissolution rate or extent *versus* time profiles are direct reflections of drug release into the dissolution media or are consistently related to it by first- or higher order lag times (transfer function) (13). However, in the extreme case where a drug dissolves so slowly that its dissolution time exceeds its transit time in the GI tract, *in vitro* dissolution curves that are run to completion will obviously predict a greater *in vivo* bioavailability than would actually be observed; conceivably, this result could be at least approximately corrected for by truncating *in vitro* dissolution experiments after a time *in vitro* that is known to exceed a correspondingly proportional time *in vivo* at which further absorption of the drug no longer proceeds. The other extreme of instantaneous drug release, as is accomplished by administering a solution of the drug, merely represents an impulse input to the GI contents (2, 13, 14) and poses no theoretical difficulties.

3. No specific chemical or biochemical effects are operative with any dosage form being tested that are not operative with the rest. The operation of such biologically specific factors can be introduced if the drug forms soluble, nonabsorbable complexes with excipients in the formulations or if such excipients alter the barrier properties of the GI mucosa through which the drug must pass to be systemically absorbed. Such biological occurrences obviously could not be easily detected or taken into account by *in vitro* testing results unless they consistently occurred in all dosage forms (3).

General Computational Procedure—With the described assumptions and limitations in mind, the application of linear systems, transfer function, analysis provides the mathematical means to relate and predict *in vivo* drug response profiles, symbolized as $Q_B(t)$, from *in vitro* dissolution rate *versus* time profiles, presently symbolized as $\dot{A}(t)_D$, once a weighting function, $G_{BD}(t)$ [or transfer function, $G_{BD}(s)$, as defined in the complex frequency domain] is established. A function, f, is converted from the time domain, $f(t)$, into the complex frequency domain, $F(s)$, by taking its Laplace transform, as defined by:

$$F(s) = \int_0^\infty f(t)e^{-st}\,dt \qquad \text{(Eq. 1)}$$

The advantage of working in the s domain relative to the time, t, domain, is that the mathematical operations of convolution and deconvolution necessary in the time domain to compute output functions from input functions and vice versa are replaced by multiplication and division, respectively. For the present purposes, there are two such input–output transfer function relationships to consider, one for the *in vitro* system and another for the *in vivo* system. The *in vivo* response to an oral dosage form would be given by Eq. 2:

$$Q_B(s) = G_B(s)\dot{A}(s)_G \qquad \text{(Eq. 2)}$$

where $\dot{A}(s)_G$ is the Laplace transform of the time curve which describes the *in vivo* rate of drug release into the GI contents and, therefore, represents the *in vivo* input function (14); $\dot{A}(s)_G$ has an *in vitro* counterpart, $\dot{A}(s)_D$, which describes the rates of dissolution *in vitro*. For example, $\dot{A}(s)_D$ for a flow-through dissolution apparatus (3) would be given by Eq. 3:

$$\dot{A}(s)_D = \dot{V}C(s) \qquad \text{(Eq. 3)}$$

where $\dot{V}(t)$ is the flow rate through the dissolution cell, and $C(t)$ is the concentration in the stream; $C(t)$ can be continuously monitored using a spectrophotometer equipped with a flowcell. The flow rate is usually kept constant.

The transfer function for a linear system(s) that is generally applicable to relating *any* input is defined and obtained in the Laplace domain as the ratio of any *known* output function from the system to the corresponding *known* input function that caused the output. If $\dot{A}(s)_{G,r}$ and $\dot{A}(s)_{D,r}$ are known for any reference dosage form, r, for which the assumptions of linearity apply to both the *in vivo* and *in vitro* systems, they can be considered as input and output functions, respectively, and interrelated by the transfer function defined by:

$$\frac{\dot{A}(s)_{G,r}}{\dot{A}(s)_{D,r}} = G(s)_{DG,r} \qquad \text{(Eq. 4)}$$

Once $G(s)_{DG,r}$ is known, it can be used to compute *in vivo* response profiles, $Q_B(s)_i$, for any ith dosage form using *in vitro* determined dissolution input functions and:

$$Q_B(s)_i = G(s)_B G(s)_{DG}\dot{A}(s)_{D,i} \qquad \text{(Eq. 5)}$$

In practice, it is computationally expeditious to treat *in vitro* dissolution data as the output, $Q_D(s)$, relating it directly to the *in vivo* output, as shown in Eq. 6:

$$\frac{Q_B(s)_r}{Q_D(s)_r} = G(s)_{BD,r} \qquad \text{(Eq. 6)}$$

This equation defines a transfer function, $G(s)_{BD,r}$, based upon data from a reference dosage form, r.

For any other dosage forms that do not violate the assumptions on which this treatment is based, the *in vivo* response profile will be given by Eq. 7 using the *in vitro* dissolution data results observed for the ith dosage form:

$$Q_B(s)_i = G(s)_{BD,r}Q_D(s)_i \qquad \text{(Eq. 7)}$$

The two approaches obviously yield the same results. The relationship between *in vitro* dissolution and *in vivo* absorption dynamics is now

implicit in $G(s)_{BD,r}$. The conditions of the *in vitro* test must, of course, be maintained while testing each dosage form. Obviously, if the dissolution test does not yield at least some type of single-point correlations, such as between the time for 50% of the drug to dissolve *in vitro* and the time for 50% of the drug to be absorbed *in vivo*, it probably cannot provide results from which entire plasma levels, urinary recovery rates, and/or pharmacological response *versus* time profiles can be predicted.

The computational operations of deconvolution (Eq. 6) and convolution (Eq. 7) can be performed by various methods. Some methods used in pharmacokinetics were described previously (13, 14, 17, 18), and all of the various techniques generally used in engineering practice were recently reviewed (17). Such computations may rapidly and conveniently be performed using a Fourier analyzer[1] computer, as was implemented to obtain the results described in the present report. However, such specialized equipment is expensive and not very common. Therefore, a computational scheme for convolution–deconvolution appropriate for analog computers is presented in the *Appendix*. The same results are obtainable from the analog computer approach, which is presented here merely as a convenience to investigators without access to a Fourier analyzer.

EXPERIMENTAL

***In Vitro* Dissolution and *In Vivo* Plasma Curve Data**—The *in vitro* and *in vivo* data for warfarin treated in this study were abstracted from a report by Wagner *et al.* (11). Four dose treatments using four different dosage forms (Tablets A[2], B[3], C[4], and D[5]) were studied by these authors. Panels of six and 12 human volunteers were used in two separate studies. In the first study, six subjects received 25-mg dose treatments of Tablet B. In the second study, 12 subjects received 10-mg doses of Tablets A, C, and D. Plasma samples were periodically collected from the volunteers and assayed for the drug.

Dissolution testing of the tablets was performed using a paddle-agitated, three-necked, round-bottom flask, in which individual tablets were initially exposed to 900 ml of 0.1 *N* HCl for 30 min followed by the addition of 100 ml of strong phosphate buffer. The buffer instantaneously raised the pH to 7.5 ± 0.1 for the remainder of the dissolution test. The amounts of warfarin dissolved from the tablets as a function of time were determined by circulating the dissolution medium through a flowcell in a spectrophotometer. The tablets used were reported to have been assayed for their drug content using the official USP XVIII method.

Data Treatment—The average data reported by Wagner *et al.* (11) for each dose treatment were used to perform the described computations. Tablet C, administered as two 5-mg tablets, was selected as the reference dosage form from which data were used to determine the *in vitro* input → *in vivo* output transfer function, $G(s)_{DB,r}$; $G(s)_{DB,r}$ was subsequently used to compute plasma level *versus* time profiles for Tablets A (two 5-mg tablets), D (two 5-mg tablets), and B (one 25-mg tablet).

To obtain data points at discrete, constant time intervals, as needed for subsequent convolution and deconvolution computations, the *in vivo* plasma level data for Tablet B were fitted to multiexponential expressions of the form $y = \Sigma_{i=1}^{n} A_i e^{-m_i t}$. An iteratively converging, least-squares, digital computer program, which performs log peeling and derives initial estimates for the equation parameters (A_i's and m_i's), was used to perform the fitting. This program, called MULTIFIT, was developed in this laboratory (19). By using the fitted equations, data points were interpolatively generated at 2-hr intervals for up to 96 hr.

The *in vitro* dissolution test data, reported as cumulative amounts of drug dissolved *versus* time profiles, were incomplete in that the testing was prematurely discontinued before all of the drug in the tablets was dissolved. Consequently, an equation of the form $Q_D(t)_\% = 100\,(1 - e^{-kt})$, where $Q_D(t)_\%$ is the percent of the drug dissolved at time t, was fitted by linear least-squares regression to the data reported by Wagner *et al.* (11); the symbol k represents an apparent first-order dissolution rate constant.

This curve fitting was performed to allow the extrapolation of the *in vitro* dissolution curves to 100% to account for all of the drug contained in the tablets; values generated by the fitted equations were only used to obtain data points lying beyond the times at which the experimental data were truncated. Before these times, the *in vitro* data were directly estimated at 5-min intervals from the dissolution curves reported previously (11).

Convolution—The convolution and deconvolution computations were made with the use of a Fourier analyzer[1]. The system performs discrete Fourier transformation of time data and arithmetical operations on functions in the frequency domain. The Fourier transform of a time function as defined by Eq. 8 has similar properties to its Laplace transform:

$$\mathcal{F}f(t) = \int_0^\infty f(t)e^{-j\omega t}\,dt \qquad \text{(Eq. 8)}$$

$$\mathcal{F}f(t) = F(\omega) \qquad \text{(Eq. 9)}$$

In Eqs. 8 and 9, $j = \sqrt{-1}$ and ω is frequency. In the Laplace complex frequency domain, transformation of time functions yields, instead of ω, functions of a complex number, $s = \sigma + j\omega$. The σ is a real part added as a convergence factor; it allows transformation of some functions that otherwise cannot be Fourier transformed (20). For present purposes, the use of Fourier transforms can be considered equivalent to Laplace transforms. The Fourier analyzer-computer system obtains discrete finite transforms of time data using the algorithm defined by:

$$f(m\,\Delta f) = \Delta t \sum_{N=0}^{N-1} f(n\,\Delta t)e^{-j2\pi mn\,\Delta\omega\,\Delta t} \qquad \text{(Eq. 10)}$$

where Δt is the time interval between data points, $f(n\,\Delta t)$ is the measured value of the data point, ω is the frequency in Hertz, N is the number of data points, and m and n are integers denoting the multiple discrete time and frequency values.

The computations were performed on the Fourier analyzer using a data block size of 256 channels. The Fourier transform of the *in vivo* data was taken using data points at 2-hr intervals for up to 96 hr. *In vitro* data points were spaced 5 min apart for up to 1280 min. The transfer function, $G(s)_{DB,r}$ [more accurately symbolized as $G(\omega)_{DB,r}$] was obtained for Tablet C data by complex division in the frequency domain as the ratio $Q_B(\omega)_c/Q_D(\omega)_c$. Fourier-transformed *in vitro* data for any particular tablet was then multiplied by the transfer function, $G(\omega)_{DB,c}$, to obtain the Fourier transform of the *in vivo* plasma level curve which was to be computationally predicted for that tablet. The result was then multiplied by a scale factor which appropriately adjusted the gain of the transfer function as needed in accordance with the actual assayed amount of drug contained in the tablet(s). The inverse Fourier transform of this result then provided the computational prediction of the *in vivo* plasma drug level *versus* time profiles for the dosage form.

The scale factor (*SF*) for dose treatments with Tablet A was 9.88 mg/8.9 mg = 1.02; for Tablet D, the *SF* was 9.40 mg/8.94 mg = 1.05; for Tablet B, the *SF* was 23.9 mg/8.94 mg = 2.67. The *SF* values are calculated using reported assay results (11) for drug content in the tablets rather than with nominal values. The *SF* values are needed to normalize the transfer function first to unit, 1-mg, doses of the drug and then to adjust the magnitude of each $Q(t)_{D,i}$ to correspond to the actual amount of drug input to the system.

The computational steps followed to convert *in vitro* drug dissolution curves into their corresponding plasma level curves are summarized in Scheme I.

$$\text{Step 1: } Q_B(t)_r \xrightarrow{\text{FT}} Q_B(\omega)_r$$

$$\text{Step 2: } Q_D(t)_r \xrightarrow{\text{FT}} Q_D(\omega)_r$$

$$\text{Step 3: } Q_D(t)_i \xrightarrow{\text{FT}} Q_D(\omega)_i$$

$$\text{Step 4: } Q_B(\omega)_i = \frac{Q_B(\omega)_r}{Q_D(\omega)_r} Q_D(\omega)_i SF = G_{DB}(\omega)Q(\omega)_i SF$$

$$\text{Step 5: } Q_B(\omega)_i \xrightarrow{\text{IFT}} Q_B(t)_i$$

Scheme I—Summary of stepwise computational procedure implemented on a Fourier analyzer to obtain the conversion of in vitro *drug product dissolution curves into* in vivo *plasma level curves. The subscript* r *corresponds to the reference dosage form from which the transfer function is obtained. FT and IFT refer to Fourier and inverse Fourier transformations, respectively.* $Q_B(t)_i$ *and* $Q_D(t)_i$ *symbolize biological response and dissolution profiles for an* ith *dosage form, and* $Q_B(\omega)_i$ *and* $Q_D(\omega)_i$ *refer to their Fourier transforms.*

RESULTS

Exponential Curve Fitting to *In Vitro* and *In Vivo* Data—Figure 1 presents the linear least-squares fits of the *in vitro* dissolution data results reported by Wagner *et al.* (11) to curves described by the equation $Q_D(t)_\infty = 100(1 - e^{-kt})$. The early observed data points on the time curve, indicated by the open symbols, were used to obtain a least-squares value for the apparent first-order dissolution rate constant, k, by fitting them to a linearized form of the equation given by $\log_e[1 - Q_D(t)_\infty/100] - kt$, where $Q_D(t)$ is the percent of the drug dissolved at any time, t. Linear correlation coefficients for comparisons of data points computed from the fitted equation with corresponding observed values were 0.96, 0.95, 0.98, and 0.99 for Tablets A, B, C, and D, respectively. Therefore, the assumed first-order dissolution of the tablets described by the fitted equations was satisfactory and could be used to estimate data points extrapolatively for dissolution curves beyond the times at which the dissolution tests were prematurely terminated. The solid symbols in Fig. 1 represent such values estimated with the use of the fitted equations.

The curve in Fig. 2 is a plot of the least-squares multiexponential fit obtained to the *in vivo* plasma level data observed for Tablet C. The data

were abstracted from Wagner *et al.* (11). The equation for the curve is given by:

$$Q_B(t)_c = 0.91e^{-0.0133t} + 0.36e^{-0.1200t} - 1.27e^{-1.261t} \quad \text{(Eq. 11)}$$

The sum of squares of deviations from the fitted curve is 0.04917. The curve provides a satisfactory representation of the observed data points.

Comparisons of Computed and Observed Plasma Curves—As already discussed, the Fourier transforms of the curve in Fig. 2 and the dissolution curve for Tablet C in Fig. 1 were deconvolved to provide the transfer function, $G_{DB}(\omega)_c$. A computer-constructed plot of the resulting inverse Fourier transform of $G_{DB}(\omega)_c$, *i.e.*, the weighting function $G_{DB}(t)_c$, is presented in Fig. 3. Mathematically, a weighting function is usually defined as the transient time response of a system to an impulse, *i.e.*, Dirac delta function (21) input. However, as a consequence of defining the cumulative warfarin dissolution profiles, $Q_D(t)_i$ [rather than using rates of dissolution, $\dot{Q}_D(t)_i$] as the inputs into the hypothetical linear system that converts *in vitro* data into *in vivo* plasma curves, the weighting function in this case is the derivative of the impulse response, *i.e.*, the doublet response (21). This fact accounts for its values being negative and lying in the fourth quadrant.

The cumulative drug dissolution profiles were chosen as the input function in order to use data for the predictive computations that were as close to those that were experimentally observed as possible. Exemplary results for Tablet D are also shown in Fig. 3, which presents a comparison of the forms of $G_{DB}(t)_c$ with $Q_D(t)_D$ (curve B) with which it is convolved to obtain the computationally predicted plasma curve, $Q_B(t)_D$, for Tablet D (curve C).

The transfer function, $G_{DB}(\omega)_c$, was consistently employed (Scheme I) to obtain the computationally predicted *in vivo* plasma curves for Tablet A (10-mg), D (10-mg), and B (25-mg) dose treatments shown in Figs. 4, 5, and 6, respectively. The computed plasma curves can be directly

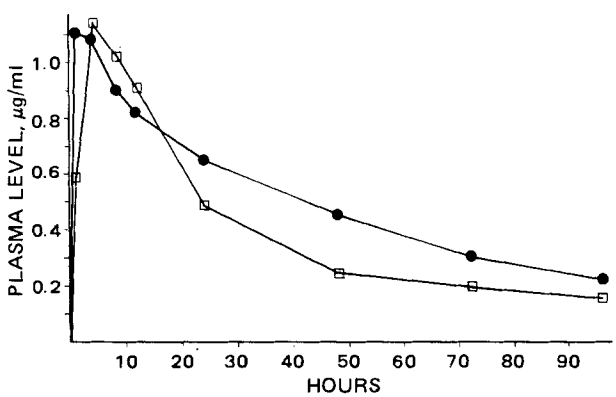

Figure 4—*Comparison of a computationally predicted (□) plasma warfarin curve for Tablet A (two 5 mg), calculated from the results of* in vitro *drug dissolution testing, with the average plasma curve (●) observed in an* in vivo *study of 12 human subjects (11).*

compared to the *in vivo* observed average curves, which are in each case plotted on the same coordinates.

Figure 6 contains an additional curve resulting from a correction of the computed curve for the incomplete absorption of only 84% of the administered dose. The corrected curve more closely resembles the observed data points. Without the *a priori* knowledge that the extent of warfarin bioavailability from Tablet B is only 84% of that obtained from Tablet C, the computed plasma curve obviously overestimates the *in vivo* drug absorption efficiency of Tablet B. In each case, as shown in Figs. 4–6, the points plotted on the predicted plasma curves were computed from the results of the convolutions at the same time at which blood sampling was performed *in vivo*; this procedure allowed a direct comparison of each computationally predicted point with its *in vivo* observed counterpart.

The results of plotting each observed plasma level data point as a function of its *in vitro*, computationally predicted, counterpart are shown in Fig. 7. The straight line in Fig. 7 is drawn through the origin with a slope of unity. If the data were exact and the correspondence between the *in vivo* and *in vitro* predicted data points was perfect, all points plotted in Fig. 7 would obviously fall exactly on this line. The largest discrepancies are seen at the upper end of the line for Tablet B for which *in vitro* predicted data points left uncorrected for incomplete *in vivo* absorption were used in constructing the plot.

The relatively excellent linear correlations of the *in vitro* predicted and *in vivo* observed data seen in Fig. 7 can be contrasted to the comparatively poor linear relationship seen between the *in vitro* and *in vivo* data plotted in Fig. 8. In this case, the *in vivo* plasma levels observed for each dosage form were merely plotted as a function of the corresponding rates of percent dissolved *in vitro* [*i.e.*, $\dot{Q}_D(t)_{\%,i}$] occurring at times ap-

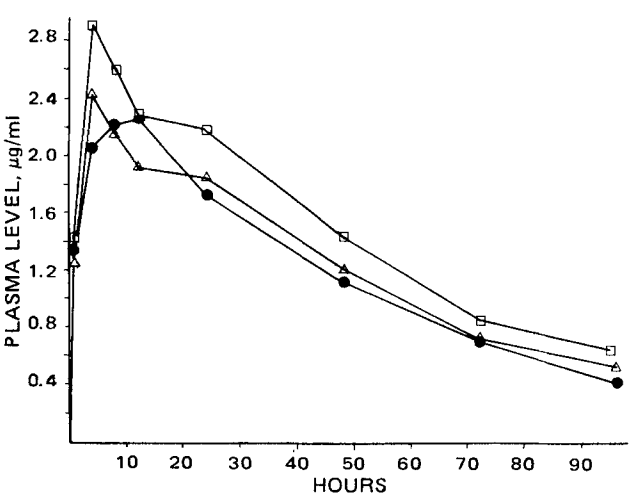

Figure 6—*Comparisons of computationally predicted* [*uncorrected* (□) *and corrected* (△) *for an incomplete, 84%,* in vivo *absorption*] *plasma warfarin curves for Tablet B (one 25 mg), calculated from the results of* in vitro *drug dissolution testing, with the average plasma curve* (●) *observed in an* in vivo *study of six human subjects (11).*

propriately scaled to correspond to the *in vivo* plasma curves. The scale factor of $\frac{1}{15}$ aligns the *in vitro* and *in vivo* curves on the time axis and is based on the relative times for dissolution to be virtually completed as compared to the return of plasma drug levels to zero; the relative time scales involved can be seen in Fig. 3 for the plot of $Q_D(t)_D$ and $Q_B(t)_D$, respectively.

The $Q_D(t)_i$ values at each time corresponding to an observed plasma level were calculated using the derivative of the equations providing the linear least-squares fits to the *in vitro* drug dissolution profiles shown in Fig. 1; *i.e.*, the values were obtained from $Q_D(t)_{\%,i} = 100k_i e^{-k_i t/15}$, where k_i is the least-squares, apparent dissolution rate constant for the ith dosage form. As was the case in Fig. 7, the straight line in Fig. 8 is again drawn through the origin with a slope of unity. The systematic deviations of the points from this line are quite apparent.

The linear correlations of *in vitro* predicted to *in vivo* observed plasma levels shown in Fig. 6 are summarily described in Table I. The Pearson, r, linear regression coefficients indicate that the calculated plasma level curves are highly correlated with the actual *in vivo* observed plasma levels. A perfect correspondence between computed and observed plasma levels would provide least-squares values of 1.00 for the slopes, zero for the intercepts, and 1.00 for the linear regression coefficients. The ratios of the areas under the calculated and observed plasma curves are also

listed in Table I to provide an indication of the fidelity with which the computations can predict the extent of drug bioavailability from the tablets.

DISCUSSION

A comparison of the two types of linear correlations (Figs. 7 and 8) of *in vitro* data derived from dissolution testing with *in vivo* plasma levels clearly justifies the added computational effort required to obtain computationally predicted plasma curves in assessing the bioavailability behavior of drug dosage forms from *in vitro* studies. Figure 8 was constructed using *in vitro* dissolution rates that proceed through a maximum and decay with time in a manner analogous to plasma level curves, which they obviously resemble much more than cumulative amount *versus* time curves; the latter proceed to a plateau at 100% dissolved. Because of their at least superficial resemblance to plasma curves, dissolution rates rather than extents were chosen for the correlations to make them appear as good as possible and comparable to those in Fig. 7.

As expected, and as confirmed by Fig. 8, multiple-point correlations of dissolution rates with plasma levels are obviously nonlinear. This is the case even when the dissolution rates are properly time scaled. Therefore, the direct use of *in vitro* dissolution data provide, at least in the present case for warfarin, a poor predictor of *in vivo* drug product performance. In contrast, the use of *in vitro* predicted plasma levels obtained by the computational conversion of observed *in vitro* dissolution data provides a theoretically rational, meaningful, and more reliable means of judging the *in vivo* behavior of drug products from the results of *in vitro* dissolution testing. However, the limitations of even this method, as exemplified by the discrepancies in Table I, must be kept in mind.

Deviations of predicted from observed *in vivo* results can be attributed to violations of any or all of the assumptions on which the linear systems treatment of the data is based. Unfortunately, linear systems theory provides the only generally applicable means of converting *in vitro* dissolution profiles into predicted *in vivo* drug response profiles. Any attempts to improve the relationships through the use of nonlinear modeling approaches require some knowledge of the specific mechanisms operating in any given case to produce the observed or suspected nonlinear systems behavior. Such information is commonly unavailable. If it were available, its applicability to any particular drug formulation might not be known *a priori*; consequently, its usefulness in predicting *in vivo* bioavailability behavior would be vitiated. Therefore, despite its shortcomings, the presently implemented linear systems method of computationally predicting *in vivo* drug performance represents the best, generally applicable, approach to converting *in vitro* data into *in vivo* drug response profiles that is likely to be devised.

Considering the many assumptions involved in the linear systems, transfer function, approach applied in this study, the predictions obtained are quite good and generally fall close to the observed *in vivo* data. The results (Figs. 4–6) are quite successful in predicting two out of three of the plasma level curves for the drug from *in vitro* dissolution profiles. Direct comparisons of the data points obtained from computationally predicted plasma profiles with their corresponding experimentally observed *in vivo* plasma curves in all cases provided linear correlation probabilities of $p \geq 0.01$ or 0.001 (Table I), indicating that the shapes of the computed and *in vivo* plasma curves over time were nearly the same.

As expected, however, differences in the extent of *in vivo* bioavailability cannot always be predicted, as was the case for Tablet B. This treatment, relative to the others, was only 84% bioavailable, even though its dissolution *versus* time profile was well within the range reported for the other tablets. This particular discrepancy may at least in part be attributable to the *in vivo* data for Tablet B having been obtained from a separate study involving a panel of six subjects whereas the other *in vivo* data came from a different panel of 12 subjects. Treatment B also consisted of a single 25-mg tablet as opposed to the other dose treatments being comprised of 10-mg doses (two 5-mg tablets). In any event, results obtained for Tablet B exemplify a limitation of all *in vitro* dissolution testing in being incapable of predicting exceptions to previously observed correlations. Although this limitation may be minimized by judiciously selecting the design of the dissolution apparatus and systematically optimizing the process conditions of the dissolution testing (3), it cannot be always entirely eliminated.

As demonstrated by the results of the present study, the *in vitro* computational predictions of *in vivo* bioavailability may be expected to have the greatest fidelity for dosage formulations that are the most similar to the reference dosage form from which the transfer function is obtained. Therefore, for dosage formulations with the same nominal dose content and of qualitatively equal composition, predictions of the *in vivo* drug response profile for the same panel of subjects from which the *in vivo* data for the reference dosage form were obtained can probably be made with an often acceptable degree of fidelity. This would particularly be the case in quality control testing for *in vivo* significance of batch-to-batch variations. Obviously, in all cases, consistency in the process variables of the test, such as the geometry of the apparatus, the dissolution medium composition, and agitation, must be maintained. Ideally, dissolution testing should be performed with a flexible method using process variables that have been systematically optimized to provide directly drug dissolution profiles that are predictive, within predetermined confidence levels, of *in vivo* drug response profiles (3). A new control engineering approach to accomplish such systematic optimization of drug dissolution testing methodologies was described previously (3).

Although optimized dissolution testing methods are always to be preferred, the predictive estimates of *in vivo* drug product performance obtained by the methods and apparatus commonly used (20) may conceivably be improved and expanded through the incorporation of data from an increasing number of dosage formulations into the transfer function as such additional data become available. For this purpose, the *in vitro* data must always be obtained using the same dissolution test conditions; however, *in vivo* data would generally be obtained with different panels of human subjects. The simplest approach would be to combine transfer functions obtained for different drug formulations into an average.

For example, in the present case, an average transfer function obtained for Tablets A, C, and D, *i.e.*, $\overline{G}_{DB}(s)_{A,C,D}$, would likely improve the prediction of plasma level curves for other dose treatments resembling A, C, and D. However, each individual, $G_{DB}(s)_i$, transfer function could not be expected to produce predictions with equal fidelity. Therefore, it is reasonable to weight the contribution of each individual transfer function on the basis of its predictive capability. Such a weighted average transfer function for different formulations could be defined by Eq. 12:

$$\overline{G}_{DB}(s) = \sum_{i=1}^{N} W_i G_{DB}(s)_i \qquad \text{(Eq. 12)}$$

where $W_i (\Sigma_{i=i}^{N} W_i = 1)$ represents the weight factors for the transfer functions derived from data observed for each ith drug formulation.

A weighting scheme that might be used to obtain W_i values could be based on the ability of the ith transfer function to predict the plasma curves observed for the other $N - 1$ dosage forms contributing to the average, as expressed by:

$$W_i = \frac{\sum_{J=1 \neq i}^{N-1} \sum_{q=1}^{K} (P_{\text{pred}} - P_{\text{obs}})_q^{-2}}{\sum_{i=1}^{N} \sum_{J=1 \neq i}^{N-1} \sum_{q=1}^{K} (P_{\text{pred}} - P_{\text{obs}})_q^{-2}} \qquad \text{(Eq. 13)}$$

where P_{pred} and P_{obs} represent computationally predicted and observed data points corresponding to the qth sampling time, respectively; and K is the total number of data points sampled for the ith dosage form. The W_i defined by Eq. 13 emphasizes the predictive capability of each $G_{DB}(s)_i$. Weighting for variability of the *in vivo* data for each dosage form contributing to the average transfer function is attenuated by the predictive capability of the transfer function and is, therefore, implicit in

the value of each W_i. By using this scheme or some alternative one, transfer functions for predicting *in vivo* temporal drug response behavior could be continuously updated as new data from additional dosage forms become available.

SUMMARY AND CONCLUSIONS

Single-point correlations of *in vitro* drug dissolution behavior with *in vivo* bioavailability results for different drug dosage forms do not take advantage of all of the observed data and can have serious shortcomings with regard to their significance and interpretation. Therefore, a mathematical, linear systems, approach to computationally predicting *in vivo* drug response *versus* time curves [such as plasma levels, pharmacological responses (22), and urinary recovery rates] from observed *in vitro* drug product dissolution time curves was developed and exemplified with data for four different dosage forms of warfarin (11).

Despite the linearity assumption implicit in the use of the approach, the method was verified by the surprisingly good computational predictions of *in vivo* plasma curves, which were produced for two of the dosage forms (A and D). The discrepancy observed for a third dosage form was in part attributed to the *in vivo* data being obtained on a different panel of human subjects and to the administered dosage being 0.84 times that of the others. This result exemplified the general inability of *in vitro* testing to predict differences in extents of bioavailability that are likely attributable to specific biological mechanisms whose operation was relatively insignificant or absent in contributing to the bioavailability behavior of other dosage forms for which relatively accurate predictions or correlations are observed.

Systematically optimized *in vitro* dissolution testing conditions based on the ability of the test to predict *in vivo* drug response behavior (3) are recommended whenever practical. Alternatively, an approach to continuously upgrading the reliability and applicability of the transfer function used to predict *in vivo* drug product response curves computationally from the results of commonly employed testing methodologies is suggested. However, the usefulness of the described approach remains to be demonstrated in actual practice.

APPENDIX: ANALOG COMPUTER METHOD FOR CONVOLUTION AND DECONVOLUTION

The operations of deconvolution (Eq. 6) and convolution (Eq. 7) can be performed with an analog computer. Although curve fitting can also be done with an analog computer, it can most readily be accomplished with a digital computer using programs such as MULTIFIT (19), MBDX-85, or PLTEST (17) to obtain a multiexponential fit of observed *in vitro* data points to:

$$Q_D(t)_r = \sum_{1=i}^{n} A_i e^{-m_i t} \qquad \text{(Eq. A1)}$$

The A_i and m_i equation parameters are then used to set the potentiometers in an analog computer circuit, which is appropriate for performing deconvolution. An analog electrical signal representing the $G_B(t)_r$ function, against which $Q_D(t)_r$ is to be deconvolved to obtain $G_{DB}(t)_r$, can be produced using a variable diode function generator. Alternatively, $G_{DB}(t)$ can be obtained directly on a digital computer using the PLTEST program (17, 23). The PLTEST program, as developed in this laboratory, is recommended because it will accept properly interpolated $Q_D(t)_r$ and $Q_B(t)_r$ observed data and perform their deconvolution to provide $Q_{DB}(t)_r$ in the form of a multiexponential expression, which it derives from curve fitting a Bode diagram generated by the program.

The analog computer approach for performing convolution described here can be modified to accomplish deconvolution, as will be shown later. However, convolution is required to obtain $Q_B(t)_i$ by convolving $Q_D(t)_i$ against $G_{DB}(t)_r$, which has been fitted with a sum of exponentials expression. The approach is developed for biexponential fits to $G_{DB}(t)_r$ [*i.e.*, $G_{DB}(t)_r = A_i e^{-m_i t} + A_2 e^{-m_2 t}$]. A similar derivation for third- or higher order systems does not involve any new principles.

For a second-order system, the ratio of biological plasma level output to *in vitro* dissolution input is given in the Laplace domain by Eqs. A2–A4 for an ith dosage form:

$$\frac{Q_B(s)_i}{Q_D(s)_i} = G_{DB}(s)_r \qquad \text{(Eq. A2)}$$

$$\frac{Q_B(s)_i}{Q_D(s)_i} = \frac{A_1}{m_1 + s} + \frac{A_2}{m_2 + s} \qquad \text{(Eq. A3)}$$

$$\frac{Q_B(s)_i}{Q_D(s)_i} = \frac{A_1 m_1 + A_2 m_2 + (A_1 + A_2)s}{s^2 + (m_1 + m_2)s + (m_1 m_2)} \qquad \text{(Eq. A4)}$$

Dividing the numerator and denominator by s^2 and substituting $\alpha = A_1 m_1 + A_2 m_2$ into Eq. A4 yield:

$$\frac{Q_B(s)_i}{Q_D(s)_i} = \frac{(A_1 + A_2)s^{-1} + \alpha s^{-2}}{1 + (m_1 + m_2)s^{-1} + (m_1 m_2)s^{-2}} \qquad \text{(Eq. A5)}$$

A variable, $R(s)$, is now defined by Eqs. A6 and A7:

$$R(s) = \frac{Q_D(s)_i}{1 + (m_1 + m_2)s^{-1} + (m_1 m_2)s^{-2}} \qquad \text{(Eq. A6)}$$

$$R(s) = \frac{Q_B(s)}{(A_1 + A_2)s^{-1} + \alpha s^{-2}} \qquad \text{(Eq. A7)}$$

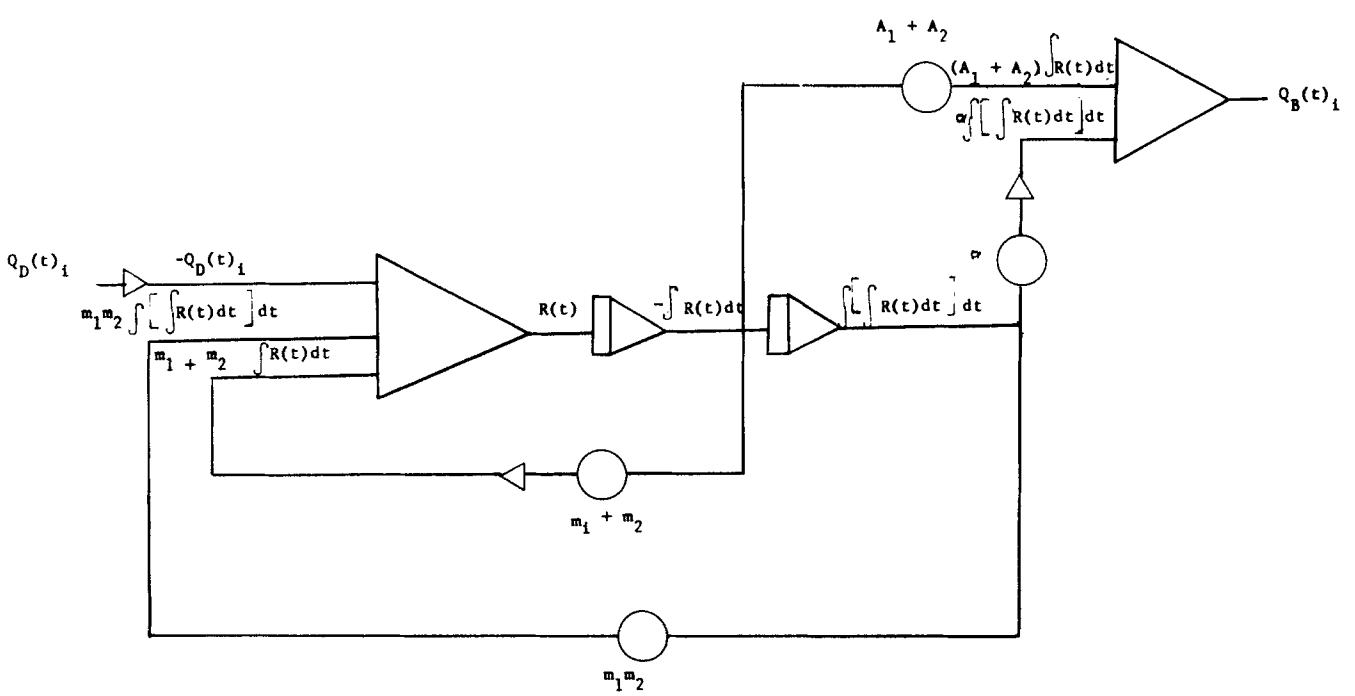

Figure 9—*Circuit diagram showing solution of Eq. A11 to give* $Q_B(t)$, *using* R(t) *and its integrals.*

Equations A6 and A7 are rearranged to yield Eqs. A8 and A10 in the Laplace domain and Eqs. A9 and A11 in the time domain:

$$R(s) = Q_D(s)_i - (m_1 + m_2)s^{-1}R(s) - (m_1m_2)s^{-2}R(s) \quad \text{(Eq. A8)}$$

$$R(t) = Q_D(t)_i - (m_1 + m_2)\int R(t)\,dt - m_1m_2\int [\int R(t)\,dt]\,dt \quad \text{(Eq. A9)}$$

$$Q_B(s)_i = (A_1 + A_2)s^{-1}R(s) + \alpha s^{-2}R(s) \quad \text{(Eq. A10)}$$

$$Q_B(t)_i = (A_1 + A_2)\int R(t) + \alpha\int [\int R(t)\,dt]\,dt \quad \text{(Eq. A11)}$$

Equation A9 is solved on the analog computer to give $R(t)$; Eq. A11 is then solved to give $Q_B(t)$ using $R(t)$ and its integrals as shown by the circuit diagram in Fig. 9.

A similar approach can be applied to solve for input functions by rearranging Eqs. A6 and A7 to give $R(s)$ and the input function and solving these on the analog computer. Therefore, both convolution and deconvolution can be performed by this general approach which, when modified in this manner, can also be used to deconvolve $Q_D(t)_r$ against $Q_B(t)_r$ to obtain $G_{DB}(t)_r$.

Pattern Recognition II: Investigation of Structure–Activity Relationships

GOVIND K. MENON and ARTHUR CAMMARATA [x]

Abstract □ A simple form of pattern recognition is successfully used to classify a set of structurally diverse therapeutic agents. By using only organic structural information, the major pharmacological classes present were correctly identified and the pharmacologically unrelated compounds were separated out. One technique of factor analysis—principal component analysis—is shown to be readily adaptable in preprocessing the data. Simple graphical representation of the results enables their direct interpretation.

Keyphrases □ Structure–activity relationships—determined using pattern recognition methods of analysis, various drugs □ Pattern recognition—analysis methods used to determine therapeutic classes of various drugs □ Factor analysis techniques—used to determine therapeutic classes of various drugs

The application of pattern recognition methods in solving chemical problems has provided the incentive for considerable research within the past few years (1–6). Recently, these methods have been applied in the development of new biological agents due to their capacity to analyze rapidly large stores of accumulated information and to detect substances worthy of further investigation (7–10). In other words, the techniques can be directed toward establishing structural specificity in biological action, providing rationales in selecting substances for biological assay, and identifying pharmacophoric patterns of molecular substitution (1).

Several detailed accounts describe the various pattern recognition techniques (11–14), but a brief conceptual summary follows. Pattern recognition involves the detection and recognition of regularities or invariant properties among accumulated (often large) sets of measurements, the purpose being to provide a basis for new hypotheses. For example, consider an attempt to derive a

Equations A6 and A7 are rearranged to yield Eqs. A8 and A10 in the Laplace domain and Eqs. A9 and A11 in the time domain:

$$R(s) = Q_D(s)_i - (m_1 + m_2)s^{-1}R(s) - (m_1m_2)s^{-2}R(s) \quad \text{(Eq. A8)}$$

$$R(t) = Q_D(t)_i - (m_1 + m_2)\int R(t)\,dt - m_1m_2\int [\int R(t)\,dt]\,dt \quad \text{(Eq. A9)}$$

$$Q_B(s)_i = (A_1 + A_2)s^{-1}R(s) + \alpha s^{-2}R(s) \quad \text{(Eq. A10)}$$

$$Q_B(t)_i = (A_1 + A_2)\int R(t) + \alpha\int [\int R(t)\,dt]\,dt \quad \text{(Eq. A11)}$$

Equation A9 is solved on the analog computer to give $R(t)$; Eq. A11 is then solved to give $Q_B(t)$ using $R(t)$ and its integrals as shown by the circuit diagram in Fig. 9.

Pattern Recognition II: Investigation of Structure–Activity Relationships

GOVIND K. MENON and ARTHUR CAMMARATA [x]

Abstract □ A simple form of pattern recognition is successfully used to classify a set of structurally diverse therapeutic agents. By using only organic structural information, the major pharmacological classes present were correctly identified and the pharmacologically unrelated compounds were separated out. One technique of factor analysis—principal component analysis—is shown to be readily adaptable in preprocessing the data. Simple graphical representation of the results enables their direct interpretation.

Keyphrases □ Structure–activity relationships—determined using pattern recognition methods of analysis, various drugs □ Pattern recognition—analysis methods used to determine therapeutic classes of various drugs □ Factor analysis techniques—used to determine therapeutic classes of various drugs

The application of pattern recognition methods in solving chemical problems has provided the incentive for considerable research within the past few years (1–6). Recently, these methods have been applied in the development of new biological agents due to their capacity to analyze rapidly large stores of accumulated information and to detect substances worthy of further investigation (7–10). In other words, the techniques can be directed toward establishing structural specificity in biological action, providing rationales in selecting substances for biological assay, and identifying pharmacophoric patterns of molecular substitution (1).

Several detailed accounts describe the various pattern recognition techniques (11–14), but a brief conceptual summary follows. Pattern recognition involves the detection and recognition of regularities or invariant properties among accumulated (often large) sets of measurements, the purpose being to provide a basis for new hypotheses. For example, consider an attempt to derive a

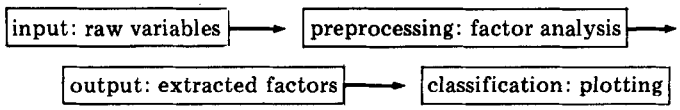
structure–activity relationship. If the relationship of structure to activity is to be developed from a basis involving a small number of structurally diverse compounds or from a large number of structurally similar compounds, then a visual examination is often sufficient. However, if a large number of structurally diverse compounds is involved, visual examination of the data to arrive at a structure–activity relationship is cumbersome if not impossible. Pattern recognition methods then can be employed to advantage.

A few reports in the recent literature describe the application of pattern recognition techniques in the investigation of structure–activity relationships (7–10). These have been concerned with two specific areas: classification of sedatives and tranquilizers (7, 9) and prediction of the activity of potential anticancer agents (8, 10). Although these investigations have been fairly successful, criticism (15, 16) has been directed at some studies (10, 17) that employed these methods in deriving structure–activity relationships. Misleading relationships have been shown to result due to the improper choice of compounds in the data set and to inappropriate structural representation. The approach taken in this article attempts to overcome these problems and, with proper researcher–computer interaction, should provide a simple and consistent means of deriving structure–activity relationships.

In a nonvisual approach to establish the structure–activity relationships, representation of molecular structures in numerical terms is necessary. Coding of molecular structures is thus a key step. Most biological effects may be readily measured and coded, and compounds possessing similar activity are readily identified. However, coding of organic structural groups or features is not as simple. In previous reports, augmented atom fragment (8), substructural fragment (18), and heteropath (9) representations were adopted in molecular structural coding. Several disadvantages are inherent in such procedures, however, especially in the identification of structure–activity relationships: (*a*) molecular structural information is lost by considering fragments of molecules independently of each other, (*b*) several such molecular discriminators may have to be specified in the representation of a given compound, (*c*) redundant codings may have to be included to distinguish between different compounds satisfactorily, and (*d*) interpretation of results in terms of structural prototypes is extremely difficult.

One method associated with pattern recognition, factor analysis, is readily applicable to structure–activity studies (19). Weiner and Weiner (19) used the method directly in deriving structure–activity relationships and obtained readily interpretable results. However, factor analysis is also adaptable as the preprocessing step of a pattern recognition procedure, and this approach is taken in this paper.

Briefly, the method requires that one view molecular structures in a manner consistent with the way medicinal chemists have done in proposing candidate compounds. To retain molecular bonding information, all molecular structures of the data set are superposed upon each other *in a chemically consistent manner.* Major discriminating features between the molecules are then identified. These molecular discriminators are coded so as to distinguish between bioisosteric atoms or groups (20). Following such representation, a factor analytical procedure is applied to reduce the dimensionality of the data matrix. Only a few molecular features need to be specified to classify correctly the compounds of the data set into the pharmacologically distinct categories present.



Scheme I

BASIS OF APPROACH

The basic operations of pattern recognition as applied in this work may be represented as shown in Scheme I. Coding of molecular structures comprising the data set leads to their numerical representation in terms of a discrete number of variables (the input). The input data are then operated on, or preprocessed, to reduce the number of variables required to represent the data, *i.e.*, to reduce the dimensionality. The preprocessing method adopted in this work is principal component analysis, which is but one of the several factor analytical methods available (21–25).

Classification of the output from the preprocessing step is performed next. This step may be done by mathematical techniques such as cluster analysis (26, 27) and discriminant analysis (28) or with the aid of "learning machines" (13, 29–31). In this paper, however, classification is done graphically to provide a clearer conceptual understanding and to point out the parallelism that exists between the classical and pattern recognition approaches for deriving structure–activity relationships. Several detailed accounts in the literature describe the theory and application of various factor analysis techniques (22–25), and only a brief discussion is presented in this article.

A set of M molecules comprising a given data set is coded so as to be represented by N molecular groups or features, giving rise to an $M \times N$ data matrix. This matrix is then used to construct an $N \times N$ correlation matrix. This correlation matrix is next operated on by a factor analytical procedure to extract factors, *i.e.*, to reduce the dimensionality. The two most commonly used methods are principal component analysis and common factor analysis. In principal component analysis (22, 23), one seeks to transform the variables of the data set into a linearly independent set of component variables consisting of the original variables. When N molecular features are chosen as independent variables, then N linear combinations are needed to account for all of the variance in the data. However, in some cases, fewer linear combinations (in comparison with the number of variables in the data matrix) suffice to account for a large proportion of the variance within the data. These may then be used to represent the data and, since these linear combinations are defined to be orthogonal to one another, a reduction in dimensionality is achieved.

In common factor analysis, however, the assumption is made that the variables in a data matrix may be influenced to varying degrees by properties common to *all* variables (*common* variance) and by properties unique to only a few variables (*unique* variance). In other words, every variable selected to represent a specific molecular feature is regarded as reflecting a common set of physical attributes for the majority of compounds in the data set and a unique set of physical attributes for others. Identification is sought of those variables that reflect common physical attributes for the majority of compounds in the data set; all other compounds are treated as unique. The method thus holds the promise of providing some insight regarding the mechanisms leading to major and minor pharmacological actions of drugs. Although some advances have been made in the application of common factor analysis to physiological studies such as olfaction (32), principal component analysis is more readily adaptable in the investigation of structure–activity relationships and is the method used here.

THEORY

The basis for a principal component analysis may be placed in perspective by considering an attempt to transform a multiple regression into a simple linear one. In a multiple regression model, one seeks to relate the biological activities, A, for M compounds to N variables, X, in the

Table I—Pharmacological Classification and Therapeutic Use of Compounds Studied

Compound	Drug	Pharmacological Classification	Therapeutic Use
I	Levarterenol	α-Agonist	Antihypotensive, vasoconstrictor
II	Methoxamine	α-Agonist	Antiarrhythmic, antihypotensive
III	Metaraminol	α-Agonist	Antihypotensive
IV	Ethylnorepinephrine	β-Agonist	Bronchodilator
V	Phenylpropanolamine	α-Agonist, CNS stimulant	Nasal decongestant, anorexiant
VI	Amphetamine	CNS stimulant	Antidepressant, minimal brain dysfunction, anorexiant, narcolepsy
VII	Chlorphentermine	CNS stimulant	Anorexiant
VIII	Phentermine	CNS stimulant	Anorexiant
IX	Hydroxyamphetamine	α-Agonist	Antihypotensive
X	Methyldopa	CNS agent	Antihypertensive
XI	Levodopa	CNS agent	Antiparkinsonian
XII	Epinephrine	α,β-Agonist	Antihypotensive, bronchodilator, decongestant, antiarrhythmic
XIII	Methoxyphenamine	β-Agonist	Bronchodilator
XIV	Phenylephrine	α-Agonist	Decongestant, antihypotensive
XV	Ephedrine	α-Agonist, CNS stimulant	Antihypotensive, decongestant, bronchodilator, antiarrhythmic
XVI	Methamphetamine	CNS stimulant	Anorexiant, minimal brain dysfunction, antidepressant, narcolepsy
XVII	Mephentermine	CNS stimulant, α-agonist	Antihypotensive
XVIII	Propylhexedrine	α-Agonist	Nasal decongestant
XIX	Phenmetrazine	CNS stimulant	Anorexiant
XX	Phendimetrazine	CNS stimulant	Anorexiant
XXI	Isoproterenol	β-Agonist	Antiarrhythmic, bronchodilator
XXII	Isoxsuprine	β-Agonist	Peripheral vascular disease
XXIII	Nylidrin	β-Agonist	Peripheral vascular disease

XXV	Benzphetamine	CNS stimulant	Anorexiant
XXVI	Diethylpropion	CNS stimulant	Anorexiant
XXVII	Phenoxybenzamine	α-Antagonist	Peripheral vascular disease, antihypertensive
XXVIII	Acetylcholine	Parasympathomimetic	Miotic
XXIX	Succinylcholine	Myoneural blocker, parasympathomimetic	Muscle relaxant
XXX	Methacholine	Parasympathomimetic	Glaucoma
XXXI	Carbachol	Parasympathomimetic	Glaucoma, miotic
XXXII	Bethanechol	Parasympathomimetic	Intestinal relaxant
XXXIII	Pilocarpine	Parasympathomimetic	Glaucoma
XXXIV	Ambenonium	Anticholinesterase	Myasthenia gravis
XXXV	Edrophonium	Anticholinesterase	Myasthenia gravis
XXXVI	Physostigmine	Anticholinesterase	Glaucoma, myasthenia gravis
XXXVII	Neostigmine	Anticholinesterase	Myasthenia gravis
XXXVIII	Demecarium	Anticholinesterase	Glaucoma
XXXIX	Pyridostigmine	Anticholinesterase	Myasthenia gravis

form of a linear combination:

$$Ai = b_1X_{1i} + b_2X_{2i} + b_3X_{3i} + \ldots + b_NX_{Ni} + \mu \qquad i = 1, 2, \ldots, M \quad \text{(Eq. 1)}$$

However, in evaluating the least-squares estimates of the b coefficients, the values of the coefficients are necessarily a function of the covariance between the independent variables, X, as well as of the covariance between the biological activities and the independent variables. One may thus seek to account for the covariance between X prior to attempting a regression analysis.

In making this attempt, a transformed variable, T, may be defined as a linear combination of the independent variables, X:

$$Ti = m_1X_{1i} + m_2X_{2i} + m_3X_{3i} + \ldots + m_NX_{Ni} \qquad i = 1, 2, \ldots, M \quad \text{(Eq. 2)}$$

This equation is fundamental to all factor analysis procedures (principal component analysis in this case). In the simple case where only three independent variables are involved, Eq. 2 is written as:

$$Ti = m_1X_{1i} + m_2X_{2i} + m_3X_{3i} \qquad i = 1, 2, \ldots, M \quad \text{(Eq. 3)}$$

Squaring both sides of Eq. 3 yields:

$$\sum_i Ti^2 = \sum_i (m_1X_{1i} + m_2X_{2i} + m_3X_{3i})^2 \quad \text{(Eq. 4)}$$

where $\sum_i$ indicates that the summation is over all compounds (1 to M) unless otherwise specified. For convenience of mathematical manipulation, u is defined by the expression:

$$u = \sum_i Ti^2 \quad \text{(Eq. 5)}$$

so that:

$$u = \sum_i (m_1X_{1i} + m_2X_{2i} + m_3X_{3i})^2 \quad \text{(Eq. 6)}$$

The coefficients m_1, m_2, and m_3 may be defined to be orthogonal; *i.e.*, they are subject to the conditional equation:

$$v = m_1^2 + m_2^2 + m_3^2 - 1 = 0 \quad \text{(Eq. 7)}$$

(v is introduced for mathematical convenience). Minimization of the coefficients of Eq. 6 under the restraint imposed by Eq. 7 can be accomplished with the aid of Lagrangian multipliers (33). Differentiation with respect to each coefficient thus leads to:

$$\frac{\partial u}{\partial m_1} - \lambda \frac{\partial v}{\partial m_1} = 0 \quad \text{(Eq. 8a)}$$

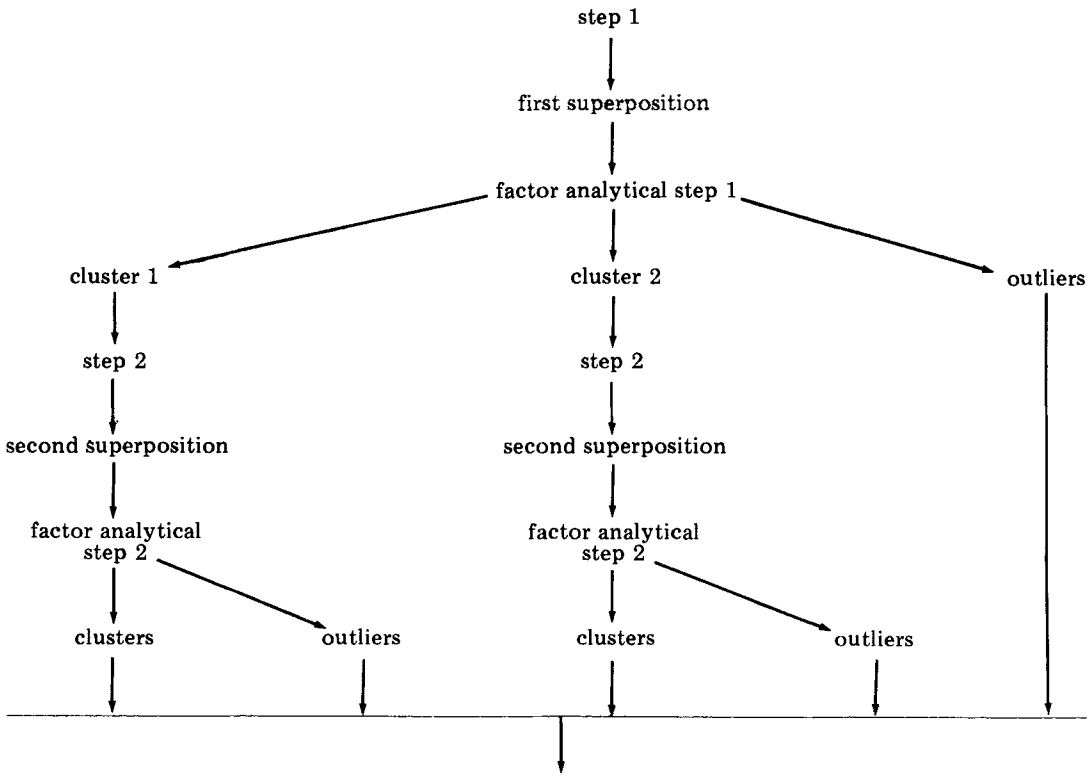
$$\frac{\partial u}{\partial m_2} - \lambda \frac{\partial v}{\partial m_2} = 0 \quad \text{(Eq. 8b)}$$

$$\frac{\partial u}{\partial m_3} - \lambda \frac{v}{\partial m_3} = 0 \quad \text{(Eq. 8c)}$$

Evaluation of Eqs. 8a–8c provides the set of relationships that may be written in matrix formalism as:

$$\begin{vmatrix} \sum X_1^2 - \lambda & \sum X_1X_2 & \sum X_1X_3 \\ \sum X_2X_1 & \sum X_2^2 - \lambda & \sum X_2X_3 \\ \sum X_3X_1 & \sum X_3X_2 & \sum X_3^2 - \lambda \end{vmatrix} \begin{vmatrix} m_1 \\ m_2 \\ m_3 \end{vmatrix} = 0 \quad \text{(Eq. 9)}$$

In Eq. 9, the matrix involving the independent variables is a covariance matrix. However, a technical problem arises in such cases as a consequence of the relative magnitudes of the values used to represent the



Scheme II

independent variables. Variables that are numerically greater in a data matrix will lead to covariances of a numerically large magnitude; therefore, these variables will be designated, artificially, as the more important contributors in a given linear combination. The potential for an artifact of this type in Fujita–Iwasa–Hansch (34) analyses has been pointed out (35). Autoscaling of variables is a means of avoiding this problem (13). Autoscaling involves the use of correlation coefficients in the place of covariances when establishing normal equations such as is represented by Eq. 9. The elements of a correlation matrix are defined by the relationship:

$$r_{rs} = \frac{\sum_i (X_{ri} - \overline{X}_r)(X_{si} - \overline{X}_s)}{\sqrt{\sum_i (X_{ri} - \overline{X}_r)^2 \sum_i (X_{si} - \overline{X}_s)^2}} \qquad \text{(Eq. 10)}$$

where r and s designate the variables whose intercorrelation is being evaluated. Equation 9 may thus be rewritten as:

$$\begin{vmatrix} r_{11} - \lambda & r_{12} & r_{13} \\ r_{21} & r_{22} - \lambda & r_{23} \\ r_{31} & r_{32} & r_{33} - \lambda \end{vmatrix} \begin{vmatrix} \beta_1 \\ \beta_2 \\ \beta_3 \end{vmatrix} = 0 \qquad \text{(Eq. 11)}$$

The β coefficients of Eq. 11 are related to the m coefficients of Eq. 9 by the expression:

$$m_k = \beta_k \lambda^{1/2} \qquad \text{(Eq. 12)}$$

By using correlation coefficients, any one of the elements of the correlation matrix can vary only between ±1 and 0, so no element of the matrix is overweighted.

The solutions for Eq. 11 can be obtained by first determining the eigenvalues, λ_i, which characterize the correlation matrix. As many eigenvalues will be obtained as there are variables in the data matrix. For each eigenvalue, an associated set of eigenvectors, T_i, is obtained.

A relative measure of the information content of the linear combinations T_i is provided by the magnitudes of the associated eigenvalues. The total variance explained by one or more of the eigenvalues is given by the expression:

$$\text{fraction "explained" variance} = \frac{\sum_{i=1}^{L} \lambda i}{N} \qquad \text{(Eq. 13)}$$

where L is the number of eigenvalues selected, and N is the number of variables in the data matrix. It is apparent that all of the eigenvalues taken together represent the data exactly; *i.e.*, the fraction of explained variance is 1. However, in some cases it may be sufficient to choose only a few high value eigenvectors so that only a predetermined fraction of the variance in the data is explained. Thus, one may choose those high value eigenvectors that explain greater than 0.95 of the data, as is often the case in physicochemical applications, or one may choose to work with an approximated form of the data matrix, selecting only those eigenvectors whose associated eigenvalues are equal to 1 or greater (23). The latter approach is taken in this paper, because fewer numbers of eigenvectors are required to represent the data graphically and because such an approximation is quite adequate for the present purposes.

Principal component analysis presents a means by which optimization procedures involving regression methods such as Fujita–Iwasa–Hansch analyses (34) can be made less prone to error due to intercorrelation between variables. Correlation analysis utilizing principal component analysis as a preprocessing method would thus be based on the multiple regression model in the form:

$$Ai = \sum_{t=1}^{K} C_t T_{ti} + \mu \qquad i = 1, 2, \ldots, M \qquad \text{(Eq. 14)}$$

where the K orthogonal variables, T, explain the major proportion of the variance in the data. An interface thus exists between pattern recognition techniques and the more widely used quantitative structure–activity methods.

METHOD

The 39 drugs comprising the data set are listed in Table I along with their known pharmacological classifications (36) and therapeutic uses (37). They consist of various pharmacological types, including α- and β-adrenergic agents, cholinergic agents, and central nervous system (CNS) stimulants. The study was directed toward separating these compounds into the distinct pharmacological groups they are known to fall into and to separate out the unrelated compounds.

Scheme II is an example of a two-step pattern recognition procedure as followed in this work. In the first step, a preliminary factor analysis is performed to separate broadly the entire data set. Classification is then accomplished by plotting the output from the preprocessing step. Clusters

(Arabic numbers correspond to the roman numerals for the compounds used in the text.)*

so obtained are then factor analyzed separately to yield smaller clusters. Such a sequential procedure has two distinct advantages: (*a*) only a few discriminating features need to be specified in each step, and (*b*) since only a few discriminators are included in the data matrix, easily interpretable results are obtained, the solutions being in two or three dimensions.

Step 1—*Superpositioning of Structures*—Since only variant molecular features are included in the basic equation (Eq. 2), all of the compounds of the data set must first be superimposed to generate the simplest possible superposed structure or "superstructure." This composite structure is so designed that all molecules of the data set can be superposed on it in a consistent manner. This is a key step of the procedure adopted here, since the complexity of the final results depends on the complexity of the superposed structure chosen. This structure has no molecular significance; it is only a geometrical construction. It may be described as a hypothetical parent structure for all compounds of the data set.

In the present case, examination of the structures of I–XXXIX shows a wide variation of structural types. The task of superimposition of all these structures is considerably simplified if representative structures are selected from among structurally related compounds. In the given data set, one might pick XXI, XXIV, XXVII, XXXIII, and XXXVI as being representatives. All of these structures have the common feature X—$(C)_n$—N, where X may be a carboxylic acid derivative or aromatic ring, *n* is the number of carbon atoms intervening, and the amine nitrogen N may be variously substituted. The superposition of the molecules is achieved by superposing the X groups and the N groups while, at the same time, carefully accounting for the length of the carbon chain between them (XL).

In the case of phenethylamines like isoproterenol (XXI) and amphetamine (VI), the aromatic ring is superposed on ring X (see Structure XL), the carbon atom joined to the ethylamine group being placed on position 2. The two-carbon chain is superposed on 4 and 11; the isopropylamino group is on N, 5, and 6; and all other positions (7, 8, 9, 10, 12, 13) are nonexistent. For a molecule like acetylcholine, the carbonyl group is superposable on 2 and 3, the esteratic methyl group on 1, the ether oxygen on 4, the two-carbon chain on 9 and 11, and the trimethylammonium function on N, 5, 6, and 7. Positions 8, 10, 12, and 13 are absent

[a] C_r = aromatic carbon atom, C_a = aliphatic carbon atom, and C_o = carbonyl carbon atom.

in this case. For compounds like neostigmine or physostigmine, the ester or amide group is treated just as for acetylcholine; the aromatic ring is superposed on the six-membered ring formed by positions 8, 9, 11, 13, 10, and 12. If the esteratic group is *para* to the amine function, then the former is linked to the aromatic ring by the 4–12 bond; if the esteratic group is *meta* to the aromatic ring, it is linked to the latter by the 4–10 bond.

Two of the molecules of the data set, pilocarpine (XXXIII) and pyridostigmine (XXXIX), are structurally distinct from the rest; they may be superposed on Structure XL as follows. The ester group of pilocarpine is treated just as for acetylcholine; the four-carbon chain between the ester group and the amine function is superposable on positions 12, 8, 9, and 11. The superpositioning of the nitrogen-containing rings is apparent from the figure. In the case of pyridostigimine, the pyridine ring is superposed on N, 11, 9, 12, and 10. Position 4 (ether oxygen) is linked to 12 to represent the *meta*-substitution.

All other structures are similarly superposable; Table II shows exactly how each compound was treated.

Selection of Discriminators—Discriminators are groups, bonds, or other functionalities that serve to distinguish between compounds of a data set. When a wide variety of structural types are being studied, the number of variables in the data matrix will be inordinately large if *all* structural differences are designated as discriminators. Therefore, it is desirable to specify the minimum number of discriminators required to differentiate between the compounds of the data set.

In the present study, more than one factor analytical step is to be applied (Scheme II). In the first step, only a broad classification is sought, so only major structural differences need be specified while selecting discriminators. Thus, fine distinctions such as aromatic or aliphatic substitution patterns may be ignored while major distinctions such as those between aromatic and aliphatic groups should be specified. On this basis, positions 1–13 of XL may be chosen as discriminators. However, closer examination of Structures I–XXXIX and of Table II shows that positions 11–13 are not major discriminators; they represent only two variations in structure (aromatic or aliphatic carbon atoms). Furthermore, these positions are equally well represented by others, *e.g.*, 12 and 13 by

Table III—Descriptor Code for Designating Discriminator Groups

Group[a]	Atomic/Structural Constant	Code
Cl	5.84	1.00

COOH	7.23	1.24

[a] C_r = aromatic carbon, C_o = carbonyl carbon, and C_a = aliphatic carbon. [b] Value was calculated. [c] Only the aromatic carbon attached to the methylene group and the two *ortho*-carbon atoms were included to be consistent in designating discriminators; the value of 16.81 was calculated using the molar refraction value for the benzene ring (38). [d] Aliphatic hydroxyl group. [e] Phenolic hydroxyl group.

8 for all compounds [except for pilocarpine (XXXIII) and pyridostigmine (XXXIX), which are in any case different from the other compounds of the data set]. Similarly, position 11 is represented by position 4 in I–XXVII and by position 9 in XXVIII–XXXIX. Positions 11–13 may therefore be ignored.

Designation of Discriminators: Coding—The discriminators selected are designated in numerical terms by a descriptor code. One has to choose a property of the groups that can adequately represent and distinguish between them. It is seen that many of the substituents involved are bioisosteric, *e.g.*, $COOCH_3$, $CONH_2$, and $CON(CH_3)_2$. Since it is generally true that classical isosteric groups have similar molar refractivities, molar refraction values were used in the coding (38). The molar refraction value of chlorine (5.84) was selected as standard, and all other codes were determined relatively. The molar refraction values used and the descriptor codes adopted are given in Table III. Several molar refraction values were calculated by using the additive-constitutive property.

With the codes given in Table III, the molecule-discriminator data matrix shown in Table IV was constructed. Comparison of Structures I–XXXIX with XL and of Tables II–IV will indicate exactly how each compound of the data set was numerically designated.

Preprocessing: Factor Analytical Step 1—By using the coded molecule-discriminator data matrix of Table IV, the correlation matrix shown in Table V was constructed (as described under *Theory*). The solution of Eq. 13 gave three eigenvalues whose values were greater than unity. These values, together with the associated eigenvectors, are given in Table VI. The three eigenvalues chosen explain $(4.87 + 1.61 + 1.32)/10 = 0.78$ of the variance. This value is not very high, but only major classification patterns are sought in this part of the analysis. That an explained variance of 78% is sufficient for the present purposes is obvious upon examination of the clustering pattern obtained (Fig. 1).

Classification: Plotting—By using the eigenvectors associated with the three eigenvalues, three factor coordinates, t_1, t_2, and t_3, were calculated for each compound of the data set. The points were then plotted by simple solid geometrical construction (Fig. 1). After plotting each point, its associated biological activity was used to label it in the distri-

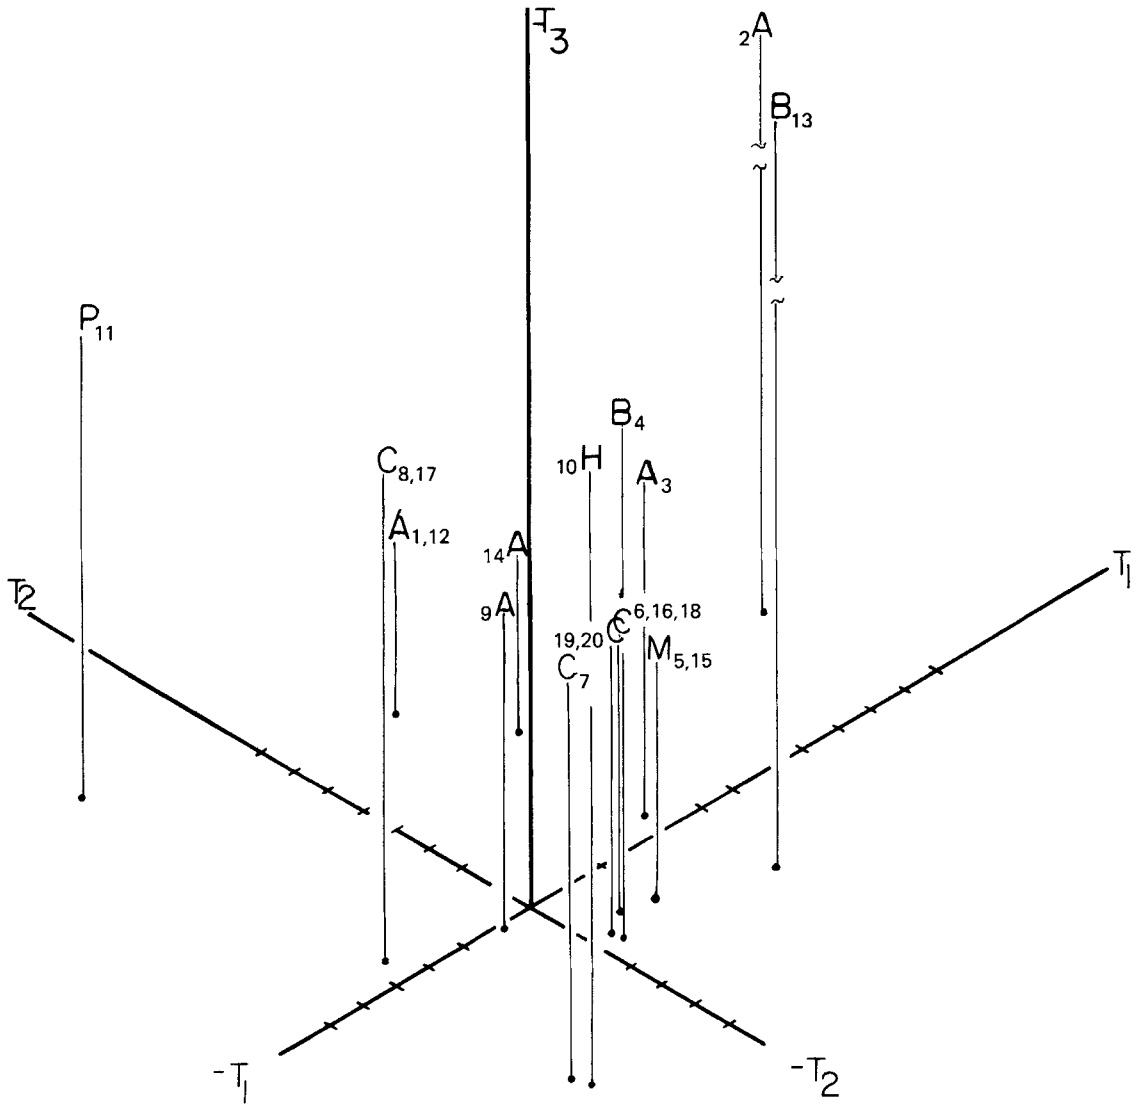

Figure 2—*Three-dimensional plot of factor coordinates from factor analytical step 2. A = α-adrenergic agonist, B = β-adrenergic agonist, C = CNS stimulant, H = antihypertensive, M = mixed-acting agent (α-adrenergic agonist and CNS stimulant), and P = antiparkinsonian. (Arabic numbers correspond to the roman numerals for the compounds used in the text.)*

bution (B for β-adrenergic agent, P for parasympathomimetic, C for anticholinesterase, A for α-adrenergic or CNS agent, and L for adrenergic blocker). Examination of Fig. 1 shows distinct patterns in the distribution. Adrenergics and cholinergics are well separated, and the β-agonists form a well-resolved cluster. The parasympathomimetics form a distinct cluster compared to the scattered distribution of the anticholinesterases. Phenoxybenzamine (XXVII), the only α-blocker, is far removed from the rest of the data set; propranolol (XXIV), the only β-blocker, is removed from, but close to, the β-agonists.

Pilocarpine (XXXIII) appears to occupy an ambiguous position; however, this compound is structurally and pharmacologically quite different from the rest so it can be regarded as well resolved. Only two compounds, ethylnorepinephrine (IV) and methoxyphenamine (XIII), are not properly classified. They are found within the cluster of α-adrenergic and CNS agents (these agents are primarily β-adrenergic agonists). However, they are well resolved after the second factor analytical step, when fine substitution patterns are considered.

Step 2—The distribution pattern of Fig. 1 indicates that, although the major pharmacological classes have been correctly identified and well separated, further separation is desirable among the adrenergic and CNS agents. The group of 20 compounds clustering around the T_3 axis (I–XX, Fig. 1) is fairly large and is subjected to another analysis. The list of

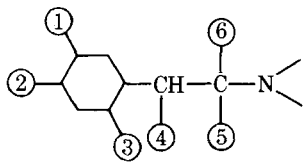
compounds is given in Table VII, which also includes the molecule-feature matrix. The distinction in this case (compared to Step 1, Table III) is that fine substitution patterns are taken into account.

By following the same operational procedures outlined earlier, a composite superstructure for all of the molecules of the data set was generated (XLI). Structure XLI is considerably simplified from Structure XL, since only a limited data set is involved and preliminary separation has already been effected.



XLI

By using the molecule-feature data matrix shown in Table VII, the coded molecule-discriminator matrix was constructed as explained earlier, using the coding given in Table III. Upon factor analyzing the data matrix, three eigenvalues with magnitudes greater than one were obtained; these values, together with their associated eigenvectors, are given in Table VIII. The three eigenvalues together explain 75% of the variance.

The factor coordinates of each compound were obtained as described earlier, and the three-dimensional plot is shown in Fig. 2. The adrenergic agents are well separated from the CNS agents. The two β-adrenergic agents present, ethylnorepinephrine (IV) and methoxyphenamine (XIII), are well resolved. The mixed acting agents, ephedrine (XV) and phenylpropanolamine (V), occupy a position between the α-adrenergic and CNS stimulant agents. This is also characteristic of their pharmacological action, because they have both types of activity. Methyldopa (X) and levodopa (XI) occupy distinct positions, reflecting their characteristically different pharmacological activities.

Table VII—Molecule-Feature Matrix for Factor Analytical Step 2

Compound	Position 1	2	3	4	5	6
I	OH_p[a]	OH_p	H	OH_l[b]	H	H
II	OCH_3	H	OCH_3	OH_l	H	H
III	OH_p	H	H	OH_l	H	CH_3
IV	OH_p	OH_p	H	OH_l	H	CH_2 CH_3
V	H	H	H	OH_l	H	CH_3
VI	H	H	H	H	H	CH_3
VII	H	Cl	H	H	CH_3	CH_3
VIII	H	H	H	H	CH_3	CH_3
IX	H	OH_p	H	H	H	CH_3
X	OH_p	OH_p	H	H	COOH	CH_3
XI	OH_p	OH_p	H	H	COOH	H
XII	OH_p	OH_p	H	OH_l	H	H
XIII	H	H	OCH_3	H	H	CH_3
XIV	OH_p	H	H	OH_l	H	H
XV	H	H	H	OH_l	H	CH_3
XVI	H	H	H	H	H	CH_3
XVII	H	H	H	H	CH_3	CH_3
XVIII	H	H	H	H	H	CH_3
XIX	H	H	H	O	H	CH_3
XX	H	H	H	O	H	CH_3

[a] Phenolic hydroxyl. [b] Aliphatic hydroxyl.

Table VIII—Eigenvalues and Associated Eigenvectors for Step 2

	Eigenvalue I = 1.96	Eigenvalue II = 1.54	Eigenvalue III = 1.10
β_1	0.43[a]	0.52	−0.30
β_2	−0.29	0.55	0.00
β_3	0.37	−0.06	−0.76
β_4	0.57	0.18	0.38
β_5	−0.51	0.35	−0.32
β_6	−0.06	−0.51	−0.30

[a] Values are the associated eigenvector coefficients.

CONCLUSIONS

When dealing with a large number of structurally diverse compounds, a likely problem with the method adopted here is incorrect structural superposition. Attempts to overcome this difficulty are underway.

To researchers accustomed to setting a cutoff level of 0.95 or greater for experimental accuracy, the approximation of 0.75 may not be satisfying. However, a highly accurate reproduction of the data is not essential here; only an approximation of the data is sought so that the major distinctions between the elements of the data set can readily be identified. Furthermore, graphical representation of the results, which is possible by such an approach, is directly interpretable and is conceptually simpler than the mathematical methods available.

To summarize, a simple factor analytical approach was successfully applied to classify a set of 39 therapeutic agents using organic structural information. The major pharmacological groups present were correctly identified and separated. Pharmacologically unrelated compounds such as levodopa (an antiparkinsonian) and methyldopa (an antihypertensive) were separated out. Inspection of the clusters indicated some degree of order; for example, ephedrine and phenylpropanolamine occupied the border region between α-adrenergic agents and CNS stimulant agents. The results show that factor analysis can be employed advantageously as the preprocessing step of a pattern recognition scheme in the investigation of structure–activity relationships.

Pharmacokinetics of β-Methyldigoxin in Healthy Humans II: Oral Studies and Bioavailability

PETER H. HINDERLING [*], EDWARD R. GARRETT [x], and RONALD C. WESTER [‡]

Abstract □ The pharmacokinetics of orally administered aqueous ^{3}H-β-methyldigoxin solutions were studied at two dose levels, 0.3 and 0.6 mg, in healthy human subjects. The drug and its metabolites were specifically assayed in biological fluids and compared with results after intravenous doses to the same subjects. No significant dose dependency was observed. The apparent half-life of absorption was 16 ± 6 min (*SEM*). Digoxin was the only metabolite observed in the plasma and comprised 28.6 ± 3.7% of the dose in the urine. ^{3}H-β-Methyldigoxin, renally excreted unchanged, comprised 25.7 ± 1.7% (*SEM*). Water-soluble metabolites in the urine comprised 9.0 ± 1.8%. Fecal and urinary excretion accounted for 85% of the dose at 144 hr. The oral absorption of unchanged ^{3}H-β-methyldigoxin from solution was 59 ± 6% by area under the curve methods and 60 ± 4% by renal excretion. A total of 73% of the dose in the solution was absorbed as β-methyldigoxin and digoxin. First-pass metabolism prior to absorption was largely prehepatic and assignable to GI degradation; 21.9 ± 2.8% was degraded with 12.8 ± 4.0% to digoxin and 9.1 ± 4.0% to water-soluble metabolites. From 14 to 18% of the administered oral dose did not reach the systemic circulation. Analog computer fitting of plasma and urine levels of drug and digoxin was consistent with the first-pass premise with a delayed absorption of GI-generated digoxin and other metabolites. There were no significant differences between the oral absorption of a tablet formulation and the solution. Orally administered β-methyldigoxin solution delivered 97% cardioactivity as itself and digoxin with respect to an equivalent amount of intravenously administered digoxin. This value contrasts to the 140% delivered by intravenously administered β-methyldigoxin on the premise of pharmacodynamic equivalence of systemically appearing digoxin and β-methyldigoxin. Literature reports on the oral bioavailability of solutions and solid dosage forms of digoxin were critically reviewed, but no reliable comparison of the extent and reproducibility of oral absorption of cardioactive agents from administered digoxin or β-methyldigoxin could be made from the widely variable digoxin studies with nonspecific assays.

Keyphrases □ β-Methyldigoxin—oral, pharmacokinetics and bioavailability in humans, radiochemical–TLC study □ Pharmacokinetics—oral β-methyldigoxin, humans, radiochemical–TLC study □ Bioavailability—oral β-methyldigoxin, humans, radiochemical–TLC study □ Radiochemistry–TLC—study of pharmacokinetics and bioavailability of oral β-methyldigoxin in humans □ Cardiac glycosides—β-methyldigoxin, oral, pharmacokinetics and bioavailability in humans, radiochemical–TLC study

Semisynthetic derivatives of digoxin (Ia) such as β-methyldigoxin (Ib), a methyl ether of digoxin, and β-acetyldigoxin (Ic), an acetyl ester of digoxin, have been claimed to have higher intrinsic rate constants and efficiencies of absorption than digoxin in animals and in humans (1–14). Presumably, the rationale for their preferred usage is that a completely absorbed compound has the most consistent bioavailability in multiple dosage regimens. This is a valid approach, since glycosides have a narrow therapeutic range (15–18) and the occurrence of toxic manifestations in patients undergoing chronic therapy is 7–20% (19). Whereas β-acetyldigoxin was extensively metabolized or degraded before reaching the systemic circulation (20), β-methyldigoxin was claimed to

[a] Apparent first-order rate constant of absorption of β-methyldigoxin from method of residuals on oral administration. [b] Determined by graphical integration of the area in micrograms-hour per liter under plasma unbound β-methyldigoxin concentration–time curve; this area is divided by the administered dose in micrograms. The parenthetical values were from the intravenous studies (25). [c] Total clearance from f_1D/area under plasma unbound concentration–time plots, where f_1 is the absorption efficiency from the ratio of the areas per unit dose for oral to intravenous administration. [d] Renal clearance from slope of plots of renal elimination rates of β-methyldigoxin, $\Delta U/\Delta t$, against plasma concentrations of unbound drug. [e] Metabolic clearance from the difference of total and renal clearances, $(Cl_p^u)_{tot} - (Cl_p^u)_r$. [f] Calculated from the micrograms of β-methyldigoxin renally excreted at infinite time, U_{∞}^{BMD}, which was estimated from adding to the amount excreted at 144 hr the amount that would have been excreted for five more half-lives if the slope of the natural logarithm of the excretory rate, $\ln \Delta U/\Delta t$, against time was a constant, $-\gamma$. [g] Calculated from the micrograms of β-methyldigoxin renally excreted at 144 hr, $U_{144\ hr}^{BMD}$. [h] Calculated from the micrograms of β-methyldigoxin equivalent of the digoxin renally excreted at 144 hr, $U_{144\ hr}^{DIG}$. [i] Calculated from the micrograms of β-methyldigoxin equivalent of water-soluble metabolites renally excreted at 144 hr, $U_{144\ hr}^{H_2O}$. [j] Value from oral administration divided by pertinent value from intravenous administration (25) for each subject. [k] Percent of total radioactivity administered excreted by 144 hr by specified route(s). [l] Percent of dose of β-methyldigoxin excreted by 144 hr renally as unchanged drug, digoxin, and water-soluble metabolite plus fecal excretion. [m] Parenthetical values were obtained from intravenous studies (25).

have a higher absorption efficiency than digoxin and β-acetyldigoxin on intraduodenal application in guinea pigs (3) and absorption efficiencies of 75–100% in humans (4–10).

These conclusions were based on pharmacodynamic cardiovascular parameters (4–6, 10) and the total radioactivity in plasma and/or excreted in urine after oral and intravenous administration (7, 8). Both methods do not give the intrinsic bioavailability of β-methyldigoxin, since the contributions of digoxin activity or the production of active or labeled metabolites prior to absorption cannot be excluded. Radioimmunoassay is a highly sensitive assay for cardiac glycosides (21, 22) and is applicable for the assay of the sum of β-methyldigoxin and its derived metabolites in biological fluids (22–24). It suffers from the same limitations as total radioactivity.

The pharmacokinetics of intravenously administered ^{3}H-β-methyldigoxin and its derived metabolites were considered previously (25). The present studies were conducted with the same subjects to determine the time course and bioavailability of ^{3}H-β-methyldigoxin and its metabolites, analyzed separately, at two dosage levels after oral administration.

EXPERIMENTAL

Details of the materials and analytical procedures used and the general pharmacokinetic procedures and design were given previously (25). The assayed solutions of 0.30- and 0.60-mg doses of ^{3}H-β-methyldigoxin in 0.9% saline solution were administered orally to the subjects (25) by a syringe with immediate swallowing to avoid sublingual or buccal absorption. A 40-ml water rinse was swallowed immediately. Blood (6 ml) was taken within 10 sec at 0, 2.5, 5, 10, 15, 20, 30, 45, 60, and 90 min and at 2, 3, 5, 7, 9, 11, 15, 20, 24, 36, 48, 60, 72, 84, 96, 120, and 144 hr after the oral drug administration through the butterfly needle with syringes; procedures were as described previously (25). The urine was collected

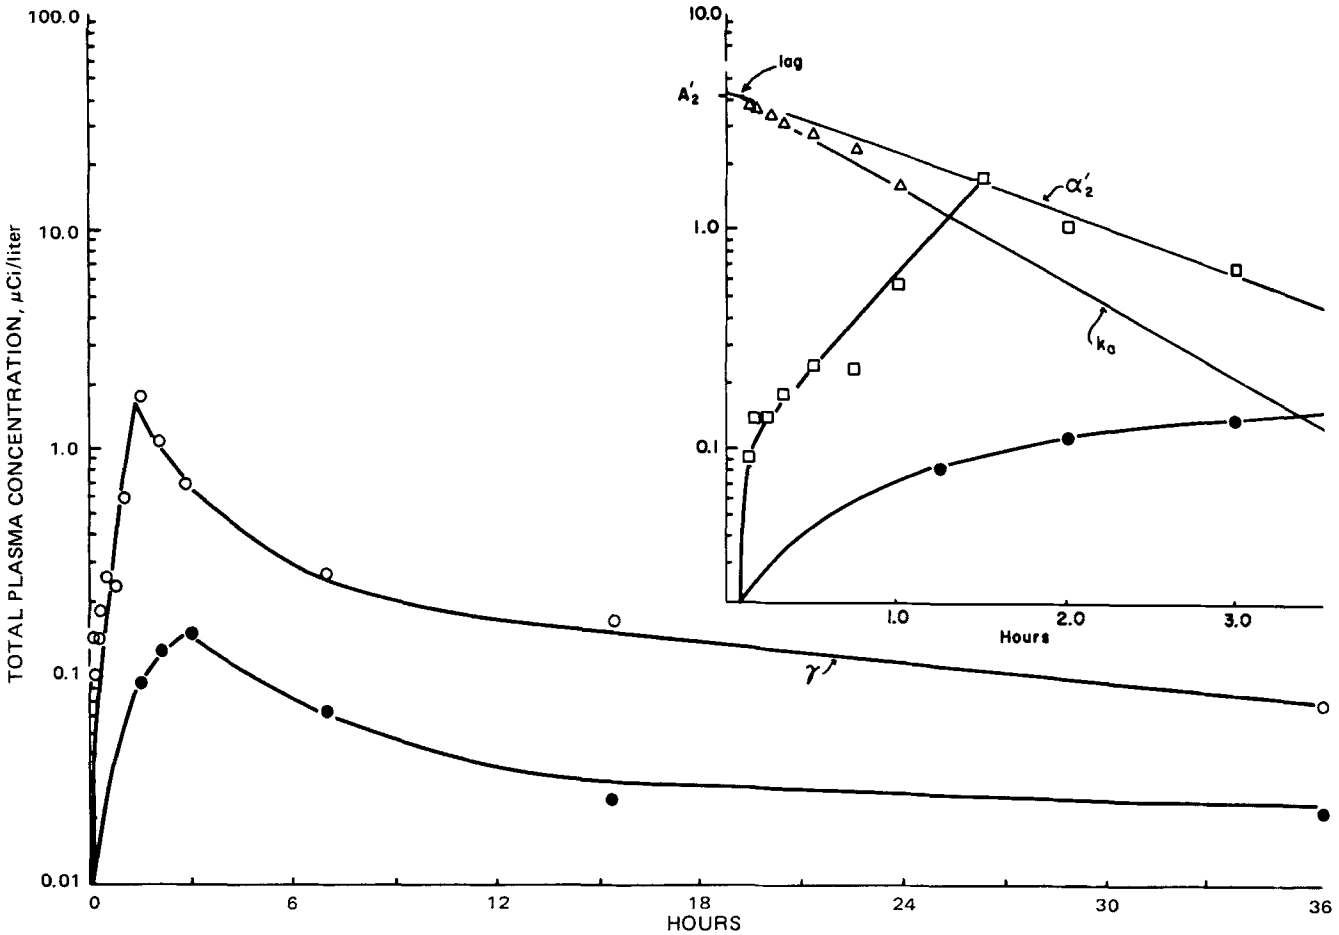

Figure 1—*Typical semilogarithmic plots of plasma β-methyldigoxin (○) and digoxin (●) concentrations, [A_p], against time for oral administration: 120.1 μCi = 278 μg of β-methyldigoxin in aqueous solution to Subject C. The insert is a plot of the plasma β-methyldigoxin (□) and digoxin (●) concentrations on an expanded time axis. The data were treated by the method of residuals by extrapolating the α_2-phase to time zero and plotting semilogarithmically the difference (△) of the antilogarithms of the extrapolated line and the plasma concentrations against time on the assumption that the absorption process was concluded during the α_2'-phase. The slope, $-k_a/2.303$, of this line permits estimation of the apparent first-order absorption rate constant, k_a. The lag time was estimated from the intersection of the extrapolated α_2-phase and the plot of the differences.*

and assayed as described in the intravenous studies (25). The subjects[1] were prostrate during the first 24 hr after drug administration.

In addition to the solutions, a tablet formulation of ^{3}H-β-methyldigoxin was administered to six of the seven volunteers. Five tablets (0.1 mg/tablet) with 100 ml of water were swallowed immediately, and biological fluids were sampled up to 24 hr after tablet administration as in the oral studies on solutions.

RESULTS AND DISCUSSION[2]

Plasma Pharmacokinetics of ^{3}H-β-Methyldigoxin after Oral Administration—The α_2-, β-, and γ-phases with pharmacokinetic constants similar to those of intravenous administration (25) were observed for ^{3}H-β-methyldigoxin. These phases were preceded by a rapid absorption phase, characterized by an apparent first-order absorption rate constant, k_a (Table I and Fig. 1). Peak plasma concentrations for total drug of 1.1 ±.0.1% of the dose/liter of plasma were reached at 50 ± 9 min after administration. The fact that these values were markedly consistent among doses, 1.14 ± 0.17 at 300 μg and 1.11 ± 0.15 at 600 μg (n = 3), was strongly indicative of a first-order absorption process. The rate constant, k_a, was obtained by "feathering" after excluding lag times of 9.4 ± 1.5 min. The α_2-phase of the semilogarithmic plot was extrapolated to zero time, and k_a was estimated from the linear slope of the differences of the antilogarithm of the extrapolated line and the plasma concentration against time (Fig. 1, insert) to give an apparent half-life of absorption of 16 ± 6 min.

The lack of dose dependency was evident by the superimposability of plots at various doses for the percent of dose per liter of plasma against time (Fig. 2).

Digoxin was the only metabolite observed in the plasma and peaked at 90 ± 24 min after oral administration of ^{3}H-β-methyldigoxin (Fig. 1), in contrast to the 32.3 ± 7.0 min observed after intravenous administration (25).

The apparent overall rate constant of elimination, γ, for the pseudo-steady state after equilibration among tissues, 19.3 ± 1.6 × 10^{-3} hr^{-1}, obtained from the slope of the semilogarithmic plot of plasma ^{3}H-β-methyldigoxin concentration against time, was not significantly different from the 17.3 ± 0.8 × 10^{-3} hr^{-1} value obtained after intravenous administration (25).

Urine Pharmacokinetics—The amounts of β-methyldigoxin cumulatively excreted in urine were plotted as percent of dose against time (Fig. 2) to estimate the total recovery and were reasonably superimposable for all doses. The apparent rate constant, γ, for the terminal phase of drug elimination in the urine, 20.5 ± 0.6 × 10^{-3} hr^{-1}, obtained from the slope of the natural logarithm of the amount yet to be excreted, $\ln(U_\infty - U)$ against time, was not significantly different from the 20.8 ± 0.5 × 10^{-3} hr^{-1} value obtained after intravenous administration (25).

The percentages of the ^{3}H-β-methyldigoxin dose renally excreted by 144 hr as β-methyldigoxin, digoxin, and water-soluble metabolites were 25.7 ± 1.7, 28.6 ± 3.7, and 9.0 ± 1.8 (Table I), respectively, in contrast to the intravenous values of 43.2 ± 1.9, 31.7 ± 2.2, and 5.3 ± 0.8, respectively (25).

The water-soluble metabolites in an 18-hr urine collection after oral administration were composed of glucuronides (42.4 ± 14.2%), sulfates

[1] Informed consent was obtained from all subjects. The protocol was approved by the Committee for Protection of Human Subjects and the Clinical Research Committee, J. Hillis Miller Health Center, University of Florida.

[2] The plus and minus values for mean values given in the text refer to the standard error, $\sigma/\sqrt{n}$, of such means, where σ is the standard deviation given in the tables of this paper or Ref. 25, and n is the number of values considered (6 unless otherwise specified).

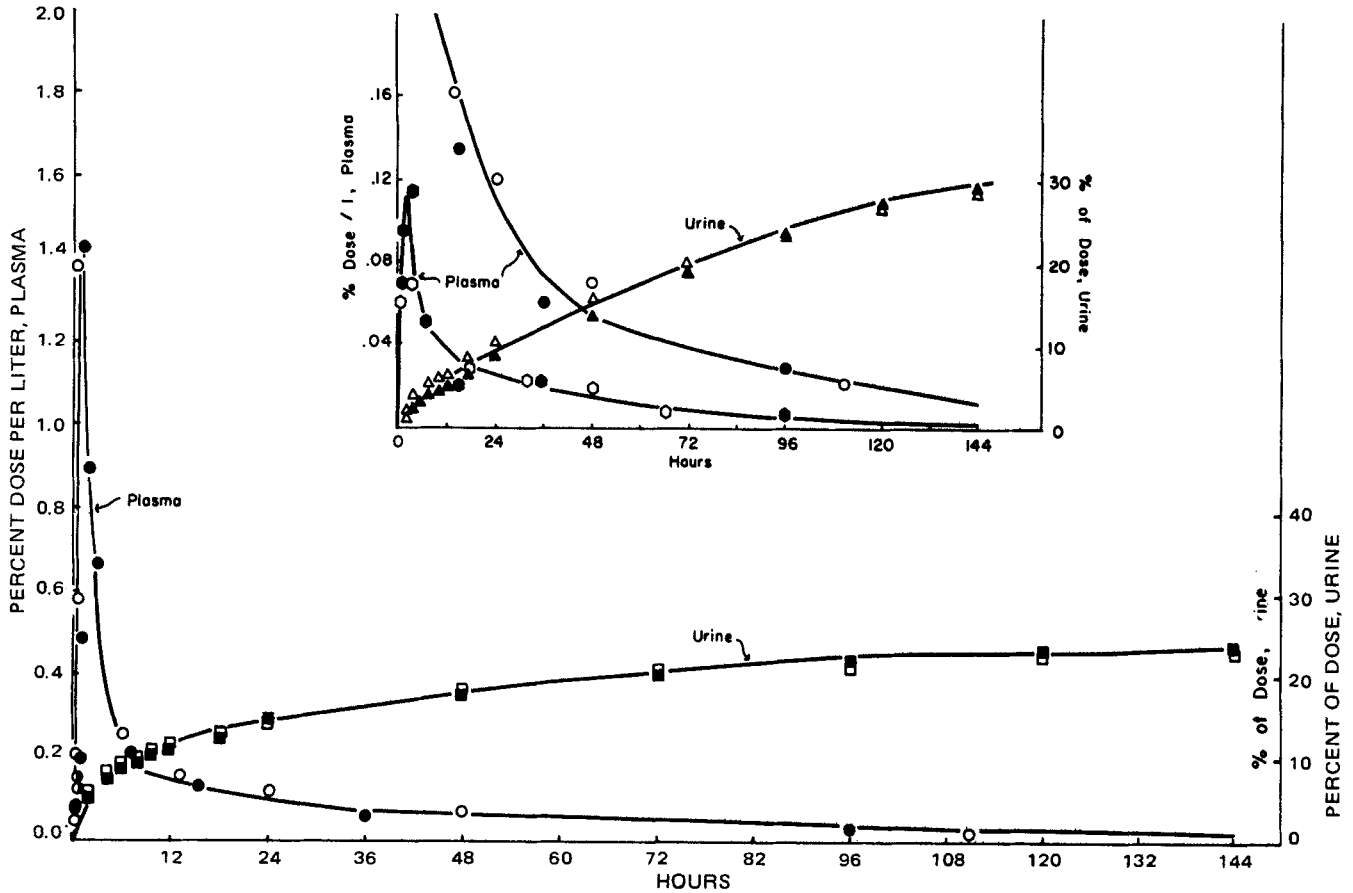

Figure 2—*Typical plasma concentrations and cumulative urine excretions in percent of β-methyldigoxin dose per liter of plasma and of dose, respectively, against time for oral solution administration: 126.7 μCi = 294 μg (open symbols) and 254.1 μCi = 590 μg (solid symbols) of β-methyldigoxin to Subject A. Key: ○, ●, plasma β-methyldigoxin levels; □, ■, urinary β-methyldigoxin amounts; ○, ● (inset), plasma digoxin levels; and △, ▲ (inset), urinary digoxin amounts.*

(24.6 ± 8.2%), and unidentifiable metabolites (33.6 ± 7.6%) (all $n = 3$). The percent compositions of these two fractions of glucuronide and sulfate conjugates were 82.4 ± 2.8 and 67.3 ± 9.8% with β-methyldigoxin, respectively, 8.6 ± 2.5 and 23.3 ± 9.6% with digoxin, respectively, and 9.0 ± 6.5 and 9.5 ± 1.2% with digoxigenin, respectively (all $n = 3$).

The percentages of the administered total radioactivity renally excreted as total radioactivity at 144 hr were 70.3 ± 1.2%, intravenous (25), and 57.7 ± 1.7%, oral ($n = 14$). The percentages of the administered total radioactivity fecally excreted as total radioactivity at 144 hr were 11.8 ± 0.6%, intravenous (25), and 25.9 ± 3.3%, oral. The combined urinary and fecally recovered amounts of total radioactivity at 144 hr were 85.8 ± 1.1%, intravenous (25), and 84.9 ± 3.%, oral, of the total radioactivity administered.

Clearances—The total clearances of unbound ^{3}H-β-methyldigoxin were calculated from:

$$(Cl_p{}^u)_{tot} = fD_{po}/area_{po} \qquad \text{(Eq. 1)}$$

where D_{po} is the orally administered dose. The area was determined under the plasma unbound concentration–time curves extrapolated to infinite time; f, the fraction of dose absorbed, was calculated from:

$$f = \frac{area_{po}}{D_{po}} \Big/ \frac{area_{iv}}{D_{iv}} \qquad \text{(Eq. 2)}$$

The areas and dose, D_{iv}, after intravenous administration to the same individual were given previously (25). Total clearance does not necessarily imply pharmacodynamic inactivation, since it includes the metabolic clearance of β-methyldigoxin where pharmacodynamically active digoxin is the major metabolite.

The total clearances of unbound β-methyldigoxin were the same after oral administration (Table I) as after intravenous administration (25). The average renal (59 ± 9 ml/min) and metabolic (66 ± 9 ml/min) clearances after oral administration were the same as those after intravenous administration, 59 ± 7 and 66 ± 10 ml/min, respectively (25). All clearances for a given individual were similar, whatever the mode of administration (Table I and Ref. 25).

The renal clearance of plasma-unbound digoxin after oral administration of ^{3}H-β-methyldigoxin was 159 ± 8 ml/min ($n = 2$) and was significantly less than that after intravenous administration, 222 ± 32 ml/min ($n = 5$).

The renal clearance of the water-soluble metabolite fraction taken as an entity can be estimated from the observed rates of renal elimination, $\Delta U/\Delta t$ (Fig. 3), obtained in these studies at the respective plasma levels,

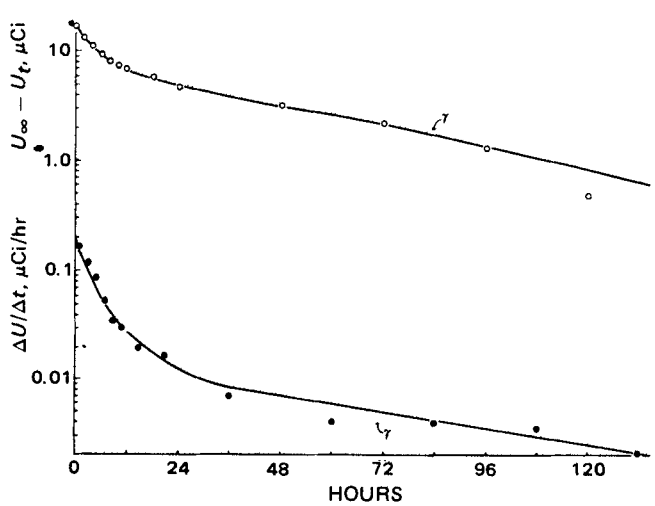

Figure 3—*Typical semilogarithmic plots of amounts of water-soluble metabolites yet to be excreted, $U_\infty - U_t$ (○), and rates of urinary excretion of water-soluble metabolites, ΔU/Δt (●), against time after oral administration: 120.1 μCi = 279 μg of β-methyldigoxin to Subject C with an apparent terminal half-life of 40 hr.*

[a] Calculated from the micrograms of β-methyldigoxin equivalent of the digoxin renally excreted at 144 hr, $U^{DIG}_{144\ hr}$, after oral administration of a dose of β-methyldigoxin, *D*, in micrograms. [b] Calculated from the product of the absorption efficiency of β-methyldigoxin (determined from the ratio of β-methyldigoxin renally excreted 144 hr after oral and intravenous administration) and the percent of the dose renally excreted as digoxin 144 hr after intravenous administration (Table I). [c] Calculated from the micrograms of β-methyldigoxin equivalent of the water-soluble metabolites renally excreted at 144 hr, $U^{H_2O}_{144\ hr}$, after oral administration of a dose of β-methyldigoxin, *D*, in micrograms. [d] Calculated from the product of the absorption efficiency of β-methyldigoxin [based on $U^{BMD}_{144\ hr}$ (po)/$U^{BMD}_{144\ hr}$ (iv) values of Table I] and the percent of the dose renally excreted as water-soluble metabolites 144 hr after intravenous administration. [e] Difference between actual and predicted values. [f] Amount of digoxin as percent of the dose formed on first pass, $10^2\ (E_{DIG}/D)_{first\ pass}$, can be estimated from the percent dose metabolized on first pass that is excreted in the urine, $10^2\ (U_{DIG}/D)_{first\ pass}$, *i.e.*, $10^2\ (E_{DIG}/D)_{first\ pass} = 10^2\ (U_{DIG}/D)_{first\ pass} \times (Cl_{DIG})_{tot}/(Cl_{DIG})_{ren}$, where the values for $(Cl_{DIG})_{tot}$ = 290 ml/min and $(Cl_{DIG})_{ren}$ = 222 ml/min were taken from the values obtained in the intravenous studies. An alternative method of estimation, on the premise that only digoxin is significantly formed on first pass and that all water solubles are derived from systemic digoxin and excreted in urine, is from $10^2\ (E_{DIG}/D)'_{first\ pass} = 10^2\ (U_{WS}/D)_{first\ pass} \times (Cl_{DIG})_{tot}/(Cl_{DIG})_{met}$, where $(Cl_{DIG})_{tot}$ = 290 ml/min and $(Cl_{DIG})_{met}$ = 68 ml/min. These $10^2\ (E_{DIG}/D)'_{first\ pass}$ values averaged 25 ± 18 (*SD*), larger than the averaged estimate of $10^2\ (E_{DIG}/D)_{first\ pass}$ = 12.2 ± 9.8 (*SD*). Although the standard deviations were large, it was concluded that water-soluble metabolites probably were not formed on first pass. [g] The total amount of water-soluble metabolites as a percent of dose, $10^2\ (E_{WS}/D)_{first\ pass}$, may be calculated from $10^2\ (U_{WS}/D)_{first\ pass} \times (Cl_{WS})_{tot}/(Cl_{WS})_{ren} - 10^2(E_{DIG}/D)_{first\ pass} \times (Cl_{DIG})_{met}/(Cl_{DIG})_{tot}$, where the latter term containing a ratio of the digoxin clearances of 0.234 corrects for water-soluble metabolites produced that result from the additional digoxin available systemically on first pass. The ratio of the water-soluble clearances in the first term on the right (the term that estimates the total amount of water solubles produced from that renally excreted) is taken as 2, since the data of Abshagen *et al.* (43) demonstrated relatively equal amounts of water solubles eliminated in the bile and urine on β-methyldigoxin administration. [h] The parenthetical values give the analog computer estimates of the total first-pass metabolism calculated from the ratio $k_{GIGI'}/(k_{GIGI'} + k_{GIB})$ (Scheme I).

$[A_p]$, of water-soluble metabolites obtained from the data of Rietbrock and Abshagen (26), where both sets of data were obtained after oral administration. No significant plasma levels of water-soluble metabolites were obtained in our studies. The average rates of renal elimination in the three subjects were 1.03, 1.16, 0.56, 0.41, and 0.27% of the total dose of radioactivity excreted per hour during 0–2-, 2–4-, 4–6-, 6–8-, and 8–10-hr intervals, respectively. The average plasma concentrations of water-soluble metabolites were 0.061, 0.070, 0.039, 0.023, and 0.013% of the dose of radioactivity per liter of plasma at 1, 3, 5, 7, and 9 hr, respectively, in the studies of Rietbrock and Abshagen (26). The respective individual quotients for the renal clearance of water-soluble metabolites, $(Cl^{H_2O}_p)_r = dU/dt/[A_p]$, were 17.0, 16.6, 14.4, 17.8, and 20.8 liters/hr and averaged 288 ± 17 ml/min.

The ratio of the renal clearance of water-soluble metabolites to creatinine clearance was 2.1 ± 0.1, indicating an excess of tubular secretion in addition to glomerular filtration.

An apparent linear terminal γ-phase with an average half-life of 36 hr was obtained from the semilogarithmic plots of $\Delta U/\Delta t$ and $U_\infty - Ut$ *versus* time for the water-soluble metabolites (Fig. 3). The slopes of these plots were similar to those observed for the terminal elimination γ-phase of the parent drug (40 hr). This terminal phase of the water-soluble metabolite fraction probably is dependent on its formation rather than its elimination, and the rate-limiting step probably is the rate of return of the parent drug from its deepest compartment, T'', with the overall rate constant of elimination of the water-soluble metabolites being a much faster process.

Absorption Efficiency and Evidence for First-Pass Metabolism—When the plasma concentrations and cumulative urine content of ^{3}H-β-methyldigoxin and digoxin were plotted against time in terms of the percent of the β-methyldigoxin dose per liter of plasma and the percent of dose, respectively, for the two dose levels of ^{3}H-β-methyldigoxin, the curves were superimposable for intravenous (25) and oral (Fig. 2) administration. Thus, the pharmacokinetics of β-methyldigoxin are dose independent, and the Dost principle (27) of corresponding areas is applicable to determine the degree of absorption. The areas (Table I) under the plasma concentration–time curves were estimated by graphical integration.

For the β-methyldigoxin curves, the area after oral absorption was 59 ± 6% of the area after intravenous administration and agreed with the fact that 60 ± 4% of the amount of β-methyldigoxin renally excreted at 144 hr and at infinite time after intravenous administration was renally excreted after oral administration. For the concentration of total radioactivity in plasma against time curves, the area after oral absorption was 76 ± 2% (n = 13) of the area after intravenous administration and was independent of dose. The amount of total radioactivity renally excreted after oral administration in 144 hr was 83 ± 3% (n = 14) of the amount renally excreted after intravenous administration. The relative percent renally excreted, oral–intravenous, did not reach reasonable constancy until after 24 hr, the minimum time that can be used for preliminary estimations of bioavailability.

This discrepancy between apparent oral absorption efficiencies from β-methyldigoxin and total radioactivity data indicates that ^{3}H-β-methyldigoxin was metabolized prior to its arrival in the systemic circulation, a first-pass phenomenon (28). This result is confirmed by the fact that apparent absorption efficiencies calculated from urinary excretion data (Table I) for digoxin (0.92 ± 0.12) and water-soluble me-

[a] Values for the microscopic rate constants of distribution and elimination were slightly modified to obtain the best fit from those obtained from the best analog computer fits of the plasma and urine data after intravenous administration (25). [b] Obtained from the best analog computer fit of the oral data with consideration of a lag time and a first-pass effect. The k_{GIB} corresponds to the intrinsic rate constant of absorption of unchanged drug absorbed. Its value is not expected to be coincident with the k_a value in Table I. The value for the latter was obtained by feathering and corresponds to the sum of the intrinsic rate constant and parallel first-order rate constant for the loss of the drug from the GI tract by other processes than absorption of unchanged drug. The value for $k_{M_1M_2} + k_{M_1\ \text{bile}}$ is 112% of $k_{M_1M_2}$, since the biliary clearance of digoxin is 12% of its total clearance (25). [c] Average values for both intravenous doses for the apparent volumes of distribution of the central compartment referenced to unbound drug in plasma were obtained from the best analog computer fit of the intravenous plasma data according to a four-compartment body model. The values of the volume of distribution of the central compartment in the oral experiments were postulated to be the same as in the intravenous experiments. [d] Values for the apparent volume of distribution of the central compartment referenced to total (bound and unbound) digoxin in plasma were obtained from the best analog computer fit of the data according to a three-compartment body model. [e] The value of the overall steady-state volume of distribution of digoxin was calculated (44) from $(V_p)_{DIG}[1 + (k_{MT'}/k_{TM}) + (k_{MT'}/k_{T'M})]$. [f] Determined from the best analog computer fits of the oral plasma data under the presumption of a first-pass phenomenon.

tabolite (1.9 ± 0.8) renal excretion were greatly in excess of the absorption efficiency of β-methyldigoxin (0.60). The area under the less precise plasma digoxin level–time curves after oral absorption of ^{3}H-β-methyldigoxin was 84 ± 10% of that area after intravenous administration and was confirmatory. A more detailed analysis of this first-pass phenomenon is given in Table II and indicates that 21.9 ± 2.8% (or 19.6 ± 1.7% by analog computer fitting) of the orally administered dose was metabolized in the GI lumen, gut wall, and/or the liver prior to absorption: 12.8 ± 4.0% to digoxin and 9.1 ± 4.0% (n = 4) to water-soluble metabolites.

Both digoxin and water-soluble metabolites probably are formed during the first pass and reach the systemic circulation. The extent of this total 22% first-pass metabolism in light of an estimated metabolic efficiency for β-methyldigoxin of 8% (25) implies a significant prehepatic first-pass metabolism. The former value, taken with the 60% absorption of β-methyldigoxin as such, implies that 18% does not reach the systemic circulation. The difference between the fecal recoveries of radioactivity between oral and intravenous administration, 25.9 ± 3.3 − 11.8 ± 0.7 = 14.1% (Table I), provides an alternative and similar estimate of the amount of material that does not reach the systemic circulation as β-methyldigoxin, digoxin, or other metabolites after oral administration. This amount may be an overestimate if the first-pass phenomenon after oral administration produces metabolites that are preferentially biliary excreted.

Evidence for an acid-catalyzed degradation of β-methyldigoxin *in vitro* and *in vivo* was given by Beerman (29), who determined individual radioactivities aspirated from the GI contents of volunteers administered labeled drug in polyethylene glycol. Non-β-methyldigoxin products were 28 and 15% of the total radioactivity in the gastric and duodenal aspirates, respectively, 10–15 min after drug administration. Their parameters of β-methyldigoxin absorption were similar to those found in this study; lag times were ~10 min, and peak concentrations occurred at ~50 min. β-Methyldigoxin incubated at pH 1.0 for 1 hr degraded 70% to digoxin, digoxigenin, and mono- and bisdigoxigenin digitoxosides. However, these three latter potential metabolites did not comprise any significant portion of the dose (<1%). The implication that the extent of the first-pass phenomenon may be a consequence of GI retention time was not confirmed by any apparent correlation with lag time for the studies in Table II.

Total radioactivities were measured in plasma and urine for 24 hr after administration of ^{3}H-β-methyldigoxin tablets. Peak plasma concentrations of 0.78 ± 0.17% of the administered radioactivity per liter were observed at 94 ± 21 min after administration. The corresponding value for the solutions given orally were 0.89 ± 0.11 at 72 ± 13 min (n = 11) after administration. A lag period of 15.8 ± 2.0 min between administration and the start of absorption was observed with the tablets compared to a lag period of 6.7 ± 1.6 min (n = 11) with the oral solutions; the latter was of the magnitude of the 5-min gastric emptying time of fluids in fasting individuals (30).

The ratios of the areas under the plasma concentration–time curves and the urinary excreted amounts of total radioactivity in 24 hr, corrected for the dose, were used to estimate the bioavailability of the tablets with respect to the solutions. They were 0.56 ± 0.05 and 0.92 ± 0.06 in plasma and urine, respectively, for tablets relative to the intravenous solutions and 0.87 ± 0.03 and 1.02 ± 0.05 in plasma and urine, respectively, for tablets relative to oral solutions. These findings indicate relatively complete absorption of β-methyldigoxin from the tablets relative to the solutions.

Pharmacokinetic Models for Orally Administered Solutions of β-Methyldigoxin and Digoxin and Their Fitting by Analog Computer—The existence of a first-pass metabolism of β-methyldigoxin was indicated by the fact that a greater percentage of the dose was excreted after oral administration relative to intravenous administration as the metabolite digoxin, M_1, and as the water-soluble metabolites, M_2 (Table II). The four-compartment body model for β-methyldigoxin and the three-compartment body model for the metabolite digoxin, developed previously for the intravenous case (25), were modified by adding a GI compartment to which the drug was administered with first-order absorption of β-methyldigoxin to the central compartment with rate constant k_{GIB} and with first-order generation of digoxin, M_1, with rate constant k_{GIM_1} to the central compartment of digoxin, M_1. Attempted analog computer fitting of the orally administered plasma β-methyldigoxin data to this model, using the microscopic rate constants obtained by fitting the intravenous data, consistently predicted initial plasma concentrations and urinary excreted amounts of digoxin greater than those actually observed. When this model was modified to include a first-pass metabolism directly to water-soluble metabolites in their

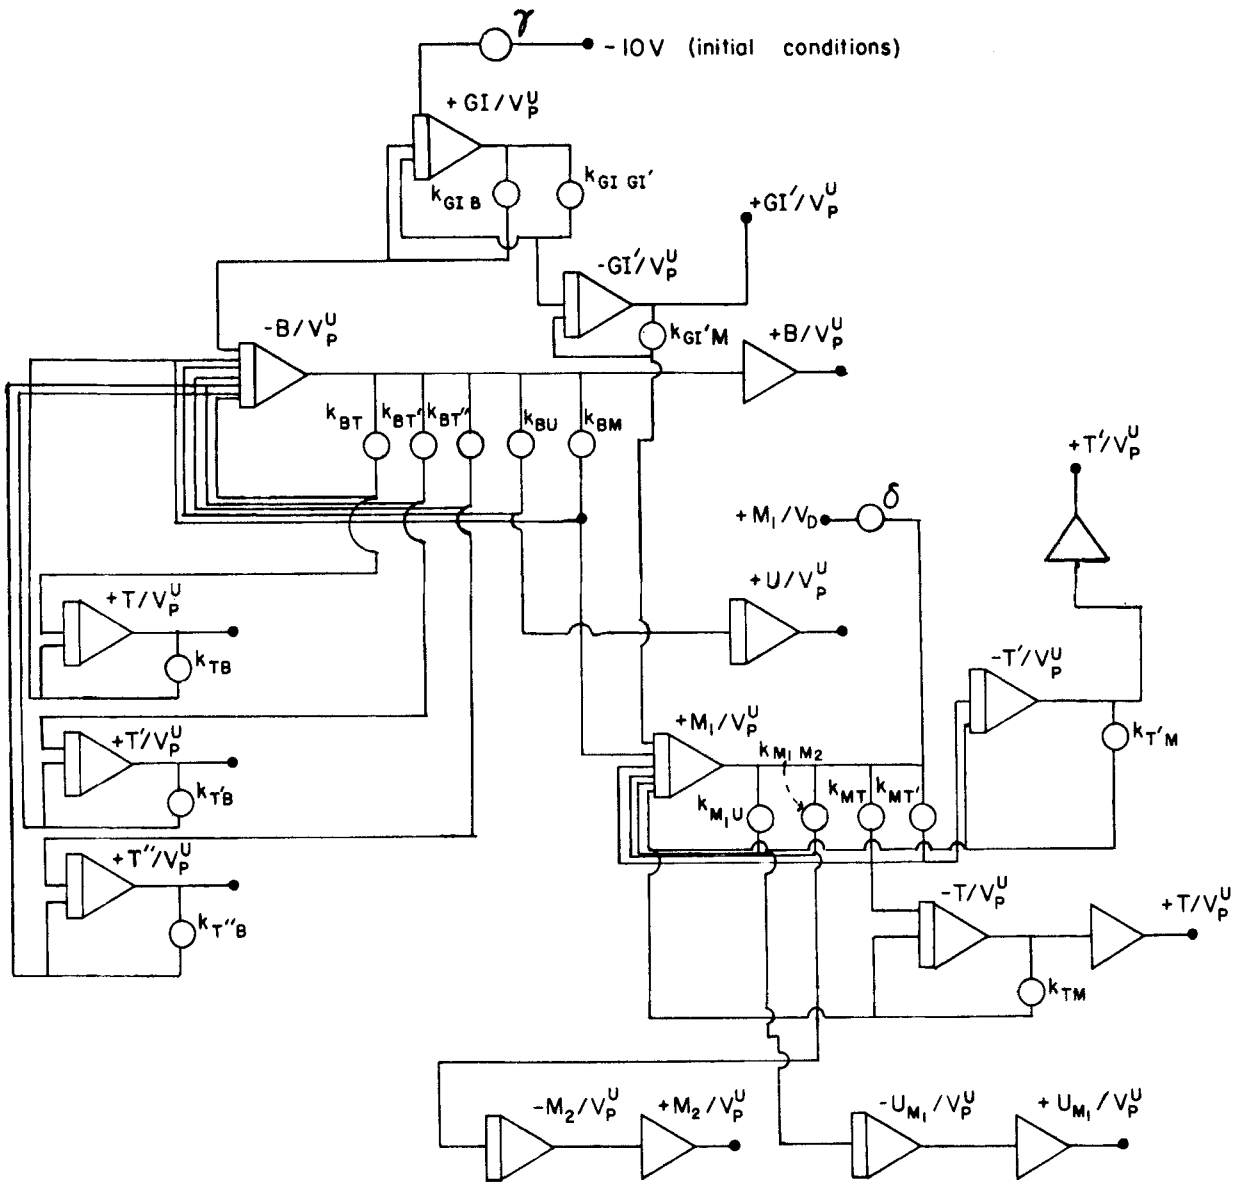

Figure 4—*Analog computer program to fit simultaneously the model of Scheme I to the experimental plasma and urine data where* $k_{GI'M_2}$ *is omitted and only* M_2 *as* $M_2/V_p{}^u$ *is generated. The route of* M_1 *to bile*$_{M_1}$ *is also omitted. Thus,* $k_{M_1M_2}$ *in the program and Table III was actually* $k_{M_1M_2} + k_{M_1 bile}$*, which overestimated the former by 12% since the biliary clearance of digoxin was estimated to be 36 ml/min out of a total clearance of 290 ml/min for digoxin in the intravenous studies* (25).

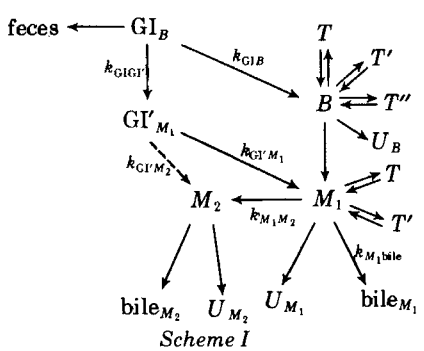
central compartment, the predicted cumulative terminal urinary amounts of digoxin generated by the analog computer were consistently lower than those actually observed.

These facts can be rationalized by postulating a delayed absorption of GI-generated digoxin, M_1, and/or water-soluble metabolites, M_2. Two alternative models are given in Scheme I, with and without the pathway indicated by the dashed line of rate constant $k_{GI'M_2}$. These models presume a significantly retarded production and absorption of GI-produced digoxin, $GI'M_1$, which is consistent with the literature reports (31) that digoxin is absorbed in the lower part of the small intestine and would be characterized by first-order rate constants $k_{GI,GI'}$ and $k_{GI'M_1}$, respectively. The plasma β-methyldigoxin and digoxin experimental values in concentration per liter were fitted to Scheme I (omitting the pathways characterized by $k_{GI'M_2}$ and k_{M_1bile}) by the analog computer program of Fig. 4. Concomitantly, the data for amounts of drug and metabolites in urine divided by the apparent volume of distribution of the central compartment for β-methyldigoxin, $(V_p{}^u)_{BMD}$, obtained in the intravenous studies were fitted.

Initial estimates of the amount of β-methyldigoxin absorbed either as drug or metabolites were made from the urinary recovery of unchanged drug and metabolites after multiplying by their respective ratios of total clearance to renal clearance. However, the initial condition, placed on



Scheme I

the GI_B compartment representing the dose, D, of ^{3}H-β-methyldigoxin that was actually absorbed as drug or metabolites [divided by this apparent volume of distribution $D/(V_p{}^u)_{BMD}$], was varied to give the best fit of the model since it cannot be presumed that the total dose, either as drug or metabolites, was transferred to the body. The $GI_B \rightarrow$ feces in Scheme I represents the route of fecal elimination of the total dose of ^{3}H-β-methyldigoxin not absorbed as drug or metabolite.

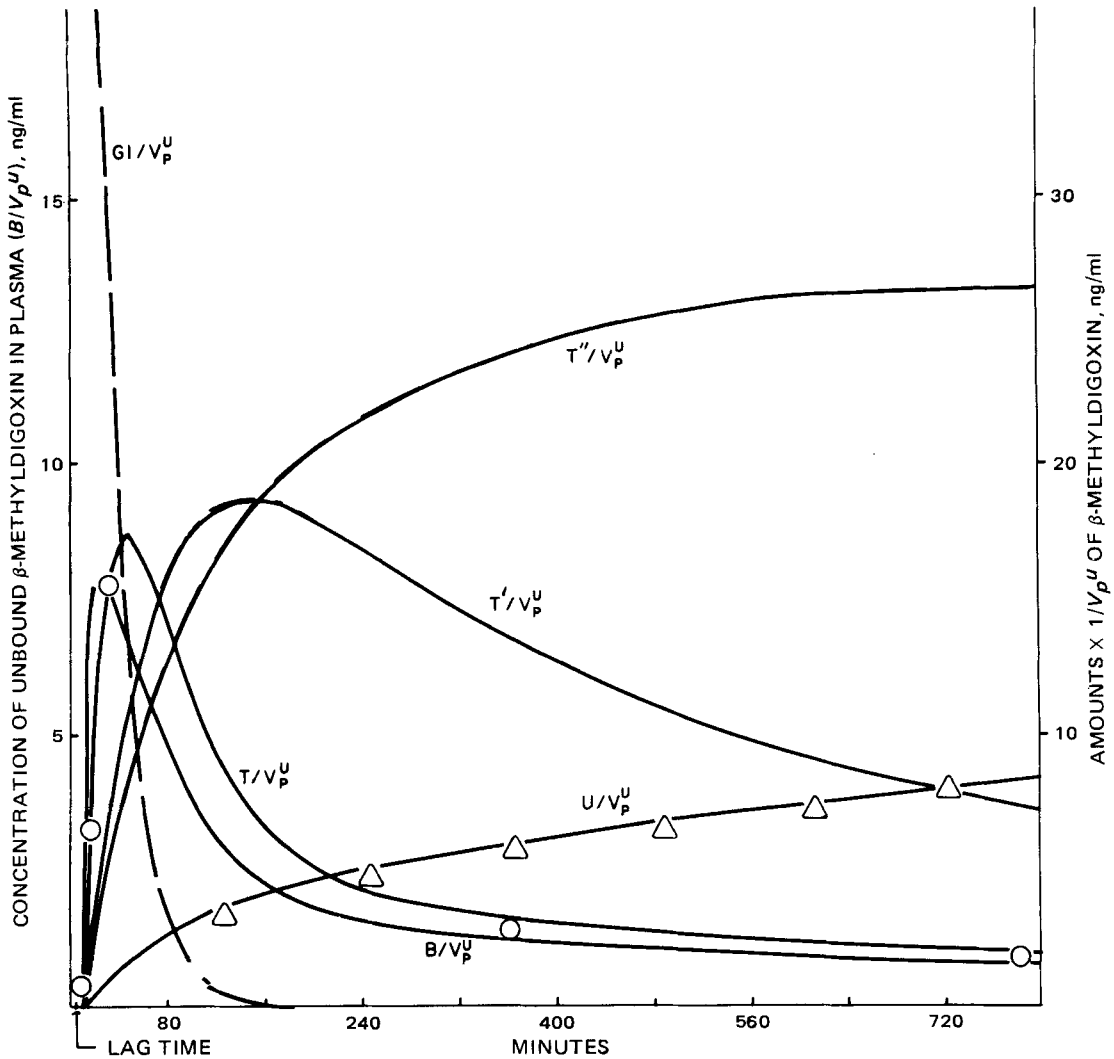


Figure 5—*Typical analog computer fitting of plasma water (unbound drug) concentration (O, left scale) and urine (Δ, right scale) data of β-methyldigoxin for 0.6-mg oral solution administration to Subject C over 13 hr in accordance with a four-compartment body model and a first-pass effect. All data are given as per milliliter of the volume of distribution of the central compartment referenced to unbound β-methyldigoxin, and the apparent concentrations of drug in the various tissues (GI, T, T′, and T″) and urine (U) (right scale) are generated with the parameters of Table III.*

The simultaneous analog computer fitting of the plasma and urine generated drug and metabolite amounts in peripheral tissues, urine, and the GI tract in terms of arbitrary concentrations (*i.e.*, amounts divided by $V_p{}^u$). The generated plasma concentrations of the metabolite $M_1/(V_p{}^u)_{BMD}$ were multiplied by a constant $\delta = (V_p{}^u)_{BMD}/(V_p)_{DIG}$ to fit best the plotted metabolite $M_1/(V_p)_{DIG}$ data so that the apparent volume of distribution, $(V_p)_{DIG}$, of M_1 could be calculated from the obtained values of δ. Lag times of absorption, 8–24 min, had to be assumed to fit best the first portion of the β-methyldigoxin data. Good fits always were obtained for the drug concentration in plasma and urine and the apparent concentration of M_1 in urine—*viz.*, $U_{BMD}/(V_p{}^u)_{BMD}$ and $U_{M_1}/(V_p{}^u)_{BMD}$; typical examples are given in Figs. 5 and 6. Only minor adjustments in the values of the microscopic rate constants found in the intravenous experiments were necessary to give optimal fits of the oral data. Their values are given in Table III.

Comparisons of Bioavailabilities of Orally Administered β-Methyldigoxin and Orally Administered Digoxin—The intrinsic bioavailability of unchanged ^{3}H-β-methyldigoxin after oral administration of solutions with respect to intravenous administration was 59.5 ± 3.3% (n = 12), evaluated by both renal excretion and areas under the unbound plasma level–time curves (Table I). The values ranged from 41 to 74% among all subjects, although urinary excretion estimates ranged only from 50 to 67% and, if one value was discarded, from 57 to 67%. However, this finding does not completely characterize the pharmacodynamic availability of such oral solutions since cardioactive digoxin is formed systemically (25, 32) from β-methyldigoxin and from first-pass prehepatic and hepatic metabolism of orally administered β-methyldigoxin (Table II). It was estimated previously (25) that the fraction of digoxin formed from the systemic β-methyldigoxin was 40% of the intravenously administered dose (34.5% renally eliminated and 5.5% biliary excreted). Thus, 0.40 × 60 = 24% is the amount of the total oral dose of ^{3}H-β-methyldigoxin absorbed as such that delivers digoxin to the body. The cardioactive digoxin formed by the first pass that reaches the systemic circulation as such (Table II) was 12.8 ± 4.0%. A total of 60 + 13 = 73% of digoxin plus β-methyldigoxin is absorbed.

However, the total systemic bioavailability of these cardioactive agents, digoxin plus β-methyldigoxin, on the premise of pharmacodynamic equivalence and similar terminal overall elimination rates of ~40 hr half-life, would be 60% (as β-methyldigoxin delivered directly) +24% (as digoxin derived from systemic β-methyldigoxin) + 13% (as digoxin derived from first-pass transformation of β-methyldigoxin prior to absorption) = 97%. On the same premise of pharmacodynamic equivalency of β-methyldigoxin and digoxin, intravenous β-methyldigoxin would deliver 100% (as β-methyldigoxin) + 40% (as digoxin derived from systemic β-methyldigoxin) = 140% of an equivalent dose of intravenously administered digoxin. Thus, the oral pharmacodynamic bioavailability of β-methyldigoxin relative to its intravenous administration would be 97/140 = 69%, where the oral pharmacodynamic bioavailability of β-methyldigoxin relative to equimolar intravenously administered digoxin, on the premise of equimolar pharmacodynamic equivalency, is 97%. These calculations were based on the presumption that the metabolites other than digoxin did not possess cardioactivity.

The proper comparison of the relative bioavailabilities of orally administered β-methyldigoxin and orally administered digoxin should be

Table IV—Critical Evaluations of Solution and Solid Dosage Form Oral Bioavailabilities of Digoxin Referenced to Intravenous Administration from Major Studies in the Literature

Reference	Oral Vehicle	Assay	Mean Estimated Absorption Efficiency, %	Method of Evaluation	Comments	Dose, mg	t_{max} (approx), min	$C_{max,po}$, % Dose/Liter of Plasma

based on crossover studies of specifically quantified separated drug and metabolites monitored in the same subjects where the results from intravenous administration of both drugs are used as relative standards. An alternative is to compare such independent studies on each drug. Surprisingly, no bioavailability comparisons of digoxin oral solutions and intravenous administrations have been attempted with specific assays of drug and metabolites in the same subjects. In general, estimates of absorption efficiency of digoxin in the literature were made by nonspecific methods using total radioactivity or radioimmunoassay.

Beerman *et al.* (31) were especially critical of a claim (33) for 85% oral absorption from a solution with different subject populations. The claim was based on the assumption that the fecal excretion of radioactivity within 5 days represented unabsorbed material since the total recovery in urine and feces averaged only 49% within 7 days. They suggested that polar metabolites may have been lost on chloroform extraction of fecal radioactivity and that digoxin decomposition before absorption was not considered. The criticism (31) of this paper (33) appears justified. The renally excreted percent of administered tritiated digoxin in Table 2 of Ref. 33 showed that the apparent bioavailability of an orally administered solution to that intravenously administered for more than 20 subjects was 100 × 34% (po)/74% (iv) = 46%, a far cry from the 85% estimated.

The urinary excretion of intravenously administered tritiated digoxin in six other patients, with biliary fistula and bile from the T-tube completely collected, was 58.5% of the dose, indicative of a minimum of 100 × {[74% (iv) − 59% (iv, fistula)]/74% (iv)} = 20% enterohepatic recirculation of digoxin. The presumption would be the same made by Doherty *et al.* (33) that the two populations, with and without bile collection, were similar. A direct measurement of biliary excretion was 8.1 ± 1.4% (*SEM*), which was significantly less then the 20% estimated. However, since 1.3 ± 0.4% (*SEM*) fecal excretion was observed with the biliary collection, it was obvious that the T-tube was not completely effective and that the 7–8% estimate (33) of enterohepatic recycling was an underestimate. The fecal excretion of non-biliary-cannulated subjects on intravenous administration was reported as 11.3 (33) and 14.8% (34). Beerman *et al.* (31) demonstrated significant decomposition of orally administered digoxin in the GI tract and claimed that absorption of intact digoxin administered in water solution was approximately 50%.

Wagner *et al.* (35) were critical of their own estimate of 80% oral bioavailability as digoxin of a 5% dextrose solution relative to intravenous bioavailability as performed in two subjects, 78.3 and 82.0%, respectively. Areas under the radioimmunoassay plasma level–time curves were used for evaluation; it was admitted that any gastroenterohepatically formed metabolites, as by first pass, would have led to overestimation. It was also stated that the use of total radioactivity and radioimmunoassay methods make extensive pharmacokinetic analysis tenuous.

Johnson *et al.* (36), who also used radioimmunoassay, studied intravenous and oral solution absorption of digoxin in eight volunteers. They estimated that oral absorption from an elixir was 78% of the intravenous absorption by the area under the curve method and 75% by urinary excretion, with the latter ranging from 57 to 96% in different subjects. This was admittedly not digoxin *per se*. The absorption of digoxin from tablets[3] relative to intravenous administration varied between 44 and 82% in different subjects with a mean of 64%. These authors were also critical of the previously mentioned claim of 85% relative absorption (33) and a similar claim of high relative absorption (37) of a 40% propylene glycol solution. In the latter case, the stated percentage urinary excretion of injected digoxin by radioimmunoassay was well below other reported values; other investigators could only claim 65% relative absorption for such an elixir (38).

When steady-state procedures were used to estimate the relative bioavailability by the authors that had previously claimed high absorption (37), the absolute bioavailability of a digoxin solution relative to intravenous bioavailability was only radioimmunologically estimated as either 77 or 87%, depending on the magnitude of the oral dose (39). However, when the bioavailability estimates within an individual by the different methods used are compared, gross inconsistencies become apparent and cast suspicion on the averaged estimates. All of these radioimmunoassay studies can be criticized for their nonspecificity. In addition, Huffman *et al.* (39), who studied apparent dose dependency, claimed that the area under the curve after oral digoxin solution administration was not proportional to dose. If true, this finding signifies that such a method for estimating relative bioavailability is not valid for digoxin.

Estimates of oral absorption efficiencies, relative to intravenous administration in the same subjects, with presumably optimumly bioa-

[3] Lanoxin.

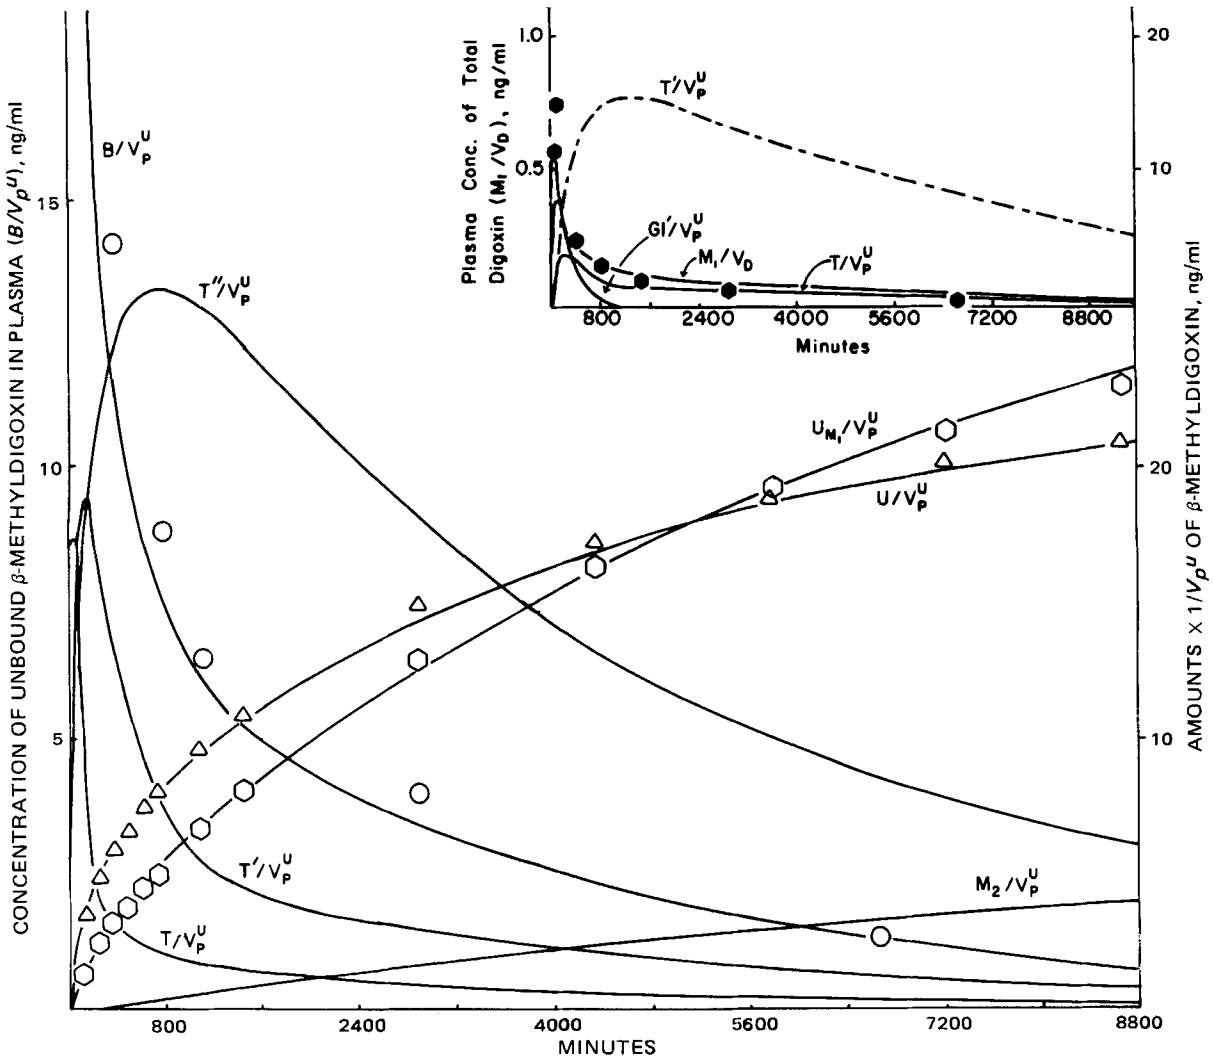

Figure 6—*Typical analog computer fitting of plasma water (unbound drug) concentration (○, left scale) and urine (△) data of β-methyldigoxin and (○) digoxin (right scale) for 0.6-mg oral solution administration to Subject C over the full time scale of 144 hr. All data are given as per milliliter of the volume of distribution of the central compartment referenced to unbound β-methyldigoxin, except for the plasma digoxin data (●) in the inset which are given as the observed concentration in terms of its own volume of distribution, V_D. The apparent concentrations of β-methyldigoxin in its various tissues (T, T′, and T″) and GI tract (GI′), M_2 in the body, and digoxin in its tissues (T and T′) are generated (right scale) with the parameters of Table III.*

vailable tablets where radioimmunoassay was used, included 57% by area methods (35) and 62% (39) and 64% (36) by urinary excretion. In one instance of total radioactivity measurements, the estimate for oral absorption efficiency of solid dosage forms compared to intravenous administration was 80.2 ± 8.8% for digoxin (40). In another, based on 96-hr urine collections, the estimates were 69.7 ± 7% for digoxin and 90.7 ± 13.1% for β-methyldigoxin (41). However, the fact that no digoxin was found in these urines (41) as a β-methyldigoxin metabolite is confusing in light of our consistent recovery of approximately equivalent amounts of ^{3}H-digoxin and ^{3}H-β-methyldigoxin in urine after ^{3}H-β-methyldigoxin administration (Table I).

A critical summary of the best estimates of absolute bioavailability of oral digoxin solution and solid dosage forms relative to intravenous administration is given in Table IV.

The appearance of a peak plasma concentration for orally administered digoxin solutions of 0.70–0.75% of total dose/liter of plasma by total assay methods at about 60–90 min (Table IV) is not inconsistent with the oral solution absorption data of β-methyldigoxin based on total radioactivity with a peak plasma level of 0.89 ± 0.11% at 72 ± 13 min and a lag time of 6.7 ± 1.6 min (n = 11). The tablet data for β-methyldigoxin showed comparable values of 0.78 ± 0.17% at 94 ± 21 min with a lag time of 15.8 ± 2.0 min but were significantly greater than the 0.37% values shown in several cases for administered digoxin tablets (36, 37).

In summary, oral absorption of digoxin from solutions and tablets varies widely with the individual (Table IV), consistent with the arguments that GI or other prehepatic degradations are the determining processes in digoxin bioavailability. Specific analytical procedures have not been generally attempted for digoxin. Thus, mean bioavailability estimates of oral solutions of digoxin assayed by methods nonspecific for digoxin relative to intravenous administration range from 50 to 93% (Table IV). Comparatively, the radioactivity absorbed for β-methyldigoxin solutions was 76 ± 2% by the area method and 83 ± 3% by urinary excretion at 144 hr compared to intravenous administration. β-Methyldigoxin plus its derived metabolite digoxin had a systemic bioavailability of 59.5 ± 3.3% as β-methyldigoxin and 12.8 ± 4.0% as digoxin for a total of 72% relative to intravenous administration in these studies using specific analysis.

It is difficult to state conclusively that β-methyldigoxin was more effectively and reproducibly absorbed than digoxin administered *per se* on oral administration based on this evidence because of the obvious difficulty in appraising the digoxin studies in the literature. Such a decision can only be made if proper crossover intravenous and oral solution studies of β-methyldigoxin and digoxin are made in the same subjects using specific analyses of the separated drug and metabolites.

However, there are suggestions of advantages of β-methyldigoxin relative to digoxin. β-Methyldigoxin apparently delivers more cardioactive agent per mole administered than digoxin. In these studies, there was more consistency in measured oral bioavailability among and within individuals (Table I) than had been indicated for digoxin (36, 39). If this finding indicates that β-methyldigoxin has a more reproducible

availability within and among individuals, it is clinically significant. The tablet studied had a bioavailability equivalent to that of the oral solution by the criteria used. Although a pilot-plant production lot rather than a normal production lot was used, the study indicates that a tablet of β-methyldigoxin can be made that is equivalent to an oral solution, something that cannot be said for digoxin.

There are several possible rationales as to why β-methyldigoxin may have properties that could favor it over digoxin. The observed 11-fold greater water solubility[4] of β-methyldigoxin (46 mg/100 ml at pH 7.5 and 22°) over digoxin (4 mg/100 ml) implies the relatively greater rate of dissolution of β-methyldigoxin. On the premise that the dissolution rate from solid dosage forms is the limiting step in glycoside availability from tablets, this property should favor β-methyldigoxin. The fact that β-methyldigoxin, notwithstanding its greater aqueous solubility, is a less polar compound than digoxin (42) and has a higher partition coefficient into chloroform—*viz.*, 85.1 to digoxin's 9.4 (41), implies that its penetration of the lipid-like GI wall may be more facile than digoxin and thus abet a more reproducible and possibly more complete absorption (3).

Pharmacokinetics of β-Methyldigoxin in Healthy Humans III: Pharmacodynamic Correlations

PETER H. HINDERLING * and EDWARD R. GARRETT ˣ

Abstract □ Significant decreases in left ventricular ejection time and heart rate were observed after the oral and intravenous administration of β-methyldigoxin. The time course of this action correlated with the time course of β-methyldigoxin and its active metabolite, digoxin, in their deepest pharmacokinetic compartments and not with their plasma levels. This pharmacodynamic activity peaked (decrease of 6.3% at 0.6 mg iv and 3.5% at 0.3 mg iv; decrease of 3.8% at 0.6 mg po and 4.5% at 0.3 mg po) at about 10 hr, concomitantly with the amounts of β-methyldigoxin in its deepest compartment and showed a terminal half-life equivalent to the 41 hr for β-methyldigoxin. The relative peak heights and area under the ejection time–time curves indicated a linear dose–response relationship on intravenous administration and an effect greater than that reported for larger amounts of digoxin. The time course of heart rate action correlated (8.3 and 12.5% decreases with 0.3 and 0.6 mg iv, respectively; 6.5 and 9.5% decreases with 0.3 and 0.6 mg po, respectively) with the time course of β-methyldigoxin and its metabolite digoxin in shallower pharmacokinetic compartments (peaks at ~80 min intravenously and 135 min orally), and significant effects had disappeared by 10 hr after drug administration. This finding indicated that the biophases differ for ejection time and heart rate action. Mean arterial blood pressure could not be correlated with the time course of drug, although a small consistent decrease (4–8%) was observed from 22 to 72 hr after drug administration.

Keyphrases □ β-Methyldigoxin—oral and intravenous, effect on left ventricular ejection time and heart rate correlated with pharmacokinetic parameters, humans □ Pharmacokinetics—β-methyldigoxin, oral and intravenous, correlated with effect on left ventricular ejection time and heart rate, humans □ Pharmacodynamics—β-methyldigoxin, oral and intravenous, effect on left ventricular ejection time and heart rate correlated with pharmacokinetic parameters, humans □ Cardiac glycosides—β-methyldigoxin, oral and intravenous, effect on left ventricular ejection time and heart rate correlated with pharmacokinetic parameters, humans

Cardiac glycosides have been shown to exert positive inotropic and negative chronotropic effects both in patients with congestive heart failure (1, 2) and in healthy subjects (3–5). Effects on the left ventricular performance are reflected in shortening of the left ventricular ejection time interval (LVET) when corrected for the heart rate. Noninvasive methods can monitor glycoside effects on these cardiovascular parameters (6).

Few attempts have been made to correlate simultaneously measured pharmacokinetics and pharmacodynamics of glycosides (7, 8). In many cases, both the parent drug and some of its metabolites are pharmacologically active (9). The availability of a specific assay is mandatory to correlate specifically the observed effects and the individual kinetics of the parent drug and its active metabolites. Such correlations may lead to the proper characterization of the biophases of drug and metabolite action.

β-Methyldigoxin undergoes significant metabolism to active metabolites such as digoxin in humans (10, 11) and has demonstrated positive inotropic and negative chronotropic effects in patients with congestive heart failure and in healthy subjects (12, 13). The purposes of these studies were to monitor such pharmacodynamic parameters with time in normal volunteers administered 0.3 and 0.6 mg of β-methyldigoxin both orally and intravenously and to relate these effects with the previously evaluated pharmacokinetics of the drug and its metabolites (11, 14).

EXPERIMENTAL[1]

The left ventricular ejection time derived from the external carotid pulse[2] and the heart rates[3] were simultaneously recorded on a three-channel recorder[4] (paper speed of 50 mm/min). The left ventricular ejection time was measured from the beginning of the upstroke to the trough of the incisura (2). The heart rate was calculated from the quotient 60/(average RR interval) of at least 10 consecutive beats (3). Besides the standard ECG, a vector ECG was recorded on a three-channel recorder[5]. The blood pressure was measured according to Korotkov, using an inflatable cuff connected to a mercury manometer on the left a brachialis. The diastolic blood pressure was measured during phase 5.

For all measurements, each individual was in a prostrate position. The subjects were prostrate during the first 24 hr after β-methyldigoxin administration and then were ambulant. They were in a prostrate position for at least 30 min prior to and during measurements taken between 24 and 144 hr after drug administration. Details of the concomitant pharmacokinetic studies on β-methyldigoxin were given previously (11, 14).

Sufficient control values were taken in each study prior to drug administration before and after the placement of the needle and the catheter. The carotid arterial pulse and the ECG's were taken continuously up to 30 min, at 5-min intervals up to 60 min, at 15-min intervals up to 4 hr, at 30-min intervals up to 11 hr, and then at 12-hr intervals up to 72 hr after drug administration. In some experiments, the measurements were expanded to 132 hr.

The left ventricular ejection time values were determined in Subjects A–F. Subject G was excluded because the beginning of the upstroke could not be defined clearly in his carotid pulse recordings. The experimentally determined values were normalized (3) for the heart rate, HR:

$$\text{LVETI} = \text{LVET} + 0.0016 \times \text{HR} \qquad \text{(Eq. 1)}$$

where LVETI is the left ventricular ejection time index. The stroke volume, SV, was calculated (2) for the control period from:

$$\text{SV} = \frac{\text{LVETI} - 0.266 + (0.0017 \times 82)}{0.0017} \qquad \text{(Eq. 2)}$$

and the cardiac output, CO, for the control period was calculated from:

$$\text{CO} = \text{SV} \times \text{HR} \qquad \text{(Eq. 3)}$$

The LVETI values were expressed as percent of the control values taken prior to drug administration (Table I).

The blood pressure was measured in Subjects A–G at 5-min intervals up to 30 min, at 15-min intervals up to 4 hr, at 30-min intervals up to 11 hr, and then at 12-hr intervals up to 72 hr after drug administration. The mean arterial blood pressure was calculated by adding to the diastolic pressure one-third of the difference between the experimental systolic and diastolic pressures (15). The cardiac outputs measured during the control period before drug administration ranged between 5390 and 6257 ml/min in all four studies and all individuals and were normal (16).

[1] The volunteers were informed orally and in writing of any and all potential risks and of the experimental protocol prior to the studies; verbal consent and written consent were obtained. The human experimentation, radioactive substance, and clinical research committees of the Health Center, University of Florida, reviewed and approved the research protocol prior to the studies. A physician was in attendance during the studies.

0.400 ± 0.010		48	1.079 ± 0.099	56

RESULTS AND DISCUSSION

Tolerance of β-Methyldigoxin—No systematic changes were found in the clinical laboratory data obtained in the subjects prior to each of the four administrations of β-methyldigoxin (11, 14). In particular, the serum sodium and potassium concentrations, reportedly critical (16) for the myocardial glycoside uptake and effect, were within the normal range for all subjects and all studies. The administered β-methyldigoxin was well tolerated at the two dosage levels (0.6 and 0.3 mg) and by both the oral and intravenous routes. No adverse cardiac effects were observed.

Pharmacodynamic Action on Left Ventricular Ejection Time of β-Methyldigoxin and Digoxin on β-Methyldigoxin Administration—The LVETI and RR values obtained for each volunteer during the control period prior to oral and intravenous administration of drug at two dosage levels are listed in Table I. The LVETI values for all subjects were within the normal range of 0.395 ± 0.017 for healthy male adults (6). Plots of the percent LVETI decrease against time, averaged for all subjects, showed a maximal decrease at 10–22 hr after both dosages of β-methyldigoxin administered intravenously or orally (Figs. 1 and 2).

The subsequently decreasing effect on the LVETI was observable for the 132-hr (0.6 mg iv) and 72-hr periods of observation (0.3 mg iv, 0.6 and 0.3 mg po), respectively.

Reuning *et al.* (8) stated that the percent LVETI decrease observed with time by Shapiro *et al.* (7) can be best correlated with tissue levels of digoxin generated by the analog computer from plasma levels on the basis of a two-compartment body model for digoxin. The pharmacokinetics of both β-methyldigoxin and the active main metabolite, digoxin, have to be considered to correlate the magnitude and time course of the LVETI effect on β-methyldigoxin administration.

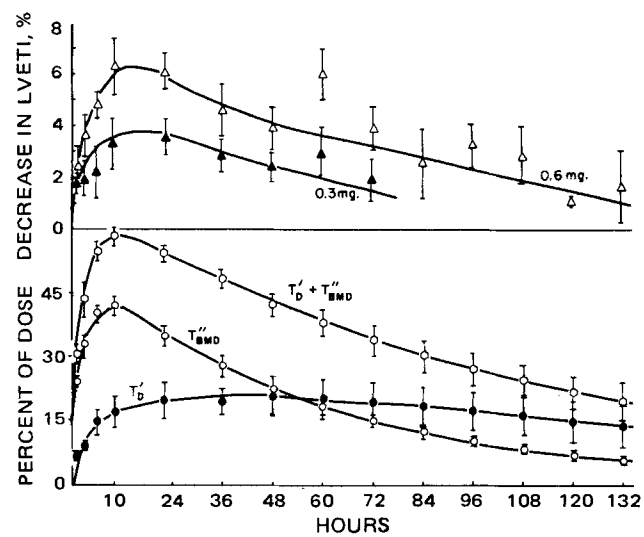

Figure 1—*Apparent correlation between the mean percent LVETI decrease at 0.3 (▲) and 0.6 (△) mg of β-methyldigoxin (BMD) and the mean amounts of β-methyldigoxin (○) and digoxin (●) in their respective deepest tissues, T_{BMD}'' and T_D', and in their sum (○) in percent of the administered intravenous dose of β-methyldigoxin as a function of time. The LVETI values obtained prior to drug administration served as controls. The vertical bars indicate ±1 SEM of the means. The amounts in the tissues were generated by the analog computer from the best fits of the experimental plasma and urine data for all studies. They are given as percent of dose and are valid for both dose levels since the intravenous pharmacokinetics were independent of dose (11).*

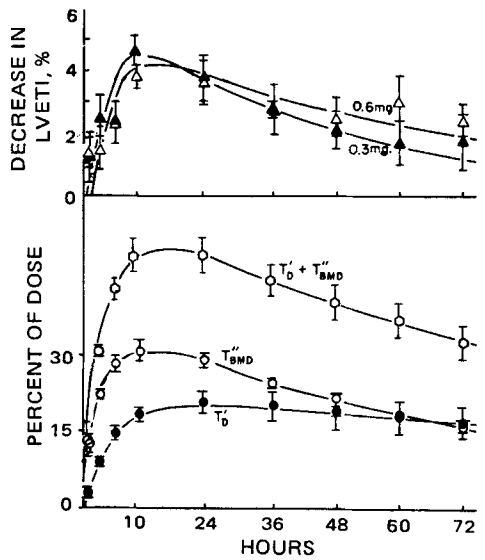

Figure 2—*Apparent correlation between the mean percent LVETI decrease at 0.3 (▲) and 0.6 (△) mg of β-methyldigoxin and the mean amounts of β-methyldigoxin (○) and digoxin (●) in their respective deepest tissues, T_{BMD}'' and T_D', and in their sum (○) in percent of the administered oral dose of β-methyldigoxin as a function of time. The LVETI values obtained prior to drug administration served as controls. The vertical bars indicate ±1 SEM of the means. The amounts in the tissues were generated by the analog computer from the best fits of the experimental plasma and urine data for all studies. They are given as percent of dose and are valid for both dose levels since the oral pharmacokinetics were independent of dose (14).*

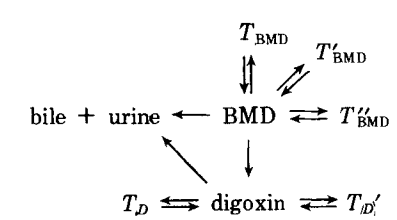
Statistically significant negative linear correlations existed between the averaged LVETI effect and both the averaged amounts of parent drug in its deepest compartment, T_{BMD}'', and the averaged amounts of digoxin in its deepest compartment, T_D', for both modes of administration and both dose levels (Table II, Scheme I, and Figs. 1 and 2). The amounts of β-methyldigoxin and digoxin in these tissues as percent of the dose were generated by the analog computer from the best fit of the experimental data in plasma and urine (11, 14). No such correlations could exist between the LVETI effect and the amounts of drug in the other tissues or plasma since the maxima of the former (Figs. 1 and 2) occurred well after the maximum values of the latter (11, 14). The peak amounts of the sum of β-methyldigoxin in the moderately deep tissues, T_{BMD}' and T_D, occurred at 80 and 135 min for intravenous (Figs. 3 and 4) and oral (Fig. 5) administration, respectively. The peak amounts in the plasma and shallower tissues such as T_{BMD} occurred much earlier (Fig. 5) (11, 14). The assumption of a linear relationship between drug content in the deepest tissues and its effect on ventricular performance during the time course of both cannot be excluded.

The peak effect of the averaged LVETI decrease occurred at 10–22 hr after drug administration for both dosage levels and routes (Figs. 1 and 2). The β-methyldigoxin amounts in T_{BMD}'' peaked at 10–12 hr after intravenous administration and at 13 hr after oral administration. The



Scheme I—Simplified pharmacokinetic model for the distribution of β-methyldigoxin from its central compartment to its successively deeper tissues in the order T_{BMD}, T_{BMD}' and T_{BMD}'' and for the distribution of metabolically generated digoxin to its successively deeper tissues in the order T_D and T_D'.

Table II—Correlations[a] between Amounts[b] of β-Methyldigoxin and Digoxin in Their Respective Tissue Compartments and the LVETI and Heart Rate Change

Dose, mg	Modes of Administration	LVETI *versus* T''_{BMD}	LVETI *versus* T_D'	Heart Rate *versus* T'_{BMD}	Heart Rate *versus* T_D
0.6	Intravenous	$r = -0.86, p \leq 0.01$	$r = -0.41, p \leq 0.20$	$r = -0.84, p \leq 0.01$	$r = -0.85, p \leq 0.01$
0.3	Intravenous	$r = -0.41, p \leq 0.50$	$r = -0.76, p \leq 0.02$	$r = -0.83, p \leq 0.01$	$r = -0.82, p \leq 0.01$
0.6	Oral	$r = -0.72. p \leq 0.05$	$r = -0.85, p \leq 0.01$	$r = -0.63, p \leq 0.10$	$r = -0.40, p \leq 0.10$
0.3	Oral	$r = -0.87, p \leq 0.01$	$r = -0.51, p \leq 0.20$	$r = -0.63, p \leq 0.01$	$r = -0.47, p \leq 0.05$

[a] r is the correlation coefficient, and p is the probability of estimate that the correlation is random. [b] As percent of β-methyldigoxin dose.

amounts of digoxin in T_D' were at maximum considerably later, at 34 or 43 hr after intravenous administration and at 20–29 hr after oral administration (11, 14).

Maximum decreases of the LVETI of 5.6 and 7.2% were reported in healthy volunteers by 6 hr after 1.6 and 1.0 mg iv of digoxin, respectively (5, 7). After 3.2 mg po of digoxin, a maximum decrease of 4.7% was reported at 12–24 hr after dosing (5). These values are not inconsistent with what was observed herein for β-methyldigoxin: maximum decreases of LVETI of 6.3 and 3.5% at about 10 hr after 0.6 and 0.3 mg iv of β-methyldigoxin, respectively. It may even imply a greater potency for the β-methyldigoxin over digoxin at equivalent doses, consistent with the fact that intravenously administered β-methyldigoxin delivers 140% more cardioactive material than an equivalent dose of digoxin (14).

A linear dose–LVETI effect relationship was indicated for deslanoside (5). In the intravenous studies reported here, the maxima (6.3% for 0.6 mg and 3.5% for 0.3 mg of β-methyldigoxin) and areas under the effect–time curves up to 72 hr (364% hr for 0.6 mg and 197% hr for 0.3 mg of β-methyldigoxin) were proportional to the dose. This finding is indicative of a linear dose–effect relationship. In the oral studies, the observed maxima (3.8% for 0.6 mg and 4.5% for 0.3 mg) and areas under the effect–time curve up to 72 hr (205% hr for 0.6 mg and 192% hr for 0.3 mg of β-methyldigoxin) were practically the same for both dose levels. However, the variability in the effect data was larger in the oral studies.

Calculations of the bioavailability of the two oral dosages of β-methyldigoxin relative to the respective intravenous dose from the areas under the LVETI effect–time curves, with admittedly high variability, gave values of 60 and 100% for 0.6 and 0.3 mg, respectively. It was shown previously (14) for both doses that an orally administered β-methyldigoxin solution delivered 70% of the cardioactivity of an equivalent intravenous dose on the presumption that the drug and its metabolite, digoxin, had equivalent cardioactivity in the body.

Pharmacodynamic Action on Heart Rate of β-Methyldigoxin and Digoxin on β-Methyldigoxin Administration—Plots of the percent heart rate decrease against time, averaged for all subjects, showed significant decreases after drug administration with apparent maximal decreases of 8.3% at 150 min and 12.2% at 80 min for 0.3- and 0.6-mg iv doses, respectively, indicative of a dose dependency (Fig. 3). The amounts of β-methyldigoxin in compartment T'_{BMD} and of digoxin in T_D both peaked at approximately 80 min after intravenous administration of β-methyldigoxin (Figs. 3 and 4). After oral administration of β-methyldigoxin, maximal amounts were reached at about 135 min for β-methyldigoxin in T'_{BMD} and at 155 min for digoxin in T_D (Fig. 5), where maximal heart rate decreases were 6.5 and 9.5% at 90–120 and 90 min for 0.3- and 0.6-mg po doses, respectively. The variabilities in the data were too great to conclude dose dependence on oral administration.

Statistically significant linear negative correlations existed between percent heart rate effect and amounts in percent of the dose of β-methyldigoxin in its moderately deep compartment, T'_{BMD}, and of digoxin in its shallower compartment, T_D, for both modes of administration and both dose levels of β-methyldigoxin (Table II and Figs. 3–5) but not with the amounts in the deep compartments, T''_{BMD} and T_D' (Fig. 4).

The possibility that the observed decrease in heart rate is a procedural effect cannot be rigorously excluded since no placebo experiments were performed. However, similar significant decreases in heart rate in healthy volunteers were attributed to such glycosides (5).

Maximum heart rate decreases of 16% at 20–120 min and of 15% at 240

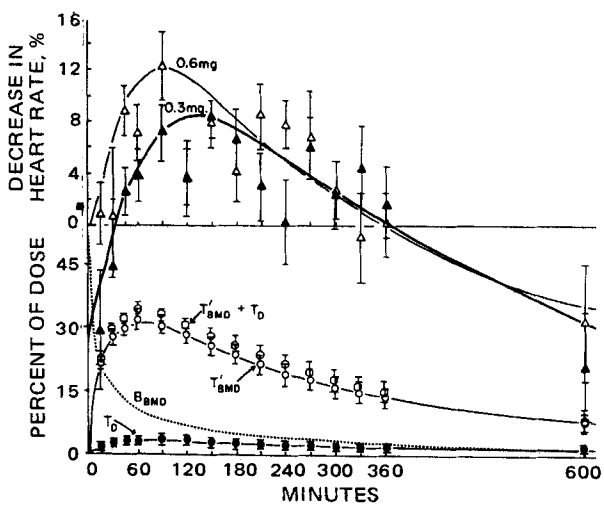


Figure 3—*Apparent correlation between the mean percent heart rate decrease at 0.3 (▲) and 0.6 (△) mg of β-methyldigoxin and the mean amounts of β-methyldigoxin (○) and digoxin (●) in their respective moderately deep tissues, T'_{BMD} and T_D, and in their sum (○) in percent of the administered intravenous dose of β-methyldigoxin as a function of time. The heart rate values obtained prior to drug administration served as controls. The vertical bars indicate ±1 SEM of the means. The amounts in the tissues were generated by the analog computer from the best fits of the experimental plasma and urine data for all studies. They are given as percent of dose and are valid for both dose levels since the intravenous pharmacokinetics were independent of dose (11). The dashed line shows the mean of the analog computer-fitted amounts of β-methyldigoxin in the central compartment, B_{BMD}, in percent of β-methyldigoxin administered as a function of time for comparison.*

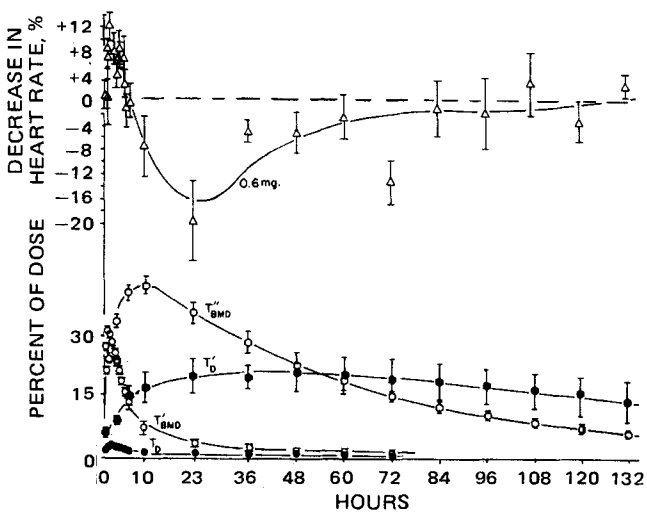

Figure 4—*Apparent correlation between the mean percent heart rate decreases at 0.6 mg (△) of β-methyldigoxin over 132 hr and the mean amounts of β-methyldigoxin (○) and digoxin (●) in their respective moderately deep tissues, T'_{BMD} and T_D, and in their sum (○) in percent of the administered intravenous dose of β-methyldigoxin as a function of time. The heart rate values obtained prior to drug administration served as controls. The vertical bars indicate ±1 SEM of the means. The amounts in the tissues were generated by the analog computer from the best fits of the experimental plasma and urine data for all studies and are given as the percent of the dose. The time course of the mean amounts of β-methyldigoxin (○) and digoxin (●) in their respective deepest compartments, T''_{BMD} and T_D', are shown for comparison in terms of the percent of administered dose. The increase in heart rate at 22 hr and subsequently is attributed to the fact that the previously prostrate patients became ambulatory at that time.*

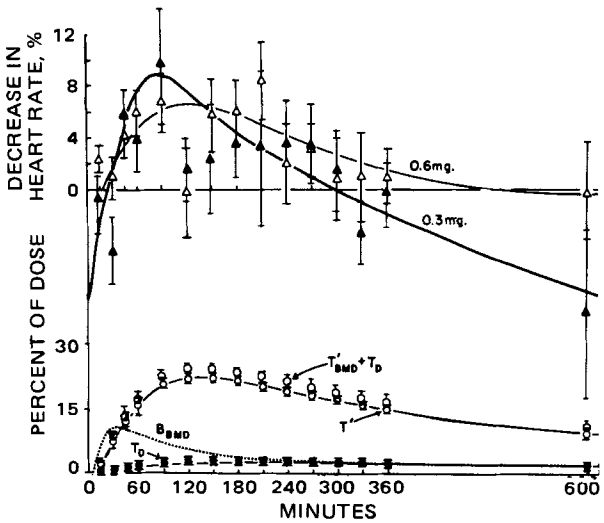

Figure 5—*Apparent correlation between the mean percent heart rate decreases at 0.3 (▲) and 0.6 (△) mg of β-methyldigoxin and the mean amounts of β-methyldigoxin (○) and digoxin (●) in their respective moderately deep tissues, T'_{BMD} and T_D, and in their sum (○) in percent of the administered oral dose of β-methyldigoxin as a function of time. The heart rate values obtained prior to drug administration served as controls. The vertical bars indicate ±1 SEM of the means. The amounts in the tissues were generated by the analog computer from the best fits of the experimental plasma and urine data for all studies. They are given as percent of dose and are valid for both dose levels since the oral pharmacokinetics were independent of dose (14). The dashed line shows the mean of the analog computer-fitted amounts of β-methyldigoxin in the central compartment, B_{BMD}, in percent of β-methyldigoxin administered as a function of time for comparison.*

min were reported after 1.6 mg iv and 3.25 mg po of digoxin, respectively (17, 18); intravenous injection of a placebo led to a maximal 3.3% heart rate decrease in these subjects. Maximal decreases in heart rate at 60–150 min were also observed in patients with coronary heart disease that were given 0.6 mg iv of β-methyldigoxin (19), consistent with our results.

Possible Differences in Apparent Biophases—The time course of this apparent negative chronotropic effect observed from heart rate measurements was remarkably different from the time course of the positive inotropic effect observed from LVETI measurements after β-methyldigoxin administration. Therefore, these two receptor site-containing biophases are kinetically different.

The mean arterial blood pressure was averaged for all subjects and showed a small, but consistent, decrease of 4–8%, 22–72 hr after administration for both doses and both modes of administration and was probably a procedural effect. The mean arterial blood pressure showed no consistent pattern, and the changes were small (±4%) during the first 22 hr.

Stability of (Pyrrolidone-5-hydroxamato)iron(III) Chelates

M. PEĆAR †, N. KUJUNDŽIĆ ˣ, and J. PAZMAN

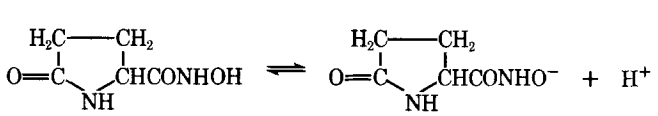
Abstract □ Overall stability constants of mono-, bis-, and tris(pyrrolidone-5-hydroxamato)iron(III) chelates were determined in aqueous solutions at 25° as log β_I = 1.49, log β_{II} = 1.55, and log β_{III} = 0.21, respectively, where $\beta_I = [Fe(C_5H_7O_3N_2)^{2+}][H^+]/[Fe^{3+}][HC_5H_7O_3N_2]$, $\beta_{II} = [Fe(C_5H_7O_3N_2)_2^+][H^+]^2/[Fe^{3+}][HC_5H_7O_3N_2]^2$, and $\beta_{III} = [Fe(C_5H_7O_3N_2)_3][H^+]^3/[Fe^{3+}][HC_5H_7O_3N_2]^3$. Stability constants of all three chelates were determined potentiometrically in the 3.00–3.23 pH region. The stability constant of the mono chelate also was determined spectrophotometrically at 25° as log β_I = 1.52 by measuring absorbance at 500 nm (absorbance maximum), where the molar absorptivity was ϵ = 1124 liters/(mole cm). Biological implications of hydroxamic acid-containing compounds are discussed.

Keyphrases □ (Pyrrolidone-5-hydroxamato)iron(III)—mono, bis, and tris chelates, stability constants determined in aqueous solutions □ Iron(III) chelates—mono, bis, and tris, with pyrrolidone-5-hydroxamic acid, stability constants in aqueous solutions □ Chelates—pyrrolidone-5-hydroxamic acid with iron(III), mono, bis, and tris, stability constants in aqueous solutions □ Hydroxamic acid derivatives—(pyrrolidone-5-hydroxamato)iron(III) mono, bis, and tris chelates, stability constants in aqueous solutions □ Stability constants—mono-, bis-, and tris(pyrrolidone-5-hydroxamato)iron(III) chelates in aqueous solutions

The role of the hydroxamic acid-containing compounds in living systems has become a lively issue since they are constituents of antibiotics, growth factors, tumor inhibitors, cell division factors, and pigments and are intimately associated with iron transport phenomena (1–7). A striking feature of hydroxamic acids is the ability to form coordination compounds with the pronounced preference for iron(III) (1). There is much interest in the hydroxamic acid–iron(III) chelates (6, 8–12). The paucity of data on heterocyclic aminohydroxamic acids and their iron(III) complexes necessitated the selection of pyrrolidone-5-hydroxamic acid and their iron(III) chelates as a model system for the nitrogen heteropentacyclic hydroxamic acids and their complexes.

A previous paper (12) described the coordination ability of pyrrolidone-5-hydroxamic acid to bind ferric ion, forming a mixture of mono, bis, and tris chelates from which the tris(pyrrolidone-5-hydroxamato)iron(III) complex was isolated and characterized.

This paper reports results related to the thermodynamic stability of mono, bis, and tris chelates in aqueous solutions. In a solution containing iron(III) ions and a bidentate pyrrolidone-5-hydroxamic acid, the system at equilibrium may be described by Schemes I–IV and Eqs. 1–4, where K_a is the acidity constant and the stepwise equilibrium constants are K_I, K_{II}, and K_{III} (12).



Scheme I

$$K_a = \frac{[C_5H_7O_3N_2^-][H^+]}{[HC_5H_7O_3N_2]} \qquad \text{(Eq. 1)}$$

$$Fe^{3+} + HC_5H_7O_3N_2 \rightleftharpoons Fe(C_5H_7O_3N_2)^{2+} + H^+$$

Scheme II

$$K_I = \frac{[Fe(C_5H_7O_3N_2)^{2+}][H^+]}{[Fe^{3+}][HC_5H_7O_3N_2]} \qquad \text{(Eq. 2)}$$

$$Fe(C_5H_7O_3N_2)^{2+} + HC_5H_7O_3N_2 \rightleftharpoons Fe(C_5H_7O_3N_2)_2^+ + H^+$$

Scheme III

$$K_{II} = \frac{[Fe(C_5H_7O_3N_2)_2^+][H^+]}{[Fe(C_5H_7O_3N_2)^{2+}][HC_5H_7O_3N_2]} \qquad \text{(Eq. 3)}$$

$$Fe(C_5H_7O_3N_2)_2^+ + HC_5H_7O_3N_2 \rightleftharpoons Fe(C_5H_7O_3N_2)_3 + H^+$$

Scheme IV

$$K_{III} = \frac{[Fe(C_5H_7O_3N_2)_3][H^+]}{[Fe(C_5H_7O_3N_2)_2^+][HC_5H_7O_3N_2]} \qquad \text{(Eq. 4)}$$

The overall β and stepwise stability constants K are related by the familiar expressions:

$$\beta_I = K_I \qquad \text{(Eq. 5a)}$$

$$\beta_{II} = K_I K_{II} \qquad \text{(Eq. 5b)}$$

$$\beta_{III} = K_I K_{II} K_{III} \qquad \text{(Eq. 5c)}$$

Constants $\beta_{1,2,3}$ and $K_{1,2,3}$ are defined by:

$$\beta_1 = \beta_I K_a^{-1} \qquad \text{(Eq. 6a)}$$

$$\beta_2 = \beta_{II} K_a^{-2} \qquad \text{(Eq. 6b)}$$

$$\beta_3 = \beta_{III} K_a^{-3} \qquad \text{(Eq. 6c)}$$

$$K_1 = K_I K_a^{-1} \qquad \text{(Eq. 7a)}$$

$$K_2 = K_{II} K_a^{-1} \qquad \text{(Eq. 7b)}$$

$$K_3 = K_{III} K_a^{-1} \qquad \text{(Eq. 7c)}$$

EXPERIMENTAL

Chemicals—The preparation of pyrrolidone-5-hydroxamic acid and its iron(III) coordination compounds was described previously (12). The iron(II) solutions were prepared *in situ* by catalytic hydrogenation of iron(III) over palladium-on-carbon. All experiments involving iron(II) ions were performed under nitrogen. All other chemicals were reagent grade, and water was distilled from aqueous acidified potassium permanganate solution and stored in glass[1] containers.

Physical Measurements[2]—The potentiometric method (13, 14) involving nucleophilic potentiometric titration of iron(III) chelates was initially applied to the determination of the stability constants. The method was abandoned because reasonable results could not be obtained; the examined chelates were too stable for this method. The stability constants of mono, bis, and tris chelates were obtained by the potentiometric method in addition to the spectrophotometric method, which could be used only for mono chelate. In spectrophotometric and potentiometric experiments, the pH was adjusted to a constant value by hydrochloric acid or sodium hydroxide solution.

Redox potential measurements of iron(II)–iron(III) solutions were used to calculate the concentration of the free iron(III) ions at low pH, since iron(II)–hydroxamate complexes cannot be formed below pH 6 and the interfering base hydrolysis takes place above pH 8 (15, 16). In a typical redox potential measurement, the iron(II)–iron(III) solution was added to a pyrrolidone-5-hydroxamic acid solution, giving 50 ml of 2.064×10^{-4} *M* Fe^{3+} and 2.064×10^{-4} *M* Fe^{2+}. The total concentration of the pyrrolidone-5-hydroxamic acid was $1–6 \times 10^{-3}$ *M*. Ionic strength was maintained at 0.1 by potassium chloride.

[1] Pyrex.

[2] The pH and potentiometric determinations were performed with a MA 5701 ISKRA pH meter and a Radiometer SRB2c/ABU 1b/TTA3 titrigraph. Visible spectra were obtained with a Opton PMQ II single-beam spectrophotometer and a Cary model 16K recording spectrophotometer equipped with quartz cells.

Table I—Stability Constant of Mono(pyrrolidone-5-hydroxamato)iron(III) Chelate from Absorbance Measurements at 500 nm and Ionic Strength 0.1 (Sodium Chloride), Using 1-cm Quartz Cells[a]

Experiment	pH	Absorbance, nm	$[H^+] \times 10^4$	$[Fe(C_5H_7O_3N_2)^{2+}] \times 10^4$	$[Fe^{3+}] \times 10^4 = [HC_5H_7O_3N_2] \times 10^4$	K_I	log K_I
1	1.90	0.260	126	2.31	2.69	40.2	1.60

[a] Total concentrations of pyrrolidone-5-hydroxamic acid and of iron(III) ions were kept equal at 5×10^{-4} *M*. K_I was calculated from Eq. 2.

RESULTS AND DISCUSSION

Spectrophotometric Determination of Stability Constant of Mono(pyrrolidone-5-hydroxamato)iron(III) Complex—The behavior of the iron(III)–pyrrolidone-5-hydroxamic acid solution depicted by Schemes I–IV was described recently (12). In view of the interference of bis and tris chelates, only the stability constant of the mono chelate can be determined spectrophotometrically, if the pH is sufficiently low and there is an excess of iron(III) over hydroxamic acid. The visible spectrum of the mono(pyrrolidone-5-hydroxamato)iron(III) complex shows the maximum absorption at 500 nm with a molar absorptivity of ϵ_{max} 500 nm = 1124 liters/(mole cm). The quantitative conversion of pyrrolidone-5-hydroxamic acid to the mono chelate is illustrated in Fig. 1. The necessary data for the calculation of K_I (Eqs. 2 and 5*a*–5*c*) are given in Table I. The concentration of $Fe(C_5H_7O_3N_2)^{2+}$ was determined spectrophotometrically, the concentration of H^+ was obtained from the measured pH, and the concentrations of iron(III) and pyrrolidone-5-hydroxamic acid were calculated from:

$$[\text{iron(III)}] = [\text{iron(III)}]_{total} - [Fe(C_5H_7O_3N_2)^{2+}] \quad \text{(Eq. 8)}$$

and:

$$[HC_5H_7O_3N_2] = [HC_5H_7O_3N_2]_{total} - [Fe(C_5H_7O_3N_2)^{2+}] \quad \text{(Eq. 9)}$$

respectively. It was assumed that there is no appreciable amount of the $C_5H_7O_3N_2^-$ anion below pH 3 due to the low acidity of pyrrolidone-5-hydroxamic acid [pKa = 8.65 (12)]. Both good constancy and reproducibility of K_I values in the pH 1.90–2.95 region were observed, and K_I = 33.4 (or log K_I = 1.52) was calculated as the arithmetic mean of the six values. At the higher pH value of 2.95, there was a decrease in K_I due to interfering reactions, such as base hydrolysis of iron(III) ions.

