Abstract □ The purpose of this investigation was to determine the effect of plasma protein binding on the pharmacokinetic parameters for warfarin that are used conventionally to describe its distribution kinetics on the basis of the time course of plasma warfarin concentrations. Following rapid intravenous injection, warfarin concentrations in the plasma of 14 selected adult male rats declined triexponentially, with the terminal exponential phase starting at about 5 hr. The free fraction, f, of warfarin in the serum of individual animals ranged from 0.303×10^{-2} to 2.89×10^{-2}. The parameters of the equation $C_t = Pe^{-\pi t} + Ae^{-\alpha t} + Be^{-\beta t}$ for plasma concentration C_t at time t were obtained from the experimental data by nonlinear least-squares computer fitting and varied markedly between animals. Strong and highly statistically significant positive correlations with f were obtained for P, B, and β, but no significant correlation was found for A, π, and α. Rate constants and apparent volumes for a three-compartment open mammillary model with elimination from the central compartment were calculated. No apparent correlation was found between f and the intercompartment distribution rate constants. However, strong positive correlations between f and the elimination rate constant, the volume of the central compartment, and the volume of distribution, V_{area}, were observed. There also was a strong linear correlation between f and total clearance. Excellent replication of the experimental data was obtained when the experiments were repeated in some animals after 2 weeks. A detailed analysis of practical pharmacokinetic problems associated with and revealed by such repeated experiments is presented.

Keyphrases □ Warfarin—distribution kinetics, effect of plasma protein binding, rats □ Distribution—pharmacokinetic parameters, effect of plasma protein binding, rats □ Pharmacokinetics—warfarin distribution, effect of plasma protein binding, rats □ Binding, plasma protein—effect on warfarin distribution kinetics, rats □ Protein binding, plasma—effect on warfarin distribution kinetics □ Anticoagulants—warfarin, distribution kinetics, effect of plasma protein binding, rats

Plasma protein binding is a major determinant of the elimination kinetics of warfarin in rats (1) and humans (2). Consistent with theoretical considerations (3), the total clearance, TC, of warfarin by the body was found to be proportional to the free fraction, f, of warfarin in plasma or serum. Wide intersubject differences in f and, consequently, in the TC of warfarin have been observed.

The purpose of this investigation was to determine the relationship between f and the pharmacokinetic constants conventionally used to describe the kinetics of warfarin distribution on the basis of the time course of drug concentrations in plasma after rapid intravenous injection. A detailed analysis of certain practical problems of pharmacokinetic data interpretation was also undertaken.

EXPERIMENTAL

Single 3-ml blood samples were obtained from 63 adult male Sprague–Dawley rats[1] for determination of f, and 14 animals with widely differing f values were selected for further study. Three weeks later, with

TC, ml/(hr × kg)	5.59	1.74–11.4

the animals then weighing 380–490 g, a two-piece cannula of silicone rubber–polyethylene was implanted in the right jugular vein under light ether anesthesia (4, 5). One or 2 days after cannulation, the rats were placed in individual metabolism cages with food[2] and water freely available.

Racemic warfarin, 0.51 mg/kg including about 5 μCi of ^{14}C-warfarin[3]/kg, was injected rapidly through the cannula; 0.25-ml blood samples were obtained at 5, 10, 20, 40, 60, and 120 min and then at less frequent intervals for about 50 hr by a technique described previously (5). Plasma was separated, and warfarin was extracted, purified by TLC, and assayed as previously described (6). At the end of the experiment, a large volume of blood was obtained for the determination of the free fraction of warfarin in serum by equilibrium dialysis (1, 7).

The warfarin concentrations in plasma as a function of time after injection were fitted to a multiexponential equation by nonlinear least-squares regression (8). Convergence was defined as a relative change in the residual sum of squares $<10^{-4}$. Data in all functions were weighted numerically equal. The parameter estimates of the multiexponential equation were used to calculate rate constants for a multicompartment open model (9). Simulations were carried out with a digital analog simulator program (10).

RESULTS

Figure 1 shows the time course of plasma warfarin concentrations in two rats, one a relatively rapid eliminator and the other a relatively slow

eliminator of the drug. Experimental data of similar quality were obtained for the other 12 animals. A triexponential equation of the type $C_t = Pe^{-\pi t} + Ae^{-\alpha t} + Be^{-\beta t}$ was required to describe the plasma warfarin concentrations, C_t, as a function of time, t. Substantially fewer than 20 iterations were required in all cases to obtain convergence; the correlation coefficient was ≥0.997 for each set of data.

The mean values and ranges for the parameters of the triexponential equation fitted to the individual data from 14 animals are listed in Table I. As is evident from the values of these constants and from Fig. 1, the terminal exponential phase of plasma concentrations began about 5 hr after injection. Rate constants for a linear three-compartment mam-

millary open model, with elimination arbitrarily defined as occurring from the central compartment (Compartment 1), were obtained for each set of experimental data and are listed in Table II.

Table II also contains the values for the apparent volume of the central compartment, V_c, the apparent volume of distribution based on the area under the triexponential curve, V_{area}, the apparent volume of distribution estimated from the dose divided by B, $V_{intercept}$, and the total body clearance, $TC = V_{area}\beta$ or $\simeq V_{intercept}\beta$. The average ± SD of the individual ratios of $V_{intercept}/V_{area}$ was 1.03 ± 0.051, indicating only a very small contribution of the initial distribution phase to the total area under the concentration–time curve.

Figure 2 shows the distribution of values for the triexponential equation (to be referred to as the direct pharmacokinetic parameters) and for f, the serum free fraction, which ranged from 0.303×10^{-2} to 2.89×10^{-2}. Since the 14 rats were selected from 63 animals to obtain a wide range of f values, the distribution patterns in Fig. 2 are not characteristic of a normal population.

The direct pharmacokinetic parameters π and α were apparently not affected by changes in f (Figs. 3 and 4), but the β values showed a strong positive correlation with f (Fig. 5). The volumes V_c, V_{area}, and $V_{intercept}$ were also strongly and positively correlated with f (Figs. 6 and 7). Linear

regression lines in Figs. 5–7 do not necessarily imply an exactly linear relationship between the variables. There was a strong ($r = -0.913$) and highly statistically significant ($p < 0.001$) negative correlation between the plasma warfarin concentration at 5 min and f. This finding constitutes an independent and direct verification of the positive correlation between f and the computer-derived values of V_c. As demonstrated previously (1–3), there was a direct linear relationship between f and the total clearance of warfarin by the body (Fig. 8).

A summary of the relationship between f and the various direct and derived pharmacokinetic parameters for warfarin is presented in Table III. Of the derived constants, the elimination constant k_{10} was strongly correlated with f while the intercompartment distribution rate constants k_{12}, k_{21}, k_{13}, and k_{31} were not.

The warfarin experiment was repeated in three animals 2 weeks after the first experiment. Excellent replication of experimental data was obtained, as shown in Figs. 9 and 10 for one of the best and the "worst" case. Nevertheless, nonlinear least-squares regression analyses yielded substantial numerical intrasubject differences in P, A, π, and α (Tables IV–VI). On the other hand, there was very little intrasubject variation in B and β, and these values had small standard deviations. The same pattern obtained with respect to the derived pharmacokinetic constants and the volume terms; there was good replication of k_{10}, V_c, and V_{area} but not of the other constants (Tables IV–VI).

$\beta \times 100$	1.40	1.38	1.38	1.38	1.38	1.38

[a] The computer outputs when the initial estimates were not changed (N.C.) and when P, A, π, and α were increased or decreased by 30% as specified by the superscripts in the column headings.

To examine the effect of the initial estimates on the computer-calculated direct pharmacokinetic parameters, the initial estimates for P, A, π, and α were increased or decreased in different combinations by 30%[4]. For 12 of the 14 rats, this change had no effect (<5%) on the calculated values. Tables VII and VIII show the results of this exercise for one of the best and for the worst case, respectively.

Despite the numerically pronounced intrasubject differences in several direct pharmacokinetic parameters for warfarin (Tables IV–VI), the plasma concentration–time curves generated by the triexponential equations for replicate experiments in any one animal were very similar (Figs. 11 and 12). However, the curves obtained from the derived constants for the time course of warfarin in the two hypothetical peripheral compartments of the three-compartment model differed greatly between experiments in any one animal (Figs. 13 and 14).

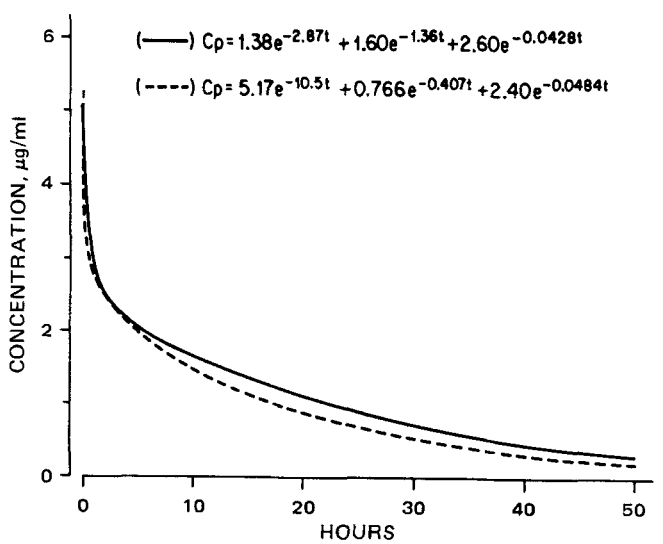

Figure 12—*Curve fitted to the data in Fig. 10 by nonlinear least-squares computer program. Key: ——, first experiment; and - - - -, second experiment.*

[4] The initial estimates for B and β were so close to the computer outputs in all cases that there was no need to vary these estimates.

DISCUSSION

The experiments were carried out under relatively ideal conditions for pharmacokinetic analysis: a large number of blood samples were obtained through an indwelling cannula; a sensitive, specific, and precise assay method was used; the experiments were done twice in some animals; and the concentration data were sufficiently "clean" so that computer calculations were not affected by substantial variations in the initial estimates of the parameters.

As expected on the basis of earlier investigations (1–3), plasma protein

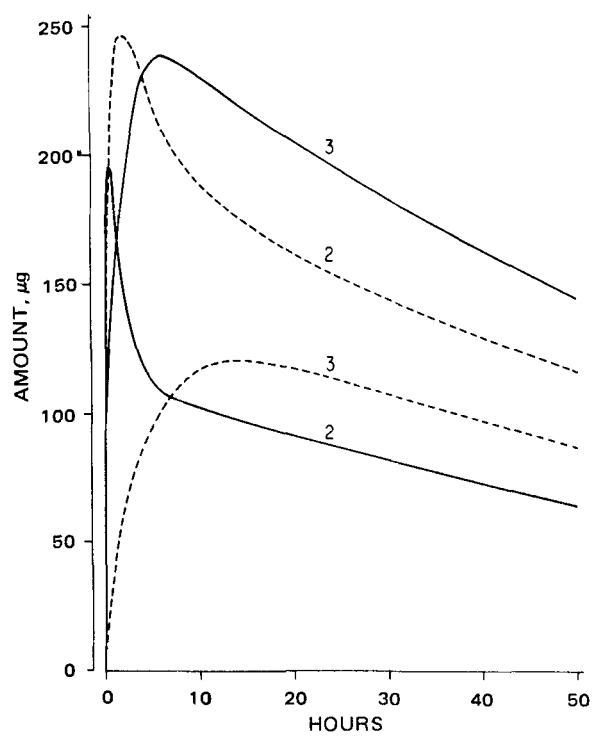

Figure 13—*Inferred time course of warfarin in the hypothetical shallow and deep peripheral compartments, based on the triexponential curves shown in Fig. 11. Key: ——, first experiment; - - - -, second experiment; 2, Compartment 2; and 3, Compartment 3.*

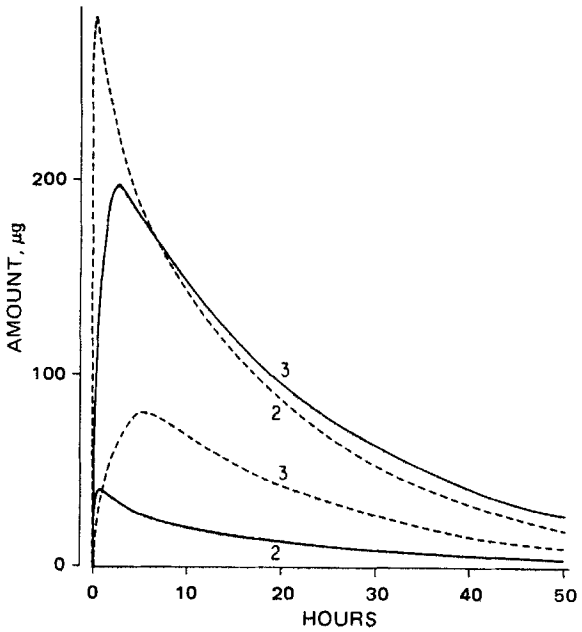

Figure 14—*Inferred time course of warfarin in the hypothetical shallow and deep peripheral compartments, based on the triexponential curves shown in Fig. 12. Key: ——, first experiment; - - - -, second experiment; 2, Compartment 2; and 3, Compartment 3.*

binding had a pronounced effect on the total clearance of warfarin. Our previous practice of using $V_{intercept}$ rather than V_{area} values to estimate TC[5] was entirely acceptable for warfarin, since the differences were on the order of 3 ± 5%.