Potentiometric Determination of Stability Constants of Mono-, Bis-, and Tris(pyrrolidone-5-hydroxamato)iron(III) Complexes—The procedure for the determination of the stability constants of mono, bis, and tris iron(III) chelates was essentially the Schwarzenbach method (16). According to Schemes II–IV, the total concentration of iron(III), Fe_T, in solutions containing pyrrolidone-5-hydroxamic acid and iron(III) ions at low pH is:

$$Fe_T = [Fe^{3+}] + [Fe(C_5H_7O_3N_2)^{2+}] + [Fe(C_5H_7O_3N_2)_2^+] + [Fe(C_5H_7O_3N_2)_3] \quad \text{(Eq. 10)}$$

Equation 10 can be rearranged to Eq. 11:

$$Fe_T/[Fe^{3+}] = \alpha = 1 + \beta_I^*[HC_5H_7O_3N_2] + \beta_{II}^*[HC_5H_7O_3N_2]^2 + \beta_{III}^*[HC_5H_7O_3N_2]^3 \quad \text{(Eq. 11)}$$

where:

$$\beta_I^* = [Fe(C_5H_7O_3N_2)^{2+}]/([Fe^{3+}][HC_5H_7O_3N_2]) \quad \text{(Eq. 12a)}$$

$$\beta_{II}^* = [Fe(C_5H_7O_3N_2)_2^+]/([Fe^{3+}][HC_5H_7O_3N_2]^2) \quad \text{(Eq. 12b)}$$

$$\beta_{III}^* = [Fe(C_5H_7O_3N_2)_3]/([Fe^{3+}][HC_5H_7O_3N_2]^3) \quad \text{(Eq. 12c)}$$

The function F_1 is defined by:

$$F_1 = (\alpha - 1)/[HC_5H_7O_3N_2] = \beta_I^* + \beta_{II}^*[HC_5H_7O_3N_2] + \beta_{III}^*[HC_5H_7O_3N_2]^2 \quad \text{(Eq. 13)}$$

Equation 14 can be similarly obtained for the total concentration of the pyrrolidone-5-hydroxamic acid moiety $C_5H_7O_3N_{2T}$:

$$C_5H_7O_3N_{2T} = [HC_5H_7O_3N_2] + [Fe(C_5H_7O_3N_2)^{2+}] + 2[Fe(C_5H_7O_3N_2)_2^+] + 3[Fe(C_5H_7O_3N_2)_3] \quad \text{(Eq. 14)}$$

The concentration of the free $C_5H_7O_3N_2^-$ anion can be neglected because of low K_a and pH values. Furthermore, a good starting approximation can be made, $[HC_5H_7O_3N_2] = C_5H_7O_3N_{2T}$, in Eq. 14 if there is a sufficient excess of $C_5H_7O_3N_{2T}$ over Fe_T as in these experiments.

By plotting F_1 *versus* $[HC_5H_7O_3N_2]$, one obtains, according to Eq. 13, β_I^* as an intercept, since $F_1 = \beta_I^*$ when $[HC_5H_7O_3N_2] = 0$.

Another approximation, $\beta_{III}^*[HC_5H_7O_3N_2]^2 = 0$, can be made for very small values of $[HC_5H_7O_3N_2]$. Under this condition, quadratic Eq. 13 is reduced to:

$$F_1 = \beta_I^* + \beta_{II}^*[HC_5H_7O_3N_2] \quad \text{(Eq. 15)}$$

with the slope being equal to β_{II}^*.

Another rearrangement of Eq. 13 leads to:

$$F_2 = (F_1 - \beta_I^*)/[HC_5H_7O_3N_2] = \beta_{II}^* + \beta_{III}^*[HC_5H_7O_3N_2] \quad \text{(Eq. 16)}$$

with β_{II}^* as an intercept and β_{III}^* as a slope.

Similarly, the third function, F_3, can be obtained from:

$$F_3 = (F_2 - \beta_{II}^*)/[HC_5H_7O_3N_2] = \beta_{III}^* = \text{constant} \quad \text{(Eq. 17)}$$

In this procedure, one starts by plotting F_1 *versus* $[HC_5H_7O_3N_2]$, which gives diagrams such as those shown in Figs. 2 and 3. The F_1 in Eq. 13 is easily calculated from the known starting concentrations of Fe_T and $C_5H_7O_3N_{2T}$ and the concentration of the free Fe^{3+} ions determined from the redox potential. Depending on the experimental conditions, such as pH, three types of diagrams are possible (Figs. 2 and 3). Figure 2 shows that F_1 at pH 1.59 does not depend on $[HC_5H_7O_3N_2]$, indicating the reduction of Eq. 13 to the form $F_1 = \beta_I^*$ and, therefore, $\beta_{II}^* = 0$ and $\beta_{III}^* = 0$. It follows from Eqs. 12*b* and 12*c* that $[Fe(C_5H_7O_3N_2)_2^+]$ and $[Fe(C_5H_7O_3N_2)_3]$ are also zero under these conditions and that only the mono chelate is formed at pH 1.59.

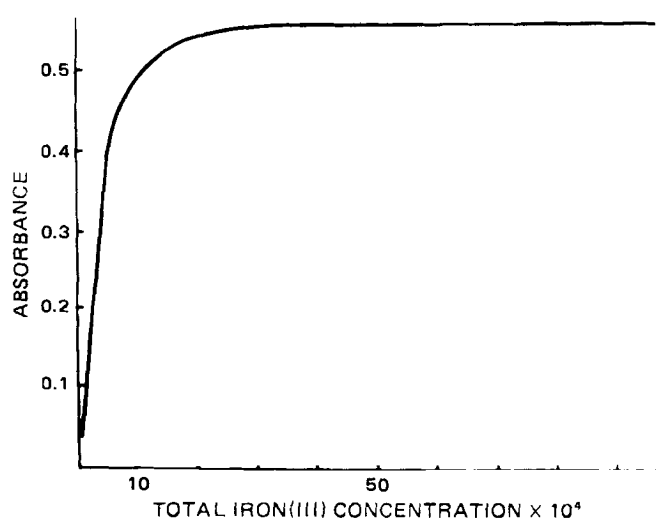

Figure 1—*Spectrophotometric titration of 5 × 10⁻⁴ M pyrrolidone-5-hydroxamic acid by iron(III) solution at 500 nm, pH 2.0, and ionic strength 0.1 (sodium chloride), using 1-cm quartz cells.*

Table II—Overall Stability Constants, β

pH	$\beta_I^* \times 10^{-3}$	$\beta_I \times 10^{-1}$	log β_I	β_{II}^*	$\beta_{II} \times 10^{-1}$	log β_{II}	β_{III}^*	β_{III}	log β_{III}
1.59	1.3	3.34	1.52	—	—	—	—	—	—
1.83	2.3	3.40	1.53	2.0×10^5	4.37	1.64	—	—	—
2.21	5.3	3.26	1.51	9.1×10^5	3.46	1.54	—	—	—
3.00	25.0	2.50	1.40	2.2×10^7	2.20	1.34	1.0×10^9	1.00	0.00
3.23	50.0	2.94	1.47	1.2×10^3	4.15	1.62	2.05×10^{10}	4.18	0.62
Mean	—	3.09	—	—	3.55	—	—	2.59	—
Log	—	1.49	—	—	1.55	—	—	0.41	—

Linear dependence of F_1 on $[HC_5H_7O_3N_2]$ is found at pH 1.83 and 2.21 (Fig. 2), indicating reduction of Eq. 13 to Eq. 15. Therefore, in this case, $\beta_{III}^* = 0$ and, from Eq. 12*c*, $[Fe(C_5H_7O_3N_2)_3] = 0$. This result is explained by the presence of both mono and bis, but not tris, chelates at pH 1.83 and 2.21. The β_I^* is always easily obtained from the intercept of F_1, and function F_2 may be calculated from Eq. 16. Figure 2 illustrates no dependence of F_2 on $[HC_5H_7O_3N_2]$, because Eq. 16 is reduced to the form $F_2 = \beta_{II}^*$, indicating an absence of the tris chelate.

The formation of all three chelates requires the nonlinear dependence of F_1 on $[HC_5H_7O_3N_2]$; furthermore, Eq. 13 must hold as is seen in Fig. 3 at pH 3.00. The nonlinear dependence is not pronounced in Fig. 3 at pH 3.23, probably due to the insufficiently high concentration of pyrrolidone-5-hydroxamic acid. In Fig. 3, β_I^* at pH 3.00 and 3.23 is obtained from the intercept of F_1, where $[HC_6H_7O_3N_2] = 0$, thus enabling the plotting of F_2 *versus* $[HC_5H_7O_3N_2]$ according to Eq. 16. The resulting straight line is used to obtain β_{II}^* from the intercept as well as to plot F_3 *versus* $[HC_5H_7O_3N_2]$ to get β_{III}^* from the intercept at pH 3.00 and 3.23. Equation 17 requires no dependence of F_3 on pyrrolidone-5-hydroxamic acid when all three chelates are present in solution (illustrated in Fig. 3 for pH 3.00). Deviation of F_3 at pH 3.23 from the expected horizontal line is negligible and due to experimental error.

This procedure yields only approximate values of β_I^*, β_{II}^*, and β_{III}^*. Therefore, only approximate values of $[Fe(C_5H_7O_3N_2)^{2+}]$, $[Fe(C_5H_7O_3N_2)_2^+]$, and $[Fe(C_5H_7O_3N_2)_3]$ can be obtained from Eqs. 12*a*, 12*b*, and 12*c*, respectively, and inserted in Eq. 14. However, Eq. 14 yields a more accurate value for $[HC_5H_7O_3N_2]$, which is again introduced in Eqs. 13, 16, and 17, giving more accurate values of β_I^*, β_{II}^*, and β_{III}^*. The procedure is to be repeated until the starting Eq. 10 is satisfied.

By following this procedure, the data for β_I^*, β_{II}^*, and β_{III}^* were obtained (Tables II and III). Figures 2 and 3 represent the corresponding diagrams. The overall stability constants, β, are calculated from β^* by the simple relations $\beta_I = \beta_I^*[H^+]$, $\beta_{II} = \beta_{II}^*[H^+]^2$, and $\beta_{III} = \beta_{III}^*[H^+]^3$. All other constants such as K_I, K_{II}, K_{III}, K_1, K_2, K_3, β_1, β_2, and β_3 are easily calculated from Eqs. 5*a*–5*c*, 6*a*–6*c*, and 7*a*–7*c*. They are listed in Table III to show the great influence of the hydrogen ion on various forms of the stability constants of chelates because of the rather high pKa value.

In this procedure, the best accuracy is expected in the determination of β_I^*; less accuracy is expected for β_{II}^*, and the least accuracy is expected for β_{III}^*. The value of $\beta_I^* = 1.3 \times 10^3$ obtained from Fig. 2 at pH 1.59 is substantiated by the excellent agreement between the calculated value of $Fe_T = 2.066 \times 10^{-4}$ *M* from Eq. 10 as an average of six determinations and the used analytical concentration of $Fe_T = 2.064 \times 10^{-4}$ *M*. The lower accuracy of β_{II}^* and β_{III}^* in the system at pH 3.23 in Fig. 3 results in less agreement between analytical and calculated values of Fe_T, 2.064×10^{-4}

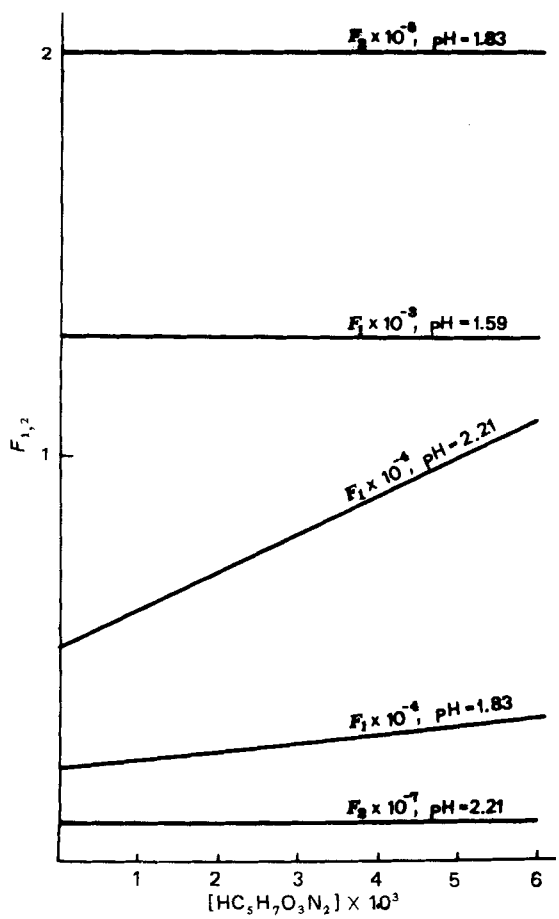

Figure 2—*Dependence of* F_1 *and* F_2 *on* $[HC_5H_7O_3N_2]$ *at pH 1.59, 1.83, and 2.21. Intercepts of* F_1 *at pH 1.59, 1.83, and 2.21 give* β_I^* *of* 1.3×10^3, 0.23×10^4, *and* 0.53×10^4, *respectively. Table III—Stability Constants of (Pyrrolidone-5-hydroxamato)iron(III)[a]

Index	K	log K	β	log β
I	3.09×10^{1}	1.49	3.09×10^{1}	1.49
II	1.15×10^{0}	0.06	3.55×10^{1}	1.55
III	4.57×10^{-2}	−1.34	1.62×10^{0}	0.41
1	1.38×10^{10}	10.14	1.38×10^{10}	10.14
2	5.13×10^{8}	8.71	7.08×10^{18}	18.85
3	2.04×10^{7}	7.31	1.44×10^{26}	26.16

[a] Chelates were calculated from Eqs. 5a–5c, 6a–6c, 7a–7c, and Table II and are expressed as K_{I}, K_{II}, K_{III}, K_{1}, K_{2}, K_{3}, β_{I}, β_{II}, β_{III}, β_{1}, β_{2}, and β_{3}.

M and 2.168×10^{-4} M, respectively. The agreement is significantly improved by rejecting one extreme value of Fe_T, which gives the calculated average value of 2.075×10^{-4} M. The precision decreases in the order $\beta_{I} > \beta_{II} > \beta_{III}$ (Table II). The value of log β_{I} (= log K_{I}) = 1.49 is in excellent agreement with the spectrophotometrically obtained value of log β_{I} = 1.52.

Overall stability constants of related iron(III) hydroxamates are listed in Table IV. The decrease in stability when going from benzohydroxamic to pyrrolidone-5-hydroxamic acid chelates of iron(III) is larger than may be expected from the increase in acidity in the same direction. Some other factors must be involved such as the interference by chelating iron(III) *via* carbonyl and imine groups of the pyrrolidone ring.

The stability of (pyrrolidone-5-hydroxamato)iron(III) chelates is important for the behavior of these complexes in living systems. There is an indication that hydroxamic acid-containing compounds are constituents of siderophilin, the iron-binding β-pseudoglobulin of human plasma (17), and of ferritin (18). It is obvious that the higher the stability of hydroxamic acid–iron(III) chelates, the easier is iron transport and the better is iron resorption at various biological pH's. Iron-containing hydroxamic acids have been patented as metalotherapeutics (5). (Pyrrolidone-5-hydroxamato)iron(III) chelates may be considered as possible metalotherapeutics in view of their stability and the presence of the pyrrolidone ring, which, like povidone, is used as a substitute for blood plasma (7) and also shows a mitostimulating effect (19).

Table IV—Comparison of Stabilities of Iron(III) Hydroxamines

Acid	pKa	log β_3
Acetohydroxamic	9.37[a]	28.30[a]
Benzohydroxamic	8.79[a]	27.83[a]
Pyrrolidone-5-hydroxamic	8.65[b]	26.36[c]

Methods for Evaluating Hermetic Closures for Screw-Capped Bottles

R. D. CILENTO

Abstract □ With the described method, a large number of sealed bottles can be tested to determine their effectiveness, integrity, and reliability in preserving an inert atmosphere. The method consists of placing milligram quantities of dry ice into the bottles, capping them, and periodically weighing them on an analytical balance; leaky bottles are detected by a loss in weight. This method can be applied to test a large number of bottles with a minimum of effort and manpower and without complicated instrumentation. The data presented are highly reproducible and correlate well with data from other methods and with the physical defects of the bottles.

Keyphrases □ Seals, hermetic—testing method developed for large numbers of screw-capped bottles □ Bottles, screw capped—method of testing hermetic seals developed for large numbers □ Technology, pharmaceutical—method of testing hermetic seals of large numbers of screw-capped bottles developed

By definition, hermetic containers are impervious to air and any other gas under ordinary conditions of handling. For the primary container of a drug to qualify as hermetic, it must be leakproof; *i.e.*, no gases or vapors must be capable of entering it or escaping from it.

A product is hermetically sealed to protect it from con-

Iron-containing hydroxamic acids have been patented as metalotherapeutics (5). (Pyrrolidone-5-hydroxamato)iron(III) chelates may be considered as possible metalotherapeutics in view of their stability and the presence of the pyrrolidone ring, which, like povidone, is used as a substitute for blood plasma (7) and also shows a mitostimulating effect (19).

Table IV—Comparison of Stabilities of Iron(III) Hydroxamines

Acid	pKa	log β_3

Methods for Evaluating Hermetic Closures for Screw-Capped Bottles

R. D. CILENTO

Abstract □ With the described method, a large number of sealed bottles can be tested to determine their effectiveness, integrity, and reliability in preserving an inert atmosphere. The method consists of placing milligram quantities of dry ice into the bottles, capping them, and periodically weighing them on an analytical balance; leaky bottles are detected by a loss in weight. This method can be applied to test a large number of bottles with a minimum of effort and manpower and without complicated instrumentation. The data presented are highly reproducible and correlate well with data from other methods and with the physical defects of the bottles.

Keyphrases □ Seals, hermetic—testing method developed for large numbers of screw-capped bottles □ Bottles, screw capped—method of testing hermetic seals developed for large numbers □ Technology, pharmaceutical—method of testing hermetic seals of large numbers of screw-capped bottles developed

By definition, hermetic containers are impervious to air and any other gas under ordinary conditions of handling. For the primary container of a drug to qualify as hermetic, it must be leakproof; *i.e.*, no gases or vapors must be capable of entering it or escaping from it.

A product is hermetically sealed to protect it from con-

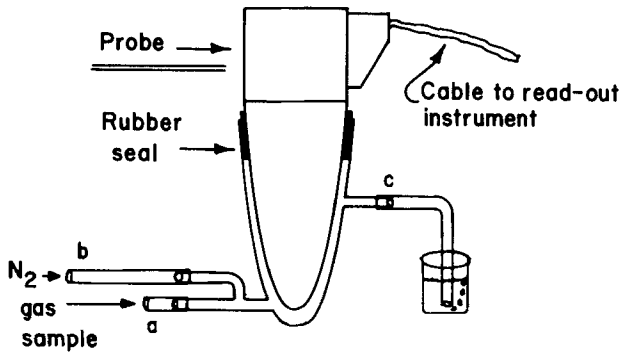

Figure 1—*Oxygen analyzer glass cell.*

tact with components of the atmosphere that may cause it to deteriorate, *e.g.*, oxygen or water vapor, or to prevent its volatile components from escaping. The need for this practice is well documented (1–17).

A review of the work done in the field of inert-gas flushing of containers has revealed an extensive effort dedicated to the development of procedures for purging primary containers (13, 15, 18) and to measurement of the effectiveness of these procedures (14, 15, 19–22). What seems to be lacking, however, is information on methods for studying the effectiveness of screw-capped bottles in preserving an inert atmosphere within them throughout their shelflife. Such methods could be subdivided into two categories: (*a*) testing the efficacy of components (in particular, seals and seal materials), and (*b*) testing the impermeability of the assembled system.

Much published work exists for the first category (3, 5, 9, 23–28). In the second category, methods have been reported for testing plastic bottles (29), single-dose pouches (28), and ampuls; but no effective, simple, fast, precise method has been reported for testing screw-capped glass bottles. It is not enough to demonstrate that seal materials are impervious to moisture or oxygen; their effectiveness must be demonstrated after they have been applied as finished closures.

This paper presents a method by which a large number of sealed bottles can be tested for determination of the most effective seal and for the cause of malfunctioning of a container, *e.g.*, the bottle, the seal, the cap, or the assembling operation. The results should provide guidance in developing necessary controls or precautions.

EXPERIMENTAL

Equipment—A vacuum chamber (20 × 20 × 30 cm), an analytical balance[1], a spring torque tester[2], a pressure vessel (a cylindrical 110-liter tank), and an oxygen analyzer[3] were used.

Materials Tested—The bottle[4] size was 100 ml with beaded glass lips, 38 mm. Standard metal screw caps matched the bottle size and finish. The liners were polyvinyl chloride, 0.7-mm thick solid disks.

Test Methods—The following test methods were developed to study the efficacy and reliability of closure systems.

Test 1: Vacuum Chamber—A number of bottles are capped at a specified torque and placed into the vacuum chamber for 4 hr. The vacuum is quickly broken, and each bottle is immediately placed, cap down, in a tray containing enough water to keep the cap entirely submerged. The bottle is vented by holding the cap with a pair of pliers or similar device and twisting the bottom of the bottle. Any bottle that had been evacuated through a leaky closure will be partially or totally filled with water.

Test 2: Dry Ice—Immediately after a chip or two of crushed dry ice has been placed into a tared bottle, the bottle is capped at a specified torque and then weighed to the nearest milligram on the analytical balance. The amount of dry ice placed in each bottle should produce enough gaseous carbon dioxide to give a pressure of 40.000–70.000 Nm^{-2} (6–10 psi). The amount varies with bottle size, *i.e.*, about 50 mg for a 25-ml bottle, 150 mg for a 100-ml bottle, and 250 mg for a 200-ml bottle.

A leak-free bottle prepared in this way maintains its weight indefinitely. A leaky bottle starts losing weight immediately and, depending on the magnitude of the defect, loses 70–80% of the carbon dioxide gas within minutes, hours, or days; the remainder of the gas diffuses out more slowly. If a perfectly sealed bottle is opened months later, the hissing sound of the escaping gas under pressure is still audible. A skilled technician can prepare more than 30 sample bottles/hr.

Test 3: Oxygen Diffusion—Each bottle is flooded with nitrogen and capped at a specified torque. The bottles are held for 1–4 days in a pressure vessel that has been flooded with oxygen. Oxygen is maintained in the vessel under a positive pressure, being permitted to flow in continuously and to bubble out through a vent tube. At the end of the storage period, the bottles are tested for oxygen content.

Nitrogen flooding of the bottles is accomplished in either of two ways.

1. The bottles are first evacuated in the vacuum chamber, and then the vacuum is broken with nitrogen. While nitrogen is still flowing, the cap is screwed on each bottle fingertip tight. A specified torque is applied to the cap as soon as the bottle has been removed from the chamber. Precautions must be taken to avoid introducing air into the bottle during capping.

2. The procedure of blowing nitrogen into open bottles is not as effective as is the use of the vacuum chamber, but it is much faster and, if properly controlled, can yield very reproducible results. The four critical factors in the control of this procedure are the nitrogen velocity, time, position of the nitrogen-delivery tube with respect to the neck of the bottle, and mode of application of the cap. The optimum conditions for each size and shape of the bottle must be determined experimentally.

Procedure 1 can produce bottles containing less than 2% oxygen, whereas Procedure 2 produces bottles containing 2–5% oxygen.

The oxygen content of the bottles is determined by use of the oxygen analyzer, which can be adapted to receive a gas sample by mounting a specially built glass cell on its probe (Fig. 1). The cell is purged with a stream of nitrogen through intake line b; as soon as the instrument reads zero, this line is closed and a 5-ml gas sample is introduced *via* syringe through line a. The instrument response is practically immediate. The instrument is calibrated by introducing samples of known oxygen composition; a straight-line relationship exists between sample composition and meter readings, with the curve passing through the zero point. The method can be used to measure accurately oxygen concentrations of 0–60 ± 0.5%. Concurrent testing of several samples proved this method to be as accurate and reproducible as a GC assay.

To obtain a gas sample, a hole is made in the cap of the bottle with an awl; a 5-ml sample of gas is withdrawn into a syringe through a hypodermic needle fitted with a rubber flange at its base. The gas is then immediately injected into the cell of the instrument. The main advantage of this method is the speed with which a large number of samples can be tested (a skilled technician can test more than 30 samples/hr) with results immediately determined from a standardized graph; its main disadvantage is the large sample of gas (5 ml) needed.

RESULTS AND DISCUSSION

The described test methods were used to determine the most effective closure system for screw-capped glass bottles. The three methods were developed concurrently, but only the dry ice method was used extensively in the screening and concluding phases of the study. The oxygen-diffusion method was used only to confirm the results of systems that had passed the dry ice test once the validity of the dry ice method had been demonstrated by good correlation between these two methods. The vacuum chamber method, developed early in the program, produced results that correlated with those of the other methods, but its use was discontinued after the superiority of the dry ice method had been demonstrated.

The data in Table I show that a good correlation exists between results obtained by the dry ice and oxygen-diffusion tests. Leakage of Bottles 1, 4, 7, 12, 15, 16, 18, and 19 was demonstrated by the dry ice test and confirmed by the oxygen-diffusion test. The data in Table II confirm the

results shown in Table I and also show that leakage could be corrected by increasing the torque applied to the caps. In this experiment, carried out with the same set of bottles used earlier (Table I), the effect of torque on the efficacy of the closure system was studied. The caps were applied at torques of 1.65–1.85, 2.50–2.75, and >2.75 mN. For the low and intermediate levels of torque, the caps were twisted to the prescribed torque and quickly released; for the high torque level, the caps were twisted to the limit of the torque tester and held so for 5 sec. For the three levels of torque, 50, 20, and 0% of the bottles had lost weight after 4, 24, and 96 hr, respectively. The complete integrity of the seal for bottles in the third group must be attributed both to the magnitude of the torque (>2.75 mN) and to the duration of its application.

The results of the first two experiments demonstrated that the set of bottles tested included highly defective, moderately defective, and perfect specimens. The third experiment sought to discover the nature of the defect. The initial assumption of the cause of leakage was a lack of flatness of the bottle lip. To test this hypothesis, a vacuum device (Fig. 2) to measure the flatness of the bottle lip was built. The testing procedure consisted of connecting the device to a source of vacuum, placing the Plexiglas plate on the bottle, and reading the gauge. The results were highly reproducible and are assumed to be an accurate measure of the degree of flatness of the lip of the bottle, the highest reading being obtained for a bottle with a perfectly flat lip (Table III).

The results of this experiment, however, showed no correlation with the results of the first two experiments. For example, Bottles 15 and 16, which were among the worst leakers, showed the highest readings; on the other hand, Bottles 11 and 22, which did not leak, showed very low readings. It was concluded that the lack of flatness of the bottle lip was not responsible for the leak. At this point, the bottles were closely inspected with a magnifying glass and a stereoscopic microscope; most of them showed thin, smooth grooves across the lip (Fig. 3). All grooves were

ranked on an arbitrary scale (from 0 = no grooves to 10 = widest).

The results showed that bottles lacking grooves or having grooves of minimal width had not leaked under any of the conditions shown in Table II. The five bottles that leaked after the caps had been applied with a torque of 2.50–2.75 mN showed grooves rated between 4 and 7. One bottle (26) that had, in another experiment, leaked even after it had been capped with a maximum torque showed a groove much larger than any other found. Grooves ranked 3, 6, 7, and 10 on this scale were later shown, by microscopic comparison with hairs of known diameter, to have widths of 50, 75, 100, and 200 μm, respectively.

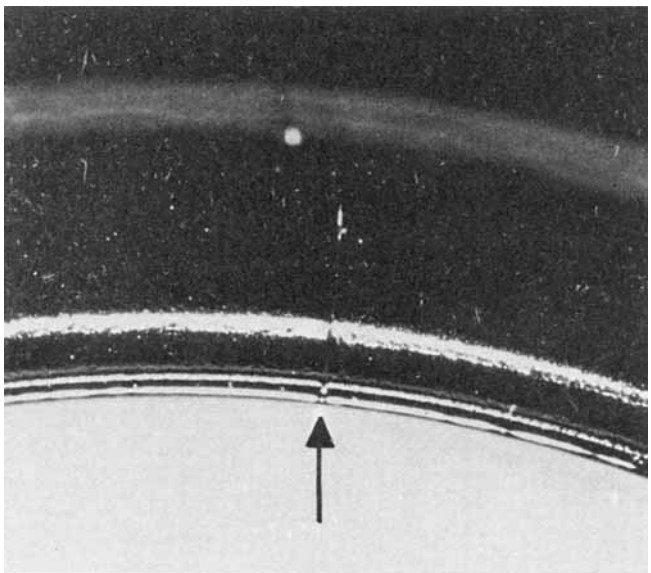

Figure 3—*Groove defect (at approximately 10×) (photograph courtesy of R. Walton)*

The dry ice test method was also used to evaluate a variety of liner seals. To compensate for the groove defects in bottle lips, polyvinyl chloride foam liners required an application torque as great as that required for polyvinyl chloride solid liners. Moreover, wax-coated laminates were inferior to polyvinyl chloride, and pressure-sensitive seals[5], applied with an acceptable torque, were more effective than the other liner seals.

SUMMARY AND CONCLUSIONS

A dry ice method has proved very useful for testing the effectiveness of screw-capped bottles in preserving an inert atmosphere within them. The method permits the testing of a large number of samples with a minimum of effort; it utilizes uncomplicated equipment and is simple to apply. The results are highly reproducible and correlate well with those of the oxygen-diffusion method and with the physical defects of the system.

This method is specifically designed to test the assembled package, but it can be used to test components or procedures. By its use, various seals were evaluated. Polyvinyl chloride proved to be an excellent sealing material which compensates very well for out-of-flat defects, but it requires too great a torque to be useful in compensating for the groove defects.

The method can be used by packaging engineers to develop and evaluate closure systems and procedures and by quality-control units for routine spot checks of container materials or for extensive tests of questionable shipments.

Convective Diffusional Analysis for Drug Transport through a Tubular Polymeric Membrane

D. R. FLANAGAN *x **and S. H. YALKOWSKY** ‡

Abstract □ The transport of three *p*-aminobenzoate esters (ethyl, butyl, and hexyl) through a tubular dimethyl polysiloxane membrane into a flowing liquid was investigated. The tubular configuration permits the exact determination of the convective diffusional contribution to membrane transport with models that account for fluid hydrodynamics. The observed transport behavior ranged from complete convective diffusion control for the hexyl ester to complete membrane control for the ethyl ester; the butyl ester exhibited a change in control with flow rate. The implications of convective diffusional considerations to intestinal absorption and dissolution studies are discussed.

Keyphrases □ Diffusion—three *p*-aminobenzoate esters through tubular dimethyl polysiloxane membrane into a flowing liquid □ Transport, drug—three *p*-aminobenzoate esters through tubular dimethyl polysiloxane membrane into a flowing liquid □ Membrane permeation—three *p*-aminobenzoate esters through tubular dimethyl polysiloxane membrane into a flowing liquid

Most studies on the transport of drugs through model membranes (1–3) have utilized transport systems with reproducible hydrodynamics and maximal surface-to-volume ratios. The stagnant diffusion layer or film model has been applied as a convenient tool for the interpretation of diffusional resistances in or on either side of the model membranes. The convenience and wide application of this model have led to the implication that it accurately reflects physical reality (4), but its limitations have been known for some time, particularly its weakness in predicting convective influences on mass transfer without use of empirical relationships (5).

By changing the experimental design for membrane transport studies, it will be shown that the convective diffusional contributions to mass transfer can be exactly determined with models that are more accurate pictures of physical reality. The experimental design utilizes a tubular membrane with an aqueous solution flowing at a constant rate through the tube. Such a system can be assembled easily and inexpensively to provide the advantages of previous systems plus the added advantage of being able to determine exactly the aqueous convective diffusional contribution to the overall transport rate. These studies also have important implications for intestinal absorption and dissolution studies.

THEORY

For an experimental design in which a flowing liquid is taking up solute from a tube wall, several models predict the extent of solute uptake under various convective conditions. The first type of convective condition may be termed plug flow (Fig. 1*a*), in which there is no velocity gradient in the flowing liquid. In this model, all liquid in the tube moves at a constant velocity, V_0, and the solute is taken up from the wall as the liquid flows through the tube. For a tube of a particular length, L, a constant solute concentration, C_{av}, is expected to be flowing out of the end if the flow rate is held constant. The differential equation describing the mass transfer due to convection and diffusion for this situation is:

$$V_0 \frac{\partial c}{\partial z} = D \frac{1}{r} \frac{\partial}{\partial r}\left(r \frac{\partial c}{\partial r}\right) \qquad \text{(Eq. 1)}$$

where $\partial c/\partial z$ = longitudinal concentration gradient, D = diffusion coefficient, r = radius, and $\partial c/\partial r$ = radial concentration gradient.

Equation 1 equates the convective contribution, $V_0(\partial c/\partial z)$, to the diffusional contribution:

$$D \frac{1}{r} \frac{\partial}{\partial r}\left(r \frac{\partial c}{\partial r}\right)$$

at steady state. This differential equation can be solved for the boundary conditions $C = 0$ at $z = 0$ for all r and $C = C_s$ (solute solubility in liquid at $r = R$, the inner radius of tube for all z) to give:

$$C_{av}/C_s = 1 - 4 \sum_{n=1}^{\infty} \frac{1}{\alpha_n} \exp\left(\frac{-\alpha_n DL}{V_0 R^2}\right) \qquad \text{(Eq. 2)}$$

where the α_n's are roots for the Bessel function, $J_0(r) = 0$. Equation 2 is an exact expression for C_{av} in terms of measurable quantities (C_s, D, L, V_0, and R) for systems adhering to the previously mentioned flow and boundary conditions.

A second, more physically realistic model is one in which the liquid velocity profile is not flat but parabolic (Fig. 1*b*). A parabolic velocity profile is in accordance with the prediction of the Navier–Stokes equations for laminar fluid flow in a tube (6). For this parabolic model, the fluid velocity is not a constant, V_0, but varies parabolically across the tube and can be characterized by a maximum velocity, V_{max}, or an average velocity, V_{av}. The differential equation describing mass transfer with a parabolic velocity profile is:

$$V_{max}\left[1 - \left(\frac{r}{R}\right)^2\right] \frac{\partial c}{\partial z} = D \frac{1}{r} \frac{\partial}{\partial r}\left(r \frac{\partial c}{\partial r}\right) \qquad \text{(Eq. 3)}$$

Equation 3 is identical to Eq. 1 for the diffusive contribution while differing in the convective term, which defines the flow conditions. A solution to Eq. 3 can be obtained numerically (7) with the same boundary conditions for Eq. 1 and takes the form:

$$C_{av}/C_0 = 1 - \sum_{n=1}^{\infty} a_n \exp\left(-\frac{b_n DL}{V_{av} R^2}\right) \qquad \text{(Eq. 4)}$$

where a_n and b_n are constants that have been determined numerically up to $n = 11$ (7). As in the plug flow model (Eq. 2), Eq. 4 for parabolic flow is an exact expression for C_{av} in terms of measurable quantities.

A third model involves parabolic flow with the added constraint that the solute concentration gradient does not penetrate to a great distance into the flowing fluid (8). Therefore, the diffusing solute is subjected to a velocity gradient that is essentially linear. With this assumption, the convective term in the differential equation for mass transfer becomes $V_{max}[2(R - r)/R]$, with $r \simeq R$ rather than the convective term given on the left-hand side of Eq. 3. The mass transfer differential equation thus becomes:

$$V_{max} 2 \frac{(R - r)}{R} \frac{\partial c}{\partial z} = D \frac{1}{r} \frac{\partial}{\partial r}\left(r \frac{\partial c}{\partial r}\right) \qquad \text{(Eq. 5)}$$

Again, the diffusive expression in Eq. 5 is identical to that in the previous models, with the difference being the convective expression. The solution to Eq. 5 becomes:

$$C_{av}/C_s = 2.53 \left(\frac{DL}{V_{av} R^2}\right)^{2/3} \qquad \text{(Eq. 6)}$$

This third model can be considered an asymptotic solution of the parabolic model, which is applicable when $DL/V_{av}R^2$ is small. Since Eq. 6 does not involve a power series or the need to evaluate constants (a_n and b_n) numerically, it is easier to handle mathematically than Eq. 4 within its limits of applicability. All of these models are similar in explicitly accounting for the increase in solute concentration as fluid travels down the tube, which continuously reduces the concentration gradient and diffusional flux, and differ only in their treatment of the convective contribution.

An inspection of Eqs. 2, 4, and 6 shows that the dimensionless term $DL/V_{av}R^2$ (for plug flow $V_0 = V_{av}$) is common to each and can be considered as a single variable, Z. Figure 2 shows a log–log plot of C_{av}/C_s predicted by the three models *versus* the variable Z. Graphically, it can be seen that the parabolic model (Eq. 4) and its asymptotic solution (Eq. 6) approach each other as Z decreases. The plug flow model (Eq. 2) gives

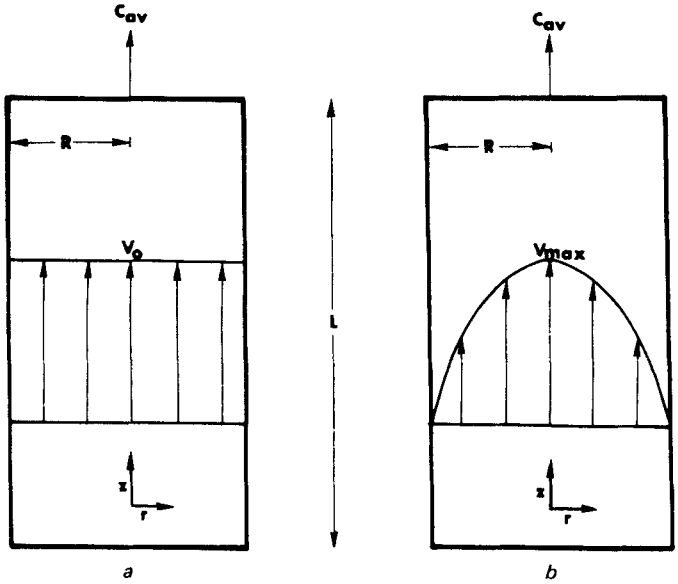

Figure 1—*Velocity profiles for liquid flow in a tube. Key:* a, *plug flow; and* b, *parabolic flow.*

the highest prediction of C_{av}/C_s throughout, with a limiting slope of 0.5 at low Z.

To evaluate the applicability of these models to experimental data, one must obtain steady-state values of C_{av} (effux concentration from the tube) for constant liquid flow rates in a tube of known diameter and length. By using the diffusion coefficient, D, and the solubility, C_s, of the solute in the liquid, the appropriate Z value and the ratio C_{av}/C_s can be calculated for each flow rate. The agreement of these model predictions can then be graphically compared with experimental data. Such comparisons of these models with experiment were conducted for solid tubes dissolving into flowing aqueous media (9).

For the application of convective diffusion models to membrane systems, an expansion of these equations is required to include a contribution due to membrane permeability. Under limiting conditions where membrane permeability is much higher than the mass transfer rate through the flowing fluid, the previously derived models can be applied without modification. Such limiting conditions imply that experimental studies on systems adhering exactly to Eq. 2, 4, or 6 would characterize only the convective diffusional properties of the solute in the flowing liquid and not the permeability of the membrane. At the opposite extreme, limiting conditions can be approached at which the membrane transport resistance is much higher than the convective diffusional resistance of the solute in the flowing liquid. At this limit, the effluent concentration, C_{av}, decreases linearly with flow rate. Between these limits, the transport behavior of a tubular membrane system exhibits varying contributions of membrane and convective diffusion control.

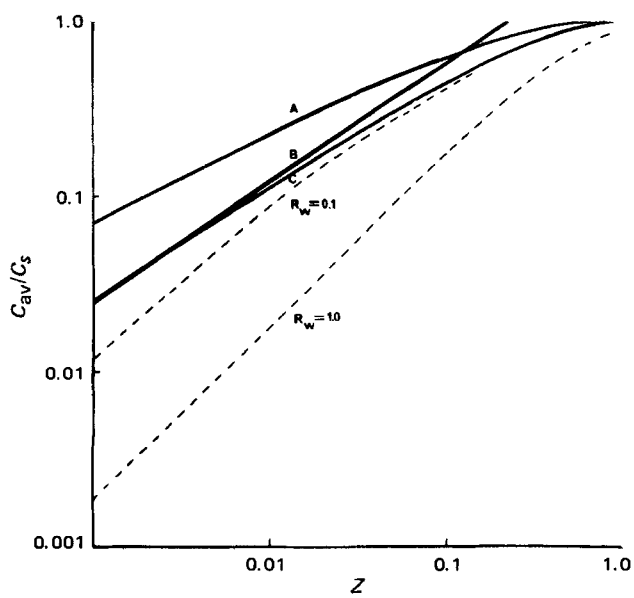

Figure 2—*Log–log plot of* C_{av}/C_s *versus* Z *for plug flow (A), parabolic asymptote (B), parabolic flow (C), and parabolic flow with wall resistance (- - -).*

Table I—Physical Constants for *p*-Aminobenzoate Esters

Compound	Membrane–Water Partition Coefficient[a]	Aqueous Diffusion Coefficient[b], $cm^2/sec \times 10^6$	Membrane Diffusion Coefficient[a], $cm^2/sec \times 10^6$
Ethyl ester	0.33	6.4	2.7
Butyl ester	3.90	6.0	2.7
Hexyl ester	46.90	5.7	2.7

[a] From Ref. 3. [b] Calculated from equations given in Ref. 15.

This behavior, of course, is not unique to tubular membrane systems. However, in this case the convective diffusional contribution in the flowing liquid is explicit and can be determined exactly without resort to semiempirical methods. The transport characteristics of liquids flowing with a parabolic velocity gradient in tubular systems with a contribution from wall resistance were treated analytically for heat transfer (10) and extended to mass transfer systems (11, 12). The treatment for mass transfer utilizes a wall resistance term, R_w, given by:

$$R_w = \frac{D_{aq}}{D_m P} \ln\left(\frac{\text{o.d.}}{\text{i.d.}}\right) \qquad \text{(Eq. 7)}$$

where D_m = membrane diffusion coefficient, D_{aq} = aqueous (liquid) diffusion coefficient, P = partition coefficient (membrane/aqueous), o.d. = outer tube diameter, and i.d. = inner tube diameter.

Figure 2 (dashed curves) shows the deviations from the parabolic model for selected values of R_w. As R_w increases, the effluent concentration, C_{av}, decreases at a particular Z value; as Z varies, the influence of a particular value of R_w on C_{av} also varies. At low Z, a particular R_w causes larger deviations from convective diffusion control than at high Z where the contribution can be small or negligible.

EXPERIMENTAL

Materials—The ethyl (benzocaine), butyl (butamben), and hexyl esters of *p*-aminobenzoic acid were obtained commercially[1] (ethyl and butyl) or synthesized (hexyl) (3). Table I includes the physical constants for these esters required for evaluating the transport data according to the theoretical equations. Medical grade silicone tubing[2] (dimethyl polysiloxane) was used in 1-m lengths with an inside diameter of 1.47 mm and an outside diameter of 1.96 mm. Deionized water was used throughout.

Analytical Procedures—All analyses for *p*-aminobenzoate esters were conducted spectrophotometrically[3] at 285 nm.

Membrane Transport Systems—The two experimental transport configurations differed from each other only by the degree of curvature of the tubing. The tubing was either threaded through stainless steel paper clips soldered to a circular stainless steel rod and mounted in a 18.95-liter (5-gallon) covered stainless steel container or suspended straight in a polyethylene-lined trough.

In both configurations, the silicone tubing was completely immersed in deionized water saturated with excess solid ester. High agitation of the saturated reservoir solution outside the tubing was maintained in the stainless steel container by a 10-cm magnetic stirring bar rotated at 600 rpm and in the trough with three magnetic stirrers and two overhead stirrers placed along its length. High agitation was required to maintain saturation and to minimize transport resistance in the reservoir solution. Temperature was ambient (23–25°). Slight variations in temperature were compensated for by measuring the saturation concentration, C_s, at regular intervals during each study.

The silicone tubing, immersed in the saturated ester solution, was attached to either a two-stage syringe pump[4] or a reciprocating pump[5] with polyethylene and stainless steel tubing. The pump was connected to a supply of deionized water, which was pumped through the tubing at a

constant flow rate. Samples of the effluent solution were collected and assayed for the concentration, C_{av}, of ester at each flow rate.

RESULTS AND DISCUSSION

Figure 3 shows the results of transport studies carried out with the hexyl, butyl, and ethyl esters. It is quite apparent that the plug flow model (Eq. 2) is not applicable to any of the systems. This result was not unexpected, since plug flow is not applicable to Newtonian liquids under laminar flow conditions in a tube. The parabolic model (and its asymptotic solution at low Z) is apparently applicable to hexyl ester throughout the range of Z values studied, while butyl and ethyl esters exhibited varying degrees of negative deviations from the parabolic model.

For hexyl *p*-aminobenzoate (Fig. 3), the parabolic model fits the data well enough to confirm that the convective diffusional contribution to mass transfer can be predicted with a high degree of accuracy. All of the constants (D_{aq}, L, V_{av}, C_s, R, a_n, and b_n) found in Eq. 4 were independently obtained and used to calculate Z and the theoretical curve. Therefore, once C_{av} was determined at a particular V_{av}, no empirical fitting or correction was required to obtain the observed correlation between theory and experiment found in Fig. 3. One must be cautious, however, in interpreting these data with regard to the membrane transport of hexyl *p*-aminobenzoate through dimethyl polysiloxane, because, in fact, only the convective diffusional contribution to mass transfer was characterized.

Without the butyl and ethyl ester studies as a comparison, little can be said about the permeability characteristics of the hexyl ester through dimethyl polysiloxane, except that it is much higher than the convective diffusional resistance in the flowing liquid. Thus, the transport rate of a solute such as hexyl *p*-aminobenzoate in this tubular membrane system is completely governed by the bulk hydrodynamics of the system and not the membrane permeability. Such behavior is not unexpected, in general, and was demonstrated in similar transport systems (12). The value of these observations on hexyl *p*-aminobenzoate lies in the fact that the convective diffusional contribution can be calculated *a priori* with the aforementioned parameters and equations and compared with experimental results.

For a convective diffusion-controlled system, close control is required over the experimental conditions to obtain reproducible results. In the case of the hexyl ester (Fig. 3), when the circular tube configuration was employed, C_{av}/C_s values (open points) were consistently higher than predicted by theory, particularly at low Z (high flow rate). This positive deviation arose from secondary flows in the flowing liquid due to centrifugal forces which increase with flow rate (13). This effect essentially increases the convective contribution to mass transfer, allowing the liquid to take up more solute from the wall than would be predicted under purely laminar flow conditions. These secondary flows do not significantly affect the butyl and ethyl ester studies because both are in at least partial membrane control at Z values (<0.1) where the centrifugal effect becomes important. Twisting the tubing into irregular configurations induces turbulent flow conditions which gives rise to even greater positive deviations from theory than are observed with the circular configuration.

Butyl *p*-aminobenzoate (Fig. 3) exhibited the same adherence to the parabolic model as the hexyl ester at large Z (low flow rates) but deviated negatively at small Z (high flow rates). Such behavior indicates that, at low flow rates, butyl *p*-aminobenzoate transport is purely convective diffusion controlled but that membrane transport resistance becomes limiting at high flow rates. As can be seen from Fig. 3 at the lowest Z values studied, the log–log plot of C_{av}/C_s *versus* Z is linear with a slope of approximately 1, indicating that the system is completely membrane controlled. This graphical characteristic allows the differentiation of complete convective diffusion control and membrane control in a laminar flow tubular membrane system; the former exhibits a slope of two-thirds for a log–log plot of C_{av}/C_s *versus* Z, while the latter gives a slope of 1.

The transition region over which the type of transport control changes depends upon the solute, membrane properties, and hydrodynamic conditions. Comparison of the butyl and hexyl esters shows that the important physicochemical difference lies in their membrane–water partition coefficients, P. There is approximately a 10-fold difference in the partition coefficients of the butyl and hexyl esters (Table I), which would predict an order of magnitude lower membrane permeability for butyl *p*-aminobenzoate compared to hexyl *p*-aminobenzoate. With lower membrane permeability, the butyl ester begins to show membrane control at $C_{av}/C_s \simeq 0.1$; it can be estimated that the hexyl ester would begin to exhibit membrane control at $C_{av} \simeq 0.01$, which is above the range of flow rates used.

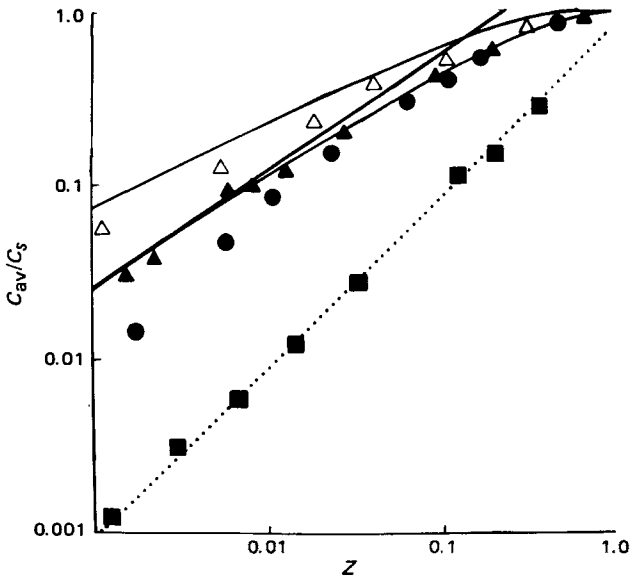

Figure 3—*Log–log plot of* C_{av}/C_s versus Z *for* p-*aminobenzoate esters. Key:* ▲, *hexyl ester (straight tube configuration);* △, *hexyl ester (curved tube configuration);* ●, *butyl ester;* ■, *ethyl ester;* —, *theoretical predictions as labeled in Fig. 2; and . . ., plot of Eq. 9 for the ethyl ester.*

By comparing the data obtained for butyl *p*-aminobenzoate to the predictions in Fig. 2, a value for R_w of 0.1–0.2 can be estimated. With values of D_m, D_{aq}, and P in Table I and the tubing dimensions, R_w was determined to be 0.15 using Eq. 7. Such a correlation between experiment and theory under membrane-controlled conditions further supports the utility of tubular membrane systems for determining the relative importance of membrane permeability and convective diffusion to overall transport rates.

The results for ethyl *p*-aminobenzoate (Fig. 3), in contrast to the previous two esters, fall significantly below theoretical convective diffusion predictions. Throughout the range of flow rates studied, the ethyl ester remained in essentially complete membrane control. Studies at very low flow rates (not shown) indicate that ethyl *p*-aminobenzoate approaches $C_{av}/C_s = 1$ at $Z > 1$. Using values for D_m, D_{aq}, and P found in Table I for the ethyl ester with Eq. 7 leads to a predicted R_w of 2.08, which indicates that membrane resistance is high and that convective diffusion is unimportant to mass transfer over the range of flow rates studied. As with the butyl ester at low Z, the log–log plot of C_{av}/C_s *versus* Z for the ethyl ester exhibits a slope of 1, indicating that the solute flux through the membrane is constant and maximal and that changes in C_{av}/C_s with Z only reflect a change in throughput of liquid.

Under complete membrane control, the transport rate is independent of hydrodynamics (laminar or turbulent flow). As a test of this independence, Eq. 8 (14), which predicts the flux, F, through a cylindrical wall at steady state with the inner wall at zero concentration and the outer wall in contact with a saturated solution, was employed:

$$F = \frac{2\pi D_m P C_s}{\ln (\text{o.d./i.d.})} \qquad \text{(Eq. 8)}$$

Since F is the flux per unit length, multiplying by the tube length, L, dividing by the volume flow rate, f, and rearranging give:

$$\frac{C_{av}}{C_s} = \frac{2\pi D_m P L}{f \ln(\text{o.d./i.d.})} \qquad \text{(Eq. 9)}$$

Using the parameters from Table I and the tubing dimensions gives $C_{av}/C_s = 0.116/f$, which is plotted in Fig. 3 (dotted line). Such a close correlation between the experimental C_{av}/C_s values and Eq. 9 confirms the independence of ethyl *p*-aminobenzoate transport from hydrodynamics, since no account is taken of the type of convection in obtaining Eq. 9. Thus, the flowing fluid serves only to carry the ethyl ester from the inner tubing wall and provides no detectable resistance to solute transport.

With the three *p*-aminobenzoate esters chosen for study, three typical transport patterns were demonstrated: the extremes of complete membrane (ethyl ester) and complete convective diffusion (hexyl ester) control and a change in transport control with flow rate (butyl ester). The ability to calculate accurately, *a priori*, the influence of hydrodynamics is unattainable by other experimental designs. These studies, of course, do not detract from previous membrane transport work in which stagnant

liquid diffusion layers were employed in the theoretical analysis (1, 3). Rather, this work demonstrates that such diffusion layers are in reality convenient "fictions," which need not be invoked with certain experimental designs. Certainly, the concept of aqueous diffusion layers has been instrumental in the understanding of membrane transport processes, but too much credence has been given to their actual existence.

Biological analogies to these polymeric tube transport studies are the isolated perfusion and *in situ* techniques for intestinal absorption. An isolated intestinal segment suspended as nearly straight as possible would serve as a means for determining the luminal convective diffusion contribution to intestinal transport. For an *in situ* intestinal system, definite bends in the intestine would induce secondary flows or turbulence, which would require that absorption data be carefully analyzed for the demarcation between convective diffusion control and membrane control. With the ability to determine accurately the luminal contribution to overall intestinal transport, absorption models can be established on a firmer physical basis. Without the need for semiempirical approaches to obtain diffusion layer or stagnant film permeability coefficients, the elucidation of membrane transport characteristics should be facilitated.

Furthermore, the tube configuration is of value pharmaceutically for obtaining the intrinsic dissolution rates of solids (9). Solid tubes, obtained by various methods, can be infused with dissolution media and the efflux concentrations can be measured as a function of flow rate. From such information, the presence or absence of surface or other kinetic barriers can be determined by comparison of efflux concentrations with the theoretical predictions for pure convective diffusion control.

Quantitative Determination of Phenacetin and Its Metabolite Acetaminophen by GLC–Chemical Ionization Mass Spectrometry

W. A. GARLAND *ˣ, K. C. HSIAO ‡, E. J. PANTUCK ‡, and A. H. CONNEY *

Abstract □ A quantitative GLC–mass spectrometric procedure was developed for the determination of phenacetin and its *O*-desethyl metabolite, acetaminophen, in human plasma. The assay utilizes selective ion detection to monitor, in a GLC effluent, the MH^+ molecular ions of both phenacetin and the methyl derivative of acetaminophen, *p*-acetanisidine, generated by isobutane chemical ionization. Deuterated analogs of phenacetin and acetaminophen, phenacetin-d_3 and acetaminophen-d_3, respectively, are added to the plasma before extraction to serve as internal standards. To determine phenacetin and unconjugated acetaminophen, 1.0 ml of plasma is extracted with 5 ml of benzene–dichloroethane (7:3). The extraction solvent is removed, and the residue is methylated with diazomethane. The solution is again evaporated to dryness, and the residue is reconstituted in ethyl acetate. A portion of this solution is then analyzed by GLC–mass spectrometry, with the mass spectrometer set to monitor *m/e* 166 (*p*-acetanisidine), 169 (*p*-acetanisidine-d_3), 180 (phenacetin), and 183 (phenacetin-d_3). To determine total acetaminophen, 0.1 ml of plasma is treated with a mixture of β-glucuronidase and sulfatase, extracted with ethyl acetate, methylated, and analyzed by GLC–mass spectrometry. The procedure has a sensitivity limit of 1 ng of phenacetin/ml and 0.1 μg of acetaminophen/ml. The curves relating the amount of phenacetin and acetaminophen added *versus* the amount of phenacetin and acetaminophen found for 12 known phenacetin concentrations over the 9.9–246.6-ng/ml range and for 16 known acetaminophen concentrations over the 0.52–13.10-μg/ml range are straight lines with intercepts of nearly zero and with slopes of unity. Analyses of six separate plasma samples, each containing 25 ng of phenacetin/ml and 1.31 μg of acetaminophen/ml, had a precision of ±1 ng/ml for phenacetin and ±0.08 μg/ml for acetaminophen.

Various nonspecific spectrophotometric (1–5) procedures or time-consuming liquid (6, 7), paper (8, 9), or thin-layer (10–12) chromatographic procedures have been developed to measure the analgesic phenacetin (I) and its analgesic biotransformation product, acetaminophen (II), in human plasma. The published GLC procedures for these compounds have a detection limit of 50 ng/ml (13–15). While this sensitivity is suitable for the measurement of

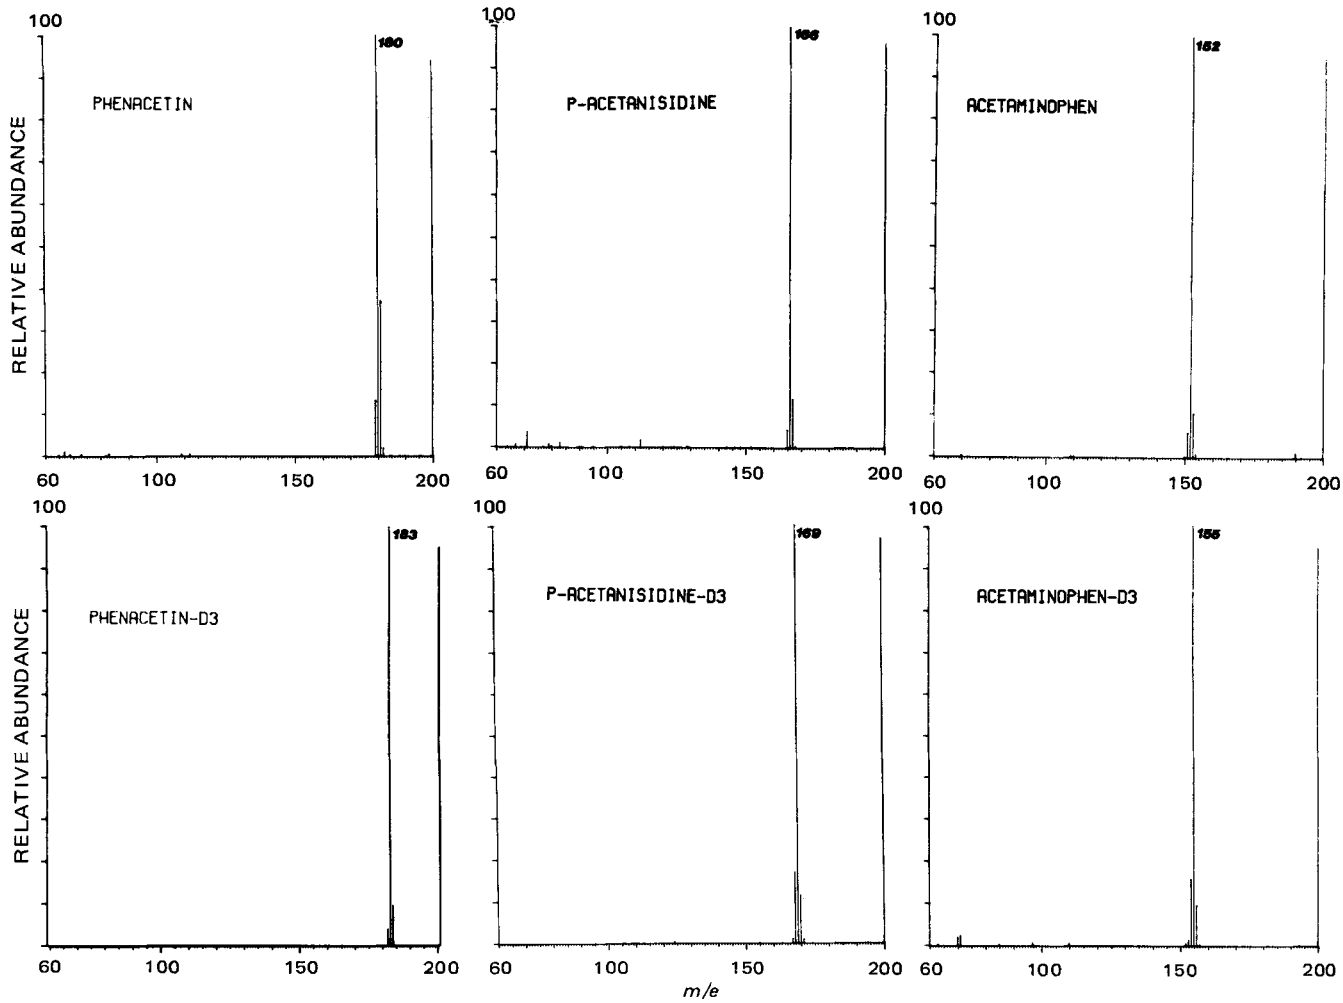

Figure 1—*Isobutane mass spectra of phenacetin, p-acetanisidine, acetaminophen, and their deuterated analogs.*

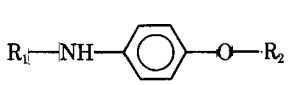
acetaminophen, it permits the determination of phenacetin concentrations in normal subjects for only a few hours after oral administration of a therapeutic phenacetin dose and is insufficient for phenacetin determinations in many subjects with induced drug-metabolizing capabilities (16, 17).

This report describes a GLC–mass spectrometric assay that requires 1.1 ml of plasma and is capable of determining 1 ng of phenacetin/ml and 0.1 μg of unconjugated and conjugated acetaminophen/ml. The method utilizes chemical ionization (18) GLC–mass spectrometry, with isobutane functioning both as a reagent and GLC carrier gas. To obtain sufficient sensitivity, selective ion detection is used to monitor the MH^+ ion of both phenacetin and the methyl derivative of acetaminophen, *p*-acetanisidine (III). Deuterated analogs of phenacetin and acetaminophen, phenacetin-d_3 (IV) and acetaminophen-d_3 (V), respectively, are added to the plasma as internal standards.



I: $R_1 = CH_3CO$, $R_2 = CH_2CH_3$
II: $R_1 = CH_3CO$, $R_2 = H$
III: $R_1 = CH_3CO$, $R_2 = CH_3$
IV: $R_1 = CH_3CO$, $R_2 = CH_2CD_3$
V: $R_1 = CD_3CO$, $R_2 = H$
VI: $R_1 = CD_3CO$, $R_2 = CH_3$

EXPERIMENTAL

Apparatus—A quadrupole mass filter[1] and data system[2] were used in conjunction with a gas chromatograph[3]. The GLC column, 1.21 m (4 ft) × 2 mm i.d., was silanized, packed with 3% OV-17 on 100–120-mesh Gas Chrom Q[4], and conditioned at 325° with no flow for 3 hr and then at 275° overnight with a 20-ml/min helium flow. The chromatographic conditions were: column oven, 180–195°; injection port, 300°; isobutane[5] pressure, 0.45–1.36 kg (1–3 lb)/in.^{2}; and interface oven and glass-lined source reentrant tube, 250°. Typical ion source settings were: ion volume, +8 v; ion repeller, +2 v; lens, −30 v; and filament, −110 v with the electron beam total emission regulated at 800 μamp. Column temperature and isobutane pressure were adjusted to provide an ion source pressure of 0.4 torr. The source was operated without external heating (temperature approximately 50°).

Materials—Nanograde quality benzene[6], methanol[6], and ethyl acetate[6] and spectrograde quality 1,2-dichloroethane[7] were used without further purification. Before each assay, ethereal diazomethane (50 ml) was prepared according to Arnt's (19) decanting procedure and dried over anhydrous sodium sulfate.

Tubes (15 ml)[8] equipped with screw caps[9] were used for the plasma extractions, and glass-stoppered centrifuge tubes (5 ml)[10] were used for the final solvent evaporation.

Phenacetin-d_3—A mixture of 4-hydroxyacetanilide (5.0 g, 32 mmoles),

[10] Pyrex 8084.

potassium carbonate (2.8 g, 20 mmoles), ethyl iodide-d_3 (3 ml, 35 mmoles)[11], and acetone (20 ml) was refluxed for 20 hr (20). The solution was cooled, transferred to a separator, and combined with water (20 ml), chloroform (75 ml), and 10% potassium hydroxide (5 ml). The chloroform extract was washed twice with 10% potassium hydroxide (10 ml), the chloroform was removed, and the resulting gum was crystallized from methanol–water to yield 3.85 g (21 mmoles, 66%) of phenacetin-d_3, mp (uncorrected) 131–132° [lit. (21) mp (phenacetin) 134–135°].

The UV (methanol) and IR (potassium bromide) spectra were identical to those of authentic phenacetin, while the PMR[12] spectrum (deuterochloroform) differed from that of phenacetin only by the lack of the triplet at 1.4 ppm. A precise mass determination[13] of the *m/e* 182 molecular ion in the electron ionization mass spectrum gave 182.1137 ($C_{10}H_{10}D_3N_1O_2$ = 182.1135). A selective ion detection analysis of this compound using the developed GLC–mass spectrometric procedure showed the presence of less than 0.5% phenacetin-d_0.

p-Hydroxyacetanilide-d_3—*p*-Hydroxyaniline (535 mg, 5 mmoles), 12 *M* HCl (71 μl), deuterium oxide (8.43 ml)[11], 0.2 *M* sodium acetate (5 ml), acetic anhydride-d_6 (510 mg, 468 μl, 5 mmoles)[11], and ether (10 ml) were combined in a 25-ml separator. The mixture was gently shaken every 5 min for 1 hr (8). Then the aqueous layer was removed, and the ether was extracted with 0.5 *M* potassium hydroxide (3 × 5 ml) and discarded. The combined alkaline extracts were then acidified to pH 1 and extracted with ethyl acetate (3 × 10 ml). The residue remaining after removal of the ethyl acetate was recrystallized from water to yield 387 mg (2.56 mmoles, 51%) of the title compound, mp (uncorrected) 166–168° [lit. (22) mp (acetaminophen) 169–170°].

The UV (ethanol) and IR (potassium bromide) spectra were identical to those of acetaminophen, while the PMR spectrum (deuterochloroform) differed from that of acetaminophen only by the lack of the three-proton singlet at 2.07 ppm. A precise mass determination[13] of the *m/e* 154 molecular ion in the electron ionization mass spectrum gave 154.0841 ($C_8H_6D_3NO_2$ = 154.0821). A selective ion detection analysis of this compound using the described GLC–mass spectrometric procedure showed the presence of less than 0.5% *p*-hydroxyacetanilide-d_0.

Mass Spectrometry—The isobutane chemical ionization mass spectra of phenacetin, phenacetin-d_3, acetaminophen, acetaminophen-d_3, acetanisidine, and acetanisidine-d_3 can be seen in Fig. 1. The spectra are quite simple, consisting principally of MH^+ molecular ions, and were obtained at 0.4 torr by the separate injections of 10 μg of each compound into the GLC–mass spectrometer with the electron multiplier run at low gain to deemphasize background ions resulting from column bleed.

If both phenacetin and acetaminophen were to be determined, the mass spectrometer was set to monitor the MH^+ molecular ions at *m/e* 166 (acetanisidine), 169 (acetanisidine-d_3), 180 (phenacetin), and 183 (phenacetin-d_3). To measure only acetaminophen, the instrument was set to monitor *m/e* 166 and 169.

Assay Procedure—*Phenacetin and Unconjugated Acetaminophen (Procedure A)*—To 1.0 ml of plasma in a 15-ml tube was added 1.0 ml of internal standard solution containing 25–300 ng of phenacetin-d_3/ml and 2.5 μg of acetaminophen-d_3/ml. The resulting solution was allowed to stand for 2 hr. Then 5 ml of benzene–1,2-dichloroethane (7:3) was added, and the mixture was shaken[14] for 20 min. After centrifugation[15] for 20 min at 150×*g*, 4.0 ml of the organic layer was transferred to a 5-ml centrifuge tube. The extraction solvent was then removed at 30° under a gentle stream of nitrogen[16].

The resulting residue was dissolved in 0.5 ml of methanol and treated with 0.5 ml of a diazomethane–ether solution. This mixture was vortexed[17] and allowed to stand for 2 hr. The solvents were removed under a stream of nitrogen, and the residue was reconstituted in 30 μl of ethyl acetate. Depending on the expected phenacetin and acetaminophen concentrations, between 0.5 and 5 μl was injected into the gas–liquid chromatograph.

Thirty seconds after injection, the electron multiplier was turned on and the GLC divert valve was turned off, allowing the GLC effluent to enter the ion source. Forty-five seconds after injection, the ion source supplies were turned on; 15 sec later, computer-controlled scanning and data collection were initiated. Approximate retention times were: *p*-acetanisidine, 1.8 min; and phenacetin, 2.3 min. Three minutes after injection, the GLC divert valve was turned on, the ion source supplies were turned off, and the computer data collection was halted.

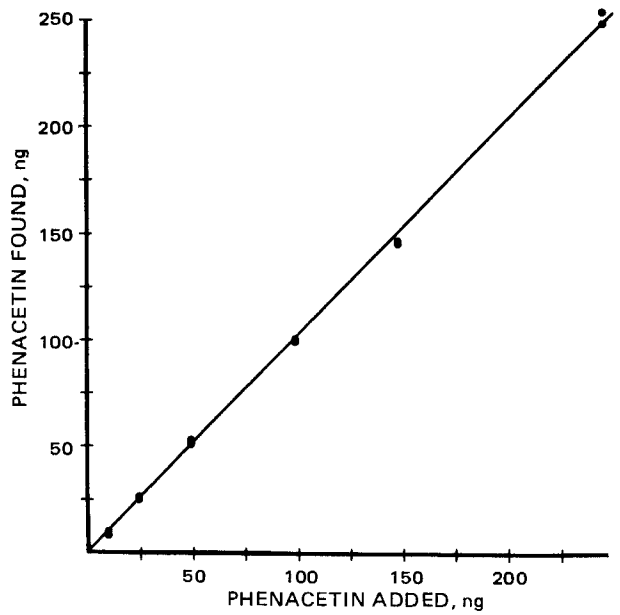

Figure 2—*Curve relating amount of phenacetin added to 1 ml of human control plasma* versus *amount of phenacetin found using Procedure A for two separate analyses at each of six different concentrations. The concentration of the phenacetin-*d_3 *internal standard was 50.5 ng/ml.*

To determine the phenacetin concentration, the area of the *m/e* 180 (phenacetin) peak was divided by that of the *m/e* 183 (phenacetin-d_3) peak and the ratio was multiplied by that of the phenacetin-d_3 concentration. A similar procedure was followed for acetaminophen, except peak heights instead of peak area were used.

Total Acetaminophen (Procedure B)—Plasma (0.1 ml), a β-glucuronidase–sulfatase mixture[18] (0.1 ml), 0.2 *M* sodium acetate pH 5.0 buffer (1 ml), distilled water (0.6 ml), and 0.5 μg of acetaminophen-d_3/ml (1 ml) were incubated with shaking[19] for 16 hr at 37°. The mixture was extracted for 20 min with 8 ml of ethyl acetate and centrifuged at 150×*g* for 15 min. A portion (5 ml) of the organic phase was removed and evaporated to dryness under nitrogen.

The residue was methylated and reconstituted in 30 μl of ethyl acetate, and 1 μl of the solution was injected into the GLC–mass spectrometer. The GLC and mass spectrometric parameters were identical to those used in Procedure A, except the mass spectrometer was set to monitor only *m/e* 166 and 169.

Samples—Plasma standards were prepared by the addition of known amounts of phenacetin and acetaminophen to human control plasma[20].

A 72-kg white male received an oral dose of phenacetin (900 mg)[21] as a fine powder followed by water (300 ml). A heparinized whole blood sample was drawn just before dosing and then every hour for 8 hr. The blood was centrifuged for 20 min at 150×*g*, and the plasma was removed for analysis.

RESULTS AND DISCUSSION

To measure phenacetin and unconjugated acetaminophen, 1 ml of plasma was extracted with benzene–1,2-dichloroethane (7:3). Recoveries for this extraction procedure (Procedure A), determined from a comparison of the peak areas of the internal standards obtained from six separate analyses with the areas from the injection of known amounts of diazomethane-treated phenacetin-d_3 and acetaminophen-d_3, were 95 ± 8% for phenacetin and 0.91 ± 0.12% for acetaminophen. This 104-fold greater extraction of phenacetin permitted both compounds to be determined from a single injection in spite of the commonly observed 100–1000-fold greater plasma acetaminophen concentration.

To determine total acetaminophen, 0.1 ml of plasma was treated with a β-glucuronidase–sulfatase mixture[18] and the acetaminophen was ex-

Circles are analyses using Procedure A with 2.52 μg of acetaminophen-d_3/ml used as the internal standard. Squares are determinations using Procedure B with 5.00 μg of acetaminophen-d_3/ml used as the internal standard.*

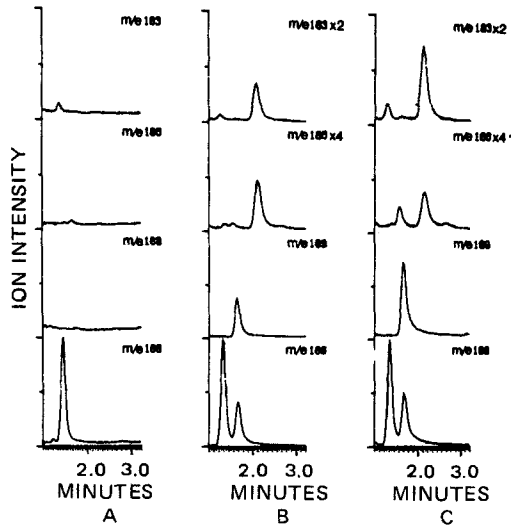

Figure 4—*Typical ion chromatograms from the determination by Procedure A of phenacetin and acetaminophen in a subject who had received an oral dose of 900 mg of phenacetin. Key: A, plasma blank, zero time; B, 6 hr after dosing, phenacetin* (m/e *180*) = *17 ng/ml, phenacetin-d_3* (m/e *183*) = *25.3 ng/ml, acetaminophen* (m/e *166*) = *2.51 μg/ml, and acetaminophen-d_3* (m/e *169*) = *2.52 μg/ml; and C, 8 hr after dosing, phenacetin = 6.1 ng/ml, phenacetin-d_3 = 25.3 ng/ml, acetaminophen = 1.62 μg/ml, and acetaminophen-d_3 = 2.52 μg/ml. For the purpose of display, ion tracings at* m/e *183 and 180 in B and C were multiplied by factors of two and four, respectively.*

tracted into ethyl acetate. The acetaminophen recovery for this extraction procedure (Procedure B), determined from a comparison of the peak heights of the internal standards for six separate analyses with the heights from the injection of known amounts of diazomethane-treated acetaminophen-d_3, was 89 ± 18%. Conjugated acetaminophen was calculated from the difference between the acetaminophen levels determined by Procedures A and B.

Both total acetaminophen and phenacetin can be simultaneously determined by preceding Procedure A with enzyme[18] treatment. The plasma blank, however, for phenacetin (*m/e* 180 and 183) after enzyme[18] treatment shows a number of small background ions that interfere with the accurate determination of low phenacetin levels (<5 ng/ml). In addition, the enzyme[18] treatment releases some compounds with prominent *m/e* 180 or 183 ions but with longer retention times than phenacetin. Thus, if phenacetin is to be determined in this manner, the sample injections must be spaced at least 20 min apart to ensure specificity. When using Procedure A, however, a sample can be injected every 3 min.

Human control plasma subjected to either Procedure A or B showed no significant background ions at *m/e* 169, 180, and 183. With Procedure A, a peak with a retention time shorter than that of acetaminophen was observed at *m/e* 166; ions with retention times both shorter and longer than acetaminophen were observed with Procedure B. Because of these background ions, peak heights—not peak areas—were used for the quantification of acetaminophen.

Neither phenacetin-d_3 nor acetaminophen-d_3 showed any isotope exchange when subjected to Procedure A or B.

Results obtained from the addition of known amounts of phenacetin and acetaminophen to human control plasma followed by processing according to Procedure A can be seen in Figs. 2 and 3. A least-squares analysis of the results for 12 phenacetin standards (Fig. 2) gave a slope of 0.999 ± 0.001 and an intercept of 0.304 ± 1.00 ng. The phenacetin-d_3 internal standard concentration for these analyses was 50.5 ng/ml. The corresponding curves (Fig. 3) for 12 acetaminophen standards analyzed by Procedure A and four acetaminophen standards analyzed by Procedure B gave a slope of 1.02 ± 0.015 and an intercept of 0.102 ± 0.103 ng. The acetaminophen-d_3 internal standard concentration for these analyses was 2.52 μg/ml with Procedure A and 5.00 μg/ml with Procedure B. Thus, these data suggest that the extraction, mass spectral, and GLC characteristics of the labeled and unlabeled compounds and their reactivity toward diazomethane are essentially identical.

To determine assay precision, six separate samples of control plasma, each containing 24.7 ng of phenacetin/ml and 1.31 μg of acetamino-

Table I—Plasma Levels of Phenacetin and Acetaminophen (Unconjugated, Conjugated, and Total) in a 72-kg White Male at Various Intervals after Oral Administration of 900 mg of Phenacetin[a]

8	6.1	1.6	9.3	11.0

[a] Phenacetin and unconjugated acetaminophen were determined using Procedure A; total acetaminophen was determined using Procedure B. Conjugated acetaminophen is the difference between that determined by Procedures A and B. [b] Not measurable.

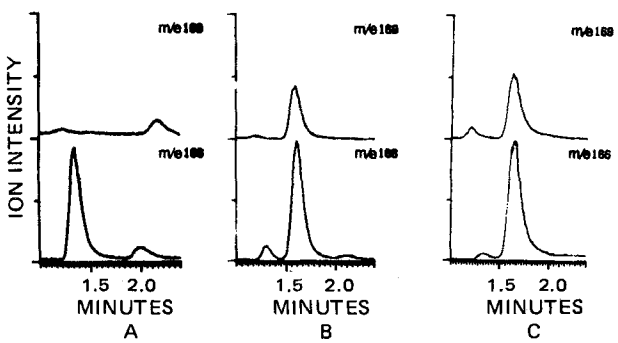

Figure 5—*Typical ion chromatograms from the determination by Procedure B of acetaminophen in a subject who had received an oral dose of 900 mg of phenacetin. Key: A, Subject 1 plasma blank, zero time; B, 6 hr after dosing, acetaminophen* (m/e *166*) = *11.7 μg/ml and acetaminophen-d_3* (m/e *169*) = *5.0 μg/ml; and C, 8 hr after dosing, acetaminophen = 11.0 μg/ml and acetaminophen-d_3 = 5.0 μg/ml. Chromatogram A is normalized to the value of the background ions at* m/e *166 which elute before* p-*acetanisidine. The intensity of these ions relative to* p-*acetanisidine in an actual assay can be seen in B and C.*

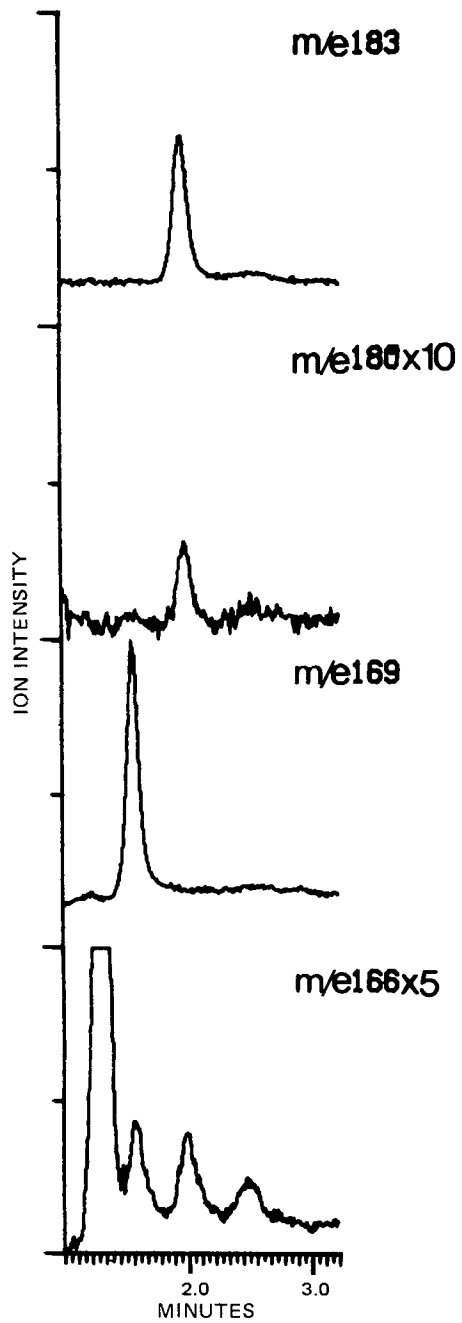

Figure 6—*Analysis of 1 ml of plasma containing 1 ng of phenacetin* (m/e *180*) *and 0.100 μg of* p-*acetanisidine* (m/e *166*) *by Procedure A. Phenacetin-*d_3 (m/e *183*) *and* p-*acetanisidine-*d_3 (m/e *169*) *internal standards were present in concentrations of 25.3 ng/ml and 2.52 μg/ml, respectively. For the purpose of display, the ion tracing at* m/e = *166 was multiplied by five while that at* m/e *180 was multiplied by a factor of 10.*

phen/ml, were analyzed using Procedure A. The average phenacetin concentration of these samples was determined to be 24.6 ± 1.0 ng/ml, while the average concentration of acetaminophen was 1.36 ± 0.08 μg/ml.

The phenacetin and unconjugated, conjugated, and total acetaminophen plasma levels for a subject who had received a 900-mg oral dose of phenacetin are reported in Table I. Typical ion chromatograms from this analysis can be seen in Figs. 4 and 5. After dosing, the phenacetin (264 ng/ml) and unconjugated acetaminophen (6.76 μg/ml) concentrations peaked at 1 and 2 hr, respectively, while the conjugated acetaminophen reached an 8–10-μg/ml plateau after 3 hr.

A least-squares analysis of the log concentration *versus* time curve for the 0–8-hr phenacetin concentrations in plasma gave a 1.3-hr elimination half-life; a similar analysis of the 3–8-hr unconjugated acetaminophen levels gave a 2.4-hr disappearance half-life. These half-lives were similar to those previously reported (23) for phenacetin and acetaminophen. Plasma levels of total acetaminophen for this subject decreased very slowly.

The sensitivity of this assay for phenacetin and acetaminophen is a function of the condition of the ion source and quadrupole rods. An analysis of a 1-ng of phenacetin/ml and a 100-ng of acetaminophen/ml plasma standard can be seen in Fig. 6. This ion chromatogram was the 113th obtained following ion source and quadrupole rod cleaning. Seven out of the available 30 μl was injected into the GLC–mass spectrometer. Both the phenacetin and acetaminophen ion peaks still had a signal-to-noise ratio greater than 5:1.

This sensitivity, while required to measure phenacetin in subjects with induced drug-metabolizing capabilities (17), should also be useful in determining basic pharmacokinetic data in humans after administration of a 300-mg therapeutic (24) phenacetin oral dose. Studies to determine the plasma concentration–time profile for phenacetin have typically required a higher than therapeutic phenacetin dose of between 1000 and 1800 mg to obtain measurable plasma levels over a sufficient timespan (23, 25–27).

Pharmacokinetics of Ampicillin and Methoxymethyl Ester of Hetacillin in Dogs

TORBEN B. KJAER *, PETER G. WELLING ‡, and PAUL O. MADSEN *x

Abstract □ Concentrations of ampicillin and the methoxymethyl ester of hetacillin were measured in plasma, prostatic fluid, and spinal fluid of dogs receiving ampicillin or the hetacillin ester by continuous intravenous infusion. The ratios of ampicillin in prostatic fluid relative to plasma levels were higher after dosing with the hetacillin ester. Pharmacokinetic parameter values were consistent with urinary excretion characteristics. Ready diffusion of the ester across biological membranes may facilitate eradication of pathogenic organisms in prostatic and spinal fluids.

Keyphrases □ Ampicillin—pharmacokinetics, plasma, prostatic fluid, and spinal fluid levels, dogs □ Hetacillin methoxymethyl ester—pharmacokinetics, plasma, prostatic fluid, and spinal fluid levels, dogs □ Pharmacokinetics—ampicillin and hetacillin methoxymethyl ester, plasma, prostatic fluid, and spinal fluid levels, dogs □ Antibacterials—ampicillin and hetacillin methoxymethyl ester, pharmacokinetics, plasma, prostatic fluid, and spinal fluid levels, dogs □ Distribution, drug—ampicillin and hetacillin methoxymethyl ester, plasma, prostatic fluid, and spinal fluid levels, dogs

The methoxymethyl ester of hetacillin[1] (I) is a new lipophilic prodrug of ampicillin, with distribution and kinetic properties different from other ampicillin precursors (1, 2). These properties include rapid absorption from the GI tract and extensive distribution into body tissues, particularly prostatic and central nervous system (CNS) tissue. The hetacillin ester appears to be absorbed after oral doses largely as the intact ester. Once absorbed, the ester undergoes hydrolysis in the blood and other tissues and body fluids to yield ultimately free ampicillin. Distribution characteristics of the unchanged ester and ampicillin are functions of the relative rates of tissue uptake and enzymatic and chemical hydrolyses.

The entry of ampicillin and the hetacillin ester into prostatic fluid and tissue of dogs during continuous intravenous infusion was described previously (2). The purposes of the present study were to examine these data from a pharmacokinetic point of view and to describe the tissue distribution characteristics of the hetacillin ester after continuous intravenous infusion in dogs.

EXPERIMENTAL

Full details regarding animal preparation, dosing, sampling, and assay procedures were given elsewhere (2). In summary, eight male beagle dogs, 17–21 kg, were anesthetized with intravenous thiopental sodium[2] and ventilated with air on a respirator. Three dogs received ampicillin sodium[3]

as an initial bolus injection of 3 (Dogs 1 and 2) and 10 (Dog 3) mg/kg and then as a constant infusion into a femoral vein in sterile lactated Ringer's solution at a rate of 10 mg/kg/hr for 4 hr. The infusion was started simultaneously with the bolus injection. Five dogs (Dogs 4–8) were similarly treated with the hetacillin ester[4], receiving a bolus injection of 1.8 mg of ampicillin equivalents/kg followed by a constant infusion of 10 mg/kg/hr iv.

All dogs were sacrificed after a 4-hr infusion. Two other dogs (Dogs 9 and 10) were similarly infused with the hetacillin ester for 2 hr, and plasma and prostatic or spinal fluid were obtained both during and fol-

[a]Not determined.

lowing the infusion. Infusion bottles containing the hetacillin ester were kept in ice water, and fresh solutions were prepared hourly to minimize ester hydrolysis during administration.

Prostatic fluid was obtained by urethral intubation in the perineum just distal to the prostate gland. Urine was collected by cannulation of both ureters, thus preventing contamination of prostatic fluid with urine. The vas deferens was ligated. Prostatic fluid secretion was stimulated by constant infusion of pilocarpine, 0.25 mg/kg/hr iv for 4 hr.

Blood samples were collected from a femoral artery in heparinized tubes at 30-min intervals, and plasma was separated. Prostatic fluid was collected at hourly intervals in vessels contained in an ice bath. Spinal fluid was obtained by suboccipital puncture. All samples were deep frozen immediately after collection until assayed.

Assays for free ampicillin and the unhydrolyzed hetacillin ester were carried out by a disk diffusion method, using *Sarcina lutea* (ATCC 9341) as the test organism as described previously (2). Renal clearances were calculated from hourly urinary excretion of ampicillin or the hetacillin ester during the 2nd, 3rd, and 4th hr of infusion.

RESULTS

Concentrations of ampicillin in plasma and prostatic fluid from the ampicillin infusion and urinary excretion details are given in Tables I and II. Average plasma and prostatic fluid concentrations of ampicillin and the hetacillin ester and urinary excretion details are given in Tables III and IV.

As shown in Tables I and III, the ratio of prostatic fluid to plasma ampicillin varied from 0.1 to 0.01 during ampicillin infusion, with prostatic fluid levels ranging from 0.2 to 2.2 μg/ml. However, during hetacillin ester infusion, mean prostatic fluid levels of ampicillin ranged from 2.2 to 7.4 μg/ml, increasing from the infusion time; the ratios of prostatic fluid to plasma ampicillin were considerably increased to about 0.4.

It can be seen from Tables II and IV that the concentrations of ampicillin in urine were lower after hetacillin ester infusion but were still very high compared to plasma levels. Approximately one-half of the infused ampicillin was recovered unchanged in urine, and renal clearance was 40–80 ml/min. During hetacillin ester infusion, recovery of ampicillin in urine was considerably reduced. However, the renal clearances, except from Dogs 5 and 6 which were atypically low, were similar to those resulting from ampicillin infusion (38–74 ml/min). These values are similar to those reported previously (3). The renal clearance of the hetacillin ester was essentially zero, confirming the quantitative hydrolysis and metabolism of this agent *in vivo*.

Table II—Urinary Excretion of Ampicillin during Infusion of Ampicillin

Dog	Urine Concentration, mg/ml	Urine Volume, ml	4-hr Recovery, % of Dose	Renal Clearance, ml/min
1	4.23 (3.95)[a]	214	44.7	65.1 (25.2)[a]
2	2.44 (1.53)	252	50.1	84.8 (33.1)
3	2.86 (2.08)	157	46.3	40.7 (8.9)

[a]Mean and standard deviation from three 1-hr collections.

Spinal fluid levels of ampicillin and the hetacillin ester were obtained in Dogs 4–7 at the end of the infusion period and in Dogs 8 and 9 at 30–60-min intervals during infusion. The mean 4-hr values for ampicillin and the hetacillin ester were 11.0 ± 8.1 and 2.6 ± 1.7 μg/ml, respectively, which were both about one-third the respective plasma levels.

In Dog 8, spinal fluid concentrations of total ampicillin activity at 30, 90, 120, 180, and 240 min during infusion were 4, 12, 19, 20, and 26.5 μg/ml, respectively. In Dog 9, spinal fluid levels of total ampicillin at 30, 60, 90, and 120 min during infusion were 0.0, 1.2, 3.4, and 4.2 μg/ml, respectively. Thus, in both dogs, there appeared to be an accumulation of the antibiotic in spinal fluid during the infusion while plasma levels remained constant. Furthermore, ampicillin appeared to be cleared from spinal fluid very slowly because the levels of ampicillin in Dog 9 remained constant during 90 min postinfusion while plasma levels decreased from 3.6 to 0.8 μg/ml.

The relative rates of loss of total ampicillin activity (ampicillin plus the hetacillin ester) from plasma and prostatic fluid were determined in Dog 10 by repeated sampling during 3 hr following a 2-hr infusion of the hetacillin ester. The similarity of the rates of decline is indicated in Fig. 1. The calculated elimination half-lives in plasma and prostatic fluid were 0.46 and 0.45 hr, respectively. The linear relationship between the various combined ester and ampicillin concentrations in prostatic and spinal fluids and plasma during infusion is illustrated in Figs. 2 and 3.

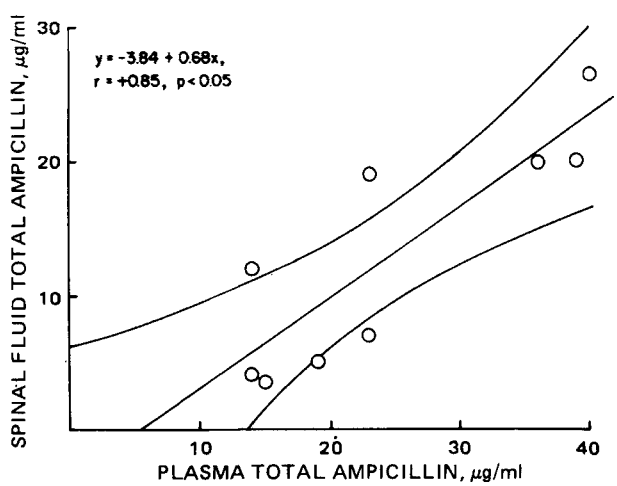

Figure 3—*Linear regression with 95% confidence limits of total ampicillin concentration in spinal fluid against total ampicillin concentration in plasma during hetacillin ester infusion.*

8[c]	Ampicillin	2.03[d]	30	6.1	21.8[d]
	Hetacillin ester	2.5		0.02	0.18

[a] Mean and standard deviation from three 1-hr collections. [b] Urinary concentration of the hetacillin ester is expressed in micrograms per milliliter in all cases. [c] Dogs 5 and 8 developed slow heart rates and low blood pressures due to pilocarpine and were generally in poor condition during the experiment. Renal excretion in these animals was low. [d] Only two collections.

DISCUSSION

If it is assumed that the hetacillin ester obeys apparent one-compartment model kinetics, plasma data during infusion of the ester can be described by Scheme I. In this model, concentration of ester in plasma at the steady state, C_{ss}, is given by (4):

$$C_{ss} = k_0/VK \qquad \text{(Eq. 1)}$$

where k_0 is the zero-order infusion rate constant, K is the apparent first-order rate constant for loss of the ester by all processes, and V is the ester distribution volume in the body. The product VK is the ester plasma clearance (5).

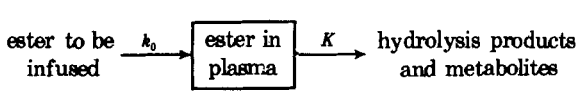
With the plasma concentrations in Table III and known infusion rates, plasma clearances of the ester for Dogs 4, 5, 6, 7, and 8 were 1087, 321, 529, 833, and 457 ml/min, respectively. The values contrast with the almost negligible renal clearances of unchanged ester.

The distribution volume of the hetacillin ester was reported to be approximately 85% of body weight (1). Substituting this value into Eq. 1 and using the relationship $t_{1/2} = \ln 2/K$ yielded a hetacillin ester half-life of 0.34 ± 0.18 hr. This value is identical to that reported for the *in vitro* degradation of the hetacillin ester in dog serum (2).

The overall ratio of ampicillin renal clearance to creatinine clearance in Dogs 1–8 was 1.31 ± 0.55, indicating some renal tubular secretion. This secretion is not as extensive as that usually observed in humans (6) but may have been influenced to some extent by the experimental conditions and surgical procedures.

The relationship between prostatic and spinal fluid levels and plasma levels of ampicillin during hetacillin ester infusion suggests that the lipophilic ester is transported readily into these fluids and that hydrolysis occurs subsequently. It is evident that drug levels in spinal and prostatic fluids can be predicted with reasonable accuracy from observed plasma levels, at least during continuous dosing. Although prostatic fluid levels of ampicillin decline with plasma levels, the antibiotic may stay within spinal fluid for longer periods.

The ability of the hetacillin ester to penetrate spinal and prostatic fluids may prove of considerable use in the eradication of pathogenic organisms resident in these sites which have been relatively inaccessible to the penicillins.



Scheme I—One-compartment open model with zero-order absorption

Serum Lipid-Lowering Properties of 6-Chloro-9-[2-(6-methyl-3-pyridyl)ethyl]-1,2,3,4-tetrahydrocarbazole-2-carboxylic Acid

COLIN DALTON ˣ and WILLIAM R. POOL

Abstract □ 6-Chloro-9-[2-(6-methyl-3-pyridyl)ethyl]-1,2,3,4-tetrahydrocarbazole-2-carboxylic acid hydrochloride lowered serum cholesterol, triglyceride, phospholipid, and free fatty acid levels in normal rats. The compound appeared to have a low toxicity and to be well tolerated in mice, adult and neonatal rats, and rabbits. At hypolipidemic doses, it caused a slight hepatomegaly associated with an increase in liver phospholipid and protein content. Liver *N*-demethylase and catalase activities were increased by the drug treatment. This acid had no *in vitro* antilipolytic activity and did not affect serum desmosterol–cholesterol ratios. The results indicate that it has a mechanism of action similar to clofibrate.

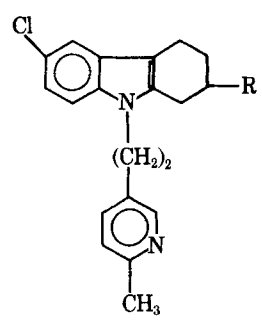
Keyphrases □ Tetrahydrocarbazole, substituted—effect on serum lipid levels in rats, toxicity in rats, mice, and rabbits □ Lipid levels, serum—effect of substituted tetrahydrocarbazole, rats □ Toxicity—substituted tetrahydrocarbazole, rats, mice, and rabbits □ Antihyperlipidemic activity—substituted tetrahydrocarbazole evaluated, rats

Interest in pharmacological agents that lower blood lipid levels is primarily based upon data that implicate elevated blood lipid levels in the etiology of coronary disease. Clofibrate[1], ethyl 2-(4-chlorophenoxy)-2-methylpropanoate, is currently marketed as an active hypolipidemic agent. It is being extensively tested in an international primary prevention trial of ischemic heart disease (1) and for its long-term influence on morbidity and mortality in patients with a history of clinical heart disease (2). This report concerns a new compound, 6-chloro-9-[2-(6-methyl-3-pyridyl)ethyl] -1,2,3,4 -tetrahydrocarbazole- 2-carboxylic acid hydrochloride (I) (3), which is structurally unrelated to clofibrate but has serum lipid-lowering properties.

EXPERIMENTAL

Treatment of Animals—Male albino rats[2], 180–200 g, were housed in individual stainless steel cages with wire screen bottoms. The cages were maintained at 23°. All animals were allowed food[3] and tap water *ad libitum*.

Drugs were suspended or dissolved in an aqueous suspending vehicle (sodium chloride, 9 g/liter; carboxymethylcellulose, 5 g/liter; polysorbate 80, 3.9 g/liter; and benzyl alcohol, 8.6 ml/liter, in distilled water) and administered at the doses indicated in 5 ml of vehicle/kg. Control rats received an equal volume of the vehicle. Routes and times of drug administration are given under *Results*.



I: R = COOH
II: R = CH_2OH

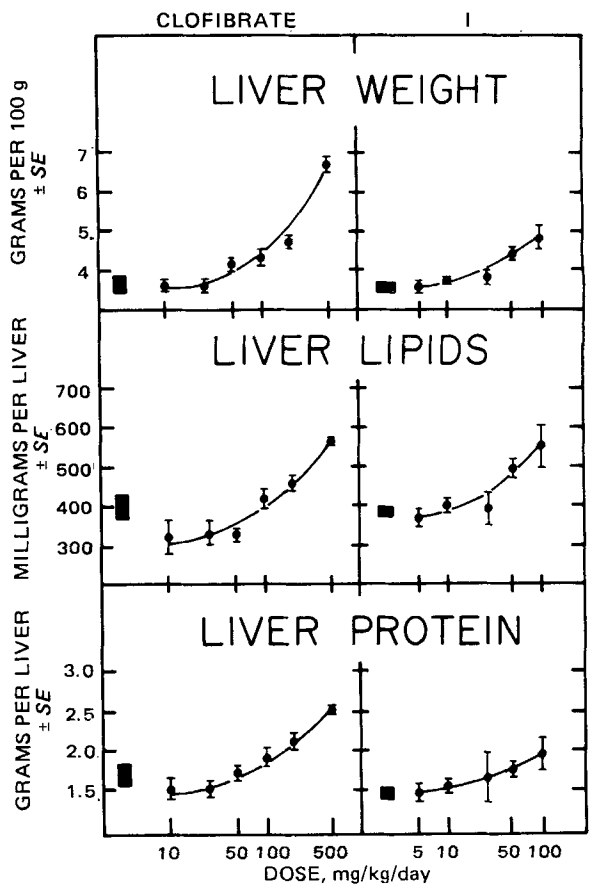


Figure 1—*Effect of hypolipidemic agents on rat liver weight and liver lipid and protein content. Key:* ■, *control.*

The animals were fasted overnight and sacrificed by decapitation. Body, liver, adrenal, and epididymal fat pad weights were recorded. Separate portions of liver were used for the preparation of subcellular fractions, analysis of lipids, and determination of *N*-demethylase activity.

Hypertriglyceridemic Rats—The test compounds were suspended in 5% gum acacia solution and administered orally for 11 days by intubation each day, except on the weekend when the compounds were administered as a dietary admix. Six animals were used for each dose level. Two groups of 10 control animals each were untreated. A 10% fructose solution was substituted for normal drinking water for the last 20 hr of the test. One control group continued to receive normal drinking water. On Day 12, the animals were sacrificed for serum triglyceride determination (4).

Preparation of Subcellular Fractions—A 10% liver homogenate in 0.25 *M* sucrose was prepared using six strokes of a motor-driven glass–plastic[4] homogenizer at 4°. Mitochondria were isolated according to the method of Schneider (5). Samples were centrifuged[5] at 800×*g* at

[a] $p < 0.01$.

2° for 10 min to remove nuclei and unbroken cells. The supernate was collected, and the residue was washed twice with isotonic sucrose. Washes were combined with the supernate, and the residue was discarded. The combined supernates were then centrifuged[6] at 8500×*g* at 2° for 10 min to sediment the mitochondria. The supernate was collected and the mitochondrial pellet was washed twice with isotonic sucrose.

Microsomes were prepared by centrifuging[7] the combined supernates from the mitochondrial fraction of 105,000×*g* at 2° for 75 min. The mitochondrial and microsomal pellets were resuspended in isotonic sucrose and rehomogenized gently with a glass–plastic[4] homogenizer to a final tissue equivalent of 150 mg/ml.

Analytical Procedures—Serum was analyzed for cholesterol (6), triglycerides (4), phospholipids (7), and free fatty acids (8). The protein content of the fractions was determined by the biuret reaction conducted on an automated analyzer[8]. Lipids were extracted with chloroform–methanol (2:1 v/v), using a modification of the Folch *et al.* procedure (9), determined gravimetrically, and analyzed for phospholipid content (7).

Determination of Hepatic *N*-Demethylase Activity—A 20% liver homogenate in 0.01 *M* phosphate buffer containing 1.15% KCl was prepared by homogenizing in a high speed blender[9] three times for 10 sec each. The homogenate was centrifuged[10] in 50-ml polyethylene tubes at 10,000×*g* for 30 min at 2°, and the supernate was removed with a syringe and either analyzed immediately or frozen overnight. *N*-Demethylase activity was assayed using an automated adaptation (10) of the method of Axelrod (11), utilizing ethylmorphine as the substrate.

GLC of Sterols—Aliquots of rat serum were saponified with 0.5 *N* ethanolic potassium hydroxide by heating for 5 min at 90°, and water was added after cooling. The nonsaponifiable fraction was extracted four times with 3 ml of petroleum ether (bp 30–60°), and cholestane was added to the extracts as an internal standard. The extracts were combined, brought to dryness at 70° under nitrogen flow, and dissolved in 0.1 ml of chloroform[11].

Isothermal GLC was performed on a gas chromatograph equipped with flame-ionization detectors using a 1.8-m (6-ft) × 4-mm glass column, 3% OV-17 on Gas Chrom Q, at 240° with a helium carrier flow rate of 90 ml/min. All peak area measurements were made in triplicate by polar planimetry and were quantitated by internal standardization with cholestane (12).

***In Vitro* Lipolytic Activity**—An isolated fat cell suspension was prepared according to Rodbell (13) and incubated in plastic vials in a total volume of 1 ml of Krebs–Ringer bicarbonate buffer (pH 7.4) containing 4% bovine plasma albumin. Theophylline (5×10^{-4} *M*) or levarterenol (5×10^{-7} *M*) was used to stimulate lipolysis. Compound I was dissolved in ethanol and added to yield the concentrations indicated. The control samples were incubated with an equal volume of ethanol. The cell suspension was incubated for 1 hr at 37°. The reaction was terminated, and glycerol was extracted by the addition of 4 ml of water to the incubation vial followed by mechanical shaking for 5 min.

The aqueous extract was used directly for the enzymatic glycerol analysis (14). Separate aliquots of the fat cell suspension were taken for triglyceride analysis (4), and the results were expressed as micromoles of glycerol released per gram of triglyceride per hour.

Catalase Determination—Livers from freshly sacrificed rats were homogenized in a glass–plastic[4] homogenizer at 4° with 1.25 m*M* phosphate buffer. The homogenate was allowed to stand for 30 min at 4°, rehomogenized, and adjusted to a final volume of 50 ml. The absorbance at 240 nm was measured[12] at room temperature. A 0.01-ml aliquot of the liver homogenate was added to 3 ml of hydrogen peroxide–phosphate buffer, and the time required for a decrease in absorbance from 0.55 to 0.50 was determined.

Catalase activity is expressed as units per milligram of wet weight of liver. A catalase unit is defined as the amount of enzyme that liberates half of the peroxide oxygen from a hydrogen peroxide solution of any concentration in 100 sec at 25° (15).

Acute Toxicity—CF-1 mice (17–25 g), Wistar-strain adult (130–175 g) and neonatal (6–9 g) rats, and albino rabbits (1.9–2.7 kg) were used. Compound I was ground in a mortar and suspended in 5% gum acacia solution or aqueous suspending vehicle and was administered orally, intraperitoneally, or subcutaneously. Eight to 10 animals were used per

dose level. The animals were observed for 5 days, and total mortality was reported. The LD_{50} was calculated by the method of Miller and Tainter (16). Some of the treated neonates were missing and were presumed to have been cannibalized after dying. The missing rats were counted as dead rats in calculating the LD_{50}.

The statistical significance of the data was determined by the Student t test and is designated as a p value.

RESULTS

Oral administration of I for 2 weeks to rats lowered serum concentrations of cholesterol, triglycerides, phospholipids, and free fatty acids (Table I). Maximum lipid lowering was observed after dosing with 50 mg/kg, and no further decrease was found at 100 mg/kg. Rats treated with I gained weight at the same rate as placebo controls, indicating that appetite was not affected and that the drug was well tolerated (Table II). Drug-tested rats looked and behaved like normal, healthy animals.

Acute toxicity determinations in mice, rats, and rabbits indicated that I had low oral, intraperitoneal, and subcutaneous toxicity (Table III). The high LD_{50} ratio for oral *versus* intraperitoneal routes of administration indicated a low bioavailability for high oral doses of I. Such decreased absorption after large oral dosage may explain the apparent lack of a dose–response curve for serum lipid lowering. A female dog receiving the compound in gelatin capsules tolerated oral doses up to 320 mg/kg without symptoms. Normal hematological and serum clinical chemical values were observed in this dog[13].

The low toxicity during 2 weeks of drug administration was corroborated by normal adrenal and epididymal fat pad weights (Table II). In common with other hypolipidemic agents (17), I increased rat liver weight (Table II). Compound I also caused a dose-related decrease in serum triglyceride levels in rats made hypertriglyceridemic by adding fructose to their drinking water (Table IV).

Compound I was studied in comparison with clofibrate to compare their mechanisms of action. Both compounds caused a dose-related increase in liver weight and in liver lipid and protein content (Fig. 1). Examination of the composition of the liver from rats treated with various hypolipidemic agents revealed no change in DNA or water content, indicating that neither hyperplasia nor edema could explain the liver enlargement (17). Significant increases in liver RNA were found. Analysis of the different lipid classes in the hepatomegalic livers, induced by two hypolipidemic drugs, revealed an apparent decrease in cholesterol and triglyceride concentrations when expressed on a milligrams per gram of liver basis. However, this result represented no change in the total cholesterol or triglyceride content of the liver (Table V). Liver phospholipid content was strikingly increased in clofibrate- and I-treated rats.

It was of interest to determine the subcellular localization of the changes in liver composition. Oral administration of 250 mg/kg of clofi-

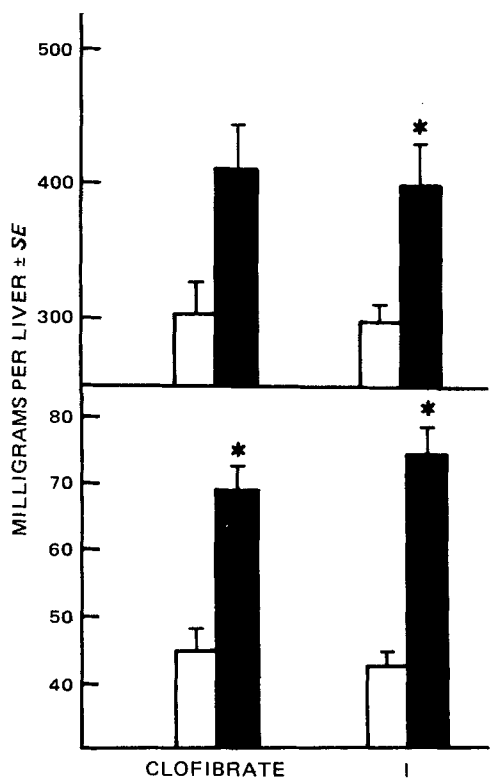

Figure 2—*Effect of chronic administration of hypolipidemic agents on liver mitochondrial protein (top) and phospholipid content (bottom). The significance of the difference between the treated and the control groups, designated by the *, was a p value of <0.05. Key: □, control; and ■, treated.*

[13] Data on file, Hoffmann–La Roche.

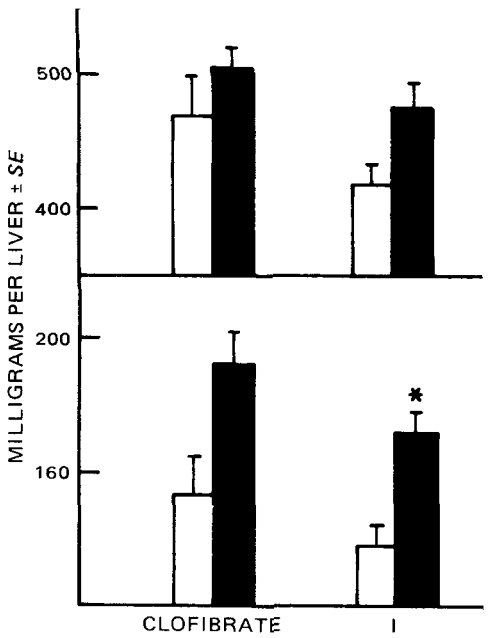

Figure 3—*Effect of chronic administration of antihyperlipidemic drugs on liver microsomal protein (top) and phospholipid content (bottom). The significance of the difference between the treated and the control groups, designated by the *, was a p value of <0.05. Key: □, control; and ■, treated.*

brate or 50 mg/kg of I for 9 days increased rat liver mitochondrial phospholipid and protein content (Fig. 2). A slight, but not statistically significant, increase in liver microsomal protein and phospholipid content was also obtained in rats treated with clofibrate (250 mg/kg/day), and a significant increase in microsomal phospholipid content was found upon treatment with I (50 mg/kg/day) (Fig. 3). Both agents induced liver microsomal drug-metabolizing enzymes, as shown by the ability of these enzymes to *N*-demethylate a test substrate, ethylmorphine (Table VI).

Triparanol, an effective lipid-lowering drug in experimental animals, is known to interfere with cholesterol synthesis by blocking the enzymatic step immediately prior to cholesterol formation, thus leading to an accumulation of desmosterol. During comparative tests, I and clofibrate had only minimal effects on serum desmosterol–cholesterol ratios, whereas serum sterols derived from triparanol-treated rats contained approximately 60% desmosterol (Table VII).

One characteristic finding in animals that have ingested clofibrate is a reversible increase in liver size, accompanied by the appearance of numerous microbodies (peroxisomes) detectable with an electron microscope (18, 19). The enzyme, catalase, is a useful peroxisome marker, since it is a major constituent of peroxisomes. Increased catalase activity in clofibrate-treated rats correlated with an increase in the number of microbodies. An increase in liver size and increased catalase activity were confirmed in clofibrate-treated rats and also found in I-treated rats (Table VIII).

Incubation of I at different concentrations had no effect on the basal rate of glycerol release from rat-isolated fat cells and did not alter the increased rates of glycerol release induced by incubation with optimal concentrations of levarterenol (0.5 μM) or theophylline (0.5 mM) (Table IX).

Table IX—Effect of I on Basal, Levarterenol, and Theophylline-Induced Lipolysis in Isolated Fat Cells

Drug	Lipolysis, μmoles of Glycerol/g of Fat Cells/hr ± *SE*		
	Control	I (1 mM)	I (0.1 mM)
	7.7 ± 0.2	7.8 ± 0.1	7.8 ± 0.8
Levarterenol, 0.5 μM	8.9 ± 0.2	9.6 ± 0.2	9.7 ± 0.1
Theophylline, 0.5 mM	21.5 ± 0.8	22.0 ± 0.5	24.1 ± 1.0

DISCUSSION

Data presented here demonstrate that I is an effective serum lipid-lowering compound in normal and hypertriglyceridemic rats. The effect of I on serum lipids resembles that of clofibrate (20), lifibrate[14] (III) (21), and nafenopin[15] (IV) (22). The chemical structure of I is quite different from III and IV, both of which structurally resemble clofibrate. All four compounds, however, have similar lipid-lowering activities. Serum lipid lowering occurred after a 50-mg/kg po regimen of I, III, or IV, whereas a 250-mg/kg regimen of clofibrate was required for consistent lipid-lowering activity (17). The low toxicity gives I a high therapeutic index so that I might be considered as a possible prophylactic agent for the prevention of hyperlipidemic "risk factor" of atherosclerosis.

Compound I was selected as one of many substituted tetrahydrocarbazoles with hypolipidemic activity (3) and studied in detail. Its analog, 6-chloro-9-[2-(2-methyl-5-pyridyl)ethyl]-1,2,3,4-tetrahydrocarbazole-2-methanol hydrochloride (II), showed similar marked hypolipidemic activity to I in rats[13]. Spectrofluorometric methods for the detection of I and II in biological systems were developed (23) and applied to a biopharmaceutical and pharmacokinetic evaluation of these substituted tetrahydrocarbazoles[16].

Many explanations have been offered for the serum lipid-lowering mechanism of clofibrate. These include an enhancement of thyroid hormone activity produced by competition for binding sites on plasma proteins (24), inhibition of cholesterol (25) and fatty acid (26) biosynthesis, increased hepatic cholesterol oxidation (27), decreased rates of release of hepatic lipoproteins (28), increased peripheral removal of lipoproteins (29), and increased neutral sterol excretion (30). More recently, Dalton *et al.* (17), in attempting to explain the mechanism of action of clofibrate, proposed that the demand for new membrane constituents by the livers of drug-treated animals restricts the production of triglycerides in order to favor that of phospholipids. Thus, the formation and transport of triglyceride-rich lipoproteins into circulating blood are reduced.

The observation that I had only minimal effects on the normal serum cholesterol–desmosterol ratio indicates that the cholesterol-lowering mechanism of action of I does not concern inhibition of the terminal stage of cholesterol biosynthesis. In this regard, it differs from triparanol and is, therefore, unlikely to give rise to an undesirable accumulation of desmosterol after chronic administration. These experiments, however, would not detect an effect of I on earlier stages of cholesterol biosynthesis.

It has been suggested (31, 32) that inhibition of free fatty acid mobilization could be indirectly responsible for serum lipid lowering in experimental animals. Compound I had no direct lipolytic or antilipolytic activity in isolated rat fat cells, indicating that the cholesterol-lowering mechanism of this compound is probably not associated with an inhibition of free fatty acid mobilization. An indirect inhibition of mobilization of free fatty acids was also ruled out, since an acute depletion of free fatty acids was not observed in fasted rats following drug administration.

An increase in liver size and the number of liver microbodies was reported in experimental animals treated with clofibrate (18, 19). Rats treated with I or clofibrate had both increased liver sizes and catalase activities, an enzyme specifically associated with peroxisomes. However, electron microscope studies to detect changes in liver peroxisomal numbers were not completed. In addition, chronic administration of either I or clofibrate caused an accumulation of phospholipids and protein but not of triglycerides or cholesterol in the liver. This result is in agreement with the findings of others with clofibrate (20, 33, 34) and clearly separates this hepatomegalic condition from the pathological types of fatty liver that have high levels of triglyceride and cholesterol esters associated in fat droplets. The increased amounts of phospholipids and proteins are probably associated with membranes of subcellular organelles. Upon cessation of drug administration, the hepatomegaly and ultrastructural changes induced by clofibrate were readily reversible (18, 19, 35).

These data might indicate that the primary event after administration of either clofibrate or I is an induction of enzyme protein resulting from

a functional enlargement of the liver. The induction of rat liver microsomal enzymes after clofibrate and I treatment is in agreement with a similar observation in rats treated with clofibrate and III (36). Clofibrate and I also increased mitochondrial protein and phospholipid content, effects that are difficult to link with drug metabolism. Our observation, however, is consistent with the increase in number (37) and protein content of the mitochondria (38) produced after clofibrate administration. These intracellular structural changes and the broad influence of clofibrate and related drugs on mitochondrial enzyme activity (39–41) are difficult to explain but may be related to the protein binding capacity of these drugs (33).

Spectrofluorometric Determination of Substituted Tetrahydrocarbazoles by a Methylene Blue Sensitized Photolytic Reaction

J. ARTHUR F. de SILVA [x], NORMAN STROJNY, FELIX RUBIO, JOHN C. MEYER, and BERNARD A. KOECHLIN

Abstract □ A spectrofluorometric method was developed for the determination of 6-chloro-9-[2-(2-methyl-5-pyridyl)ethyl]-1,2,3,4-tetrahydrocarbazole-2-methanol hydrochloride and its carboxylic acid analog in blood and urine. It involves extraction of both compounds at neutral pH, either from blood into ethyl acetate (the residue of which is dissolved in ether) or from urine directly into ether. Both the alcohol and the acid are separated from each other by selective extraction into acid or base, respectively, and then reextracted into ether from the respective aqueous medium by appropriate pH adjustment. The residues of the ether extracts containing the compounds are dissolved separately in 0.25 *N* NH_4OH. Methylene blue is added to all samples, which are then exposed to UV energy for 15 min to produce the fluorophores. The fluorescence of the solutions is read at 370 nm, with excitation at 340 nm. The linear range of quantitation of both compounds is 0.02–10 μg each/ml of final solution. The method was applied to the determination of blood levels and urinary excretion of the alcohol and its acid metabolite in a dog.

Keyphrases □ Tetrahydrocarbazoles, substituted—spectrofluorometric analysis, human blood and urine □ Spectrofluorometry—analysis, various substituted tetrahydrocarbazoles, human blood and urine □ Photolytic reactions—substituted tetrahydrocarbazoles sensitized with methylene blue, spectrofluorometric analysis, human blood and urine □ Antihyperlipidemic agents, potential—various substituted tetrahydrocarbazoles, spectrofluorometric analysis, human blood and urine

Compounds containing the indole moiety have been extensively studied because of their anti-inflammatory (1–4), analgesic, and hallucinogenic (5–7) properties, their inhibition of monoamine oxidase (8), and their cardiovascular effects (5). The compound 6-chloro-9-[2-(2-methyl-5-pyridyl)ethyl]-1,2,3,4-tetrahydrocarbazole-2-methanol (I) hydrochloride and its 2-carboxylic acid analog (II) hydrochloride were synthesized (9) and are of clinical interest, because they have shown marked hypolipidemic activity in animals (10).

Spectrofluorometric analysis of catecholamines (levarterenol and epinephrine) as their trihydroxyindole derivatives has led to the use of condensation reactions to produce fluorescent derivatives. Condensation reactions have been used to determine: (*a*) catecholamines that condense with formaldehyde to form highly fluorescent 3,4-dihydroisoquinolines (11), (*b*) 5-hydroxytryptamine by condensation with *o*-phthalaldehyde as the phthalimidine derivatives (12) and with ninhydrin as the β-carboline derivative (13), (*c*) indole-3-acetic acid by condensation with acetic anhydride (catalyzed with boron trifluoride) as the highly fluorescent indolo-α-pyrone derivative (14), and (*d*) tryptophan by photolytic condensation with acetic acid, using methylene blue as a "sensitizer," to yield highly fluorescent β-carboline derivatives (15, 16).

A spectrofluorometric assay was developed for the quantitation of I and II in blood and urine based on a photolytic reaction of the tetrahydrocarbazole to produce a fluorophore of strong intrinsic fluorescence. The reaction is performed in an alkaline medium catalyzed by methylene blue used as a sensitizer. The overall recovery of both compounds from blood and urine is 90 ± 5.0%. The assay is specific for each compound by virtue of the differential extraction procedure used and has a sensitivity limit of 0.10–0.20 μg/ml of blood or urine using a 2-ml specimen/assay and a sample to blank fluorescence ratio of 2:1 as the limit of detectability.

The method was applied to the determination of the blood levels of I and the urinary excretion of I and its metabolite, II, in a dog following a single intravenous dose of 10 mg/kg.

EXPERIMENTAL

Standard Solutions—Compound I hydrochloride, mol. wt. 391.34, mp 191–193°, and Compound II hydrochloride, mol. wt. 405.33, mp 218.5–220° (pharmaceutical grade purity >98%), are the analytical standards required.

Dissolve 11.02 mg of I hydrochloride and 11.00 mg of II hydrochloride equivalent to 10 mg of the respective free base or acid separately in 100 ml of methanol to give stock solutions containing 100 μg of free base/ml. Dilute 1 ml of each stock solution separately in 10 ml of methanol to give working solutions containing 10 μg/ml, suitable aliquots of which are added to blood or urine as internal standards for the determination of percent recovery. Prepare all solutions in amber actinic volumetric flasks and store in a refrigerator.

Instrument—The spectrofluorometer[1] used was equipped with a 150-w xenon arc energy source[2] and photomultiplier[3]. It was used with the 10-nm slit arrangement in all four positions, with the instrument energy adjusted for maximum sensitivity using a Pyrex reference rod and a standard solution of the compound(s) to be analyzed.

Reagents—All reagents were analytical reagent grade (ACS) and were used without further purification; all aqueous solutions were made in distilled deionized water. These solutions included 1.0 *M* (pH 7.0) phosphate buffer, 2 *N* HCl, 0.5 and 10.0 *N* NaOH, 0.25 *N* NH_4OH, and 0.025% methylene blue[4] (USP grade dissolved in water). Ethyl acetate[5] (spectrograde), ether[5] (absolute) from a freshly opened can, chloroform[6], and formaldehyde[7] (37%) were the other reagents used.

Assay in Blood—To 50-ml glass-stoppered centrifuge tubes, add 2 ml of whole blood, 2.0 ml of 1.0 *M* pH 7 buffer, 1.5 g of potassium chloride, and 10 ml of ethyl acetate. Stopper[8] the tubes and extract by shaking for 10 min on a reciprocating shaker. Centrifuge the samples at 0–5° in a refrigerated centrifuge at 2000 rpm for 10 min and transfer the supernate to another 50-ml centrifuge tube. Along with the samples, process a 2-ml specimen of control blood and three 2-ml specimens of control blood to which 0.5, 2.5, and 5.0 μg of I and II (0.05, 0.25, and 0.5 ml of the respective working solutions evaporated to dryness at 40–50° under nitrogen) are added as internal standards.

Repeat the extraction with another 10 ml of ethyl acetate, combine the extracts, and evaporate to dryness under nitrogen in a 60° water bath. Dissolve the residues in 15 ml of ether. Add 5 ml of 0.5 *N* NaOH to the

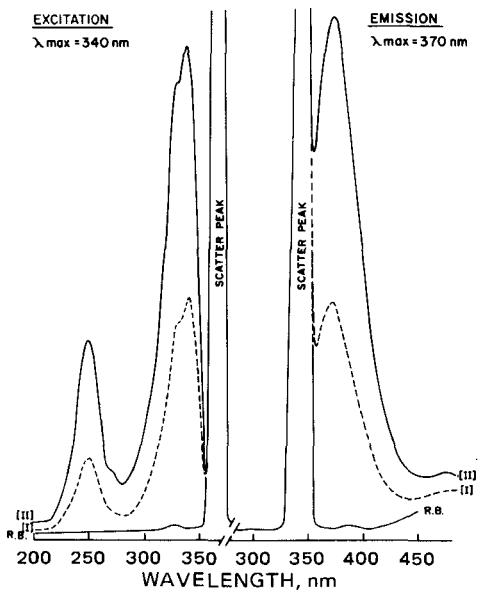

Figure 1—*Excitation and emission spectra of the photochemically produced fluorophores of I and II determined at room temperature for equivalent concentrations of 5 μg/ml.*

ether phase, extract by shaking, centrifuge, and transfer the supernatant ether quantitatively into another 50-ml tube. Wash the sodium hydroxide solution with 10 ml of ether by shaking, centrifuge, and combine the ether wash with the original ether extract. The sodium hydroxide phase contains the carboxylic acid (II) while the ether supernate contains the alcohol (I).

Add 5 ml of 2 *N* HCl to the ether extract containing I and shake for 10 min. Then centrifuge, aspirate, and discard the ether layer. Wash the acid phase containing I with another 10-ml portion of ether, shake, centrifuge, and aspirate off the ether as before. Neutralize the acid with 1.0 ml of 10 *N* NaOH, add 5 ml of 1.0 *M* pH 7.0 phosphate buffer, and extract with 2 × 10-ml aliquots of ether by shaking for 10 min per extraction. Centrifuge and then combine the ether extracts in another 50-ml centrifuge tube.

Evaporate the ether extracts containing I to dryness and dissolve the residues in 5 ml of 0.25 *N* NH_4OH. Add 0.1 ml of 0.025% methylene blue solution to each series containing I and II, and mix well on a Vortex action supermixer. Expose all samples to UV energy[9] for exactly 15 min, placing the tubes in a single row approximately 30.5 cm (12 in.) in front of the lamp. After irradiation, to the sample series containing I *only*, immediately add 0.25 ml of formaldehyde to reduce the excess methylene blue reagent to stop any further autocatalyzed photochemical reaction. The final solution is turquoise blue in color, and its fluorescence is read directly. The blue color does not apparently affect the fluorescence reading of I, since the fluorescence due to the reagent blank is quite low. Wash the sample series containing II, which are reddish purple in color, with 5 ml of chloroform to remove the colored material from the sodium hydroxide phase, resulting in a colorless solution containing the fluorophore of II.

The fluorescence of all solutions is read in a 1-cm path quartz cell at 370 nm, with excitation at 340 nm (Fig. 1).

Calculations—Correct all sample readings for their respective control (blank) reading and calculate the concentrations of I and II in the unknowns by interpolation of the fluorescence readings from their respective internal standard curves. The percent recovery from blood or urine is determined by direct comparison of the fluorescence of known amounts of the internal standards against that of similar concentrations of the external standards processed along with the samples to standardize the process of fluorophore formation. The percent recovery of the internal standards should be determined routinely as a check on the reproducibility of the method.

Assay in Urine—To 5 ml of urine in a 50-ml erlenmeyer flask (adjusted approximately to pH 5.5 with 1 *N* HCl), add 5 ml of 0.2 *M* (pH 5.5) acetate buffer and 200 μl of the glucuronidase–sulfatase preparation[10] (2% by volume). Along with the unknowns, process 3 × 5-ml specimens of control urine containing internal standards of I and II added in the same concentrations as in the blood assay.

Incubate all samples at 37° for 2 hr in an incubation shaker[11]. Cool to room temperature and transfer the specimens to 50-ml centrifuge tubes. Titrate the specimen to pH 7.0 with 2 *N* NaOH, add 5 ml of 1.0 *M* (pH 7.0) phosphate buffer and 5.0 g of potassium chloride, and extract with 2 × 10-ml aliquots of ether by shaking for 10 min on a reciprocating shaker. Centrifuge the samples for 10 min (at 0–5° in a refrigerated centrifuge) at 2000 rpm and combine the ether extracts in another 50-ml centrifuge tube. Process the samples from this point using the differential extraction procedure described for blood.

RESULTS AND DISCUSSION

The intense fluorescence of carbazole and polynuclear carbazoles was used in their quantitation in the nanogram range (17). Therefore, the fluorometric analysis of the tetrahydrocarbazoles (I and II) by chemical oxidation to their aromatized carbazole derivatives was investigated. Several oxidation reactions were attempted but did not yield a suitable fluorophore.

A photochemical reaction using methylene blue as a catalytic sensitizer, reported for the formation of highly fluorescent β-carbolines (15, 16), was investigated and gave the most reproducible and optimal yields of a fluorophore for both I and II.

Methylene blue is highly soluble in water, yielding a deep-blue solution (λ_{max} 609 and 668 nm). The free base can be quantitatively extracted into organic solvents (chloroform) at alkaline pH. This fact was used to advantage in the analysis of II in that the reagent was extracted, resulting in a colorless solution of 0.5 *N* NaOH containing the fluorophore of II. This "cleanup" step is not possible in the analysis of I, since both the reagent and the fluorophore are coextracted into organic solvents.

The presence of the methylene blue reagent in the analysis of I appears to catalyze the further reaction of I or its fluorophore, since the fluorescence readings increased on standing, resulting in poor reproducibility, especially in 0.5 *N* NaOH. Formaldehyde was used to oxidize the excess methylene blue to a turquoise blue-colored product, which stabilized the fluorophore of I. The absorption maximum of this colored product (350–400 nm) apparently absorbs sufficient UV energy during fluorometric analysis (excitation of 340 and emission of 370 nm) to quench the fluorescence of I compared to that of II where the methylene blue reagent has been removed.

This fact is seen in the spectra of the photochemical products of the two compounds (Fig. 1) for equivalent concentrations of 5 μg/ml of each. The peak heights of the excitation–emission spectra of I were about half those of II, both determined at the same instrument settings. This difference was probably due to a quenching effect and/or to the fact that the fluorophore of I is chemically different from that of II (Schemes I and II). The fluorescence of the two reaction products, however, was linear with concentration over 0.10–5.0 μg/ml of final solution, with excitation at 340 nm and emission at 370 nm for each compound (Fig. 1).

Characterization of Fluorophores of I and II—Characterization of the reaction products of I and II was attempted following their separation by TLC. Compounds I and II (100 μg of each) were reacted separately as previously described. The reaction products of I were extracted into ether from the reaction medium (0.25 *N* NH_4OH) following neutralization with 1 *N* HCl and pH adjustment with 1 *M* pH 7.0 buffer. The reaction products of II were extracted into ethyl acetate–1-butanol (80:20) following acidification of the reaction medium (0.5 *N* NaOH) with 2 *N* HCl and pH adjustment to 5.5 with 1 *M* phosphate buffer.

The respective organic solvent extracts were evaporated to about 100 μl, transferred quantitatively onto silica gel chromatoplates[12], and developed to 15 cm in acetone–ammonium hydroxide (90:10). In the respective extracts, I migrated with R_f Ω 0.9; its reaction product had R_f Ω 0.7, while II had R_f Ω 0.2 and its reaction product had R_f Ω 0.3. The respective reaction products were eluted from the silica gel into ethanol and then examined by UV absorption, fluorescence, and phosphorescence emission spectrophotometry.

The UV spectra of the authentic compounds in methanol showed a major band at 235–237 nm with minor bands at 265 and 290 nm. Fol-

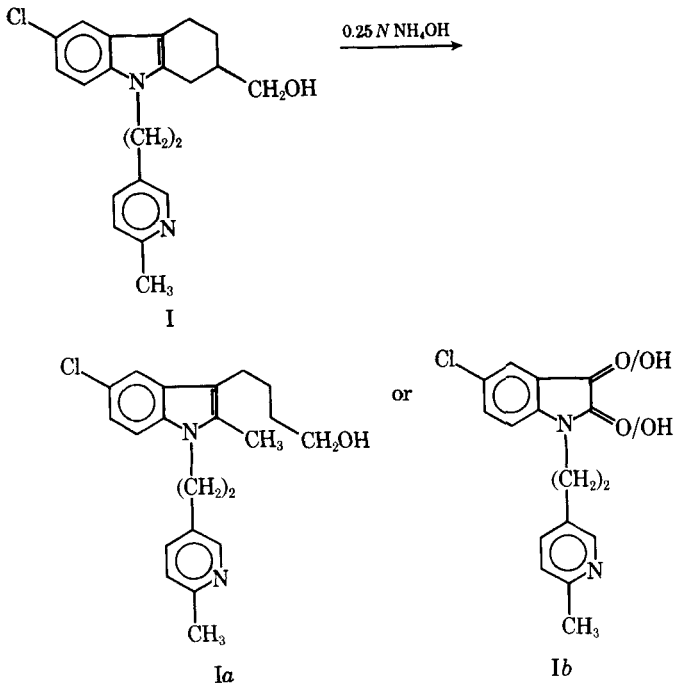


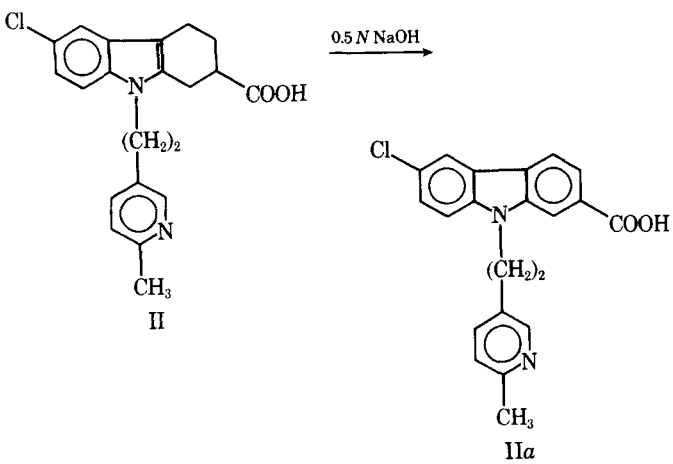
Scheme I

lowing photochemical reaction, the spectrum of I showed a bathochromic shift to 258 nm with secondary peaks at 330 and 343 nm, respectively. The spectrum of II also showed a similar bathochromic shift to longer wavelengths, with the major band at 250 nm and minor bands at 308, 330, and 345 nm. These UV spectral changes indicated major structural changes.

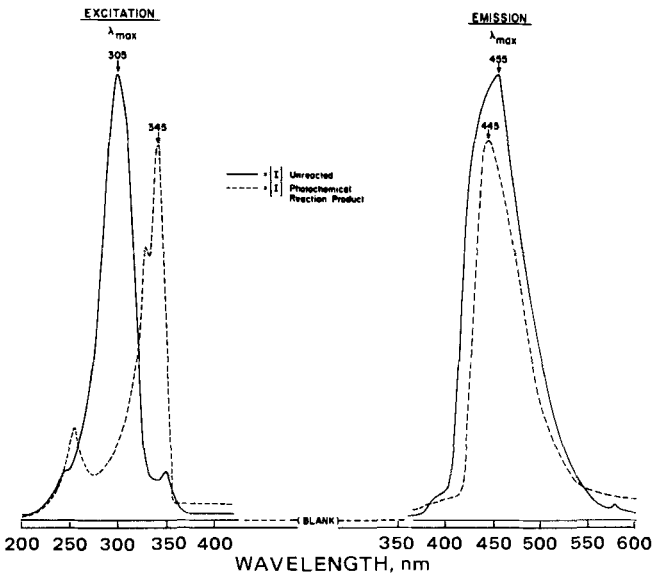
The fluorescence spectra of the reaction products of I and II (5 μg/ml) at room temperature (Fig. 1) were practically identical. Both exhibited excitation maxima at 250 and 340 nm and a broad emission maximum at 370 nm; the excitation bands corresponded fairly well with the UV absorption maxima of the reaction products.

Further insight into the character of these products was sought from a comparison of their phosphorescence spectra (77° K) in ethanol (18) with those of I and II. The spectra showed characteristic differences, permitting certain structural deductions by reference to spectra of known analogous compounds (19). The phosphorescence spectra of unreacted authentic I (Fig. 2A) and II (Fig. 3A) were almost identical, with excitation–emission maxima at 305 and 455 nm, respectively. The excitation spectra of both reaction products possessed considerable fine structure. The spectrum of I (Fig. 2A) had excitation maxima at 250, 330, and 345 nm (major bands); that of II (Fig. 3A) had maxima at 250, 315 (major bands), 340, 350, 365, and 380 nm, indicating a higher degree of aromaticity.

The emission spectrum of the reaction product of I showed a hypsochromic shift to a single maximum at 445 nm; that of II showed a similar



Scheme II



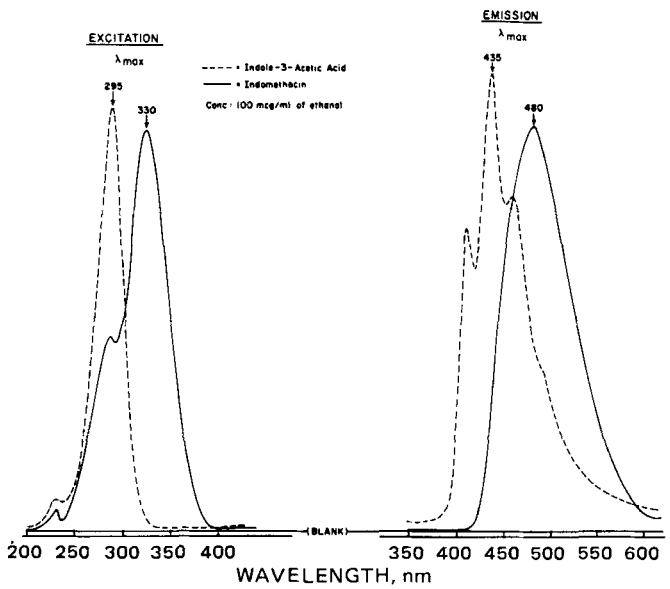


Figure 2—*Phosphorescence spectra in ethanol (77° K) of (top) authentic I and its photochemical reaction product and (bottom) indole acetic acid and indomethacin.*

shift, with a characteristic doublet at 440 and 450 nm of approximately equal intensity. The striking differences in the phosphorescence spectra suggested marked structural differences in the respective reaction products.

The phosphorescence excitation–emission spectrum of the reaction product of I (Fig. 2A) exhibited maxima at 345 and 445 nm, respectively. The absence of a high degree of fine structure suggests that it is not a carbazole derivative. The phosphorescence spectral characteristics were fairly similar to that of indomethacin, whose excitation–emission maxima were at 330 and 480 nm, respectively (also with very little fine structure). Indole-3-acetic acid (III), whose excitation–emission maxima were at 295 and 435 nm, respectively, showed a more complex emission spectrum (Fig. 2B) (20) than either indomethacin (IV) or the reaction product of I. This result was probably due to a reduction of the aromaticity of the indole ring in indomethacin and in the reaction product of I because of the electron-withdrawing effects of the *p*-chlorobenzoyl group in the former and the *p*-methyl-3-pyridylethyl group in the latter, which are attached to the indole nitrogen.

These similarities suggest that the tetrahydrocarbazole ring has either been partially cleaved, resulting in a product structurally similar to indomethacin (Scheme I, Ia), or totally cleaved with possible concomitant oxidation of the indole ring to an indoxyl derivative (Scheme I, Ib). The formation of such an indole or indoxyl derivative could also lead to further

Table I—Luminescence Properties of I and II, Their Photochemical Reaction Products, and the Analogous Carbazole, V, as a Reference Compound

Compound	Fluorescence (25°) Excitation/ Emission Maxima, nm	Intensity, $TM^a/\mu g/ml$	Sensitivity Limit, $\mu g/ml$	Phosphorescence (77° K) Excitation/ Emission Maxima, nm	Intensity, $TM/\mu g/ml$	Sensitivity Limit, $\mu g/ml$

II	—	Nil	>100 $\mu g/ml$	305/450	10	10.0
II Reaction product	340/370	550	0.1	305/445	Ω 450	0.5[b]
V	310/400	1250	0.02	312/445, 475	4100	0.001

[a] Fluorescence (TM) units = transmittance (T) × meter multiplier factor (M). [b] Phosphorescence of the reaction products of I and II was approximately corrected for reaction efficiency, extraction efficiency, and efficiency of TLC elution.

reaction under the photolytic conditions to form other condensation products which would be difficult to isolate (21).

The phosphorescence excitation–emission spectrum of the reaction product of II (Fig. 3A) was similar in its fine structure to that of 6-chloro-2-carbazolecarboxylic acid (V) (Fig. 3B). The excitation spectrum of the reaction product of II and V exhibited similar fine structure with multiple peaks at 250, 300, 315 (major bands), 340, 350, and 365 nm. The emission spectra of the reaction product of II and V exhibited a characteristic doublet with maxima at 430 and 445 nm for II and 445 and 475 nm for V. The similarities in the spectral characteristics of the photochemical reaction product of II to those of V and of other known carbazoles (17, 18, 22) strongly suggest that it is a carbazole derivative (Scheme II, II*a*). Attempts to characterize these products further by electron-impact mass spectrometry were unsuccessful due to the poor fragmentation patterns obtained.

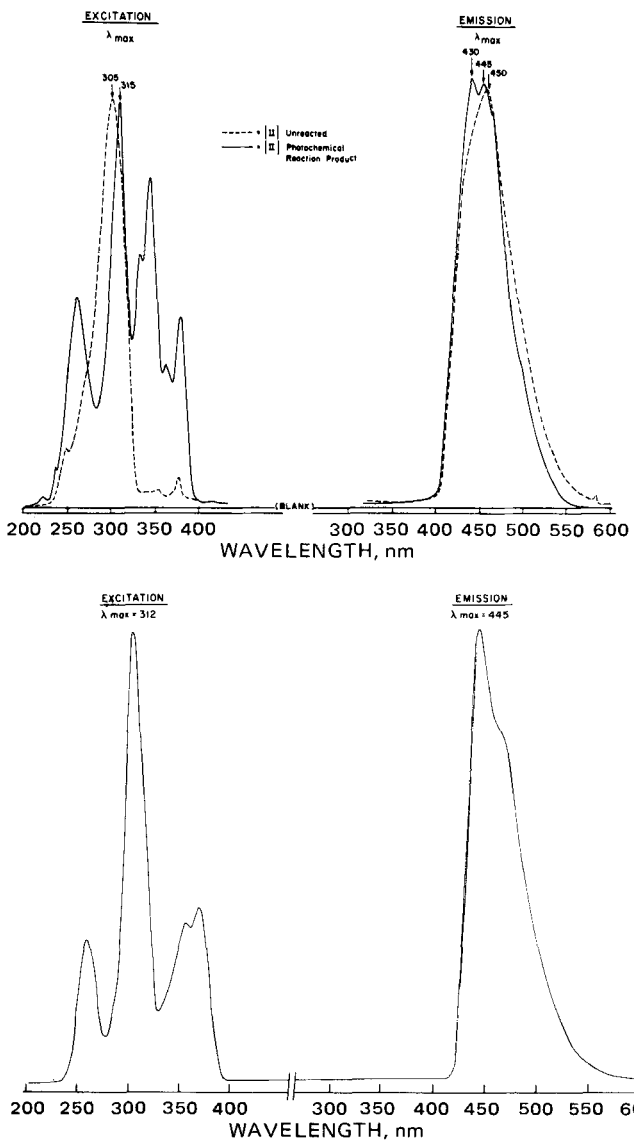

Figure 3—*Phosphorescence spectra in ethanol (77° K) of (top) authentic II and its photochemical reaction product compared with that of (bottom) V, a 9-unsubstituted analog. (Attenuation = 3×.)*

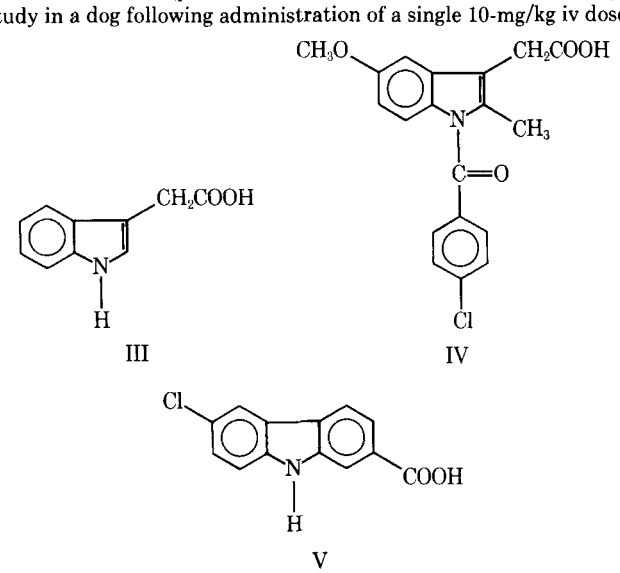
The relative sensitivities of the luminescence properties of I, II, their photochemical reaction products, and the analogous carbazole (V) are given in Table I. Compounds I and II had no measurable fluorescence at room temperature, whereas their intrinsic phosphorescence provided detection limits of 10 μg for I and 0.5–1.0 μg for II and can also be used to analytical advantage where high sensitivity is not a requirement.

Assay Specificity—Preliminary studies in the dog indicated that the carboxylic acid analog, II, is not a major metabolite. Compound I is excreted as a glucuronide conjugate in the urine and feces[13]. However, the presence of small amounts of II in blood or urine would impair the accuracy of the assay for I if it is not resolved from it, because of the relatively high fluorescence yield of its photochemical reaction product.

The spectrofluorometric assay is specific for each compound due to the differential extraction procedure used to separate the two compounds prior to photochemical irradiation and quantitation. The overall recovery of I hydrochloride or II hydrochloride added to blood or urine in the concentration range of 0.10–10.0 $\mu g/ml$ is of the order of 90 ± 5.0% (SD). The sensitivity limits of the assay for I and II are 0.15–0.20 and 0.10–0.15 $\mu g/ml$, respectively, of blood or urine using a 2-ml specimen per assay and a sample–blank fluorescence ratio of 2:1 as the limit of quantitation.

Applications to Biological Specimens—The blood levels and urinary excretion of I and II (produced as a metabolite) were determined in a pilot study in a dog following administration of a single 10-mg/kg iv dose of



[13] S. A. Kaplan, D. E. Maynard, A. Maggio, V. Mattaliano, C. Abruzzo, and S. Cotler, to be published.

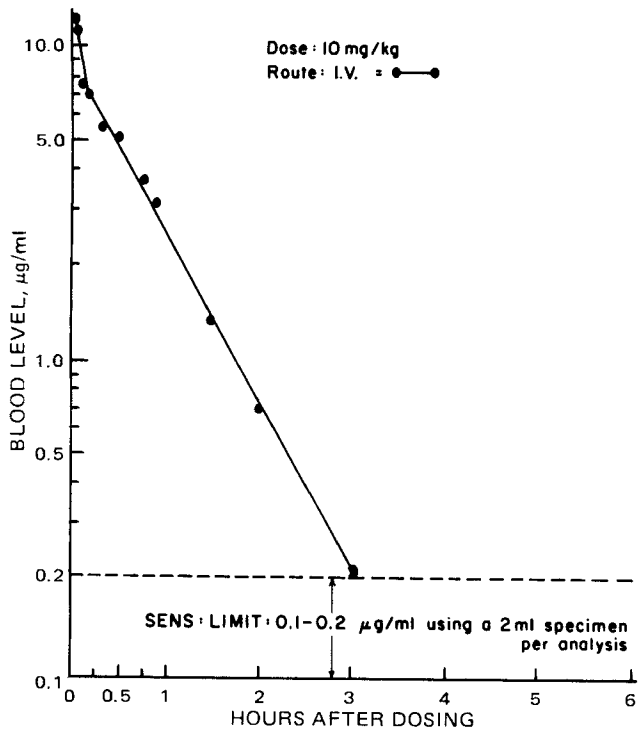


Figure 4—*Blood level curves of I in a dog following the administration of a single 10-mg/kg iv dose of I hydrochloride.*

I hydrochloride. The blood levels of the intact drug I (Fig. 4) showed a biphasic fall-off pattern with an apparent half-life of elimination of about 30 min. Urinary excretion of the parent drug accounted for only 0.1% of the administered dose, present mainly as a glucuronide–sulfate conjugate. No measurable levels of II were seen in either the blood or urine. The utility of the assay was demonstrated in the evaluation of the biopharmaceutic and pharmacokinetic profile of the drug in the dog[13].

Oxidative Reactions of Hydroxylated Chlorpromazine Metabolites

RICHARD L. McCREERY

Abstract □ The oxidation pathways of two hydroxylated chlorpromazine metabolites were investigated using modern electrochemical techniques. Upon oxidation, the 7-hydroxy derivative of chlorpromazine rapidly reacts to form the 7,8-dihydroxy derivative and a substituted quinone. The oxidation potentials for both compounds were determined in the pH 3–8 range. The importance of these redox reactions and potentials to the pharmacology of the materials is discussed.

The widespread use of phenothiazine derivatives in the treatment of mental illness has inspired a large amount of research on their chemical properties and reactions. Of relevance to the present discussion are studies of the importance of redox reactions to the metabolism and mode of action of chlorpromazine and related neuroleptic drugs.

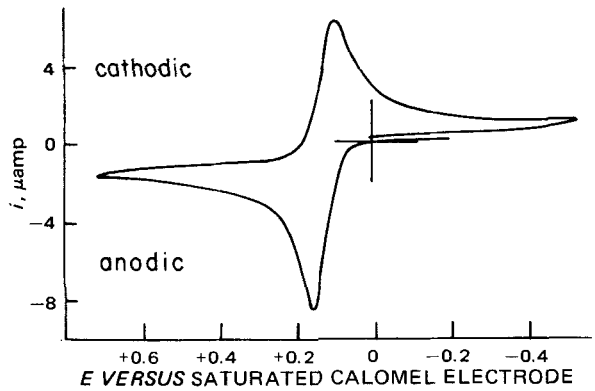

Figure 1—*Cyclic voltammogram of 5 × 10^{-4} M II in pH 4 McIlvaine buffer (carbon paste electrode; scan rate = 0.10 v/sec).*

The one-electron oxidation product of chlorpromazine, its cation radical, has been associated with membrane interactions that may be responsible for the drug's effect (1), and the radical has been suggested as a metabolic intermediate in the formation of chlorpromazine sulfoxide and hydroxylated chlorpromazine metabolites (2).

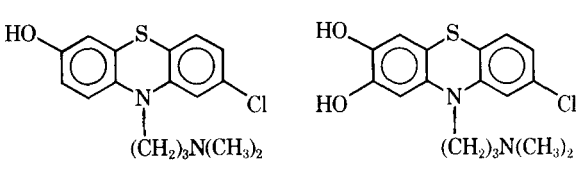
BACKGROUND

More recent investigations involved the importance of two hydroxylated metabolites of chlorpromazine to the beneficial and toxic effects of chlorpromazine therapy. The 7-hydroxy derivative of chlorpromazine (I) has pharmacological effects comparable to chlorpromazine in animal tests and has been suggested as the active form of the drug in neuroleptic therapy (3). In addition, the 7-hydroxy compound has been associated with the corneal opacity and skin pigmentation that occur in 5–25% of the patients receiving chlorpromazine chronically (4, 5). The 7,8-dihydroxy derivative of chlorpromazine (II) is also a metabolite of chlorpromazine in humans (6) and is a strong candidate for an agent producing toxic side effects. It also causes corneal opacity in rabbits (5) and has pronounced effects on mitochondrial membranes (7) and Na^+–K^+-dependent adenosine triphosphatase (8).

It is important to consider the possible role of oxidation in the metabolism and side effects of chlorpromazine. Oxidation of II by molecular oxygen produces hydrogen peroxide, the superoxide ion, and hydroxyl radicals (9). Heikkila *et al.* (9) suggested that this oxidation and the accompanying generation of reactive species are responsible for the neurotoxicity of the dihydroxy compound. In addition, it has been proposed that oxidation and polymerization of II result in the purple pigmentation of the skin or corneal opacity observed in chronic chlorpromazine patients. A further effect of II may be degeneration of nerve tissue, similar to that caused by 6-hydroxydopamine. The mechanism of neurotoxicity of the 6-hydroxy derivative of dopamine remains an active subject of research, but the ease of oxidation is important for its effects. Information about the oxidation potential of II would be useful in appraising its possible chemical similarity to the 6-hydroxy derivative of dopamine.

Although photoxidation of I has been associated with skin pigmentation, the reaction is not well characterized (4). The mushroom tyrosinase-catalyzed oxidation of I generates the dihydroxy derivative, as shown by UV and electron spin resonance spectra (10).

The work described here was undertaken to clarify the oxidative reactions of chlorpromazine, I, and II in solutions near physiological pH. Hopefully, information about oxidation potentials and reaction mechanisms will clarify the role of hydroxylated chlorpromazine metabolites in the toxic and beneficial effects of chlorpromazine therapy. The electrochemical results show that II is oxidized at a potential near that of the 6-hydroxy derivative of dopamine and that the product is stable on the time scale used here. Compound I rapidly undergoes further reaction upon oxidation to yield II and a quinone intermediate. The results provide an overall picture of the oxidation pathways of these compounds consistent with previously reported observations.



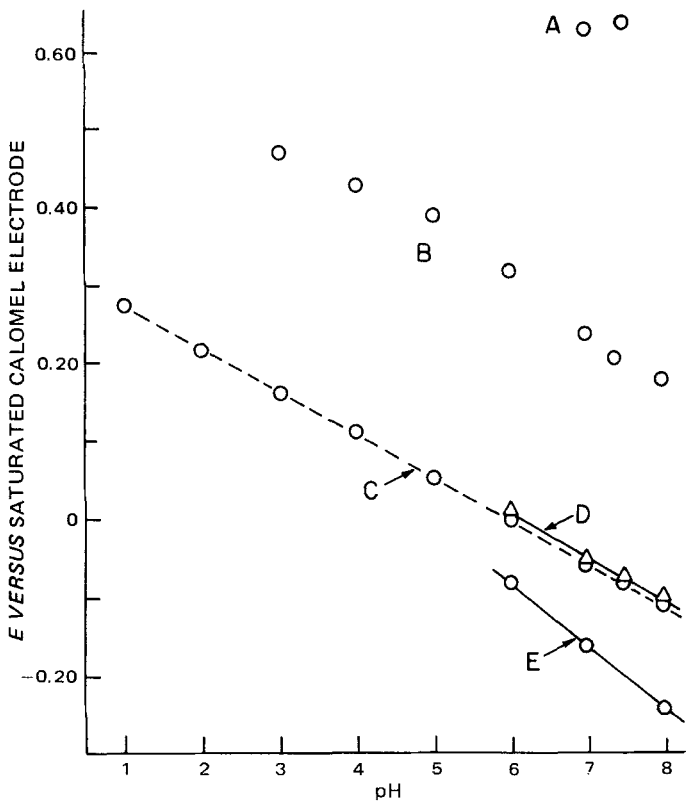


Figure 2—*Potential* versus *pH profiles for chlorpromazine and two hydroxylated metabolites. Key: A, $E_{p/2}$ for chlorpromazine; B, $E_{p/2}$ for I; C, $E_{p/2}$ for II; D, $E^{o'}$ for II; and E, $E^{o'}$ for dopamine 6-hydroxy derivative. Voltammograms were obtained using a carbon paste electrode. $E^{o'}$ values are midpoint potentials for titrations with the ferricyanide ion using a platinum indicator electrode.*

EXPERIMENTAL

All voltammetric experiments with scan rates below 0.5 v/sec were performed with an operational amplifier potentiostat of conventional design (11). A 27.9 × 35.5-cm (11 × 14-in.) *x–y* recorder was used to record slow scan voltammograms. Large-scale electrolysis was performed using a more powerful potentiostat based on a 50-w power amplifier. A 25.4-cm (10-in.) strip-chart recorder was used to record electrolysis current. High speed (above 0.5 v/sec) voltammograms were performed with a fast rising potentiostat interfaced to a laboratory scale minicomputer. The system allowed control of high speed experiments, with sampling of current occurring at a maximum rate of 200 kHz. The resultant voltammograms were displayed on an *x–y* oscilloscope monitor.

Electrochemical cell design was conventional and utilized a carbon paste working electrode, platinum wire auxiliary electrode, and saturated calomel reference electrode (12). To avoid any question about electrode fouling from electrolysis products, a new carbon paste surface was prepared for each voltammetric scan. To conserve the supply of phenothiazine derivatives, cell volume was limited to 1.5 ml; typical experiments consumed 400–600 μg of electroactive material. McIlvaine buffers made from 0.2 *M* Na_2HPO_4 and 0.1 *M* citric acid were utilized in the pH 3–8 range. Phosphate buffer, 0.2 *M*, at pH 2 and 0.1 *M* HCl were used below pH 3. In many cases, phenothiazines were dissolved with a few drops of 10^{-3} *M* HCl before addition of the buffer solutions.

Chlorpromazine hydrochloride[1], I[2], and III[2] were used without further purification.

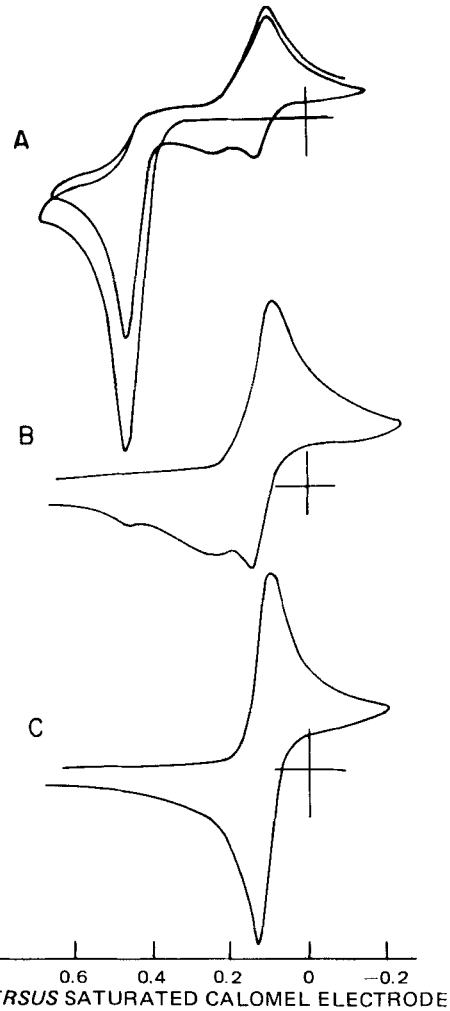

Figure 3—*Voltammograms before and during the coulometric oxidation of 554 μg of I in 3 ml of pH 4 McIlvaine buffer. Key: A, before electrolysis was initiated* (n = *0); B,* n = *3.2; and C,* n = *4.02.*

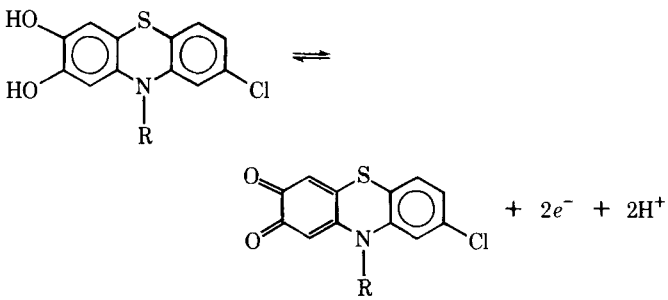
RESULTS

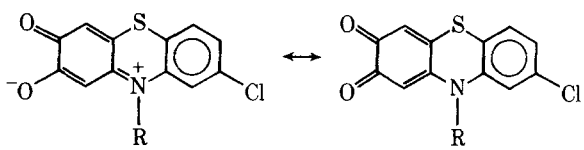
The electrochemistry of II was the simplest of the three compounds studied. Figure 1 shows the nearly reversible, well-defined voltammetric wave of II at pH 4. A similar wave was observed from pH 1 to 8, with the only effect of pH being a shift in the oxidation potential. Figure 2 includes a graph of the half-peak potential of the anodic wave *versus* pH. The plot is linear from pH 1 to 8, with a slope of 0.056 v/pH unit, indicating that the number of protons and electrons involved in the oxidation process is equal. The linearity of the pH profile for II below pH 4 was unexpected, since the reported value for the pKa of the thiazine nitrogen is 3.4 (13). Unless the pKa for the thiazine nitrogen is the same for both the oxidized and reduced forms of II, one would expect a change in slope in the $E_{p/2}$ *versus* pH profile in the region of pH 3.4.

After considering the pKa's of diphenylamine (0.79) and the 3-hydroxy derivative of phenothiazine (−2) (14), one has reason to doubt the published value of 3.4. The inconsistency may arise from the possibility that the value of 3.4 represents the titration of free hydrogen ions rather than the protonated thiazine nitrogen, in light of the fact that the investigators reporting that value started with a 10^{-3} *M* solution of II. Potentiometric titrations of II with ferricyanide yielded an average *n* value of 1.93 electrons per molecule in the pH 6–8 region. Titrations below pH 6 were not possible because the redox potential of ferricyanide is too low. The $E^{o'}$ values derived from these titrations are also plotted in Fig. 2. Coulometry of II at a carbon cloth electrode confirmed the value of two electrons per molecule for the oxidation. The UV–visible spectra of oxidized material agree well with those published by Grover *et al.* (10), with peaks at 262 and 508 nm. The molecular implications of these bands were discussed previously (15).

A cyclic voltammogram of I at pH 4 is shown in Fig. 3A. The voltammograms in the pH 3–8 range were qualitatively similar, with the only



Scheme I

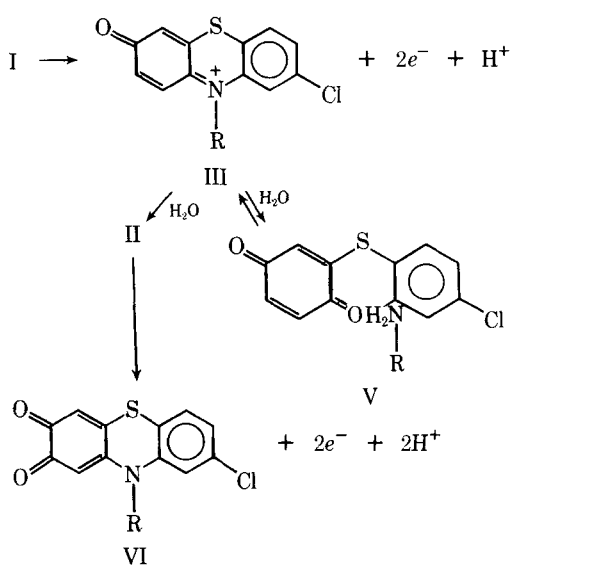


Scheme II

change being in the positions and magnitudes of the peaks. Figure 2 shows a plot of the half-peak potential for the major anodic peak as a function of pH. The cathodic peak shifted with pH in a fashion identical to the dihydroxy derivative. Since the oxidation of I is chemically irreversible, no attempt was made to titrate it potentiometrically. Coulometry of I at pH 4 consumed 4.04 electrons per molecule. Changes in the voltammograms that occurred during coulometry are shown in Fig. 3. Voltammogram A was performed before electrolysis was started at +0.6 v *versus* the saturated calomel electrode. After about three electrons per molecule were passed (*n* = 3.20), voltammogram B was taken; C was taken when *n* = 4.02. The UV–visible spectra and voltammetry of the electrolysis product were identical to those of oxidized II at all pH's, with UV–visible peaks at 262 and 508 nm. Reduction of the electrolysis product at −0.2 v *versus* the saturated calomel electrode consumed between 1.7 and 1.9 electrons per molecule of original I.

The voltammetric oxidation of chlorpromazine itself was studied briefly for comparison. Figure 4A is a voltammogram of chlorpromazine hydrochloride in pH 6 McIlvaine buffer at a scan rate of 0.1 v/sec. The oxidation potential was pH independent, with a value for the half-peak potential of +0.65 v *versus* the saturated calomel electrode. The absence of a reverse (reduction) wave indicates that the product of the oxidation was unstable under these conditions. At the fast scan rate of 10 v/sec (Fig. 4B), a reverse wave was apparent, indicating that the oxidized material had not had time to react to an electroinactive material. The nature and kinetics of the reactions of the oxidized form are presently under study, but an estimate of the half-life of the oxidized material from these data is 10 msec.

Table I summarizes the electrochemical data for the three compounds studied. All potentials are referred to the saturated calomel electrode; to determine the potential referred to the normal hydrogen electrode, 0.246 v must be added.



Scheme III

Table I—Half-Peak and Midpoint Potentials for Chlorpromazine Derivatives

Compound	pH 6	pH 7	pH 7.4	pH 8	Method[a]
Chlorpromazine	—	0.63	0.64	—	A
I	0.322	0.242	0.210	0.181	A
II	−0.002	−0.060	−0.080	−0.105	A
II	0.010	−0.051	−0.074	−0.103	B
6-Hydroxy derivative of dopamine[b]	−0.078	−0.160	—	−0.240	B

[a] A = potential when the current equals half the peak current for the anodic (oxidation) wave, and B = $E^{o'}$ for potentiometric titration (potential at half-titration point). [b] Data from Ref. 21.

DISCUSSION

The results of potentiometric titrations, coulometry, and voltammetry indicate that the oxidation of II is an uncomplicated two-electron process, with an accompanying loss of two hydrogen ions [Scheme I, R = $(CH_2)_3N^+H(CH_3)_2$]. Although the product of the oxidation is shown here as an *ortho*-quinone, it has been pointed out that it has some zwitterionic character due to the quinone–imine resonance form (15) (Scheme II).

For an ideal, reversible, voltammogram, the formal redox potential, $E^{o'}$, for the system is the potential when the current equals 85% of the peak current (16). Since all studied systems yielded quasireversible waves, $E^{o'}$ cannot be determined accurately from the waves. The half-peak potential, $E_{p/2}$, is a useful indication of the ease of oxidation and can be used for observations of trends and for purposes of comparison. In the case of II, it can be seen that $E_{p/2}$ and $E^{o'}$ are equal to within 10 mv.

The $E_{p/2}$ *versus* pH profile for I is nonlinear, probably due to the complex nature of the followup reactions occurring immediately after oxidation. These reactions distort the voltammetric wave, and the pH dependence is unpredictable. Due to the instability of oxidized I, potentiometric titrations were not attempted. However, for reasons discussed already, $E_{p/2}$ is a good approximation for the redox potential. The observations are consistent with the oxidation mechanism shown in Scheme III.

This mechanism is supported by the following evidence. The complete oxidation of I liberates four electrons per molecule of starting material. The product is voltammetrically and spectroscopically indistinguishable from oxidized II quinone (VI). An intermediate is observed during oxidation, which is not present after four electrons have been passed, and which has a voltammogram consistent with Structure V. The electrolysis of I occurs in two distinct phases: a rapid, initial oxidation corresponding to the consumption of I to form V and VI and a slower phase corresponding to the cyclization of V back to III and eventual complete generation of VI. The oxidation slows down when approximately three electrons have been passed per molecule of I. The reduction of the final oxidation product required 1.7–1.9 electrons per molecule. Although the suggested mechanism predicts a value of 2.0 electrons, slow degradation of the quinone might account for the low values.

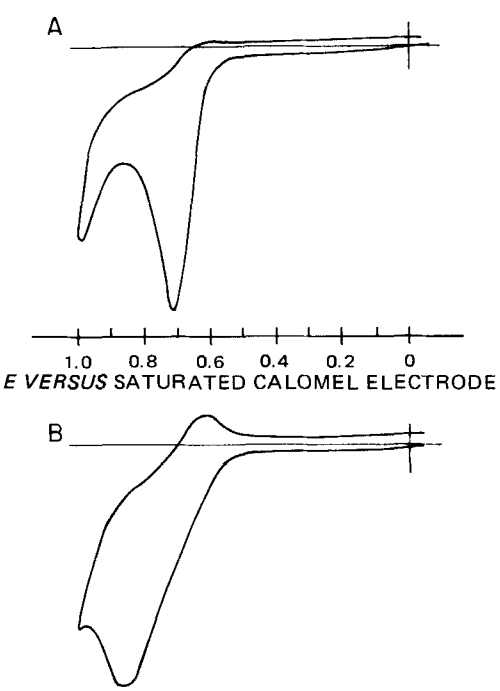


Figure 4—*Voltammograms of chlorpromazine in pH 6 McIlvaine buffer (carbon paste electrode). Key: A, scan rate = 0.1 v/sec; and B, scan rate = 10 v/sec.*

$$IV \longrightarrow IV^+ + e^-$$
$$\downarrow$$
$$IV^{2+} + e^-$$

Scheme IV

Although several reports have been published on the electrochemical oxidation of chlorpromazine in acidic media (17–19), the author is unaware of any studies near physiological pH. Figure 4 indicates that the product of the oxidation rapidly degrades to an electroinactive product, probably the sulfoxide. At a fast scan rate, the reduction of the initial product can be observed, since the product has insufficient time to degrade completely. The distortion of the oxidation wave could be caused by two distinct phenomena: adsorption of the chlorpromazine (IV) on the electrode or splitting of the wave into two one-electron oxidations (Scheme IV). Two waves are not observed at slow scan rates, since the dication rapidly degrades to the sulfoxide, shifting the disproportionation equilibrium toward the dication and resulting in a single peak at the potential of the first oxidation. Further studies are being carried out to clarify this process.

The important conclusions that can be drawn from these results are the mechanism of oxidation of I and the relative oxidation potentials of the three chlorpromazine derivatives studied. Of the molecules studied, II oxidizes at the lowest potential, near that of the 6-hydroxy derivative of dopamine (Fig. 2). The 6-amino derivative of dopamine, another cytotoxic agent, has an oxidation potential of −0.135 v *versus* the saturated calomel electrode at pH 7.4 (20), which is even closer to the dihydroxy derivative. The importance of oxidation to cytotoxic action remains unconfirmed, but the similarity of II to the catecholamine derivatives is obvious in this respect.

Although I is more difficult to oxidize, its immediate oxidation product (III) is unstable near physiological pH. Compound III can hydrolyze to the quinone (V) or hydroxylate to II and eventually oxidize to II quinone (VI). The hydrolysis of III to form V is reversible in these experiments, but interactions of V with tissue components must be considered when examining I pharmacology. Since both degradative reactions of III are fast, even slow oxidation of I would result in formation of both V and VI. The pH dependence of these reactions and the interactions of the products with tissue components are subjects of current study.

GI Drug Absorption in Rats Exposed to Cobalt-60 γ-Radiation I: Extent of Absorption

MICHAEL E. BRADY * and WILLIAM L. HAYTON ˣ

Abstract □ The extent of absorption of sulfanilamide, bretylium tosylate, sulfisoxazole acetyl, and riboflavin was determined in rats exposed to 850 rad of cobalt-60 γ-radiation or sham irradiated. The drugs were administered orally at 1 or 5 days postirradiation, and the amount of drug excreted in the urine was used as the measure of absorption. Following intravenous drug administration, there was no difference between irradiated and control animals in the amount of drug excreted in the urine. At 1 day postirradiation, the absorption of sulfanilamide and bretylium was not affected by radiation; the absorption of sulfisoxazole acetyl and riboflavin was increased. The fraction of sulfanilamide excreted in the urine as N^4-conjugate was increased at 1 day postirradiation. At 5 days postirradiation, there was no detectable difference between irradiated and control animals in the extent of drug absorption. The effects of radiation on the extent of absorption of orally administered drugs were most pronounced immediately following irradiation. Irradiation apparently does not affect the absorption of drugs that are normally well absorbed or poorly absorbed due to slow transport across the GI mucosa. Following irradiation, there may be an increase in the extent of absorption of drugs that are poorly absorbed due to low aqueous solubility or that are absorbed by a saturable transport mechanism.

Keyphrases □ Absorption, GI—various drugs, effect of cobalt-60 γ-radiation, rats □ Radiation, gamma—effect on GI absorption of various drugs, rats □ Sulfanilamide—GI absorption, effect of cobalt-60 γ-radiation, rats □ Bretylium tosylate—GI absorption, effect of cobalt-60 γ-radiation, rats □ Sulfisoxazole acetyl—GI absorption, effect of cobalt-60 γ-radiation, rats □ Riboflavin—GI absorption, effect of cobalt-60 γ-radiation, rats

Patients exposed to ionizing radiation for the treatment of cancer commonly receive drugs during or following radiation therapy. When the GI tract is involved in radiation therapy, its structure and function may be altered for several days. Such alterations may affect the bioavailability of orally administered drugs.

The potential mechanisms by which radiation may alter drug absorption were explored by studying the absorption of several drugs in rats that were exposed to cobalt-60 γ-radiation. The drugs used were chosen so that the absorption rate of each drug was controlled by a different step in the overall process of absorption (Table I). Experiments were performed to assess the effects of radiation on the rate and extent of absorption of each drug and on the permeability of the intestinal mucosa. The studies on the extent of drug absorption are presented here; the other studies are reported elsewhere (1, 2).

BACKGROUND

Following oral administration, the rate and extent of absorption of many drugs are determined by one or more of the following steps: dissolution in the lumen of the GI tract, transport across the GI epithelium, and gastric emptying (3, 4). The primary rate-controlling step (or steps) in the absorption of a particular drug depends on dosage formulation and on the physicochemical properties of the drug; *e.g.*, the solubility in water affects the rate of solution, and the oil/water partition coefficient affects epithelial permeability. Since drugs with low solubility in water tend to dissolve slowly following oral administration, dissolution is usually the step that controls the absorption rate of poorly water-soluble drugs. As water solubility increases, the dissolution rate increases, but the permeability of the intestinal epithelium tends to decrease due to the lipophilic nature of this barrier. The rate-controlling step in the absorption of very polar drugs is the transport of the dissolved drug across the intestinal epithelium.

The rate of gastric emptying may determine the rate of drug absorption since most drugs tend to be absorbed more rapidly from the intestine than from the stomach. For drugs that are absorbed by a saturable transport process in the intestine, slowed gastric emptying may enhance absorption by maintaining a low concentration of drug at the site of absorption for

Patients exposed to ionizing radiation for the treatment of cancer commonly receive drugs during or following radiation therapy. When the GI tract is involved in radiation therapy, its structure and function may be altered for several days. Such alterations may affect the bioavailability of orally administered drugs.

The potential mechanisms by which radiation may alter drug absorption were explored by studying the absorption of several drugs in rats that were exposed to cobalt-60 γ-radiation. The drugs used were chosen so that the absorption rate of each drug was controlled by a different step in the overall process of absorption (Table I). Experiments were performed to assess the effects of radiation on the rate and extent of absorption of each drug and on the permeability of the intestinal mucosa. The studies on the extent of drug absorption are presented here; the other studies are reported elsewhere (1, 2).

BACKGROUND

Following oral administration, the rate and extent of absorption of many drugs are determined by one or more of the following steps: dissolution in the lumen of the GI tract, transport across the GI epithelium, and gastric emptying (3, 4). The primary rate-controlling step (or steps) in the absorption of a particular drug depends on dosage formulation and on the physicochemical properties of the drug; *e.g.*, the solubility in water affects the rate of solution, and the oil/water partition coefficient affects epithelial permeability. Since drugs with low solubility in water tend to dissolve slowly following oral administration, dissolution is usually the step that controls the absorption rate of poorly water-soluble drugs. As water solubility increases, the dissolution rate increases, but the permeability of the intestinal epithelium tends to decrease due to the lipophilic nature of this barrier. The rate-controlling step in the absorption of very polar drugs is the transport of the dissolved drug across the intestinal epithelium.

The rate of gastric emptying may determine the rate of drug absorption since most drugs tend to be absorbed more rapidly from the intestine than from the stomach. For drugs that are absorbed by a saturable transport process in the intestine, slowed gastric emptying may enhance absorption by maintaining a low concentration of drug at the site of absorption for

Table I—Drugs Selected for Study

Drug and Dosage Form	Physicochemical and Biological Properties	Probable Rate-Limiting Step in Absorption
Sulfanilamide suspension	Relatively high aqueous solubility, high oil/water partition coefficient, normally well absorbed	Gastric emptying
Bretylium tosylate solution	Ionized, high aqueous solubility, low oil/water partition coefficient, not well absorbed due to low mucosal permeability	Mucosal permeability
Sulfisoxazole acetyl suspension	Low aqueous solubility, high oil/water partition coefficient, not well absorbed due to slow dissolution	Dissolution
Riboflavin solution	Low aqueous solubility, low oil/water partition coefficient, may be absorbed in part by a capacity-limited mechanism	Mucosal permeability

a prolonged time. In addition, changes in intestinal motility may affect the absorption of drugs that dissolve slowly or are absorbed slowly by altering the time available for dissolution or absorption.

Exposure of the GI tract to ionizing radiation could alter bioavailability by altering the normal rates of the primary rate-controlling steps, particularly transfer across the GI epithelium, and GI motility. The normally rapid rate of cell division in the intestinal epithelium is slowed following irradiation, resulting in villi that are abnormal in size and shape (5). In addition, the mass of the epithelium decreases following irradiation, *e.g.*, 50% in mice exposed to 600 rad (6). In rodents, the maximal change in the structure of the epithelium occurs 4–6 days postirradiation (5, 7). A decrease in the surface area of the intestinal mucosa could significantly reduce the absorption of drugs that slowly cross the normal intestinal epithelium. The impaired absorption of digoxin in a human (8) and slowed absorption of diazepam and aminobenzoic acid in rats[1] following irradiation may have resulted from a reduction in the capacity of the intestinal epithelium to absorb these drugs.

Both gastric emptying and intestinal motility are altered following irradiation of the gut. Radiation-induced changes in GI motility depend on the dose of radiation and are greatest immediately following irradiation. Slowed gastric emptying was shown to be the major cause of the reduced rate of absorption of sulfadiazine and quinine observed in irradiated mice and rats (9). Following irradiation, both an increase and a decrease in the motility of the rat small intestine, as reflected by the rate of intestinal transit of a nonabsorbed marker, have been reported. The intestinal transit rate increased in irradiated animals following intraduodenal administration of the marker (10) but decreased following intragastric administration. The greatest reduction in transit rate occurred in the middle segment of the intestine (11).

Other mechanisms by which irradiation of the GI tract could alter absorption include an alteration in blood flow to the intestine (12, 13) and inactivation of carriers associated with transport across the intestinal epithelium (14–16).

EXPERIMENTAL

Materials—Sulfisoxazole acetyl[2], bretylium tosylate[3], riboflavin[4], and sulfanilamide[5] were used as received. ^{14}C-Riboflavin[6] was dissolved in a pH 5.0 aqueous buffer and stored at 5° in an opaque container. The labeled radiochemical purity of ^{14}C-riboflavin was 99%; it was verified periodically by TLC on silica gel G-coated plates developed with either methanol–benzene–acetone–acetic acid (20:70:5:5) or pyridine–acetic acid–water (20:2:80). Methylcellulose 4000, polyethylene glycol 400[7], 2,2′,4,4′,6,6′-hexanitrodiphenylamine[8] (dipicrylamine), sodium nitrite[9], sulfamic acid[9], and *N*-(1-naphthyl)ethylenediamine dihydrochloride[4] were used as received. All other reagents and solvents were reagent grade.

Irradiation Procedure—A 7000-Ci cobalt-60 source, stored in a lead chamber at the bottom of a bulk shielding reactor pool, was used to irradiate rats. Animals were placed in a Plexiglas restraining cage, rotated at 20 rpm, and lowered down a watertight sample tube to a position near the source of radiation. To irradiate animals, the source was elevated automatically from its storage chamber.

The dose of radiation was checked regularly with an ionization-type dosimeter[10], and the sample-to-source distance was adjusted to maintain a dose of 850 ± 42 rad delivered over 5.0 min. Sham-irradiated animals were manipulated as were irradiated animals, except that the source of radiation remained in its storage chamber.

The level of radiation in the sample tube when the source was shielded was less than 1 rad/hr.

Bioavailability Studies—Experiments were conducted on the 1st and 5th days postirradiation to maximize the potential effects of radiation on gastric emptying (9, 17, 18) and intestinal epithelial permeability (19–21), respectively. Equal numbers of irradiated and sham-irradiated male Sprague–Dawley rats (170–250 g) were fasted for 16–20 hr prior to and for 3 hr following drug administration. Drug was administered at the same time of day either intravenously *via* the penile vein or orally by gastric intubation. Animals were anesthetized lightly with ether to facilitate drug administration.

After drug administration, animals were housed individually in metabolism cages[11] which permitted quantitative separation of urine and feces. The room in which the animals were housed was maintained at 16° and lighted 9 hr followed by 15 hr of darkness per day. Urine was collected until the drug and metabolites were no longer excreted. Each urine sample was combined with a distilled water rinse of the lower section of the metabolism cage and was stored at −20° until assayed.

Sulfanilamide, 200 mg/kg, and sulfisoxazole acetyl, 100 mg/kg, were administered orally suspended in 8.0 ml of 0.5% methylcellulose solution/kg. Identical doses of the sulfonamides were dissolved in 2.0 ml of polyethylene glycol 400–water (9:1)/kg and administered intravenously. Prior to administration, suspensions were agitated for 24 hr at room temperature and sonicated. Riboflavin, 0.8 and 4.0 mg/kg, was given orally and intravenously in 12.0- and 1.6-ml/kg doses, respectively; the intravenous solutions contained 200 mg of niacinamide[12]/ml. ^{14}C-Riboflavin was diluted with unlabeled riboflavin to a specific activity of approximately 0.5 mCi/g. Bretylium tosylate was administered orally, 30 mg/kg, and intravenously, 5 mg/kg, dissolved in 8.0 and 2.0 ml of water/kg, respectively.

Analytical Methods—Free (unconjugated) and total (free + N^4-conjugated) sulfanilamide and sulfisoxazole acetyl were determined in urine by a colorimetric method[13] involving extraction of the free drug with ethyl acetate and acid hydrolysis for total drug (22). Sulfisoxazole acetyl was measured as sulfisoxazole and converted on a molar basis to equivalent amounts of sulfisoxazole acetyl. Radioactivity was determined by liquid scintillation spectrometry[14]; ^{14}C-toluene was used as an internal standard to correct for quenching. Bretylium was analyzed by a spectrophotometric method[13] involving ion-pair extraction of drug from urine (23).

Recovery of sulfanilamide and sulfisoxazole acetyl from urine was greater than 95%; urine blanks of free and total sulfonamides were 0.25 and 0.31 mg/day, respectively. Recovery of bretylium and ^{14}C-riboflavin from urine was 101 and 97%, respectively; urine blanks of both were negligible.

RESULTS AND DISCUSSION

Sulfanilamide—Similar recoveries of sulfanilamide in the urine following oral and intravenous administration (Fig. 1) indicate that the orally administered drug was absorbed completely, as reported by others (24, 25). Following intravenous administration, neither the total recovery of the drug in the urine nor the fraction excreted in the urine as N^4-conjugate was affected significantly by prior irradiation of the animals (Fig. 1). Other studies in mice and rats found that serum and whole blood levels following intravenous or intraperitoneal administration of certain sulfonamides were not affected by prior irradiation (9, 26). Thus, the differences between irradiated and sham-irradiated animals in the urinary recovery of sulfanilamide administered orally reflect the effects of radiation on the absorption of sulfanilamide rather than on the distribution or elimination of the drug.

The lack of effect of radiation on the extent of metabolism of sulfanilamide *in vivo* is interesting in view of *in vitro* drug metabolism studies with homogenates of liver from irradiated rats. In these studies, prior whole-body exposure to γ-radiation induced a subsequent decrease in microsomal enzyme activity at 3–5 days postirradiation for several drugs (27, 28), including sulfanilamide (29). Recent pharmacokinetic analyses showed that *in vitro* studies of drug metabolism do not necessarily provide information about the intrinsic capacity of liver tissue to metabolize drugs (30, 31). Apparently, the *in vivo* rate of metabolism of sulfanilamide

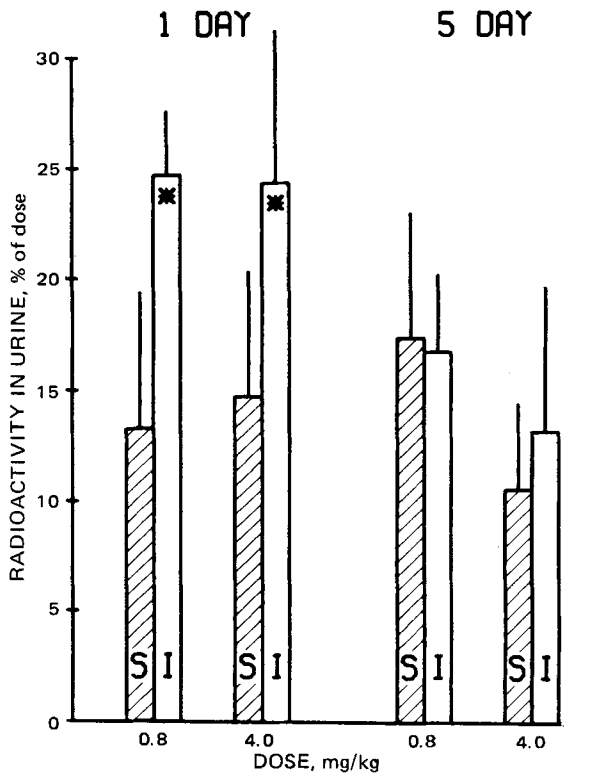

Figure 5—*Recovery of radioactivity in the urine of rats exposed to 850 rad of γ-radiation (I) or sham irradiated (S) 1 or 5 days before oral administration of 0.8 or 4.0 mg of ^{14}C-riboflavin/kg. Each bar represents the mean of six animals, the vertical line in the center of each bar indicates 1* SD, *and the * indicates that recovery was significantly different ($p < 0.05$) from the corresponding S group.*

is not controlled by the intrinsic metabolic capacity of the liver; changes in this capacity, as indicated by *in vitro* microsomal enzyme studies, do not result in changes in the *in vivo* rate of elimination or extent of metabolism of the drug.

Exposure of rats to 850 rad of γ-radiation 1 or 5 days prior to oral administration of sulfanilamide did not affect the total urinary recovery of the drug and its metabolites (Fig. 1). At 1 day postirradiation, however, the fraction of sulfanilamide excreted as metabolite increased significantly; this increase was not evident at 5 days postirradiation. Since the extent of metabolism of intravenously administered sulfanilamide was not affected by prior irradiation of the animals, the observed increase in the extent of metabolism of orally administered sulfanilamide apparently occurs before the drug reaches the systemic circulation. Whole-body irradiation is known to cause a subsequent transient reduction in the rate of gastric emptying (1, 32). The increased residence time of sulfanilamide in the stomachs of irradiated animals compared to controls may have resulted in metabolism of part of the dose prior to absorption. Both the gastric emptying rate (1) and the extent of metabolism of sulfanilamide (Fig. 1) returned to control values by 5 days postirradiation.

Following irradiation, rats alter their pattern of food consumption (6). In this study, food consumption was increased immediately following irradiation but reduced on Days 1–4 postirradiation (Fig. 2). In addition, the stomach at 1 day postirradiation was markedly distended by food following an overnight fast. By 5 days postirradiation, both food intake and the amount of food in the stomach were similar in irradiated and control animals.

To determine whether differences in food consumption between irradiated and control animals affected sulfanilamide absorption, the experiment was repeated with animals that were fasted from the time of irradiation or sham irradiation to 3 hr after drug administration. The results (Table II) were similar to the results of the study shown in Fig. 1. Thus, the effect of radiation on sulfanilamide absorption at 1 day postirradiation is apparently not due to a radiation-induced alteration in food consumption.

Bretylium—Following oral administration, the urinary recovery of bretylium was less than 20% of the recovery following intravenous administration (Fig. 3). This comparatively low recovery indicates that bretylium was poorly absorbed, probably due to low permeability of the GI epithelium to this ionized compound. The urinary recovery of intravenously administered bretylium was not affected by prior irradiation of the animals (Fig. 3). Thus, differences between irradiated and sham-irradiated animals in the urinary recovery of bretylium indicate the effect of prior irradiation on the absorption of orally administered bretylium.

Because bretylium is poorly absorbed following oral administration, the extent of drug absorption was anticipated to be sensitive to radiation-induced alterations in the permeability of the GI mucosa. At both 1 and 5 days postirradiation, the absorption of bretylium by irradiated rats was not significantly different from drug absorption by sham-irradiated animals (Fig. 3). There is evidence that the rate of small intestinal transit is increased in rats at 1 day postirradiation (10). Such an increase would reduce the time available for bretylium absorption, possibly explaining the tendency toward decreased absorption at 1 day postirradiation (Fig. 3). The extensive histological changes occurring in the small intestinal epithelium following irradiation (5, 33) probably do not affect significantly the capacity of the intestine to absorb bretylium.

Sulfisoxazole Acetyl—Following intravenous administration of sulfisoxazole acetyl, neither the total urinary recovery of the drug nor the fraction excreted unchanged was affected by prior irradiation of the animals (Fig. 4). In addition, irradiation did not affect significantly the extent of metabolism of sulfisoxazole acetyl (Fig. 4). As shown previously (34), the urinary recovery of orally administered sulfisoxazole acetyl was significantly lower than after intravenous administration, indicating incomplete absorption (Fig. 4). The low oral bioavailability was presumably due to the low aqueous solubility of the drug.

At 1 day postirradiation, the extent of sulfisoxazole acetyl absorption was significantly greater in irradiated animals than in sham-irradiated controls (Fig. 4). Since the sulfisoxazole acetyl absorption is dissolution rate limited (1, 34), the reduced rate of gastric emptying in irradiated animals apparently allows additional time for dissolution of sulfisoxazole acetyl and, therefore, increases absorption. At 5 days postirradiation, both the gastric emptying rate (1) and the extent of sulfisoxazole acetyl absorption (Fig. 4) were not significantly different from control values.

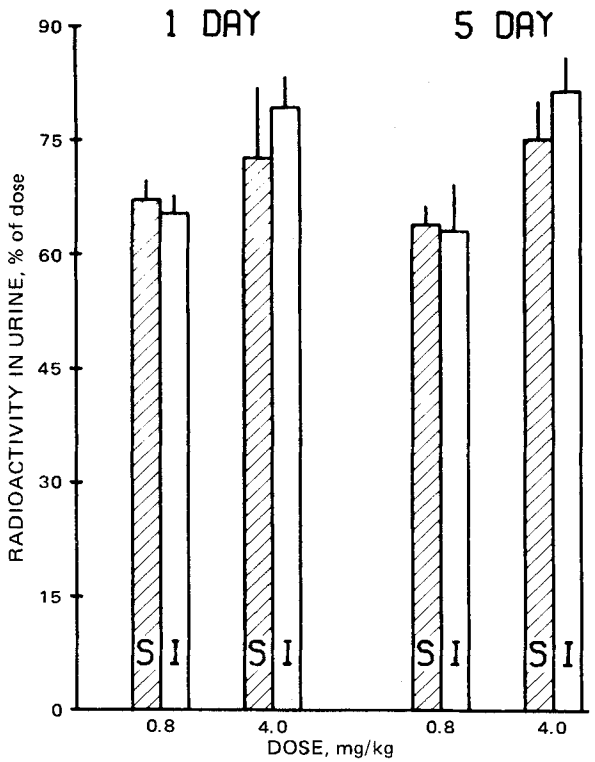

Figure 6—*Recovery of radioactivity in the urine of rats exposed to 850 rad of γ-radiation (I) or sham irradiated (S) 1 or 5 days before intravenous administration of 0.8 or 4.0 mg of ^{14}C-riboflavin/kg. Each bar represents the mean of six animals, and the vertical line in the center of each bar indicates 1* SD.

Riboflavin—The low recovery of radioactivity in the urine following oral administration of ^{14}C-riboflavin (Fig. 5) compared to intravenous administration (Fig. 6) indicates that riboflavin was not completely absorbed. The absorption of the vitamin in rats is probably limited by its low oil/water partition coefficient and low solubility in water.

Irradiation had a negligible effect on the excretion of riboflavin following intravenous administration of either 0.8 or 4.0 mg/kg (Fig. 6). However, irradiated animals receiving riboflavin orally at 1 day postirradiation excreted 70–85% more radioactivity than controls (Fig. 5). A similar increase in the bioavailability of orally administered riboflavin was reported in humans pretreated with propantheline to reduce the rate of gastric emptying (35). Delayed gastric emptying in humans apparently increased absorption by prolonging the contact of the vitamin with a capacity-limited mechanism for absorption. Although capacity-limited absorption of riboflavin has not been found in rats (36 and references therein), a reduction in the gastric emptying rate could increase the bioavailability of a passively absorbed drug as was reported for phenolsulfonphthalein (37).

The recovery of radioactivity (percent of dose) in urine following intravenous administration of riboflavin increased with dose (Fig. 6). This dose-dependent increase may be due to saturable tubular reabsorption in the kidney (38) or to saturable tissue binding (36). The urinary recovery of riboflavin following oral and intraperitoneal administration decreases as the dose is increased, apparently because of a nonlinear biliary excretion mechanism (36, 39).

In summary, there was no detectable difference between irradiated and sham-irradiated animals in the extent of drug absorption at 5 days postirradiation. At 1 day postirradiation, the extent of sulfisoxazole acetyl and riboflavin absorption was increased significantly while sulfanilamide and bretylium tosylate absorption was not affected. The extent of metabolism of sulfanilamide was increased at 1 day postirradiation.

GI Drug Absorption in Rats Exposed to Cobalt-60 γ-Radiation II: *In Vivo* Rate of Absorption

MICHAEL E. BRADY * **and WILLIAM L. HAYTON** ˣ

Abstract □ The rate of absorption of sulfanilamide, bretylium tosylate, sulfisoxazole acetyl, and riboflavin was studied in rats exposed to 850 rad of cobalt-60 γ-radiation either 1 or 5 days before oral drug administration. Polyethylene glycol 4000 was administered with sulfanilamide; its distribution along the GI tract indicated that the gastric emptying rate was reduced threefold at 1 day postirradiation but returned to normal at 5 days postirradiation; the small intestinal transit rate was not detectably altered by irradiation. At 1 day postirradiation, there was a marked decrease in the absorption rate of sulfanilamide, a smaller, although significant, decrease in the absorption rate of sulfisoxazole acetyl and bretylium, and an increase in the absorption rate of riboflavin. At 5 days postirradiation, the drug absorption rate was normal. The changes in the absorption rate of the drugs were due to a radiation-induced reduction in the gastric emptying rate; the permeability of the GI epithelium did not appear to be affected by radiation. The results indicate that, immediately following irradiation, a marked reduction in the gastric emptying rate causes a pronounced reduction in the absorption rate of rapidly absorbed drugs, a less pronounced reduction in the absorption rate of drugs that are absorbed slowly because of slow dissolution or slow diffusion across the GI epithelium, and an increase in the absorption rate of drugs that are absorbed by a saturable mechanism provided the mechanism is not impaired by irradiation.

Keyphrases □ Absorption, GI—various drugs, effect of cobalt-60 γ-radiation, rats □ Radiation, gamma—effect on GI absorption of various drugs, rats □ Sulfanilamide—GI absorption, effect of cobalt-60 γ-radiation, rats □ Bretylium tosylate—GI absorption, effect of cobalt-60 γ-radiation, rats □ Sulfisoxazole acetyl—GI absorption, effect of cobalt-60 γ-radiation, rats □ Riboflavin—GI absorption, effect of cobalt-60 γ-radiation, rats

The results of a previous study (1) showed that prior exposure of rats to cobalt-60 γ-radiation may significantly alter the absorption pattern of orally administered drugs. In irradiated animals, the extent of absorption of sulfisoxazole acetyl and riboflavin was increased compared to control animals. Irradiation did not have a detectable effect on the extent of absorption of bretylium tosylate or sulfanilamide, although the extent of metabolism of sulfanilamide was significantly increased in irradiated animals.

While the previous study dealt with the effects of ionizing radiation on the extent of drug absorption, radiation-induced changes in GI structure and motility may also affect the rate of drug absorption. To explore this possibility, the *in vivo* absorption rate of sulfanilamide, bretylium tosylate, sulfisoxazole acetyl, and riboflavin was studied in irradiated and sham-irradiated rats.

EXPERIMENTAL

Materials—The drugs and reagents used were described previously (*1*). 1,2-^{14}C-Polyethylene glycol 4000[1] (specific activity 0.3 mCi/g) was dissolved in water and stored at 5° in an opaque container.

Absorption Rate—Male Sprague–Dawley rats, 170–250 g, were irradiated or sham irradiated as described previously (1). At 1 or 5 days postirradiation, 8.0 ml/kg of a water–propylene glycol (1:1) solution of sulfanilamide (200 mg/kg) and ^{14}C-polyethylene glycol (4.0 mg/kg) was administered by gastric intubation (2) to animals that had been fasted overnight. Equal numbers of irradiated and sham-irradiated animals were used each time an experiment was performed.

At 0.5, 1.0, 2.0, and 6.0 hr after dosing, the animals were sacrificed by exposing the head to microwave radiation[2] for 15 sec (3, 4). Blood was immediately removed by cardiac puncture, and the GI tract was excised and separated into five portions: stomach, small intestine divided into three segments of equal length, and the caecum and colon. The intestinal segments and serum separated by centrifugation from clotted blood were frozen until assayed.

In similar studies, 8.0 ml/kg of an aqueous sulfisoxazole acetyl suspension (100 mg/kg), a bretylium tosylate solution (30 mg/kg), or 12 ml/kg of an aqueous riboflavin solution (0.80 mg/kg, 0.12 μCi/ml) was administered by gastric intubation; polyethylene glycol 4000 was not present. At 0.5 or 2.0 hr after dosing, the animals were sacrificed; the GI tract and a sample of serum were removed and frozen until analysis.

Analytical Methods—Each portion of the GI tract was homogenized[3], and the amount of drug or radioactivity in the homogenate and serum was assayed by methods described previously (1). Radioactivity was not detected in serum following administration of ^{14}C-polyethylene glycol or ^{14}C-riboflavin. Recovery of radioactivity from homogenates containing ^{14}C-riboflavin or ^{14}C-polyethylene glycol was greater than 94%; chemiluminescence was not a problem since homogenate blanks were negligible.

Mean recoveries of bretylium tosylate, free sulfanilamide, and total sulfisoxazole acetyl from GI homogenates were 96, 96, and 101%, respectively. Blank values of free sulfanilamide from homogenates of the stomach, small intestine, and caecum and colon were 0.32, 0.22, and 0.64 mg, respectively. Blank values of total sulfisoxazole acetyl from stomach and intestinal homogenates were 0.10 and 0.56 mg, respectively; bretylium blank values were negligible. Recovery of free sulfanilamide and sulfisoxazole acetyl from serum was nearly 100% with serum blanks of 8.6 and 6.1 μg/ml, respectively.

RESULTS AND DISCUSSION

At 1 day postirradiation, the distribution of orally administered polyethylene glycol, a nonabsorbable marker (5), along the GI tract of irradiated animals was quite different from that of the controls (Figs. 1 and 2, respectively). The most notable difference in distribution was the increased level of polyethylene glycol in the stomachs of irradiated animals, indicating that prior irradiation reduced the gastric emptying rate as reported by others (6, 7). In both irradiated and control animals, the gastric emptying of polyethylene glycol followed apparent first-order kinetics with half-lives of 3.4 and 0.8 hr, respectively. At 5 days postirradiation, the GI distribution of polyethylene glycol was not altered appreciably by irradiation. Since the distribution appeared similar to that in Fig. 2 for both groups of animals, it is not shown.

Small intestinal transit times for polyethylene glycol were calculated by a method described previously (8). No radiation-induced change in the motility of the small intestine was detected. This finding agrees with previous studies in which a nonabsorbable marker was administered to the stomach (6, 9). However, when the marker was administered intraduodenally, the small intestinal transit rate was increased in irradiated rats (10). Since this latter study was not complicated by the effects of radiation on gastric emptying, it may be a more sensitive measure of the effects of radiation on intestinal motility than studies that involved gastric administration of the marker.

The recovery of polyethylene glycol from the GI tract of both irradiated and control animals was nearly complete (>90%) at all times up to 6 hr following its administration (Table I). Thus, the very low permeability of the GI epithelium to large, polar molecules is not altered by prior irradiation of the epithelium, even though marked anatomical and phys-

iological changes are manifest for several days following irradiation (11, 12).

Sulfanilamide was administered simultaneously with polyethylene glycol; its distribution along the GI tract at 1 day postirradiation is shown in Figs. 3 and 4 for irradiated and control animals, respectively. In both groups, less than 10% of the administered drug was recovered below the level of the stomach at any time. In addition, sulfanilamide disappeared from the stomach at the same rate as polyethylene glycol 4000 (Fig. 5). Since polyethylene glycol 4000 was not absorbed, sulfanilamide apparently was not absorbed from the stomach. The intestine is the primary site for absorption of sulfanilamide, and gastric emptying is the rate-controlling step in the absorption of this drug.

Table I—Recovery of Polyethylene Glycol from GI Tract following Oral Administration to Irradiated and Sham-Irradiated Rats

Time after Dosing, hr	Percent of Dose Recovered[a]			
	1 Day Postirradiation		5 Days Postirradiation	
	Sham	850 rad	Sham	850 rad
0.5	94.4 ± 2.23	96.0 ± 4.46	102.3 ± 7.72	91.7 ± 4.35
1.0	92.9 ± 5.22	94.6 ± 2.28	94.2 ± 3.38	104.4 ± 11.25
2.0	94.6 ± 1.62	96.7 ± 4.40	94.1 ± 2.00	103.2 ± 4.28
6.0	94.0 ± 2.81	91.7 ± 2.57	100.5 ± 5.18	92.7 ± 2.42
Mean	94.0 ± 0.76	94.8 ± 2.22	97.8 ± 4.25	98.2 ± 6.73

[a] Mean of six animals ± *SD*.

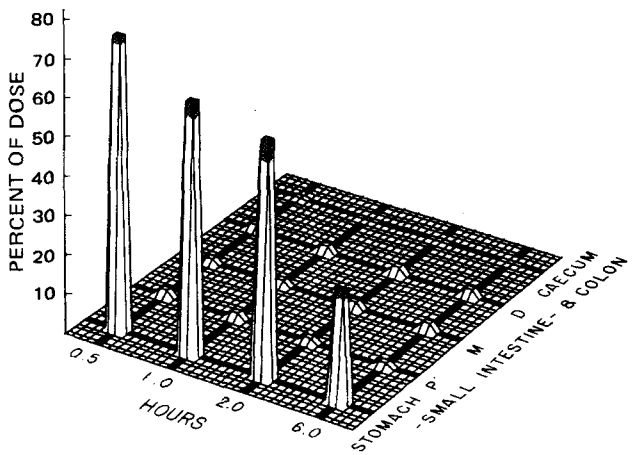

Figure 3—*Distribution of sulfanilamide along the GI tract following oral administration of 200 mg/kg to rats exposed to 850 rad of cobalt-60 γ-radiation 1 day previously. Each bar represents the mean of six animals; stippling represents 1* SE. *P, M, and D are proximal, middle, and distal thirds of the small intestine, respectively.*

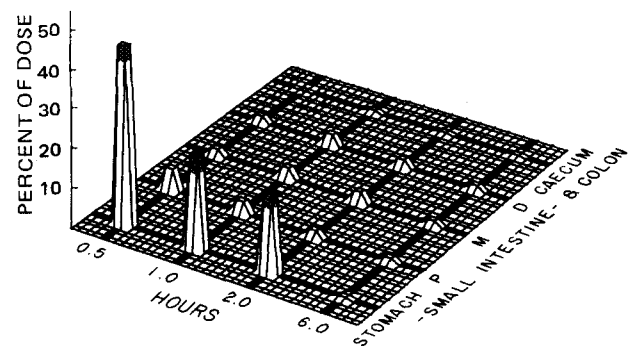

Figure 4—*Same as Fig. 3 except that the rats were sham irradiated.*

The reduced rate of absorption of sulfanilamide in irradiated animals at 1 day postirradiation is apparent in Figs. 3 and 4. The relatively slow absorption of sulfanilamide is also evident in the serum concentration–time curve of sulfanilamide; the serum level was threefold higher in control animals than in the irradiated group (Fig. 6). The linear relationship between serum concentrations of sulfanilamide and the amount of drug absorbed for both irradiated and control animals indicates that

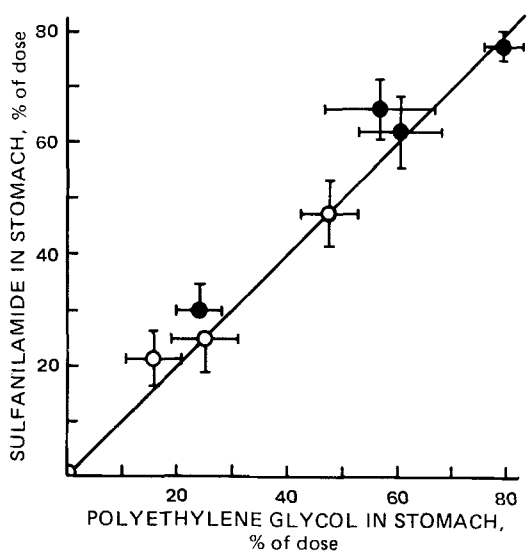

Figure 5—*Relationship between the recoveries of sulfanilamide and polyethylene glycol from the rat stomach at various times following their oral administration 1 day postirradiation. Key: ●, irradiated (850 rad); and ○, sham irradiated. Each point represents the mean of six animals, and lines indicate ± 1* SE.

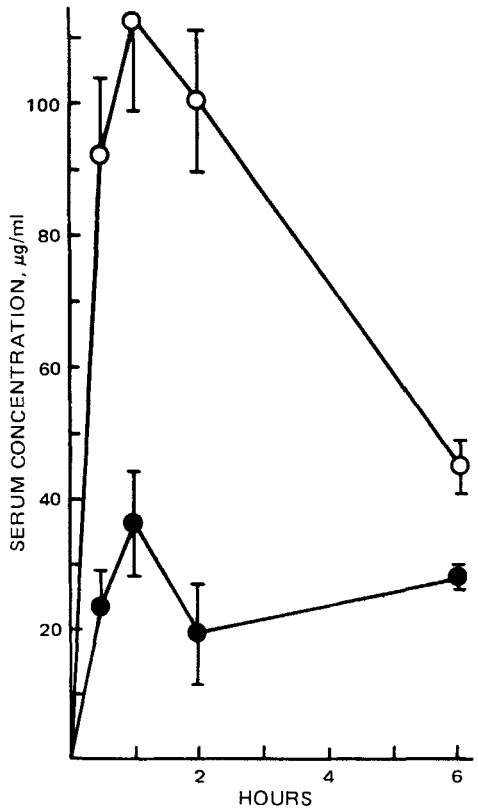

Figure 6—*Serum levels of sulfanilamide in rats following oral administration of 200 mg/kg 1 day postirradiation. Key: ●, irradiated (850 rad); and ○, sham irradiated. Each point represents the mean of six animals; bars indicate ± 1 SE.*

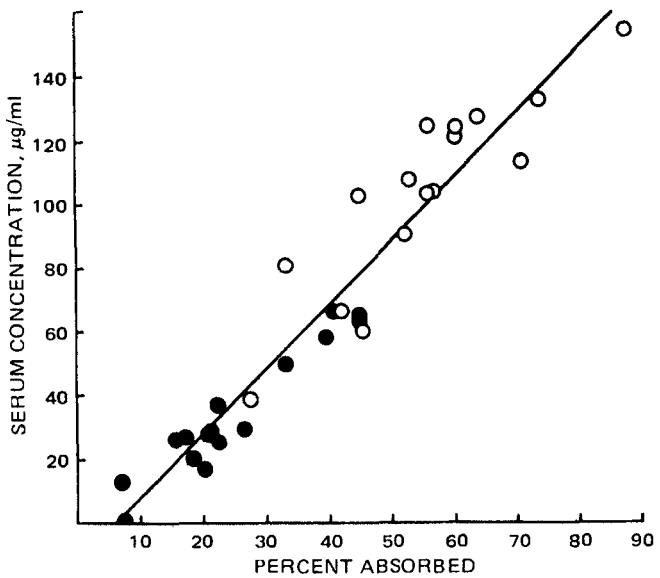

Figure 7—*Serum levels of sulfanilamide in rats and corresponding percent of dose absorbed at 0.5 and 1.0 hr following oral administration of 200 mg/kg 1 day postirradiation. Key: ●, irradiated (850 rad); and ○, sham irradiated.*

differences in serum levels were due solely to differences in the absorption rate (Fig. 7); distribution and elimination of the drug following absorption were apparently not affected by irradiation with 850 rad.

Immediately following irradiation, irradiated animals consume considerably more food than sham-irradiated animals (1). The stomachs of irradiated animals were greatly distended at 1 day postirradiation, even following an overnight fast. To determine whether food in the stomachs of irradiated animals caused the reduced absorption rate of sulfanilamide, the experiment was performed with animals that were not permitted food following irradiation. The sulfanilamide absorption rate remained significantly lower in the irradiated animals (Table II), indicating that these differences between irradiated and sham-irradiated animals were not due to differences in food consumption.

In agreement with the studies on polyethylene glycol 4000 and sulfanilamide, the gastric emptying rate of bretylium tosylate in irradiated animals was significantly reduced at 1 day postirradiation compared to sham-irradiated animals (Table III). This difference was not apparent at 5 days postirradiation. High levels of bretylium in the intestine indicate that the rate-controlling step in the absorption of this drug is diffusion across the GI mucosa to the blood rather than gastric emptying. Radiation-induced slowing of the gastric emptying rate, therefore, did not markedly reduce the bretylium absorption rate (Table III) as it did for sulfanilamide. The tendency for the absorption rate of bretylium to be reduced in irradiated animals is probably due both to a reduced rate of gastric emptying and a reduced mucosal permeability. The absorption rate of bretylium is probably more rapid from the intestine than the stomach, and both *in vitro* and *in situ* studies indicate that irradiation may cause a subsequent reduction in the permeability of the GI mucosa (13–15). Bretylium concentrations in serum were below the sensitivity of the analytical procedure, 5 μg/0.5 ml of serum.

The gastric emptying rate and the absorption rate of sulfisoxazole acetyl were reduced significantly in irradiated animals compared to the sham-irradiated group at 1 day postirradiation, but no detectable difference between the two groups was observed at 5 days postirradiation (Table IV). The reduced rate of drug absorption in irradiated animals compared to controls was also apparent from the significantly lower concentration of the drug in serum at 1 day postirradiation (Table IV).

Sulfisoxazole acetyl is absorbed more rapidly than sulfanilamide from solution by the rat small intestine (15). The relatively high level of sulfisoxazole acetyl in the intestine following its oral administration as a suspension indicates that the rate-controlling step in the absorption of this drug is dissolution. Although the absorption rate of sulfisoxazole acetyl is reduced in irradiated animals, the extent of absorption is increased (1), apparently because the reduced rate of GI transit allows more time for the drug to dissolve.

The gastric emptying rate of riboflavin was decreased in irradiated animals at 1 day postirradiation. In accord with previous studies, it appeared normal by 5 days postirradiation (Table V). The riboflavin level in the intestine was quite high. Since the vitamin was administered in solution, the rate-controlling step in the absorption process is apparently transport across the intestinal epithelium, in a manner similar to bretylium absorption. In contrast to the absorption of bretylium, however, the absorption rate of riboflavin was significantly *greater* in irradiated than in sham-irradiated animals. A possible explanation for this difference is that riboflavin is absorbed by a saturable process at a specific site in the proximal small intestine (16 and references cited therein) while the

5	2.0	Sham	2.54 ± 2.98	88.2 ± 4.93	9.3 ± 3.1
5	2.0	850 rad	2.76 ± 3.28	85.0 ± 5.13	12.1 ± 5.33

[a] Administered as a solution in water. [b] Rats were exposed to 850 rad of cobalt-60 γ-radiation or sham irradiated 1 or 5 days before administration of riboflavin. [c] Mean of five animals ± *SD*. [d] Difference between dose and recovery from the stomach and intestine. [e] Significantly different ($p < 0.05$) from corresponding sham-irradiated animals.

absorption of bretylium is not saturable. Slow release of riboflavin from the stomach of irradiated animals at 1 day postirradiation presents the vitamin to the absorption site at a relatively low concentration for a relatively long time. This increased time of contact allows a greater fraction of the dose to be absorbed. The *in vivo* extent of riboflavin absorption was also increased in irradiated rats at 1 day postirradiation (1).

An alternative explanation for the radiation-induced increase in riboflavin absorption is that riboflavin is absorbed more rapidly from the stomach than from the intestine, and slowed gastric emptying thereby increases the absorption rate. In view of the very slow absorption of practically all drugs from the stomach compared to the intestine, this latter mechanism is not likely.

With regard to the drug absorption rate, the primary effect of irradiation is the marked reduction in the gastric emptying rate immediately following irradiation. The slowed gastric emptying appears to be a normal response to intestinal injury in the rat (17). By 5 days postirradiation, the gastric emptying rate had returned to normal.

The net effect on the drug absorption rate of a reduction in the gastric emptying rate depends partly on the drug. Irradiation markedly slows the absorption rate of drugs that are rapidly absorbed from the intestine; it causes a less pronounced reduction in the absorption rate of drugs that are slowly absorbed from the intestine, whether slow absorption is due to low mucosal permeability or low dissolution rate. The drug absorption rate may be increased for drugs that are absorbed by a saturable, relatively low capacity mechanism.

In this study, the effect of radiation on the permeability of the GI mucosa appeared to be negligible, although the large reduction in the rate of gastric emptying may have masked a change in mucosal permeability. To explore further the possible effects of radiation on the permeability of the intestinal mucosa, the effects of radiation on the rate of drug absorption from solution by the *in situ* rat intestine were determined and will be reported elsewhere (15).

Application of Gluconolactone in Direct Tablet Compression

S. S. NASIR [x], L. O. WILKEN, Jr., and BEHROZE AKHTAR

Abstract □ Gluconolactone was evaluated as an excipient for tablets prepared by direct compression using various drugs known to be difficult to compress. The physical properties of the tablets were evaluated after compression and after storage and were satisfactory. Comparative studies were conducted between gluconolactone and anhydrous lactose, a common direct compression diluent, for development of static charges during blending, flow, drug distribution, drug stratification, color distribution, compressibility, and preservation against mold growth. Gluconolactone possesses those properties necessary to produce high quality tablets by the direct compression process. Separate powdered mixtures of aspirin USP with gluconolactone, anhydrous lactose, spray-dried lactose, mannitol, and sorbitol were stored at various humidities and temperatures for specified periods and tested for the integrity of aspirin. Gluconolactone contributed least to the degradation of the drug as compared to other excipients studied. A preliminary *in vivo* study also was conducted on the bioavailability of aspirin from separate and similar mixtures with gluconolactone, anhydrous lactose, and starch. Gluconolactone did not show any inhibitory effect on aspirin absorption.

Keyphrases □ Gluconolactone—excipient in directly compressed tablets of various drugs, effect on physical characteristics □ Excipients—gluconolactone in directly compressed tablets of various drugs, effect on physical characteristics □ Tablets, direct compression—various drugs, gluconolactone as excipient, effect on physical characteristics □ Dosage forms—directly compressed tablets of various drugs, gluconolactone as excipient, effect on physical characteristics

In terms of economics and stability, the direct compression process offers distinct advantages over other methods used in the manufacture of compressed tablets. During the last decade, considerable interest has been shown in this process. Excipients such as spray-dried lactose (1), microcrystalline cellulose (2), fused mannitol (3), calcium phosphate (4), dextrose (5), amylose (6), anhydrous lactose (7), and directly compressible starch (8) have been studied for their ability to aid in the preparation of compressed tablets. The use of these materials had certain limitations including the difference in particle size and bulk density leading to stratification, the excipients to drug ratio necessary to effect compression, the requirement of an optimum amount of moisture, incompatibility with the drugs, the development of static charges during processing, and cost.

Table I—Properties of Gluconolactone (I) and Anhydrous Lactose

Property	I	Anhydrous Lactose
Solubility in water at 25°, g/ml	0.59	0.2
Particle-size distribution[a] of commercial powders used, % retained		
20 mesh	0.0010	0.00257
30 mesh	0.0450	0.02318
40 mesh	3.4000	0.21894
60 mesh	3.8975	4.6623
80 mesh	4.0525	11.9391
100 mesh	4.250	14.90907
Flow properties, angle of repose		
Plain	26° 23′	22° 43′
With 1% magnesium stearate	23° 50′	20° 12′

[a] A total of 84.354% of I and 64.246% of anhydrous lactose passed through the 100-mesh sieve.

Due to these factors, evaluation of new excipients is warranted. Preliminary experiments with gluconolactone (D-glucono-1,5-lactone, I) indicated considerable potential as an excipient in direct compression; therefore, a thorough study was undertaken.

Compound I was used previously in pharmaceuticals as a stabilizer for multivitamins (9) and tetracycline (10). It is prepared by the oxidation of glucose with bromine water (11) or by oxidation of glucose in *Acetobacter suboxydans* (12). Compound I has a sweet taste and is highly soluble in water (59 g/100 ml); it is slowly hydrolyzed by water to gluconic acid. The calcium and ferrous salts of this acid are

Table III—Estimation of Sticking of Powders during Blending

Drug	Weight per 500 ml of Powder, g	Amount Retained, g ± *SD*	Percent Retained
I	336.8	3.8 ± 0.12	1.13
Anhydrous lactose	361.0	4.3 ± 0.10	1.19
Spray-dried lactose	318.0	0.8 ± 0.03	0.25

commonly administered orally in large doses for the effect of the cations.

EXPERIMENTAL

Particle-Size Analysis—The particle-size distribution of I was determined with a testing sieve shaker[1] using stainless steel U.S. standard sieve series in 20-, 30-, 40-, 60-, 80-, and 100-mesh sizes. A 200-g sample was tested in the sieve shaker for 10 min.

Moisture Content—The moisture content of I was determined on a moisture determination balance[2]. The test was continued until three consecutive readings at 3-min intervals were constant.

Flow Pattern of I—The flow properties of I were estimated by determination of the angle of repose without and with 1% magnesium stearate by a described procedure (13). Flow properties of anhydrous lactose also were studied by the same method for comparison.

Development of Static Charges during Blending—A plastic V-shaped container with a volume of 848 ml and a smooth inner surface was used. The container was dried at 45° for 12 hr, cooled to room temperature in a desiccator, and filled with 500 ml of the specified powder of known weight. The V-shaped container with the material was then rotated[3] at 36 rpm for 15 min. Then the material was immediately poured out gently, without disturbing the powder sticking to the container, and weighed. The weight of the sticking material was then calculated. The environmental working conditions for the test were maintained at 29° and a relative humidity of 42%.

Tablet Preparation—Five thousand tablets of I and 5000 tablets each of I in combination with the following drugs were prepared: ferrous sulfate, phenobarbital, sodium chloride, ephedrine hydrochloride, isoniazid, methenamine, ascorbic acid, sulfathiazole, ferrous gluconate, calcium lactate, aspirin, riboflavin, multivitamins with minerals, aminosalicylic acid, and powdered digitalis.

Appropriate changes in the formulas were made to establish minimum quantities of I and other essential ingredients required to produce satisfactory tablets. All tablets were prepared on a four-station press[4] at 300 tablets/min using various types and sizes of punches and dies, with the exception of riboflavin and multivitamin tablets which were compressed on a single-punch press[5] at 60 tablets/min. The resulting tablets were

Table IV—Color Distribution in Powder Mixture[a]

Amaranth Concentration, mg/0.1 g ± *SD*		
I	Anhydrous Lactose	Spray-Dried Lactose
0.439 ± 0.001	0.475 ± 0.007	0.590 ± 0.005

[a] Powder formula was I, anhydrous lactose, or spray-dried lactose, 345.23 mg, and amaranth, 18.97 mg.

evaluated for the following properties:

1. Hardness[6].
2. Thickness—Thickness was measured by means of a vernier caliper graduated in millimeters.
3. Weight—Tablets were randomly collected during compression, and groups of 20 tablets from those collected were weighed individually. The weight variation was then calculated.
4. Friability—Friability was ascertained with a friabilator[7] using a 4-min cycle and at least 20 tablets or a minimum 6.0-g tablet sample.
5. Disintegration Time—Disintegration time of all tablets in water at 37° was determined by means of a USP XVIII apparatus using disks. Disintegration time of plain I tablets was also determined in simulated gastric fluid USP without pepsin and simulated intestinal fluid USP without pancreatin using the same apparatus and procedure.

Drug Stratification—Sufficient I to make 5000 tablets was mixed with the specified drug and other essential ingredients in a blender[8] for 5 min. Then a specified quantity of magnesium stearate was added and mixed for an additional 5 min.

Six samples were collected from different portions of mixed powder and analyzed for the drug content.

The mixed powder was collected in a hopper, a six-mesh stainless steel screen was fixed at the bottom of the hopper, and the hopper was then attached to a sieve shaker[9] and vibrated at a constant speed until all of the powder passed through the screen into a container. Six samples were withdrawn from different portions of the powder and analyzed for drug concentration.

The remaining powder, without further mixing, was compressed into tablets on a four-station press[4] at 300 tablets/min. Six 20-tablet samples were tested for drug distribution. Tablets of sulfathiazole, riboflavin, and aspirin were prepared and studied for drug distribution and stratification. Sulfathiazole and riboflavin were assayed by the USP XIV procedure and a described procedure (14), respectively.

Aspirin tablets were assayed by the following method. A sample of 20 tablets was powdered. A portion of this powder, equivalent to 300 mg of

aspirin, was weighed accurately, mixed with 60 ml of ether, stirred for 5 min, and then filtered to remove the excipients. Then 45 ml of water and 5 ml of 95% alcohol were added to the filtrate, and the filtrate was heated to remove the ether. The resulting solution was assayed according to a described procedure (15). For comparison, anhydrous lactose was evaluated for drug stratification by the same procedure using the same drugs.

Color Distribution—To study the color uniformity in I tablets, 0.5% amaranth USP was used as a source of color. A specified quantity of amaranth was mixed with a portion of I, added to the remainder of the lactone in a blender[8], and mixed for 15 min. The intensifier was turned on at 5-min intervals for 15 sec. Six random samples were withdrawn from the mixture and assayed for amaranth spectrophotometrically at 385 nm.

Specified quantities of methylcellulose, 1500 cps, and magnesium

stearate were added to the amaranth–I mixture and compressed on a four-station rotary press; 5000 such tablets were prepared. Six 20-tablet random samples were collected and assayed for amaranth by this procedure. Anhydrous and spray-dried lactose also were studied for color distribution by the same procedure as described for I. Finished tablets were stored at room temperature for 6 months and observed for color changes.

Dissolution Studies—To investigate the effect of I on tablet dissolution, phenobarbital, benzoic acid, aspirin, and ferrous sulfate were selected as representative drugs. Tablets of these drugs were prepared with I and anhydrous lactose as excipients. Attempts were made to maintain equal weight and hardness for similar tablets.

Dissolution rates of these tablets were determined in water at 37° with the USP XVIII dissolution apparatus. Samples were withdrawn at specified intervals and assayed for drug concentration. Phenobarbital was assayed according to a described procedure (16). Similarly, benzoic acid (17) and aspirin (18) were analyzed by reported procedures. Ferrous sulfate was assayed by the following procedure.

To each 1-ml sample were added 1 ml of hydrogen peroxide and 5 ml of a reagent consisting of 5.835 mg of sodium salicylate, 200 mg of mercuric chloride, and 0.6 ml of 1 *N* hydrochloric acid dissolved in water. The resulting solution was assayed spectrophotometrically at 540 nm.

Mold Growth—Tablets of phenobarbital, ferrous sulfate, and aspirin prepared with I and anhydrous lactose for dissolution studies and plain tablets of I from Batch 1 were stored at 95% relative humidity at room temperature for 2 months and observed for mold growth.

Effect of I on Stability of Moisture-Sensitive Drugs—Aspirin was selected as a representative drug, and anhydrous lactose, spray-dried lactose, mannitol, and sorbitol were selected as excipients for comparison with I.

Aspirin, 6 g, and 59 g of each excipient were mixed separately. Six samples of each type were prepared and stored at 52 and 81% relative humidity and 50 and 60°. These samples were assayed at 1-week intervals for 4 weeks for free salicylic acid content by a reported procedure (19). These mixtures also were stored at room temperature for 3 months and then assayed for free salicylic acid by the same procedure.

Preliminary Bioavailability Assessment—To obtain some rudimentary information about the influence of I on drug absorption, a comparative *in vivo* study was conducted on aspirin absorption from separate combinations with I, anhydrous lactose, and starch. Each dose consisted of 50 mg of aspirin mixed with 50 mg of I or anhydrous lactose and with 12.5 mg of starch.

Each combination was studied on a group of six male rabbits, approximately 3 kg. Each dose, in a No. 2 gelatin capsule, was administered

orally to a rabbit. Blood samples were taken at 0, 30, 60, 90, 120, 150, 210, 270, and 330 min from the ear marginal vein and assayed for salicylic acid by a reported procedure (20).

RESULTS AND DISCUSSION

Most particles of I are finer than 100 mesh. This particle-size distribution is advantageous for tableting (Table I) because most drugs formulated as tablets fall in a fine particle-size range. Due to the similarity in particle size, the drugs can be blended with the excipient more easily, and stratification and separation can be avoided at the compression stage.

Compound I has only 0.5% moisture, which can be an advantage in the preparation of compressed tablets of drugs that decompose by hydrolysis and of drugs whose deterioration or interaction with other drugs is accelerated by moisture.

Compound I has a higher angle of repose than anhydrous lactose (Table I). This property does not seem disadvantageous, because the flow of I in the tablet press did not differ from that of anhydrous lactose. Pharmaceutically acceptable tablets of various drugs with different properties and amounts per tablet were prepared with I (Table II). After 6 months of storage at room temperature, the tablets did not show any undesirable changes in hardness, friability, and disintegration time, with the exception of calcium lactate tablets, the hardness of which decreased considerably.

The disintegration time and hardness of sodium chloride and ferrous sulfate tablets did not increase considerably. Undesirable increases are expected in conventionally prepared tablets of these salts.

Since the aminosalicylic acid tablets were not coated, no attempt was made to evaluate their physical properties on storage. Properties of ascorbic acid, sulfathiazole, aspirin, and aminosalicylic acid tablets prepared with I indicate that this excipient can be used successfully with

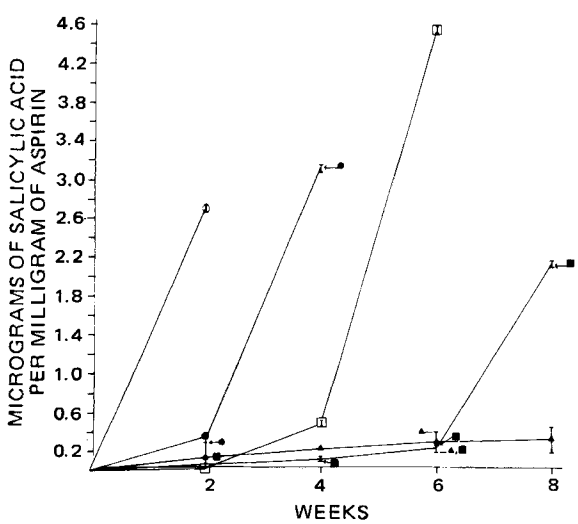

Figure 8—*Stability of aspirin with various diluents at 60°. Key: ○, anhydrous lactose; □, I; ■, mannitol; ●, spray-dried lactose; and ▲, pure aspirin.*

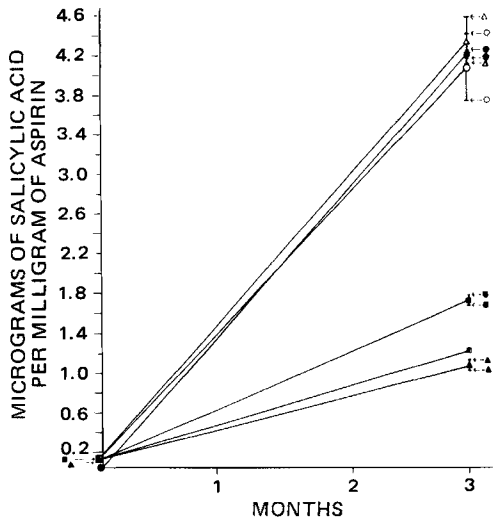

Figure 9—*Stability of aspirin with various diluents after 3 months of storage at room temperature. Key: ●, spray-dried lactose; ○, anhydrous lactose; ■, mannitol; □, I; ▲, aspirin; and △, sorbitol.*

these materials. The amount of I required depends on the amount and inherent compression properties of the drug.

In the test for estimation of sticking of a material to a surface due to static charges (Table III), the amounts of anhydrous lactose lost were approximately 0.05% less and 0.91% more than those lost with I and spray-dried lactose, respectively. Less sticking of spray-dried lactose was probably due to its larger particle size. In addition to production of static charges, the loss of material in this test can be attributed to the shape and size of particles and the number of fines in the powder.

In the color distribution studies with amaranth, the dye was more uniformly distributed in I than anhydrous lactose and spray-dried lactose; the deviations between samples assayed for amaranth concentration were less with I compared to the other two materials (Tables IV and V).

Similar results were obtained from tablets compressed from these powders. Color distribution was most uniform in tablets with I, followed closely by anhydrous lactose tablets. Mottling was predominant in spray-dried lactose tablets. None of these tablets showed any signs of fading after 6 months of storage.

Sulfathiazole, riboflavin, and aspirin were selected for drug stratification studies. The quantity of each drug was such that it represented a certain drug to excipient ratio.

In all cases, the drug distribution at blending, sieving, and compression stages was well within acceptable limits, both with I and anhydrous lactose, but anhydrous lactose had considerably higher deviation at the sieving stage as compared to I. The uniform distribution of a small quantity of riboflavin in a large quantity of I shows that this material also can be used for making tablets with small quantities of drugs by the direct compression process (Table VI).

A comparative dissolution rate study was conducted between tablets prepared with I and anhydrous lactose. Aspirin, ferrous sulfate, phenobarbital, and benzoic acid were studied. Similar tablets of these drugs were prepared with each excipient and tested for dissolution. Properties of these tablets are shown in Table VII. Aspirin and ferrous sulfate tablets

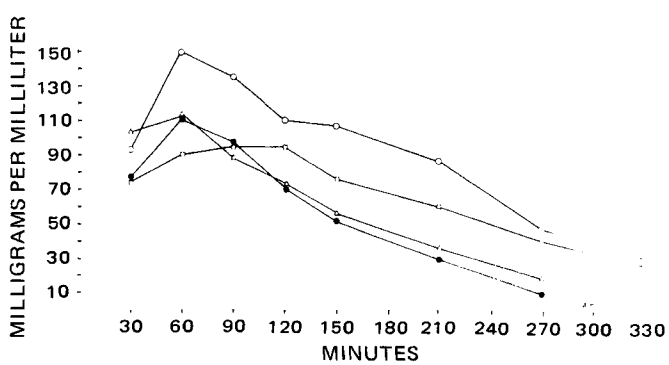

Figure 10—*In vivo bioavailability of aspirin from tablets with various diluents. Key: ○, lactose; □, I; △, starch; and ●, pure aspirin.*

prepared with I had faster dissolution than the tablets with anhydrous lactose. The dissolution rate of phenobarbital tablets with anhydrous lactose was higher than that of tablets with I. This result may be due to the greater hardness of tablets with I. This hardness was needed to produce satisfactory tablets. The dissolution rate of benzoic acid tablets with I was considerably less than that of tablets made with anhydrous lactose. This finding can be attributed to a further decrease in dissolution medium pH due to the hydrolysis of I to gluconic acid. The results of the dissolution studies are shown in Figs. 1–4.

Aspirin, ferrous sulfate, and phenobarbital tablets prepared with I, anhydrous lactose, and spray-dried lactose and plain tablets of I were stored at 95% relative humidity for 2 months. Mold growth was observed on aspirin tablets and phenobarbital tablets prepared with anhydrous lactose and spray-dried lactose, respectively. None of the tablets prepared with I showed any signs of mold growth.

A comparative study was conducted at various humidity and temperature conditions on the stability of aspirin in a mixture with I and other excipients such as anhydrous lactose, spray-dried lactose, mannitol, and sorbitol. Aspirin hydrolyzed less when mixed with I as compared to other excipients (Figs. 5–9). Mannitol, which is an excellent excipient for moisture-sensitive drugs due to its water-repellent properties (21), contributed more to the hydrolysis of aspirin as compared to I.

No attempt was made to study aspirin–sorbitol mixtures at higher temperatures because a preliminary investigation showed excessive hydrolysis of aspirin in such mixtures.

These results on the stability of aspirin indicate that I probably takes up the environmental moisture for its own hydrolysis into gluconic acid, thereby preventing the hydrolysis of aspirin. A similar mechanism is expected for the stability of other drugs that deteriorate in moisture. A detailed study on this aspect is being conducted.

A preliminary *in vivo* bioavailability study was conducted to obtain information on the effect of I on drug absorption. The results shown in Fig. 10 do not indicate any inhibitory effect of I on aspirin absorption. Detailed bioavailability studies are being conducted on various drugs in combination with I using different test animals. Compound I and anhydrous lactose seem to prolong blood aspirin levels for a greater period as compared to pure aspirin and aspirin–starch mixtures.

Compound I merits serious consideration for use as a direct compression excipient. It can effect compression of problem drugs at relatively low concentrations and yields tablets possessing desired characteristics for pharmaceutical use. The enhancement of stability of moisture-sensitive drugs with I is an additional advantage.

Electrochemical Analysis of the Cephalosporin Cefamandole Nafate

EUGENE C. RICKARD [x] and GARY G. COOKE

Abstract □ The polarographic assays for cefamandole sodium and its formyl ester, cefamandole nafate, are described. Controlled potential coulometry is used as an absolute method for the assignment of purity of these compounds without the need for a reference material. The precision, accuracy, and selectivity of these assays were better than for the microbiological autoturbidimetric and automated iodometric assays. NMR, TLC, GC, and polarography are used to detect and quantitate likely impurities and degradation products.

Keyphrases □ Cefamandole nafate—polarographic analysis, prepared samples □ Polarography—analysis, cefamandole nafate, prepared samples □ Antibacterials—cefamandole nafate, polarographic analysis, prepared samples

Cefamandole (I) has *in vitro* activity against various Gram-positive and Gram-negative bacteria (1–3). A formyl ester, cefamandole nafate (II), was prepared for use in the clinical formulation because it can be purified in a crystalline form having good long-term stability. The ester is hydrolyzed rapidly to cefamandole *in vivo* (4) or in basic aqueous solution (5). Title 21 of the Code of Federal Regulations, Part 442, Cepha Antibiotics, generally provides for both microbiological and chemical assay procedures for cephalosporin antibiotics. However, the microbiological assay results are considered conclusive even though this assay is not specific for any one compound. This paper focuses on the additional tests necessary to characterize completely antibiotic materials such as cefamandole and cefamandole nafate.

Electrochemical techniques are uniquely suited for the assay of compounds containing reducible or oxidizable functions. These include the cephalosporin antibiotics

prepared with I had faster dissolution than the tablets with anhydrous lactose. The dissolution rate of phenobarbital tablets with anhydrous lactose was higher than that of tablets with I. This result may be due to the greater hardness of tablets with I. This hardness was needed to produce satisfactory tablets. The dissolution rate of benzoic acid tablets with I was considerably less than that of tablets made with anhydrous lactose. This finding can be attributed to a further decrease in dissolution medium pH due to the hydrolysis of I to gluconic acid. The results of the dissolution studies are shown in Figs. 1–4.

Aspirin, ferrous sulfate, and phenobarbital tablets prepared with I, anhydrous lactose, and spray-dried lactose and plain tablets of I were stored at 95% relative humidity for 2 months. Mold growth was observed on aspirin tablets and phenobarbital tablets prepared with anhydrous lactose and spray-dried lactose, respectively. None of the tablets prepared with I showed any signs of mold growth.

A comparative study was conducted at various humidity and temperature conditions on the stability of aspirin in a mixture with I and other excipients such as anhydrous lactose, spray-dried lactose, mannitol, and sorbitol. Aspirin hydrolyzed less when mixed with I as compared to other excipients (Figs. 5–9). Mannitol, which is an excellent excipient for moisture-sensitive drugs due to its water-repellent properties (21), contributed more to the hydrolysis of aspirin as compared to I.

No attempt was made to study aspirin–sorbitol mixtures at higher temperatures because a preliminary investigation showed excessive hydrolysis of aspirin in such mixtures.

These results on the stability of aspirin indicate that I probably takes up the environmental moisture for its own hydrolysis into gluconic acid, thereby preventing the hydrolysis of aspirin. A similar mechanism is expected for the stability of other drugs that deteriorate in moisture. A detailed study on this aspect is being conducted.

A preliminary *in vivo* bioavailability study was conducted to obtain information on the effect of I on drug absorption. The results shown in Fig. 10 do not indicate any inhibitory effect of I on aspirin absorption. Detailed bioavailability studies are being conducted on various drugs in combination with I using different test animals. Compound I and anhydrous lactose seem to prolong blood aspirin levels for a greater period as compared to pure aspirin and aspirin–starch mixtures.

Compound I merits serious consideration for use as a direct compression excipient. It can effect compression of problem drugs at relatively low concentrations and yields tablets possessing desired characteristics for pharmaceutical use. The enhancement of stability of moisture-sensitive drugs with I is an additional advantage.

Electrochemical Analysis of the Cephalosporin Cefamandole Nafate

EUGENE C. RICKARD [x] and GARY G. COOKE

Abstract □ The polarographic assays for cefamandole sodium and its formyl ester, cefamandole nafate, are described. Controlled potential coulometry is used as an absolute method for the assignment of purity of these compounds without the need for a reference material. The precision, accuracy, and selectivity of these assays were better than for the microbiological autoturbidimetric and automated iodometric assays. NMR, TLC, GC, and polarography are used to detect and quantitate likely impurities and degradation products.

Keyphrases □ Cefamandole nafate—polarographic analysis, prepared samples □ Polarography—analysis, cefamandole nafate, prepared samples □ Antibacterials—cefamandole nafate, polarographic analysis, prepared samples

Cefamandole (I) has *in vitro* activity against various Gram-positive and Gram-negative bacteria (1–3). A formyl ester, cefamandole nafate (II), was prepared for use in the clinical formulation because it can be purified in a crystalline form having good long-term stability. The ester is hydrolyzed rapidly to cefamandole *in vivo* (4) or in basic aqueous solution (5). Title 21 of the Code of Federal Regulations, Part 442, Cepha Antibiotics, generally provides for both microbiological and chemical assay procedures for cephalosporin antibiotics. However, the microbiological assay results are considered conclusive even though this assay is not specific for any one compound. This paper focuses on the additional tests necessary to characterize completely antibiotic materials such as cefamandole and cefamandole nafate.

Electrochemical techniques are uniquely suited for the assay of compounds containing reducible or oxidizable functions. These include the cephalosporin antibiotics

having a thioether linkage to a substituent at the 3-cephem position. Specifically, cefamandole and cefamandole nafate are easily reduced at the dropping mercury electrode.

This paper reports the polarographic reduction characteristics of these compounds and describes the use of polarography in analytical control and stability procedures. Controlled potential coulometry is proposed as an absolute method for purity evaluation. The purities obtained from these two electrochemical techniques are evaluated by comparison with the microbiological autoturbidimetric and automated iodometric assays. Finally, the effect of impurities on each assay technique is presented. Electrochemical techniques were found to be less affected by impurities than other assay techniques. The use of NMR, TLC, GC, and polarography to monitor the types and levels of impurities also is discussed.

EXPERIMENTAL

Apparatus—Polarograms were recorded using a three-electrode polarograph[1]. Either a natural drop time dropping mercury electrode or a mechanically controlled drop time of 1 sec was used. Potential scan rates were 1 or 2 mv/sec. Instantaneous currents were measured. Electronic damping was not used. The three-compartment, water-jacketed polarographic cell was thermostated at the desired temperature (20–25°). The cell compartments were separated by medium-porosity sintered-glass disks and 4% agar–potassium chloride salt bridges. A saturated calomel reference electrode (SCE) and a 1-cm^2 platinum foil counter electrode were used. Water-saturated nitrogen was used for deaeration of the sample solutions.

A potentiostat[2] with current-to-voltage converter was used for coulometry. The current-to-voltage converter output was integrated electronically using an operational amplifier circuit constructed with a differential input, low drift, chopper-stabilized operational amplifier[3]. The integrator-calibrated time constant was 10.73/sec. The coulometric cell consisted of a 40-mm (diameter) × 45-mm Pyrex weighing bottle fitted with a rubber stopper containing the appropriate cell connections.

The working electrode was a 12.6-cm^2 stirred mercury pool. A magnetic stirrer was used for agitation. A 4-cm^2 platinum foil or wire counter electrode was separated from the working electrode compartment by a medium-porosity sintered-glass disk. The saturated calomel reference electrode was double isolated from the cell through a two-compartment salt bridge having sintered-glass disks. To exclude oxygen, a continuous stream of nitrogen was bubbled through the solution from a 10-mm, medium-porosity, fritted-disk immersion filter.

NMR spectra[4] were acquired from 99.7% deuterium oxide solutions, except for IV where solubility dictated the use of deuterated dimethyl sulfoxide. Sodium 3-(trimethylsilyl)propanesulfonate was used as the zero delta standard. All spectra were obtained at the equilibrium probe temperature.

Procedure—Solutions for polarography were prepared by weighing approximately 5 mg (measured to 0.01 mg) of sample into a 25-ml volumetric flask, dissolving in water, adding buffer, and diluting to volume. No surfactants were used for analytical investigations. The pH of this solution was measured. An aliquot was transferred to the polarographic cell and deaerated, and the polarogram was recorded. The diffusion current, i_d, and half-wave potentials, $E_{1/2}$, were measured by the usual procedures (6).

Coulometric solutions were prepared in deionized water at a nominal concentration of 5 mg/ml. Aliquots (5 ml) were pipetted into the coulometric cell containing the supporting electrolyte preelectrolyzed at the electrolysis potential. The number of coulombs consumed during electrolysis was determined using the calibrated time constant of the integrator, its output voltage (measured to 1 mv), and the current range of the potentiostat.

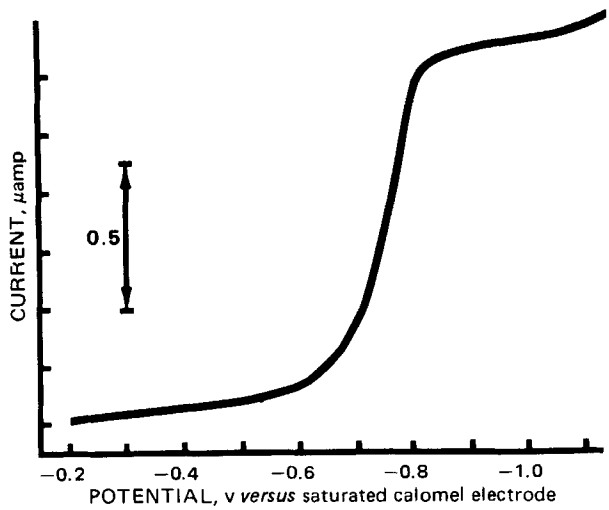

Figure 1—*Polarogram of 0.4 m*M *cefamandole nafate in pH 2.3 McIlvaine buffer.*

The total number of coulombs was corrected for the residual current observed after the electrolysis by integration of the residual current. This residual current was higher in the presence of the electrolysis products than in the preelectrolyzed electrolyte. The purity was calculated by comparison to the theoretical charge that should have been transferred for the amount of sample. These calculations were performed using:

$$Q\text{ (observed)} = RC \times V\text{ (out)} \times \text{sensitivity} \quad \text{(Eq. 1)}$$

$$Q\text{ (net)} = Q\text{ (observed)} - Q\text{ (correction)} \quad \text{(Eq. 2)}$$

$$Q\text{ (theory)} = \text{sample weight, mg} \times n \times F/\text{MW} \quad \text{(Eq. 3)}$$

$$\text{purity, \%} = Q\text{ (net)} \times 100/Q\text{ (theory)} \quad \text{(Eq. 4)}$$

where Q is charge in millicoulombs; RC is the integrator time constant per second; V (out) is integrator output voltage; sensitivity is the current-to-voltage sensitivity in milliamperes per volt; n is the number of electrons transferred per species; F is Faraday's constant, 96,500 mcoulombs/mEq; and MW is molecular weight in milligrams per mmole. Analytical results were obtained using an electrode potential of −0.875 v *versus* the saturated calomel reference electrode.

Electrochemical buffer solutions were prepared using reagent grade chemicals and were checked for contamination from electroactive impurities in the potential region of interest. Phosphate–citrate–potassium chloride 0.5 *M* constant ionic strength buffers were used unless otherwise stated.

The best NMR results were obtained when special attention was given to instrument adjustment. Optimization of spin rate, spectrum amplitude, and phasing was crucial. A spin rate of 45–50 rps prevented interference from spinning side bands. For best precision, the α-phenylmethine resonance amplitude was adjusted to full scale. Proper phasing was necessary for accurate measurements of peak heights. Spectra were acquired on 200-mg/ml solutions.

Thin-layer chromatograms were obtained using a 250-μg sample loading from an aqueous solution on silica gel plates[5]. The developing solvent was ethyl acetate–acetone–acetic acid–water (5:2:1:1). Chromatographic zones were examined by either shortwave UV light (254 nm) or after exposure to iodine vapors.

RESULTS

Polarography—Cefamandole and cefamandole nafate each gave a two-electron reduction wave at the dropping mercury electrode (Fig. 1). The transfer of two electrons was apparent from the coulometric results and by comparison of the observed diffusion current with that observed from compounds having known two-electron reductions (7). The polarographic wave corresponded to the reductive cleavage of the thioether linkage at position 3 of the cephalosporin (7). It exhibited a maximum of the first kind (8) at concentrations greater than 0.2 m*M* when the capillary drop time was 1 sec. When surfactant[6] or surface-active impurities were present, the maximum was suppressed.

[a] Data were obtained using a capillary with $m^{2/3}\,t^{1/6}$ of 1.382, open circuit, 1 *M* KCl, 1-sec mechanically controlled drop time. All supporting electrolytes were 0.5 *M* constant ionic strength McIlvaine buffers except as noted. [b] i_d = 3.991 (±0.010 *SD*) *C* + 0.0234 (±0.034 *SD*) and 3.902 (±0.031 *SD*) *C* + 0.058 (±0.052 *SD*) least-squares calculation for data obtained in pH 2.3 buffer. Instantaneous currents measured at the half-wave potential are reported. [c] Hydrochloric acid, 0.32 and 0.2 *M* ionic strength for pH 0.67 and 1.60, respectively. [d] Acetic acid—acetate, 0.7 *M* ionic strength.

Plots of $\log i/(i_d - i)$ *versus* *E* of the polarograms were nonlinear at all concentrations investigated. At very low concentrations such as 2×10^{-5} *M*, the logarithmic plots became nearly linear. The limiting current was proportional to concentration and to the square root of the corrected mercury column height. It had a temperature coefficient of approximately +0.8%/degree at 25°. These observations indicate that the limiting current was diffusion controlled.

The half-wave potentials of cefamandole and cefamandole nafate were complex functions of pH and concentration (Table I), as was previously observed for related compounds (7, 9). In the pH 0.6–2.3 range, $E_{1/2}$ was generally independent of pH. In contrast, a shift of $E_{1/2}$ with pH was observed from pH 2.3 to 7. The carboxylate pKa of these compounds was about 2.6–2.9 as determined by aqueous titration or 3.0 as determined by spectrophotometry. The diffusion current normalized with respect to concentration was approximately independent of pH at or below pH 5.8 and nearly equal for both compounds (diffusion current constant, *I*, equals 2.89). The half-wave potential was dependent upon concentration. This variation is reported in Table I, but it was impossible to measure "true" values of $E_{1/2}$ when maxima were present (concentrations above 0.2 m*M*).

The precision obtained for the normalized diffusion current in the pH 2.3 supporting electrolyte for individually weighed samples of identical material was 1.1% (n = 12). Thus, for the comparison of a sample to a standard reference material, a relative standard deviation of 1.6% may be expected. Decreases in the diffusion current of approximately 0.4%/hr (3.1% in 7 hr and 9.2% in 24 hr) were observed. Therefore, all polarograms were acquired on freshly prepared solutions.

Compounds III–VIII were not polarographically reducible under the assay conditions. However, 1-methyl-5-mercapto-1,2,3,4-tetrazole sodium salt (VII) can be oxidized at either platinum or mercury electrodes. At the platinum electrode, the oxidation product of thiols is the disulfide. However, the oxidation product of thiols at a mercury electrode is the mercurous salt (10).

[a] See text for explanation of assay procedures.

Comparison of Polarographic with Microbiological and Iodometric Assays—The relative purities of raw material lots of cefamandole sodium and cefamandole nafate determined by the polarographic, microbiological, and iodometric techniques are compared in Table II. All assays used a common cefamandole reference material. The polarographic assay was performed as already described. The microbiological turbidimetric assay measured the inhibition of growth of *Staphylococcus aureus* (ATCC 9144). The assay precision is about 2–4% as measured by relative standard deviation. The automated iodometric titration measured the increase in iodine uptake by the β-lactam following alkaline hydrolysis (11). The relative standard deviation for this assay is 1–2%.

The polarographic purity results were in excellent agreement with the purities determined by the other assay techniques. The observed ratio of assay results was less than 1 *SD* from unity for both cefamandole and cefamandole nafate (Table II).

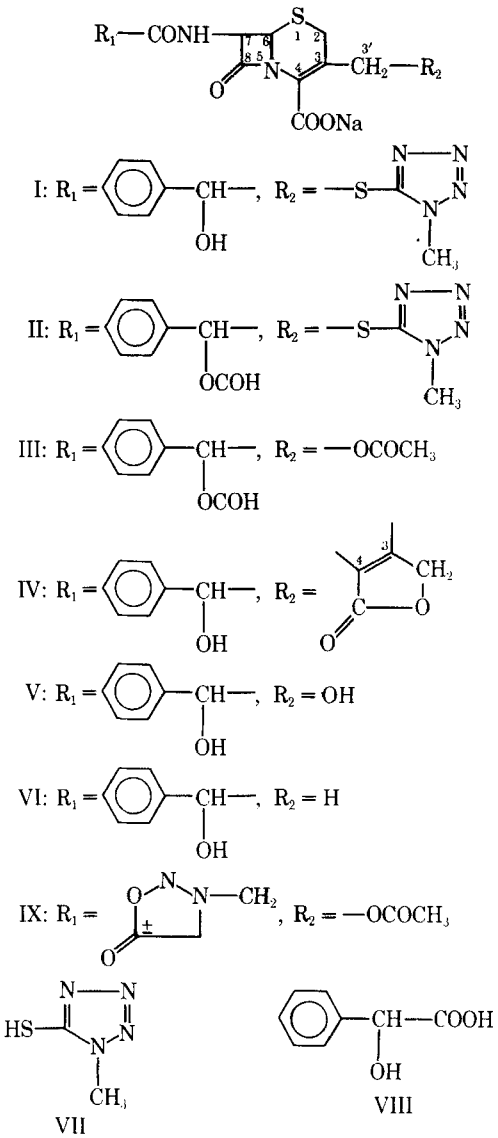
Controlled Potential Coulometry—When the anode and cathode compartments of the coulometric cell were separated, a two-electron reductive cleavage of the thioether bond was obtained. This arrangement corresponded to the normal experimental one. If the anode were located in the main portion of the cell, then the 1-methyl-5-mercapto-1,2,3,4-tetrazole formed at the mercury pool cathode would be transported to the platinum anode and oxidized to the corresponding disulfide. Under these conditions, a net three-electron transfer would be observed.

Analytical data were obtained using a cell with separated anode and cathode compartments. Plots of the logarithm of the current *versus* time were not linear, indicating that the reduction was not a simple electron transfer. This result was consistent with previous observations (7).

The products of the controlled potential coulometric reduction of cefamandole were examined by TLC and polarography. TLC indicated the presence of two major, one minor, and several trace zones. The retention factors for the major zones corresponded to the tetrazole derivative (VII) and VI. The minor zone retention factor correlated with 7-D-mandelamidocephalosporanic acid (mandelic acid form of III). The only identified trace zone appeared to be V. The amount of free VII as measured by polarography was greater than 80% of the amount expected for quantitative formation of this compound.

Comparison of Coulometry with Other Assay Techniques—The relative purities obtained for raw material lots of cefamandole and cefamandole nafate using the coulometric, microbiological, and iodometric assays are given in Table II. A comparison of the coulometric and polarographic assays is included also.

The coulometric assay results were in good agreement with results obtained by the other techniques. However, the ratio of the coulometric assay to the microbiological assay was more than 1 *SD* from unity for cefamandole nafate. This result may be explained by the relatively small number of samples from which the comparison was made. Moreover, the difference probably partially resulted from the nature of the microbiological assay for cefamandole nafate. For this assay, the sample is hydrolyzed to cefamandole in a sodium carbonate solution at room temperature and then is compared to a standard of cefamandole. In contrast, the polarographic and iodometric assays of cefamandole nafate use a standard lot of cefamandole nafate for the comparison. Thus, the mi-



crobiological assay for cefamandole nafate uses a different reference material and a more complicated procedure than do the chemical assays. The coulometric assay does not need a reference material.

NMR—Spectra of I–V are shown in Fig. 2. The spectrum of IV obtained in dimethyl sulfoxide exhibits the expected solvent shifts when compared to the other compounds. The assigned chemical shift values are listed in Table III.

Significant spectral differences occurred between compounds in the areas of δ 5.2–6.2 and 2.05. The α-phenylmethine resonance shifts from the region of δ 5.25 in mandelic acid derivatives to the δ 6.2 region in compounds containing the formyl ester of mandelic acid. This shift

provides a convenient means of detecting substances containing the mandelic acid functionality (*e.g.*, I and IV–VI) in cefamandole nafate. Accurate measurements for the amounts of these compounds in cefamandole nafate were possible by comparing the height of the δ 5.25 peak to the sum of the heights of the peaks at δ 5.25 and 6.2. The detection level was 2 mole %, and a linear calibration curve was obtained for samples spiked with known amounts of impurities. The slope of the calibration curve was unity when the observed ratio was plotted *versus* mole percent added.

Cefamandole and cefamandole nafate had no resonances upfield of δ 2.5. Trace solvent peaks were occasionally observed such as acetone at δ 2.2 and acetates at δ 2.0. However, impurities containing an acetoxy function such as III had a very sharp resonance at δ 2.05. This resonance provided a positive indication of their presence. A quantitative measure of the mole ratio of these compounds was obtained by comparison of the acetoxy peak height to the α-phenylmethine peak height (δ 6.2). The detection level was about 1 mole % of acetoxy compounds, and the calibration curve was linear with a slope of one when the acetoxy peak height was normalized to one proton.

TLC—TLC was used to identify impurities, degradation products, and the products of the electrochemical reduction. It also provided a rough estimate of the levels of these substances. The relative retention factors for this series of compounds are given in Table IV. With a 250-μg plate loading, generally 1% of a substance was visible on the developed plate. However, D-mandelic acid was not visible except above the 10% impurity level.

DISCUSSION

The initial description of the electrochemistry of cephalosporins was given by Jones *et al.* (9). Those investigators (9) and Hall (7) used the

Table IV—TLC Data

[a] Detection limit using a 250-μg sample of cefamandole nafate.

polarographic reduction wave for quantitative assays. Controlled potential electrolysis has been used to obtain n values (7) and for electrosynthesis (12) but not for quantitative analysis. We found that, under appropriate conditions, cefamandole and cefamandole nafate may be quantitatively reduced at a mercury pool electrode at a controlled potential.

Hall (7) was able to identify explicitly the functional group that undergoes reduction in cephaloridine, cephalothin, cephalosporin C, and IX, a cephalosporin similar to cefamandole. In all cases, the substituent at the 3-position was reductively eliminated in a two-electron, irreversible polarographic wave. The initial reduction products probably were the free, protonated 3-position substituent and the anion radical of the cephalosporin nucleus. In aqueous solutions, the anion radical immediately reacted with a proton donor such as the hydronium ion or the supporting electrolyte components. Typical products reported (7, 12) were the 3-methylenecepham derivatives, which were easily isomerized to the corresponding 3-deacetoxycephalosporanic acid derivatives such as VI[7]. These observations are consistent with the partial identification of the coulometric reduction products described.

The shift of the polarographic half-wave potential observed with pH indicated involvement of hydronium ions in the reduction mechanism. This potential shift is between 50 and 90 mv cathodic per pH unit but is apparently not linear with pH.

Cyclic voltammetry was used to elucidate the mechanism of this reaction. The qualitative features—no anodic peak at scan rates up to 5 v/sec, approximately constant current function (peak current/square root of scan rate) at low scan rates, and a cathodic shift of reduction peak potentials with increasing scan rate—were in agreement with a chemical reaction following charge transfer (13). However, the large effects due to adsorption of impurities, uncompensated potential drops, and variation of parameters with concentration prevented any detailed correlation of experimental results with theoretical expectations. It can, however, be assumed that the 1-methyl-5-mercapto-1,2,3,4-tetrazole is eliminated and then protonated. Simultaneously, the cephalosporin nucleus moiety undergoes successive chemical reactions, probably involving the solvent. Thus, the products of the electrochemical reaction are quickly removed and unavailable for an electrochemical reoxidation step except at extremely short times. These chemical reactions account for the irreversible electrochemical reduction observed on the experimentally accessible time scale.

The data presented indicate that polarography and controlled potential coulometry are useful assay techniques for purity determinations on raw material samples of cefamandole and cefamandole nafate. The electrochemical assay results were essentially identical to the microbiological and iodometric assay results. However, a good analytical assay also must be selective or essentially free from interferences. The various assay techniques were examined to determine what effect impurities or degradation products had on each technique.

The most likely impurity in cefamandole nafate is III. This impurity occurs when the acetoxy group is not displaced by the substituted tetrazole in the synthetic sequence. In solution, cefamandole nafate is hydrolyzed by an alkaline-catalyzed reaction (5). Cefamandole nafate and any cefamandole formed by hydrolysis respond essentially identically in the chemical assay procedures. The degradation of cefamandole or cefamandole nafate then follows one of two possible sequences according to the pH of its environment. These sequences were reviewed for a general cephalosporin (7) and studied for these particular compounds[8].

In acidic media, cefamandole initially loses the substituted tetrazole to give the hydroxymethyl compound, V, and VII. Compound V rapidly dehydrates to form the α,β-unsaturated lactone, IV. Under extremely harsh conditions, mandelic acid (VIII) is cleaved and the cephalosporin nucleus is destroyed. In basic media, the substituted tetrazole is initially lost also. At prolonged times or high temperatures in basic media, the mandelic acid substituent is cleaved and the β-lactam ring is opened[8]. Therefore, III–V, VII, and VIII can be present in aged cefamandole nafate as either initial impurities or degradation products. The polarographic assay for cefamandole or cefamandole nafate, which measures the thioether linkage, will not have interference from these compounds and can be considered a selective assay technique.

In the microbiological assay, any compound that inhibited the growth of the test organism was a positive assay interference. In general, compounds with an intact cephalosporin nucleus exhibited some activity. Compounds III–V interfered with the microbiological assay. Compound III had the highest activity of these interferences. The iodometric assay is based on the reaction at the β-lactam. The likely impurities and degradation products III–V interfered with this assay.

Even though the electrochemical assays were very selective, the presence of large amounts of impurities, especially if they were surface active, tended to distort the polarographic wave and make it irreproducible. This problem was not a major concern until the contaminant content was more than 20–30%. In controlled potential coulometry, none of the known contaminants interfered directly. At high levels of impurity (10–20%), a decrease in precision was noted. The greatest value of the coulometric technique was in the evaluation of relatively pure raw materials such as the establishment of an analytical reference standard material. This reference material was then used to assay material by a precise, selective technique such as polarography.

In addition to a selective, precise assay, one needs a thorough screen for impurities and methods of quantitating detected contaminants. NMR, TLC, GC, and polarography are useful. The use of NMR for the initial evaluation of impurities and for monitoring the extent of degradation was discussed. TLC was used to detect the presence of cefamandole and III–V and VII in cefamandole nafate with an approximate sensitivity level of 1–3%. Mandelic acid may be determined by a separate GC assay if necessary. The free substituted tetrazole (VII) can be measured using the polarographic oxidation wave.

SUMMARY

Both cefamandole and its formyl ester, cefamandole nafate, can be assayed by two electrochemical methods. Dropping mercury electrode polarography was used to determine the purity of the samples by comparison to a reference material of known purity. Controlled potential coulometry was used as an absolute measure of the purity of these compounds without the need for a reference material. These techniques utilize reductive cleavage of the thiotetrazole substituent at the 3-position.

With pure raw material, the results from the electrochemical assays are essentially identical to the purity results obtained with the microbiological autoturbidimetric and automated iodometric assays. The precision of the electrochemical assays is better than the microbiological assay and comparable to the iodometric assay.

For raw material samples containing typical impurities or degradation products, polarography is the most selective of the three types of purity assays. NMR, TLC, GC, and polarography are used for the detection and quantitative measurement of compounds that could interfere with the various assay procedures.

Electron-Capture GLC Determination of Nanogram to Picogram Amounts of Isosorbide Dinitrate

J. O. MALBICA [x], K. MONSON, K. NEILSON, and R. SPRISSLER

Abstract □ A GLC method for the determination of plasma isosorbide dinitrate using electron-capture detection is described. The organic nitrates are especially suited for electron-capture detection if the detector temperature is optimized for maximum sensitivity, *e.g.*, 175°. Proper maintenance of the detector and column assures reproducible data in the low nanogram range. The extraction procedure described is simple, efficient, and expedient for processing large numbers of samples. The method was used to study plasma levels in four human volunteers after a single dose of a 5-mg chewable isosorbide dinitrate tablet. Concentration levels of isosorbide dinitrate as low as 0.5 ng/ml of plasma can be measured by this procedure.

Keyphrases □ Isosorbide dinitrate—electron-capture GLC analysis, human plasma □ GLC, electron capture—analysis, isosorbide dinitrate, human plasma □ Vasodilators, coronary—isosorbide dinitrate, electron-capture GLC analysis, human plasma

The low dosage of isosorbide dinitrate sufficient for pharmacological effectiveness results in low circulating blood levels of the drug, and difficulties exist in assaying for low nanogram to picogram amounts. Previously described GLC methods (1, 2) were either laborious or not sensitive enough to follow rapidly declining blood levels of isosorbide dinitrate.

Since only limited data are available on the blood levels of isosorbide dinitrate following administration of therapeutic doses, a method was needed that would allow reliable estimations of blood isosorbide dinitrate levels in the low nanogram to picogram range using conventional electron-capture GLC instrumentation. This report describes an assay method for isosorbide dinitrate that is expedient, sensitive, and reproducible for routinely handling large numbers of samples.

EXPERIMENTAL

Reagents and Materials—Benzene[1] and ethyl acetate[1] were glass-distilled reagent grade solvents. Anhydrous sodium sulfate[2] was reagent grade, ACS certified. Charcoal-treated paper disks[3], 6.5-mm diameter, were made with a paper punch-out.

One hundred grams of anhydrous sodium sulfate powder was washed with benzene for 20 min, allowed to air dry, and then placed in an oven at 100° until needed.

The charcoal-treated paper disks were similarly washed in benzene. Excess benzene was removed, and the paper disks were allowed to air dry. The disks were stored in an air-tight container until required.

Isosorbide dinitrate[4] and isoidide dinitrate[4] were purified by recrystallization from ethanol.

Plasma Level Study—Isosorbide dinitrate was administered to four healthy volunteers (one male, age 34; three females, ages 23, 25, and 27); each received a 5-mg chewable isosorbide dinitrate tablet[5]. Blood, 10 ml, was drawn from the cubital vein into a heparinized tube from each subject 0, 15, 30, 60, 120, and 180 min following isosorbide dinitrate administration. The blood was immediately centrifuged at 3000 rpm in an angular head clinical centrifuge[6] for 15 min. The plasma was collected and stored at −10° prior to analysis.

Extraction of Isosorbide Dinitrate—Five-milliliter aliquots of benzene were added to a 15.0-ml graduated conical centrifuge tube containing 1.0 ml of plasma spiked with 10 ng of isoidide dinitrate as an internal standard. The tube was mixed on a vortex[7] for 1 min and centrifuged at 2000 rpm to separate the phases. Then the benzene phase was carefully removed to another 15-ml centrifuge tube. A 0.5-g portion of benzene-washed sodium sulfate and three benzene-washed charcoal-treated paper disks were added to the benzene extract.

The tube and its contents were again vortexed for 15 sec and centrifuged as previously described. As much of the benzene layer as possible was carefully removed to another centrifuge tube and dried completely under a nitrogen stream (using an in-line activated silica gel desiccant filter). To each residue was added 100 μl of ethyl acetate just prior to injection. Samples to be analyzed at a later time, *i.e.*, up to 24 hr, were stored, covered tightly, and protected from light.

Electron-Capture GLC Detection—The prepared GLC samples were analyzed using a gas chromatograph[8] equipped with a ^{63}Ni-electron-capture detector. A glass column (120 cm × 4 mm i.d.) was packed with 3% QF-1 on Gas Chrom Q, 100–200 mesh. The injection port and oven temperatures were maintained at 210 and 150°, respectively. The detector was set at 175° and operated with a pulse interval of 150 μsec. The flow rate of the carrier gas, argon with 5% methane, was 95 ml/min. Under these conditions, the retention times of isoidide dinitrate and isosorbide dinitrate were 2.0 and 3.0 min, respectively. The injection volume was 5 μl, and the injection was performed in duplicate.

Calculations—A stock solution of isosorbide dinitrate in absolute ethyl alcohol (1 μg/ml) was used to spike plasma in the 5–75-ng/ml range. A stock solution of isosorbide dinitrate (0.5 μg/ml) was used to spike plasma in the 0–5-ng/ml range. The samples were likewise spiked with 10 ng of isoidide dinitrate as an internal standard. A response factor (peak area ratio) was calculated for the standard. The concentration of isosorbide dinitrate in the samples was determined from the standard's response factor.

Extraction Efficiency—The overall recovery of isosorbide dinitrate by the described extraction procedure was determined by spiking plasma

The low dosage of isosorbide dinitrate sufficient for pharmacological effectiveness results in low circulating blood levels of the drug, and difficulties exist in assaying for low nanogram to picogram amounts. Previously described GLC methods (1, 2) were either laborious or not sensitive enough to follow rapidly declining blood levels of isosorbide dinitrate.

Since only limited data are available on the blood levels of isosorbide dinitrate following administration of therapeutic doses, a method was needed that would allow reliable estimations of blood isosorbide dinitrate levels in the low nanogram to picogram range using conventional electron-capture GLC instrumentation. This report describes an assay method for isosorbide dinitrate that is expedient, sensitive, and reproducible for routinely handling large numbers of samples.

EXPERIMENTAL

Reagents and Materials—Benzene[1] and ethyl acetate[1] were glass-distilled reagent grade solvents. Anhydrous sodium sulfate[2] was reagent grade, ACS certified. Charcoal-treated paper disks[3], 6.5-mm diameter, were made with a paper punch-out.

One hundred grams of anhydrous sodium sulfate powder was washed with benzene for 20 min, allowed to air dry, and then placed in an oven at 100° until needed.

The charcoal-treated paper disks were similarly washed in benzene. Excess benzene was removed, and the paper disks were allowed to air dry. The disks were stored in an air-tight container until required.

Isosorbide dinitrate[4] and isoidide dinitrate[4] were purified by recrystallization from ethanol.

Plasma Level Study—Isosorbide dinitrate was administered to four healthy volunteers (one male, age 34; three females, ages 23, 25, and 27); each received a 5-mg chewable isosorbide dinitrate tablet[5]. Blood, 10 ml, was drawn from the cubital vein into a heparinized tube from each subject 0, 15, 30, 60, 120, and 180 min following isosorbide dinitrate administration. The blood was immediately centrifuged at 3000 rpm in an angular head clinical centrifuge[6] for 15 min. The plasma was collected and stored at −10° prior to analysis.

Extraction of Isosorbide Dinitrate—Five-milliliter aliquots of benzene were added to a 15.0-ml graduated conical centrifuge tube containing 1.0 ml of plasma spiked with 10 ng of isoidide dinitrate as an internal standard. The tube was mixed on a vortex[7] for 1 min and centrifuged at 2000 rpm to separate the phases. Then the benzene phase was carefully removed to another 15-ml centrifuge tube. A 0.5-g portion of benzene-washed sodium sulfate and three benzene-washed charcoal-treated paper disks were added to the benzene extract.

The tube and its contents were again vortexed for 15 sec and centrifuged as previously described. As much of the benzene layer as possible was carefully removed to another centrifuge tube and dried completely under a nitrogen stream (using an in-line activated silica gel desiccant filter). To each residue was added 100 μl of ethyl acetate just prior to injection. Samples to be analyzed at a later time, *i.e.*, up to 24 hr, were stored, covered tightly, and protected from light.

Electron-Capture GLC Detection—The prepared GLC samples were analyzed using a gas chromatograph[8] equipped with a ^{63}Ni-electron-capture detector. A glass column (120 cm × 4 mm i.d.) was packed with 3% QF-1 on Gas Chrom Q, 100–200 mesh. The injection port and oven temperatures were maintained at 210 and 150°, respectively. The detector was set at 175° and operated with a pulse interval of 150 μsec. The flow rate of the carrier gas, argon with 5% methane, was 95 ml/min. Under these conditions, the retention times of isoidide dinitrate and isosorbide dinitrate were 2.0 and 3.0 min, respectively. The injection volume was 5 μl, and the injection was performed in duplicate.

Calculations—A stock solution of isosorbide dinitrate in absolute ethyl alcohol (1 μg/ml) was used to spike plasma in the 5–75-ng/ml range. A stock solution of isosorbide dinitrate (0.5 μg/ml) was used to spike plasma in the 0–5-ng/ml range. The samples were likewise spiked with 10 ng of isoidide dinitrate as an internal standard. A response factor (peak area ratio) was calculated for the standard. The concentration of isosorbide dinitrate in the samples was determined from the standard's response factor.

Extraction Efficiency—The overall recovery of isosorbide dinitrate by the described extraction procedure was determined by spiking plasma

samples in triplicate with 20 μl of ^{14}C-isosorbide dinitrate (18 μCi/mg, 4.5 μg/ml). Likewise, a triplicate set of plasma samples was spiked with 5 and 10 μl of ^{14}C-isosorbide dinitrate solution (18 μCi/mg, 0.45 μg/ml). The samples were extracted as previously described and dried under nitrogen. The residue was dissolved in 1.5 ml of ethyl acetate, and 1.0 ml was counted to determine the ^{14}C-isosorbide dinitrate content. The recovered ^{14}C-isosorbide dinitrate was compared with the actual amount of ^{14}C-isosorbide dinitrate added.

RESULTS AND DISCUSSION

A typical gas chromatogram of isosorbide dinitrate extracted from plasma is shown in Fig. 1B; the chromatogram obtained from blank plasma is shown in Fig. 1A. The lower limit of detection was 0.5 ng/ml and was reproducible under the experimental conditions.

Table I—Response Ratios[a] (Day-to-Day Variations in the Mean)

Isosorbide Dinitrate Concentration, ng/ml of Plasma	Day 1		Day 2		Day 3

[a] N.D. = not detected.

The results from quadruplicate runs on plasma spiked with varying amounts of isosorbide dinitrate are summarized in Table I where the day-to-day mean, standard deviation, and coefficient of variation are given. The overall coefficient of variation of the procedure in the 1–75-ng/ml range was less than 20% except in the 1–10-ng/ml range where, as expected, it sometimes increased with decreasing concentration.

A plot of the response ratio *versus* concentration showed that the described procedure was reproducible from day to day and that linearity was established throughout the 0–75-ng/ml range.

Isosorbide dinitrate was stable when stored frozen in plasma up to 1 week. Isosorbide dinitrate can be extracted from plasma and stored as the dry residue for at least 24 hr.

To obtain maximum sensitivity for the GLC measurement of isosorbide dinitrate, the optimal detector response with temperature was determined (Table II). The detector produced the maximum response for a given quantity of isosorbide dinitrate (4 ng) in the 175–200° temperature range. It is suggested that the optimal electron-capture detector temperature be determined for each GLC unit. The detector temperature was raised to 350° overnight to eliminate the accumulation of any plasma-derived components as a result of operating at a lower temperature during the assay.

Priming the column was essential to achieve high sensitivity. Several 1-μl injections of an isosorbide dinitrate solution (10 ng/ml) were made until a constant peak height for isosorbide dinitrate in the chromatogram was obtained.

After a period of weeks, as a result of numerous injections, a gradual

Table IV—Overall Recovery of ^{14}C-Isosorbide Dinitrate Added to Human Plasma

Isosorbide Dinitrate, ng/ml	Disintegrations per Minute Added	Disintegrations per Minute Recovered	Recovery, % ± *SD*
2.2	99	81	81.8
2.2	99	79	79.8
2.2	99	78	78.8
		Average	80.1 ± 1.2
4.5	192	147	76.6
4.5	192	141	73.4
4.5	192	144	75.0
		Average	75.0 ± 1.3
90.0	3621	2752	76.0
90.0	3621	2754	76.1
90.0	3621	2732	75.4
		Average	75.8 ± 0.3

loss in sensitivity was observed as well as the appearance of interfering peaks in the chromatogram. At this time, a new column was installed and primed.

The isosorbide dinitrate human plasma levels following a 5-mg dose of chewable isosorbide dinitrate were highest at 15 min after administration in all four subjects (Table III). No isosorbide dinitrate levels were detectable at 120 min or more after administration.

The overall recovery of ^{14}C-isosorbide dinitrate in the 2.2–90-ng/ml concentration range is shown in Table IV. The recovery of 75–80% was independent of concentration.

Previous attempts to quantitate isosorbide 2-mononitrate and isosorbide 5-mononitrate in the same concentration range as isosorbide dinitrate were unsuccessful. Certain plasma components that appeared in the benzene extract from time to time interfered with the determination of the mononitrates of isosorbide dinitrate.

Potency of Synthetic Luteinizing Hormone Releasing Hormone Preparations in Rat Anterior Pituitary Cell Cultures

W. C. DERMODY [x], C. A. PASTUSHOK, R. SAKOWSKI, J. W. VAITKUS, and J. R. REEL

Abstract □ Selected synthetic luteinizing hormone releasing hormone preparations were assayed, and their potencies were determined relative to one sample utilizing primary cultures of enzymatically dispersed rat anterior pituitary cells. Preliminary cell culture experiments indicated that luteinizing hormone releasing hormone had to be in constant contact with cells for continued luteinizing hormone secretion. Luteinizing hormone levels in media reached a maximum concentration after 4 hr of continuous luteinizing hormone releasing hormone exposure. Cell culture bioassay was selected over the bioassay employing chronically ovariectomized steroid-blocked rats due to greater sensitivity and economy. The assay of each luteinizing hormone releasing hormone preparation was replicated four to seven times. Preparations from several companies were less potent ($p < 0.05$) than the reference product. Contaminants were disclosed by TLC in preparations with potencies lower than the reference product.

Keyphrases □ Luteinizing hormone releasing hormone—various synthetic preparations analyzed by TLC and radioimmunoassay, potencies determined, rat anterior pituitary cells □ TLC—analysis, luteinizing hormone releasing hormone, various synthetic preparations □ Radioimmunoassay—analysis, luteinizing hormone releasing hormone, various synthetic preparations □ Hormones—luteinizing hormone releasing hormone, various synthetic preparations analyzed by TLC and radioimmunoassay, potencies determined, rat anterior pituitary cells

Although luteinizing hormone releasing hormone has been synthesized in many laboratories, no potency comparisons of various synthetic preparations have been published. However, it was reported that luteinizing hormone releasing hormone, synthesized by several laboratories (1–3), exhibited biological activity equivalent to an isolated natural porcine luteinizing hormone releasing hormone preparation[1]. These results were obtained utilizing either short-term incubations of minced pituitary tissue or ovariectomized estrogen–progesterone-blocked rats. This report presents potency comparisons of various synthetic luteinizing hormone releasing hormone preparations assayed with cultures of rat anterior pituitary cells.

EXPERIMENTAL

Various synthetic luteinizing hormone releasing hormone preparations (Samples 1–6[2–6]) were obtained commercially. These preparations were compared to Sample 7[7] luteinizing hormone releasing hormone.

The reference product (Sample 7) was prepared by fragment condensation and purified by partition chromatography[8] with 1-butanol[9]–acetic acid–water (4:1:5, upper phase). The major fraction from the partition column was homogeneous in the following TLC systems on silica gel 60 F-254 glass plates[10]: System 1, chloroform–methanol–water (45:45:10); System 2, chloroform–methanol–water–acetic acid (60:45:10:1); System 3, chloroform–methanol–32% acetic acid (60:45:20); System 4, 1-butanol–acetone–water–acetic acid–5% ammonium hydroxide (45:15:20:10:10); System 5, 2-propanol–1 *M* acetic acid (2:1); System 6, 1-butanol–acetic acid–water (upper phase) (4:1:5); System 7, pyridine–ethyl acetate–acetic acid–water (5:5:1:3); and System 8, 1-butanol–pyridine–acetic acid–water (30:20:6:24).

The reference product corresponded to 89% peptide content (1.4 acetate salt, 3.5 hydrates) with a molecular weight of 1329.6 and $[\alpha]_D^{25} - 55.8°$ (c, 1 in 1% CH_3CO_2H)[11].

Molecular weights and peptide contents (Table I) of comparative luteinizing hormone releasing hormone preparations were obtained from package inserts or the company of origin. Peptide content varied from 80 to 88%. The purity of these preparations was examined using TLC System 2. Preliminary experiments indicated that System 2 was superior

Various synthetic luteinizing hormone releasing hormone preparations (Samples 1–6[2–6]) were obtained commercially. These preparations were compared to Sample 7[7] luteinizing hormone releasing hormone.

The reference product (Sample 7) was prepared by fragment condensation and purified by partition chromatography[8] with 1-butanol[9]–acetic acid–water (4:1:5, upper phase). The major fraction from the partition column was homogeneous in the following TLC systems on silica gel 60 F-254 glass plates[10]: System 1, chloroform–methanol–water (45:45:10); System 2, chloroform–methanol–water–acetic acid (60:45:10:1); System 3, chloroform–methanol–32% acetic acid (60:45:20); System 4, 1-butanol–acetone–water–acetic acid–5% ammonium hydroxide (45:15:20:10:10); System 5, 2-propanol–1 *M* acetic acid (2:1); System 6, 1-butanol–acetic acid–water (upper phase) (4:1:5); System 7, pyridine–ethyl acetate–acetic acid–water (5:5:1:3); and System 8, 1-butanol–pyridine–acetic acid–water (30:20:6:24).

The reference product corresponded to 89% peptide content (1.4 acetate salt, 3.5 hydrates) with a molecular weight of 1329.6 and $[\alpha]_D^{25} - 55.8°$ (c, 1 in 1% CH_3CO_2H)[11].

Molecular weights and peptide contents (Table I) of comparative luteinizing hormone releasing hormone preparations were obtained from package inserts or the company of origin. Peptide content varied from 80 to 88%. The purity of these preparations was examined using TLC System 2. Preliminary experiments indicated that System 2 was superior

to the other systems in elucidation of contaminants in luteinizing hormone releasing hormone preparations. Preparations were dissolved in 95% ethanol, and 30 μg of each sample was applied to thin-layer plates followed by one-dimensional chromatography and exposure to iodine vapor for visualization.

Anterior pituitary cells were isolated from diestrous female rats[12] (200–250 g) and incubated as described previously (4), except that Hanks balanced salt solution[13] (calcium and magnesium free) was substituted for *N*-(2-hydroxyethyl)piperazine-*N*-2-ethanesulfonic acid buffer and enzymatic cell dispersion was carried out in a humidified carbon dioxide incubator[14]. The sensitivity of the primary cell culture system was compared to the classical luteinizing hormone releasing hormone bioassay (5) employing ovariectomized estrogen–progesterone-blocked rats as described previously (6, 7).

Fresh luteinizing hormone releasing hormone solutions were prepared for each assay from the lyophilized powder stored over a desiccant. Samples, 1–2 mg, were weighed[15] on the day of assay, and solutions were prepared at three or four treatment levels to extend over the effective dose–response range of luteinizing hormone releasing hormone in the cell culture (0.06–0.60 ng/ml). Included in each assay was Sample 7; all curves within an assay were compared to the curve for the standard.

Luteinizing hormone concentrations of media removed from cell cultures were evaluated by double antibody radioimmunoassay (8) employing reagents for rat luteinizing hormone[16]. Anti-rat luteinizing hormone serum-2 (final dilution 1:250,000) and ^{125}I-rat luteinizing hormone-I-3[17] were added per test tube. A computer program (9) was employed for analysis of radioimmunoassay data[18].

Comparison of 10 luteinizing hormone assays, selected at random, indicated that 31.59 ± 1.98% (mean ± *SEM*) of labeled hormone was found in the absence of unlabeled hormone, the midrange of the luteinizing hormone dose–response curve was 1.31 ± 0.05 ng/ml, and the minimum detectable concentration was 77.51 ± 10.87 pg/ml. Within assay variability at the 80 and 20% binding points on the luteinizing hormone curve was 13.93 ± 2.54 and 7.00 ± 1.29%, respectively. Within each radioimmunoassay, analyses of two rat serum pools containing either high (71.69 ± 2.91 ng/ml) or low (6.87 ± 0.20 ng/ml) luteinizing hormone levels were employed for determining between assay variability. The coefficients of variation between assays for these two serum pools were 8.87 and 9.37%, respectively.

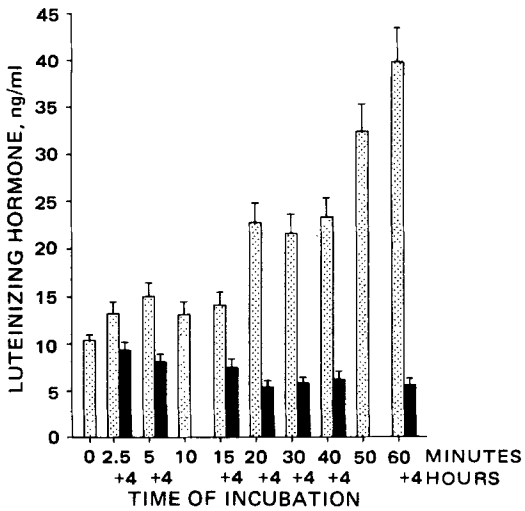

Figure 1—*Luteinizing hormone concentrations in the presence (dotted bars) and following removal (black bars) of luteinizing hormone releasing hormone. The 4-hr samples following luteinizing hormone releasing hormone for 10 and 50 min were lost. Values represent the mean* ± SEM *of triplicate observations.*

Potency estimates were determined within each cell culture experiment relative to Sample 7 (potency = 1.0). Each luteinizing hormone releasing hormone dose–response curve was first tested for linearity (*t* test) and then for parallelism (*F* test) to the Sample 7 curve prior to estimation of potency. Relative precision (λ) for symmetrical experimental designs was determined according to Finney (10).

RESULTS AND DISCUSSION

Some preliminary studies were necessary to validate and standardize the *in vitro* system. Cell culture experiments were performed to determine if luteinizing hormone releasing hormone (0.6 ng/ml) had to be in

constant contact with cells for continued luteinizing hormone secretion and at what time maximum luteinizing hormone concentrations were found in the medium. Media were removed at selected times and assayed for luteinizing hormone (Fig. 1). Cells were washed and fresh medium, without luteinizing hormone releasing hormone, was added; incubations were continued for an additional 4 hr. In the presence of luteinizing hormone releasing hormone, the increase in luteinizing hormone concentration in the medium was linearly related to time during the 60-min observation. Following removal of luteinizing hormone releasing hormone, there was a dramatic fall in the luteinizing hormone concentration observed at the end of 4 hr of additional incubation. Data indicate that luteinizing hormone secretion depends upon constant cell contact with luteinizing hormone releasing hormone. Maximum luteinizing hormone

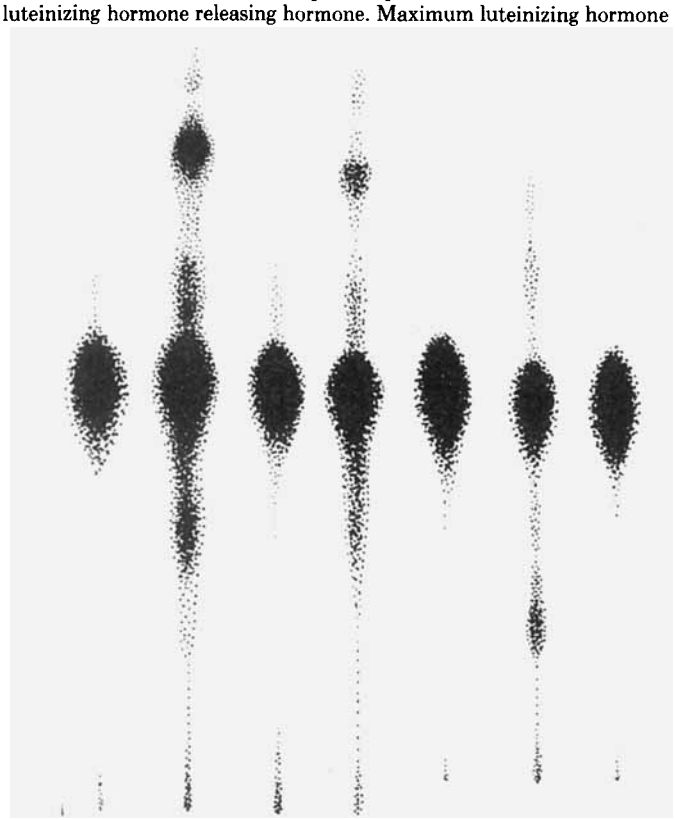

Figure 4—*Thin-layer chromatograms of luteinizing preparations. In Solvent System 2, the* R_f *of luteinizing hormone releasing hormone was 0.25 visualized by iodine vapor. From left to right, the preparations (30 μg each) were: Samples 7, 2, 5, 4, 7, 3, and 6.*

levels in the medium were observed after 4 hr of incubation with luteinizing hormone releasing hormone (Fig. 2); therefore, all subsequent experiments involved 4-hr incubation periods.

Various assays may be employed to determine the potency of luteinizing hormone releasing hormone preparations. Dose–response curves were compared (Fig. 3) for bioassays employing chronically ovariectomized, steroid-blocked rats (7–9) and primary pituitary cell culture. The slope of the dose–response curve obtained *in vivo* was 53.84 ± 5.15 (n = 5) over the dose range of 1–50 ng/rat. The average slope of Sample 7 dose–response curves in cell cultures was 44.32 ± 3.20 (n = 14). Similar luteinizing hormone responses of 30.90 ± 2.21 ng/ml in cell cultures and 39.64 ± 4.73 ng/ml *in vivo* were obtained in response to 0.06 ng/ml and 1.0 ng/rat, respectively. Primary cell cultures were selected for evaluation of synthetic luteinizing hormone releasing hormone preparations due to greater assay sensitivity and economy.

Of the five preparations compared to Sample 7, all but Sample 6[6] were less potent ($p < 0.05$) (Table I). The average potency of the preparations varied from 0.49 to 0.94. Differences in molecular weights were minor (8%) and could not account for the potency differences. Thin-layer chromatograms of 30-μg samples of the preparations (Fig. 4) showed the presence of materials that do not migrate with luteinizing hormone releasing hormone. These contaminants may account for the lower potencies of Samples 1–4. Identification of the impurities was not germane to the current investigation. However, the contaminants may create difficulties in radioimmunoassays (11), where the purity of the labeled antigen is critical.

The data indicate that a sensitive and precise assay for luteinizing hormone releasing hormone was obtained by utilizing primary cultures of enzymatically dispersed rat anterior pituitary cells. This assay procedure demonstrated differences in biological potency of synthetic luteinizing hormone releasing hormone preparations that might account for certain reported biological and immunological differences.

Quantitative Assay of Physostigmine in Human Whole Blood

WILLIAM A. GROFF ˣ, ROBERT I. ELLIN, and RICKIE L. SKALSKY

Abstract □ A quantitative assay for measuring physostigmine in human whole blood is described. Blood samples are maintained at 37°, and cholinesterase activity is measured periodically. The time required for enzyme reactivation is related to physostigmine concentration. The precision of the method is within ±4% over a physostigmine concentration range of 0.5–5.0 × 10^{-7} M.

Keyphrases □ Physostigmine—quantitative analysis by measurement of duration of cholinesterase inhibition, human blood □ Cholinesterase—duration of inhibition by physostigmine measured, related to physostigmine concentration, human blood □ Cholinergics, ophthalmic—physostigmine, quantitative analysis by measurement of duration of cholinesterase inhibition, human blood

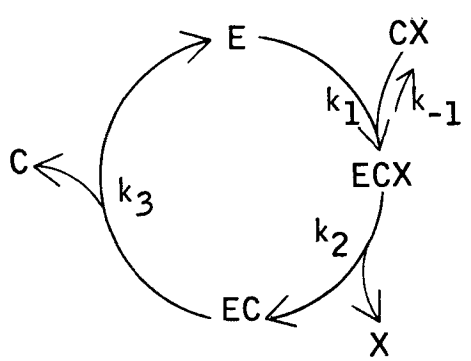
Physostigmine has been used to treat various clinical conditions: to reduce intraocular pressure in glaucoma (1), to treat muscular weakness in myasthenia gravis (2), to counteract atropine coma (3) and scopolamine delirium (4), and as an antidote against certain hallucinogenic agents (5). The primary physiological effect of physostigmine results from the inhibition or inactivation of cholinesterase at sites of cholinergic transmission.

BACKGROUND

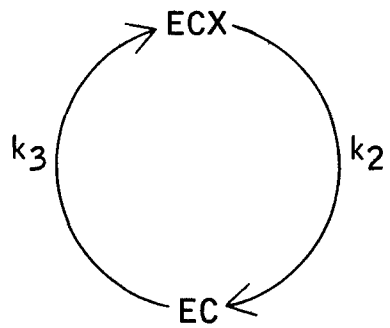
The inhibition of cholinesterase by carbamates occurs by a mechanism analogous to that of organophosphorus inhibition. With both, a reversible complex is formed first, followed by acylation of the enzyme and, finally, deacylation to yield the original enzyme. However, since the rate of decarbamylation is relatively fast as compared with dephosphorylation (6), progressive carbamate inhibition levels off before complete inhibition is attained.

The cyclic reaction of carbamate inhibition is shown in Scheme I. In the presence of excess inhibitor, an apparent steady-state condition ensues, since the free enzyme, E, resulting from decarbamylation is promptly recomplexed. Since k_1 is extremely fast with relation to k_{-1}, one can simplify the cyclic reaction as shown in Scheme II. Because the rate of carbamylation (k_2 = ~10 min^{-1}) is slower than the rate of complex formation ($K_a = k_{-1}/k_1 = 3.3 \times 10^{-6}$ mole/liter) and the rate of decarbamylation ($k_3 = 1.8 \times 10^{-2}$ min^{-1}) is much slower than the rate of carbamylation, there is a small accumulation of the complex, ECX. Almost all inhibited enzyme is the carbamylated enzyme, EC. The ECX complex is readily reversible (6–9) by high concentration of substrate, dilution, and dialysis. Due to this reversibility and the rate of decarbamylation, it is not possible to demonstrate complete enzyme inhibition even with high concentrations of carbamate (7).

The degree of inhibition of blood cholinesterase is generally accepted as a reflection of the intensity and duration of action of the drug in the body. The purpose of this work was to develop a method that would quantitatively relate the duration of enzyme inhibition to the concentration of physostigmine in blood. Since the drug is given to patients in low doses (2 mg) and its metabolism in the body is quite rapid, only nanogram levels of the drug are found in the blood. Existing colorimetric (10), spectrophotofluorometric (11), phosphorescent (12), and TLC (13) methods are not sufficiently sensitive to measure these low levels.



Scheme I



Scheme II

The problem is further complicated by the fact that inhibition of the enzyme by physostigmine is reversible. However, by taking these parameters into consideration, along with temperature and time control of a sample obtained under clinical conditions, an assay for physostigmine sensitive to 2.5 × 10^{-8} M or 7 ng of drug/ml of blood was developed.

EXPERIMENTAL

Materials—Physostigmine salicylate[1] USP was used as received. A stock solution (10^{-3} M) was prepared by dissolving 0.0413 g in 100 ml of distilled water. A working solution (10^{-5} M) was prepared fresh each week by diluting 1 ml of the stock solution to 100 ml with isotonic saline. These solutions were stored at 4°. An aliquot of the working solution was brought to room temperature each day before use. Human whole blood[2] was collected by vacuum tubes[3], with edetic acid as the anticoagulant.

Cholinesterase Measurement—Whole blood cholinesterase activity was determined by an automated procedure (14). Enzyme activity was expressed as micromoles of substrate hydrolyzed by 1 ml of sample per minute of incubation time. The substrate was acetylthiocholine iodide at 2 × 10^{-3} M. The reaction mixture, containing sample, substrate, and 5,5′-dithiobis(2-nitrobenzoic acid) (I), was buffered to pH 8.2 with 0.05 M tromethamine and incubated for approximately 6 min at 37°. Thiocholine, resulting from enzymatic hydrolysis of the substrate, reacts with I to form a colored anion. This colored anion is dialyzed into pH 8.2 buffer, and the absorbance was measured at 420 nm.

***In Vitro* Assay**—Microliter volumes of physostigmine solution were added, using micropipets[4], to 5-ml aliquots of whole blood. Concentrations of inhibitor were 0.25, 0.50, 1.00, 1.25, 2.50, and 5.00 × 10^{-7} M; 10 whole blood samples were prepared at each concentration. Each tube was immediately stoppered, shaken, and placed in a water bath at 37°. Zero time was recorded for each tube. At selected times, the blood samples were gently mixed; transfer pipets were used to remove aliquots to sample cups[5] for enzyme assay. Each aliquot was assayed within 1 min after removal from the incubation bath.

***In Vivo* Assay**—Physostigmine was administered intravenously to 10 subjects and intramuscularly to nine subjects. Blood samples for the physostigmine assay were collected from all subjects 30 min after dosing. These samples were placed immediately in a 37° incubation bath, and

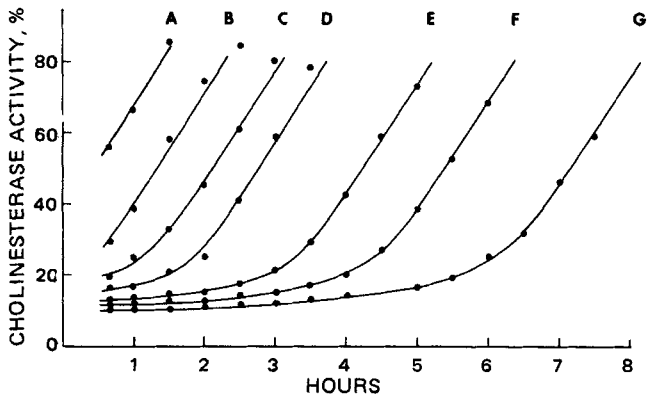

Figure 1—*Time course of whole blood cholinesterase activity after inhibition by physostigmine. Key: A, 0.5 × 10^{-7}; B, 1.0 × 10^{-7}; C, 1.5 × 10^{-7}; D, 2.0 × 10^{-7}; E, 3.0 × 10^{-7}; F, 4.0 × 10^{-7}; and G, 5.0 × 10^{-7}* M.

the time was recorded. Cholinesterase activity was measured periodically as described. The concentration obtained is a measure of the physostigmine present in the blood at the time the sample is withdrawn.

Precision—The precision of the method was determined by statistical analysis of the data obtained at the six concentrations of physostigmine that were added to blood *in vitro*.

Correlation—Concentration values measured in the precision study were correlated with concentrations added, and a regression curve was plotted.

RESULTS

The time course of human whole blood cholinesterase inhibition produced by physostigmine exhibits three phases: rapid inhibition; steady state, during which the cyclic reaction occurs; and reactivation (decarbamylation). A family of curves is shown in Fig. 1 for physostigmine concentrations ranging from 0.5 to 5.0 × 10^{-7} *M* at 37°. Percent cholinesterase activity is plotted *versus* time on Cartesian coordinate graph paper for each concentration of inhibitor until the enzyme activity has recovered to approximately 80% of the control level. The plot of activity *versus* time over the range of 30–70% activity is nearly linear, even though the decarbamylation rate is not zero order. This apparent linearity was used to determine the concentration of physostigmine present at the time of inhibition.

The time required for activity to reach a given percent activity level (between 30 and 70% on each curve) is proportional to the initial physostigmine concentration. For example, at the 50% cholinesterase activity level in Fig. 1, time values are 1.8 hr at 1.50 × 10^{-7} *M*, 2.4 hr at 2.00 × 10^{-7} *M*, 3.9 hr at 3.00 × 10^{-7} *M*, 5.0 hr at 4.00 × 10^{-7} *M*, and 6.8 hr at 5.00 × 10^{-7} *M* physostigmine. These values and values for other activity levels are plotted *versus* concentration on Cartesian coordinate graph paper in Fig. 2. This set of standard curves is used to convert time/percent activity values of an unknown blood sample to physostigmine concentration.

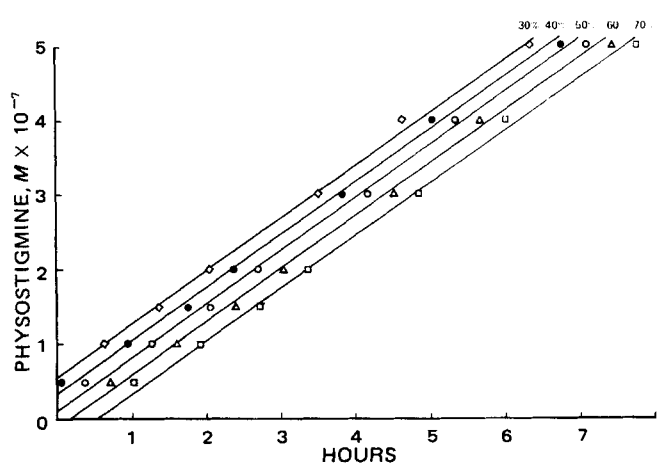

Figure 2—*Standard curves to convert time/percent activity values to physostigmine concentration.*

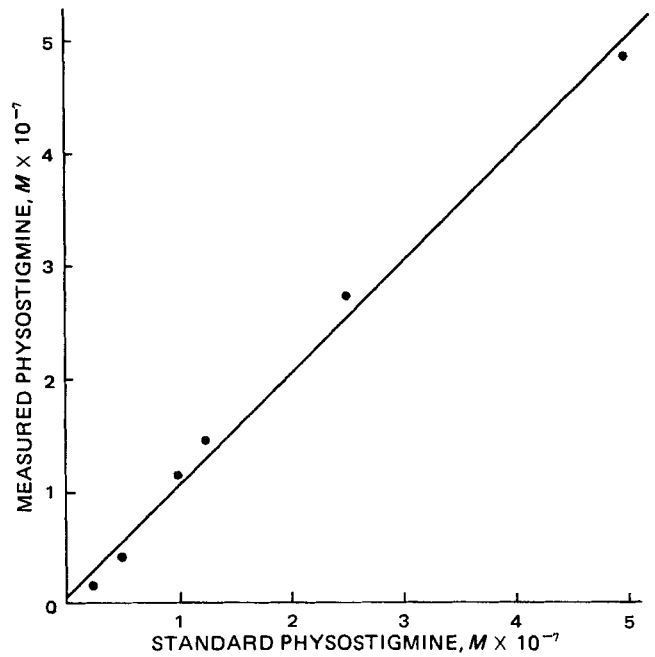

Figure 3—*Comparison of measured physostigmine concentrations with theoretical concentrations added to whole blood samples* (y = 0.975x + 0.079; r = 0.996_6).

A blood sample containing an unknown concentration of physostigmine is incubated at 37° and periodically assayed to determine cholinesterase activity until several data points are obtained that fall within the 30–70% activity range. These points are plotted on Cartesian coordinate graph paper, and a line is drawn through the points. A time value is taken from this line at any activity level for which a line is graphed in Fig. 2. The time value is then converted to concentration by means of this figure. The resulting concentration value must be corrected for any difference between the control (uninhibited) activity (in micromoles per milliliter per minute) of the unknown blood sample and the control activity of the standard blood sample. This correction is necessary because the time required for decarbamylation is proportional to the enzyme concentration in the blood.

The physostigmine concentration in the unknown can be calculated from:

$$\text{physostigmine concentration } [\times 10^{-7} \text{ mole/liter}] = \frac{\text{unknown control activity}}{\text{standard control activity}} \times \frac{\text{concentration}}{\text{(from Fig. 2)}} \quad \text{(Eq. 1)}$$

A micromole per milliliter per minute activity unit is a fixed unit for the conditions of assay expressed in this report. A percent activity unit is variable and is dependent upon the relative activity of each blood sample.

If the control activity level of the unknown blood sample cannot be determined in advance, it must be obtained by assaying the sample until no further increase in activity is obtained.

The precision of the method was determined by statistical evaluation

Table I—Precision of Physostigmine Assay

Concentration Added, × 10^{-7} *M*	Concentration Measured: Mean, × 10^{-7} *M*	*SD*, × 10^{-7} *M*	Coefficient of Variation, %

of data obtained from a reproducibility study. Ten whole blood samples were prepared at each of six different concentrations of physostigmine, ranging from 0.25 to 5.00 $\times 10^{-7}$ *M*. Means, standard deviations, and coefficients of variation for each set of 10 assays are presented in Table I. Precision was within ±3.8% for physostigmine concentrations ranging from 0.50 to 5.00 $\times 10^{-7}$ *M*. At 0.25 $\times 10^{-7}$ *M*, precision was ±10.0%.

The mean physostigmine concentrations obtained in the precision study were correlated with the concentrations added to the blood samples. The plot of data points and the equation of the regression line are given in Fig. 3.

Blood levels at 30 min after intravenous and intramuscular injections of physostigmine are presented in Table II. The relationship of dose administered to blood levels was approximately the same for both routes of administration.

DISCUSSION

To relate physostigmine concentration to cholinesterase inhibition, it is necessary to measure enzyme activity after inhibition has progressed until none of the enzyme remains in the complexed form. At this time, when the enzyme activity is between 30 and 70% of the control level, only decarbamylation occurs. The time course at 37°, from inhibition until a near linear reactivation rate is attained, together with the enzyme activity level at this time, can be used to determine the concentration of physostigmine in the blood at the time the *in vitro* sample was inhibited. With an *in vivo* blood sample, the physostigmine concentration can be determined for the time the blood was withdrawn from the patient.

This assay method assumes that decarbamylation occurs over the entire period from the time of inhibition. The error in the assumption is quite small, since an initial time period of less than 2 min is required for formation of an appreciable concentration of carbamylated enzyme. The time required for enzyme reactivation should be, and has been shown to be, a function of the inhibitor concentration. The time required to complete an assay varies directly with the physostigmine concentration, from approximately 1 hr for 0.50 $\times 10^{-7}$ *M* to approximately 7.5 hr for 5.00 $\times 10^{-7}$ *M*. Considering the inherent errors, the precision of this method is excellent.

Influence of Zinc–Ligand Mixtures on Serum Zinc Levels in Rats

EUGENE GIROUX [x] and N. J. PRAKASH

Abstract □ The influence of various salts, chelates, and other complexes of zinc given by gavage on serum zinc levels in rats was studied. Serum zinc concentrations were determined over 6 hr after administration of zinc sulfate at doses of 5, 10, 20, 50, and 100 mg of zinc/kg. Serum zinc levels following doses of zinc salts and complexes were compared with those after zinc sulfate. Phytic acid, aminopolycarboxylic acids (including edetate disodium), and penicillamine significantly suppressed increases in serum zinc concentration. Some natural amino acid–zinc sulfate mixtures (those with lysine, cysteine, glycine, and histidine) produced greater levels than the equivalent dose of zinc sulfate alone. Several thiocarboxylic acids, such as mercaptoacetic acid and thiosalicylic acid, also increased serum zinc concentrations. These observations form a basis for attempted modification of zinc absorption in other species.

Keyphrases □ Zinc—serum levels, effect of various salts, chelates, and other complexes, rats □ Salts, zinc—effect on serum zinc levels, rats □ Chelates, various—with zinc, effect on serum zinc levels, rats □ Complexes, various—with zinc, effect on serum zinc levels, rats □ Metals—zinc, various salts, chelates, and other complexes, effect on serum zinc levels, rats

Treatment of humans with zinc usually involves administration of zinc sulfate heptahydrate, taken with meals to avoid gastric irritation. However, Schelling *et al.* (1) reported that when it is given simultaneously with meals, the apparent absorption of zinc may be nil. Poor absorption may partly account for equivocal clinical results of zinc therapy (2–7).

GI absorption of zinc in several species has been studied

Table II—Blood Physostigmine Levels ($\times 10^{-7}$ *M*) in Humans 30 min after Administration

Route	Dose Administered, μg/kg				
	15	20	25	30	45
Intravenous	—[a]			0.40	0.90
	—[a]			0.29	0.59
	—[a]				0.90
	—[a]				0.78
Intramuscular	—[a]	0.35	0.25		
	—[a]	—[a]	0.31		
		—[a]	0.27		
			—[a]		

[a] $<0.25 \times 10^{-7}$ *M*.

of data obtained from a reproducibility study. Ten whole blood samples were prepared at each of six different concentrations of physostigmine, ranging from 0.25 to 5.00 $\times 10^{-7}$ *M*. Means, standard deviations, and coefficients of variation for each set of 10 assays are presented in Table I. Precision was within ±3.8% for physostigmine concentrations ranging from 0.50 to 5.00 $\times 10^{-7}$ *M*. At 0.25 $\times 10^{-7}$ *M*, precision was ±10.0%.

The mean physostigmine concentrations obtained in the precision study were correlated with the concentrations added to the blood samples. The plot of data points and the equation of the regression line are given in Fig. 3.

Blood levels at 30 min after intravenous and intramuscular injections of physostigmine are presented in Table II. The relationship of dose administered to blood levels was approximately the same for both routes of administration.

DISCUSSION

To relate physostigmine concentration to cholinesterase inhibition, it is necessary to measure enzyme activity after inhibition has progressed until none of the enzyme remains in the complexed form. At this time, when the enzyme activity is between 30 and 70% of the control level, only decarbamylation occurs. The time course at 37°, from inhibition until a near linear reactivation rate is attained, together with the enzyme activity level at this time, can be used to determine the concentration of physostigmine in the blood at the time the *in vitro* sample was inhibited. With an *in vivo* blood sample, the physostigmine concentration can be determined for the time the blood was withdrawn from the patient.

This assay method assumes that decarbamylation occurs over the entire period from the time of inhibition. The error in the assumption is quite small, since an initial time period of less than 2 min is required for formation of an appreciable concentration of carbamylated enzyme. The time required for enzyme reactivation should be, and has been shown to be, a function of the inhibitor concentration. The time required to complete an assay varies directly with the physostigmine concentration, from approximately 1 hr for 0.50 $\times 10^{-7}$ *M* to approximately 7.5 hr for 5.00 $\times 10^{-7}$ *M*. Treatment of humans with zinc usually involves administration of zinc sulfate heptahydrate, taken with meals to avoid gastric irritation. However, Schelling *et al.* (1) reported that when it is given simultaneously with meals, the apparent absorption of zinc may be nil. Poor absorption may partly account for equivocal clinical results of zinc therapy (2–7).

GI absorption of zinc in several species has been studied

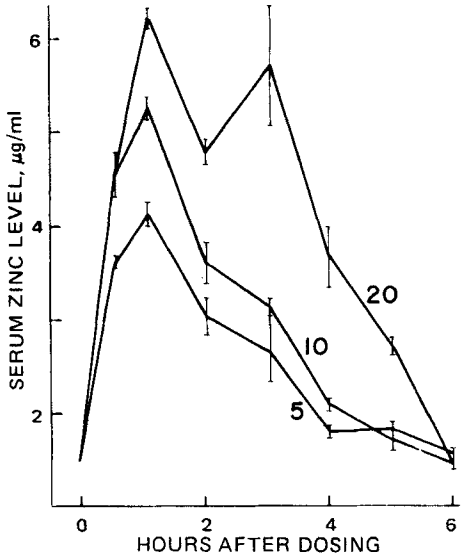

Figure 1—*Serum zinc levels following gavage of 5, 10, and 20 mg of zinc/kg, given as zinc sulfate heptahydrate dissolved in water. Points indicate mean values; vertical bars denote ± SEM. At least five rats were used for each point except for the 1- and 4-hr points at 5 mg of zinc/kg, where three and four rats were used, respectively.*

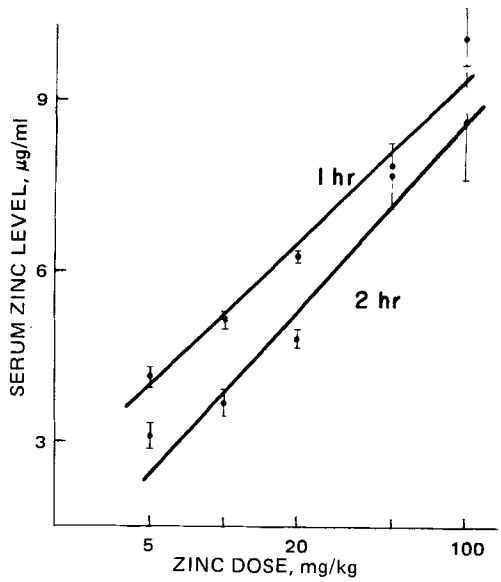

Figure 2—*Serum zinc levels 1 and 2 hr after gavaging of zinc sulfate heptahydrate dissolved in water. (See Fig. 1 for further explanation.)*

in vivo and *in vitro*. Various experimental designs have been employed including conventional balance studies, radioisotopic tracer studies, and studies of the bioavailability of zinc from foodstuffs as monitored by correction of zinc deficiency symptoms. Zinc absorption was discussed in several reviews (8–12). In one study, edetate and ascorbic acid depressed gut mucosal uptake of zinc but enhanced transmural transport during *in vitro* perfusion experiments on rats (13). Zinc–edetate complexes and zinc–histidine complexes were absorbed intact from the gut and appeared in the plasma of chickens further complexed with plasma proteins (14). Zinc–aspirin complexes were broken down and did not appear intact in serum (14).

Apparently, some compounds potentiate zinc absorption when given with an oral dose of zinc sulfate while other substances suppress it. Accordingly, serum zinc levels were measured in rats after gavage of mixtures of zinc sulfate with various complexing agents. Compounds with different zinc coordinating sites were studied including thiol, amino, and carboxylic acid groups. Phytic acid and various amino acids were chosen because of their relevance to trace metal metabolism.

EXPERIMENTAL

Materials[1]—Reagents and chemicals, including bis[*N*,*N*-di(carboxymethyl)aminoethoxy]ethane (I), the ammonium salt of pyrrolidine-*N*-carboxydithioic acid (II), and 3-mercaptopropionylglycine (III), were obtained commercially, except for *N*-acetylhydroxyproline, which was prepared in this laboratory.

Animals and *In Vivo* Procedure—Male Sprague–Dawley rats[2], 140–240 g, were maintained in open mesh, stainless steel cages for at least 1 week in the laboratory environment (12-hr dark cycle beginning at 7 pm and controlled temperature and humidity). They were fed laboratory ration[3] and tap water *ad libitum* until 20–24 hr before an experiment. From that time and throughout the experiment, animals were fasted and allowed access only to demineralized water.

Each experiment began at 9–10 am. Various zinc mixtures were introduced by gavage. After 0.5–6 hr, animals were lightly anesthetized with ether and blood was taken from the heart with plastic syringes and stainless steel needles. The blood was allowed to clot in acid-washed glass tubes, and serum was obtained by centrifugation. A second centrifugation removed from the serum traces of erythrocytes carried over from the initial centrifugation.

Aliquots of serum were treated with trichloroacetic acid to a final concentration of 5% (15), and protein-free supernates were analyzed for zinc by atomic absorption spectrophotometry[4]. Zinc contamination was reduced through use of plastic zinc-free labware, disposable plastic test tubes, acid-washed pipets, and demineralized, double-distilled water for preparation of all reagents. Statistical comparison of means was by the Student two-tailed *t*-test with the assumption that variances of the populations were not necessarily identical (16).

Preparation of Mixtures—With few exceptions, test mixtures were prepared by combining aqueous zinc sulfate with an aqueous solution (or suspension) of the other component. A few mixtures were adjusted to pH 5–6, but the pH of the test mixtures generally was not controlled. The concentration of zinc in the final mixture was always chosen so that the volume administered was 5 ml/kg. If the mixture contained insoluble components, it was homogenized[5] immediately prior to gavage.

Butanol Solubility Measurements—Solubility of zinc in an organic phase as modified by the presence of ligand was determined by partitioning zinc-65 between 1-butanol and an aqueous solution [0.1 *M* NaCl–0.1 *M* 2-(*N*-morpholino)ethanesulfonic acid] buffered at pH 6.5. Each mixture contained 2 ml of aqueous buffer, 2.5 ml of 1-butanol, 5 μmoles of complexing agent, and 2 μmoles of ^{65}Zn-labeled zinc sulfate. Butanol and aqueous phases were repeatedly mixed and then separated by centrifugation. An aliquot of the butanol phase was counted in a γ-spectrometer[6].

[a] The numbers in parentheses are the number of animals. [b] Significantly below control value, $p < 0.005$. [c] Data obtained 3 hr following dosing were not significantly different from control values. [d] Significantly above control value, $p < 0.005$.

RESULTS

Serum Zinc Levels following Zinc Sulfate—The serum zinc concentration was determined 1, 2, 3, 4, and 6 hr after gavage of rats with demineralized water. The mean values at these points were not significantly different from one another; the overall mean (28 rats) was 1.50 ± 0.03 (*SEM*) μg of zinc/ml of serum. Serum zinc levels were determined at 0.5, 1, 2, 3, 4, 5, and 6 hr following doses of 5, 10, 20, 50, and 100 mg of zinc/kg, given as aqueous solutions of zinc sulfate heptahydrate.

Serum concentration–time curves after 5, 10, and 20 mg of zinc/kg are shown in Fig. 1. With these doses, maximum serum zinc concentrations were observed 1 hr after gavage, and the level returned to the baseline concentration within 6 hr. Semilogarithmic curves relating all doses administered to the resulting serum concentrations were approximately linear (Fig. 2). The data indicated that measurable increases in serum zinc concentrations would not be observed at doses less than 1–2 mg of zinc/kg. Peak serum levels of 20 μg of zinc/ml (approximately 15 times greater than normal) did not produce any lethality over 8 hr.

Serum Zinc Levels following Zinc–Ligand Mixtures—Serum zinc concentrations were measured 1 and 4 hr following gavage (Table I). Doses of test mixtures contained 10 mg of zinc/kg, and the molar ratio of zinc to ligand was either 1:1 or 1:2. Serum zinc levels following gavage of zinc–ligand mixtures ranged from little or no increase above serum zinc levels in untreated animals to highly significant increases beyond the increase caused by zinc sulfate alone. Aminopolycarboxylic acids of the edetate type suppressed increases in serum zinc concentrations. Other aminopolycarboxylic acids tested in addition to those listed in Table I were nitrilotriacetic acid, ethylenediaminediacetic acid, and 1,2-*trans*-cyclohexyldiaminetetraacetic acid. These chelators also significantly ($p < 0.005$) diminished the increase in the serum zinc level.

The dithiol compounds 1,3-dimercapto-2-propanol, 2,3-dimercapto-1-propanol, and dithioerythritol significantly inhibited the elevation of serum zinc levels at 1 hr, but the levels were greater than the control value after 4 hr. After gavage of several compounds listed in Table I, serum levels of zinc were greater than those following equivalent doses of zinc sulfate. Notable among these latter compounds were some natural amino acids (lysine, glycine, cysteine, and histidine) and compounds containing thiol and carboxylic acid groups such that five- and six-membered chelate complexes with zinc could be formed.

Time–concentration curves following gavage of mixtures of zinc sulfate with penicillamine and with thiosalicylic acid are shown in Fig. 3A. Maximum serum zinc levels were noted 1 hr after dosing, with return to baseline concentration within 6 hr. When given in a mixture with zinc sulfate, D,L-penicillamine significantly ($p < 0.005$) suppressed the increase in the serum zinc level while thiosalicylic acid significantly ($p < 0.005$) enhanced the increase. The levels following gavage of ligands in the absence of zinc sulfate also were determined. Penicillamine reduced and thiosalicylic acid increased the serum zinc levels (Fig. 3B).

Time–serum zinc concentration curves for sodium phytate and β-hydroxybutyric acid given with and without zinc sulfate were obtained similarly (Fig. 4). Areas between the curves (Figs. 3 and 4) in the presence and absence of zinc sulfate were calculated: zinc sulfate (control), 9.2; thiosalicylic acid, 21.1; β-hydroxybutyric acid, 11.5; penicillamine, 3.8; and sodium phytate, 0.1 μg hr/ml. These results are consistent with the hypothesis that thiosalicylic acid and β-hydroxybutyric acid increase zinc absorption while penicillamine and sodium phytate suppress zinc absorption from zinc sulfate heptahydrate.

Butanol Solubility of Zinc–Ligand Mixtures—Partitioning of zinc-65 between aqueous buffer and butanol was compared for poorly absorbed and well-absorbed zinc–ligand mixtures. Ligands that sup-

pressed zinc absorption also tended to suppress zinc solubility in the butanol phase (Table II), as did some ligands that augmented zinc absorption. In the absence of ligand, 0.9% of the ^{65}Zn-radioactivity was recovered in the butanol phase.

DISCUSSION

Ligands markedly influenced the serum zinc levels following their administration by gavage together with zinc sulfate. While these ligands might influence distribution or elimination of zinc after their absorption, it seems more likely that their major effect is on zinc absorption from the GI tract, particularly when the time course of serum zinc concentrations after dosing with ligands is similar to that seen after zinc sulfate. Thus, the form in which zinc is presented to the GI tract apparently influences zinc absorption. Phytic acid, considered responsible for dietary zinc deficiencies reported in Near Eastern adolescents (17), completely prevented increases in the serum zinc levels when coadministered with zinc sulfate. Most α-amino acids enhanced the increases. Penicillamine markedly suppressed such increases, but the structurally similar cysteine enhanced them. These two compounds form equally stable zinc complexes (18). For some mixtures of zinc sulfate and ligand, serum zinc levels at 4 hr were greater than at 1 hr after gavage; thus, the temporal pattern of zinc levels after these mixtures did not resemble that after zinc sulfate.

Constants for zinc complex formation are available (18) for several tested compounds. There was no obvious relationship between the effect on serum zinc levels and the complex formation constant, although some of the strongest complexes were among the most poorly absorbed mixtures. Furthermore, the solubility of the complexes in the test mixture did not seem to be the decisive factor. The water-soluble edetate–zinc mixture suppressed apparent zinc absorption, as did the insoluble 2,3-dimercapto-1-propanol–zinc mixture. The insoluble thiosalicylic acid–zinc mixture appeared significantly effective in enhancing zinc absorption. Lipid solubility of zinc species presented to GI absorption sites may play a role in absorption, but the data on the effect of ligands on butanol solubility of zinc are inconclusive in support of this hypothesis.

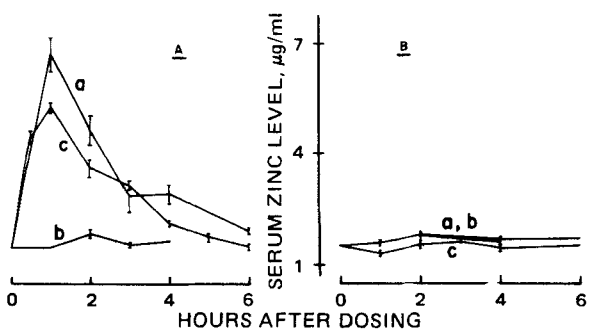

Figure 4—(*A*) *Serum zinc levels following gavage of zinc sulfate* (*c*) (*10 mg of zinc/kg*) *given alone or mixed with sodium phytate* (*b*) (*1:1 molar ratio*) *or β-hydroxybutyric acid* (*a*) (*1:2 molar ratio*). (*B*) *Serum zinc levels following gavage of β-hydroxybutyric acid* (*a*) *or sodium phytate* (*b*) *at the same concentrations as in A or of distilled water* (*c*). *Points* (*at least four rats per point*) *indicate mean values; vertical bars denote* ± SEM.

Table II—Stability and Butanol Solubility of Zinc Complexes

Ligand	Apparent Log K_1 pH 6.5[a]	Butanol-Soluble ^{65}Zn[b], %
Sodium phytate	—	<0.1
I	9.2	<0.1
8-Thioquinoline	8.3	55
Penicillamine	4.2	0.9
Oxalic acid	4.9	0.3
Edetate disodium	12.5	<0.1
1,3-Dimercapto-2-propanol	—	<0.1
Dithioerythritol	—	0.1
2,3-Dimercapto-1-propanol	7.3	0.5
8-Hydroxyquinoline	5.1	37
Cysteine	3.8	0.5
Histidine	3.8	1.3
Glycine	2.0	0.9
Malonic acid	2.8	0.9
Mercaptoacetic acid	4.2	1.4
2-Mercapto-3-pyridinol	—	85
β-Hydroxybutyric acid	1.1	1.0
Mercaptosuccinic acid	4.6	<0.1
α-D-Galacturonic acid	1.7[c]	0.8
Thiosalicylic acid	6.1	34

[a] Data were taken from Ref. 18; values at pH 6.5 were calculated as described in Ref. 22. [b] Distribution of isotope in presence of ligand between aqueous and 1-butanol phases as described in the text; each value is the average of two determinations. Butanol-soluble isotope in absence of ligand, 0.9%. [c] Ref. 19.

These observations apply only to the rat. However, in other species, oral intake of certain zinc–ligand mixtures may also increase serum levels of zinc more than oral zinc sulfate treatment. Alternatively, a smaller amount of zinc–ligand mixture may provide the equivalent effect of a greater amount of zinc sulfate, thereby reducing GI side effects of oral zinc sulfate therapy. Ligand effects may also partly account for diminished apparent zinc absorption when zinc sulfate is administered with meals (1, 20, 21).

Pharmacokinetics of Δ^9-Tetrahydrocannabinol in Dogs

EDWARD R. GARRETT [x] and C. ANTHONY HUNT [x]

Abstract □ The pharmacokinetics of intravenously administered ^{14}C-Δ^9-tetrahydrocannabinol and derived radiolabeled metabolites were studied in three dogs at two doses each at 0.1 or 0.5 and 2.0 mg/kg. Two dogs were biliary cannulated; total bile was collected in one and sampled in the other. The time course for the fraction of the dose per milliliter of plasma was best fit by a sum of five exponentials, and there was no dose dependency. No drug was excreted unchanged. The mean apparent volume of distribution of the central compartment referenced to total drug concentration in the plasma was 1.31 ± 0.07 liters, approximately the plasma volume, due to the high protein binding of 97%. The mean metabolic clearance of drug in the plasma was 124 ± 3.8 ml/min, half of the hepatic plasma flow, but was 4131 ± 690 ml/min referenced to unbound drug concentration in the plasma, 16.5 times the hepatic plasma flow, indicating that net metabolism of both bound and unbound drug occurs. Apparent parallel production of several metabolites occurred, but the pharmacokinetics of their appearance were undoubtedly due to their sequential production during liver passage. The apparent half-life of the metabolic process was 6.9 ± 0.3 min. The terminal half-life of Δ^9-tetrahydrocannabinol in the pseudo-steady state after equilibration in an apparent overall volume of distribution of 2170 ± 555 liters referenced to total plasma concentration was 8.2 ± 0.23 days, based on the consistency of all pharmacokinetic data. The best estimate of the terminal half-life, based only on the 7000 min that plasma levels could be monitored with the existing analytical sensitivity, was 1.24 days. However, this value was inconsistent with the metabolite production and excretion of 40–45% of dose in feces, 14–16.5% in urine, and 55% in bile within 5 days when 24% of the dose was unmetabolized and in the tissue at that time. These data were consistent with an enterohepatic recirculation of 10–15% of the metabolites. Intravenously administered radiolabeled metabolites were totally and rapidly eliminated in both bile and urine: 88% of the dose in 300 min with an apparent overall volume of distribution of 6 liters. These facts supported the proposition that the return of Δ^9-tetrahydrocannabinol from tissue was the rate-determining process of drug elimination after initial fast distribution and metabolism and was inconsistent with the capability of enzyme induction to change the terminal half-life.

Keyphrases □ Δ^9-Tetrahydrocannabinol—intravenous, radiochemical study of pharmacokinetics, dogs □ Pharmacokinetics—intravenous, Δ^9-tetrahydrocannabinol, radiochemical study, dogs □ Radiochemistry—study of pharmacokinetics of intravenous Δ^9-tetrahydrocannabinol, dogs

(−)-Δ^9-Tetrahydrocannabinol is the major active component of marijuana. An essential prerequisite to understand its pharmacological action, presumably related to the plasma levels of the drug and its metabolites (1, 2), is the quantification of the time course of the drug and its metabolites in biological tissues to relate to the psychoactive effects.

Agurell *et al.* (3, 4) demonstrated that when tritium-labeled Δ^9-tetrahydrocannabinol was intravenously administered to the mouse and rabbit, the radioactivity was slowly excreted as metabolites in the feces and urine with no unchanged drug observed in the urine. The relative amounts excreted biliary and renally varied with the species (3–5), and enterohepatic recirculation of metabolites was indicated (5, 6). The major studies to date with pharmacokinetic significance are those of Agurell *et al.* (4, 5) in rabbits and humans and Lemberger *et al.* (5, 7, 8) in humans. The general pattern appears to be a rapid initial fall of Δ^9-tetrahydrocannabinol concentration in plasma with an apparent half-life of 12 min in rabbits (4) and 30 min in humans (8), with a slower decline to a terminal apparent half-life of 50–60 hr in humans (8). A similar pattern was observed in a preliminary experiment with dogs (9). Metabolite levels in human plasma increased rapidly to two to three times that of the drug (8). The slower terminal phase decline of the log metabolite level with time paralleled the similarly plotted decline of plasma Δ^9-tetrahydrocannabinol.

It has been proposed (7, 10) that these facts can be explained by concomitant rapid hepatic metabolism and distribution to binding sites and other tissues such as fat (11) with a subsequent slow release of sequestered Δ^9-tetrahydrocannabinol from these stores. The suggestion that induced metabolism significantly lessens the terminal half-life of Δ^9-tetrahydrocannabinol in chronic users over that of naive individuals (2, 12) is inconsistent with this premise. The release rate from the "deep" tissues should be rate determining, not the metabolic rate. Changes in the latter would merely affect the relative plasma Δ^9-tetrahydrocannabinol levels, not the terminal half-life.

The purposes of this paper are to present the results of studies designed to elucidate the rate-determining pro-

A similar pattern was observed in a preliminary experiment with dogs (9). Metabolite levels in human plasma increased rapidly to two to three times that of the drug (8). The slower terminal phase decline of the log metabolite level with time paralleled the similarly plotted decline of plasma Δ^9-tetrahydrocannabinol.

It has been proposed (7, 10) that these facts can be explained by concomitant rapid hepatic metabolism and distribution to binding sites and other tissues such as fat (11) with a subsequent slow release of sequestered Δ^9-tetrahydrocannabinol from these stores. The suggestion that induced metabolism significantly lessens the terminal half-life of Δ^9-tetrahydrocannabinol in chronic users over that of naive individuals (2, 12) is inconsistent with this premise. The release rate from the "deep" tissues should be rate determining, not the metabolic rate. Changes in the latter would merely affect the relative plasma Δ^9-tetrahydrocannabinol levels, not the terminal half-life.

The purposes of this paper are to present the results of studies designed to elucidate the rate-determining pro-

cesses for disposition of intravenously administered Δ^9-tetrahydrocannabinol in the dog and to give a detailed pharmacokinetic analysis and model to fit the data. The effects of dose and other variables on the metabolism of drug and biliary and renal excretion of metabolites are delineated. Sensitive analytical methods, previously developed (9, 13, 14) for Δ^9-tetrahydrocannabinol in biological tissues, were used. The metabolites were characterized by the partition properties of their radiolabels derived from ^{14}C-labeled drug and were monitored in all available biological fluids. In addition, radiolabeled metabolites were intravenously administered to challenge the pharmacokinetic model. The previously studied physicochemical properties and protein binding (13) were taken into account.

EXPERIMENTAL

Preparation of Δ^9-Tetrahydrocannabinol Intravenous Dosages—Labeled and unlabeled Δ^9-tetrahydrocannabinols were purified on the evening prior to a pharmacokinetic study by methods given previously (14). They were combined to give the desired specific activity, and amounts sufficient to dose at 0.1, 0.5, or 2.0 mg/kg were transferred to a 50-ml glass centrifuge tube and dried in a water bath (50°) under a nitrogen stream. The residue was dissolved in 1 ml of absolute ethanol. The solution and 3 × 1-ml ethanol rinsings were transferred to a 20-ml vial and reduced to dryness. The residue in the vial was dissolved in 0.5 ml of absolute ethanol, and the vial was capped and placed in a freezer. On the morning of the study, the vial containing a small stirring bar[1] was placed on a magnetic stirrer set at low speed and 1 ml of water was added dropwise over 2–3 min to form an emulsion.

Dog plasma, 10 ml taken 1 hr after the last meal, was added to ultrafiltration cones[2] and centrifuged (3000 rpm) until an ultrafiltrate (2–5 ml) was obtained. The concentrated plasma was delivered dropwise from a pipet to the aqueous ethanol emulsion of Δ^9-tetrahydrocannabinol. This method produced a true solution of drug in plasma protein which, within 10 min, was administered intravenously to the dog in a 10-ml silanized syringe. This method is the method of choice for intravenously administering highly protein-bound materials normally insoluble in water.

Treatment of Animals—Two weeks prior to the first pharmacokinetic study, each mongrel dog was transferred to a metabolic cage. The next day, the dog was weighed and anesthetized with pentobarbital (30 mg/kg iv). One external jugular vein of the neck was exposed and cannulated under sterile conditions with 51 cm of 0.32-cm (0.125-in.) o.d. tubing[3]; at least 20.3 cm was inserted into the vein. The incision was closed after verifying the patency of the cannula and filling with heparinized[4] saline.

On the following day, the dog was placed on a table in a standing position and restrained by two straps placed around the fore- and hindlegs and fixed to a horizontal bar above. After 8 hr, the dog was returned to the cage. This training procedure was repeated daily until the dog would remain on the table unattended and unrestrained. At the end of each day, the dog was walked briefly, the regularly deposited stool sample was collected uncontaminated on an aluminum foil sheet, and the patency of the jugular cannula was checked.

A laparatomy was performed on Dogs A and C at the same time as the jugular was cannulated. The gallbladder was tied off, and an incision was made in the common bile duct distal to the gallbladder. One end of a 1.22-m length of 0.32-cm (0.125-in.) o.d. tubing was inserted in the bile duct incision approximately 6 cm toward the liver, and the other end was inserted in the incision approximately 16 cm into the intestine. When bile flow was visibly observed through the tubing, an incision was made in the abdominal wall; the tube was then passed through the opening and subcutaneously to an exit incision on the back of the neck. All incisions were closed, and the exposed bile cannula was cut. Bile flow was checked, and unrestricted flow to the intestine was confirmed. The tube was reconnected with 14-gauge stainless steel tubing.

After a 1-day recovery period, the dogs were transferred to a table and conditioned as described. At the end of all surgical procedures, the dogs were given 8×10^6 units of penicillin G intravenously.

Table I—Doses and Biliary Modifications in the Pharmacokinetic Studies after Intravenous Administration of ^{14}C-Δ^9-Tetrahydrocannabinol

Dog	Weight, kg	Average Hematocrit	Dose, mg/kg	10^{-6} × Total, cpm	Bile Cannulation
A	12.4	0.30	0.1	145.2	Yes[a]
A	14.1	0.42	2.0	85.36	Yes[a,b]
B	12.7	0.31	0.5	76.22	No
B	14.4	0.38	2.0	116.3	No
C	13.3	0.39	0.5	229.4	Yes[c]
C	16.6	0.38	2.0	150.8	Yes[c,d]

[a] Bile was sampled, but all was returned to the intestine. [b] Bile flow was stopped at approximately 1300 min after dosing. [c] All bile was collected, and none was allowed to return to the intestine. [d] Metabolites were extracted from the bile of this dog, and 8.62×10^6 cpm was administered intravenously to this biliary-cannulated 14.1-kg dog.

The dogs were fasted for 24 hr before each experiment and then weighed. A water load of 10 ml/kg was administered through a stomach tube, and a continuous 0.9% NaCl iv drip (0.5 ml/min) was started 30 min prior to dosing.

Experiments on a given dog were spaced at least 28 days apart. All dogs required transfer of the jugular cannula to the remaining jugular vein between the first and second pharmacokinetic experiments.

The bile from Dog A was collected over a specified time, sampled, and then returned *via* the intestinal tube. The bile from Dog C was collected but not returned *via* the intestinal tube. Bile flow in Dog C was maintained by four daily oral doses (with food) of 150 mg of taurocholic acid[5] and by incorporating taurocholic acid into the 0.5-ml/min iv saline drip at 0.833 mg/ml.

The weights, hematocrits, and intravenous doses administered to the dogs are listed in Table I, and their treatments for bile study are summarized.

Collection and Treatment of Samples—Δ^9-Tetrahydrocannabinol was administered intravenously as a freshly prepared suspension solubilized in doubled plasma protein concentration, prepared by plasma filtration through filters[6]. The drug was injected into the jugular catheter over 0.05 min. The dosing syringe and catheter were flushed with 10 ml of normal saline.

Blood was withdrawn from the jugular catheter, after filling the dead space of the catheter with fresh undiluted blood, into a sterile, disposable syringe containing 0.01 ml of heparin (10,000 units/ml). The blood sample was transferred to a sterile 15-ml centrifuge tube and centrifuged at 1500 rpm for 10 min. Plasma, 1–2 ml, was transferred to a 50-ml centrifuge tube with a sterile pipet, and the tube was quickly stoppered and frozen. A known volume (0.05–0.2 ml) of the remaining plasma was analyzed for total carbon-14 as described previously (14). The small amount of blood remaining in the syringe was used to determine blood pH in selected instances.

The separated red blood cells were refrigerated at 5°. Blood, 5 ml, was sampled at 0.5, 1, 1.5, 2, 3, 5, 7, 10, 13, 16, 19, 22, 27, 32, 37, 45, 55, 65, 80, 100, 130, 180, 210, 260, 310, 400, 500, 600, 700, and 1000 min and at 500-min intervals up to 7000 min (4.86 days). Sterile red blood cells were collected over the first 1500 min. They were pooled, washed once with an equal volume of sterile normal saline, resuspended in 50 ml of normal saline, and returned to the animal in equal portions after the next three blood samplings. Hematocrits were obtained on selected blood samples prior to centrifugation.

Urine was collected from the catheterized animal at approximately 20, 40, 60, 85, and 100 min; then every 50 min up to 500 min; then every 200 min through Day 1; then every 6 hr of Day 2; and then twice daily thereafter for 5–25 days. The volumes of each collection were measured. Urine pH was determined in selected instances, and an aliquot was removed to determine total carbon-14. A 2-ml aliquot of freshly collected urine was transferred to a 50-ml centrifuge tube, which was stoppered and frozen. The remaining urine (up to 50 ml) was stored frozen.

Bile was collected in glass tubes (containing 0.2–0.5 ml of cyclohexane) and pooled between the following times: 0, 1, 2, 3, 4, 8, 11, 14, 18, 22, 26, 30, 35, 40, 45, 50, 60, 70, 80, 110, 140, 170, 200, 250, 300, 350, and 400 min

and thereafter as plasma samples were taken. The volumes of the pooled bile samples were recorded, and aliquots were obtained for extraction and determination of total carbon-14.

The pooled bile samples from Dog A were returned through the intestinal side of the biliary cannula during the next collection period. Pooled bile samples from Dog C were stored frozen.

Biliary Elimination and Enterohepatic Recirculation of Δ^9-Tetrahydrocannabinol and Its Metabolites—The collected bile fractions from Dog A were sampled prior to their intestinal return and analyzed for tetrahydrocannabinol and metabolites. Bile flow rates were determined at the start of each interval of bile flow collection, and the averages of the flow rates at the start and end of each interval were multiplied by the concentration of metabolites as equivalents of ^{14}C-Δ^9-tetrahydrocannabinol in bile and by the time of collection to obtain the total biliary excretion of metabolites in that interval. No bile was collected from Dog B. No enterohepatic recirculation would be possible with Dog C. The feces of Dog C between 0 and 24 hr were collected and analyzed for total carbon-14 to confirm complete collection of all bile.

Pharmacokinetics of ^{14}C-Labeled Metabolites—The 0–300-min bile from the 0.5-mg/kg study in Dog C was pooled, the volume was measured, and the solution was adjusted to pH 10.0–10.5 with 0.5 *M* Na_2CO_3 and extracted twice with an equal volume of heptane (containing 1.5% isopentyl alcohol), which removed approximately 2% of the radioactivity. The remaining bile solution was adjusted to pH 2.0, saturated with sodium chloride, and extracted twice with three equivalent volumes of tetrahydrofuran, which removed over 90% of the original radioactivity.

An aliquot (30 ml) of the metabolites extracted into tetrahydrofuran at pH 2 was reduced to dryness, reconstituted in 1 ml of ethanol, and diluted with 9 ml of normal saline. Two 0.1-ml aliquots were counted for total carbon-14, and 9.5 ml of the solution was administered intravenously to Dog C. Blood, bile, and urine collections were the same as described for tetrahydrocannabinol.

Effect of Isotope Placement on Pharmacokinetics and Metabolism of Δ^9-Tetrahydrocannabinol—Two types of ^{14}C-labeled Δ^9-tetrahydrocannabinol were available: C-11 labeled[7] and aromatic ring labeled[8]. Metabolism at C-11 could result in loss of the ^{14}C-label. This hypothesis was tested by conducting the 0.5-ml/kg study in Dog C with the ring-labeled tetrahydrocannabinol and the 2.0-mg/kg study in Dog C with C-11 labeled agent. The null hypothesis was that no difference in metabolism or distribution would result.

Effect of Altered Bile Flow on Pharmacokinetics of Δ^9-Tetrahydrocannabinol—After the 2.0-mg/kg injection of Δ^9-tetrahydrocannabinol in Dog C, 150 mg of taurocholic acid was rapidly infused (30 mg/min and 6 mg/ml in normal saline) at 400 min over 5 min in lieu of the normally infused 0.417 mg/min. Additional blood samples (1 ml) were taken at 410, 420, 430, 460, 530, and 560 min; additional bile samples were collected between 400, 410, 420, 430, 460, 480, 510, and 550 min. These samples were analyzed for total carbon-14 only. Oral taurocholic acid (150 mg four times a day) was reinstituted after 24 hr.

The taurocholic acid infusion was designed to increase bile flow sharply, which presumably would decline after cessation of infusion.

Analysis of Δ^9-Tetrahydrocannabinol in Biological Fluids—A 2-ml plasma sample was adjusted between pH 9.5 and 11.0, extracted, treated, and analyzed as described by Garrett and Hunt (9, 14). It was shown (14) that the electron-capture GLC analysis of the high-pressure liquid chromatographic (HPLC) collected tetrahydrocannabinol gave the same assay results as the liquid scintillation analysis of the separated tetrahydrocannabinol when both methods of analysis were conducted in Dog A on administration of 0.1 and 0.5 mg of Δ^9-tetrahydrocannabinol/kg iv. However, the sensitivity of the GLC analysis was approximately 1 ng/ml of plasma and that of the radiochemical analysis was 0.16 ng/ml. Since the former method only permitted plasma assays no more than 1000 min and the latter no more than 7000 min after the stated doses were administered (Table I), all other assays of plasma tetrahydrocannabinol in the remaining pharmacokinetic studies were obtained by the liquid scintillation analysis of the radiolabel after collection and separation of ^{14}C-tetrahydrocannabinol from plasma on the normal phase HPLC.

A 2-ml urine sample suspected of containing Δ^9-tetrahydrocannabinol was adjusted to pH 9.5–11 by addition of 0.2 ml of 0.5 *M* Na_2CO_3. A bile sample was diluted with distilled water to yield a 5–25% (v/v) solution. A 2-ml aliquot of this solution was adjusted to pH 9.5–11 by addition of 0.2 ml of 0.5 *M* Na_2CO_3. Subsequent steps for urine and bile were the same as described for the liquid scintillation analysis of tetrahydrocannabinol (14) in plasma.

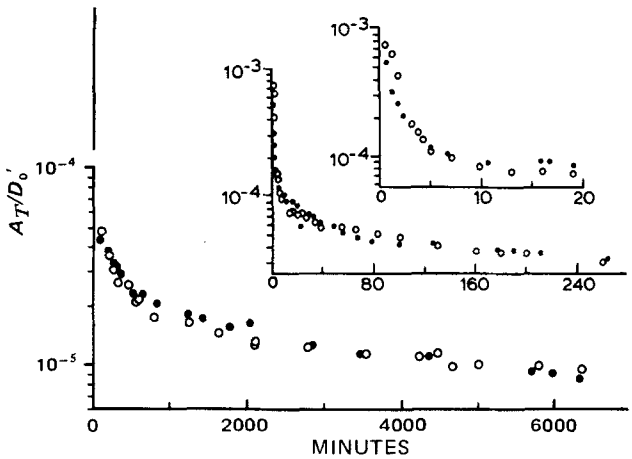

Figure 1—*Semilogarithmic plots of the fractions, A_T/D_0', of the total radioactive dose, D_0', per milliliter of plasma against time for the 2.0-mg/kg (●) (116.3 × 10^6 cpm) and 0.5-mg/kg (○) (76.22 × 10^6 cpm) doses of ^{14}C-Δ^9-tetrahydrocannabinol in Dog B. The activities per milliliter corresponding to $A_T/D_0' = 10^{-4}$ are 11,630 (●) and 7620 (○) cpm and correspond to 2880 and 635 ng/ml as Δ^9-tetrahydrocannabinol equivalents, respectively.*

Determination of Total Carbon-14 in Urine and Bile—An aliquot (0.2 or 0.4 ml) of freshly collected urine was transferred to a scintillation vial containing 0.1 ml of 0.1 *N* KOH. The sample was bleached to avoid quench by adding 0.2 ml of *tert*-butyl hydroperoxide[9]. The vial was tightly capped, placed in a water bath (50°), and reacted for 12–24 hr. Residual peroxide was hydrolyzed by the addition of 0.5 ml of water, and the capped vial was returned to the water bath for 1–3 hr. Six milliliters of scintillation solution was added to the vial, which was dark adapted for at least 6 hr before counting.

An aliquot of 0.05–0.2 ml of freshly collected bile was transferred to a vial containing 0.1 ml of 0.1 *N* KOH. Samples were bleached after addition of 0.1 ml of *tert*-butyl hydroperoxide/0.1 ml of bile. Subsequent manipulations were the same as for urine.

Samples with low counts (less than 400 cpm) were counted twice and averaged. This procedure resulted in negligible quench for 95% of all urine and bile samples.

Determination of Total Carbon-14 in Plasma—An aliquot of 0.05, 0.1, 0.2, or 0.5 ml of fresh plasma was transferred to a vial and 0.6, 0.5, 0.4, or 0.2 ml, respectively, of water was added. Six milliliters of scintillation solution was added to each, and the capped samples were dark adapted for at least 6 hr. Samples with low counts were counted twice and averaged. Selected plasma samples were checked for sedimentation error; if this error was observed, each sample was counted twice manually after vigorous shaking. Plasma samples showing evidence of hemolysis were treated as described for bile samples. This procedure resulted in negligible quench for all plasma samples.

Determination of Total Carbon-14 in Feces—The collected feces were transferred to a weighed sheet of aluminum foil, wrapped, weighed, and frozen. At the time of analysis, the frozen feces were transferred to a flask containing a measured volume of 15% ethanol in water. The volume of solvent was designed to give a 10–25% fecal suspension. The suspension was homogenized[10] for 15 min, and a 0.5-ml aliquot was transferred to a vial containing 0.2 ml of 0.5 *N* KOH and 0.5 ml of *tert*-butyl hydroperoxide. The vial was capped and placed in a water bath (50°) for 12–24 hr. One milliliter of water and 10 ml of scintillation solution were added, and the samples were dark adapted for at least 6 hr before counting. When an error due to sedimentation was suspected, each sample was manually counted twice after vigorous shaking. Quench corrections were required on all fecal samples.

Analysis of Metabolites in Plasma—The concentration of total metabolites in plasma, $[M_p]$, in terms of equivalents of Δ^9-tetrahydrocannabinol was calculated from:

$$[M_p] = (A_T/S) - C \qquad \text{(Eq. 1)}$$

[7] Sample DW-III-23, 68 μCi/mg, R.T.I., Research Triangle Park, N.C.
[8] Sample 3168-145-37, 38.7 μCi/mg, R.T.I., Research Triangle Park, N.C.

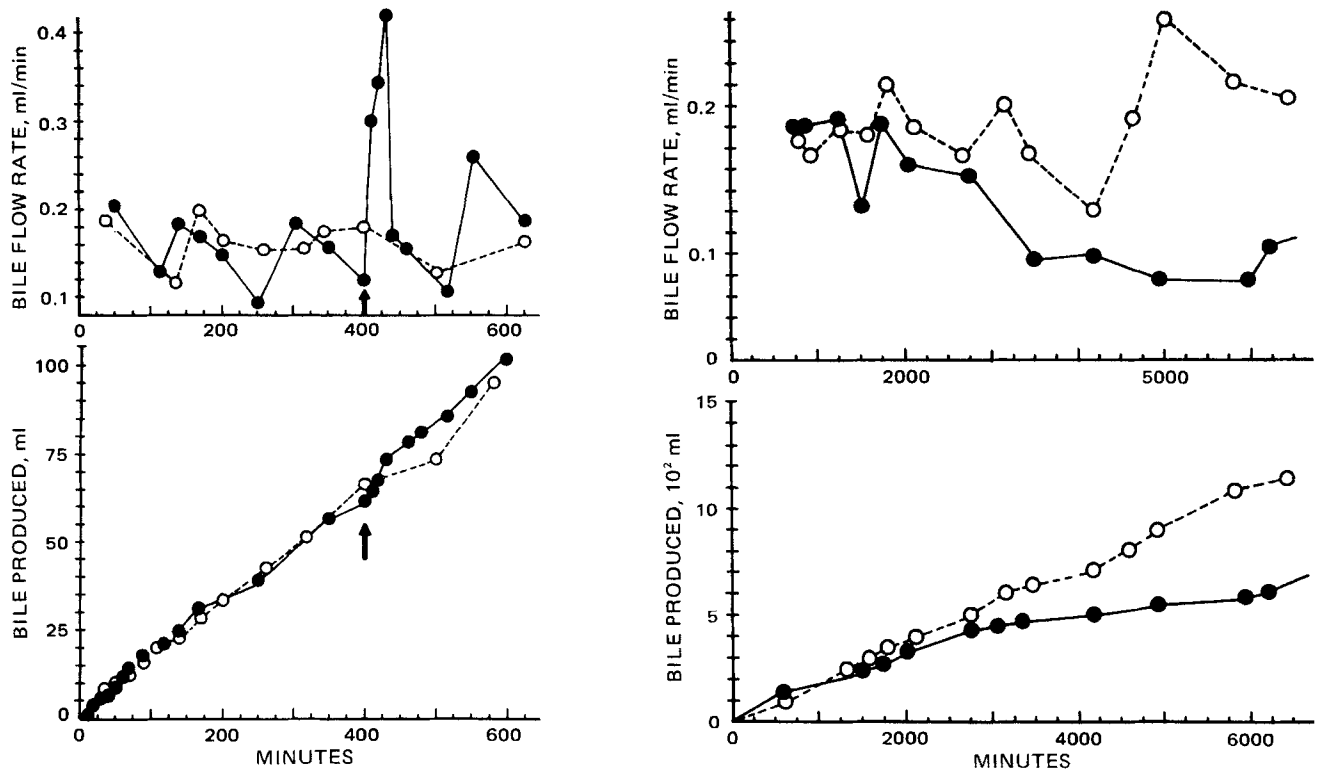

Figure 2—*Bile flow rates and cumulative volumes of bile produced with time after the 0.5- (○) and 2.0- (●) mg/kg iv doses of Δ^9-tetrahydrocannabinol in Dog C. The arrows indicate the time of increased infusion of taurocholic acid from 0.42 to 30 mg/min for 5 min.*

where A_T is the total radioactivity per milliliter of plasma, S is the activity of tetrahydrocannabinol in counts per minute per nanogram, and C is the experimentally observed plasma concentration of tetrahydrocannabinol. After extraction of plasma with heptane for determination of tetrahydrocannabinol and other heptane-extractable metabolites, the aqueous layer was adjusted to pH 2.0–2.3 by addition of 0.2–0.4 ml of a hydrochloric acid–acetic acid buffer [5.2 *N* HCl–1.0 *M* acetic acid–water (1:3:2)]. The final volume was either (*a*) adjusted to 3.0 ml by addition of 0.01 *M* acetic acid and then adding 15 ml of ethyl acetate or (*b*) prepared by adding 1 g of sodium chloride and 15 ml of tetrahydrofuran. The tube was stoppered, shaken for 15 min, and centrifuged.

In Case *a*, an aliquot (1–14 ml) of the organic layer was transferred to a scintillation vial and dried. The remaining organic layer was aspirated off, and 15 ml of tetrahydrofuran and 1 g of sodium chloride were added. This solution was shaken and centrifuged as before. An aliquot (1–14 ml) of the organic layer was transferred to a scintillation vial and dried. The contents of both vials were counted for total carbon-14 as described previously. In Case *b*, an aliquot (1–14 ml) of the organic layer was transferred to a scintillation vial, dried, and counted as described previously.

The concentration of metabolites in plasma in terms of tetrahydrocannabinol equivalents, extracted into heptane at pH 10.5, $[M_h]$, was calculated from:

$$[M_h] = (A_h/F_1S) - C \qquad \text{(Eq. 2)}$$

where A_h is the activity extracted per milliliter of plasma, F_1 is the extraction efficiency of tetrahydrocannabinol (14), S is the specific activity of the dose, and C is the concentration of tetrahydrocannabinol in plasma. The calculation assumed that the metabolites extractable into heptane had extraction efficiencies equivalent to tetrahydrocannabinol. The plasma concentration of metabolites extracted into ethyl acetate, $[M_{ea}]$, or tetrahydrofuran, $[M_{thf}]$, under acid conditions following a heptane extraction was calculated from:

$$[M_{ea}] = \frac{A_{ea} - A_h/(1 - F_1)}{S} \qquad \text{(Eq. 3)}$$

and:

$$[M_{thf}] = \frac{A_{thf} - A_h/(1 - F_1)}{S} \qquad \text{(Eq. 4)}$$

where A_{ea} and A_{thf} are the activities of the extracts per milliliter of plasma and are corrected for the unextracted heptane-extractable metabolites; *i.e.*, $A_h/(1 - F_1)$.

RESULTS AND DISCUSSION

Time Course of Total Radioactivity in Plasma—Semilogarithmic plots of the total radioactivity in plasma as A_T/D_0', where A_T is the total activity per milliliter of plasma and D_0' is the activity of the dose, are given in Fig. 1 for typical studies at two dose levels of ^{14}C-Δ^9-tetrahydrocannabinol for Dog B (Table I). The data plotted in this manner from the different doses were superimposable for the high and low doses in Dogs A and B, demonstrating no significant dose dependency. Differences in bile flow (Fig. 2) may have been responsible for the greater discrepancy between plasma levels for the two doses given to Dog C (Fig. 3).

An extended study of plasma levels of total carbon-14 was conducted in Dog C for 23 days at 2.0 mg/kg (Fig. 4). The data after 2000 min were

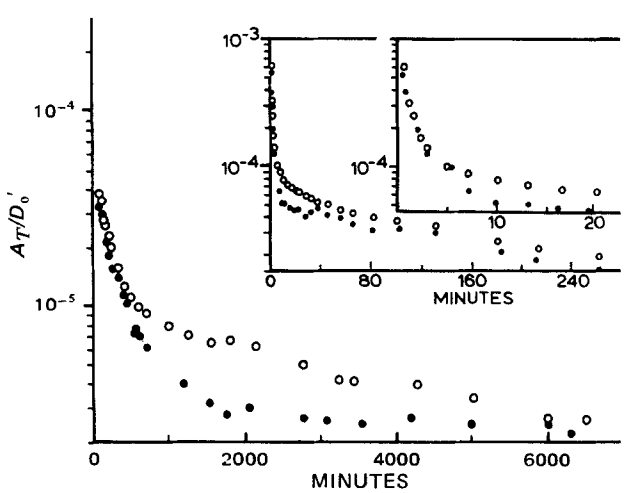

Figure 3—*Semilogarithmic plots of the fractions, A_T/D_0', of the total radioactive dose, D_0', per milliliter of plasma against time for the 2.0-mg/kg (●) (150.8 × 10^6 cpm) and 0.5-mg/kg (○) (229.4 × 10^6 cpm) doses of ^{14}C-Δ^9-tetrahydrocannabinol in Dog C. The activities per milliliter corresponding to $A_T/D_0' = 10^{-4}$ are 15,080 (●) and 22,940 (○) cpm and correspond to 3320 and 665 ng/ml as Δ^9-tetrahydrocannabinol equivalents, respectively.*

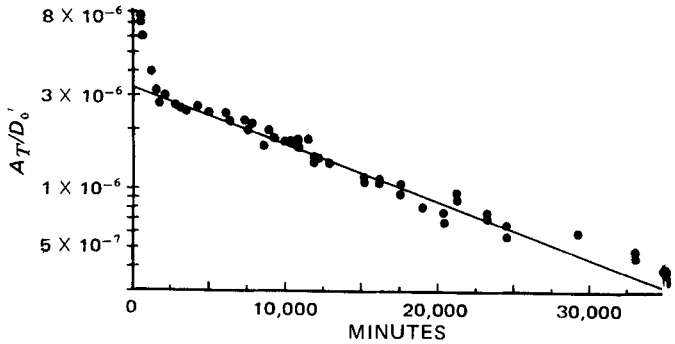

Figure 4—*Semilogarithmic plot of the fraction A_T/D_0' of the total radioactive dose, D_0', per milliliter of plasma against an extended time of study for the 2.0-mg/kg dose of Δ^9-tetrahydrocannabinol in Dog C. The apparent rate constant, k_5, obtained by least-squares regression was 6.74×10^{-5} min^{-1}.*

consistent with a single exponential of 171.4 hr half-life ($k_i = 6.7 \times 10^{-5}$ min). It was presumed that the terminal half-life for each study would be similar.

The variability of the data prior to 300 min was no different among dogs than within dogs. After 300 min, the total activity in plasma for both doses in Dog C (Fig. 3) dropped significantly below the levels in Dogs A and B (Fig. 1). The collection of total bile from Dog C (Table I), preventing any enterohepatic circulation of metabolites, could explain this difference.

Excretion of Total Radioactivity in Urine and Bile—No significant amount (<0.01%) of tetrahydrocannabinol was in the urine or bile on analysis of the HPLC collection (14). The total radioactivity as the percentage of dose recovered in urine was plotted against time (Fig. 5) and ranged from 14.7 to 16.6% at 7000 min for Dogs A and B.

The excretion rate of total radiolabeled metabolites in bile, dB_T/dt, in Dog C, where all bile was collected and bile flow was maintained by intravenous or oral solutions of taurocholic acid, was proportional to the radioactivity concentration in bile, $[B_T]$, and both values peaked between 25 and 45 min after drug administration. The concentrations of metabolites in bile were approximately 500 times the concentrations of total activity in plasma at this time and subsequently decreased to less than 50% of the plasma concentration at $t \geq 2500$ min.

Linear plots of the bile flow rates and the cumulative volume of bile produced as a function of time are given in Fig. 2 for the high and low dose studies in Dog C.

The percent of the dose recovered in bile for both doses in Dogs C (all bile collected) and A (bile sampled) was approximately 50% after 1 day or 1400 min (Fig. 5). Thereafter, only 5% of the dose was recovered.