Protein binding of warfarin in plasma had no apparent effect on the directly determined pharmacokinetic parameters π and α and on the derived rate constants k_{12}, k_{21}, k_{13}, and k_{31}, which are conventionally used to describe the distribution kinetics of a drug on the basis of plasma concentration data. This conclusion must be viewed in the context that these parameters are also the ones with the greatest uncertainty in their calculated values (as reflected by their relative coefficients of variation and by the results of replicate experiments).

Of interest are the strong correlations of P and V_c [*i.e.*, $D/(P + A + B)$] with f (Table III). If V_c is the volume of a "real" initial homogeneous compartment, then differences in plasma protein binding should not affect its value. The increase of V_c with f suggests that V_c is a hybrid affected by some aspects of drug distribution and that it does not reflect the volume of a distinct, homogeneous, well-defined, and instantaneously accessible (by intravenous injection) physiological space under the experimental conditions. However, V_c is essentially equal to the plasma volume of 35 ml/kg in Sprague–Dawley rats (11) when f is very small (Fig. 6).

From a theoretical assessment of problems associated with the analysis of pharmacokinetic models, Westlake (12) concluded that: "When a pharmacokinetic model is fitted to blood levels of a drug, the estimates of the pharmacokinetic parameters are likely to be subject to considerable error. These errors are probably unimportant as long as the model is used only to predict blood levels. However, when the parameters are used to predict other features of the system (*e.g.*, tissue drug levels), considerable errors in prediction may result." The results of our replicate studies, carried out under ideal conditions for good replication, afford the best opportunity to examine this problem experimentally.

[5] This practice is necessitated by the requirement of nonheparinized blood for most of these studies, since it is usually desired to determine not only drug concentrations but also the intensity of the anticoagulant effect. Blood samples must then be collected by serial arterial punctures (rather than by cannula) and at more frequent time intervals at later times, thereby limiting the number and frequency of early samples.

Table VIII—Effect of Initial Estimates on Computer-Derived Parameters for Triexponential Equation, Rat 3

Parameter	Initial Estimate	Computer Output[a] N.C.	−30%*	+30%*	−30%* +30+	+30%* −30%+
P	1.20	1.38	1.36*	1.78*	1.50*	0.888*
A	2.00	1.60	1.39*	1.19*	1.51+	2.35+
B	2.59	2.60	2.59	2.57	2.61	2.67
π	3.50	2.87	2.42*	2.37*	2.15*	5.14*
α	1.40	1.36	1.01*	1.32*	1.93+	1.97+
$\beta \times 100$	4.26	4.28	4.27	4.23	4.29	4.40

[a] The computer outputs when the initial estimates were not changed (N.C.) and when P, A, π, and α were increased or decreased by 30% as specified by the superscripts in the column headings.

Pharmacokinetic analysis of the data demonstrated that Westlake's conclusions are fully justified. The tool of pharmacokinetics is powerful and effective when focused on directly measurable concentrations or effects but becomes a potentially misleading and meaningless mathematical manipulation when used to infer the events or conditions that are thought (often mistakenly) to occur in the "black box" portion of the body and that cannot be measured directly.

Kinetics and Mechanisms of Hydrolysis of 1,4-Benzodiazepines II: Oxazepam and Diazepam

WESLEY W. HAN ˣ, GERALD J. YAKATAN, and DALE D. MANESS

Abstract □ The hydrolysis kinetics of oxazepam and diazepam leading to a benzophenone product and a glycine derivative were quantified from pH 1 to 11. For oxazepam, two intermediates were isolated and identified, indicating a parallel consecutive reaction mechanism. The hydrolysis occurred uncatalyzed and demonstrated acid–base catalysis for both reaction steps. One intermediate was observed by TLC for diazepam hydrolysis. This intermediate, resulting from breakage of the azomethine linkage, was different than the major intermediate isolated for oxazepam hydrolytic degradation (amide hydrolysis preferred). Stability parameters involving rate constant–temperature dependence are reported.

Keyphrases □ Oxazepam—kinetics and mechanism of hydrolysis, effect of pH □ Diazepam—kinetics and mechanism of hydrolysis, effect of pH □ Hydrolysis—oxazepam and diazepam, kinetics and mechanism, effect of pH □ 1,4-Benzodiazepines—oxazepam and diazepam, kinetics and mechanism of hydrolysis, effect of pH

In a previous report (1), the kinetics and mechanisms of hydrolysis of chlordiazepoxide and demoxepam, 1,4-benzodiazepines of therapeutic interest, were quantitatively described. Chlordiazepoxide undergoes facile transformation to demoxepam by hydrolysis of the methylamino substituent in the 2-position. Subsequently, the 1,4-benzodiazepine nucleus is lost by hydrolysis of the 1,2- and 4,5-bonds, leading to the final products: 2-amino-5-chlorobenzophenone and a glycine derivative.

Although the kinetic and TLC data indicated a parallel consecutive reaction mechanism (*i.e.*, either 1,2- or 4,5-bond hydrolysis may initially occur), complete data analysis showed that initial azomethine hydrolysis was relatively unimportant to the overall hydrolysis kinetics. An investigation of kinetics and mechanisms of hydrolysis of oxazepam (I*a*) and diazepam (I*b*) was initiated to delineate structural effects on the relative importance of the two mechanistic paths leading to the final products.

EXPERIMENTAL

Materials—TLC was used to verify the purity of oxazepam[1], 2-amino-5-chlorobenzophenone[1], and diazepam[2]. These compounds were chromatographically pure and were used as received. All other chemicals were reagent grade quality. Aqueous solutions were prepared using distilled deionized water. All aqueous solutions were buffered using the following systems: hydrochloric acid, acetate, phosphate, borate, and sodium hydroxide.

Kinetic Measurements and Compound Identification—Hydrolysis kinetics were followed spectrophotometrically. Detailed procedures describing the kinetic measurements and methods used in isolation and identification were reported previously (1). TLC analysis of hydrolytic reaction solutions of diazepam was identical to that used for chlordiazepoxide (1).

For oxazepam, samples of about 10^{-3} *M* solution were withdrawn at appropriate times. These samples were extracted three times with an equal volume of chloroform. A UV scan of the aqueous phase indicated that extraction was complete. The chloroform extract was concentrated and subjected to TLC analysis, using 250-μm silica gel GF plates and chloroform–toluene–methanol (52:48:7) as the developing solvent.

RESULTS AND DISCUSSION

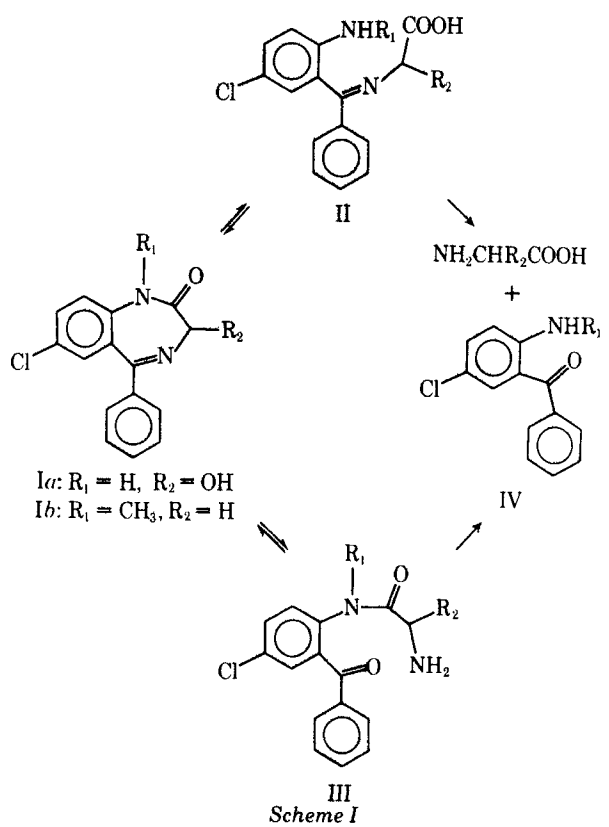
Scheme I gives the general expected mechanism if concomitant 1,2-amide and 4,5-azomethine hydrolyses occur. Compound II would result from 1,2-amide hydrolysis; III is the intermediate derived from hydrolysis of the 4,5-azomethine bond; and IV represents the final products, the substituted benzophenone and the glycine derivative. The initial parallel reaction steps may be reversible under appropriate conditions (1, 2) and are shown. A mathematical treatment of this scheme according to differential absorbance measurements may be found in a prior report (1).

Spectral Changes and Rate Constant Determinations—Two pKa's, 1.7 and 11.6, have been reported for oxazepam at 25° (3). The lower value is attributable to protonation of the azomethine nitrogen, and the larger one is due to deprotonation of the amide nitrogen. Since the proposed intermediates and products are also subject to prototropic reactions, it is not surprising that the kinetic spectra are influenced by pH changes. Throughout the entire pH region, two apparent reaction steps were spectrally observed for oxazepam. Typical spectral changes, demonstrating a two-step reaction, are shown in Fig. 1. The final spectrum is identical to that of 2-amino-5-chlorobenzophenone.

For oxazepam, time plots of the logarithm of differential absorbance measurements at any time and time infinity ($A_t - A_\infty$) consisted of two linear segments according to the biexponential equation:

$$A_t - A_\infty = M \exp(-b_1 t) + N \exp(-b_2 t) \qquad \text{(Eq. 1)}$$

where M and N are preexponential constants and b_1 and b_2 are exponential factors related to the observed rate constants of the first-order reactions in Scheme I. Typical apparent first-order plots are given in Figs. 2 and 3. Feathering was employed to differentiate the two linear seg-



Scheme I

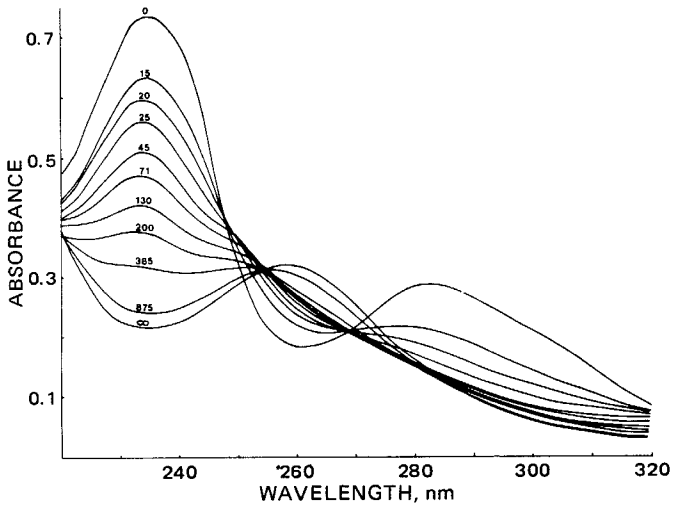


Figure 1—*Typical spectral changes for the hydrolysis of 10^{-5} M oxazepam in 0.1 N HCL, μ = 1.0, at 80°. Curves are labeled as to minutes after initiation of the reaction.*

ments. The apparent first-order rate constants, calculated by least-squares fitting, are reported in Table I.