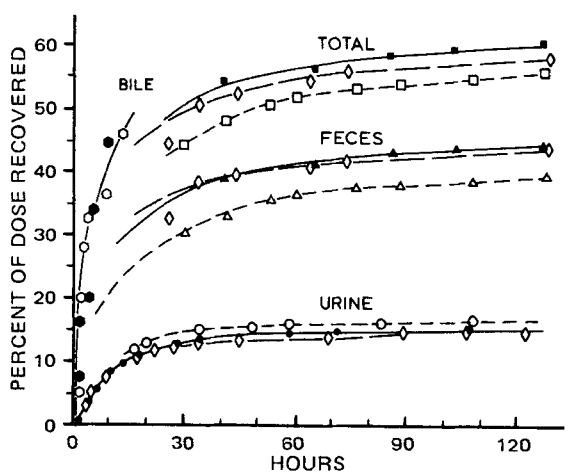

Figure 5—*Linear plots of the percent of dose recovered in urine and feces against time for the two intravenous doses in Dogs A and B. Key: Dog B urine, 0.5 (●) and 2.0 (○) mg/kg; Dog B feces, 0.5 (△) and 2.0 (▲) mg/kg; Dog B total (urine plus feces), 0.5 (□) and 2.0 (■) mg/kg; Dog A urine, feces, and total, 0.1-mg/kg dose (◇). The percent of dose excreted in the sampled bile of Dog A, corrected for the "dead" time of the cannula, is given as ○ for the 0.1-mg/kg dose and as ● for the 2.0-mg/kg dose. The percent of dose was calculated from [Δt × bile flow rate (mg/min) × 100]/dose, where Δt is the time of collection.*

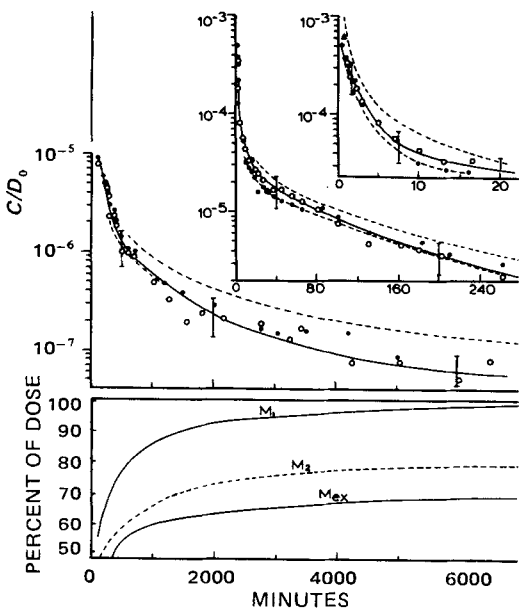

Figure 6—*Semilogarithmic plots of the plasma levels of Δ^9-tetrahydrocannabinol as C/D_0 against time for the 0.5- (○) and 2.0- (●) mg/kg iv doses to Dog C. The solid curve gives the calculated values for C/D_0, $\hat{Y}$, for the five-exponential fit of the 0.5-mg/kg data, and the vertical bars are the range for ±2 SD of the weighted residuals (Table II). The dashed lines represent the range for the maximum and minimum of all $\hat{Y}$ values calculated. The concentrations of Δ^9-tetrahydrocannabinol in plasma corresponding to the fraction $C/D_0 = 10^{-4}$ are 665 (○) and 3320 (●) ng/ml. Curves M_1 and M_2 were calculated from Eq. 14 using the $\hat{Y}$ expressions of Eqs. 5 and 6, respectively, and represent the total metabolite in percent of dose formed with time, where M_{ex} is the experimentally determined metabolite in percent of dose excreted in both urine and bile.*

During this time, the biliary excretion rate decreased asymptotically to approximately 0.72%/week.

The rates of excretion of total metabolites per unit dose and their concentrations in bile were similar for both Dogs A and C. The consistency in the percent of radiolabeled dose recovered in bile for both doses in Dogs A (Fig. 5) and C demonstrated no significant dose dependency. The percentage recovered in feces ranged from 39.5 to 44.5% over 130 hr for Dogs A and B, whereas the percentage recovered in bile (Dog A) was always consistently higher at any given time (Fig. 5). When all bile was collected, as for Dog C, approximately 55% of the radioactive dose was excreted therein for the same time period. No radioactivity was found in feces when all bile was collected.

Since the percent of the dose recovered in urine was essentially the same for $t > 1000$ min between doses and among dogs, the 10–15% excess recovered in bile compared to feces can be attributed to the enterohepatic circulation of 15% of the biliary excreted metabolites.

Pharmacokinetics of Intravenously Administered Δ^9-Tetrahydrocannabinol—There may not be a unique linear sum of time exponentials, $\hat{Y}$, that best fits the actual data, $Y = C/D_0$, where C is the concentration per milliliter of Δ^9-tetrahydrocannabinol in plasma, and D_0 is the dose; instead, there may be several. A unique solution could only be obtained if the drug transferred into other compartments or transformed into metabolites was analyzed with time in its respective compartments. For example, the plasma data for Dog C at the dose of 0.5 mg of Δ^9-tetrahydrocannabinol/kg where the fraction of the dose per milliliter of plasma is plotted against time (Fig. 6) could be fitted by the method of residuals (15) to:

$$\hat{Y}_1 = \hat{C}/D_0 = 6.80 \times 10^{-4}e^{-1.01t} + 1.25 \times 10^{-4}e^{-0.202t} + 2.30 \times 10^{-5}e^{-0.0206t} + 7.65 \times 10^{-6}e^{-4.36\times10^{-3}t} + 5.30 \times 10^{-7}e^{-3.87\times10^{-4}t} \quad \text{(Eq. 5)}$$

or to:

$$\hat{Y}_2 = \hat{C}/D_0 = 5.02 \times 10^{-4}e^{-0.587t} + 4.25 \times 10^{-5}e^{-0.0877t} + 2.15 \times 10^{-5}e^{-1.16\times10^{-2}t} + 1.88 \times 10^{-6}e^{-1.28\times10^{-3}t} + 9.50 \times 10^{-8}e^{-4.98\times10^{-5}t} \quad \text{(Eq. 6)}$$

Table II—Parameters of the Best Fit Sum-of-Exponentials, $\hat{Y} = \sum_{i=1}^{5} A_i e^{-k_i t}$, Describing the Fraction of the Dose of Δ^9-Tetrahydrocannabinol per Milliliter of Plasma against Time in Minutes

$10\ k_2$	1.26	0.37	1.43	1.31	0.88	0.90	1.03 (0.16)	6.8 min
$10^2 k_3$	1.09	0.70	1.16	1.01	1.16	0.93	1.01 (0.07)	1.15 hr
$10^3 k_4$	1.18	1.54	1.17	1.26	1.28	1.27	1.28 (0.05)	9.0 hr
$10^5 k_5$	5.0	5.0	6.80	6.60	4.98	6.74	5.85 (0.39)	197 hr
$10^2 \bar{\epsilon}$, mean of residuals[c]	0.96	0.40	−1.3	0.17	−0.16	2.1	—	—
$2s$[d]	0.273	0.191	0.284	0.162	0.363	0.289	—	—

[a] The A_i values are in fraction of dose per milliliter of plasma; k_i are in minutes^{-1}. [b] The parenthetical values are standard errors of the mean. [c] The average values of the weighted residuals, $\epsilon = (Y - \hat{Y})/\hat{Y}$, where $\hat{Y}$ is the predicted value and Y is the experimental, none of which is significantly statistically different than zero. [d] Twice the standard deviation of the weighted residuals.

where time, t, is in minutes. The terminal data of the 7000-min span in Fig. 6 were approximated by the best straight line for estimation of the parameters of the last exponential in Eq. 5. The parameters for the last exponential in Eq. 6 were based on the assumption that the terminal slope was close to the rate constant characteristic of the rate of decline of the total radioactivity in the plasma up to 35,000 min (Fig. 5).

The validities of both Eqs. 5 and 6 were confirmed by the demonstration that a plot of the weighted residuals:

$$\epsilon = \frac{Y - \hat{Y}_i}{\hat{Y}_i} \qquad \text{(Eq. 7)}$$

for both $\hat{Y}_1$ and $\hat{Y}_2$ against log Y = log C/D_0 gave a calculated mean, $\bar{\epsilon}$, of zero and where the standard deviations of their ϵ values were practically the same, *i.e.*, 0.13 for Eq. 5 and 0.12 for Eq. 6 (16).

The decision that a linear sum of five exponentials was necessary to fit the plasma tetrahydrocannabinol data for all studies was based on the fact that, when a linear sum of four or less exponentials was used, the plot of the weighted residuals (Eq. 8) against log C/D_0 demonstrated biases above and below the line of the mean of the n weighted residuals:

$$\bar{\epsilon} = \sum_{i=1}^{n} \left[\frac{(Y - \hat{Y})_i}{\hat{Y}_i} \right] \Big/ n \qquad \text{(Eq. 8)}$$

which were not statistically significant from zero (Table II). In the particular case of the data of Fig. 6, the standard deviation for a best fit of a linear sum of four exponentials was higher, *i.e.*, 0.21, than for five. The best fitting to a linear sum of six exponentials was similar to the sum of five and did not show significant nonrandom scatter about $\bar{\epsilon} \sim 0$, but the standard deviation (0.15) was not significantly improved.

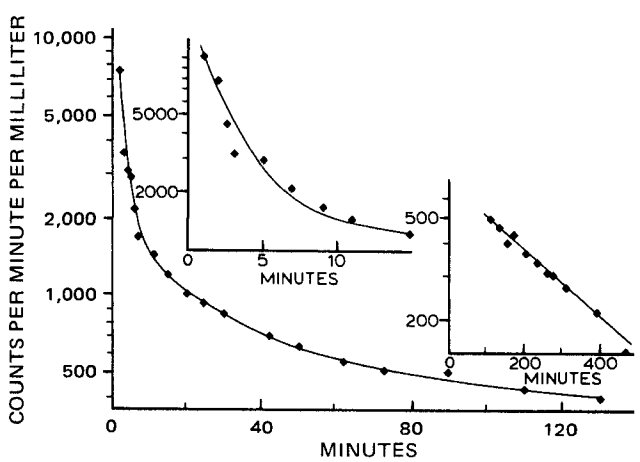

Figure 7—*Semilogarithmic plot of the activity (counts per minute) per milliliter of plasma against time for the intravenous administration of biliary Δ^9-tetrahydrocannabinol metabolites to Dog C. The inserts are for expanded and extended time scales. The curves through the data are given by* $\hat{Y}_m = \sum_{i=1}^{3} A_i e^{-k_i t}$, *where* $A_1 = 15{,}013$, $A_2 = 1330$, *and* $A_3 = 584$ *cpm/ml and* $k_1 = 0.542$, $k_2 = 0.0477$, *and* $k_3 = 3.005 \times 10^{-3}$ *min*$^{-1}$.

When the fraction of the dose per milliliter of plasma as tetrahydrocannabinol or its logarithm (Fig. 6) was plotted against time for widely variant doses, the curves were superimposable, indicative of no dose dependency.

Pharmacokinetics of Intravenously Administered Biliary Metabolites of Δ^9-Tetrahydrocannabinol—The plasma levels of the intravenously administered radiolabeled metabolites were adequately described in Dog C by a sum of three exponentials (Fig. 7). These metabolites were those collected in the bile for 300 min after ^{14}C-Δ^9-tetrahydrocannabinol administration, and 98% of the collected radioactivity was retained after heptane extraction at pH 10 to remove highly lipid-soluble components. The metabolites administered were those extracted from the aqueous bile by tetrahydrofuran. This extract contained over 90% of the original radioactivity. The calculated terminal half-life for these metabolites in plasma was 230 min. At 500 min, a total of 90.7% of the administered dose was eliminated in bile and urine (Fig. 8). Ninety-six percent of the administered dose was eliminated by 24 hr, with the majority (73%) eliminated in bile. The final ratio of metabolites eliminated in bile to that in urine, 2.4, was slightly lower than the ratio, 3.2, for *in vivo* produced metabolites.

Evidence that Rates of Terminal Decline of Total Plasma Radioactivity Estimates Rates of Terminal Decay of Plasma Tetrahydrocannabinol Concentration and that the Ultimate Rate-Determining Step for Elimination is Return from Deep Tissues—Since no dose-dependent pharmacokinetics for tetrahydrocannabinol or its metabolites were observed, it can be postulated that the metabolism was first order and dependent only on the estimated concentration, $\hat{C}$, of tetrahydrocannabinol in the central compartment or:

$$dM/dt = k_m V_c \hat{C} \qquad \text{(Eq. 9)}$$

where $k_m V_c$ is the metabolic clearance. Thus:

$$M = \int_0^M dM = k_m V_c \int_0^t \hat{C}\, dt \qquad \text{(Eq. 10)}$$

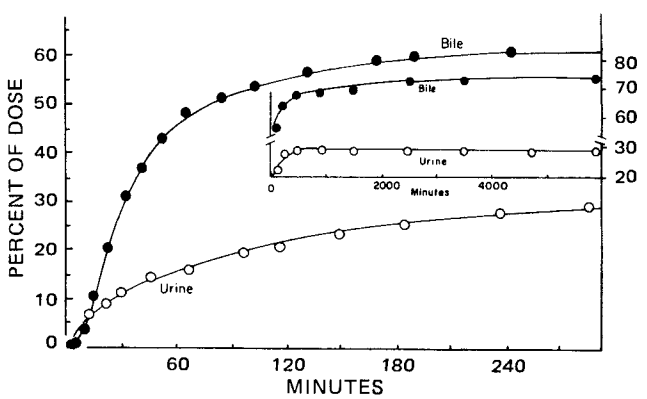

Figure 8—*Linear plots of the percent of the radioactivity recovered in bile (●) and urine (○) against time for the intravenous administration of biliary Δ^9-tetrahydrocannabinol metabolites to Dog C.*

[a] The fractions of the dose of tetrahydrocannabinol per milliliter of plasma at time zero estimated from $\hat{Y} = \Sigma_{i=1}^{5} A_i e^{-k_i t}$ for $t = 0$, where the A_i and k_i parameters are given in Table II. [b] Apparent volume of distribution of the central compartment referenced to total drug concentration in plasma, $D_0/10^3\ C_0$. [c] Clearance referenced to total concentration in plasma, calculated from Eq. 14 where the parameters of Y are given in Table II. [d] The rate constant with respect to total concentration in plasma calculated from $Cl_p/10^3\ V_c$. [e] The volume of plasma in the dog calculated from $(1 - H)\ V_{B,\text{true}}$, where $V_{B,\text{true}}$ = dog weight in kilograms × 100 ml/kg (18), and H is the hematocrit (Table I). [f] Clearance referenced to unbound drug in plasma, calculated from $Cl^u = Cl_p/f_u$, where f_u is the fraction of the unbound drug in plasma and is 0.03 (13). [g] The apparent volume of distribution referenced to total plasma concentration in the ultimate pseudo-steady state of tetrahydrocannabinol elimination from the body calculated from $10^{-3}\ Cl_p/k_5$, where k_5 is given in Table II.

where M is the amount of metabolite(s) produced in the first metabolic step from tetrahydrocannabinol, k_m is the first-order metabolic rate constant, and $V_c = D_0/C_0$ (Table III) is the apparent volume of distribution of the central compartment for tetrahydrocannabinol of dose D_0. The $\hat{C}_0$ is the estimated concentration of tetrahydrocannabinol in plasma at $t = 0$ and can be calculated from Eq. 5 or 6 with $t = 0$.

Substitution of Eq. 5 or 6 into Eq. 10 gives:

$$M = k_m V_c D_0 \int_0^t \hat{Y}\, dt \qquad \text{(Eq. 11)}$$

At $t = \infty$, $M = M_\infty = D_0$, since tetrahydrocannabinol was not excreted unchanged but was transformed to metabolites. Thus, the apparent metabolic rate constant is:

$$k_m = 1/V_c \int_0^\infty \hat{Y}\, dt \qquad \text{(Eq. 12)}$$

Substitution of Eq. 12 into Eq. 11 yields:

$$M = D_0 \frac{\int_0^t \hat{Y}\, dt}{\int_0^\infty \hat{Y}\, dt} = D_0 A_t / A_\infty \qquad \text{(Eq. 13)}$$

and the total metabolites, both excreted and unexcreted, produced at time t can be calculated from the pertinent fit, $\hat{Y}$, of the plasma tetrahydrocannabinol data against time or from the ratio of the area under the *C versus t* plot at time t, A_t, to the total area, A_∞. The values calculated for total metabolites with time, M_1 and M_2, as the percent of dose from the $\hat{Y}_1$ and $\hat{Y}_2$ obtained with Eqs. 5 and 6, respectively, are plotted in Fig. 6 against time. For comparative purposes, the experimentally determined total amount of radiolabeled drug, M_{ex}, excreted into bile and urine as the percent of dose is also plotted against time for 0.5 mg/kg. At 7000 min, the total amounts of metabolites excreted by Dog C (Table IV), M_{ex}, comprised 68% of the dose, whereas the calculated amounts of metabolites formed, M_1 and M_2, were 98 and 79%, respectively (Fig. 8).

If the M_1 values, and thus the parameters of Eq. 5 with an apparent terminal half-life of 30 hr, were accepted as valid for tetrahydrocannabinol administration, it must be concluded that tetrahydrocannabinol metabolism was virtually concluded at 7000 min, that 98 − 68% = 30% of the formed metabolites was still in the body, and that this large amount of metabolites was very slowly eliminated well after 7000 min (Fig. 4) with an apparent half-life of 171 hr. The result implies that these metabolites are highly sequestered in, and/or bound to, body tissues so that they have extremely large apparent volumes of distribution. However, these hypotheses are inconsistent with the fact (Fig. 8) that 90.7% of intravenously administered biliary metabolites was eliminated in both bile and urine within 500 min of administration, with 96% eliminated by 1500 min. Also, the terminal plasma half-life of administered radiolabeled metabolites of 230 min (Fig. 7) supports the hypothesis that the rate-determining step for metabolite elimination on Δ⁹-tetrahydrocannabinol administration is not the elimination of such metabolites.

The estimate of M_2 from Eq. 13 as the amount of total metabolites formed at any time is greater than M_1, since M_2 was obtained from the $\hat{Y}_2$ of Eq. 6 where the terminal slope was smaller and the plotted area, A_∞, was greater than would be obtained in Eq. 13 from the M_1 calculated from the $\hat{Y}_1$ of Eq. 5. This M_2 is more consistent than M_1 with the fraction of the dose excreted as metabolites, M_{ex} (Fig. 6). It follows that the ob-

Table IV—Percent Disposition of Δ⁹-Tetrahydrocannabinol at 7000 min after Intravenous Administration

	Dog A		Dog B		Dog C[a]	
	0.1 mg/kg	2.0 mg/kg[b]	0.5 mg/kg	2.0 mg/kg	0.5 mg/kg	2.0 mg/kg
Δ⁹-Tetrahydrocannabinol in central compartment[c]	0.018	0.023	0.011	0.013	0.012	0.010
Δ⁹-Tetrahydrocannabinol in tissues[d]	29.2	29.0	24.4	21.3	20.4	16.1
Metabolized[e]	70.8	71.0	75.6	78.7	79.6	83.9
Excreted metabolites[f]	57.1	—	56.0	59.5	68.4	71.5
Metabolites in body[g]	13.7	—	19.6	19.2	11.2	12.4

[a] All bile was collected, and enterohepatic circulation was not possible. [b] Study terminated at 1300 min; all values given are extrapolated values, and no feces were collected. [c] $10^5 \times V_c \hat{Y}$, where $\hat{Y} = \Sigma_{i=1}^{5} A_i e^{-k_i t}$ in fraction of dose per milliliter of plasma, and the A_i and k_i parameters of Table II were used. The V_c values in liters are listed in Table III. [d] $10^2\ T/D_0$, where T is the amount of the dose, D_0, not in the central compartment, $V_c C$, or transformed to metabolite, M; *i.e.*, $D_0 - V_c C - M$, where $V_c C = 10^2\ V_c \hat{Y} D_0$. [e] The percent metabolized is $10^2\ M/D_0$, where M was obtained from Eq. 13, $M = D_0 \int_0^t \hat{Y}\, dt / \int_0^\infty Y\, dt$. [f] Percent of dose excreted in urine plus bile (Dog C) or feces (Dogs A and B). [g] Difference of above two values.

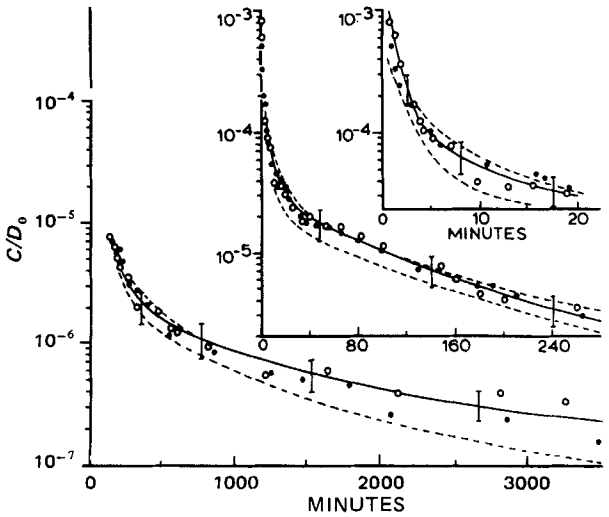

Figure 9—*Semilogarithmic plots of the plasma Δ^9-tetrahydrocannabinol levels as C/D_0 against time for the 0.5- (○) and 2.0- (●) mg/kg iv doses to Dog B. The solid curve gives the calculated values for C/D_0, $\hat{Y}$, for the five-exponential fit of the 0.5-mg/kg data, and the vertical bars are the range for ±2 SD of the weighted residuals (Table II). The dashed lines represent the range for the maximum and minimum of all $\hat{Y}$ values calculated. The concentrations of Δ^9-tetrahydrocannabinol in plasma corresponding to the fraction $C/D_0 = 10^{-4}$ are 635 (○) and 2880 (●) ng/ml.*

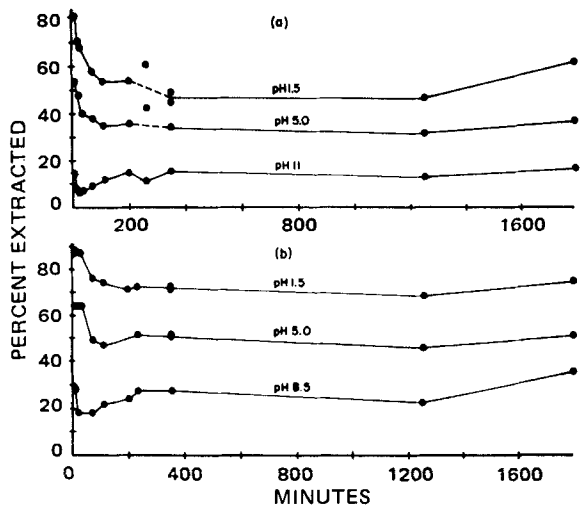

Figure 10—*Percent of biliary metabolites in a given sample that were extracted into benzene (a) or ethyl acetate (b) at selected pH values plotted against time after the administration of 0.5 mg of Δ^9-tetrahydrocannabinol/kg iv to Dog C.*

served rate of terminal loss of plasma total radioactivity from 2000 to 35,000 min (Fig. 4) is consistent with the terminal loss of Δ^9-tetrahydrocannabinol in the plasma as characterized by the last exponential in Eq. 6, which cannot normally be observed since the available analytical sensitivity did not permit assay of plasma tetrahydrocannabinol for more than 5000–6000 min after administration of the given doses.

This terminal rate of the 171.4-hr half-life (Fig. 4) for the loss of total radioactivity provided initial estimates of the terminal half-life and the derived k_5 values for the plasma Δ^9-tetrahydrocannabinol data in each dog. The determined parameters for the linear sum of five exponentials used to fit the assayed plasma levels of Δ^9-tetrahydrocannabinol with time (Figs. 6 and 9) are given in Table II and are considered as the most appropriate parameters. An expression for $\hat{Y}$ using the mean values of the parameters obtained for all studies reasonably fit all plasma–time data for tetrahydrocannabinol. The data from each study lay within ±2 *SD* of the resultant common equation (Figs. 6 and 9).

The consistency of these terminal rates of plasma total radioactivity and Δ^9-tetrahydrocannabinol decay indicates a typical "flip-flop" (17), where the rate-determining step in plasma decay of both tetrahydrocannabinol and its formed metabolites is the slow return of the tetrahydrocannabinol in the tissues to the central compartment where it can be metabolized (Eq. 9). A logical consequence of this assertion is that the composition of the metabolites would remain constant and in pseudo-steady-state equilibrium when the rate-determining step is return of tetrahydrocannabinol from the tissues since metabolism is a relatively fast process. This was confirmed (Fig. 10) by the reasonable constancy of the percent of biliary metabolites extracted into benzene and ethyl acetate after 100–200 min. The similarity of data for the low and high doses of Δ^9-tetrahydrocannabinol confirmed the lack of dose dependency. Similarly, the percent of urinary metabolites extracted into various solvents at selected pH values did not significantly vary with time (Fig. 11), and the pseudo-steady state exemplified by these studies was reached prior to the collection of the 50–73-min urine.

The plasma levels of metabolites, $[M_p]$, in terms of tetrahydrocannabinol equivalents were calculated from Eq. 1. The fact that the ratio of plasma levels of total metabolites, M_p, to Δ^9-tetrahydrocannabinol, C, were constant after 3000 min subsequent to drug administration provided further evidence that the return of tetrahydrocannabinol from tissues was the rate-determining step for metabolism and subsequent elimination of metabolites.

Clearance and Apparent Volume of Distribution of Δ^9-Tetrahydrocannabinol—Tetrahydrocannabinol was cleared from the body solely by metabolism. This clearance, Cl_p, referenced to total plasma concentration is a product of the metabolic microscopic rate constant, k_m, and the apparent volume of distribution of the central compartment, V_c, and can be obtained from a rearrangement of Eq. 12 to:

$$Cl_p = k_m V_c = 1 \Big/ \int_0^\infty \hat{Y}\, dt \qquad \text{(Eq. 14)}$$

where the values of $\hat{Y}$ can be obtained from the linear sum of five exponentials using the parameters of Table II.

The average metabolic clearance, Cl_p, for all six studies was 124 ± 22.6 ml/min (Table III). The calculated hepatic blood flow for these dogs ranged from 372 to 747 ml/min, 30–45 ml/min/kg (18). Multiplication of the hepatic blood flow by $(I - \overline{H})$, where $\overline{H} = 0.363$ was the mean hematocrit (Table I), gave a range for hepatic plasma flows of 237–476 ml/min and was approximately twice the metabolic clearance of both bound and unbound drug in plasma. Thus, Δ^9-tetrahydrocannabinol was not completely cleared in a single pass through the liver as previously reported (10). If only the unbound drug were cleared, then the mean clearance referenced to unbound drug, $Cl_p{}^u = Cl_p/f^u$ (Table III), would be 4132 ± 753 ml/min, an order of magnitude greater than hepatic plasma flow, where $f^u = 0.03$ (13), the fraction of unbound drug in plasma. Since the liver is the primary metabolizing organ (19), an apparent substantial fraction of the bound drug was cleared in a single pass through the liver.

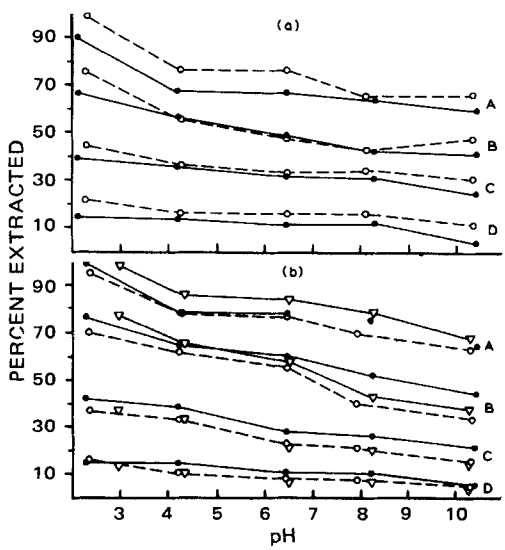

Figure 11—*Plots of the percent of urinary metabolites extracted into various solvents as a function of pH. Aliquots of the urine from the 2.0-mg Δ^9-tetrahydrocannabinol/kg study in Dog B were adjusted to the indicated pH and extracted with tetrahydrofuran (A), ethyl acetate (B), heptane containing 1% butanol (C), or heptane containing 1.5% isopentyl alcohol (D). Urine collection intervals in (a) were 50–73 (○) and 133–195 (●) min; in (b), they were 325–381 (●), 646–855 (○), and 1244–1474 (▽) min.*

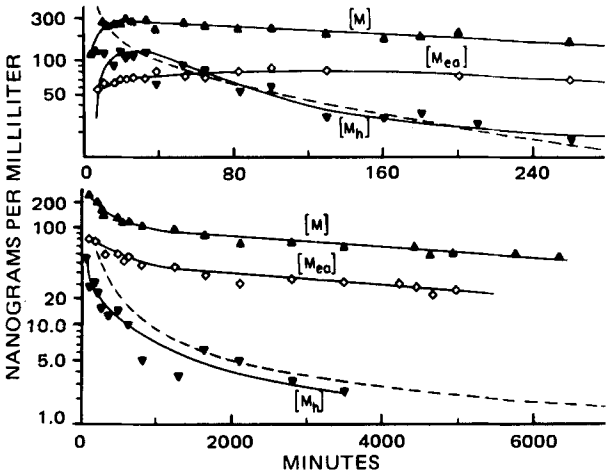

Figure 12—*Semilogarithmic plots of Δ^9-tetrahydrocannabinol metabolites in plasma against time for the 0.5-mg/kg iv dose of Δ^9-tetrahydrocannabinol in Dog B. The concentration of total metabolites in plasma [M] (▲), as nanograms per milliliter equivalents of Δ^9-tetrahydrocannabinol, was calculated from Eq. 1. The concentration of heptane-extractable metabolites (at pH 10.5) in plasma, [M_h] (▽), as nanograms per milliliter equivalents of Δ^9-tetrahydrocannabinol, is given by Eq. 2. The concentration of ethyl acetate-extractable metabolites (at pH 2.5; 5 ml of solvent/ml of plasma) in plasma, [M_{ea}] (◇), as nanograms per milliliter equivalents is given by Eq. 3. The best fit values for $C/D_0\hat{Y}$ (Table II), are given as concentration of Δ^9-tetrahydrocannabinol per milliliter of plasma in the dashed curve.*

The transit time of plasma in the liver may be sufficient for a series of reequilibrations between bound and unbound drug, with only the latter being actually metabolized.

The apparent first-order metabolic rate constants, k_m (Table III), calculated from the metabolic clearances (Eq. 14) ranged from 0.0636 to 0.1446 min^{-1} and were consistent with rapid metabolism ($t_{1/2}$ values from 4.8 to 10.9 min).

The high plasma protein binding (97%) and comparatively lower red blood cell partitioning (13) from plasma of Δ^9-tetrahydrocannabinol require that the expected apparent volume of distribution of the central compartment referenced to total plasma Δ^9-tetrahydrocannabinol concentration should be close to the plasma volume. Consistent with this premise, the apparent volumes of distribution, V_c, ranged from 0.66 to 1.76 liters, close to those of the calculated plasma volumes, V_p, which ranged from 0.77 to 1.05 liters (Table III).

Unfortunately, it is difficult to estimate accurately the apparent volume of distribution of the central compartment referenced to unbound drug in plasma when a drug such as Δ^9-tetrahydrocannabinol is highly bound, *i.e.*, 97%. The equation (20) for the estimation of this volume depends on the fraction unbound, the apparent volume of distribution, and the true volume, V_p, of the plasma. When the latter two are similar, as in the present case, and literature values of V_p are used, large errors in such estimates are inevitable.

The apparent volume of distribution ($V_{p_{ss}}$ in Table III) of the pseudo-equilibrated fluids in the final pseudo-steady state of drug elimination referenced to the total drug concentration in plasma can be obtained from the quotient of the metabolic clearance, Cl_p (Table III), and the terminal apparent first-order rate constant of metabolism, k_5 (Table II). The value of $V_{p_{ss}}$ ranged from 1500 to 3000 liters. This apparent volume of distribution would be much higher (20) if it could be referenced to the unbound concentration in plasma. The high degree of sequestration and distribution of Δ^9-tetrahydrocannabinol in body tissues is apparent from the fact that dog weights ranged only from 12 to 17 kg.

Time Course of Plasma Levels of Total and Extractable Metabolites—Typical plasma levels of total metabolites, [M_p], were calculated from Eq. 1 for the six studies (Table I) where Δ^9-tetrahydrocannabinol was administered intravenously and are given in Fig. 12 for the 0.5-mg/kg dose in Dog B. Peak concentrations, in terms of tetrahydrocannabinol equivalents, ranged from 1050 to 1450 ng/ml at 22–36 min in Dogs B and C for the 2.0-mg/kg doses and from 250 to 280 ng/ml at 22–28 min in Dogs B and C for the 0.5-mg/kg doses; a peak of 58 ng/ml occurred at 28 min for the 0.1-mg/kg dose given to Dog. A. The peak levels were proportional to dose and confirmed the lack of dose dependency.

The pH 10.5 heptane-extractable metabolites, [M_h], from plasma (Eq. 2), corrected for any possible tetrahydrocannabinol in plasma (Fig. 12), increased rapidly to a broad maximum between 12 and 40 min and then decreased, paralleling the loss of tetrahydrocannabinol (Fig. 12) from plasma to indicate a similar metabolic clearance of these relatively nonpolar metabolites. At the earliest times, [M_h] accounted for less than 50% of the concentration of [M_p] in plasma, whereas at later times ($t > 2000$ min) [M_h] accounted for less than 10% of [M_p]. The semilogarithmic plots of the pH 2.0 ethyl acetate-extractable metabolites, [M_{ea}] (Eq. 3), which were identical with the tetrahydrofuran-extractable metabolites (Eq. 4), against time (Fig. 11) paralleled the total metabolite concentration in plasma [M_p] after its maximum was achieved. This finding indicated that these more polar acidic metabolites maintained a constant ratio to the total metabolites in plasma subsequent to 70–100 min after tetrahydrocannabinol administration.

The simultaneous appearance in plasma of both nonpolar (heptane extractable, [M_h]) and acidic polar metabolites (ethyl acetate and tetrahydrofuran extractable, [M_{ea}] and [M_{thf}]) may be explained by either parallel metabolic processes or by sequential metabolic processes during each pass through the liver.

This extremely rapid appearance of metabolites in the plasma, which peaked at 25–30 min, demonstrated the extremely rapid metabolism of tetrahydrocannabinol consistent with the metabolic half-lives of 4.8–10.9 min estimated from the derived k_m values (Table III). Since the experimentally observed plasma tetrahydrocannabinol values persisted for 7000 min, it must be stated that the nonmetabolized drug rapidly distributed into tissues concomitantly with its rapid metabolic clearance from the central compartment. Estimates of the disposition at that time are given in Table IV.

These phenomena can be dramatically demonstrated by analog computer fitting of the data obtained for the first 60 min after intravenous administration of Δ^9-tetrahydrocannabinol; the computer need only be programmed to a three-compartment body model, rather than the five needed for 7000 min, since negligible amounts of drugs were returned from the deeper third and fourth tissues during the 60 min. Programs, techniques, and procedures for fitting pharmacokinetic data by the analog computer were described previously (20).

The most highly divergent data from the various studies, the 0.1- and 0.5-mg/kg studies in Dogs A and C, were used for the analog computer fitting of the scheme in Fig. 13. They included the experimentally obtained plasma levels of Δ^9-tetrahydrocannabinol with time and the total amount of metabolites, M, produced with time as calculated from Eq. 13. The sets of microscopic rate constants are listed in Table V. The simultaneous rapid distribution of large amounts of drug into the tissues—*viz.*, T_1 and T_2, and the transformation into metabolites, M, are apparent from the example of Fig. 13.

Pseudo-Clearances and Pseudo-Apparent Volumes of Distribu-

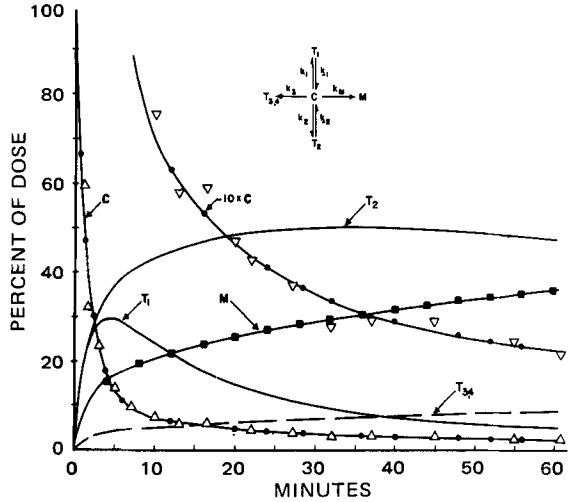

Figure 13—*Analog computer fitting of plasma Δ^9-tetrahydrocannabinol data (△) and metabolites (■) produced, M (as calculated from Eq. 13), for 60 min after the 0.1-mg/kg study in Dog A for the scheme given. The plasma values (●) were calculated with the pertinent constants of Table II. The plasma values of Δ^9-tetrahydrocannabinol (▽) were also fit on a 10-fold expanded ordinate. The generated tissue levels of Δ^9-tetrahydrocannabinol, T_1, T_2, and $T_{3,4} = T_3 + T_4$, are also given.*

Table V—Pharmacokinetic Parameters after Intravenous Administration of Δ^9-Tetrahydrocannabinol Obtained by Analog Computer Fitting to the Scheme in Fig. 13[a]

Parameter	Dog A 0.1 mg/kg	Dog C 0.5 mg/kg
V_c, liters	1.35	1.77
$10^2 k_M$, min^{-1}	9.11	8.68
$10^2 k_1$, min^{-1}	34.62	21.83
$10^2 k_{-1}$, min^{-1}	20.11	11.38
$10^2 k_2$, min^{-1}	29.74	19.73
$10^2 k_{-2}$, min^{-1}	1.81	1.27
$10^2 k_3$, min^{-1}	7.59	2.11

[a]The fit was considered adequate when the experimental values of $10^5 V_C C/D_0$ in terms of percent of dose in plasma (where V_C is apparent volume of distribution of the central compartment in liters from Table III) and the $10^2 M/D_0$ values (from M calculated by Eq. 13) were reasonably fit.

tion of Metabolites of Δ^9-Tetrahydrocannabinol—Pseudo-clearances, Cl_R and Cl_B, of total metabolites after tetrahydrocannabinol administration were estimated from the quotients of the rates of appearance of total radioactivity in the urine or bile, respectively, and the plasma concentrations of radiolabeled metabolites, $[M_p]$, where:

$$Cl_R = (\Delta U_T/\Delta t)/[M_p] \quad \text{(Eq. 15)}$$

and:

$$Cl_B = (\Delta B_T/\Delta t)/[M_p] \quad \text{(Eq. 16)}$$

where ΔU_T and ΔB_T are the amounts of radioactivity collected in an interval, Δt, and $[M_p]$ is the plasma concentration at the midpoint of the interval. These apparent clearances were plotted against the time at the midpoint of the collection interval, and typical examples are given for bile (Fig. 14) and urine (Fig. 15).

The maximum pseudo-renal clearances (Fig. 15) for Dogs A and B (5.5–8.4 ml/min at about 300 min) were similar, but those for Dog C were higher (17–21 ml/min). The pseudo-renal clearances did plateau after their decrease from the maximum during the 400–1200-min interval and then gradually decreased toward zero over the remaining 5000 min. The pseudo-biliary clearances (Fig. 14) for Dog C (80–100 ml/min) showed a maximum slightly earlier at 60 min but did plateau after their decrease during the 100–500-min interval and then gradually decreased to an apparent asymptote of 1–3 ml/min by 3000 min.

The initially low, but subsequently increasing, pseudo-renal and biliary clearances are consistent with an initial production of nonpolar metabolites that can be extensively reabsorbed back to plasma in the kidneys and liver. The fact that peak renal clearances are low (Fig. 15) implies high plasma protein binding of metabolites and/or their large tubular reabsorption. A glomerular filtration rate of 80 ml/min (18) and a 92% plasma protein binding of such metabolites, a fact substantiated in preliminary binding studies, could account for the observed low peak pseudo-renal clearances of 6.0–6.4 ml/min in Dog B (Fig. 15).

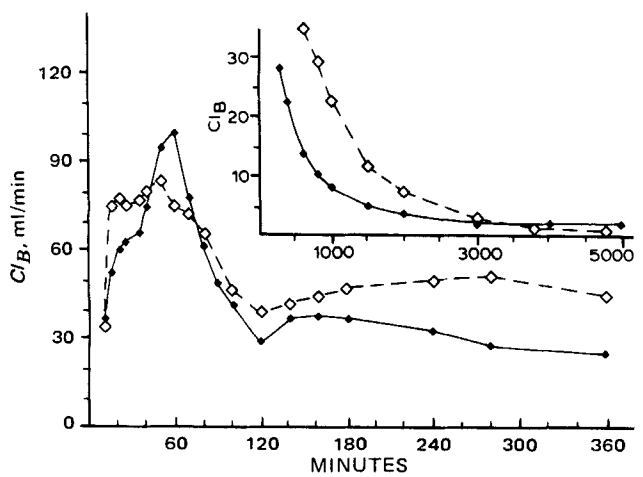

Figure 14—*Plots of the biliary clearance,* Cl_B, *against time for the 0.5- (♦) and 2.0- (◊) mg/kg iv doses in Dog C.* $Cl_B = (dB_T/dt)/[M_p]$, *where* dB_T/dt *and* $[M_p]$ *were estimated from data such as are given in Figs. 8 and 12, respectively.*

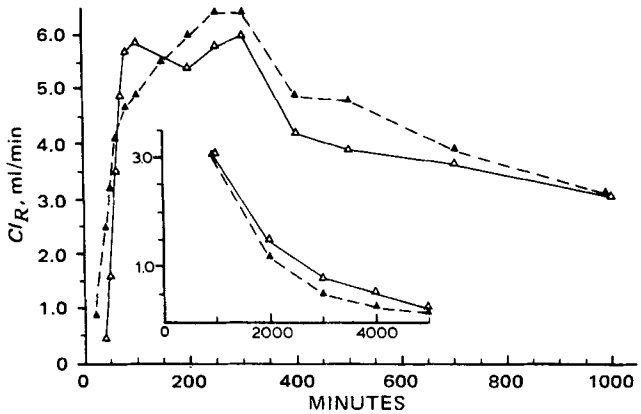

Figure 15—*Plots of the renal clearance,* Cl_R, *of total metabolites excreted in urine against time for the 0.5- (△) and 2.0- (▲) mg/kg doses in Dog B.* $Cl_R = (dU_T/dt)/[M_p]$, *where* dU_T/dt *and* $[M_p]$ *were estimated from data such as are given in Figs. 8 and 12, respectively.*

These observed differences in pseudo-clearances with time undoubtedly reflected changes in the metabolite composition of plasma where the approach to the maximum resulted from the transition from production of less polar, reabsorbable metabolites to those of higher polarity. The subsequent decrease resulted from the relatively rapid elimination of these more polar compounds, with a subsequently relatively higher retention and accumulation in the circulating fluids of less rapidly eliminated metabolites. The fact that over 88% of the biliary metabolites intravenously administered was eliminated by 300 min (Fig. 8) is confirmatory. It should be remembered that material, <10%, had been extracted by heptane before these metabolites had been administered. The general invariance of extraction characteristics for the metabolites in bile (Fig. 10) and urine (Fig. 11) in the 200–1000-min interval was consistent with the reasonable constancy of the pseudo-clearances (Fig. 14) in the same interval.

The subsequent slow decay to the lower asymptotic value achieved after 2000–3000 min can only be explained by the formation of a metabolite that is not further metabolized easily which is initially a small percent of the dose but is not readily biliary or renally excreted. Thus, at a later time, it accounts for an increasing percentage of the radiolabeled metabolites in the plasma until a new pseudo-steady state among metabolite components is reached at 3000 min. At this time, sufficient amounts of this metabolite have accumulated so that its formation rate is approximately equal to its elimination rate from the body. This is the achievement of the final pseudo-steady state when the rate-determining step for the overall elimination of Δ^9-tetrahydrocannabinol from the body is the slow return of the drug from the deepest tissues where it has been sequestered.

Pseudo-apparent volumes of distribution, V_m, of the metabolite formed on intravenous administration of Δ^9-tetrahydrocannabinol as a function of time (Fig. 16) can be calculated from the quotient of the amount of metabolites in the body, M_{in}, and the observed concentration of metabolites in the plasma, $[M_p]$ (Fig. 12). These M_{in} values were estimated from the differences between the predicted amount, M, of total metabolites produced (Eq. 13 and Fig. 6) and the total amounts of radiolabeled metabolites, M_{ex}, excreted in the bile and urine at a given time (Fig. 8) so that:

$$M_{in} = M - M_{ex} \quad \text{(Eq. 17)}$$

Thus:

$$V_m = M_{in}/[M_p] = (M - M_{ex})/[M_p] \quad \text{(Eq. 18)}$$

These pseudo-apparent volumes of distribution as a function of time depend on the calculated M values (Eq. 13) and, thus, the set of parameters chosen to describe the time course, $\hat{Y}$, of tetrahydrocannabinol in plasma. Curves A and B in Fig. 16 were calculated on the premises of the validity of Eqs. 6 and 5, respectively, where the former was based on presumption that the half-life of tetrahydrocannabinol elimination was reflected by the terminal half-life for total radioactivity in the body (Fig. 4). Support for this presumption was afforded by the fact that the estimated apparent volume of distribution, $(V_m)_{est}$, of the intravenously administered biliary metabolites (curve C) was the same 6 liters between

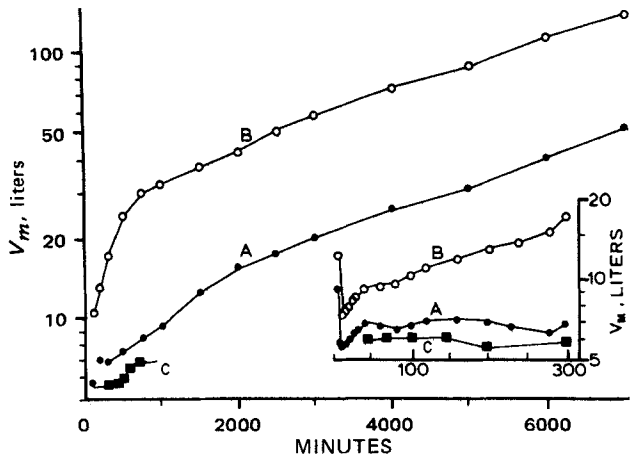

Figure 16—*Pseudo-apparent volumes of distribution of total metabolites for the intravenously administered biliary metabolites,* $V_{m_{est}}$ *(curve C), and those formed on intravenous administration of 0.5 mg of* Δ^9*-tetrahydrocannabinol/kg to Dog C,* V_m*. The calculations of* V_m *for curves A and B were based on the premise of the validity of Eqs. 6 and 5, respectively, for the* Δ^9*-tetrahydrocannabinol administration.*

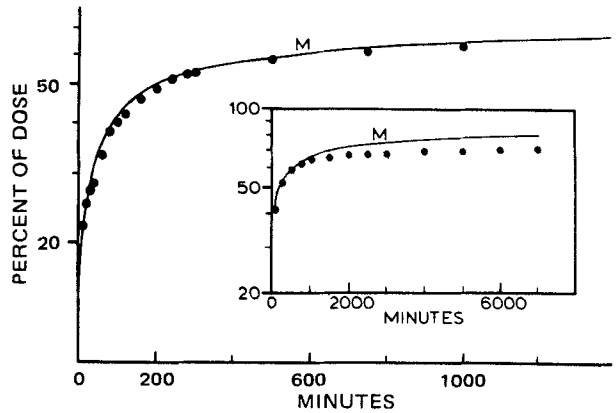

Figure 17—*Semilogarithmic plots of the total metabolites,* M, *produced as percent of dose against time for the 0.5-mg* Δ^9*-tetrahydrocannabinol/kg dose in Dog C. The values were calculated from Eq. 16 using an estimated pseudo-apparent volume of distribution,* $(V_m)_{est}$ *= 6.0 liters, and the drawn curve was calculated from Eq. 13.*

50 and 300 min as observed with curve A. These values were obtained from:

$$(V_m)_{est} = \frac{CPM_0 - CPM_{ex}}{[CPM]_p} \qquad \text{(Eq. 19)}$$

where CMP_0 is the total activity of the administered metabolites, CPM_{ex} is the total activity excreted in bile and urine at a given time, and $[CPM]_p$ is the concentration of activity per milliliter in plasma at that time.

The presumption of 6 liters as the apparent volume of distribution of metabolites should permit proper estimation of the cumulative total, M (Eq. 13), of metabolites produced:

$$M_{est} = (V_m)_{est}[M_p] + M_{ex} \qquad \text{(Eq. 20)}$$

if the composition of the metabolites comprising $[M_p]$ did not change significantly with time. The fact that M_{est} satisfactorily estimates M prior to 1000 min is clearly shown in Fig. 17. The deviations between them after 1000 min of approximately 10% at 7000 min are a consequence of the increase in the pseudo-apparent V_m (Fig. 16, curve A). This increase could have resulted from the accumulation in tissues of slowly eliminated nonpolar metabolites comprising less than 10% of the total metabolites formed, a fact consistent with: (*a*) the previous explanations of the observed declines in the apparent biliary and urinary clearances of total metabolites, (*b*) the fact that the biliary metabolites intravenously administered had 10% of the radiolabeled metabolites removed prior to administration and also had 88% of the administered dose eliminated by 300 min (Fig. 7), and (*c*) the fact that the fraction of the dose as metabolites in the body at 7000 min during the final pseudo-steady state was close to these 10% values (Table IV).

Significances and Implications of Observed Pharmacokinetics—The sequestration of administered Δ^9-tetrahydrocannabinol in deep tissues (Table IV) and its large retention over long periods produced a terminal half-life of approximately 8 days on acute dosing. Thus, there should be significant accumulation of drug on chronic administration. If daily chronic dosing is intravenously administered, a steady state of the amount of drug in the central compartment associated with the plasma results by approximately 7 days, oscillating between 0.03% of the daily dose at 3 hr after dosing and 2% at 24 hr after dosing. However, a steady-state oscillation of the amount of drug in the tissues is not achieved until after 30 days of chronic dosing and varies after each dose, from 450% of the single dose at 3 hr to 360% at 24 hr. The amounts in the tissues increase fivefold over that from a single dose at 7 days and 10-fold by 27 days. Thus, a pharmacodynamic response could increase with chronic dosing or be maintained for weeks after its cessation if tolerance did not develop.

The rate-determining step in drug elimination from the body, subsequent to the first several hundred minutes after administration, is not the rate of metabolism but the rate of return from deep tissues. Thus, it is unlikely that any claimed decrease (8, 12) in the apparent half-life for tetrahydrocannabinol in the plasma of chronic marijuana smokers relative to naive smokers could be a consequence of marijuana-induced enzymes. If this were the case, the relative plasma levels would change but not the terminal half-life of decay.

The calculated accumulation in tissues is consistent with the observations of Kreuz and Axelrod (11) that the drug accumulates in the body fat of rats after repetitive administration and implies that significant differences in the disposition and pharmacodynamics of tetrahydrocannabinol may be anticipated between lean and obese individuals. If the fat to lean ratio of the chronic marijuana smokers were higher than that of naive smokers, claimed apparent differences (12) in apparent plasma half-lives could be best explained as resulting from differences in the rates of return of plasma of the rate-determining release of drug from such lipophilic deep compartments.

11-Hydroxy-Δ^9-tetrahydrocannabinol, a metabolite of Δ^9-tetrahydrocannabinol (21–29), has similar pharmacological properties and could contribute to the total pharmacodynamic action. In fact, it was suggested (1, 30) that the action was primarily due to this metabolite, although other researchers did not reach the same conclusion (31–34).

Since the disposition and metabolism of the intravenously administered metabolite were claimed (32–34) to be similar to that of Δ^9-tetrahydrocannabinol, equivalent pharmacokinetic parameters may be assumed. It is on this premise that the scheme in Fig. 18 is based, where *PI* is considered to be the primary intermediate(s) in metabolism, including pharmacodynamically active metabolites such as 11-hydroxy-Δ^9-tetrahydrocannabinol that can be metabolized further. The analog computer-generated curves in Fig. 18 demonstrate the time course of the maximum amounts of *PI* as percent of dose in its central compartment

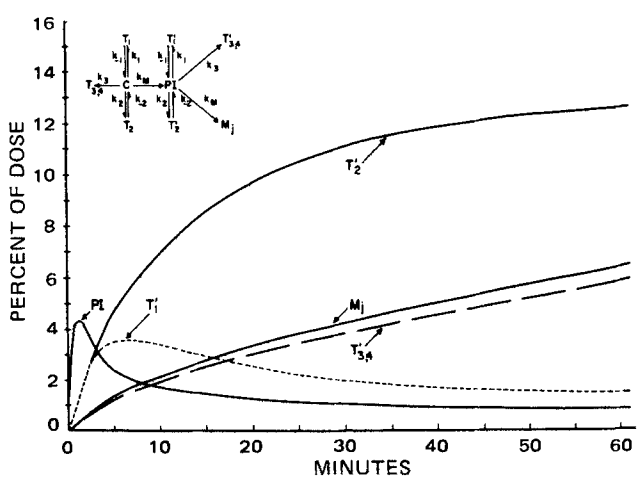

Figure 18—*Analog computer-generated curves of active metabolites,* PI, *which are primary intermediates in the metabolic sequence to* M_j *in the specified scheme for 60 min after intravenous administration of* Δ^9*-tetrahydrocannabinol in the 0.1-mg/kg study in Dog A. The generated* M_j *and tissue levels of* PI *in the tissues* T_1', T_2', *and* $T_{3,4}' = T_3' + T_4'$ *are also given.*

and in the various tissues, T_1', T_2', and $T_{3,4}'$, for 60 min after Δ^9-tetrahydrocannabinol administration. The time course of the amounts of the inactive metabolites, M_j, produced subsequently is also given. The ratios, R, of the amounts of PI to Δ^9-tetrahydrocannabinol in corresponding tissues approached asymptotes within these 60 min (compare Figs. 13 and 18). For example, T_1'/T_1 or PI/C approached one-half, whereas T_2'/T_1 or $T_{3,4}'/T_{3,4}$ approached lower values (one-fourth to one-third). Thus, PI would make the largest contribution to the observed activity if T_1 and T_1' were the biophases. Ryrfeldt *et al.* (6) observed R ratios in mice in blood and brain of this magnitude after intravenous administration of Δ^9-tetrahydrocannabinol.

Extant evidence from experimental animals (33) suggests that the relative potency, r, of 11-hydroxy-Δ^9-tetrahydrocannabinol to Δ^9-tetrahydrocannabinol ranges between 2 and 18; and if the central compartment and its rapidly equilibrating tissues, T_1 or T_1', are taken as the biophase, the contribution of PI to the observed pharmacological effect would be 50% at $r = 2$ and 90% at $r = 18$. If other tissues are the biophase, the contributions would be less.

However, these are maximum estimates since they are based on the premises that all PI produced in the liver is active and wholly returned to the plasma unchanged. This would not be so if PI were metabolized at the same rate as Δ^9-tetrahydrocannabinol. The fraction of the Δ^9-tetrahydrocannabinol entering the liver that left unmetabolized could be given by:

$$q = C_2/C_1 = e^{-\alpha T} \qquad \text{(Eq. 21)}$$

where α is the intrinsic first-order metabolic rate constant, and T is the time required for complete replacement of the liver blood volume, *i.e.*, the time of blood transit through the liver. The C_1 and C_2 are the concentrations in the plasma entering and leaving the liver, respectively. If the active metabolites are further metabolized to M_j with the same rate dependency, the rate of change in the amount of PI in the liver could be given by:

$$d(PI)_L/dt = \alpha V_L C_1 - \alpha(PI)_L \qquad \text{(Eq. 22)}$$

The fraction of the entering concentration, C_1, that retains its identity at the end of the interval, T, can be obtained by the integration (35) of Eq. 22 over the interval $t = T$ and is:

$$p = (PI)_L/V_L C_1 = \alpha T e^{-\alpha T} \qquad \text{(Eq. 23)}$$

where V_L is the apparent volume of distribution of the liver.

If the logarithms of both sides of Eq. 19 are taken:

$$\alpha T = \ln q \qquad \text{(Eq. 24)}$$

which may be substituted into Eq. 23. Equation 23 can be rearranged and divided by $1 - q$ to give the fraction of metabolites formed from Δ^9-tetrahydrocannabinol in the liver that remain as PI on exit from the liver:

$$p/(1 - q) = q \ln q/(q - 1) \qquad \text{(Eq. 25)}$$

Since the apparent metabolic efficiency of tetrahydrocannabinol, $q = C_2/C_1$, is 0.5, only 69.3% of the PI formed in the liver would exit from this organ. Thus, if the central compartment is taken as the biophase for a relative potency of 2, the estimated ratio of amounts therein at 60 min becomes 0.35 rather than 0.5, and the contribution of PI to the observed pharmacological effect would be 41% rather than the 50% estimated if PI is not metabolized further during its passage through the liver prior to its return to the plasma.

On the basis of this discussion, an appropriate model for the pharmacokinetics of Δ^9-tetrahydrocannabinol is given in Fig. 18 on the premise that PI has pharmacokinetic properties similar to its precursor, where PI and M_j appear to be produced in parallel rather than sequentially when Δ^9-tetrahydrocannabinol is supplied continuously to the liver. When the hepatic efficiency, $q = C_2/C_1$, is small, negligible PI would be formed by the route designated with the microscopic rate constant $k_m[1 - p/(1 - q)]$. Even if PI were 20 times more potent than tetrahydrocannabinol, it could account for a maximum of only 30% of the observed response for a central compartment biophase when $q = 0.01$. The contribution of PI-type active metabolites, such as 11-hydroxy-Δ^9-tetrahydrocannabinol, to the observed pharmacological response of its precursor cannot be resolved until the true biophase is ascertained, their unique metabolic efficiencies are known, and the true relative potencies are determined.

Effects of ^{14}C-Label Position on Pharmacokinetics of ^{14}C-Δ^9-Tetrahydrocannabinol—Although the differently labeled ^{14}C-Δ^9-tetrahydrocannabinol in plasma, when radioactivity of the separated compound was monitored with time, showed the same pharmacokinetics (Fig. 6), this was not so for total concentrations of radioactivity in plasma (Fig. 3) where the C-11-labeled drug showed significantly less plasma concentration per unit dose than the 1,3-ring-labeled drug at comparable times. A definite conclusion that metabolites tend to lose the C-11 group, as through decarboxylation of C-11 carboxylic acid metabolites, is clouded by the fact that the studies were conducted in biliary-cannulated Dog C where different bile flows had a pronounced effect on biliary excretions of the two studies (Fig. 2).

However, the total percents of dose excreted into bile for the differently labeled tetrahydrocannabinols were equivalent, although the metabolite derived from C-11-labeled drug showed less of a percentage excreted in the urine and totally excreted than the ring labeled. Nevertheless, the variation in total radioactivity as percent of dose excreted for the two differently labeled compounds in Dog C at the two different doses was not significantly different from the variation in total radioactivity as percent of dose excreted for the two studies at different doses of 1,3-^{14}C-Δ^9-tetrahydrocannabinol in Dog B (Fig. 5), where the relative amounts recovered in feces accounted for the latter's variability. Thus, the null hypothesis that there were no significant differences between the pharmacokinetics in the dog of the radiolabeled compounds derived from the two differently labeled Δ^9-tetrahydrocannabinols cannot yet be rejected.

Determination of Porosity and Pore-Size Distribution of Aspirin Tablets Relevant to Drug Stability

H. GUCLUYILDIZ *, G. S. BANKER, and G. E. PECK x

Abstract □ Total porosity and pore-size distribution of aspirin tablets prepared from aspirin, starch USP, and precipitated colloidal silicon dioxide were determined using mercury porosimetry. The model represented a hydrolyzable drug substance in combination with simple excipients. The role of starch and silicon dioxide on the microstructure of the tablets was investigated, as was the chemical stability of various systems. In general, the porosity of tablets containing a constant quantity of starch increased linearly with silicon dioxide concentration. Examination of the pore-size distribution, however, revealed that at low concentrations silicon dioxide functioned primarily to reduce the size and volume of coarse pores representing the spaces between the agglomerates of starch and aspirin particles. This effect was optimum at 3%. A further increase in silicon dioxide concentration produced tablets with relatively larger pore sizes. Studies of changes in the porosity characteristics of tablets as influenced by water vapor over time showed distinct differences in this complex parameter. A unique trend in the change of the pore-size distribution was noted with tablets containing 3% silicon dioxide. These observations are discussed relative to the stability of aspirin tablets in which this concentration of silicon dioxide produced a maximum stabilizing effect.

Keyphrases □ Aspirin—tablets, stability, porosity and pore-size distribution determined, effect of colloidal silicon dioxide □ Porosity and pore-size distribution—aspirin tablets, effect of colloidal silicon dioxide □ Stability—aspirin tablets, porosity and pore-size distribution determined, effect of colloidal silicon dioxide □ Silicon dioxide, colloidal—effect on stability of aspirin tablets, porosity and pore-size distribution determined □ Dosage forms—aspirin tablets, stability, porosity and pore-size distribution determined, effect of colloidal silicon dioxide

In any systematic and fundamental approach to the design of solid dosage forms, a comprehensive elucidation of the physical characteristics of the solid components is necessary and basic. Knowledge of the physical nature of solid pharmaceutical systems is often confined to determinations of such properties as particle size, particle-size distribution, and true and bulk density. To relate the disintegration, dissolution, and stability characteristics to meaningful physicochemical parameters, a direct examination of the porosity characteristics also may be essential.

The pharmaceutical and chemical literature clearly documents that the pore-size distribution of solids is frequently among the controlling variables in processes involving disintegration, dissolution, adsorption, and diffusion. In tablet disintegration and dissolution, the initial stage is probably typically the penetration of the solvent medium into the tablet through the tablet pore system. The solvent penetration rate, in turn, was shown to be intimately related to the volume and size of tablet pores (1–6). From the standpoint of tablet stability, especially when dealing with hydrolyzable drugs, a physical description of the porous state of tablets may be important, since porosity and pore-size distribution affect the diffusion of water vapor and the accessibility of condensed vapor to the labile drug.

Studies on the porous nature of tablets have been conducted with increasing frequency recently (7). Porosity characteristics of tablets are primarily influenced by compression as a result of fragmentation, deformation, and consolidation of particles. Additional factors include particle size, particle shape, and the compressibility of particles (5, 6, 8).

As evident from review articles, the stability of aspirin in the solid state was the subject of numerous studies (9, 10). Many adjuvants have been proposed to enhance aspirin stability. Studies in these laboratories showed that inclusion of precipitated colloidal silicon dioxide into tablets prepared from aspirin and starch significantly improved aspirin stability. The maximum stabilizing effect of silicon dioxide occurred at 3%. Above this level, a continuous decrease in the stability of aspirin was observed. Although the major mechanism of this effect may be the large adsorptive capacity of silicon dioxide which functions as an internal tablet desiccant, an evaluation of tablet porosity characteristics may add significant dimensions in the interpretation of the physicochemical phenomena involved in aspirin decomposition.

The present study was undertaken to determine the influence of colloidal silicon dioxide on the porosity and pore-size distribution of aspirin tablets using mercury

[a] Determined by displacement of mercury at 1.6 psia.

porosimetry. Of major interest were the structural changes that occur in tablets under the influence of water vapor. On the basis of these observations, the role played by silicon dioxide was assessed and, inferentially, extended to the general utility and significance of pore-size distribution measurements in compressed pharmaceutical systems.

EXPERIMENTAL

Materials—Aspirin USP (200–250-mesh powder), starch USP (80 mesh), and an experimental precipitated colloidal silicon dioxide meeting NF specifications were used in the preparation of aspirin tablets. Before use, starch and silicon dioxide were pretreated for about 12 hr by evacuation in a vacuum oven at 60 and 150°, respectively. The nitrogen surface areas of these substances were determined by the Brunauer, Emmett, and Teller (BET) method (11) using a commercially available instrument[1]. The corresponding values were 0.6 m^2/g for starch and 556 m^2/g for silicon dioxide. The true density measurements were performed by a helium-displacement technique utilizing the instrument[1] employed in the BET surface area determinations. The following values were obtained: aspirin, 1.40 g/ml; starch, 1.59 g/ml; and silicon dioxide, 2.29 g/ml.

Tablet Preparation—Several tablet formulations with various silicon dioxide concentrations (0, 1, 3, 5, 10, and 15%) were prepared. Each tablet contained 23 mg of starch in addition to the total aspirin–silicon dioxide content of 460 mg. Silicon dioxide concentrations were expressed on the basis of a 460-mg tablet weight, excluding the weight of starch. Tablets also were made from aspirin powder alone to serve as control samples. The components for 10 tablets of each formulation were weighed and mixed for 15 min in a miniblender of approximately 20-g capacity. The miniblender consisted of a V-shaped shell fabricated from clear plastic prescription bottles and was operated at 14 rpm by a motor.

An accurately weighed quantity of the powder mixture was then placed in a 12.7-mm flat-faced punch and die set and compressed at a calculated punch face pressure of 15.3×10^3 psi between the plates of a hydraulic press[2]. The weight of the compressed sample was again determined, and the tablet dimensions were measured with a micrometer. These physical measurements assured compliance of each tablet to identical compression conditions for consecutive samples and allowed the calculation of the apparent volume of the tablet.

To evaluate the chemical stability of tablets and the changes in their porosity characteristics with time, a relative water vapor pressure of 0.82 and a temperature of 40° were selected as the storage conditions. Constant relative pressure was maintained in a desiccator by a saturated potassium chloride solution (12). Samples were placed in the desiccator and stored in an oven until testing.

Evaluation of Porosity and Pore-Size Distribution—The total porosity of a tablet was determined from its apparent volume, its weight, and the true density of the individual tablet components. Pore-size distribution determinations were performed by intrusion of mercury using a commercial porosimeter[3] with a pressuring capacity of 15,000 psi. Approximately 20 increments of pressure were recorded in a typical determination, allowing sufficient time at each pressure for mercury to reach equilibrium in the sample. Equilibrium was assumed to have been reached when the liquid ceased penetration into the sample or penetrated at a rate of not more than 0.0001 ml/min.

In the derivation of pore-size distribution from basic intrusion data, the equation derived by Washburn (13) was used. The surface tension of mercury was taken to be 484 dynes/cm at 24°, the temperature of the measurements, as the best available value (14, 15). In the absence of specific data for the contact angle between mercury and the samples studied, this value was assumed to be 130°, a value commonly used for most solids (16, 17). Appropriate corrections were applied for the compressibility of mercury and of the residual air entrapped in the penetrometer in the initial evacuation step. Any volume change due to the compressibility of the sample itself was considered negligible. A correction factor for effective compressibility of mercury was determined by measuring the effect of applied pressure on the penetrometer (sample cell) filled entirely with mercury, *i.e.*, without any sample being present. Under the experimental conditions, the required corrections did not exceed 0.0075 ml. A description of the pore-size distribution calculations is presented elsewhere (18).

Evaluation of Aspirin Stability—The residual aspirin content of the tablets was determined by a spectrophotometric method (19). Basically, this procedure was based on a simultaneous determination of aspirin with salicylic acid in a pH 7.0 buffer solution at 296.5 and 262 nm.

RESULTS AND DISCUSSION

Effect of Silicon Dioxide on Porosity Characteristics—The results of pore volume and porosity determinations of aspirin tablets prepared with varying concentrations of silicon dioxide are outlined in Table I. The data are based on calculations from tablet dimensions and on results of mercury intrusion studies. The pore volume determined by intrusion of mercury represents the volume of pores in the pore radius range of about 60–0.006 μm. These limits of measurable pore radius are imposed by the pressure used in the initial introduction of mercury to the sample and by the maximum pressuring capacity of the instrument.

The close agreement seen in Table I between the measurements of apparent and displacement volumes of tablets shows that pores with radii larger than 60 μm were absent. The pore-size range determined by mercury intrusion represents virtually all of the pore volume present. The pore volume calculated to be present but remaining unintruded by mercury, in fact, constitutes an overestimate of the volume of pores smaller than 0.006 μm in radii. This unintruded volume also includes:

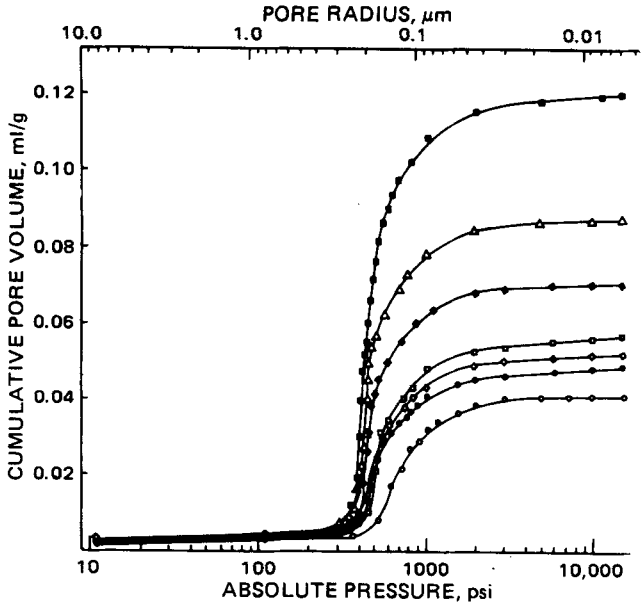

Figure 2—*Cumulative pore-size distribution of aspirin tablets containing various silicon dioxide concentrations. Key:* ○, *control;* ●, *0%;* ◇, *1%;* □, *3%;* ◆, *5%;* △, *10%; and* ■, *15%.*

(*a*) the volume of pores with radii larger than 0.006 μm but accessible to mercury only through smaller openings, and (*b*) the volume of pores that may be completely isolated from the pore network in the tablets. The total measured porosity (Table I) is in excellent agreement with the porosity calculated from the apparent volume and the true volume (Table I). However, the pore sizes determined by the mercury intrusion method represent the size of pore openings rather than the actual size of the pores.

A comparison of tablet porosity results given in Table I reveals that the total porosity of tablets prepared from aspirin only (control) was slightly lower than that prepared with 0% silicon dioxide. Since the latter formulation contained starch (5% of the total aspirin–silicon dioxide content), starch apparently did not alter significantly total tablet porosity under these compression conditions. On the other hand, the major effect of silicon dioxide on the porosity characteristics of aspirin tablets, containing a constant 5% level of starch, was immediately evident as a consistent increase in the total porosity with silicon dioxide concentration (Fig. 1). Despite its smaller specific volume, silicon dioxide contributed to the porosity of tablets to a greater extent than aspirin.

The manner by which silicon dioxide alters the porosity characteristics of aspirin tablets can best be inferred by examining the pore-size distribution of the samples shown in Fig. 2, where the cumulative pore volume intruded by mercury is plotted *versus* the pressure applied on the sample. The corresponding pore radius is also indicated on the upper abscissa. The data are presented in the form of a cumulative distribution function, which has the advantage that the fraction of pore volume between any arbitrary bounds of pore radii can be quickly assessed. The sigmoid shape of the cumulative distribution curves is characteristic of this determination. Although the pore-size measurements were originally made starting from a pore radius of about 60 μm, almost negligible intrusion was observed in the pore-size range of 60–10 μm. Therefore, these portions of the curves were omitted from the graph. The experimental points shown represent the average of at least two separate determinations. The reproducibility of the data was excellent.

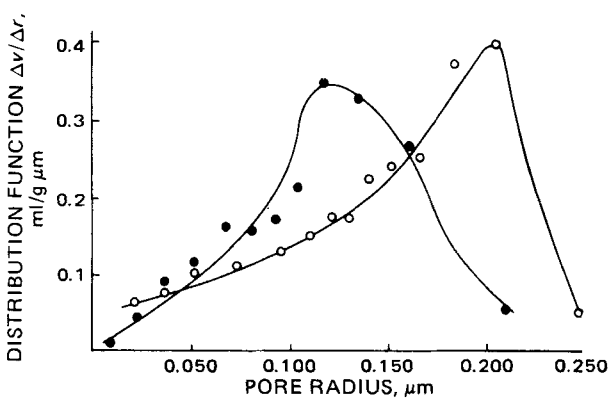

Figure 3—*Pore-size distribution of aspirin tablets. Key:* ●, *aspirin (control); and* ○, *aspirin with 5% starch (0% silicon dioxide).*

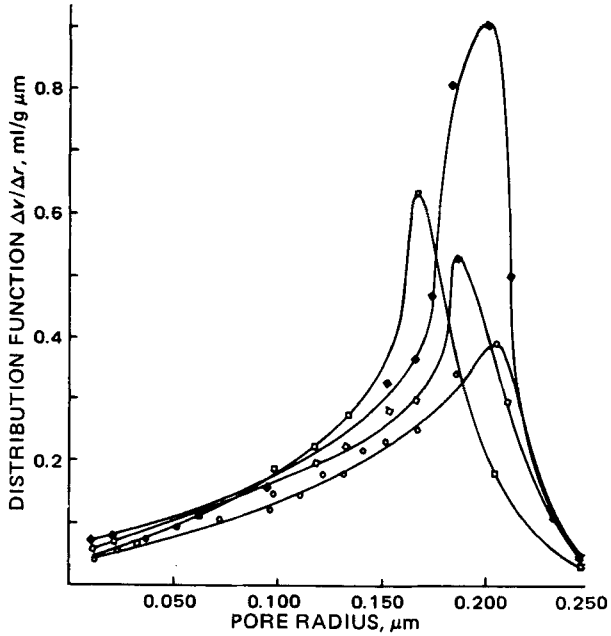

Figure 4—*Pore-size distribution of aspirin tablets containing various silicon dioxide concentrations. Key:* ○, *0%;* ◇, *1%;* □, *3%; and* ◆, *5%.*

Inspection of Fig. 2 shows the absence of significant pore volume for pores larger than about 0.2 μm followed by an abrupt upward trend, indicating that the distribution of pores was confined over a relatively narrow size range in all formulations. A greater portion of the pore volume was in the lower pore-size region as the silicon dioxide concentration increased. Judging from the slopes of the curves toward the lower pore-size limit of the instrumentation employed, essentially all of the pore volume present in tablets existed in accessible pores larger than 0.006 μm in radii.

The distribution curves display an apparent threshold radius characterized by a sudden, significant intrusion of mercury into the tablet pore system. The threshold radius may represent the minimum radius of pores that are essentially continuous throughout the tablet.

An alternative way of examining the results is to present the distribution curves as the derivative distribution function, *i.e.*, differential or derived pore-size distribution curves. Figures 3–5 represent typical distribution curves for the aspirin tablets investigated. The pore system developed in each formulation had a simple continuous distribution of pores. The pore-size distribution of tablets was drastically altered by the addition of 5% starch to the tablets, as judged from the shift in the maximum frequency toward a greater pore radius (Fig. 3). Apparently, starch promotes a tablet pore system characterized by a relatively larger size and volume of coarser pores. This observation seems to be rather significant in view of the fact that the influence of starch to total porosity is not quite so pronounced (Table I).

On the other hand, tablets containing 1% silicon dioxide in addition to starch showed a pore-size distribution with a maximum frequency at a smaller pore size (Fig. 4) than the tablets prepared from aspirin and starch only. This trend continued upon further addition of silicon dioxide, *i.e.*, up to 3%, but it was reversed at higher levels of silicon dioxide (Figs. 4 and 5). When the silicon dioxide concentration exceeded 3%, the general distribution moved consistently to relatively larger pore sizes with increasing silicon dioxide concentration. This concentration appeared to be rather characteristic, since the observed maximum frequency corresponded to the smallest pore size among tablets containing various silicon dioxide concentrations.

The major differential effect of incorporating silicon dioxide in the formulations was to decrease the size of coarser pores (Figs. 4 and 5). At a concentration level of 5%, the pore size corresponding to the maximum frequency of the distribution approached that of tablets containing no

silicon dioxide (Fig. 4). This finding suggests that the process of reduction in pore size by the addition of silicon dioxide was essentially completed at 3% silicon dioxide.

The aforementioned observations may be explained by considering that the small silicon dioxide particles were capable of filling the coarse interparticle voids developed by starch. Although the net effect of the presence of silicon dioxide in the formulations was to increase the total pore volume of tablets, in fact, silicon dioxide reduced the size and volume of coarser pores at low concentrations. This phenomenon is not at all in contrast with what is expected. From the value of the BET nitrogen surface area (556 m^2/g) and knowledge of the density of silicon dioxide (2.29 g/ml), it can be shown that the volume–surface diameter of spherical silicon dioxide particles corresponds to 4.7 nm. As compared to the size of aspirin and starch particles, which lie in the micrometer range, it does not appear unusual that silicon dioxide particles can easily undergo such a packing arrangement at low concentrations so as to limit the size of coarser pores.

In discussing the pore-size distribution of aspirin tablets, attention also must be focused on the compression characteristics of the tablet components. The absence of coarse pores in tablets prepared from aspirin powder alone can be attributed to relatively superior compressibility as well as deformability of aspirin particles. On the other hand, the development of coarser pores with formulations containing starch reflects the poor ability of this material to bond and compress. Similarly, the trend toward larger pore sizes with increasing silicon dioxide concentration presumably results from the resistance of silicon dioxide particles to consolidation during the compaction process.

Changes in Porosity Characteristics of Aspirin Tablets with Time—The susceptibility of the porosity characteristics of aspirin tablets to various changes with time is presented in Figs. 6–12 in the order of increasing silicon dioxide content. These figures depict the cumulative pore-size distribution of the samples exposed to a relative water vapor pressure of 0.82 at 40° for various times. The volume parameter is expressed in milliliters of pore space intruded by mercury per gram of sample previously outgassed in a vacuum oven at room temperature.

The mercury intruded pore volume of aspirin tablets (control) decreased consistently with increasing exposure to water vapor (Fig. 6). On the other hand, comparison of the distribution curves of the tablet for-

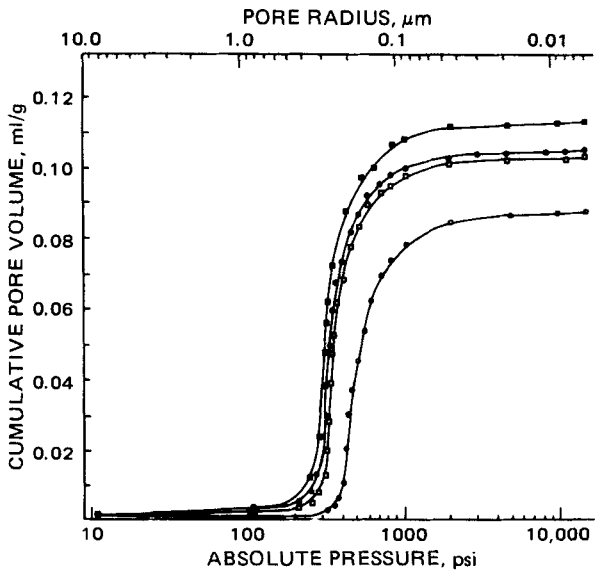

Figure 11—*Cumulative pore-size distribution of aspirin tablets containing 10% silicon dioxide after exposure to a relative water vapor pressure of 0.82 at 40° for various periods. Key: ○, 0 month; □, 1 month; ●, 3 months; and ■, 5 months.*

mulation containing 0% silicon dioxide (Fig. 7) shows that the pore volume first increased on 1 month of exposure to water vapor and then decreased. This initial increase in the pore volume on exposure of the samples to water vapor for 1 month can also be seen by inspection of Figs. 8–12, which represent the cumulative pore-size distribution of aspirin tablets containing 1, 3, 5, 10, and 15% silicon dioxide. Further changes that occurred with time in the measured pore volume and the pore-size distribution differed depending on the silicon dioxide content of the samples.

At the end of 3 months, samples containing 1, 5, 10, and 15% silicon dioxide (Figs. 8 and 10–12) displayed additional increases in the pore volumes intruded by mercury, whereas the measured pore volume of the tablets having 3% silicon dioxide (Fig. 9) actually decreased with respect to the volume determined at the end of 1 month. Examination of the samples exposed to water vapor over 5 months revealed that the pore volumes of the tablets containing 5, 10, and 15% silicon dioxide continued to increase (Figs. 10–12) and those of the tablets having 3% silicon dioxide showed a further decrease (Fig. 9). Interestingly, as opposed to the previously observed trend that the mercury-intruded volume of tablets with 1% silicon dioxide increased with time, these samples appeared to have smaller pore volumes at the end of 5 months (Fig. 8).

Attention can be focused more sharply on these results with reference to Table II, where the values for the total pore volumes intruded by mercury are expressed as the percent of those obtained with corresponding samples not subjected to water vapor. The data may be explained as follows. When aspirin tablets are subjected to water vapor, water vapor is adsorbed on the surfaces of the tablet components. Since the tablet matrix is porous, and the relative pressure of water vapor is high enough for capillary condensation to occur, it is reasonable to expect that adsorption is accompanied by condensation of vapor to liquid in the small pores of the tablet. The quantity of water vapor adsorbed and subsequently condensed invariably depends on the adsorptive capacity of the particular formulation, which, as was experimentally confirmed, increases consistently with silicon dioxide concentration. Once the water vapor enters the tablet, decomposition of aspirin results, giving acetic acid and salicylic acid as the decomposition products. Acetic acid is highly volatile, but salicylic acid is partly sublimed through the tablet, as evidenced by the appearance of the crystals of this material on the sample

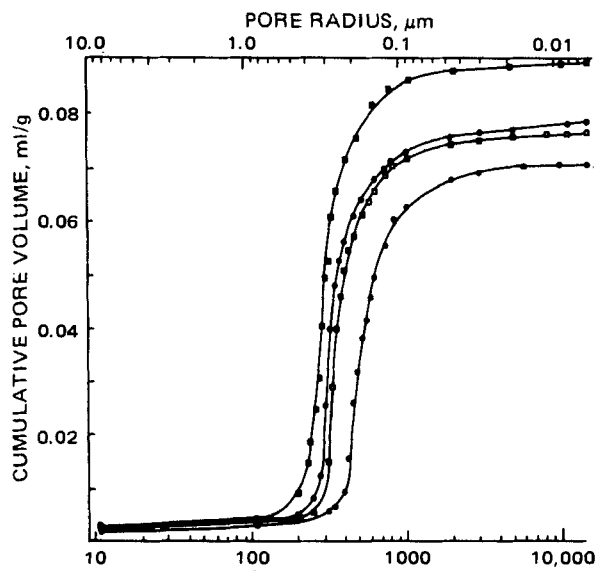

Figure 10—*Cumulative pore-size distribution of aspirin tablets containing 5% silicon dioxide after exposure to a relative water vapor pressure of 0.82 at 40° for various periods. Key: ○, 0 month; □, 1 month; ●, 3 months; and ■, 5 months.*

Table II—Percent Pore Volume Ratios of Aspirin Tablets Exposed to a Relative Water Vapor Pressure of 0.82 at 40° for Various Periods

Silicon Dioxide Concentration, %	Pore Volume Ratio after Indicated Period of Exposure, %		
	1 Month	3 Months	5 Months
Control	86.2	82.5	79.3
0	116.8	104.2	100.7
1	121.9	124.7	117.9
3	112.8	109.5	105.5
5	110.7	111.3	126.4
10	111.6	117.9	124.5
15	110.0	117.1	129.1

surface. A substantial portion of salicylic acid, however, is undoubtedly deposited in the pore system of the tablets. This result is evident from Table II, which shows a continual reduction with time in the pore volume ratios of control samples prepared from aspirin only.

Aside from influencing the porosity and pore-size distribution of the samples by causing chemical changes, water vapor also affects these parameters by physically altering the arrangement of pore spaces between the particles of the tablet components. The presence of starch in the formulations significantly increased their porosity, as reflected clearly by the increase in the pore volume ratios of the samples exposed to water vapor for 1 month (Table II). This result is naturally due to the swelling of starch grains upon penetration of water vapor into the tablet, which, in turn, distorts the arrangement and size distribution of pores. After exposure to water vapor for 1 month, tablets containing the lowest silicon dioxide concentration (1%) exhibited the maximum increase in pore volume. Further addition of silicon dioxide to the tablet formulations resulted in the reduction of the pore volume ratios with respect to this value. However, when the silicon dioxide concentration exceeded 3%, the pore volume ratios were essentially unaffected by silicon dioxide concentration. This trend presumably reflects the fact that the presence of silicon dioxide in tablets at concentration levels of 3% or above restricts the access of water vapor to starch in the tablet so that the swelling of this material is impeded.

Examination of the pore volume results obtained at the end of 3 months (Table II) shows that the samples containing starch but no silicon dioxide had a smaller pore volume ratio than that of corresponding samples analyzed after 1 month of exposure to water vapor. The deposition of salicylic acid in the tablet pores becomes the important factor in affecting the volume as well as the distribution of pores. Further reduction in the pore volume occurred when identical samples were exposed to water vapor for 5 months.

The situation, however, is quite different for tablets containing silicon dioxide, with the notable exception of tablets with 3% silicon dioxide. The data obtained at the end of 3 months show that the pore volume ratios of the samples with silicon dioxide were higher than their respective values determined after 1 month of exposure to water vapor. The divergence observed with samples containing 3% silicon dioxide indicates that in this particular formulation of the two opposing factors influencing porosity, *i.e.*, swelling of starch grains and deposition of salicylic acid in the pores, the latter predominates. Inspection of data resulting from the analysis of tablets at the end of 5 months showed that at the 3% silicon dioxide level the pore volume ratios continued to decrease. At this stage, a similar pattern is also evident with tablets containing 1% silicon dioxide.

Table IV—Stability of Aspirin Tablets under a Relative Vapor Pressure of 0.82 at 40°

Silicon Dioxide Concentration, %	Undegraded Aspirin after Indicated Period, %			
	1 Month	2 Months	3 Months	4 Months
Control	95.0	94.4	93.6	93.3
0	95.1	94.5	93.9	93.6
1	98.9	98.6	—	98.1
3	99.1	99.4	—	99.0
5	97.6	97.0	97.0	96.7
10	97.8	96.4	—	—
15	96.7	95.5	94.3	93.6

However, the increase in the pore volume ratios at higher silicon dioxide concentrations indicates that the effect of swelling of starch grains is more pronounced in these formulations. This suggests that the presence of a higher silicon dioxide content not only favors the adsorption of greater quantities of water vapor, but also as a result of this, the water vapor recedes from the silicon dioxide surface as it approaches the liquid state and becomes available for hydration of starch.

In discussing the changes in the pore characteristics of aspirin tablets with time, changes taking place in the pore sizes of the various formulations should also be considered. Therefore, the values of pore radii that may be used to characterize the pore-size distribution of aspirin tablets investigated are presented in Table III. With the exception of the control tablets, there was a general tendency for the pore sizes to attain greater values with increasing exposure of samples to water vapor. This observation is in accord with ordinary expectations based on the pore volume changes of the tablets. For a given formulation, the numerical change was the greatest between the untreated samples and samples exposed to water vapor for 1 month and diminished at longer periods of exposure. The trends evident in Table III are consistent with those obtained while considering the changes in the pore volume (Table II).

Table III also shows that the agreement between respective values of r_{med}, median pore radius, and r_{mode}, radius corresponding to the maximum frequency of pores in the sample, was reasonably close and that the pattern of change in their values was somewhat similar. Furthermore, after any period of exposure to water vapor, except for control tablets, samples containing 3% silicon dioxide exhibited the smallest values for r_{med} and r_{mode}. This finding reflects the apparent ability of this particular formulation to retain its unique feature irrespective of relative changes in the size and volumes of pores.

Interpretation of Stabilizing Properties of Colloidal Silicon Dioxide in Hydrolytic Decomposition of Aspirin—The pore-size distribution results discussed previously clearly indicate that this parameter is of significant value in following the microstructural changes that occur in aspirin tablets as a result of exposure to water vapor. Furthermore, the examination of such changes sheds considerable light on the stabilizing properties of silicon dioxide in the hydrolytic decomposition of aspirin in tablets (Table IV).

The results obtained from a direct examination of the changes in porosity characteristics indicate that the desiccant effect of silicon dioxide apparently was not the only factor favoring aspirin stability in these formulations. The pore volume data (Table II) indicate that the presence of silicon dioxide in the tablets did not preclude the access of water vapor to starch. Water vapor continued to be available for aspirin hydrolysis. The availability of water vapor to starch and, presumably, to aspirin was

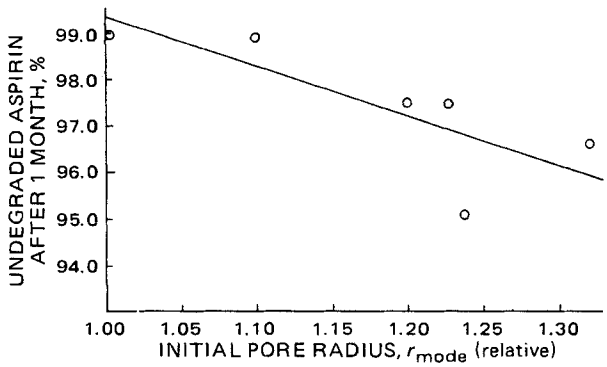

Figure 13—*Relationship between aspirin stability and pore size.*

not a simple function of silicon dioxide concentration in the tablets studied. Undoubtedly, the precise mechanism by which silicon dioxide affected the stabilization of aspirin did not involve the simple retention of water vapor by silicon dioxide to limit the availability of water vapor to aspirin *per se*. A complex combination of factors was possibly responsible for the optimum stability observed at the 3% silicon dioxide concentration.

Aspirin decomposition in tablets involves a heterogeneous reaction, the rate of which may be controlled both by diffusional processes and the hydrolytic reaction at the unreacted aspirin surface. The two general diffusional processes of importance include the diffusion of water vapor into the tablet and the transfer of salicylic acid in and out of the tablet pores. As the present experimental data verify, salicylic acid is deposited in the tablet pore system. In this process, salicylic acid may easily form a protective layer on the aspirin surface, which, in turn, results in slow diffusion of water vapor through this layer. It is also possible to conceive that the hydrolytic reaction may approach an equilibrium state. In either event, the aspirin degradation rate becomes diffusion controlled, and the complex internal pore structure and the nature of individual pores may become determining factors in the accessibility of water vapor to the aspirin surface. The characteristic pore-size distribution pattern observed with tablets containing 3% silicon dioxide may, therefore, be helpful in interpreting the relatively small extent of aspirin degradation in this formulation.

To determine whether a simple correlation existed between aspirin stability and the pore size attained in the formulations, the stability results shown in Table IV were plotted against the values of r_{mode}, the pore radius corresponding to the maximum frequency of pores in the tablet. The trend representing aspirin stability at the end of 1 month as a function of initial pore size is illustrated in Fig. 13, where r_{mode} is expressed in normalized form relative to that of the tablets having the smallest pore size (Table III). Figure 13 shows that aspirin stability is apparently related to the initial pore size.

An extension of the relationship seen in Fig. 13 to stability data over longer periods did not appear feasible, because of the complexity of the interactions of various variables involved in aspirin stability. When a similar plot was prepared for the 3-month data, for example, the trend remained the same, but the correlation was relatively poor. The deviation occurred primarily due to the formulation containing 1% silicon dioxide, which had relatively greater stability despite the larger pore size attained in this formulation with time (Table III).

This apparent lack of direct correlation between aspirin stability and pore size suggests that the water vapor accessible to starch is not equally available to the aspirin surface. Presumably, at low silicon dioxide concentration, starch itself retains the water vapor, resulting in its greater hydration and an increased pore volume and pore size in the tablets. With increased silicon dioxide concentration, however, starch grains are isolated from each other; silicon dioxide adsorbs the water vapor to a greater extent, since it has a much larger surface area and greater adsorption capacity than starch.

Another explanation that may be offered for the slower decomposition of aspirin in formulations containing low silicon dioxide concentrations may be related to the effect of salicylic acid on the system. As pointed out previously, a protective layer of salicylic acid is probably formed on the aspirin surface to control further the access of water vapor to the aspirin. Additionally, the deposition of salicylic acid in the tablet pore system at low silicon dioxide concentrations (Tables II and III) decreases the pore volumes and sizes with longer periods of exposure to water vapor. With formulations containing silicon dioxide levels higher than 3%, the accessibility of water vapor to aspirin is expected to be much greater. This is attributed to the fact that the increased silicon dioxide concentration favors the adsorption of greater quantities of water vapor which recede from the silicon dioxide surface with time as it approaches the liquid state and becomes available for aspirin degradation. The superior adsorptive capacity of these formulations and the favorable pore size may simultaneously operate to facilitate the access of water to unreacted aspirin surfaces. The transfer of salicylic acid also may be enhanced because of the greater pore sizes. This point is evidenced simply by the physical appearance of the tablets, which showed more localized salicylic acid crystals on the external surfaces consistent with increasing silicon dioxide content.

Finally, none of the aforementioned factors, *i.e.*, the superior water vapor adsorptive capacity of silicon dioxide, sublimation of salicylic acid, and the distinct pore size distribution of each formulation, can alone be directly related to the differences in the stability of aspirin at various silicon dioxide levels. However, the present observations along with the foregoing discussion promote additional insight into the stabilizing properties of silicon dioxide in aspirin degradation. It should also be evident that pore-size distribution can be a very useful parameter in interpreting aspirin stability in compressed pharmaceutical systems.

SUMMARY AND CONCLUSIONS

1. The influence of colloidal silicon dioxide on the porosity characteristics of aspirin tablets containing a constant quantity of starch was investigated. The porosity of the samples prepared under constant compression conditions increased linearly with silicon dioxide concentration.

2. Pore-size distribution determinations by mercury intrusion allowed a complete elucidation of the microstructural changes produced by the inclusion of silicon dioxide. At low concentrations, silicon dioxide functioned primarily to reduce the size and volume of coarser pores, presumably representing the spaces between the aggregations of starch and aspirin particles. This effect was optimum at 3%.

3. An assessment of the changes in the pore-size distribution patterns occurring under the influence of water vapor revealed distinct differences in this parameter as functions of the silicon dioxide concentration and the period of exposure to water vapor. These results were explained in terms of the accessibility of water vapor to tablet components.

4. A unique trend in the change of pore-size distribution was noted with tablets containing 3% silicon dioxide. Irrespective of relative changes in the size and volume of pores as a result of swelling of starch grains and the deposition of salicylic acid in the tablet pore system, this formulation consistently exhibited the smallest average pore size among the tablets containing several concentrations of silicon dioxide.

5. The present observations shed considerable light on the interpretation of the stabilizing properties of silicon dioxide in aspirin tablets. It was concluded that pore-size distribution measurements appear to be useful in elucidating aspirin stability in compressed pharmaceutical systems.

Analysis of Sulindac and Metabolites by Combined Isotope Dilution–Radioimmunoassay

L. E. HARE, C. A. DITZLER, M. HICHENS, A. ROSEGAY, and D. E. DUGGAN [x]

Abstract □ Sulindac, a new anti-inflammatory agent, and its sulfone and sulfide metabolites were conjugated to bovine serum albumin by the *N*-hydroxysuccinimide active ester procedure. Antiserum from rabbits immunized with each of these haptens exhibited extensive cross-reactivity, precluding differential analyses of the three species by displacement assay without prior separation. Therefore, an analytical method based on a combination of isotope dilution and radioimmunoassay was devised. A known mixture of the three chemical species, each labeled with tritium, was equilibrated with plasma or urine samples, reisolated chromatographically, and quantitated by binding to an appropriate immunoglobulin. The radiolabeled materials thus served as recovery standards as well as labeled antigens for each displacement assay. Sulindac and each of its metabolites in plasma or urine at concentrations as low as 500 ng/sample were differentially determined by this procedure. However, since an extraction is required, several milliliters of plasma can be used for each sample, thus increasing the actual sensitivity of the assay.

Keyphrases □ Sulindac—and metabolites, combined isotope dilution–radioimmunoassay, human plasma and urine □ Radioimmunoassay—combined with isotope dilution, analysis of sulindac and metabolites, human plasma and urine □ Isotope dilution–radioimmunoassay—analysis of sulindac and metabolites, human plasma and urine □ Anti-inflammatory agents—sulindac and metabolites, combined isotope dilution–radioimmunoassay, human plasma and urine

Sulindac, *cis*-5-fluoro-2-methyl-1-[*p*-(methylsulfinyl)benzylidenyl]indene-3-acetic acid (I), is a new anti-inflammatory agent (1, 2) currently in clinical trials. Its two principal metabolites, the sulfone (II) and sulfide (III), differ from the parent drug only with respect to the oxidation state of the sulfur moiety (3). Metabolic reduction of sulindac to the sulfide is reversible, but oxidation to the sulfone is irreversible; thus, disposition patterns of this drug are complex. Furthermore, the sulfide metabolite has been proposed as the pharmacologically active species[1]. Thus, any analytical procedure should ideally be capable of distinguishing among these closely related compounds.

GC analysis of sulindac and metabolites was attempted without success[2]. The principal difficulties encountered were the lack of sensitivity for sulfide and the insufficient separation of sulindac and its sulfone metabolite. Another potentially useful method is mass fragmentography, and such an assay for sulindac is in the final stages of development[3].

A third possible method is radioimmunoassay, provided that specific antiserums to each compound are available. Early results suggested that specific antibodies to sulindac and metabolites could not be obtained. One solution to the problem of poor selectivity is to separate the compounds chromatographically prior to radioimmunoassay. This approach has been applied to assays of steroids and prostaglandins (4–6). A slightly different technique utilizing isotope dilution in combination with radioimmunoassay has been devised for the differential determination of sulindac and its metabolites and is the subject of this report.

EXPERIMENTAL

Materials—Bovine serum albumin[4], *N*-hydroxysuccinimide[5], dicyclohexylcarbodiimide[5], neutral charcoal[6], and dextran[7] were used. Dextran-coated charcoal was prepared by suspending 6.25 g of prewashed charcoal and 0.625 g of dextran in 100 ml of 0.05 *M* phosphate buffer, pH 7.5.

Preparation of Labeled Antigens—*[^{3}H-Methylene]sulindac Sulfide*—A mixture of sulindac sulfide (0.5 g), potassium *tert*-butoxide (0.6 g), and tritiated water (2 ml, 25 Ci) was heated at 90° for 2 hr. Water was then added, and the mixture was acidified. The labeled sulfide that precipitated was collected and dissolved in methanol. The solution was evaporated (several times) to remove labile tritium. Several recrystallizations from benzene afforded pure tritiated sulfide (350 mg), mp 186–187°, specific activity 172 μCi/mg.

[^{3}H-Methylene]sulindac—Sodium metaperiodate (144 mg) in water (2 ml) was added to a solution of tritiated sulindac sulfide (102 mg) in methanol (8 ml) and acetone (2 ml), and the mixture was stirred at 25° for 16 hr. The mixture was concentrated, diluted with water, acidified, and extracted with ethyl acetate. The solid obtained by evaporating the ethyl acetate was recrystallized several times from ethyl acetate to yield 53 mg of pure sulindac, mp 181–183°, specific activity 167 μCi/mg.

Analysis of Sulindac and Metabolites by Combined Isotope Dilution–Radioimmunoassay

L. E. HARE, C. A. DITZLER, M. HICHENS, A. ROSEGAY, and D. E. DUGGAN [x]

Abstract □ Sulindac, a new anti-inflammatory agent, and its sulfone and sulfide metabolites were conjugated to bovine serum albumin by the *N*-hydroxysuccinimide active ester procedure. Antiserum from rabbits immunized with each of these haptens exhibited extensive cross-reactivity, precluding differential analyses of the three species by displacement assay without prior separation. Therefore, an analytical method based on a combination of isotope dilution and radioimmunoassay was devised. A known mixture of the three chemical species, each labeled with tritium, was equilibrated with plasma or urine samples, reisolated chromatographically, and quantitated by binding to an appropriate immunoglobulin. The radiolabeled materials thus served as recovery standards as well as labeled antigens for each displacement assay. Sulindac and each of its metabolites in plasma or urine at concentrations as low as 500 ng/sample were differentially determined by this procedure. However, since an extraction is required, several milliliters of plasma can be used for each sample, thus increasing the actual sensitivity of the assay.

Keyphrases □ Sulindac—and metabolites, combined isotope dilution–radioimmunoassay, human plasma and urine □ Radioimmunoassay—combined with isotope dilution, analysis of sulindac and metabolites, human plasma and urine □ Isotope dilution–radioimmunoassay—analysis of sulindac and metabolites, human plasma and urine □ Anti-inflammatory agents—sulindac and metabolites, combined isotope dilution–radioimmunoassay, human plasma and urine

Sulindac, *cis*-5-fluoro-2-methyl-1-[*p*-(methylsulfinyl)benzylidenyl]indene-3-acetic acid (I), is a new anti-inflammatory agent (1, 2) currently in clinical trials. Its two principal metabolites, the sulfone (II) and sulfide (III), differ from the parent drug only with respect to the oxidation state of the sulfur moiety (3). Metabolic reduction of sulindac to the sulfide is reversible, but oxidation to the sulfone is irreversible; thus, disposition patterns of this drug are complex. Furthermore, the sulfide metabolite has been proposed as the pharmacologically active species[1]. Thus, any analytical procedure should ideally be capable of distinguishing among these closely related compounds.

GC analysis of sulindac and metabolites was attempted without success[2]. The principal difficulties encountered were the lack of sensitivity for sulfide and the insufficient separation of sulindac and its sulfone metabolite. Another potentially useful method is mass fragmentography, and such an assay for sulindac is in the final stages of development[3].

A third possible method is radioimmunoassay, provided that specific antiserums to each compound are available. Early results suggested that specific antibodies to sulindac and metabolites could not be obtained. One solution to the problem of poor selectivity is to separate the compounds chromatographically prior to radioimmunoassay. This approach has been applied to assays of steroids and prostaglandins (4–6). A slightly different technique utilizing isotope dilution in combination with radioimmunoassay has been devised for the differential determination of sulindac and its metabolites and is the subject of this report.

EXPERIMENTAL

Materials—Bovine serum albumin[4], *N*-hydroxysuccinimide[5], dicyclohexylcarbodiimide[5], neutral charcoal[6], and dextran[7] were used. Dextran-coated charcoal was prepared by suspending 6.25 g of prewashed charcoal and 0.625 g of dextran in 100 ml of 0.05 *M* phosphate buffer, pH 7.5.

Preparation of Labeled Antigens—*[^{3}H-Methylene]sulindac Sulfide*—A mixture of sulindac sulfide (0.5 g), potassium *tert*-butoxide (0.6 g), and tritiated water (2 ml, 25 Ci) was heated at 90° for 2 hr. Water was then added, and the mixture was acidified. The labeled sulfide that precipitated was collected and dissolved in methanol. The solution was evaporated (several times) to remove labile tritium. Several recrystallizations from benzene afforded pure tritiated sulfide (350 mg), mp 186–187°, specific activity 172 μCi/mg.

[^{3}H-Methylene]sulindac—Sodium metaperiodate (144 mg) in water (2 ml) was added to a solution of tritiated sulindac sulfide (102 mg) in methanol (8 ml) and acetone (2 ml), and the mixture was stirred at 25° for 16 hr. The mixture was concentrated, diluted with water, acidified, and extracted with ethyl acetate. The solid obtained by evaporating the ethyl acetate was recrystallized several times from ethyl acetate to yield 53 mg of pure sulindac, mp 181–183°, specific activity 167 μCi/mg.

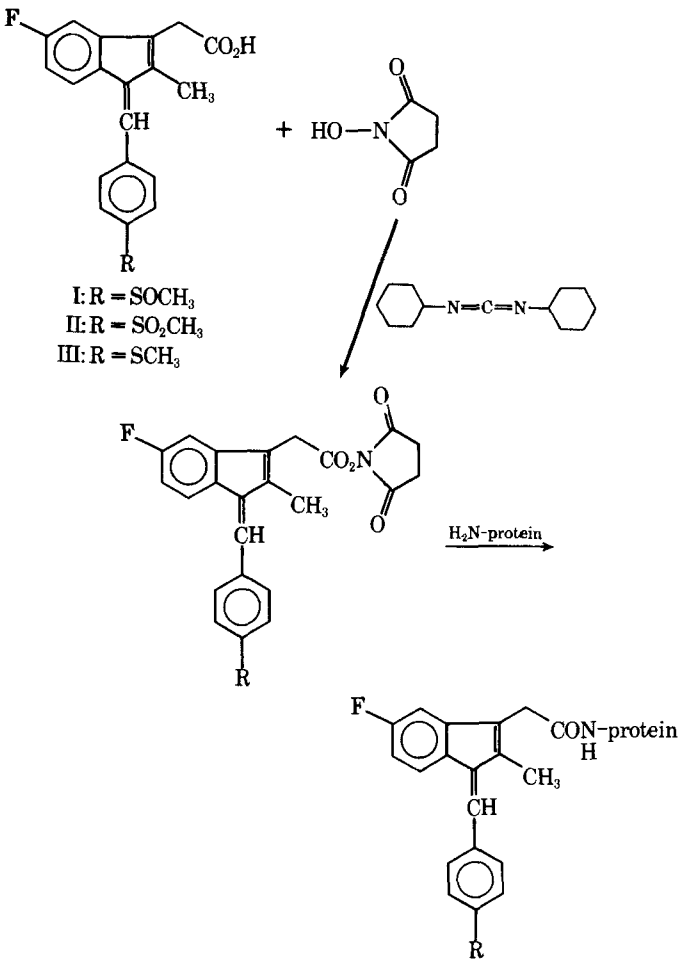

Scheme I

[^{3}*H-Methylene, vinyl*]*sulindac Sulfone*—Sulindac sulfone was labeled in the same manner as the sulfide. The crude product was redissolved in 1 *N* sodium hydroxide for 5 min and then precipitated with acid (several times) to remove labile tritium from the sulfonylmethyl and carboxyl groups. Two recrystallizations from acetic acid–water afforded pure tritiated sulfone, mp 200–201°, specific activity 337 μCi/mg. The NMR spectrum of the deuterated analog showed partial exchange of the vinyl proton as well as the methylene protons.

Preparation of Conjugates—Sulindac and metabolites were each conjugated through the carboxylic acid moiety to bovine serum albumin by the *N*-hydroxysuccinimide active ester procedure (7, 8) (Scheme I). Conversion of the acids to the succinimide esters was verified by the appearance of characteristic imide peaks at 1800, 1780, and 1720 cm^{-1} in the IR spectrum. Each active ester (0.15 mmole) in dioxane (4 ml) was added dropwise to a solution of albumin (340 mg, 0.3 mmole of lysine equivalents) in 0.1 *M* borate buffer, pH 9.0 (30 ml).

The solutions were allowed to stand at room temperature overnight and then were extensively dialyzed against distilled water. Insoluble material was removed by centrifugation, and the solution was lyophilized. The extent of conjugation was 10–30 molecules of sulindac or metabolites per molecule of protein, as estimated by UV absorption (sulindac, ϵ 325 nm = 1.31×10^4; sulindac sulfone, ϵ 327 nm = 1.17×10^4; and sulindac sulfide, ϵ 350 nm = 1.72×10^4).

Immunization of Animals—New Zealand White rabbits were given sulindac–albumin conjugates (2–5 mg im) dissolved in saline and emulsified with an equal volume of Freund's complete adjuvant. Booster injections of 1 mg of conjugate were given at monthly intervals in incomplete adjuvant. Bleedings were taken from central ear arteries about 2 weeks after booster injections.

To determine antibody titer, the quantity of tritiated sulindac and metabolites bound to the various antiserums was compared with the binding observed for normal serums. The high degree of sulindac sulfide binding to serum proteins necessitated the purification of the γ-globulin fraction of antiserum to this compound by precipitation from 18% sodium sulfate (9). Antiserums were used at dilutions that bound 30–50% of the added label in control tubes containing no unlabeled antigen.

Table I—Cross-Reactivity of Sulindac Antiserums

	Unlabeled Antigen, I_{50}[a], ng/ml		
Immunoglobulin	I	II	III
Anti-I or anti-II[b]	40	40	>1000
Anti-III[c]	29	23	33

[a] I_{50} = drug concentration resulting in 50% inhibition of binding of labeled antigen. [b] Labeled antigen = ^{3}H-I or ^{3}H-II (50 ng). [c] Labeled antigen = ^{3}H-III (20 ng).

Combined Isotope Dilution–Radioimmunoassay—A known mixture of I–III, each labeled with tritium (250 ng, ~1×10^5 dpm each), was equilibrated with 1-ml plasma or urine samples containing standard or unknown solutions of sulindac and metabolites in the 500–3000-ng/ml range. The aqueous solutions were adjusted to pH 5 by the addition of 0.2 ml of 1 *M* citrate buffer, pH 5, and were extracted with 3 ml of benzene–2-propanol (9:1). The aqueous phase was discarded.

The organic phase was removed and evaporated to dryness. The residue was dissolved in 0.03 ml of ethanol, and approximately one-third was chromatographed on paper[8] with toluene–xylene–2-propanol–dioxane–6% ammonium hydroxide (1:1:3:3:2) as the developing solvent. Areas containing the three chemical species (sulindac, R_f 0.45; sulindac sulfone, R_f 0.54; and sulindac sulfide, R_f 0.71) were excised and eluted with 15 m*M* sodium hydroxide (1 ml). The aqueous solutions were adjusted to pH 7.5 by the addition of 30 m*M* monobasic sodium phosphate (0.5 ml), and one 0.3-ml aliquot was used for determination of recovery.

For the binding assay, a solution consisting of 0.9 ml of the eluate and 0.1 ml of the appropriate immunoglobulin was mixed and allowed to equilibrate at 4° overnight. "Bound" and "free" antigens were separated by addition of 0.2 ml of dextran-coated charcoal. The charcoal suspension was kept at 4° for 10–12 min and then separated by centrifugation; the supernate was counted to determine the fraction of radioactivity bound to the antibody.

Standard curves were plotted as drug concentration (labeled plus unlabeled drug) in the assay tube *versus* percent of total radioactivity bound to antibody. Concentrations of unknowns (*C*, nanograms per milliliter) were calculated from the following equation: $C = (c/r) - 250$, where *c* and *r* represent drug concentration as extrapolated from the standard curve and recovery, respectively. The 250 value represents the mass of each radioactive species added to the original sample.

In urine, glucuronide conjugates were hydrolyzed before analysis, thereby providing a measure of the total amount of each species present in free and conjugated forms. Appropriately diluted urine samples (0.75 ml) and 0.25 ml of 1 *N* sodium hydroxide were incubated for 30 min at room temperature and adjusted to pH 5 by the addition of 2 *M* acetic acid (0.17 ml). The mixture of the labeled compounds was added, and the samples were chromatographed and assayed as described.

Cross-Reactivity—Conventional radioimmunoassay was used for the estimation of cross-reactivity. This procedure was similar to that already described, except that extraction was necessary only in the case of sulindac sulfide due to binding of this species to plasma proteins. In addition, all chromatography steps were eliminated.

Comparison of Methods—Plasma samples containing labeled sulindac and metabolites of low specific activity (8 μCi/mg) were prepared to mimic concentrations found in humans following sulindac administration. Each sample was analyzed by isotope dilution–radioimmunoassay as already described and by reverse isotope dilution. In the latter procedure, samples (1 ml) were equilibrated with a known mixture (0.25 μmole each) of the three compounds and were extracted with benzene–2-propanol (9:1). The organic phase was evaporated to dryness, and the mixture was chromatographed as described. Papers were eluted with ethanol, and drug concentrations were determined spectrophotometrically. The eluates were counted, and the concentration of each component was determined from the specific activities of each species and the known ratio of carrier to radioactivity initially present.

RESULTS

Antibodies to sulindac and metabolites were detected within 6 weeks after immunization of rabbits. Antibody titers reached plateau values after 6 months and began to fall off after 1 year despite continued boosting. The amount of drug attached to the protein did not appear to

be critical, since conjugates in which 25–50% of the lysine residues were modified afforded equivalent antibody titers. Final antiserum dilutions of approximately 1:500 in the reaction tube bound 35% of labeled antigen and were used for routine assay.

All antiserums exhibited extensive cross-reactivity (Table I). Antiserums to I and II each possessed identical affinity for I and II. However, neither antibody bound III significantly. The anti-III immunoglobulin was less selective, exhibiting virtually 100% cross-reactivity to all three compounds. Thus, these serums possessed high affinity but low selectivity and were unsuitable for direct, differential determinations of sulindac and metabolites.

The combined isotope dilution–radioimmunoassay method produced the necessary specificity *via* the chromatography step while retaining the sensitivity of the antibody-binding assay. Radioactive recovery following sample extraction, aliquoting, and chromatography ranged from 20 to 70%, and good reproducibility of the assay was obtained within this range. This variability of recovery was probably due to the inability to locate with certainty the three redox species on the paper. Absolute recovery is not critical, since the recovery standard also serves as labeled antigen.

Standard displacement curves are illustrated in Fig. 1. These curves were linear when drawn on a log–log scale and possessed correlation coefficients greater than 0.997. Significant displacement was obtained with approximately 20 ng of unlabeled antigen/tube. Therefore, the effective sensitivity of the assay was 200 ng/sample, assuming a 50% re-

Table II—Assay of Sulindac and Metabolites Added to Normal Plasma

[a] Means of 10 samples ± *SD*.

covery. However, since an extraction step is employed, sensitivity can be increased by using sample volumes larger than 1 ml with a concomitant increase in the volume of the first organic phase.

Precision and accuracy were demonstrated by analysis of replicate standards in pooled normal plasma (Table II). Coefficients of variance for sulindac and the sulfide at 0.1 μg/ml were unacceptable. However, at concentrations near the midpoint of the standard curves, *i.e.*, 0.5–1.0 μg/ml, coefficients of variance averaged 7% while mean accuracy was 102 ± 7% for all three compounds. Thus, samples should be adjusted to the 0.5–5.0-μg range by dilution or concentration prior to assay.

Results obtained by this method also were validated by comparison with results of the classical reverse isotope dilution assay. The two methods were employed to analyze levels of ^{3}H-sulindac and its sulfone and sulfide metabolites in plasma. The specific activity of these samples was much lower than that of the labeled antigen and did not interfere with the combined isotope dilution–radioimmunoassay procedure. Plasma concentrations are shown in Fig. 2. In general, good correlation was seen among values obtained by the two methods.

Since sulfoxides are enantiomeric, the binding of partially resolved biogenic sulindac to the antibody was examined. Biogenic material was purified from the urine of rabbits treated with sulindac sulfide and possessed an $[\alpha]_D$ of +11° compared to the value of +21° determined for chemically resolved compound[9]. Thus, biogenic sulindac was approximately 67% enriched with respect to the dextrorotatory isomer. Standard displacement curves for the biogenic sample and for racemic sulindac were identical.

DISCUSSION

A common disadvantage of many radioimmunoassay procedures is a lack of specificity. Thus, closely related compounds often cannot be distinguished. For this reason, separation procedures have been utilized in combination with radioimmunoassay in several cases. For example, prostaglandins E, A, and F were separated on silicic acid columns (4), estrogens were analyzed by dextran gel[10] chromatography (5), and dehydroepiandrosterone was purified by paper chromatography (6) prior to radioimmunoassay. In all of these procedures, tracer quantities of radiolabeled drug were added to samples to determine recovery. Then, larger amounts of radioactive drug, usually two to 10 times the tracer amount, were added as labeled antigen for radioimmunoassay. Relatively high specific activities are required to ensure that the recovery standard is indeed added in negligible amounts relative to the material being measured and, therefore, will not interfere with radioimmunoassay.

The described procedure (combined isotope dilution–radioimmunoassay) for sulindac differs from radioimmunoassay in that it is fundamentally an isotope dilution method employing a binding assay for detection. Added radioactive drug serves as both the recovery standard and labeled antigen, and standard curves represent total labeled and unlabeled drug (*i.e.*, specific activity of diluted material) present in the assay tube. Thus, whereas radioimmunoassay is an indirect measurement of unlabeled material causing a certain degree of displacement of labeled antigen from the antibody, combined isotope dilution–radioimmunoassay is a direct measure of the total material bound to the antibody. Therefore, the modified procedure offers the advantages that absolute recovery is not a limiting factor and that standards are treated in the same manner as unknowns, thus avoiding unaccountable procedural changes or losses. In addition, a lower specific activity of the labeled antigens is acceptable and a pipetting step is eliminated.

An apparent disadvantage of this method is that the critical antibody–labeled antigen ratio can vary with recovery, resulting in irreproducible data. This is true if recovery falls below a certain critical value of approximately 15%. However, as indicated by the precision of the assay, this is not generally a problem. Combined isotope dilution–radioimmunoassay requires that labeled antigens be chemically identical to each compound being determined and is not applicable to materials such as peptide hormones that utilize iodine-labeled antigens.

Incorporation of isotope dilution into radioimmunoassay procedures does result in a rather tedious method, but such a combination will, in most cases, provide specificity and sensitivity not otherwise obtainable. The disadvantages, in the case of sulindac, may be eliminated in some instances by determining the parent drug plus sulfone or all three compounds directly by radioimmunoassay using a nonselective antibody such as the anti-III immunoglobulin (Table I). Such an approach might be justified in certain bioavailability or drug interaction studies in which drug absorption is the principal consideration.

Examination of the sulindac metabolic pattern suggested that the sulfoxide might be resolved into one enantiomeric form *in vivo* by repeated reduction to sulfide followed by reoxidation, and this has been shown to be the case. The stereospecificity of antibodies was first demonstrated by Landsteiner and Scheer (10), who found that antibodies produced against one enantiomer of a pair were far less reactive to the second enantiomer. Since the sulindac antibody was produced against a recemic compound, the possibility exists of altered displacement kinetics involving an optically pure or even partially resolved enantiomer of the drug. However, the superimposability of standard curves for biogenic and racemic sulfoxide indicates that partial resolution does not compromise the validity of this assay.

Synthesis and *In Vivo* Antimalarial Evaluation of Isopropyl [(4-Chlorophenyl)amino]iminomethylcarbamimidate

VICTOR D. WARNER *x, **DONALD M. LYNCH** *, **CHARLES A. MESZOELY** ‡, and **WILLIAM G. DYKSTRA, Jr.** ‡

Abstract □ Isopropyl [(4-chlorophenyl)amino]iminomethylcarbamimidate was synthesized as a potential antimalarial agent. Biological activity was evaluated against *Plasmodium lophurae* in turkeys. The activity of this compound was compared to its nitrogen isostere, chloroguanide.

Keyphrases □ Carbamimidate ester, substituted—synthesized, screened for antimalarial activity, turkeys □ Antimalarial activity—screened in substituted carbamimidate ester, turkeys □ Structure–activity relationships—substituted carbamimidate ester screened for antimalarial activity, turkeys

During an *in vitro* study of the antiplaque activity of N^1-(4-chlorophenyl)-N^5-alkylbiguanides (I), it became necessary to prepare larger quantities of these compounds (1). To optimize yields, the ratio of alkylamine to N^1-(4-chlorophenyl)-N^3-cyanoguanidine (II) in ethanol was changed from 4:1 to 1:1. The product obtained from this reaction was the ethyl ester of [(4-chlorophenyl)amino]-iminomethylcarbamimidic acid (III) rather than the expected alkylbiguanide. The similarity between this compound and chloroguanide (IV) prompted the synthesis of the isopropyl derivative (V) as a potential antimalarial agent.

Reaction of II with isopropyl alcohol in the presence of triethylamine and copper acetate (Scheme I) yielded isopropyl [(4-chlorophenyl)amino]iminomethylcarbamimidate (V). This compound and chloroguanide were tested as their acetate salts against turkeys infected with *Plasmodium lophurae*.

EXPERIMENTAL

Chemistry[1]—N^1-*(4-Chlorophenyl)*-N^3-*cyanoguanidine (II)*—This compound was prepared from 4-chloroaniline hydrochloride and sodium dicyanamide, as previously reported (2), mp 202–203° [lit. (2) mp 204–205°].

Isopropyl [(4-Chlorophenyl)amino]iminomethylcarbamimidate (V)—Compound II (4.86 g, 0.025 mole), copper acetate monohydrate (2.5 g, 0.0125 mole), triethylamine (10 ml), and isopropyl alcohol (100 ml) were refluxed with stirring for 12 hr. The purple reaction mixture was evaporated *in vacuo* to yield a semisolid. Water (100 ml) was added, and the remaining alcohol was removed by azeotropic distillation. An additional 100 ml of water was then added, and the insoluble copper complex was destroyed with acetic acid (25 ml).

Gaseous hydrogen sulfide was bubbled through the mixture, and the resulting copper sulfide was removed by filtration. The filtrate was adjusted to pH 7 with concentrated ammonium hydroxide and allowed to stand at 4° for 12 hr, which resulted in the precipitation of the acetate salt. The acetate salt was then recrystallized using methanol to yield 2.88 g (36.2%) of a white solid, mp 181–182°.

Anal.—Calc. for $C_{13}H_{19}ClN_4O_3$: C, 49.60; H, 6.08; N, 17.80. Found: C, 49.65; H, 6.15; N, 17.85.

Antimalarial Activity—Turkey poults (3–4 weeks old) from the same brood were used. The turkeys were given food and water *ad libitum*. The strain[2] of *P. lophurae* used was maintained by weekly serial blood passage from an infected donor turkey to an uninfected poult. The turkeys used in both the Davey test (eight turkeys) and the Patency test (six turkeys) were infected intravenously *via* the wing vein with an inoculum (50 million parasitized red blood cells in 0.2 ml) taken from the same donor turkey.

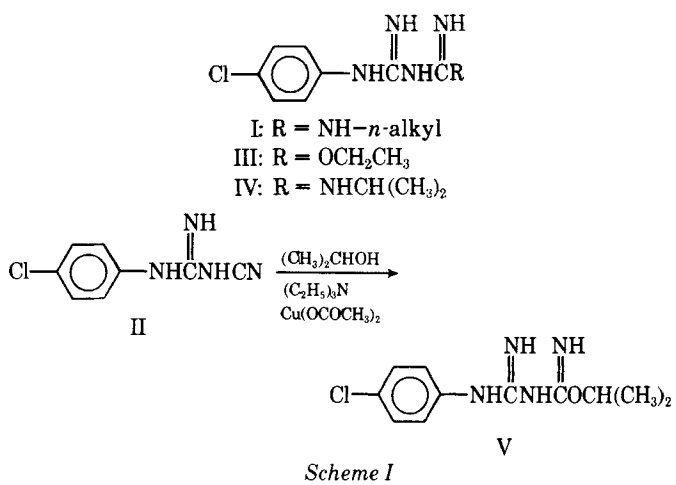
Modified Davey Test—This test was modified as suggested by Peters (3). The day of infection was termed D 0, and the following day was designated D + 1. The drugs were given as aqueous solutions by oral intubation. The first dose of the drug (10 mg/kg) was given 4 hr prior to infection. Doses of 5 mg/kg were then administered twice daily for 3 days for a total of seven doses (40 mg/kg). Blood smears were taken daily, and the percent parasitemia was determined by counting the parasites in 500 red blood cells.

Patency Test[3]—This test involved the measurement of the schizonticidal activity of the test compounds. Percent parasitemia levels of the untreated, infected turkeys were determined daily. When the levels were above 10%, a large, single oral dose (100 mg/kg) was administered.

RESULTS AND DISCUSSION

The results of the modified Davey test are summarized in Table I. Chloroguanide displayed suppressive activity against the blood forms of *P. lophurae* 7 days after infection. The carbamimidate ester suppressed parasitemia for only 1 day. At D + 8, the controls and carbamimidate ester-treated turkeys died, but the chloroguanide-treated animals showed only a trace of parasitemia. According to the Davey test criterion (percent parasitemia on D + 4), the carbamimidate ester-treated turkeys did not show a significant difference of suppression from that of the controls.

From these results, it may be concluded that the carbamimidate ester has no suppressive activity at a total dose of 40 mg/kg. Conceivably, the carbamimidate ester may display suppressive activity at a higher dose,



Scheme I

[1] Melting points were determined on a Thomas-Hoover capillary melting-point apparatus and are uncorrected. Microanalysis was performed by Midwest Microlab, Ltd., Indianapolis, Ind. A Varian Associates model T-60 NMR spectrometer and a Perkin-Elmer model 700 IR spectrometer were used. Spectral data were in accord with assigned structures.

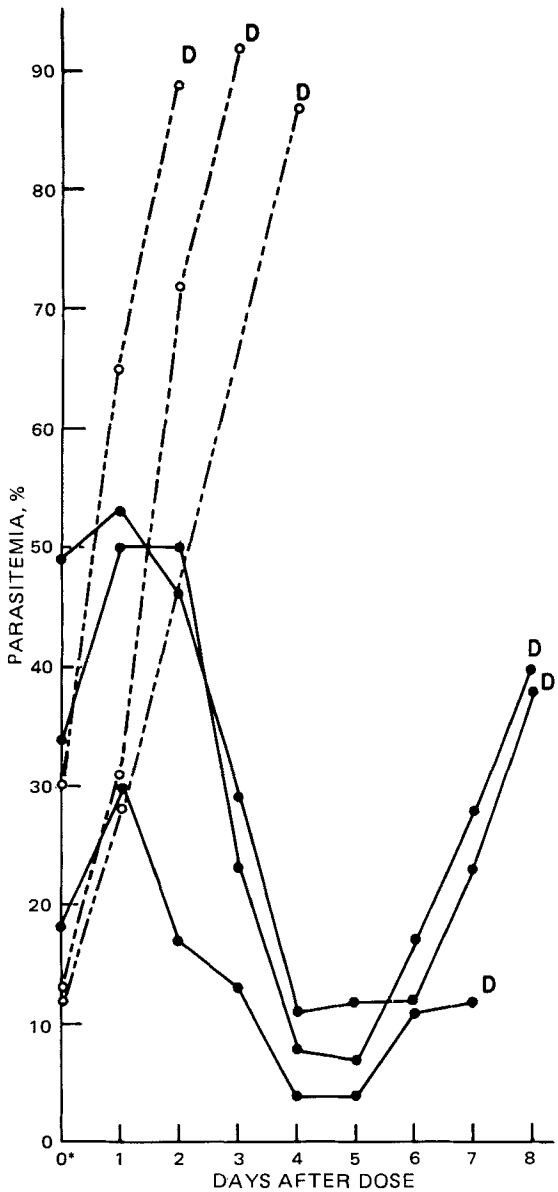

Figure 1—*Schizonticidal activity of single oral dose (100 mg/kg) of the test compounds. Key: *, birds given oral dose; O, carbamimidate ester; ●, chloroguanide; and D, bird died.*

Table I—Results of the Davey Test[a]

Time	Control	Chloroguanide[b]	Carbamimidate[b]
D + 1	1 ± 1	0	0
D + 2	1.1 ± 0.3	0	1
D + 3	3.5 ± 2.5	0	3.1 ± 2.1
D + 4	22.3 ± 13.3	0	15.5 ± 10.5
D + 5	65.3 ± 25.3	0	36.0 ± 17
D + 6	89.6 ± 9.4	0	58.0 ± 25
D + 7	97[c]	0	82[d]
D + 8	Death	1	Death
D + 9		6 ± 4	
D + 10		13.3 ± 5.3	
D + 11		54.3 ± 17.7	
D + 12		83.0 ± 3[d]	
D + 13		Death	

[a] Blood smears compared on D + 4 are used as Davey test criteria; there were three turkeys in each group. [b] Percent parasitemia is expressed as mean ± range. [c] Death of two birds. [d] Death of one bird.

but results from the Patency test (Fig. 1) indicate that this effect is not too likely. The blood smears taken at daily intervals show that chloroguanide possesses potent schizonticidal activity, whereas the carbamimidate ester displays no schizonticidal activity at the same dose (100 mg/kg).

The apparent lack of antimalarial activity for the carbamimidate ester may be due to: (*a*) an inability to form some biologically active metabolite [chloroguanide must cyclize prior to displaying antimalarial activity (4)] or (*b*) nonspecific esterase hydrolysis of the isopropyl group, yielding a product that could rearrange to a urea derivative.

β-Lipoproteins: Possible Plasma Transport Proteins for Basic Drugs

J. J. VALLNER ˣ and L. CHEN

Abstract □ Various drugs were screened for possible interaction with β-lipoprotein. The results suggest that β-lipoproteins may act in conjunction with albumin in the plasma transport of basic or cationic drugs.

Keyphrases □ β-Lipoproteins—interactions with various acidic and basic drugs screened □ Drug–biomolecule interactions—various acidic and basic drugs with β-lipoproteins □ Interactions, drug–biomolecule—various acidic and basic drugs with β-lipoproteins □ Plasma transport proteins—β-lipoprotein interactions with various acidic and basic drugs screened

Numerous literature reports deal with the binding of drugs to human or bovine serum albumin, and it is generally agreed that albumin is the main transport protein for many anionic drug molecules. In contrast, there have been few reports of albumin binding of positively charged species.

When the binding of three sulfonylureas to serum proteins was examined (1), almost no binding to lipoproteins could be demonstrated. The largest portion of each hypoglycemic was bound to the albumin fraction. However, in an examination of the binding of the basic drugs chlorpromazine and imipramine (2), the interaction with lipoproteins was as avid as that with albumin or red cells. In this same study, the binding of an anionic agent, salicylic acid, to lipoprotein could not be shown. In another study, lipoproteins demonstrated an affinity for the basic drug quinidine almost equal to that of serum albumin (3). The high affinity quinidine site on lipoprotein (low and high density) was about 2×10^5.

This work was undertaken to test whether lipoproteins have a greater affinity for basic drugs than other agents. β-Lipoproteins may serve as plasma transporters of basic drugs as albumin does of primarily anionic species. To examine this possibility, numerous acidic and basic drugs were screened. The method of absorbance difference spectrophotometry was employed because of its capability for detecting small changes should binding occur between the drug and lipoprotein.

EXPERIMENTAL

The drugs were used as received from the manufacturers without further purification. All other materials were USP grade. The β-lipoprotein[1] was used as supplied, except that, in some experiments, it was dialyzed against 10 volumes of buffer for 5 hr prior to the drug binding examination. Sorenson phosphate buffer, adjusted to pH 7.4, was used throughout this study.

The drug–macromolecule interaction was assessed on a spectrophotometer[2] using the tandem cell technique (4). As in a previous study employing the difference spectrophotometric method, the concentrations of drug and protein had to be kept constant in both reference and sample beams throughout the titration of the macromolecule (5). All reported results are the averages of at least 3-μl aliquot titrations of the β-lipoprotein with the drug.

[1] Cohn fraction III-0, lot 4351, Nutritional Biochemical Corp., Cleveland, Ohio.

[2] Cary model 118C, Cary Instruments, Monrovia, Calif.

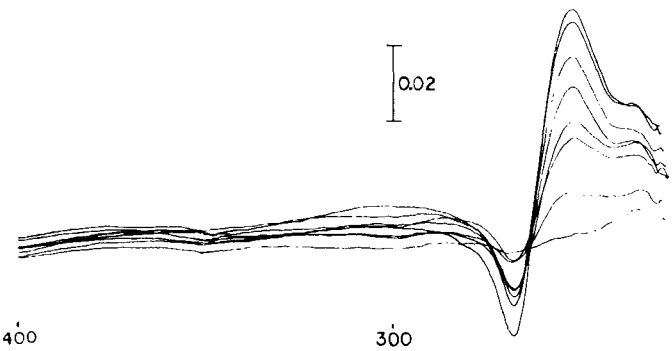

Figure 1—*Example of a difference spectrophotometric titration of β-lipoprotein (0.02%) with trifluoperazine dihydrochloride (0.104 mg/ml). The lower curve is the baseline, and each subsequent curve was generated by the addition of 50 μl of drug as described in the text.*

RESULTS AND DISCUSSION

Interactions between β-lipoprotein and various drugs were examined by difference spectrophotometry. Typical difference absorption spectra for the association of a drug with lipoprotein in phosphate buffer are shown in Fig. 1. A family of curves was generated by the incremental addition of a drug to a protein solution of constant concentration; the solutions ranged from 0.01 to 0.8% in lipoprotein. Drug solutions employed in the titrations ranged from 0.005 to 0.5 mg/ml.

Inspection of these difference absorbance spectra suggests that more than a single class of sites exists on the β-lipoprotein. A distinct isosbestic point was not maintained throughout the titration with any drug. However, the phenomenon of increased difference absorption spectra in the presence of increased amounts of β-lipoprotein was upheld throughout the range of lipoprotein employed.

Table I presents the results of the screening of drugs for binding to

Table I—Results of Drug Screening for Binding Interaction with β-Lipoprotein

Drug	Character	Absorbance Difference[a]	Drug–Protein Ratio
Trifluoperazine hydrochloride	Basic	0.089	0.08
Pyridostigmine bromide	Basic	0.103	1.25
Tolbutamide sodium	Acidic	0[b]	—
Tolazoline hydrochloride	Basic	0	—
Decamethonium bromide	Basic	0.010	5.00
Chlorpromazine hydrochloride	Basic	0.041	0.15
Phenylbutazone sodium	Acidic	0	—
Edrophonium chloride	Basic	0.051	3.07
Isopropamide iodide	Basic	0	—
Propranolol hydrochloride	Basic	0.027	1.67
Warfarin sodium	Acidic	0	—
Clofibrate sodium	Acidic	0.020	2.50
Prednisone	Neutral	0.068	1.10
Phenobarbital sodium	Acidic	0	—
Phenoxybenzamine hydrochloride	Basic	0.017	3.33
Hexamethonium chloride	Basic	0	—

[a] The absorbance difference is measured from a peak (or trough) to the adjacent trough (or peak). The drug to protein ratio at which this absorbance difference occurs is given in the succeeding column. [b] If the absorbance difference is zero, the drug–protein ratio is not given. However, with most drugs, a ratio greater than 8 was tried.

β-lipoproteins. A large number of the basic drugs examined resulted in a perturbation of the macromolecule baseline, reflecting that an interaction had taken place. Most of the cationic drugs showing a perturbation had a large hydrophobic portion in the molecule. Perhaps the β-lipoprotein, in order to bind these basic drugs, requires not only the center of deficient electron density but also a hydrophobic area. With the two aliphatic, yet basic, drugs tested, decamethonium and hexamethonium, only a very weak interaction resulted from the larger drug, decamethonium.

The description of the interaction was based on measuring a suitable absorbance difference from at least three titrations and also providing the drug–lipoprotein ratio of such absorbance diferences. In a number of aliquot titrations of the protein, saturation was not reached. In these instances, the results in Table I are the largest absorbance differences recorded at the ratio causing the perturbation.

Considering the results of Refs. 1–3 and those of this preliminary work, it is possible that cationic drugs may be preferentially transported by β-lipoproteins as well as other plasma proteins. If so, then research can be directed toward examining drug–β-lipoprotein interactions when new basic drugs are introduced. The β-lipoprotein can be assessed as to the strength of binding and the numbers of binding sites if some work is done on purification and exact molecular weight determination. Competitive displacement of drugs by concurrently administered agents may be an area in need of further examination if β-lipoproteins have a high affinity for specific basic drugs.

GLC Determination of Opium Alkaloids in Papaveretum

G. FISHER [x] and R. GILLARD

Abstract □ A GLC method for the determination of the opium alkaloids in papaveretum, based on the formation of the acetyl derivatives of morphine and codeine, is described. The analytical results are compared with those obtained by the official method. The proposed method is fast and accurate and is particularly suited to the analysis of the raw material.

Keyphrases □ Opium alkaloids—GLC analysis in papaveretum, prepared samples □ Papaveretum—GLC analysis of opium alkaloids, prepared samples □ GLC—analysis, opium alkaloids in papaveretum, prepared samples □ Narcotics—GLC analysis of opium alkaloids in papaveretum, prepared samples

Papaveretum raw material (1) is a synthetic mixture of the hydrochlorides of the opium alkaloids, containing the equivalent of anhydrous morphine (47.5–52.5%), anhydrous codeine (2.5–5.0%), noscapine (16.0–22.0%), and papaverine (2.5–7.0%). It has the analgesic and narcotic properties of morphine but is claimed to produce fewer side effects and may be used in all cases where morphine or opium is indicated (2).

The official method of analysis (1, p. 346), involves a titrimetric method for morphine and gravimetric methods for the other alkaloids. Gravimetric analyses, due to their very nature (3), are prone to error, and the many operations required in the official procedure make it tedious and time consuming. For example, the method involves some 30 extractions, more than 40 washings (*i.e.*, of filter papers and solvent layers), and more than 20 actual transfers of the substances to be determined. A skilled and experienced analyst would require about 2 working days to complete an assay in duplicate.

The GLC determination of the opium alkaloids has been described (4–9). These methods involve initial extraction of the alkaloids, followed by GLC as either the free bases or derivatives. The direct injection of hydrochlorides of various other classes of drugs, which relies on subsequent quantitative breakdown to the free base, was reported (10, 11).

In the present study, a GLC method was investigated involving derivatization of the alkaloid hydrochlorides in papaveretum without prior extraction, followed by direct injection into the gas chromatograph. The acetate derivatives of the hydrochlorides of morphine and codeine are formed, while the hydrochlorides of noscapine and papaverine are not derivatized due to the absence of any free hydroxyl groups. Since no extractions are required, some error-prone steps are eliminated. This study apparently was the first application of this technique specifically to the hydrochlorides of the opium alkaloids in papaveretum.

EXPERIMENTAL

Materials—Standards of morphine, codeine, papaverine, and noscapine bases[1] were used, together with morphine hydrochloride[2]. These materials were dried at 120° for 2 hr immediately before use. Anhydrous analytical reagent grade pyridine was used, and all other solvents were also analytical reagent grade.

A solution of 100 mg of squalane in 100 ml of 95% ethyl acetate and 5% acetic acid was prepared as the internal standard solution.

Equipment and Operating Conditions—The analysis was performed on a gas chromatograph[3] equipped with dual flame-ionization detectors and a 5-mv recorder with a chart speed of 10 mm/min. The columns used were 1120-mm (4-ft) × 3-mm o.d. glass-lined metal tubing[4] packed with

[1] All alkaloid bases were BP grade material, recrystallized before use until they assayed at >99.5% by both GLC and nonaqueous titration.

Noscapine	19.83		19.61	

[a] Duplicate assays.

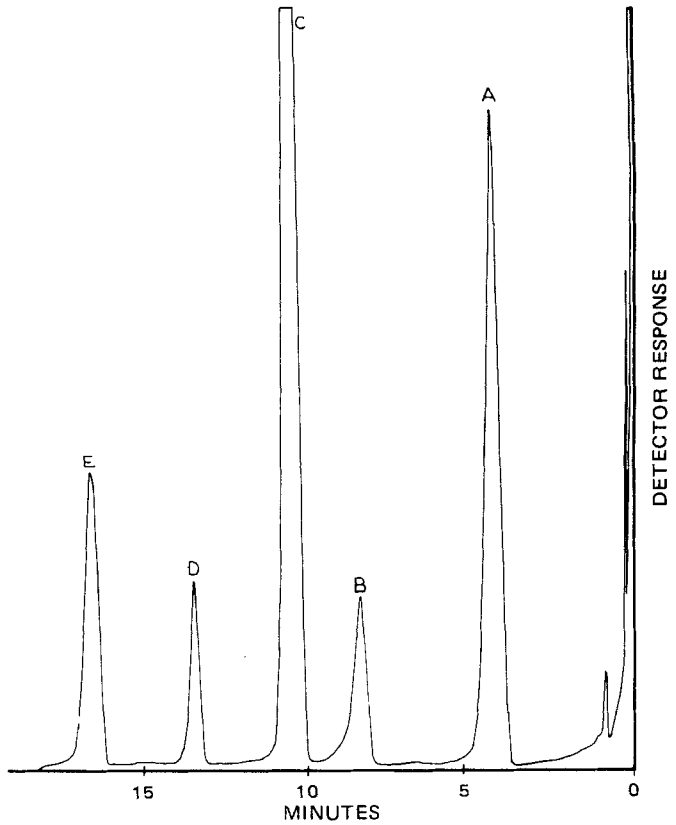

Figure 1—*Typical chromatogram of papaveretum standard preparation. Key: A, squalane; B, codeine; C, morphine; D, papaverine; and E, noscapine.*

Pipet 1.0 ml of Solution A and 1.0 ml of Solution B into a 10-ml conical flask[5] fitted with a septum[6]. Add 1.0 ml of acetic anhydride and allow to stand for 20 min. Evaporate to dryness with a stream of dry nitrogen and add 0.5 ml of internal standard solution. Inject 0.5 μl of this solution into the gas chromatograph, recording the areas of each component using an electronic digital integrator[7].

Preparation of Sample Solution—Accurately weigh approximately 170 mg of the papaveretum sample into a 50-ml volumetric flask, diluting to volume with anhydrous pyridine. Pipet a 2.0-ml aliquot of this solution into a 10-ml flask and then proceed as under *Preparation of Standard Solution* beginning with: "Add 1.0 ml of acetic anhydride . . . ."

The assay is normally performed in duplicate.

Quantitation—Calculate R_{st} and R_s for each component peak from the standard and sample chromatograms, respectively, as follows:

$$R_s = \frac{\text{peak area of particular component in sample chromatogram}}{\text{peak area of internal standard in sample chromatogram}} \quad \text{(Eq. 1)}$$

$$R_{st} = \frac{\text{peak area of particular component in standard chromatogram}}{\text{peak area of internal standard in standard chromatogram}} \quad \text{(Eq. 2)}$$

The amounts of the respective alkaloids in the papaveretum sample are then calculated from the following equation:

$$C_a = \frac{R_s \times C_{st}}{R_{st} \times C_s \times 2} \times 100 \quad \text{(Eq. 3)}$$

where C_a = percent (w/w) of the particular alkaloid base, C_{st} = concentration of that alkaloid in the standard solution in milligrams per milliliter, and C_s = concentration of papaveretum in the sample solution in milligrams per milliliter.

Linearity of Response—The linearity of response of the GLC procedure was checked for each alkaloid using a sample of papaveretum raw

[5] Reacti-Flask, Pierce Chemical Co.
[6] Lined with Teflon (du Pont).
[7] Infotronics CRS-208.

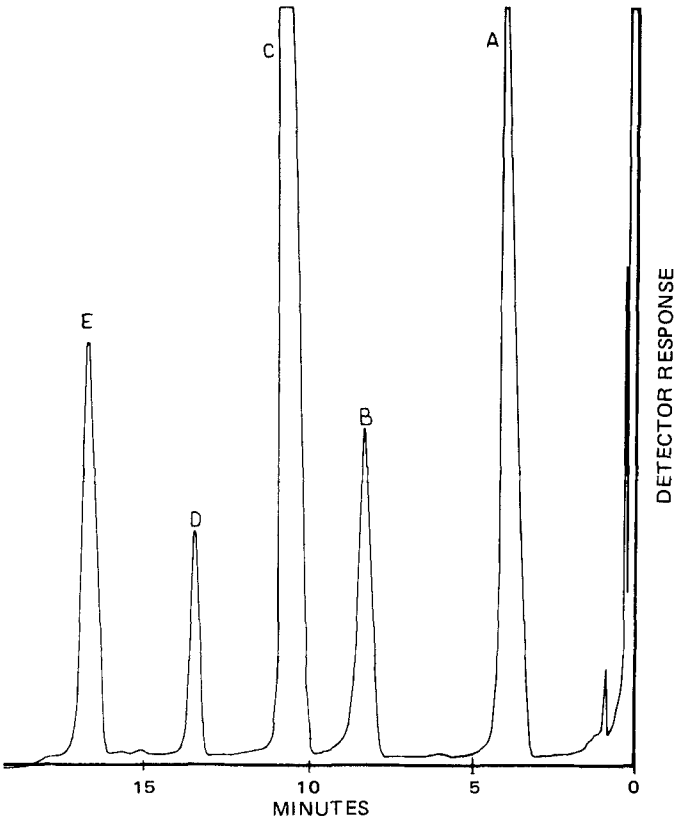

Figure 2—*Typical chromatogram of papaveretum sample preparation. Key: A, squalane; B, codeine; C, morphine; D, papaverine; and E, noscapine.*

material. The response was linear over the 2–20-mg/ml range of papaveretum in the sample solution under the assay conditions described.

RESULTS AND DISCUSSION

Figures 1 and 2 illustrate typical chromatograms of a standard and sample, respectively. The peak due to the acetyl derivative of codeine showed a tendency to tail slightly due to hydrolysis of the derivative to codeine base, brought about by the trace presence of moisture. Normally, the derivatives were stable for at least 4 hr if protected from moisture.

A mixed solvent (95% ethyl acetate and 5% acetic acid) was necessary to keep the derivatives in solution. Ethyl acetate is, by itself, an excellent recrystallizing solvent for diacetylmorphine; therefore, acetic acid was added to increase the solubility of this derivative. The original column has been in use for over 12 months, and no significant deterioration has been observed due to the injection of the acetic acid onto the column.

Recovery experiments were also carried out to check the validity of the method. Table I lists the results for the four alkaloid bases and morphine hydrochloride. Recoveries were quantitative, with an acceptable standard deviation for each alkaloid determination. With the morphine hydrochloride, the results were calculated as morphine base and then factored to the hydrochloride using the theoretical molecular weight ratio. The recovery results obtained in this way verify that the morphine hydrochloride does break down quantitatively to the free base on introduction to the chromatographic system under the conditions described.

Three different commercial lots of papaveretum raw material were assayed in duplicate by both the 1973 BPC method and the proposed GLC method (Table II). Agreement between the two methods was excellent, further validating the applicability of the GLC method.

Synthesis and Antiparasitic Activity of Certain 2-Imino-3-[(*N*-arylcarbamoyl)methyl]-2,3,4,5-tetrahydrothiazoles

H. H. FARAG [*], ADEL F. YOUSSEF [*x], and LAILA A. OMRAN [‡]

Abstract □ New derivatives of 2-imino-3-[(*N*-arylcarbamoyl)methyl]-2,3,4,5-tetrahydrothiazole were prepared. Six compounds were tested for their antiparasitic activities and were active in varying degrees against *Hymenolepis diminuta* without any clinical toxicity manifestations.

Keyphrases □ Thiazoles, substituted—synthesized, screened for antiparasitic activity, rats □ Antiparasitic activity—various substituted thiazoles screened □ Structure–activity relationships—substituted thiazoles screened for antiparasitic activity

During the past few years, significant progress has been made in the continuing struggle against parasitic diseases. However, better drugs are still needed for the treatment of many debilitating human and animal parasites. A number of reviews (1, 2) provide background information on the types of chemical structures that possess antipar-

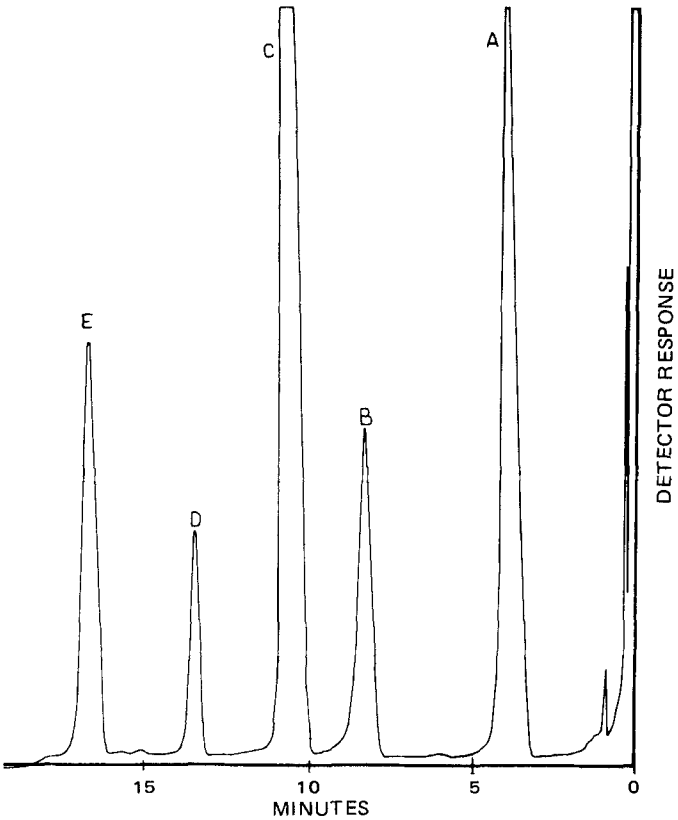

Figure 2—*Typical chromatogram of papaveretum sample preparation. Key: A, squalane; B, codeine; C, morphine; D, papaverine; and E, noscapine.*

material. The response was linear over the 2–20-mg/ml range of papaveretum in the sample solution under the assay conditions described.

Synthesis and Antiparasitic Activity of Certain 2-Imino-3-[(*N*-arylcarbamoyl)methyl]-2,3,4,5-tetrahydrothiazoles

H. H. FARAG [*], ADEL F. YOUSSEF [*x], and LAILA A. OMRAN [‡]

Abstract □ New derivatives of 2-imino-3-[(*N*-arylcarbamoyl)methyl]-2,3,4,5-tetrahydrothiazole were prepared. Six compounds were tested for their antiparasitic activities and were active in varying degrees against *Hymenolepis diminuta* without any clinical toxicity manifestations.

Keyphrases □ Thiazoles, substituted—synthesized, screened for antiparasitic activity, rats □ Antiparasitic activity—various substituted thiazoles screened □ Structure–activity relationships—substituted thiazoles screened for antiparasitic activity

During the past few years, significant progress has been made in the continuing struggle against parasitic diseases. However, better drugs are still needed for the treatment of many debilitating human and animal parasites. A number of reviews (1, 2) provide background information on the types of chemical structures that possess antipar-

asitic activity.

Recent research on the thiazoles resulted in the development of the leading antiparasitic compounds including nithiamide (3), niridazole (4), thiabendazole (5), and tetramisole (6). Most of these compounds are nitrated thiazole derivatives (3, 4, 7); however, some nonnitrated derivatives are active too (4–6). Certain totally or partially hydrogenated thiazoles (6, 8) are among the active compounds. Antiparasitic nonalkylated thiazoles (4) as well as ring-nitrogen alkylated derivatives (9) also were reported in the literature.

The present paper is concerned with the synthesis and preliminary parasitological testing of new 2-imino-3-[(*N*-arylcarbamoyl)methyl] -2,3,4,5-tetrahydrothiazoles (Table I).

EXPERIMENTAL[1]

2-Aminothiazole—This compound was prepared according to the reported method (10), yielding 39%, mp 76–78° [lit. (10) mp 84–85°].

***N*-Aryl-2-chloroacetamides (X–XVII, Table II)**—These compounds were prepared according to the reported methods.

2-Imino-3-[(*N*-arylcarbamoyl)methyl]-2,3,4,5-tetrahydrothiazoles (I and III–IX, Table I)—To a solution of 2-aminothiazole (0.01 mole) in 10 ml of 2-propanol, 0.01 mole of the appropriate *N*-aryl-2-chloroacetamide was added. The mixture was refluxed for 1.5 hr, and the separated compound was filtered off, washed with cold 2-propanol, and dried. In experiments where no solid separated after cooling, 2-propanol was distilled under reduced pressure and the residue was crystallized from the proper solvent.

2-Acetylimino-3-[(*N*-phenylcarbamoyl)methyl] -2,3,4,5-tetrahydrothiazole (II, Table I)—To a mixture of 2.7 g (0.01 mole) of I and 1.6 g (0.02 mole) of pyridine in 20 ml of chloroform was added 2.04 g (0.02 mole) of acetic anhydride. The mixture was stirred and refluxed for 1.5 hr. After cooling, the mixture was made alkaline with dilute ammonium hydroxide and the organic layer was separated. The aqueous layer was extracted twice with 20 ml of chloroform, and the combined chloroform extract was washed with water and dried (magnesium sulfate). The residue remaining after the distillation of chloroform was crystallized from water.

Materials and Methods of Anthelmintic Testing—The diagnosis of natural infection in laboratory rats was carried out by examination of their stools. Each positive rat was isolated in a separate cage. Positive controls were also isolated in separate cages. A dose of 100 mg/rat (mean weight 100 g) was given orally to a group of rats (two rats were given the same drug). A dose of 20 mg/rat was given in the same way. The stools of all rats were examined daily for *Hymenolepis* ova. Positive rats were redosed and followed up. Negative rats were autopsied to look for the adult worms or scolices. The rat was considered cured when neither ova nor cestodes were recovered.

RESULTS AND DISCUSSION

Chemistry—The new compounds (Table I) were prepared by the interaction of the proper *N*-aryl-α-chloroacetamide (Table II) with 2-aminothiazole (10). Alkylation of 2-aminothiazole by alkyl halides took place at the nuclear nitrogen (19). Compound I was acetylated with acetic anhydride to yield II. The IR spectrum of I showed multiple bands in the 3300–3200-cm^{-1} region (NH stretching), broad multiple bands at

3100–3000 cm^{-1} (secondary amine salt), and strong bands at 1700 and 1570 cm^{-1} (amide, I and II). Compound II revealed broad multiple bands at 3200–3100 cm^{-1} (NH stretching) and strong bands at 1700 (amide-I), 1620 (tertiary amide), and 1540 cm^{-1} (amide-II) (20).

Parasitological Screening—Compounds III, V, and VIII were tested for anthelmintic efficacy in mice naturally infected with *H. diminuta* and were active at the dose level (100 mg/rat, single dose) that showed no activity for VI and VII. Only VIII was active at 20 mg/rat (single dose); a further dose reduction abolished the activity.

Preliminary test revealed the activity of II against *Oxyuris* in naturally infected rats (100 mg/rat, single dose).

All of the drugs tested showed no clinical toxic manifestations even at the highest dose level.

CONCLUSION

The experimental results demonstrate that the replacement of the nitro group in 2-imino-3-[(*N*-4-nitrophenylcarbamoyl)methyl]-2,3,4,5-tetrahydrothiazole (VIII) by ethoxycarbonyl (V) or bromo (VI) substituents results in partial or complete loss of anthelmintic activity. Electronegativity alone cannot explain the crucial role played by the nitro group, and *in vivo* drug bioactivation may be involved.

Quantitative High-Pressure Liquid Chromatographic Determination of Epinephrine in Pharmaceutical Formulations

CHERNG-CHYI FU and MURRAY J. SIBLEY ˣ

Abstract □ A quantitative high-pressure liquid chromatographic method, using a cationic exchange resin column and an aqueous phosphate buffer as the mobile phase, was employed for the determination of epinephrine in liquid pharmaceutical preparations. The method is stability determining and can differentiate epinephrine in the presence of oxidative and other degradation products.

Keyphrases □ Epinephrine—high-pressure liquid chromatographic analysis, liquid pharmaceutical preparations □ High-pressure liquid chromatography—analysis, epinephrine, liquid pharmaceutical preparations □ Adrenergics—epinephrine, high-pressure liquid chromatographic analysis, liquid pharmaceutical preparations

Epinephrine solutions are widely used for the treatment of open angle glaucoma and are also used as cardiac stimulants and vasoconstrictors. Air oxidation is a major degradation process involved in epinephrine pharmaceutical preparations (1). Antioxidants such as bisulfite are used in many commercial liquid formulations. Bisulfite causes a degradation of epinephrine to form 1-(3,4-dihydroxyphenyl)-2-methylaminoethanesulfonic acid (2).

A stability-indicating method that differentiates epinephrine from its oxidation products as well as sulfonic acid derivatives is needed. The USP XIX assay method requires the formation of the triacetyl epinephrine derivative and is very lengthy (3). Several spectrofluorometric methods have the disadvantage of interference from the antioxidants (4). The addition of antioxidants is necessary to stabilize the final fluorescence in these assay methods.

This report describes a high-pressure liquid chromatographic (HPLC) assay method for epinephrine in liquid pharmaceutical preparations which will differentiate epinephrine from these major degradation products.

3100–3000 cm^{-1} (secondary amine salt), and strong bands at 1700 and 1570 cm^{-1} (amide, I and II). Compound II revealed broad multiple bands at 3200–3100 cm^{-1} (NH stretching) and strong bands at 1700 (amide-I), 1620 (tertiary amide), and 1540 cm^{-1} (amide-II) (20).

Quantitative High-Pressure Liquid Chromatographic Determination of Epinephrine in Pharmaceutical Formulations

CHERNG-CHYI FU and MURRAY J. SIBLEY ˣ

Abstract □ A quantitative high-pressure liquid chromatographic method, using a cationic exchange resin column and an aqueous phosphate buffer as the mobile phase, was employed for the determination of epinephrine in liquid pharmaceutical preparations. The method is stability determining and can differentiate epinephrine in the presence of oxidative and other degradation products.

Keyphrases □ Epinephrine—high-pressure liquid chromatographic analysis, liquid pharmaceutical preparations □ High-pressure liquid chromatography—analysis, epinephrine, liquid pharmaceutical preparations □ Adrenergics—epinephrine, high-pressure liquid chromatographic analysis, liquid pharmaceutical preparations

Epinephrine solutions are widely used for the treatment of open angle glaucoma and are also used as cardiac stimulants and vasoconstrictors. Air oxidation is a major degradation process involved in epinephrine pharmaceutical preparations (1). Antioxidants such as bisulfite are used in many commercial liquid formulations. Bisulfite causes a degradation of epinephrine to form 1-(3,4-dihydroxyphenyl)-2-methylaminoethanesulfonic acid (2).

A stability-indicating method that differentiates epinephrine from its oxidation products as well as sulfonic acid derivatives is needed. The USP XIX assay method requires the formation of the triacetyl epinephrine derivative and is very lengthy (3). Several spectrofluorometric methods have the disadvantage of interference from the antioxidants (4). The addition of antioxidants is necessary to stabilize the final fluorescence in these assay methods.

This report describes a high-pressure liquid chromatographic (HPLC) assay method for epinephrine in liquid pharmaceutical preparations which will differentiate epinephrine from these major degradation products.

Table I—Comparison of Spectrofluorometric and HPLC Methods for Epinephrine Determination

Assay Method	Epinephrine Found, Product A[a], %	Percentage of Label Claim	Epinephrine Found, Product B[a], %	Percentage of Label Claim
Spectrofluorometric[b]	0.262	105	2.14	107
HPLC	0.255	102	2.10	105

[a] Label claim of Product A was 0.25%; label claim of Product B was 2%. [b] See Footnote 4.

EXPERIMENTAL

Apparatus—A high-pressure liquid chromatograph[1], composed of a pump (7000 psig maximum) and equipped with dual-channel UV detectors at 254 and 280 nm, was used. A 3 × 500-mm stainless steel column was packed with cationic exchange resin[2]. The mobile phase consisted of 0.05 *M* KH_2PO_4 at pH 4.5, which was degassed by using vacuum suction.

Reagents—1-(3,4-Dihydroxyphenyl)-2-methylaminoethanesulfonic acid was prepared according to a literature method (5).

Preparation of Epinephrine Standard Solutions—Dissolve epinephrine bitartrate[3], 181.8, 272.7, and 363.6 mg, in water and dilute to 100 ml. These solutions represent concentrations of 0.1, 0.15, and 0.2% of epinephrine base, respectively.

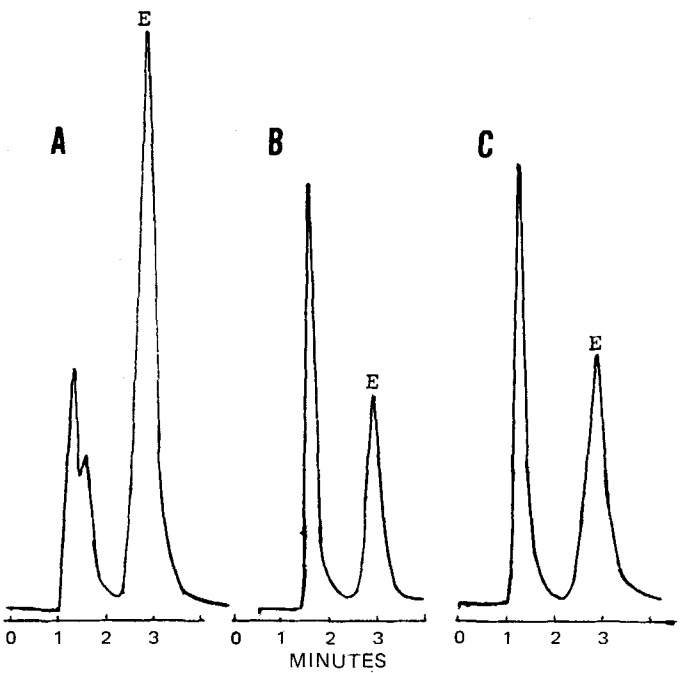

Figure 1—*Chromatographic separation of epinephrine (E) from degradation products. Key: A, air oxidation of 0.1% epinephrine at pH 7; B, hydrogen peroxide oxidation of epinephrine solution at pH 5; and C, mixture of epinephrine and its sulfonic acid derivative.*

[1] Spectra Physics Isocratic model 3500B.
[2] Vydac, Applied Science Laboratories, State College, Pa.
[3] 3M Laboratories, Loughborough, England.

Degradation of Epinephrine—*Method A*—Dissolve 181.8 mg of epinephrine bitartrate in water, adjust the pH to about 7 with 0.02 *N* NaOH, and dilute to 100 ml. Bubble air through this solution overnight.

Method B—Dissolve 181.8 mg of epinephrine bitartrate in water, adjust the pH to about 5 with 0.02 *N* NaOH, and dilute to 100 ml. To 50 ml of this solution, add 2 ml of 30% hydrogen peroxide and heat the mixture in an 80° water bath for 1 hr.

Preparation of Sample Solution—Dilute the liquid sample with water to obtain a concentration of 0.1% epinephrine.

Chromatographic Separation—The procedure was run at ambient temperature, and the solvent flow was 1.6 ml/min. The UV monitor was set at 280 nm with a sensitivity of 0.32 absorbance unit. The samples and standards were injected at 10 μl in duplicate. Peak heights were used for calculating epinephrine concentrations; the concentration of epinephrine samples was obtained from a standard curve.

RESULTS AND DISCUSSION

Excellent linearity of peak height response over the concentration range from 0 to 2 mg/ml was obtained. Figure 1 contains three individual chromatograms and shows the different retention times of epinephrine, the oxidation products, and the sulfonic acid derivative. The difference in chromatograms A and B is probably the result of the complexity of the epinephrine oxidation process. Epinephrine eluted at about 3 min; therefore, the degradation products did not interfere with the epinephrine assay.

The results of adding known amounts of epinephrine to a commercially available formulation[4] in two different concentrations were assayed by both HPLC and spectrofluorometric (4) methods. The results are given in Table I.

Complement Fixing Site of Human IgG1

BRIAN J. JOHNSON ˣ and KENNETH E. THAMES

Abstract □ A number of chemical modifications were made to purified human IgG1. The effects of these modifications on the complement activity of the immunoglobulin were studied using aggregation on latex and measuring the consumption of the complement by CH_{50}-quantitation. Tryptophan and tyrosine are implicated in the complement fixing site of this human immunoglobulin, and an arginine moiety probably provides a binding site for the complement.

Keyphrases □ Complement fixing—human IgG1, effect of chemical modifications on active site □ Immunoglobulins—human IgG1, effect of chemical modifications on complement activity □ Amino acids—residues of human IgG1 involved in complement fixing defined

It has been shown that modification of a few tryptophan residues of rabbit immunoglobulin G with 2-hydroxy-5-nitrobenzyl bromide reduces the anticomplementary activity of this protein (1, 2). This observation prompted interest in defining some of the amino acid residues of human immunoglobulin G1 (IgG1[1]) involved in its complement fixing ability. For this purpose, studies were conducted on the change in anticomplementary activity by chemical modification of human IgG1.

EXPERIMENTAL

Preparation of Human IgG1—The plasma[2] containing IgG1 was isolated from a patient with multiple myeloma. Sufficient ϵ-aminocaproic acid was added to the plasma to make the final concentration of the amino acid 1×10^3 *M*. For every 100 ml of plasma, 1 ml of 25% $CaCl_2$ and 1 ml of 10% NaN_3 were added. The material was allowed to clot overnight at 4°, the clot was then removed, and ammonium sulfate (50%) precipitation of the serum was performed.

The precipitate was dissolved in distilled water and reprecipitated with ammonium sulfate (33%). This latter precipitation was repeated. Then the precipitate was dissolved in distilled water and dialyzed against tris(hydroxymethyl)aminomethane buffer, 0.005 *M*, pH 8.0. This solution was concentrated[3] and then chromatographed on a column (44 × 2.5 cm) of cellulose[4] in the same buffer. Elution of the column with 0.015 *M* tris(hydroxymethyl)aminomethane, pH 8.0, produced human IgG1.

The purity of the product was indicated by Ouchterlony double diffusion in agar gels using goat anti-human serum, from which only a single precipitin band was obtained. Similarly, only a single band was obtained upon polyacrylamide electrophoresis of the sample of human IgG1.

Modifications of Human IgG1—*2-Hydroxy-5-nitrobenzyl Bromide (I)*—The reaction with I was performed in a similar manner to that described by Allen and Isliker (1, 2). To 4 ml of a 2.7% solution of human IgG1 in 0.1 *M* sodium acetate buffer, pH 4.5, was added 0.2 ml of a 0.33 *M* dioxane solution of I. The mixture was stirred for 1 hr at room temperature, centrifuged, and then dialyzed for 24 hr against 4 × 250 ml of 0.1 *M* sodium acetate. The number of moles of I bound per mole of IgG1 was calculated by determining the absorbance at 410 nm (E_{410} = 18,000 M^{-1} cm^{-1}, pH >12.0) (6) for the modified IgG1 and at 280 nm ($E^{1\%}_{1cm}$ = 13.6, pH 7.0) for IgG1. A molecular weight of 150,000 was used for human IgG1.

5-(Dimethylamino)-1-naphthalenesulfonyl Chloride (II)—The reaction with II was performed in a similar manner to that previously reported (7, 8). Typically, 2.50 ml of a 7.4×10^{-3} *M* II solution in acetone was added to 8.75 ml of a 5.4% solution of human IgG1 dissolved in 0.1 *M* $NaHCO_3$, pH 8.0. The mixture was stirred for 2 hr at 4°. The ratio of II to protein was 6:1. The reaction mixture was dialyzed for 24 hr against 4 × 250 ml of 0.05 *M* tris(hydroxymethyl)aminomethane–0.15 *M* NaCl, pH 8.0. Then the solution was centrifuged, and the number of moles of the 5-(dimethylamino)-1-naphthalenesulfonyl moiety bound per mole of IgG1 was calculated by determining the absorbance at 280 nm ($E^{1\%}_{1cm}$ = 13.6, pH 7.0) for IgG1 and at 335 nm ($E_{335} = 4.4 \times 10^6\ M^{-1}\ cm^{-1}$) for bound IgG1. A molecular weight of 150,000 was assumed for human IgG1.

Tetranitromethane (III)—The method of Atassi and Habeeb (9) was used for the nitration of human IgG1. To a solution of 1.8 μmoles of human IgG1 in 5 ml of 0.05 *M* tris(hydroxymethyl)aminomethane–1 *M* NaCl, pH 8.0, was added 21.4 μmoles of III in 75 μl of ethanol. The mixture was stirred at room temperature for 2 hr and then dialyzed for 24 hr against 4 × 250 ml of barbital-buffered saline, pH 7.4, containing 0.15 m*M* calcium and 1.0 m*M* magnesium ions (10). The number of moles of nitrotyrosine associated with each mole of IgG1 was calculated by determining the absorbance at 280 nm ($E^{1\%}_{1cm}$ = 13.6, pH 7.0) for IgG1 and at 428 nm ($E = 3800\ M^{-1}\ cm^{-1}$) (11) for nitro IgG1. Amino acid analysis of the modified IgG1 confirmed this result.

2,3-Butanedione (IV)—This modification of human IgG1 was done using the method of Grossberg and Pressman (12). To 2 ml of a 5.4% solution of human IgG1 in 0.001 *M* phosphate buffer, pH 7.5, was added 2 ml of IV reagent (optical density = 0.5/ml), and the pH of the reaction mixture was adjusted to 8.6. After 6 hr at room temperature, the mixture was centrifuged and dialyzed for 24 hr against 4 × 250 ml of barbital-buffered saline, pH 7.4, containing 0.15 m*M* calcium and 1.0 m*M* magnesium ions (10). Comparison of the amino acid analysis of acid hydrolysates of IgG1 and modified IgG1 showed that half of the arginine residues of the immunoglobulin had been modified.

Protein Absorption on Latex Particles—To 0.25-ml aliquots of an aqueous 1.5% latex suspension (particle size 0.81 μm) was added 1 ml of barbital-buffered saline, pH 7.4, containing 0.15 m*M* calcium and 1.0 m*M* magnesium ions (8). To each sample was added 20 μg of the pertinent human IgG1 or its modifications, and the suspension was gently inverted through 180° every 5 sec to ensure complete mixing. Complete adsorption of the protein to the latex was accomplished by incubation for 16 hr at 4°.

Hemolytic Complement Fixation Assay—The method employed for the quantitative fixation test was based on one described previously (10). All operations were performed in barbital-buffered saline, pH 7.4, containing optimal concentrations of calcium and magnesium ions. The protein–latex suspensions were centrifuged, and to each pellet was added 1.2 ml of human complement containing 20 CH_{50} units/ml. Each pellet was suspended in the complement and incubated for 2 hr at 37°. The suspensions were inverted every 15 min to ensure reaction.

After this incubation, the suspensions were centrifuged and 1 ml of the supernate from each reaction mixture was removed. These supernates were assayed for residual complement activity. Each supernate was diluted in ratios of 1:7, 1:10, and 1:15 with barbital-buffered saline containing 0.15 m*M* calcium and 1.0 m*M* magnesium ions. To 1-ml aliquots of each dilution were added 5×10^8 sensitized sheep erythrocytes, and

Table I—Anticomplementary Activity of Modified Human IgG1

Protein[a]	Amount of Modification[a]	Number of CH_{50} Units Removed per Microgram of Protein	Decrease in Anticomplementary Activity, %
Human IgG1	None	1	0
II-Bound IgG1	4.5	0.65	35
I-Bound IgG1	6.6	0.41	59
Nitro IgG1	7.3	0.28	72
IV-Modified IgG1	16.0	0.23	77

[a] The amount of protein used was 20 μg adsorbed to 3.75 mg of latex. [b] Moles of chemical modifier per mole of immunoglobulin.

Table II—Comparison of Amino Acid Sequences of Various Anticomplementary Immunoglobulins

Immunoglobulin C_H2 Domain	Amino Acid Residues	Sequence
Human IgG1 (Ref. 13)	271–282	Pro-Gln-Val-Lys-Phe-Asn-Trp-Tyr-Val-Asp-Val-Gln
Guinea pig IgG2 (Ref. 14)	271–282	Pro-Glu-Val-Gln-Phe-Thr-Trp-Phe-Val-Asp-Lys-Pro
Rabbit IgG (Ref. 15)	271–282	Pro-Glu-Val-Glx-Phe-Thr-Trp-Ile-Asx-Glu-Gln-Val
Murine IgG2a (Ref. 16)	271–282	Pro-Asp-Val-Gln-Ile-Ser-Trp-Phe-Val-Asp-Val-Glu

the volumes were made up to 7.5 ml with the barbital buffer. These suspensions were incubated for 1 hr at 37° and then centrifuged.

The optical density of each supernate was obtained at 541 nm. The following controls were run concurrently with the latex–protein samples: no latex–protein, latex only, sensitized sheep erythrocytes without complement, complement only, and total lysis of sensitized sheep erythrocytes.

RESULTS

The 2,3-butanedione reagent (12) modified 16 moles of arginine/mole of human IgG1. The amino acid analysis indicated no reaction with the lysine residues. Each mole of human IgG1 bound 4.5 moles of 5-(dimethylamino)-1-naphthalenesulfonyl moiety. Nitration, using tetranitromethane, of human IgG1 indicated 7.3 moles of nitrotyrosine bound/mole of immunoglobulin. Alkylation of the tryptophan residues with 2-hydroxy-5-nitrobenzyl bromide showed that 6.6 moles of this alkylating agent was bound per mole of IgG1.

To quantitate the complement fixing abilities of the human IgG1 and its various modifications, it was necessary to aggregate the various proteins on latex particles. The standard used was 20 μg of human IgG1 aggregated to 3.75 mg of latex particles. At this ratio, all immunoglobulin was adsorbed. This amount of IgG1 routinely removed all of the measurable complement from human serum. Of the controls run concurrently with the samples, the latex by itself removed 5–10% of the available complement. This reduction of complement for consumption by the immunoglobulins has been incorporated in the results shown in Table I.

By using these standard conditions, it was possible to compare the complement fixing abilities of human IgG1 with those of the various modifications of the immunoglobulin. Compared to the native immunoglobulin, the complement fixing activity of the alkylated material was reduced by 59%. Binding of human IgG1 to II was not as effective, causing a decrease of 35% in the complement fixing ability of the modified immunoglobulin. Nitration of human IgG1 lowered the anticomplementary activity by 72%. This finding suggests that a tyrosine residue may be implicated as a moiety in the complement fixing area of the immunoglobulin. The reaction of IgG1 with the 2,3-butanedione reagent (12) gave the greatest decrease, 77%, in the complement fixing activity of the immunoglobulin. However, amino acid analysis of this material indicated that only the arginine residues were affected by this reagent.

DISCUSSION

Allen and Isliker (1, 2) showed that modification of rabbit IgG with 2-hydroxy-5-nitrobenzyl bromide reduced the complement fixing ability of the immunoglobulin. It was suggested that the moiety modified by this alkylating agent was a tryptophan residue located in the Fc portion (3–5) of the immunoglobulin close to the hinge region (3–5). Furthermore, the tryptophan at position 277 within the first domain of the Fc portion of rabbit immunoglobulin appears to be involved in complement fixation (1).

With human IgG1, a similar change in anticomplementary activity was observed when tryptophan was alkylated. Nitration of the tyrosine residues also affected the anticomplementary activity of the modified immunoglobulin. Comparison of the sequences of immunoglobulins that possess anticomplementary activity is shown in Table II. There is a great similarity of amino acid residues around the tryptophan moiety at position 277. The close proximity of the aromatic residues, phenylalanine and tyrosine, is also evident. Possibly nitration of human IgG1 with tetranitromethane modified one of these residues.

The present results also implicate an arginine residue playing a role in complement consumption. However, the sequences shown in Table II do not include this amino acid residue. It has been suggested (2) that different parts of the Fc region (3–5) of the immunoglobulin may provide points of attachment for the Clq subcomponent of complements (17). Thus, a possible explanation for the reduction in anticomplementary activity of human IgG1 upon modification of the arginine residues is that such residues are necessary for the binding of the complement to the immunoglobulin.

The synthesis of peptides and polypeptides that mimic the sequences shown in Table II and their anticomplementary activities will be reported later.

Determination of Oxamniquine in Serum

N. M. WOOLHOUSE [x] and P. R. WOOD

Abstract □ A method for the analysis of oxamniquine in serum (or plasma), sensitive to 10 ng/ml, was developed. Oxamniquine and a close structural analog as the internal standard were extracted from serum with ether. After derivatization with *N,O*-bis(trimethylsilyl)acetamide, oxamniquine was determined as its trimethylsilyl ether derivative by GLC using an electron-capture detector. The method was developed to study serum concentration profiles of different dosage forms of oxamniquine.

Keyphrases □ Oxamniquine—GLC analysis, human serum or plasma □ GLC—analysis, oxamniquine, human serum or plasma □ Antischistosomals—oxamniquine, GLC analysis, human serum or plasma

Oxamniquine[1], 6-hydroxymethyl-2-isopropylaminomethyl-7-nitro-1,2,3,4-tetrahydroquinoline (I), is a potent schistosomicide, active principally against *Schistosoma mansoni*. Extensive clinical trials with this drug in South America and in Africa have shown that oxamniquine is curative after a single intramuscular dose (1–6) and is also effective when given orally (7).

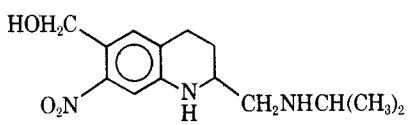
An assay was developed so that serum and plasma concentration profiles of the drug could be determined after both intramuscular and oral administrations of different dosage forms to humans and experimental animals.

EXPERIMENTAL

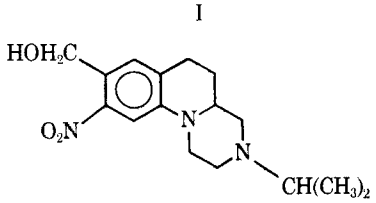
Reagents—The following were used: ether[2]; ethyl acetate[2], redistilled from molecular sieve 4A; pyridine[2], dried over potassium hydroxide; *N,O*-bis(trimethylsilyl)acetamide[3]; citrate–phosphate buffer, pH 5.0, prepared from stock solutions by mixing 51.5 ml of 0.2 *M* Na_2HPO_4 with 48.5 ml of 0.1 *M* citric acid; and 8-hydroxymethyl-3-isopropyl-9-nitro-2,3,4,4a,5,6-hexahydro-1*H*-pyrazine[1,2-*a*]quinoline (II), synthesized according to Baxter and Richards (8).

GLC—A gas-liquid chromatograph[4] fitted with a glass column, 1.85 m in length × 1.0 mm i.d., and a ^{63}Ni-electron-capture detector was used. The stationary phase was dimethyl silicone (OV-101), 5%, on Gas Chrom Q, 80–100 mesh. Operating temperatures were: injector, 250°; oven, 260°; and detector, 290°. The carrier gas was oxygen-free nitrogen with a flow rate of 40 ml/min. Retention times were: oxamniquine, 5 min; and internal standard (II), 7 min.

Standard Curve—Solutions of I and II were prepared daily at a concentration of 50 μg/ml by dissolving 2.5 mg of the compounds in methanol (5.0 ml) and adjusting the volume to 50 ml with distilled water.



I



II

A standard calibration curve was prepared daily by spiking blank serum samples with varying amounts of oxamniquine together with a fixed amount of internal standard. To 1.0 ml of control samples of serum in 10-ml stoppered tubes, 50, 100, 200, 300, and 400 ng of oxamniquine were added (*i.e.*, 1, 2, 4, 6, and 8 μl of the stock solution) using a 10-μl syringe[5]. A constant amount of internal standard, 250 ng, was then added

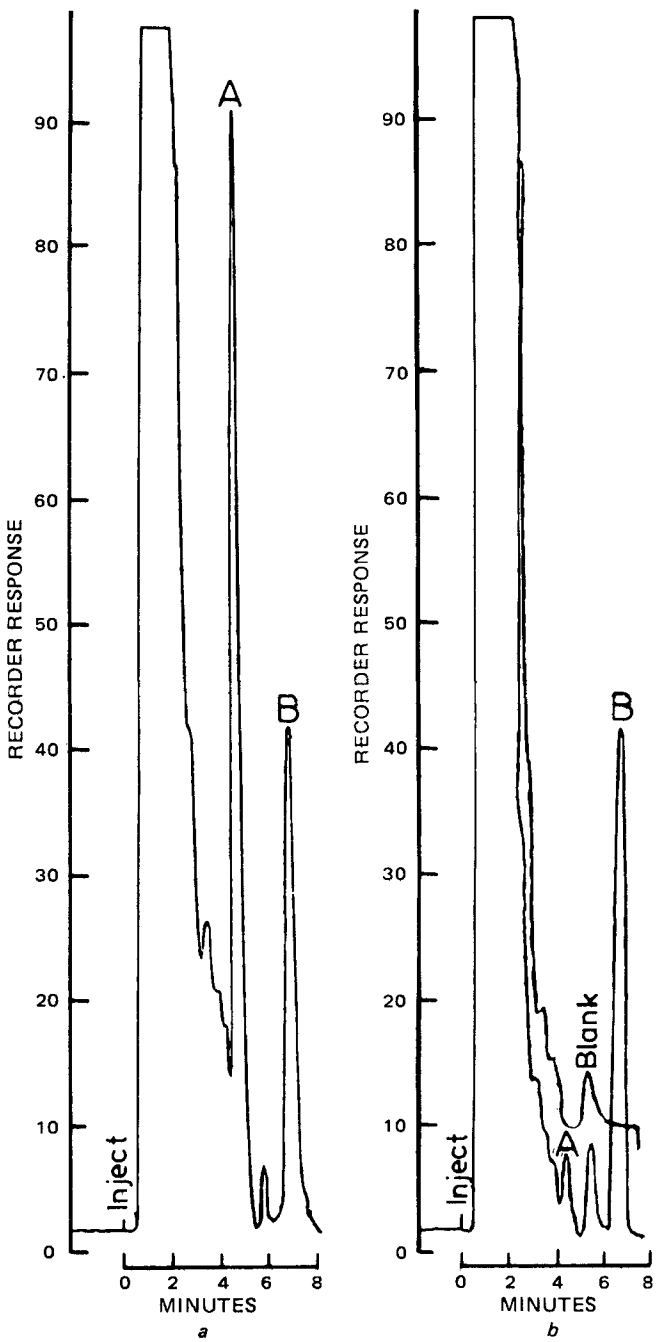


Figure 1—*Chromatograms of oxamniquine (A) and internal standard (B) showing* (a) *a high (440 ng/ml) and* (b) *a low (30 ng/ml) concentration of oxamniquine in human serum and a superimposed blank serum sample chromatogram.*

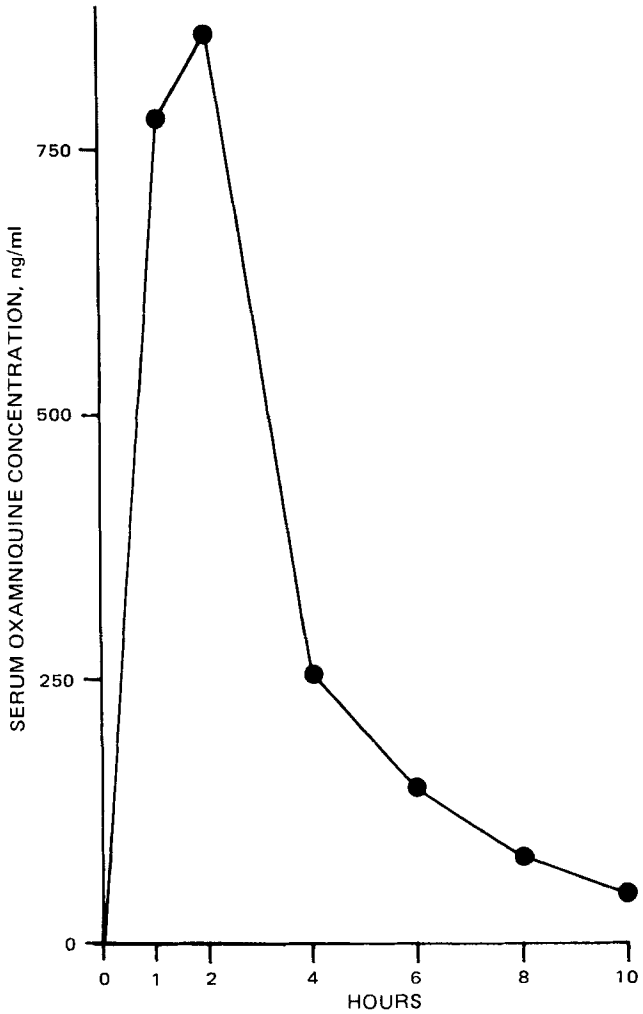

Figure 2—*Serum concentrations of oxamniquine in a human volunteer following administration of a single oral dose of oxamniquine (1000 mg).*

to each of the spiked serum samples containing different amounts of oxamniquine. Sodium hydroxide, 1 *M* (1.0 ml), and ether (4.0 ml) were added and the samples were extracted by mixing for 30 sec using a vortex mixer.

The phases were separated by centrifugation, and the organic layer was carefully removed to a second stoppered tube. A second ether extraction was carried out, and the second extract was added to the first. The combined organic extracts were extracted with citrate–phosphate buffer (5.0 ml) and, after separation of the phases by centrifugation, the organic layer was removed and discarded. Sodium hydroxide, 1 *M* (1.0 ml), was added, and the aqueous phase was then extracted twice with 4.0-ml portions of ether as described.

The extracts were combined in a clean centrifuge tube and placed in a water bath at ambient temperature, and the solvent was evaporated to dryness under a stream of nitrogen. Dry pyridine (50 μl) was added to redissolve the extract. *N,O*-Bis(trimethylsilyl)acetamide (10 μl) was then added, and the tube was stoppered and allowed to stand for 5 min at room temperature. The derivatized material was then diluted with ethyl acetate (0.5 ml) and, after mixing, an accurately measured aliquot (2 μl) was injected onto the column.

The peak heights due to oxamniquine and the internal standard were measured, and peak height ratios (oxamniquine–internal standard) were calculated. The relationship between peak height ratio and oxamniquine concentration was linear for serum concentrations up to 500 ng/ml. The actual mean recovery of oxamniquine in ether extracts of serum determined by comparison of peak height ratios using the described method with those obtained by direct injection of pure sample mixtures was 92 ± 4% (*SEM*).

Sample Analysis—Test serum samples or suitably diluted samples (1.0 ml) to be assayed were transferred to chemically clean stoppered tubes and spiked with 250 ng of the internal standard. These samples were analyzed as already described. The typical sample chromatograms obtained, showing high (440 ng/ml) and low (30 ng/ml) concentrations of oxamniquine in human serum, and a blank sample chromatogram are shown in Fig. 1. A typical serum concentration *versus* time curve in a healthy human volunteer following administration of a single oral dose of oxamniquine (1000 mg) is shown in Fig. 2.

Accuracy and Reproducibility—The accuracy of the assay over the 50–500-ng/ml concentration range was determined. Eight spiked serum samples of concentrations unknown to the operator were assayed. The spiked concentrations (nanograms per milliliter) together with the assayed values (in parentheses) were 49 (50), 98 (97), 123 (128), 148 (168), 197 (202), 246 (240), 395 (404), and 450 (470).

Six replicate assays were carried out on a serum sample spiked at a concentration of 115 ng/ml. The mean value found was 114.5 ± 4.0 ng/ml (*SEM*).

Identity of Oxamniquine Derivative—After derivatization of oxamniquine with *N,O*-bis(trimethylsilyl)acetamide under the described conditions, only one peak was seen on the gas–liquid chromatogram. Combined GLC–mass spectrometry indicated a mass of 351, showing that only a monotrimethylsilyl derivative is formed under the conditions employed. A prominent M − 89 fragment ion peak in the mass spectrum confirmed that the trimethylsilyl group is attached to oxygen (9).

DISCUSSION

A method for the assay of oxamniquine was first developed in these laboratories to determine serum concentrations in toxicity trial animals. The method employed was essentially the same as that described here but used a flame-ionization detector. With this method, drug concentrations down to 750 ng/ml could be determined. However, the method was not sufficiently sensitive to determine with precision the serum concentrations achieved at therapeutic dose levels in clinical trials.

The presence of the nitro group in the oxamniquine molecule suggested that an increase in sensitivity might be gained by employing an electron-capture detector. This change increased the sensitivity of detection some 75-fold, and concentrations of oxamniquine in serum or plasma can be readily determined down to 10 ng/ml. This sensitivity makes the method suitable for the determination of serum concentration profiles of oxamniquine in patients receiving therapeutic doses where maximum plasma concentrations of drug ranging up to approximately 1 μg/ml are found.

Synthetic Acetylenic Antifungal Agents

D. Z. SIMON, S. BROOKMAN [x], J. BELIVEAU, and R. L. SALVADOR

Abstract □ Several monoamino bis(propynyloxy)benzenes were prepared by a Mannich reaction and tested for antifungal activity against *Trichophyton schoenleini, T. mentagrophytes, T. tonsurans, Candida albicans,* and *Epidermophyton flocossum.* In addition, the bis(propynyloxy)benzene intermediates were tested and comparisons were made with standard drugs. The intermediates were found to be the most active, although two Mannich bases possessed considerable activity.

Keyphrases □ Bis(propynyloxy)benzenes and monoamino derivatives—synthesized, screened for antifungal activity □ Antifungal activity—screened in various bis(propynyloxy)benzenes and monoamino derivatives □ Structure–activity relationships—various bis(propynyloxy)benzenes and monoamine derivatives screened for antifungal activity

The isolation of 1-oxo-1-phenylhexa-2,4-diyne from the essential oil of *Artemisia capillaris* Thunb. (Compositae) (1) and the subsequent isolation and synthesis of acetylenecarboxamide (2, 3) have led many investigators to synthesize related acetylenic compounds and to examine their antifungal properties (4). Some mercury acetylides (5), amino polyenes (6), and monoamino alkynes (7) were prepared that were effective antifungal agents. In addition, acetylenic amino esters and diamines with antifungal action were synthesized (8).

Among a large series of compounds (9–13), 3-iodopropargyl ethers exhibited considerable antifungal activity when they possessed an aryl group that was either phenyl or naphthyl substituted by at least one electronegative group. This finding led to the clinically successful agent haloprogin, 1,2,4-trichloro-5-[(3-iodo-2-propynyl)-oxy]benzene (14). A new series of phenyl ethers, which might prove interesting from this aspect, was synthesized (Scheme I).

RESULTS AND DISCUSSION

Bis(propynyloxy)benzenes (I) were prepared *via* a Williamson synthesis, as previously described (15). Under Mannich reaction conditions with formaldehyde solution and various dialkylamines, a series of monoamino bis(propynyloxy)benzenes (II) was obtained; confirmation was by elemental analysis and IR and NMR spectroscopy (Table I). Attempts at synthesizing the *o*-dimethylamino and *o*-diethylamino Mannich bases failed, probably due to steric hindrance.

The antifungal activity of all compounds, *i.e.*, types I and II, was determined *in vitro* [1] against *Trichophyton schoenleini, T. mentagrophytes, T. tonsurans, Candida albicans,* and *Epidermophyton flocossum.* All compounds were dissolved in dimethyl sulfoxide at a concentration of 5 μg/ml. The antifungal properties of the active substances are reported in Table II and were compared to haloprogin and griseofulvin.

Antifungal activity was observed with I*a*, I*b*, and I*c*. The Mannich bases II*a* and II*d* showed some activity, although the remaining bases did not. In addition, considerable growth inhibition was visible by II*a* against *E. flocossum.* Therefore, it appeared that the introduction of an alkylamino group onto one propargyl chain led to diminished antifungal properties.

[1] A cylinder plate method on a Sabouraud dextrose agar medium (Difco), pH 5.9, was used. The plates were subjected to preincubation (period of diffusion) at 4° for 1 hr and then incubated at 25° for 72 hr. The zones of inhibition were measured, each value representing the average of three trials. Control agar plates using dimethyl sulfoxide were included in each trial series. The microorganisms were obtained from the fungi collection of the Department of Microbiology, University of Montreal, Montreal 101, Canada.

EXPERIMENTAL [2]

1,2-Bis(2-propynyloxy)benzene (I*a*)—To 75 ml of acetone, 11 g (0.1 mole) of catechol, 27.6 g (0.2 mole) of anhydrous potassium carbonate, and 23.8 g (0.2 mole) of propargyl bromide were added, and the mixture was refluxed under nitrogen for 8 hr. The mixture was filtered, and the resulting filtrate was evaporated under reduced pressure. The residue was dissolved in ether, washed with 10% sodium hydroxide and water, and dried over anhydrous potassium carbonate. The solvent was evaporated under reduced pressure, and the resulting oil was heated in *n*-pentane. Decanting and evaporating the supernate yielded 13.1 g (70%) of I*a*, mp 30.5–31°; IR (ν_{max}): 3285 (acetylenic CH) and 2115 (monosubstituted C≡C) cm^{-1}; NMR: 2.4 (t, 2H, J = 2.6 Hz), 4.65 (d, 4H, J = 2.6 Hz), and 6.95 (s, 4H) ppm; TLC: R_f 0.50 (chloroform).

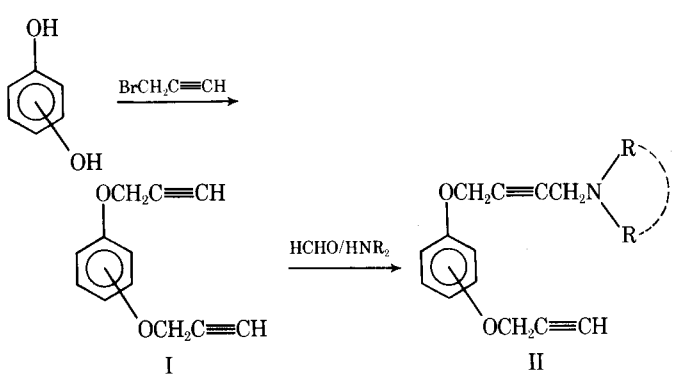
1,3-Bis(2-propynyloxy)benzene (I*b*)—Compound I*b* was prepared from resorcinol as described for I*a*, yielding 15.8 g (85%), mp 37.5–38°; NMR: 2.6 (t, 2H, J = 2.6 Hz), 4.7 (d, 4H, J = 2.6 Hz), 6.6 (m, 3H), and 7.2 (t, 1H, J = 8.0 Hz) ppm; TLC: R_f 0.8 (chloroform).

1,4-Bis(2-propynyloxy)benzene (I*c*)—Compound I*c* was prepared from hydroquinone as described for I*a*, yielding 16.8 g (87%), mp 49.5–50°; NMR: 2.6 (t, 2H, J = 2.6 Hz), 4.8 (d, 4H, J = 2.6 Hz), and 7.2 (s, 4H) ppm; TLC: R_f 0.55 [chloroform–carbon tetrachloride (7:3)].

1-(4-Dimethylamino-2-butynyloxy)-4-(2-propynyloxy)benzene (II*a*)—To 35 ml of dioxane, 16.2 ml (0.216 mole) of 40% formaldehyde and 10 g (0.054 mole) of I*c* were added, and the solution was placed in a 250-ml pressure flask. Dimethylamine, 19.4 g (0.432 mole), was added, and the flask was sealed and heated at 80° for 140 hr. The reaction flask was cooled prior to opening. The solvents were evaporated under reduced pressure; the residue was dissolved in ether and washed with several portions of 10% sodium bisulfite and then water until neutral washings resulted. The organic phase was extracted with 250 ml of 10% HCl, the aqueous fraction was made alkaline with a slurry of sodium bicarbonate, and the free base was extracted with ether and dried over anhydrous potassium carbonate. The solvent was removed to yield 4.02 g (31%) of II*a*, mp 34–35°; IR (ν_{max}): 3290 (acetylenic CH) and 2110 (monosubstituted C≡C) cm^{-1}; NMR: 2.15 (s, 6H), 2.4 (t, 1H, J = 2.6 Hz), 3.2 (d, 2H, J = 2.0 Hz), 4.6 (m, 4H), and 6.9 (s, 4H) ppm.

Mannich Bases—The following Mannich bases were prepared similarly.

1-(4-Diethylamino-2-butynyloxy)-4-(2-propynyloxy)benzene (II*b*)—NMR: 1.0 (t, 6H, J = 6.3 Hz), 2.4 (m, 5H), 3.35 (t, 2H, J = 2.0 Hz), 4.6 (m, 4H), and 6.85 (s, 4H) ppm.



Scheme I

[2] Melting points were measured by the capillary method on a Buchi melting-point apparatus and are uncorrected. Carbon, hydrogen, and nitrogen were determined by Dr. C. Daessle, Montreal, Canada. Amine bases were analyzed in the form of their picrate salts, and the results obtained are within 0.4% of the theoretical values. IR spectra were recorded on a Beckman IR 18A spectrophotometer. NMR spectra were recorded on a Perkin-Elmer R 12B spectrometer in carbon tetrachloride. The tetramethylsilane signal was taken as the internal reference. The proton signals are designated by the following abbreviations: s, singlet; d, doublet; t, triplet; and m, multiplet. TLC plates, 0.5 mm thick, were prepared using silica gel G, and the compounds were detected with iodine vapors.

Fluorometric Determination of Naproxen in Serum

MARKKU ANTTILA

Abstract □ The fluorometric measurement of naproxen following its extraction from serum by a two-step procedure is described. Different parameters in the analysis were examined. The method was useful in biopharmaceutic and pharmacokinetic studies of naproxen.

Keyphrases □ Naproxen—fluorometric analysis, human serum □ Fluorometry—analysis, naproxen in human serum □ Anti-inflammatory agents—naproxen, fluorometric analysis, human serum

Naproxen, (+)-6-methoxy-α-methyl-2-naphthaleneacetic acid, is a potent nonsteroidal anti-inflammatory, analgesic, and antipyretic drug (1). The pharmacokinetics of naproxen in various animal species and in humans have been reported (2). These studies were based on an assay method, described briefly previously (2), which involves GLC with flame-ionization detection. In the present study, a fluorometric method was developed; it is more sensitive and, because of its simplicity, may be more widely applicable than the GLC method.

EXPERIMENTAL

Materials and Equipment—Naproxen was synthesized[1], and all other chemicals were analytical grade and used as supplied[2]. Standard solutions were prepared by dissolving naproxen in 0.1 *M* NaOH. Fluorescence spectra (uncorrected) and measurements were made with a fluorescence spectrophotometer[3].

Procedure—Serum or plasma, 0.10 ml, was added to 1 ml of 1 *M* hydrochloric acid and 5.00 ml of benzene containing 1.5% isoamyl alcohol in 10-ml screw-capped[4] tubes. These tubes were then shaken for 10 min on a reciprocating shaker. Following a brief centrifugation (5 min at 2000×*g*), 4.00 ml of the organic phase was transferred to a second tube containing 3.00 ml of 0.1 *M* sodium hydroxide.

After shaking and centrifuging again, the organic phase was aspirated and discarded. The fluorescence of the water phase was measured at excitation and emission maxima of 330 and 355 nm, respectively. The concentrations of naproxen in the samples were estimated by reference to standard solutions of naproxen in serum prepared simultaneously.

RESULTS AND DISCUSSION

Naproxen showed strong native fluorescence in aqueous solution with three distinct excitation maxima at wavelengths of 240, 275, and 330 nm and an emission maximum at 355 nm (Fig. 1). The fluorescence was insensitive to changes in pH (the fluorescence changed by less than 3% over the pH 0.1–14.0 range). For routine assay, the excitation maximum at 330 nm was used because fluorescence remained linearly related to naproxen concentration up to 10 μg/ml. At excitation maxima of 240 and 270 nm, linearity was preserved only up to 2.5 and 1 μg/ml, respectively.

The extraction of naproxen from serum into several organic solvents was tested. Quantitative recovery was obtained with heptane and benzene (both containing 1.5% isoamyl alcohol); 99 ± 2% (mean ± *SD*, *n* = 10) of the drug added at a concentration of 50 μg/ml to serum samples was found in the aqueous phase after two extractions. Benzene was selected for the assay because it produced a lower background fluorescence.

The optimum conditions for extraction of naproxen from aqueous solution into organic solvents were found by studying the distribution of the compound between various buffer solutions and benzene. For the transfer of naproxen from an aqueous into an organic phase, a pH lower than 7 was required; reextraction into water required a pH above 9.

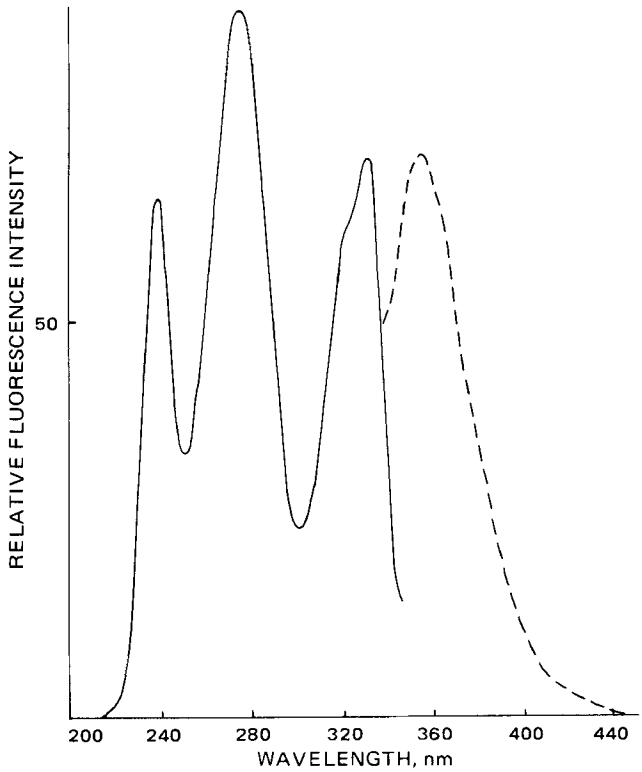

Figure 1—*Uncorrected excitation (—) and emission (- - -) spectra of the fluorescence of naproxen (1 μg/ml of 0.1 M NaOH).*

The detection limit of the present method is 0.5 μg/ml of serum. At this concentration, the fluorescence is twice that of the reagent blank. The sensitivity of the procedure is such that it will detect therapeutic plasma concentrations of naproxen. The sensitivity could be increased by using larger volumes (to 1 ml) of serum, since this change did not excessively increase background fluorescence and did not affect the recovery. Because

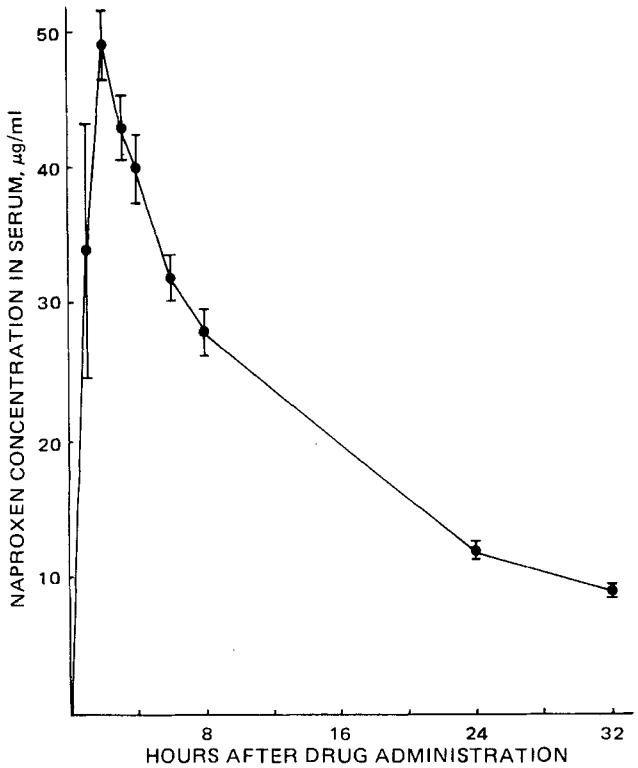

Figure 3—*Mean (±SEM) serum levels of naproxen in humans (n = 6) following single-dose oral administration of 250 mg of drug as a compressed tablet.*

of the linearity of the standard curve, serum concentrations up to 250 μg/ml can be measured using 0.1 ml of sample.

Several drugs at normal serum concentrations were examined for interference with this fluorometric assay of naproxen. Basic drugs were removed in the extraction procedure and caused no interference. The following acidic drugs also did not interfere: chlorpropamide, furosemide, ibuprofen, indomethacin, mefenamic acid, phenobarbital, phenylbutazone, phenytoin, sulfamethoxazole, and warfarin. Interference was observed with salicylic acid; 200 μg of salicylic acid/ml of serum gave a fluorescence value equivalent to about 10 μg of naproxen/ml. Therefore, this fluorometric assay method is not suitable for the determination of serum levels of naproxen in patients simultaneously receiving salicylates.

Interference by metabolites of naproxen was not studied, because the concentrations of metabolites in serum after naproxen administration are negligible (3).

The precision of the method was determined at three different concentrations. Naproxen solution was added to serum to give final concentrations of 5, 50, and 200 μg/ml. Ten 0.1-ml samples of each serum solution were analyzed by the proposed method at the same time. The relative standard deviations obtained were 2.6, 1.4, and 1.1%, respectively.

To test the accuracy of the method, 32 serum samples containing unknown concentrations of naproxen were assayed by both the present method and the GLC method (2). The results (Fig. 2) showed excellent correlation between the two methods.

To demonstrate the utility of this fluorometric method, serum concentrations of naproxen were measured in six normal human subjects after oral administration of a single dose of 250 mg of naproxen (one 250-mg tablet). The resulting serum levels (Fig. 3) agreed well with the serum levels of naproxen obtained by other workers using the GLC method (2).

The described fluorometric method is simple, rapid, and sensitive and can serve as a useful tool in the study of biopharmaceutics and pharmacokinetics of naproxen.

Fluorescent Inhibitors of Thymidylate Synthetase

THOMAS L. DEITS, GEORGE R. GAPSKI, and JOHN M. WHITELEY ×

Abstract □ Two fluorescent derivatives of 2′-deoxy-5-fluorouridine 5′-*p*-aminophenyl phosphate were prepared by treatment of this compound with fluorescein isothiocyanate in dimethyl sulfoxide or 5-(dimethylamino)naphthalenesulfonyl chloride in pyridine. The products of the reactions were isolated by diethylaminoethylcellulose chromatography and were shown to be homogeneous by polyacrylamide electrophoresis and TLC. Confirmation of the structure was provided by elemental analysis, absorption and fluorescence spectra, PMR measurements, and liberation of nucleotide upon hydrolysis with snake venom phosphodiesterase. The fluorescent derivatives are good competitive inhibitors ($K_i \simeq 10^{-6}$ *M*) of thymidylate synthetase from a methotrexate-resistant strain of *Lactobacillus casei*.

Keyphrases □ Thymidylate synthetase—inhibition by fluorescent derivatives of 2′-deoxy-5-fluorouridylate ester evaluated □ 2′-Deoxy-5-fluorouridylate ester—fluorescent derivatives synthesized, inhibition of thymidylate synthetase evaluated □ Enzyme inhibitors—fluorescent derivatives of 2′-deoxy-5-fluorouridylate ester synthesized, effect on thymidylate synthetase

The *de novo* enzymatic synthesis of thymidylate (2′-deoxy-5-methyluridylate) is achieved by transfer of the methylene substituent of 5,10-methylenetetrahydrofolate to 2′-deoxyuridylate with the associated conversion of the hypothetical methylene intermediate (1) to methyl using the inherent reducing power of the folate cofactor (Scheme I). A metabolic cycle is completed when the ensuing dihydrofolate is reduced to the tetrahydro level in the presence of dihydrofolate reductase, and an additional one-carbon unit is reintroduced enzymatically (2). Scheme I

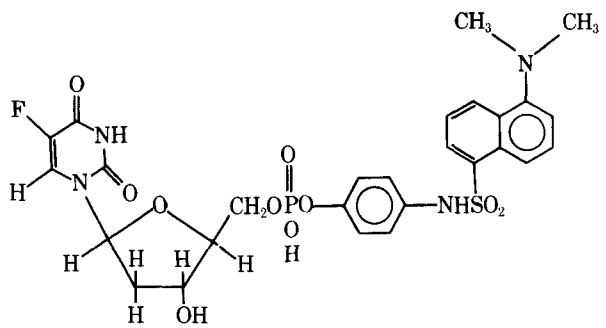
I



II

thymidylate is a required precursor of DNA, these two enzymes are essential for cellular replication; their interrelationship and mechanism of action have been of considerable interest during the past decade (3, 4).

Earlier experiments showed that fluorescein isothiocyanate coupled *via* a diaminopentyl group to methotrexate gives a compound that exhibits significant fluorescence changes in the presence of dihydrofolate reductase but retains its inhibitory properties and coelectrophoreses with this enzyme on polyacrylamide gels (5). As a result of this observation and earlier reports by Stryer (6) who demonstrated how variations in fluorescence intensity could be used as indicators of the nature of the heme-binding site in myoglobin, it appeared possible that similar fluorescent derivatives of the potent inhibitor of thymidylate synthetase, 2′-deoxy-5-fluorouridylate[1], might be useful as probes for the active site of this enzyme.

The syntheses and properties of the fluorescein and 5-(dimethylamino)naphthalenesulfonyl derivatives of 2′-deoxy-5-fluorouridylate are described in this paper. The two compounds (I and II) were obtained by condensing equimolar quantities of 2′-deoxy-5-fluorouridine 5′-*p*-aminophenyl phosphate (III), a compound previously synthesized in this laboratory (7), with fluorescein isothiocyanate[2] in dimethyl sulfoxide or 5-(dimethylamino)-naphthalenesulfonyl chloride[2] in pyridine. In each case, the desired fluorescent products were purified by chromatography on diethylaminoethylcellulose[3] and isolated by lyophilization. Further purification was achieved by fractional crystallization of the barium salts from ethanol–water. When I and II were irradiated at 492 and 360 nm, respectively, they showed strong fluorescence maxima at 523 and 543 nm, respectively, and the intensity varied markedly with the polarity of the solvent. Both compounds were good competitive inhibitors of thymidylate synthetase from a methotrexate-resistant strain of *Lactobacillus casei* (4).

EXPERIMENTAL[4]

Materials and Methods—Quantum yields were determined by comparison with quinine sulfate as a standard. Two systems were used for TLC: A, cellulose layers developed with 1-butanol–5 *N* acetic acid (2:1); and B, diethylaminoethylcellulose layers developed with 0.5 *M* ammonium acetate.

Thymidylate synthetase was isolated from a methotrexate-resistant strain of *L. casei* according to the procedure of Whiteley *et al.* (7) and was assayed spectrophotometrically (8). Inhibition constants were obtained from plots of $1/v$ against i at varying substrate concentrations, where v is the initial rate of reaction and i is the inhibitor concentration. Disc electrophoresis on 7.5% (w/v) polyacrylamide gels was carried out in 0.6 × 6-cm tubes. Enzymatic hydrolysis of the fluorescent derivatives was achieved by incubating an aliquot of the sample with snake venom phosphodiesterase[5] in 0.5 *M* tromethamine hydrochloride[2] buffer, pH 9, at ambient temperatures for 1 hr. The nucleotide product was identified by comparison with an authentic standard on TLC using System A.

Preparation of Fluorescent Derivatives of III—*Fluorescein Derivative (I)*—Fluorescein isothiocyanate (61.8 mg, 0.159 mmole) and the barium salt of III (89.7 mg, 0.159 mmole) were dissolved in dimethyl sulfoxide (1 ml). After standing for 4 hr at room temperature, the solution was applied to a 2 × 40-cm column of diethylaminoethylcellulose, which was then washed with 0.3 *M* ammonium acetate (2 liters). The product (I) was recovered by eluting with a 0.6 *M* solution of the same buffer, followed by lyophilization (126 mg, 99%). The product was either isolated as the free acid at this stage by trituration with 1-propanol and filtration or converted to the barium salt by dissolving in water and adjustment of the resulting solution to pH 8 with saturated barium hydroxide.

After lyophilization, the residue was taken up in the minimum quantity of water, precipitated with absolute ethanol, filtered, and dried; TLC: System A, R_f 0.69; System B, R_f 0.22; λ_{max} (0.1 *M* HCl) 251 and 438 nm (ϵ 41,200 and 40,000); λ_{max} (0.1 *M* potassium phosphate, pH 7) 236, 262, and 492 nm (ϵ 48,200, 35,300, and 53,900); λ_{max} (0.1 *M* NaOH) 237, 260, and 488 nm (ϵ 56,700, 34,600, and 67,700); fluorescence maximum (0.1 *M* potassium phosphate, pH 7): 492 nm (excitation) and 523 nm (emission) (quantum yield = 0.51); PMR (D_2O): δ 2.1 (2H, m) (2′-protons), 4.0 (3H, m) (4′- and 5′-protons), 4.3 (1H, m) (3′-proton), 6.0 (1H, m) (1′-proton), and 6.2–7.8 (broad multiplet containing the remaining 14 nonexchangeable proteins attached to unsaturated carbon).

Anal.—Calc. for $C_{36}H_{28}FN_4O_{13}PS \cdot 5.5\ H_2O$: C, 47.74; H, 4.34. Found: C, 47.48; H, 3.93.

5-(Dimethylamino)naphthalenesulfonyl Derivative (II)—A mixture of 5-(dimethylamino)naphthalenesulfonyl chloride (59.4 mg, 0.22 mmole) and the barium salt of III (113 mg, 0.2 mmole) dissolved in pyridine (5 ml) was allowed to react at ambient temperatures for 20 hr. The solution was then applied directly to a 2 × 40-cm column of diethylaminoethylcellulose. Application of water (300 ml) followed by 0.2 *M* ammonium bicarbonate (2 liters) eluted the gold fluorescent product (II). The principal fractions were combined and lyophilized (111 mg, 86%). The free acid was purified by dissolving the residue in a minimum quantity of methanol, followed by precipitation with ether. To obtain the barium salt, the material was taken up in water (15 ml), adjusted to pH 8 with barium hydroxide, filtered, and lyophilized.

The residue was dissolved in a minimum quantity of water, and the nucleotide was precipitated by the addition of acetone; TLC: System A, R_f 0.60; λ_{max} (0.1 *M* HCl) 275 and 320 nm (ϵ 13,300 and 2850); λ_{max} (0.1 *M* potassium phosphate, pH 7) 248 and 320 nm (ϵ 17,800 and 4040); λ_{max} (0.1 *M* NaOH) 244 and 318 nm (ϵ 22,400 and 5240); fluorescence maximum (0.1 *M* potassium phosphate, pH 7): 360 nm (excitation) and 543 nm (emission) (quantum yield = 0.02); PMR (D_2O): δ 2.0 (8H, m) (*N*-dimethyl and 2′-protons), 3.9 (3H, broad s) (4′- and 5′-protons), 4.2 (1H, m) (3′-proton), 6.0 (1H, m) (1′-proton), and 6.3–8.2 (broad multiplet containing the remaining 11 nonexchangeable protons attached to unsaturated carbon).

Anal.—Calc. for $C_{27}H_{28}FN_4O_{10}PS \cdot 2.5H_2O$: C, 46.62; H, 4.78. Found: C, 46.63; H, 5.03.

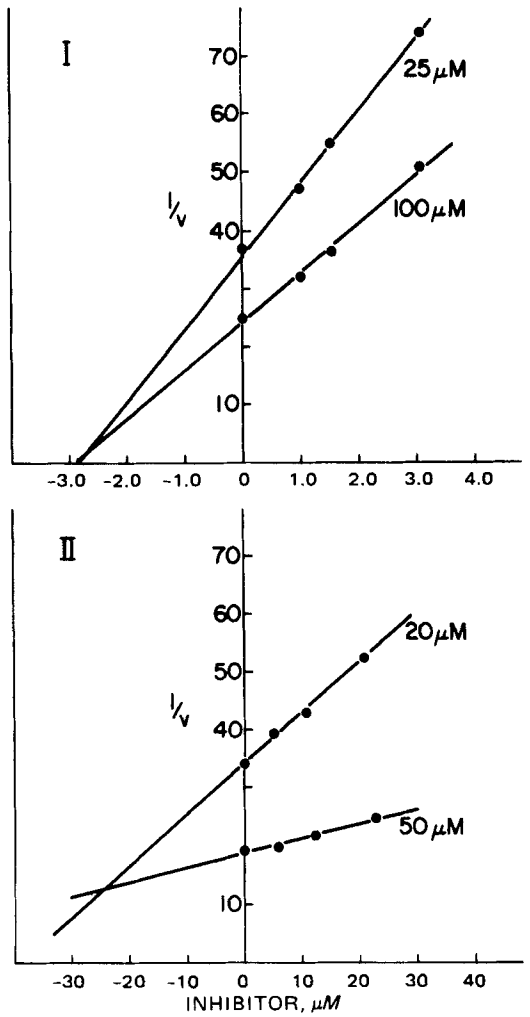

Figure 1—*Inhibition of thymidylate synthetase by I and II. The activity of the synthetase from a methotrexate-resistant strain of* L. casei *(specific activity = 3; 1.2 μg of protein) was measured as described under* Experimental. *Enzyme, 5,10-methylenetetrahydrofolate, and inhibitor were incubated together for 10 min prior to the addition of the indicated concentrations of 2′-deoxyuridylate to initiate the reaction.*

RESULTS AND DISCUSSION

The two fluorescent derivatives (I and II) were shown to be homogeneous by polyacrylamide electrophoresis and TLC. Structure confirmation was afforded by hydrolysis with snake venom phosphodiesterase to liberate free 2′-deoxy-5-fluorouridylate, elemental analysis, and PMR and absorption spectra. The absorption spectrum of each product contained the chromophore of the fluorescent moiety superimposed on that of the nucleotide ester; however, the absorptivity of the fluorescein derivative at 492 nm (pH 7) was only 54,000. This figure is 26% lower than the value recorded for free fluorescein under the same conditions (9), which suggests that there may be some interaction between the pyrimidine and fluorescein components.

This inference is supported (Table I) by the lower quantum yield (0.51) recorded for this compound when compared with the quantum yield (0.64) of free fluorescein at pH 7 (10). In the presence of ethanol, the quantum yield was depressed a further 40%, suggesting that the interaction of the two chromophores is increased in the less polar solvent. Derivative II showed a much smaller efficiency of fluorescence (quantum yield = 0.019, *cf.*, Table I); but in the presence of increasing amounts of ethanol, solutions of this compound showed a progressive increase in quantum yield. These disparate observations suggest that the two derivatives may complement each other when used as probes for the active site of the enzyme.

Table I—Quantum Yields for I and II

Derivative	Solvent	Quantum Yield
I	0.1 *M* PO_4, pH 7.0	0.51
	0.1 *M* PO_4–25% ethanol	0.31
	0.1 *M* PO_4–50% ethanol	0.32
II	0.1 *M* PO_4, pH 7.0	0.019
	0.1 *M* PO_4–25% ethanol	0.047
	0.1 *M* PO_4–50% ethanol	0.10

The inhibition constants (K_i) derived at pH 7 for the interaction of purified thymidylate synthetase with I, II, and III were 2.8, 24, and 8 μM, respectively. Clearly, introduction of the fluorescent groups made little change in the inhibitory properties. In fact, the large fluorescein moiety slightly enhanced the inhibitory capacity of the nucleotide ester, although a small decrease was observed for II. That the inhibition (for both I and II) was competitive with the normal substrate of the reaction is shown in Fig. 1, where the reciprocal velocity is plotted *versus* the inhibitor concentration at different concentrations of the substrate (2′-deoxyuridylate).

The strongly inhibitory properties demonstrated by I and II, coupled with their observed variation in fluorescence intensity with solvent polarity, suggest that these compounds may be useful aids for probing the active site of thymidylate synthetase. The compounds may provide information concerning the interaction of the nucleotide substrate or its fluorinated analog with the synthetase and may also have an additional function as visual protein markers during enzyme purification.

Survival of Pleomorphic Sarcoma-37 Transplanted Virgin Female DBA/2J Mice: Hyperthermia and Hyperglycemia, Alone and in Combination with Drugs

RONALD E. ORTH ˣ, HOWARD J. SWIDLER, and MILO S. ZARAKOV

Abstract □ Sarcoma-37 (S-37) transplanted DBA/2J mice were submitted to a controlled whole body hyperglycemic–hyperthermic ("double attack") treatment. A single exposure to the 3-hr 400–500-mg % blood glucose level coupled with 1 hr of whole body 40.0° warming was safe and extended longevity by 40% over the nontreated controls. This increase suggests that additive or potentiated effects follow the two-parameter procedure. The treatment safety and resultant increased longevity were not enhanced by single-dose chemotherapy with doxorubicin and/or dacarbazine.

Keyphrases □ Blood glucose—high levels, combined with hyperthermia and doxorubicin or dacarbazine, effect on survival of tumor-transplanted mice □ Dextrose infusion—combined with hyperthermia and doxorubicin or dacarbazine, effect on survival of tumor-transplanted mice □ Hyperthermia—combined with dextrose infusion and doxorubicin or dacarbazine, effect on survival of tumor-transplanted mice □ Doxorubicin—combined with hyperglycemia and hyperthermia, effect on survival of tumor-transplanted mice □ Dacarbazine—combined with hyperglycemia and hyperthermia, effect on survival of tumor-transplanted mice □ Antineoplastics—doxorubicin and dacarbazine, combined with hyperglycemia and hyperthermia, effect on survival of tumor-transplanted mice

Nearly a half century ago, investigators attempting to characterize functional differences between normal and cancerous tissue from the same organ found a higher rate of aerobic glucose metabolism for the latter (1). von Ardenne (2) attempted to capitalize on the resultant higher intracellular lactic acid levels in glucose-stressed cancerous tissue. The premise is that the more acidic neoplastic tissue offers a better substrate for support of intrinsic catabolic lysosomal enzyme activity. A single safe 3-hr 400–500-mg % blood glucose level was followed by a significant increase in the longevity for Sarcoma-37 (S-37) transplanted virgin female DBA/2J mice (3).

A review on the association of heat and cancer (4) and data on whole body hyperthermia in humans (5) and animals (6) are available. One hour of whole body 40.0° warming was found to be a safe, statistically significant factor in prolonging the longevity of S-37 transplanted DBA/2J mice[1].

Doxorubicin (I) and dacarbazine (II), drugs known to interfere with cell membrane protein synthesis, were effective alone and in combination against human (7) and mouse (8) sarcomas *in vivo*.

A dextrose infusion–whole body warming technique was evaluated *in vitro* and *in vivo* in seven different rodent tumor types (9), and tumor diameter decreases were noted.

The effects of a single incident of 3-hr 400–500-mg % whole blood glucose levels, 1 hr of warming at 40.0°, 5 mg/kg sc of I, and 200 mg/kg ip of II were individually evaluated for safety and resultant longevity under controlled conditions in S-37 transplanted mice (Table I, cages 2–5). Various combinations of these four treatments also were evaluated (Table I, cages 6–10 and 12). Virgin female DBA/2J mice were the treatment and control subjects in cages 2–10 and 1, respectively. Transplanted male DBA/2J mice were subjected to control and dextrose–warming ("double attack") procedures (cages 11 and 12, respectively) to determine differences in responses by sex.

[1] R. E. Orth, H. J. Swidler, and M. S. Zarakov, unpublished results.

EXPERIMENTAL

Transplantation—An S-37 bearing donor mouse[2] was sacrificed 7 days after serial subcutaneous transplantation. The tumor was removed, moistened with isotonic saline, and minced. One cubic millimeter of tissue was placed in a 15-gauge trocar and administered to 15–20-g DBA/2J mice subcutaneously into the thigh 6 days before treatment.

Drugs—Whenever drugs were administered to experimental animals, isotonic saline was given to the paired control animal in the same way, at the same site, and in the same chronological sequence. When used, I[3] and II[3] were given 15 min prior to the hypnotic agent. Pentobarbital sodium, 80 mg/kg po, was administered (3.2 mg/ml of 1:2150 diluted B complex elixir). Aqueous dextrose (40% w/v) and isotonic saline were the infusion solutions used.

Dextrose Intravenous Infusion Procedure —Unconscious mice were secured with their heads down (shock position), on their backs, with immobilized tails. An adapted infusion pump[4] syringe holder contained six 1-ml syringes[5]. Each syringe was connected by tubing[6] to a 26-gauge 12.7-mm needle[7] for insertion into the tail vein of each of six mice. The syringes, filled with the dextrose solution[8], were activated at pump speed setting No. 19. Postorbital venous blood samples of approximately 0.05 ml were periodically obtained using heparinized capillary tubes[9].

Blood glucose levels were determined by reading glucose oxidase–peroxidase reagent strips[10] in a reflectance colorimeter[11]. Once 400–500-mg % levels were obtained, the infusion was slowed to a replacement rate with a pump setting of No. 20 or 21, and these levels were maintained for 2 hr.

Water Bath Procedures—Conscious mice were immersed to the neck in a water bath[12] for 1 hr at 40.0 ± 0.3°[13] (Table I, cages 3, 7–10, and 12) or 37.0 ± 0.3° (Table I, cages 1, 2, 4–6, and 11) following oral administration of 0.01 ml of B complex elixir. A stream of 95% O_2 was directed to the head of each animal during this period. Following the immersion, the animals were gently toweled and placed in a 37.0° oxygenated compartment for 1 hr before being returned to their cages.

[f] Isotonic saline tail vein 3-hr 0.5-ml iv infusion. Whole body 40.0° water bath immersion during the 3rd hr. [g] Forty percent (w/v) dextrose tail vein infusion at rate that maintains 3-hr 400–500-mg % blood glucose level. Whole body 40.0° water bath immersion during the 3rd hr.

RESULTS AND DISCUSSION

All mice (cages 1–12) were subcutaneously transplanted with S-37, given B complex, anesthetized, secured, infused (dextrose or saline), subjected to blood sampling, immersed 1 hr in a water bath (40.0 or 37.0°), and dried. The use of I and/or II was the only variation.

Blood glucose levels of 450–500 mg % were obtained in 60 ± 15 min by infusing approximately 0.2 ml of the 40% dextrose solution. Blood glucose samples obtained after warming the mice remained at or above 400 mg %. Therefore, 1 hr after discontinuing the infusion or 3 hr after establishing the necessary blood glucose level, the desired concentration still existed. To obviate excessive dextrose or volume problems, no more than 0.5 ml was given to any subject.

Treatment of S-37 transplanted virgin female DBA/2J mice with dextrose (cage 2), 1 hr of warming at 40° (cage 3), or 200 mg/kg ip of II (cage 5) was safe (100% treatment survival) and significantly increased longevity. The dextrose–40.0°/1-hr therapy (cage 7) was safe and effectively increased longevity by 40% over the transplanted controls of cage 1. The adjunctive use of I and/or II (cages 8–10) did not enhance this combination. In this study, only mice treated with 5 mg/kg sc of I (cage 4) failed to show a significant increase in lifespan over the controls of cage 1 according to the Student two-tailed t test with 95% confidence limits.

Male mice transplanted with S-37 responded less dramatically to either the tumor (cage 11) or the dextrose–40.0°/1-hr treatment (cage 12) than did virgin females of the same DBA/2J strain (cages 1 and 7). The control males lived significantly longer than the control females; however, the dextrose–1-hr warmed males lived longer than the male controls but not as long as the treated females.

The results of this study are in good general agreement with those of von Ardenne (6). Under different conditions, 1 hr of warming at 40°[2] increased the length of life for S-37 transplanted mice, and 3-hr 400–500 mg % blood glucose levels (3) were even more effective at safely prolonging longevity. A single application of these two procedures together is safe and appears to effect an additive if not a potentiated longevity increase. The results are not improved upon by concurrently administering I and/or II, although II is effective alone. The tumor is less virulent and more susceptible to the "double attack" in males than in females of the DBA/2J strain.

IR Spectrophotometric Assay of Carbachol Solutions

JOHN FRANK and LESTER CHAFETZ ˣ

Abstract □ Carbachol ophthalmic solutions can be assayed by evaporating a measured volume, dissolving the residue in methanol, and scanning the carbonyl stretching frequency in an IR spectrophotometer using a cell with calcium fluoride windows. Methylcellulose and other formulation vehicle components do not interfere. The method is stability indicating with respect to hydrolysis. It affords a recovery of 99.5 ± 0.51% (*RSD*).

Keyphrases □ Carbachol—IR spectrophotometric analysis, commercial ophthalmic preparations □ IR spectrophotometry—analysis, carbachol, commercial ophthalmic preparations □ Cholinergics, ophthalmic—carbachol, IR spectrophotometric analysis, commercial preparations

Carbachol, the carbamoyl ester of choline, has been shown to be stable in aqueous solution at pH values lower than 7. A kinetic study of its hydrolysis was reported in which choline separated from carbachol by TLC was determined photometrically as its dipicrylamine complex (1). USP XVIII (2) used a reinecke salt colorimetric method for the assay of carbachol ophthalmic solution; however, the method does not discriminate between carbachol and choline. It was replaced in the First Supplement (3) by a stability-indicating method, apparently based on the work of Puckett and Poe (4). The procedure involves formation of the *N*-chloro derivative of carbachol by reaction with alkaline hypochlorite, destruction of excess hypochlorite with phenol, and oxidation of iodide by the *N*-chloro derivative to iodine, which is determined as its amylose complex. Erratic results with the method led to the development of the simple and highly selective IR spectrophotometric method described here.

EXPERIMENTAL

Pipet a volume of carbachol ophthalmic solution[1], equivalent to about 90 mg of carbachol, into a 250-ml round-bottom flask. Add about 10 ml of methanol and evaporate the solution to dryness in a rotary evaporation apparatus[2], using reduced pressure and a water bath temperature of 50°. Add exactly 10.0 ml of methanol to the flask, stopper, and swirl to dissolve the carbachol. (Methylcellulose, in the test preparations used in this work, forms a thin film which does not dissolve.)

Fill a 0.1-mm path length IR cell, equipped with calcium fluoride windows, with the solution. Record its spectrum in the carbonyl region (1970–1550 cm^{-1}) three times, using a suitable double-beam IR spectrophotometer[3] and a matched cell filled with methanol in the reference beam. Concomitantly scan the carbonyl region of a methanol solution of carbachol USP reference standard containing a known concentration of about 9 mg/ml. Draw a horizontal straight line from the shoulder at about 1980 cm^{-1} and draw a straight line from the absorption band maximum at 1720 cm^{-1} perpendicular to the first line and intercepting it. The length of this line, in the units of the recorder chart paper, is the percent transmittance from which absorbance is calculated from the relation $A = \log_{10}(1/T)$.

Calculate the concentration, in percent (w/v), of carbachol in the ophthalmic solution from the formula $C/V(A_U/A_S)$, where C is the concentration, in milligrams per milliliter, of carbachol in the standard solution; V is the volume, in milliliters, of carbachol ophthalmic solution taken for assay; and A_U and A_S are the average absorbances determined for the assay preparation and the standard solution, respectively.

[2] Buchler flash evaporator.

[3] Perkin-Elmer model 621 ratio-recording double-beam IR spectrophotometer.

Table I—Recovery of Carbachol Added to 1.5 and 3.0% Formulation Vehicles

Vehicle	Amount Added, mg	Amount Found, mg	Percent Recovered
1.5%	39.1	39.0	99.7
	78.2	78.0	99.7
	156.4	155.0	99.1
3.0%	94.9	94.4	99.5
	189.9	189.0	99.5
	379.8	380.0	100.0

RESULTS AND DISCUSSION

The feasibility of the method was first investigated using ordinary sodium chloride cells; however, these cells are fogged by methanol and require polishing after only a few uses. Calcium fluoride windows are impervious to methanol. Methanol was chosen as the solvent because of its excellent solvent powers for carbachol and its transparency in the spectral area of interest.

Precision and Recovery—The vehicles for the 1.5 and 3.0% test preparations differ in that the latter contains a borate buffer and sodium chloride as well as methylcellulose and benzalkonium chloride. However, both vehicles gave IR spectra indistinguishable from a methanol blank when tested in the procedure. Carbachol was added in three concentrations to each vehicle. Average recovery (Table I) for the six trials was 99.6% with a relative standard deviation of ±0.51%.

Standard solutions containing 3.91, 7.82, and 15.64 mg of carbachol/ml in methanol provided absorbances of 0.140, 0.280, and 0.572, respectively. These data afford a straight-line graph that intercepts the origin.

Selectivity—None of the constituents of the ophthalmic solution vehicles used interfered in the assay. Other commercially available carbachol eye solutions list 1.4% polyvinyl alcohol and edetate disodium as vehicle components. Since polyvinyl alcohol contains acetate ester groups to some extent and edetate disodium has carboxyl functions, solutions of 1.4% polyvinyl alcohol and 0.1% edetate were assayed by the proposed method. Neither interfered in the assay; both gave spectra identical with the blank in the spectral region used for analysis.

The validity of the assay as a stability-indicating method was verified by heating 5 ml of water containing 100 mg of carbachol and 4 ml of 1 *N* sodium hydroxide in a sealed ampul at 105° overnight to saponify the carbamate. Assay of this solution by the proposed method showed no carbonyl band.

Synthesis of Sulfonates of 4-Chloro-3,5-dimethylphenol and 5-Chloro-7-iodo-8-quinolinol

JITENDRA J. SHAH

Abstract □ Seven sulfonates of 4-chloro-3,5-dimethylphenol and seven sulfonates of 5-chloro-7-iodo-8-quinolinol were synthesized, characterized, and evaluated for antimalarial activity. None of the sulfonates was effective against *Plasmodium berghei*.

Keyphrases □ Sulfonates—of substituted phenols and quinolinols, synthesized and evaluated for antimalarial activity □ Phenols, substituted—sulfonates synthesized and evaluated for antimalarial activity □ Quinolinols, substituted—sulfonates synthesized and evaluated for antimalarial activity □ Antimalarial activity—sulfonates of substituted phenols and quinolinols evaluated □ Structure–activity relationships—sulfonates of substituted phenols and quinolinols evaluated for antimalarial activity

The sulfonation of quinoline occurs more readily than that of pyridine but less readily than that of naphthalene. Sulfonation with 30% sulfuric acid at approximately 80° yields 8-quinolinesulfonic acid (54% recovered after isolation) and possibly some 5- and 7-quinolinesulfonic acid as well (1). With mercury as a catalyst, however, 5-quinolinesulfonic acid is the sole reaction product (2). Sulfonation of quinoline with sulfur trioxide in the presence of mercury as a catalyst at 180° leads to a mixture of the 5- and 8-quinolinesulfonic acids (3). The velocity constant of sulfonation is influenced only by the temperature of the reaction and varies considerably.

The methyl group in either the 2- or 4-position to the hydroxyl group has the effect of retarding the speed of sulfonation at all temperatures from 20 to 80°. The methyl group in the 3-position both accelerates and retards the speed of sulfonation according to reaction temperature. Phenol is sulfonated at 2.11 times the rate of 4-methylphenol and 2.21 times the rate of 2,4-dimethylphenol at 40°. The esters, carbonates, and sulfonates of clopidol (3,5-dichloro-2,6 dimethyl-4-pyridinol) were prepared by treating the sodium salt of clopidol suspended in dimethylformamide with the corresponding alkyl or aryl chlorides (4, 5).

This study reports the synthesis of sulfonates of 4-chloro-3,5-dimethylphenol and 5-chloro-7-iodo-8-quinolinol. Sulfonation was carried out with different sulfonyl chlorides in the presence of sodium hydride and dimethylformamide at 3° (4). These sulfonates were evaluated for their antimalarial activity against *Plasmodium berghei* and toxicity in albino mice.

[a] The mortality observed after administration of 5 g/kg of VIII, IX, XI, XII, and XIII was 90, 40, 100, 100, and 30%, respectively, during 14 days. Gross necropsies performed in mice treated with VIII, IX, and XI–XIII showed congested lungs of varying degree; advanced autolysis was found in mice treated with VIII and XI–XIII. [b] Due to mortality, classification of toxicity cannot be made because the compound may be highly toxic.

The mixture was cooled to 3° and added to the desired sulfonyl chloride (0.22 mole) dissolved in 75 ml of dimethylformamide. The reaction mixture was stirred for 1.5 hr, filtered, and washed with chloroform. The filtrate was partially concentrated under reduced pressure and, on cooling, gave the desired product. The analytical product was purified by two recrystallizations from ethanol. The sulfonates of 4-chloro-3,5-dimethylphenol and 5-chloro-7-iodo-8-quinolinol are recorded in Tables I and II, respectively.

Antimalarial Activity—All sulfonates were evaluated[2] for antimalarial activity (6) against *P. berghei* in mice. They were inactive at dose levels of 40, 160, and 640 mg/kg.

Toxicity Studies[3]—The acute oral toxicity was determined by oral administration of sulfonates by stomach tube to 10 albino mice[4], 12–20 g, kept on an *ad libitum* diet. Each sulfonate was administered as a 50% (w/v) suspension in corn oil[5] at a dose of 5 g/kg. The mice were kept in two cages of five animals each and starved for 18 hr prior to the sulfonate administration. The animals were observed closely, and their mortality was recorded. Gross necropsies were performed on the mice that died during the 14-day period. The surviving mice were weighed and then sacrificed by cervical dislocation, and gross necropsies were performed.

Use of ^{99m}Tc-Labeled Triethylenetetramine–Polystyrene Resin for Measuring the Gastric Emptying Rate in Humans

Keyphrases □ Technetium Tc 99m—as radiolabel on triethylenetetramine–polystyrene resin, scintigraphic determination of gastric emptying rate, humans □ Scintigraphy, external—determination of gastric emptying rate using ^{99m}Tc-labeled triethylenetetramine–polystyrene resin □ Triethylenetetramine–polystyrene resin—^{99m}Tc-labeled, use in scintigraphic determination of gastric emptying rate, humans □ Gastric emptying rate—scintigraphic determination using ^{99m}Tc-labeled triethylenetetramine–polystyrene resin, humans □ Radiopharmaceuticals—^{99m}Tc-labeled triethylenetetramine–polystyrene resin, scintigraphic determination of gastric emptying rate, humans

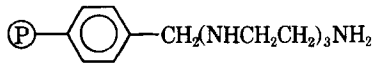
To the Editor:

The introduction of γ-emitting short-lived radionuclides provides the opportunity for the determination of gastric emptying time using external scintigraphy. Quantitative dynamic data can be obtained with these radionuclides without physical or physiological influences on the GI tract (1). Futhermore, excellent scintigraphic images of the stomach, intestines, and colon can be obtained with a low target organ and total body radiation dose.

Several radiopharmaceutical preparations have been introduced for measuring gastric motility and emptying: ^{51}Cr-sodium chromate (2, 3), ^{113m}In- or ^{99m}Tc-labeled diethylenetriaminepentaacetic acid (3, 4), ^{113m}In-microcolloid (5), an insoluble colloid of ^{99m}Tc-antimony sulfide (6), ^{99m}Tc-labeled human albumin microspheres (7), and their combinations (3, 8).

After a meal, the liquid phase of gastric contents is discharged through the pylorus more rapidly than the solid phase. Therefore, radiopharmaceutical preparations dispensed as liquids give lower values for the half-time of gastric emptying (4), and minor deviations in time would provide opportunity for greater error. Comparison of emptying rates using ^{113m}In-diethylenetriaminepentaacetic acid and ^{51}Cr-sodium chromate showed that significantly slower rates were obtained with chromate. Subsequent *in vitro* studies demonstrated adsorption of chromate on the solid component of the meal (3). Thus, difficulties may be encountered with radiopharmaceuticals that appear to interact with the solid particles in a meal and the stomach wall. Colloidal preparations are difficult to prepare, and their physicochemical properties offer disadvantages such as the formation of micelles and coagulation.

Additional criteria in selecting a radiopharmaceutical preparation for gastric emptying are that it should: (*a*) not influence the osmolality of the stomach content (9), (*b*) be nonabsorbable and nonadsorbable (10), (*c*) bind the radionuclide tenaciously and provide no opportunity for physical or chemical interaction with food particles or the stomach wall, (*d*) possess ideal food mixing characteristics and have a particle size comparable to that of food, and (*e*) be nontoxic and inert and give reproducible and noninvasive estimates of the gastric emptying time without exposing the patient to a high radiation dose. The last prerequisite becomes exceedingly important in gastric emptying determinations involving pediatric patients (5).



I

Polystyrene beads (40–100 mesh) bearing triethylenetetramine (I) functions (11) (2 mEq/g) efficiently and quantitatively chelated pertechnetate[1] ($^{99m}TcO_4^-$) from aqueous solutions (12). The ^{99m}Tc-labeled resin is stable in simulated gastric juice USP, releasing only 2.0% of the radioactivity in 25 hr at 37°. When the ^{99m}Tc-complex with I was administered to dogs and humans with a standardized meal, it satisfied all of the previously mentioned criteria for the determination of gastric emptying times. The release of radioactivity from the resin was monitored by collecting blood and urine samples from dogs and human volunteers. Less than 0.2% of the radioactivity was released during the passage of the resin throughout the entire GI tract.

In a typical experiment, 0.25 g of I in 20 ml of water was stirred with the $^{99m}TcO_4^-$ solution[1] (20 μCi) for 10 min. The resin was recovered by filtration, washed with water, and subsequently added to the test meal. This meal consisted of 33.3 g of cream of wheat and 2.4 g of sodium chloride in 235 ml of water. After the subject ingested the labeled test meal, the time was recorded and the subject was placed in a supine position under the collimated detector of a multicrystal scintillation γ-camera[2]. The positions of the γ-camera and of the patient were adjusted so that the entire stomach appeared in the center of the monitoring oscilloscope.

Several scintiphotos of the stomach were obtained at certain time intervals. In each time interval, a series of seven or eight points was collected. Each point represented the integrated relative radioactivity per minute of the desired flagged area of the stomach. The data were stored on a magnetic tape for future reference. The logarithm of the relative radioactivity of the stomach was plotted against time. The half-time of the gastric emptying of the test meal and the ^{99m}Tc-labeled I resin beads was determined from the slope of the line. A whole body survey at the end of each study failed to show any detectable activity outside of the GI tract.

By utilizing the described technique, gastric emptying times ranging from 45 to 60 min were obtained for 10 healthy volunteers (Fig. 1). These times agree with results obtained with other radiopharmaceuticals (6). In all normal subjects studied, monoexponential kinetics were obtained for gastric emptying. Similar kinetic profiles were obtained with patients with pyloric stenosis, although

[1] Technetium Tc 99m, obtained from a ^{99}Mo-generator (E. R. Squibb and Sons, Princeton, NJ 08540) in its pertechnetate form ($^{99m}TcO_4^-$), is a γ-emitting radionuclide with a half-life of 6 hr and an energy of 140 Kev.

[2] Baird Atomic System 77 (Baird Atomic Nuclear Division, Bedford, MA 01730) equipped with a computer and magnetic tape and possessing storage and replay capability.

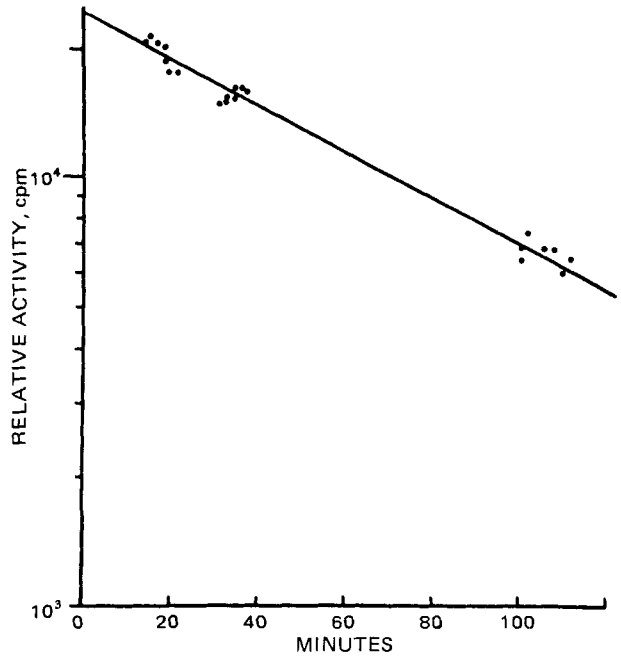


Figure 1—*Rate of clearance of ^{99m}Tc-labeled polystyrene beads bearing triethylenetetramine functions from the stomach of a normal human male subject (half-time of gastric emptying = 51 min).*

these subjects exhibited longer gastric emptying times (115 min) (Fig. 2).

Measurement of gastric emptying is an important aid to the clinician studying gastroduodenal disease, dumping syndrome, and postvagotomy disturbances. Gastric emptying is delayed in malignant disease of the stomach, gastric ulcers, and pyloric stenosis. On the other hand, hastened emptying has been associated with duodenal ulcers. Symptoms of dumping syndrome and diarrhea following gastrectomy and vagotomy are due to altered gastric emptying (10). A simple, accurate, and noninvasive technique for measuring gastric emptying is needed. ^{99m}Tc-Labeled I has a great potential for becoming a popular radiodiagnostic agent for routine clinical determinations of gastric emptying times.

Gastric emptying has been suggested to be a major determinant in the absorption rate of drugs. Individual variations in the rate of drug absorption from any one dosage form may be due largely to differences in the rate of gastric emptying (13, 14). Experiments are now in progress to assess ^{99m}Tc-labeled I in studying the effects of drugs on the gastric emptying rate as well as the gastric emptying influence on drug bioavailability.

Identification of an Impurity in Illicit Amphetamine Tablets

Keyphrases □ Amphetamine—illicit tablets, impurity identified as α-benzylphenethylamine ■ α-Benzylphenethylamine—identified as impurity in illicit amphetamine tablets ■ Contaminants—α-benzylphenethylamine identified in illicit amphetamine tablets

To the Editor:

An impurity detected in exhibits of illicit amphetamine tablets has been identified as α-benzylphenethylamine (I). The tablets, of a type known as "mini-bennies," were found to contain caffeine as well as *dl*-amphetamine (II), the latter as a sulfate salt. TLC examination on silica gel plates[1] revealed an additional spot, R_f 0.7, which, upon

[1] Mobile phase consisted of ammonia-saturated chloroform–methanol (18:1); visualization was by shortwave UV.

extraction with chloroform and subsequent conversion to the hydrochloride salt, produced an IR spectrum somewhat similar to that of II hydrochloride. The pattern at 2300–2700 cm^{-1} was typical of primary amine salts; strong, sharp bands at 703 and 754 cm^{-1} were indicative of monosubstituted phenyl; intense bands appearing at 1452, 1491, and 1599 cm^{-1} were attributed to phenyl and methylene absorption.

The mass spectrum of I[2] exhibited a base peak at *m/e* 120 with further fragmentation indicative of benzyl (*m/e* 91, 77, 65, 51, and 39). Additional intense ions appeared at *m/e* 103 and 42. Considering that amines generally produce their most intense peaks by β-fission or α,β'-fission with hydrogen rearrangement (1), it was felt that the amino group was attached to a carbon atom with two substituents. The absence of any significant fragmentation above *m/e* 120 ruled out additional substitution. The possibility of a single α-substituent was eliminated by the absence of an intense *m/e* 30 fragment. From the foregoing considerations, the structure of I was deduced.

Support for the proposed structure was obtained from the NMR spectrum[3] of the salt (deuterium oxide), which displayed the following features: singlet at 7.37 ppm[4] (phenyl), multiplet at 3.0–4.0 ppm (methine), and a pair of doublets at 3.00 and 3.02 ppm (nonequivalent methylene hydrogens). Integration indicated a ratio of two phenyl and two methylene groups to one methine.

For verification of the assigned structure, a hydrochloride salt, mp 202–202.5° [lit. (2–5) mp 200–205°], was prepared from a known material[5]; IR and NMR spectra were identical to those prepared from extracts of the unknown substance.

The origin of I as a contaminant has been postulated as follows.

The presence of traces of *N*-formylamphetamine (III) in the tablet extracts, as determined by GLC–mass spectrometry (6), indicated that II was prepared by some form of the Leuckart synthesis, in which methyl benzyl ketone (IV) reacted with ammonium formate or formamide (7, 8), producing III as an intermediate. Subsequent hydrolysis converted it to II (Scheme I).

$(C_6H_5CH_2)_2CO \rightarrow (C_6H_5CH_2)_2CHNHCHO \rightarrow (C_6H_5CH_2)_2CHNH_2$

V VI I

Scheme II

Dibenzyl ketone (V), a by-product in the Aonuma *et al.* (9) synthesis of IV, was found as a contaminant accompanying IV in illicit preparations of amphetamine-type drugs (6). It has already been reported to produce I *via* Leuckart procedures (2, 10; Scheme II); hence, its presence as an impurity in IV is a likely cause for the accompaniment of II by I.

The appearance of I as an amphetamine contaminant poses serious implications due to its reported toxicity (11, 12).

REVIEWS

Ethical Safeguards in Research on Humans. Vol. 5. Philosophy and Technology of Drug Assessment. Edited by JOSEPH D. COOPER and HERBERT L. LEY. Interdisciplinary Communication Associates, 1717 Massachusetts Ave., N.W., Washington, DC 20036, 1976. 235 pp. 14.5 × 23 cm. Price $9.00.

This publication consists primarily of the transcripts of an April 1973 conference on "Ethical Problems in Drug Experimentation," which was the fifth in a series on the Philosophy and Technology of Drug Assessment. The 3-year time lag was due to the death of the coordinator, Dr. Joseph D. Cooper, following the seventh conference of the series in March 1975. Human research is a subject with many recent developments, and there are current publications that diminish the significance and timeliness of these proceedings.

The conference dialog was divided into several aspects of human research including surgical experimentation, patients and prisoners as subjects, state moratoriums on research, how to turn off an experiment, national and local review mechanisms, extrapolating results from animal to human, and payments and indemnification. Unfortunately, the majority of the book is merely transcripts of the dialog among the 22 nationally renown medical scientists who are listed as the conference participants. Other than the brief introductory summaries of each chapter, the dialog is sometimes difficult to follow. With the emphasis on dialog, the book suffers from a lack of references that might be useful in documenting the seemingly anecdotal comments of the participants.

The most valuable portion of the book is the introductory "Background Notes on Issues in Experimentation with Human Subjects." This 32-page segment of preconference material summarizes the issues prior to 1973 rather well. The background includes 63 references and a selected bibliography of eight publications. Readers who are following the human experimentation issue very closely may be interested in this publication.

Drug Metabolism Reviews. Vol. 4. Edited by FREDERICK J. DiCARLO. Dekker, 270 Madison Ave., New York, NY 10016, 1976. 340 pp. 16 × 24 cm. Price $32.50.

According to the press release for reviewers, "Volume 4 includes treatises on the disposition of used and abused drugs, the effects of liver disease upon drug disposition, the biotransformation of insecticides by insects, the clinical usefulness of organic nitrates and the logistics of drug metabolism studies." This is a factual and bald description of a fascinating volume.

The trend toward the complete integration of drug metabolism and pharmacokinetics continues and is very apparent in these reviews. We might as well stop referring to drug metabolism and pharmacokinetics and recognize that we are dealing with an integrated science of drug disposition. The term "drugs" does not just refer to human health products but also to animal health products, pesticides, industrial chemicals, and just about any other nonnutritive material that can enter any type of living organism.

There are three reviews on compounds that have been in use from centuries to millenia: morphine and heroin (Boerner, Abbot, and Roe), nitroglycerin (DiCarlo), and caffeine (Burg). It is always surprising to realize that, despite the length of their use, a great deal about each of them remains unknown. They present active and ongoing research problems of fundamental importance. The review on nitroglycerin is fun to read as well as informative. It got some "Gee whiz, I didn't know that" reactions from me. I'd recommend it as a model for authors.

A great deal of experimental work has been done, and clinical experience exists concerning renal dysfunction and its effects on drug disposition. Much less information exists on the effects of dysfunction of the liver, the other major organ of drug elimination. Wilkinson and Schenker's review on drug disposition and liver disease plays its part in redressing this balance.

The two most important reviews in this volume were written by Ruelius and Weiner on the logistics of drug disposition studies. The discipline of drug disposition is of fundamental importance in industry, where it constitutes an important part of the safety evaluation process, *de facto* or *de jure*. This is not simply to meet regulatory requirements; the regulatory agencies can only lag and react to what is found in the research laboratory and in the field when a drug is in use. Drug disposition studies can occupy a central place in the development process and interact with screening studies, pathology, toxicology, and "clinical" development and use. An academically engendered desire to know all that there is possible to know must give way to the imposition of priorities and the use of finite resources to find out what is of fundamental but practical importance. The primary question must be: "Within what limits is this agent safe and effective?" Each new drug represents a different problem. It would be impractical and impossible to impose rigid checklists or rules of procedure on drug disposition studies. The only valid approach, which both Ruelius and Weiner adapted, is to discuss general principles and then to illustrate the application of those principles by case studies of the problems presented by specific compounds. Many times they are saying the same things but what they are saying needs a lot of repetition.

This book costs almost 10¢ a page but it's well worth it. Buy a copy through your library or your own budget or even personally (it is tax deductible). Once you've got a copy, read it!

Calculations in Pharmacy. Third Edition. By SUE H. ROUSE and M. GEORGE WEBBER. Lippincott, East Washington Square, Philadelphia, PA 19105, 1976. 264 pp. 15.5 × 23.5 cm. Price $12.75.

The familiar strengths of this useful textbook in pharmaceutical calculations have for the most part remained intact in the second revision of the work. Substantially little has changed in format, content, or presentation of the third edition. Most helpful is its continued logical approach to the reasoned solution for pharmaceutical calculations in a way that deemphasizes rote methods and confusing proportionalities.

To accommodate newer concepts, nearly 800 revised practice problems with answers have been prepared, and "much of the emphasis on the 'art of compounding' has been reduced or neglected in favor of orientation toward patients." The art of the printer, however, is very much evident in the presentation of the book. The new table of contents is expanded in topical outline and detail. It visually organizes the material chapter by chapter, thereby eliminating any need for an index. Answers for sample problems in the text are always given and in many instances underlined for added clarity and emphasis. The use of unit labels is judiciously observed; and wherever factor reduction by cancellation occurs in the sample problems, smaller faced type indicates the results of the operation, thereby making this edition uniformly more readable and understandable for the student.

Chapter 6 contains useful additions contemplated for inclusion in the second edition (1968) but dropped because of a perceived overlap

Calculations in Pharmacy. Third Edition. By SUE H. ROUSE and M. GEORGE WEBBER. Lippincott, East Washington Square, Philadelphia, PA 19105, 1976. 264 pp. 15.5 × 23.5 cm. Price $12.75.

The familiar strengths of this useful textbook in pharmaceutical calculations have for the most part remained intact in the second revision of the work. Substantially little has changed in format, content, or presentation of the third edition. Most helpful is its continued logical approach to the reasoned solution for pharmaceutical calculations in a way that deemphasizes rote methods and confusing proportionalities.

To accommodate newer concepts, nearly 800 revised practice problems with answers have been prepared, and "much of the emphasis on the 'art of compounding' has been reduced or neglected in favor of orientation toward patients." The art of the printer, however, is very much evident in the presentation of the book. The new table of contents is expanded in topical outline and detail. It visually organizes the material chapter by chapter, thereby eliminating any need for an index. Answers for sample problems in the text are always given and in many instances underlined for added clarity and emphasis. The use of unit labels is judiciously observed; and wherever factor reduction by cancellation occurs in the sample problems, smaller faced type indicates the results of the operation, thereby making this edition uniformly more readable and understandable for the student.

Chapter 6 contains useful additions contemplated for inclusion in the second edition (1968) but dropped because of a perceived overlap

with pharmacology. This edition more boldly and appropriately includes the material on dosage calculations based on body surface area and Fried's rule for the calculation of children's doses based upon age in months. Standard nomograms are included for the conversion of doses based on body weight to doses based on body surface.

Much less successful is the material added in the newly appended Chapter 14. The authors preface their book with an indication that the material contained in this last chapter results from acknowledgment of requests from many instructors. The appended chapter, prepared by two of the authors' colleagues, attempts to review important concepts from chemistry [milliequivalents, electrolyte replenishment, and operator p (pH and pK)], pharmaceutics (alligation involving the HLB system), and mathematics (logarithms, unit label analysis, and elementary statistics), all within 18 pages and 29 practice problems! The task is hopelessly more global than the space allotted, with the result that nothing in the chapter works well. A seven-page section (with nine practice problems on the elements of statistics, the operator p, and the unit analysis) is totally inadequate and will confuse even the proficient student who turns to it for review. It has no potential as a teaching chapter and the authors would have been wiser in reapplying their reasoning from the preface of the second edition: to reject the inclusion of these materials in the third edition because of duplication with much more authoritative and useful treatments in other standard pharmaceutical textbooks, rather than blemish the new edition with so inadequate a treatment.

Ignoring at least portions of the newly appended chapter as a misplaced and nonfunctioning appendage to the book, Rouse and Webber have provided a useful third edition that will undoubtedly continue to serve as a mainstay textbook for traditional courses in pharmaceutical calculations and as a wealthy storehouse of reference material and practice problems for the student engaged in competency based self-directed study.

Amino-Acids, Peptides, and Proteins. Vol. 7. Edited by R. C. SHEPPARD. The Chemical Society, Burlington House, London, W1V OBN, England, 1976. 431 pp. 14.5 × 22.5 cm. Price $57.75.

This volume is the seventh in the series of literature reviews in the field of amino acids, peptides, and proteins. Under the leadership of Dr. Sheppard, a selected group of researchers summarize the developments during 1974 in six chapters. As with previous volumes, the reader can expect the high standards associated with publications of the Chemical Society.

The first four chapters are primarily concerned with an extensive review of the literature regarding amino acids, structural investigations of peptides and proteins, peptide synthesis, and peptides with structural features not typical of proteins. In addition to the usual format, the second chapter contains tables summarizing features of affinity chromatography separations, molecular weights and subunit composition of proteins, uses of chemical modifications of proteins, affinity labeling of proteins, and proteins whose partial or complete sequence was published in 1974. These tables are followed by a summary of references to authors and published articles in an orderly and useful fashion.

A most important feature of this seventh edition is Chapter 5, which covers enzymes for the first time in the series. Dr. Fersht, in a sophisticated yet enjoyable manner, reviews some of the more important papers published during 1974 that were concerned with chemical structure and biological activity of enzymes; very appropriately mentions earlier work done in the area; and presents all sides of current work and some current problems. Chapter 6 is the biennial review of metal derivatives of amino acids, peptides, and proteins. The format is that followed by previous volumes, and the reader is given a survey of the literature for 1973–1974.

This seventh volume presents the reader with some interesting developments, with further applications of known chemistry, and some presentations of old principles which have been given ingenious new applications. This volume is certainly a comprehensive source of information to researchers interested in amino acids, peptides, proteins, and enzymes. The information should, of course, be supplemented by reading the original literature, especially by students.

Advances in Mass Spectrometry In Biochemistry and Medicine. Vol. 1. Edited by ALBERTO FRIGERIO and NEAL CASTAGNOLI. Spectrum Publications, 86-19 Sancho St., Holliswood, NY 11423, 1976. 586 pp. 16 × 23.5 cm.

This volume is a compilation of 51 separate papers of varying quality, with titles ranging from "Biomedical Applications of Chemical Ionization" to "Gas Chromatography–Mass Fragmentography Pharmacokinetics of Antineoplastic Agents." The text was taken from the proceedings of the Second International Symposium of Mass Spectrometry in Biochemistry and Medicine at the Mario Negri Institute for Pharmocological Research, Milan, Italy, in June 1974. Each chapter was contributed by different authors, and each relates to a different potential application of mass spectrometry in biochemistry and medicine. The topics range in value from prime import to minimal interest. Most chapters contain illustrations such as normalized mass spectra, gas chromatographs, and fragmentation schemes. The illustrations are clearly presented and well labeled. Each chapter includes a thorough bibliography which would enable the reader to do further research on the given theme, if desired.

Topics such as mass fragmentography, gas chromatography–mass spectrometry, stable isotope measurements, field ionization, field desorption, chemical ionization, atmospheric pressure ionization, high-resolution studies, and data acquisition and processing are discussed. In particular, the major topics include detection and identification of drug metabolites and other biomedical applications including biosynthesis and toxicology studies. Applications of mass spectrometry to the study of such important groups of compounds as peptides, steroids, prostaglandins, nucleotides, carbohydrates, and many other natural products and medicinal agents are given. Although mass spectrometry is the principal means of identification of these compounds, various means of isolation and separation are discussed. Also described are derivatization techniques that not only enhance volatility but also generate more intense ions in their spectra.

The papers contained in this volume represent a large cross section of mass spectrometric techniques presently being developed over a broad range field of mass spectrometry. Owing to the scope of this book, it is impossible to evaluate all of the topics covered at one level of criticism. This book does, however, have definite merit, since various mass spectrometry systems represent one of the most powerful means of analysis now available for the study of samples of biologic origin.

This book should serve as a useful source of information to many chemists, biochemists, pharmacologists, and medical researchers. Mass spectrometrists, in particular, will find this book useful in keeping abreast of the many faceted advances in their technology.

The task is hopelessly more global than the space allotted, with the result that nothing in the chapter works well. A seven-page section (with nine practice problems on the elements of statistics, the operator p, and the unit analysis) is totally inadequate and will confuse even the proficient student who turns to it for review. It has no potential as a teaching chapter and the authors would have been wiser in reapplying their reasoning from the preface of the second edition: to reject the inclusion of these materials in the third edition because of duplication with much more authoritative and useful treatments in other standard pharmaceutical textbooks, rather than blemish the new edition with so inadequate a treatment.

Ignoring at least portions of the newly appended chapter as a misplaced and nonfunctioning appendage to the book, Rouse and Webber have provided a useful third edition that will undoubtedly continue to serve as a mainstay textbook for traditional courses in pharmaceutical calculations and as a wealthy storehouse of reference material and practice problems for the student engaged in competency based self-directed study.

Amino-Acids, Peptides, and Proteins. Vol. 7. Edited by R. C. SHEPPARD. The Chemical Society, Burlington House, London, W1V OBN, England, 1976. 431 pp. 14.5 × 22.5 cm. Price $57.75.

This volume is the seventh in the series of literature reviews in the field of amino acids, peptides, and proteins. Under the leadership of Dr. Sheppard, a selected group of researchers summarize the developments during 1974 in six chapters. As with previous volumes, the reader can expect the high standards associated with publications of the Chemical Society.

The first four chapters are primarily concerned with an extensive review of the literature regarding amino acids, structural investigations of peptides and proteins, peptide synthesis, and peptides with structural features not typical of proteins. In addition to the usual format, the second chapter contains tables summarizing features of affinity chromatography separations, molecular weights and subunit composition of proteins, uses of chemical modifications of proteins, affinity labeling of proteins, and proteins whose partial or complete sequence was published in 1974. These tables are followed by a summary of references to authors and published articles in an orderly and useful fashion.

A most important feature of this seventh edition is Chapter 5, which covers enzymes for the first time in the series. Dr. Fersht, in a sophisticated yet enjoyable manner, reviews some of the more important papers published during 1974 that were concerned with chemical structure and biological activity of enzymes; very appropriately mentions earlier work done in the area; and presents all sides of current work and some current problems. Chapter 6 is the biennial review of metal derivatives of amino acids, peptides, and proteins. The format is that followed by previous volumes, and the reader is given a survey of the literature for 1973–1974.

This seventh volume presents the reader with some interesting developments, with further applications of known chemistry, and some presentations of old principles which have been given ingenious new applications. This volume is certainly a comprehensive source of information to researchers interested in amino acids, peptides, proteins, and enzymes. The information should, of course, be supplemented by reading the original literature, especially by students.

Advances in Mass Spectrometry In Biochemistry and Medicine. Vol. 1. Edited by ALBERTO FRIGERIO and NEAL CASTAGNOLI. Spectrum Publications, 86-19 Sancho St., Holliswood, NY 11423, 1976. 586 pp. 16 × 23.5 cm.

This volume is a compilation of 51 separate papers of varying quality, with titles ranging from "Biomedical Applications of Chemical Ionization" to "Gas Chromatography–Mass Fragmentography Pharmacokinetics of Antineoplastic Agents." The text was taken from the proceedings of the Second International Symposium of Mass Spectrometry in Biochemistry and Medicine at the Mario Negri Institute for Pharmocological Research, Milan, Italy, in June 1974. Each chapter was contributed by different authors, and each relates to a different potential application of mass spectrometry in biochemistry and medicine. The topics range in value from prime import to minimal interest. Most chapters contain illustrations such as normalized mass spectra, gas chromatographs, and fragmentation schemes. The illustrations are clearly presented and well labeled. Each chapter includes a thorough bibliography which would enable the reader to do further research on the given theme, if desired.

Topics such as mass fragmentography, gas chromatography–mass spectrometry, stable isotope measurements, field ionization, field desorption, chemical ionization, atmospheric pressure ionization, high-resolution studies, and data acquisition and processing are discussed. In particular, the major topics include detection and identification of drug metabolites and other biomedical applications including biosynthesis and toxicology studies. Applications of mass spectrometry to the study of such important groups of compounds as peptides, steroids, prostaglandins, nucleotides, carbohydrates, and many other natural products and medicinal agents are given. Although mass spectrometry is the principal means of identification of these compounds, various means of isolation and separation are discussed. Also described are derivatization techniques that not only enhance volatility but also generate more intense ions in their spectra.

The papers contained in this volume represent a large cross section of mass spectrometric techniques presently being developed over a broad range field of mass spectrometry. Owing to the scope of this book, it is impossible to evaluate all of the topics covered at one level of criticism. This book does, however, have definite merit, since various mass spectrometry systems represent one of the most powerful means of analysis now available for the study of samples of biologic origin.

This book should serve as a useful source of information to many chemists, biochemists, pharmacologists, and medical researchers. Mass spectrometrists, in particular, will find this book useful in keeping abreast of the many faceted advances in their technology.

with pharmacology. This edition more boldly and appropriately includes the material on dosage calculations based on body surface area and Fried's rule for the calculation of children's doses based upon age in months. Standard nomograms are included for the conversion of doses based on body weight to doses based on body surface.

Much less successful is the material added in the newly appended Chapter 14. The authors preface their book with an indication that the material contained in this last chapter results from acknowledgment of requests from many instructors. The appended chapter, prepared by two of the authors' colleagues, attempts to review important concepts from chemistry [milliequivalents, electrolyte replenishment, and operator p (pH and pK)], pharmaceutics (alligation involving the HLB system), and mathematics (logarithms, unit label analysis, and elementary statistics), all within 18 pages and 29 practice problems! The task is hopelessly more global than the space allotted, with the result that nothing in the chapter works well. A seven-page section (with nine practice problems on the elements of statistics, the operator p, and the unit analysis) is totally inadequate and will confuse even the proficient student who turns to it for review. It has no potential as a teaching chapter and the authors would have been wiser in reapplying their reasoning from the preface of the second edition: to reject the inclusion of these materials in the third edition because of duplication with much more authoritative and useful treatments in other standard pharmaceutical textbooks, rather than blemish the new edition with so inadequate a treatment.

Ignoring at least portions of the newly appended chapter as a misplaced and nonfunctioning appendage to the book, Rouse and Webber have provided a useful third edition that will undoubtedly continue to serve as a mainstay textbook for traditional courses in pharmaceutical calculations and as a wealthy storehouse of reference material and practice problems for the student engaged in competency based self-directed study.

HOW MUCH IS "ENOUGH"?

For the past year or two, articles, speeches, testimony, and assorted other means of communication have been rife with comment and opinion to the effect that either additional regulation is needed in the area of drug discovery and introduction or, conversely, that already drug discovery and introduction are subjected to excessive regulation.

On the one side, those who advocate additional legal controls present persuasive arguments based upon statistics showing significant toxicity, adverse reactions, and related harmful effects associated with a particular drug which often come to light only after its widespread or long-term use. On the other hand, opponents to further regulation present equally persuasive arguments that already drug innovation has been inhibited, a so-called "drug lag" has developed, and patients are presently being denied the benefit of important new drug discoveries, all due to what they regard as the excessively restrictive current regulations which delay or prevent new drug marketing approval.

It is, of course, just such differences of viewpoint which are said "to make a horse race." All of this reminds us of an anecdote which may or may not have basis in fact but certainly is pertinent. We were told that the river which ran through a small rural town was closed to swimming by the local health department on grounds that it was polluted and a menace to health. The town leaders went to extensive effort to correct the problem and to clean up their river. But when they then requested the health department to open the river to swimming, their request was again denied—this time with the explanation that the river constituted the source of the local drinking water supply and it would be unsanitary, therefore, to permit swimming!

Whether or not such an incident actually occurred, we do know for a fact that rather comparable incidents repeatedly have happened in the area of drug standards. For example, on many occasions, critics from the drug industry have alleged that official compendia specifications were insufficient to assure an aspect of drug quality whether it be potency, identity, bioavailability, stability, or some other related characteristic. Subsequently, the compendia proposed adoption of either a new or more stringent specification in order to remedy the alleged deficiency. Not uncommonly, such proposals then met with objection from the very same critics on grounds that such test requirements were excessive, or would contribute prohibitively to manufacturing costs, or even that the proposed requirements were too "severe" because their own products could not meet the new standard!

It is well to recognize that the genesis of any proposed new law or regulation generally can be traced back to some sort of abuse or problem. For example, the Good Laboratory Practice regulations which were discussed in our February editorial were the direct result of falsified test data submitted to FDA in support of certain New Drug Applications. Consequently, as a general observation, most disinterested parties would tend to feel that society and government must impose regulatory controls to avoid problems or to prevent repeated abuses.

Our view tends to concur but, at the same time, we also recognize that such regulations must be reasonable and properly tempered to avoid excessive restrictions which will unduly inhibit and discourage future research by destroying legitimate incentives. Drug regulation is particularly susceptible to "overkill," and care must be exercised to avoid a result which might be even more disastrous than the problem it is intended to control.

"ZERO-BASED" DRUG STANDARDS

President Carter has introduced the management approach of "zero-based budgeting" in reviewing federal programs and their financing. Indeed, so much has been said and written about this concept in recent months that few of our readers are probably unfamiliar with the term and its meaning. However, a brief explanation may be useful.

Basically, in contrast to taking last year's projects and programs and simply adding to them by way of staff, budget, and so on, zero-based budget calls for a complete reassessment of each such project or program to determine if the activity itself, as well as all of its components, can be currently justified. The premise is that there is a natural tendency for activities to be initiated which in time come to outlive their usefulness, in part or in whole. In the absence of any positive step to reassess their function and value by today's perspective, they drone on indefinitely.

The thought has long been with us that some such comprehensive reassessment would be highly desirable with respect to drug standards and specifications—particularly those appearing in the official compendia. Frequently, additions or revisions are made to *United States Pharmacopeia* or *National Formulary* monographs which interrelate with other elements within the compendia.

Those responsible for the compendial revision programs generally have done a good job of making whatever modifications were necessary to avoid any outright discrepancies or contradictions. However, in the absence of a "start from scratch" review, any process that introduces changes or new material in a piecemeal fashion will result in a patchwork product to some degree.

An example or two might help to explain both what we have in mind as well as how it happens to come about.

Effective April 1 of this year, a new standard requires that certain drugs be packaged in containers meeting specified criteria of "tightness." This significant advance now provides the compendia with objective procedures to test the tightness of containers and to specify well-defined limits of performance that the containers must meet. The drugs involved are all those whose individual monographs specifically include provision for such packaging. And, a review of the USP and NF reveals that a substantial number of monographs do call for use of either "well-closed" or "tight" containers.

However, such provisions were placed in most, if not all, of these drug monographs at a time when there was no real method for evaluating container tightness. Hence, the standard was more qualitative than quantitative.

The question now arises as to whether all drugs, for which there is a tightness requirement in the pertinent monographs, actually need this degree of protection now that we have defined it and have established methodology for its determination.

Compendia officials are well aware of this situation, but there is only one way that it can be rectified. That would require a drug-by-drug, monograph-by-monograph review, complete with stability data and the like, in order to conclude that the requirement may safely be deleted from certain monographs. But this review would necessitate considerable time and effort just to "clean up" the subject; that is, there is no risk or hazard with the present situation—it simply is one that, on purely scientific grounds, probably could not be justified as necessary to the extent that it applies.

Drug identification tests are another illustration of this problem. For many years, simple qualitative tests were included in compendia monographs to confirm the identity of a specimen. For example, such a test might describe a certain color change in a solution of the sample upon addition of a certain reagent.

With the introduction and wide application of infrared spectrophotometry—especially in conjunction with a reference standard—these antiquated spot tests and color tests became superfluous in the extreme. Yet they often were not deleted because certain parties—due to limitations in available equipment or misguided nostalgia—argued for their retention.

Again, there is nothing wrong *per se* with their continued presence. However, they have outlived their usefulness and they add a lot of undesirable "clutter" to what should be a concise set of drug standards.

All of these defects could be remedied by a start from scratch review of the entire USP and NF content. In line with President Carter's approach to budget development, it appears timely to consider a zero-based review of the compendial standards, with a goal of streamlining the monographs, eliminating duplication, correcting inconsistencies, and achieving uniformity of treatment.

REVIEW ARTICLE

Binding of Drugs by Albumin and Plasma Protein

JOSEPH J. VALLNER

Keyphrases □ Binding, protein—various drugs to albumin and plasma proteins, pharmacokinetics, drug displacement, and clinical significance, review □ Protein binding—various drugs to albumin and plasma proteins, pharmacokinetics, drug displacement, and clinical significance, review □ Pharmacokinetics—various drugs, binding to albumin and plasma proteins, review □ Displacement, drug—various drugs, binding to albumin and plasma proteins, review

Many drug–protein binding papers have been published since the often-cited review by Meyer and Guttman (1). This review is intended to be a sequel to that one; published research on drug–albumin binding since 1969 is covered. Only results with human or bovine serum albumin are discussed, and attention is focused on the physical and clinical significance of drug–protein binding and on results obtained with particular drug classes.

Various reviews and articles have appeared since 1969 concerning methods of investigating drug–protein binding phenomena. These methods can be summarized into two broad categories: (*a*) equilibrium methods based upon measuring changes in ligand concentration as a result of the establishment of a binding equilibrium, and (*b*) direct measurement methods in which a property of the drug, protein, or complex may be examined during the binding process. A short but complete coverage of the various specific methods in these two categories was pubished (2). Other articles dealing solely with one method may also be of interest (3–9).

Once binding data are accumulated, the binding parameters must be obtained by employing some data reduction technique. Various articles have appeared dealing with graphical and computer treatment of binding data. It is now well recognized that the Scatchard (10) and Klotz (11) methods of examining binding data are suitable when only one class of sites is displayed by the protein but are at best approximate when more than a single class exists on the protein. The subject of binding data reduction is not dealt with here; however, Refs. 12–22 are either applications of various methods or critical treatises of existing techniques.

Articles dealing with ways to estimate drug–albumin affinity constants rapidly (23) have extremely limited use, since most apply mathematics of the mass action law based upon a single protein site for the drug and require that the free concentration of the drug in the blood be known or determined. Presumably, if one is interested in the binding constant from the clinical standpoint, the affinity is high and measurement of the minute amount free from a therapeutic dose is at best hazardous.

Drug binding to various blood proteins and tissue proteins can influence the therapeutic, pharmacodynamic, and toxicologic actions of drugs. Protein binding may also exert profound effects on drug distribution. The protein–drug complex acts as a transport system to carry drug to the sites of action; this transport is extremely important for drugs that exhibit low solubility in the water portion of the plasma. Protein binding slows the disappearance of free drug from the plasma into tissues by decreasing the concentration gradient. It also provides a source of free drug to replace that removed by various distribution and elimination processes.

In a short overview of the consequences of drug–protein binding, Gillette (24) suggested some important questions to be answered from experiments examining binding phenomena. For example, he pointed out that not only are drugs bound to serum albumin but that other proteins in the blood and tissues may be important in the drug complexation interaction. In addition, the volumes of distribution of the bound forms of the drug usually differ from that of unbound drug. Also lacking in most articles is the consideration that the blood contains other substances that compete with drugs for binding sites. In addition,

correlation of *in vitro* binding results with *in vivo* drug–macromolecule interactions is sorely lacking.

Serum or plasma protein binding, principally to albumin, may have a profound effect on overall drug activity. The following effects have become evident from protein binding investigations: (*a*) only free drug (unbound) is available for activity or tissue distribution; (*b*) tightly bound drugs tend to be distributed in a smaller body space or volume; (*c*) marked decreases in protein binding occur in uremia, hypoalbuminemia, hyperbilirubinemia, and hepatic failure; and (*d*) the delayed elimination of highly bound drugs is a result of glomerular filtration and hepatic uptake being directly proportional to free drug in the serum.

PHYSICAL SIGNIFICANCE OF PROTEIN BINDING

Pharmacokinetics—Until the 1960's, protein binding as a basic principle in drug behavior was neglected in pharmacokinetic models. Drug–albumin interactions may profoundly influence the kinetics of drug elimination, *e.g.*, some sulfa drugs, or the relationship between renal clearance and the apparent biological half-life of the drug (25, 26).

In a short review article, Wagner (27) discussed plasma protein binding effects on nonlinear pharmacokinetic models. He pointed out that drugs showing a high affinity for serum albumin may have their plasma concentration–time profiles convex curvilinear in the terminal phase, and, indeed, this was the case in several reports (25–27). Wagner also pointed out, as did Gillette (24), that tissue binding may be much more important pharmacokinetically than albumin binding.

Gillette (24) added a useful criticism of some pharmacokinetic interpretations of bioavailability data by stating that estimations of volumes of distribution from area under the plasma concentration–time curves and the rate constant of the terminal phase of elimination assume that the drug is not highly bound to plasma proteins and that the ratio of the concentrations of bound and unbound drug in the plasma is constant. The researcher may make erroneous conclusions if it is not determined that the areas under the blood level–time curves are dose dependent.

The binding of chlorpromazine was examined pharmacokinetically (28) in an attempt to explain rapid drug decreases in the plasma. Through theoretical computer simulations, it was determined that a rapid redistribution is possible for such a highly protein-bound drug after small changes in tissue binding. As with many other studies, these results suggest that more experimental work on the actual degree of tissue binding may be important in determining a drug's time course in the plasma.

The pharmacokinetic consequences of plasma protein binding were examined for one- and two-compartment models (29). The computer-simulated data treatment suggested that, if an elimination process operates on bound drug in the plasma for either the one- or two-compartment case, considerable alterations in half-life and area under the free drug concentration–time curve would be seen. However, no *in vivo* data were presented to show the existence of such an elimination mechanism for the bound drug.

Drug Displacement—Concurrent administration of drugs with high albumin binding affinities may produce competition at the binding sites, producing a higher free drug concentration and greater biological activity of each drug than if either is administered alone. Competitive protein binding was studied by using sulfaethidole and bovine serum albumin (30). By using a circular dichroic technique, the drug was found to exhibit optical activity only at its primary binding site, resulting in the unique opportunity to examine the effects of added drugs on the optical activity of sulfaethidole. Drugs that underwent binding at the same site, but were not themselves optically active, reduced the signal due to the sulfa drug. The data for acidic drugs showed that the same primary binding site may be shared by a wide variety of these molecules; basic drugs did not compete for the sulfaethidole site on bovine albumin. However, these same investigators reported that a series of basic alkyldimethylbenzylammonium chlorides did displace sulfaethidole from bovine serum albumin (31). Tryptophan and tyrosine residues of the protein may be involved, and some conformational changes may take place when these surfactant molecules are added to the protein solutions.

In another study employing the circular dichroic technique (32), various drugs were examined with regard to their competition for the two binding sites of dicumarol on human serum albumin. Acidic drugs displaced dicumarol, whereas basic drugs displayed no competition at the binding sites.

The displacing effect of endogenous fatty acids on diazepam bound to human serum albumin was examined (33). At therapeutic levels of diazepam, about 14% of the drug was displaced by laurate anion. The investigators concluded that, if the albumin binding of a drug was extensive, displacement interactions with other endogenous substances should not be ignored. Also, fluctuations of diazepam in blood could result from such a free fatty acid competition phenomenon. Considerable support for such a hypothesis could have been warranted if an attempt had been made to support these *in vitro* results with *in vivo* findings.

Diazepam competed for binding sites on thyroxine binding globulin and thyroxine binding prealbumin in a study using electrophoresis of serum containing thyroid hormone isotopes (34). Since this steroid binding globulin and prealbumin are endogenous macromolecules, the *in vivo* displacement of diazepam may be quite complex. A series of equilibrium–displacement–redistribution may take place *in vivo*. In some individuals having either a diminished concentration or malfunctioning macromolecules, a clinical manifestation of fluctuating drug concentrations and perhaps related toxicities may ensue.

Wardell (35) and McQueen (36), working independently and together (37), examined displacement of protein-bound drug and found that the displacement of initially bound drug upon injection of a more highly protein-bound drug results mainly in redistribution of the initially administered agent. The redistribution is caused by a displacement of drug from plasma protein, not from changes in absorption, metabolism, and excretion.

Dayton *et al.* (38), in a brief discussion of possible clinical effects resulting from plasma binding displacement, noted that drug displacement had not been studied adequately *in vivo*. A clinically oriented study was published concerning the displacement of warfarin from human al-

bumin (39). Drugs used as competitors included diazoxide and ethacrynic, mefenamic, and nalidixic acids. Levy and Oie (40) suggested that displacement can be quantitated for bilirubin. They found a strong correlation between the free fraction of bilirubin in plasma containing no drugs and the free fraction of bilirubin when sulfisoxazole or salicylic acid was present.

The effects of sodium 2-(4-chlorophenoxy)-2-methylpropanoate, the active form of clofibrate, on the possible displacement of phenindione derivatives from human albumin were investigated (41). This work was undertaken because clofibrate presumably had the same binding site on albumin as phenylbutazone. Moreover, phenylbutazone was shown to induce hemorrhagic accidents if patients were concurrently receiving coumarin drugs but not if they were receiving phenindione derivatives. 2-(4-Chlorophenoxy)-2-methylpropanoate inhibited the binding of coumarin agents but did not alter the binding of phenindione derivatives.

The displacement of urate from plasma proteins by anti-inflammatory drugs was examined (42, 43). A relationship was shown between the ability of acidic uricosuric agents to displace albumin-bound urate and to interact at the primary albumin binding site of 5-dimethylaminonaphthalene-1-sulfonamide *in vitro*. Since some of the uricosuric action of these agents was thought to depend on displacement of urate, four of the seemingly best displacing agents were tested clinically. All four drugs tested *in vivo* lowered serum urate concentrations. These two papers demonstrated excellent *in vitro–in vivo* correlations of drug displacement data.

Effect of Fatty Acids—The effects of free fatty acids on the subsequent binding of drugs to human and bovine serum albumins were studied extensively (44). Albumin solutions were prepared with 7, 3.5, or <0.05 mole of palmitate or oleate per mole of protein. Palmitate and oleate are the major free fatty acids of mammalian plasma. By using the equilibrium dialysis technique, studies were conducted on the binding of eight drugs to these fatty acid–albumin solutions. The results indicated that inhibition of drug binding was greater with palmitate than oleate and that inhibition was manifested either as a reduction in the number of drug binding sites or in the association constant for that binding site. The experiments suggested that free fatty acids in serum in the 7–3.5-mole ratio range are inhibitors of serum albumin binding of many drugs. At ratios less than 3.5 (free fatty acid to albumin), the inhibition is essentially negligible.

Spector *et al.* (45) examined the effects of palmitate and oleate at free fatty acid to albumin ratios of 0 to 4 on the ability of previously defatted human serum albumin to bind the antihypertriglyceridemics 2-(4-chlorophenoxy)-2-methylpropanoate and halofenate. The added fatty acid greatly reduced the binding of the 2-(4-chlorophenoxy)-2-methylpropanoate while little effect on halofenate binding was seen. The affinity of halofenate to fatty acid free albumin is much greater than the affinity of the 2-methylpropanoate drug to free albumin. As a result of their data, the investigators suggested that the ability of free fatty acids to regulate drug binding depended upon the affinity with which the drug was bound to albumin. They also suggested a hypothetical mechanism to explain the variation in results for free fatty acid effects on drug binding: that at low mole ratios, allosterism predominates, while both allosterism and a competitive interaction ensue at high mole ratios.

Effect on Bilirubin—Albumin binds significant amounts of the endogenous substance bilirubin. Numerous clinical studies document displacement of bilirubin by sulfa drugs, particularly sulfisoxazole. Many drugs have the ability to displace bilirubin from albumin and thereby potentiate its cytotoxicity (46). Albumin was shown to have two classes of bilirubin binding sites from *in vitro* studies. Of highest affinity was a single site from which bilirubin was not displaced by drugs; however, the availability of this site to bilirubin may be related to free fatty acid concentrations in the serum. The second class of site was multiple in nature, and it was from this class of site that drugs may have displaced bilirubin.

A model was postulated for bilirubin–albumin binding and the propensity of drugs to compete with this highly bound endogenous material. A rapid methodology for detection of free bilirubin in plasma or serum, especially in the newborn, has become important from the standpoint of concurrent drug administration. Published methods attempt to quantitate bilirubin in the presence of various drugs, and some of these methods are quite complex (47–51).

Although drugs may increase the free concentration of bilirubin, as already pointed out, a recent study (52) suggested that phototherapy in the case of hyperbilirubinemia did not increase the unbound fraction of bilirubin in blood. In fact, the bound fractions of both bilirubin and salicylate to albumin remained unchanged after phototherapy compared to prephototherapy levels.

CLINICAL SIGNIFICANCE OF PROTEIN BINDING

Most clinicians and pharmaceutical scientists believe that a drug's action is dependent on its concentration in plasma water. However, most blood level measurement methods include the amount of drug bound to plasma proteins as well as the free amount. The concept of a plasma therapeutic level is now becoming more important (53). Information on the changes in free and bound levels in the presence of various disease states is in its initial stages.

In Renal Dysfunction—Recent studies indicated that, for many drugs, the percent of therapeutic amounts of drug bound to albumin in the plasma was significantly reduced in patients with uremia (54). Patients with renal dysfunction have a higher incidence of adverse drug reaction. Drug dosage modification to obtain plasma therapeutic levels appears most beneficial in patients with these abnormalities of drug excretion. The dosage modification in uremic patients was quantitated using a one-compartment model to predict changes in the elimination rate constant of drugs (55).

The protein binding of phenytoin (diphenylhydantoin) in the uremic patient has been well studied. Phenytoin binding was reduced in such patients, and this reduction was not strongly dependent on concentration of albumin or total protein (56). It was suggested that there had been a qualitative change in the drug binding proteins in uremic patients. The decrease in drug binding was not due to the presence of dialyzable substances in the plasma.

Blum *et al.* (57) concurred with these results and also showed that the principal metabolite of phenytoin was not responsible for a competition phenomenon and therefore could not be decreasing phenytoin binding. They postulated that the free plasma concentration of phenytoin may have been much lower in the uremic patient than in a normal individual, yet adequate seizure control was maintained. To the contrary, Andreasen (58) found phenytoin to have increased binding after dialysis of the plasma proteins from both normal and uremic individuals. He concluded that: (*a*) a competing substance of molecular weight greater than 700 may have been present (nondialyzable in his experiments), (*b*) some very strongly bound small molecules may have been present, or (*c*) alterations in the macromolecules may have been involved. Shoeman *et al.* (59) also suggested a qualitative difference in the albumins of normal and uremic patients.

Other studies showed decreased phenytoin binding in patients with renal abnormalities (60–62). In an excellent comparative study (62), it was pointed out that both normal and uremic patients should have about equal levels of unbound drug in plasma, provided tissue binding has not changed. The total plasma phenytoin concentration would, however, be decreased since there was a smaller amount of protein-bound drug and therefore a shift to a new equilibrium amount. The investigators stated that decreased plasma protein binding in uremic patients would potentiate pharmacological effects only if the drug was highly protein bound in normal subjects and, thus, minimal free drug levels were required for the principal pharmacological action. They further stated that monitoring of the plasma levels of drugs in uremic patients should be combined with the knowledge of the extent of the drug's binding to plasma protein. A more recent study (63) provided information on phenytoin binding to blood cells and showed that the distribution of drug in whole blood was different in the uremic *versus* the healthy subjects.

The binding of sulfamethazine to albumin was reduced in six nephrectomized patients (64). Dialysis of the patient blood did not increase the *in vivo* binding capacity over nondialyzed blood samples, supporting the belief that a defect in the binding properties of serum albumin existed in uremic patients. Also, a study of furosemide binding in patients with acute renal failure seemed to support the possibility of a defective drug binding mechanism (65, 66). The furosemide binding affinities determined in these two studies were in close agreement.

In the case of diazoxide in uremia (67), it appeared that the main determinant of decreased binding was the reduction in serum albumin concentration. Likewise, morphine binding was reduced in patients with renal failure and was shown to be dependent on the concentration of total serum proteins and albumin but not on the severity of renal dysfunction measured by creatinine clearance (68). Other studies were conducted with phenylbutazone (69) and cardiac glycosides (70, 71) in the plasma of uremic patients, and similar reductions in binding in uremic conditions were found.

The pharmacokinetics of trimethoprim, sulfamethoxazole, and cefazolin were studied in normal and uremic patients (72, 73). The distribution of free sulfamethoxazole in tissues increased during renal insufficiency, and this result was suggested to be due to reduced protein binding. However, no change in tissue distribution was seen for trimethoprim. With cefazolin, higher serum levels were observed in uremic subjects after identical doses to uremic and normal subjects, and serum half-lives increased with decreasing renal function. The apparent volume of distribution of cefazolin was elevated in the uremic state, probably due to decreased protein binding.

Campion (74) and Dromgoole (75) examined the reduction in binding of dyes during renal failure. Both found a decrease in binding; but while Campion determined that the decrease was unrelated to competition with metabolites, Dromgoole suggested either competition or conformational changes in albumin as the reason for the reduction. The binding of drugs, essential amino acids, and waste metabolites was investigated in normal and uremic subjects (76). Binding was reduced in the uremic subjects in all cases.

In Hypoalbuminemia—Generally, the concentration of albumin or total protein is decreased in various chronic diseases. Therefore, the unbound fraction of most drugs could be elevated; that is, the concentration of drug in plasma water could be increased. The intensity of drug effect may become greater than expected and may fall into the toxic range, as was documented in the case of phenytoin (77). Phenytoin was extensively bound to albumin and had increased adverse reactions when decreased serum albumin levels were present. A similar explanation was advanced for toxicity due to prednisolone, the major metabolite of prednisone (78).

Perhaps the best *in vivo* correlation of serum protein concentration and adverse drug reaction was reported by Greenblatt and Koch-Weser (79). In more than 1200 patients monitored while receiving diazepam, adverse reactions ranged from 2.9% in patients with normal serum albumin concentrations ($\geq$4.0 g %) to 9.3% in those with hypoalbuminemia (<3.0 g %). Similarly, methadone has a large variation in its binding fraction as a result of varying albumin levels in patients (80).

Another study (81) examined diluted serum from two subjects with regard to its binding of four drugs. In all cases, the amount of unbound drug increased as the albumin concentration was diminished. It was recommended that the albumin concentration be determined when examining plasma drug levels.

Wosilait (82) computed the theoretical amount of free drug in the plasma at various clinical concentrations of a number of drugs and at levels of albumin ranging from 2 to 5 g %. His results implied that the amount of free drug increased significantly in hypoalbuminemia and that care should be exercised when using highly protein-bound drugs in patients with decreased albumin levels.

In Liver Dysfunction—The influence of liver disease on the binding and kinetics of drugs in humans has received limited attention. Some reported results conflict as to the importance, if any, of drug–protein binding in hepatic dysfunction. The binding of five drugs to plasma proteins from patients with alcoholic liver disease was studied (83). The data for basic drugs indicated that liver disease decreased binding. With quinidine, the unbound fraction increased three times over normal amounts, an elevated level that may be clinically significant. For the organic bases studied, the decreased binding was most sensitive to decreased levels of serum albumin. Since cir-

rhotic patients have lower albumin concentrations, they consequently should have increased fractions of unbound drug. The data presented for acidic drugs lacked correlation with liver disease or albumin levels.

The percentage of unbound phenytoin increased by about 33% in five patients with acute viral hepatitis (84). In patients with hepatic dysfunction, monitoring plasma drug concentrations was the best means for adjusting dosages and schedules. The unbound phenytoin fraction in patients with hepatic disease increased by about 50% over that in normal healthy individuals (61). These changes in protein binding correlated better with changes in albumin and bilirubin levels in plasma than with any of 13 other biochemical parameters monitored. The binding of both morphine and phenytoin was decreased in liver failure (66). The binding depended on albumin concentration, but more data are needed to assess the effect of liver dysfunction on protein binding.

The degree of protein binding of amobarbital was reduced in five chronic liver disease patients who also had abnormally low serum albumin levels but was normal in five chronic liver diseased patients with normal serum albumin concentrations (85). Meperidine disposition and elimination were examined in patients with acute viral hepatitis (86). The significant increase in plasma half-life in patients with hepatitis was tested against protein binding of meperidine in normal *versus* hepatitis patients. The binding of meperidine was about equal in both groups; although elimination was significantly impaired in acute viral hepatitis, the effect seemed independent of protein binding.

Likewise, the effect of cirrhosis on the disposition and elimination of clindamycin was examined (87) and compared to normal individuals. Although the half-life was prolonged in the cirrhotic condition, the effect of clindamycin protein binding was about equal in both groups. The effect of liver disease in patients taking diazepam was studied (88). Plasma protein binding of diazepam in cirrhosis was decreased compared to that in normal subjects.

In Neonates—The neonate may respond quite differently than adults to drug substances (89). Drug binding to plasma proteins is of special interest in the neonate due to its regulatory effect on pharmacodynamic processes. Neonatal distribution, metabolism, and excretion processes differ from adults partly because infants have a greater total body water and lower fat content. This composition difference is larger and of extreme importance in premature infants.

The binding of phenytoin, salicylate, and nafcillin to plasma protein from newborn infants was investigated (90). The unbound fraction of phenytoin was significantly greater in neonates than adults, and the percentage of unbound drug correlated with the serum bilirubin level, suggestive of a possible competition phenomenon. Likewise, salicylate binding differed in the newborn as compared to adults. Nafcillin binding in the neonate exhibited large reductions from amounts bound to adult serum, and the levels of unbound drug were much higher. In a more recent paper (91), the low degree of nafcillin binding suggested that albumin was not the primary binding protein for this drug. Diazepam binding to neonatal and adult serum proteins also was discussed; in this case, the same binding affinity was observed with both the adult and newborn proteins.

Two studies (92, 93) compared the binding of some drugs to adult, fetal, and neonatal plasma. Both studies found reduced binding capacity in the newborn as compared with plasma from adults. Differences in the total protein concentration between these two age groups may have been responsible for the binding disparity. Hyperbilirubinemia further decreased the binding capacity. Data were given for phenytoin, imipramine, diazoxide, and cephalothin (92) at levels comparable to therapeutic concentrations; neonatal binding was reduced by 4–12% compared to adult plasma in all cases.

It was similarly reported (94) that drugs were less bound in newborn than in adult plasma, but this study also fractionated the plasma from each group into albumin and globulin fractions. With the six drugs studied, no difference was found in binding in the albumin fraction of newborn or adult plasma; however, binding to the globulin fraction was less in the newborn than in adults. Three possible mechanisms were suggested for the observed binding disparities: (*a*) a bilirubin competition phenomenon, (*b*) the decrease in globulin–drug interaction, and (*c*) the possibility for less drug binding due to albumin–globulin interaction in the plasma of the newborn.

A binding disparity between maternal and fetal plasma protein affinities for bupivacaine also was reported (95). Maternal protein bound approximately twice as much drug as did fetal protein on a per gram basis. The drug concentration was in the therapeutic range of 0.05–5.0 μg/ml, and the binding decreased from 92–78% to 35–31% in the maternal and fetal plasma, respectively. However, Gorodischer *et al.* (96), in an attempt to rationalize high digoxin doses in infants, reported that at therapeutic levels the affinity of digoxin for cord serum was low and about equal to that in adult serum. The higher therapeutic concentrations of digoxin in infants probably are a result of a higher dose (per unit body weight or surface area) than in adults. The pharmacological basis for the traditionally used high doses of digoxin in infants cannot be rationalized as due to binding differences, and more work is required.

In a study of hydrocortisone binding to plasma proteins from maternal, fetal, and infant plasma, a large difference was found in the binding capacity of maternal and fetal plasma (97). That this result might be due to a physicochemical difference in the respective proteins was deemed unlikely because the binding or affinity constants (K_a) were similar ($5–8 \times 10^8\ M^{-1}$) in all blood compartments examined. It was also reported (98) that the binding proteins in the maternal compartment may be highly active in the control of steroid metabolism. This report (98) found that, in comparison with nongravid women, fetal and neonatal steroid serum binding protein concentrations were one-thirtieth in the 5th month of gestation, one-twentieth immediately postpartum, and at normal adult nongravid levels 1 month postpartum.

In attempts to understand the binding disparity of phenytoin in neonatal and adult stages, it has been suggested (99) that there are large variations in circulating free fatty acids during the neonatal period and that the differences in both the acids present and their concentrations can influence the degree of drug binding during this period.

In plasma from newborn infants, phenytoin binding correlated with the albumin concentration and with the concentration ratios of bilirubin and free fatty acid to albumin. A reasonable correlation coefficient for phenytoin binding was obtained when compared to the ratio of total plasma bilirubin and albumin concentrations in infants (100).

RESULTS OBTAINED WITH PARTICULAR DRUG CLASSES

Antibacterial Chemotherapeutic Agents—*Penicillins and Cephalosporins*—A paper dealing with the pharmacological effects of the binding of various antibiotics (101) noted that, although most penicillins are bound by serum proteins, in only a few cases does this binding exceed 80%. (This percentage figure is misleading, because it is definitely related to some specific concentration or at least a concentration range.) Consequences of extensive binding of antibiotics by serum proteins may be interference with biological activity, delayed renal excretion, reduced urine concentration, restricted distribution volume, and decreased penetration of drug into intracellular spaces or inflammatory fluids. These effects were examined in relation to the binding of antibiotics by serum proteins and other endogenous substances. It was concluded that serum protein binding exerted an effect on these parameters and that this effect was particularly important for penicillinase-resistant penicillin and newer analogs of tetracyclines. Also included in this paper was a tabulation of binding percentages for various penicillin and tetracycline analogs.

In a study of six antibiotics, binding was well correlated with the ability of antibiotics to diffuse into interstitial fluid (102), as suggested previously. By using an *in vivo* skin chamber device, antibiotics with lower percentages of protein binding were found to diffuse into the interstitial fluid better than those with high binding percentages. Floxacillin (flucloxacillin), 95% of which is bound to protein, exhibited no detectable interstitial fluid levels. Also, increased protein binding influenced the renal clearance of four penicillins inversely (103).

Using a diafiltration technique to examine the association–dissociation rate of drug–protein interactions, a question about which information is still scarce, Barza *et al.* (104) presented data for oxacillin, nafcillin, and cephalothin. The binding of all three antibiotics was rapidly reversible and complete. The results of their experiments, in terms of percentages bound, are included in Table I, along with the results of some other papers having protein-binding data on penicillin and cephalosporin drugs.

In another study designed to demonstrate the reversible-ion binding between a series of penicillins and bovine serum albumin (105), the penicillin side chain had considerable influence over the binding process. According to the reactions of hydrated electrons produced by pulse radiolysis, the binding of the first molecule of penicillin G (benzylpenicillin) or penicillin V (phenoxymethylpenicillin) resulted in a greater decrease in protein reactivity towards e_{aq}^- than succeeding molecules. The results were interpreted in terms of the carboxyl group of penicillins interacting with cationic sites on the protein; however, other short-range weak forces may be significant.

In a study of the pharmacokinetics of various cephalosporins compared to cefazolin (106), extensive binding of a few congeners to serum protein took place. This degree of binding (Table I) apparently affected the serum half-life, the renal clearance, and the apparent volume of distribution of these drugs. Cefazolin, the most highly bound cephalosporin, had the lowest distribution volume, a result also obtained by other workers (110). In a study of the levels of ampicillin and cloxacillin in synovial fluid of arthritic patients, the non-highly-bound ampicillin reached about the same concentration in synovial fluid as in serum; the highly bound cloxacillin had synovial fluid levels much lower than serum levels (111). A rapid equilibrium apparently was established between the free concentration of cloxacillin in serum and synovial fluid. The primary effect of binding was to confine the drug to the vascular fluid. Distribution to other fluids was governed by levels of free drug in serum and not total levels. Along these same lines, a wide variation was found in the clearance of seven antibiotics by an artificial kidney (112). These differences were attributed to the variation in protein binding among the antibiotics.

Table I—Penicillin and Cephalosporin Antibiotic Binding to Human Serum

Antibiotic	Antibiotic Concentration, μg/ml[a]	Percent of Antibiotic Bound[b]	Reference
Oxacillin	20 (99)	85.2 (83.5)	103
Nafcillin	20 (100)	87.2 (80.5)	103
Cephalothin	10 (40)	57.0 (53.9)	103
Carbenicillin	80	50	107, 109
Ticarcillin	124	65	107
Penicillin V	30 (60)	52.7 (45.2)	108
Cefazolin	30	86	106
Cephanone	30	88	106
Cephaloridine	30	20	106
Cephalexin	30	15	106
Cephalothin	30	65	106
Cephradine	86.9	12.5	110
Ampicillin	—	13.5	111

[a] Number in parenthesis denotes second concentration of drug used in the literature report; results for this concentration are given in parenthesis in percent bound column. [b] Results are given in terms of percent of drug concentration bound. The serum consisted of 100% human serum or 100% pooled human serum.

Tetracyclines—A quantitative study of the interaction of therapeutic concentrations of tetracycline with human serum proteins was reported (113). In serum, 53% of tetracycline was complexed with various proteins and just over half of that amount was with albumin (most of the rest being associated with lipoprotein fractions). The results showed that tetracycline bound to two sites on albumin. The high affinity site had an association constant of $4.38 \times 10^4\ M^{-1}$ but very limited capacity (0.032 site/mole of albumin); the low affinity site exhibited a binding constant of $1.01 \times 10^2\ M^{-1}$ but had 39.50 sites associated with it. The physical meaning of having less than one-tenth of a binding site per mole of albumin was not discussed and was quite confusing to the reader. Such a minute number of sites on a large globular protein is difficult to envision.

The binding of tetracycline and various analogs to human serum albumin was examined using a probe displacement technique (114). Methacycline displaced the greatest amount of probe followed, in order, by doxycycline, chlortetracycline, oxytetracycline, and tetracycline. The association constants are included in Table II. As with

Table II—Literature Values for the Binding of Tetracycline Antibiotics to Serum Albumin

Tetracycline Analog	Primary Binding Constant or Percentage Bound	Number of Binding Sites or Concentration of Tetracycline	Reference
Tetracycline[a]	$4.38 \times 10^4\ M^{-1}$	0.032	113
Tetracycline[a]	$3.15 \times 10^4\ M^{-1}$	—	114
Oxytetracycline[a]	$3.53 \times 10^4\ M^{-1}$	—	114
Chlortetracycline[a]	$4.03 \times 10^4\ M^{-1}$	—	114
Doxycycline[a]	$5.32 \times 10^4\ M^{-1}$	—	114
Methacycline[a]	$6.28 \times 10^4\ M^{-1}$	—	114
Oxytetracycline[a,b]	$4.44 \times 10^3\ M^{-1}$	0.27	115
Demeclocycline	38%	10 μg/ml	116
Oxytetracycline	31%	10 μg/ml	116
Doxycycline	52%	10 μg/ml	116

[a] The tetracycline concentration was varied over a wide range, and more than one protein concentration was used in most cases. [b] Study used bovine serum albumin; 50% of the drug was bound at therapeutic concentrations.

other probe studies, the number of binding sites associated with these binding constants cannot be calculated. However, the technique was confined solely to the number of sites upon which the probe itself was bound. A drug binding at a site different than the probe may not have been detected. In addition, the possibility of probe-caused conformational changes in the protein structure was not, or cannot be, accounted for with such a technique.

Aminoglycosides—Conflicting reports concerning aminoglycoside antibiotic binding exist. The problem seemingly arose due to the ion content of the buffers used in various studies. For example, human serum binding of gentamicin, tobramycin, and kanamycin was about zero whereas streptomycin was about 35% bound (117). The system was not described except that a physiological pH was used with an ultrafiltration method.

In contrast, at gentamicin concentrations between 1.7 and 8.9 μg/ml (therapeutic levels of this antibiotic), 70% was bound to human serum albumin (118, 119). When the concentration was increased to 10–20 μg/ml, the binding of gentamicin was decreased to about 50% (118). Similar results were obtained for tobramycin, sisomicin, kanamycin, and amikacin; they were bound to the extent of 75, 85, 54, and 69%, respectively, at therapeutic levels. However, under *in vivo* conditions, these binding levels would not be expected to be reached; these values were obtained in 0.05 *M* tromethamine–hydrochloric acid buffer, which was void of any divalent cations. As levels of Ca^{2+} and Mg^{2+} increased, the binding of these agents decreased (118). The variations reported for *in vitro* experiments might carry over to the *in vivo* situation only under certain pathological conditions.

Another conflict arose from the results of a report comparing the pharmacokinetics of kanamycin and amikacin (120). Only 3.6% binding of amikacin could be detected when 15 μg of drug/ml was present in an *in vitro* system. This figure was about 200% less than the results reported previously (118).

Erythromycin, Lincomycin, and Clindamycin—Few papers have been published since 1969 concerning the binding of these drugs to human serum albumin. Prior to 1969, various reports stated that these molecules bound with high affinity while other papers indicated that only a low binding of these drugs occurred.

The binding of these three related antibiotics to serum albumin was studied using an ultrafiltration technique (121) (Table III). Also included in this work was a discussion of erroneous techniques and conclusions that resulted in some previously reported low levels of binding of these drugs. In a report examining the protein binding influence on the relative merits of the blood levels produced by erythromycin stearate and erythromycin estolate (erythromycin propionate lauryl sulfate) (122), doubts were raised as to the ability of blood levels to predict the effectiveness of these two forms of the same drug. Of utmost importance, in the author's opinion, was that the unbound levels of the estolate form were significantly lower than the unbound parent drug levels, even though total levels were higher. Thus, the difference in serum levels produced by the two forms of erythromycin reflected the difference in protein binding (Table III). It was suggested that unbound drug was a better measure of activity in the case of erythromycin congeners (122).

Table III—*In Vitro* Human Serum Binding of Erythromycin, Lincomycin, and Clindamycin[a]

Antibiotic	Percentage Bound	Antibiotic Concentration, μg/ml	Reference
Erythromycin base	73.4	5	121
	81.4	0.59–2.87	122
Erythromycin propionate	92.6	5	121
Erythromycin estolate	95.7	0.94–4.05	122
Lincomycin	71.9	5	121
	57	1	123
Clindamycin	93.6	5	121
	93	1	123

[a] Protein consisted of human serum (in a few cases pooled). The results reported are with 100% human serum, although some studies also used 25, 50, and 75% serum solutions.

Sulfas—In a series of articles dealing with drug–macromolecule complex formation, sulfa drug–albumin interactions were studied (124–127). For the many sulfas studied, the binding was considerably greater for the ionic form of the drugs than for the nonionized form. Also, two sets of binding sites apparently existed on albumin for most of these agents. Various drugs, such as phenobarbital and penicillin V (phenoxymethylpenicillin), were able to compete for these sulfa binding sites. Some of the binding data results are given in Table IV.

Table IV—Literature Parameters for Sulfa Drug Binding by Human Serum Albumin

Agent[a]	Primary Binding Affinity	Number of Binding Sites	Reference
Sulfadiazine	$3.6 \times 10^3\ M^{-1}$	1	125
Sulfamerazine	$2.9 \times 10^4\ M^{-1}$	1	125
Sulfamethazine	$4.4 \times 10^4\ M^{-1}$	1	125
Sulfameter	$5.9 \times 10^4\ M^{-1}$	1	125
Sulfadimethoxine	$1.8 \times 10^5\ M^{-1}$	1	125
Sulfisomidine	$5 \times 10^3\ M^{-1}$	1.1	128
Sulfamethomidine	$1 \times 10^4\ M^{-1}$	2.1	128
Sulfaortho-dimethoxine	$1.25 \times 10^4\ M^{-1}$	2.1	128
Sulfadimethoxy-pyrimidine	$4 \times 10^3\ M^{-1}$	2.2	128
Sulfadimethoxine	$1 \times 10^4\ M^{-1}$	1.9	128
Sulfaethidole[b]	1.2×10^5 liters/mole	1 primary (3 secondary)	129
Sulfathiazole[b]	2.96×10^3 liters/mole	1.98 primary (9.77 secondary)	130

[a] The concentration of drug used for these data varied over a wide range; the albumin concentration was also varied in most cases. [b] Study used bovine serum albumin.

The influence of sulfa drug binding on the excretion of two very long-acting, two long-acting, and one short-acting sulfa drugs was reported (128). The short-acting agent was bound to a lesser extent at clinical concentrations, and only a single binding site was evident for this drug in contrast to the two sites for the other sulfas. Small changes in sulfa drug structure may have altered plasma protein binding. At the plasma concentration of 0.4 mM, which is within the therapeutic range of these drugs, the short-acting agent was 67% bound whereas the longer acting drugs were 90–96% bound.

Perrin and Nelson (129), using the highly specific direct technique of induced optical activity, especially appropriate at low levels of added drug, found that with sulfaethidole only the single high affinity site was being examined by their method. Dialysis investigations had shown two classes of binding sites and thus made drug competition examination difficult. A primary binding affinity of 1.2×10^5 was obtained for sulfaethidole binding to bovine serum albumin. Binding constants of various drugs competing for the sulfaethidole binding site were reported.

Recently, the binding of sulfathiazole to bovine serum albumin and other blood constituents was examined (130). The results for serum albumin are included in Table IV. Also, some interesting possibilities were offered to explain unusual binding data. Data treatment of binding may be altered in whole blood systems, so normal methods to characterize the data may be inappropriate in these instances.

Rifampin—The binding of rifampin (rifampicin), a semisynthetic antibiotic with a broad antibacterial spectrum, often used as an antituberculous agent, has been examined (131–135). Rifampin concentrations ranging from 0.8 to 1000 μg/ml were used, and all studies except one (134) showed the drug to be 70–91% bound. This extent of binding resulted from using human and bovine serum as well as the albumin fractions of each. The report with percentage binding outside this range used human serum and a rifampin concentration of 10 μg/ml in an equilibrium dialysis investigation (134). The binding was 8–41%; however, these results are confusingly reported as rates of binding.

In one study (135), binding was examined in healthy volunteers (mean 88.9% bound) as well as in tuberculous patients (mean 86.1% bound). The difference between these two groups was significant, but the binding of rifampin to plasma proteins was of relatively minor importance clinically.

Anticoagulants—The interaction of warfarin and dicumarol with human albumin has been the subject of many investigations. This is to be expected since the relatively low therapeutic index of these agents and the propensity for other concurrently administered drugs to displace small amounts of the anticoagulants from their binding sites raise free drug levels and possibly increase prothrombin time.

O'Reilly (136–138) found that warfarin was bound to albumin with an affinity constant of $2.17 \times 10^5\ M^{-1}$ at 37° (137) and that the 6-, 7-, and 8-hydroxy metabolites showed a 7–23-fold reduction in binding (136). These data (136) suggested that the interaction was exothermic and had a positive entropy and that the albumin–drug interaction was probably the result of cooperative hydrogen bonding–hydrophobic forces. Recent studies (139, 140) discussed the effect of protein binding of warfarin in rats related to its pharmacological action, distribution, and elimination. A substantial variation was found in the free fraction of drug in the serum, and strong correlations were observed between the free serum fraction and the elimination rate constant, the volume of distribution, and the total plasma clearance of the drug. The amount of total warfarin required to elicit a specific anticoagulant response varied widely between animals, and this response was a function of free warfarin levels in plasma (140).

An investigation of warfarin and dicumarol interaction with human serum albumin was reported using a circular dichroic technique (141). Warfarin, in contrast to dicumarol, gave no induced Cotton effect, suggesting a different mode of binding for the two anticoagulants. On the other hand, another study (142) found that warfarin was capable of generating extrinsic Cotton effects and that the binding constant could be calculated from such data. Based on equilibrium dialysis data, Chignell (141) also reported that dicumarol (bishydroxycoumarin) was bound to human serum albumin at three primary homogeneous sites and exhibited a binding constant of $2 \times 10^5\ M^{-1}$. However, he also studied the interaction by monitoring the quenching of the single tryptophan residue of human serum albumin and concluded that one primary binding site existed with a binding affinity of $5.2 \times 10^5\ M^{-1}$. In addition, he showed that the dicumarol–albumin interaction gave rise to large negative extrinsic Cotton effects. Thus, it was proven that the interaction could be studied by the circular dichroic technique, but no quantitative attempt was made.

Recently, a report (32) appeared using this sensitive circular dichroic method for low dicumarol to protein ratios (*i.e.*, those of clinical significance), and a binding constant of $2.9 \pm 10\% \times 10^6\ M^{-1}$ at the single high affinity site was calculated. Results from dicumarol displacement studies using other acidic drug molecules are contained in the same report (32). A competition between warfarin and dicumarol for a human albumin binding site also was shown.

A computer program was used to determine the binding capacities, association constants, and amounts of unbound and bound dicumarol at different drug levels as well as at various levels of protein concentrations (143–145). An association constant of 2.2×10^6 liters/mole containing two homogeneous sites was reported. A second class of seven sites with a binding constant of 1.3×10^4 liters/mole also was determined (144), and for warfarin a primary binding affinity of 8.9×10^4 liters/mole at two equivalent binding sites was found.

Warfarin, dicumarol, sulfonamides, and other acidic drugs may share the same binding site on albumin (146). However, such acidic drug competition may not always be the case. A recent report dealt with the lack of interaction between warfarin and ibuprofen (147). Ibuprofen, an acidic drug bound to plasma protein when administered alone, failed to inhibit competitively or to interfere with warfarin binding, thus producing no alteration in the degree of hypoprothrombinemia.

Antiepileptics—Phenytoin has been well studied with respect to its protein binding and pharmacokinetic characteristics. In normal human plasma, 92.6% of the drug was bound at a therapeutic concentration of 16 μg/ml using an

ultrafiltration technique (148). No binding differences were found with respect to sex, and there was a 64% increase in the unbound fraction of drug at 37°. Thirteen drugs were also examined as to their propensity to affect phenytoin binding. Only salicylic acid, sulfisoxazole (sulfafurazole), and phenylbutazone were able to increase the unbound fraction of phenytoin. In another study (149), phenytoin was extensively bound to both human and rat albumin and the major metabolite (the 5-*p*-hydroxy species) was also strongly plasma protein bound. The binding levels of both the parent compound and the metabolite were suggested as possible explanations of the species selectivity in the drug-induced toxicity observed.

A study was designed to examine the protein binding of phenytoin in eight patients with epilepsy and in drug-free volunteers as well as to determine total drug in plasma and cerebrospinal fluid (150). Only minor variations were seen between individuals in each group. The mean unbound fraction of phenytoin in patient plasma was 6.3% at room temperature and 10.3% at body temperature at a mean drug level of 11.2 μg/ml. The ratio of total phenytoin in cerebrospinal fluid to that in plasma in the eight patients was unusually constant with a mean of 9.6%. A comparison between the unbound fraction of phenytoin in plasma and the same cerebrospinal fluid to plasma ratio exhibited a good correlation, a result not unexpected since only the unbound fraction of drug was available for equilibration.

Phenytoin binding was examined to determine if individual differences in the degree of protein binding might explain the variance between total serum levels and clinical intoxication (151). Adverse clinical symptoms were better correlated to free levels of the drug than to total serum concentration. When free phenytoin levels were above 5 μg/ml, signs of intoxication would probably be present no matter what the total serum level. These individual variations in ability to bind this drug may have been due to a qualitative change in the drug binding proteins (152). In a study of plasma from 11 different species of mammal, such a change in binding proteins was observed.

For highly bound phenytoin, the unbound plasma level can be readily obtained in the clinical laboratory by measuring the red blood cell to plasma concentration ratio of an unknown sample (153). The red blood cell binding to plasma binding ratio was constant throughout therapeutic plasma phenytoin levels. As a result of this finding, one could readily individualize drug dosage and minimize adverse effects. A recent paper (154) concerned with phenytoin effects and plasma protein binding reported that, in rats, prior treatment with phenylbutazone had no effect on the potency of unbound phenytoin. Thus, the action of this antiepileptic depends upon the unbound concentration in plasma and not upon dose or total plasma concentration. These results agree well with those previously described (151–153).

A recent abstract (155) further supported the idea of binding when more than one highly bound drug was present. Diazoxide lowered the phenytoin binding levels, requiring considerable dosage adjustment. Concurrent drug administration may also have changed the rate of drug metabolism, further necessitating dosage adjustment.

The protein binding of the antiepileptic carbamazepine was the topic of two recent investigations (156, 157). Carbamazepine had a low association constant for albumin (1.35×10^3 liters/mole) at approximately one site per mole (156). For therapeutic concentrations of drug (5–30 μg/ml), the unbound fraction was 24% following ultrafiltration of plasma samples from six volunteers. The results from an excellent study (157) confirmed this observation of the unbound fraction. A linear relationship was observed between unbound and total drug throughout the therapeutic region of 5–50 μg/ml. Carbamazepine binding in 54 plasma samples from treated patients was examined with the result that 26.9% of the drug was found to be unbound. Erythrocyte uptake, measured in 23 of these patients, was 38.3% of the plasma levels. Six other anticonvulsants were examined at high therapeutic concentrations for effects on carbamazepine binding and were shown not to alter carbamazepine free drug levels significantly. Also, no difference was seen when renal disease was present and only a slightly lower percentage of carbamazepine was bound if the patient had hepatic dysfunction.

Antihypertensives—The binding of diazoxide to human albumin was investigated, and the binding accounted for its long half-life. At 37°, the dissociation constant for the diazoxide–albumin interaction was $5.2 \times 10^5\ M^{-1}$, with 1.2 sites exhibiting this constant. At pH 7.4, the free energy change upon binding was −5.9 kcal/mole and was accounted for from hydrogen and ionic bonds (158). Protein binding may be implicated in the kinetics of the diazoxide effect (159). A rapid intravenous injection produced an effective hypotensive action, whereas injections lasting longer than 1 min greatly reduced the intensity. At therapeutic concentrations, 97.6% of the drug was in the protein-bound form, so free diazoxide reached effective levels at the arteriolar wall only during rapid injection. These results duplicated those of Andreasen (160).

Propranolol binding was studied and related to its disposition in humans (161–163). At therapeutic concentrations, 93.2% of the drug was bound to human plasma (163); the volume of distribution increased as the free propranolol fraction in the blood increased (162). However, the ratio of the volume of distribution to the free drug was relatively constant. After examination of propranolol binding in four species (humans, monkeys, dogs, and rats) as well as the clearance, half-life, and volume of distribution, it was concluded that increased drug binding was associated with a decrease in drug half-life when the influence of variable drug clearance was accounted for. Differences in binding were responsible for interindividual variations in the half-life of the drug in humans after intravenous administration. This was the result of an increase in the rate of drug delivery to the elimination sites (163). Human albumin (5%) alone accounted for only about 50–60% of the binding to plasma over the drug concentration of 1–10 μg/ml. Similarly, serum albumin alone accounted for only 42% of propranolol binding at drug concentrations less than $1 \times 10^{-4}\ M$ (164). From these data, an intrinsic binding constant of very low magnitude was calculated for propranolol (about 120 liters/mole). The binding of the β-adrenergic receptor antagonists alprenolol, its 4-hydroxy derivative, and a chemically related compound metoprolol[1]

[1] H 93/26.

Table V—Summary of Results Obtained from Investigations of Analgesic–Anti-Inflammatory Agent Binding to Plasma or Serum Albumin

Drug	Drug Concentration	Protein	Protein Concentration	Affinity Constant or Percent Bound	Number of Sites	Reference
Salicylate	50 μg/ml	Human plasma	5.3%	72%	—	166
Salicylate	50 μg/ml	Human albumin	3%	73%	—	166
Salicylate	Wide range	Bovine albumin	4%	5×10^4 liters/mole	1.04	130
Salicylate	Wide range	Human albumin	0.7%	$2.19 \times 10^5\ M^{-1}$	4	169
Salicylic acid	$0.002–5 \times 10^{-3}\ M$	Human albumin	0.3%	$7.07 \times 10^4\ M^{-1}$	1.28	168
Indomethacin	$0.002–2 \times 10^{-3}\ M$	Human albumin	$1 \times 10^{-4}\ M$	$8.4 \times 10^5\ M^{-1}$	4–5	169
Indomethacin	57–756 μg/ml	Human plasma	2.35%	$3 \times 10^5\ M^{-1}$	1	174
Phenylbutazone	Wide range	Human albumin	$1 \times 10^{-5}\ M$	$1 \times 10^5\ M^{-1}$	1	177
Fenoprofen	40 μg/ml	Human albumin	$7.1 \times 10^{-5}\ M$	$3 \times 10^4\ M^{-1}$ (>99% bound)	4–5	180
Fenoprofen	$0.075–37.9 \times 10^{-5}\ M$	Human albumin	$7.25 \times 10^{-5}\ M$	$1.86 \times 10^5\ M^{-1}$	1	181
Pentazocine	—	Human plasma	—	61.1%	—	182
Diftalone	Wide range	Human albumin	$2.5 \times 10^{-5}\ M$	3.85×10^4 liters/mole	1.38	183
Methadone	$0.006–2.87 \times 10^{-5}\ M$	Human plasma	—	83–87%	—	185
Morphine	$1.3–1.7 \times 10^{-7}\ M$	Human albumin	4%	31.4 ± 1.4%	—	187

also was studied. Alprenolol had about the same percentage binding and intrinsic constant for human serum albumin as propranolol; however, alprenolol was bound to a much higher extent in human serum *in vitro* (165).

Analgesic–Anti-Inflammatory Agents—Many of these agents have been examined for the intensity of their interaction with albumin or plasma. Some of these results are given in Table V.

Salicylic acid and its salts and aspirin have been the subject of many investigations, often with wide variations in results. Salicylate binding in the plasma obtained from six mammalian species was compared (166). After equalizing the protein concentration from each species, the binding was greatest in humans (72% at a drug concentration of 50 μg/ml). Salicylate bound to albumin was closely correlated with that bound to plasma in four species, including humans, but was not correlated in rats and dogs. Similar results were obtained for salicylate binding to adult plasma, but binding was progressively and perhaps significantly less in children (5–8 years) and newborns (to 5 days old) (167).

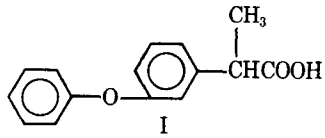
Cruze and Meyer (130), studying salicylate binding to bovine serum albumin and bovine plasma, found close agreement in the extent of binding for these two systems. Keresztes-Nagy *et al.* (168) examined the salicylate–albumin interaction by two methods and found results compatible with those of Cruze and Meyer (130). Another investigation of the salicylic acid–human albumin interaction found four strong primary binding sites exhibiting an affinity constant of about 2.19×10^5 (Table V) (169). The culmination of such *in vitro* binding experiments can be seen in a report by Levy and Yaffe (170), which pointed out the protein binding and dose-dependent change in the volume of distribution of salicylate. These data were used to explain the clinical severity of salicylate poisoning in cases of single-dose ingestion (171): once the binding capacity of available serum proteins was surpassed, the apparent volume of distribution increased and a given serum salicylate level reflected larger amounts of total salicylate in the body than at low doses. The larger volume of distribution possibly includes the central nervous system, which then may manifest toxicity.

Aspirin and salicylates also were examined from the standpoint of their effects on endogenous substances. The ingestion of aspirin caused a release of tryptophan from its serum albumin binding site (172). Subsequently, there was a decrease in bound and total serum amino acid levels, a rise in free levels of tryptophan, and an increased effect on tryptophan metabolism. Aspirin produced an increase in free 11-hydroxysteroids in an *in vitro* system employing human plasma (173). In summary, salicylate may not be highly protein bound, but the levels ingested may have some deleterious effects on the binding of concomitantly administered agents or on endogenous substances.

The interaction of indomethacin with human plasma protein was investigated at 37° using an ultrafiltration technique (174). A surprisingly high affinity constant was obtained for indomethacin (Table V), and plasma protein displayed one primary site and at least seven secondary sites for the drug. Displacement of albumin-bound indomethacin was also investigated. Hvidberg *et al.* (175) found about 90% indomethacin binding to human plasma over the therapeutic concentration range of 0.5–10 μg/ml. From these data, they calculated an association constant of $8.6 \times 10^2\ M^{-1}$ with about 15 sites present on the albumin; however, this binding constant may be somewhat suspect in relation to other indomethacin binding studies due to the fact that only 4 hr was used for the equilibrium dialysis procedure and more time to equilibrate may be required. The indomethacin–human plasma interaction also was studied using an equilibrium dialysis procedure (176). The results showed plasma binding to an extent of about 75% at a drug concentration of $2 \times 10^{-4}\ M$.

The binding of phenylbutazone, flufenamic acid, and some of their analogs to human serum albumin was investigated using a circular dichroic method (177, 178). Based upon the induced Cotton effects and solvent perturbation studies, it appears that hydrophobic interactions, along with polar binding, were important for the phenylbutazone–protein complex (177). Likewise, these forces may play a major role in the flufenamic acid–albumin interaction. The primary association constant for flufenamic acid bound to albumin appears to be very large; when less than 2 moles of drug were bound per mole of protein, no free drug apparently existed (178).

The binding of the nonsteroidal anti-inflammatory drug fenoprofen (I) and some of its analogs to human serum



I

albumin was investigated using the circular dichroic technique (179). Fenoprofen was bound nonstereospecifically to albumin as a result of hydrophobic bonding of the aromatic rings and hydrogen bonding of the carbonyl and ether oxygen. Another study (180) found an association constant of about 3×10^4 for the fenoprofen–human albumin interaction. In an investigation of competition phenomena, only the highly bound phenylbutazone, in concentrations 10 times that of fenoprofen, was able to displace fenoprofen from human serum albumin. These data supported the binding constant data of Vallner (181) for the fenoprofen–human albumin interaction. He found a primary association constant of 1.86×10^5 liters/mole at a single site on albumin, indicating that displacement by added drugs would probably require a strongly bound agent.

In a study of the relationship of the nonsteroidal anti-inflammatory agent diftalone to its interaction with human serum proteins (183), the largest association took place with the albumin fraction, and an association constant of 3.85×10^4 liters/mole was calculated (Table V). The diftalone–albumin interaction was strongly temperature dependent. It was concluded that the binding was primarily due to either van der Waals or hydrophobic forces.

Recently, morphine, heroin, and methadone have been examined with regard to their plasma and albumin binding capacity. Initially, Olsen (184, 185) found that the percent of methadone bound to albumin was independent of drug concentration but dependent on albumin concentration. He obtained a range of 8.0–43.8% bound as the albumin increased from 0.4 to 5.0 g % (184). Subsequently, Olsen (185) examined the contribution of γ-globulin to the total amount of methadone binding and found a small addition of 13–17% bound to this macromolecule fraction. At therapeutic levels in human plasma, methadone was about 85% bound (185).

Morphine and heroin binding to human serum proteins and red blood cells was examined and found to be minimal (186). The morphine–plasma protein interaction also was investigated; morphine bound to albumin and γ-globulin (187). In the therapeutic range, 34.0–37.5% of morphine was bound to human plasma, with albumin accounting for the largest binding fraction. A recent report concerned the possible production of a morphine-binding globulin in subcutaneous pellet-implanted rabbits receiving narcotic drugs (188). Opiates could form specific protein conjugates, so binding to albumin may be minimal. The possibility that immunogenic drug–protein complexes were formed deserves further study.

Antitumor Agents—A paucity of information is available concerning the plasma protein binding of antineoplastic agents. Binding information coupled with pharmacokinetic data could be exploited advantageously in the clinical cancer chemotherapy setting. In a report (189) on protein binding and renal clearance data for methotrexate, the mean protein-bound methotrexate was 70% of the serum levels (in 15 patients) over the 90–200-ng/ml range. Alterations in renal clearance of the antimetabolite were affected by concomitant administration of organic acid drugs. These alterations may have been due to altered protein binding or renal mechanism and may be useful in the clinical situation. These results (189) were confirmed in a recent study (190) employing a different technique.

Camptothecin binding to various plasma proteins as well as to whole plasma has been investigated in various species including humans (191). This antitumor agent was extensively bound in human plasma: 98.3% at a drug concentration of 30 μg/ml. It also showed a high association constant, $7.9 \times 10^6\ M^{-1}$, for human plasma albumin at a single site on the macromolecule. Albumin, however, was not the only plasma protein with significant affinity for this agent. High binding levels in the human may be one reason that significant antineoplastic effects have not been seen, whereas this agent showed marked potential in the mouse but had a low binding affinity.

The binding of the antineoplastic agents vinblastine, vincristine, and colchicine to plasma and serum proteins was examined (192). These agents adsorbed to serum proteins, with the result that vinblastine and vincristine were about 75% bound while colchicine was 50% bound. Saturation of binding could not be shown with these drugs; however, it was evident that α- and β-globulins were the more important macromolecular serum species involved in the adsorption.

A subsequent study (193) showed that, although vinblastine binding in two patients was highest in their platelet fractions, red blood cells and white blood cells also accounted for significant binding. The extent of protein binding of this agent was not so great as to prevent rapid distribution into other body organs. A study (194) of the binding of a number of antineoplastic dinitrophenylaziridines found that the five congeners studied were weakly and reversibly bound to bovine serum albumin.

Barbiturates—Most protein binding work concerning these agents was done prior to 1969. However, the influence of pH on the bovine albumin binding of barbituric acid and amobarbital was evaluated (195). At pH 4, barbituric acid had an association constant of $1.6 \times 10^3\ M^{-1}$ for albumin; at pH 2, no binding occurred. According to the report, such behavior was consistent with an ionic mechanism of binding for this agent. Similarly, with amobarbital, no binding was evident at pH 5.8 but was detected at a higher pH.

In a subsequent study (196), the binding of amobarbital, pentobarbital, and phenobarbital to human albumin was examined over the pH range of 5.7–8.4; the ionized forms of these drugs were preferentially bound, with the primary binding constant ranging from 2.0 to 6.2×10^3. In a pharmacokinetic study of pentobarbital at therapeutic levels in seven human volunteers, little of this drug was associated with plasma protein whereas tissue binding was extensive (197). The large extent of tissue binding elevated the distribution volume such that it exceeded total body water. In another patient study (198), thiopental binding was better correlated with hemoglobin than with plasma protein levels. That such a conclusion was reached was not surprising since therapeutic levels of barbiturates do not seem to have a high affinity for albumin or other plasma proteins.

Cardiovascular Agents—An excellent study concerned the binding of digitoxin and digoxin and related cardiac glycosides and genins (199). Digitoxin in the plasma was bound almost exclusively by a single site on albumin and to the extent of 97% of concentrations ranging

Table VI—Literature Results of *In Vitro* Binding of Diuretics to Human Serum Albumin

Drug	Drug Concentration, μg/ml	Albumin Concentration, %	Binding Constant or Percent Bound	Number of Sites	Reference
Chlorothiazide	5–100	0.1–4	3–3.4 × 10^4 M^{-1}	1 or 2	208
Hydroflumethiazide	—	5	74%	—	209
Bendroflumethiazide	—	5	94%	—	209
Furosemide	3.4	5	97.2%	—	212

as high as 12 μg/ml. An association constant of 9.62 × 10^4 liters/mole at 37° was calculated. The digitoxin–albumin interaction was endothermic with a gain in enthalpy of 3.5 kcal/mole, a free energy change of −7.06 kcal/mole, and an entropy change of 33.8 cal/mole/°K. These results were suggestive of a hydrophobic mechanism between digitoxin and albumin. In contrast to digitoxin, only 23% of digoxin bound to albumin at concentrations up to 2 μg/ml. The binding differences for these two closely related drugs are reflected by higher plasma levels, lower urinary excretion rates, and a longer half-life of digitoxin compared to digoxin when these agents are administered to humans.

In other studies of digitoxin (200) and digoxin (201) binding to human serum proteins, digitoxin had a large association constant for albumin (K = 1–5 × 10^5 liters/mole), but the number of sites calculated was 0.5 in contrast to the 1.0 site seen previously. The binding was observed to be pH dependent; maximum binding occurred at pH 4.8. This finding might explain the somewhat lower binding constant observed by Lukas and DeMartino (199) who carried out their work at pH 7.4. For the digoxin–albumin interaction, Brock (201) found that increases in pH from 5 to 9 decreased the association constant from 8 × 10^2 to 1 × 10^2 liters/mole at 37°. The binding of these same two drugs was examined in a wide variety of mammalian species, and some substantial binding differences were noted, especially in the less tightly bound digoxin (202).

Two other studies (203, 204) on digoxin binding reported results contradictory to those given above. One study (203) found a total lack of protein binding of digoxin in human serum, and the other (204) showed that digoxin was about 30% bound in human serum using a wide range of digoxin concentrations. The calculated association constant was 6.8 × 10^4 liters/mole at an infinite number of digoxin sites on the albumin molecule (204). Seemingly, the binding constant calculated was larger than expected based on results of other studies and the low percentage binding in the plasma.

The antiarrhythmic drug quinidine was bound to albumin at two different classes of sites, and the primary binding affinity was 2.06 × 10^4 M^{-1} (205). Another study also examined the binding of quinidine to human plasma and human albumin (206). At a concentration of 1.6 × 10^{-5} M quinidine, 74% of the drug was bound to plasma and 71% to albumin. Like the previous study, two classes of sites on albumin were found, and the primary binding affinity was calculated to be 1.28 × 10^4. In the same study, binding of the new antiarrhythmic disopyramide had a lower binding affinity (4.6 × 10^3). A computer program was used to predict free and bound levels of quinidine, based on binding to albumin at two sets of sites (209). The analysis was limited to drug concentrations that may be obtained clinically (1–10 μg/ml). Over this concentration range, 74–88% of the drug would be predicted to be bound to serum albumin.

Diuretics—Relatively little work has been done concerning the binding of diuretic drugs to serum albumin since the Meyer and Guttman (1) review. A study of the binding of chlorothiazide to plasma proteins found that plasma binding was due almost entirely to the albumin fraction (208). At 37° with a 0.4% albumin solution and a drug concentration of 5–100 μg/ml, a maximum of 68% of chlorothiazide was bound; larger percentages of binding occurred at lower temperatures. Other binding data for diuretic agents are given in Table VI. In addition, it was found that the chlorothiazide–albumin interaction was accompanied by a negative entropy change and a relatively large change in enthalpy (208). It was suggested that the interactive force was due to nonionic bond formation.

Agren and Back (209), examining the binding of hydroflumethiazide and bendroflumethiazide to human serum albumin, found the primary binding affinity for hydroflumethiazide to be 1.8 × 10^3. For bendroflumethiazide, the affinity constant was 2.6 × 10^5 when the drug was ionized to 6.5% (at pH 7.35) and about 50 times less if 0.7% ionized. It was concluded that bendroflumethiazide was bound primarily by ionic bond formation. Another study (210) mentioned that bumetamide was 95–97% bound to human plasma protein *in vitro*.

Furosemide binding has been studied both *in vitro* and *in vivo* in cardiac patients and normal volunteers. In these individuals, the diuretic was bound exclusively to plasma albumin; at concentrations of furosemide from 10 to 400 μg/ml, 99.1–95.8% of the drug was bound (211). Similar results were observed using therapeutic concentrations of furosemide (212); phenytoin, phenobarbital, diazoxide, trifluoperazine, or chloramphenicol did not displace any furosemide.

Hypoglycemics—The natural hypoglycemic agent insulin has been studied in the serum of normal and diabetic patients. With a gel permeation method, addition of iodine-labeled insulin to normal human serum showed a binding of 4.3% if analyzed immediately and 5.4% if incubated for 24 hr (213). In contrast, these values were 37.7 and 66.9%, respectively, in insulin-treated diabetics. Another study (214) found that the binding of insulin to macromolecular serum proteins was about 10 times higher in the diabetic than the normal individual.

An investigation of the binding of acetohexamide, chlorpropamide, and tolbutamide to human serum proteins showed that the albumin fraction was responsible for the greatest binding (215). At pH 7.4, the primary binding affinities were 3.4 × 10^4, 1.1 × 10^4, and 4.1 × 10^4 for acetohexamide, chlorpropamide, and tolbutamide, respectively. The interaction of a number of drugs with the sulfonylurea–albumin complex was examined for each of these agents. Sulfaphenazole appeared to be a potent in-

Table VII—Reported Sulfonylurea–Albumin Binding Parameters

Drug	Drug Concentration, M	Albumin Source	Albumin Concentration	Primary Binding Constant	Number of Sites	Reference
Tolbutamide	$2–84 \times 10^{-5}$	Human serum	2.9×10^{-4} M	4.06×10^{4} M^{-1}	1.36	215
Tolbutamide	—	Human serum	1%	2.18×10^{5} liters/mole	2.27	216

[a] In this report, human plasma was used as the biomacromolecule.

hibitor of the sulfonylurea–albumin binding while aspirin had little displacing ability. In contrast to these data (215), substantial differences were reported in the binding of tolbutamide and chlorpropamide (216). This study demonstrated that an interaction between buffer contents and serum albumin may have had significant effects upon the binding parameters calculated by Judis (215).

In 1% human serum albumin using phosphate buffer and tromethamine buffer, the numbers of primary binding sites were 2.27 and 1.42 and the primary affinity constants were 21.86×10^4 and 0.97×10^4 liters/mole, respectively (216). It appears important to characterize binding at several buffer or protein concentrations and perhaps employ more than a single buffer system to calculate more meaningful constants. Various other studies using the same sulfonylureas, tolbutamide, chlorpropamide, and acetohexamide, and newer agents, such as glyburide and glipizide, have appeared (217–222). These results are given in Table VII.

Hsu *et al.* (220) reported that the binding of glipizide and glyburide to human and bovine serum albumin was fundamentally different than the other sulfonylureas. Using a fluorescent probe study, they found a difference in competition for the probe binding site between glipizide and glyburide, which interacted with one of their probes, and the other sulfonylureas, which interacted with a probe with which glipizide and glyburide did not. In their opinion, this probe-specific interaction differentiated the binding sites. Zia and Price (221), on the other hand, showed that acetohexamide, glipizide, glyburide, and tolbutamide bound at the same or closely located sites on the protein.

An evaluation was made recently of the nature of the molecular interaction between sulfonylureas and serum albumin using a circular dichroic technique (222). The sulfonylurea–albumin complex failed to generate a specific conformation among these various agents. This finding could be interpreted in terms of a dissimilar mode of binding for these agents. The binding of the biguanides metformin, buformin, and phenformin to human and dog whole blood and plasma was studied (223). Relatively small percentages (7.4–12%) of these agents were bound in human plasma at drug concentrations from 0 to 3×10^{-4} M.

Local Anesthetics—The binding of the anilide-type local anesthetic agents lidocaine, mepivacaine, and bupivacaine was reported (224). The binding of these agents was evaluated in two patients at plasma drug concentrations of 0.4–23.3 μg/ml. Binding of bupivacaine was greatest (96.5–61.5%), mepivacaine was less (84.3–31.5%), and lidocaine was least (75.0–28.2%). At levels greater than 5.0–10.0 μg/ml of any of these agents, there was a marked reduction in binding, presumably due to binding site saturation. Identification of the main plasma binding macromolecule for these basic drugs was not successful; however, albumin was probably not the protein of greatest importance. A subsequent paper reported that differences between the plasma binding of these three agents may partly explain observed differences between their umbilical–maternal concentrations (225).

The results of another study (226) examining the interaction of bupivacaine with human plasma proteins are in close agreement with those of Tucker *et al.* (224). It was found (226) that at bupivacaine levels of 1 μg/ml, the mean unbound fraction of drug in 10 healthy volunteers was 6.3%. In a study of lidocaine disposition kinetics (227), 60.8% of the drug was bound over the plasma concentration range of 0.8–4.1 μg/ml. A rapid bolus injection of lidocaine and its seemingly rapid saturation of binding sites may be important in determining the immediate toxicity of this drug (227). The suggestion of administering this drug over 1–2 min may be important in decreasing toxic symptoms.

Psychopharmacological Agents—Many reports concerning the binding of tricyclic and benzodiazepine derivatives to human plasma and albumin have been published since 1969. An ultrafiltration technique was used to examine the binding of various tricyclic antidepressants to human plasma proteins (228). At a total concentration of 0.29 μg/ml, the percentage of unbound desipramine (desmethylimipramine) was 9.5 ± 1.4 in 41 individuals; this degree of binding was relatively constant over a wide drug concentration range. Other tricyclics studied at 1.1 μM concentrations had the following percentages of unbound drug: nortriptyline, 5.5 ± 0.6; amitriptyline, 3.6 ± 0.8; and protriptyline, 8.0 ± 0.6. The *in vitro* percentage of unbound nortriptyline correlated well with *in vivo* measurements of free drug concentration in cerebrospinal fluid. The protein responsible for the greatest amount of binding in the plasma was not determined.

Imipramine interacted with bovine serum albumin at six equivalent binding sites, possibly involving tyrosyl

Table VIII—Reported Tricyclic Antidepressant–Protein Binding Parameters

Drug	Drug Concentration, M	Protein	Protein Concentration, M	Primary Binding Constant	Number of Sites	Reference
Chlorpromazine	—	Human albumin	1.8×10^{-5}	4.2×10^{4} liters/mole	4	7
Trifluopromazine	$0.365–14.6 \times 10^{-5}$	Human albumin	1.8×10^{5}	5.5×10^{4} liters/mole	4	7
Chlorpromazine	$40–1600 \times 10^{-6}$	Human plasma	—	$1.5 \times 10^{4}\ M^{-1}$	—	236
Chlorpromazine	$40–1600 \times 10^{-6}$	Human albumin	—	$1.3 \times 10^{3}\ M^{-1}$	—	236
Imipramine	$40–1600 \times 10^{-6}$	Human plasma	—	$1 \times 10^{4}\ M^{-1}$	—	236
Imipramine	$40–1600 \times 10^{-6}$	Human albumin	—	$4.9 \times 10^{2}\ M^{-1}$	—	236
Chlorpromazine	$1–20 \times 10^{-6}$	Human albumin	6.8×10^{6}	1.9×10^{5} liters/mole	1.94	237
Promazine	$1–20 \times 10^{-6}$	Human albumin	5.8×10^{-6}	8.5×10^{4} liters/mole	1.31	237
Promethazine	$1–20 \times 10^{-6}$	Human albumin	5.8×10^{-6}	7.9×10^{4} liters/mole	1.64	237
Trifluoperazine	$1–20 \times 10^{-6}$	Human albumin	5.8×10^{-6}	2.86×10^{5} liters/mole	1.18	237
Imipramine	$1–20 \times 10^{-6}$	Human albumin	5.8×10^{-6}	2.39×10^{4} liters/mole	1.31	237
Trimipramine	$1–20 \times 10^{-6}$	Human albumin	5.8×10^{-6}	2.38×10^{4} liters/mole	1.24	237
Clomipramine	$1–20 \times 10^{-6}$	Human albumin	5.8×10^{-6}	7.35×10^{4} liters/mole	1.03	237
Desipramine	$1–20 \times 10^{-6}$	Human albumin	5.8×10^{-6}	7.02×10^{4} liters/mole	1.53	237
Chlorpromazine	4.6×10^{-5}, 15×10^{-4}	Bovine albumin	6.9×10^{-5}	$2.57 \times 10^{4}\ M^{-1}$	—	221
Trifluoperazine	4.6×10^{-5}, 15×10^{-4}	Bovine albumin	6.9×10^{-5}	$2.32 \times 10^{4}\ M^{-1}$	—	221
Perphenazine	4.6×10^{-5}, 15×10^{-4}	Bovine albumin	6.9×10^{-5}	$1.96 \times 10^{4}\ M^{-1}$	—	221
Fluphenazine	4.6×10^{-5}, 15×10^{-4}	Bovine albumin	6.9×10^{-5}	$1.82 \times 10^{4}\ M^{-1}$	—	221
Promazine	4.6×10^{-5}, 15×10^{-4}	Bovine albumin	6.9×10^{-5}	$1.04 \times 10^{4}\ M^{-1}$	—	221

residues of the protein, with an intrinsic association constant of $5 \times 10^{3}\ M^{-1}$ (229). The related tricyclic desipramine exhibited a more complicated binding mechanism, perhaps involving a drug-induced conformational change. From a study of nortriptyline binding in seven identical and 10 fraternal sets of twins, Alexanderson and Borga (230) concluded that drug binding was influenced by environmental, that is, statistically significant differences in the binding ratio within monozygotic twin pairs, as well as genetic factors. They found no significant correlation between the bound to free nortriptyline ratio and the steady-state drug concentration.

Another study (231) showed that there was far less variation in plasma protein binding of imipramine among children (bound fraction 77–94.6%) (92) than among adults and that children bound substantially less of this drug. Adult-like binding values may be reached at about age 13, and the relatively high doses of imipramine administered at bedtime to children with behavior disorders may be unsound from a binding–pharmacokinetic standpoint.

In a study relating the plasma protein binding of chlorpromazine to the apparent volume of distribution and the rate constant of elimination, chlorpromazine plasma binding influenced tissue localization; a high degree of tissue localization occurred in the species in which plasma protein binding was low and vice versa (232). It was also shown that over 90% of chlorpromazine in human plasma was present in bound form (233). The binding was reversible, and very large amounts of chlorpromazine, 15 μg/ml of plasma or more, were required to saturate the plasma binding sites.

One study (234) found that the apparent binding constant for chlorpromazine was 1355 with human albumin and 1545 with a human α-globulin fraction; although each of these proteins demonstrated a large number of binding sites for the drug, the results indicated that a different plasma protein fraction may display a larger affinity. Mao and Noval (235) suggested that the serum protein binding of the phenothiazines might explain the low *in vivo* hemolytic activity found for these agents. Administration of large amounts of tricyclics over extended times showed that erythrocytes were protected from hemolysis due to the plasma protein binding of these agents.

Another study determined the groups or positions on the phenothiazines responsible for drug–albumin complexation (7). The whole phenothiazine nucleus takes part in the binding process; predominantly hydrophobic forces are involved, but ionic interactions must not be completely ignored. The binding parameters are included in Table VIII.

Chlorpromazine and imipramine were bound to three major blood components: erythrocyte membranes, albumin, and lipoproteins (236). The affinity displayed by lipoprotein for these drugs was as high as that of albumin. The binding of various tranquilizer–antidepressant drugs to human albumin was examined (237) (Table VIII). A drug displacement study of these drugs found that phenothiazines displace iminodibenzyl compounds but not vice versa, since the affinities of the phenothiazines for the albumin are greater than the affinities of the iminodibenzyl agents.

In a subsequent study (238), the binding of tricyclic compounds to human albumin was correlated with linear free energy models. The major force in the binding of these molecules was electronic, and only a minor contribution of hydrophobic forces was involved. To the contrary, a previous report (221) stated that the interaction of phenothiazine drugs with bovine serum albumin was of a predominantly hydrophobic nature. Another study (239) also showed that the binding of phenothiazines to bovine serum albumin was of a hydrophobic nature. Recently, excellent evidence was presented that hydrophobic forces are more responsible for the phenothiazine–albumin interaction than are charge transfer or electronic forces (240).

Dialysis of plasma from 14 patients receiving diazepam (0.1 mg/kg) showed that plasma bound 97.7% of this benzodiazepine (241). Similarly, in seven patients the plasma proteins bound 98% of the diazepam in the serum from a 10-mg im dose (242). Diazepam was among 11 benzodiazepine derivatives quantitatively studied for binding to bovine serum albumin (243). Diazepam had a binding constant of 8.23×10^{3} liters/mole with 5.56 binding sites on bovine albumin. Binding constants calculated for the 11 benzodiazepines demonstrated that their binding affinities for bovine albumin were smaller than for human

albumin. Furthermore, these agents have more than the characteristic one or two binding sites on bovine albumin than would be expected on human albumin.

Some benzodiazepines were shown to be competitors for the binding of L-tryptophan to human serum albumin (244). There was a single highly stereospecific site on human albumin which bound L-tryptophan and with which the benzodiazepines competed. Lucek and Coutinho (245) presented results showing that the protein binding of benzodiazepines increased with increases in the lipophilic character of substituents in the 1-, 2-, 3-, 4-, 7-, and 4′-positions. The electronic character of 1-, 3-, and 7-substituents also correlated with protein binding but to a lesser degree than the lipophilic parameter.

Amphetamine binding was studied *in vitro* in different species, including humans (246), and was less than 45% in all species in the drug concentration range of 2.5×10^{-7}–4×10^{-6} *M*. Drug diffusion to cerebrospinal and ocular fluids was not retarded by the binding. An *in vitro* investigation of bovine serum albumin and amphetamine and one of its derivatives (247) arrived at similar results (246). Amphetamines appeared to be bound primarily to the albumin fraction of plasma. However, Δ^1-tetrahydrocannabinol was 80–95% bound to lipoprotein fractions *in vitro,* and no binding to albumin could be demonstrated (248).

Steroids and Catecholamines—Most steroid hormones are bound to hormone-specific macromolecules such as various binding globulins. However, some literature reports have concerned steroid–albumin binding. The protein binding of 10 steroids was studied in women with benign breast disease, early breast cancer, and advanced breast cancer and was compared to the binding in normal women (249). The data showed that the percentage binding in the plasma varied considerably between steroids. However, for a given steroid, there was no significant difference in the mean amount of steroid bound among these groups of women.

An investigation of progesterone binding to different polymeric fractions of human serum albumin found similar parameters in the mono- and dimeric species; two independent sets of binding sites were determined (250). In the first class, there was one site with an affinity of 3.6×10^5 M^{-1}; in the second class, there were eight sites with an affinity of 6×10^3 M^{-1}. The trimeric and higher forms had significantly lower binding affinities. Clark and Bird (251) examined the binding of 5α-androstane-3α,17β-diol, an important biologically active metabolite of testosterone, to human plasma proteins. They found that 96.6% of the drug was bound in male plasma and that the albumin fraction contained the greatest amount of the steroid. Albumin bound more of this steroid than the parent testosterone, and the authors concluded that this result was due to a higher association constant for the metabolic dihydroxysteroid.

Estriol and some of its conjugates were studied for their binding to plasma proteins during pregnancy (252). These compounds were bound principally in the albumin fraction, and such binding was stated to play an important role in the transport, metabolism, and excretion of these steroidal agents. Although albumin has been reported to be the main binding protein for some steroid hormones and related molecules, other results suggest that the globulin fraction may be principally responsible (253, 254). Ryan and Gibbs (255) found that Ca^{2+} was bound to human serum albumin in direct competition with testosterone and that such ion binding was associated with inhibition of testosterone binding to hydrophobic albumin sites but not with inhibition to sites involving hydrogen bonding.

Recently, several studies were published concerning the binding of catecholamine hormones to plasma proteins. Two distinct plasma binding sites were found for epinephrine; the binding was highly specific, similar to that reported for steroids (256). The first site was present in small numbers and had a large binding constant (6.9×10^5 liters/mole). The second site was more plentiful and had a smaller binding affinity. The enthalpy associated with the epinephrine–plasma protein interaction was small, because the activation energies for association and dissociation were essentially equal.

Both epinephrine and norepinephrine binding to human serum albumin was studied, and a similar binding affinity of approximately 10^7 was observed (257). Other catechols were studied, and neither the nature of the alkyl side chain nor it presence affected the binding affinity. It was also determined that 50% of a physiologic concentration of norepinephrine circulates bound to plasma protein. In apparent contrast to these results, Zia *et al.* (258) reported that the most probable binding site on epinephrine, when bound to bovine albumin, was the alkyl side chain. A possible reason for such a conclusion was that the concentrations of epinephrine used were high. Therefore, Zia *et al.* (258) were examining nonspecific binding in contrast to Danon and Sapira (257). Another report (259) implicated the phenolic hydroxyl groups as well as the alkyl side chain of catecholamines as being responsible for the binding interaction. In a recent study (260), an excellent discussion of the binding observed (257–259) in human serum was given. Several serum macromolecules were implicated as being responsible for catecholamine binding, and such binding may be responsible for the stability of these agents in blood.

Miscellaneous—The interaction of the antimalarial agent pamaquine with bovine albumin was examined (261), and three pamaquine molecules were bound per molecule of protein; the primary binding affinity was very strong, 6.4×10^7. Because the drug was positively charged and the binding constant was large, the binding site on the protein probably involved negatively charged groups. The binding of dapsone, a drug important in the treatment of leprosy, and its principal metabolite, monoacetyldapsone, was studied *in vitro* and *in vivo* in patients known to be rapid acetylators of the drug and in patients metabolizing the agent normally (262). At therapeutic concentrations of dapsone, 70–80% was bound to plasma protein while 90–100% of the monoacetyldapsone was bound. No difference in binding was seen in the plasma of rapid and normal acetylators. The results suggested that protein binding of monoacetyldapsone may account for limited excretion of this compound in the urine and the long plasma half-lives of these agents.

The binding of the antiprotozoal agent metronidazole and four derivatives to plasma proteins was assessed (263). The nature of the alkyl side chain had a significant effect on binding; however, the lipophilicity of these agents was not correlated with plasma protein binding. The parent compound showed good lipophilic character, as did one of

the metabolites, yet these compounds were bound to very small extents (less than 5% over a wide concentration range). A metabolite with poor ability to partition exhibited extensive binding (65–70%), and the binding was principally related to the frontier electron density on the terminal portion of the alkyl side chain. Recently, a good correlation was observed between lipophilicity in a series of related drugs, measured by a reversed-phase thin-layer technique, and the drug binding constants (264). Seemingly, if hydrophobic forces are responsible for the binding interaction, good correlation between partition coefficient and protein binding should be observed. The binding of therapeutic levels of ornidazole and metronidazole to human plasma proteins was less than 15% (265), and this binding was not correlated with the lipophilicity of these agents.

The binding of dantrolene sodium to human serum albumin recently was reported (266). The binding constant, calculated over a wide range of drug concentrations by two different techniques, was 4×10^4–$4 \times 10^5\ M^{-1}$. Ionic as well as hydrophobic forces were responsible for the interaction. Dantrolene added to a cationic surfactant produced perturbations similar to the drug added to human albumin solutions. Albumin also was shown to be the plasma protein most responsible for the binding of prostaglandins (267, 268). The binding of prostaglandins A_2, E_2 (dinoprostone), and F_2 to human plasma was reported to be 88, 73, and 58%, respectively, over the 10–120-ng/ml concentration range (267). The apparent association constants were $1–4 \times 10^4$ liters/mole. Another report (268) also indicated that albumin was the plasma protein principally responsible for binding prostaglandin E_1 and that no E_1 interaction with blood cells or γ-globulin occurred.

Conclusions—The binding of drugs by plasma proteins in general and isolated specific proteins, such as serum albumin and various lipoproteins and globulins, has continued to interest many researchers. Binding parameters (n's and K's), percentages bound, and possible displacement effects may be the clinically important contributions of this research and may be beneficial to dosage adjustment and prediction of the duration of drug action. From a physical standpoint, drug–protein interactions are studied to gain information about denaturation or unfolding of the protein, to determine cooperative interactions and mechanisms, to examine saturation and the total number of binding sites on the protein, and to examine molecular phenomena such as the active site, molecular conformation, or molecular distance involved in the drug–protein complex.

The vast majority of articles reviewed here were *in vitro* investigations and provided quantitative binding data. However, much of the work was of a more qualitative nature, since data were presented in terms of percent binding without specification of the drug concentration to which the binding data pertain; at times, drug concentrations were higher than therapeutic or toxic concentrations expected in the *in vivo* situation. Often plasma was considered by itself as the binding biomacromolecule without an attempt to define the primary protein component responsible for the binding interaction. Seldom were *in vitro–in vivo* correlations of binding attempted. Many results failed to furnish the reader with the temperature of the binding study, and it is well known that less binding is found at 37° than at ambient temperatures. Much of the binding literature could serve as a useful source of information to the clinician, pharmacokineticist, and other interested pharmaceutical researchers if the data presentation, data reduction, and use of multiple methods to support conclusions could be uniformly imposed on new articles pertaining to drug binding results.

Considerable research attention in the area of drug–protein binding could be directed at one or more of the following points, as well as inclusion of the calculated binding parameters: tissue binding, complexation of drugs by red cells and blood vessels, binding effects on pharmacokinetic models and parameters, protein active sites, and other molecular events associated with binding phenomena, displacement interactions, especially in the *in vivo* situation, and binding changes that may alter the course or effects of therapy associated with specific disease states. It is quite evident that strongly bound drugs influence drug effects and drug dynamics, and new drugs ought to be assessed as to whether or not they fit in the category of strongly bound agents.