Diazepam differs from oxazepam in that only one pKa has been observed in the normal pH region (3). The pKa of 3.3 is reportedly due to protonation at the azomethine nitrogen in the 4-position. Due to the methyl substitution on the amide nitrogen, the higher pKa observed with oxazepam, attributable to deprotonation of the amide proton, is absent. At pH values below the pKa of diazepam, observed spectral changes indicated an apparent two-step reaction, both being first order. Above this pKa, spectra of sequential samples demonstrated clear isosbestic points, implicating a single reaction step in a one-to-one kinetic transformation of diazepam to 2-methylamino-5-chlorobenzophenone. Throughout the pH region, the final spectrum was superimposable on that of an equimolar solution of this product.

Below the pKa of diazepam, the apparent rate constants were calculated by the same procedure as used for oxazepam. In the pH region showing a single reaction step, the observed rate constants were determined according to the integrated first-order expression:

$$\ln(A_t - A_\infty) = \ln(A_0 - A_\infty) - kt \qquad \text{(Eq. 2)}$$

Linear segments for both the biexponential and monoexponential plots were clearly first order, as indicated by the correlation coefficients, r, in Tables I and II. The least-squares estimates of the rate constants for diazepam are given in Table II.

Rate–pH Profiles—The log k–pH profile for oxazepam hydrolysis (Fig. 4) was generated from the rate constants given in Table I. The two reaction steps are shown on the same log k–pH profile: the initial step, hydrolysis of oxazepam to an intermediate(s), and the second, slower reaction representing hydrolysis of the intermediate(s) to the final products. For the initial hydrolytic step, the equation that defines the

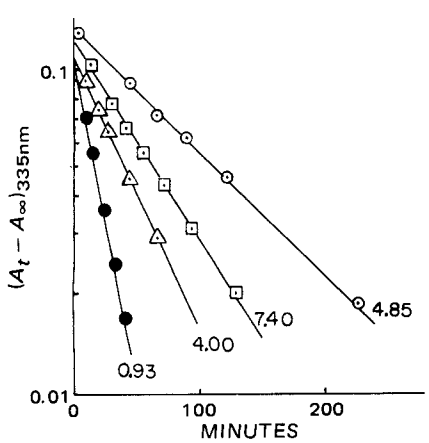

Figure 2—*Typical apparent first-order plots for the first hydrolytic reaction step of oxazepam at 85°, μ = 1.0. Feathered lines are labeled as to pH values.*

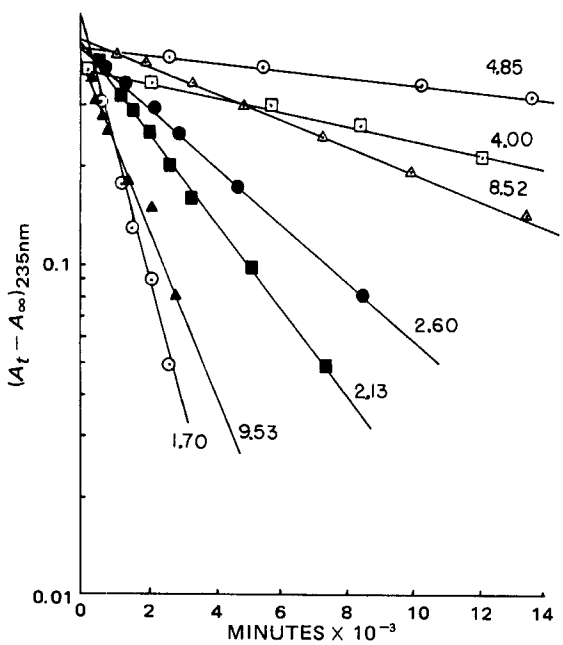

Figure 3—*Typical apparent first-order plots for the second hydrolytic reaction step of oxazepam at 85°, μ = 1.0. Lines are labeled as to pH values.*

theoretical curve drawn through the experimental points is:

$$k_{obs} = k_H[H^+]f_{H_2S} + k_{H'}[H^+]f_{HS} + k'_{H_2O}f_{HS} + k_{OH'}[OH^-]f_{HS} + k_{OH''}[OH^-]f_S \qquad \text{(Eq. 3)}$$

where the observed rate constant (k_{obs}) is defined as a function of the specific bimolecular rate constants (k_H, k_{H_2O}, and k_{OH}), the specific catalyzing species (H^+ and OH^-), and the fractions of diprotic (f_{H_2S}), monoprotic or uncharged (f_{HS}), and deprotonated oxazepam (f_S), respectively. This general equation may be substituted with the following

[a] Standard deviations were calculated from a linear regression analysis of the data.

kinetic equivalents:

$$k_{H_2O}f_{H_2S} = k_{H'}[H^+]f_{HS} \quad \text{(Eq. 4)}$$

$$k_{OH}[OH^-]f_{H_2S} = k'_{H_2O}f_{HS} \quad \text{(Eq. 5)}$$

$$k_{OH'}[OH^-]f_{HS} = k''_{H_2O}f_S \quad \text{(Eq. 6)}$$

The respective fractions may also be written in terms of proton concentration and the acidity constants of oxazepam, K_1 and K_2, as, for example:

$$f_{H_2S} = \frac{[H^+]^2}{[H^+]^2 + K_1[H^+] + K_1K_2} \quad \text{(Eq. 7)}$$

The bimolecular rate constants and kinetic pKa's that provided the optimal fit to the experimental data points are listed in Table III. The calculated pKa's, 3.0 and 8.8, deviated substantially from those previously given as 1.7 and 11.6 at 25°. This deviation is reconcilable with the temperature difference between 85° (kinetic determination) and 25° (literature value). The directions of the shifts would be expected from thermodynamic consideration of the charged species in the protropic reactions.

The log k–pH profile for the second reaction step mirrors that of the initial step, and Eq. 3 may be used to generate the theoretical curve through the experimental data points. However, the fractions present (f_{H_2S}, f_{HS}, and f_S) would in this case refer to the intermediate(s), as would the kinetic pKa's. The theoretical curve was constructed from the values of the bimolecular rate constants and pKa values given in Table III.

The log k–pH profile for diazepam is given in Fig. 5. For pH values below the pKa of diazepam, two reaction steps were observed. The first reaction step is quantitatively described by the expression:

$$k_{obs} = k_{H_2O}f_{HS} \quad \text{(Eq. 8)}$$

or by its kinetic equivalent:

$$k_{obs} = k_H[H^+]f_S \quad \text{(Eq. 9)}$$

The kinetic pKa was determined to be 2.9, compared to the value of 3.3 at 25°. The magnitude and direction of the change in the pKa do not agree with those observed for the lower pKa value of oxazepam, both involving deprotonation of the azomethine nitrogen. The reason for this difference is not apparent. The second reaction step, as well as the single reaction step at higher pH values, is attributable to hydrolysis of a reaction intermediate according to the expression:

$$k_{obs} = k_H[H^+]f_{HS} + k_{H'}[H^+]f_S + k_{OH}[OH^-]f_S \quad \text{(Eq. 10)}$$

The second term, involving acid catalysis of the deprotonated intermediate, is kinetically equivalent to uncatalyzed hydrolysis of the protonated form. Table III lists the bimolecular rate constants and pKa values used to generate the theoretical curve shown in Fig. 5.

Isolation and Identification—Oxazepam samples withdrawn at appropriate times were subjected to TLC analysis as previously described. Throughout the entire pH region, the oxazepam spot (R_f 0.23) showed a gradual decrease in intensity with a concomitant relative intensity increase for that of the product 2-amino-5-chlorobenzophenone (R_f 0.75). The glycine derivative was observed at the origin upon spraying with

[a] Except that 55.5 M water is incorporated into the k_{H_2O}, the rate constants are in units of minutes^{-1} M^{-1}. [b] The calculated kinetic pKa for the hydrolysis.

ninhydrin aerosol (0.5%). Two additional spots appeared transiently (R_f 0.48 and 0.68) and were ascribed to reaction intermediates. At pH values below pKa, the relative intensities of the intermediate spots appeared similar. However, at higher pH values, the spot at R_f 0.68 was much more intense than that at R_f 0.48.

The intermediates were isolated by preparative TLC and characterized spectroscopically. Structure IIa of Scheme I was assigned to the intermediate (R_f 0.68) predominating at the higher pH values by these measurements. The IR spectrum of a potassium bromide disk showed a typical carbonyl absorption peak at 1725 cm^{-1} for the carboxylic acid functional group. The NMR spectrum taken in dimethyl sulfoxide-d_6 demonstrated an acid proton (τ = −0.2). The expected molecular ion at m/e 304 was not observed in the mass spectrum analysis. The ion of greatest mass was observed at m/e 284. Sadee and Kleijn (4) demonstrated that the thermolysis of oxazepam leads to 6-chloro-4-phenylquinazoline-2-carboxaldehyde in GLC. It is possible that a comparable rearrangement of intermediate IIa, leading to the formation of 6-chloro-4-phenylquinazoline-2-carboxylic acid (mol. wt. 284), occurred in the ionization chamber of the mass spectrometer.

The IR and NMR spectra of the second intermediate were compatible with Structure IIIa of Scheme I but not definitive. The mass spectrum showed a parent peak of m/e 287 instead of the molecular ion of IIIa (m/e 304). Oxazepam, mol. wt. 286, gives a parent peak at m/e 269, indicating that dehydroxylation is a favored fragmentation. A similar preference for IIIa would account for the absence of the 304 peak and the appearance of the 287 peak. Thus, Structure IIIa was tentatively assigned to the intermediate (R_f 0.48).

TLC analysis of the hydrolysis of diazepam indicated formation of one intermediate (R_f 0.58) at pH values below the pKa. Diazepam and the product 2-methylamino-5-chlorobenzophenone were observed at R_f 0.43 and 0.69, respectively. At pH values above the pKa, no spots attributable to reaction intermediates were observed. The product glycine was identified at the origin by spraying with 0.5% ninhydrin aerosol reagent throughout the entire pH region. Attempts to isolate sufficient quantities of the intermediate for identification were unsuccessful due to the small amount present.

If the assumption is made that the intermediate is either IIb or IIIb, then the log k–pH profile may be used to suggest which is the most likely candidate. The discontinuity observed for the first reaction step at pH values above the pKa may be attributable to a recyclization reaction, adding a reversible reaction to the consecutive kinetic scheme. Structure IIb would exist as a protonated amine at pH values below its pKa and in the neutral form above the pKa. No recyclization would be expected with the protonated form due to the expected decreased nucleophilicity. However, the free base form could be expected to undergo facile recyclization. Thus, Structure IIIb was tentatively assigned to the intermediate resulting from diazepam hydrolysis.

Hydrolytic Mechanisms—The mechanisms of hydrolysis for oxazepam and diazepam may be interpreted according to Scheme I. For each, the pKa in the acidic pH region provides a pivotal point. At pH values above this point, II should exist as the carboxylate anion. This charge character would decrease the likelihood of nucleophilic attack of the aromatic amine necessary for reversibility. At lower pH values, the conjugate acid form should be susceptible to recyclization analogous to that observed with chlordiazepoxide (1) and demoxepam (2).

Intermediate III should demonstrate the opposite charge character as a function of pH. At pH values below its pKa, the amine function should be predominately protonated and thus have a resident positive charge. In this form, the nitrogen should be ineffective as a nucleophile, and recyclization would not occur. As the conjugate base above the pKa, reversibility would be much more favorable.

The observation that two intermediates are present during oxazepam hydrolysis implies that the parallel consecutive reaction mechanism shown in Scheme I is operable throughout the entire pH region. At pH values below the pKa, biphasic kinetic behavior was observed. These kinetics would be consistent with the parallel consecutive scheme if the transformation of the intermediates to final products is of approximately equal magnitude. The appearance and loss of the intermediates were qualitatively observed by TLC to be occurring at equal rates. At pH values above the pKa, TLC indicated that IIa formation was preferred. This phenomenon, coupled with the biphasic character of the kinetics, implies that the kinetically relevant mechanism is that shown in Scheme II.

$$Ia \rightarrow IIa \rightarrow IVa$$

Scheme II

Recyclization of intermediate IIIa and the absence of reversible reaction for Ia → IIa kinetically favor this pathway. Models show that sterically amide hydrolysis should be preferential to breakage of the azomethine bond. The competitiveness observed in the lower pH region appears to be attributable to the reversibility differences of the initial,

Table IV—Apparent First-Order Rate Constants, 10^4 k (in Minutes^{-1}) and Thermodynamic Parameters for Hydrolysis of Diazepam and Oxazepam

pH	k_i	85°	80°	75°	70°	E_a[a], kcal/mole	ln P[a]

parallel steps. Additionally, the charge character of the intact benzodiazepine, brought about by protonation of the azomethine nitrogen at lower pH values, electronically favors nucleophilic attack on the 5-position.

Diazepam hydrolysis proceeds through one intermediate (Scheme III).

$$Ib \rightarrow IIIb \rightarrow IVb$$

Scheme III

Apparently, methyl substitution on the amide nitrogen makes initial azomethine hydrolysis the preferred pathway. At pH values below the pKa, III*b* is not subject to recyclization; clear biphasic kinetics result. In the higher pH region, facile recyclization of III*b* causes the kinetics to be monophasic in character (Scheme IV).

$$Ib \rightleftharpoons IIIb \rightarrow IVb$$

Scheme IV

The Arrhenius parameters for hydrolysis were obtained from the slope and intercept of a plot of the logarithm of the apparent first-order rate constant, k, *versus* the reciprocal of the absolute temperature, T, shown by the expression:

$$\ln k = \ln P - E_a/RT \qquad \text{(Eq. 11)}$$

where R is the gas constant equal to 1.987 cal deg^{-1} mole^{-1}; $\ln P$ is related to the entropy of activation, ΔS_a, by:

$$\Delta S_a = R[\ln P - \ln(kT/h) - 1] \qquad \text{(Eq. 12)}$$

where h and k are the Planck and Boltzman constants, respectively; and E_a is related to the enthalpy of activation of the hydrolysis, ΔH_a, by:

$$\Delta H_a = E_a - RT \qquad \text{(Eq. 13)}$$

The Arrhenius parameters for oxazepam and diazepam hydrolyses at various pH values are given in Table IV. These values allow stability prediction in the pH regions showing rapid degradation. For oxazepam, buffer catalysis was studied according to the relationship:

$$k_{obs} = k_0 + \left(\frac{k_{HA}[H^+]}{K_a} + k_A\right)[A^-] \qquad \text{(Eq. 14)}$$

where K_a is the dissociation constant for the buffer species; k_0 is the hydrolysis rate constant in the absence of buffer catalysis; and k_{HA} and k_A are the rate constants for buffer catalysis of the acid buffer species, HA, and its conjugate base, A^-, respectively. Buffer effects were investigated by changing the original buffer concentration fourfold in a gradient manner. Buffer effects were not significant, and thus the specific rate constants were not delineated.

Thermal Decomposition of 1,3-Dimethyl Derivative of Phenobarbital in Trimethylanilinium Hydroxide

PATRICK S. CALLERY and JAMES LESLIE ˣ

Abstract □ Extensive degradation of the 1,3-dimethyl derivative of phenobarbital occurs when it is injected with trimethylanilinium hydroxide in methanol into a gas chromatograph. The application of mass spectrometry demonstrated that the major products are *N*-methyl-2-phenylbutyramide, *N,N*-dimethyl-2-phenylbutyramide, methyl 2-phenylbutyrate, *N,N,N'*-trimethylethylphenylmalondiamide, and *N,N,N',N'*-tetramethylethylphenylmalondiamide. The methyl group of the ester arises from the methanol solvent, whereas the methyl groups of the substituted amides arise from the parent compound or the methylating reagent. Tetramethylammonium hydroxide causes much more degradation than trimethylanilinium hydroxide under comparable conditions.

Keyphrases □ 1,3-Dimethyl derivative of phenobarbital—thermal decomposition in gas chromatograph, major products identified by mass spectrometry □ Phenobarbital 1,3-dimethyl derivative—thermal decomposition in gas chromatograph, major products identified by mass spectrometry □ Decomposition, thermal—1,3-dimethyl derivative of phenobarbital, in gas chromatograph, major products identified by mass spectrometry □ GLC–mass spectrometry—thermal decomposition of 1,3-dimethyl derivative of phenobarbital, major products identified

Phenobarbital is frequently analyzed by a GC technique in which the drug is injected simultaneously with trimethylanilinium hydroxide (I) (1). The peak quantified was shown to be the 1,3-dimethyl derivative of phenobarbital (II) (2), but the presence of an additional peak with a much shorter retention time was consistently reported (3–7). This "early peak" was identified as *N*-methyl-2-phenylbutyramide (V) (5), although the presence of *N,N*-dimethyl-2-phenylbutyramide (VI) also was demonstrated (7).

In preliminary studies, a mixture of I and II was injected into a gas chromatograph under the conditions of phenobarbital analysis, and it was observed that II degraded to several products (8). In view of the extensive use of the on-column GC methylation procedure for phenobarbital determination and the interest in the structure of the early peak, the products of the reaction of I and II were examined by mass spectrometry; the results are reported in this paper.

RESULTS

Injection of II in methanol into a gas chromatograph[1] yielded a single peak, whereas injection of this compound in I (0.1–1.8 *M*) at temperatures usually used in the analysis of phenobarbital yielded several peaks (Fig. 1). Peaks A and B had the same retention times as the early peak and major peak, respectively, observed when phenobarbital is injected with I under the same conditions. Peaks C and D were not reported previously.

Furthermore, analysis of the mixture of I and II at a programmed temperature starting at 90° revealed the presence of two additional components, E and F, and resolved peak A into two peaks, A_1 and A_2 (Fig. 2*a*). The relative areas of the peaks were dependent on a number of factors, including the absolute and relative concentrations of I and II, the water content of the mixture injected, and the pH of the solution of I used. By comparison of their mass spectra to those obtained for authentic compounds, the identities of peaks A_1, A_2, B, E, and F were established as VI, V, II, dimethylaniline, and methyl 2-phenylbutyrate (VII), respectively.

The mass spectra of peaks C and D (Figs. 3 and 4) indicated that these compounds were *N,N,N'*-trimethylphenylethylmalondiamide (III) and *N,N,N',N'*-tetramethylphenylethylmalondiamide (IV), respectively. The fragmentation pattern of peak D corresponded closely to the literature values for IV (9). Peak C was assigned Structure III on the basis of

an analysis of its fragmentation pattern. Peak C exhibited significant ions also found for IV at *m/e* 120, 117, 103, 91, and 72, which suggested that C and D were derived from a similar skeleton structure.

The molecular ion of peak C (*m/e* 248), which was 14 mass units less than the tetramethyl Compound IV, was consistent with the trimethyldiamide III. Ions at *m/e* 176 $[M-(CH_3)_2NCO]^+$ and 72 $[(CH_3)_2NCO]^+$ indicated that peak C contained a dimethylamide moiety; the ion at *m/e* 58 $(CH_3NHCO)^+$ suggested that the parent molecule also contained a monomethylamide group. Further support for the presence of a monomethylamide function was derived from an intense ion at *m/e* 191, which can be accounted for by the loss of methylisocyanate by a McLafferty-type rearrangement of the molecular ion.

On-column methylation performed with deuterated I coupled with mass spectrometric analysis demonstrated that deuterium was incorporated into one methyl group in VI and into one and two methyl groups in III and IV, respectively. No deuterium was observed in VII under these conditions. However, deuterium was incorporated into the ester when the methylation was carried out in the presence of deuterated methanol[2], indicating that the source of the methyl group in this compound was the methanol solvent. When a mixture of I and II was allowed to stand for several days at room temperature and then neutralized with dilute hydrochloric acid, only the peaks corresponding to dimethylaniline and II were observed upon GLC analysis. This result indicates that the decomposition of the barbiturate in alkaline solution occurs after injection and not at ambient temperatures and that the decomposition is base catalyzed. Injection of the amides V and VI into the gas chromatograph with I in methanol did not result in the formation of the ester VII.

When II was injected into the gas chromatograph with 0.13 *M* tetramethylammonium hydroxide[3] in methanol, the results were more striking. As illustrated in Fig. 2*b*, II was almost completely degraded under these conditions to V–VII. Acidification of the reaction mixture prior to injection resulted in little or no decomposition of II upon injection.

DISCUSSION

A GLC–mass spectrometric study of the reaction of I and II shows that extensive degradation of the barbiturate occurs at high temperatures to form a number of products. This degradation is of interest, since phenobarbital is frequently determined by quantification of the area of its

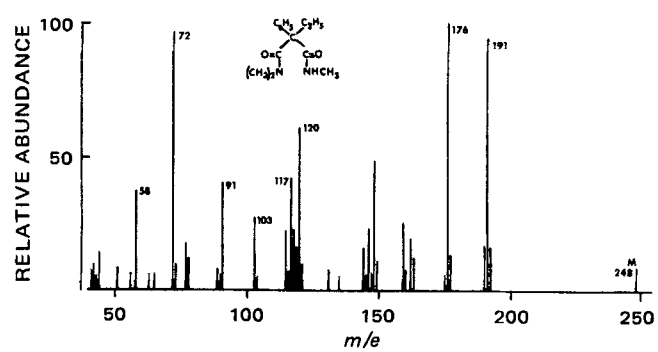

Figure 3—*Mass spectrum of peak C of Fig. 2.*

1,3-dimethyl derivative obtained after on-column methylation with I (1) and in at least one laboratory by quantification of the area of the early peak (7).

The degradation of II occurs in the injector port at high temperatures in the presence of base, since it does not occur in alkaline solutions at ambient temperatures or in neutral solutions at high temperatures. The first step in the degradation is likely to be the loss of a carbonyl group from II with the formation of *N,N*-dimethylphenylethylmalondiamide, which is then subsequently methylated to the tri- and tetramethyl derivatives. The formation of IV was observed previously in the reaction of phenobarbital with methylsulfinylmethide carbanion and methyl iodide (9) but not with phenobarbital and diazomethane (10). The methylated phenylbutyramides probably arise from III and IV, since it was shown that phenylethylmalondiamide forms V and VI when injected into a gas chromatograph with I (7), although this result was interpreted as either V and phenylethylmalondiamide having similar retention times (5) or the early peak being phenylethylmalondiamide (4).

The reaction pathway leading to the formation of VII has not been elucidated at this time, but it apparently is not formed from the methylated 2-phenylbutyramides. A possibility is that a 1,6-cleavage of II occurs, leading to a product that could form the ester with methanol. It was demonstrated that 1,6-cleavage in addition to 3,4-cleavage can occur in the degradation of barbiturates (11).

In view of the instability of II in solutions of I at high temperatures, the on-column methylation of phenobarbital might be expected to result in the formation of degradation products. The lack of the formation of significant amounts of products other than V indicates that reactions involving methylation and decomposition of I are completed before extensive degradation of II can occur. However, it does suggest that any analytical method for phenobarbital determination involving quantification of a decomposition product should be applied with caution, since the amounts of degradation products depend on experimental parameters such as injection port temperatures and the concentration of the methylating reagent.

EXPERIMENTAL

Materials—Compound II was prepared by reacting 2.3 g of phenobarbital[4] with 11.4 g of methyl iodide and 0.5 g of sodium hydroxide in 10 ml of methanol for 4 hr at ambient temperature. The product, which separated from the mixture upon dilution with water, was recrystallized from ethanol–water. The purified product, mp 88° [lit. (12) mp 84°],

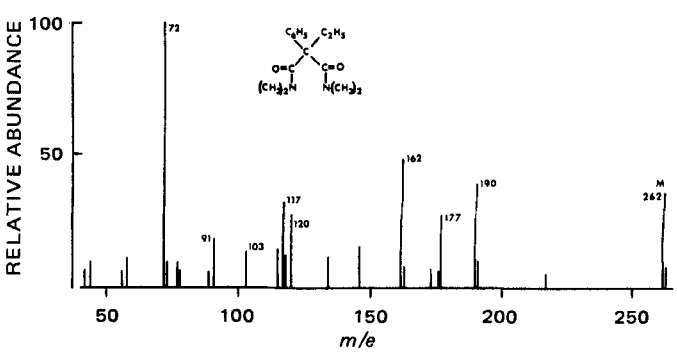

Figure 4—*Mass spectrum of peak D of Fig. 2.*

[4] Merck and Co.

chromatographed as a single peak with the same retention time as that observed by on-column methylation of phenobarbital; its mass spectrum was consistent with that previously reported (13). Compound I was prepared by the method of Brochmann-Hanssen and Oke (2), and deuterated I was prepared in a similar manner using methyl iodide-d_3[5]. A 1.8 *M* solution of I was obtained from a commercial source[6].