ACKNOWLEDGMENTS AND ADDRESSES

Received from the *Department of Pharmaceutics, School of Pharmacy, University of Georgia, Athens, GA 30602.*

The author expresses appreciation to Dr. L. C. Schramm for discussions during the preparation of this review and to Ms. K. Minter and Ms. J. Lemmon for help with manuscript preparation.

Fenbufen, a New Anti-Inflammatory Analgesic: Synthesis and Structure–Activity Relationships of Analogs

RALPH G. CHILD ˣ, ARNOLD C. OSTERBERG, ADOLPH E. SLOBODA, and ANDREW S. TOMCUFCIK

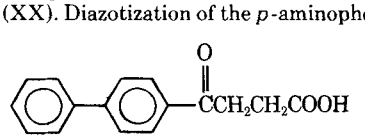
Abstract □ One hundred analogs of fenbufen were prepared and tested using the carrageenan, polyarthritis, and UV erythema anti-inflammatory tests and the 2-phenyl-1,4-benzoquinone writhing and inflamed paw pressure analgesic tests. Only three retained the same full spectrum of activity as fenbufen: *dl*-4-(4-biphenylyl)-4-hydroxybutyric acid, *dl*-4-(4-biphenylyl)-1,4-butanediol, and 4-biphenylacetic acid. Fenbufen had the same spectrum of activity as aspirin, phenylbutazone, and indomethacin in the five tests. In addition, dose–response derived potencies show fenbufen more potent than aspirin and at least as potent as phenylbutazone in all five tests. Two related compounds were generally similar.

Keyphrases □ Fenbufen—and various analogs, synthesized and evaluated for anti-inflammatory and analgesic activity □ Anti-inflammatory activity—evaluated in fenbufen and various analogs □ Analgesic activity—evaluated in fenbufen and various analogs □ Structure–activity relationships—fenbufen and various analogs, evaluated for anti-inflammatory and analgesic activity

While designing and synthesizing compounds for an immunosuppressive program, fenbufen (I) (1) was prepared as an intermediate potentially capable of imparting anti-inflammatory activity. Although fenbufen was uninteresting as an immunosuppressive, its activity in the ancillary anti-inflammatory tests (2) and its recognition as belonging to the well-known arylaliphatic carboxylic ("arylalkanoic") acid class of anti-inflammatory analgesics (3–5) prompted its full testing in this area. The biological testing program supporting this effort included the carrageenan-induced edema of the rat paw (6) and the guinea pig erythema (7) as anti-inflammatory tests, the polyarthritis test in rats as a model of chronic inflammation (8, 9), and the 2-phenyl-1,4-benzoquinone writhing (10) and paw pressure threshold (11) tests for analgesic action. When the preliminary screening data on I indicated activity in all five tests, a program was initiated to explore the structure–activity relationships of a series of analogs.

DISCUSSION

Chemistry—Most of the synthesized compounds were prepared by the Friedel–Crafts condensation of succinic anhydride with various aromatic compounds catalyzed by aluminum chloride. The reaction was described previously (12), and no unexpected difficulties were encountered. Twelve compounds were prepared by modification of preformed aryl keto acids. Thus, the benzylphenyl analog (VIII) was oxidized with chromic acid to the benzoylphenyl analog (XVI); similarly, the fluorene ring (III) gave the oxofluorene analog (XXV). Oxidation of the thioether (XIX) with peroxide gave the sulfoxide (XXI), whereas chromic oxide gave the sulfone (XX). Diazotization of the *p*-aminophenyl analog (13) followed by coupling to 2,6-diaminopyridine gave the azo compound (XXVII), which was oxidatively cyclized to the triazolo analog (XXVIII). The same *p*-aminophenyl analog reacted with *p*-chlorobenzoyl chloride to give the benzamido derivative (X). Table I summarizes the physical and pharmacological properties of the 3-(4-arylcarbonyl)propionic acids synthesized.



I

In the miscellaneous group (Table II) of compounds not previously described, sodium borohydride reduction of 4-phenoxybenzoylpropionic acid (V) gave the 4-hydroxybutyric acid analog (XXXIII) and bromination of 4-benzylbenzoylpropionic acid (VIII) gave the 3-bromopropionic acid analog (XXXIV).

The compounds listed in Table III consist of variations in the alkyl chain with the biphenyl moiety kept constant. The procedures used to modify the acid function of I or to replace it with various terminal substituents included esterification of I with ethanol and sulfuric acid to give the ester (XXXVIII) (Scheme I, R_1 = biphenylyl). The 4-hydroxy acid hydrazide (LXXII) came from the lactone (LX) (Scheme I) and hydrazine; the three polyols (XCI, C, and CI) were produced by reduction of the keto ester (XXXVIII), the diketone (XCVII), and the diketo ester (XCVI), respectively, with sodium bis(2-methoxyethoxy)aluminum hydride[1]. The chloro derivative (XLIV), obtained by Friedel–Crafts reaction of 3-chloropropionyl chloride and biphenyl, served as the intermediate for a number of products: the sodium sulfonate (L) *via* the acrylophenone (XLIII), the thioimidazoline (LI) from the corresponding imidazoline-2-thione, the nitrile (LII), and the *p*-tolylsulfinate (LIV).

The three amides (LXV, LXVI, and LXVII) were readily prepared directly from I and the corresponding amine at room temperature with the aid of the peptide-forming reagent, 1-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline[1] (CIII), in tetrahydrofuran (Scheme I, R_1 = biphenylyl). The procedure is simple, the by-products are volatile, and the yields are good.

Modifications to the carbonyl included the enol lactone (XXXIX) from I in boiling acetic anhydride (Scheme I, R_1 = biphenylyl). Reduction of I with excess sodium borohydride gave the *dl*-4-hydroxy analog (LV) (Scheme I). Resolution into the *d*- and *l*-isomers (LVI and LVII) was accomplished using the *d*- and *l*-isomers, respectively, of 2-aminobutanol. The *dl*-4-hydroxy acid (LV) cyclized readily in acid media to the lactone (LX) (Scheme I).

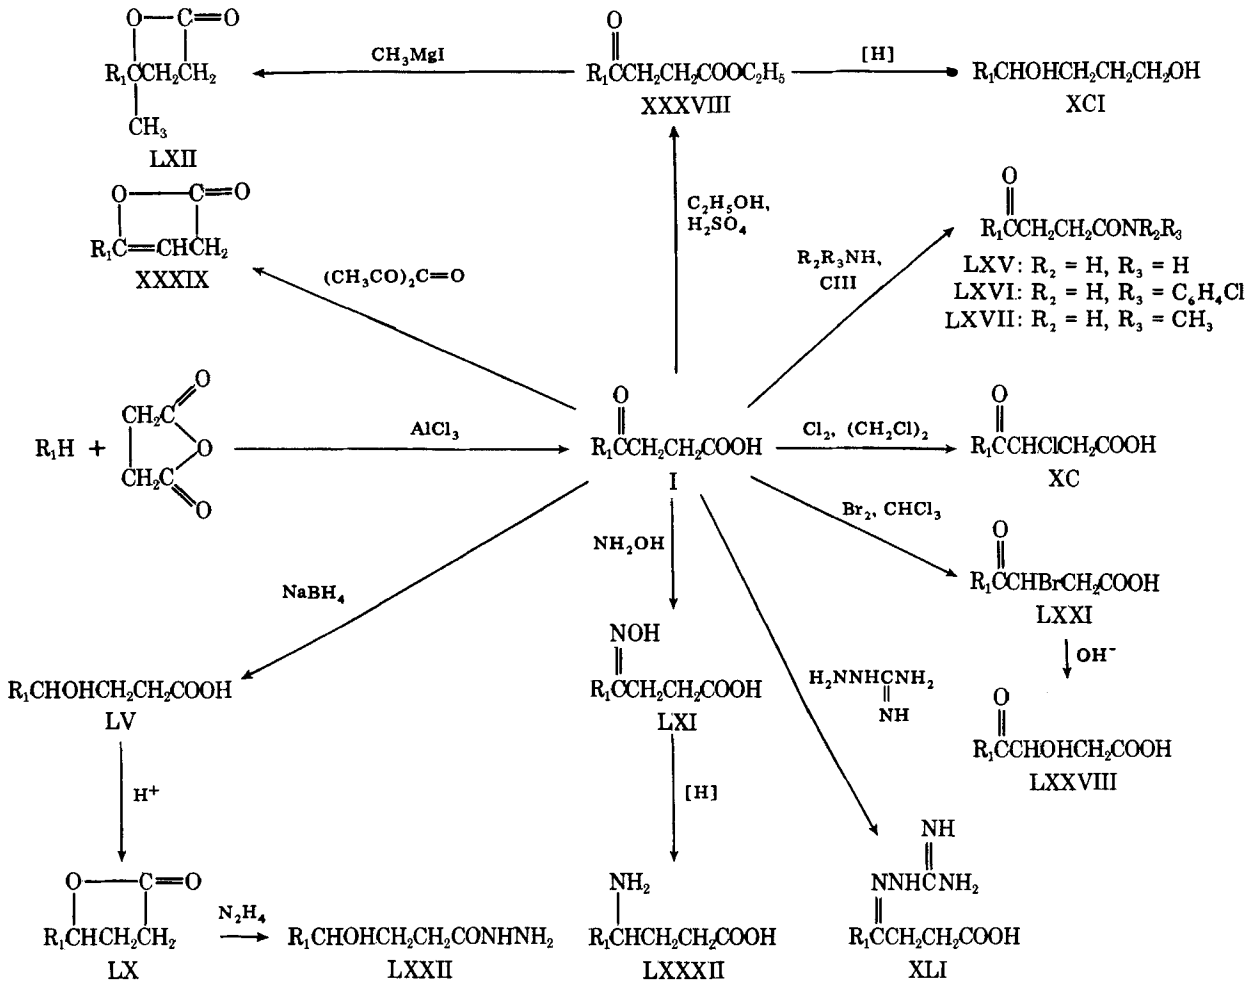
The keto group of I reacted with aminoguanidine to give the corresponding guanylhydrazone (XLI) and with hydroxylamine to give the oxime (LXI) (Scheme I, R_1 = biphenylyl). Reduction of the oxime with zinc and ammonium hydroxide afforded the 4-amino derivative (LXXXII). Methyl magnesium iodide added to the 4-carbonyl of the ester (XXXVIII), which subsequently lactonized by loss of ethanol to the lactone (LXII) (Scheme I). Dilute alkali opened the lactone to the corresponding 4-hydroxyvaleric acid analog (LXIII).

The Wittig reaction was employed in two instances to prepare biphenylbutenoic acids with the unsaturation conjugated to the biphenyl group. Thus, 4-acetylbiphenyl and the Wittig reagent, 2-carboxyethyltriphenylphosphonium chloride, yielded 4-(4-biphenylyl)-3-pentenoic acid (LXX). Similarly, 4-biphenylcarboxaldehyde yielded the 3-butenoic acid (XCIV).

The preparation of the sulfonyl (in place of carbonyl) analog of I required the preparation of 4-phenylthiophenol from diazotized 4-aminobiphenyl followed by condensation with 3-bromopropionic acid to give the thioether. This thioether was then oxidized *in situ* with peroxide to give the desired 3-(4-biphenylsulfonyl)propionic acid (LXXV).

The α,β-unsaturated chain analog of I was prepared directly from bi-

[1] Aldrich Chemical Co.

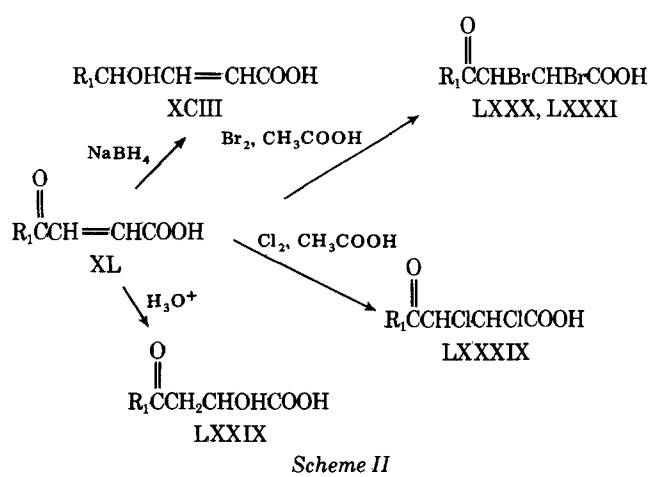


Scheme I

phenyl and maleic anhydride *via* the Friedel–Crafts reaction, giving 3-(4-biphenylylcarbonyl)acrylic acid (XL). On reduction with sodium borohydride, XL gave the unsaturated alcohol derivative (XCIII) (Scheme II, R_1 = biphenylyl).

The α,β-unsaturated analog (XL) was used to prepare a series of products by addition to the double bond. Thus, bromination in acetic acid gave one racemate isomer of the 2,3-dibromo analog (LXXX); bromination in chloroform gave the other 2,3-dibromo racemate (LXXXI) (Scheme II, R_1 = biphenylyl). Chlorination in acetic acid gave a 2,3-dichloro derivative (LXXXIX). Refluxing XL in dilute hydrochloric acid gave the 2-hydroxy analog (LXXIX) (Scheme II).

Bromination of I in ethanol-free chloroform gave the 3-bromo analog (LXXI) (Scheme I, R_1 = biphenylyl), which when stirred in dilute sodium carbonate solution, hydrolyzed to the 3-hydroxy derivative (LXXVIII). Similarly, chlorination of I in dichloroethane gave the 3-chloro analog (XC) (Scheme I).



Scheme II

Only the 2-methyl analog (XLVIII) was isolated from the Friedel–Crafts reaction of biphenyl and methylsuccinic anhydride. The 2-phenyl congener (XLIX) was prepared by hydrochloric acid hydrolysis in acetic acid of the corresponding nitrile (XLVII) which, in turn, was obtained by addition of hydrocyanic acid to 4′-phenylchalcone.

The Friedel–Crafts reaction of biphenyl and glutaric anhydride gave far lower yields than with succinic anhydride. Nevertheless, 4-(4-phenylbenzoyl)butyric acid (LXIX) was obtained in sufficient quantity and also brominated to the 4-bromo derivative (LXXVI). Finally, 4-biphenylcarboxaldehyde condensed smoothly with cyanoacetic acid in base to give good yields of 3-(4-biphenylyl)-2-cyanoacrylic acid (LXXXVIII).

Biological Activity—All compounds were tested in the carrageenan anti-inflammatory and 2-phenyl-1,4-benzoquinone writhing analgesic tests. The decision to use the remaining three tests was dictated by the activity in the two basic tests and the availability of sufficient quantities of the compounds. These initial screening data were not designed to provide a comparison between compounds in any one test. The spectrum of activity over the range of all five tests using a standard large dose (250 mg/kg) provided a rapid initial evalution of a fairly large series of compounds, enabling selection of compounds for further study.

Table I lists the modifications to the biphenyl moiety or its replacement by other bulky groups and shows that all changes generally resulted in a reduced spectrum of activity. For example, substitution in the 4-position of the terminal phenyl group by chloro (II), methoxy (XI), phenyl (XVII), or fluoro (XXIX) groups decreased the carrageenan anti-inflammatory activity overall, and, where tested, there was a similar decrease in polyarthritis, UV erythema, and analgesic activity. In the single instance of a substituent on the ring adjacent to the alkyl chain, the 2-methoxy-5-phenyl analog (XII), there was complete loss of activity.

Separation of the two phenyl groups by oxygen, as in V, depressed

[a] Reference 26. [b] NA = not active. [c] See *Experimental*. [d] Mass spectrum showed a mass ion of 346 and a 195, 4-$(C_6H_5CH_2)C_6H_4CO$, indicative of bromination in the propionic acid chain. [e] Reference 27. [f] Triethylene glycol. [g] Precipitated from alkaline solution by addition of hydrochloric acid.

activity in all five tests; the addition of a dibenzofuran group (IV) reduced activity further.

Separation by sulfur (XIX) showed about the same order of reduction of activity as the oxygen analog (V). Oxidation of the sulfur in XIX to sulfoxide (XXI) and sulfone (XX) destroyed activity completely. In contrast, where the phenyl groups were separated by a methylene (VIII), oxidation to a carbonyl (XVI) caused a slight increase in the low order of activity. Again, addition of a fluorene (III) or 9-oxofluorene (XXV) reduced activity further.

Separation of the two phenyl groups by an ethylene (XXIII) resulted in total loss of activity. Similarly, separation by a carboxamide group (X) gave much lower activity when compared to the analogous II. With phenyl as a separating group in the terphenyl analog (XVII), activity was totally eliminated.

Replacement of the terminal phenyl group by various substituents such as butoxy (XV), morpholino (XXII), 3-phenoxyphenoxy (XXVI), diaminopyridylazo (XXVII), its cyclized triazolopyridyl (XXVIII), and cyclohexyl (XXX) likewise eliminated all activity.

None of the other various bulky aromatic groups such as VI, VII, IX, XIII, XIV, and XVIII showed any activity. The one case of a bis(carboxypropionic acid)-substituted diphenyl ether (XXIV) similarly was inactive.

With the miscellaneous compounds of Table II, reduction of the carbonyl of V to a carbinol (XXXIII) made no significant change, nor did the complete reduction of the carbonyl of XIX to a methylene (XXXV). Similarly, bromination of the chain in the 3-position of VIII giving XXXIV made no change in the activity spectrum.

Among the numerous changes to the alkyl chain moiety of I listed in Table III, only three retained the full spectrum of activity: the racemic 4-hydroxy analog (LV), the racemic 1,4-diol (XCI), and the acetic acid analog (CII). Although the full spectrum of tests was not carried out on the *d*-LVI and *l*-LVII isomers of LV, it appears that they were comparable.

Halogenation in the 3-position of I, *e.g.*, the 3-bromo product (LXXI), or its ester (LXIV) and the 3-chloro product (XC), retained the anti-inflammatory activity but reduced the analgesic activity. The 2,3-dichloro derivative (LXXXIX), as well as both racemates of the 2,3-dibromo analog (LXXX and LXXXI), showed minimal activity in both the anti-inflammatory and analgesic tests.

The effect of modifying the carboxylic acid group of I was dramatic and surprising in that only the 4-hydroxy acid hydrazide (LXXII) and the 1,4-diol (XCI) of 13 congeners retained anti-inflammatory activity. Unexpectedly, the ethyl ester (XXXVIII) and the three amides (LXV, LXVI, and LXVII) were devoid of carrageenan activity. Other substitutions for the carboxylic acid function that were inactive were the chloro (XLIV), the sodium sulfonate (L), the thioimidazole (LI), the nitrile (LII), the *p*-toluenesulfonate (LIV), the acetyl (XCVII), and the hydroxyethyl (C).

Modifications of the 4-carbonyl function of I, other than its reduction to a carbinol (LV), produced less active compounds. Thus, complete reduction to the methylene (XXXVI) eliminated the polyarthritis and paw pressure activity. The lactone (LX) of the 4-hydroxy acid (LV) showed only UV erythema and writhing activity, whereas the enol lactone (XXXIX) showed no activity. The oxime (LXI) and the 4-amino derivative (LXXXII) were completely inactive, yet the guanyl hydrazone ester (XLI) showed carrageenan activity. Reductive alkylation of the carbonyl to the 4-methyl-4-hydroxy analog (LXIII) and its lactone (LXII) also reduced overall activity. Replacement of the carbonyl by sulfonyl (LXXV) or oxygen (LXXIV) likewise reduced activity.

Unsaturation along the butyric acid chain at the 2,3-position as in XL or its ester (LXVIII) and XCIII eliminated anti-inflammatory activity, leaving minimal analgesic activity. However, unsaturation at the 3,4-position (XCIV) retained, except for the paw pain, a full spectrum of activity. Similarly, the 4-methyl 3,4-unsaturated analog (LXX) retained carrageenan activity but lost analgesic activity.

Aryl substitution as in the 2-phenyl (XLIX) and 3-phenyl (LXXVII) derivatives destroyed all activity. Alkyl substitution as in the 2-methyl (XLVIII) derivative retained only writhing activity.

Lengthening the alkyl chain as in the valeric acid 5-oxo analog (LXIX) reduced anti-inflammatory activity and eliminated analgesic activity. The 4-bromo derivative (LXXVI) was completely inactive.

Both the 2- and 3-hydroxy-substituted analogs of I (LXXIX and LXXVIII, respectively) showed only carrageenan activity. The remaining miscellaneous substituted biphenyls of Table III were inactive.

Summary—The only modifications or analogs of I that, at best, did not reduce the spectrum of activity over the five tests were the reduction of the 4-carbonyl to a carbinol, giving *dl*-4-(4-biphenylyl)-4-hydroxy-

Table IV—Potency Relative to Aspirin

Compound	Anti-Inflammatory			Analgesic	
	Carrageenan Edema	Adjuvant Arthritis	UV Erythema	2-Phenyl-1,4-benzoquinone-Induced Writhing	Paw Pain Pressure Threshold
Aspirin	1	1	1	1	1
Phenylbutazone	4.1	4.5	5.5	0.8	10.0
Indomethacin	25.0	118.0	9.2	119.0	20.0
Fenbufen (I)	4.2	6.3	6.3	3.7	10.0
4-Biphenylacetic acid (CII)	4.2	11.9	22.0	2.9	—
dl-4-(4-Biphenylyl)-4-hydroxybutyric acid (LV)	10.0	4.8	4.9	—	—

butyric acid (LV); the reduction of the carboxylic acid function to a carbinol, giving *dl*-4-(4-biphenylyl)-1,4-butanediol (XCI); and the acetic acid analog (CII).

From these data, I, CII, and LV were selected for dose–response studies. Table IV gives their relative potencies compared to aspirin, as the standard, along with phenylbutazone and indomethacin for comparison. The detailed pharmacological examination of fenbufen is the subject of a recent paper[2]; however, the long duration of action of this compound was noteworthy. It can be seen that all three compounds were considerably more potent than aspirin and at least as potent as phenylbutazone in the five test systems. Moreover, CII was more potent than indomethacin in the UV erythema test.

EXPERIMENTAL

Biological Tests—The carrageenan edema test was a modification of the test of Winter *et al.* (6). Drugs were administered by gavage at a dose of 250 mg/kg, except when resultant mortality required lower doses. Foot volume measurements were made 5 hr after drug administration (4 hr after carrageenan challenge). Results were expressed as a control (C)/treated (T) efficacy ratio (the ratio of mean edema volume of eight control rats over the mean edema volume of two treated rats). Compounds found to have activity were retested, and the final decision concerning such drugs was based on 32 control rats and eight treated rats.

The adjuvant-induced arthritis test was based on the procedures of Newbould (8) as well as Ward and Cloud (9). Test compound was administered orally at a dose of 50 mg/kg (occasionally lower because of toxicity) once daily on Days 0–13 postchallenge. On the 14th day postchallenge, the diameter of the injected paw (primary lesion) was measured with a micrometer caliper. From these measurements of inflamed paws, a determination was made of the rat paw volume. Results are expressed as the percent inhibition of inflamed control paw volume (mean volume of three treated rats compared with paw volume of 12 controls). Decisions of interesting activity were based on a minimum of 36 controls and nine treated rats.

The UV-induced erythema test followed that of Winder *et al.* (7). Groups of four albino guinea pigs received by gavage a 250-mg/kg dose (occasionally lower because of toxicity) 1 hr prior to UV exposure (−1 hr). At +1 and +4 hr after UV exposure, the degree of erythema for each of the three sites was assessed according to the following scoring system: 0, no erythema; 0.5, incomplete circle or faint erythema; and 1.0, complete circle of distinct erythema. In general, only compounds showing greater than 70% inhibition of erythema were considered of interest. The activity of compounds was confirmed with a second independent run; thus, the decision concerning activity was based on a minimum of 16 control guinea pigs and eight treated guinea pigs.

The 2-phenyl-1,4-benzoquinone test for analgesic activity was a modification of that described by Hindershot and Forsaith (10). The test compounds were administered orally at a dosage of 200 mg/kg to groups of two mice each 30 min before injection of 2-phenyl-1,4-benzoquinone. A compound was considered active if it reduced the total number of writhes in two test mice from a control value of approximately 30 per pair to 18 or less during a 3-min observation.

The inflamed paw pressure analgesic test was based on a modification of the method of Randall and Selitto (11). Pressure-pain thresholds were recorded 2 hr after the brewer's yeast injection. The agents being tested were given at the same time as the yeast at a dosage of 200 mg/kg. The ratios of treated (T)/control (C) reaction threshold were calculated as estimates of analgesic efficacy. A compound was considered an active analgesic if its T/C ratio was >1.5.

All results indicating activity were statistically significant ($p < 0.05$) by the t test.

Chemistry—Each analytical sample had an IR (potassium bromide) spectrum compatible with its assigned structure. Where deemed necessary, IR, mass, UV, and NMR spectral data are given. The melting points[3] of known compounds agreed with reported values within narrow limits.

General Method A: Friedel–Crafts Condensation of Succinic Anhydride and Aromatic Compounds—With the solvent listed in Table I in sufficient quantity to dissolve or suspend 0.2 mole of the aromatic compound and 0.21 mole of succinic anhydride at 0°, 0.42 mole of aluminum chloride was added portionwise with stirring. The reaction was allowed to warm to room temperature. It was stirred a few hours and then poured into 1 liter of ice water containing 125 ml of 12.2 *N* HCl. The solvents were removed by vacuum or steam distillation, and the residue was recrystallized from the solvent listed in Table I.

3-(4-Benzoylbenzoyl)propionic Acid (XVI)—A solution of 5.36 g (0.02 mole) of VIII in 150 ml of acetic acid and 1.9 ml of concentrated sulfuric acid was heated with 10.14 g (0.34 mole) of sodium dichromate and stirred at 40–60° for 4 hr. After standing at 20° for 2.5 days, the mixture was filtered. The filtrate was diluted with 1 liter of water, giving a crude product. This product was filtered, washed with water, and dried. Recrystallization gave 2.6 g of faintly green crystals. The mass spectrum showed *m/e* 282 and a strong 209 for 4-$(C_6H_5CO)C_6H_4CO$.

3-[4-(5-Amino-2H-triazolo[4,5-b]pyridin-2-yl)benzoyl]propionic Acid (XXVIII)—Eleven grams (0.035 mole) of XXVII was dissolved in 750 ml of refluxing pyridine. A solution of 32 g (0.2 mole) of copper sulfate in 250 ml of water was then added carefully (exotherm!). After the addition, refluxing was continued for a further 3 hr. Spot tests indicated complete conversion of the azo dye in about 30 min. The hot solution was added to 6 liters of water, and the suspension was treated with 12.2 *N* HCl until a clear solution was obtained. Solid sodium acetate was then added until the pH reached 4–5.

After cooling at 4° overnight, the precipitate was collected and extracted with 200 ml of boiling 12.2 *N* HCl. The insoluble portion was filtered off hot, washed with ethanol and ether, and dried. It was dissolved in 25 ml of hot water and 15 ml of concentrated ammonia, clarified with charcoal, and precipitated with 15 ml of acetic acid, giving 1.8 g of a bright-yellow product.

3-(4-Biphenylyl)-4,5-dihydro-6(1H)-pyridazinone (XXXVII)—A solution of 12.6 g (0.05 mole) of I in 300 ml of water containing 3.2 g (0.05 mole) of 85% KOH was treated with 2.5 ml of hydrazine hydrate (0.05 mole), and the mixture was stirred and heated on the steam bath for 4 hr. Acidification with 10 ml of acetic acid gave a precipitate, which was collected, washed with water, and dried. Recrystallization gave 4.1 g of pure product.

2,2′-[4-Biphenylylmethylene]bis(1,3-indandione) (XLV)—A mixture of 7.3 g (0.05 mole) of 1,3-indandione and 9.1 g (0.05 mole) of *p*-biphenylcarboxaldehyde in 125 ml of ethanol was refluxed for 3 hr and cooled. The formed solid was filtered off, washed well with ethanol, and dried, leaving 11 g of a pale-yellow solid. Recrystallization gave colorless crystals.

2-(4-Phenylbenzylidene)-1,3-indandione (XLVI)—A mixture of 4.4 g (0.03 mole) of 1,3-indandione and 5.5 g (0.03 mole) of *p*-biphenylcarboxaldehyde in 100 ml of acetic acid and 3 drops of concentrated sulfuric acid was heated on a steam bath for 2.5 hr and cooled. The formed bright-yellow plates were filtered and washed with acetic acid, water, and ethanol, yielding 5.0 g.

γ-Oxo-α-phenyl-4-biphenylbutyronitrile (XLVII)—A solution of 14.2 g (0.05 mole) of 4′-phenylchalcone, 700 ml of ethanol, 150 ml of di-

[2] See A. Sloboda and A. Osterberg, *Inflammation*, 1, 415 (1976).

[3] Melting points were taken on a Fisher-Johns block and are uncorrected.

methylformamide, and 3 ml of acetic acid at 55–60° was treated with 6.5 g (0.1 mole) of potassium cyanide in 25 ml of water during 15 min. The solution was stirred at 55–60° for an additional 5 hr and then at 20° for 2 days. The precipitate was collected, washed with water, dried, and recrystallized, giving 9.5 g of product. Concentration of the mother liquor to half-volume and cooling gave an additional 2.6 g with the same melting point. The total yield was 12.1 g.

1,4-Bis(4-biphenylyl)butane-1,4-dione (LIII)—An intimate mixture of 15.4 g (0.1 mole) of biphenyl and 11.4 g (0.1 mole) of glutaric anhydride was added portionwise to a cold (5°) solution of 28 g (0.21 mole) of aluminum chloride in 175 ml of nitrobenzene. The mixture was allowed to warm to 20° and was stirred for 4 days. After working up in the usual way, the crude product was precipitated from sodium carbonate solution with hydrochloric acid. After recrystallizing from acetic acid and benzene, 1.2 g of straw-yellow rods was obtained.

d-*4-(4-Biphenylyl)-4-hydroxybutyric Acid (LVI)*—A solution of 2.56 g (0.1 mole) of LV in 50 ml of warm ethanol was filtered, treated with 0.9 g (0.01 mole) of *d*-2-aminobutanol[1], and cooled. After 2 days at 5°, 1 g of colorless crystals was filtered off, mp 144–146°. Concentration of the mother liquor to half-volume gave a second crop (0.2 g, mp 144–148°). Two recrystallizations of the combined crops from ethanol gave 0.5 g (mp 152–153°) of the salt. Acidification of the salt in 50 ml of water with 5 *N* HCl to pH 2 gave a white precipitate. This precipitate was filtered, washed well with water, and dried, yielding the optically pure hydroxy acid, 0.2 g, $[\alpha]_D^{25}$ + 14.1 ± 0.18° (ethanol). The IR curve was identical to that of the racemic acid (LV).

l-*4-(4-Biphenylyl)-4-hydroxybutyric Acid (LVII)*—In the same manner as described for the previous resolution, *l*-2-aminobutanol[1] was used to separate the stereoisomeric salt (mp 150–152°) and yielded the optically pure hydroxy acid, $[\alpha]_D^{25}$ −14.1 ± 0.2° (ethanol). The IR curve was identical to that of the racemic acid (LV).

4-(4-Biphenylylthioacetyl)morpholine (LVIII)—A mixture of 29.4 g (0.15 mole) of 4′-phenylacetophenone, 8 g (0.25 mole) of sulfur, and 50 ml of morpholine was refluxed on steam for 8 hr and cooled. The reaction mass was triturated with 100 ml of ether; the insolubles were collected, washed with 100 ml of petroleum ether (bp 30–60°), and dried. Recrystallization gave 16.4 g.

4-[1-(4-Biphenylyl)-2-(methylthio)ethylidene]morpholinium Iodide (LIX)—A solution of 25.5 g (0.09 mole) of LVIII in 600 ml of acetone and 15 ml of methyl iodide was allowed to stand at 20° for 3 days. The crystalline precipitate was collected, washed with ether, and dried, giving 34.0 g.

4-(4-Biphenylyl)-4-valerolactone (LXII)—Grignard reagent, made in the usual way from 10 g (0.07 mole) of methyl iodide and 1.71 g (0.07 mole) of magnesium in ether, was added dropwise to a cold (5°) suspension of 14.1 g (0.05 mole) of the ester (XXXVIII) in 500 ml of ether (Scheme I, R_1 = biphenylyl). After stirring at 5° for 1.5 hr, the complex was decomposed with 15 ml of saturated ammonium chloride solution, allowed to warm to 20°, filtered, dried over calcium chloride, and concentrated to dryness. The residue was crystallized, yielding 10 g of lactone; IR (KBr): 5.65 μm.

Ethyl 3-Bromo-3-(4-phenylbenzoyl)propionate (LXIV)—A solution of 2.54 g (0.01 mole) of I in 300 ml of commercial grade chloroform containing ethanol was treated dropwise with 1.6 g (0.01 mole) of bromine in 25 ml of chloroform over 0.5 hr. The mixture was then refluxed for 4 hr and stripped to dryness. The residual oil was crystallized once from ether–hexane and finally from methanol, yielding 2.3 g; mass spectrum: *m/e* 360.

3-(4-Phenylbenzoyl)propionamide (LXV)—A saturated solution of ammonia in 75 ml of tetrahydrofuran was treated with 2.54 g (0.01 mole) of I (Scheme I). The resulting suspension of ammonium salt was treated with 2.96 g (0.012 mole) of CIII and stirred overnight at 20°. The mixture was stripped to dryness, and the residue was recrystallized, giving 1.2 g of colorless flakes.

Ethyl 3-(4-Phenylbenzoyl)acrylate (LXVIII)—A warm mixture of 2.7 g (0.045 mole) of acetic acid and 2.77 g (0.028 mole) of triethylamine in 100 ml of acetone was treated all at once with 1.805 g (0.005 mole) of LXIV and stirred for 2 hr. After cooling and filtering, the acetone solution was poured into two volumes of water. The formed solid was filtered, washed with water, dried, and recrystallized, yielding 0.8 g.

4-(4-Phenylbenzoyl)butyric Acid (LXIX)—Glutaric anhydride (12 g, 0.11 mole) was condensed with biphenyl (15.4 g, 0.1 mole) in tetrachloroethane by addition of aluminum chloride according to Carter *et al.* (36); 0.8 g of a yellow material was obtained.

4-(4-Biphenylyl)-3-pentenoic Acid (LXX)—By using the general procedure described by Corey *et al.* (37), 4-acetylbiphenyl (14.72 g, 0.075 mole) was condensed with the Wittig reagent, (2-carboxyethyl)triphenylphosphonium chloride, in the presence of sodium hydride. A pale-yellow solid (1 g) was obtained; UV λ_{max} (ethanol): 276 nm, consistent with an unsaturated alkyl conjugated with biphenyl.

3-(4-Biphenylylsulfonyl)propionic Acid (LXXV)—A solution of 7.2 g (0.04 mole) of crude 4-phenylthiophenol (38) in a mixture of 100 ml of water, 50 ml of ethanol, and 4.5 ml of 10 *N* NaOH was treated with a mixture of 6.3 g (0.04 mole) of 3-bromopropionic acid, 100 ml of water, and 4.5 g (0.04 mole) of sodium bicarbonate. The mixture was heated and stirred on the steam bath for 4 hr and then clarified. The filtrate was successively acidified (concentrated hydrochloric acid) and basified (concentrated ammonium hydroxide).

The insolubles in ammonia solution were removed by filtration, and the filtrate was reacidified with concentrated hydrochloric acid. The acid mixture was extracted with 250 ml of chloroform. Removal of the chloroform left 1.0 g of oily residue, which was taken up in acetic acid. Addition of 4 ml of 30% H_2O_2 and heating on steam for 5 hr, followed by dilution with 450 ml of cold water, produced a precipitate. This precipitate was collected, dried, and recrystallized, yielding 200 mg.

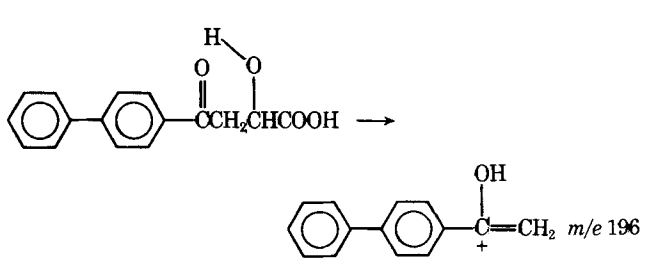
3-(4-Phenylbenzoyl)-3-phenylpropionic Acid (LXXVII)—A suspension of 13.6 g (0.05 mole) of benzyl biphenyl ketone (39) in 500 ml of absolute ethanol was treated with 1.2 g (0.05 mole) of sodium hydride followed by 8.35 g (0.05 mole) of ethyl bromoacetate. After refluxing for 20 min, the mixture was treated with 5 g of potassium hydroxide in 25 ml of water, refluxed for 2 hr more, and then poured into 1 liter of water. After filtering, acidification of the filtrate with concentrated hydrochloric acid gave a crude product. This product, when crystallized from acetic acid once and finally from benzene–hexane, gave 1 g of a colorless product.

3-Hydroxy-3-(4-phenylbenzoyl)propionic Acid (LXXVIII)—A mixture of 5 g (0.015 mole) of LXXI in 500 ml of 10% Na_2CO_3 was stirred at room temperature for 16 hr (33) (Scheme I). The formed peach-colored sodium salt was removed, suspended in water, and acidified with acetic acid, giving 3.2 g of colorless product; mass spectrum: *m/e* 270; $C_6H_5C_6H_4C{\equiv}O^+$, 181; and $C_6H_5C_6H_4^+$, 153.

2-Hydroxy-3-(4-phenylbenzoyl)propionic Acid (LXXIX)—A mixture of 5.7 g (0.023 mole) of XL and 100 ml of concentrated hydrochloric acid in 400 ml of water was refluxed for 20 hr and filtered hot, yielding 5.6 g of unreacted XL (Scheme II). On cooling, the filtrate yielded 0.2 g of a product whose IR curve indicated it to be a hydroxy keto acid. Boiling the unreacted material three times with large volumes of 1:4 diluted hydrochloric acid gave an accumulation of 5 g of crude product, mp 160–165°. Recrystallization gave 4.3 g of colorless product. A mixed melting point of this product with the 3-hydroxy analog (LXXVIII) was 150–155°; mass spectrum: *m/e* 270; $C_6H_5C_6H_4C{\equiv}O^+$, 181; $C_6H_5C_6H_4^+$, 153; and a 196 which results from a McLafferty rearrangement (40) of a β-hydroxy ketone (Scheme III). The α-hydroxy ketone (LXXVIII) described previously cannot undergo this fragmentation and does not show an *m/e* 196.

2,3-Dibromo-3-(4-phenylbenzoyl)propionic Acid (LXXX): Racemic Mixture A—In a manner similar to that described by Rice (41), 7.5 g (0.03 mole) of XL in 400 ml of acetic acid at 15° was treated dropwise with 4.8 g (0.03 mole) of bromine (Scheme II). The solution was then concentrated to dryness, and the residue was washed with water and dried. Recrystallization yielded 4.1 g of colorless grains.

4-Amino-4-biphenylbutyric Acid (LXXXII)—By using the general method of Tochims (42), 9.5 g (0.035 mole) of LXI was stirred into 500 ml of concentrated ammonium hydroxide, warmed, and held at 60–65° while 50 g of zinc dust was carefully added in small portions (Scheme I). After the addition, stirring at 60–65° was continued for 18 hr. The reaction mixture was clarified by filtration, and the filtrate was taken to dryness *in vacuo*. The residue was shaken with 500 ml of 0.1 *N* NaOH solution and clarified, and the filtrate was acidified with 10 ml of acetic acid. The semigelatinous precipitate was collected, washed with water, and dried. It was then extracted with 500 ml of boiling ethanol. The insoluble portion was recrystallized, giving 0.8 g of the amino acid. Con-



Scheme III

centration of the ethanol extract to 250 ml and cooling gave an additional 0.4 g; the total yield was 1.2 g.

2-(4-Phenylbenzoyl)cyclohexanone (*LXXXIII*)—4-Phenylbenzoyl chloride [formed from 19.8 g (0.1 mole) of 4-phenylbenzoic acid, benzene, and thionyl chloride under reflux for 1 hr] was dissolved in 250 ml of chloroform and added during 2 hr to a stirred mixture of 18.5 g (0.11 mole) of 1-morpholinocyclohexene, 18 ml (0.13 mole) of triethylamine, and 250 ml of chloroform at 30–35°. After stirring at 20° for 16 hr, 50 ml of water and 25 ml of concentrated hydrochloric acid were added; the mixture was then refluxed for 2 hr. The chloroform layer was separated, washed with water, dried over magnesium sulfate, and concentrated to dryness. The residual oil was dissolved in a hot mixture of 150 ml of benzene and 300 ml of *n*-heptane, decolorized with carbon, and cooled, yielding 3.6 g.

Maleic Acid Mono-4-biphenylyl Ester (*LXXXIV*)—A solution of 5.04 g (0.02 mole) of XL in 200 ml of acetic acid was treated with 12 ml of 30% H_2O_2 and heated at 60° for 24 hr. An additional 10 ml of hydrogen peroxide was added, and the reaction was stirred on steam overnight. Dilution of the clear yellow solution with 1.5 volumes of water gave a crude product. When this product was recrystallized, 1.0 g of colorless product was obtained. Hydrolysis of a sample of the product yielded 4-phenylphenol, mp 164–165°; mass spectrum: *m/e* 268; and $C_6H_5C_6H_4OH$, 170.

Ethyl 4-Phenylbenzoylmethylthioacetate (*LXXXV*)—A solution of 7.2 g (0.06 mole) of ethyl mercaptoacetate and 3.4 g (0.06 mole) of sodium methoxide in 500 ml of ethanol was treated with 13.8 g (0.05 mole) of 2-bromo-4′-phenylacetophenone. The mixture was stirred at 20° for 5 hr, refluxed for 4 hr, and then concentrated to a thick oil. Trituration with 250 ml of cold water left a solid, which was filtered, washed with water, and dried, yielding 19 g. Recrystallization gave 15 g of colorless crystals.

Ethyl 4-Phenylbenzoylmethylthioacetate Hydrazone (*LXXXVI*)—A solution of 7.0 g (0.022 mole) of LXXXV in 200 ml of boiling ethanol was treated with 1.1 ml (0.022 mole) of 100% $N_2H_4 \cdot H_2O$ and refluxed for 6 hr, clarified with carbon, filtered, and cooled, yielding 2 g of hydrazone.

3-(4-Phenylbenzoyl)-2,3-dichloropropionic Acid (*LXXXIX*)—A solution of 5 g (0.02 mole) of XL in 300 ml of acetic acid at 20° was treated with a steady stream of chlorine for 3 hr (Scheme II). The yellow solution was concentrated to dryness, and the residue was washed with water and dried. Two recrystallizations gave 1.8 g of colorless crystals.

3-Morpholino-4′-phenylacrylophenone (*XCII*)—A solution of 4.1 g (0.01 mole) of LXXX in 500 ml of boiling benzene was treated with 6 ml (0.07 mole) of morpholine. Extensive carbon dioxide evolution was detected by bubbling the evolved gas through barium hydroxide solution. After 8 hr of refluxing, the precipitate of morpholine salt was filtered off (3.2 g, 95%). The benzene filtrate was concentrated to 100 ml, diluted with 200 ml of petroleum ether (bp 30–60°), and cooled. The precipitate was collected and recrystallized, giving 1.5 g of product; IR (KBr): C=O, 6.08 (vinylogous amide); C=C, 6.5; *trans*-CH=CH, 10.1 μm; no COOH; mass spectrum: *m/e* 293.

3-Anilino-4′-phenylacrylophenone (*XCV*)—A mixture of 8.3 g (0.02 mole) of LXXX, 15 ml (0.16 mole) of aniline, and 500 ml of benzene was stirred under reflux for 16 hr. The precipitate of aniline salt was filtered from the hot suspension and washed with 100 ml of benzene. Concentration of the filtrate and wash to 150 ml and cooling to 20° gave a precipitate, which was washed with 100 ml of warm water and dried, giving 2.0 g.

1-(4-Biphenylyl)tetrazole (*XCVIII*)—A solution of 4.23 g (0.025 mole) of 4-aminobiphenyl in 180 ml of ethyl orthoformate was distilled slowly until the temperature reached 143° (3 hr). The remainder was evaporated to dryness, dissolved in 40 ml of acetic acid, treated with 6.5 g (0.1 mole) of sodium azide, and stirred at 20° for 24 hr. After addition of 100 ml of water, the solid was filtered off, washed with water, dried, and recrystallized (two times), giving pale-yellow crystals, 3.0 g.

Determination of Pentobarbital in Serum by Electron-Capture GLC

SY-RONG SUN [x] **and A. H. C. CHUN**

Abstract □ A GLC method was developed for pentobarbital in serum. After extraction from serum, a pentafluorobenzyl derivative was prepared and quantitated by electron-capture detection. The method has a sensitivity of 0.1 μg/ml of serum, and the amount detectable is less than 0.2 ng/injection. Hexethal was used as the internal standard. Derivatives of other barbiturates were also made. NMR and mass spectrometric analyses confirmed the proposed structure of the 1,3-bis(pentafluorobenzyl) derivative of pentobarbital. The procedure was successfully applied to measurement of serum pentobarbital levels in humans.

Keyphrases □ Pentobarbital—electron-capture GLC analysis, human serum □ GLC, electron capture—analysis, pentobarbital in human serum, retention times, various barbiturates □ Barbiturates, various—electron-capture GLC retention times □ Sedatives—pentobarbital, electron-capture GLC analysis in human serum, retention times, various barbiturates

The GLC determination of barbiturates was reported by numerous authors in the past several years. Some investigators (1, 2) methylated the barbiturate with dimethyl sulfate prior to GLC analysis. A direct "on-column" flash-heater methylation of barbiturates with trimethylanilinium hydroxide was also reported. Ehrnebo *et al.* (4) used similar methodology to assay amobarbital and pentobarbital in serum after ether extraction at pH 5.5. Other investigators (5–12) also described the determination of barbiturates in biological fluids. These methods primarily utilized GLC with flame-ionization detection.

This report describes a new GLC method for the determination of pentobarbital (I). It is sensitive to 0.2 ng/injection, using electron-capture detection of the 1,3-bis(pentafluorobenzyl) derivative of pentobarbital (III, Scheme I) in serum.

EXPERIMENTAL

Reagents and Materials—Pentobarbital[1] (I), hexethal[2] (II), the internal standard, and pentafluorobenzyl bromide[3] were used as supplied. Ether[4] and benzene[4] were nanograde, absolute alcohol[5] was USP grade, and the other chemicals were analytical reagent grade. Aqueous solutions of sodium tungstate (10%), sodium bicarbonate (3%), sodium carbonate (250 μg/ml), and sulfuric acid (1 *N*) were stored in glass containers.

Apparatus—A two-speed reciprocating shaker[6] and a refrigerated centrifuge[7] were used. Sample solutions in the test tubes were mixed by a mixer[8]. Pentafluorobenzyl derivative formation at high temperature was carried out on a heating block[9].

GLC—A gas chromatograph[10] equipped with a ^{63}Ni-electron-capture detector containing a 2-mCi ^{63}Ni-β-ionization source and an electronic integrator were used for the GLC assay. The glass column was 1.82 m (6 ft) × 2 mm (i.d.), packed with 3% OV-17[11] on Gas Chrom Q[11] (80–100 mesh). The column was conditioned at 280° for 1 hr without carrier gas flow and for 16 hr with a carrier gas [argon–methane[12] (95:5)] at a flow rate of 50 ml/min. Before connecting the column to the detector, three to five 5-μl injections of *N,O*-bis(trimethylsilyl)acetamide[13] were made into the column every 10 min.

The cylinder of the carrier gas was fitted with an oxygen trap filter[14]. The operating conditions were: column oven temperature, 225°; electron-capture detector temperature, 325°; injection port temperature,

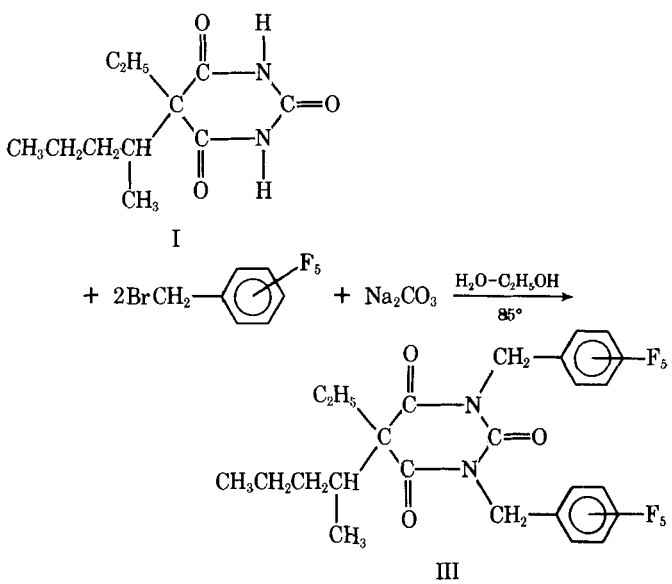
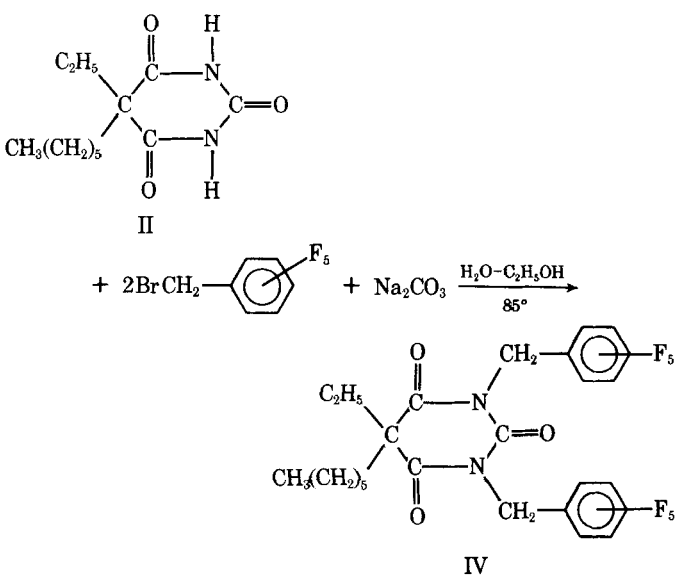
Spectrometry—A mass spectrometer[15] was used under the following conditions: energy of the ionization beam, 70 ev; ion source temperature,



Scheme I



Scheme II

[15] MS-902, Associate Electronic Industry, Manchester, England.

160°; accelerating voltage, 8 kv; and trap current, 100 μamp. The NMR spectrum was recorded at ambient temperatures on a spectrometer[16] using a solution in dimethyl sulfoxide containing tetramethylsilane as the internal standard. The IR spectrum[17] was measured using a potassium bromide pellet.

Preparation of Serum Standards—For human studies, serum standards spiked with I at 0.5, 1.0, 1.5, 2.0, and 2.5 μg/ml were used. This range covered the human serum pentobarbital levels expected after oral administration of a 100-mg dose of pentobarbital sodium capsules[18].

Extraction Procedure—To 1.0 ml of serum in a 20-ml screw-capped test tube were added 3.0 ml of hexethal internal standard solution in water (1 μg/ml) and 1.0 ml of 1 *N* H_2SO_4. The tube was vortexed, 1.0 ml of 10% sodium tungstate solution in water was added, and the tube was then shaken mechanically for 10 min. After centrifugation at 3000 rpm for 15 min at 20°, all of the aqueous phase (supernate) was separated and transferred to a 15-ml conical test tube and recentrifuged at 3000 rpm for 10 min at 20°. Four milliliters of aqueous phase was then pipetted into a 20-ml screw-capped test tube and extracted with 11.5 ml of ether by shaking for 10 min and centrifuging at 3000 rpm for 10 min at 10°.

Ten milliliters of the organic phase was transferred to a 20-ml screw-capped test tube and washed with 2 ml of 3% $NaHCO_3$ aqueous solution by shaking and centrifuging as previously described. The ether layer (9 ml) was transferred into the 15-ml screw-capped conical test tube and evaporated to dryness at 40° with filtered air. The residue was reconstituted with 1 ml of ether and dried again at 40° with filtered air.

1,3-Bis(pentafluorobenzyl) Derivative (III) Formation—To the dry residue were added 0.1 ml of sodium carbonate solution (250 μg/ml of water), 0.1 ml of alcohol, and 50 μl of pentafluorobenzyl bromide in alcohol (2 μg/μl) (Schemes I and II). The mixture was capped and vortexed twice for 15 sec and reacted at 85° for 4 hr on the heating block. Then the mixture was cooled to room temperature; 0.5 ml of water and 4.5 ml of benzene were added, followed by shaking and centrifugation for 10 min. Four milliliters of the benzene extract was separated and evaporated to dryness at 40° with filtered air. The clear residue was reconstituted with 1.0 ml of benzene by vortexing for about 30 sec, and 2 μl of the solution was injected into the GLC column by the automatic sampler[19].

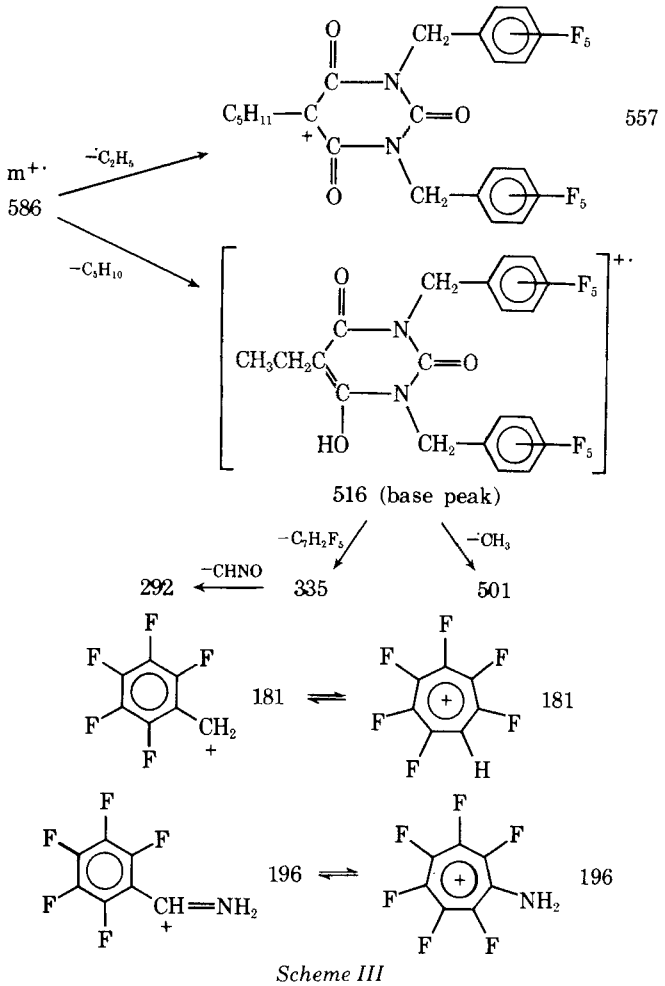
Table I—Peak Area Ratio of III to IV at Various Pentobarbital Serum Concentrations

Pentobarbital Serum Concentration, μg/ml	Peak Area Ratio	Mean ± *SD*	*RSD*
0.1	0.35 0.32 0.38	0.35 ± 0.03	8.6
0.2	0.83 0.70 0.73	0.75 ± 0.07	9.3
0.3	1.03 1.39 1.40	1.27 ± 0.21	16.5
0.4	1.70 1.82 2.14	1.89 ± 0.23	12.2
0.5	2.25 2.39 2.21	2.28 ± 0.10	4.4
0.6	2.54 2.73 2.70	2.66 ± 0.10	3.8
0.8	3.64 3.69	Average 3.67	—
1.0	4.92 5.17 5.13	5.07 ± 0.13	2.6

Under these conditions, derivatization of pentobarbital with pentafluorobenzyl bromide gave one peak on GLC analysis with a retention time of 7.7 min. Hexethal also gave a single peak with a retention time of 10.6 min. Spiked standards of pentobarbital in serum were extracted and reacted with pentafluorobenzyl bromide as previously described.

Calculations—The peak area ratios of III to IV were plotted against known standards of pentobarbital expressed as micrograms per milliliter of serum. Values for unknown concentrations of pentobarbital in serum were calculated by the least-squares regression method from the calibration curve.



Scheme III

RESULTS AND DISCUSSION

Synthesis and Identification of 1,3-Bis(pentafluorobenzyl) Derivative of Pentobarbital (III)—Structural confirmation of III was accomplished by synthesizing sufficient pure drug under similar conditions. The derivative collected was white crystalline material, mp 106–107°. The gas chromatogram (Fig. 1A) of pure III thus formed was identical to that prepared with the serum extract under the same conditions (Fig. 1B).

The NMR spectrum (Fig. 2) showed the presence of benzyl protons at a chemical shift 5.20 ppm downfield from tetramethylsilane. High-resolution mass spectral measurement (Fig. 3) confirmed a small, but distinct, molecular ion at *m/e* 586, consistent with the proposed structure (III). From the empirical formulas calculated, Scheme III was proposed, indicating two pentafluorobenzyl groups attached to the two nitrogen atoms. The IR spectrum (Fig. 4) showed bands at 1700 and 1760 cm^{-1}, assigned to carbonyl stretching. This spectrum also indicates that derivatization occurs on the ring nitrogens and not on the oxygen.

Assay Sensitivity, Reproducibility, and Specificity—The amount of III detectable by the electron-capture detector was less than 0.2 ng/

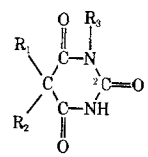


Table II—Retention Times of the Pentafluorobenzyl Derivatives of 15-Barbiturates by the Electron-Capture Detector

Barbiturate	R_1	R_2	R_3	R_f, min

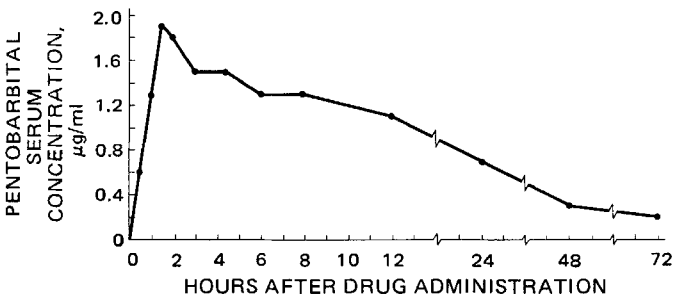

Figure 5—*Serum concentration of pentobarbital* versus *time in one human subject after single-dose oral administration of 100 mg of drug/capsule.*

injection (Fig. 1A). However, under the assay conditions, the lower limit of quantitation for I in extracts of human serum was 0.1 μg/ml, using 1 ml of serum sample (Table I). A linear relationship between peak area ratios and concentrations was obtained for I up to 1.0 μg/ml. Analyses of triplicate serum samples at 0.1–1.0 μg/ml gave a relative standard deviation of 2.6–16.5% with 1 μg of internal standard (Table I).

The method is specific for pentobarbital. Except for thiopental, it was resolved from 13 other barbiturates. The retention times for the pentafluorobenzyl derivatives of 15 barbiturates synthesized individually under similar conditions and detected by the electron-capture detector are shown in Table II. However, the derivatives did not resolve well when all 15 barbiturates were reacted simultaneously with pentafluorobenzyl bromide.

Serum Pentobarbital Levels in Humans—This analytical methodology was used for the measurement of serum pentobarbital (I) concentrations in normal human subjects after a single oral dose of 100 mg of pentobarbital sodium (capsule form). The subjects were fasted for a minimum of 12 hr prior to dosing and for 2 hr after dosing. The drug was administered with 120 ml (4 oz) of water.

Peak levels of pentobarbital ranged from 1.2 and 3.1 μg/ml and were observed at 0.5–2.0 hr after drug administration. Substantial amounts of drug (0.30 ± 0.08 μg/ml) were found in the 48-hr serum samples. A typical serum concentration *versus* time curve for one subject is shown in Fig. 5.

0.4	68.0	86.1
0.5	81.2	93.8
0.6	90.0	97.1
0.7	95.9	98.9
1.0	99.0	99.8

[a] Powder 1 was Norit A, Matheson, Coleman and Bell, Norwood, Ohio. Powder 2 was from Amend Drug and Chemical Co., New York, N.Y. [b] Quantities per 50 ml of acetaminophen solution, 2.5 mg/ml.

methylcellulose solution, absorption in humans was reduced by 63% (1). When activated charcoal was given 60 min after acetaminophen ingestion, a 23% reduction in absorption was noted. When 10 g of activated charcoal was administered immediately after a 1-g dose of acetaminophen, a reduction of 69–77% was observed (2). Activated charcoal can be administered alone or following ipecac or apomorphine-induced emesis. A 10:1 ratio of activated charcoal to acetaminophen reduced absorption by 51% within 30 min (3).

Large quantities of activated charcoal can be administered safely, are well tolerated, and can be used in an emergency for various poisonings (4). To understand the effects of time of administration, pH of the medium, and amount of activated charcoal on the adsorption of acetaminophen, the following study was performed.

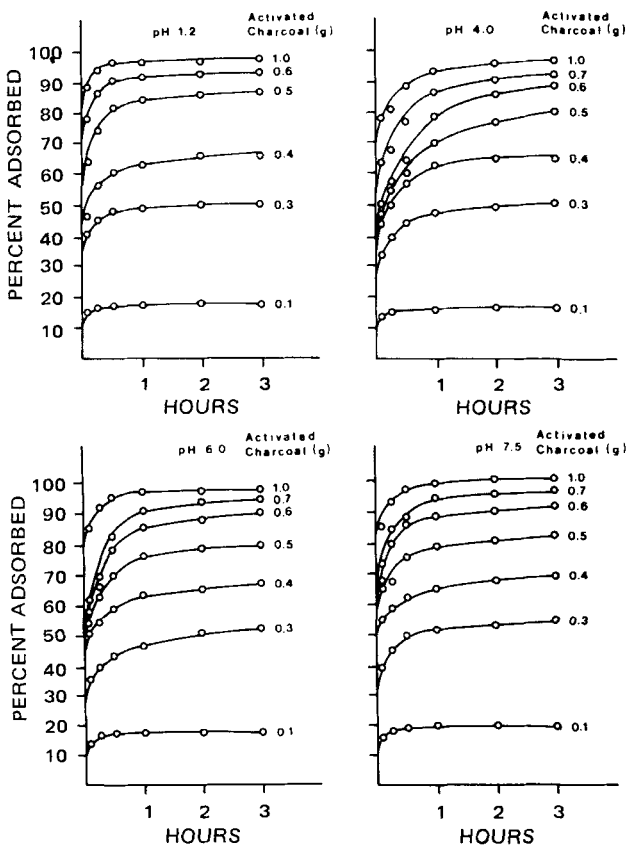

Figure 1—*Percent acetaminophen adsorbed onto activated charcoal at 37.5°.*

pH	*n*	*b*	Correlation Coefficient (*r*)
1.2	4.39	0.268	0.996
4.0	4.63	0.223	0.999
6.0	4.16	0.269	0.997
7.5	3.84	0.288	0.998
Composite	4.28	0.282	0.991

EXPERIMENTAL

Materials—Acetaminophen solutions, 2.5 mg/ml, were prepared with the following vehicles: simulated gastric fluid USP without pepsin (pH 1.2), McIlvaine citrate-phosphate buffers (pH 4.0, 4.5, and 6.0), and simulated intestinal fluid USP without pancreatin (pH 7.5).

Analytical—Concentrations of acetaminophen were determined by diluting the samples with acidified methanol and analyzing on a spectrophotometer[1] at 247 nm.

Particle Size—Particle diameters were determined on an automated counter[2].

Adsorption—Various amounts of activated charcoal powder[3] (0.1–1.0 g) were shaken with 50 ml of standard acetaminophen solution at various hydrogen-ion concentrations. The suspensions were shaken at 37.5°, and samples were priodically removed, filtered, and assayed. Samples for equilibrium studies were shaken for 24 hr and centrifuged, and the supernates were assayed.

Desorption—Three variations in desorption experiments were performed.

1. To determine the rate of desorption, various amounts of activated charcoal (0.1–1.0 g) were equilibrated (shaken) overnight with acetaminophen solutions (pH 1.2, 4.5, and 7.5) at 37.5°. The suspensions were centrifuged, the supernates were assayed, and the excess supernates were aspirated. Fifty milliliters of fresh buffer (without acetaminophen) of the same pH as the equilibrating solution was added to the bottles, and the suspensions were shaken again. Samples were removed periodically, filtered, and assayed.

Once it was established that desorption equilibrium could be achieved within 1 hr, the effects of activated charcoal concentration and pH were studied by using only the results from 1-hr samples.

2. Various amounts of activated charcoal (0.2–1.0 g) were equilibrated for 1 hr with pH 1.2 acetaminophen solution. The desorption procedure was the same as Variation 1, but the eluting solutions were of a different pH (4.0 and 7.5).

3. Various amounts of activated charcoal (0.05–1.00 g) were equilibrated for 1 hr with pH 1.2 acetaminophen solution. The desorption procedure was the same as Variation 1 with pH 1.2 eluting solutions. However, each elution was performed four times to determine how repeated elution would affect the accumulative amount of acetaminophen desorbed.

RESULTS AND DISCUSSION

Activated charcoal was demonstrated to be an effective adsorbant for acetaminophen. Within 30 min, most acetaminophen was adsorbed onto the activated charcoal (Fig. 1). Within 1 hr, adsorption was complete at all activated charcoal quantities and over the pH range tested. The percent of acetaminophen adsorbed depended upon the quantity of activated charcoal present. The addition of each 0.1 g of activated charcoal above 0.5 g did not appreciably improve the effectiveness of the activated charcoal for adsorbing 125 mg of acetaminophen. With the reduction of each 0.1 g of activated charcoal below 0.5 g, a large difference in the effectiveness of adsorbing 125 mg of acetaminophen was seen. Consequently, at least four times as much activated charcoal as acetaminophen was required for effective adsorption.

This observation agreed well with suggested doses derived from *in vivo* experiences. Picchioni (5) suggested that a dose of activated charcoal five times the estimated overdose of acetaminophen be employed in acute situations. Levy and Gwilt (3) suggested a 10:1 ratio of activated charcoal to acetaminophen.

Table III—Percent Acetaminophen Adsorbed on Activated Charcoal as a Function of pH at 37.5°

Activated Charcoal, g[a]	Percent Adsorbed			
	pH 1.2	pH 4.0	pH 6.0	pH 7.5
0.05	10.3	8.4	11.2	8.7
0.1	16.8	17.2	19.4	16.4
0.2	29.0	34.1	36.8	36.7
0.3	58.2	50.2	53.7	59.1
0.4	64.9	65.3	68.0	71.0
0.5	77.7	77.7	81.2	85.3
0.6	87.2	87.0	90.0	93.9
0.7	94.5	89.9	95.9	97.2
1.0	98.3	98.8	99.0	99.7

[a] Quantities per 50 ml of acetaminophen solution, 2.5 mg/ml.

Activated charcoal powder from another source[4] was compared to the activated charcoal[3] employed throughout the rest of the study. The mean particle diameters of the activated charcoal powder from the two sources were similar (one source[4] had a mean of 8.3 μm and a 70% range of 3.6–16.5 μm; the other[3] had a mean of 9.1 μm and a 70% range of 3.7–18.5 μm). Only slight differences in their equilibrium concentrations were found. Table I shows the differences in the percent adsorbed at equilibrium onto the two brands of activated charcoal. These differences should not have a bearing on the effectiveness of activated charcoal in overdose situations.

Langmuir adsorption isotherms were determined for the adsorption of acetaminophen onto activated charcoal powder at various hydrogen-ion concentrations. The Langmuir isotherm is defined as follows:

$$c/(x/m) = nc + b \qquad \text{(Eq. 1)}$$

where c = concentration of acetaminophen in milligrams per milliliter at equilibrium, x/m = amount of adsorbed drug in milligrams (x) per milligram of activated charcoal (m), and n and b are constants for the isotherms. The constants (n and b) were determined by linear regression analysis at each pH (Table II). Since the differences between the isotherms at various pH values were not significant, the data from all four pH values were pooled and a composite isotherm was obtained. The parameters for this isotherm are listed in Table II as "composite."

Table IV—Percent Acetaminophen Desorbed from Activated Charcoal at 37.5°

Activated Charcoal, g[a]	Percent Desorbed	
	pH 4.0	pH 7.5
0.2	25.7	17.8
0.3	19.9	13.7
0.4	15.9	10.2
0.5	12.0	7.2
0.6	8.3	4.4
0.7	5.8	2.3
1.0	1.4	0.3

[a] Equilibrium was attained with 50 ml of pH 1.2 acetaminophen solution, 2.5 mg/ml, and elution was performed with 50 ml of pH 4.0 and 7.5 buffers.

Table V—Desorption by Four Successive Elutions at 37.5°[a]

Activated Charcoal, g	Accumulative Percent Desorbed			
	Elution 1	Elution 2	Elution 3	Elution 4
0.05	30.8	40.3	45.8	48.8
0.1	26.5	36.1	41.4	45.1
0.2	18.9	27.5	32.5	36.0
0.3	13.7	21.0	25.7	29.0
0.4	10.4	16.5	20.6	23.6
0.5	7.4	12.2	15.7	18.8
0.6	4.2	7.3	9.9	12.0
0.7	2.0	3.7	5.1	6.5
1.0	0.4	0.7	0.9	1.2

[a] Equilibrium was attained with 50 ml of pH 1.2 acetaminophen solution, 2.5 mg/ml, and elution was performed with 50 ml of pH 1.2 solution.

Adsorption onto activated charcoal is greater for unionized compounds. Since acetaminophen has a pKa of 9.9 (6), it is unionized in the pH 1.2–7.5 range. Therefore, the compound is well adsorbed at all physiological pH values. Under *in vivo* conditions, small differences such as were seen in the Langmuir isotherms would probably be negated by ions, enzymes, *etc.*, which would also be adsorbed onto the charcoal.

The maximum adsorption capacity (1/n) was 234 mg of acetaminophen/g of activated charcoal. This value is in agreement with the 279 mg of acetaminophen/g of activated charcoal found by Levy and Gwilt (3).

The effect of pH on the percent of acetaminophen adsorbed at equilibrium onto activated charcoal is more evident from the data in Table III. For each activated charcoal quantity, only a slight difference was seen. For example, 0.5 g of activated charcoal adsorbed 77.7% of acetaminophen at pH 1.2 and 85.3% at pH 7.5. Normal deviations in data and the use of different buffer systems might account for the differences seen.

Desorption studies were performed to determine if acetaminophen, once adsorbed, could be desorbed from activated charcoal as a result of a change in pH or in the acetaminophen concentration in the solution. Figure 2 illustrates the effect of variations in the quantity of activated charcoal employed and in the pH of the desorption medium. Desorption was essentially complete within 15 min. Desorption decreased with decreasing pH and with increasing quantities of activated charcoal.

Table IV describes desorption when the eluting solution was at a pH (4.0 and 7.0) higher than the pH (1.2) of the adsorbing solution. Desorption was greater in the pH 4.0 solution than in the pH 7.0 solution. The exact reason for this result is not known, but it is probably related to the buffer compositions. Also, as in the previous case, the greater the amount of activated charcoal employed, the smaller was the percent desorption of acetaminophen.

Data in Table V indicate that the most desorption occurred with the first elution. Subsequent elutions had a much smaller effect on desorption, especially when large amounts of activated charcoal were employed.

Conformational Studies of Antiradiation Agents by NMR: Cysteamine and Its Derivatives

VITHAL M. KULKARNI and GIRJESH GOVIL x

Abstract □ The conformations of cysteamine, thiazolidine, and thiazolidine-4-carboxylic acid were determined in aqueous solutions using NMR spectroscopy. At physiological pH, the population ratio of *gauche*- and *trans*-conformers was 3:1. The *gauche*-rotamer is probably responsible for the antiradiation activity and acts through metal chelation involving sulfur and nitrogen atoms. The puckering of the thiazolidine ring was calculated using NMR coupling constants. The observed results were compared with those obtained in the solid state using X-ray diffraction.

Keyphrases □ Cysteamine—and derivatives, NMR conformational study in aqueous solutions □ Thiazolidine—and derivatives, NMR conformational study in aqueous solutions □ NMR—conformational study of cysteamine, thiazolidine, and derivatives in aqueous solutions □ Conformations—cysteamine, thiazolidine, and derivatives, NMR study in aqueous solutions □ Antiradiation agents—cysteamine, thiazolidine, and derivatives, NMR conformational study in aqueous solutions

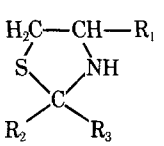
Cysteamine (2-aminoethanethiol, I) is a well-established antiradiation agent (1). The sulfur-substituted derivative of this molecule (2), 2-aminoethanethiosulfuric acid (II), is as active as I. Some 2-substituted thiazolidines (III and IV), prepared by condensing I with carbonyls, are also good antiradiation agents (3). To explain the mechanism of radioprotection offered by these compounds, several postulations (4, 5) have been suggested such as mixed disulfide formation (6) with protein constituents, chelation of vital metal ions (7), and binding to DNA (8).

The conformations in the solid state by X-ray diffraction for these molecules were reported (9–12). Recently, quantum chemical calculations using extended Hückel theory (EHT) and complete neglect of differential overlap (CNDO) methods were made in this laboratory. The results showed that I has both *gauche*- and *trans*-conformations, with a preference toward the *trans*-structure.

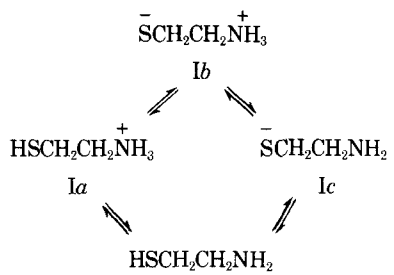
In this paper, the application of NMR spectroscopy for the determination of the preferred conformation in solution of cysteamine and some thiazolidine derivatives is reported. Attempts were made to correlate these findings with their biological action.

$HSCH_2CH_2NH_2$ I

$HO_3SSCH_2CH_2NH_2$ II



III: $R_1 = COOH$, $R_2 = R_3 = H$
IV: $R_1 = H$, $R_2 = R_3 = CH_3$



Scheme I

In physiological solution, cysteamine undergoes multiple ionization (9) (Scheme I). The ionization constants governing these equilibria have been reported, so it is possible to calculate the fraction of each species as a function of pH. The concentration of I is low at all pH values. Form I*a* predominates in acidic media, while I*c* predominates at pH values greater than 12. Form I*b* is present at intermediate pH's and reaches its maximum concentration of 84.6% around pH 9.5. Therefore, NMR studies of cysteamine were made at three different pH values. Other compounds were studied in neutral solution and in deuterochloroform.

EXPERIMENTAL

Materials—Cysteamine hydrochloride[1] was recrystallized from 95% ethyl alcohol until it was free from disulfide traces. 2-Aminoethanethiosulfuric acid and thiazolidine derivatives were prepared using reported procedures (3, 13).

NMR Measurements—Samples were dissolved in deuterium oxide to a known concentration, and spectra[2] were recorded using the sodium salt of 2,2-dimethyl-2-silapentane-5-sulfonic acid as the internal reference. The pH values were adjusted using trifluoroacetic acid.

RESULTS AND DISCUSSION

Spectral Analysis—The studied molecules are of the 1,2-disubstituted ethane type and show the usual rotational isomerism around the carbon–carbon bond. In the case of thiazolidines, this rotation is hindered, but a small degree of conformational freedom is still present due to the puckering modes of the ring. The spectrum of cysteamine recorded in

RESULTS AND DISCUSSION

Spectral Analysis—The studied molecules are of the 1,2-disubstituted ethane type and show the usual rotational isomerism around the carbon–carbon bond. In the case of thiazolidines, this rotation is hindered, but a small degree of conformational freedom is still present due to the puckering modes of the ring. The spectrum of cysteamine recorded in

[1] Fluka grade.
[2] Varian Associates HA-100 and A-60 spectrometers.

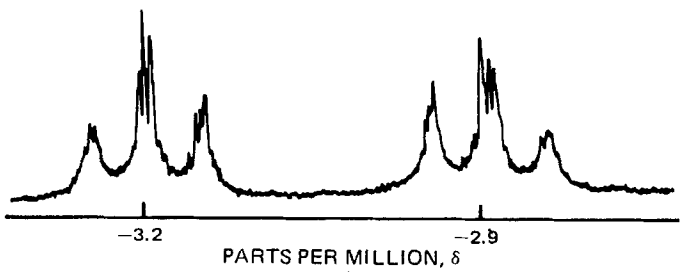

Figure 1—*The 100-MHz spectrum of cysteamine in deuterium oxide (pH 7).*

a neutral medium (pH 7.0) is shown in Fig. 1. Figures 2 and 3 show the spectra of thiazolidine-4-carboxylic acid hydrochloride and 2,2′-dimethylthiazolidine hydrochloride, respectively.

The chemical shift and coupling constant data for all these molecules are given in Table I. The spectra of I and IV show two methylene proton absorptions due to the CH_2CH_2 fragment. The chemical shift difference in acidic solution is greater than in neutral and basic solutions, indicating the effect of pH on the acid–base equilibrium. The spectrum is of the *AA′BB′* type and was analyzed by an iterative LAOCOON program (14). As usual with such spectra, only the sum of the coupling constants ($J_{AB} + J_{AB'}$) was estimated accurately. The spectrum of thiazolidinecarboxylic acid, on the other hand, is of the *ABC* type and all coupling constants were evaluated accurately. 2-Aminoethanethiosulfuric acid shows a single methylene proton at −3.00 ppm (δ), indicating a very small chemical shift difference (spectrum not shown).

Conformational Analysis of Cysteamine—Due to rotation about the carbon–carbon bond, the spectrum is an average of the individual rotamers, each of which belongs to the *AA′BB′* class (15). In the system of three equilibrating staggered rotamers, G, T, and G′ (Fig. 4), the weighted mean of the couplings between protons *A* and *B* are observed.

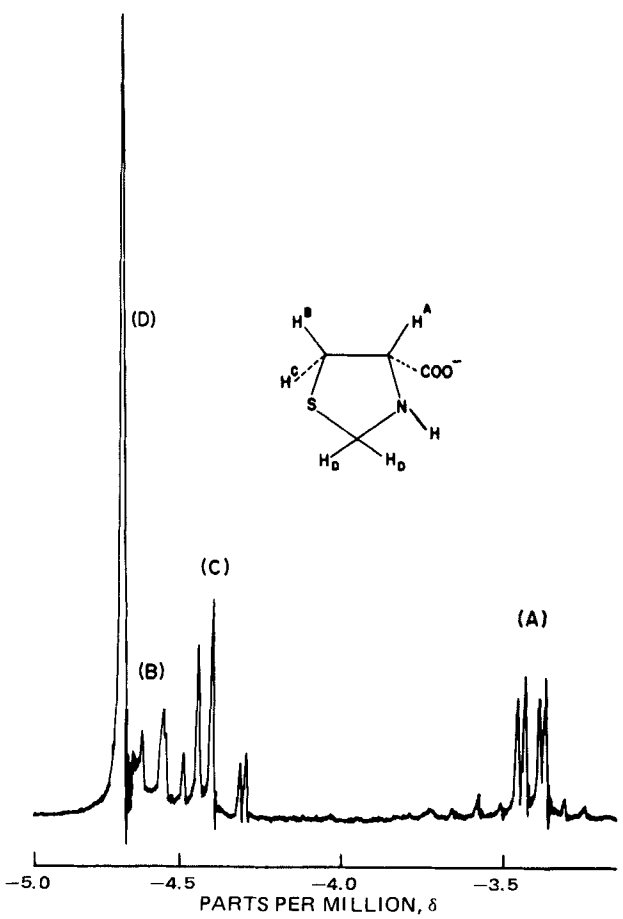

Figure 2—*The 100-MHz spectrum of thiazolidine-4-carboxylic acid in deuterium oxide.*

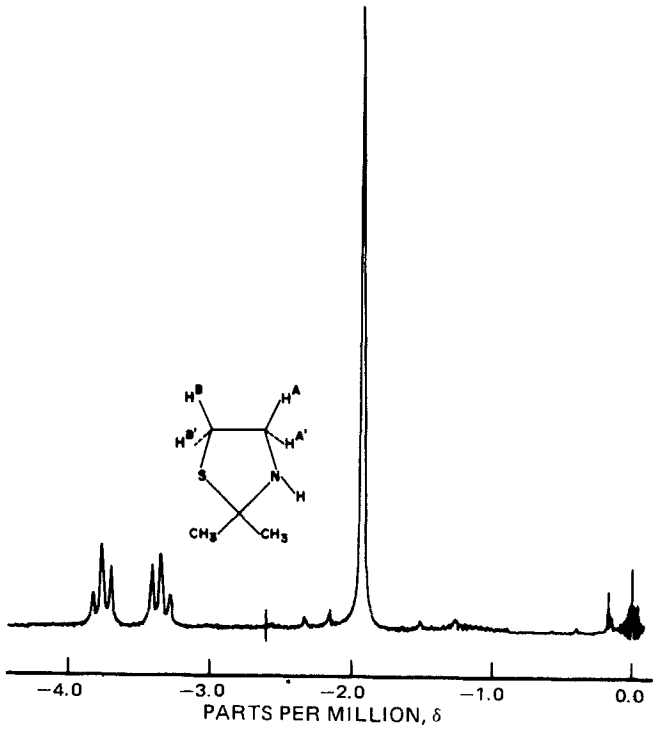

Figure 3—*The 100-MHz spectrum of 2,2-dimethylthiazolidine in deuterochloroform.*

In the present case, rotamers G and G′ are identical. The observed coupling constants (J_{AB} and $J_{AB'}$) contain information about the relative populations of the three rotamers.

In an $X\text{-}CH_2CH_2\text{-}Y$ fragment, the *vicinal* coupling constants depend on the electronegativity of the substituents and the dihedral angles. Abraham and Gatti (16) made a detailed analysis of the two effects. For staggered conformations of 1,2-disubstituted ethanes, the individual *gauche-* and *trans-vicinal* proton–proton couplings (J_g and J_t) are related to the electronegativities of the substituent atoms X and Y as follows.

For *trans*-rotamer T:

$$J_g{}^T = 1.35 + 0.63(E_X + E_Y) \quad \text{(Eq. 1)}$$

$$J_t{}^T = 18.07 - 0.88(E_X + E_Y) \quad \text{(Eq. 2)}$$

For *gauche*-rotamers G and G′:

$$J_g{}^G = 8.94 - 0.94(E_X + E_Y) \quad \text{(Eq. 3)}$$

$$J_{g'}{}^G + J_t{}^G = 26.92 - 2.03(E_X + E_Y) \quad \text{(Eq. 4)}$$

where E_X and E_Y are Huggins electronegativities (17) for atoms S and N, which are 2.60 and 3.05, respectively. From Eqs. 1–4, $J_g{}^T = 4.91$, $J_t{}^T = 13.04$, $J_g{}^G = 3.63$, and $J_t{}^G = 11.83$. From these values, one estimates $(J_{AB} + J_{AB'})^T = J_g{}^T + J_t{}^T = 17.95$ and $(J_{AB} + J_{AB'})^{G,G'} = \frac{1}{2}[(J_{AB} + J_{AB'})^G + (J_{AB} + J_{AB'})^{G'}] = \frac{1}{2}[3J_g{}^G + J_t{}^G] = 11.36$. The population of the *trans*-isomer, p_T, can now be evaluated using the observed values of $(J_{AB} + J_{AB'})$:

$$(J_{AB} + J_{AB'})_{obs} = 17.95p_T + 11.36(1 - p_T) \quad \text{(Eq. 5)}$$

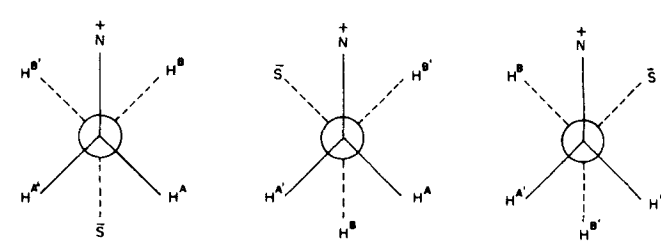

Figure 4—*Conformational rotamers of cysteamine.*

or:

$$p_T = \frac{(J_{AB} + J_{AB'})_{obs} - 11.36}{6.59} \quad \text{(Eq. 6)}$$

The population analysis of the rotamer isomers is given in Table I.

Two factors can contribute to errors in the estimates of the population distributions reported in Table I. Basic values of component coupling constants, estimated using empirical generalizations made on the basis of experimental measurements on a large number of compounds (16), may be in error. Recently, Feeney (18) made an accurate determination of component coupling constants for carbon–carbon bonds in peptides using data from methyl-substituted piperidine and cyclohexylamine. The electronegativities of the substituents in this case are similar to those in cysteamine, as are the component coupling constants for the G and T isomers. Nevertheless, errors of ~0.5 Hz in the estimation of $J_{AB} + J_{AB'}$ for either the G or T isomer are possible and will be reflected as a maximum error of 6 in the estimated population of the *trans*-conformer.

Errors also may occur in the observed values of $J_{AB} + J_{AB'}$. In neutral and acidic media, the NMR lines are fairly sharp and the sum of the coupling constants can be estimated to an accuracy of ±0.1 Hz. This value corresponds to an accuracy of ±2 in estimated percentage values of p_T. However, in basic solutions, the linewidths are about 1 Hz and the sum of the estimated coupling constants can be in error by ±0.5 Hz, leading to an error of ±10 in the percentage values of p_T.

Clearly, a significant population of both *gauche*- and *trans*-conformers is present at all three pH values. The population distribution of p_G to p_T is close to the value of 2:1 expected from purely statistical considerations. If it is assumed that the component coupling constants are not sensitive to the ionization state of the molecule, then the population distribution does show a detectable change with pH. At physiological pH, the ratio of p_G to p_T is around 3:1. A slightly higher population of the *gauche*-conformer around pH 7 may be associated with a preferential stabilization of such a conformer by electrostatic charge–charge interaction or the nitrogen–hydrogen–sulfur–hydrogen bond.

Puckering Angle in Thiazolidine and Thiazolidinecarboxylic Acid—Thiazolidine and its derivatives cannot acquire fully staggered conformations about their various single bonds because of the restrictions imposed by ring closure. In general, a saturated five-member ring system may lie in a twisted conformation, with two of its atoms lying out of the plane defined by the other three.

It is possible to estimate the dihedral angle (δ) along the nitrogen–carbon–carbon–sulfur bond (Fig. 5) using *vicinal* NMR coupling constants between protons on the two carbon atoms[3]. In general, a Karplus-type relationship between the *vicinal* hydrogen–carbon–carbon–hydrogen coupling constant and the relevant dihedral angle (ϕ) is used in such studies:

$$J(\phi) = A\cos^2\phi + B\cos\phi + C \quad \text{(Eq. 7)}$$

The first term in the Karplus relationship generally dominates, since the value of A is almost 10 times larger than that of B or C.

The available coupling constants, $J_g^G(\phi = 60°)$ and $J_t^G(\phi = 180°)$, for cysteamine can be used to calibrate the Karplus relationship for thiazolidine. However, these data are insufficient for estimating all three parameters. Fortunately, as will be seen later, results are not sensitive to values of B and C. Accordingly, attempts are made on the following combinations of A, B, and C values to estimate δ in thiazolidine and thiazolidinecarboxylic acid: (*a*) $A = 10.93$, $B = 0$, and $C = 0.90$ (analogous to the relationship suggested by Feeney (18) for amino acids); (*b*) $A = 12.7$, $B = 0.9$, and $C = 0$; (*c*) $A = 11.8$, $B = 0$, and $C = 0$; and (*d*) $A = 14.5$, $B = 0$, and $C = 0$. The estimated value of δ does not differ by more than ±5° from the mean values reported in the subsequent discussion.

For thiazolidine itself, two identical conformations correspond to positive or negative values of δ. The NMR spectrum of the NCH_2CH_2S fragment is a weighted average of the two identical conformers. As is evident from Fig. 5*b*, the sum of coupling constants $J_{AB'} + J_{A'B}$ is related to δ by the following equation:

$$(J_{AB'} + J_{A'B})_{obs} = \tfrac{1}{2}[2J(\delta) + J(120 - \delta) + J(120 + \delta)] \quad \text{(Eq. 8)}$$

Using a value of 13.2 Hz for $J_{AB'} + J_{A'B}$, one obtains $\delta = 42 \pm 3°$.

With thiazolidinecarboxylic acid, the two conformers become nonequivalent, but the NMR spectrum (*ABC* type) enables one to determine which of the two conformers is preferred because both J_{AB} and J_{AC} are measurable. The observed values of 2.1 Hz for J_{AC} and 6.6 Hz for J_{AB} indicate that the preferred conformer in solution is as shown in Fig. 5c with $\delta = 45 \pm 5°$. The result is not significantly affected when the parameters of the Karplus relationship are calibrated using $J_g^G = 3.2$ and $J_t^G = 11.4$, which are the values obtained when allowing for the electronegativity of the substituent on thiazolidine.

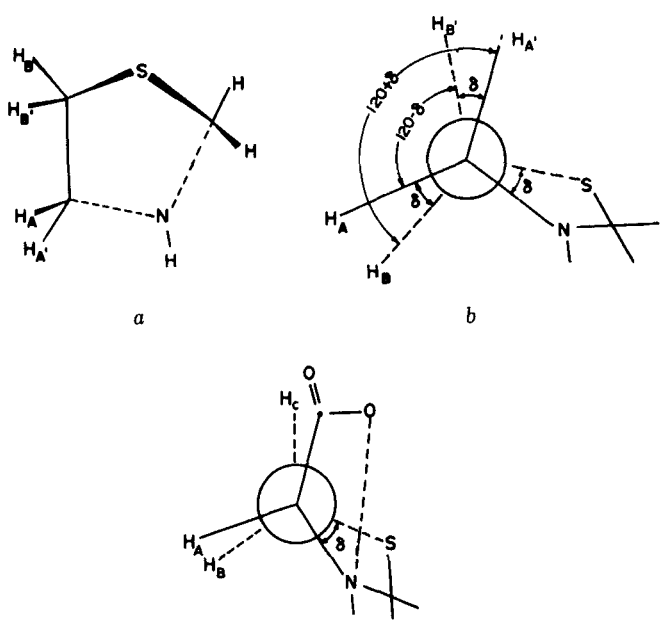

Figure 5—*Conformations of thiazolidine. Key:* a, *ring puckering of thiazolidine showing both nitrogen and sulfur atoms puckered with respect to the plane passing through the three carbon atoms (twisted conformation);* b, *dihedral angles around the carbon–carbon bond in thiazolidine; and* c, *ring puckering in thiazolidinecarboxylic acid.*

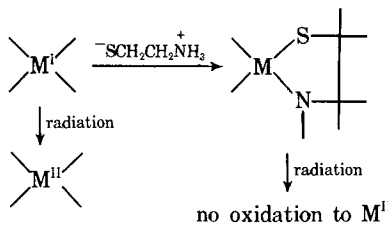
[3] In principle, it is also possible to estimate dihedral angles along the carbon–carbon–nitrogen–carbon and carbon–nitrogen–carbon–sulfur bonds through hydrogen–carbon–nitrogen–hydrogen coupling constants. Unfortunately, such coupling constants were not detected in the molecules under study.



Scheme II

Comparison with Conformational Studies by Other Methods—While the solid-state and solution data on the preferred conformations of the compounds are not identical, they do show a high degree of similarity. For cysteamine in deuterium oxide at physiological pH, the relative population of the *gauche*-conformer is greater (75%) than the *trans*-conformer. X-ray diffraction studies (9), on the other hand, showed that in the solid state the molecule crystallizes only in the *gauche*-form. In crystals, the observed structure is stabilized by intramolecular nitrogen–hydrogen–sulfur bonds.

For thiazolidinecarboxylic acid, X-ray crystallography indicates that the ring has a one-atom pucker (envelope) conformation, with the sulfur atom lying about 0.8 Å ($\delta = 27°$) out of the plane described by the other four atoms. The solution data indicate a slightly higher pucker ($\delta = 45°$) for both thiazolidine and thiazolidinecarboxylic acid. If the bond length and bond angles observed in the solid state are preserved in solution, then the NMR data indicate that both sulfur and nitrogen atoms are puckered relative to the plane described by the three ring carbon atoms. The structure of thiazolidinecarboxylic acid is held in the crystal by several intra- and intermolecular NH···O=C hydrogen bonds. When such hydrogen bonds are replaced by solute–solvent hydrogen bonds in aqueous solutions, the molecular conformation apparently switches to a more relaxed two-atom twisted conformation.

The solution results are in better agreement with those predicted by EHT and CNDO theory. Theoretical results correspond more closely to conformations for isolated molecules and indicate a slight preference for the intramolecularly hydrogen-bonded form of I*b* while almost equal energies are predicted for the G, T, and G′ conformers of I*a* and I*c*. For thiazolidine systems, such calculations indicate that a two-atom twisted conformation (with $\delta = 38°$) is most stable.

Biological Action—Based on the conformer population of cysteamine in solution, it can be argued that the radioprotective action of this molecule arises from a structure in which the essential atoms, sulfur and nitrogen, are placed in a *gauche*-arrangement. In this conformation, the sulfur and nitrogen atoms come in close proximity and their steric repulsion may be offset by intramolecular hydrogen bond NH···S and charge interactions. This type of molecular arrangement allows the possibility of chelation of metal ions involving sulfur and nitrogen atoms (Scheme II) and prevents their oxidation by free radicals formed in the biophase by the radiolysis of water (19). With thiazolidines, the antiradiation action may be due to their *in vivo* hydrolysis (20) to a protective compound, cysteamine, which then undergoes molecular arrangement as shown in Scheme II.

Radioimmunoassay of Indomethacin in Biological Fluids

L. E. HARE, C. A. DITZLER, and D. E. DUGGAN [x]

Abstract □ A radioimmunoassay was developed for the determination of indomethacin in biological fluids at concentrations as low as 50 ng/ml. Antibodies were produced in rabbits immunized with a conjugate of bovine serum albumin and indomethacin. This conjugate was prepared by an *N*-hydroxysuccinimide active ester procedure. Antiserums exhibited minimal cross-reactivity with the *O*-desmethyl and deschlorobenzoyl metabolites. However, the glucuronide conjugate was about three times as reactive as indomethacin, thus invalidating direct determinations of indomethacin in urine. This difficulty was circumvented by analyzing urine aliquots before and after conjugate hydrolysis. Concentrations of free and conjugated indomethacin were calculated by difference.

Keyphrases □ Indomethacin—radioimmunoassay, human plasma and urine □ Radioimmunoassay—indomethacin, human plasma and urine □ Anti-inflammatory agents—indomethacin, radioimmunoassay, human plasma and urine

Analyses of the widely used anti-inflammatory agent indomethacin[1] have previously been accomplished by spectrofluorometric (1) or radioisotopic (2) methods. These procedures are useful in certain situations but are subject to limitations. The spectrofluorometric method lacks sensitivity, and the presence of other fluorescent materials,

Comparison with Conformational Studies by Other Methods—While the solid-state and solution data on the preferred conformations of the compounds are not identical, they do show a high degree of similarity. For cysteamine in deuterium oxide at physiological pH, the relative population of the *gauche*-conformer is greater (75%) than the *trans*-conformer. X-ray diffraction studies (9), on the other hand, showed that in the solid state the molecule crystallizes only in the *gauche*-form. In crystals, the observed structure is stabilized by intramolecular nitrogen–hydrogen–sulfur bonds.

For thiazolidinecarboxylic acid, X-ray crystallography indicates that the ring has a one-atom pucker (envelope) conformation, with the sulfur atom lying about 0.8 Å ($\delta = 27°$) out of the plane described by the other four atoms. The solution data indicate a slightly higher pucker ($\delta = 45°$) for both thiazolidine and thiazolidinecarboxylic acid. If the bond length and bond angles observed in the solid state are preserved in solution, then the NMR data indicate that both sulfur and nitrogen atoms are puckered relative to the plane described by the three ring carbon atoms. Radioimmunoassay of Indomethacin in Biological Fluids

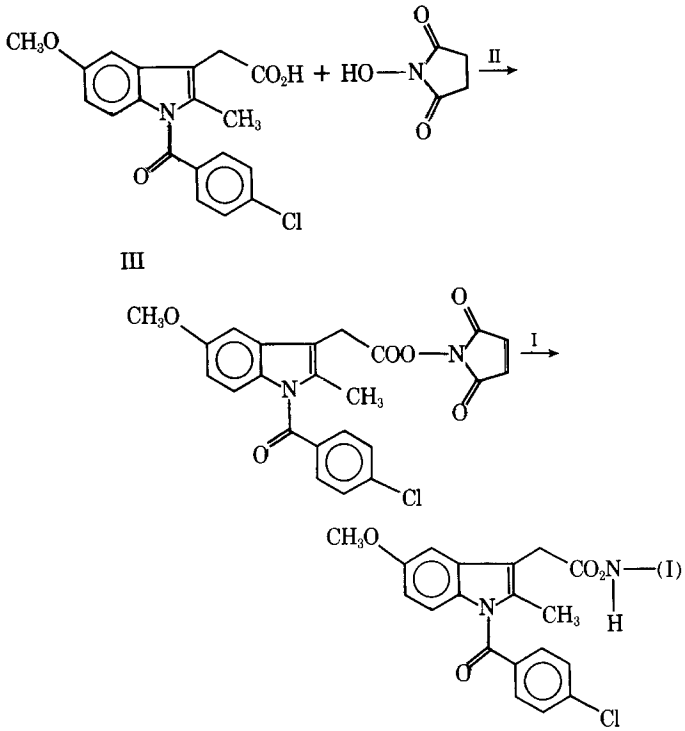
L. E. HARE, C. A. DITZLER, and D. E. DUGGAN [x]

Abstract □ A radioimmunoassay was developed for the determination of indomethacin in biological fluids at concentrations as low as 50 ng/ml. Antibodies were produced in rabbits immunized with a conjugate of bovine serum albumin and indomethacin. This conjugate was prepared by an *N*-hydroxysuccinimide active ester procedure. Antiserums exhibited minimal cross-reactivity with the *O*-desmethyl and deschlorobenzoyl metabolites. However, the glucuronide conjugate was about three times as reactive as indomethacin, thus invalidating direct determinations of indomethacin in urine. This difficulty was circumvented by analyzing urine aliquots before and after conjugate hydrolysis. Concentrations of free and conjugated indomethacin were calculated by difference.

Keyphrases □ Indomethacin—radioimmunoassay, human plasma and urine □ Radioimmunoassay—indomethacin, human plasma and urine □ Anti-inflammatory agents—indomethacin, radioimmunoassay, human plasma and urine

Analyses of the widely used anti-inflammatory agent indomethacin[1] have previously been accomplished by spectrofluorometric (1) or radioisotopic (2) methods. These procedures are useful in certain situations but are subject to limitations. The spectrofluorometric method lacks sensitivity, and the presence of other fluorescent materials,

[1] Indocin, Merck Sharp & Dohme.



Scheme I

such as salicylic acid, causes interference. Reverse isotope dilution offers the advantage of quantitating all metabolites but necessitates administration of radioactive drug.

GC (3), mass fragmentographic (4), and liquid chromatographic (5) techniques recently were developed. Their primary disadvantages are the necessity of careful sample preparation and the relatively slow rate of analysis. This paper reports a radioimmunoassay procedure for the direct analysis of indomethacin in biological fluids requiring no prior isolation.

EXPERIMENTAL

2-^{14}C-Indomethacin[2] (52 μCi/mg), bovine serum albumin[3] (I), *N*-hydroxysuccinimide[4], dicyclohexylcarbodiimide[4] (II), β-glucuronidase[5], neutral charcoal[6], and dextran[7] were used as received. Dextran-coated charcoal was prepared by suspending 6.25 g of previously washed charcoal and 0.625 g of dextran in 100 ml of 0.05 *M* phosphate buffer (pH 7.5).

Preparation of Conjugates—Indomethacin (III) was conjugated through the carboxylic acid moiety to I by an *N*-hydroxysuccinimide active ester procedure (6, 7) (Scheme I). Conversion of indomethacin to the succinimide ester was verified by the appearance of characteristic imide peaks at 1800, 1780, and 1720 cm^{-1} in the IR spectrum. Indomethacin active ester (125 mg, 0.35 mmole) in dioxane (3 ml) was added dropwise to a solution of I (200 mg, 0.18 mmole lysine equivalents) in 0.05 *M* phosphate buffer (pH 7.8) (20 ml).

The solution was allowed to stand at room temperature overnight and was then extensively dialyzed against distilled water. The small amount of insoluble material present was removed by centrifugation, and the solution was lyophilized. The extent of conjugation was 17 molecules of indomethacin/molecule of I as estimated by UV absorption (indomethacin $\epsilon_{320} = 6.3 \times 10^3$). Protein concentration was determined by a microbiuret method (8).

Immunization of Animals—New Zealand White rabbits were injected intramuscularly with indomethacin–I conjugates (5 mg), which had been dissolved in 0.5 ml of saline and emulsified with an equal volume of Freund's complete adjuvant. Booster injections of 1 mg of conjugate were given at monthly intervals in incomplete adjuvant. Bleedings were taken from central ear arteries about 2 weeks after booster injections. The antibody titer was determined from the binding of 2-^{14}C-indomethacin by the antiserums, corrected for binding to normal serum.

Radioimmunoassay of Plasma—Antiserum was used at a dilution that bound 35–50% of the added label in control tubes containing no unlabeled antigen. The assay solution consisted of 0.1 ml of pooled human plasma containing unlabeled indomethacin standards (50–3000 ng/ml) or 0.1 ml of plasma from indomethacin-treated subjects, 0.1 ml of a 1:12 dilution of the antiserum, 20 ng of 2-^{14}C-indomethacin (2.3×10^3 dpm) in 0.1 ml of 0.05 *M* phosphate buffer (pH 7.4), and sufficient buffer to achieve a final volume of 1.0 ml. The solutions were allowed to equilibrate at 4° overnight, and then 0.2 ml of dextran-coated charcoal suspension was added with thorough mixing. The tubes were allowed to stand at 4° for 10–12 min, and the charcoal was separated by centrifugation. Antibody-bound radioactivity contained in the supernate was determined by scintillation counting.

Standard curves were plotted on log-probit paper as unlabeled indomethacin added *versus* percent of control binding ($100 \times B/B_0$, where B = bound antigen in the presence of unknown sample, and B_0 = bound antigen in the absence of unlabeled drug).

Radioimmunoassay of Urine—*Unconjugated Indomethacin*—One aliquot (1 ml) of each appropriately diluted urine sample (5–300 ng/ml) was treated with 0.2 ml of 1 *M* citrate buffer (pH 5.0) and extracted with 3 ml of benzene–2-propanol (9:1). The organic phase was allowed to evaporate, and the residue was dissolved in 0.1 ml of 0.05 *M* phosphate buffer (pH 7.4). Radioimmunoassay was performed as described for plasma.

Total Indomethacin—A second 1-ml aliquot (5–300 ng/ml) was treated with 1 ml (5000 units) of β-glucuronidase in the same buffer as was used for unconjugated indomethacin for 3 hr at 37° to hydrolyze the glucuronide conjugate. Thereafter, this aliquot was treated in an identical manner as the first.

Indomethacin Glucuronide—The numerical difference between results of total and unconjugated procedures represents conjugated indomethacin.

RESULTS

Antibodies to indomethacin could be detected in two of five rabbits 8 weeks after immunization. With continued boosting, antibody titers increased slowly up to about 4 months, at which time a final antiserum dilution of 1:120 bound 35% of added 2-^{14}C-indomethacin in the absence of unlabeled drug. Antiserum was used at this dilution for routine assay.

Standard curves for detecting indomethacin in human plasma were prepared as described under *Experimental*. Significant displacement was seen with 5 ng of added indomethacin, and the curves were linear (r = 0.98) up to about 300 ng. Thus, the useful range of the method is 50–3000 ng/ml plasma. Nonspecific binding to antiserum was less than 5%, indicating that there were no interfering substances in normal plasma. Assay of standards prepared in urine resulted in standard curves that were slightly displaced from plasma curves but had identical slopes. Thus, separate standard curves are required for urine and plasma.

Recovery and reproducibility of the assay were determined by 10 replicate assays of known indomethacin samples in pooled normal plasma:

standard concentration, ng	7	25	100
mean ± *SD* of 10 assays, ng	9.5 ± 0.9	29 ± 1.5	98 ± 7.0
CV, %	9.5	5.2	7.1
recovery, %	135 ± 13	115 ± 6	98 ± 7

Recovery was rather poor at lower indomethacin levels due, in part at least, to errors in sample preparation as well as variations in the assay itself.

Potential interference of metabolites and other substances with the assay was evaluated by determining the concentrations of these compounds necessary to displace 50% of the bound 2-^{14}C-indomethacin from the antibody (Table I). The *O*-desmethyl metabolite (IV) was 12% as reactive as indomethacin, whereas the deschlorobenzoyl metabolite (V) was nonreactive. Salicylate, which is sometimes present in indomethacin plasma samples (following simultaneous aspirin administration), also did not interfere with the assay. However, several ester and amide derivatives of indomethacin were highly cross-reactive. The glycoside de-

Table I—Cross-Reactivity of Indomethacin–I Antiserum

Compound	R_1	R_2	R_3	Mass Required to Displace 50% of Bound 2-^{14}C-Indomethacin, ng	Relative Cross-Reactivity, %
III	CH_3		OH	35	100
IV	H		OH	296	12
V	CH_3	H	OH	>20,000	<0.2
VI	CH_3			9	390
VII	CH_3			3	1170

rivatives (VI and VII) were several times more reactive than indomethacin. Thus, the glucuronide conjugate of indomethacin, which accounts for at least 50% of the drug-derived material excreted in urine, might be expected to interfere with the determination of urine indomethacin levels.

To explore this possibility, indomethacin and indomethacin glucuronide concentrations were determined in human urine by both radioimmunoassay and reverse isotope dilution (2) (Table II). In this study, 2-^{14}C-indomethacin (25 mg, 1 μCi/mg) was administered intravenously; urine was collected over the 0–2-hr period. The specific activity of the injected indomethacin was <2% of that used in radioimmunoassay and, therefore, did not interfere.

Both methods afforded comparable total indomethacin concentrations following glucuronidase treatment of the samples. Unconjugated indomethacin was determined by extraction of the urine samples with benzene–2-propanol (9:1) prior to analysis. Similar results were obtained by both methods. The slightly high radioimmunoassay value may have been due to 10% interference by IV (2.6 μg equivalent/ml as determined by reverse isotope dilution).

Direct radioimmunoassay or reverse isotope dilution of untreated urine samples should also afford unconjugated indomethacin concentrations if the glucuronide conjugate does not interfere with either method. Values obtained by reverse isotope dilution (3.7 μg/ml) were as expected, but results of the radioimmunoassay analysis were much too high (17.3 μg/ml). Thus, the assay is highly cross-reactive to indomethacin glucuronide. Whether this effect involves perturbation(s) of the indomethacin–antibody or indomethacin–charcoal equilibria or both is not apparent.

The difference between free indomethacin measured by radioimmunoassay after extraction (4.63 μg/ml) and total indomethacin in unextracted samples (17.3 μg/ml) represents the apparent glucuronide level. This value (12.7 μg equivalent/ml) is 3.25 times higher than the true conjugate concentration (3.91 μg equivalent/ml). Radioimmunoassay of indomethacin in unextracted urine samples, therefore, will result in high estimates of indomethacin concentrations. Furthermore, the small but significant cross-reactivity to the desmethyl metabolite (Table I), which is a major constituent of later urine samples (2), precludes the use of direct radioimmunoassay for specific measurement of indomethacin in urine. However, urine concentrations can be determined by analyzing aliquots before and after conjugate hydrolysis as described later.

The utility of the assay for determination of plasma indomethacin concentrations was also demonstrated by a comparison of results obtained by radioimmunoassay and reverse isotope dilution following administration of labeled drug (Fig. 1). Results from the two procedures were in excellent agreement (r = 0.995).

DISCUSSION

The production of antiserums to indomethacin has permitted development of a simple and sensitive method for the determination of this drug in biological fluids. The present sensitivity (50 ng/ml) is adequate for pharmacological levels commonly encountered but could be improved by the use of radiolabeled indomethacin of greater specific activity.

The indomethacin radioimmunoassay is not a totally specific method. The described antiserum is not reactive with V but is about threefold more reactive with indomethacin glucuronide than with indomethacin

Table II—Indomethacin and Indomethacin Glucuronide Concentrations in Urine[a]

Method	Total Indomethacin[b] and Indomethacin Glucuronide	Unconjugated[c] Indomethacin	Indomethacin[d] Glucuronide	Indomethacin[e] and Indomethacin Glucuronide	Indomethacin[f] Glucuronide

itself. Furthermore, IV exhibits 12% cross-reactivity to the antibody used, and some animals produce serums with 100% cross-reactivity to IV. Even animals with serums of good selectivity produce less selective antibodies over time. Therefore, care must be taken to select appropriate antiserums. Several animals should be immunized, and bleedings should be taken very early.

The cross-reactivity of the antiserum with indomethacin glucuronide is not surprising, since the material used for immunization of rabbits was an acyl conjugate of indomethacin and I. Thus, antibodies were expected to be more reactive to amide and ester derivatives than to the free acid of indomethacin. This supposition was verified by cross-reactivity studies in which glycosyl esters were bound more tightly to the antibody than was free indomethacin and by experiments with human urine samples.

Indomethacin and its conjugate in urine can be estimated accurately by analyzing two sample aliquots as described under *Experimental*. One aliquot is extracted with benzene–2-propanol, thus providing a measure of unconjugated indomethacin. The second aliquot is treated with β-glucuronidase to hydrolyze the conjugate before assay. The value obtained by the latter procedure represents total indomethacin, and the difference between the two values is an estimate of indomethacin glucuronide concentration.

Plasma samples can be analyzed directly without extraction. The small amount of interference (12%) caused by IV would not generally be a problem, since plasma levels of this metabolite only begin to approach indomethacin concentrations about 6 hr after administration of the parent drug, whose plasma half-life is about 2 hr (2). Urinary concentrations of indomethacin are also much greater than concentrations of IV for the first 4 hr. However, IV equals or exceeds indomethacin levels for the 4–48-hr period; IV will, therefore, interfere with the radioimmunoassay procedure outlined for urine.

If differentiation is necessary, a combined isotope dilution–radioimmunoassay method analogous to that described for sulindac (9) could be used. In this case, metabolites are separated chromatographically prior to radioimmunoassay, thus allowing the determination of each compound if suitable antiserums and labeled antigens are available.

Sustained-Release Hormonal Preparations XV: Release of Progesterone from Cholesterol Pellets *In Vivo*

A. A. JOSEPH *, J. L. HILL ‡, J. PATEL §, S. PATEL ¶, and FRED A. KINCL ˣ

Abstract □ Progesterone–sterol pellets were made that provided a zero-order release of progesterone for 80 days. 4-^{14}C-Progesterone was used to measure the release *in vitro* and *in vivo*. The dissolution rate *in vitro* (distilled water as the desorbing medium) for progesterone–cholesterol (59:41 w/w) and progesterone–β-sitosterol (47:53 w/w) pellets was 72 μg/100 mm^2/24 hr. The average *in vivo* absorption from subcutaneously implanted pellets in rabbits was 2 ± 0.1 μg/ml of plasma/cm^2 of surface area. Of this amount, 20–25% was progesterone; the remainder was progesterone metabolites and conjugates. Zero-order release (plasma levels) was obtained for approximately 80 days or until about 70% of the available progesterone was exhausted. During this time, the level of excreted radioactivity in urine continuously decreased, indicating that monitoring only this parameter would lead to erroneous conclusions. A long-term effect and increased effectiveness were obtained with a 5–20-mg progesterone equivalent dose, using gel prepared from 2% methylcellulose as the suspending medium.

Keyphrases □ Progesterone—in sustained-release cholesterol implant pellets, *in vivo* and *in vitro* release, biological effectiveness, rabbits and rats □ Cholesterol—implant pellets containing progesterone, *in vivo* and *in vitro* release and biological effectiveness, rabbits and rats □ Dosage forms—sustained-release progesterone–cholesterol implant pellets, *in vivo* and *in vitro* release and biological effectiveness of progesterone, rabbits and rats □ Sustained-release implant pellets—progesterone–cholesterol, *in vivo* and *in vitro* release and biological effectiveness of progesterone, rabbits and rats □ Hormones—progesterone in sustained-release cholesterol implant pellets, *in vivo* and *in vitro* release, biological effectiveness, rabbits and rats

Over the past several years, the biological effectiveness of drugs as a function of dosage form has been evaluated. In most studies, subcutaneously implanted sustained-release poly(dimethylsiloxane) capsules were used as the drug carrier (1). Animal studies demonstrated a significant increase in the potency of steroid hormones given in a sustained-release form; when released continuously from silicone rubber implants, considerably less hormone was needed to produce a given biological effect than when the same compound was given by injection or orally (2). The lower dose resulted in lower plasma levels and less accumulation of the steroid and of its metabolites in various organs (3).

Steroid–lipid implants as drug carriers have also been used (4–8). Mixing of steroids and lipids in arbitrary proportions resulted in steroid release in sufficient amounts to provide a pharmacological effect, but "the reproducibility of pellets of the same composition but made at different times varied . . . ." (4).

The present experiments were designed to test the release and biological effectiveness of steroid–sterol pellets combined in the region of eutectic mixtures.

EXPERIMENTAL

Pellet Preparation—Weighed amounts of progesterone and the respective sterol were dissolved in minimal amounts of chloroform. The solvent was removed by evaporation in a rotary evaporator, and the resulting crystalline mass was dried at 37°. The dry powder was transferred into a hand press preheated to about 100°. The temperature of the brass block was then slowly raised until the mass began to soften (115–120°). The soft mass was extruded through a perforated disk; the emerging rods (3 and 1 mm thick), which cooled and hardened rapidly, were cut into 1–3-mm long, cylindrical sections and marumerized to spherical pellets.

Marumerizer—The marumerizer was made from a Plexiglas block containing a circular chamber 6.4 cm in diameter. The wall was inlaid with aluminum oxide-coated abrasive[1]. For operation, the chamber was loaded with about 2–5 g of material; a current of air led in through tangential air inlets imparted a rapid rotation to the pellets. The average time for a 3-g load was 15 min with an air flow of about 200 liters/hr.

To minimize the loss of material, the outlets of the marumerizer were connected to a small Plexiglas cyclone separator. Five different pellet sizes between 177 and 1705 μm were obtained by screening marumerized material through a set of analytical sieves.

Preparation of Radioactive Progesterone—A known amount of 4-^{14}C-progesterone was added to cold progesterone dissolved in chloroform. The solvent was removed by distillation in a rotary evaporator, and the crystalline material was dried *in vacuo*. Specific activity of the resulting material was determined by weighing two or three samples on an analytical microbalance. Weighed samples were dissolved in toluene, and the radioactivity was determined.

Determination of Radioactivity—Toluene-based scintillation medium containing 1% of a fluor was used; plasma samples (1 ml) were solubilized with 1 ml of a tissue solubilizer[2] by digesting at 45–50° for about 1.5 hr. When a clear solution was obtained, 10 ml of a medium[3] was added. Prior to counting, the samples were kept at 0° for approximately 24 hr to eliminate photoluminescence. Urine and feces samples (*vide infra*) were decolorized with 30% aqueous hydrogen peroxide solution (0.5 ml) by incubating at 37° for 48–64 hr. A solubilizing solution (10 ml) prepared from two parts of toluene and one part of a surfactant[4] and containing 1% of a fluor was added. Counting efficiency (liquid spectrophotometer[5]) was determined by using external (and where appropriate, internal) standards. The efficiency in toluene scintillation medium was 80–85%; the efficiency in aqueous scintillation medium was 20–45%.

Studies *In Vitro*—A known weight (and number) of pellets was gently shaken[6] in 100 ml of distilled water at room temperature. To determine the amount of progesterone in the desorbing medium, 2-ml aliquots were taken periodically. Water was evaporated (IR lamps), and the radioactivity present was counted upon addition of toluene scintillation medium. Fresh desorbing medium was used every 24–72 hr. Other conditions were as stated previously (4).

Metabolic Studies in Rabbits—With the use of a local anesthetic[7], ethylene oxide-sterilized pellets (suspended in a sterile medium prepared from 2% aqueous gel of methylcellulose; 0.75 ml of the medium to suspend 100 mg of pellets) were implanted in the left hindleg of rabbits[8] by means of a thin walled No. 9 trocar. One-milliliter graduated pipets were used to deliver the desired amount. The wound was closed by clips[9].

Two rabbits were implanted with 23 and 27 tablets (compressed in a small press, hardness >5 kg) having a surface area of 456 and 535 mm^2, respectively. Two rabbits were implanted with 67 and 70 pellets with an average diameter of 1705 μm (surface area of 612 and 639 mm^2, respectively), and two rabbits were implanted with 78 and 94 pellets with an average diameter of 1205 μm (surface area of 356 and 429 mm^2, respectively). The average hardness of the pellets was <1 kg.

The animals were kept in metabolic cages, and water and food were given *ad libitum*. Peripheral blood (by ear puncture), urine, and feces were collected as stated. For blood collection, the ear and the collection

vessel were siliconized to minimize hemolysis. Citrate solution, 1 ml/10 ml of blood, was added, and plasma was separated by centrifugation. At autopsy, body weights were recorded and blood was collected by heart puncture. Liver and kidneys were excised, weighed, and frozen. The implantation site was examined for capsule formation, and the pellets were collected.

Sample Preparation—*Urine*—Weekly collections were combined, and the volume was reduced about fourfold by evaporation in a rotary evaporator under reduced pressure. The resulting volume was recorded, and a 30-ml aliquot was diluted with 70 ml of absolute ethanol. The solution was kept for 48 hr at −20° to precipitate the proteins and was then centrifuged, and the clear supernate was separated. Radioactivity was determined in 2-ml aliquots.

Feces—Feces collected separately two or three times a week were combined and weighed. A 30-g sample was ground in a blender[10] with 100 ml of 70% aqueous methanol, and the resulting slurry was centrifuged. An aliquot of the clear supernate diluted with an equal volume of absolute methanol was kept at −20° for 48 hr. Radioactivity was determined in 1-ml aliquots.

Implantation Site—Surrounding tissue, including the pellets, was excised; the tissue was exhaustively extracted at room temperature with acetone–dichloromethane (1:3), the extracts were combined, and the solvent was removed by evaporation. Then the residue was redissolved in methanol, the volume was brought to 10 ml, and the residual radioactivity was determined by counting 1-ml aliquots in a toluene scintillation medium.

Calculations—Data were usually expressed in micrograms of progesterone per milliliter of plasma per surface area of the implant in square centimeters. *In vivo* data were analyzed with a two-factor repeated-measures design analysis of variance (9). Factors found to be significant were further analyzed with Duncan's new multiple range tests (10). All data met the assumptions of variance homogeneity and independence of means and variance (11, 12).

Two separate analyses were performed because data for some individuals were not collected for the entire experimental period. Data for all six animals were available for the first 5 weeks, and these data were utilized in one analysis. Data for four animals, the two given hard tablets and the two given large (1705-μm diameter) pellets, were available for Weeks 6 and 8–10. These data were analyzed independently.

The amount of radioactivity excreted in urine was submitted to regression analysis to determine if there was a significant change in the amount of progesterone excreted as a function of time. Data were expressed as $\log_{10}$ micrograms of progesterone equivalent per day per 100-mm² surface area of implanted pellets. Only the data from four animals, the two given hard tablets and the two given large pellets, were available for the entire period, and only these data were analyzed.

Biological Experiments—Pellets having an average particle size of 750 μm suspended in 2% aqueous methylcellulose gel were used in all experiments. Subcutaneous insertion was used in both tests.

Antiovulatory Tests—Following subcutaneous insertion, ovulation was induced in rabbits (different periods of therapy) by intravenous injection of 0.3 ml of 1% copper acetate–sodium chloride solution (13). Laparotomy was performed 18–24 hr after the injection, and the ovaries were examined for ovulation points.

Maintenance of Pregnancy—Rats[11] were bilaterally ovariectomized (ether anesthesia) on Day 5 following insemination, and progesterone pellets were inserted in the neck region. At autopsy, on Day 18 of the test, the number of viable (and resorbing) fetuses was counted and recorded. On the day of the ovariectomy and 1 week later, some animals received (in addition to progesterone) 1 μg of estradiol benzoate dissolved in 0.2 ml of sesame oil. A small group of ovariectomized animals with no treatment was included for comparison.

RESULTS

The present studies confirmed previous observations (4) that the amount of progesterone found in the desorbing medium is dependent upon the frequency of sample collection and the total pellet surface area exposed to the desorbing medium. As noted (4), dissolution rates were high during the first few days of the test, most likely due to the liberation of small particles loosely attached to the surface of the pellets; after a few days, the values became more uniform and variations between different samples of the same pellet size from day to day were small. In addition to the sampling frequency, the *in vitro* release rate was also influenced by the volume and temperature of the desorbing medium and the frequency (or speed) of agitation.

Table I shows average dissolution of progesterone from cholesterol (41% w/w) and β-sitosterol (53% w/w) pellets of various sizes based on 4- and 6-hr sampling (observation period of 6–28 days) calculated as micrograms of progesterone released per 24-hr interval from 100-mg pellets. The relative dissolution rate of progesterone per unit weight increased with the decrease in pellet size. This finding is in accord with the observation that the dissolution rate is dependent upon the surface area of the pellets; smaller pellets have a large surface area per unit weight. When calculated on the basis of unit area (100 mm²), good correlation between the various sizes was obtained.

Progesterone absorption (as total radioactivity) from pellets of three different sizes, monitored by measuring plasma levels, is shown in Table

II. The release of radioactive material was high the 1st day after implantation; there was then a decrease in circulating levels, which remained stable until about Day 80. On Day 90, the amount of radioactivity in peripheral blood was found to be declining. Statistical evaluation (calculated in terms of unit surface area) revealed no differences in values between the three types of pellets used. The high levels noted immediately after implantation were significantly higher ($F = 6.79$, $df = 41$, $p < 0.005$) as compared to Weeks 1–4. This difference resulted because the plasma level for Week 0 was significantly greater ($\bar{x} \pm SE = 3.8 \pm 0.6$ μg/ml/cm^2) than that of the other 4 weeks, which did not differ from each other (overall $\bar{x} \pm SE = 2.1 \pm 0.2$ μg/ml/cm^2).

For Weeks 6 and 8–10, there was no significant difference between individual animals and there was no significant difference due to the time factor. The mean overall plasma level of 2.0 ± 0.1 μg/ml/cm^2 for this period did not differ significantly from that for Weeks 1–4 ($t = 0.75$, $df = 38$, $p > 0.40$). These data indicate that high plasma progesterone levels are reached shortly after implantation. Within less than 1 week, the plasma progesterone level decreased to a stable level, which was maintained for at least 10 weeks.

Of the total radioactivity in plasma, about 40% was ether extractable. The remaining 60% was in the aqueous phase, presumably associated with polar progesterone metabolites and conjugates. Partial purification of the ether extract by TLC in silica separated 40–60% of material with the same mobility as progesterone. This result indicates that the 100-mm^2 surface area of pellets provided 0.3–0.5 μg of progesterone/ml of plasma; the balance was presumably free and conjugated progesterone metabolites.

Elimination of radioactive progesterone metabolites was significantly lower in feces than in urine (Table III). The average values were below 5% for Animals 1–4 and less than 10% for Animals 5 and 6. Since excretion of progesterone metabolites in feces represented usually less than 5% of the total metabolic products (occasional higher values being due most likely to contamination from urine), the metabolic cages were modified to minimize this possibility; feces were not collected during the last 2 weeks of the experiment.

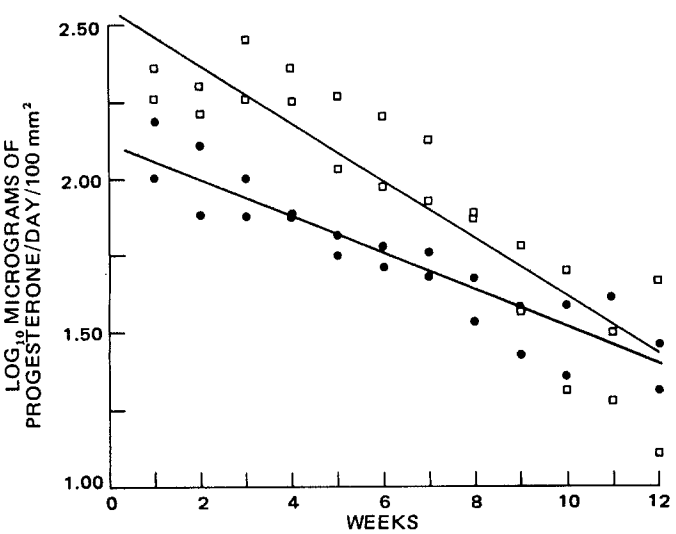

Figure 1—*Excretion of radioactivity in rabbits implanted with progesterone–cholesterol acetate pellets. Key: ●, Animals 1 and 2 (hard tablet); and □, Animals 3 and 4 (large pellet).*

The patterns of excreted radioactivity, expressed as $\log_{10}$ micrograms of progesterone per day per 100-mm^2 surface area implanted pellets, are shown in Fig. 1. There was a significant difference between the slopes of the two regression lines shown ($t = 4.06$, $df = 44$, $p < 0.001$); the amount of progesterone excreted by the animals implanted with the large pellets was initially at a higher level and declined more rapidly than in those animals implanted with the hard tablets. For both treatments there was no significant deviation from linearity; the r^2 values (the proportion of the variation in progesterone excreted explained by a linear relationship with time) were 0.81 for Animals 1 and 2 and 0.86 for Animals 3 and 4.

There was a significant increase in body weight during the 10-week experiment. The average initial body weight was 1430 g (1110–1680 g), and the final body weight was 2100 (1860–2445 g); this difference represents an average increase of 47%. Because the animals implanted with the large pellets had a higher average proportional weight increase than did those implanted with the hard tablets (60 *versus* 50%), the data were submitted to the following transformation to adjust for any differential effects of weight gain. For each individual for each week, the amount of progesterone excreted ($\log_{10}$ micrograms progesterone equivalent per day per 100-mm^2 surface area of implanted pellets) was multiplied by the estimated weight of that individual for that week and divided by that individual's initial weight.

Only initial and final body weights were recorded, so estimation of an individual's weight for each week was made by linear interpolation. For the data so treated, the regression equations are: for the hard tablet, $y = 2.10 - 0.005x$; and for the large pellets, $y = 2.59 - 0.029x$. The difference between the slopes is not significant ($t = 1.46$, $df = 44$, $p > 0.10$), which suggests that the difference in the slopes of the excretion rates in Fig. 1 is probably a function of the difference in weight gain.

Pellets were routinely recovered from the deposits under the skin; some migrated into the proximal muscle. In a few animals, the implant site was covered with a thin membrane, forming a pouch. No macroscopic manifestation of an inflammatory reaction at the implantation site was observed in any animal. The amount of radioactivity left in the remaining pellets varied from 4 to 27%. The overall recovery of ^{14}C-radioactive material in urine (and feces) and from the subcutaneous tissue at implant site varied from 70 to 99%; the average value was about 85%.

The results of antiovulation tests in rabbits are summarized in Table IV. The weights of pellets used in the experiment were 25, 75, and 225 mg, representing a dose of progesterone from 13.5 to 121.5 mg. Ovulation was inhibited for at least 45 days (duration of experiment) at the highest dose used. Based on the *in vivo* release data, it can be assumed that this dose released about 145 μg of progesterone/day.

Gravid rats deprived of progesterone by ovariectomy lost the ability to maintain pregnancy, and fetuses were rapidly resorbed; none was viable after 2 weeks (Table V). A single dose of 25 mg of progesterone pellets (13.5 mg progesterone equivalent) provided an incomplete fetal support;

Table IV—Duration of Antiovulatory Activity with Progesterone–Cholesterol Pellets

Progesterone Dose, mg	Rabbits Used	Average Ovulation ± *SE*	
		15 Days	45 Days
0	6	4.5 ± 0.4	6.5 ± 0.7
13.5	4	2.5 ± 0.4	4.0 ± 1.0
40.5[a]	5	0.5 ± 0.1	2.0 ± 0.3
121.5	5	0.0	0.0

[a] Estimated daily release, 450 μg.

Table V—Pregnancy Maintenance in Ovariectomized Rats with Progesterone–Cholesterol Pellets

Progesterone Dose, mg	Number of Rats			Mean Number (Range)	
	Total	with Fetuses	with Resorbed Fetuses	Fetuses	Resorbed Fetuses
4	6	0	0	0	0
13.5	6	0	3	0	7.2 (0–14)
13.5[a]	5	4	4	3.8 (3–13)	4.2 (0–6)
27.0[b]	4	2	4	4.5 (4–5)	4.8 (2–9)
27.0[a]	5	5	4	11.6 (10–14)	1.2 (0–2)
54	8	3	5	3.8 (0–8)	6.9 (3–12)
54[a]	3	3	0	12.0 (11–13)	0

[a] Indicates groups injected twice with 1 μg of estradiol benzoate. [b] Estimated daily release, 300 μg.

only resorption sites were found at autopsy. Addition of 1 μg of estradiol at weekly intervals was sufficient to increase significantly fetal salvage. In animals given 50-mg pellets (27 mg progesterone equivalent), there was an average of 11.6 live fetuses (a value usually seen in our colony) and only a few resorbing sites. Based on the same assumption as already given, the dose used was about 32 μg of progesterone/day.

DISCUSSION

Properties that influence absorption rates of drug implants, such as area, dissociation constant, solubility, and the diffusion coefficient, have been recorded (14). Most investigators considered absorption of materials released from pure crystalline implants of spherical shape. Mathematical relationships have been derived to predict the rates, but such relationships are not valid for drug systems combining two substances of unequal dissolutions.

Progesterone dissolution from steroid–sterol pellets was more rapid than sterol dissolution. When a "diffusion" constant was calculated using the slope of the regression line of cumulative release rate ($b^2\pi/16/3600$), similar values were obtained for progesterone regardless of pellet diameter. The values varied from 1.90×10^{-11} to 2.22×10^{-11} cm^2/sec for 750-, 1205-, and 1705-μm diameter pellets independent of period. The calculated value for 375-μm diameter pellets was 1.05×10^{-11} cm^2/sec, while the value for a "powder" (particle size <177-μm diameter) was 3.48×10^{-12} cm^2/sec. Corresponding values for β-sitosterol pellets (1205 and 1705 μm) were 1.87×10^{-11} and 1.99×10^{-11}, respectively.

Measurement of radioactivity in peripheral plasma showed a steady dissolution of progesterone, indicative of zero-order release rates in the presence of continuously declining excretion of radioactive material in urine and feces. The overall decline in the amount of progesterone excreted with time was most likely associated with the increase in body weight of the individuals. The difference in the origins in the regression equations (Fig. 1) suggests that animals implanted with the large pellets had a higher rate of progesterone excretion than did animals implanted with the hard tablets. However, this possible difference was not a function of any difference in circulating levels of progesterone in plasma, because these levels did not differ significantly as a function of treatment difference. Also, circulating plasma progesterone levels did not change as a function of time, as did the levels of excreted progesterone, which further indicates that plasma and excretory levels may vary independently.

Weight gain could have been the result of progesterone therapy; overeating and weight gain induced by progesterone have been observed in several species (15). Since there was no control group in these experiments and food consumption was not measured, additional experiments would be needed to confirm this conclusion. However, it is well documented that many steroid hormones, including progesterone, are deposited selectively in lipid tissues. In the present study, the concentration of radioactivity in intestinal fat (five observations) was 0.4 μg progesterone equivalent/g of fat. This observation supports the data showing that, in part, released progesterone was stored in the continuously formed lipid tissue.

These observations lead to the conclusion that, in studying absorption dynamics from implanted material, measurement of plasma levels provides more reliable information than measurements of excretion rates.

Progesterone was released from the pellets in a sufficient amount to exert biological effects. The effectiveness of sustained-release progesterone in maintaining pregnancy in ovariectomized rats was potentiated by injecting small amounts of estradiol as reported by others (16). Based on previously published data, it is possible to estimate that progesterone in a lipid delivery system is about 20 times more active than a daily injection of progesterone dissolved in oil. This value is in good agreement with previous findings (2).

Dissolution Rates of Corticosteroids Utilizing Sugar Glass Dispersions

LOYD V. ALLEN, Jr. ˣ, VICTOR A. YANCHICK *, and DALE D. MANESS *

Abstract □ A method of increasing the dissolution rates of some orally administered corticosteroids was investigated. This method involved glass dispersions using dextrose, galactose, and sucrose as the carriers. These dispersions were prepared by the fusion process and were subjected to a modified NF XIII dissolution rate determination. The results revealed a marked increase in the dissolution rate of the corticosteroids contained in the solid dispersions when compared to the dissolution rate of the plain corticosteroid powder. The increase in dissolution rates was attributed to the presence of the corticosteroid in a very fine state of subdivision and to the increased wettability of the corticosteroid powder.

Keyphrases □ Corticosteroids, various—glass dispersions using sugar carriers, dissolution rates compared to plain powder □ Glass dispersions—various corticosteroids, sugar carriers, dissolution rates compared to plain powder □ Dissolution rates—various corticosteroids, glass dispersions using sugar carriers compared to plain powder □ Sugars—dextrose, galactose, and sucrose as carriers in glass dispersions of various corticosteroids, dissolution rates compared to plain powder □ Solid-state dispersions—various corticosteroids, sugar carriers, dissolution rates compared to plain powder

In 1961, Sekiguchi and Obi (1) introduced a unique approach of utilizing solid dispersions to reduce the particle size of drugs and to increase their dissolution and absorption rates. They proposed the formation of a eutectic mixture of a poorly soluble drug, such as sulfathiazole, with a physiologically inert, easily soluble carrier, such as urea.

The possibility of using a solid solution approach in which a drug is molecularly dispersed in a soluble carrier was subsequently introduced (2, 3). A series of reports (4–7) presented a detailed discussion of the advantages of the solid solution over the eutectic mixture.

A method was reported for preparing aqueous colloidal dispersions of β-carotene by using water-soluble polymers, *e.g.*, povidone (8). The dissolution rate of griseofulvin was enhanced markedly when dispersed in povidone by the same solvent method (9). The term "solid-state dispersions" was used to refer to these solid dispersions. The mechanisms of increased dissolution rates of drugs solid dispersed in povidone carriers were reviewed (10). Additional studies supported the significance of the solid dispersion technique (11–19).

The concept of glass solutions was introduced recently to increase dissolution rates (14). This concept also was discussed in an extensive review of the pharmaceutical applications of solid dispersions (20). In this investigation, when a melt of a griseofulvin–citric acid mixture, which was highly viscous, was solidified, it was transformed into a glassy state. This glassy state, or glass solution, exhibited a very rapid dissolution rate with griseofulvin. The glass dispersion technique was used successfully with sulfabenzamide (21).

The corticosteroids are considered to be generally poorly water soluble and have demonstrated unpredictable dissolution rates (22–27). Polyethylene glycol solid dispersions were used to increase the dissolution rates of prednisolone acetate and hydrocortisone acetate (15). The purpose of this investigation was to apply the glass dispersion technique to alter the dissolution rates of several orally administered corticosteroids, *e.g.*, betamethasone acetate, cortisone acetate, hydrocortisone acetate, methylprednisolone acetate, prednisolone, and prednisone. Conceptually, this method could result in increased and more predictable dissolution rates, benefiting the therapeutic response.

EXPERIMENTAL

It was desired to use nontoxic, physiologically acceptable carriers that possessed no significant therapeutic effects and had melting points less than or close to the melting points of the corticosteroids used. The latter was considered a requirement since the corticosteroids melt with some decomposition. The use of sucrose and dextrose as glass-forming substances was discussed (14) and, upon investigation, galactose also was found to form a glass upon rapid cooling from a melt. These three sugars also met the other listed criteria.

Preparation of Dispersion Systems—All dispersion systems were prepared by the fusion method as follows. A suitable amount of the drug–carrier mixture [in a ratio containing 6 mg of betamethasone acetate or methylprednisolone acetate added to 200 mg of the carriers (sugars), or 5 mg of each of the other corticosteroids added to 200 mg of the carriers] was weighed and placed in a preformed aluminum foil boat, 7 cm in diameter and 2 cm in depth. The materials were mixed thoroughly and placed on a wire screen positioned on a preheated electric heating plate. Heat was applied with constant stirring until a melt was obtained.

This melt was heated further to the following temperatures: dextrose carriers, 185°; galactose carriers, 169°; and sucrose carriers, 200°. This melt was rapidly solidified by placing the boat containing the melt on a hollowed out portion of a block of dry ice. After solidification, the dispersion system was quickly removed from the dry ice to prevent water condensation and placed in a glass desiccator containing a drying agent where it was stored for 24 hr at 37°.

The solid was pulverized to the desired particle size, and the 60–100-mesh fraction (250–150-μm particle size) was collected by standard sieves[1] placed on a sieve shaker[2] and shaken for 5 min. The powder was then placed in an amber, screw-capped glass vial and stored in a desiccator at 25°. The plain corticosteroids used as the controls possessed a particle size of 250–150 μm (60–100-mesh fraction).

Dissolution Rate Determinations—The dissolution rate determinations were carried out using a modified NF XIII dissolution rate apparatus (23).

An appropriate amount of the dispersion system, containing 6 mg of betamethasone acetate or methylprednisolone acetate or 5 mg of the other corticosteroids, was weighed and placed in the basket of the dissolution apparatus. This amount was used because it allowed absorption within the 0.2–0.8 range on a spectrophotometer[3] (all corticosteroids followed Beer's law throughout the concentration ranges used). A thin circular piece of clear plastic was fitted at the bottom of the dissolution basket to prevent the powder from falling out. The temperature and sample flow rate were established, and the basket was lowered into 1000 ml of the dissolution medium (deionized water) to a point 2 cm from the bottom of the kettle and rotated at a constant speed of 100 rpm. There was a lag time of about 4 sec for the sample to reach the flowcell, and a complete circuit required about 10 sec.

As the dispersion system dissolved, the concentration of the corticosteroid in solution was monitored and recorded with a chart recorder[4].

The determinations were made for 90 min and were done at least in duplicate. The wavelengths of maximum absorption used were determined experimentally in aqueous solutions and were: betamethasone acetate, 239 nm; cortisone acetate, 238 nm; hydrocortisone acetate, 243 nm; methylprednisolone acetate, 243 nm; prednisolone, 242 nm; and prednisone, 239 nm. These substances followed Beer's law in the concentration range used.

Short-Term Stability Study—A short-term stability study was performed by storing the powdered dispersion systems at 25° for 30 days and repeating the dissolution rate determinations described.

Corticosteroid Stability Studies—The chemical stability of the corticosteroids during the preparation of the dispersion systems was studied using TLC. Chromatogram sheets[5] were spotted with an aqueous solution of the respective dispersion systems and a methanol solution of the reference corticosteroids. The sheets were allowed to dry at room temperature and placed in a chamber containing chloroform–ether–methanol (6:3:1). The plates were removed, air dried, and visualized under UV light. UV scans of the dispersion systems in deionized water also were obtained before and after preparation of the dispersion systems.

RESULTS

Glass Formation—Dextrose, galactose, and sucrose formed glasses quite readily. Dry ice was used to hasten solidification of all melts so that the systems would not be exposed to atmospheric moisture and contamination longer than necessary. The corticosteroids were not necessarily completely miscible with the carriers in the glass systems because of the generally lower temperatures used in their preparation. Complete melting was not attempted in these cases because of decomposition of the sugars and the corticosteroids at the high temperatures that would be required. All systems were relatively easy to prepare. The glass dispersion systems were hygroscopic and, as such, required storage in a desiccator.

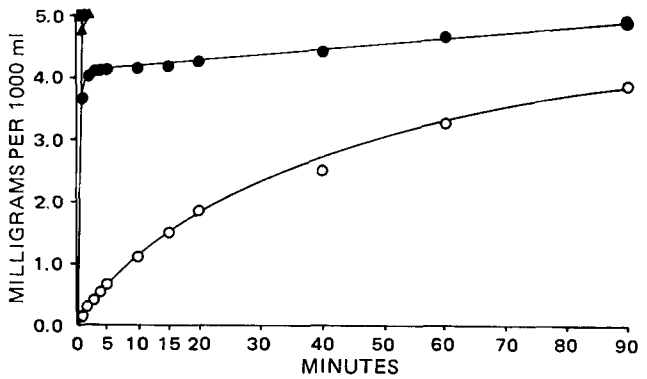

Figure 3—*Dissolution rates of hydrocortisone acetate. Key:* ○, *plain;* ▲, *dextrose carrier;* ●, *galactose carrier; and* ■, *sucrose carrier.*

Dissolution Rate Determinations—As shown in Figs. 1–6, the dissolution rate determinations revealed marked increases in the dissolution rates of all corticosteroids utilizing all three sugar carriers. The dextrose and sucrose glass dispersions possessed the fastest release characteristics for 50 and 100% dissolution (Table I).

Samples of the glass dispersions prepared at different times reproduced these results. The glass dispersion samples assayed after storage for 30 days showed no decrease in the dissolution rates. These amorphous systems may recrystallize upon aging for a longer time. One would expect that a return to the crystalline state would result in a decrease in the dissolution rate of the system. The time required for these systems to return to the crystalline state has not been determined.

Stability of Components—None of the corticosteroids demonstrated any decomposition products after being subjected to the preparation of the dispersion systems according to the analytical methods used. TLC revealed no additional spots, and there was good correspondence with the reference samples. UV spectra of the dispersion systems in deionized water revealed no decomposition products, and the absorbance values were unchanged.

A light-amber discoloration of the melt and of the cooled glass was observed during the dextrose and sucrose glass formation process, possibly indicating slight decomposition of these sugars. This color change did not appear to interfere with the fast release characteristics of the carrier.

DISCUSSION

The dissolution of these powders occurred in two phases: a very rapid initial phase followed by a slower, more prolonged, second phase. The rapid initial rate was attributed to the release of the corticosteroid present in a state of very fine subdivision. With the glass dispersion, a portion of the corticosteroid probably is solubilized during preparation by the molten carrier. Since this melt quickly solidifies, crystallization would be retarded because of the high viscosity of the melt and the very short time interval required for solidification. When this portion of the dis-

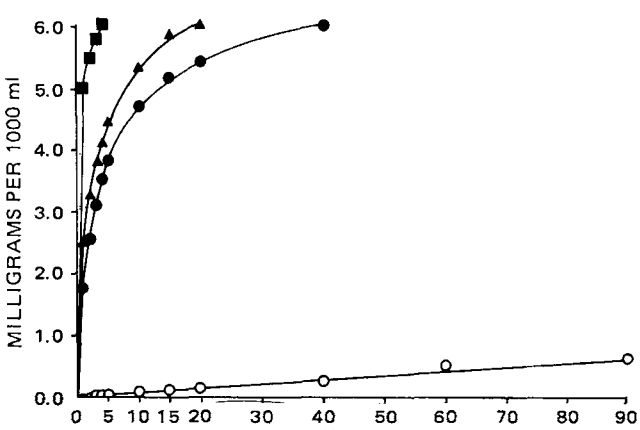

Figure 4—*Dissolution rates of methylprednisolone acetate. Key:* ○, *plain;* ▲, *dextrose carrier;* ●, *galactose carrier; and* ■, *sucrose carrier.*

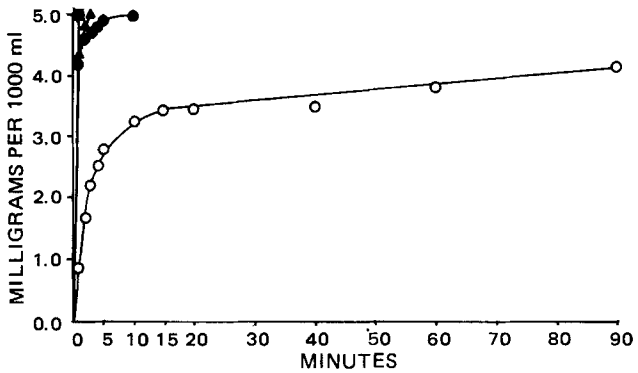

Figure 5—*Dissolution rates of prednisolone. Key:* O, *plain;* ▲, *dextrose carrier;* ●, *galactose carrier; and* ■, *sucrose carrier.*

persion system is exposed to the aqueous medium, the corticosteroid would immediately be released in its molecular state.

The second phase of dissolution, exhibited by most systems, was the more prolonged phase. The dissolution rates of the second phase of the glass dispersions were somewhat more rapid than that of the plain powder. This difference can be attributed to the increased wettability of the corticosteroid powders. Glass carriers may act similarly to wetting agents, as follows.

It is frequently difficult to disperse a finely divided powder in a liquid because of entrapped or adsorbed air or some other contaminant. When a strong affinity exists between a liquid and a solid, the liquid easily forms a film over the surface of the solid. However, when this affinity is nonexistent or weak, the liquid has difficulty displacing the air or other substances surrounding the solid. The sugars used in this investigation are readily soluble in an aqueous medium. During the preparation of the dispersion system, intimate contact was achieved between the sugar and the corticosteroid particles. The high temperatures involved in the preparation process aided in removing adsorbed and entrapped air. Upon exposure of this system to an aqueous medium, the sugar rapidly dissolved and a complete wetting of the corticosteroid occurred at the same time.

The temperatures reached during the preparation of the melts were greater than the melting points of the sugars but less than the melting points of the corticosteroids. There were two main reasons for reaching this temperature before quenching the melt. First, since this temperature was somewhat less than the melting point of the corticosteroids, decomposition of the corticosteroid did not occur or was negligible. This factor was desirable since the corticosteroids decompose to some degree at their melting points (22). Second, the sugars could not be heated much higher than the preparation temperatures because of decomposition, manifested by an amber discoloration. The temperatures used were a compromise between the melting points of the corticosteroids and the decomposition ranges of the sugars.

These solutions were not glass solutions, since complete melting of both components did not occur and a molecular dispersion of the corticosteroid in the glassy carrier did not result. The portion of the corticosteroid molecularly dispersed in the glass carriers could account in part for the extremely rapid initial release rate. This phase was followed by a slower rate of release of the dispersed particles.

Table I—50 and 100% Dissolution Times (Minutes) for Corticosteroids in Glass Dispersions

Corticosteroid	$t_{50\%}$	$t_{100\%}$
Dextrose carrier		
Betamethasone acetate	<15	>90
Cortisone acetate	<2	20
Hydrocortisone acetate	<1	2
Methylprednisolone acetate	<2	20
Prednisolone	<1	3
Prednisone	<1	3
Galactose carrier		
Betamethasone acetate	<2	20
Cortisone acetate	<4	>90
Hydrocortisone acetate	<1	>90
Methylprednisolone acetate	<3	40
Prednisolone	<1	10
Prednisone	<1	15
Sucrose carrier		
Betamethasone acetate	1	15
Cortisone acetate	<1	10
Hydrocortisone acetate	<1	<1
Methylprednisolone acetate	<1	4
Prednisolone	<1	1
Prednisone	<1	2

In view of present-day considerations of the effect of dissolution rates on drug bioavailability, these glass dispersions offer a unique opportunity of making available an extremely fine state of subdivision of active ingredients and a unique method of increasing the wettability of the active ingredients. The sugars enjoy many advantages over other forms of solid dispersion carriers in addition to their being relatively nontoxic, inexpensive, and physiologically acceptable. They have long been utilized in the preparation of pharmaceutical dosage forms, and the only difference in their past use and the newly proposed use is in the physical state. In the past, they have been used in physical mixtures; now it is suggested that they be used as solid dispersion carriers in a glassy state. These solid dispersions should be considered as potential dosage form modifications for the corticosteroids and for other poorly soluble or insoluble drugs with fairly high melting points where an increase in the dissolution rate is desirable.

Distribution, Dilution, and Elimination of Polychlorinated Biphenyl Analogs in Growing Swine

L. G. HANSEN ˣ and M. E. WELBORN

Abstract □ Growing swine were given 15 mg/kg po of purified polychlorinated biphenyl analogs and a commercial mixture. Backfat biopsies for 16–18 weeks exhibited two-compartment elimination kinetics when based on concentration. Total body fat was estimated from potassium-40 abundance, and the calculated total fat load indicated that most of the decline in residue concentrations was due to dilution by growth and expansion of the fat compartment. Redistribution in the fat was apparent for various analogs at different times, and tissue distribution varied significantly among analogs.

Keyphrases □ Biphenyls, polychlorinated—tissue distribution, dilution by growth, and elimination, swine □ Polychlorinated biphenyls—tissue distribution, dilution by growth, and elimination, swine □ Distribution, tissue—various polychlorinated biphenyls, swine □ Elimination—various polychlorinated biphenyls, swine

Stable compounds of low water solubility and high lipid affinity such as chlorinated pesticides and polychlorinated biphenyls comprise a special class of pharmacokinetically distinct xenobiotics. Recent studies involving intravenous and oral administrations of a polychlorinated biphenyl mixture containing 54% chlorine to swine and sheep showed that component peaks were distributed at different rates (1, 2). The smaller isomers of low chlorine content generally distributed at a faster rate than those of higher chlorination and were metabolized to a greater extent (1–4).

The high fat–blood concentration ratios of polychlorinated biphenyls (PCB) make sampling of the fat more meaningful for pharmacokinetic modeling. Because the apparent $t_{1/2}$ for elimination is on the order of weeks when fat concentration alone is presented (5), dilution due to growth is a required parameter for studies of rapidly growing animals such as young swine. In addition, the fat compartment is neither static nor a constant proportion of body weight.

This paper presents methods for evaluating the total amount of three pure polychlorinated biphenyl analogs and a commercial mixture[1] in the fat of growing swine. The "total fat load," L_t, is defined as the weight of chlorinated biphenyl present in the fat compartment. The pharmacokinetic parameters defined from these calculations demonstrate that traditional models must be reconstructed for persistent chemicals in food-producing animals.

EXPERIMENTAL

Fifteen matched weanling pigs of mixed Yorkshire/Hampshire breeding were divided into four experimental and one control group of three animals each. The pigs were fed a wet mash containing 100 ppm of 2,5,2′,5′-tetrachlorobiphenyl (I), 2,4,5,3′,4′-pentachlorobiphenyl (II), 2,4,5,2′,4′,5′-hexachlorobiphenyl (III), and a commercial mixture[1] (IV) for 1 week. The mash was offered every morning and left until totally consumed in quantities sufficient to produce a 2.14-mg/kg/day or 15-mg/kg/week dosing regimen.

Total body fat was estimated by a variation of the potassium-40

[a] $Y_{(fat\ weight)} = B_0 + B_1X_{weeks} + B_2X^2_{weeks\ kg}$.

method of Lohman *et al.* (6). The equation describing the conversion of potassium-40 to total potassium and finally to body fat is:

$$\text{potassium (g)} = \frac{[(A_1 - A_2) + (0.0583B) - (A_3)][C]}{(0.2028 - 0.000174B)(\gamma)} \quad \text{(Eq. 1)}$$

where:

A_1 = total potassium-40 counts per second
A_2 = background potassium-40 counts per second
A_3 = net counting capsule counts per second
B = weight of subject (pounds); $0.0583B$ is background depression factor, correcting for background absorbed by mass of subject

$$C = \frac{\text{net cps of standard on date of calibration}}{\text{net cps of standard on date of subject count}} = \frac{10^5 \text{ cps}}{\text{std cps}}$$

γ = gamma ray disintegrations/sec/g, $K = 3.0$

The $(0.2028 - 0.000174B)$ function was determined experimentally by Lohman *et al.* (6).

Blood samples and bilateral backfat biopsies were taken on Days 3, 7 (last day of treatment), 14, 28, and every 28 days thereafter for 16 or 18 weeks. A pilot study showed that backfat concentrations accurately reflected concentrations of polychlorinated biphenyl in other dissectible fat stores of swine (e.g., mesenteric and perirenal); concentrations within the same pig did not vary anteriorly-posteriorly, but each side varied consistently from the other. Bilateral biopsies were analyzed independently, and the results are reported as an average of the two. Blood and tissues were analyzed by electron-capture GLC as described previously (1, 7).

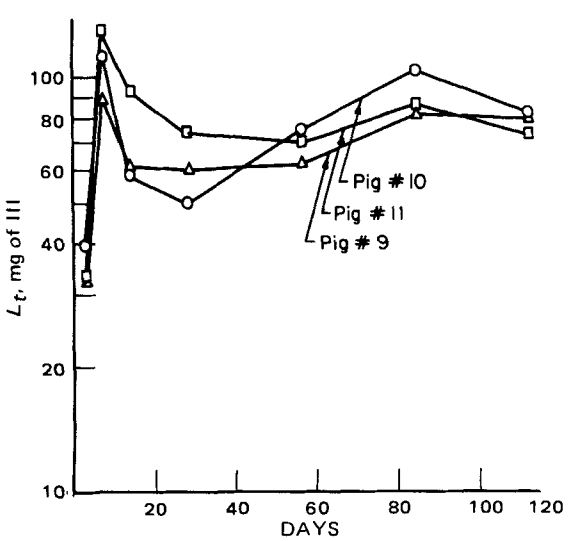

Figure 2—*Total fat content of III in three pigs receiving 2.14 mg/kg/day for 7 days.*

The animals were weighed and counted in a whole body counter for potassium-40 at 0, 3, 9, and 15 or 18 weeks. Fat content was calculated, and both the gross weight and fat compartment weight were plotted against time. The data were fit to a second-degree polynomial using the Chebyshev method where $\max|P(X_i - Y_i)|$ is a minimum for all A_i.

The program was run on a computer[2] and produced the polynomial parameters A_0, A_1, A_2, and D_{max} (maximum deviation from fit) so that:

$$Y \text{ (total weight)} = A_0 + A_1t + A_2t^2 \quad \text{(Eq. 2)}$$

where t is weeks after dosing, and:

$$Y \text{ (fat weight)} = B_0 + B_1t + B_2t^2 \quad \text{(Eq. 3)}$$

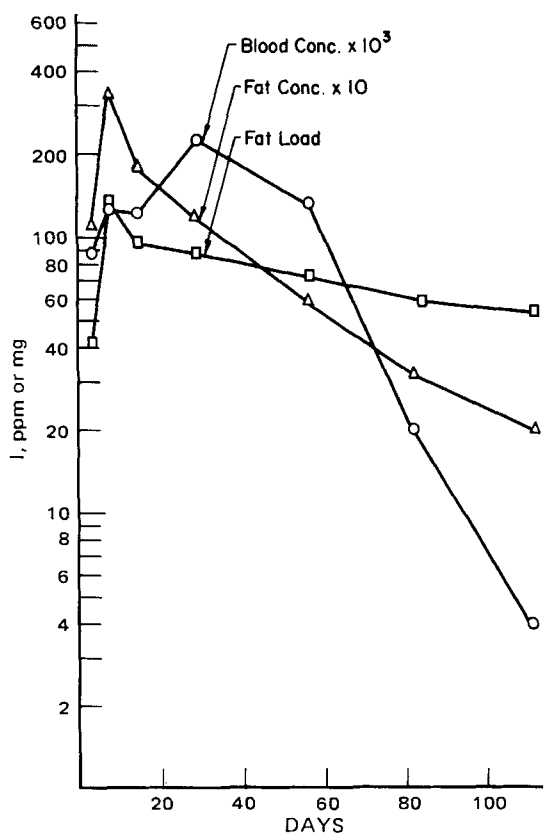

Figure 3—*Mean blood and fat concentrations (parts per million) and total fat content (milligrams) in pigs receiving 2.14 mg/kg/day of I for 7 days* (n = 3).

Table III—Apparent Pharmacokinetic Parameters for Fat Elimination

Treatment	Concentration Basis		Total Load Basis	
	$t_{1/2}$ Elimination, weeks	K_{el}, week^{-1}	$t_{1/2}$ Elimination, weeks	K_{el}, week^{-1}
I[a]	3.43	0.202	15.4	0.045
II[a]	3.57	0.194	38.3	0.018
III[b]	9.00	0.077	DI[c]	DI[c]
IV[b]	6.00	0.116	40.5	0.017
Peak 127[d]	5.36	0.129	24.2	0.028
Peak 149[e]	6.00	0.116	23.3	0.030

[a] Start of elimination phase at 2 weeks. [b] Start of elimination phase at 4 weeks. [c] Data were inadequate for estimate; a longer sample time was required. [d] 16.7% of polychlorinated biphenyl mixture; predominantly II. [e] 13.7% of polychlorinated biphenyl mixture; III is a significant, but not predominant, component.

The total fat load, L_t, is calculated by:

$$L_t \text{ (mg PCB)} = \text{(concentration PCB)}(t)(B_0 + B_1t + B_2t^2) \quad \text{(Eq. 4)}$$

RESULTS AND DISCUSSION

Computer Design—The computer-generated coefficients and D_{max} values for total weight and fat weight are presented in Tables I and II. Three sample curves are given in Fig. 1: for a control animal, for one treated with III, and for one treated with IV. The computer-fitted curves were drawn with the raw data points to permit visual comparison of fit to the polynomial. The trends in growth shown are consistent with the means and indicative of possible effects of polychlorinated biphenyls on swine performance. Percent weight gains (n = 3) were: control, 555 ± 105; III, 482 ± 62; II, 471 ± 52; I, 410 ± 67; and IV, 372 ± 42.

Pharmacokinetics—Figure 2 shows the total fat load data for pigs given the hexachlorobiphenyl ration[3]. In each case, a rise in total load occurred at 60–84 days after dosing due to the possible redistribution of residues (8). If the means of each group are examined for total fat load, fat concentration, and blood levels (Figs. 3–6), it becomes apparent that a redistributive phase existed in the pigs receiving II and III between 56 and 84 days after dosing. Although redistribution also may have occurred with I, its lower molecular weight and size made it easier to mobilize in the animal and the redistribution phase may have been missed in the sampling.

Generally, the amplitude and time shift of this redistribution are directly proportional to lipid solubility and degree of chlorination and inversely proportional to mobility and water solubility. The large time lag before redistribution discounts the more common factors responsible for nonlinearity such as enterohepatic recirculation and saturated tubular secretion. Changes in plasma protein binding characteristics might be suspect, but the volume of the blood compartment is less than fat and the concentration in blood is 10^{-3} that of fat so that the amounts in blood are inadequate.

Induction of microsomal oxidases by polychlorinated biphenyls (4) may account for the more rapid elimination rate at early times, followed

Peak 149	283 ± 42	2.7 ± 0	ND[c]	11 ± 7	23 ± 5	26 ± 16

[a] Sixteen weeks. [b] Eighteen weeks. [c] Not determined due to interference.

by reduced activity as the blood concentration drops and microsomal parameters return to near normal; however, this should result in a flattening in the decline of the fat load rather than a rise. The redistribution must result from, or be partially dependent on, changes in concentration throughout the sampled fat subcompartment due to nonparallel changes in this and other fat subcompartments. Further delineation of the redistribution requires more extensive (destructive or more traumatically invasive) sampling of several subcompartments.

Fat concentration alone provides pharmacokinetic curves indicative of the fast distribution and slow elimination phases of a two-compartment model (9). The elimination from a single compartment and the β-elimination phase are calculated exactly the same as long as both processes exhibit a first-order decline.

Elimination constants (K_{el} in Table III) were calculated on the basis of first-order elimination from the fat compartment using:

$$K_{el} = 0.693/t_{1/2} \qquad \text{(Eq. 5)}$$

The values based on concentration half-lives are not indicative of elimination only but rather a combination of elimination and dilution due to compartment growth. Elimination constants based on total fat load, however, can be used as a precise measure of true elimination from fat. Compared to fat concentrations, blood concentrations indicate a faster elimination rate for all compounds (Figs. 3–6); however, the actual elimination phase for blood is delayed beyond that for fat. In addition, blood concentrations tend to increase (Fig. 4) or deviate from linearity (Fig. 5) at the times the total fat load indicates a redistribution of residues. The smaller, more mobile tetrachlorobiphenyl (I) maintains relatively higher blood concentrations than the heavier analogs and implicates a redistribution at about 28 days (Fig. 3).

Total fat load curves show that the true elimination half-lives based on total content are much longer than indicated by concentration (Figs. 2–6). In no case did the total fat load curve ever reach a half-life due to true elimination (starting at 2–4 weeks, depending on the isomer). In Table III, elimination half-lives based on total fat load are compared to those computed from more familiar concentration methods. It is necessary to use the apex of the redistributive phase as the initial start of elimination, since growth at this time is linear and a decrease in total load seems due to metabolism and elimination. It is possible that the total body load of polychlorinated biphenyls does not decrease at all in swine (10); however, the declines seen after redistribution is complete (Figs. 3 and 4) indicate that, although slow, some elimination does occur.

The commercial mixture (IV) used in this study contained 54% chlorine by weight and was composed of several components identified by GLC retention times (11, 12). Two predominant peaks produced by GLC separation occurred at retention times of 127 and 149 with respect to 1,1-dichloro-2,2-bis(*p*-chlorophenyl)ethane = 100. Peak compositions were confirmed by mass spectrometry, and studies of individual components were conducted previously (4, 11, 12).

When components 127 and 149 of IV are compared to their respective analogs (Figs. 7 and 8), the pentachlorobiphenyl analog (II) more closely matches the course of absorption and redistribution than the hexachlorobiphenyl analog (III). This result must be considered primarily due to the fact that II is a major component of peak 127 while III is only a minor component of peak 149 (11, 12). Therefore, conclusions concerning the behavior of the purified analogs compared with their behavior in a mixture cannot be drawn from these data alone.

Tissue Residues—According to the data in Table IV, II is the least persistent in all tissues analyzed, including blood. The fat load curves in Figs. 3–6 show, however, that fat content remains high. This finding indicates an increased vulnerability to metabolism rather than low lipophilicity. Compound II is the only isomer present that can assume two adjacent *ortho*-positions which are open to attack. This singularity would also produce a more planar molecule, which would be susceptible to dibenzofuran formation or hydroxylation.

The tetrachlorobiphenyl (I) maintained its presence in the blood and in the highly vascularized liver and kidney to a greater degree than did II and III, indicating a low level of biotransformation. It was the only analog significantly eliminated from the fat compartment, but this elimination was probably due to mobility rather than biotransformation.

The components of the mixture were generally distributed in the tissues according to degree of chlorination (Table V). Peaks 85 and 105, tetra- and pentachlorobiphenyl(s) (12), were eliminated from most tissues after 16 weeks. Peak 85 was apparently highly mobile and present in high levels in blood and liver only. Peaks 83 and 99 were concentrated in all

tissues above the relative levels present in the mixture administered. Otherwise, the peaks of longer relative retention time (more highly chlorinated) accumulated in fat while blood carried the peaks of shorter relative retention time. Other tissues were intermediate, except that the liver maintained high levels of component 70, which is rapidly distributed or eliminated from swine and sheep fat and blood (1, 2, 4, 5); the level of peak 253, which is rapidly eliminated by fish (13), was lower in the liver than in any other tissue.

Renal Function Testing: Differentiation between a Nephrotoxic Agent and Diuretic Drugs

E. E. VOGIN

Abstract □ Preliminary studies indicate that it may be possible to differentiate the effects of a nephrotoxic substance from those of diuretic agents by the measurement of both urine and plasma osmolality. The nephrotoxic substance, mercuric chloride, decreases urinary osmolality and increases plasma or serum osmolality. The diuretic agents, at exceedingly high dosages, may show a dose-related decrease in urine osmolality. However, serum osmolality either remains unchanged or is only slightly lowered. This difference in the serum response of animals treated with a nephrotoxin or diuretic agents may allow for the differentiation in toxicological studies.

Keyphrases □ Osmolality, urine and plasma—effects of nephrotoxic and diuretic agents compared, dogs □ Renal function testing—differentiation between nephrotoxic and diuretic agents by urine and plasma osmolality measurements, dogs □ Nephrotoxic agents—mercuric chloride, effect on urine and plasma osmolality compared to various diuretic agents, dogs □ Diuretics, various—effects on urine and plasma osmolality compared to nephrotoxic agent, dogs □ Mercuric chloride—effect on urine and plasma osmolality compared to various diuretic agents, dogs

The evaluation of nephrotoxicity in safety evaluation studies has always posed a problem to the toxicologist. The need to determine histopathological changes in the urinary bladder prohibits catheterization because of possible irritant effects. The clinical evaluation of nephrotoxicity evolves about the determination of blood (serum) urea

nitrogen and urine analytical studies. Osmolality measurements have been used extensively in clinical situations to assess renal function. The concept, physiology, and clinical application of this procedure were described previously (1).

One of the most easily studied functions of the kidney is its capacity to conserve water under dehydration conditions. In these circumstances, water is reabsorbed from the tubular fluid against an osmotic gradient through the influence of endogenous antidiuretic hormones, and the maximum concentration of the solutes is used as an indication of the kidney's capacity to perform osmotic work (2).

Low protein diets and habitual consumption of large quantities of fluid may result in the excretion of urine of low specific gravity or inhibit the concentrating ability of the kidneys. Since diuretics also can reduce the renal concentrating capacity, preliminary studies were undertaken to determine if osmolality measurements of urine and serum can differentiate between pharmacodynamic and nephrotoxic effects of chemical agents. This report presents the initial findings.

EXPERIMENTAL

Eighteen purebred male and female beagle dogs were individually housed in metabolism cages in air-conditioned and humidity-controlled quarters and were maintained on a standard laboratory chow. Osmolality measurements were made according to the following procedures. At approximately 1 pm on the test day, all food and water were withdrawn from the cages. At 4:30 pm, a clean urine-collecting vessel was placed beneath the cage. A filter was positioned above the vessel to prevent contamination of the urine with feces, hair, *etc.*

Urine was collected from each animal until 8:30 am the following morning, at which time aliquots were taken for the determination of osmolality. Blood, with or without anticoagulant, was obtained from representative dogs by venipuncture. Following centrifugation, 2 ml of plasma or serum was used for the determination of osmolality. Osmolality measurements[1] were performed by the freezing-point method.

Physiological measurements included the volume, sodium, potassium, chloride, and specific gravity of urine and the sodium, potassium, chloride, urea nitrogen, alkaline phosphatase, and glutamic oxaloacetic transaminase of plasma or serum.

Six dogs were divided into three groups (one male and one female in each) and dosed with the diuretic agents according to the schedule shown in Table I; a table of random numbers was used for assignments to drug and dosage level. Seven days were allowed to elapse between each drug or dosage change to obviate measurable drug interactions. Twelve dogs were given two intravenous doses of mercuric chloride for 2 consecutive days. Dosage levels were 0.5, 1.0, 2.0, and 3.0 mg/kg. Following collection of urine and plasma for the various physiological measurement, these animals were sacrificed and examined in detail at necropsy, and histomorphological studies of renal tissues were made.

RESULTS

Urine osmolality measurements made on 88 colony dogs revealed values ranging from 975 to 2904 mOsm/kg. The results also indicated a linear correlation with specific gravity. Plasma osmolality measurements were made on 46 dogs and resulted in a mean value of 325 ± 3.7 (*SD*) mOsm/kg. Serum values were somewhat less, about 307 mOsm/kg. The ratio of urine osmolality to plasma osmolality (for 24 dogs on which both measurements were performed) was 7.51 ± 1.49 (*SD*).

The effects of mercuric chloride administration on blood chemistry and osmolality measurements are shown in Tables II and III. At doses of 0.5 and 1.0 mg/kg for 2 consecutive days, no overt renal toxicity was evident. Values for urea nitrogen, transaminase, and urine and serum osmolality were within the normal ranges. The urine–plasma (U/P) ratio was reduced but also remained within normal limits.

One of two dogs at 2.0 mg/kg and all dogs at 3.0 mg/kg showed clinical evidence of nephrotoxicity as manifested by elevated urea nitrogen and serum osmolality values, marked inhibition in renal concentrating ability with marked reduction in urine osmolality, and reduction of U/P ratios to unity. Alkaline phosphate values were not altered; transaminase was markedly elevated. Histopathological examinations showed evidence of renal tubular pathology consistent with the clinical findings.

The results of administration of the diuretic agents resulted in slight to marked reductions in urine osmolality. These data are shown in Tables IV, V, VI, and VII for hydrochlorothiazide, chlorothiazide, acetazolamide, and ethacrynic acid, respectively. Acetazolamide and ethacrynic acid were most potent in decreasing urine osmolality. Dogs given hydrochlorothiazide or chlorothiazide generally had urine osmolality levels within the normal range. If the measurements had been obtained under circumstances whereby treatment was not known, the values would have been considered as normal.

Serum osmolality was slightly decreased following administration of hydrochlorothiazide or chlorothiazide, whereas variable responses were seen in dogs administered ethacrynic acid or acetazolamide. The U/P ratio of the dogs treated with hydrochlorothiazide, although reduced, was still greater than 3, which clinically has served as an indication of normality of the renal concentrating ability. Only one dog, Dog 4, in the group treated with chlorothiazide showed a U/P ratio of less than 3. Ethacrynic acid and acetazolamide resulted in marked decreases in U/P ratios in most instances. In general, the posttreatment values were less than 3.

[a] The numerator is the predrug value; the denominator is the postdrug value.

In an attempt to analyze the data with regard to pharmacological effects, urinary excretion of sodium, potassium, and chloride ions was determined after treatment with the respective diuretic agents. While some pre- and postdrug values differed markedly, considerable overlap was seen and no definite increase in the excretion of electrolytes was observed. These findings are shown in Table IV for hydrochlorothiazide, which served as the prototype agent. Similar patterns were seen in chronic toxicity studies with diuretics when urine was collected on the 3rd day of dosing. This response is not unusual and appears to reflect the homeostatic mechanisms of the animal to maintain normal electrolyte balance.

No significant changes were found in sodium levels subsequent to the administration of the diuretic agent. Administration of chlorothiazide and acetazolamide tended to reduce blood potassium-ion levels, while animals given hydrochlorothiazide and chlorothiazide generally showed a slight reduction in the blood chloride-ion levels. However, the values recorded are within the normal limits for the species. In general, only dogs given ethacrynic acid demonstrated slight elevations in blood urea nitrogen values.

Microscopic examination of renal tissue from these animals revealed no pathological changes attributable to the administration of diuretic agents.

DISCUSSION

These studies indicate that the use of plasma or serum and urine osmolality tests may be useful in evaluating renal function during subacute or chronic toxicity studies with diuretic agents.

Mercuric chloride administration resulted in an apparent dose–response in renal pathology. At doses less than 2.0 mg/kg, no clinical evidence of nephrotoxicity was evident; however, U/P osmolality ratios were reduced in a manner consistent with diuretic activity. This finding appears to reflect the mercuric-ion effect on sulfhydryl enzymes at these subtoxic levels (3). At higher dosages (2 and 3 mg/kg), the dogs showed renal toxicity that could be correlated with marked elevations of urea nitrogen, serum osmolality, and histopathology affecting the proximal renal tubule.

Mercuric chloride toxicity causes severe tubular necrosis with acute oliguric renal failure (4) but sparing of the glomeruli (5). Renal blood flow and glomerular filtration continue at rates which, in chronic renal failure, should provide adequate volumes of urine. However, it is postulated that oliguria results from filtrate disappearance by nonselective back-diffusion through damaged tubules (5).

Since serum osmolality is primarily dependent upon electrolyte concentration and concentrations of urea and glucose, the high levels seen in these nephrotoxic dogs may be attributed to the oliguric state and consequent uremia resulting from mercuric chloride toxicity.

Although diuretics can reduce the renal concentrating ability of the kidney and likewise alter the U/P ratio in a manner similar to that caused by the nephrotoxin mercuric chloride, the determination of plasma or serum osmolality may serve as the basis for the differentiation of effects. In cases of renal disease, serum or plasma osmolality is generally elevated; however, in the present program, serum osmolality remained unchanged or was slightly decreased subsequent to the administration of diuretic agents. Serum sodium concentrations and urea nitrogen levels were not elevated.

The data indicate that this method appears to be of value in assessing and differentiating renal function subsequent to diuretic agents and a nephrotoxic agent. While these results are preliminary, they can serve as a basis for extending the scope of testing by evaluating a series of less potent nephrotoxins during subacute oral toxicity studies and comparing these data to those obtained subsequent to more prolonged administration of a diuretic agent.

Instrumentation of an Automatic Capsule-Filling Machine

L. E. SMALL and L. L. AUGSBURGER [x]

Abstract □ Techniques similar to those used in instrumenting tablet presses were applied to an automatic capsule-filling machine. The dosing unit was modified to allow the bonding of strain gauges to the compression piston. The gauges formed the arms of a Wheatstone bridge circuit. Thus, compression and ejection events were monitored by measuring the bridge unbalance voltage using a suitable amplifier–recording system. The instrumented piston was calibrated in a physical testing machine. Dosing unit rotation required the interposing of a mercury contact swivel between the amplifier and instrumented piston. The instrumentation system required only one minor, permanent modification to the machine, a cut in the dosator tube. Since the same dosator piston sensed both compression and ejection, only one of the two dosing units was instrumented and the other was removed from the machine. A solenoid switching system was devised which only permitted the feeding of empty gelatin shells into the filling cycle for the instrumented piston. Representative fillers were run at constant powder bed and piston heights. Oscilloscope tracings showed two stages in slug formation: (*a*) "precompression," representing the force sensed during dipping of the dosator into the powder before actual compression, and (*b*) actual piston compression. Generally, the maximum slug compression force fell to zero rapidly on retraction of the piston, but in some cases a retention force was noted, possibly due to elastic rebound of the slug against the retracted piston. A negative deflection due to binding of the piston also was observed in tracings of one material. Lubricated batches exhibited ejection forces of less than 1 kg.

Keyphrases □ Capsule-filling machine, automatic—instrumentation for monitoring compression and ejection forces described □ Instrumentation—described for monitoring compression and ejection forces in automatic capsule-filling machine □ Compression forces—in automatic capsule-filling machine, instrumentation described □ Ejection forces—in automatic capsule-filling machine, instrumentation described □ Technology, pharmaceutical—instrumentation described for monitoring compression and ejection forces in automatic capsule-filling machine

One significant advance in pharmaceutical technology in recent decades was the application of instrumentation techniques to monitor the forces developed in the formation and ejection of tablets. Applied first to single-punch presses and later to high-speed rotary presses, this instrumentation has brought about great insights into the fundamentals of tablet compaction, facilitated product formulation, and permitted continuous in-process monitoring and control of tablet weight (1–4). In light of the successful application of instrumentation to tablet formulation and production, the application of this technology to modern capsule-filling equipment should be of equal value.

Modern, fully automatic, capsule-filling equipment, employing filling principles similar to tablet compression, appeared uniquely suited to the application of instrumentation techniques. Although both the traditional semiautomatic and the newer fully automatic capsule-filling machines generally require that formulations have good flow properties and be lubricious, the machine used in this study[1] required that formulations also be compressible enough to form slugs sufficiently cohesive to be transported within the machine and ejected into open capsules.

The similarity of this filling mechanism to tablet compression suggested that slug compression force and ejection force would be meaningful parameters that could be monitored in a manner similar to that presently used in tableting. Therefore, the specific aim of this research was the development of an instrumentation system capable of monitoring the compression and ejection forces developed during the filling cycle of this capsule filling machine.

A literature review revealed only two references related to the instrumentation of capsule filling machines. Cole and May (5), in a short article, noted the instrumentation of the same model automatic capsule filling machine[1] using strain gauges but gave no details regarding the method of instrumentation. They did, however, report forces ranging from 5 to 350 N (0.5–35 kg) required for compression and ejection of the powder slugs.

Coinciding with the completion of the present work, Cole and May (6) reported in detail their method of instrumentation. A size No. 00 piston was fitted with strain gauges. The rotating dosator head was modified by incorporating a planetary gear system, which prevented the continuous twisting of the cable connecting the gauges with the monitoring equipment. Compression, retention, and ejection forces of representative capsule fillers were reported. However, as will be pointed out, several important differences exist between the methodology and results of Cole and May and those reported here.

EXPERIMENTAL

A primary concern throughout the design process was to keep the modification of the machine to a minimum. The attachment of mounting brackets or guides should be by existing hardware. The system should not alter the normal functioning of the filling process nor reduce normal operating speeds. Finally, the machine should retain the capability of operating uninstrumented, and restoration to this mode should be easily accomplished.

Modification of Dosator Piston—The dosator piston of this capsule filling machine is analogous to the upper punch of a single-punch tableting machine and also to the lower punch in both single-punch and rotary machines because the piston is responsible for both compression of the powder slug and ejection of the slug from the filling head. Since the piston must, therefore, sense the forces generated during compression and ejection, it provided the logical site for bonding of the strain gauges used to detect these forces.

The piston (Fig. 1A) can be conveniently divided into four areas: (1) an upper graduated shank, (2) a collar supporting a metal rod used to adjust the height of the piston in the dosator, and (3) a middle shank tapering to (4) a lower shank with a slightly flared, flattened end. To facilitate bonding of strain gauges and to increase sensitivity, a new piston was machined from No. 304 machinable stainless steel (Fig. 1B). The new piston is identical in all respects to the original, except that the normally cylindrical middle shank was altered to a rectangular cross-section 1.12 cm wide and 0.234 cm thick. In addition, part of this area was reduced to a 0.742-cm width, affecting a portion of the middle shank 1.89 cm in length.

This reduced area (1.89 × 0.742 × 0.234 cm) is the bonding site of the strain gauges. This reduction further increases sensitivity and provides clearance for connecting wires to pass to the reverse side of the piston

[1] Zanasi LZ-64 automatic capsule filling machine, USM Corp., Machinery Division, Beverly, MA 01915.