2-Phenylbutyryl chloride was prepared by refluxing 10 g of 2-phenylbutyric acid[7] and 15 g of thionyl chloride for 30 min and then distilling off the excess thionyl chloride. The acid chloride was divided into three portions. Compounds V and VI were prepared by reacting portions of the 2-phenylbutyryl chloride with 20 g of methylamide hydrochloride and 25 g of dimethylamine hydrochloride, respectively, which had been previously adjusted to about pH 12. The reaction mixture was allowed to stand overnight, during which time the crude products separated. The mixture was again made alkaline and extracted with ether. The extract was dried with anhydrous sodium sulfate, and the ether was evaporated. Compound V was obtained as a solid, which was purified by treatment with charcoal[8] in ethanol. Then the ethanol was evaporated, and the compound was recrystallized from hexane, mp 97° [lit. (14) mp 95–96°]. Compound VI was obtained as a viscous liquid, which was purified by repeated treatment with charcoal in ethanol.

Compound VII was prepared by refluxing 5 g of 2-phenylbutyric acid, 10 ml of methanol, and 0.2 ml of concentrated sulfuric acid for 4 hr. Then the cooled reaction mixture was poured into 25 ml of water and saturated with sodium bicarbonate. The alkaline solution was extracted with ether and dried overnight with anhydrous sodium sulfate, the ether was evaporated, and the ester was distilled, bp 225° [lit. (15) bp 228°].

Methods—GLC was performed on a 1.82-m × 3.2-mm o.d. glass column packed with 3% OV-17 on Chromosorb WHP[9]. The carrier gas was helium at a flow rate of 30 ml/min, the injector temperature was 250°, and the oven temperature was either maintained at 220° or programmed from 90 to 260° at 10°/min during the chromatography. A flame-ionization detector was used.

In the appropriate experiments, a portion of the effluent was passed through a heated glass jet separator into a mass spectrometer[10] operating in the electron-impact mode with an ionizing voltage of 70 ev. A mass range of 41–500 was automatically scanned at 2 sec/decade approximately every 5 sec during the elution of peaks. Normalized mass spectra of compounds included all ions within the mass range scanned with intensity greater than 5% of the base peak.

Use of Pharmacological Data for Bioavailability and Pharmacokinetic Analyses

PAUL A. KRAMER

Abstract □ The use of pharmacological responses such as pupil diameter for dosage individualization, bioavailability, and pharmacokinetic analyses is becoming more widespread. Attempts to use pupil diameter to assess morphine bioavailability illuminate the fact that multiple responses, nonlinearities, and the condition of the subject can produce misleading results unless the applicability of the method is confirmed.

Keyphrases □ Pharmacological response data—use in bioavailability and pharmacokinetic analyses, situations producing misleading results determined □ Bioavailability—analyses based on pharmacological response data, situations producing misleading results determined □ Pharmacokinetics—analyses based on pharmacological response data, situations producing misleading results determined □ Pupil diameter—measurements used to assess morphine bioavailability □ Morphine—bioavailability analyzed using pupil diameter measurements

Several recent publications underscored the utility of pharmacological response data for performing drug bioavailability and pharmacokinetic analyses (1–3). The theoretical foundation and limits of applicability of the approach were described in detail (2, 4), and this approach was applied successfully to several systems that would have been difficult or impossible to analyze by conventional means (5, 6). An obvious necessity for using pharmacological data is the existence of a clearly defined, measurable, graded response to the administered drug, but the availability and quantitation of such responses are often cited (7) as limiting factors in applying the method.

The objective of this study is to determine the usefulness of pharmacological methods for analyzing the bioavail-

chromatographed as a single peak with the same retention time as that observed by on-column methylation of phenobarbital; its mass spectrum was consistent with that previously reported (13). [a] Using 50 mg/ml in normal saline. [b] Maximum miotic response intensity defined by $(D_0 - D_{t_{max}})/D_0$, where D_0 = baseline pupillary diameter and $D_{t_{max}}$ = diameter at time of maximum miosis. [c] Time of occurrence of maximum miotic response intensity. [d] Measured 30 min after dosing by radioimmunoassay.

ability and pharmacokinetics of narcotics or narcotic antagonists. Narcotics such as morphine and heroin produce pupillary diameter changes that can be quantitated accurately, and the abolition of these changes by narcotic antagonists might also be interpreted as a pharmacological effect and used to assess the bioavailability and absorption characteristics of these agents. The steady-state miotic response to morphine could, for example, be utilized to determine the rate and extent of bioavailability of naloxone from a sustained-release device by analysis of the antagonist's ability to abolish these miotic effects.

Besides a graded pharmacological response, another criterion for using the method is that the rate-limiting process in the production of that response be the drug's ability to gain access to the biophase. All processes must also be entirely reversible, *i.e.*, nonhysteretic and the instantaneous result of a continuous equilibrium between free and receptor-bound drug, and the biokinetic behavior of the drug must be linear. As pointed out previously: "It is not generally sufficient to assume arbitrarily that these conditions are met for any given drug and biological system" (4).

Preliminary results with morphine in rabbits are reported here to underscore the importance of testing these assumptions before using a dose–effect curve to perform pharmacokinetic analyses.

EXPERIMENTAL

Pupillometry—Male New Zealand White rabbits, 3.0–4.0 kg, were fasted overnight and placed in a rabbit restrainer consisting of a rectangular metal box with a neck ring through which the rabbit's head could extend. An IR illuminator provided a constant low level of background light for accentuating the miotic effects of morphine and facilitated drug administration and plasma sampling. All rabbits were acclimated to the experimental setup by putting them through mock experiments for several weeks.

A closed circuit TV camera[1], equipped with an IR light source and a telephoto lens[2], was positioned about 17 cm from the rabbit's right eye and connected to a 22.9-cm television monitor[3]. The near IR light used did not affect pupillary diameter. The camera was set at a fixed focal length and was not altered during the measurements of pupillary diameter. Head movements, which were infrequent, were corrected for by repositioning the camera so that the pupil was returned to perfect focus.

Pupillary diameters were calibrated to the TV screen image by measuring with calipers the TV image size of a series of dots of known diameter located at the position of the rabbit's eye. Pupil diameters were then measured with the calipers on the TV screen and converted to actual diameters using the calibration curve. When a rabbit pupil was not a perfect circle, all measurements were made vertically through the center point of the pupil. Pupil diameters at any given time were measured four times, and the average value was recorded.

Drug Administration—A 23-gauge butterfly infusion set was placed in the marginal vein of one ear. After a brief acclimation, pupillary diameters were measured in the absence of drug to obtain baseline miotic data. Morphine sulfate was then administered in 0.9% NaCl either as a bolus dose or with an infusion pump[4]. Saline solutions buffered to the pH (4.8) of morphine sulfate did not produce a miotic effect when injected into the ear vein as a control.

Plasma Sampling and Radioimmunoassay—Blood samples (100 μl) were collected in heparinized capillary tubes through a small cut in the marginal vein of the opposite ear. The cut was made prior to the experiment and reopened by gentle rubbing to minimize discomfort. Plasma was obtained by centrifugation and was assayed using a commercially available tritiated morphine radioimmunoassay kit[5]. Dialysis studies showed that the procedure measured both free and plasma protein-bound morphine. However, at the high plasma concentrations found in this study during miosis (1–20 μg/ml), a negligible fraction (less than 3%) of the total morphine present was protein bound.

RESULTS

Table I lists the miotic responses of nine rabbits to intravenous doses of morphine sulfate. The intensity of response, I, was taken to be the fractional reduction in pupil diameter at any given time after dosing. Large intrasubject variability was observed, with four rabbits showing substantial responses, four not responding, and one exhibiting a transient response. Plasma morphine levels in nonresponders verified that high plasma levels often did not produce miosis.

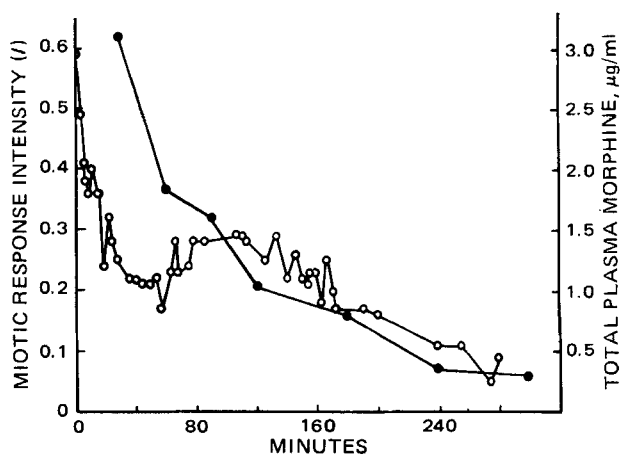

Figure 1—*Typical plot of miotic response intensity (I) as a function of time in a responding rabbit (Rabbit 2) after intravenous administration of a 5-mg/kg dose of morphine sulfate. Each response is the average of four determinations.*

[2] Wollensack Reptar 7.62 cm f/2.5.
[3] Sony.
[4] Harvard dual syringe, model 2681, Millis, Mass.
[5] Roche Diagnostics, Nutley, N.J.

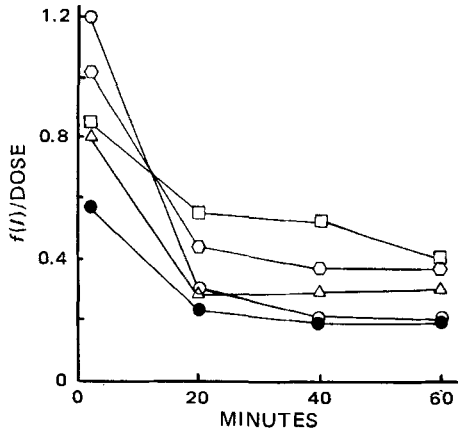

Figure 2—*Congruency test on dose-normalized relative quantities of drug in the biophase, f(I). Each value is the average of four replications on the rabbit that provided the dose–effect data (Fig. 3) used to determine f(I). Doses were 2.0 (□), 3.0 (○), 4.0 (△), 5.0 (○), and 6.0 (●) mg/kg. Curves would be superimposable if system were linear.*

Plots of the time course of I in responding rabbits (Fig. 1) consisted of three phases: an initial rapid decline, a plateau where response was independent of time, and a final slow decline. The relative quantities of drug in the biophase, $f(I)$, at various times were computed from these data (4) and normalized for dose. Plots of dose-normalized values of $f(I)$ *versus* time (Fig. 2) for various intravenous doses are not superimposable as they would be if the system were linear. Therefore, this "congruency test" (4) indicates that the use of a linear compartment model to describe the data is inappropriate. Failure to recognize this nonlinearity can lead to erroneous predictions of expected responses in multiple dose or infusion therapy (see *Discussion*).

When the maximum response intensities (occurring 1–3 min after administration) were plotted as a function of dose, a hyperbolic dose–effect curve was obtained (Fig. 3). The fact that a parallel curve was not obtained when intensities were chosen at times other than t_{max} (such as 30 min) indicated that the response to the drug was hysteretic and not solely the instantaneous result of a continuous equilibrium between free and receptor-bound drug at the site of action ["function of I ratio test" (4)]. Identical challenge doses of morphine were administered to a responding rabbit 1 week after each experiment that contributed to the dose–effect curve (Fig. 3) over several months. No alteration in the miotic response to the challenge dose was observed, indicating that the development of tolerance to morphine did not affect the dose–response relationship.

DISCUSSION

While the rabbit may not be the ideal species for studying the miotic effects of morphine because of the large number of nonresponders, researchers are not totally free to select an appropriate species for many applications; the effective utilization of pharmacological response data ultimately depends on measurements made in a single species, humans.