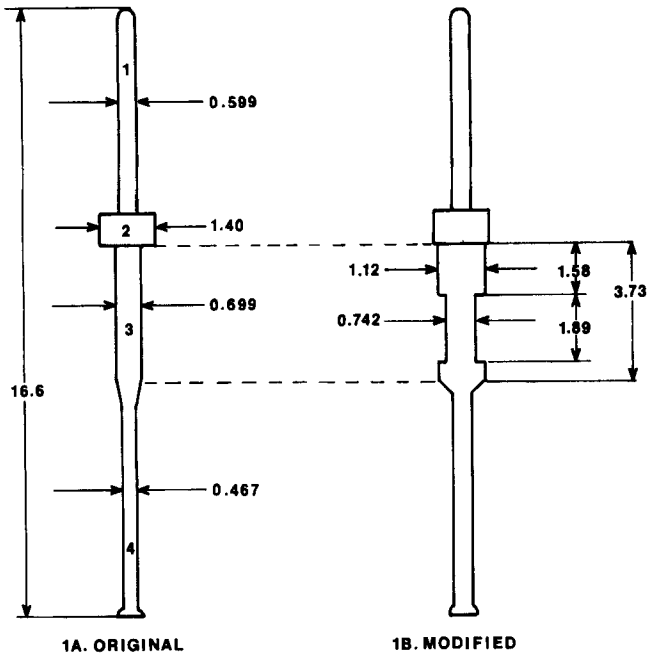

Figure 1—*Sketch of original and modified pistons (all dimensions in centimeters).*

when in the dosator unit. A groove was also cut into the collar on one side of the piston, 3.18 mm wide, to allow passage of connecting wires. The plane of the modified rectangular cross section is parallel to the axis of the hole drilled in the collar. The piston, thus modified, is fitted in the dosator unit in the same fashion as the original piston.

Axial strain produced in the bonding area originates only from stress generated at the flared end of the lower shank. The piston is pushed downward, externally, at the tip of the upper shank. The flared, lower end presses on the powder sectioned by the filling head during compression and ejection. The piston is retracted to its original position by a spring acting on the base of the collar.

Installation of Strain Gauges—Two sets of strain gauges[2] were bonded to the reduced area of the modified piston, one set on each side. The strain-gauge configuration chosen for this project consisted of two grid elements, perpendicular to each other, mounted along the length of the gauge backing. The gauges were oriented so that the grid elements closest to the flared end of the piston were parallel to the axis of the piston.

Bonding of the gauges was carried out according to a standard procedure provided by the strain-gauge manufacturer (7). The gauges were mounted such that the center alignment mark of one gauge was perfectly matched with the center alignment mark of the gauge on the opposite side of the piston. A four-post terminal strip was bonded to the grooved collar side of the piston, midway between the collar and gauges (Fig. 2).

Circuitry and Connections—The gauge elements parallel to the axis of the piston serve as the active arms of a Wheatstone bridge. The gauge elements perpendicular to the piston axis serve as temperature-compensating gauges and complete the Wheatstone bridge circuit. The active gauges are connected in opposite arms of the Wheatstone bridge to double the sensitivity of the instrumented piston (Fig. 3).

To protect the bridge and eliminate strain on the gauges induced by the connecting wiring, the terminal strip was interposed between the bridge circuitry and connecting wiring. The connecting wiring was fed from the terminal strip through the groove in the collar and loosely wrapped once counterclockwise behind the upper shank of the piston. Narrow strips of plastic electrical tape secured the connecting wires on each side of the collar. The completed bridge was coated with a polyurethan preparation[3].

Assembly of Dosator with Instrumented Piston—The dosator was assembled in the same manner as an original piston. The retracting spring was fitted over the lower and middle shanks of the piston, coming to rest

[2] Type EA-06-125TF-120, MicroMeasurements, Romulus, MI 48174.

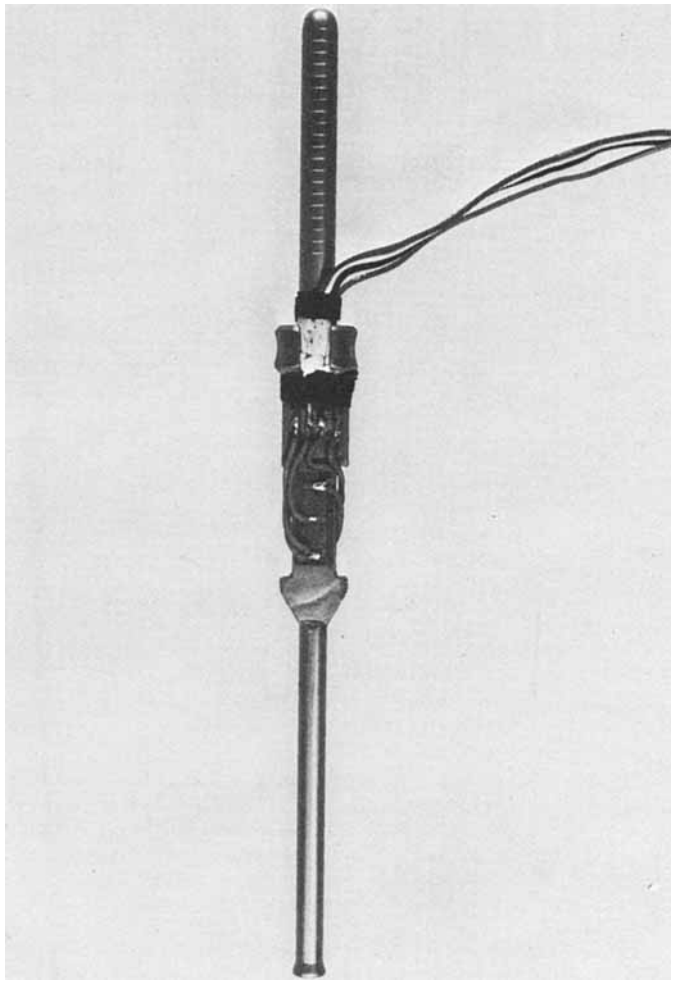

Figure 2—*Overall view of instrumented piston.*

against the lower edge of the collar. The spring and piston were then inserted into the dosator tube. The piston was then manually pushed below the adjusting rings, the cross bar was inserted through the collar, and the set screw was tightened.

The adjusting rings thread onto the outside of the dosing tube. The ends of the cross bar in the collar of the piston protrude from the dosing tube through slots, cut on a quarter-turn, extending most of the threaded length of the dosing tube. Since the rings function as a stop for the cross bar, the position of the adjusting rings determines the piston height. Thus, as the piston is pushed downward, it is caused to rotate a quarter-turn (or less, depending on the initial piston height) counterclockwise and then clockwise to its original position upon retraction. Since the connecting wire from the terminal strip through the groove in the collar was also wrapped counterclockwise, the piston unwraps the wire slightly as it descends and recoils the wire as it is retracted. In this manner, the required length of wire inside the dosing tube is held as compactly as possible to avoid damage.

To facilitate the installation and removal of the instrumented piston, one of the quarter-turn slots was continued vertically by making a cut in the dosing tube. This modification enabled the connecting wires to pass freely through the side of the dosing tube. This modification was the *only* permanent one made in the capsule filling machine.

The connecting wire was then supported at the upper end of the dosing tube by an auxiliary set of adjusting rings and a wire brace. The wire brace around the dosing tube was held securely by tightening the rings, one on either side of the brace. A cap, which centers the upper shank of the piston, was then screwed in the top of the dosing tube. The assembled dosator was then mounted, with the filling head, to the dosator arm.

The completed assembly is depicted in Fig. 4. The graduated shank of the piston (A) can be seen projecting from the dosator (B) mounted to the dosator arm (C). As the cable passes through the quarter-turn slot in the dosator, it is supported by the wire brace (D).

Mercury Contact Swivel—One problem inherent in the instru-

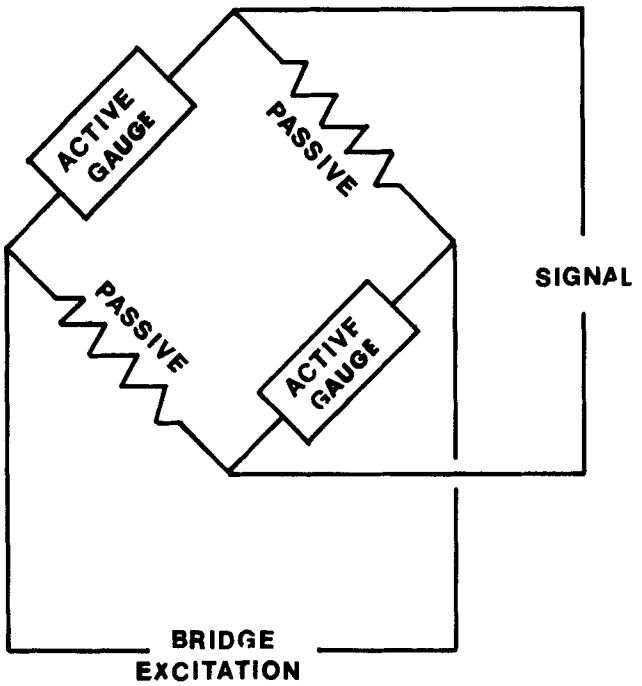

Figure 3—*Diagram of Wheatstone bridge circuit for the instrumented piston.*

mentation of this capsule filling machine was that the dosator arm, carrying the instrumented dosator, continuously rotated through 360°. To prevent the continuous twisting of the connecting cable, it was necessary to interpose a slip ring or swivel between the instrumented dosator and monitoring equipment. A mercury contact swivel[4] was selected in lieu of the usual mechanical type to minimize the possibility of noise in the output.

Figure 4 shows the swivel (E) mounted on the bracket (F) fashioned from 0.48-mm thick, 3003-H14 aluminum. The bracket is bolted to the machine by the existing mounting bolts of the capsule hopper. The swivel is supported by the bracket level with the top of the capsule hopper and directly over the dosator arm.

The swivel consists of a stationary plate and a rotating wheel. The upper cable connects the stationary plate to the monitoring equipment. The lower cable connects the piston with the wheel, which moves freely with the rotation of the dosator. Electrical continuity is maintained through the swivel by means of platinum-tipped electrodes, mounted on the stationary plate, which dip into mercury-filled annular canals cut into the rotating wheel. Additional electrodes passing through the bottom of each canal are connected to a standard connector by wires passing through the hollow axle of the swivel. Figure 4 shows the lower cable extending from the dosator to the standard connector.

Since the dosator arm not only rotates but also moves up and down to position the dosator, slack must be provided in the cable between the dosator and the swivel. To prevent the slackened cable from being snagged by the compression and/or ejection knobs, a wire guide was fashioned and mounted, using existing bolts, to the compression–ejection arm (Fig. 4G).

The compression and ejection events, detected by the instrumented piston, are monitored by measuring the bridge unbalance voltage using a carrier preamplifier[5], which also serves to activate the bridge. The compression and ejection events are recorded continuously on an oscillographic recorder[6] or displayed on an oscilloscope[7].

Calibration of Piston—Calibration was necessary to convert microstrains to kilograms of force. The associated monitoring equipment was capable of directly measuring the strain on the gauges during compression and ejection. The instrumented piston was calibrated statically by applying known loads to the piston in a physical testing machine[8].

Two trials were run, and the observed microstrain readings, resulting from the applied loads, were noted (Table I). Linear regression analysis, using data from both trials, revealed excellent linearity over the range of forces tested (correlation coefficient = 0.999). The slope was 3.96 microstrains/kg. The internal calibration of the recording system, determined by the gauge factor and the gain set on the galvanometer pen, set each millimeter of deflection equal to 1.60 microstrains. Dividing the internal calibration factor by the slope of the regression line resulted in the calibration factor of 0.404 kg/mm for this system.

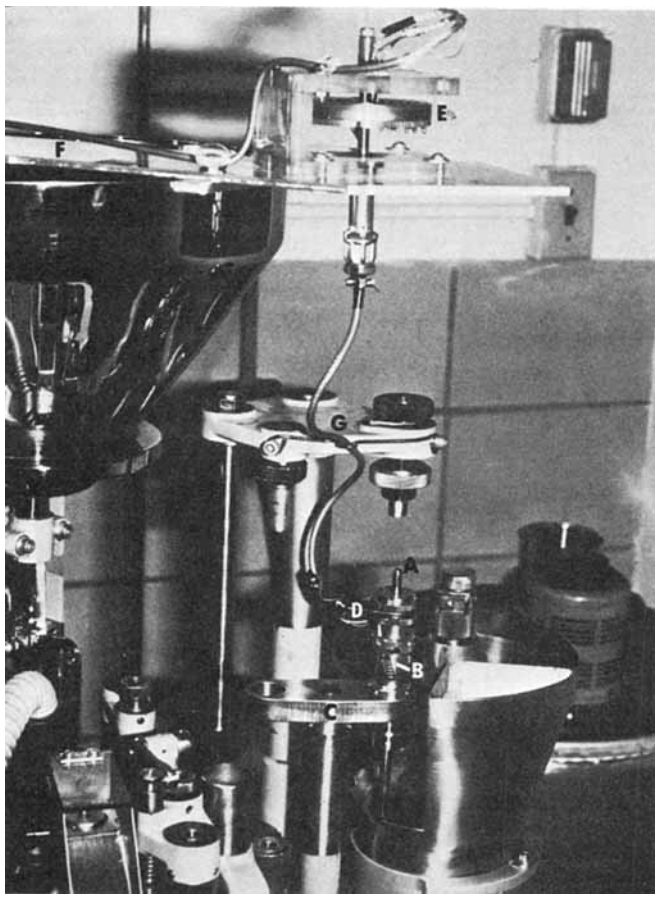

Figure 4—*Perspective view of instrumented dosator, cable, and swivel. Key: A, piston; B, dosator; C, dosator arm; D, wire brace; E, mercury contact swivel; F, swivel bracket; and G, compression–ejection arm.*

Alternate Feeding of Capsule Shells—Since the same dosator was used to monitor both compression and ejection, only one dosator was instrumented. This procedure also eliminated errors that could occur because of possible differences in piston height adjustment. This filling machine was designed to operate with two dosators in place. Thus, for every capsule that was filled, the machine ejected one empty capsule that had gone through the filling cycle but had not been filled because of the missing dosator.

This procedure presented a number of problems. The empty capsules had to be manually separated from the filled capsules for economic reasons and simply for ease of handling the filled capsules for further study. However, even when the capsules were separated, they risked being contaminated by the formulation used. Furthermore, damage to the capsule may have occurred during a previous run, which could cause the machine to stop during a subsequent run.

To eliminate these problems, a means to feed the capsules alternately into the filling cycle was devised. A standard 120-v solenoid[9] (Fig. 5A) was mounted and connected to the rod (Fig. 5B) controlling the position of the metal shoulder (Fig. 5C), which lifts the rocker arm assembly to allow one capsule to feed into the turntable bushings. Again, mounting was accomplished using existing hardware. The solenoid, energized by house current, was connected in series with a microswitch mounted on the support rod of the orientating block so that the lever of the microswitch rode on the edge of the turntable.

When the lever was tripped, the solenoid was activated to retract the

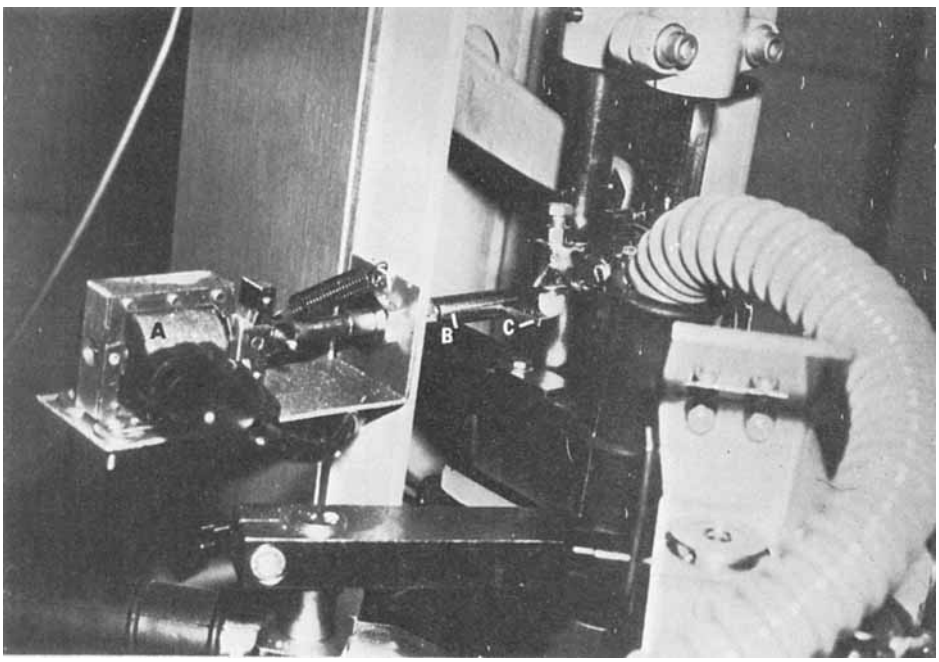

Figure 5—*Solenoid mechanism for alternate capsule feed. Key: A, solenoid; B, rod; and C, metal shoulder.*

metal shoulder, thereby preventing capsule feed. The tripping of the microswitch was timed so that omission of a capsule feed coincided with the missing dosator cycle by causing the lever to ride over hex nuts strategically fixed to the turntable edge. A return spring caused the metal shoulder to return to its original position, which permitted capsule feed for the instrumented dosator.

Preliminary Experience with Instrumentation System—To evaluate the system and to obtain force–time traces, No. 1 capsules were filled with representative fillers. The fillers were microcrystalline cellulose[10] NF, lactose[11] USP, pregelatinized starch[12] USP (compressible starch), and dibasic calcium phosphate[13] NF (unmilled). Fifteen hundred-gram batches of these materials were lubricated with 0.5% magnesium stearate[14], 80 mesh, by mixing in a twin-shell blender[15] for 15 min. The intensifier bar was run during the final 2 min to ensure efficient distribution of the lubricant. Abbreviated runs with unlubricated materials were also made.

The two piece star-wheel, which rotates at the bottom of the hopper, was adjusted to yield the maximum powder bed height of 49.4 mm. This was the height of the bed into which the dosators dipped. Then, with the star-wheel rotating and the dosators removed, powder was gradually added and allowed to come to an equilibrium bulk density at a hopper reservoir powder height of 25 mm. To prevent any possible change in powder bulk density due to changes in reservoir powder weight, care was taken to maintain this reservoir bed height to within approximately ±12 mm during all runs.

The dosator was then fitted to the dosator arm, and the instrumented piston was set to a height of 18.7 mm. This piston height, representing a setting of 9.5 graduated divisions on the upper shank of the piston, was the highest setting that would allow the apparent complete fill of the capsule at zero compaction at the maximum powder bed height regardless of the material being filled. The powder bed height and piston height were then kept constant throughout the evaluation.

The Zanasi filling principle includes compression of the dosed powder prior to ejection into the capsule. The degree of compression or the compaction level is controlled by the extent of displacement of the piston. This, in turn, is regulated by the length of the compression knob located on the compression–ejection arm. The length of the compression knob was adjusted such that it just touched the tip of the upper shank of the piston when the compression–ejection arm was at the lowest point of its downward stroke. At this setting, no displacement of the piston would occur for this piston height. This setting was taken to be the zero reference for compaction. Batches were run first at this setting and then, starting from this point, at knob length increments of 1.27 mm until the final free displacement of the piston was 6.35 mm.

Free displacement is, however, a theoretical displacement because, under filling conditions, the piston may or may not actually be displaced the full adjusted distance due to an overload relief mechanism. Much like the overload mechanism in a rotary tablet press, the compression knob is equipped with a spring in its support to prevent damage to the machine. Care was taken not to exceed the limits of this system.

DISCUSSION

Analysis of Force–Time Trace—Study of the force–time trace yields information about the forces generated during the filling cycle and the

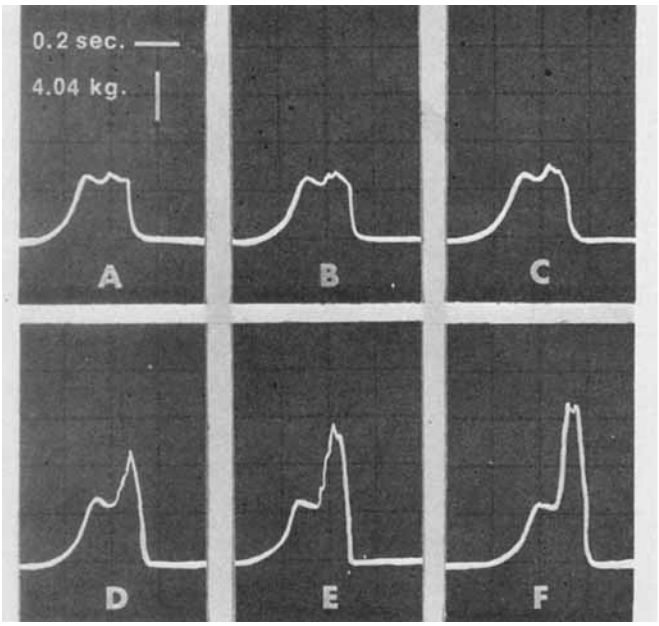

Figure 6—*Progressive changes in the force–time trace of lubricated microcrystalline cellulose.*

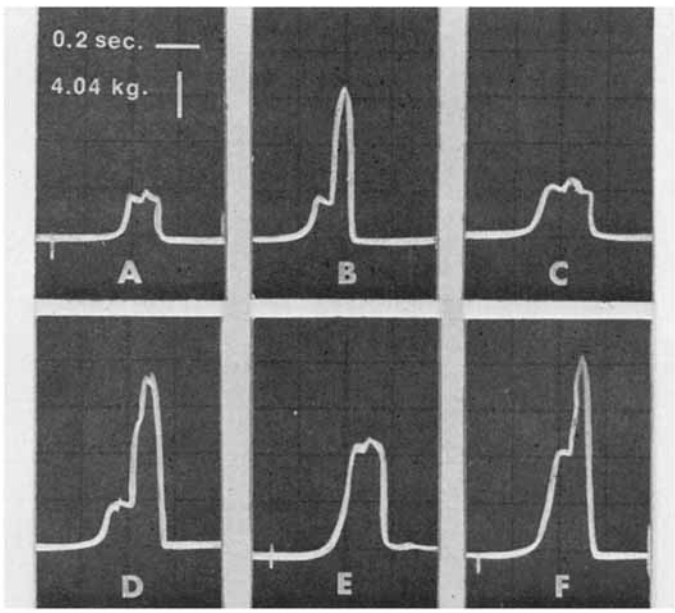

Figure 7—*Contrast of force–time traces of three materials (lactose, A and B; compressible starch, C and D; and dibasic calcium phosphate, E and F) at 0- (A, C, and E) and 6.35- (B, D, and F) mm compaction levels.*

sequence in which these forces occur. Figure 6 is a composite of single-compression force tracings of microcrystalline cellulose containing 0.5% magnesium stearate. Tracing A represents no compaction due to piston displacement (zero compaction level); tracings B–F represent the force trace changes as a result of continually increasing the compaction level with all other factors being held constant.

As the dosator dips into the powder bed, no force is recorded until the dosator penetrates the powder bed to a depth equal to the piston height. However, as the dosator continues its downward stroke, a force begins to be recorded and builds to a maximum at the maximum penetration of the filling head into the powder bed. At zero compaction level, this "precompression" force remains until the dosator is withdrawn from the powder bed (Fig. 6A). Since the powder bed height is greater than the piston height, it follows that the volume of powder sectioned by the filling head during the downward stroke of the dosing unit be either displaced or compressed into the adjusted volume of the filling head, resulting in the precompression force.

The pulse that appears to separate the wave form in Fig. 6A is not attributable to actual compression by the piston. This pulse coincides with the downward stroke of the compression–ejection arm which, when the compression knob is so adjusted, would ordinarily cause the piston to compress the sectioned powder. Because of the mechanical linkage between the compression–ejection arm and the dosator arm, some slight downward motion takes place in the dosator arm as the compression–ejection arm is in its lowest downward travel. Thus, the complete dosator unit essentially acts to compress the powder slightly at an adjusted zero compaction level.

As the compaction level increases, the second half of the trace begins to rise. This increase in compression force reflects the actual compression of the powder in the filling head. The rise in compression, to a maximum of 12.9 kg of force, is shown in Figs. 6B–6F.

The precompression force decays slightly in every case. After the dosator penetrates the powder bed and the precompression force is generated, there is a lag time (about 0.1 sec) that represents the travel time of the compression knob to the piston. During this period, the compressed powder probably undergoes some rearrangement or slight displacement of powder between the lower end of the filling head and the floor of the powder hopper.

Some slight decay also occurs in the compression part of the trace (Figs. 6D and 6E) during the short, but finite, dwell time of the maximum compressive force. As the compression knob lifts, the spring retracts the piston and the force trace drops rapidly to the zero baseline.

Figure 6F, for microcrystalline cellulose, and Figs. 7B, 7D, and 7F, for lactose, compressible starch, and dibasic calcium phosphate, respectively, depict the force responses generated by a constant piston displacement or compression of 6.35 mm. An evaluation of these tracings reveals the following decreasing order of compression forces developed under these circumstances: dibasic calcium phosphate, 16.2 kg; compressible starch, 14.8 kg; lactose, 13.3 kg; and microcrystalline cellulose, 12.9 kg.

These differences are, no doubt, due to differences in initial packing densities as well as to differences in the relative ability of these substances to undergo further consolidation and voids reduction under the present experimental conditions. As previously noted, all samples were allowed to reach their own characteristic equilibrium packing density (due to the agitation induced by the star-wheel) at the same powder bed height prior to capsule filling. Under these relatively low compressive forces, such consolidation is likely mainly due to particle rearrangement with only slight elastic and/or permanent deformation.

Regardless of the material, all force tracings resemble one another in these runs. Also, all lubricated batches exhibit barely measurable ejection forces of less than 1 kg. This finding is surprising in view of the fact that these batches employ only 0.5% magnesium stearate. Stoyle (8), for instance, empirically determined lubricant requirements of up to 3% magnesium stearate for running lactose in a larger model of the same type of machine. Although there were no indications of poor lubrication in the small batches run here, lubrication requirements possibly would be greater under the stress conditions of a full-scale production run. For a given compression force, longer slug lengths may also increase lubrication requirements due to the increased area of contact with the filling tube.

Cole and May (5) made no mention of the compaction adjustment in their report, although the Zanasi filling principle clearly is based on the compaction of the slug prior to positioning over the capsule body. Also, the tracings published by Cole and May did not reflect the two stages, precompression and compression, as presented in this work.

Unlubricated Materials—The effect of varying levels of lubricant on the ejection force was not an objective of this work. However, the force–time traces of unlubricated materials were considered important, particularly since two fillers, microcrystalline cellulose and compressible starch, are self-lubricating when used alone as tablet fillers (9, 10). The force–time traces of these two materials are shown in Fig. 8. The compression event precedes ejection. The occasional small spikes appearing between the compression and ejection events are due to the cycling solenoid.

Figure 8A shows the usual compression trace (compression force = 9.7 kg) and the ejection event (ejection force = 5.5 kg) of microcrystalline cellulose. This trace contrasts markedly with the trace for the compressible starch (Fig. 8B), which exhibits a retention force (positive deflection of trace above baseline between compression and ejection) and a negative deflection just after ejection. Similar findings were reported by Cole and May (6).

The retention force noted in the unlubricated starch run (Fig. 8B) indicates a residual pressure on the end of the piston as the slug is trans-

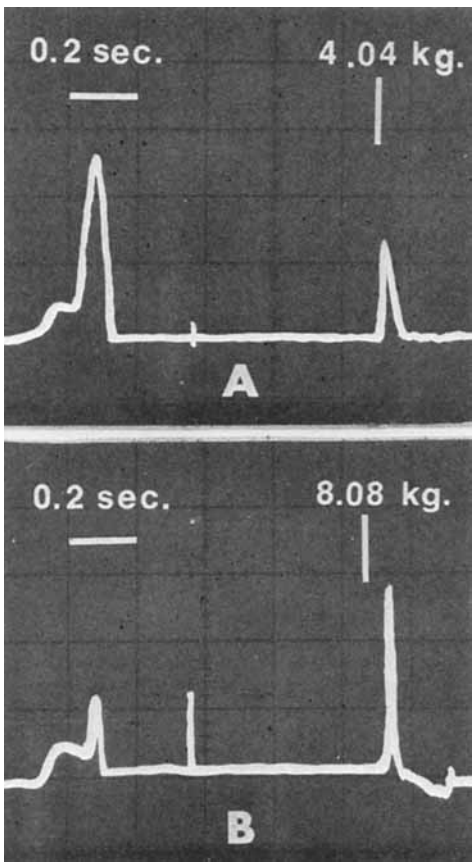

Figure 8—*Force–time traces of unlubricated materials. Key: A, microcrystalline cellulose; and B, compressible starch.*

ported to be ejected, possibly due to elastic rebound of the slug against the piston. This phenomenon occurs not only with compressible starch but also with unlubricated microcrystalline cellulose and lactose when run under conditions of relatively low compression force (*i.e.*, low powder bed heights and zero or low compaction levels). Apparently, under these conditions, bonding within the slug is insufficient to prevent expansion against the piston. However, unlubricated starch also produces a retention force when compressed at the maximum powder bed height and/or with a high compression force. This result is possibly due to a high modulus of elasticity in the case of starch. Lubricants presumably allow the slug to slip to relieve the residual pressure; this phenomenon was not observed in any lubricated run.

The negative deflection following ejection in Fig. 8B indicates tension on the piston as it is being retracted. A similar observation was reported by Cole and May (6), who suggested that this tension is likely to be caused by the adherence of material between the wall of the filling head and the piston. Under such circumstances, binding of the piston would be expected to occur, thereby leading to tension on the piston as it is being retracted by the spring. In the present study, particle adherence was observed in such cases, particularly on the piston. A similar phenomenon in tableting gives rise to a lower punch pulldown force (11).

Extreme care was taken when running unlubricated lactose and basic dicalcium phosphate. Very high ejection forces (up to 30 kg) developed after only 20–30 capsules had been filled, and the runs were terminated to prevent possible damage to the machine.

Abstract □ Shear deformation was shown to occur during the decompression of large compacts made by nonisostatic compression. Some materials undergo fracture when these shear stresses are developed. Other materials withstand these stresses but fracture upon ejection when the stress concentrations at the edge of the die are large. Failure to fracture seems to be related to the ability to relieve stresses by plastic deformation. A test was devised to measure this property, called the brittle fracture propensity.

Keyphrases □ Tablet formation—fracture caused by shear stresses during decompression, effect of plastic deformation □ Dosage forms—tablets, fracture caused by shear stresses during decompression, effect of plastic deformation □ Plastic deformation—effect on tablet fracture caused by shear stresses during decompression

It is generally accepted that compact formation by pressure occurs because of forces acting at the areas of true interparticle contact. However, the failure to obtain an intact compact from the compression–decompression cycle is a bit more mysterious. A series of arguments and some supporting evidence indicate that the stresses induced by elastic rebound and the associated deformation processes during decompression are principally responsible for the success or failure of compact formation. This report presents experimental results obtained by using several, sometimes complementary procedures. These data support the shift of emphasis to the decompression process.

To present a coherent, conceptual thesis, the discussion of each individual experimental procedure is not comprehensive. Instead, the emphasis is on the contribution of the results to the total concept. Bits are taken from various on-going research investigations. Cumulatively, these studies, even though incomplete, contribute much to the evidence.

Under high compression pressures, the powder particles in a compact are forced into intimate contact, and extensive areas of true contact between particles are formed. Because the magnitude of van der Waals forces across these interfaces is adequate to provide strong bonds, one might expect all materials to form strong, intact compacts after being subjected to compression. However, if too much energy is stored elastically when under compression, the elastic recovery during decompression may break most of these bonds and a soft, crumbly compact will be formed. Excipients are added to most pharmaceutical formulations to compensate for inherent, undesirable properties of the medicament. For example, it is possible to eliminate the storage of excess elastic energy during compression by mixing a plastic excipient with the harder "elastic" material. The plastic material will permanently deform and establish large, true contact areas with the harder material and will do so at relatively low pressures. Thus, during recovery, the stored elastic energy will be inadequate to separate extensive areas of contact, and strong bonding will result.

Even though these statements are reasonable explanations of many observations, every tablet formulator knows that they are inadequate. Often a laminated compact is produced. The individual pieces are dense, strongly bonded fragments. Therefore, sufficient areas of true contact must form during compression; in general, these areas are not destroyed during the elastic recovery, even though those in the fracture plane are destroyed. Thus, the mechanism of fracture is different from that of the formation of a crumbly tablet. Both are believed to result from inadequate plastic flow. A much more detailed look at compression and decompression is necessary to explain the compaction properties of materials and the fracture phenomenon.

EXPERIMENTAL

Tablet Compression—Many of the tablets used were made in a hand press. A square die was used. The cross section of the faces of the punches was 38.1 mm on a side. The tablet compression force was applied by placing the assembly, with punches in place, into an 18-metric ton hydraulic press[1]. The hand press could be pumped manually or by a motor-driven external cylinder to obtain the desired compression force. Both the punch and die had inserts containing diaphram-type strain gauges on the end of a screw[2]. One gauge was flush with the face of the die, and the other gauge was flush with the face of the punch and centered in it.

In one mode of operation, the output from the gauges was coupled at the y-input of an x–y recorder through a switching circuit that converts the recorder into a two-channel input on the y-axis. Calibration was made by placing a square rubber plug into the die and compressing it with known force. At low pressures, a rubber bag filled with water was used in a similar manner.

The known total force on the punches was obtained from a load cell[3] mounted on the press. The load cell was calibrated by applying a dead weight to check the supplier's calibration. Its output could be coupled to the x-input of the x–y recorder. Thus, it was possible to record simultaneously the total applied force, a local punch face pressure, and a local die wall pressure throughout the entire compression–decompression cycle.

An alternative mode of operation was to monitor the output of the load cell on a voltmeter[4] and to couple the die wall gauge to the y-axis and the punch gauge to the x-axis of the recorder.

In addition to the plain punch and an instrumented one, a special punch was made which contained at its center a spring-loaded, retractable pin 1.09 mm in diameter. This punch was used to form the tablet with a center hole to be used in the brittle fracture propensity determination.

The rotary tableting machine used in the lamination study was an instrumented (1) 16-station press[5]. A direct compaction formulation[6], selected to produce desired levels of lamination, was used. Dies and punches (extra deep cup 12.7 mm diameter) were used in the major study. Flat punches were used only to demonstrate the effect of punch shape. To obtain the data on fracture conditions, the precompression force and speeds were selected arbitrarily, with the final compression increased stepwise until lamination or capping occurred.

Tensile Strength—The tensile strength measurements were made by the transverse compression of square compacts. The procedure and apparatus were described previously (2). Since the hydraulic pressure

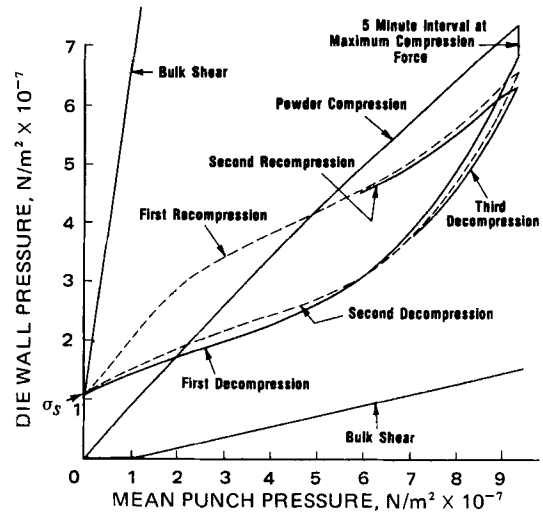

Figure 2—*Die wall* versus *average punch pressure for some compression–recompression cycles of the same sucrose compact. Constant maximum pressure was held on the punch for 5 min before the first decompression. Note that each successive recompression led to a lower maximum die wall pressure. Bulk shear lines were estimated from the uniaxial compression test, which gave* $\alpha = 67°$; σ_s *is failure stress under uniaxial compression.*

in the jack was developed by compression from an external motor-driven cylinder whose speed could be selected, the rate of stress application was controlled. This rate was not critical in experiments exploring this factor. Nevertheless, it is desirable to use a standard rate so that any time-dependent effects are reproduced, should they become important. Even though the external cylinder was driven at a constant rate, the rate of increase of force approximates an exponential curve. In the work reported herein, the rate was selected so that the time between $1/e$ of maximum force to the maximum force was 15 sec.

This apparatus also was used to determine the uniaxial compressive force required to cause a compact to shear. A 38.1-mm square compact was cut into two pieces. One-half was placed in the press with the long axis vertical. The platens covered the entire end of the compact. Blotter material was used on the platen as a pad.

A ring strain-gauge system was used to supply input to a chart recorder to observe the force at fracture. The area of the compact under the platen was calculated from measured dimensions obtained with a micrometer.

Stress Relaxation—The apparatus used by Milosovich was used in the form described by Shlanta and Milosovich (3). One addition was made—*viz.*, an oscilloscope[7] to the output. This oscilloscope permitted one to record photographically the transducer output for the first few seconds of the experiment. The output for the remaining time was recorded on a strip-chart recorder. A 12.7-mm diameter die was used in the studies done in air. The vacuum die was 13 mm in diameter. Powder weights were adjusted to give the same tablet thickness in the two dies.

Another procedure for observing stress relaxation was performed with the hand press, using the instrumented die and punch described previously. This apparatus is flexible, and various procedures may be used. In the work reported in Fig. 1, while the total force on the punch was held constant, the x–y recorder monitored the output of the strain gauges in the punch and die wall. Local pressure changes were observed at the center of the punch face while the mean pressure remained constant. With sucrose (Fig. 2), the punch gauge was not used (due to gauge failure), but the relaxation of the die wall pressure was followed. The load cell on the press indicated the total force on the punch.

Indentation Hardness—The indentation hardness values were measured using the dynamic impact method described previously (4). The chordal radius of the dent was measured with a low powered microscope. The initial and rebound heights were calculated from the arc of the pendulum movement. The indenter was a 25.4-mm diameter steel ball suspended on a 1-m long steel wire (to form the pendulum).

RESULTS AND DISCUSSION

Compression—The nonisostatic compression of a powdered or granular material to produce a compact is not a simple process. The complexity arises from the numerous simultaneous internal processes that lead to consolidation and bonding. These events include particle rearrangement (consolidation), fracture, and plastic deformation. At the start of the compression, the first dominates; at the end of the compression, the third dominates. In some cases, a fourth phenomenon occurs (5, 6)—*viz.*, localized melting at the interparticle contact points. This phenomenon is believed to be important only with relatively low melting materials. Even very hard asperities are pushed into a more plastic substrate. Thus, the stresses that could produce melting of an asperity are limited by particle hardness. Particle fracture occurs when the stresses within the particles become large enough for a crack to propagate. With some materials, the particles need not fracture because the stresses are relieved by plastic deformation of the particle before their magnitude is sufficient to initiate fracture.

Except in the case of localized asperity melting, the effective area of true contact in a cross-sectional area normal to the direction of pressure application is determined by the product of the force across the plane divided by the permanent deformation pressure of the solid. For simplicity, assume that only one material is present. If the deformation pressure is a constant, then:

$$F = PA \qquad \text{(Eq. 1)}$$

where F is the applied force, P is the permanent deformation pressure of the solid, and A is the effective true contact area in the normal plane.

Therefore, under pressure, a desired maximum true contact area can be established simply by applying adequate pressure. Equation 1 gives no information about the true contact area after elastic recovery; therefore, it is not adequate to predict final compact strength.

By making some general assumptions about the maximum interatomic separation distances that permit significant contributions to bond strength and then applying the Hertz elastic contact relationships (7), it can be deduced that smaller particles should yield larger true contact areas and, thereby, stronger bond strengths. However, the results are not independent of the particle permanent deformation pressures, *i.e.*, their hardness, and hardness may vary with particle size. Furthermore, plastic deformation tends to increase the number of dislocations in a crystal; a hard crystal may first become softer and, if sufficiently "worked," may then become hard again. Thus, the magnitude of P in Eq. 1 usually is unknown. Also, particle size and shape changes may influence the packing density. Thus, speculations on the effect of particle size on tablet bond strength are at best precarious.

Theoretical approaches that use models for the summation of contact areas and forces over a cross-sectional area to obtain true contact areas

are interesting (8, 9) but have not found significant application for solving real problems. Usually, the results deviate only slightly from a linear relationship between true area and force. Unfortunately, the proportionality constant is not known; it is known that the extent of the plastic deformation influences the magnitude of the proportionality constant. Thus, P is an important parameter influencing bond strength.

A more complete description of compaction must include the effects of interparticle friction and friction with the die wall and punches. These contribute to variations of the degree of packing in the die and, therefore, cause a nonuniform density compact to be formed. The variations of density within a compact were reported by Train (10). Furthermore, the effect of die wall friction on pressure at various levels in a compact was studied and described by (11):

$$P_b = P_a \exp\left(-\frac{4L\mu\eta}{D}\right) \qquad \text{(Eq. 2)}$$

where P_a is the applied pressure (punch), P_b is the transmitted pressure at L distance from the punch, D is the diameter, μ is the coefficient of friction, and η is the ratio of radial to axial stress in the compact.

Compression involving movement of both upper and lower punches significantly reduces the density variation within a compact; however, this fact does not eliminate the problem completely. Also, the use of a lubricant and glidant to reduce both interparticle friction and friction with the surfaces of the punch and die contribute significantly to the formation of a more homogeneous compact. Usually, these agents cause an increase in the die wall pressure for a given punch pressure (12), probably because the particles compact more tightly before plastic deformation becomes the dominant consolidation process. Possibly, interparticle "wedging" occurs more easily when friction is reduced and, thereby, increases the die wall pressure.

Thus, several factors may influence the structure of a compact and the magnitude of the die wall pressure at the maximum compression force. It is not easy to establish the relative importance of each. However, a valid qualitative generalization is that when either powders or granules are compressed into a compact, regions of different relative density are produced and the die wall pressure is of higher magnitude than would result from the elastic deformation of a single piece of an isotropic solid. During decompression, this extra die wall pressure may lead to excessively large shear stresses in the compact.

It is instructive to think of plastic deformation both as a change in particle shape and as the sliding of groups of particles within the compact. This approach provides a more macroscopic perspective and is used to explain the redistribution of stresses when under compression. For example, when sitosterols were held under constant compressional force (the total punch force held constant), a localized die wall pressure decreased as a function of time and the pressure at the center of the punch increased simultaneously (Fig. 1, insert graph, which was obtained with the instrumented 38.1-mm square punch and die set). Apparently, at maximum compression, some points in the compact were stressed to the limit of their strength. Since their instantaneous or dynamic shear strength exceeded their static shear strength, internal plastic flow occurred over time to relieve some stress[8]. The center of the punch always is a lower pressure region (10), so the flow was toward the center. Thus, regional density changes occurred and the compact density became slightly less heterogeneous as a result of this macroscopic plastic flow. The rate of the process decreased sharply; thus, a totally uniform density compact did not result.

In Fig. 1, the pressures reported were local pressures known at only two small regions because the strain gauges were less than 6.35 mm in diameter; the compact was a 38.1-mm square. In the absence of better data, it is expedient to use these pressures as very rough estimates of the principal stresses for an assumed isotropic homogeneous compact. In this case, the shear stress is given by:

$$\tau = \frac{\sigma_a - \sigma_r}{2} \sin 2\alpha \qquad \text{(Eq. 3)}$$

where τ is the shear stress at angle α from the direction of the minor principal stress, σ_a is the axial or punch pressure, and σ_r is the radial or die wall pressure.

Whenever τ just exceeds the shear strength of the material, shear failure occurs. If the failure does not cause a fracture plane to develop, the failure is by plastic flow. Obviously, τ has its largest value when $\alpha = 45°$. The shear strength also is a function of the angle α; therefore, the shear strength may be exceeded at some angle greater than 45° before

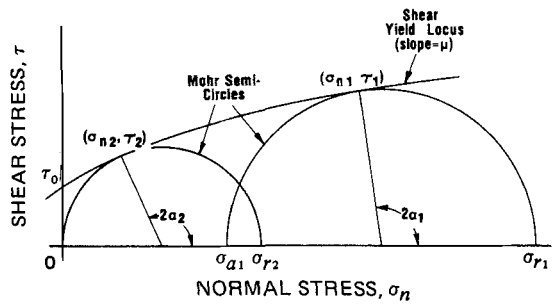

Figure 3—*Shear yield conditions based on the use of a geometric representation of stress analysis equations, a Mohr diagram. Semicircle on right (subscript 1) represents the higher pressure case when the radial pressure is less than the axial pressure. Semicircle on left (subscript 2) represents case when the axial pressure is zero and the residual die wall pressure is* σ_{r2} *(*σ_{r0} *in Eq. 6); it also could describe the uniaxial compression case. In Eq. 5, the yield locus is assumed to be a straight line and* μ *is a constant.*

it is exceeded at $\alpha = 45°$. For a Mohr body, the shear strength is assumed to be a nearly linear function of the compressive stress normal to the shear plane. The normal stress, σ_n, is given by:

$$\sigma_n = \frac{\sigma_a + \sigma_r}{2} + \frac{\sigma_a - \sigma_r}{2} \cos 2\alpha \qquad \text{(Eq. 4)}$$

For the Mohr body, the internal friction coefficient, μ, becomes the proportionality constant for calculating the shear strength, τ_f, and for the linear case:

$$\tau_f = \mu\sigma_{nf} + \tau_0 \qquad \text{(Eq. 5)}$$

where σ_{nf} is the magnitude of the normal stress, σ_n, at failure; τ_0 is the shear strength when $\sigma_n = 0$; and μ is the internal friction coefficient and is related to α by $\mu = -\cot 2\alpha$.

Equations 3–5 are useful in providing some insight into shear failure conditions. A standard geometric representation of Eqs. 3–5 is called a Mohr diagram. Because of symmetry, only half of a Mohr diagram is shown in Fig. 3. It should be useful to use Eqs. 3–5 and the Mohr diagram to discuss shear failure in both the compression and decompression of compacts. The graphical representation of shear failure is correct only when the Mohr circle of stress is tangent to the shear failure yield locus.

Decompression—In this discussion, it is assumed that adequate compressional force was applied to produce densification and bonding; *i.e.*, crumbling from lack of adequate compression with plastic deformation will not be considered further. Even though adequate pressure is applied, the compression–decompression cycle may or may not produce an intact compact without fracture lines in it. Success is determined primarily by the internal processes that occur as the compression stresses are removed. These processes include both removal of punch pressure and ejection from the die.

Powder under compression in a cylindrical die is confined in a radial direction until ejected from the die. Therefore, the major dimensional change during decompression is in the axial direction. Of course, the same is true for recompression of the compact if it is recompressed without removal from the die. Equation 6 describes the stresses associated with elastic deformation of an isotropic solid when the strain in the radial direction is zero:

$$\sigma_r - \sigma_{r0} = \frac{\nu}{1 - \nu} \sigma_a \qquad \text{(Eq. 6)}$$

where ν is the Poisson ratio[9], and σ_{r0} is the die wall pressure intercept value.

The residual die wall pressure, σ_{r0}, would be zero if the compression of an isotropic solid is started with a confined, but unstressed, solid body. If only elastic deformation occurred during compression and decompression, σ_{r0} would remain zero. When one starts with a powder, a finite residual die wall pressure is always observed after completion of the compression–decompression cycle. Obviously, if the compact undergoes shear deformation in both recompression and decompression, gross deviations from the elastic case would be expected and Eq. 6 would not be applicable. (Later, it will become obvious that Eq. 6 is not applicable

[8] This viscoelastic flow is believed to result from random thermal fluctuations breaking prestressed bonds.

[9] The Poisson ratio is defined as the transverse expansion per unit dimension of a solid of uniform cross section to its contraction per unit length when subjected to a uniaxial compressive stress (during elastic deformation).

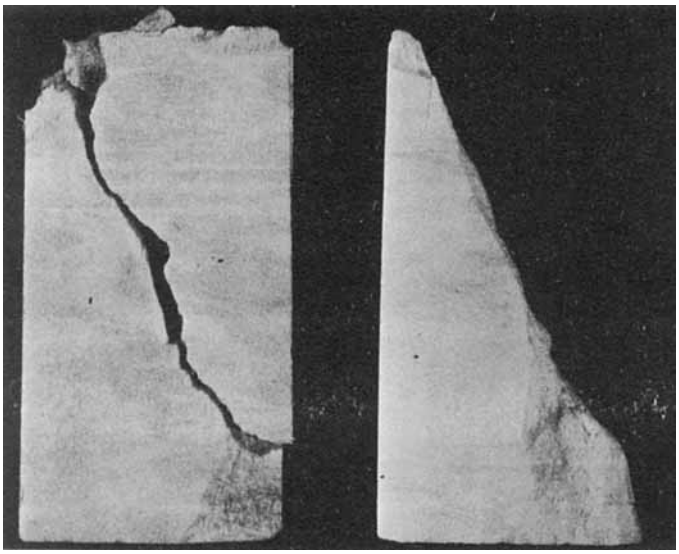

Figure 4—*Sucrose compact fractured in shear under uniaxial compressive stress of 1.1 × 10⁷ N/m². Compact was compressed at 9.2 × 10⁷ N/m². Fracture plane was irregular so value of α was not precise. With various compacts, values ranged from 64 to 67°.*

during the decompression process.) Others (13, 14) considered the possibility of plastic deformation during decompression but approached the subject differently than will be done in the following discussion.

To describe the magnitudes of the die wall and punch pressures that would cause the compact to fail in shear, the following equations are developed. Taking derivatives of Eqs. 3 and 4 with respect to σ_r and combining to obtain $d\tau_f/d\sigma_{rf}$ yield:

$$\frac{d\tau_f}{d\sigma_{nf}} = \frac{\left(\frac{d\sigma_{af}}{d\sigma_{rf}} - 1\right)\sin^2 2\alpha_f + 2(\sigma_{af} - \sigma_{rf})\frac{d\alpha_f}{d\sigma_{rf}}}{\left(\frac{d\sigma_{af}}{d\sigma_{rf}} + 1\right)\cos 2\alpha_f + \left(\frac{d\sigma_{af}}{d\sigma_{rf}} - 1\right)\cos^2 2\alpha_f - 2(\sigma_{af} - \sigma_{rf})\frac{d\alpha_f}{d\sigma_{rf}}} \cot 2\alpha_f \qquad \text{(Eq. 7)}$$

The subscript f was added to indicate a condition of failure.

By definition:

$$\frac{d\tau_f}{d\sigma_{nf}} = \mu = -\cot 2\alpha \qquad \text{(Eq. 8)}$$

Combining Eqs. 7 and 8 gives:

$$\frac{d\sigma_{af}}{d\sigma_{rf}} = \frac{1 - \cos 2\alpha}{1 + \cos 2\alpha} = \frac{\sqrt{1+\mu^2} + 1}{\sqrt{1+\mu^2} - 1} \qquad \text{(Eq. 9)}$$

Equation 9 permits the estimation of the limiting stresses beyond which shear occurs once μ or an equivalent value has been determined. While μ may not be a constant, large variations are not expected as long as only compressive stresses are used.

At least in theory, the uniaxial compression of a compact should provide the necessary data for use of Eq. 9. For this experiment, a large square compact was cut into two equal pieces and a compressive stress was applied along its long axis until it fractured. If both the fracture angle, α, and the compressive stress at fracture can be measured, Eqs. 8 and 9 can be evaluated. Figure 4 shows a sucrose compact fractured under uniaxial stress; the magnitude of the observed fracture stress is plotted on Fig. 2 (point σ_s). The irregular fracture line shown in Fig. 4 makes an accurate evaluation difficult. Compacts of most materials are even less satisfactory because of laminations and other aberrant fracture planes.

The two bulk shear lines in Fig. 2 have slopes calculated by Eq. 9 using the uniaxial compression data. Both α and μ were taken as constants; hence, straight lines are shown. These lines cross the axis at the uniaxial compression stress for fracture. The slopes of the two lines are reciprocals of each other; the distinction between σ_{af} and σ_{rf} in Eq. 9 is artificial; *i.e.*, it does not matter which is larger, only the difference is important. As is obvious in Fig. 2, these lines do not correspond to the experimental range of σ_{rf} *versus* σ_{af}. While this finding suggests that the experimental compression–decompression stresses are within the elastic limits of the material, further examination, such as of the data in Fig. 5, indicates that shear is occurring in the regions between these lines.

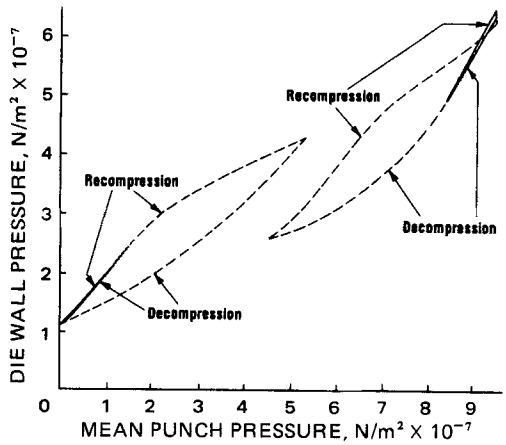

Figure 5—*Sucrose compact compressed as in Fig. 2 but recompression–decompression cycles were partials. Key: solid lines on left, recompression–decompression over very limited range of pressure; dashed lines on left, recompression–decompression cycle extended into decreasing slope region; solid lines on right, decompression–recompression cycle over limited range of pressures but starting from maximum values; and dashed lines on right, decompression–recompression cycle extended into decreasing slope region. Loops are believed to indicate that plastic deformation occurred at local points. Very small loops with solid lines may be due to friction resisting punch movement.*

The uniaxial fracture stress is an estimate of the magnitude of the die wall pressure at failure when the punch pressure is zero and vice versa. Figure 2 shows data for die wall *versus* punch pressures obtained for compression–decompression cycles using sucrose. The die wall pressure is that measured at the center of one side of a square compact. The punch pressure is the mean value based on the total force applied to the punch. When the punch pressure went to zero, the die wall pressure became identical to the uniaxial compressive strength, σ_s. Obviously, the shear strength limited the residual die wall pressure. This value remained essentially constant even after repeated recompression cycles.

The shapes of the decompression plot reported here are very different from those reported by Leigh *et al.* (13) and Carless and Leigh (14). Possibly, the differences arise from differences in the procedure and instrumentation. Those investigators measured total die wall force and not local pressures. Furthermore, the present apparatus is very rigid; *i.e.*, the entire die expands very little under pressure. Other differences are size and shape of compacts and the rate of compression and decompression. When Poisson ratios are calculated from the data reported here, unrealistically large values are obtained. Thus, the data measured at separated regions of the compact surface do not seem to be representative of a single, small volume element. However, the theoretical arguments developed from these data do not depend on the exact shape of the die wall *versus* punch pressure plot.

Upon recompression followed by decompression, as was done to obtain the data in Fig. 2, a "hysteresis" type of loop is formed. If the compression–decompression involves only elastic deformation, the compression–decompression pathway should be identical. Therefore, plastic deformation must be occurring during each recompression–decompression cycle. Partial recompression–decompression cycles are even more revealing (Fig. 5). If the recompression pressure is limited to a value below the first bend, the decompression line from that point superimposes onto the compression line (solid lines on the left of Fig. 5). However, when the recompression pressure is increased to a point beyond the first bend, a loop is formed upon decompression. Apparently, the first portion of the recompression curve represents elastic deformation while larger compression forces introduce plastic deformation.

Results of a similar experiment at the start of the decompression is shown on the right side of Fig. 5. If the decompression from maximum applied force is stopped short of the first bend, recompression from that point retraces essentially the same line. (A slight deviation occurs, possibly due to friction.) Therefore, the first part of the decompression is an elastic deformation. However, if the decompression is stopped at a pressure beyond the first bend, the recompression from that point forms a loop. Therefore, shear or plastic deformation is occurring during much of the decompression.

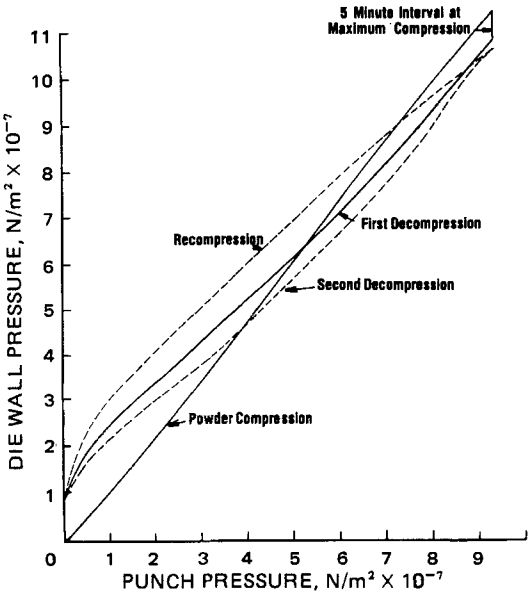

Figure 6—*Sitosterols: local die wall pressure* versus *mean punch pressure for compression–decompression cycles.*

The authors hope to equip the apparatus with a distance-measuring sensor so that the work of recompression and decompression may be determined. Certainly, the loop in Fig. 2 suggests that the work of recompression is much greater than the work done on the punch during decompression. Without a distance or volume measurement, the calculations cannot be made.

Figures 6–13 show similar results for sitosterols, spray-dried lactose, erythromycin, and sodium chloride. While differences in the detailed shapes of the curves are apparent, the general characteristics remain the same. Apparently, the previous discussion for sucrose applies equally to these materials.

Localized plastic deformation may occur at lower stresses than would be required to produce gross shear across the compact. The local shear stresses exceed the shear strength because of stress concentrations that occur around imperfections such as pores and density gradients. These internal local regions of shear may account for the apparently anelastic behavior in the recompression–decompression cycle. If localized shear occurs, the recompression–decompression cycle might not be completely reproducible, since there is no reason to expect the shapes of the stress concentrator regions that flow plastically during compression to be reconstructed in the decompression stage. Thus, it is not surprising that the observed maximum die wall pressure is less after each recompression (Fig. 2). This direction of change would be expected, since the die wall

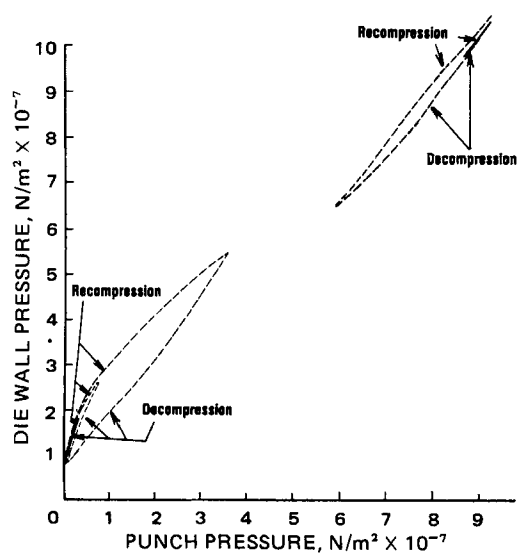

Figure 7—*Sitosterols: partial recompression–decompression cycles of a compact.*

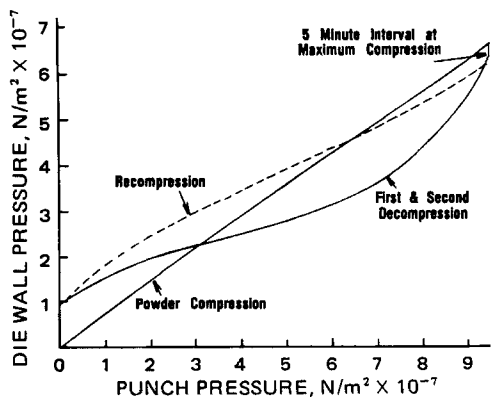

Figure 8—*Spray-dried lactose USP (hydrous): local die wall pressure* versus *mean punch pressure for compression–decompression cycles.*

pressure decreased during stress relaxation under constant punch pressure. The combined evidence of these observations and the time-dependent stress redistribution reported in Figs. 1, 2, and 14[10] strongly indicates the conclusion that local plastic deformation occurs in compacts.

Table I shows tensile strength values for compacts subjected to recompression–decompression cycling. The increase in strength that occurred with these materials is interpreted as an increase in true contact area between particles. Shear under a compressive load could produce an increased contact area. However, shear also may induce fracture, especially during decompression. Since the two processes produce opposite effects on the strength, not all materials will show the same trend. Most plastic materials, such as those used for the data in Table I, show increased strength. Figure 15 illustrates the case where the stresses during decompression led to fracture on the first decompression. Obviously, tensile strengths could not be determined. Phenacetin, methenamine, and acetaminophen, materials known to induce capping, show this kind of fracture. Apparently, these materials do not adequately relieve local stresses by plastic deformation; hence, fracture in shear occurs across the entire compact. For these materials, recompression curves are meaningless.

Brittle Fracture—The Griffith crack theory teaches that, for crack growth to occur, the energy stored at the tip of a crack must just exceed the energy required to form the two new surfaces resulting from the propagation of the crack. Also, the amount of energy stored at the tip of a crack is a function of the dimensions of the crack. An elementary description of the critical condition for crack growth is given by:

$$\sigma_c = K\sqrt{\frac{\gamma E}{L}} \qquad \text{(Eq. 10)}$$

where σ_c is the critical tensile stress for crack growth, γ is the surface energy, E is Young's modulus of elasticity, L is one-half the crack length, and K is a constant. In deriving this equation, the radius of curvature at the tip of the crack was assumed to be of molecular dimensions. The radius does not appear in Eq. 10 because it cancels against the same radius term, which occurs in the expression for the applicable stress concentration factor.

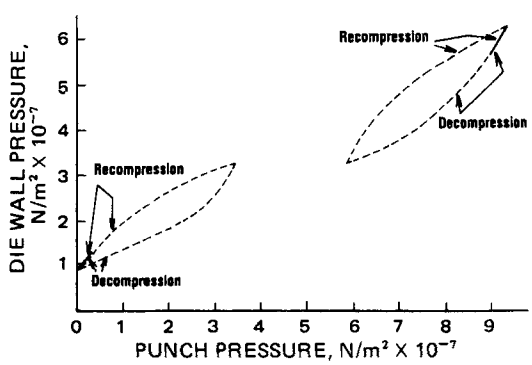

Figure 9—*Spray-dried lactose USP (hydrous): partial recompression–decompression cycles of a compact.*

[10] Figure 14 is basically a stress relaxation determination using the Milosovich apparatus (3) to obtain the data.

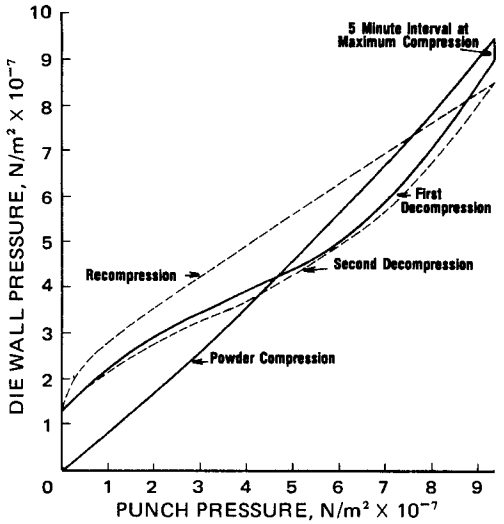

Figure 10—*Erythromycin USP: local die wall pressure* versus *mean punch pressure for compression–recompression cycles.*

The extent of the stress concentration, the stress concentration factor f, is a multiplier applied to the magnitude of the uniform stress calculated as if no flaw were present. A simple case may be used to illustrate stress concentration. If a slab is subjected to only a uniform tensile stress and the slab contains an elliptical hole with the long axis normal to the direction of the tensile stress, the tensile stress at the edge of the hole, as long as the hole is much smaller than the width of the slab, is given by:

$$f = 1 + 2\sqrt{\frac{L}{R}} \qquad \text{(Eq. 11)}$$

where L is one-half the length of the hole, and R is the radius of curvature of the tip of the hole.

Note that Eq. 11 reduces to a stress concentration factor of 3 for a round hole, regardless of its radius (its size still must be very much less than the slab size). When a second uniform stress is applied to the slab normal to the direction of the tensile stress, the stress concentration factor around a hole is not exactly 3. Figure 16 shows the stress concentration factor at a hole for various stress conditions (15).

The stress concentration concept is useful in understanding why ejection from a die can cause a compact to laminate. Theoretically, the radius of curvature at the edge of the die could be of molecular dimensions. Therefore, the stress concentration factor to be applied to the die wall pressure when a compact is partially ejected could be a very large number. Figure 17 is a photograph of an erythromycin compact that split off many layers as it was slowly ejected. The assumed mechanism is that a crack initiated at the edge and propagated across the compact. Materials that exhibit a high shear strength and, therefore, a high residual die wall pressure and also have a high propensity for brittle fracture may undergo

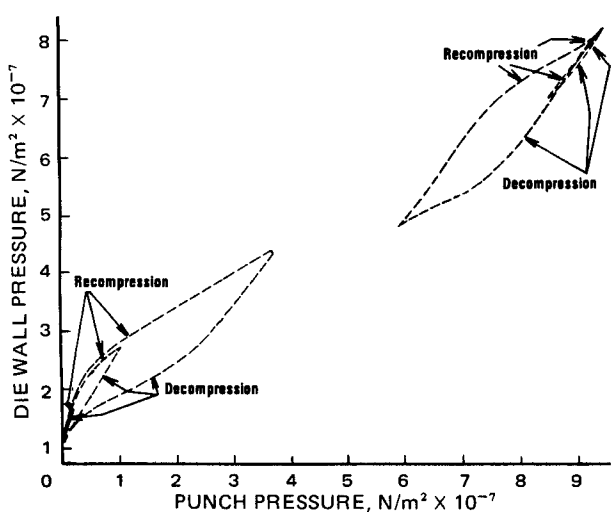

Figure 11—*Erythromycin USP: partial recompression–decompression cycles of a compact.*

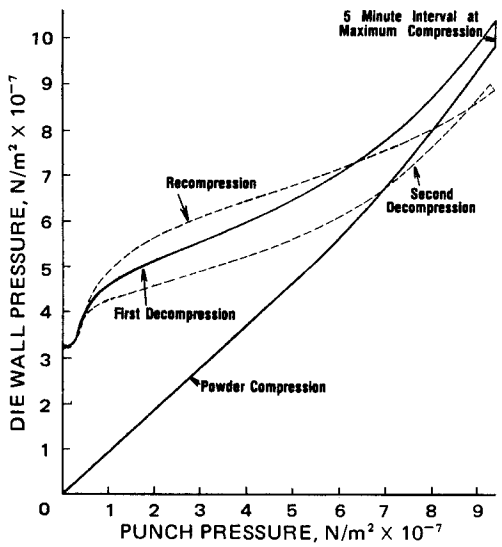

Figure 12—*Sodium chloride: local die wall pressure* versus *mean punch pressure for compression–decompression cycles different from other materials. The die wall pressure increased during the 5-min interval the maximum punch pressure was held constant.*

brittle fracture from points of very high stress concentration such as the die edge.

It should be possible to use the knowledge of stress relief at sites of stress concentration to characterize the tendency of compacts to propagate cracks. Suppose that a round hole is placed in the center of a compact and that it is subjected to a tensile stress. Tensile fracture might be expected to occur at exactly one-third of the tentile stress required to produce tensile fracture when no hole is present. However, this would be true only if the compact did not relieve the locally concentrated stresses at the edge of the hole by plastic deformation. If all excess stresses at the hole's edge were relieved, no observable differences in the tensile fracture force would be observed. Real materials should fracture at some intermediate value, the magnitude depending on their ability to relieve localized stresses. Since fracture by crack propagation from a flaw that concentrates stress is called brittle fracture, comparison of the strength with and without a hole has been used to define a parameter called the brittle fracture propensity (BFP). The BFP is calculated by:

$$\text{BFP} = 1/2\left[\frac{\sigma_T}{\sigma_{TO}} - 1\right] \qquad \text{(Eq. 12)}$$

where σ_T is the tensile strength without a hole, and σ_{TO} is the apparent tensile strength with a hole present.

The subtraction of one and division by two normalize the values of BFP so that the theoretical value range is 0–1 when the stress concentration factor is 3. Since the BFP value is an inverse measure of localized stress relief, it should indicate the tendency of a compact to laminate or cap.

A technique for measuring the BFP of compacts is based on the transverse compression of squares (2). Earlier work showed that if a

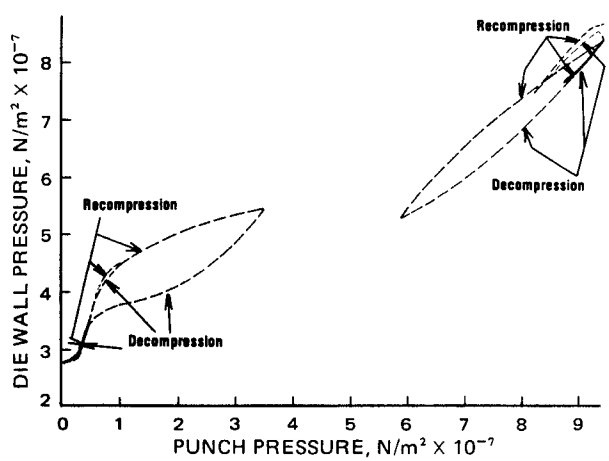

Figure 13—*Sodium chloride: partial recompression–decompression cycles of a compact.*

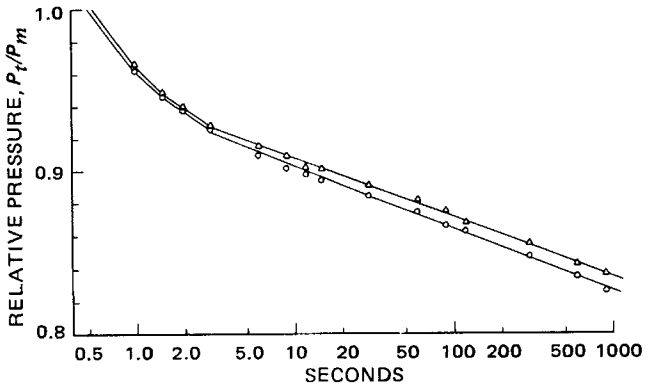

Figure 14—*Microcrystalline cellulose: relative punch pressure* versus *log time;* P_t *is pressure at time* t, P_m *is the maximum pressure applied, zero time corresponds to the start of the stress application, circles are data for an in air measurement, and triangles are data for an* in vacuo *measurement. Escape of air following compression did not alter the general shape of the curve. Maximum pressures applied were* 7.24×10^7 N/m^2 *in air and* 6.89×10^7 N/m^2 in vacuo; *slope values varied slightly with the maximum applied compression pressure and were usually steeper with an increase in the maximum pressure.*

square compact is centered on edge between two platens whose width is four-tenths of the width of the compact, the central region of the compact is under a nearly uniform shear stress (16). Figure 18 shows the fringe patterns obtained with polarized light through a transparent model substance, poly(methyl methacrylate). (Photoelastic methods of determining stress distributions use more sophisticated techniques to obtain and evaluate fringe patterns.) Comparison of the two fringe patterns clearly shows that when the hole is present, the magnitude of the stresses is changed markedly. Although isochromatic fringe lines are isoshear stress lines, one cannot determine the principal stresses without additional information. The techniques of photoelasticity are outside the scope of this discussion but do indeed permit the determination of stress concentration factors such as those shown in Fig. 16.

The stress condition at the center of a square compact in transverse compression is not simple tension. A compression stress is present in the direction normal to the tensile stress. Therefore, from the data displayed in Fig. 16 and from the analysis of Berenbaum and Brodie (16), which show that the ratio of tension to compression is approximately 0.28, it is evident that the stress concentration factor is approximately 3.25. The use of Eq. 12 with this method of tensile strength measurement will not limit the BFP values to less than unity, at least in theory, since the equation was normalized for a stress concentration factor of 3. In practice, one probably cannot make an intact compact of a material with a BFP of 1. Therefore, the observed range of values may not exceed the 0–1 range.

While it might be preferable to base the BFP on an exact theoretical analysis, one must recognize that the heterogeneous relative densities of a compact make a high level of precision most difficult to attain. Furthermore, difficulties not yet understood arise with this test. Therefore, the authors elected to use Eq. 12 to estimate the BFP, even when the evaluation of tensile strengths was made by the transverse compression of squares[11]. Added specifications should include the relative density of the compact because very soft compacts do not yield useful data. Nevertheless, sufficient accuracy exists for useful relative values to be obtained simply by adopting a standard procedure. Of course, compacts containing other flaws such as laminations will yield false values. When one observes a stepped fracture plane, one should suspect lamination and reject the data. If various laboratories were to attempt to obtain identical values for the BFP, very detailed specifications would be needed for high levels of precision.

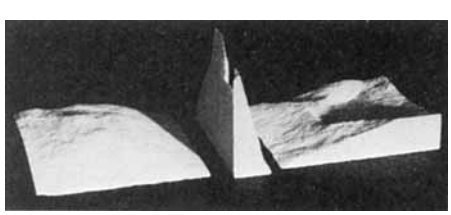

Figure 15—*Phenacetin compact that fractured in the die without ejection. Similar fracture occurs with acetaminophen and with some mixtures of these materials with excipients.*

[11] In the authors' studies, the platen width was 0.4 the tablet width, pads were used on the platens, and the hole diameter was 1.09 mm in a 38.1-mm square compact.

Table I—Tensile Strength of Compacts Subject to Various Compression Procedures

Material	Number of Compressions	Tensile[a] Strength, $N/m^2 \times 10^{-6}$	Significant[b] Difference, p
Aspirin	1	1.10	] <0.001
	4	1.26	
Sucrose	1	1.32	] 0.18
	4	1.37	
Lactose (spray dried)	1	1.45	] 0.08
	4	1.50	

[a] Average of five compacts. Maximum compression of 9.50×10^7 N/m^2. [b] Strengths are significantly different at listed p values. Brackets indicate the pair of values compared to obtain p value.

Experimental values for a few materials are listed in Table II. Materials known to induce capping have relatively large BFP values, as expected. The punch used to form compacts with a hole in the center is shown in Fig. 19.

Stress Relaxation—So far, the discussion has ignored an important variable—*viz.*, time. Plastic deformation is a time-dependent phenomenon. Shlanta and Milosovich (3) showed that compression stresses are relieved with time. Their experiments were similar to a relaxation study, since the size of the compact was fixed and the change in punch pressure with time was recorded. The authors used the Milosovich apparatus and confirmed the basic observation. Furthermore, every material examined by the authors with this apparatus underwent relaxation of the punch pressure (Figs. 14, 20, and 21). Because the compact is not under uniaxial compression during the stress relaxation, the quantitative interpretation of the experimental results is complicated. Furthermore, the slope is a function of the porosity of the compact. However, for the examples shown, the rank order is obvious. Materials that are known to cap exhibit slower stress relaxation.

The change of slope at the short time intervals observed in these stress *versus* log time plots suggests that some initially prominent mechanism soon becomes negligible. Because air entrapment has been propounded as the cause of lamination and capping, it was of interest to establish whether the diffusion of air from the compact was an initially prominent mechanism. Therefore, the stress relaxation experiments were repeated but with the powders in an evacuated die[12]. In no case were the general characteristics of the stress relaxation curves altered. Apparently, the air must escape in less than 0.4–0.7 sec from these materials (Figs. 14, 20, and 21). An apparatus that reduces the compression time to very small values is needed to explore this point further.

The relaxation of die wall pressure was discussed previously. Obviously, pressures at all points in a compact may not be undergoing stress relaxation identically. As indicated previously, the pressure at the center of the punch was increasing while the die wall pressure decreased (Fig. 1).

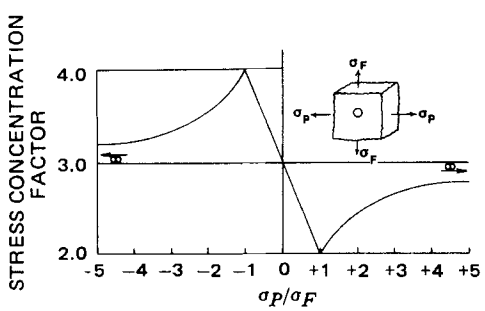

Figure 16—*Tensile stress concentration factor at the edge of a hole for biaxial stress conditions;* σ_P *and* σ_F *are stresses acting at right angles to each other. A negative value arises for* σ_P/σ_F *when one stress is compression and the other is tension. Hole diameter is much much smaller than dimensions in direction of stress. (Data from Ref. 12.)*

Table II—Deformation and Fracture Properties of Pure Materials

Material	BFP[a]	P/σ_t[b]	E_e/E_p[c]
Methenamine	0.83	58	0.134
Erythromycin base	0.65	25	3.56
Ibuprofen	0.40	87	0.145
Sucrose	0.35	102	0.590
Starch, modified[d]	0.27	78	1.07
Lactose (spray dried)	0.18	193	0.844
Microcrystalline cellulose	0.04	25	1.45

[a] Brittle fracture propensity. All compacts were compressed at 9.5×10^7 N/m². [b] Mean deformation pressure divided by the tensile strength. All compacts had a relative density of 0.85. [c] Relative deformation energies (elastic/plastic) for deformation beneath a steel sphere; $E_e + E_p$ was the same for all materials. The relative density of all compacts was 0.85. [d] StaRx.

However, mean pressures may be decreasing if the compact increases its relative density as a result of stress relaxation, *i.e.*, as a function of time. Therefore, there is no reason to conclude that the two apparatuses yield conflicting results.

The evidence clearly indicates the existence in compacts of time-dependent properties of plastic deformation and stress relief. Therefore, the incidence of fracture also should be time dependent. Intact compacts of some pure medicaments, *e.g.*, acetaminophen, methenamine, and erythromycin, were made when the decompression was extended over several hours, even though rapid decompression produced fractured compacts.

Differences in the slopes of the initial segments of these plots should reflect the ability of the material to relieve stresses in a tableting machine. As expected, the stresses in methenamine decayed very slowly while those in sitosterols decayed much more rapidly. Stresses in erythromycin decayed much more rapidly than might be expected since they produced laminated compacts. This finding may account for the ability of erythromycin to withstand (not fracture) decompression but to fracture upon ejection where the time interval for decay of stress is very short.

Indentation Hardness—If a sphere is pressed against a compact surface hard enough to produce plastic flow beneath it, the mean pressure over the sphere–compact interface is essentially a constant when the chordal radius of the dent is much less than the radius of the sphere. This mean deformation pressure[13], P, is a measure of the hardness of the compact. The yield value for plastic flow is approximately 0.36 P.

The role of plastic flow in determining residual die wall pressure and in relieving concentrated stresses was emphasized in the preceding discussion. Therefore, the determination of P should be of direct interest. A method based on the rebound of a steel sphere from a compact was used (4). For comparison, the values of P for compacts with a relative density, ρ_r, of 0.85 were used for all materials. Plots of log P *versus* ρ_r are nearly straight lines and were used in interpolation to obtain the 0.85 relative density value.

Perhaps the ratio of the deformation pressure, P, divided by the tensile strength is of more interest than the deformation pressure alone. If both shear strength and tensile strength arise from the same bonded areas in a given compact, then the ratio P/σ_T for materials should have similar values unless the mechanical structure of the compact influences disproportionally the magnitude of these terms. The magnitude of P should not be influenced by crack propagation, but that of σ_T should be. Thus, if the ratio of P to σ_T varies over a large range, the pore structure may be affecting the tensile strength values. Crack propagation occurs

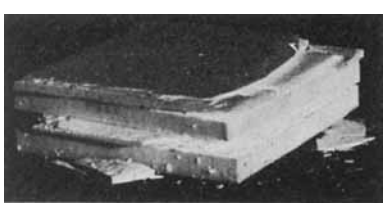

Figure 17—*Erythromycin base compact that fractured when ejected from the die. Starch and methenamine compacts fractured in a similar manner.*

[13] Analogous to P in Eq. 1, except that Eq. 1 was measured at contact points between particles. Here, the mean pressure is over a macroscopic area that may contain pores. Nevertheless, the equations for nonporous materials may be used (4).

Table III—Influence of Machine Speed and Precompression Force on the Final Compression Force that Produced Fractured Tablets[a]

Machine Speed, rpm	Precompression Force, Metric Tons	Final Compression Force, Metric Tons	
		No Lamination	Lamination
	Cupped Punches[b]

	0.225	1.361	1.814
	0.454	1.814	1.905
32	0	1.270	1.361
	0.225	1.814	1.905
	0.454	1.905	2.041
24	0	1.588	1.814
	0.225	2.268	2.495
	0.454	2.268	2.495
	Flat Punches[c]		
37	0	1.361	2.268

[a] See footnote 6 in text for the composition of the formulas. [b] When 11.9-mm flat punches and die were used with the same formulation, no lamination was observed. [c] Very little work was done with the flat punches because a formula that produced a good bond at lower pressures and laminated at the highest pressures was not developed.

when the tensile stresses at a flaw exceed the tensile strength without the shear stresses exceeding the shear strength, *i.e.*, without stress relief occurring by plastic flow. Thus, the ratio of P/σ_T might correlate with the BFP. If true, a relatively large value of P/σ_T should indicate an increased propensity for brittle fracture. Factors that could affect this comparison are differences in the surface energy of the solid, the modulus of elasticity of the compact, and the internal flaw structure that concentrates stresses. Table II shows the results of these measurements.

It is obvious from Table II that the P/σ_T values do not correlate with the BFP values. Nor do the P/σ_T values correlate with the tendency to form fractured tablets. It seems more reasonable to conclude that both σ_T and P are measuring different manifestations of the strength of the true contact areas without gross effects from stress concentration at pores controlling the values.

The impact–rebound method of determining P provides measurements of both the energy used in the permanent deformation and the energy of the elastic recovery from the impact. A high energy of elastic deformation per unit of plastic deformation energy, E_e/E_p, could indicate that large elastic stresses develop within the compact. Thus, it is of interest to compare the magnitude of E_e/E_p for the various materials. The last column of Table II lists the experimental values for several materials. Obviously, the magnitudes of the ratios of E_e/E_p do not correlate with the brittle fracture properties of the compact.

Tablet Making—Stress relaxation is believed to explain some practical problems encountered in tableting. When lamination is a problem and the production volume of a rotary machine is needed, a machine that provides precompression should be selected. The precompressed compact has time to undergo some stress relaxation before the final compression is applied. To maximize the stress relaxation, the precompression pressure should be near the maximum that will not by itself introduce lamination. This will maximize the stress relaxation that can occur before the final compression. A long dwell time under compression also will increase the time for stress relaxation. Thus, a slow operating speed also increases the time available for stress relaxation. The final compression should use as small a force as possible to obtain an acceptable tablet, since there is less stress acting at a smaller compression force to cause the compact to fracture. If the BFP of the formulation is not too high, one should be able to make a satisfactory product under the conditions described.

The use of deep oval punches is known to engender capping. Obviously, a large quantity of material in the "dome" is expanding radially as the punch is removed. Since the main body of the tablet cannot expand radially into the die wall, large shear stresses develop. Flat punches avoid this contribution to the shear stress. Therefore, when possible, tablet shape selection should be made to reduce stress gradients during tableting.

Other studies have demonstrated the effects of precompression[14]. They were repeated in the present study to observe the effects of precom-

[14] A. C. Shah, The Upjohn Co., unpublished data.

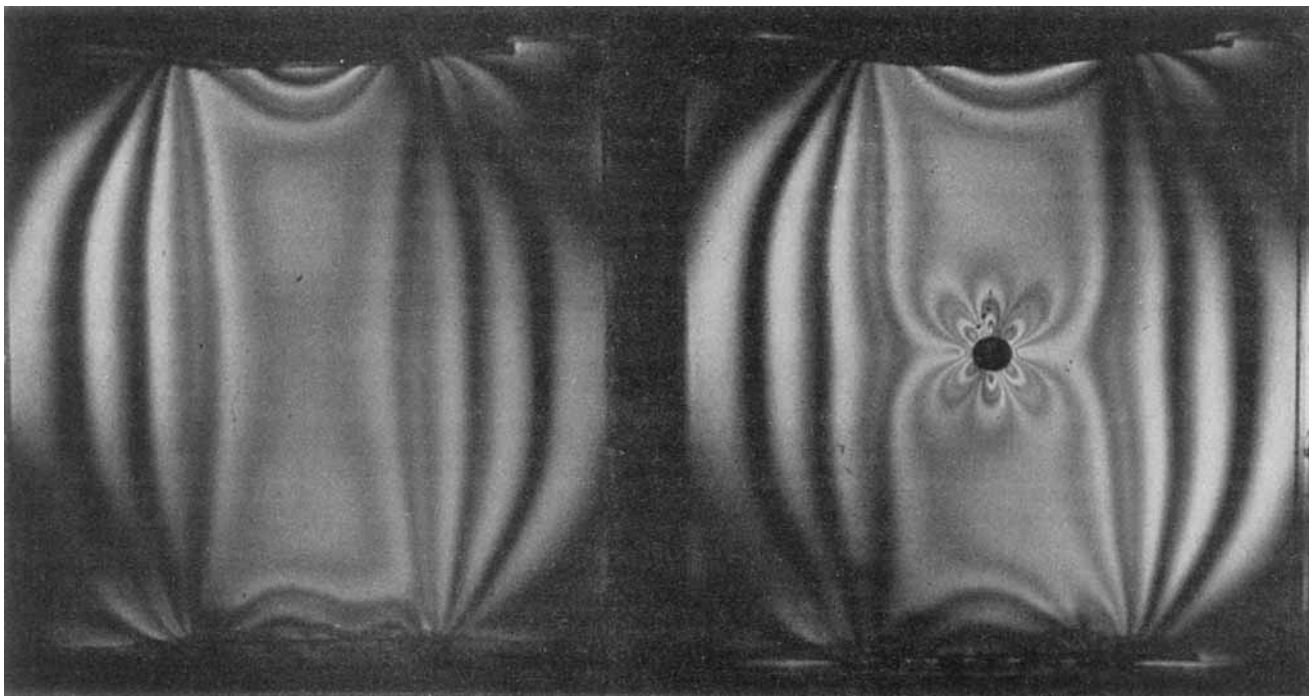

Figure 18—*Examples of simple fringe patterns obtained with and without a hole in a compact subjected to transverse compression. These photographs were made with white light and simple polarizers and are not suitable for stress analysis use. However, they identify high stress gradient areas.*

pression on final compression, the influence of machine speed, and the influence of punch shape (Table III). The theory predicts the pattern of the experimental results. Of course, quantitative predictions are not possible with the present knowledge. The minimum precompression force for intact compacts was a function of machine speed, final compression force, and punch shape. Conversely, the maximum final compression force that produced intact compacts was a function of the precompression force, the machine speed, and the punch shape. Conditions that increased the amount of stress relaxation permitted increased compression force and vice versa.

If even the best conditions of tableting still produce laminated tablets, reformulation is necessary. One should then seek an excipient material that has a very low BFP value to add to the high BFP medicament. Of course, in practice, one must also consider effects on disintegration, *etc.* Nevertheless, an understanding of the discussed principles provides much guidance in the formulation of the compressed tablet dosage form.

SUMMARY

Under the nonisostatic compression force of tableting, the powder particles undergo sufficient plastic deformation to produce a die wall pressure in excess of that that can be relieved by the elastic recovery accompanying the removal of the punch pressure. This die wall pressure produces internal stress sufficiently high to cause internal shear in the compact during the decompression. Plastic deformation occurs in repeated recompression and decompression cycles. In some materials, the internal shear stresses cause a crack to propagate and fragmentation occurs. If the stresses during decompression are not sufficient to produce crack propagation within the die during decompression, the stress concentrations developed at the edge of the die may produce crack propagation (lamination) as the tablet is ejected.

Since shear stresses develop during decompression and/or ejection, the failure to fracture appears to be due to the ability of a material to relieve shear stresses by localized shear flow, *i.e.*, plastic deformation. This property can be measured by comparing the tensile strength of a compact that contains a built-in stress concentrator "defect" with one that does not. By using this knowledge, a test was designed that indicates a property of a material called the "brittle fracture propensity." The brittle fracture propensity value indicates whether or not capping or lamination may be a problem in tableting the material.

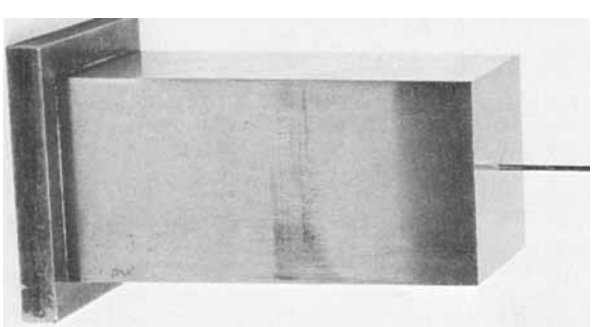

Figure 19—*Special punch used to make compacts with small hole in center. Pin is spring loaded and retractable so that any reasonable compact thickness can be used.*

Solubility Studies of Silver Sulfadiazine

R. U. NESBITT, Jr. *, and B. J. SANDMANN [x]

Abstract □ The solubility of silver sulfadiazine as a function of pH was determined in nitric acid–potassium nitrate buffer for pH 2–3 and in 2-(*N*-morpholino)ethanesulfonic acid buffer for pH 6–7. As the salt of a weak organic acid, silver sulfadiazine exhibits the anticipated increase in solubility with an increasing hydrogen-ion concentration. Measurement of the silver-ion concentration was carried out using a silver-ion selective electrode. The methods of known subtraction and known addition were utilized to measure the total concentration of the silver ion in solution. Evidence was obtained to indicate that the salt is completely ionized in aqueous solution.

Keyphrases □ Silver sulfadiazine—solubility as a function of pH, potentiometric study □ Solubility—silver sulfadiazine as a function of pH, potentiometric study □ pH—effect on solubility of silver sulfadiazine, potentiometric study □ Potentiometry—study of solubility of silver sulfadiazine as a function of pH □ Anti-infectives, topical—silver sulfadiazine, solubility as a function of pH, potentiometric study

Silver sulfadiazine, a substance with extremely low water solubility, was reported to be particularly efficacious as a topical antibacterial agent for the control of *Pseudomonas* infection in burns (1). When applied locally to burned skin, silver sulfadiazine is claimed to offer definite therapeutic advantages over other similar chemotherapeutic agents used to treat infection. Unlike other drugs that diffuse rapidly or deplete chloride ions from body fluids, silver sulfadiazine remains in the wound exudate for a prolonged effect and appears to enhance conditions favorable for epithelial regeneration.

BACKGROUND

The mode of antibacterial action is different than that of sulfonamides, because the drug is not antagonized *in vitro* by aminobenzoic acid. In binding studies using radioactive silver sulfadiazine prepared from radioactive ^{110}Ag- and ^{35}S-tracers, the silver ion was found to bind with the *Pseudomonas* cells. No cellular binding of sulfadiazine was detected (2, 3).

The binding of silver to bacterial DNA was proposed as important for inhibiting microbial growth. Silver displaces the hydrogen bonds between adjacent nitrogens of the purines (adenine or guanine) and pyrimidines (thymine and cytosine) in the DNA molecule. The nitrogen–silver bonds, once formed, appear to be stronger than the nitrogen–hydrogen bonds; therefore, bacteria having this silver–nucleic acid complex presumably

Solubility Studies of Silver Sulfadiazine

R. U. NESBITT, Jr. *, and B. J. SANDMANN [x]

Abstract □ The solubility of silver sulfadiazine as a function of pH was determined in nitric acid–potassium nitrate buffer for pH 2–3 and in 2-(*N*-morpholino)ethanesulfonic acid buffer for pH 6–7. As the salt of a weak organic acid, silver sulfadiazine exhibits the anticipated increase in solubility with an increasing hydrogen-ion concentration. Measurement of the silver-ion concentration was carried out using a silver-ion selective electrode. The methods of known subtraction and known addition were utilized to measure the total concentration of the silver ion in solution. Evidence was obtained to indicate that the salt is completely ionized in aqueous solution.

Keyphrases □ Silver sulfadiazine—solubility as a function of pH, potentiometric study □ Solubility—silver sulfadiazine as a function of pH, potentiometric study □ pH—effect on solubility of silver sulfadiazine, potentiometric study □ Potentiometry—study of solubility of silver sulfadiazine as a function of pH □ Anti-infectives, topical—silver sulfadiazine, solubility as a function of pH, potentiometric study

Silver sulfadiazine, a substance with extremely low water solubility, was reported to be particularly efficacious as a topical antibacterial agent for the control of *Pseudomonas* infection in burns (1). When applied locally to burned skin, silver sulfadiazine is claimed to offer definite therapeutic advantages over other similar chemotherapeutic agents used to treat infection. Unlike other drugs that diffuse rapidly or deplete chloride ions from body fluids, silver sulfadiazine remains in the wound exudate for a prolonged effect and appears to enhance conditions favorable for epithelial regeneration.

BACKGROUND

The mode of antibacterial action is different than that of sulfonamides, because the drug is not antagonized *in vitro* by aminobenzoic acid. In binding studies using radioactive silver sulfadiazine prepared from radioactive ^{110}Ag- and ^{35}S-tracers, the silver ion was found to bind with the *Pseudomonas* cells. No cellular binding of sulfadiazine was detected (2, 3).

The binding of silver to bacterial DNA was proposed as important for inhibiting microbial growth. Silver displaces the hydrogen bonds between adjacent nitrogens of the purines (adenine or guanine) and pyrimidines (thymine and cytosine) in the DNA molecule. The nitrogen–silver bonds, once formed, appear to be stronger than the nitrogen–hydrogen bonds; therefore, bacteria having this silver–nucleic acid complex presumably

do not replicate (4). In another report, silver sulfadiazine was said to bind to cell membranes rather than to interact with cellular DNA (5).

The mechanism of action of silver sulfadiazine is incompletely defined, and the exact role of the sulfadiazine moiety remains unclear. One proposal suggests that sulfadiazine localizes the action of the drug to the microbial cells (2). The very slow reaction of silver sulfadiazine with endogenous chloride ions is interesting when enough silver ions are apparently present to produce a strong antibacterial effect, but silver chloride reportedly does not precipitate in tissue fluids. The dissociation of silver sulfadiazine during inhibition of bacterial growth was described (3) in contrast to an earlier report that silver sulfadiazine does not ionize (6). Additional studies to determine the solubility and ionization properties of silver sulfadiazine are necessary for a complete understanding of its mechanism of action.

The crystallization and structure of silver sulfadiazine were recently reported, and the drug was characterized as a salt of a weak acid (7). A study using X-ray diffraction confirmed the assigned structure (8). The current report is concerned with the behavior of silver sulfadiazine in aqueous solutions in the presence of electrolytes and buffers. The objectives of this study were to investigate the ionization and solubility of silver sulfadiazine using recently developed potentiometric methods and to relate these properties with those of the silver salts of other N^1-substituted sulfonamides.

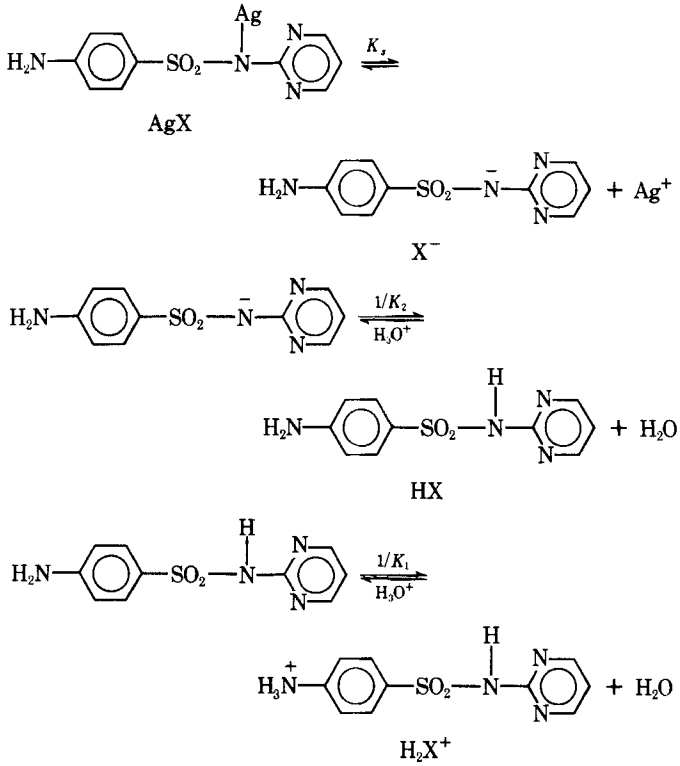
EXPERIMENTAL

Equipment—Potentiometric measurements were made using a pH meter[1], accurate to ±0.1 mv or ±0.001 pH unit, in a thermostated bath regulated at 25 ± 0.1°. The silver-ion concentration was measured with a silver-ion selective electrode[2]. The hydronium-ion concentration was measured with a triple-purpose pH electrode[3]. A double-junction silver chloride reference electrode[4] with a filling solution of 10% KNO_3 was used to eliminate the possible precipitation of silver chloride in the sample solutions.

Reagents—All reagents were of analytical grade, unless otherwise stated. Water with a specific conductivity of $1–10 \times 10^{-7}$ ohm^{-1} cm^{-1} was employed. Silver nitrate[5] and sodium sulfadiazine[5] were obtained commercially. Silver sulfadiazine was prepared by the method of Braun and Towle (9) and recrystallized as previously described (7). The 2-(*N*-morpholino)ethanesulfonic acid buffer[6] was prepared by titration of the acid with a standard sodium hydroxide solution.

Preparation of Equilibrium Mixtures—Silver sulfadiazine was screened through a size 80 standard screen[7]. Paraffin-coated vials with film-covered[8] rubber closures held in place by aluminum bands were utilized. Mixtures of 100 mg of silver sulfadiazine, 25 ml of nitric acid buffer, or 25 ml of 0.05 *M* 2-(*N*-morpholino)ethanesulfonic acid buffer were prepared, adjusted to an ionic strength of 0.1 *M* with potassium nitrate, and placed in the coated vials. For the measurement of total silver, 27 ml of buffer solution was used. The vials were rotated end-over-end in the thermostated bath until equilibrium solubility was obtained.

Measurement of Silver—After filtration of the equilibrated mixtures, the solutions were analyzed at 25 ± 0.1° in paraffin-coated beakers for the silver-ion concentration using a silver-ion selective electrode[2] standardized at 25 ± 0.1° and an ionic strength of 0.1 *M*. The electrode displayed a Nerstian response throughout the concentration range of 1×10^{-2}–1.5×10^{-6} *M* for the silver ion. The pH was measured with a pH electrode[3] standardized using standard buffers meeting National Bureau of Standards requirements (10). The total silver concentration was determined by the method of known subtraction (11, 12) in the nitric acid-buffered solution, to which a sufficient amount of a standard solution of potassium iodide was added to precipitate approximately one-half of the free silver ion. In the 2-(*N*-morpholino)ethanesulfonic acid-buffered solutions, the total silver concentration was determined by the method of known addition (12); the added reagent was a standard solution of silver nitrate representing a 100-fold increase in the free silver ion present in the sample solutions.



Scheme I

RESULTS AND DISCUSSION

In aqueous solutions, silver sulfadiazine would be expected to exhibit the general properties of the salt of a weak acid. The measurement of these properties, however, presents an analytical problem due to its extremely low water solubility. The recent development of ion selective electrode technology along with two new techniques for measuring total ion concentrations suggested the application of a potentiometric method for the analysis of silver sulfadiazine. In distilled water, the solubility of silver sulfadiazine is below the limits of analysis by any potentiometric method. However, in dilute acid, enough silver ions are ionized to give a concentration well within the sensitivity of a silver-ion specific electrode. Hydrolysis of the silver ion at near neutral or alkaline pH limits the study of silver sulfadiazine solubility to pH values less than 7.

The tendency of the silver ion to complex with various molecules and other ions reduced the number of possible buffering agents. Of the common inorganic salts of strong electrolytes, only nitrate and perchlorate ions remain in solution in the presence of silver ions. Nitric acid–potassium nitrate buffers were employed over a limited pH range. A suitable buffer for silver ions in the pH 6–7 range has not been identified. The sulfonic acid buffer system chosen exhibits minimal complexation with the silver ion (13). The use of conditional solubility product constants permits limited conclusions on solubility at this pH range.

Saturated solutions of silver sulfadiazine were analyzed for free and total silver concentrations by the analytical techniques of known addition (12) and known subtraction (11, 12). These methods were necessary due to the high probability of complexation of the silver with the sulfonic acid buffer as well as the uncertainty of the ionization properties of silver sulfadiazine. With nitrate buffers, the known subtraction method was utilized to determine the extent of ionization of the silver ion from the sulfadiazine. With this method, a complexing agent that will completely precipitate about one-half of the ion measured is added to the sample and the observed change in potential is used to calculate the original total ion concentration. By measuring the activity of free ion by a direct measurement using a calibration curve, it is possible to calculate the amount undissociated.

Due to the complexation of silver with the sulfonic acid buffer, the known addition method was used wherein a known solution of the ion being measured is added to the sample of interest. The original ion concentration is then calculated from the observed increase in potential. The usefulness of these methods depends on how well the system obeys the inherent assumptions.

The equilibria of the saturated solutions depicted by Scheme I may

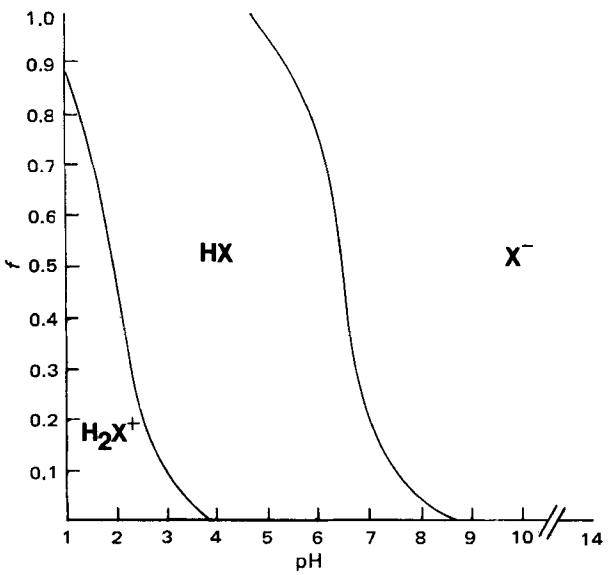

Figure 1—*Distribution diagram: fraction of sulfadiazine present as some particular form, f, as a function of pH; $pK_1 = 2.09$, and $pK_2 = 6.45$ (14).*

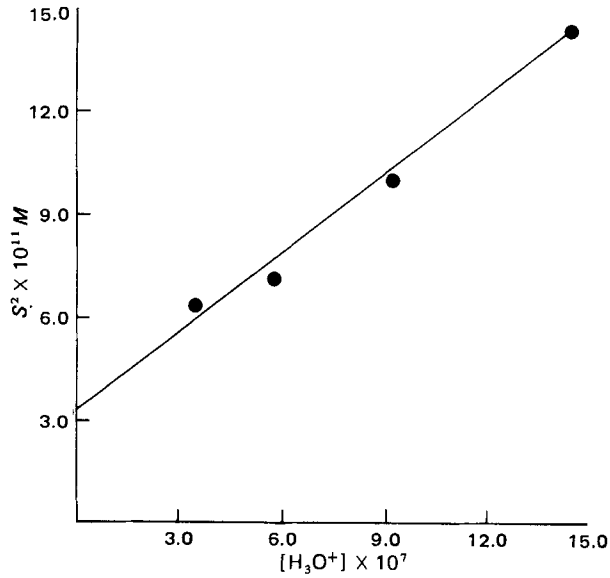

Figure 3—*Equilibrium values of* S^2 versus $[H_3O^+]$ *in 0.05* M *2-(N-morpholino)ethanesulfonic acid buffer at 0.1* M *ionic strength and 25 ± 0.1°.*

be described by:

$$K_s = [Ag^+][X^-] \quad \text{(Eq. 1)}$$

$$\frac{1}{K_2} = \frac{[HX]}{[H_3O^+][X^-]} \quad \text{(Eq. 2)}$$

$$\frac{1}{K_1} = \frac{[H_2X^+]}{[HX][H_3O^+]} \quad \text{(Eq. 3)}$$

$$S = [Ag^+] \quad \text{(Eq. 4)}$$

$$S = [H_2X^+] + [HX] + [X^-] \quad \text{(Eq. 5)}$$

where S is the total molar solubility of silver sulfadiazine. Substituting Eqs. 1–4 into Eq. 5 gives an equation that describes the solubility of silver sulfadiazine in terms of only the silver- and hydronium-ion concentrations of the saturated solution:

$$S^2 = [Ag^+]^2 = \frac{[H_3O^+]^2K_s}{K_1K_2} + \frac{[H_3O^+]K_s}{K_2} + K_s \quad \text{(Eq. 6)}$$

where K_s is the solubility product constant, and K_1 and K_2 are the ionization constants of the N^4- and N^1-hydrogens, respectively.

Equation 6 may be simplified by using the limiting conditions of low pH (2–3) and high pH (6–7). These approximations were derived by using the theoretical distribution diagram for sulfadiazine (Fig. 1), noting which species of sulfadiazine were not present in the pH range of interest, and neglecting this term in the mass balance (Eq. 5).

At the low pH range, Eq. 6 may be approximated to give:

$$S^2 = [Ag^+]^2 = \frac{[H_3O^+]^2K_s}{K_1K_2} + \frac{[H_3O^+]K_s}{K_2} \quad \text{(Eq. 7)}$$

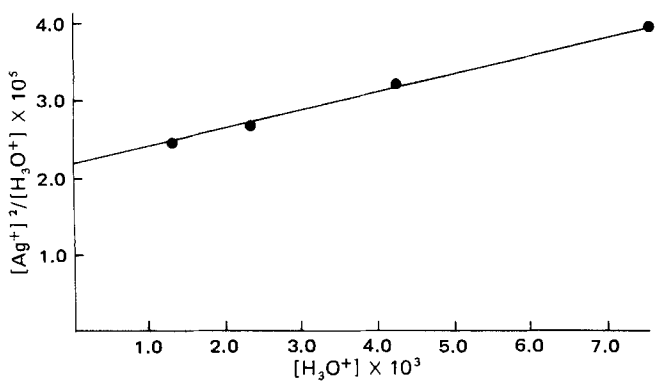

Figure 2—*Equilibrium values of* $[Ag^+]^2/[H_3O^+]$ versus $[H_3O^+]$ *at 0.1* M *ionic strength and 25 ± 0.1°.*

by neglecting the X^- species in Eq. 5. This equation may be linearized by dividing both sides by the hydronium-ion concentration, giving Eq. 8:

$$\frac{[Ag^+]^2}{[H_3O^+]} = \frac{[H_3O^+]K_s}{K_1K_2} + \frac{K_s}{K_2} \quad \text{(Eq. 8)}$$

When $[Ag^+]^2/[H_3O^+]$ is plotted against $[H_3O^+]$, a linear relationship should exist with an intercept of K_s/K_2 and a slope of K_s/K_2 $(1/K_1)$. From the slope and intercept, K_1 may be experimentally determined under the given conditions.

In the pH range of 6–7, Eq. 6 may be approximated to give:

$$S^2 = [Ag^+]^2 = \frac{[H_3O^+]K_s}{K_2} + K_s \quad \text{(Eq. 9)}$$

where the H_2X^+ species in Eq. 5 has been neglected. The application of Eq. 9 to the experimental data in the presence of the 2-(*N*-morpholino)-ethanesulfonic acid buffer does not completely represent the system due to apparent complexation of the free silver ion with the buffer, giving an increased value of the solubility, S, and subsequently a higher value for K_s, the solubility product constant.

A suitable modification of Eq. 9 to include this complexation may be made by using a conditional solubility product constant, K_s', defined by:

$$K_s' = [Ag^+]'[X^-] \quad \text{(Eq. 10)}$$

where $[Ag^+]'$ represents the concentration of all silver in solution irrespective of the form in which the silver ion may be present. Equation 9 may now be rewritten as:

$$S^2 = \frac{[H_3O^+]K_s'}{K_2} + K_s' \quad \text{(Eq. 11)}$$

Table I—Comparison of Total Molar Solubility, *S*, of Silver Sulfadiazine Determined by the Method of Known Subtraction with the Molar Concentration of the Silver Ion Determined by Direct Potentiometry on Identical Samples at 25 ± 0.1°, Ionic Strength 0.1 *M*, in Nitric Acid Buffers

2.373	6.024×10^{-5}	1.352×10^{-7}	8.16×10^{-12}
2.630	1.279×10^{-4}	6.165×10^{-8}	7.90×10^{-12}
2.891	2.583×10^{-4}	3.139×10^{-8}	8.14×10^{-12}
Mean	$8.06 \times 10^{-12} \pm 0.12$		

[a] $K_1 = 8.59 \times 10^{-3}$, and $K_2 = 3.82 \times 10^{-7}$.

where S is the total molar solubility, and K_2 is defined by Eq. 2. A plot of S^2 *versus* $[H_3O^+]$ would be expected to be linear with an intercept of K_s' and a slope of K_s'/K_2, from which K_2 may be experimentally determined.

Figure 2 is a linear plot of the equilibrium values of $[Ag^+]^2/[H_3O^+]$ against the equilibrium $[H_3O^+]$ value, having a slope of 2.459×10^{-3} and an intercept of 2.112×10^{-5}. From the slope and intercept, pK_1 was found to be 2.07 ± 0.06 at an ionic strength of 0.1 *M*. This value is in agreement with a literature value of 2.09 (14). As shown in Fig. 3, a plot of S^2 *versus* $[H_3O^+]$ at equilibrium is linear with an intercept of 3.05×10^{-11} and a slope of 7.98×10^{-5}. From the slope and intercept, pK_2 was evaluated experimentally to be 6.42 ± 0.04, in agreement with a previously reported value of 6.45 (14).

The possibility of intact silver sulfadiazine in solution in a pH range of 2.1–3.8 was investigated by comparison of the total molar solubility, S, as determined by the method of known subtraction, with the molar concentration of free silver ion, $[Ag^+]$, by direct potentiometric analysis on identical samples under the given experimental conditions. By the use of one-way analysis of variance, the means displayed in Table I are not statistically different at the 5% level. Therefore, in the pH 2–3 range,

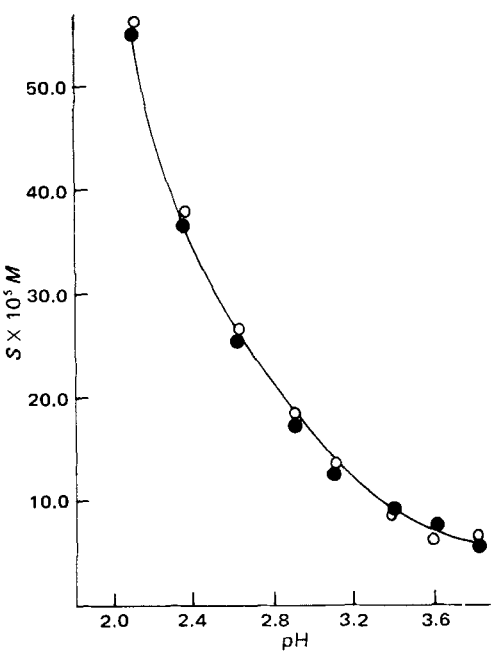

Figure 4—*Molar solubility (S) of silver sulfadiazine* versus *pH at 0.1 M ionic strength and 25 ± 0.1°. Key: ●, experimental values; and ○, calculated from Eq. 7 and the equilibrium constants determined in this study.*

the solubility, S, of silver sulfadiazine is given by Eqs. 4 and 5. The solubility product of silver sulfadiazine is given by Eq. 1. By substituting Eqs. 2 and 3 into Eq. 5, an expression may be derived giving the ratio, f_0, of the sulfadiazine anion to the total solubility, where:

$$f_0 = \frac{[X^-]}{S} = \left(1 + \frac{[H_3O^+]}{K_2} + \frac{[H_3O^+]^2}{K_1K_2}\right)^{-1} \quad \text{(Eq. 12)}$$

Combining this expression with Eq. 1 gives:

$$K_s = f_0S^2 \quad \text{(Eq. 13)}$$

Application of this equation to the experimental data at the low pH range is given in Table II, where the mean solubility product constant for silver sulfadiazine was $8.06 \pm 0.12 \times 10^{-12}$.

A plot of the molar solubility, S, of silver sulfadiazine against pH over the pH range studied is displayed in Fig. 4. This plot at pH 2–3 compares very closely with the distribution of the sulfadiazine cation over the same pH range. Thus, the solubility of silver sulfadiazine is directly a function of sulfadiazine ionization.

The solubility would be expected to be nearly pH independent in the pH 4–5 range where the predominant sulfadiazine species is the neutral molecule. For pH 6–7, the solubility is estimated by Eq. 9. At pH 6, the calculated solubility, S, was 5.40×10^{-6} *M*; at pH 7, it was 3.19×10^{-6} *M*. Where the predominant sulfadiazine species is the sulfadiazine anion, the limiting value of the solubility would be expected to be the square root of the solubility product constant, $\sqrt{K_s} = 2.83 \times 10^{-6}$ *M*.

GLC Assay of Conjugated Estrogen Formulations

K. M. McERLANE ˣ and N. M. CURRAN

Abstract □ A procedure is described for the enzyme hydrolysis and GLC assay of conjugated estrogens in commercial formulations. Resolution of up to nine of the components is achieved on a methyl phenyl cyanopropyl silicone-coated column using a dual-derivatization and dual-injection technique. Replicate results from analyses of a commercial tablet formulation yielded coefficients of variation between 1.0 and 17.2%, depending mainly on the quantity present; a coefficient of variation of 0.4% was obtained for the assay for total conjugated estrogens. Similar results were obtained with other commercial formulations.

Keyphrases □ Estrogens, conjugated—enzyme hydrolysis and GLC analysis, commercial formulations □ GLC—analysis, conjugated estrogens, commercial formulations □ Enzyme hydrolysis—for GLC analysis of conjugated estrogens, commercial formulations □ Hormones—conjugated estrogens, enzyme hydrolysis and GLC analysis, commercial formulations

According to the USP (1), conjugated estrogens contain "a mixture of the sodium salts of the sulfate esters of the estrogenic substances, principally estrone and equilin, that are of the type excreted by pregnant mares." The USP also requires that conjugated estrogens contain dihydroequilin-17α, dihydroequilin-17β, estradiol-17α, estradiol-17β, 8-dehydroestrone, and equilenin. In addition, other sulfate esters of dihydroequilenin-17α and dihydroequilenin-17β have been identified in the urine of pregnant mares (2).

The USP XIX assay for conjugated estrogens is a long and difficult procedure, in which only estrone (I) and equilin (II) are quantified after acid hydrolysis of the sulfates. Dihydroequilin-17α and 17β (III), estradiol-17α and 17β (IV), 8-dehydroestrone (V), and equilenin (VI) are separately identified only by GLC following enzyme hydrolysis. The assay for total conjugated estrogens is performed separately using a color-producing reagent.

Experience in these laboratories indicated that the acid hydrolysis of the sulfate may lead to decomposition of some estrogens, notably dihydroequilin.

Because of the complex nature of the product, many methods have been suggested to resolve the components including column (3–6), thin-layer (7, 8), paper (9–13), high-speed liquid (14), and gas–liquid (15–17) chromatographic techniques. Earlier studies (18) showed the feasibility of resolving the estrogen steroids by GLC using a dual-derivatization and dual-injection procedure on a methyl phenyl cyanopropyl silicone (OV-225) column.

In the present procedure, the sulfate esters of equine estrogens are hydrolyzed by enzyme incubation and subsequently quantified by GLC.

EXPERIMENTAL

Enzyme Hydrolysis—*Tablet Samples*—Twenty tablets were weighed and finely powdered, and an aliquot equivalent to 1.5 mg of conjugated estrogens was weighed directly into a 50-ml round-bottom, polytetrafluoroethylene[1]-lined, screw-capped centrifuge tube. Fifteen milliliters of acetate buffer (pH 5.2, 0.02 *M*) was added, and the tubes were shaken on a horizontal shaker for 30 min.

Injectable Samples —The contents of a multiple injection vial (25 mg) were transferred quantitatively to a 50-ml volumetric flask, using the acetate buffer, and brought to volume. A 3-ml aliquot (1.5 mg) of this solution was then placed in a 50-ml round-bottom, polytetrafluoroethylene-lined, screw-capped centrifuge tube containing 12 ml of acetate buffer.

Redistilled benzene (10 ml) was added to all tubes, and they were gently shaken on a horizontal shaker for 20 min. The tubes were centrifuged, and the top benzene layer was removed as completely as possible with a 10-ml pipet. An additional 10 ml of benzene was added, and the process was repeated. The tubes were then shaken to resuspend the solid material, and the contents were transferred to a 250-ml round-bottom flask; the tubes were rinsed with 2 × 2 ml of acetate buffer, which was added to the flask. By using a rotary evaporator and taking care to avoid frothing, the residual benzene was removed until its odor was no longer apparent. Traces of benzene remaining in the centrifuge tube were removed with a gentle stream of air.

The contents of the flask were then transferred back to the original centrifuge tube with 3 × 2 ml of acetate buffer, 7500 units of sulfatase enzyme was added, and the tubes were incubated for 30 min at 45° with occasional shaking. The tubes were then cooled to room temperature, 15 ml of pure redistilled chloroform was added, and the tubes were shaken for 30 min on a horizontal shaker.

After centrifuging, the chloroform layer was removed as completely as possible by driving the tip of a pipet down through the aqueous layer and gently blowing out any water that may have entered the pipet before drawing up the chloroform. The chloroform was transferred to a stoppered tube through a funnel containing a pledget of glass wool covered with a bed of anhydrous sodium sulfate. The free phenolic estrogens were stored in the refrigerator until required for derivatization. (Storage times did not exceed 2 days.)

Sample Preparation—Two 5-ml polytetrafluoroethylene-lined, screw-capped, conical vials[2] were used for each sample. One milliliter of an ethanolic solution of the internal standard, ethinyl estradiol[3] (VII), was added to one vial, and then 3 ml of the estrogen hydrolysate in chloroform was added to each vial. To the vial containing the estrogens and the internal standard, 0.1 ml of pyridine and 0.05 ml of a silylating reagent[4] were added; the sample was capped and heated for 10 min at 60°. To the other sample (no internal standard), 0.1 ml of a 2% solution of methoxamine in pyridine was added; this sample was heated at 60° for 3 hr. After this time, 0.05 ml of silylating reagent was added and the solution was further heated at 60° for 10 min.

At the completion of the silylation reaction, 2–4-μl aliquots of the samples were injected in the 3% OV-225 column.

Column Packing—Experience has shown that the method of column preparation is important in achieving good resolution. Therefore, the procedure is described in detail.

The coated support, 3% OV-225 on Chromosorb W (HP), 100–120 mesh[5], was prepared by uniformly depositing a chloroform solution (50 ml) of the stationary phase (0.75 g), using a Pasteur pipet, over the surface of a bed of the support phase (25 g) uniformly dispersed in a 13.97-cm (5.5-in.) petri dish. The vessel in which the stationary phase was prepared was rinsed with 2–3 ml of chloroform onto the support in the same manner.

The barely moist cake of coated support was then transferred to a fluidizer sitting on a hot plate. With a gentle stream of clean dry nitrogen flowing through the fluidizer, the temperature of the hot plate was raised until a thermometer inserted in the base of the fluidizer registered about 175°. Heating was continued for 0.5 hr or until the coated support tumbled freely and no odor of chloroform was detectable.

A 1.8-m × 0.63-cm (6-ft × 0.25-in.) o.d., glass, U-shaped column was filled with chromic acid and allowed to sit for 0.5 hr. The column was emptied, rinsed with water and methanol, and then dried by drawing air through it. It was then filled with 5% dimethylchlorosilane in dry toluene

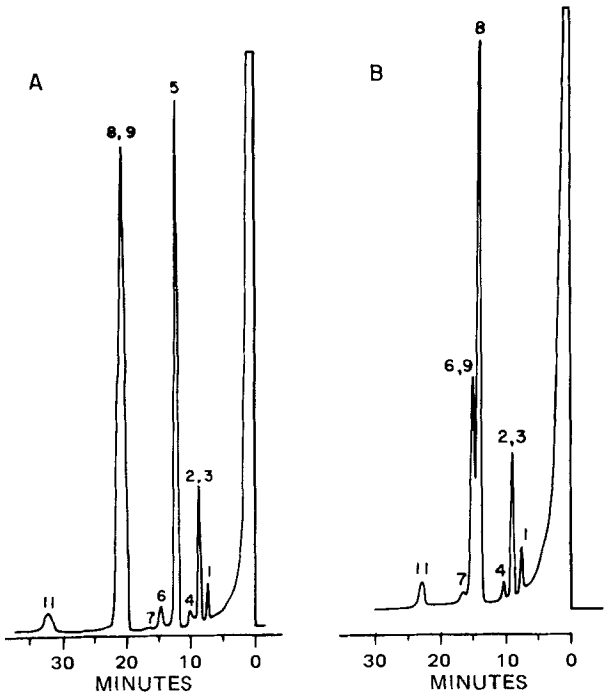

Figure 1—*Trimethylsilyl (A) and methoxamine–trimethylsilyl (B) derivatives of a synthetic composite of equine estrogens. Key: 1, estradiol-17α; 2, estradiol-17β; 3, dihydroequilin-17α; 4, dihydroequilin-17β; 5, ethinyl estradiol; 6, dihydroequilenin-17α; 7, dihydroequilenin-17β; 8, estrone; 9, equilin; and 11, equilenin.*

and allowed to stand for 1 hr. Then it was emptied, rinsed with methanol and acetone, and thoroughly dried as before.

The column was packed by applying vacuum on one end while adding about 15.2-cm (6-in.) sections of coated support to the other and gently vibrating each section.

The column was conditioned in the gas chromatograph oven at 175° with a nitrogen flow of 45 ml/min for 8 hr. The oven temperature was then raised to 235° at 3°/min and held for an additional 16 hr or until a stable baseline was achieved. An occasional injection of a mixture of *N,O*-bis-(trimethylsilyl)acetamide, trimethylsilyldiethylamine, and hexamethyldisilazane[6] shortened conditioning times.

RESULTS AND DISCUSSION

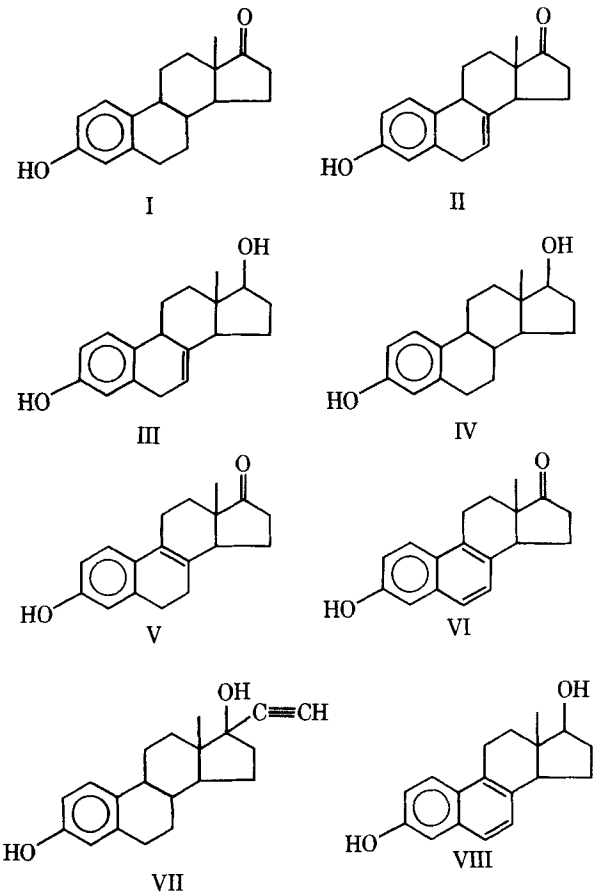
The resolution achieved using a 3% methyl phenyl cyanopropyl silicone (OV-225) column for the trimethylsilyl derivatives of a synthetic composite of sulfates of equine estrogens (I–VIII) is shown in Fig. 1A. In this chromatogram, baseline separation of all steroids is apparent except for the pairs estradiol-17β–dihydroequilin-17α and estrone–equilin within a total chromatographic analysis time of less than 55 min.

Separation of the two major steroids, estrone and equilin, was achieved by forming the methoxamine–trimethylsilyl derivatives of the keto steroids present in the mixture with the resulting resolution (R = 0.8) of the keto steroids as shown in Fig. 1B. The pair estradiol-17β–dihydroequilin-17α could not be resolved under any conditions employed. However, since the former is known to contribute little to the normal natural balance of the components of equine estrogens (2), little interference would be observed in the determination of dihydroequilin-17α. (The steroid 8-dehydroestrone was not included in the synthetic mixture due to a short supply.)

Quantitative Aspects—To utilize this resolution of estrogens as the basis of a quantitative method for the individual determination of most, if not all, of the components of conjugated estrogens, area response factors for the trimethylsilyl derivatives of the estrogens were determined in relation to an internal standard, ethinyl estradiol (Table I).

With the addition of a known amount of internal standard, the absolute amounts of each steroid in a mixture could then be determined from:

$$A = \frac{B \times C \times D}{E} \qquad \text{(Eq. 1)}$$



where A = weight of steroid, B = response factor, C = weight of internal standard, D = area of steroid, and E = area of internal standard.

The determination of the amounts of the equine estrogens observed in a sample from the foregoing calculation will yield a total for estrone and equilin. However, the proportions of these two steroids can be determined from the chromatogram of the methoxamine–trimethylsilyl derivatives (which does not contain any internal standard) by their relative peak heights. Peak height responses for estrone and equilin were identical. The peak observed for equilin as its methoxamine–trimethylsilyl derivative overlaps with that for the trimethylsilyl derivative of dihydroequilenin-17α (VIII). The contribution of the latter is most easily determined by the peak height ratio between the chromatogram of the trimethylsilyl derivatives and that for the methoxamine–trimethylsilyl derivatives by:

$$F = \frac{G \times H}{I} \qquad \text{(Eq. 2)}$$

where F = height of dihydroequilenin-17α in the methoxamine–trimethylsilyl chromatogram, G = height of dihydroequilenin-17α in the trimethylsilyl chromatogram, H = height of dihydroequilenin in the methoxamine–trimethylsilyl chromatogram, and I = height of dihydroequilin in the trimethylsilyl chromatogram.

Subtraction of the contribution of dihydroequilenin-17α from equilin

Table I—Response Factors for Equine Estrogens

Trimethylsilyl Steroid Ethers	Response[a]
Estradiol-17α	0.91
Estradiol-17β	1.04
Dihydroequilin-17α	1.04

Equilenin	2.8–3.7	3.4	9.6
Assay[a]	2.49–2.51 mg	2.5 mg	0.4

[a] $n = 6$.

yields the true height of the equilin peak. This value can then be used, along with the height of the peak observed for estrone, to determine the relative amounts of estrone and equilin from the total of these two estrogens obtained as their combined trimethylsilyl derivatives. The quantitation of the individual estrogens is then complete, and these values can simply be added to give the total assay amount of the free phenolic estrogens. The equivalent weight of the conjugates can then be calculated by:

$$\text{total assay} = \text{weight of free steroids} \times 1.38 \times \text{dilution factor} \quad \text{(Eq. 3)}$$

where 1.38 represents the weighted molecular weight ratio between free phenol and the sulfate ester.

To test the robustness of the 3% OV-225 column to varying conditions of the gas chromatograph, the column oven temperature was adjusted ±15° around the normal 225° used for the assay. The nitrogen flow was also adjusted ±15 ml/min around the 40 ml/min employed. None of these conditions, either singly or in combination, markedly affected the assay results of the individual steroids or the total assay. Under the extreme conditions of the column temperature and gas flow, the total chromatogram time for the trimethylsilyl derivatives varied between 20 and 45 min with no apparent lack of resolution.

To evaluate the variability of the GLC assay of a synthetic mixture of equine estrogens, a sample of the free phenolic steroids was prepared and then assayed according to the described method (Table II).

Enzyme Hydrolysis—Before the assay method could be applied to commercial conjugated estrogen formulations, the hydrolytic cleavage

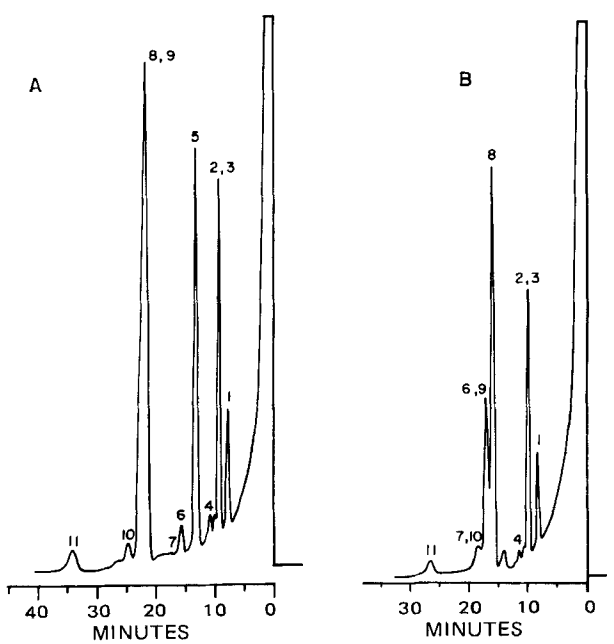

Figure 2—*Trimethylsilyl (A) and methoxamine–trimethylsilyl (B) derivatives of equine estrogens obtained from a 2.5-mg commercial tablet. Key: 1, estradiol-17α; 2, estradiol-17β; 3, dihydroequilin-17α; 4, dihydroequilin-17β; 5, ethinyl estradiol; 6, dihydroequilenin-17α; 7, dihydroequilenin-17β; 8, estrone; 9, equilin; 10, 8-dehydroestrone; and 11, equilenin.*

of the sodium sulfate esters of the phenolic steroids was investigated. The sulfatase enzyme derived from *Helix pomatia*[7] was subjected to varying time, temperature, buffer concentration, and pH conditions. Many methods (19, 20) showed the effectiveness of sulfatase enzyme in pH 5.2 acetate buffer at 37° toward the hydrolysis of estrone sulfate. However, the time interval quoted was frequently about 18 hr, and this time was deemed inappropriate for this study. Therefore, the variables of temperature (40, 45, 50, and 55°), pH (4.5, 5.2, 5.5, and 6.0), hydrolysis time (20, 30, and 40 min), and acetate buffer molarity (0.02, 0.1, and 0.2) were studied. The results indicated that quantitative recovery of the free steroid could be expected under all conditions and combinations of these conditions when potassium estrone sulfate was used as a substrate. As a laboratory convenience, commercial sulfate conjugates of equine estrogens were routinely hydrolyzed at 45° for 30 min in 0.02 *M* acetate buffer at pH 5.2.

When conjugated estrogen samples were initially hydrolyzed under these conditions and then extracted into chloroform (a single extraction was quantitative), the samples revealed, after evaporation and silylation, an extraneous peak in the chromatogram interfering with the less retentive diols. A benzene prewash of the formulation samples, after they had been extracted into the acetate buffer, removed the interference. This peak, appearing between the trimethylsilyl derivatives of estradiol-17α and dihydroequilin-17α, was purified by preparative GLC of the silylated prewash residue. Mass spectral analysis of the compound giving rise to the impurity showed an apparent molecular ion at *m/e* 396 with other prominent ions at *m/e* 381, 323, 277, 217, 216, 203, 189, 188, 187, and 159. Comparisons of the mass spectra with other similarly prepared estrogen samples failed to provide any similarities between the samples.

To ascertain that sufficient enzyme was being used to obtain complete hydrolysis of estrogen conjugates in formulations (phosphate inhibits the action of sulfatase enzyme and is used in tablet formulas), a series of tablet samples was prepared using 1000, 2000, 4000, 8000, and 10,000 units of sulfatase. In some cases, 1000 units of enzyme was sufficient to yield theoretical quantitative recovery of the estrogens, but other samples required at least 4000 units. Consequently, for new tablet formulations, each analysis was performed in triplicate using 1000, 5000, and 7500 units of enzyme to expose enzyme inhibition.

Formulation Quantitation—A commercial 2.5-mg tablet was assayed by obtaining the trimethylsilyl derivative of the steroid hydrolysate (Fig. 2A). The peak due to dihydroequilenin-17β is not noticeable in the chromatogram but was detected by the integrator. A peak following the estrone–equilin peak was identified as 8-dehydroestrone from chromatographic comparison with authentic material. The chromatogram of the methoxamine–trimethylsilyl derivative (Fig. 2B) displays the partial resolution of estrone and equilin, sufficient to allow their quantitation (Table III).

The chromatograms of the trimethylsilyl and methoxamine–trimethylsilyl derivatives of a 1.25-mg tablet obtained from the same manufacturer are shown in Figs. 3A and 3B, and the quantitative assay is given in Table IV. The similarity of relative estrogen amounts is quite obvious and would likely be related to the manufacturer's source of pregnant mare's urine. The label claim of 1.25 mg was exceeded in this instance by 16%, the USP maximum.

Similar results (Table V) were obtained for the analysis of an injectable preparation from the same manufacturer; again the similarity of the relative proportions of steroids points to a uniform source.

The method has been applied with equal facility to various tablet

[7] Type H-2, Sigma Chemical Co., St. Louis, Mo.

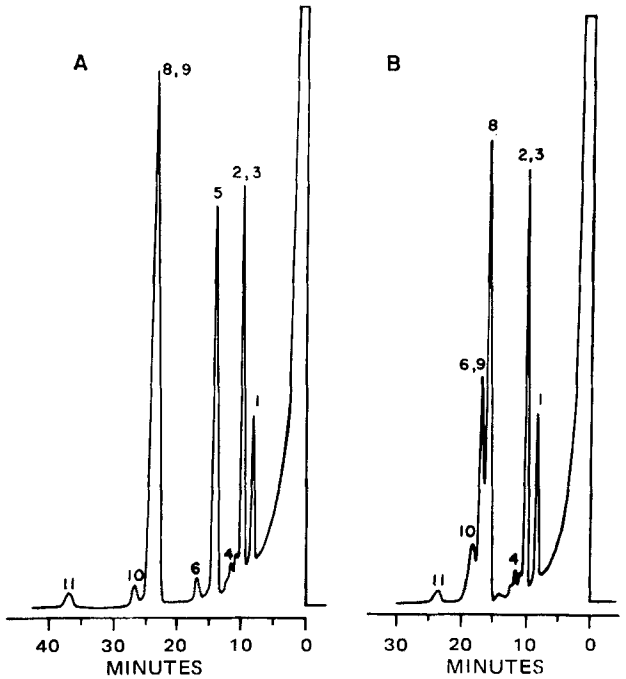

Figure 3—*Trimethylsilyl (A) and methoxamine–trimethylsilyl (B) derivatives of equine estrogens obtained from a 1.25-mg commercial tablet. formulations and has provided the basis of a GLC identification and quantitation of the main estrogenic components of conjugated estrogen preparations.

Comparison with Literature Methods—Other GLC methods for the quantitative analysis of esterified (16) and conjugated (17) estrogens have been reported. They are based on the resolution of the trimethylsilyl ether derivatives of the free equine estrogens on a diethylene glycol succinate-coated column. The steroids are resolved, except that the peak due to estradiol-17β appears as a shoulder on the dihydroequilin-17α peak. On an OV-225 column as used in the present study, the peak due to the minor constituent, estradiol-17β, is not resolved from dihydroequilin-17α.

The proposed OV-225 column is apparently indefinitely stable under conditions of normal usage. Diethylene glycol succinate columns, however, are limited to a useful lifetime to 2–3 weeks in equine estrogen analysis (2), probably due to column breakdown from oxidative processes and to bleed at the temperature of the analysis (21). In addition, there are reportedly batch-to-batch variations in the properties of diethylene glycol succinate (22), and these variations may affect the chromatographic behavior of the steroids.

The time and cost of the OV-225 and diethylene glycol succinate procedures are comparable. The time required for preparation of the additional samples for the OV-225 procedure is compensated for by the chromatographic time of 55 min as compared to 75 min for the diethylene glycol method. The peaks observed on the OV-225 column are sharp, whereas those seen on the diethylene glycol succinate are broadened due to the longer retention times; the peak due to equilenin, therefore, may be difficult to quantify. Calculations associated with the OV-225 method are marginally longer due to the double-injection technique, but this factor is not significant in practice[8].

Both the OV-225 and diethylene glycol succinate methods have advantages. For the analysis of a single sample, the preference may be for the diethylene glycol succinate method because of the slightly better resolution. For the long-term analysis of many samples, the stability and robustness of the OV-225 method appear to be highly advantageous.

Table IV—Assay of 1.25-mg Tablet

Steroid	Weight, mg	Percent
Estradiol-17α	0.08	5.5
Estradiol-17β–dihydro-equilin-17α	0.21	14.5
Dihydroequilin-17β	0.01	0.7
Dihydroequilenin-17α	0.03	1.7
Dihydroequilenin-17β	0.01	0.3
Estrone	0.74	50.6
Equilin	0.32	21.9
8-Dehydroestrone	0.03	2.0
Equilenin	0.04	2.7
Total	1.46 mg	(116% of label claim)

Table V—Assay of 25-mg Multiple Injection Vial

Steroid	Weight, mg	Percent
Estradiol-17α	0.81	3.0
Estradiol-17β–dihydro-equilin-17α	4.14	15.4
Dihydroequilin-17β	0.97	3.6
Dihydroequilenin-17α	0.36	1.3
Dihydroequilenin-17β	0.06	0.2
Estrone	12.66	47.2
Equilin	6.64	24.7
8-Dehydroestrone	0.56	2.1
Equilenin	0.68	2.5
Total	26.9 mg/vial	(107% of label claim)

GLC Analysis of Acetazolamide in Blood, Plasma, and Saliva following Oral Administration to Normal Subjects

SYLVIA M. WALLACE *, VINOD P. SHAH ‡, and SIDNEY RIEGELMAN ˣ

Abstract □ An electron-capture GLC assay for acetazolamide in biological fluids was developed. Extraction efficiency was 96–104%. The minimum detectable amount of acetazolamide was 10 ng/sample. Concentrations of acetazolamide were determined by GLC in blood, plasma, plasma water, and saliva after oral administration of a single 250-mg dose to five volunteers. Erythrocyte levels were calculated from whole blood and plasma data. Concentration of free drug in the plasma was measured in samples of plasma water obtained by microultrafiltration. Peak plasma levels of 10–18 μg/ml were reached 1–3 hr after the dose. At least 1 hr later, erythrocyte levels reached peak concentrations of 13–29 μg/ml. Over 31 hr, plasma levels declined more rapidly than erythrocyte levels. Saliva concentrations averaged 1% of those in plasma and decreased at a rate equal to that of plasma. Saliva levels were proportional to, but not equal to, plasma water concentration. Saliva to plasma ratios were consistent for any given individual and, therefore, offer a means of monitoring drug dosage without resorting to frequent blood sampling.

Keyphrases □ Acetazolamide—GLC analysis, human blood, plasma, and saliva □ GLC—analysis, acetazolamide, human blood, plasma, and saliva □ Carbonic anhydrase inhibitors—acetazolamide, GLC analysis, human blood, plasma, and saliva

Acetazolamide is used primarily to control intraocular pressure in the treatment of glaucoma. Side effects of the drug, although not life threatening, are often severe enough to warrant discontinuing therapy. At present, dosage regimens are adjusted empirically to balance therapeutic and toxic effects. However, by using as a guideline the minimum effective plasma concentration for lowering intraocular pressure (10 μg/ml) established by Lehmann *et al.* (1), a more efficient, individualized control of therapy should be possible.

The present study was designed to:

1. Develop a rapid, sensitive method for quantitating acetazolamide in biological fluids. Until recently (2), techniques for analyzing acetazolamide have been limited to the carbonic anhydrase inhibition method (3). However, the lower limit of the enzyme assay is 0.2 μg/ml of plasma.

2. Determine the feasibility of monitoring acetazolamide dosage in glaucoma patients by measurement of saliva concentrations. Saliva has been suggested (4–6) as a satisfactory alternative to plasma for routine monitoring of pharmacokinetic parameters. Use of saliva as the sampling fluid precludes the discomfort and inconvenience of multiple venipunctures but still yields the requisite information for dosage regimen adjustment.

3. Establish the relationship between plasma, saliva, and erythrocyte (red blood cell) concentrations of acetazolamide after oral administration of a single 250-mg dose to humans. Acetazolamide has a high affinity for binding sites, purportedly carbonic anhydrase enzymes, within the red blood cells (7). To define the kinetics of multiple dosing, the pool of drug within the red blood cells must be examined.

EXPERIMENTAL

Materials—Acetazolamide[1], fluoranthene[2], analytical grade solvents[3] (ether, dichloromethane, and 2-propanol), and trimethylphenylammonium hydroxide[4] (0.1 *M* in methanol) were used as obtained from standard sources without further purification. Tetramethylammonium hydroxide[5] (20% in methanol) diluted with methanol to 0.2% was used as an alternative derivatizing reagent, since many lots of trimethylphenylammonium hydroxide produce interfering peaks on electron-capture GLC.

Sample Preparation—Aliquots of blood, plasma (50–100 μl), and saliva (1–2 ml), adjusted to approximately pH 5 by the addition of 0.5 ml of 0.1 *M* acetate buffer, were extracted with 10 ml of organic solvent (six volumes of ether, four volumes of dichloromethane, and two volumes of 2-propanol). Tubes were centrifuged[6] for 15 min at 1500 rpm. The lower aqueous layer was frozen in a dry ice–acetone bath, and the upper organic layer was decanted quantitatively. Alternatively, if the concentration of acetazolamide in plasma or saliva exceeded the linear range of the standard curve, an aliquot of the organic layer was removed. The organic extract was evaporated to dryness under a slow stream of nitrogen.

Chromatographic Analysis—The internal standard, fluoranthene (2.5 μg in an ether solution), was added to the dried organic extract of plasma and saliva samples. The solvent was evaporated to dryness under nitrogen. After addition of 50 μl of methylating reagent (0.1 *M* trimethylphenylammonium hydroxide or 0.2% tetramethylammonium hydroxide in methanol), 2-μl aliquots were chromatographed. Chromatograms obtained with the two methylating reagents were identical.

The gas chromatograph[7] equipped with a ^{63}Ni-electron-capture detector was operated at 280, 215, and 340° for the injector, column, and detector, respectively. Solutions were chromatographed on a 1.8-m, 0.3-cm (6-ft, 0.124-in.) o.d. glass column packed with 3% OV-17 on Gas Chrom Q[8] (100–120 mesh). Carrier gas (95% argon, 5% methane) flow was 30 ml/min.

Sample Collection—Five healthy volunteers (two females and three males) between the ages of 24 and 31 years were each given a 250-mg tablet of acetazolamide[9] on an empty stomach. Blood samples were collected in heparinized tubes[10] at 0, 0.25, 0.5, 1, 2, 3, 5, 7, 9, 24, 27, and 31 hr after drug administration. At the same time, saliva (stimulated by chewing an elastic band) was collected in wide mouth vials. Saliva and plasma (separated from whole blood by centrifugation) were stored at 0° prior to analysis. Aliquots (100 μl) of plasma water were obtained from the 1-, 2-, 3-, 5-, 7-, and 9-hr plasma samples using a microultrafiltration procedure (8).

Calculation of Red Blood Cell Levels—Concentrations of acetazolamide in plasma, plasma water, blood, and saliva were measured directly by electron-capture GLC. Concentrations of the drug in the red blood cell fraction were calculated using the hematocrit:

$$C_B = C_{RBC}(H) + C_P(1 - H) \quad \text{(Eq. 1)}$$

$$C_{RBC} = \frac{C_B - C_P(1 - H)}{H} \quad \text{(Eq. 2)}$$

where C_B is the concentration in the blood, C_P is the concentration in the plasma, C_{RBC} is the concentration in the red blood cells, and H is the hematocrit.

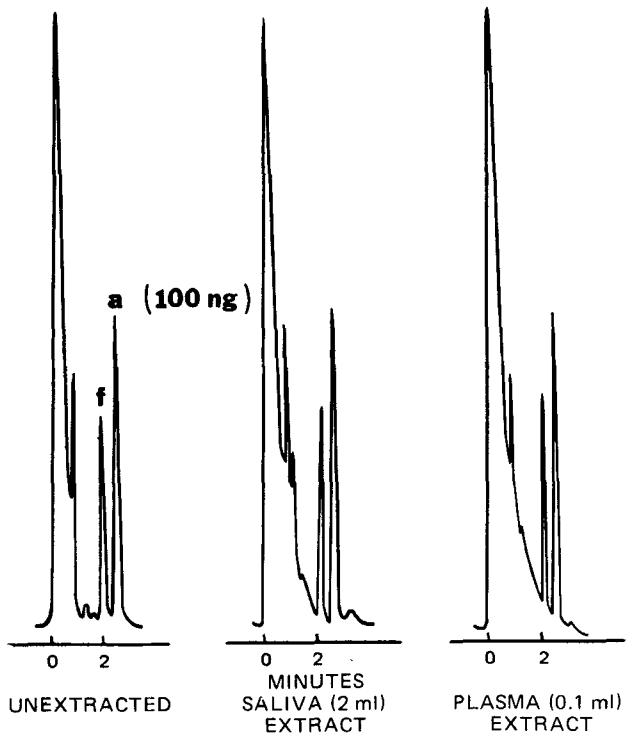

Figure 1—*Gas chromatogram of 2.5 μg of fluoranthene (f) internal standard and 100 ng of acetazolamide (a) unextracted, extracted from 2 ml of saliva, and extracted from 100 μl of plasma.*

RESULTS AND DISCUSSION

With a single extraction into the organic solvent mixture, recovery of acetazolamide from blood, plasma, and saliva was 96–104%. Two milliliters of saliva and up to 100 μl of plasma did not produce any significant interfering peaks. With a column temperature of 215° and a carrier gas flow of 30 ml/min, retention times for fluoranthene and acetazolamide were 2 and 2.5 min, respectively (Fig. 1). Peak height ratios of acetazolamide relative to fluoranthene were calculated, and standard curves were plotted as peak height ratio *versus* acetazolamide concentration.

Standard curves, prepared daily using at least four concentrations of acetazolamide, were linear ($r^2 = 0.98$) to a maximum concentration of 100 ng of acetazolamide/50 μl of methylating reagent. Concentrations of 10 ng/50 μl were easily visualized. Thus, for a 2-ml sample of saliva and a 100-μl sample of plasma or blood, the GLC method could quantitate saliva levels of 5 ng/ml and plasma or blood levels of 100 ng/ml.

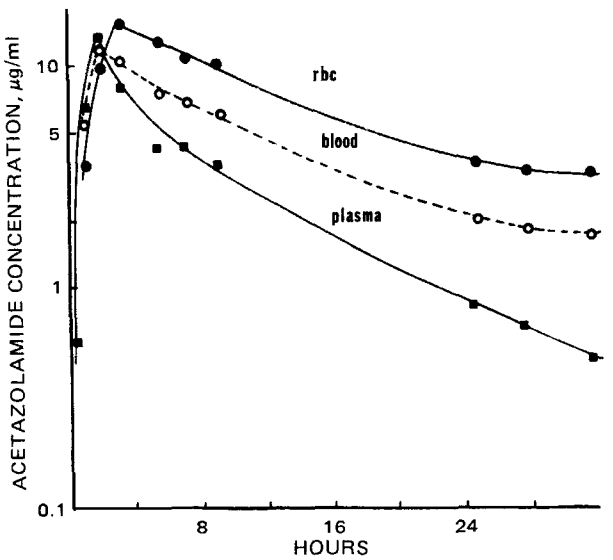

Figure 3—*Semilogarithmic plot of plasma, blood, and red blood cell levels of acetazolamide in Subject TS after a 250-mg oral dose.*

In the five subjects studied, peak plasma levels of 10–18 μg/ml were reached 1–3 hr after oral administration of the 250-mg dose (Figs. 2 and 3). These levels were approximately half those reported (1) after oral administration of a 500-mg dose. At least 1 hr later, whole blood and red blood cell levels reached peak concentrations of 10–19 and 13–29 μg/ml, respectively (Table I). This lag between the time for plasma and red blood cell levels to reach peak concentrations was apparent in all subjects.

Previous studies of elimination kinetics of acetazolamide in humans rarely analyzed plasma beyond 12 hr. These levels, if determined, were usually single-point measurements at 24 hr. Subsequent plasma concentrations were frequently too low to be measured accurately by the carbonic anhydrase inhibition method. Thus, data have heretofore not permitted evaluation of more than one exponential decay phase. With the more sensitive GLC assay, elimination from the plasma no longer appears to be a simple monoexponential process.

Over the 31 hr studied, plasma levels decayed more rapidly than red blood cell or blood levels. The area under the blood level–time curve from 0 to 31 hr was 1.5 times that under the plasma curve. If sufficient data are available, *i.e.*, for times greater than 31 hr after the dose, plasma levels should eventually decline parallel to red blood cell levels. This conjecture is suggested by the data for Subject PJ (Fig. 2). The plasma decay curve appeared biexponential with a half-life of just over 2 hr for the initial phase and 13 hr for the terminal phase. The half-life for the decay curve in the red blood cells was also 13 hr.

Red blood cell levels obtained up to 27 hr could be fit adequately to a one-compartment pharmacokinetic model with an elimination half-life of 10–12 hr. However, when more samples were obtained beyond 24 hr, a second elimination phase was apparent. In Subject TS (Fig. 3), where data at 24, 28, and 31 hr were available, the down slope of the red blood cell *versus* time curve was biphasic with half-lives of 6 and 33 hr. For Subjects PJ (Fig. 2), CA, and SG, data were only available at 24 and 28 hr. Obviously, although a straight line with a half-life of 40–50 hr can be drawn through these last two data points, such estimates of a terminal slope are highly questionable. Maren *et al.* (7) reported similar biphasic decay curves for red blood cell binding of acetazolamide in dogs with half-lives of 12 hr for the initial phase and 2–3 days for the terminal phase.

Saliva levels were approximately 1% of plasma levels and decreased at a rate equal to that of the plasma rather than the blood (Fig. 4). The proportionality factors relating plasma to saliva concentration calculated by least-squares linear regression analysis (Figs. 5 and 6) and by an arithmetic average were similar (Table II). The saliva–plasma ratio did not change with time or plasma concentration of acetazolamide. However, saliva samples obtained within the 1st hr after oral administration frequently gave unpredictable results (Fig. 5). In the population tested, saliva levels were 0.7–1.1% of plasma levels. Maren and Robinson (9) reported that in hydrocephalic children treated with acetazolamide, cerebrospinal fluid levels were also 1% of plasma levels. Although there was no significant difference (analysis of variance, $p < 0.05$) between the saliva–plasma ratio of the five subjects, it is still advisable to obtain individual estimates of the ratio rather than rely on a population average.

The fraction of drug bound to plasma protein did not change significantly for the first 9 hr after oral administration. Thereafter, free drug concentration in the 100 μl of ultrafiltrate [using the microultrafiltration apparatus (8)] was too low to measure accurately. Plasma water, or free drug, concentrations averaged 6% of plasma concentrations (Table II). Thus, saliva levels were proportional to, but not equal to, levels of unbound drug in plasma (Fig. 4). In addition to protein binding, other parameters such as the oil-in-water partition coefficient and the degree of ionization obviously affect membrane transport and secretion into the saliva and cerebrospinal fluid.

CONCLUSIONS

In this single-dose study, although saliva–plasma ratios varied in the normal population, they were consistent for a given individual. Thus, saliva measurements offer a convenient means of monitoring plasma acetazolamide levels in glaucoma patients. The biexponential decay of saliva levels mirrors that of plasma.

Blood and plasma levels of acetazolamide were not equivalent. From

Table II—Relationship of Saliva, Plasma, and Plasma Water Concentrations of Acetazolamide in Five Subjects after Oral Administration of a 250-mg Dose

Subject	Saliva Concentration / Plasma Concentration × 100			Plasma Water Concentration / Plasma Concentration × 100	
	Mean	(± *SEM*)	Linear Regression Slope	Mean	(± *SEM*)
PJ	1.11	(±0.07)	1.12	3.02	(±0.32)
CA	0.70	(±0.10)	0.51	4.22	(±0.41)
SG	0.85	(±0.09)	0.77	10.74	(±0.73)
AS	0.94	(±0.14)	0.93	5.17	(±0.52)
TS	0.84	(±0.06)	0.92	5.35	(±0.40)
Pooled data	0.90	(±0.04)	0.88	5.66	(±0.58)

24 to 31 hr after administration of a single oral dose, the ratio of red blood cells to plasma levels was greater than 4:1. Therefore, to ensure accurate determination of plasma levels, plasma should be separated from blood immediately, before hemolysis occurs. An appreciable degree of hemolysis may lead to overestimation of plasma concentrations.

The significance of the slowly declining red blood cell levels during chronic therapy with the drug remains to be determined.

Pharmacokinetic Analysis of Drug Concentration Data Obtained during Repetitive Drug Administration

WAYNE A. COLBURN and MILO GIBALDI ˣ

Abstract □ A digital computer curve-fitting method, designed to estimate pharmacokinetic model constants by utilizing all drug concentration–time data collected during repetitive dosing studies, was applied to data manifesting systematic dose-to-dose variability in one or another of the pharmacokinetic parameters. The method accurately determined dose-to-dose changes in absorption or elimination rate constants or in the apparent volume of distribution, and it would be useful for detecting phenomena such as self-induction and self-inhibition that may occur during multiple-dose administration. The method can also be used to analyze multiple-dose data of drugs exhibiting capacity-limited elimination and to obtain estimates of the Michaelis–Menten parameters.

Keyphrases □ Pharmacokinetics—model constants estimated by computer curve-fitting method, drug concentration data obtained during repetitive drug administration □ Computer curve-fitting method—pharmacokinetic model constants estimated, drug concentration data obtained during repetitive drug administration □ Repetitive drug administration—drug concentration data obtained, model constants estimated by computer curve-fitting method

A previous report (1) described the development of a digital computer method which utilized all plasma or blood concentration data collected during repetitive dosing studies to estimate pharmacokinetic model constants and, simultaneously, to fit the entire time course of drug concentration in plasma or blood. The method readily accommodates changes in dose or dosing interval during a multiple-dose regimen.

Several investigations found that pharmacokinetic parameters of certain drugs change in a systematic way

during repetitive drug administration (2–8). Self-induction, self-inhibition, and product inhibition of metabolism are possible causes of variation in elimination rate constants. Variability in absorption rate constants and/or the amount absorbed as well as changes in the apparent volume of distribution from dose to dose may also occur during a repetitive dose regimen.

Changes in elimination rate constants are usually detected by comparing the half-life of a drug after a single dose with that determined during the washout period following the last dose of a multiple-dose regimen. The interpretation of such results may be obscure if an inappropriate pharmacokinetic model is assigned to the data (9). In situations where self-induced changes in metabolism appear to be operative, little is known about the time course of these changes. No studies have been directed to detecting systematic variations in bioavailability or in the apparent volume of distribution from dose to dose during repetitive administration.

Under certain conditions, a drug subject to capacity-limited metabolism will demonstrate pharmacokinetic characteristics similar to those of a drug subject to self-inhibition or product inhibition; *i.e.*, the half-life will appear to increase during multiple dosing. The characterization of Michaelis–Menten kinetics is usually attempted by analyzing data after administration of a large single dose, administration of different single doses, or administration of the last dose of a repetitive dose regimen. Although the most dramatic consequences of capacity-limited elimination are the unusual rate and extent of drug accumulation, little effort has been directed to the characterization of such kinetics by analyzing data obtained during repetitive drug administration.

[a]The term $k_{a(n)}$ denotes the first-order absorption rate constant after the nth dose (hours^{-1}). [b]First-order elimination rate constant (hours^{-1}). [c]Apparent volume of distribution (liters).

The present report concerns the use of the previously described digital computer method (1) for detecting changes in pharmacokinetic model constants and for characterizing Michaelis–Menten kinetics during repetitive drug administration.

COMPUTER METHOD

The development of the computer method was detailed previously (1). The main element of the method is NONLIN (10), a nonlinear least-squares regression computer program specifically developed for pharmacokinetic applications, used in conjunction with DASCRU[1] (11), a subprogram that provides numerical solutions to differential equations.

To detect changes in pharmacokinetic constants during repetitive dosing, it is necessary to estimate independently model parameters for drug concentration data after each dose. While this approach is possible in principle, it requires considerably more data than are obtained in the usual metabolic or clinical study. Hence, it was decided that only one parameter would be estimated independently for each dose while all other parameters would be estimated by assuming that they were invariant from dose to dose. This procedure can be repeated for each parameter, and it becomes possible to detect systematic variability in absorption rate constants, amounts absorbed or volumes of distribution, and elimination rate constants.

To estimate a parameter for individual doses independently, the DFUNC section of NONLIN requires that each dose uses a separate in-

tegration routine. Therefore, an F subroutine was included for each dose. The integration subprogram DASCRU was called using the F subroutine corresponding to the number of the dose.

Specific programs[2] were developed to fit data described by the following one-compartment pharmacokinetic models: I, constant first-order absorption and constant simultaneous Michaelis–Menten and first-order elimination; II, variable first-order absorption and constant first-order elimination; III, constant first-order absorption and variable first-order elimination; and IV, constant first-order absorption and elimination but variable apparent volume of distribution.

APPLICATIONS

Ideal drug concentration–time data after repetitive dosing were generated by means of appropriate equations satisfying the conditions of each program. Each data set consisted of five values during the first dosing interval, four values during the last interval, and two values for each of the six interceding intervals. A normally distributed random absolute error of 10% was introduced into each data set as previously described (1). Ten errant data sets were generated for each ideal data set. The errant data and the appropriate differential equations served as input for Programs I–IV.

Table I shows the average computer-estimated pharmacokinetic parameters for data described by first-order absorption and simultaneous Michaelis–Menten and first-order elimination. Good agreement between the pharmacokinetic parameters used to generate the ideal data and the means of the parameter estimates that best describe the errant data was obtained.

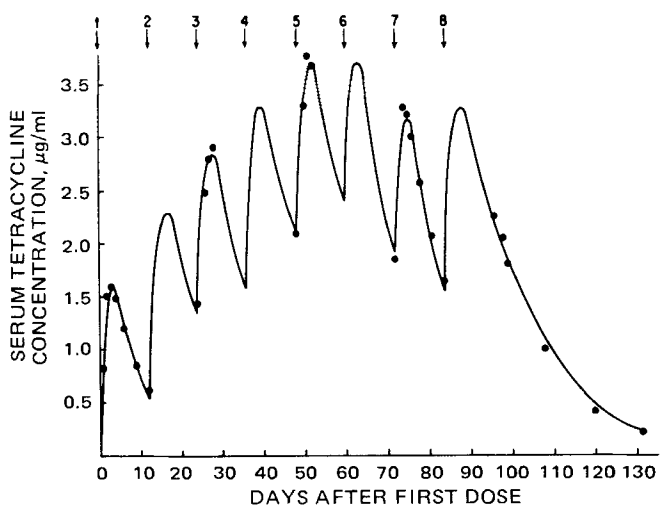

Figure 2—*Curve fit to mean serum tetracycline concentrations during repetitive oral dosing of 500 mg twice a day for eight consecutive doses to 12 healthy subjects. Data were fit using Program III.*

[2] Information concerning these programs may be obtained by writing the authors.

Programs II, III, and IV, which were intended to characterize dose-to-dose variation in the absorption rate constant (Tables II and III), in the elimination rate constant (Tables IV and V), and in the amount absorbed or the apparent volume of distribution (Table VI), respectively, also provided highly acceptable results.

The computer programs were evaluated further by determining their applicability to previously published experimental data. In a multiple-dose trial, subjects were given 300-mg oral doses of phenytoin once daily for 14 days (12). Blood samples were obtained during the first 6 days and the last 3 days of dosing as well as for 3 days following the last dose. These data were evaluated using Program I, which assumes first-order absorption and simultaneous Michaelis–Menten and first-order elimination. The computer fit to the average drug concentration data is shown in Fig. 1. The correlation coefficient was 0.996. The parameter estimates are listed in Table VII.

Several investigations indicated that the elimination of phenytoin in humans is capacity limited and can be described by Michaelis–Menten kinetics or simultaneous first-order and Michaelis–Menten kinetics (13–15). The values of the pharmacokinetic parameters determined in the present study differ considerably from previous estimates. For example, the K_m value of 20.7 mg/liter is three to five times larger than those values previously reported from single-dose data. The V_m value is about 100% larger than previously reported average values but comparable to values observed in certain individuals (14). The ratio of V_m/K_m is comparable to that reported by Gerber and Wagner (13) but much smaller than the ratios found by others (14, 15). In view of the narrow therapeutically effective range of plasma concentrations found with phenytoin, additional studies are needed to determine which set of parameter estimates is more realistic in predicting the relation between the dose and steady-state concentration of the drug.

Doluisio and Dittert (8) found that the average apparent half-life of

tetracycline in 10 subjects increased from 6.3 hr (after the first dose) to 10 hr (after the eighth dose) during 4 days of repetitive oral dosing (every 12 hr). Although at least one blood sample was taken during each dosing interval, pharmacokinetic analysis was limited to the data obtained from the first and last doses.

The average serum concentration–time data from this study were fit using Program III, which accommodates dose-to-dose variation in the first-order elimination rate constant. The computer fit of the data is shown in Fig. 2. The correlation coefficient was 0.997. The parameter estimates are listed in Table VIII.

A substantial change in the elimination rate constant is evident when the first dose is compared with each subsequent dose. The elimination rate constants for Doses 2–8 tend to fluctuate about a mean value of 0.078 hr^{-1} ($t_{1/2} \simeq 9$ hr), which is much smaller than the value estimated after the first dose.

Table VIII—Pharmacokinetic Model Parameters Derived from Fitting Multiple-Dose Tetracycline Data Assuming Constant First-Order Absorption and Variable First-Order Elimination

$K_{(8)}$	0.061	0.003

[a] First-order absorption rate constant ($hours^{-1}$). [b] Ratio of the apparent volume of distribution, V, to the fraction, F, of the dose absorbed (liters). [c] The term $K_{(n)}$ denotes the first-order elimination rate constant after the nth dose ($hours^{-1}$).

The reason for this apparent change in half-life remains obscure. Whether it is due to a real change in the pharmacokinetics of the drug upon repetitive dosing or to a mathematical artifact that arises from selecting the wrong pharmacokinetic model (9) is not known. The present analysis suggests that if an inhibitory mechanism is operative, it is fully induced after the first dose.

The described analyses of hypothetical and experimental multiple-dose data further support the utility and flexibility of the recently reported digital computer-fitting method (1).

Metal-Ion Interaction with Penicillins: Kinetics of Complexation of Nickel(II)

G. V. FAZAKERLEY [x] and G. E. JACKSON

Abstract □ The kinetics of complexation of nickel(II) with some penicillins and related compounds show that the zwitterionic form of the ligand has very low reactivity compared to the anionic form. The resolved rate constants are interpreted in terms of binding to the ring nitrogen and carboxyl group and not to the side chain.

Keyphrases □ Penicillin G—and related compounds, complexation with nickel(II) ions, reaction kinetics □ Nickel(II)—complexation with penicillin G and related compounds, reaction kinetics □ Complex formation—penicillin G and related compounds with nickel(II) ions, reaction kinetics □ Kinetics, reaction—complexation of nickel(II) with penicillin G and related compounds □ Metal ions—nickel(II), complexation with penicillin G and related compounds, reaction kinetics □ Antibacterials—penicillin G and related compounds, complexation with nickel(II) ions, reaction kinetics

Penicillin antibiotics interact with metal ions in a complex manner. Copper(II) has a very pronounced effect on the hydrolysis rate of the β-lactam ring (1, 2), which is not shown by other first-row transition metal ions (3, 4).

Metal-Ion Interaction with Penicillins: Kinetics of Complexation of Nickel(II)

G. V. FAZAKERLEY [x] and G. E. JACKSON

Abstract □ The kinetics of complexation of nickel(II) with some penicillins and related compounds show that the zwitterionic form of the ligand has very low reactivity compared to the anionic form. The resolved rate constants are interpreted in terms of binding to the ring nitrogen and carboxyl group and not to the side chain.

Keyphrases □ Penicillin G—and related compounds, complexation with nickel(II) ions, reaction kinetics □ Nickel(II)—complexation with penicillin G and related compounds, reaction kinetics □ Complex formation—penicillin G and related compounds with nickel(II) ions, reaction kinetics □ Kinetics, reaction—complexation of nickel(II) with penicillin G and related compounds □ Metal ions—nickel(II), complexation with penicillin G and related compounds, reaction kinetics □ Antibacterials—penicillin G and related compounds, complexation with nickel(II) ions, reaction kinetics

Penicillin antibiotics interact with metal ions in a complex manner. Copper(II) has a very pronounced effect on the hydrolysis rate of the β-lactam ring (1, 2), which is not shown by other first-row transition metal ions (3, 4).

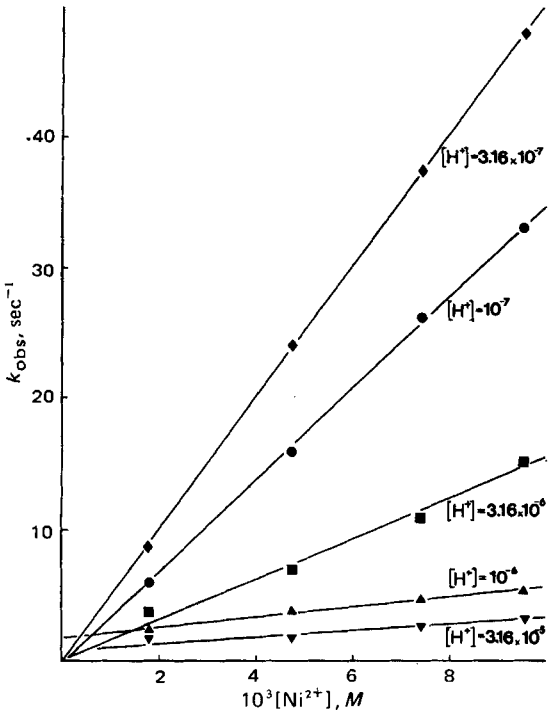

Figure 1—*Plot of* k_{obs} versus $[Ni^{2+}]$ *at constant* $[H^+]$ *for penicilloic acid.*

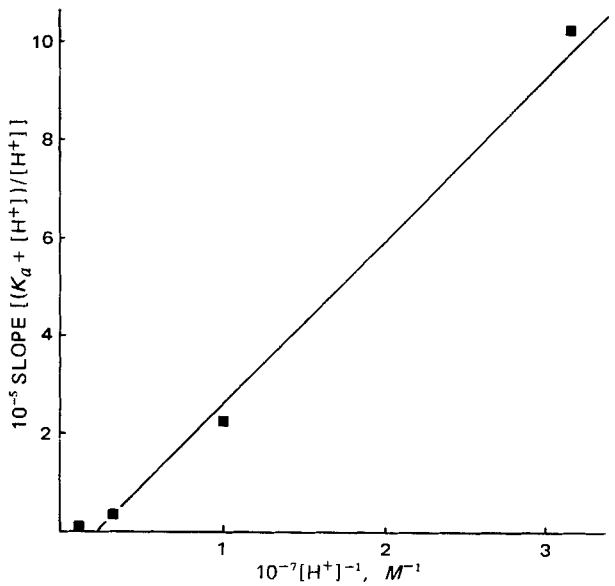

Figure 2—*Plot of slope* $(K_a + [H^+])/[H^+]$ versus $1/[H^+]$ *for penicilloic acid.*

Previous kinetic studies dealt exclusively with the hydrolysis rate in the presence of metal ions rather than with the complexation reaction itself. The differing effects of metal ions have been explained in terms of two possible binding sites (1). This paper describes the complexation reaction kinetics of nickel(II) with penicillin G and some related compounds.

EXPERIMENTAL

Penicillin G sodium, ampicillin, and thiaproline were commercial products used without further purification. Penicilloic acid was prepared by the method of Rapson and Bird (5). Nickel(II) perchlorate was prepared from nickel(II) sulfate and sodium bicarbonate by treating the nickel bicarbonate produced with perchloric acid. Excess nickel bicarbonate was filtered off, and nickel perchlorate was crystallized. Solutions of nickel perchlorate were standardized by adding a known concentration of edetate and back titrating[1] with standard magnesium sulfate.

Reactions were followed at 220 nm for thiaproline and penicillin G, 225 nm for ampicillin, and 250 nm for penicilloic acid on a stopped-flow spectrophotometer at 298 ± 0.5° K. The ionic strength was adjusted to 0.15 *M* with sodium perchlorate, and a 0.02 *M* sodium borate–mannitol buffer was used to maintain the pH.

The pH measurements were made using a glass–calomel electrode in which the potassium chloride had been replaced by sodium chloride. The meter was calibrated at pH 4 and 7. Reactions were carried out in the following pH regions: penicillin G, pH 6.1–7.8; thiaproline, pH 4.5–6.0; ampicillin, pH 6.7–7.4; and penicilloic acid, pH 4.5–6.5.

Ligand concentrations were 10^{-4} *M*. Reactions were run under pseudo-first-order conditions with nickel(II) concentrations in 10–100-fold excess to ensure that only 1:1 species were formed. Oscilloscope traces yielded excellent first-order rate constants, linear for at least 90% completion of the reaction. Value of k_{obs} used in evaluating further parameters were an average of three to five individual determinations.

RESULTS AND DISCUSSION

Penicilloic Acid, Ampicillin, and Thiaproline—All three ligands showed the same behavior in that the observed rate of reaction, k_{obs}, increased markedly with increasing pH at constant nickel(II) concentration. Figure 1 shows the effect of pH upon the reaction rate with penicilloic acid. The reactions showed the same characteristics as those of nickel(II) with amino acids (6) and were accounted for by the increasing concentration of the deprotonated zwitterion at high pH.

The reactions are shown in Scheme I, where L is the singly charged anion for thiaproline and ampicillin and the doubly charged anion for penicilloic acid. The pKa's for thiaproline, penicilloic acid, and ampicillin are 6.1 (7), 5.19 (7), and 7.25 (5), respectively.

$$Ni^{2+} + L \xrightarrow{k_1} [NiL]^{2+}$$

$$Ni^{2+} + LH^+ \xrightarrow{k_2} [NiL]^{2+} + H^+$$

$$LH^+ \overset{K_a}{\rightleftharpoons} L + H^+$$

Scheme I

The usual rate equation (6) is:

$$k_{obs} = \frac{k_1K_a + k_2[H^+]}{K_a + [H^+]}[Ni^{2+}] \qquad \text{(Eq. 1)}$$

Thus, the slopes in Fig. 1 are equal to $(k_2[H^+] + k_1K_a)/(K_a + [H^+])$. Since the intercepts are not experimentally different from zero, the dissociation reactions can be ignored.

Rearranging Eq. 1 gives:

$$\text{slope}\frac{(K_a + [H^+])}{[H^+]} = \frac{k_2 + k_1K_a}{[H^+]} \qquad \text{(Eq. 2)}$$

Figure 2 shows a graph of the left-hand side of Eq. 2 against $1/[H^+]$ for penicilloic acid. The slope is k_1K_a, and the intercept is k_2. However, the intercepts are not experimentally different from zero, so only the overall forward rate constant, k_f, is determined (Table I).

The unreactivity of the protonated species has been explained (6) in

Table I—Rate Constants for the Formation (k_f) and Dissociation (k_d) of Nickel(II) Complexes at 25° and Ionic Strength 0.15 *M*

Ligand	Reacting Form of Ligand	k_f, M^{-1} sec^{-1}	k_d, sec^{-1}
Thiaproline	L^-	7.5×10^2	0.15[a]
Penicilloic acid	L^{2-}	5.2×10^3	4.3[a]
Ampicillin	L^-	6.9×10^2	—
Penicillin G	L^-	2.3×10^3	19.3

[a] Calculated using $k_d = k_f/K$ (9).

[1] Using Erichrome Black T as indicator.

terms of an extreme sterically controlled substitution (SCS) mechanism, since, upon protonation, first-bond formation must switch from the amino group to the carboxylic group. The rate of ring closure is comparable with, or smaller than, the rate at which the first bond is broken.

Penicillin G—The reaction was again found to be first order with respect to ligand concentration, the metal being in at least 10-fold excess. It was also first order with respect to the metal-ion concentration observed in the linearity of the k_{obs} *versus* $[Ni^{2+}]$ graph. In the region of study, pH 6.1–7.8, k_{obs} was independent of $[H^+]$. This finding was expected because the reactions were carried out well above the pKa (2.73) and, thus, in the absence of the protonated species.

The reaction shown in Scheme II:

$$[Ni^{2+}] + L^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [NiL]^+$$

Scheme II

gives the rate equation (8):

$$k_{obs} = k_1[Ni^{2+}] + k_{-1} \qquad \text{(Eq. 3)}$$

The forward and dissociation rate constants are shown in Table I.

At lower pH values, there was no observable reaction.

The rate constant for thiaproline was much lower than that expected for "normal" substitution (9). There are two possible explanations for this finding: a shift to another rate-determining step (an SCS mechanism) occurs or hydrogen bonding between a water molecule in the metal-ion coordination sphere and the sulfur atom disorients the ligand for attack on the metal. The value of k_f was an order of magnitude less than for proline and hydroxyproline (9). Some reduction in k_f was observed with hydroxyproline relative to proline and was attributed to a hydrogen bonding mechanism. However, the large drop with thiaproline cannot be explained in this way because hydrogen bonding through sulfur is weaker than that through oxygen. Thus, a shift to another rate-determining step is postulated.

The inductive effect of sulfur is known (10) to reduce the basicity of nitrogen. This effect increases the rate at which the first bond formed is broken. This result is shown by the dissociative rate constant (0.15), which was higher than that for proline (0.024) and hydroxyproline (0.014).

The forward rate constant for penicillin G was also lower than that for normal substitution mechanisms but higher than that for thiaproline. If reaction occurs at the ring nitrogen and carboxyl group, then, by analogy with thiaproline, an SCS mechanism will lower the rate. The increase in rate over thiaproline can be explained by hydrogen bonding of the β-lactam carbonyl to water around the metal ion, which promotes the correct orientation of the ligand for attack in an internal conjugate base type of mechanism (11).

The alternative site, β-lactam carbonyl and side-chain amide nitrogen, would react as a neutral species for which the normal substitution rate is about 3×10^3, in good agreement with the observed rate. However, this normal value was obtained for strong nitrogen chelates. If comparison is made with acetylacetonate in the enol form, a value of 5.0 is found (12) because an SCS mechanism is operative. From this discussion, a similar mechanism seems to be operative, suggesting a forward rate constant much lower than 10^3 for coordination at the side chain. For this reason, and by comparison with penicilloic acid, the former postulate is favored.

The reaction rate with penicilloic acid was 5.2×10^3. A potentiometric study (7) indicated that penicilloic acid acts as a bidentate ligand, with one carboxyl group not being involved in coordination. The lower than normal rate is attributed to the nitrogen basicity.

The reactions with ampicillin are known (13) to involve coordination only at the side chain through the amino and carbonyl groups. As an effectively neutral donor involving no ring strain, a forward rate constant of $3–4 \times 10^3$ is expected. Since the pKa of the amino group is 7.25, an SCS mechanism is not likely. The decreased reactivity must be due to hydrogen bonding.

The two most likely coordination metal sites on penicillin are: A, the β-lactam carbonyl and the side-chain amide nitrogen; and B, the carboxyl group and the ring nitrogen. Structure A has been used to explain the rapid hydrolysis rate in the presence of certain metal ions of penicillin G compared to penicillanic acid (2). This interpretation is suspect because the hydrolysis rate of acylamino-substituted β-lactams is known to be several orders of magnitude faster than that of unsubstituted β-lactams in the absence of metal ions (14). Structure B is supported by potentiometric studies of nickel(II) with *N*-benzylpipecolic acid and *N*-hippurylpipecolic acid (15). The two complexes have similar stability constants, although one has the penicillin G side chain and the other does not.

Amide nitrogens are poor donors because binding results in a loss of the amide resonance stabilization energy through change in hybridization from sp^2 to sp^3. The ring nitrogen of penicillin G is already much distorted from an sp^2 planar structure. The nitrogen lies 0.4 Å out of the plane and close to the position (0.56 Å) expected for sp^3 (16). Consequently, the amide resonance is already largely lost even before coordination, making this nitrogen a better donor.

Furthermore, molecular models show that whereas it is possible to accommodate a metal ion in Structure B with normal metal ion–ligand bond lengths, a very long (~3.4 Å) and consequently weak metal nitrogen bond would result from Structure A.

From these results and those from potentiometry (7) and NMR (13) studies, it is clear that the dominant binding site for penicillin G is at the ring nitrogen and carboxyl group. In itself, this finding does not explain the different hydrolysis rates in the presence of different metal ions. This result must arise from the nature of the binding rather than a shift in the site of binding. Copper(II) will form a stronger bond to the ring nitrogen than nickel(II). The stronger tendency of copper(II) to remove electrons from the nitrogen will weaken the β-lactam ring and promote hydrolysis.