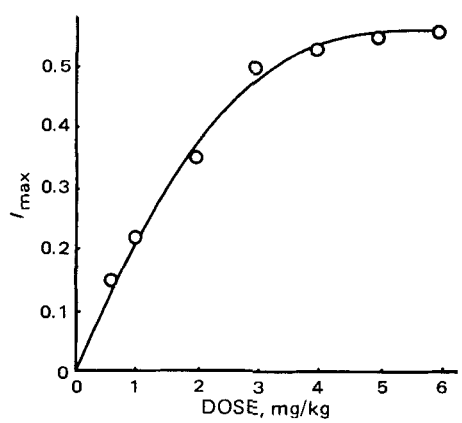

Figure 3—*Intravenous dose–response curve for morphine sulfate in a responding rabbit (Rabbit 2). Response was taken at time of maximum miotic effect (1–3 min), and each response is the average of four determinations. Parallel curves are not obtained using I values obtained at longer times (such as 30 min) after dosing.*

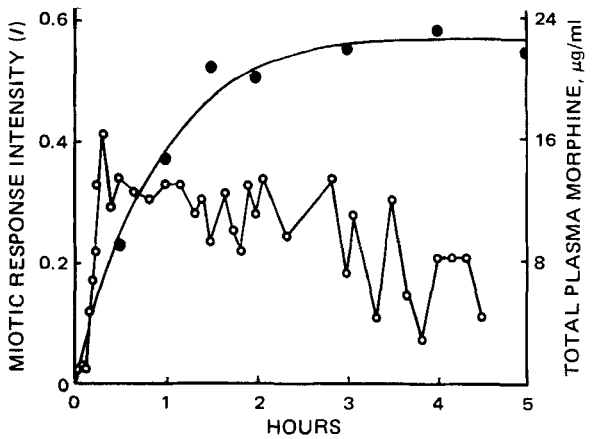

Figure 4—*Miotic response intensity (I) and plasma total morphine levels during an intravenous infusion of morphine sulfate (48 mg/hr) into a responding rabbit (Rabbit 2). Each response is the average of four determinations.*

The presented results are indicative of the potential pitfall one may encounter when a substantial number of nonresponding subjects are encountered for a given drug in a given species. While careful selection of responding subjects or averaging of results over a large number of subjects might prove adequate for some applications such as the determination of bioavailability, dosage individualization using pharmacological responses and attendant calculations specific to a particular subject may not be possible in a substantial fraction of a given subject population.

Even when graded responses are observed in an individual subject, one could easily obtain a dose–effect curve like that shown in Fig. 3, fail to check if the required conditions were met before applying the pharmacological method, and proceed to predict erroneously the outcome of subsequent drug administrations. Figure 4 shows measured plasma total morphine levels during intravenous drug infusion and the miotic response that resulted in a single responding rabbit. This analysis could serve as a model for dosage individualization in a single human or as a check on the validity of using miotic response data to determine the bioavailability from a zero-order sustained-release dosage form.

The responses to the intravenous bolus doses were nonlinear, and one would not expect the miotic response data to be useful in calculating the cumulative amount of drug entering the bloodstream for comparison with what was actually administered. The data confirm that this was indeed the case. The peak miotic responses (Fig. 4) occurred much earlier than peak plasma total morphine levels, and the miotic response to the zero-order infusion never really plateaued but rather continuously diminished with time. Kinukawa (8) also was unable to observe plateau miotic responses during infusions in rabbits.

One must also be aware of factors that may confound the pharmacological response of interest. These factors can render certain pharmacological response baselines so "noisy" that the use of the technique for dosage individualization may be jeopardized. Factors of potential concern include the effects of coadministered drugs in the patient's overall therapy, physiological effects associated with the patient's disease state, and multiple pharmacological responses that are not independent but rather interact. The last factor is illustrated by these data in rabbits. Previous investigators observed a parallelism between morphine miosis and respiratory rate in the rabbit and showed that miosis increased as the carbon dioxide content of plasma rose (9). Thus, observation of the primary pharmacological effect (miosis) appears to be confounded by the depressant effects of the drug. Patients often take several drugs simultaneously, so similar effects in human subjects can be expected to complicate the practical application of pharmacological response methods.

Pharmacological methods of analysis are extremely powerful and hold great potential in systems where they can be quantitated accurately and applied properly. This preliminary study points out that investigators must proceed cautiously in selecting responses to be monitored.

High-Pressure Liquid Chromatographic Analysis of Drugs in Biological Fluids II: Determination of an Antiarrhythmic Drug, Tocainide, as Its Dansyl Derivative Using a Fluorescence Detector

PETER J. MEFFIN ˣ, SANDRA R. HARAPAT, and DONALD C. HARRISON

Abstract □ A sensitive and specific method is described for the determination of a new primary aliphatic amine antiarrhythmic drug, tocainide. Tocainide, together with an internal standard, is selectively extracted from plasma or blood and reacted with dansyl chloride. The highly fluorescent dansyl derivatives are separated using high-pressure liquid chromatography and measured using a fluorescence detector. The method can measure therapeutic and subtherapeutic concentrations of the drug (0.1–5.0 μg/ml of plasma) with a standard deviation of less than 2%.

Keyphrases □ Tocainide—high-pressure liquid chromatographic analysis, plasma or blood □ High-pressure liquid chromatography—analysis, tocainide, plasma or blood □ Dansyl chloride—derivatizing reagent in high-pressure liquid chromatographic analysis of tocainide □ Antiarrhythmics—tocainide, high-pressure liquid chromatographic analysis, plasma or blood

Within the last 5 years, advances in high-pressure liquid chromatography (HPLC), the commercial availability of reliable HPLC equipment, and the development of efficient columns have resulted in the application of HPLC to many analytical problems. However, the application of HPLC to drug analysis has lagged behind the increase in its general use (1, 2). Many papers reported the chromatographic conditions required to separate drugs (3–7), but only a few described the quantitative application of HPLC to the analysis of drugs in dosage forms (8–11).

A major cause of the failure to apply HPLC to the analysis of drugs in biological fluids has been the lack of suitable detectors. UV absorption detectors have been commonly used in HPLC. The microgram or nanogram per milliliter concentrations of many drugs found in plasma after therapeutic doses have confined the use of HPLC analysis to drugs having high molar absorptivities at 254 or 280 nm, the wavelengths most frequently used in these detectors (12–18).

The derivatization of pesticides with reagents yielding fluorescent derivatives and their subsequent HPLC analysis have been reported (19–22). Many drugs unsuited for analysis with UV absorption or fluorescence detectors have primary or secondary amino, phenolic or alcoholic hydroxyl, or aldehyde and keto functions suitable for the formation of fluorescent derivatives. The ability of HPLC to resolve compounds with small differences in molecular structure permits derivatization prior to injection onto the column while still achieving adequate separation of the drug of interest from other molecules reacting with the reagent.

This paper reports the use of HPLC with a commercially available fluorescence detector to determine blood and plasma concentrations of a new primary aliphatic amine antiarrhythmic drug, tocainide [2-amino-*N*-(2,6-dimethylphenyl)propanamide], after derivatization with dansyl chloride [5-(dimethylamino)-1-naphthalenesulfonyl chloride]. The described techniques should be generally applicable to drugs containing derivatizable functional groups. The use of reagents such as dansyl chloride may result in the increased utilization of HPLC for drug analysis in biological fluids, in a manner similar to that which occurred with electron-capture detection in GLC when halogenated acylating and alkylating reagents became available.

EXPERIMENTAL

Reagents—Ethyl acetate[1], hexane[1], acetone[1], and carbon tetrachloride[1] were used as received. Hexane[2], dichloromethane[2], and methanol[2] were used as chromatographic solvents. Stock solutions of tocainide[3] were prepared in 0.05 *N* HCl over the range of 0.1–10 μg/100 μl. The internal standard [2-amino-*N*-(2,6-dimethylphenyl)butanamide hydrochloride[3] (I)] was prepared in 0.05 *N* HCl at a concentration of 0.675 μg/50 μl.

A solution of dansyl chloride (1 mg/ml) was prepared in acetone and

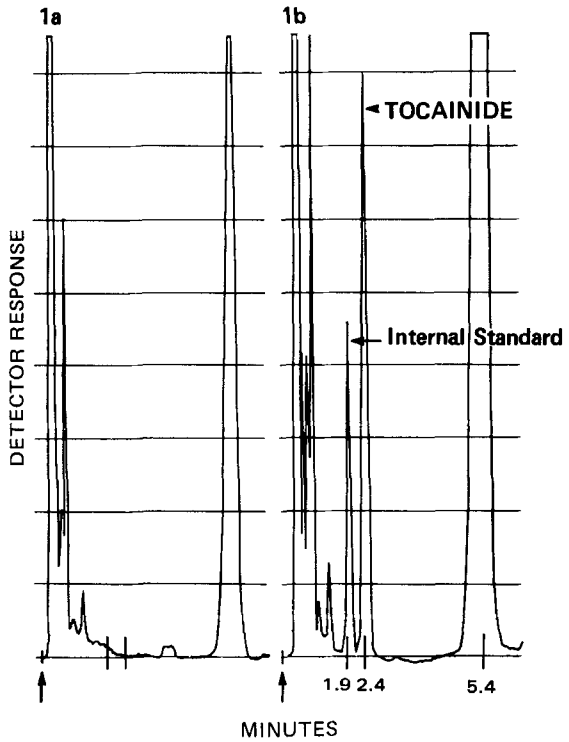

Figure 1—*Chromatograms obtained with plasma from a patient prior to receiving tocainide* (a) *and with a plasma concentration of tocainide of 1.10 μg/ml* (b). *The vertical lines in Fig. 1a correspond to the retention times of tocainide and the internal standard.*

stored in the dark under refrigeration. A fresh solution was prepared each week. Buffer (pH 6.0) was prepared by making a half-saturated solution of disodium citrate in water and adjusting the pH to 6.0 with 85% H_3PO_4. Solutions of 2 and 0.5 *N* NaOH, 0.1 *N* H_2SO_4, and 1 *M* $NaHCO_3$ were also employed.

General Procedure: Extraction and Derivatization of Tocainide—Between 0.05 and 2.0 ml of plasma or whole blood containing an estimated 0.1–5.0 μg of tocainide was transferred with a pipet[4] to a screw-capped[5] centrifuge tube (15 ml) together with 50 μl of internal standard solution containing 0.675 μg of 1, 200 μl of 2 *N* NaOH, and 3 ml of ethyl acetate. The samples were extracted by mixing, using gentle hand-tilting of the tubes for 5 min, followed by centrifugation at 2500 rpm for 10 min to separate the organic and aqueous phases.

The aqueous phase was discarded. Approximately 2 ml of the ethyl acetate phase was transferred to a second tube, which had an elongated cone at its base of nominal 0.1-ml capacity, containing 50 μl of 0.1 *N* H_2SO_4. The tube was mixed[6] for 1 min and centrifuged for 5 min to separate the phases. The ethyl acetate phase was then discarded, and hexane (1 ml) was added to the acidic extract in the tube. The mixing and centrifugation steps were then repeated. The tube was then immersed in a dry ice–acetone bath to freeze the aqueous phase; the hexane, together with the remaining ethyl acetate, was decanted and discarded.

After thawing, 50 μl of 1 *M* $NaHCO_3$ and 200 μl of dansyl chloride solution were added to the tube, which was heated[6] for 30 min at 40°. Sodium hydroxide solution (100 μl of 0.5 *N*) was then added to the tube to convert the remaining dansyl chloride to the sodium salt of 5-(dimethylamino)-1-naphthalenesulfonic acid. Most of the acetone was then removed by heating[6] the tube to 40°, at reduced pressure, for 3 min. Buffer (pH 6.0, 1 ml) was added, together with 200 μl of carbon tetrachloride. The tube was mixed for 2 min and centrifuged for 5 min to separate the aqueous and organic phases. Between 2 and 5 μl of the carbon tetrachloride phase, sampled through the aqueous phase with a 10-μl syringe, was injected into the chromatograph.

Chromatography—A high-pressure liquid chromatograph[7] fitted with a 30-cm × 4-mm i.d. column[8] was used. A fluorometer[9] having both excitation[10] and emission[11] filters was used as a detector. Pressure was maintained in the detector to prevent the formation of bubbles by a 0.5-μm porosity stainless steel frit[12], placed on the efferent side of the detector. One pump of the dual-pump gradient elution chromatograph contained hexane, and the other contained 2% methanol in dichloromethane. An isocratic 1:1 mixture of the two solvents was used in the analysis[13].

Calibration and Accuracy—Calibration curves were constructed by adding known amounts of tocainide and the internal standard to blood and plasma, which were then taken through the analytical procedure. The peak height ratio of tocainide to the internal standard was plotted *versus* the amount of tocainide added to construct the calibration curve. Replicates (10 samples) at tocainide concentrations of 0.3 and 3.0 μg were carried through the procedure to determine the reproducibility of the method.

To calibrate the method and obtain an estimate of accuracy for each particular batch of unknown samples, standards of 0.1, 1.0, and 5.0 μg of tocainide were added to 1-ml samples of blank plasma, which were assayed for tocainide at the same time as the unknown samples. The peak height ratio of each standard was divided by the amount of tocainide added to give a normalized peak height ratio. The average normalized peak height ratio was used to calculate the amount of tocainide in the unknown samples and to estimate accuracy. The effect of sample size on the method was investigated by adding 1.0 μg of tocainide to tubes containing 0.05–2.0 ml of plasma and then assaying for tocainide.

Mass Spectra—Solvent corresponding to the peaks resulting from tocainide and internal standard was collected and reduced to a small volume with a stream of air at room temperature. The mass spectra of these materials were determined by direct probe insertion into the mass spectrometer[14], which had undergone minor modifications to permit use in the chemical ionization mode (23). The reactant gas was isobutane, and the instrument was operated at 200°.

Plasma Level Study—Tocainide tablets were administered to a patient (60 years old, 67 kg) on two separate occasions after approximately 12 hr of fasting. Either 400 or 800 mg of tocainide was administered on each occasion, and food was allowed after 3 hr. Samples of venous blood (10 ml) were withdrawn by means of heparinized containers[15] at appropriate intervals for 60 hr after dosing. The blood samples were centrifuged, and the plasma was transferred to glass containers and stored at −15° until analyzed.

RESULTS AND DISCUSSION

Preliminary work showed that tocainide was satisfactorily and conveniently extracted from plasma by ethyl acetate under strongly alkaline conditions. The conditions for the reaction of tocainide with dansyl chloride were optimized for pH, reagent concentration, solvent composition, temperature, and time using published data on the reaction of the reagent with primary aliphatic amines as a guide (24). The excitation and emission maxima of the peaks corresponding to both tocainide and internal standard in the mixture of solvents used for the chromatography were at 360 and 490 nm, respectively. The excitation and emission filters used in the detector (see *Experimental*) were chosen to minimize the radiation from sources other than the fluorescence of the dansyl derivatives reaching the photomultiplier tube, consistent with a high input in the region of the excitation maxima.

With the solvents used in this analysis, the column[8] required a pressure of 120 atm to produce a flow rate of 300 ml/hr. Under these conditions, the peaks corresponding to tocainide and the internal standard had retention times of 2.4 and 1.9 min, respectively. A large peak at 5.4 min, present also in reagent blanks, prevented injection of samples into the chromatograph at intervals more frequent than 6 min. A typical chromatogram of a patient sample having 1.10 μg of tocainide/ml of plasma is shown in Fig. 1*b*. A chromatogram of blank plasma from this patient is also shown in Fig. 1*a*. In general, no peaks that interfered with the tocainide or internal standard peak, other than the partially resolved small peaks shown in Fig. 1*a*, were encountered in analysis of plasma from some 20 patients. To date, only one column[8] has been used and has shown no deterioration in performance after 6 months of use on a daily basis under the conditions described.

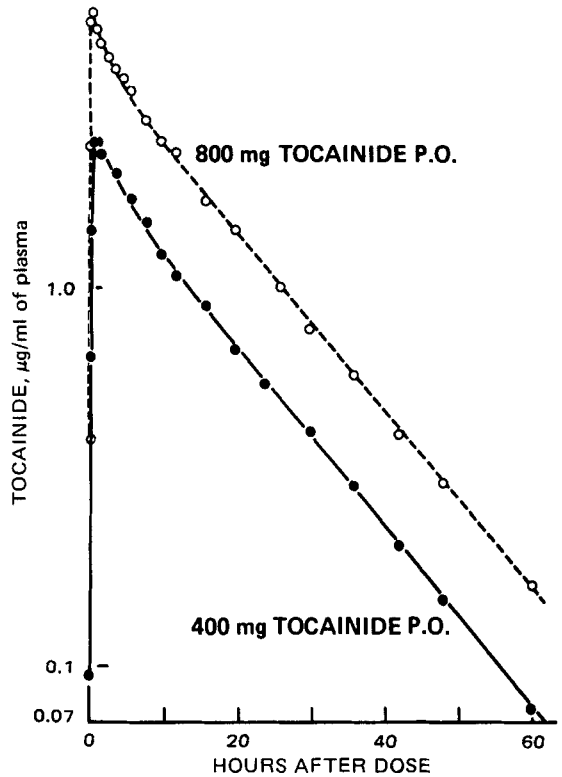

Figure 2—*Plasma concentrations of tocainide at various times in a patient receiving 400 and 800 mg po of tocainide on two separate occasions.*

Calibration curves from water, plasma, and whole blood were superimposable within the error of the method. However, the increased background observed in the chromatograms of blood extracts made the application of the method unreliable at tocainide concentrations below approximately 0.5 μg/ml of blood. The calibration curve from plasma was linear in the 0.1–5.0-μg range and passed through the origin. The average normalized peak height ratio (see *Experimental*) obtained from the daily three-point calibration curves had a mean coefficient of variation of 3.4% for 32 separate calibration curves obtained over approximately 6 months.

This estimate of accuracy probably gives a higher estimate of error than normally would be encountered during the routine application of the method to pharmacokinetic studies, since two of the three calibration points (at 0.1 and 5.0 μg of tocainide/ml of plasma) are at the maximum and minimum of the calibration curve. At the time of analysis of unknown samples, sample volumes were chosen to yield peak height ratios as close to 1.0 as possible to minimize error. Replicates of 10 samples of 3.0 and 0.3 μg of tocainide/ml of plasma had coefficients of variation of 1.1 and 1.8%, respectively.

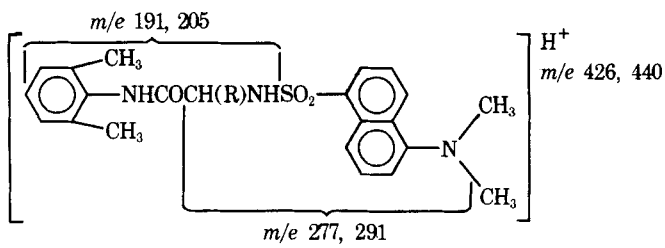
Since it was convenient to take variable volumes of plasma to determine the tocainide concentration in unknown samples, the effect of plasma volume on the peak height ratio of tocainide to the internal standard was examined. The results of this investigation indicated that the peak height ratios were independent of the volume of plasma added between 0.05 and 2.0 ml of plasma, having a coefficient of variation of 3.7% with no systematic trend apparent in the data.

The sensitivity of the method is more than adequate to measure antiarrhythmic concentrations of tocainide, which preliminary data indicate to be in the range of 4–10 μg/ml of plasma. The sensitivity of the presently described method could be increased by extracting the final reaction mixture into a volume of carbon tetrachloride less than the 0.2 ml used or by sampling a larger portion of solvent than the 1–2% injected into the chromatograph. The lower limit of sensitivity is imposed by the competition of solvent with the drug during the derivatization step. It is impractical to scale down the derivatization conditions described (total volume of 300 μl) by more than an order of magnitude. The addition of excess dansyl chloride to compensate for the low concentrations of drug gives rise to an increased solvent signal and produces no net beneficial result.

The described method was applied during the initial clinical evaluation of tocainide in some 20 patients and yielded consistent data after both single and multiple oral doses. The use of the vortex-evaporator[6] in conjunction with the rapid chromatographic analysis allowed the extraction and analysis of 30–35 samples in 8 hr. Typical data are shown in Fig. 2 for a patient who received 400 and 800 mg of tocainide on two separate occasions. Computation of the area under the plasma concentration–time curve from zero to infinite time for the low dose divided by the high dose yields a value of 0.497. This ratio is very close to 0.5, which would be expected if the product of the fraction of the dose absorbed and the clearance of the drug remained constant in this subject.

The use of dansyl chloride as a reagent for the determination of drugs and their metabolites in the biological fluids has been restricted by the lack of suitable methods for the routine separation of the compounds of interest from the many other products of the reaction. Dansyl chloride undergoes many side reactions and, as a result, the compound being assayed may be a minor constituent of the reaction mixture (24). The utility of HPLC in achieving difficult separations is evidenced in the separation of the dansyl derivative of tocainide from its internal standard. The structures of these two compounds, differing by only one methylene unit, are supported by their mass spectra.

The protonated molecular ion, *m/e* 426, was the base peak of the chemical ionization mass spectrum of the dansyl derivative to tocainide (mol. wt. 425). Peaks were also observed at *m/e* 277 (relative abundance 36%) and 191 (55), corresponding to the fragments shown in Structure II (tocainide, R = CH_3; internal standard, R = CH_2CH_3).



II

A similar series of peaks at *m/e* 440 (relative abundance 100%), 291 (30), and 205 (25), 14 amu higher than those obtained for the dansyl derivative of tocainide, was observed for the derivative of the internal standard (mol. wt. 439). All of these data are consistent with the proposed structures of the derivatives.

The ability of HPLC to separate the dansyl derivatives of two such similar compounds may be indicative of the usefulness of the combination of HPLC and fluorescence detectors. The use of similar reagents with this combination might increase significantly the number of drugs that can be measured in biological fluids and the sensitivity with which they can be measured.

NOTES

Cytotoxic and Tumor Inhibitory Agent from *Polygala macradenia* Gray (Polygalaceae): 4′-Demethyldeoxypodophyllotoxin

JOSEPH J. HOFFMANN, RICHARD M. WIEDHOPF, and JACK R. COLE [x]

Abstract □ The chloroform fraction of *Polygala macradenia* exhibited activity against the P-388 lymphocytic leukemia and human epidermoid carcinoma of the nasopharynx test systems. The constituent responsible for this activity was a lignan, 4′-demethyldeoxypodophyllotoxin ($C_{21}H_{20}O_7$). The identity was proven by elemental analysis; PMR, IR, mass spectrometric, and melting-point determinations; and preparation of a derivative.

Keyphrases □ *Polygala macradenia*—chloroform fraction of extract of aerial parts, lignan isolated, evaluated for cytotoxic and tumor inhibitory activity □ 4′-Demethyldeoxypodophyllotoxin—isolated from chloroform fraction of extract of aerial parts of *Polygala macradenia*, evaluated for cytotoxic and tumor inhibitory activity □ Cytotoxic activity—lignan isolated from chloroform fraction of extract of aerial parts of *Polygala macradenia* evaluated □ Tumor inhibitory activity—lignan isolated from chloroform fraction of extract of aerial parts of *Polygala macradenia* evaluated

In the continuing search for plants having tumor inhibitory constituents, it was found that the chloroform fraction of *Polygala macradenia* Gray (Polygalaceae)[1], obtained by partitioning the ethanol extract of the stems, leaves, flowers, and fruit between chloroform and water, showed inhibitory activity against the P-388 lymphocytic leukemia (PS) test system and the human epidermoid carcinoma of the nasopharynx (KB) test system[2].

DISCUSSION

The lignan 4′-demethyldeoxypodophyllotoxin (I), previously isolated from *Polygala paenea* L. (Polygalaceae) (1), was isolated from the chloroform fraction by column chromatography, treatment with activated charcoal, preparative TLC, and recrystallization. The structure of the lignan was confirmed by elemental analysis; PMR, IR, mass spectrometric, and melting-point determinations; and conversion to the known lignan, deoxypodophyllotoxin (II).