Synthesis of ^{14}C-Meglumine Salicylate and Its Disposition in Humans after Oral Administration

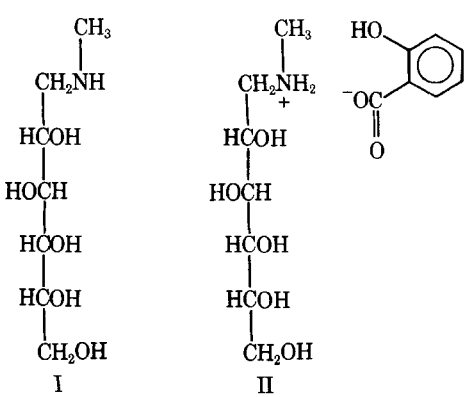
NAGY A. FARID *, GORDON S. BORN ×, WAYNE V. KESSLER, HENRY T. RUSSELL ‡, STANLEY M. SHAW, and WINTHROP E. LANGE §

Abstract □ The synthesis of ^{14}C-meglumine salicylate was accomplished by heating ^{14}C-meglumine with salicylic acid, in equimolar ratios, in 2-propanol. The average radiochemical yield was 97.5%. Ten healthy adult male volunteers were given 1.2 g of the compound orally. Five took 1.2 g of 1-deoxy-1-[^{14}C]-methylamino-D-glucitol salicylate (containing about 47 μCi), and five others took 1.2 g of 1-deoxy-1-methylamino-D-[U-^{14}C]-glucitol salicylate (containing about 45 μCi). Urine and feces were collected for 5 days, and blood was sampled for 24 hr. The peak urinary excretion of meglumine and/or its metabolites occurred between 4 and 8 hr after administration (about 7.2% of the administered dose). Meglumine was excreted primarily in the feces (72.4% over 5 days) and, to a smaller extent, in urine (21.3% over 5 days). No activity was detected in blood. The excretion rate and percentage excreted were the same for both groups of subjects, suggesting that meglumine was not metabolized by *N*-demethylation or conversion to carbon dioxide. The highest blood salicylate level, 44.4 ± 1.9 μg/ml, was observed 1 hr after administration. Urinary levels of salicylic acid and its metabolites were observed to be at a maximum at 8 hr. Total salicylate recovery was 94.7 ± 1.5% in 48 hr. Salicyluric acid was the major metabolite, accounting for 69.5 ± 3.6% of the dose. Salicylic acid accounted for 6.8 ± 1.2%.

Keyphrases □ ^{14}C-Meglumine salicylate—synthesized, administered orally, biological distribution and excretion measured, humans □ Distribution, biological—^{14}C-meglumine salicylate, oral administration, humans □ Excretion—^{14}C-meglumine salicylate, oral administration, humans □ Radiochemistry—^{14}C-meglumine salicylate synthesized, administered orally, biological distribution and excretion measured, humans

Meglumine[1] (I) was first synthesized in 1935 (1). The use of I in pharmaceuticals began with the preparation of I antimonate for the treatment of leishmaniasis. Presently, several pharmaceutical preparations contain I. Some X-ray contrast media, for example, contain I as a solubilizing agent, and I was found to decrease the toxicity of such contrast media (2–4). Also, it was reported that I–coumermycin mixtures (4:1) elevated the blood antibiotic levels five- to 15-fold over those for the antibiotic alone (5, 6). The disposition of I in rats and dogs was reported recently (7).

Meglumine salicylate (II) is a promising new water-soluble salicylate under investigation. The suggested indications for the use of II include all conditions requiring systemic salicylate therapy. Since the compound is relatively new, its blood and urinary salicylate levels have not been reported. The literature also does not contain information about the disposition of I in humans.



The purpose of this study was to gain such information and to show the effect, if any, I had on the absorption and urinary excretion of the salicylate moiety. To this end, 1-deoxy-1-[^{14}C]-methylamino-D-glucitol salicylate (II-M) and 1-deoxy-1-methylamino-D-[U-^{14}C]-glucitol salicylate (II-G) were synthesized and administered orally to humans. Two different positions of ^{14}C-labeling were used to gain preliminary information on the metabolism of I in humans.

EXPERIMENTAL

Radiosyntheses—The syntheses of I-M and I-G were described previously (8). Several preliminary reactions for the synthesis of II were conducted with ethanol or 2-propanol as a reaction medium. When ethanol was used, as previously suggested (9), a syrup of II was formed. By using a small volume of 2-propanol and conducting the synthesis in low humidity (50%), II could be synthesized in high yields.

Compound II-M—A solution of 2.91 g of I-M (14.9 mmoles, 0.067 mCi/mmole) and 2.06 g of salicylic acid in 35 ml of 2-propanol was warmed in a water bath at 50° to allow complete dissolution of I-M. After the solution was allowed to cool to room temperature, it was placed in a refrigerator overnight. The resulting compound was filtered in a low humidity (50%) atmosphere, since it was slightly hygroscopic, and dried under vacuum. The yield was 4.90 g (first crop, 98.6% of theoretical) of II-M, mp 98–101°. The specific activity was 0.19 ± 0.002 μCi/mg or 0.063 mCi/mmole.

Anal.[2]—Calc. for $C_{14}H_{23}NO_8$: C, 50.45; H, 6.90; N, 4.20. Found: C, 50.52; H, 7.08; N, 4.09.

Compound II-G—A solution of 849 mg of I-G (4.35 mmoles, 0.204 mCi/mmole) and 601 mg of salicylic acid in 10 ml of 2-propanol was treated as described for II-M. The yield was 1.4 g (first crop, 96.5% of theoretical) of II-G, mp 98–100°. The specific activity was 0.56 ± 0.005 μCi/mg or 0.19 mCi/mmole.

Anal.—Found: C, 50.23; H, 7.30; N, 4.00.

A mixed melting point of each labeled compound gave no melting-point depression. The IR spectrum of II (Fig. 1) was compared with spectra of the labeled compounds. From these analyses, the two ^{14}C-labeled compounds were determined to be chemically pure.

TLC analysis of II for radiochemical purity determination was not successful. Solvent systems of varying polarities and compositions failed to give a single spot for II. Two spots, one corresponding to I and the other to salicylic acid, were obtained, apparently due to the dissociation of II when dissolved in water or methanol. The two labeled compounds were assumed to be radiochemically pure, since it was predetermined that the ^{14}C-labeled I compounds had a radiochemical purity of 98.4%.

Procedure—Two volunteer groups of five healthy male subjects were used. Their weight range was 66–90 kg (average 77.6 kg), and their age range was 21–29 years. Blood and urine samples were collected from each volunteer at 7:30 am to serve as controls. At 8 am following an overnight fast, each subject received orally a capsule (assigned by random number drawing) containing an exactly weighed amount of either II-M (referred to as the M group) or II-G (referred to as the G group). [a] Expressed as percentage of administered dose. [b] Prefixes M and G refer to the position of the ^{14}C-label. See text. [c] No sample was supplied; subject was constipated. Result was entered as zero in average calculations.

^{14}C-activity ingested was 42.2–49.3 μCi, based on the determined specific activities. Each subject also received two more capsules containing II to make the total ingested amount of II equal to 1200 mg. Food, but not water, was withheld until noon, when the same lunch was served to all subjects.

Urine and feces were collected for 5 days. Urine was collected at the intervals shown in Table I. Feces were collected during each 24-hr period and were pooled for each subject before analysis when there were more than one. All urine and feces samples were frozen until analyzed. Blood was collected at 1, 2, 4, 8, 12, and 24 hr after drug administration in tubes containing edetic acid. All blood samples were refrigerated until analyzed.

Salicylate Analysis—The levels of salicylic acid, salicyluric acid, and total salicylate in urine were determined (at least in duplicate) using the method of Farid *et al.* (10). Blood salicylate was determined using the method of Trinder (11), with at least three determinations per sample. Blood and urine salicylate data from the 10 volunteers were pooled for the determination of the mean and standard error of the mean at each time interval.

Sample Preparation and Radioanalysis—The volume of urine of each subject for a given time interval was measured. Aliquots of 0.5 ml, or 1 ml when the activity was expected to be low, of urine in triplicate were placed in low potassium vials, and 0.1 ml of acetic acid was added. Fifteen milliliters of scintillator[3] was added, and the radioactivity was determined.

A preliminary study compared three agents for digesting feces: a quaternary ammonium hydroxide[4], perchloric acid–hydrogen peroxide (12), and a tissue digestant[5]. The use of perchloric acid–hydrogen peroxide led to a loss of about 15% of the activity in the case of I-G. The quaternary ammonium hydroxide caused a loss of about 12%. These losses were attributed to the long digestion times required for feces. The use of the tissue digestant did not cause a loss of activity and, moreover, gave the highest counting efficiency (77.9%).

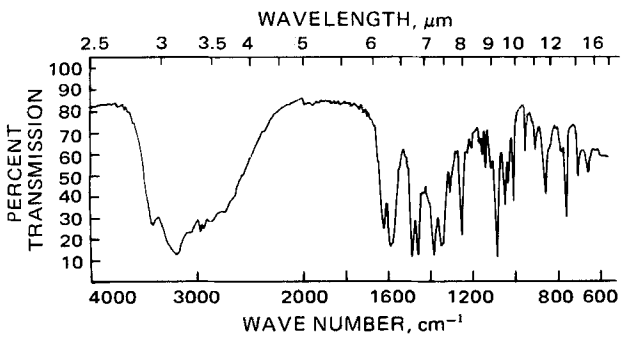

Figure 1—*IR spectrum of meglumine salicylate.*

The tissue digestant procedure was as follows. Feces were weighed and placed in a blender. Water, two to three times the sample weight, was added, and the mix was blended for 5–7 min. Quadruplicate samples of the resulting slurry, weighing 150–250 mg, were accurately weighed in tared counting vials. Two milliliters of tissue digestant and 0.3 ml of hydrogen peroxide were added, and the samples were left at room temperature. Six hours later, 0.3 ml of hydrogen peroxide was added, and the samples were left at room temperature for 24–36 hr. Then 0.1 ml of acetic acid was added followed by 15 ml of scintillator, and the radioactivity in the sample was determined.

Triplicate blood samples were prepared for counting by heating, in a counting vial, 0.1 ml of blood and 2 ml of tissue digestant at 50° for 4 hr. The vial was cooled to room temperature, and 0.3 ml of hydrogen peroxide was added dropwise. Four hours later, 0.3 ml of hydrogen peroxide was added. The samples were counted 3–4 hr later after the addition of 15 ml of scintillator.

All counting data were converted to disintegrations per minute with corrections for background and counter efficiency by internal standardization. Disintegrations per minute for the total volume or weight were calculated, and the result was reported as the percentage of the administered dose for each subject.

RESULTS AND DISCUSSION

Blood analysis showed no detectable activity above background. With the method used, the detection limit was 10 μg/ml of blood. Table I shows the concentration of ^{14}C-I and/or its radioactive metabolites in the urine and feces, expressed as the percentage of the administered dose. As can

Table II—Blood Salicylate Levels

	Salicylate Level, μg/ml

[a] All values are the average of at least two determinations per sample. Values listed were not corrected for background salicylic acid levels because of the daily variability of the background levels. [b] For salicyluric acid, the amount in milligrams is listed as salicyluric acid; percentage of dose, however, is based on salicylic acid equivalent.

be seen, the excretion of I and/or its metabolites in the urine peaked 4–8 hr after drug administration. The average of the excreted I-M and/or its metabolites in urine over 5 days was 25.6 ± 5.7% of the administered dose. For the G group, the average was 17.0 ± 5.5% over the same period. This difference was attributed to biological variations between subjects. A t-test indicated that there was no significant difference in the excretion rate and the percentage excreted of I and/or its metabolites in urine over time between the M and G groups ($p > 0.1$).

About 68% of I-M and 77% of I-G and/or their metabolites were excreted in the feces (Table I) over 5 days. Again, a t-test indicated there was no significant difference between the excretion rate and the percentage of the administered activity excreted in the feces between the two groups ($p > 0.1$).

The 10 data points for each time interval were averaged (Table I), and the cumulative percentage of activity excreted in both the urine and feces was calculated. The resulting data showed that 21.3 ± 4.0% of the administered activity was excreted in the urine and 72.4 ± 4.1% was excreted in the feces over 5 days. Thus, 93.7 ± 2.8% of the administered dose was excreted in 5 days. Further examination of the data indicated that 50% of the administered dose was excreted during the first 35 hr.

After a single oral dose of 1.2 g of II, equivalent to 0.65 g of aspirin, blood salicylate levels (Table II) were 44.4 ± 1.9 and 43.0 ± 1.6 μg/ml in the 1st and 2nd hr, respectively. These values are comparable to the published blood salicylate levels after equivalent single doses of aspirin (13, 14), buffered aspirin (15), and sodium salicylate (16).

Table III shows the recovery of salicylic acid, salicyluric acid, and total salicylate in urine over 48 hr. Total salicylate concentration in urine samples collected beyond the 48-hr postdrug period were within the same concentration range as in the control samples and, therefore, were not included in Table III.

A semilogarithmic plot of the percentage of salicylate remaining in the body *versus* time showed that the half-life of the salicylate moiety in II was 6 hr. This value is in agreement with the previously reported half-life of a single 1-g dose of aspirin of 6 hr (17).

As with other salicylates (18), the major metabolite excreted in the urine was salicyluric acid, which accounted for 69.5 ± 3.6% of the administered dose. Salicylic acid excretion accounted for 6.8 ± 1.2% of the administered dose. Total salicylate excretion was 92.1 ± 1.6 and 94.7 ± 1.5% of the administered dose 24 and 48 hr after dosing, respectively.

These results show that the blood salicylate levels and the excretion of salicylic acid and its metabolites in urine followed the well-documented pattern of other salicylates. Thus, the salicylate moiety in II is absorbed and metabolized in humans like other salicylates.

The fact that, regardless of the position of the ^{14}C-label on I, the same percentage of the administered dose was excreted indicates that I is not metabolized through N-demethylation or through the formation of carbon dioxide. Whether I is excreted unchanged in the urine or metabolized needs further investigation.

Comparative Bioavailability of Four Commercial Quinidine Sulfate Tablets

JEFFREY D. STRUM, JOHN L. COLAIZZI ×, JAMES M. JAFFE, PERRY C. MARTINEAU *, and ROLLAND I. POUST

Abstract □ A comparative bioavailability study was performed using four commercially available, chemically equivalent brands of quinidine sulfate tablets. Two 200-mg tablets were administered to 11 different subjects following a completely randomized crossover design. Serum levels, urinary excretion data, and derived pharmacokinetic parameters were compared statistically. There were no statistical differences in the extent of quinidine absorption from the four brands of tablets as evidenced by the cumulative urinary excretion values and the areas under the serum level–time curves. Significant differences in the mean serum levels at 0.5 and 1 hr and differences in the peak times and absorption rate constants indicate that there was a difference in the absorption rate between Treatments A and D and C and D. A significant difference in the peak times also was noted for Treatments B and C. When mean disintegration times for the four tablet formulations were compared with their values for k_a, t_{max}, and mean serum levels at 0.5 and 1 hr, rank-order correlations were observed. A considerable degree of variability in quinidine elimination was noted, with half-life values ranging from 2.71 to 8.12 hr (mean half-life of 5.36 hr).

Keyphrases □ Quinidine sulfate—bioavailability of four commercial tablets compared, humans □ Bioavailability—quinidine sulfate, four commercial tablets compared, humans □ Cardiac depressants—quinidine sulfate, bioavailability of four commercial tablets compared, humans

Emphasis has been placed recently on the importance of establishing the biological equivalence of quinidine sulfate tablets. The APhA Academy of Pharmaceutical Sciences classified quinidine sulfate as one of the "commonly prescribed multiple source drugs whose solid dosage forms exhibit the most serious bioavailability and/or quality assurance problems" (1). However, since no published articles report the comparative bioavailability of chemically equivalent quinidine sulfate tablets, the classification of the Academy of Pharmaceutical Sciences must be taken to mean that there is a potential for bioavailability differences with this drug dosage form.

The Food and Drug Administration (FDA) also indicated that quinidine sulfate is one drug for which a bioequivalence requirement is currently anticipated and specified that *in vivo* testing would be necessary to compare different commercial products (2). A list of approved manufacturers and distributors of bioequivalent problem drugs recently published by the FDA included four manufacturers[1] and one distributor[2] of quinidine sulfate tablets (3).

BACKGROUND

Quinidine is a frequently prescribed antiarrhythmic drug. In 1975, it ranked 14th among the most frequently prescribed generic drugs in the United States (4). Currently, at least 60 different generic brands of 200-mg quinidine sulfate tablets are on the market (5). Studies established the blood level profiles of several salt and sustained-release dosage forms of quinidine to define an optimal dosage regimen (6–11). Other reports compared the blood levels produced by administering quinidine by different routes (12). The bioavailability of the drug is variable, especially when taken with food, since it is known to interact with bile anions to form an insoluble complex (13).

A specific range of serum quinidine levels (3–6 μg/ml) must be maintained to achieve the desired pharmacological effect (14). This therapeutic range varies, however, depending upon the assay methodology employed and may be as low as 2–4 μg/ml (11). Several studies indicated that there is a definite correlation between serum levels and clinical effect (15–17). However, a recent report (18) stressed cautious interpretation of serum level when predicting therapeutic or toxic response since individual patient sensitivity to the drug may be more important. Toxic reactions may occur at any serum level due to allergy or idiosyncrasy but are more likely to appear at levels above 8 μg/ml (19, 20).

Studies employing intravenous infusions of quinidine gluconate defined the kinetic disposition of the drug and showed that there is considerable interpatient variability in quinidine elimination (21). A recent study[3] employing capsule, tablet, and solution forms of quinidine sulfate and an intramuscular injection of the gluconate confirmed that there is a high degree of intersubject and intrasubject variability in the biological half-life of the drug as well as a difference in the bioavailability of the tablet and intramuscular dosage forms.

Based on the low therapeutic index of this drug, the critical purpose for which it is indicated, its reported potential for bioequivalency problems, its wide generic availability, and the lack of published comparative bioequivalency data, the objective of this study was to compare the bioavailability of four commonly available, chemically equivalent brands of quinidine sulfate tablets.

EXPERIMENTAL

***In Vivo* Study Protocol**—Eleven healthy, normal adult male volunteers, 20–37 years of age, were the subjects. The treatments consisted of four different brands of quinidine sulfate tablets acquired by the normal channels of drug distribution. A dose of 400 mg of quinidine sulfate (as two 200-mg tablets) was administered to each subject with approximately 180 ml of water. The subjects received each of the four treatments, A[4], B[5], C[6], and D[7], in a completely randomized crossover design. A 2-week period was employed between each dosage interval to allow for complete drug elimination. All subjects fasted for 8 hr before and 3 hr following drug administration.

Blood samples (6 ml) were drawn using evacuated glass containers[8] just prior to dosing and at 0.5, 1, 2, 3, 4, 6, 8, 12, 24, and 32 hr following drug administration. The samples were immediately centrifuged[9] at 3000 rpm, and the serum was separated and analyzed for quinidine. Complete urine voids were collected at intervals of 2, 4, 6, 8, 12, 16, 24, 28, 32, 40, 48, 58, and 72 hr following drug administration and analyzed for quinidine.

***In Vitro* Assessment of Dosage Forms**—Weight variation tests were performed on 20 tablets of each of the four brands following the method outlined in USP XIX (22) for determining permissible limits of weight variation.

Disintegration times were determined using an apparatus conforming

Table I—Parameters Derived from Serum Levels and Urinary Excretion of Unchanged Drug

Parameter	Treatment[a] A	B	C	D	Statistical Method	Statistical Evaluation
Mean value of peaks of individual serum concentration–time curves, μg/ml	1.42	1.45	1.43	1.33	ANOVA	NS[b]
Mean time of peak value of individual serum concentration–time curves, hr	1.84	2.27	1.63	2.54	Wilcoxon's matched-pairs signed ranks test	$p < 0.05$
Mean corrected area under individual serum concentration–time curves, (μg/ml) × hr	14.41	15.80	15.11	14.63	ANOVA	NS
Mean k_a value of individual serum concentration–time curves, hr^{-1}	2.88	2.08	2.91	1.12	Wilcoxon's matched-pairs signed ranks test	$p < 0.05$
Mean K_E value of individual serum concentration–time curves, hr^{-1}	0.142	0.130	0.125	0.138	Wilcoxon's matched-pairs signed ranks test	NS

[a] See text for explanation of treatment conditions. [b] NS = not statistically significant.

to USP specifications[10] and employing six tablets of each of the four products. Tablets were tested according to the official specifications with purified water maintained at 37 ± 2° as the immersion fluid.

Although a content uniformity test is not specified for quinidine sulfate tablets, the relative potency of the tablets was determined by performing individual assays on each of 10 randomly chosen tablets of the four different brands. An additional 10 tablets of each brand were chosen and collectively assayed for mean quinidine content. The assay was conducted by following the nonaqueous titration procedure outlined in USP XIX (23) for quinidine sulfate tablets.

Fluorometric Determination of Quinidine in Biological Fluids—The analytical method used for the determination of quinidine in serum and urine was a modified form of the fluorometric assay developed by Cramer and Isaksson (24). This method utilizes a double-extraction procedure, which limits the extraction of water-soluble metabolites of quinidine and dihydroquinidine. Fluorescence was determined on a spectrofluorometer[11] at 450-nm emission and 340-nm excitation. Stock solutions for the calibration plots were prepared such that results are reported in terms of quinidine base.

Statistical Evaluation of Results—The following parameters were analyzed for variance for a crossover design using a computerized statistical program (BMD08V) (25): (*a*) serum concentrations at each time period, (*b*) peak serum concentrations, (*c*) corrected area under the serum concentration–time curve, and (*d*) total urinary excretion of the unchanged drug. Any variance established among treatments was further analyzed for differences between all possible treatment pairs using Tukey's allowable difference test (26).

Wagner (27) and Westlake (28) pointed out that univariate parameters, such as absorption rate constants and elimination rate constants estimated from serum level–time data, should not be analyzed by methods assuming uniform error variance. Therefore, values for the absorption rate constant, k_a, elimination rate constant, K_E, and calculated peak time, t_{max}, were analyzed nonparametrically using Wilcoxon's matched-pairs signed ranks test (29).

RESULTS

Based on the shapes of semilogarithmic plots of individual serum concentration–time data for the 11 subjects, the data were fitted to the classical one-compartment model, both with and without a lag time (30, 31), using a nonlinear least-squares regression computer program (32) on a digital computer[12]. Comparison of the values of the individual sums of squares of the deviations between experimental data and calculated values showed the one-compartment model with a lag time to have the better fit. The individual areas under the serum concentration–time curves (*AUC*) were calculated using the trapezoidal rule, including a correction for the *AUC* beyond the last data point. The peak time is the sum of the calculated peak time and the calculated lag time, t_{lag}. The calculated peak time was determined using (33):

$$t_{max} = \frac{2.303}{k_a - K_E} \log \frac{k_a}{K_E} \quad \text{(Eq. 1)}$$

The lag time was calculated from (34):

$$t_{lag} = \frac{2.303(\log A_2 - \log A_1)}{k_a - K_E} \quad \text{(Eq. 2)}$$

where A_2 and A_1 represent the coefficients for the exponential terms describing absorption and elimination, respectively.

Table I summarizes the pharmacokinetic data obtained from the individual serum and urinary excretion data. An analysis of variance and Wilcoxon's matched-pairs signed ranks test were performed on the appropriate parameters. A statistical difference was evidenced for the time of the peak concentration of the individual serum concentration–time curves between Treatments A and D, B and C, and C and D at the 95% level of confidence. Statistical differences ($p < 0.05$) were also found between Treatments A and D and C and D for the k_a values derived from the individual serum concentration–time curves.

Figure 1 illustrates the mean cumulative urinary excretion of the unchanged drug for the four brands of tablets. Statistical analyses (ANOVA)

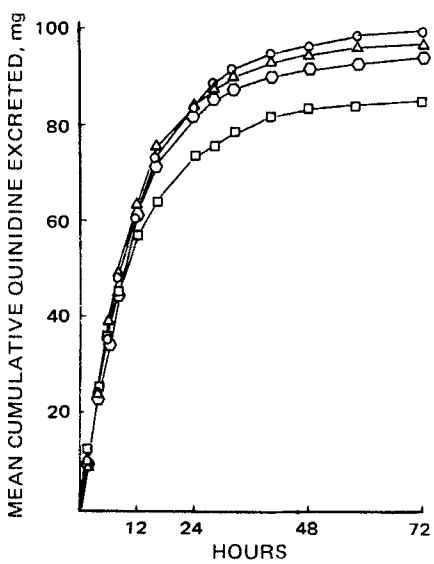

Figure 1—*Mean cumulative milligrams of unchanged quinidine excreted in urine (0–72 hr). Key: ○, Treatment A; △, Treatment B; □, Treatment C; and ○, Treatment D.*

[10] Van Kel Industries, Livingston, N.J.
[11] Turner model 430, G. K. Turner Associates, Palo Alto, Calif.
[12] PDP-10, Digital Equipment Corp., Maynard, Mass.

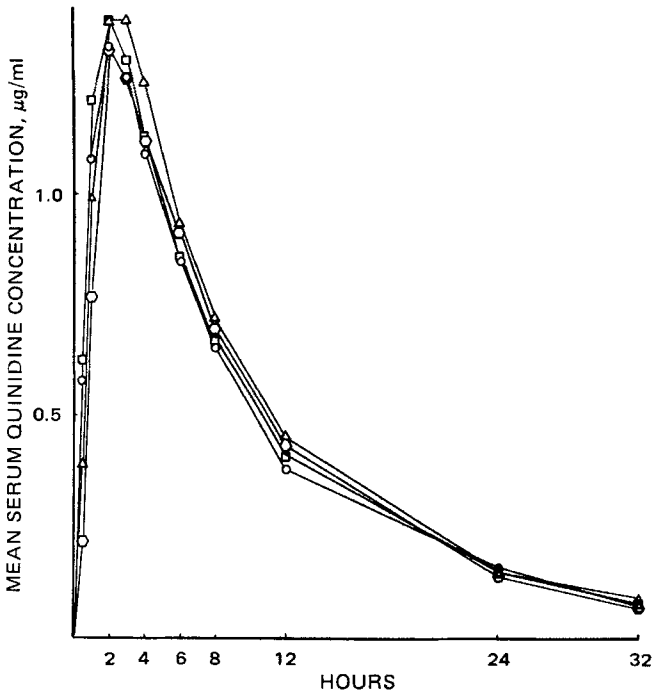

Figure 2—*Mean serum concentrations for 11 subjects for four different brands of quinidine sulfate tablets (0–32 hr). Key: ○, Treatment A; △, Treatment B; □, Treatment C; and ◇, Treatment D.*

revealed no differences between the four tablet brands based on the urinary excretion data. Figure 2 represents the mean serum level values for each treatment at each of the 10 sampling times following drug administration. An analysis of variance revealed a statistical difference ($p < 0.05$) among the treatment values for the mean serum values obtained at 0.5 and 1.0 hr following drug administration.

Differences among treatments were analyzed to determine the difference between treatment pairs using Tukey's test. A statistical difference was evidenced between Treatments A and D and C and D at 0.5 hr. There was also a statistical difference between Treatments C and D at 1.0 hr. The mean elimination half-life was calculated using (35):

$$t_{1/2} = \frac{0.693}{K_E} \qquad \text{(Eq. 3)}$$

and the individual K_E values were obtained from the computer program. The mean $t_{1/2}$ for all subjects and all treatments was 5.36 ± 1.07 hr, with all values falling into a range of 2.71–8.12 hr.

All four brands passed the weight variation and disintegration tests for quinidine sulfate tablets as specified in USP XIX. Mean disintegration times were 4.08 ± 0.20 min for Treatment A, 7.16 ± 1.94 min for Treatment B, 1.00 ± 0.0 min for Treatment C, and 17.83 ± 2.22 min for Treatment D. The relative potency of the individual tablets was also confirmed, with all individual tablet assays for all four brands resulting in 86.7–104.9% of the average of the monograph potency definition for the drug (36). The data confirmed the assumption that the various brands were chemical equivalents.

DISCUSSION

The bioavailability of a drug from tablet dosage forms depends on both the rate and extent of drug absorption into the general circulation. These factors can be evaluated by examining the pharmacokinetic parameters derived from blood level–time profiles and urinary excretion patterns for the unchanged drug. Bioequivalence is assured when the serum level–time curves for different brands of tablets are superimposable. Bioequivalence can also be established by comparing the peak serum concentrations of the drug, the times of the peak concentration, and the extent of absorption as reflected by the areas under the serum level–time curves.

Comparison of the area under the curve values revealed no significant differences in the extent of absorption of quinidine sulfate among the four different brands of tablets tested. The amount of drug excreted unchanged in the urine was also employed as an indicator of drug absorption. The urinary excretion of quinidine sulfate is pH dependent (37). Although no attempts were made to control urine pH in this study, comparison of the amounts excreted unchanged in the urine for 72 hr following administration showed no significant differences among the four brands tested. No apparent differences in urine pH values for the different treatments were noted.

The peak concentration and time of the peak concentration serve as indicators of the drug absorption rate. The peak concentration is generally achieved 2–3 hr following oral administration of a single dose of quinidine sulfate (38). Analyses of the data in Table I revealed a significant difference in the times of peak concentration between Treatments A and D, C and D, and B and C. A statistical difference also was evidenced for the mean serum levels between Treatments A and D and C and D at 0.5 hr and between Treatments C and D at 1.0 hr. Examination of the k_a values also revealed significant differences between Treatments A and D and C and D. The treatment pairs that exhibited significant differences in mean serum levels (A and D and C and D) and k_a values (A and D and C and D) also showed a statistical difference in the peak times (A and D and C and D), indicating that there was a difference in the absorption rate between these two formulation pairs. Treatment pair B and C also demonstrated a statistical difference in the peak time but not in serum levels or k_a values.

When mean disintegration times for the tablet brands were compared with the values for k_a, t_{max}, and mean serum levels at 0.5 and 1.0 hr, rank-order correlations were observed. Treatment C, with the shortest mean disintegration time, had the largest k_a value, highest serum levels at the first two sampling times, and the shortest t_{max}. Treatments A, B, and D followed in numerical ranking of mean disintegration times. There is currently no dissolution requirement in the compendial monograph of quinidine sulfate tablets, but dissolution studies are now underway in these laboratories to determine if a correlation between dissolution rates and *in vivo* parameters exist.

Although there was no significant difference among treatments for the mean biological half-life of the drug, there was considerable intersubject variability, in agreement with previously reported variability in the biological elimination of quinidine (39). The mean half-life for all subjects using all formulations was 5.36 ± 1.07 hr with a range of 2.71–8.12 hr. This range is less than that reported by Mason *et al.*[3] of 1.16–15.75 hr but corresponds more closely to the results of Ueda *et al.* (21), who reported a half-life of 6.33 hr with a range of 3.61–9.00 hr.

Mechanism of Histamine Binding II: Effect of Alkali Metal and Alkaline Earth Cations on Histamine Binding to Peptide H

PAUL A. KRAMER, JOHN R. HAZLETT, and DANE O. KILDSIG [x]

Abstract □ The association constants of histamine with Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+} were determined in buffer solutions at constant pH using an ion selective electrode. These cations enabled histamine to bind to peptide H. A minimum cation binding concentration was required for histamine binding. A linear relationship existed between the minimum cation binding concentration and the log of the equilibrium constant for the histamine–cation complexes, indicating that the specificity of the alkaline earth cations in promoting histamine binding was due to the difference in their ability to complex with histamine. The monovalent cations, Na^+, K^+, and Cs^+, inhibited histamine binding to peptide H, with the extent of inhibition dependent on cation concentration. An ion-exchange mechanism or a conformation change in the peptide may account for the inhibition.

Keyphrases □ Histamine—binding to peptide H, effect of alkali metal and alkaline earth cations, association constants determined □ Peptide H—binding to histamine, effect of alkali metal and alkaline earth cations, association constants determined □ Alkali metal and alkaline earth cations—effect on binding of histamine to peptide H, association constants determined □ Binding—histamine to peptide H, effect of alkali metal and alkaline earth cations, association constants determined □ Association constants—determined for binding of histamine to peptide H, effect of alkali metal and alkaline earth cations □ Metals—alkali metal and alkaline earth cations, effect on binding of histamine to peptide H

Previous reports indicated that Ca^{2+} is involved in the binding of histamine to serum protein (1, 2). Cations other than Ca^{2+} also appear to affect histaminopexy. Serum Mg^{2+} levels in asthmatics are low during attacks but normal while patients are free of symptoms (3); magnesium sulfate given intravenously to severe asthmatics gives relief for 18–20 hr (3). Injections of magnesium chloride restore histaminopexy in adrenalectomized and ovariectomized rats for up to 3 months, an effect similar to that of Ca^{2+} but longer lasting (4). In contrast to the divalent alkaline earth cations, the monovalent cation K^+ appears to inhibit histaminopexy (2, 5–7).

Previously (8), histamine was found to bind to a plasma peptide, termed peptide H, through the formation of a Ca^{2+}–histamine complex. Apparently, only one extensive investigation of histamine–alkaline earth complexes has been reported. Chawla (9) measured association and other thermodynamic constants for Be^{2+}, Ca^{2+}, and Mg^{2+} complexes with histamine, antistine, and similar molecules at several temperatures. Several studies determined association constants for histamine complexes with various other metals (10–12), and the method of pH titration generally has been used. For accurate results, this technique requires extensive experimental precautions such as those used by Chawla (9).

This report describes the determination of histamine–cation constants at constant pH, using a cation selective electrode. The purpose of this investigation was to deter-

Mechanism of Histamine Binding II: Effect of Alkali Metal and Alkaline Earth Cations on Histamine Binding to Peptide H

PAUL A. KRAMER, JOHN R. HAZLETT, and DANE O. KILDSIG [x]

Abstract □ The association constants of histamine with Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+} were determined in buffer solutions at constant pH using an ion selective electrode. These cations enabled histamine to bind to peptide H. A minimum cation binding concentration was required for histamine binding. A linear relationship existed between the minimum cation binding concentration and the log of the equilibrium constant for the histamine–cation complexes, indicating that the specificity of the alkaline earth cations in promoting histamine binding was due to the difference in their ability to complex with histamine. The monovalent cations, Na^+, K^+, and Cs^+, inhibited histamine binding to peptide H, with the extent of inhibition dependent on cation concentration. An ion-exchange mechanism or a conformation change in the peptide may account for the inhibition.

Keyphrases □ Histamine—binding to peptide H, effect of alkali metal and alkaline earth cations, association constants determined □ Peptide H—binding to histamine, effect of alkali metal and alkaline earth cations, association constants determined □ Alkali metal and alkaline earth cations—effect on binding of histamine to peptide H, association constants determined □ Binding—histamine to peptide H, effect of alkali metal and alkaline earth cations, association constants determined □ Association constants—determined for binding of histamine to peptide H, effect of alkali metal and alkaline earth cations □ Metals—alkali metal and alkaline earth cations, effect on binding of histamine to peptide H

Previous reports indicated that Ca^{2+} is involved in the binding of histamine to serum protein (1, 2). Cations other than Ca^{2+} also appear to affect histaminopexy. Serum Mg^{2+} levels in asthmatics are low during attacks but normal while patients are free of symptoms (3); magnesium sulfate given intravenously to severe asthmatics gives relief for 18–20 hr (3). Injections of magnesium chloride restore histaminopexy in adrenalectomized and ovariectomized rats for up to 3 months, an effect similar to that of Ca^{2+} but longer lasting (4). In contrast to the divalent alkaline earth cations, the monovalent cation K^+ appears to inhibit histaminopexy (2, 5–7).

Previously (8), histamine was found to bind to a plasma peptide, termed peptide H, through the formation of a Ca^{2+}–histamine complex. Apparently, only one extensive investigation of histamine–alkaline earth complexes has been reported. Chawla (9) measured association and other thermodynamic constants for Be^{2+}, Ca^{2+}, and Mg^{2+} complexes with histamine, antistine, and similar molecules at several temperatures. Several studies determined association constants for histamine complexes with various other metals (10–12), and the method of pH titration generally has been used. For accurate results, this technique requires extensive experimental precautions such as those used by Chawla (9).

This report describes the determination of histamine–cation constants at constant pH, using a cation selective electrode. The purpose of this investigation was to deter-

Table I—Values for the Stoichiometry and Association Constants for Alkaline Earth Cation–Histamine Complexes at 37° and pH 7.4

Cation	n	log K	K, M^{-1}
Mg^{2+}	1.00	2.50	3.2×10^2
Ca^{2+}	1.02	3.07	11.8×10^2
Sr^{2+}	0.88	2.96	9.2×10^2
Ba^{2+}	0.80	2.87	7.4×10^2

mine the effect of the alkaline earth and alkali metal cations on the binding of histamine to peptide H.

EXPERIMENTAL

Materials—Histamine dihydrochloride[1] and tromethamine hydrochloride, ultrapure[1], were used. All other chemicals were reagent grade. The isolation of peptide H and the preparation of the tromethamine buffer were described previously (8).

Minimum Detectable Binding Concentration—To determine the minimum concentration of the alkaline earth cation necessary for detectable histamine–peptide binding, a series of dynamic dialysis runs was carried out with increasing concentrations of the alkaline earth cation added to internal and external solutions. The apparatus and experimental procedure for dynamic dialysis were described previously (8). Plots of log total histamine remaining in the internal cell *versus* time were made. When no binding occurred, the slopes of these linear plots were the same as the slope with no peptide present. When binding occurred, the slope decreased, indicating less free histamine present.

Association Constants for Histamine and Alkaline Earth Cations—Calcium-ion and calomel electrodes were used with a pH meter[2]. Solutions were maintained at 37 ± 0.1° in a jacketed beaker and agitated with a magnetic stirrer. A titrant, alkaline earth chloride solution in isotonic tromethamine buffer (pH 7.4), was added in 0.1-ml increments to either 50 ml of 1.81×10^{-3} M histamine in the same tromethamine buffer or 50 ml of a buffer blank containing no histamine. Each 0.1-ml increment of titrant produced a 0.0005 M increment of cation.

Plots of cation concentration *versus* millivolt reading, both in the presence and absence of histamine, were made. From these plots, the concentration of free cation and, by subtraction, the concentration of bound cation were determined.

Millivolt Titrations with Histamine, Peptide, and Calcium: Effect of Alkali Metal Cation—Alkali metal chloride was added to 25 ml of peptide H, 7.8 mg/ml, in 0.9% NaCl. Sodium, potassium, and cesium chlorides were used. Since 0.9% NaCl was used in the buffer system throughout all investigations, 0.154 M, corresponding to 0.9% NaCl, was the lowest concentration of potassium and cesium chlorides used. The peptide H solution was also made 0.770 and 1.1540 M in sodium chloride; 0.308, 0.616, and 1.232 M in potassium chloride; and 0.308 and 0.770 M in cesium chloride. To these solutions, histamine dihydrochloride solution was added in 0.1-ml increments such that each addition produced a 0.001 M increment in histamine.

A pH meter[3] was used with combination electrode to determine the millivolt readings. Identical runs were conducted with calcium chloride added to the peptide H–alkali metal chloride solutions.

RESULTS AND DISCUSSION

Cation–Histamine Association Constants—Total valence electron calculations show that histamine, in both its neutral and monoprotonated forms, exists in a configuration theoretically favorable to metal and intramolecular hydrogen binding (13). The equilibria involved are shown in Schemes I and II:

$$n_1M^{2+} + Hi^+ \overset{K}{\rightleftharpoons} M_{n_1}Hi^+$$

Scheme I

$$n_2M^{2+} + Hi \overset{K'}{\rightleftharpoons} M_{n_2}Hi$$

Scheme II

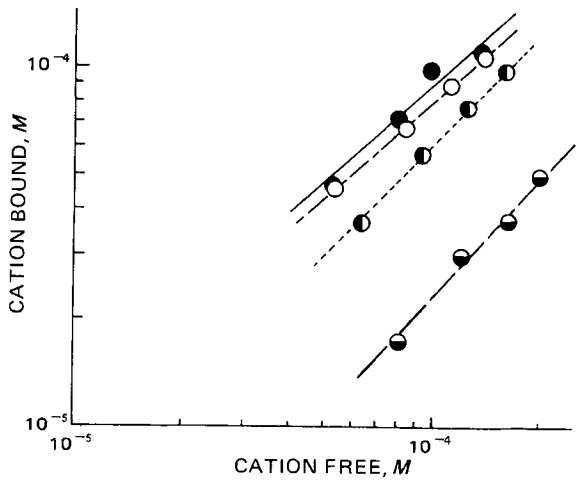

Figure 1—*Log–log plot of the bound alkaline earth cation* versus *the free alkaline earth cation for various histamine–alkaline earth cation complexes. The slope is equal to the number of cations bound per histamine molecule. Key:* ◒, *Mg;* ◐, *Ba;* ○, *Sr; and* ●, *Ca.*

where Hi and Hi^+ are the unionized and monoprotonated forms of histamine, M^{2+} is the alkaline earth divalent cation concentration, n is the number of moles of cation bound per mole of histamine, and $M_{n_1}Hi^+$ and $M_{n_2}Hi$ are the concentrations of the complexes formed.

If $n_1 = n_2 = n$, then:

$$K'/K = [M_nHi]/[M_nHi^+]\{[Hi^+]/[Hi]\} \qquad \text{(Eq. 1)}$$

Since the side-chain pKa of histamine is about 9.4, the ratio Hi^+/Hi is between 30 and 100 at a physiologic pH of 7.4. Therefore, the species M_nHi makes only a minor contribution to the total bound alkaline earth cation at pH 7.4 unless the affinity constant, K', for the unionized histamine–metal complex is an order of magnitude higher than that for ionized histamine, K. Assuming Scheme I represents the primary association, one can calculate the cation–histamine$^+$ association constant, K, for Mg^{2+}, Ca^{2+}, Sr^{2+}, and Ba^{2+} from determinations of free and bound alkaline earth cation concentrations at pH's where Hi^+ predominates. The equilibrium expression for Scheme I is:

$$K = \frac{[M_nHi^+]}{[M^{2+}]^n[Hi^+]} \qquad \text{(Eq. 2)}$$

which may be written as:

$$\log K = \log [M_nHi^+] - \log [Hi^+] - n \log [M^{2+}] \qquad \text{(Eq. 3)}$$

or:

$$\log [M^{2+}_{\text{bound}}] = \log K + \log [Hi^+] + n \log [M^{2+}_{\text{free}}] \qquad \text{(Eq. 4)}$$

where $\log [M^{2+}_{\text{bound}}] = \log [M_nHi^+]$. A plot of log cation bound *versus* log cation free was linear (Fig. 1), and the slope, n, was approximately one for all four cations, indicating a 1:1 complex (Table I). The association constants may then be calculated using Eq. 2, since the concentrations of bound and free cation, and thus of complex and free histamine, are known (Table I). The complexes of histamine with Ca^{2+}, Sr^{2+}, Ba^{2+}, and Mg^{2+} were found to be 1:1 with association constants for Ca^{2+}, Sr^{2+}, and Ba^{2+} with histamine being fairly close at about 10^3 M^{-1} and for the histamine–Mg^{2+} complex being considerably lower.

The association constants determined for the histamine–alkaline earth complexes by the ion selective electrode at constant pH are in good agreement with Chawla's (9) results (for Mg^{2+}, a log K of 2.26; for Ca^{2+}, a log K of 2.91) determined at 25° using the pH titration method. The

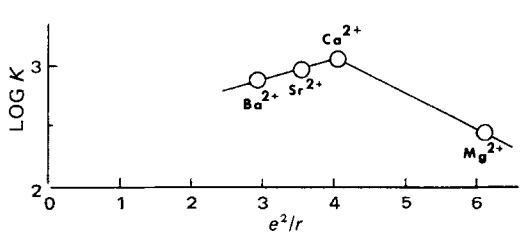

Figure 2—*Log* K versus e^2/r *for histamine–alkaline earth cation complexes.*

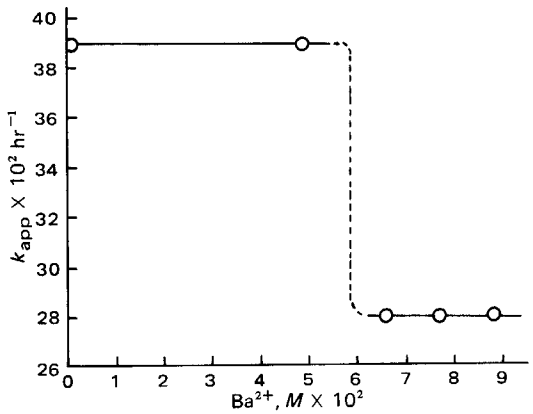

Figure 3—*Relationship between apparent first-order dialysis rate constant, k_{app}, and concentration of Ba^{2+} indicating the minimum detectable binding concentration of Ba^{2+}.*

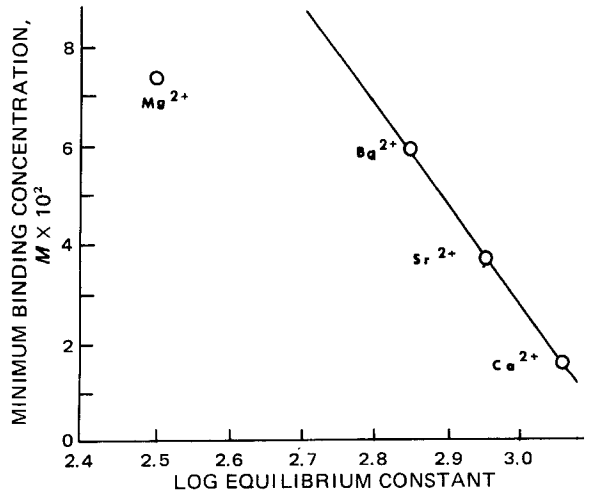

Figure 4—*Relationship between the minimum detectable binding concentration and log of the histamine–alkaline earth cation association constants.*

pH titration method, however, approaches its limit of application for association constants under 10^3, limiting the accuracy of Chawla's values for Ca^{2+}–histamine and, particularly, for Mg^{2+}–histamine (9). While it is difficult to draw conclusions based on only these two systems, the larger deviation of Chawla's log K for Mg^{2+}–histamine from the log K determined by the ion selective electrode was most likely due to the pH titration limitation, with the ion selective electrode measurement of log K being the more accurate.

A plot of the data according to the Born equation, as described by Martell and Calvin (14), provides some insight into the influence of the charge and radius of the alkaline earth ion on the binding constant:

$$E = \frac{e^2}{2r}\left(1 - \frac{1}{D}\right) \qquad \text{(Eq. 5)}$$

where E = energy of solvation for gaseous ions, r = ionic radius, e = charge, and D = dielectric constant of solvent. If the energy of solvation is assumed to be directly related to log K, then a linear relationship should exist between log K and e^2/r. When the log of the association constants for histamine–alkaline earth cations are plotted *versus* e^2/r, it is seen (Fig. 2) that while Ba^{2+}, Sr^{2+}, and Ca^{2+} follow the expected order, Mg^{2+} is low. It is not unusual, however, for Ca^{2+} complexes to have higher log K's than Mg^{2+}, particularly with ligands forming a highly chelated structure.

One might also expect a relationship between the proton affinity (pK) of the chelating agent and the free energy of the binding process as represented by log K. Martell and Calvin (14) showed a plot of log K *versus* pK for the alkaline earth complexes of a series of structurally similar weak acid chelating agents. A linear relationship was observed for each alkaline earth cation studied. For chelating agents with pK's above 9, the affinity constants were in the order $Mg^{2+} > Ca^{2+} > Sr^{2+} > Ba^{2+}$. At pK's below 7.5, the order seemed to be altered; this same order, $Ca^{2+} > Sr^{2+} > Ba^{2+} > Mg^{2+}$, was observed for histamine affinities. The present system seems to exhibit the expected metal specificity for a species with a conjugate acid dissociation constant below 7.5, *i.e.*, the monoprotonated form of histamine, the conjugate acid of which has a pK of 5.8, and for a species that predominates at pH 7.4. The binding affinities of the alkaline earth cations for vitamin D-induced calcium binding protein also follow the order $Ca^{2+} > Sr^{2+} > Ba^{2+} > Mg^{2+}$ (15). This effect may be due to ionizable groups of pK less than 7.5 on the binding protein.

Effect of Alkaline Earth Divalent Cations—When Sr^{2+}, Ba^{2+}, or Mg^{2+} was substituted for Ca^{2+} in the dynamic dialysis runs, it also enabled the peptide to bind histamine. The difference was only in the concentration of cation necessary to promote binding.

When the apparent first-order rate constants were determined from the slopes of plots of log total histamine remaining in the dialysis cell *versus* time and plotted against the concentration of cation at which they were obtained, the apparent first-order rate constants were the same whether the cation was present or not until a minimum cation concentration was reached. At this point, the rate constants decreased, indicating that binding, perhaps mediated by a conformational change, had occurred (Fig. 3). The minimum concentrations of the alkaline earth cation required for binding are shown in Table II. As the divalent cation concentration was increased beyond the minimum for binding, a rate of dialysis independent of cation concentration was reached (Fig. 3). Since the concentration of peptide H was much smaller than the histamine or divalent cation concentrations and was constant, the peptide H concentration probably became a limiting factor, resulting in the apparent constancy of the binding.

When association constants for histamine–alkaline earth cations were logarithmically plotted *versus* their respective minimum detectable binding concentrations (Fig. 4), a linear relationship was observed between the threshold concentration and the free energy of the binding process. Thus, the specificity of the alkaline earth cations in promoting binding of histamine to peptide H is due to the difference in their ability to complex with histamine as indicated by their association constants.

Botre *et al.* (16) studied the binding of histamine to bovine serum albumin at various ionic strengths and reported that, for a given ionic strength, the protein required a threshold concentration of histamine for binding and that this threshold varied with the nature of the inorganic cations present in the system. The explanation given is that the albumin undergoes a "conformational perturbation that is induced by histamine and dependent on ionic strength." Apparently, a similar phenomenon occurs for peptide H, where the conformational change is induced by the alkaline earth cation–histamine complex.

Effect of Monovalent Cations on Histamine–Ca^{2+}–Peptide H Binding—Peptide H in distilled water, with varying concentrations of alkali metal chloride added, was titrated with histamine dihydrochloride, and the millivolt readings were recorded using a pH electrode. A plot of the millivolt readings *versus* the log of the concentration of histamine added was linear (Fig. 5). Since histamine does not bind to peptide H in the absence of Ca^{2+} (8) (or other divalent cations), the pH electrode was responding to free histamine hydrochloride. The addition of calcium chloride resulted, as expected, in a decrease in free histamine due to binding to peptide H, as evidenced by a decreased slope of the millivolt titration curve. This Ca^{2+} effect was most noticeable at the lower concentrations of the alkali metal chlorides, 0.154 M, with the effect of the alkali metal chloride increasing as its concentration increased.

Table II—Minimum Detectable Binding Concentrations for the Alkaline Earth Cations

Cation	Minimum Binding Concentrations, M
Mg^{2+}	7.4×10^{-2}
Ca^{2+}	1.6×10^{-2}
Sr^{2+}	3.7×10^{-2}
Ba^{2+}	5.9×10^{-2}

Table III—Minimum Alkali Metal Chloride Concentrations for Complete Inhibition of Histamine Binding

Cation	Inhibitory Concentration, M
Cs^+	0.52
Na^+	0.86
K^+	1.43

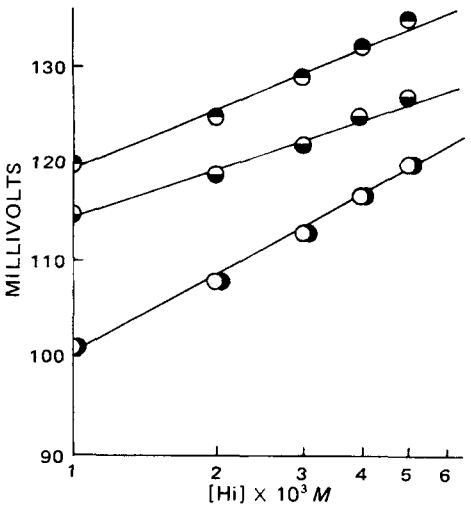

Figure 5—*Relative millivolt readings* versus *concentration of histamine for determining the effect of Na^+ on peptide–histamine–Ca^{2+} binding. Key: ◓, peptide, low Na^+; ◒, peptide, Ca^{2+}, low Na; ○, peptide, high Na^+; and ●, peptide, Ca^{2+}, high Na^+. The concentrations were: peptide, 1.7 × 10^{-4} M; Ca^{2+}, 1.8 × 10^{-2} M; low Na^+, 0.154 M; and high Na^+, 0.770 M.*

As seen in Fig. 5, the curves for both the peptide H and peptide H–calcium chloride solutions containing the higher alkali metal concentration approach one another. Apparently, an alkali metal chloride concentration can be reached that completely inhibits histamine binding to peptide H. That this is indeed the case is shown in Fig. 6, where the millivolt difference between the peptide H and peptide H–calcium chloride solutions was plotted *versus* the concentration of alkali metal chloride present in the solution. An extrapolation to the abscissa gives the concentration of alkali metal chloride necessary to inhibit histamine binding completely. This finding is verified by the complete inhibition of binding by Na^+ and Cs^+ at concentrations over the predicted inhibitory concentration.

The alkali metal cations may inhibit the histamine–peptide H binding

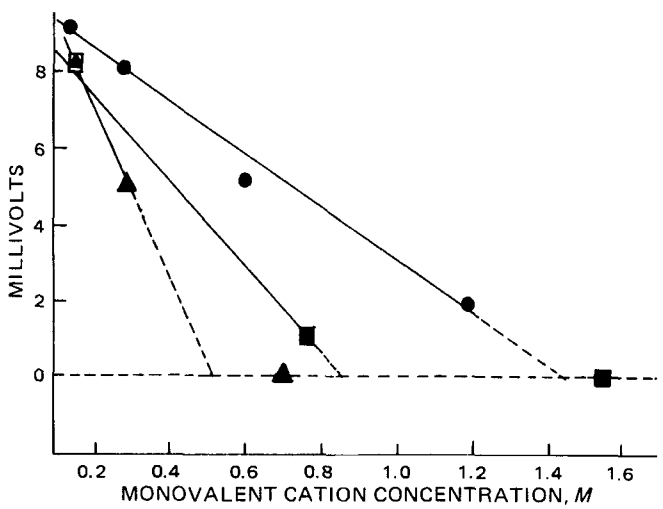

Figure 6—*Relationship between the change in millivolt reading produced by added Ca^{2+} and the concentration of the monovalent cation present in solution. The intercept at 0 mv is predictive of the minimum inhibitory concentration of the monovalent cation. Key: ▲, Cs^+; ■, Na^+; and ●, K^+.*

by affecting either the Ca^{2+}–histamine complex formation or the binding of the complex to peptide H. To determine if Na^+ affected the complexation between histamine and Ca^{2+}, histamine was titrated with Ca^{2+} solution using a Ca^{2+} ion selective electrode in the same manner as was used to determine the histamine–Ca^{2+} association constant, except that more sodium chloride was added to increase the Na^+ concentration from 0.154 to 0.770 *M*. There was no difference in the concentration of bound Ca^{2+} in the presence of increased Na^+. However, the increase of Na^+ to 0.770 *M* did interfere with the Ca^{2+}-mediated binding of histamine to peptide H (Fig. 5); therefore, the Na^+ effect must occur in the interaction between the histamine–Ca^{2+} complex and peptide H.

Two possible mechanisms for the alkali metal cation inhibition of histamine binding may be considered. One possibility is an ion exchange between the alkali metal cation and the bound calcium–histamine complex, similar to that reported by Aborg and Uvnas (17) for Na^+ inhibition of histamine binding to a heparin–clupeine complex. The inhibition by Na^+ was due to a competition with histamine for carboxyl groups on the clupeine. Peptide H provides nine weak acid groups per peptide molecule, and a similar competitive displacement from these anionic sites is a possible explanation of the present observations. Alternatively, conformational changes in peptide H favorable to binding may be induced by the Ca^{2+}–histamine complex and, above a critical alkali metal salt concentration, these conformational changes cannot be effected. It was reported that alkali metal cations prevent a conformational change in bovine serum albumin that is essential for albumin–histamine binding (16). The order of specificity of this inhibitory effect was $K^+ > Rb^+ > Na^+ > Li^+ = Cs^+$, which is the reverse of the order observed for the inhibition of Ca^{2+}–histamine binding to peptide H (Table III).

Synthesis and PMR and Mass Spectra of Potential Metabolites and Other Derivatives of Bis(2-ethylhexyl) Phthalate

JAMES E. CARTER, ROBERT V. PETERSEN, and DAVID B. ROLL ˣ

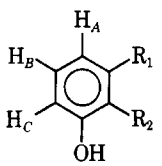
Abstract □ The 3- and 4-hydroxylated derivatives of the plasticizer bis(2-ethylhexyl) phthalate and the monoesters derived from these hydroxylated derivatives were synthesized. The structures of the two 4-hydroxy monoesters were confirmed by lithium borohydride reduction to their corresponding hydroxymethylbenzoic acids, followed by cyclization of the reduced compounds to known phthalides. All compounds were characterized by PMR and mass spectra. The PMR data reiterate the difficulty in predicting chemical shifts in multisubstituted benzene rings.

Keyphrases □ Phthalate esters, mono- and bis(2-ethylhexyl)—3- and 4-hydroxy derivatives synthesized and characterized by PMR and mass spectra □ Hydroxyphthalate esters, mono- and bis(2-ethylhexyl)—synthesized and characterized by PMR and mass spectra □ PMR—characterization of mono- and bis(2-ethylhexyl) esters of 3- and 4-hydroxyphthalic acid □ Mass spectrometry—characterization of mono- and bis(2-ethylhexyl) esters of 3- and 4-hydroxyphthalic acid

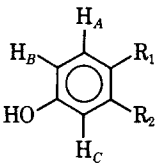
It has been shown that bis(2-ethylhexyl) phthalate (I) is converted into the corresponding monoester, mono(2-ethylhexyl) phthalate (II), both *in vivo* (1) and *in vitro* (2) followed by ω and ω-1 oxidation of II (3). Since II is 50–100 times more toxic than I (4), as determined by acute LD_{50} studies in mice and rats, other toxic metabolites, such as those formed by aromatic hydroxylation of I, might be formed in the body. In conjunction with studies aimed at the identification of such metabolites, the 3-hydroxy (III*a* and III*b*) and 4-hydroxy (IV*a*–IV*c*) derivatives of I and II and related compounds necessary for their unequivocal structural elucidation were synthesized and characterized by PMR and mass spectra.

EXPERIMENTAL

Instrumentation—PMR spectra[1] were obtained using dimethyl sulfoxide-d_6[2] as the solvent and sodium 2,2-dimethyl-2-silapentane-5-sulfonate as the internal standard and are reported in δ, parts per million (ppm), relative to the internal standard. Mass spectra[3] were obtained by direct probe operating at 70 ev with an accelerating voltage of 3.5 kv and an ion source temperature of 250°.



III*a*: $R_1 = R_2 = COOCH_2CH(C_2H_5)(CH_2)_3CH_3$
III*b*: $R_1 = COOCH_2CH(C_2H_5)(CH_2)_3CH_3$, $R_2 = COOH$



IV*a*: $R_1 = R_2 = COOCH_2CH(C_2H_5)(CH_2)_3CH_3$
IV*b*: $R_1 = COOH$, $R_2 = COOCH_2CH(C_2H_5)(CH_2)_3CH_3$
IV*c*: $R_1 = COOCH_2CH(C_2H_5)(CH_2)_3CH_3$, $R_2 = COOH$

Melting points were determined using a micro hot stage or, where specified, a capillary melting-point apparatus[4] and are uncorrected. The TLC solvent system employed was chloroform–methanol–acetic acid (250:10:1).

For the PMR spectra, the aromatic protons in both the 3-hydroxy (III*a* and III*b*) and 4-hydroxy (IV*a*–IV*c*) derivatives were designated H_A, H_B, and H_C. The PMR data for the relevant protons of the 4-hydroxy derivatives are shown in Table I.

Mono(2-ethylhexyl) Phthalate (II)—This compound was synthesized from phthalic anhydride[5] and 2-ethylhexanol[5] according to the procedure of Kenyon and Platt (5); PMR: δ 7.65 (m, 4), 4.17 (d, 2), and 0.77–1.58 (m, 15) ppm; mass spectrum[6]: *m/e* 278 (M^+, 0.5%), 279 (M + 1, 7.5), 167 (30), 149 ($C_8H_5O_3$, 100), 113 (6), 112 (13), 104 (14), 57 (29), and 43 (55).

Bis(2-ethylhexyl) 4-Hydroxyphthalate (IV*a*)—To 3 g (16.4 mmoles) of 4-hydroxyphthalic acid[5] (V*a*) were added 33.4 g (256 mmoles) of 2-ethylhexanol and 3 drops of concentrated sulfuric acid dissolved in 75 ml of toluene (Scheme I, R = 2-ethylhexyl). The mixture was refluxed for 16 hr, the sulfuric acid was removed by shaking with 5% $NaHCO_3$, and the organic phase was washed with water. Toluene was removed with a flash evaporator, and 2-ethylhexanol was removed by vacuum distillation, leaving 5 g (75%) of crude liquid. The product was purified by silica gel[7] dry column chromatography (3.0 × 15 cm) (6) employing chloroform as the eluent; IV*a* eluted mainly in the first 100 ml, which then was concentrated and placed over a second silica gel dry column (1.2 × 20 cm). Elution with chloroform and solvent removal resulted in a clear viscous liquid of analytical quality; mass spectra: *m/e* 406 (M^+, 0.8%), 295 (21), 183 (43) m* 113.5, 165 (100) m* 148.8, 113 (9.5), 112 (20), 71 (25), 70 (30), 59 (29), and 43 (25).

Anal.[8]—Calc. for $C_{24}H_{38}O_5$: C, 70.90; H, 9.42. Found: C, 70.71; H, 9.18.

2-(2-Ethylhexyl) 4-Hydroxyphthalate (IV*b*)—Two grams (10.9 mmoles) of V*a* was sublimed under vacuum to 4-hydroxyphthalic anhydride (V*b*) (1.69 g, 94%) and refluxed for 6 hr with 1.2 equivalents (1.6 g, 13 mmoles) of 2-ethylhexanol in 20 ml of toluene (Scheme I, R = 2-ethylhexyl). The reaction mixture contained only one product, as shown by TLC. The solution was filtered while hot. On cooling, the product crystallized in 70% (2.1 g) yield, mp 142–144°, when recrystallized from acetone–hexane; mass spectra: *m/e* 294 (M^+, 0.3%), 295 (M + 1, 0.9), 183 (10), 165 (50), 164 (82.5), 120 (100), 112 (19), 98 (28), 92 (25), 84 (30), 70 (40), 69 (35), and 57 (90).

Anal.—Calc. for $C_{16}H_{22}O_5$: C, 65.29, H, 7.53. Found: C, 65.51; H, 7.62.

1-(2-Ethylhexyl) 4-Hydroxyphthalate (IV*c*)—Two grams (10.9 mmoles) of V*a*, 8.2 g (62.9 mmoles) of 2-ethylhexanol, and 2 drops of concentrated sulfuric acid were refluxed in 20 ml of toluene for 16 hr and yielded IV*a*, which was hydrolyzed by refluxing for 4 hr after the addition of 2 g of sodium hydroxide (Scheme I). In addition to the desired product (IV*c*), small amounts of IV*b* and V*a* were shown to be present by silica gel[9] TLC. The reaction mixture was acidified with 4 *N* sulfuric acid and extracted with ether, and the product was purified by passage through a silica gel dry column (1.5 × 16 cm). The column was eluted with 100 ml of chloroform followed by increasing concentrations of methanol in chloroform, resulting in elution of the product (1.1 g, 34%) with 25% methanol, mp 124–126° from acetone–hexane; mass spectra: *m/e* 294

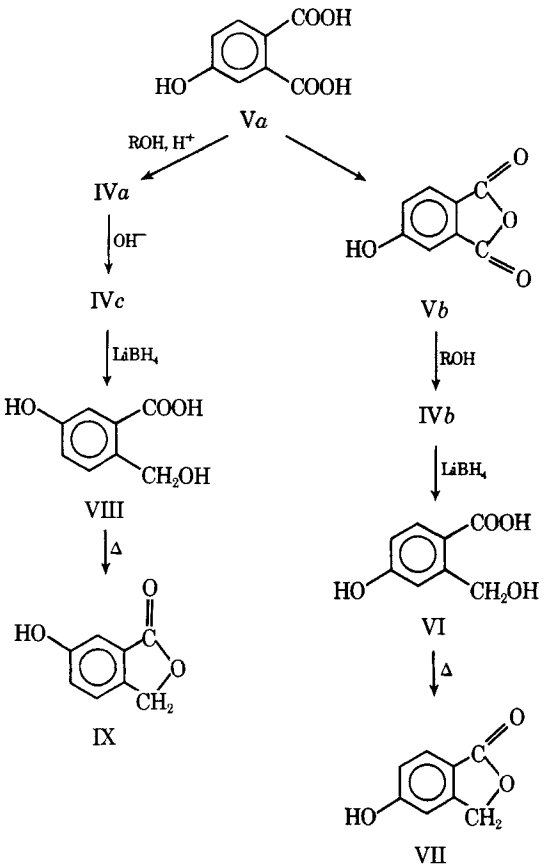


Scheme I

(M+, 0.3%), 295 (M + 1, 1.0), 183 (19.5), 165 (95), 164 (20.0), 120 (40), 92 (28), 83 (26), 70 (45), 57 (100), 43 (35), and 41 (33).

2-Hydroxymethyl-4-hydroxybenzoic Acid (VI)—To confirm the structure of IV*b*, VI was prepared by refluxing IV*b* (0.81 g, 2.77 mmoles) for 24 hr with a 10-fold excess of lithium borohydride[10] (0.60 g, 28 mmoles) in 30 ml of dioxane (Scheme I). The reaction mixture was acidified with 2 *N* hydrochloric acid and extracted with ether, and the ether was removed under vacuum. The product (0.27 g, 58%), recrystallized from methanol–water, slowly sublimed between 140 and 170°, probably forming the corresponding lactone but never giving a sharp melting point; mass spectra: *m/e* 168 (M+, 4%), 150 (70), 121 (100) m* 97.6, 93 (19) m* 71.5, and 65 (21) m* 45.4.

2-Hydroxymethyl-4-hydroxybenzolactone (VII)—To aid in the identification of IV*b*, VI was converted quantitatively to its corresponding lactone (VII) by heating at 100° for 72 hr (Scheme I), mp 219° with softening at 210° (capillary) [lit. (7) mp 223° with softening at 210°]; mass spectra: *m/e* 150 (M+, 74%), 121 (100) m* 97.6, 93 (21) m* 71.5, and 65 (25) m* 45.4.

2-Hydroxymethyl-5-hydroxybenzoic Acid (VIII)—This compound was prepared by refluxing 2.5 g of IV*c* (8.5 mmoles) with 1.85 g (85 mmoles) of lithium borohydride in dioxane for 36 hr (Scheme I). Excess borohydride was destroyed by the addition of 2 *N* hydrochloric acid, the solution was extracted with ether and dried with sodium sulfate, and the ether was removed, giving the desired product (0.52 g, 36%). This product was recrystallized from methanol–water, mp 129–130° (capillary); mass spectra: *m/e* 168 (M+, 1.1%), 150 (46), 121 (100) m* 97.6, 93 (28) m* 71.5, and 65 (26) m* 45.4.

2-Hydroxymethyl-5-hydroxybenzolactone (IX)—Compound VIII was quantitatively converted to IX by heating at 100° for 6 hr (Scheme I), mp 199–200° (capillary) [lit. (7) mp 201–202°]; mass spectra: *m/e* 150 (M+, 57%), 121 (100) m* 97.6, 93 (35) m* 71.5, and 65 (25) m* 45.4.

3-Hydroxyphthalic Anhydride (X*c*)—3-Aminophthalic acid[5] (X*a*) (2.0 g, 11.0 mmoles) was diazotized with 0.76 g (11.0 mmoles) of sodium nitrite in 20 ml of 15 *N* sulfuric acid (Scheme II, R = 2-ethylhexyl) following the procedure of Eliel *et al.* (8). The resultant 3-hydroxyphthalic acid (X*b*) was sublimed *in vacuo* to the anhydride (X*c*) (0.71 g, 40%), mp 195–196° [lit. (9) mp 199–200°], and was used without further purification in the following syntheses.

Table I—Chemical Shift Values (δ) for Derivatives of 4-Hydroxyphthalic Acid (V*a*)

Compound	H_A	H_B	H_C	$-CH_2-$
V*a*	7.65 (d, $J \simeq 9$)	6.90	6.90	—
↓ IV*a*	7.66 (d, $J \simeq 9$)	6.95	6.90	4.10
↓ IV*c*	7.35 (d, $J \simeq 8$)	6.72 (dd, $J \simeq 2,8$)	7.00 (d, $J \simeq 2$)	4.05
↓ VIII	7.47 (d, $J \simeq 8$)	6.94 (dd, $J \simeq 2,8$)	7.28 (d, $J \simeq 2$)	4.73
↓ IX	7.53 (d, $J \simeq 9$)	7.23	7.15	5.30
IV*b*	7.72 (d, $J \simeq 8$)	6.92	6.83	4.13
↓ VI	7.77 (d, $J \simeq 8$)	6.67 (dd, $J \simeq 2,8$)	7.12 (d, $J \simeq 2$)	4.82
↓ VII	7.67 (d, $J \simeq 9$)	6.97	6.97	5.27

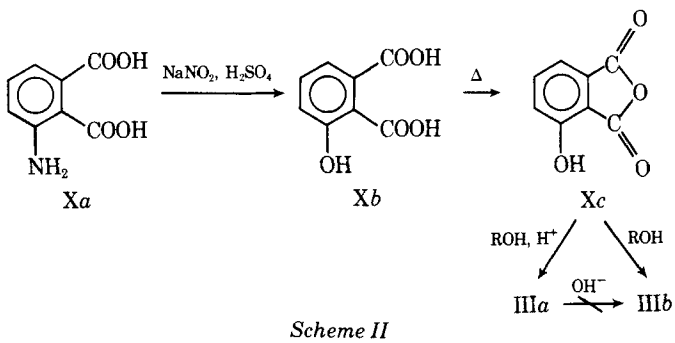
Bis(2-ethylhexyl) 3-Hydroxyphthalate (III*a*)—Compound X*c* (1.0 g, 6.1 mmoles) was added to 20 ml of 2-ethylhexanol (16.7 g, 128.5 mmoles) in 30 ml of toluene plus 3 drops of concentrated sulfuric acid and refluxed for 16 hr (Scheme II, R = 2-ethylhexyl). The reaction mixture was treated similarly to that in the synthesis of IV*a*. The crude product (1.5 g, 60%) was purified for analysis by silica gel dry column chromatography (1.4 × 15 cm) by elution with hexane followed by increasing concentrations of chloroform in hexane. Fractions containing III*a* were concentrated and placed over a neutral alumina[11] dry column (1.2 × 20 cm), which was eluted with benzene followed by 25% chloroform in benzene. Removal of the solvent yielded a clear, viscous liquid; PMR: δ 7.68 (dd, H_A), 6.98 (m, H_B and H_C), 4.15 (d, 4), and 0.77–1.58 (m, 30) ppm; mass spectra: *m/e* 406 (M+, 7.5%), 295 (9), 294 (10.5), 183 (31.5), 182 (28.5), 165 (100), 164 (29), 149 (24), 113 (30), 112 (56), and 71 (47.5).

Anal.—Calc. for $C_{24}H_{38}O_5$: C, 70.90; H, 9.42. Found: C, 71.02; H, 9.86.

1-(2-Ethylhexyl) 3-Hydroxyphthalate (III*b*)—This compound was synthesized from X*c* (0.71 g, 4.3 mmoles) and 2-ethylhexanol (1.1 g, 8.6 mmoles) by refluxing in 20 ml of pyridine for 8 hr (Scheme II, R = 2-ethylhexyl). The reaction mixture was acidified to pH 3 with 4 *N* sulfuric acid, extracted with ether, and then shaken with 50 ml of 5% Na_2CO_3. The basic solution was carefully acidified, resulting in the precipitation of III*b* (0.85 g, 72%), mp 191–192° when recrystallized from acetone–hexane. TLC indicated that only one isomer was formed (R_f 0.51). Attempts to synthesize the other isomer of III*b* by hydrolysis of III*a* (analogous to hydrolysis of IV*a* to IV*c*) were unsuccessful. Compound III*b* is probably the 1-(2-ethylhexyl) ester; PMR: δ 7.20 (dd, H_A), 6.88 (m, H_B and H_C), 4.08 (d, 2), and 0.77–1.58 (m, 15) ppm; mass spectra: *m/e* 294 (M+, 1.3%), 221 (32), 183 (2.5), 182 (3.5), 165 (20), 164 (100), 120 (95), 112 (36), 92 (90), 83 (86), and 70 (60).

RESULTS AND DISCUSSION

Chemistry—Scheme I shows the reactions involved in the synthesis of the various derivatives of 4-hydroxyphthalic acid (V*a*). The reaction



Scheme II

[10] ICN, Inc.

[11] Woelm, Waters Associates.

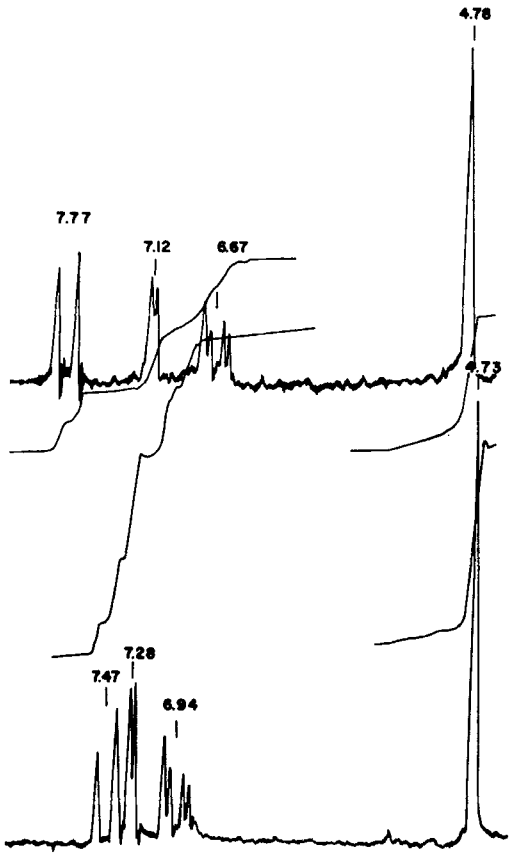


Figure 1—*PMR spectra of the hydroxymethylbenzoic acids VI (upper) and VIII (lower).*

of 4-hydroxyphthalic anhydride (V*b*) and 2-ethylhexanol yielded only one isomer, subsequently shown to be IV*b*. Alkaline hydrolysis of IV*a*, however, resulted mainly in the formation of the geometric isomer, IV*c*; small amounts of phthalic acid and IV*b* also were obtained. The results in both cases are explicable when one considers that the 2-ethylhexanol or the hydroxide ion in the two reactions, respectively, would be most likely to attack the more electropositive carbonyl group, which is the one *meta* to the phenolic hydroxyl in both cases.

Scheme II shows the reaction pathway for the synthesis of the derivatives of 3-hydroxyphthalic acid (X*b*). Although the position of the ester group in the 3-hydroxy monoester (III*b*) was not unequivocally established, the electron-donating effect of the hydroxyl group to the *ortho*-position suggests that the 1-(2-ethylhexyl) ester is the compound formed under the reaction conditions employed. There was no evidence by TLC of formation of the isomer of III*b*, even when III*a* was subjected to hydrolysis in base, a procedure successful in the conversion of IV*a* to IV*c*. Regardless of the preparation method of III*b*, the products isolated had identical PMR and mass spectra. Compound III*b* was the only hydroxylated metabolite subsequently found on incubation of liver homogenates[12].

Lithium borohydride was chosen as the reducing agent for IV*b* and IV*c*, since this reagent selectively reduces esters in the presence of carboxylic acids (10). A large excess of lithium borohydride was required for quantitative reduction because of the ionization of the carboxylic acid and consequent insolubility of the complex. The hydroxymethylbenzoic acids formed (VI and VIII) were then cyclized to their known lactones. This conversion was quite facile, particularly in the case of IX, since it was formed when the reaction mixture for the synthesis of VIII from IV*c* was made too acidic when destroying the excess borohydride.

Attempted reduction of III*b* with lithium borohydride to distinguish unequivocally the position of the 2-ethylhexyl group was unsuccessful.

PMR Spectra—The relevant PMR data for the various derivatives of 4-hydroxyphthalic acid are shown in Table I. The assignment of the signals of H_A, H_B, and H_C were made by their coupling constants and chemical shifts. Whereas the signal for H_A in V*a* (δ 7.65) and IV*a* (δ 7.66) had nearly identical chemical shifts, the same signal in two monoesters, IV*b* (δ 7.72) and IV*c* (δ 7.35), showed a significant difference. From these data, it became obvious that the unequivocal structural assignment of IV*b* and IV*c* could not be made on the basis that H_A was adjacent to the acid in one isomer and the ester in the other. Although it is difficult to predict the chemical shift of a given proton on multiple-substituted benzene rings (11), it was felt that selective reduction of the ester carbonyl of IV*c* to the corresponding hydroxymethyl compound (VIII) would result in a significant upfield shift of H_A and that a similar reduction of the ester group of IV*b* would result in little change in the chemical shift of H_A.

Similarly, the signal of H_C in VIII would be expected to remain relatively unchanged compared to that of H_C in IV*c*, and the signal of H_C in VI might be expected to move upfield compared to that of IV*b*; in the latter case, H_C would be *ortho* to the hydroxymethyl group instead of the deshielding carbonyl moiety. From an examination of Table I, it is apparent that, upon reduction of IV*b* and IV*c*, there was an unexpected small downfield shift in the signal of H_A in both cases whereas there was a more significant downfield shift of 0.29 and 0.28 ppm in the signal of H_C of the reduced products, VI and VIII, respectively.

The PMR spectra of VI and VIII are shown in Fig. 1. The assignments of H_A in VI (upper spectrum, δ 7.77) and VIII (δ 7.47) were made on the basis of their being furthest downfield and their coupling constants of 8 Hz. The signal of H_C was assigned at δ 7.12 and 7.28 in VI and VIII, respectively, by the small *meta*-coupling of 2 Hz; the signal of H_B was the furthest upfield in both cases, appearing as a doublet of doublets with coupling constants of about 8 and 2 Hz, respectively.

Although the PMR data for the reduction of IV*b* and IV*c* were not entirely expected, as expected the signals of H_A and H_C were at lower fields when adjacent to a carbonyl group than when adjacent to a hydroxymethyl group; *i.e.*, the signal of H_A was downfield in VI compared to VIII and, similarly, the signal of H_C was downfield in VIII compared to VI (Table I). Unequivocal proof of structure of the monoesters IV*b* and IV*c* was obtained by conversion of VI and VIII to their corresponding known lactones, VII and IX, respectively, which were characterized by their melting points and PMR and mass spectra. The most noteworthy feature of the PMR spectra of these compounds was that the signal for the methylene protons was downfield approximately 0.5 ppm from the analogous signals in VI and VIII. This downfield shift was consistent with that observed for the methylene protons of alcohols and their corresponding esters (12).

The PMR spectra of the 3-hydroxyphthalates, III*a* and III*b*, were unremarkable but consistent with the structures assigned.

Mass Spectrometry—The mass spectral data for II and IV*a*–IV*c* were consistent with the assigned structures. One of the most characteristic fragments for phthalate esters occurred at *m/e* 149 (13), and this fragment was the base peak for II. Since IV*a*–IV*c*, III*a*, and III*b* are hydroxyphthalates (with 16 additional amu), the main fragment for these compounds appeared at *m/e* 165. For diesters such as IV*a*, the most characteristic fragmentation was the loss of the alkyl fragment with transfer of one or two hydrogen atoms to produce the carboxylic acid ion or the protonated carboxylic acid ion, respectively (14). In the case of IV*a*, the protonated carboxylic acid ion (*m/e* 295) was formed, which then lost a second 2-ethylhexyl fragment in a typical McClafferty reaction (15) to form the protonated diacid (*m/e* 183). This transition, although uncomplicated, was also supported by the metastable ion[13] at *m/e* 113.5. Loss of water gave a peak at *m/e* 165 (again consistent with a metastable ion at *m/e* 148.8) and was followed by loss of CO_2 (*m/e* 121). Fragments between 41 and 113 amu mostly arose from fragmentation of the 2-ethylhexyl side chain.

The mass spectra of IV*b* and IV*c* were similar and explicable, except that an artifact appeared for both compounds at *m/e* 295, 1 amu higher than the expected molecular ion *m/e* 294. Such an artifact also appeared in the mass spectrum of II. This unexpected peak was shown to be the result of a bimolecular collision, with a fragment ion donating a proton to the molecular ion. The abundance of the M + 1 species was dependent upon the sample pressure in the ion source. The proper identification of the molecular ion and of M + 1 as an artifact was accomplished by scanning the total ion current peak and noting the disappearance of M + 1 as the sample pressure decreased.

The mass spectra of the 3-hydroxyphthalates were consistent with the structures assigned. In the case of the monoester III*b*, the formation of both the carboxylic acid ion (*m/e* 182) and the protonated carboxylic acid ion (*m/e* 183) was apparent, but the formation of the base peak at *m/e*

[12] Unpublished data.

[13] Metastable peaks (m*) are formed when an ion, m, decomposes during flight through the instrument and is analyzed with a mass m_2. The masses are related by the expression $m^* = (m_2^2/m_1)$ (16).

164 (182 − H_2O) indicated that the former fragmentation path predominated.

The mass spectral data for the reduced products VI and VIII and their corresponding lactones, although unremarkable, were compatible with the assigned structures. As might be expected for the hydroxymethylbenzoic acids, a major fragment at *m/e* 150 indicated the loss of water with cyclization to the corresponding lactones.

Bioavailability of Ampicillin and Amoxicillin in Fasted and Nonfasted Subjects

P. G. WELLING [*x], H. HUANG [*], P. A. KOCH [*], W. A. CRAIG [‡], and P. O. MADSEN [‡]

Abstract □ The influence of various test meals and fluid volume on the relative bioavailability of ampicillin and amoxicillin was studied in healthy human subjects. Serum amoxicillin levels were somewhat, but not always, significantly higher than those of ampicillin from equivalent oral doses. Food ingested immediately before dosing reduced serum levels and urinary excretion of both antibiotics to a similar extent. Reduction of dosed water volume caused a marked decrease in serum amoxicillin levels in fasted subjects.

Keyphrases □ Ampicillin—bioavailability, oral administration, effect of fasting and fluid volume, humans □ Amoxicillin—bioavailability, oral administration, effect of fasting and fluid volume, humans □ Bioavailability—ampicillin and amoxicillin, oral administration, effect of fasting and fluid volume, humans □ Antibacterial agents—ampicillin and amoxicillin, bioavailability, oral administration, effect of fasting and fluid volume, humans

Ampicillin and amoxicillin have similar antibacterial activity against various organisms (1). Amoxicillin has twice the activity of ampicillin against enterococci and *Salmonella* species but is somewhat less active than ampicillin against *Haemophilus* and *Shigella* species (2, 3).

Various reports indicated that, despite the similar antibacterial spectrum of the two compounds, amoxicillin has superior bioavailability properties from oral dosage forms and may, therefore, be the compound of choice when this route of administration is used (4–6). Amoxicillin absorption may be less influenced by food than ampicillin absorption, so less variation in circulating antibiotic levels might be expected during repeated oral doses of amoxicillin (7, 8).

In this study, the bioavailability of ampicillin and amoxicillin was compared in fasted and nonfasted subjects under carefully controlled conditions.

EXPERIMENTAL

The subjects were three male and three female healthy volunteers. Male subjects were 24–30 years old (mean 27) and weighed 64–81 kg (mean 74). Female subjects were 21–27 years old (mean 23) and weighed 50–68 kg (mean 60). All subjects were shown by medical examination to be in good physical condition with normal blood and urine laboratory values. The subjects had no histories of allergic reaction to penicillins.

Protocol—Verbal assurance was obtained from all subjects that they had taken no known enzyme-inducing agents for 1 month and no other drugs for 1 week preceding the study. Subjects were instructed to take no drugs other than the required doses of antibiotic during the study.

The subjects were fasted overnight before each treatment and were permitted to eat no food, apart from test meals, until 4 hr after dosing. On the morning of a treatment, each subject drank 250 ml of water on arising, at least 1 hr before dosing. Medication was administered at 8 am; blood samples (4–5 ml) were collected from a forearm vein into vacuum tubes[1] containing no anticoagulant immediately before dosing and at 20 and 40 min and 1, 1.5, 2, 3, 4, 6, and 8 hr after dosing. Serum was separated and deep frozen at −18° until assayed. Urine was collected through 8 hr

[1] Vacutainers.

164 (182 − H_2O) indicated that the former fragmentation path predominated.

The mass spectral data for the reduced products VI and VIII and their corresponding lactones, although unremarkable, were compatible with the assigned structures. As might be expected for the hydroxymethylbenzoic acids, a major fragment at *m/e* 150 indicated the loss of water with cyclization to the corresponding lactones.

Bioavailability of Ampicillin and Amoxicillin in Fasted and Nonfasted Subjects

P. G. WELLING [*x], H. HUANG [*], P. A. KOCH [*], W. A. CRAIG [‡], and P. O. MADSEN [‡]

Abstract □ The influence of various test meals and fluid volume on the relative bioavailability of ampicillin and amoxicillin was studied in healthy human subjects. Serum amoxicillin levels were somewhat, but not always, significantly higher than those of ampicillin from equivalent oral doses. Food ingested immediately before dosing reduced serum levels and urinary excretion of both antibiotics to a similar extent. Reduction of dosed water volume caused a marked decrease in serum amoxicillin levels in fasted subjects.

Keyphrases □ Ampicillin—bioavailability, oral administration, effect of fasting and fluid volume, humans □ Amoxicillin—bioavailability, oral administration, effect of fasting and fluid volume, humans □ Bioavailability—ampicillin and amoxicillin, oral administration, effect of fasting and fluid volume, humans □ Antibacterial agents—ampicillin and amoxicillin, bioavailability, oral administration, effect of fasting and fluid volume, humans

Ampicillin and amoxicillin have similar antibacterial activity against various organisms (1). Amoxicillin has twice the activity of ampicillin against enterococci and *Salmonella* species but is somewhat less active than ampicillin against *Haemophilus* and *Shigella* species (2, 3).

Various reports indicated that, despite the similar antibacterial spectrum of the two compounds, amoxicillin has superior bioavailability properties from oral dosage forms and may, therefore, be the compound of choice when this route of administration is used (4–6). Amoxicillin absorption may be less influenced by food than ampicillin absorption, so less variation in circulating antibiotic levels might be expected during repeated oral doses of amoxicillin (7, 8).

In this study, the bioavailability of ampicillin and amoxicillin was compared in fasted and nonfasted subjects under carefully controlled conditions.

EXPERIMENTAL

The subjects were three male and three female healthy volunteers. Male subjects were 24–30 years old (mean 27) and weighed 64–81 kg (mean 74). Female subjects were 21–27 years old (mean 23) and weighed 50–68 kg (mean 60). All subjects were shown by medical examination to be in good physical condition with normal blood and urine laboratory values. The subjects had no histories of allergic reaction to penicillins.

Protocol—Verbal assurance was obtained from all subjects that they had taken no known enzyme-inducing agents for 1 month and no other drugs for 1 week preceding the study. Subjects were instructed to take no drugs other than the required doses of antibiotic during the study.

The subjects were fasted overnight before each treatment and were permitted to eat no food, apart from test meals, until 4 hr after dosing. On the morning of a treatment, each subject drank 250 ml of water on arising, at least 1 hr before dosing. Medication was administered at 8 am; blood samples (4–5 ml) were collected from a forearm vein into vacuum tubes[1] containing no anticoagulant immediately before dosing and at 20 and 40 min and 1, 1.5, 2, 3, 4, 6, and 8 hr after dosing. Serum was separated and deep frozen at −18° until assayed. Urine was collected through 8 hr

after dosing, and aliquots were deep frozen until assayed. All assays were carried out within 72 hr of sampling.

Treatments—It is recognized that bioavailability comparisons between compounds are best studied in a crossover fashion. However, the primary aim of the overall study was to compare bioavailability among treatments for each compound. Therefore, the amoxicillin study was done immediately following the ampicillin study. All subjects participated in both studies.

Subjects received single 500-mg doses of ampicillin[2] or amoxicillin[3] as two 250-mg capsules. High carbohydrate, high fat, and high protein test meals were prepared and standardized as described previously (9). Each drug was administered as the following treatments:

Treatment 1—Two capsules with 250 ml of water immediately following a standard high carbohydrate meal.

Treatment 2—Two capsules with 250 ml of water immediately following a standard high fat meal.

Treatment 3—Two capsules with 250 ml of water immediately following a standard high protein meal.

Treatment 4—Two capsules with 25 ml of water on an empty stomach.

Treatment 5—Two capsules with 250 ml of water on an empty stomach.

All subjects received the same treatment at the same time. Treatments were administered 2 weeks apart, and all subjects received all treatments. Capsules were swallowed whole.

Assay—Serum and urine ampicillin and amoxicillin were assayed using a microbiological disk diffusion method with *Sarcina lutea* (ATCC 9341) as the test organism as described elsewhere (10).

Interpretation of Results—Individual serum antibiotic levels were fitted graphically to the standard one-compartment open model with first-order absorption and elimination. With this model, serum concentrations, C, at any time, t, after dosing are described by:

$$C = \frac{FD}{V}\frac{k}{k-K}(e^{-Kt} - e^{-kt}) \qquad \text{(Eq. 1)}$$

where F is the fraction of the dose, D, absorbed, V is the drug distribution volume in the body, and k and K are first-order rate constants for absorption and elimination, respectively. Improved estimates of parameters, together with coefficients of determination, r^2, were obtained by iterative least-squares methods using the program NREG on a digital computer[4] (11). Data fitting was improved in some cases by incorporating a lag time, t_0, representing the time period between dosing and the appearance of the antibiotic in the circulation.

Serum levels at each sampling time, urine data, and pharmacokinetic parameters were examined by analysis of variance. If significant differences due to treatments were obtained ($p < 0.05$), results from individual treatments were compared by a paired t-test.

RESULTS

Serum Levels—Mean serum antibiotic concentrations, together with statistical analysis, are given in Table I; the data are summarized

[2] Ampicillin trihydrate, Polycillin, Bristol Laboratories.
[3] Amoxicillin trihydrate, Polymox, Bristol Laboratories.

Concentration, μg/ml	540 ± 278	478 ± 143	341 ± 247	827 ± 289	1491 ± 382	5 > 1–4
Recovery, %	41.3 ± 20.1	55.7 ± 21.4	36.6 ± 25.0	49.1 ± 9.2	85.3 ± 29.7	5 > 1–4

[a] Complete recoveries were obtained from two subjects only. [b] Amoxicillin recoveries significantly higher than ampicillin recoveries.

graphically in Figs. 1 and 2. Urine antibiotic concentrations and recoveries are summarized in Table II, and averaged results from the pharmacokinetic analyses are given in Tables III and IV.

It is clear from Table I and Figs. 1 and 2 that circulating levels of both ampicillin and amoxicillin were significantly reduced by the test meals under conditions used in this study. Treatments 4 and 5 yielded high serum levels of ampicillin compared to the food treatments for the first 3 hr after dosing. After this time, similar serum levels were obtained from all treatments. Serum amoxicillin levels were reduced similarly by the food treatments. These levels also were reduced following the 2-hr postdosing period when amoxicillin was given with 25 ml of water (Treatment 4).

Despite the higher serum levels generally observed with amoxicillin, differences between ampicillin and amoxicillin levels for the same treatment were significant in only a few cases. No significant differences were obtained during the first 2 hr after dosing, due, in part at least, to the scatter between individual serum levels. No significant differences were observed in serum levels among food treatments for either compound.

Urine Recovery—Failure by some subjects to provide complete 8-hr urine samples prevented the statistical comparison of urine concentration and recovery data in some instances (Table II). However, both fasting treatments resulted in higher urine concentrations and recoveries of ampicillin than the food treatments. Whereas Treatment 5 also resulted in increased amoxicillin concentrations and recoveries than the food treatments, values from Treatment 4 did not differ significantly from food treatment values.

Pharmacokinetic Analysis—Analysis of individual serum ampicillin and amoxicillin levels in terms of the simple one-compartment model was complicated by the similar numerical values obtained in many cases for the absorption and elimination rate constants. Almost identical values for these rate constants were reported before for ampicillin and amoxicillin (12). In this type of situation, it is difficult to determine which of the two rate constants, obtained by graphical analysis, represents absorption and elimination. This type of "flip-flop" model was discussed previously (13). Where this problem arose in the present study, the rate constant equivalent to an elimination half-life closest to 1 hr was designated as the elimination rate constant. This arbitrary designation was based on considerable evidence from the literature that both ampicillin and amoxicillin half-lives are close to 1 hr in normal subjects (4–6, 12).

The degree of fit of individual serum levels to the one-compartment model is reflected in the coefficient of determination values in Tables III and IV. Although less than perfect fits were obtained in some cases, this result appeared to be a function of data noise rather than the model. Analysis of the data in terms of the two-compartment model resulted in a greater variance in pharmacokinetic parameter values and no improvement in the coefficients of determination.

From Tables III and IV, it is apparent that the various treatments had little influence on absorption and elimination rates. Ampicillin appeared to be eliminated somewhat faster after Treatment 5 than after all other treatments, although this finding may have been due to the continued absorption of small amounts of antibiotic during the postabsorptive phase in the food treatments resulting in a prolonged apparent elimination half-life.

The influence of food on the overall absorption efficiency of both compounds was reflected in reduced peak heights and FD/V values, reduced areas under serum level–time curves to 2 and 8 hr after dosing, and reduced calculated areas from time zero to infinity. Both fasting treatments yielded significantly greater values for these parameters than the food treatments for ampicillin. In the case of amoxicillin, however, Treatment 5 tended to give higher values than all other treatments. The serum levels, urinary excretion, and pharmacokinetic parameter values from Treatment 5 were similar to reported values in fasted subjects (1–6).

DISCUSSION

Although the superior bioavailability of amoxicillin over ampicillin in fasted subjects is well documented (4–6), there is less comparative information to support the popular notion that amoxicillin absorption is not significantly influenced by food. Neu and Winshell (14) obtained similar serum amoxicillin levels in four fasted and nonfasted subjects. However, the nature of the meal and the actual time relationship between eating and dosing were not described. No comparison was made with ampicillin.

In a subsequent study (2), the times of average peak ampicillin levels were delayed by 2 hr and amoxicillin levels by 1 hr in nonfasting subjects. Peak serum amoxicillin levels were unchanged by food, while peak serum ampicillin levels were reduced by approximately 20%. A third study reported similar serum amoxicillin levels when the drug was administered as repeated doses either before or 0.5 hr after lunch (7). The actual time

elapsed between the prelunch dose and eating was not indicated, and no comparison was made with ampicillin.

When 500 mg of ampicillin and amoxicillin were given immediately following a standard breakfast, peak serum levels of 2.1 and 5.9 μg/ml were obtained, respectively (8). These values were similar to those obtained from the food treatments in the present study.

During this study, in which nonfasted subjects received the drugs immediately following a standard meal, all food treatments reduced peak serum antibiotic levels by about 50%. However, serum amoxicillin levels in nonfasted subjects were almost identical to ampicillin levels in fasted subjects. Thus, although serum levels of both antibiotics appeared to be reduced to the same extent by food, the reduction was probably of less clinical significance for amoxicillin.

Reducing the dosed water volume from 250 to 25 ml in fasted subjects caused a significant reduction in serum amoxicillin levels, but ampicillin levels were affected to only a small extent. This difference may be explained by comparing the water solubilities of the antibiotics. One gram of ampicillin trihydrate dissolves in about 90 ml of water whereas 1 g of amoxicillin trihydrate dissolves in about 370 ml (15). Thus, any reduction in dosed water volume is likely to reduce the dissolution and subsequent absorption of amoxicillin to a greater extent than ampicillin.

The results of this study indicate that oral absorption of both ampicillin and amoxicillin is reduced to a similar extent when administered immediately following a meal, although the reduction in ampicillin levels may be of greater clinical significance. The bioavailability of amoxicillin is reduced when given with small water volumes in fasted subjects.

Dissolution Profile for Multisized Drug Particles: New Approximate Expression

JOHN W. MAUGER *, DANA BROOKE ‡x, and EARL Z. DAMEWOOD §

Abstract □ New approximate expressions for the weight fraction undissolved were obtained using the Taylor series expansion. These approximations were tested using simulated data for multisized drug particle populations. The resulting calculations show that: (*a*) the approximations are not dependent on a knowledge of the analytical form of the particle-size density function, (*b*) the distribution effects are accounted for, but only a knowledge of the sample mean and standard deviation is required, and (*c*) the approximations (especially on a weight basis) lead to values within the limits of error in dissolution studies, thus posing the question of whether published exact expressions have practical value.

Keyphrases □ Dissolution—multisized drug particles, approximate expressions for weight fraction undissolved □ Particles, multisized—dissolution profile, approximate expressions for weight fraction undissolved □ Weight fraction undissolved—multisized drug particles, approximate expressions

The effects of multisized particle distributions on dissolution kinetics were studied using either experimental or simulated data (1–7). One area of particular concern has been the acceptability of treating the kinetics of dissolution for a multisized particle population with an approximate mathematical treatment for the kinetic model of interest.

The importance of including the distribution effects was recognized in the mathematical treatment of a diffusional model proposed for the dissolution of micronized methylprednisolone (1, 2). The complexity of these equations led to simplified forms *via* an approximation for the particle-size density function.

Approximate expressions were discussed in connection with the cube root kinetic model (3–5). For example, an approximation to the cube root model was described for a log-normal particle-size population that relaxes to the exact cube root law when the standard deviation of the particle population approaches zero. However, such an approximation, requiring a knowledge of the mean and variance of the log normal population, has limited practical value (5). Certainly, the approximation could not be used intelligently unless the powder of interest was *confirmed* to obey the log-normal distribution and the parameters of the distribution could be estimated.

An interest in an approximation illustrating the effects of different particle sizes derives, in part, from difficulties in obtaining monosized powder cuts for dissolution studies. The mathematical treatment of dissolution data from actual drug powders, which may contain a range of sizes, has often been based on the assumption of monosized particles. Recent papers (8, 9) proposed treatments of dissolution data on powders without a calculation of the effect of a distribution of particle sizes. Because of such difficulties, the relationship between dissolution theory and its experimental justification remains fragile. The approximations reported here enable one to estimate the effect of varying particle sizes on dissolution data and may strengthen the relationship between theory and data.

Interest in an approximation can also be appreciated if one considers the complex and cumbersome calculations involved. The use of a distribution function in connection with the dissolution model of interest, *i.e.*, cube root, Dankwert's, *etc.*, requires integration over the random variable of particle size as well as a consideration of time. Therefore, any reasonable approximation is inviting.

To date, no convenient treatment can be justified for any particular kinetic model with a particular distribution function. This report describes a simplified procedure that can be justified by a standard mathematical (and statistical) derivation. The procedure utilizes estimators of the dispersion of sizes in a powder, which are readily accessible from particle-size data (*e.g.*, automated counter and microscopic data). The limitations and uses of the procedure are tested using simulated data.

THEORETICAL

Let there be a population of spherical particles of initial diameters A_0 that are randomly distributed on a numbers basis according to the continuous density function $f_n(A_0)$ or on a weight basis according to the density function $f_w(A_0)$. The dissolution profile of such a population of particles exposed to a dissolution medium is often analytically expressed in terms of the weight fraction undissolved. Let there be a function $g(A_0, t)$ of the random variable A_0 and the dissolution time t that reflects a suitable dissolution model. For example, let A_τ be the diameter of a particle exposed to a dissolution medium for some function τ of time so that:

$$g(A_0, t) = A_\tau{}^3 \qquad \text{(Eq. 1)}$$

If the dissolution is diffusion rate limited and takes place under sink conditions, then $g(A_0, t)$ describes the well-known cube root law kinetic model:

$$g(A_0, t) = A_\tau{}^3 = (A_0 - \tau)^3 \qquad \text{(Eq. 2)}$$

For a numbers distribution, the weight fraction undissolved, W_{fn}, will be seen to be a ratio of expected values as follows:

$$W_{fn} = \frac{\int_{\text{all } A_0 \text{ undissolved}} g(A_0, t) f_n(A_0) d(A_0)}{\int_{\text{all } A_0} g(A_0, 0) f_n(A_0) d(A_0)} = \frac{E(A_\tau{}^3)}{E(A_0{}^3)} \qquad \text{(Eq. 3)}$$

If the initial population of particles is described on a weight basis, the weight fraction undissolved, W_{fw}, is the expected value of a ratio as follows:

$$W_{fw} = \int_{\text{all } A_0 \text{ undissolved}} \frac{g(A_0, t)}{g(A_0, 0)} f_w(A_0) dA_0 = \int_{\text{all } A_0 \text{ undissolved}} h(A_0, t) f_w(A_0) dA_0 = E\left(\frac{A_\tau{}^3}{A_0{}^3}\right) \qquad \text{(Eq. 4)}$$

where $h(A_0, t)$ is $g(A_0, t)$ divided by $g(A_0, 0)$.

If the mean $E(A_0) = \mu$ and variance $V(A_0) = \sigma^2$ of the population of particles are known, the important expected value terms in Eqs. 3 and 4 can be approximated, provided that $f(A_0)$ takes significant values in an interval near $A_0 = \mu$ of the order of σ and that $g(A_0, t)$ is "smooth" in this interval. The approximation given in Eqs. 5 and 6 in the terminology of this derivation is found in standard texts on probability and statistics (10, 11) and can be proved using a Taylor series expansion[1]. The ap-

[1] See *Appendix* for additional information on this technique.

Table I—Dissolution Profiles for Simulated Log-Normal Powders with Narrow Distribution Using the Cube Root Law

Summary of Population Parameters	
Numbers Basis	Weight Basis
$E(\ln A_0) = 3.68888$	$E(\ln A_0) = 3.71888$
$V(\ln A_0) = 0.01$	$V(\ln A_0) = 0.01$
$E(A_0) = 40.20$	$E(A_0) = 41.43$
$V(A_0) = 16.24$	$V(A_0) = 17.25$

τ	W_f(exact)	W_{fn}(approx)	W_{fw}(approx)	$\left(\frac{\bar{A}_0 - \tau}{\bar{A}_0}\right)^3_w$
10	0.4337	0.4336	0.4337	0.4366
20	0.1381	0.1379	0.1381	0.1384
29.63	0.0255	0.02534	0.02575	0.0231
30	0.0234	0.02328	0.02370	0.0210
35	0.0063	0.00589	0.00646	0.0037

proximations of interest are:

$$E(A_\tau{}^3) = g(\mu, t) + \frac{\sigma^2}{2} g''(\mu, t) \quad \text{(Eq. 5)}$$

and:

$$E\left(\frac{A_\tau{}^3}{A_0{}^3}\right) = h(\mu, t) + \frac{\sigma^2}{2} h''(\mu, t) \quad \text{(Eq. 6)}$$

Thus, approximations for the weight fraction undissolved on a numbers basis or a weight basis are:

$$W_{fn}(\text{approx}) = \frac{g(\mu, t) + \frac{\sigma^2}{2} g''(\mu, t)}{g(\mu, 0) + \frac{\sigma^2}{2} g''(\mu, 0)} \quad \text{(Eq. 7)}$$

and:

$$W_{fw}(\text{approx}) = h(\mu, t) + \frac{\sigma^2}{2} h''(\mu, t) \quad \text{(Eq. 8)}$$

Generally, the sample mean, μ, of a population will be understood to be the numbers or weight average, $\bar{A}_0$, and the variances, σ^2, will be the square of the sample standard deviations[2]. Thus, for the cube root dissolution model, the weight fraction undissolved of a multisized particle distribution will be:

$$W_{fn}(\text{approx}) = \frac{(\bar{A}_0 - \tau)^3 + 3\sigma^2(\bar{A}_0 - \tau)}{\bar{A}_0{}^3 + 3\sigma^2\bar{A}_0} \quad \text{(Eq. 9)}$$

or:

$$W_{fw}(\text{approx}) = \left(\frac{\bar{A}_0 - \tau}{\bar{A}_0}\right)^3 - \frac{\sigma^2}{2}\left(\frac{6\tau}{\bar{A}_0{}^3} - \frac{18\tau^2}{\bar{A}_0{}^4} + \frac{12\tau^3}{\bar{A}_0{}^5}\right) \quad \text{(Eq. 10)}$$

For another popular dissolution model, the Higuchi–Hiestand model (1):

$$g(A_0, t) = A_\tau{}^3 = (A_0{}^2 - \tau)^{3/2} \quad \text{(Eq. 11)}$$

and the weight fractions become:

$$W_{fn}(\text{approx}) = \frac{(\bar{A}_0{}^2 - \tau)^{3/2} + \frac{3\sigma^2}{2}\left[\frac{\bar{A}_0{}^2}{(\bar{A}_0{}^2 - \tau)^{1/2}} + (\bar{A}_0{}^2 - \tau)^{1/2}\right]}{\bar{A}_0{}^3 + 3\sigma^2\bar{A}_0} \quad \text{(Eq. 12)}$$

or:

$$W_{fw}(\text{approx}) = \left(\frac{\bar{A}_0{}^2 - \tau}{\bar{A}_0{}^2}\right)^{3/2} + \frac{\sigma^2}{2}\left[\frac{3\tau}{\bar{A}_0{}^5}\right]\left[\frac{\tau}{(\bar{A}_0{}^2 - \tau)^{1/2}} - 3(\bar{A}_0{}^2 - \tau)^{1/2}\right] \quad \text{(Eq. 13)}$$

RESULTS AND DISCUSSION

An examination of the adequacy of the approximations derived for the cube root model (Eqs. 9 and 10) or for the Higuchi–Hiestand model (Eqs. 12 and 13) is limited to cases where drug particle sizes follow the log-normal distribution as given by:

$$f(\ln A_0) = \frac{1}{s\sqrt{2\pi}} e^{-(\ln A_0 - m)^2/2s^2} \quad \text{(Eq. 14)}$$

where m and s^2 refer to the (numbers basis) population mean $E(\ln A_0)$ and variance $V(\ln A_0)$, respectively. The approximations, however, require a knowledge of the arithmetic mean $E(A_0)$ and the corresponding variance $V(A_0)$. These may be calculated from:

$$E(A_0) = e^{m + s^2/2} \quad \text{(Eq. 15)}$$

and:

$$V(A_0) = E(A_0{}^2) - [E(A_0)]^2 = (e^{s^2} - 1)e^{2m + s^2} \quad \text{(Eq. 16)}$$

These transformations arise from the appropriate use of Eq. 9 of Ref. 4. Since approximations are given for populations where particle-size parameters are evaluated on a numbers basis or a weight basis, it is also necessary to use the Hatch and Choate relationships for log-normal distributions (12), which state:

$$m_{\text{weight}} = m_{\text{numbers}} + 3s^2_{\text{numbers}} \quad \text{(Eq. 17)}$$

$$s^2_{\text{weight}} = s^2_{\text{numbers}} \quad \text{(Eq. 18)}$$

Cube Root Model—The exact and approximate weight fraction undissolved quantities for the cube root kinetic model are presented in Tables I–III. The exact weight fraction undissolved is taken from published data (4). The data in Table I are for a log-normal population with a relatively narrow distribution, as evidenced by the near quality between $E[A_0]_{\text{numbers}}$ and $E[A_0]_{\text{weight}}$. The approximate W_f values are reasonably close to W_f(exact) throughout the dissolution profile, although W_{fw}(approx) from Eq. 10 appears to give slightly better results.

The populations shown in Tables II and III stress the approximations by increasing the magnitude of the standard deviation. The approximation values given in Table II are adequate throughout most of the dissolution time frame. Only at $\tau = 40$ do the approximate values for W_{fw}(approx) begin to diverge from the exact values. The W_{fn}(approx) values begin to diverge from the exact values at $\tau = 25$, but this approx-

imation is satisfactory over at least 80% of the total dissolution profile.

A log-normal population, where $E[\ln A_0]_{\text{numbers}} = 3.68888$ and $V[\ln A_0]_{\text{numbers}} = 0.25$, represents a rigorous test for the approximate expressions for the weight fraction undissolved. This population stresses the approximations by virtue of the large standard deviation and the skewed shape of the density function. The approximate and exact W_f values for this population are presented in Table III. Both the W_{fn} and W_{fw} values are consistently lower than the exact values. Again, the weight fractions undissolved calculated using Eq. 10 are more satisfactory than those calculated using Eq. 9.

Also presented in Tables I–III are $(\bar{A}_0 - \tau)^3/\bar{A}_0^3$ values, which reflect the dissolution profile for a monosized powder that obeys the cube root law. This term obtains from either approximation in Eq. 9 or 10 when σ^2 becomes zero. For a monosized population, the average diameter on a numbers basis is equal to the average diameter on a weight basis so that $(\bar{A}_0 - \tau)^3/\bar{A}_0^3$ calculated on either basis leads to the same estimate of weight fraction undissolved. However, for powders where particles have a wide range of sizes, the calculation on a *weight basis* generally provides a better estimate of the undissolved weight fraction. The calculation provided in Tables I–III employs the average diameters on a weight basis as signified by a subscript w.

The first term of Eq. 10 is actually $[(\bar{A}_0 - \tau)^3/\bar{A}_0^3]_w$. The remaining term in Eq. 10 indicates the effect of the particle-size distribution on the dissolution profile. Thus, this approximation provides a means of quantitating the errors that may occur when data on a polydisperse powder are treated as having come from a monosized powder. Although the simple $[(\bar{A}_0 - \tau)^3/\bar{A}_0^3]_w$ is useful for narrow distributions, the data of Tables I–III indicate that the weight basis approximation, which includes consideration of size distribution, provides better estimates of the weight fraction undissolved.

500.00	0.2007	—	0.1385	0.1935

Equation 10 can be written in expanded form and expressed as:

$$W_{fw}(\text{approx}) = 1 - 3\left(\frac{\tau}{\bar{A}_0}\right)\left(1 + \frac{\sigma^2}{\bar{A}_0^2}\right) + 3\left(\frac{\tau}{\bar{A}_0}\right)^2\left(1 + 3\frac{\sigma^2}{\bar{A}_0^2}\right) - \left(\frac{\tau}{\bar{A}_0}\right)^3\left(1 + 6\frac{\sigma^2}{\bar{A}_0^2}\right) \quad \text{(Eq. 19)}$$

If $\bar{A}_0$ and σ^2 are known, Eq. 19 can be solved by using a one-parameter model. Furthermore, as $\sigma^2 \to 0$, Eq. 19 assumes a perfect cube form:

$$W_f = 1 - 3\frac{\tau}{\bar{A}_0} + 3\left(\frac{\tau}{\bar{A}_0}\right)^2 - \left(\frac{\tau}{\bar{A}_0}\right)^3 \quad \text{(Eq. 20)}$$

Recently, dissolution data for 20–40-mesh salicylic acid particles were reported (9). These data were treated using the cubic form of the expression to fit the experimental weight fraction undissolved values. For a sieve cut of this width, a considerable bias can be introduced if the terms accounting for the distribution effects are neglected. In fact, the curve fitting of data to a cubic form without regard for particle-size effects would lead to a parameter that would be in error by a factor having a value between $[1 + (\sigma^2/\bar{A}_0^2)]$ and $[1 + 6(\sigma^2/\bar{A}_0^2)]^{1/3}$. For a powder uniformly distributed over a size range of 20–40 mesh, the factor would be between 1.037 and 1.069[3]. This point is significant in cases where critical model testing is the objective.

Higuchi–Hiestand Model—The approximate expressions for the Higuchi–Hiestand kinetic model (Eqs. 12 and 13) were tested (Tables IV–VI). The exact weight fraction undissolved was calculated from Eq. 4 using standard numerical integration techniques.

The weight fraction undissolved values shown in Table IV are for a log-normal population where $E[\ln A_0]_{\text{numbers}} = 2.99573$ and $V[\ln A_0]_{\text{numbers}} = 0.01$. The approximate expressions yield values that are less than 3% in error when compared with those calculated using numerical integration over almost the total dissolution profile. At $\tau = 369.23$, the approximate expressions give values that are more than 5% in error when compared with the "exact" values. However, at this point, more than 90% of the initial population weight has dissolved.

The data in Table V are for a log-normal population where $E[\ln A_0]_{\text{numbers}} = 2.99573$ and $V[\ln A_0]_{\text{numbers}} = 0.04$. This population was designed to provide a more exacting test of the approximations by virtue of a large population variance. In this case, the coefficient of variation, *i.e.*, $(V[A_0])^{1/2}/E[A_0]$, is about 20%; the coefficient of variation for the data in Table IV is about 10%. The W_{fw}(approx) values for this example follow the exact values closely over about 75% of the total dissolution profile. At $\tau = 369.23$ and 461.54, the approximations begin to drift away from the exact values; at $\tau = 470$, the approximation fails. The failure at the latter end of the dissolution profile is closely related to the magnitude of the variance and the form of the approximate expression. It can be seen from Eq. 13 that as $(\bar{A}_0^2 - \tau) \to 0$, $\tau/(\bar{A}_0^2 - \tau)^{1/2}$ approaches infinity and becomes the dominating term.

Analysis of the W_{fn}(approx) values shown in Table II shows that the approximation is useful over about 75% of the total dissolution profile.

[3] The terms $E(A_0)$ and $V(A_0)$ for a uniform distribution are calculable from Eq. 3 of Ref. 13 where $R = 1$.

Again, however, the magnitude of the variance and the form of the approximation contribute to the failure. According to Eq. 12, the term $\overline{A}_0^2/(\overline{A}_0^2 - \tau)^{1/2}$ approaches infinity as $\overline{A}_0^2 - \tau$ approaches zero. This is even more critical for a population based on numbers because $E[A_0]_{\text{numbers}} < E[A_0]_{\text{weight}}$ for the log-normal populations under study.

The data in Table VI are for a log-normal drug population where $E[\ln A_0]_{\text{numbers}} = 2.99573$ and $V[\ln A_0]_{\text{numbers}} = 0.09$. The coefficient of variation for this population is about 30%. Therefore, this population represents a severe test of the approximation. The data in Table VI show that the approximations are useful over about 60% of the total dissolution even for this population. Again, the failure of the approximations is related to the magnitude of the standard deviation and the form of the approximate expression.

The first term in Eq. 13, $[(\overline{A}_0^2 - \tau)/\overline{A}_0^2]^{1.5}$, was also tested as an approximation for the weight fraction undissolved. The data presented in Tables IV–VI show that this approximation is only useful for narrow distributions. Therefore, experimental dissolution data for many multisized drug populations will be incorrectly interpreted if the term for the distribution effects is not included.

When testing the approximate expressions for different kinetic models, some consideration must be given to the mathematical form of the kinetic equation. For the cube root model, each particle, independent of size, dissolves at the same rate with regard to diameter. On the other hand, small particles dissolving according to the Higuchi–Hiestand model dissolve much more rapidly than larger particles. The approximate expressions for the cube root model are only concerned with a population of particles all dissolving at a uniform rate. Approximate expressions for the Higuchi–Hiestand kinetic model, however, must deal with a population where the temporal characteristics of the sample mean and variance at time τ are more complex. With this in mind, it is interesting to compare the data in Table II with the data in Table VI. The approximate weight fraction undissolved values in Table II are for the cube root model, and those in Table VI are for the Higuchi–Hiestand model. The coefficient of variation in both cases is about 30%. Comparison of the data in Tables II and VI shows that the approximations for the cube root model are better than those for the Higuchi–Hiestand model.

SUMMARY

Approximate expressions for the weight fraction undissolved were tested using multisized (log-normal) distributions in connection with the cube root and Higuchi–Hiestand kinetic models. These simulated data show several important features:

1. The approximations are based on a recognized mathematical treatment and *not* on empirical relationships.
2. The distribution effects are accounted for, but only a knowledge of the arithmetic mean and standard deviation of the sample is required.
3. The approximations are not dependent upon a knowledge of the exact analytical form of the particle-size density function, *i.e.*, whether gamma, normal, log normal, *etc.*
4. The approximations lend themselves to usefulness with real laboratory data such as might be acquired by an automated counter (number or weight data), microscopic examination (numbers data), or sieve fractions (weight data).
5. The approximations are general and are potentially useful with any kinetic model that is at least twice differentiable at $A_0 = \mu$.
6. The approximations may find usefulness in a modeling technique to determine dissolution rate constants from dissolution data.

APPENDIX

The approximation of an expected value of a function of a random variable, as set forth in various texts on statistics (10, 11), first requires approximating that function through a Taylor series expansion and then taking the expected value of the approximation to the function. In this case, the function of the random variable A_0 (the initial particle diameter) is the dissolution model, *e.g.*, $g(A_0, t)$. It must be appreciated that the expected value of this function:

$$E[g(A_0, t)] = \int_{\text{all } A_0 \text{ remaining}} g(A_0, t) f(A_0) dA_0 \qquad \text{(Eq. A1)}$$

must be evaluated considering t as a constant whose value can be supplied after the integration. This consideration is important in derivations of dissolution equations by Brooke (4, 5, 13) and Pedersen and Brown (7). Therefore, it is imperative that all operations prior to the actual calculation of W_f consider t a constant.

The Taylor series approximation to a function of the random variable A_0, *e.g.*, $g(A_0, t)$, is most accurate in a region where values of A_0 are within 1 *SD*, σ, of the initial population mean, μ. Both μ and σ are parameters of the initial (time zero) particle-size distribution. The expansion about μ is written:

$$g(A_0, t) \simeq g(\mu, t) + (A_0 - \mu)g'(\mu, t) + \tfrac{1}{2}(A_0 - \mu)^2 g''(\mu, t) + \ldots \qquad \text{(Eq. A2)}$$

For t as a constant, $g(\mu, t)$, $g'(\mu, t)$, *etc.*, are constants and the expected value $E[g(A_0, t)]$ is approximated by:

$$g(\mu, t) + g'(\mu, t)E(A_0 - \mu) + \tfrac{1}{2} g''(\mu, t)E(A_0 - \mu)^2 + \ldots \qquad \text{(Eq. A3)}$$

By neglecting higher order terms in the expansion and by recognizing that $E(A_0 - \mu)$ is zero and $E(A_0 - \mu)^2$ is σ^2, the approximation for $E[g(A_0, t)]$ is written:

$$E[g(A_0, t)] \simeq g(\mu, t) + \tfrac{1}{2} g''(\mu, t)\sigma^2 \qquad \text{(Eq. A4)}$$

The use of Eq. A4 is illustrated by deriving the approximate weight fraction undissolved when the particle distribution is expressed on a numbers basis and the particles dissolve according to the Higuchi–Hiestand model. Here:

$$g(A_0, t) = (A_0^2 - \tau)^{3/2} = A_\tau^3 \qquad \text{(Eq. A5)}$$

which is twice differentiated in respect to the initial particle size, A_0, while t is considered a constant. That is:

$$g'(A_0, t) = 3(A_0^2 - \tau)^{1/2} A_0 \qquad \text{(Eq. A6)}$$

and:

$$g''(A_0, t) = 3(A_0^2 - \tau)^{1/2} + 3A_0^2/(A_0^2 - \tau)^{1/2} \qquad \text{(Eq. A7)}$$

In using Eq. A4, it is necessary to evaluate $g(A_0, t)$ and $g''(A_0, t)$ at the population mean μ. For this purpose, the arithmetic mean of the initial diameters, $\overline{A}_0$, is considered an appropriate estimator. Furthermore, it is experimentally available. Therefore:

$$E[g(A_0, t)] = E(A_\tau^3) \simeq (\overline{A}_0^2 - \tau)^{3/2} + \frac{3\sigma^2}{2}\left[\frac{\overline{A}_0^2}{(\overline{A}_0^2 - \tau)^{1/2}} + (\overline{A}_0^2 - \tau)^{1/2}\right] \qquad \text{(Eq. A8)}$$

and:

$$E[g(A_0, t)_{t=0}] = E(A_0^3) \simeq \overline{A}_0^3 + 3\sigma^2\overline{A}_0 \qquad \text{(Eq. A9)}$$

and W_{fn}(approx) for the Higuchi–Hiestand model becomes Eq. 12 of the text by dividing Eq. A8 by Eq. A9.

The use of the approximate equations for weight undissolved is illustrated by considering W_{fn}(approx) for the Higuchi–Hiestand model. Here, data are taken from Table V where the average particle size, $\overline{A}_0$, for the numbers distribution is 20.40 μm and the squared standard deviation, $V(A_0)$, is 16.99 μm^2. By using Eq. 12 of the text, W_{fn}(approx) for $\tau = 153.85$ μm is:

$$W_{fn}(\text{approx}) = \frac{[(20.40)^2 - 153.85]^{3/2} + \tfrac{3}{2}(16.99)\left[\dfrac{(20.40)^2}{[(20.40)^2 - 153.85]^{1/2}} - [(20.40)^2 - 153.85]^{1/2}\right]}{(20.40)^3 + 3(16.99)(20.40)} = 0.5587 \qquad \text{(Eq. A10)}$$

Dissolution Profiles for Multisized Prednisolone Acetate Suspensions

STEPHEN A. HOWARD ˣ, JOHN W. MAUGER, and LAWAN PHUSANTI

Abstract □ Particle-size measurements and *in vitro* dissolution characteristics of commercial and formulated suspensions of prednisolone acetate were determined using a resistance particle counter and a spinning filter apparatus, respectively. Significant differences in dissolution rates were noted for the commercial suspensions. Particle size affected dissolution but did not account for all observed variations in the dissolution rate. Formulation differences, specifically the presence of hydroxypropyl methylcellulose, in suspensions seemed to be important in dissolution.

Keyphrases □ Prednisolone acetate—multisized suspensions, dissolution profiles and particle-size measurements □ Suspensions, multisized—prednisolone acetate, dissolution profiles and particle-size measurements □ Dissolution—multisized suspensions of prednisolone acetate, effect of particle size □ Particle size—effect on dissolution of prednisolone acetate suspensions □ Glucocorticoids—prednisolone acetate, multisized suspensions, dissolution profiles and particle-size measurements

The dissolution rate and *in vivo* physiological availability of drugs are important research areas (1–5). The dissolution rate of a solid dosage form such as a tablet or a capsule can be the rate-limiting step in availability for the *in vivo* absorption of the active ingredient (6–8), particularly for poorly soluble or poorly wetted drugs (9).

At present, almost all dissolution rate research efforts are directed toward tablets and capsules. Although suspensions share many physical–chemical characteristics of tablets and capsules with respect to the dissolution process, they are almost completely ignored. Since tablets and capsules disintegrate into powder suspensions, pharmaceutical suspensions share the dissolution process as a rate-limiting step for absorption and bioavailability.

Bates *et al.* (10) studied the dissolution rates of nitrofurantoin tablets and suspensions and commented that it was inconsistent to provide a USP dissolution test for nitrofurantoin tablets without including a dissolution rate test for the suspension. They concluded that: "the rationale underlying the official dissolution rate specification for nitrofurantoin tablets appears quite arbitrary and inconsistent with the dissolution profile and potential toxicity of the official suspension dosage form."

These comments substantiate a need to pursue dissolution rate testing of suspension dosage forms. In the current study, the dissolution and particle-size profiles of several commercially available suspensions were determined to obtain information about brand-to-brand variation and formulation characteristics directly related to dissolution.

Commercially available steroid ophthalmic/otic suspensions were studied. They represent a dosage form that requires dissolution as a prerequisite to therapeutic availability. These products contain a poorly soluble micronized steroid in a suitable vehicle. The solubility and particle-size characteristics of these products make them desirable prototype suspensions to study.

EXPERIMENTAL

Dissolution Testing—All reported dissolution data were obtained using a device[1] described by Shah *et al.* (11). The basic features of the apparatus are a large volume fluid container, a rotating filter assembly, and an external variable-speed magnetic stirrer. The sample basket was removed.

The rotating filter assembly provides variable intensity of mild laminar liquid agitation and also functions as an *in situ* nonclogging filter to permit efficient intermittent or continuous filtration of dissolution fluid samples during the dissolution process. The assembly is suspended and freely rotates in the center of the flask on the flared end of a glass capillary pilot tube. The assembly rotates by means of a controlled, variable-speed, external magnetic stirrer coupled with a magnetic bar embedded in the bottom part of the assembly. A 0.5-μm porosity sintered stainless steel filter also was employed.

One liter of distilled water was transferred into the flask, and the fluid was allowed to equilibrate at 25°. The stirring speed of the filter assembly was 960 rpm. A strobe lamp[2] was used to standardize the stirring speed.

Filtered fluid samples were continuously withdrawn through the capillary pilot tube at the rate of 100 ml/min and were circulated through the spectrophotometer and back to the flask. Air bubbles were periodically released from an air trap. The system was allowed to run for at least 15 min to ensure the consistency of the flow and stirring rate. The spectrophotometer[3] was then calibrated for zero absorbance at 246 nm with the dissolution medium in the reference cell. The baseline on the stripchart[4] paper also was adjusted corresponding to zero absorbance.

The dissolution rate and *in vivo* physiological availability of drugs are important research areas (1–5). The dissolution rate of a solid dosage form such as a tablet or a capsule can be the rate-limiting step in availability for the *in vivo* absorption of the active ingredient (6–8), particularly for poorly soluble or poorly wetted drugs (9).

At present, almost all dissolution rate research efforts are directed toward tablets and capsules. Although suspensions share many physical–chemical characteristics of tablets and capsules with respect to the dissolution process, they are almost completely ignored. Since tablets and capsules disintegrate into powder suspensions, pharmaceutical suspensions share the dissolution process as a rate-limiting step for absorption and bioavailability.

Bates *et al.* (10) studied the dissolution rates of nitrofurantoin tablets and suspensions and commented that it was inconsistent to provide a USP dissolution test for nitrofurantoin tablets without including a dissolution rate test for the suspension. They concluded that: "the rationale underlying the official dissolution rate specification for nitrofurantoin tablets appears quite arbitrary and inconsistent with the dissolution profile and potential toxicity of the official suspension dosage form."

These comments substantiate a need to pursue dissolution rate testing of suspension dosage forms. In the current study, the dissolution and particle-size profiles of several commercially available suspensions were determined to obtain information about brand-to-brand variation and formulation characteristics directly related to dissolution.

Commercially available steroid ophthalmic/otic suspensions were studied. They represent a dosage form that requires dissolution as a prerequisite to therapeutic availability. These products contain a poorly soluble micronized steroid in a suitable vehicle. The solubility and particle-size characteristics of these products make them desirable prototype suspensions to study.

EXPERIMENTAL

Dissolution Testing—All reported dissolution data were obtained using a device[1] described by Shah *et al.* (11). The basic features of the apparatus are a large volume fluid container, a rotating filter assembly, and an external variable-speed magnetic stirrer. The sample basket was removed.

The rotating filter assembly provides variable intensity of mild laminar liquid agitation and also functions as an *in situ* nonclogging filter to permit efficient intermittent or continuous filtration of dissolution fluid samples during the dissolution process. The assembly is suspended and freely rotates in the center of the flask on the flared end of a glass capillary pilot tube. The assembly rotates by means of a controlled, variable-speed, external magnetic stirrer coupled with a magnetic bar embedded in the bottom part of the assembly. A 0.5-μm porosity sintered stainless steel filter also was employed.

One liter of distilled water was transferred into the flask, and the fluid was allowed to equilibrate at 25°. The stirring speed of the filter assembly was 960 rpm. A strobe lamp[2] was used to standardize the stirring speed.

Filtered fluid samples were continuously withdrawn through the capillary pilot tube at the rate of 100 ml/min and were circulated through the spectrophotometer and back to the flask. Air bubbles were periodically released from an air trap. The system was allowed to run for at least 15 min to ensure the consistency of the flow and stirring rate. The spectrophotometer[3] was then calibrated for zero absorbance at 246 nm with the dissolution medium in the reference cell. The baseline on the stripchart[4] paper also was adjusted corresponding to zero absorbance.

[1] The dissolution apparatus was made available through the courtesy of The Upjohn Co., Kalamazoo, Mich.
[2] Glass Instrument Co., Quincy, Mass.
[3] Perkin-Elmer double-beam spectrophotometer, Coleman 124, Hitachi, Ltd., Tokyo, Japan.
[4] Chart recorder model SRG, Sargent-Welch Scientific Co., Cleveland, Ohio.

All test conditions (*i.e.*, fluid temperature, stirring rate, cycling through the flowcell, and calibration of the spectrophotometer) were adjusted properly. The dissolution experiment was started by injecting a measured amount of suspension (0.5 ml except for Product A which was 1 ml) at a fixed position in the beaker using a syringe fitted with an extra long needle. The strip-chart paper was marked at the exact same time that the suspension was introduced into the flask. The recorder was switched to "stand by" until the drug readings, which were taken periodically, reached a plateau. The plateau of the curve was recorded and represented the equilibrium value. Generally, 2 hr was needed to reach equilibrium in this study.

The absorbance of dissolution profiles was then edited from the chart recording. For this report, the absorbance was edited at 5-sec intervals until 200 sec and then at every 100-sec interval until 1500 sec. The edited value was then used to calculate the weight fraction undissolved at any time t by simply dividing each absorption value by the equilibrium value and subtracting the resulting fraction from one.

Particle-Size Analysis—All particle-size data were obtained with a resistance particle counter[5] that employs the basic automated principle of sizing particles for a 16-channel (size) distribution analysis.

One convenient aspect provided by this instrument is that the volumetric size of the particle is automatically converted to the equivalent spherical diameter without any calculations by the operator. The calibration materials for the 50- and 200-μm aperture tubes were 2.02-μm diameter latex[6] beads and 27–28-μm diameter Lycopodium[7], respectively.

To avoid coincidence errors, size distribution must be measured within the limits given in the instrument manual. A meter on the instrument facilitates this process. A reading of approximately 0.05 on the concentration meter essentially eliminates coincidence problems.

The particle-size distribution data obtained from the resistance particle counter were provided by a numeric display of the cumulative and differential distributions. An oscilloscope display and the histograms were also available. Readout of total particle counts accumulated in the active channels was available during accumulation and held until the counter was reset. Also available were elapsed time data. Accumulations were continued for approximately 60 sec.

Electrolyte Preparation—Particle-size determinations of the suspensions were made using a balanced electrolyte[8] saturated with prednisolone acetate. Particulate contamination of the electrolyte was avoided by filtering the saturated solutions twice through a 0.22-μm filter[9].

Sample Preparation and Assay—The handmade suspensions were prepared in a glass mortar. Air-micronized prednisolone acetate[10] was triturated with presaturated water with or without hydroxypropyl methylcellulose[11], depending on the experiment.

The dissolution of prednisolone acetate from a suspension was measured by a spectrophotometric assay. A Beer's law plot was obtained at 246 nm. The linearity throughout the full range of concentrations was evidenced by a correlation coefficient of 0.9998.

An analytical methodology was developed to determine if components in the formulations, other than prednisolone acetate, interfered with the assay. A sample of the commercial suspension was filtered through a 0.22-μm filter, and the filtrate was diluted to the same concentration as that used for the actual dissolution study. These solutions showed little or no absorbance.

RESULTS AND DISCUSSION

Prednisolone acetate suspensions were chosen as the first product to be tested. This drug product was chosen for the following reasons: (*a*) multiple brands were marketed, (*b*) formulations were available from the labels, (*c*) dissolution of the active ingredient could be followed spectrophotometrically, (*d*) only the active ingredient was suspended, and (*e*) the dissolution rate was presumed to be the rate-limiting step for therapeutic availability.

Commercially available products were purchased from a pharmaceutical source other than directly from the manufacturer. Product A (ophthalmic suspension) contained prednisolone acetate, 0.12%; phenylephrine hydrochloride, 0.12%; antipyrine, 0.1%; benzalkonium chloride; polysorbate 80; boric acid; sodium citrate–sodium bisulfite; edetate disodium–sodium chloride; hydroxypropyl methylcellulose; and purified water.

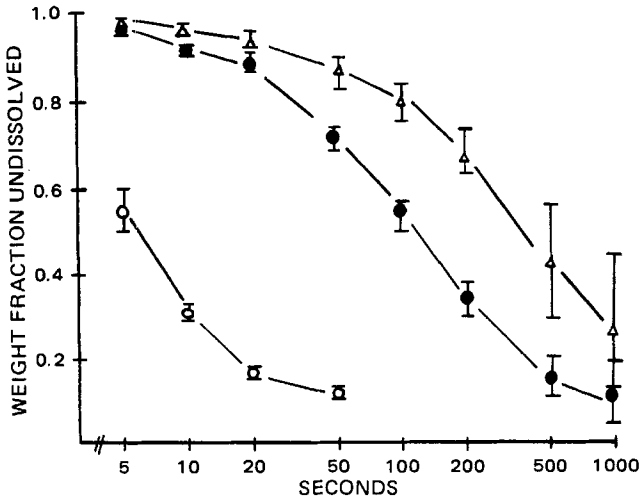

Figure 1—*Dissolution profiles for three commercial prednisolone acetate suspension products. Key: ○, Product A; ●, Product B; and △, Product C. Each point is the average of three experiments, and the bars show the extremes of the experiments.*

Product B (otic–ophthalmic suspension) contained prednisolone acetate, 2.5 mg/ml; neomycin sulfate, 5.0 mg/ml; sodium citrate; polyethylene glycol 4000; povidone; myristyl γ-picolinium chloride; sodium hydroxide and/or hydrochloric acid when necessary to adjust the pH; and water for injection.

Product C (ophthalmic suspension) contained prednisolone acetate, 0.25%; phenylephrine hydrochloride, 0.125%; benzalkonium chloride, 0.01%; hydroxypropyl methylcellulose, 0.2%; sodium bisulfite, 0.2%; edetate disodium; monobasic and dibasic sodium phosphates; sodium chloride; and water.

The results of the dissolution studies for the three commercial prednisolone suspensions are shown in Fig. 1. The dissolution of Product A was the most rapid; 80% dissolved in about 20 sec.

The initial release rate of Product B was much more rapid than that of Product C; the half-life of B occurred at approximately 110 sec, and the half-life of C occurred at approximately 550 sec. Moreover, 65% of Product B dissolved in about 200 sec, while only about 30% of Product C dissolved in the same period.

Since dissolution characteristics are closely related to particle size, a

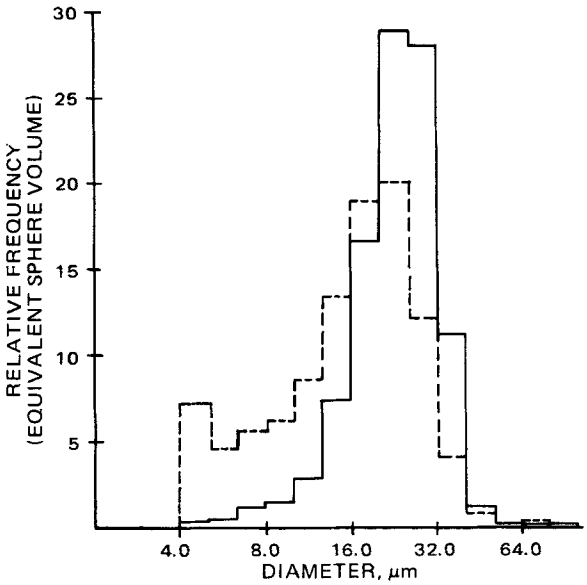

Figure 3—*Particle-size distributions of suspensions of prednisolone acetate (- - -) and prednisolone acetate with hydroxypropyl methylcellulose (——) measured by an automated counter using a 200-μm aperture tube.*

comparison of the particle-size distributions for Products A, B, and C is shown in Fig. 2. Product A was characterized by a population of small particles; about 70% of the particles, by volume, were less than 2 μm in diameter. The cutoff on the left side of Fig. 2 is the limitation of the 50-μm aperture tubes. The very rapid dissolution profile for Product A correlates with the particle-size analysis, because a particle-size reduction is generally regarded as a means of increasing the dissolution rate. According to label information, Product A utilizes a patented micronization process; at one time the package insert specifically mentioned the relationship between particle size and dissolution rate.

The bottom section of Fig. 2 shows the size distribution of Products B and C using the same scale as for Product A. These two products yielded essentially log-normal distributions with an approximate mean diameter of 6–7 μm. The similar particle-size distributions did not predict the significantly different dissolution profiles that were experimentally determined for these products. Since particle size did not provide an explanation, formulation differences between the two suspensions might have been responsible.

A comparison of the formulas for Products B and C shows that C contains hydroxypropyl methylcellulose whereas B does not. To test the effect of this ingredient, aqueous suspensions containing 0.25% prednisolone acetate and 0.2% hydroxypropyl methylcellulose were prepared. Aqueous suspensions containing just 0.25% prednisolone acetate and prepared in exactly the same manner served as a control. A mortar and pestle were used; this method yielded the finest and most reproducible suspensions compared to any other small-scale method of preparation attempted. No dispersing agent was used because it might have altered the dissolution of the suspensions.

Figure 3 shows the size distribution for these two handmade suspensions. The particle-size analysis for each suspension yielded similar distributions. The suspension containing hydroxypropyl methylcellulose yielded a slightly higher percentage of large particles. The mean particle diameter for the hydroxypropyl methylcellulose-containing formula was approximately 26 μm, whereas the mean particle diameter for the control formula was approximately 22 μm.

The dissolution data (Fig. 4) showed a striking difference between the two handmade prednisolone acetate suspensions that would not be predicted on the basis of particle-size analysis. Hydroxypropyl methylcellulose increased the dissolution time of prednisolone acetate compared to the control suspension. Twenty percent of the hydroxypropyl methylcellulose-containing suspension dissolved in about 750 sec, whereas only 100 sec was required for the control suspension. These data were similar

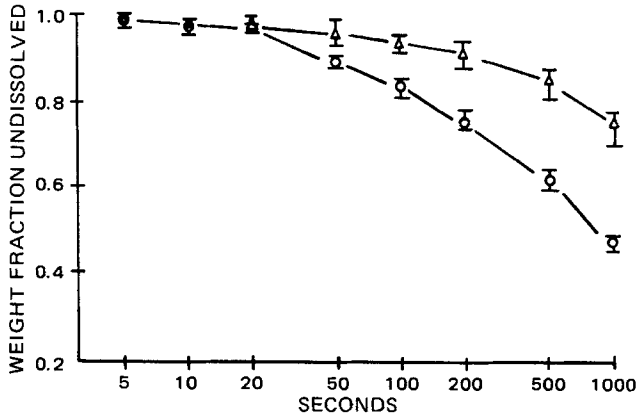

Figure 4—*Dissolution profiles for suspensions of prednisolone acetate (○) and prednisolone acetate containing hydroxypropyl methylcellulose (△) prepared by using a mortar and pestle.*

to those for Products C and B, where C is the hydroxypropyl methylcellulose-containing product. Although Product A also contains hydroxypropyl methylcellulose, the extremely small particle size seemed to dominate to yield a more rapid dissolution rate.

These data suggested that the hydroxypropyl methylcellulose in Product C may be related to its slower dissolution characteristics when compared to Product B, a suspension with similar particle size but without the polymer. It was also evident from a dissolution profile and particle-size analysis for Product A that the particle size can be the dominating factor.

In view of the results, it is believed that dissolution equivalency testing of pharmaceutical suspensions and the factors that cause the dissolution inequivalency, other than particle size, should be the subject of further study.

Although the therapeutic importance of these findings is only speculative, one would argue that the dissolution rate is usually interpreted as being the rate-limiting step for bioavailability. However, the dissolution profiles (Fig. 1) showed that there was inequivalency between the products. Establishment of routine dissolution tests can, therefore, considerably affect the control of lot-to-lot uniformity of the suspension dissolution rate.

Selective GLC Determination of Epinephrine, Isoproterenol, and Phenylephrine in Pharmaceutical Dosage Forms

J. R. WATSON ˣ and R. C. LAWRENCE

Abstract □ A simple, specific GLC analytical procedure for the quantitation of epinephrine, isoproterenol, and phenylephrine in commercial tablets, powders, inhalation solutions, ophthalmic and nasal drops, and injectable preparations is presented. Samples are taken to dryness where required, the dried residue is reacted with an appropriate trimethylsilylating reagent, and the derivatives are eluted from a methyl silicone column using temperature programming. Quantitation of the flame-ionization detector signal is achieved relative to the dibenzyl succinate internal standard by an electronic integrator. The results obtained by applying the method to the analysis of each of the three drugs in several simulated decomposed mixtures were in good agreement with theoretical values, even at impurity levels of up to 80% by weight. When applied to commercial formulations, the procedure was feasible for tablets, powders, and solutions at drug concentrations of 0.2% or greater. The commonly incorporated buffering and antioxidant excipients did not interfere.

Keyphrases □ Epinephrine—GLC analysis, pharmaceutical dosage forms □ Isoproterenol—GLC analysis, pharmaceutical dosage forms □ Phenylephrine—GLC analysis, pharmaceutical dosage forms □ GLC—analyses, epinephrine, isoproterenol, and phenylephrine, pharmaceutical dosage forms □ Adrenergics—epinephrine, isoproterenol, and phenylephrine, GLC analysis, pharmaceutical dosage forms

The sympathomimetic drugs epinephrine (I), isoproterenol (II), and phenylephrine (III) comprise some of the most extensively studied pharmacological agents employed in chemotherapeutics. Their wide acceptance is reflected by the many marketed formulations and the variety of pharmaceutical dosage forms.

BACKGROUND

Because of their amphoteric properties and attendant highly unfavorable extraction characteristics into organic solvents, the analysis of epinephrine, isoproterenol, and phenylephrine in pharmaceutical dosage forms is difficult. Moreover, in an alkaline medium, the water-soluble salts formed by the catecholamines epinephrine and isoproterenol are very unstable and undergo a rapid but complex oxidative decomposition to reddish aminochromes and, subsequently, to brown melanin-type compounds (1, 2). Degradation of phenylephrine occurs less readily, but, above pH 7, cleavage of the side chain of the parent molecule results in the formation of formaldehyde, which immediately reacts with a second molecule of phenylephrine in a Pictet–Spengler-type reaction to produce a mixture of isomeric dihydroxytetrahydroisoquinoline derivatives (2).

In view of the intrinsic susceptibility of these drugs to oxidative degradation, most of their preparations are stabilized with antioxidants such as chlorobutanol, ascorbic acid, or sodium bisulfite. Several reports showed that the stability of many important epinephrine and isoproterenol pharmaceutical products may be seriously impaired by anaerobic interaction of these drugs with sodium bisulfite to give zwitterionic sulfonate derivatives. These derivatives are both optically and physiologically inactive and exhibit UV spectra identical in absorption characteristics to the parent compounds (3–8). Phenylephrine differs in this respect apparently because it lacks the 4-hydroxyl group and the required resonating quinoid structure (4).

The current USP (9) and BP (10) procedures for the assay of epinephrine in commercial formulations are based on the measurement of the specific optical rotation after conversion to the triacetyl derivative. This method is self-limiting in scope and specificity and involves tedious and time-consuming manipulations. Although limit tests for the presence of adrenalone and levarterenol (norepinephrine) are described in the monographs for the drug substance, none is specified for pharmaceutical dosage forms.

In the USP (9), both isoproterenol and phenylephrine hydrochlorides are extracted quantitatively from pharmaceutical solutions or tablet matrixes by ion-pair formation with bis(2-ethylhexyl)phosphoric acid in ether, followed by partition chromatography of the solution through a suitably buffered siliceous earth column. Isoproterenol sulfonic acid, if present, reportedly remains adsorbed on the stationary phase (8). The USP monographs include a limit test for congeneric ketone compounds in the drug substances and in the commercial isoproterenol formulations. The assay procedure may lack precision because many important variables, such as tightness of the column packing and rate of elution, are not described.

Both BP 1973 (10) and NF XIV (11) employ a nonspecific colorimetric method for the analysis of isoproterenol sulfate in tablets and aerosol spray preparations. In the former pharmacopeia, phenylephrine hydrochloride injection is determined by simple absorbance measurement at 273 nm after appropriate dilution with aqueous sulfuric acid. This procedure would be inadequate where the product has undergone oxidative decomposition or is contaminated with other UV-absorbing phenylalcoholamine substances.

As a consequence of the limitations, most notably in specificity, of the compendial assay procedures for epinephrine, isoproterenol, and phenylephrine in dosage forms, alternative methods that encompass various analytical techniques have appeared (12–30).

Evidence was given previously that the highly polar functional groups of levodopa (31), α-methyldopa (32), and their respective congeners can be suitably altered by trimethylsilylation to give less polar and more thermally stable derivatives. These derivatives can be easily eluted as single sharp peaks from a methyl silicone column under relatively moderate temperature conditions. Since the catecholamines and other related sympathomimetic amines readily undergo similar well-documented transformations, it seemed reasonable to apply essentially the same quantitative GLC method to the analysis of epinephrine, isoproterenol, and phenylephrine.

The present investigation was conducted to integrate the available information and to develop a rapid, accurate, and selective GLC procedure for the analysis of epinephrine, isoproterenol, and phenylephrine in both liquid and solid pharmaceutical dosage forms in the presence of excipients and high levels of decomposition products and/or contaminating congeners. The method obviates the need for extraction or prior on-column cleanup manipulations inherent in most published procedures.

EXPERIMENTAL

Materials and Solutions—The following were used: *dl*-epinephrine hydrochloride[1], *dl*-norepinephrine hydrochloride[2], adrenalone hydrochloride[1], *l*-adrenochrome free base[1], epinephrine bitartrate[3], isoproterenol hydrochloride[3], isoproterenol sulfate[4], *N*-isopropylnoradrenalone sulfate[1], phenylephrine hydrochloride[3], norphenylephrine hydrochloride[2], *N,O*-bis(trimethylsilyl)acetamide[5], and *N*-trimethylsilylimidazole[5].

Epinephrine sulfonic acid and isoproterenol sulfonic acid were synthesized by applying the general method of Schroeter and Higuchi (5). The structures of the synthesized compounds were confirmed by elemental analysis and by their IR and NMR spectral characteristics.

The following examined excipients were all analytical grade standards: glycerin, lactic acid, ascorbic acid, citric acid, lactose, chlorobutanol,

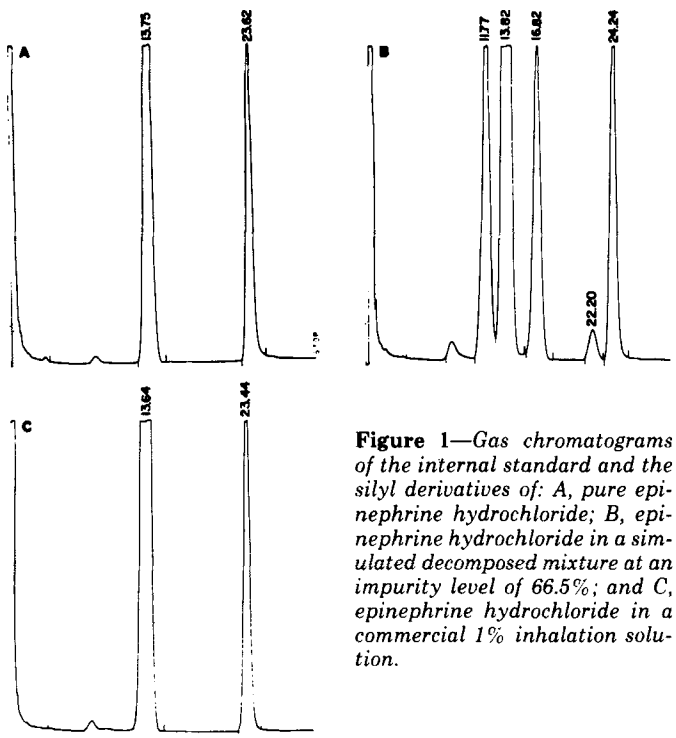

Figure 1—*Gas chromatograms of the internal standard and the silyl derivatives of: A, pure epinephrine hydrochloride; B, epinephrine hydrochloride in a simulated decomposed mixture at an impurity level of 66.5%; and C, epinephrine hydrochloride in a commercial 1% inhalation solution.*

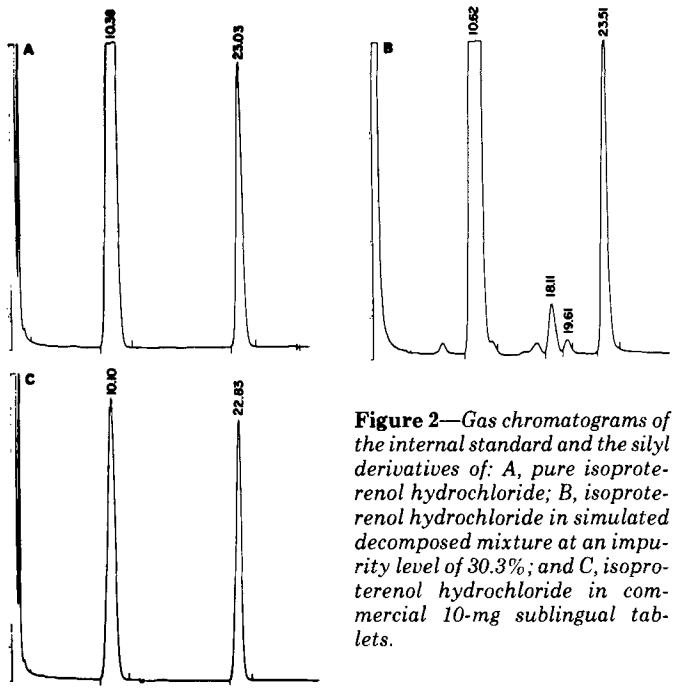

Figure 2—*Gas chromatograms of the internal standard and the silyl derivatives of: A, pure isoproterenol hydrochloride; B, isoproterenol hydrochloride in simulated decomposed mixture at an impurity level of 30.3%; and C, isoproterenol hydrochloride in commercial 10-mg sublingual tablets.*

saccharin sodium, sodium bisulfite, sodium citrate, edetate sodium, phenol, and benzalkonium chloride.

The internal standard solution was dibenzyl succinate[6] in spectrograde dimethylformamide[6], accurately weighed to contain about 2.5 mg/ml.

Sample Preparation—*Response Factor Calibration Mixtures*—For I, II, or III, varying quantities of the pure substance (as the salt), ranging from about 2 to 18 mg, were accurately weighed into five separate 5-ml septum-sealed vials. Then 2.00 ml of the internal standard solution was dispensed into each vial from a 5-ml microburet graduated in 0.01 ml.

Simulated Decomposed Mixtures—For each drug, five separate simulated decomposed mixtures of widely differing impurity levels were prepared by accurately weighing known quantities of the following compounds into 5-ml septum-sealed vials to obtain about 20–30 mg of material in each mixture.

For epinephrine mixtures (Series 1), epinephrine hydrochloride, epinephrine sulfonic acid, norepinephrine hydrochloride, adrenalone hydrochloride, and adrenochrome free base were used. The impurity range varied from about 20 to 80%.

For isoproterenol mixtures (Series 2), isoproterenol hydrochloride, isoproterenol sulfonic acid, norepinephrine hydrochloride, and *N*-isopropylnoradrenalone sulfate were used. The impurity range was from about 16 to 77%.

For phenylephrine mixtures (Series 3), phenylephrine hydrochloride and norphenylephrine hydrochloride were used. The impurity range was from about 7 to 26%.

To simulate the analysis of aqueous commercial formulations, each of the 15 mixtures was dissolved in water (1 ml) and the water was then removed at 60° under a stream of pure dry nitrogen on a heating block module[5]. To ensure complete desiccation, the vial was placed in a drying pistol assembly under vacuum over phosphorus pentoxide at 80° for 30 min under subdued light conditions. The dried residues were then treated with 2.00 ml of the internal standard solution.

Commercial Products—Ten tablets were selected at random, weighed, and finely powdered. An amount of powdered tablet (or powder) equivalent to about 10–15 mg of isoproterenol hydrochloride (or sulfate) was weighed into a 5-ml vial, and 2.00 ml of the internal standard solution was dispensed into the vial.

Aqueous formulations included inhalation solutions, ophthalmic and nasal drops, and injectable preparations. A volume of solution theoretically equivalent to about 5–15 mg of active drug was pipetted into a 5-ml vial, and the water was removed as indicated previously. Then 2.00 ml of the internal standard solution was added to the dried residue in the vial.

[6] J. T. Baker Chemical Co., Phillipsburg, N.J.

Derivatization Procedure—Each isoproterenol sample solution containing the internal standard was treated with *N*-trimethylsilylimidazole (1.0 ml) and allowed to stand for 30 min in the dark at ambient temperature with occasional shaking.

Each epinephrine and phenylephrine sample solution containing the internal standard was treated with *N,O*-bis(trimethylsilyl)acetamide (1.0 ml) and allowed to stand for 30 min in the dark at ambient temperature with occasional shaking.

GLC—Two microliters of silylated solution was injected into a gas chromatograph[7] (flame-ionization detector) fitted with a 5% OV-101[5] on Chromosorb 750[8] (100–120-mesh) U-shaped glass column [1.82 m (6 ft) × 6 mm o.d.] preconditioned at 265° for 18 hr. The support was coated using a fluidizer[9] maintained at 150° for 2 hr with a suitable nitrogen flow to ensure gentle, yet thorough, drying of the packing material.

Temperature conditions were: column, 170° (10 min) and then programmed to 245° at 2°/min; injection port, 225°; and detector, 225°. Gas flows were: nitrogen, 70 ml/min; hydrogen, 40 ml/min; and air, 380 ml/min.

The detector signal was fed to an electronic integrator[10] with an input signal range capacity of 0–1 v.

RESULTS AND DISCUSSION

Although the catecholamine acids are readily silylated in acetonitrile, the catecholamine salts are not, probably because of poor solubility in this solvent. For these drugs, dimethylformamide is a superior medium because it possesses enhanced solubilizing properties and accelerates the trimethylsilylation 10–20 times by comparison with pyridine and other solvents (23).

The criteria adopted for choosing the appropriate silylating reagent for each of the three drugs were based on the following considerations: (*a*) the derivatization of the drug should take place quantitatively in a minimum amount of time and at ambient temperature if possible, (*b*) the silyl derivative of the pure drug should elute as a single sharp peak, and (*c*) this peak should be clearly resolved from that of the internal standard and from the peak or peaks generated by potential contaminating by-products or decomposition products. In the present study, *N,O*-bis(trimethylsilyl)acetamide was employed for the silylation of epinephrine hydrochloride (and bitartrate) and phenylephrine hydrochloride but was less suitable for isoproterenol sulfate, yielding two peaks in the approximate area ratio of 4:1. Consequently, *N*-trimethylsilylimidazole was selected as the preferred silyl donor for the analysis of isoproterenol hydrochloride and isoproterenol sulfate formulations.

[a] The percent values are defined in grams per 100 ml of solution.

Relevant information on the average retention times of epinephrine, isoproterenol, and phenylephrine salts and their respective congeners and/or interaction and degradation products are presented in Table I. In the epinephrine series, the bitartrate salt of the drug afforded two peaks. The first (at 3.1 min) was due to the tartaric acid moiety while the adrenochrome gave only one small broad noninterfering peak at around 22 min. For the two compounds in the isoproterenol series for which more than one peak was generated, the individual peak values, expressed as percentages of total area, have been included in parentheses. *N*-Isopropylnoradrenalone sulfate appears to be particularly prone to multiple peak formation, due perhaps to *in situ* enolization, but none of the peaks would interfere with the quantitation of isoproterenol even in the presence of unusually large amounts of *N*-isopropylnoradrenalone.

No data are given with respect to the aminochrome analog of isoproterenol since it was not commercially available and is not readily prepared in the laboratory. However, it appears safe to assume a flame-ionization detector response for this compound quite similar to that of adrenochrome. The sulfonic acids of epinephrine and isoproterenol were not converted to silyl derivatives of sufficient volatility or thermal stability to be detectable under the GLC conditions. However, attempts to investigate further the nonelutive properties of these two compounds were not made.

In Table I, the listed response factors of the pure drugs were computed automatically by the digital processor and are expressed in weight/area relative to dibenzyl succinate. Their respective coefficients of variation were well within acceptable limits of precision. The chromatograms of the silyl derivatives of pure epinephrine hydrochloride, isoproterenol hydrochloride, and phenylephrine hydrochloride are reproduced in Figs. 1A, 2A, and 3A, respectively.

The results obtained by applying the GLC method to the analysis of several simulated decomposed mixtures of each drug are given in Table II and support the conclusion that the procedure is feasible and selective even at unrealistically high levels of contamination. The term "decomposed" is employed here in the broader sense to embrace other chemical entities that would not arise from the normal degradation but rather are artifacts incompletely removed during drug synthesis. The mixtures were dissolved in water prior to sample treatment and analysis to duplicate as closely as possible the conditions existing in the assay of commercial aqueous formulations and to demonstrate that the correct amount of chemically intact parent drug could be recovered.

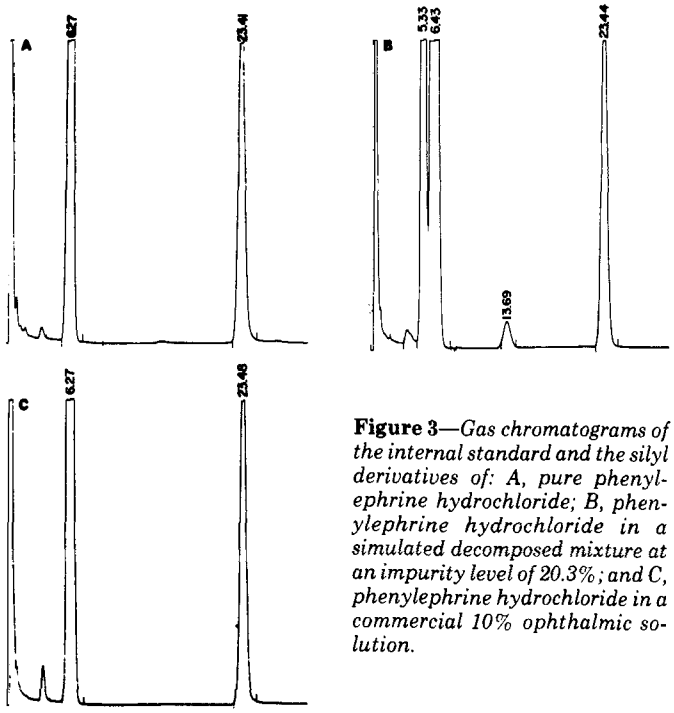

Figure 3—*Gas chromatograms of the internal standard and the silyl derivatives of: A, pure phenylephrine hydrochloride; B, phenylephrine hydrochloride in a simulated decomposed mixture at an impurity level of 20.3%; and C, phenylephrine hydrochloride in a commercial 10% ophthalmic solution.*

The percent recovery values varied from 97.2 to 101.2% for epinephrine, from 94.9 to 103.4% for isoproterenol, and from 98.5 to 100.7% for phenylephrine. The value of 94.9% for isoproterenol Mixture 5 is admittedly somewhat of an outlier, but the high level of impurity in this case (76.6%) is really not one that would normally be encountered in the day-to-day analysis of commercial formulations. Sample chromatograms of each of the three drugs in simulated decomposed mixtures are presented in Figs. 1B, 2B, and 3B.

To document further the validity of the present GLC method for the analysis of commercial formulations, 12 commonly incorporated buffering and antioxidant excipient compounds were chromatographed after dissolution or suspension in the silylation medium at ambient temperature for 30 min. No potentially interfering signals were observed for any substance examined. Most adjuvants listed under *Experimental* either gave peaks that were eluted close to or under the solvent or produced no peak that could be detected under the temperature conditions used. Single sharp peaks, well resolved from those of the particular drug with which they were formulated, were observed for citric acid (7.6 min) and ascorbic acid (12.6 min). Benzalkonium chloride gave four small noninterfering peaks at about 17, 26, 36, and 44 min.

The results of the analysis of commercial tablets, powder mixes, nasal drops, inhalation and ophthalmic solutions, and an injectable preparation are delineated in Table III. Chromatograms for epinephrine, isoproterenol, and phenylephrine in commercial formulations are given in Figs. 1C, 2C, and 3C.

High-Performance Liquid Chromatographic Analysis of Isoniazid and Its Dosage Forms

LEONARD C. BAILEY [x] and HAMED ABDOU

Abstract □ A high-performance liquid chromatographic analysis is described for isoniazid as a drug entity and in its tablet and injectable dosage forms. After incorporation of the drug or dosage form in a solvent mixture and addition of an internal standard, tribenzylamine, an aliquot is chromatographed using a pellicular silica gel medium followed by UV spectrophotometric detection at 254 nm. The response of the chromatographic system was linear over a concentration range corresponding to 20–200% of the labeled amount of isoniazid. Comparison of the results with those obtained by the official USP XIX method indicates similar accuracy and precision. The advantages of the proposed method are its simplicity and rapidity, its potential for automation, and its specificity. The specificity was demonstrated in the presence of potential degradation products of isoniazid, other drugs used with isoniazid in combination dosage forms, and an adduct formed by the reaction of isoniazid with lactose in the tablet.

Keyphrases □ Isoniazid—high-performance liquid chromatographic analysis, tablets and injectables □ High-performance liquid chromatography—analysis, isoniazid, tablets and injectables □ Tuberculostatic antibacterials—isoniazid, high-performance liquid chromatographic analysis, tablets and injectables

Because isoniazid (isonicotinic acid hydrazide) is the drug of choice for the treatment of tuberculosis, many attempts have been made to develop methods for its quantitation in dosage formulations. The procedures rely primarily on the redox reactivity of the hydrazide group or upon color formation with an appropriate chromogen.

One analysis is based on the addition of excess standard iodine followed by back-titration with standard thiosulfate (1). This procedure was official in four USP revisions but was supplanted in the current USP XIX (2) by a nitrous acid titration similar to that used for the determination of sulfa drugs. The method official in the BP (3) is similar to the earlier USP method, except that excess bromine is used instead of iodine. These oxidimetric methods and a nonaqueous titration procedure were reviewed and compared previously (4).

Another method (5) involves the determination of isoniazid and other hydrazine-derived drugs by potentiometric titration in an acid solution, using chloramine-T as the titrant. However, its applicability to dosage forms was not explored. A colorimetric method was proposed based on the reaction of isoniazid with 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (6). A colorimetric procedure uses 9-chloracridine as the chromogenic reagent (7).

The purpose of this study was to investigate the utility of high-performance liquid chromatography (HPLC) in the determination of isoniazid in its dosage forms. The speed and accuracy of this technique and the availability of relatively inexpensive modular instrumentation should make such analysis particularly applicable in quality assurance situations.

The proposed method is simple, involving only the dissolution of the sample, addition of the internal standard, and introduction of an aliquot of the resulting mixture onto a liquid chromatograph with an adsorption column and a

Another method (5) involves the determination of isoniazid and other hydrazine-derived drugs by potentiometric titration in an acid solution, using chloramine-T as the titrant. However, its applicability to dosage forms was not explored. A colorimetric method was proposed based on the reaction of isoniazid with 7-chloro-4-nitrobenzo-2-oxa-1,3-diazole (6). A colorimetric procedure uses 9-chloracridine as the chromogenic reagent (7).

The purpose of this study was to investigate the utility of high-performance liquid chromatography (HPLC) in the determination of isoniazid in its dosage forms. The speed and accuracy of this technique and the availability of relatively inexpensive modular instrumentation should make such analysis particularly applicable in quality assurance situations.

The proposed method is simple, involving only the dissolution of the sample, addition of the internal standard, and introduction of an aliquot of the resulting mixture onto a liquid chromatograph with an adsorption column and a

UV detector operated at 254 nm. The accuracy and precision of the method are comparable to those of the current USP XIX analysis, but the time required for a determination is significantly less. In addition, the HPLC method is more specific in that it is insensitive to isonicotinic acid, a possible hydrolysis product of isoniazid, and 1-isonicotinoyl-2-lactosylhydrazine, the hydrazone formed by the reaction of isoniazid with lactose, which may be present as a diluent in the formulation.

EXPERIMENTAL

Reagents and Chemicals—High purity isoniazid[1] was recrystallized twice from 95% ethanol, dried at 105° for 4 hr, and stored in a vacuum desiccator, mp 171°. Isonicotinic acid[1] was recrystallized twice from distilled water. Tribenzylamine[2] was recrystallized twice from 95% ethanol and dried *in vacuo*, mp 93–93.5°.

The lactose hydrazone of isoniazid, 1-isonicotinoyl-2-lactosylhydrazine, was prepared as follows. Isoniazid, 6.85 g (0.05 mole), was mixed with 300 ml of 95% ethanol in a 500-ml round-bottom flask and warmed on a steam bath until solution was complete. In a 100-ml beaker, 17.1 g (0.05 mole) of lactose was mixed with 40 ml of distilled water and warmed on a hot plate until the lactose was dissolved. The aqueous lactose solution was added slowly, with continuous stirring, to the isoniazid solution and refluxed for 8 hr. The mixture was concentrated under vacuum until a pasty mass was obtained.

After mixing the crude product with 20 ml of methanol and refrigerating overnight, the resulting slurry was filtered and the residue was dried in a desiccator under vacuum. Recrystallization from the minimum amount of 95% ethanol–water (3:1) yielded white needles, mp 199° (uncorr.) [lit. (8) mp 202°]; λ_{max} (ethanol, 95%): 261.5 nm.

Anal.—Calc. for $C_{18}H_{27}N_3O_{12}$: C, 46.85; H, 5.90; N, 9.10; O, 38.14. Found: C, 46.24; H, 6.04; N, 9.14; O, 35.58.

TLC of the hydrazone, using silica gel G plates[3] and a mobile phase of methanol–chloroform (60:65) (9), showed a single spot with an R_f of 0.17 (R_f of isoniazid under these conditions is 0.60). Analysis of the product using the USP XIX procedure specified for isoniazid (2) indicated an apparent purity of 97%.

Solvents—Reagent grade methanol[4] was redistilled from an all-glass apparatus. Reagent grade methylene chloride[4] and spectranalyzed chloroform[4] and 2-propanol[4] were used as received.

Apparatus—HPLC was performed with an apparatus consisting of a pump[5] with a pulse dampener[6] and a UV monitor[6] operated at 254 nm. Samples were introduced through a septum injector[6] using a 10-μl syringe[7]. The output of the detector was displayed on a recorder[8] having a full-scale range of 10 mv. The output signal was integrated, and results were calculated using an electronic integrator[9]. A 1-m × 2.1-mm i.d. stainless steel column was packed with a pellicular silica gel adsorbent[10] according to the manufacturer's instructions. The mobile phase was pumped at a pressure of 300 psig, which resulted in a flow rate of 1.20 ml/min.

USP analyses for isoniazid were performed using standard 10.00- and 50.00-ml burets[11] and an expanded scale pH meter[12].

Mobile Phase—The mobile phase was a mixture of either methylene chloride or chloroform with methanol, 2-propanol, and water in the following proportions: 85:5:10:0.5.

Standard Solutions—*Solvent Mixture* —The solvent mixture used was methylene chloride (or chloroform, if the mobile phase was chloroform based)–methanol–2-propanol (85:5:10).

Isoniazid Standard Solution—Accurately weigh 0.2000 g of isoniazid, transfer to a 100-ml volumetric flask, and dilute to the mark with the solvent mixture.

Internal Standard Solution—Accurately weigh 3.0000 g of tribenzylamine, transfer to a 100-ml volumetric flask, and dilute to the mark with the solvent mixture.

Standard Preparation—Into a 50-ml volumetric flask, pipet 25.0 ml of isoniazid standard solution, 5.0 ml of internal standard solution, and 0.5 ml of water. Mix well to ensure incorporation of the water into the solution. Dilute to volume with the solvent mixture and shake until a homogeneous mixture is obtained. Introduce 5 μl into the liquid chromatograph. Measure the areas under the two peaks and calculate the ratio, R_s, by dividing the area of the isoniazid peak by the area of the internal standard peak.

Isoniazid—*Assay Preparation*—Dissolve 100 mg of isoniazid, accurately weighed, in 50 ml of the solvent mixture in a 100-ml volumetric flask. Then add 1.0 ml of water and 10.0 ml of internal standard solution and shake until the water is incorporated. Dilute to the mark with the solvent mixture and mix until homogeneous.

Assay Procedure—Introduce a 5-μl portion into the liquid chromatograph. Measure the areas under the two peaks and calculate the ratio, R_u, by dividing the area of the isoniazid peak by the area of the internal standard peak. Calculate the quantity, in milligrams, of isoniazid present in the sample taken by the formula:

$$\text{isoniazid} = W_s(R_u/R_s) \qquad \text{(Eq. 1)}$$

where R_u and R_s are as defined previously, and W_s is the weight, in milligrams, of isoniazid in 100.0 ml of the standard preparation.

Isoniazid Tablets—*Assay Preparation*—Weigh and finely powder not less than 20 isoniazid tablets. Weigh accurately a portion of the powder, equivalent to 100 mg of isoniazid, and transfer it to a 100-ml volumetric flask using about 50 ml of the solvent mixture. Add 1.0 ml of water and 10.0 ml of internal standard solution. Mix well for 1 min to ensure extraction of the isoniazid from the powder. Dilute to volume with the solvent mixture and mix until homogeneous.

Assay Procedure—Proceed as directed in the assay procedure for isoniazid.

Isoniazid Injection—*Assay Preparation*—Transfer 1.0 ml of isoniazid injection to a 100-ml volumetric flask and add about 75 ml of the solvent mixture. Mix well to ensure incorporation of the aqueous injection vehicle with the solvent mixture and add 10.0 ml of internal standard. Dilute to volume with the solvent mixture and mix until homogeneous.

Assay Procedure—Proceed as directed in the assay procedure for isoniazid.

RESULTS AND DISCUSSION

Mobile Phase—The mobile phase may contain either methylene chloride or chloroform as its main constituent. The initial separations were accomplished using methylene chloride, but lot-to-lot variations with this solvent were more pronounced than with chloroform.

Some batches of methylene chloride contained impurities which deactivated the surface of the column packing after 2–3 liters of mobile

phase passed over it. Moreover, the compound(s) responsible for this effect could not be removed by distillation or by passing the solvent through a column packed with 6–16-mesh silica gel. For batches of solvent containing these deactivating impurities, a suitable level of purity may be attained by passing the solvent twice through 2.8 × 25-cm columns of small particle (76–230 mesh) silica gel 60.

Because the solvent properties of chloroform and methylene chloride are very similar, there were only slight differences in the separations achieved when either of them was in the mobile phase. As a measure of the efficiency of the separation of tribenzylamine and isoniazid, the resolution factor, R, was calculated as described in USP XIX (10). For the methylene chloride-based mobile phase, R was 4.12; for the chloroform-based system, it was 3.14. Either of these results is indicative of a separation greater than 99%.

The overlap between the isoniazid and internal standard peaks was, therefore, slightly greater when chloroform was used, but no effect on the quantitative results was noted whether peak heights or areas were used. No significant difference (t-test) was found between samples of the same dosage forms when analyzed using chloroform or methylene chloride.

Chromatographic Response—The typical response of the internal standard and isoniazid to the chromatographic system is shown in Fig. 1. This chromatogram was obtained from the analysis of a quantity of powdered tablet material containing 100 mg of isoniazid. A methylene chloride-based mobile phase was used.

To determine the linearity of the chromatographic response, a calibration curve was run in which the concentration of the internal standard was maintained constant while that of isoniazid was varied. The curve was linear (r = 0.999) over a 10-fold range, corresponding to quantities of isoniazid that would be obtained in the analysis of dosage forms containing 20–200% of the label claim. The intercept was essentially zero.

The integration method used to measure the response of each component was not critical, since both peaks were nearly symmetrical and almost completely resolved. Peak heights, peak areas obtained by manual methods (height times width at half-height), and electronic integration were used, and similar results were obtained.

Analysis of Dosage Forms—Table I gives the results obtained from the analysis of a number of commercially available dosage forms containing isoniazid. To verify the reliability of the method, portions of the same material taken for analysis by HPLC were also assayed using the method official in USP XIX. The results obtained by the HPLC method were comparable in accuracy and precision to those given by the USP method, with the exception of the two different lots of tablets from Manufacturer A (Table I). These lots gave results consistently 5–10% lower in isoniazid content than indicated by the USP method. Since it was assumed initially that the cause of the lower results was incomplete extraction of the isoniazid from the powdered tablet mass, various techniques, including heating, longer extraction times, and the use of an ultrasonic generator, were employed to improve recoveries. However, none of these procedures resulted in an increase in the quantity of isoniazid found.

To determine the cause of the anomalously low results, a study was initiated based on the observations (9) that isoniazid was capable of interacting with dosage form ingredients, particularly reducing sugars, to form hydrazones. These derivatizations were reported to occur even in the solid state. A portion of powdered material from the tablets that assayed at 85.90% isoniazid by HPLC was extracted by shaking with methanol. The same was done to the powdered mass of a tablet that had been shown to contain 99.24% isoniazid by HPLC.

Aliquots of the filtered extracts were applied to a TLC sheet along with methanol solutions of isoniazid and its lactose hydrazone. After development in methanol–chloroform (60:65), the lane containing the extract of the anomalous tablet showed two spots under UV light. The R_f of one spot corresponded to that of isoniazid; the other was the same as that of its lactose hydrazone. The lane containing the extract of the normal tablet had only one spot, that of pure isoniazid.

It was apparent, therefore, that the low results were due to the derivatization of a portion of the isoniazid by the lactose used as a diluent in the tablet formulation. Blake *et al.* (4) reported, and this work has verified, that the USP analysis does not distinguish between free isoniazid and the hydrazone it forms with a reducing sugar. The fact that HPLC is stability indicating in this regard is considered advantageous in view of the observations of Rao *et al.* (11), which indicated that the absorption of isoniazid from syrups containing reducing sugars was seriously impaired. Attempts to elute the lactose hydrazone of isoniazid using the conditions specified for the analysis of isoniazid were unsuccessful, with no peaks being observed even after 1 hr. Since the hydrazones formed by isoniazid with other reducing sugars would have similar structures and polarities, it is assumed that they too will not interfere with the HPLC method.

Potential Interfering Substances—Retention times were determined, using a chloroform-based mobile phase, for a number of compounds that might potentially interfere with the HPLC analysis. The results (Table II) indicate that the method retains its specificity despite the presence of degradation products of isoniazid or of other drugs frequently administered in combination dosage forms with isoniazid.

Two possible degradation products, isonicotinic acid and *N,N'*-bis-(isonicotinoyl)hydrazine, were completely separated. Aminosalicylic acid, an antitubercular drug available in combination with isoniazid, was also completely resolved by HPLC. Pyridoxine hydrochloride, which is administered concurrently with isoniazid to counteract the latter's antagonistic effect on vitamin B_6 activity, also did not interfere.

Table II—Retention Times of Isoniazid, Tribenzylamine, and Potential Interferences

Compound	Retention Time, min
Isoniazid	2.3
Tribenzylamine (internal standard)	1.5
Isonicotinic acid	44.0
Niacin	57.0
N,N'-Bis(isonicotinoyl)hydrazine	8.6
1-Isonicotinoyl-2-lactosylhydrazine	>60.0
Aminosalicylic acid	34.5
Pyridoxine hydrochloride	4.1

Comparative Pharmacokinetics of Coumarin Anticoagulants XXI: Effect of Plasma Protein Binding on Distribution Kinetics of Warfarin in Rats

AVRAHAM YACOBI and GERHARD LEVY [x]

Abstract □ The purpose of this investigation was to determine the effect of plasma protein binding on the pharmacokinetic parameters for warfarin that are used conventionally to describe its distribution kinetics on the basis of the time course of plasma warfarin concentrations. Following rapid intravenous injection, warfarin concentrations in the plasma of 14 selected adult male rats declined triexponentially, with the terminal exponential phase starting at about 5 hr. The free fraction, f, of warfarin in the serum of individual animals ranged from 0.303×10^{-2} to 2.89×10^{-2}. The parameters of the equation $C_t = Pe^{-\pi t} + Ae^{-\alpha t} + Be^{-\beta t}$ for plasma concentration C_t at time t were obtained from the experimental data by nonlinear least-squares computer fitting and varied markedly between animals. Strong and highly statistically significant positive correlations with f were obtained for P, B, and β, but no significant correlation was found for A, π, and α. Rate constants and apparent volumes for a three-compartment open mammillary model with elimination from the central compartment were calculated. No apparent correlation was found between f and the intercompartment distribution rate constants. However, strong positive correlations between f and the elimination rate constant, the volume of the central compartment, and the volume of distribution, V_{area}, were observed. There also was a strong linear correlation between f and total clearance. Excellent replication of the experimental data was obtained when the experiments were repeated in some animals after 2 weeks. A detailed analysis of practical pharmacokinetic problems associated with and revealed by such repeated experiments is presented.

Keyphrases □ Warfarin—distribution kinetics, effect of plasma protein binding, rats □ Distribution—pharmacokinetic parameters, effect of plasma protein binding, rats □ Pharmacokinetics—warfarin distribution, effect of plasma protein binding, rats □ Binding, plasma protein—effect on warfarin distribution kinetics, rats □ Protein binding, plasma—effect on warfarin distribution kinetics □ Anticoagulants—warfarin, distribution kinetics, effect of plasma protein binding, rats

Plasma protein binding is a major determinant of the elimination kinetics of warfarin in rats (1) and humans (2). Consistent with theoretical considerations (3), the total clearance, TC, of warfarin by the body was found to be proportional to the free fraction, f, of warfarin in plasma or serum. Wide intersubject differences in f and, consequently, in the TC of warfarin have been observed.

The purpose of this investigation was to determine the relationship between f and the pharmacokinetic constants conventionally used to describe the kinetics of warfarin distribution on the basis of the time course of drug concentrations in plasma after rapid intravenous injection. A detailed analysis of certain practical problems of pharmacokinetic data interpretation was also undertaken.

EXPERIMENTAL

Single 3-ml blood samples were obtained from 63 adult male Sprague–Dawley rats[1] for determination of f, and 14 animals with widely differing f values were selected for further study. Three weeks later, with