Compound I demonstrated an ED_{50} of 0.0012 μg/ml in the KB test system. Activity in the KB system is defined as $ED_{50} \leq 20$ μg/ml (2). In the PS test system, the lignan demonstrated activity of 132% test/control (T/C) at 2.1 mg/kg. Activity in the PS system is defined as an increase in the survival of treated animals over that of control animals resulting in a T/C ≥ 125% (3).

EXPERIMENTAL[3]

Isolation Procedure—The stems, leaves, flowers, and fruit of *P. macradenia* (16 kg) were ground and extracted exhaustively in a Lloyd-type extractor with ethanol. The air-dried residue was partitioned between chloroform (10 liters) and water (10 liters). A 200-g sample of the air-dried chloroform phase was then subjected to alumina III (2 kg) column (7 × 65 cm) chromatography. The solvents used, in increasing order of polarity, were hexane, hexane–benzene (1:1), benzene, chloroform, and methanol; elution was continued with each solvent until the eluent was colorless. The benzene fraction (1.2 g) was subjected to silica gel 60 (75 g) column (3.5 × 24 cm) chromatography, eluting with benzene–ether (4:1). Fractions 16–38 (25 ml each), consisting of one major component according to TLC, exhibited activity.

Isolation of I—The combined active fractions were treated with activated charcoal and purified by preparative TLC with a chloroform–

[1] The plant was collected in Texas in August 1974. Identification was confirmed by Dr. Robert E. Perdue, Jr., Medicinal Plant Resources Laboratory, U.S. Department of Agriculture, Bethesda, Md. A reference specimen is maintained by the U.S. Department of Agriculture.

NOTES

Cytotoxic and Tumor Inhibitory Agent from *Polygala macradenia* Gray (Polygalaceae): 4′-Demethyldeoxypodophyllotoxin

JOSEPH J. HOFFMANN, RICHARD M. WIEDHOPF, and JACK R. COLE [x]

Abstract □ The chloroform fraction of *Polygala macradenia* exhibited activity against the P-388 lymphocytic leukemia and human epidermoid carcinoma of the nasopharynx test systems. The constituent responsible for this activity was a lignan, 4′-demethyldeoxypodophyllotoxin ($C_{21}H_{20}O_7$). The identity was proven by elemental analysis; PMR, IR, mass spectrometric, and melting-point determinations; and preparation of a derivative.

Keyphrases □ *Polygala macradenia*—chloroform fraction of extract of aerial parts, lignan isolated, evaluated for cytotoxic and tumor inhibitory activity □ 4′-Demethyldeoxypodophyllotoxin—isolated from chloroform fraction of extract of aerial parts of *Polygala macradenia*, evaluated for cytotoxic and tumor inhibitory activity □ Cytotoxic activity—lignan isolated from chloroform fraction of extract of aerial parts of *Polygala macradenia* evaluated □ Tumor inhibitory activity—lignan isolated from chloroform fraction of extract of aerial parts of *Polygala macradenia* evaluated

In the continuing search for plants having tumor inhibitory constituents, it was found that the chloroform fraction of *Polygala macradenia* Gray (Polygalaceae)[1], obtained by partitioning the ethanol extract of the stems, leaves, flowers, and fruit between chloroform and water, showed inhibitory activity against the P-388 lymphocytic leukemia (PS) test system and the human epidermoid carcinoma of the nasopharynx (KB) test system[2].

DISCUSSION

The lignan 4′-demethyldeoxypodophyllotoxin (I), previously isolated from *Polygala paenea* L. (Polygalaceae) (1), was isolated from the chloroform fraction by column chromatography, treatment with activated charcoal, preparative TLC, and recrystallization. The structure of the lignan was confirmed by elemental analysis; PMR, IR, mass spectrometric, and melting-point determinations; and conversion to the known lignan, deoxypodophyllotoxin (II).

Compound I demonstrated an ED_{50} of 0.0012 μg/ml in the KB test system. Activity in the KB system is defined as $ED_{50} \leq 20$ μg/ml (2). In the PS test system, the lignan demonstrated activity of 132% test/control (T/C) at 2.1 mg/kg. Activity in the PS system is defined as an increase in the survival of treated animals over that of control animals resulting in a T/C ≥ 125% (3).

EXPERIMENTAL[3]

Isolation Procedure—The stems, leaves, flowers, and fruit of *P. macradenia* (16 kg) were ground and extracted exhaustively in a Lloyd-type extractor with ethanol. The air-dried residue was partitioned between chloroform (10 liters) and water (10 liters). A 200-g sample of the air-dried chloroform phase was then subjected to alumina III (2 kg) column (7 × 65 cm) chromatography. The solvents used, in increasing order of polarity, were hexane, hexane–benzene (1:1), benzene, chloroform, and methanol; elution was continued with each solvent until the eluent was colorless. The benzene fraction (1.2 g) was subjected to silica gel 60 (75 g) column (3.5 × 24 cm) chromatography, eluting with benzene–ether (4:1). Fractions 16–38 (25 ml each), consisting of one major component according to TLC, exhibited activity.

Isolation of I—The combined active fractions were treated with activated charcoal and purified by preparative TLC with a chloroform–

[1] The plant was collected in Texas in August 1974. Identification was confirmed by Dr. Robert E. Perdue, Jr., Medicinal Plant Resources Laboratory, U.S. Department of Agriculture, Bethesda, Md. A reference specimen is maintained by the U.S. Department of Agriculture.

Topical Mosquito Repellents X: 2-Oxazolidones

W. A. SKINNER [x], H. T. CRAWFORD, D. SKIDMORE, and H. I. MAIBACH *

Abstract □ A number of 2-oxazolidones were evaluated for their effectiveness as topical mosquito repellents. Although some compounds approached diethyltoluamide in potency, none was superior.

Keyphrases □ 2-Oxazolidones, various—synthesized, evaluated as topical mosquito repellents □ Repellents, mosquito—various 2-oxazolidones synthesized and evaluated □ Structure–activity relationships—various 2-oxazolidones evaluated as topical mosquito repellents

Several derivatives of 2-oxazolidone have been prepared and evaluated for effectiveness as topical mosquito repellents. The repellency of all of the compounds against female *Aedes aegypti* (yellow fever) mosquitoes was determined by topical application on human subjects as previously described (1).

Since the majority of effective repellents are either amides or esters, it is surprising that carbamates have not been more extensively investigated. The two literature reports (2, 3) of repellent carbamates indicate that simple alkyl derivatives of the type $R_1OC(=O)N(R_2)R_3$ have provided some degree of protection against *A. aegypti* mosquitoes.

The fact that little data were available in a structural area of reported repellent activity, combined with the intriguing similarity between the two most common classes of repellents (esters and amides) and carbamates, encouraged further studies. 2-Oxazolidones were chosen because of practical considerations. Physical properties for a number of 2-oxazolidones were available (proper volatility is an important consideration for a topically applied insect repellent), as were some well-documented synthetic methods for their preparation.

With few exceptions, all compounds tested were prepared *via* published procedures. Table I gives their structures, boiling points, and topical repellency data. Diethyltoluamide was used as the standard repellent in all tests.

EXPERIMENTAL[1]

Preparation of 3-Methoxymethyl-2-oxazolidone (XIX)—Thionyl chloride (9.5 g, 0.08 mole) was placed in a 20-ml flask and stirred at room temperature. 3-Hydroxymethyl-2-oxazolidone (3.2 g, 0.03 mole) was added dropwise over 30 min, and the resulting solution was stirred overnight.

Excess thionyl chloride was removed *in vacuo*, and the residue was distilled. The desired product (bp 100–103°/0.25 mm) was obtained as a colorless oil, 2.9 g; IR (film): 2970, 1740, 1480, 1260, 1031, and 766 cm^{-1}; NMR ($CDCl_3$): δ 5.31 (s, 2H), 4.45 (t, 2H), and 3.74 (t, 2H).

The 3-chloromethyl-2-oxazolidone was not stable at room temperature (loss of hydrogen chloride), but it could be stored for short periods at −20°.

A solution of sodium methoxide in methanol was prepared by the addition of sodium (0.345 g, 0.015 mole) to a stirred solution of dry methanol under nitrogen. 3-Chloromethyl-2-oxazolidone (2.0 g, 0.015 mole) was then added dropwise over 30 min. After stirring for 1 hr at room temperature, TLC indicated no remaining starting material.

The crude reaction mixture was filtered, and methanol was removed under reduced pressure. Distillation (bp 76°/0.20 mm) afforded XIX as a colorless oil, 1.2 g; IR (film): 2930, 1740, 1421, 1259, and 1080 cm^{-1}; NMR ($CDCl_3$): δ 4.70 (s, 2H), 4.45 (t, 2H), 3.71 (t, 2H), and 3.38 (s, 3H).

Anal.—Calc. for $C_5H_9NO_3$: C, 45.79; H, 6.92; N, 10.68. Found: C, 45.82; H, 6.81; N, 10.95.

Preparation of 3-Acetoxymethyl-2-oxazolidone (XX)—Acetic anhydride (2.04 g, 0.02 mole) was added dropwise to a stirred solution of 3-hydroxymethyl-2-oxazolidone (2.0 g, 0.017 mole) in dry pyridine (5 ml). The colorless solution was then stirred overnight at room temperature.

The crude reaction mixture was concentrated *in vacuo;* the residue was dissolved in methylene chloride, washed with saturated sodium chloride, dried, and reconcentrated *in vacuo*. Distillation (100–104°/0.1 mm) afforded XX as a colorless oil, 1.9 g; IR (film): 2950, 1760, 1740, 1420, 1210, 1020, and 940 cm^{-1}; NMR ($CDCl_3$): δ 5.37 (s, 2H), 4.40 (t, 2H), 3.76 (t, 2H), and 2.07 (s, 3H).

[1] Melting points were determined on a capillary melting-point apparatus and are uncorrected. Boiling points were determined using a short path distillation apparatus and also are uncorrected. IR and NMR spectra were taken of all compounds and were consistent with the assigned structures. Elemental analyses were performed by the Microanalytical Laboratory, Department of Chemistry, Stanford University, Stanford, Calif.

Tests on Skin—Compounds were uniformly applied in ethanol to an exposed area of the forearm of a human subject as described previously (1). Repellency was evaluated utilizing female *A. aegypti*.

RESULTS AND DISCUSSION

As discussed previously (11), the utility of a particular compound as a topical insect repellent is determined by its volatility and its inherent intrinsic repellency. Analysis of the data presented in Table I allows structural characteristics resulting in maximum intrinsic repellency as well as a range of volatilities appropriate to the 2-oxazolidones (resulting in maximum duration of repellency) to be elucidated.

Of the 2-oxazolidones examined (Table I), the 3-alkyl derivatives were the best repellents. Compounds containing an unsubstituted nitrogen or those having electronegative atoms or an aromatic substituent in the side chain attached at position 3 all afforded less protection. Since some compounds have boiling points similar to the more repellent 3-alkyl derivatives, the differences in protection time probably reflect differences in intrinsic repellencies or skin absorption differences. The apparent decrease in intrinsic repellency with the introduction of an aromatic substituent (XIII and XIV) was surprising and contradictory to results obtained earlier in the isoquinoline system (11).

Another interesting observation concerns the relationship between steric bulk and repellency. Wright (12) recently suggested that repellents function by blocking moisture-sensitive pores in the cuticle of the mosquito's sensory hairs, thus preventing the sensors from responding normally to the raised humidity levels of a host. The argument is that steric bulkiness is a desirable characteristic of an effective repellent (pore blocker).

The bulky, somewhat spherically shaped, repellents dimethyl phthalate and 2-ethyl-1,3-hexanediol were compared with their essentially long and flat isomers, dimethyl terephthalate and 1,6-hexanediol, both poor repellents. The facts that dimethyl phthalate has a boiling point of 250° while dimethyl terephthalate melts at 142° and that 2-ethyl-1,3-hexanediol and 1,6-hexanediol are not isomers at all were overlooked. In addition, just how the lipophilic repellent dimethyl phthalate is to be attracted to, and held in, the presumably hydrophilic environment of a pore designed to be a water receptor was not discussed.

Data obtained with the 3-alkyl-2-oxazolidones indicate that proper volatility (not steric bulkiness) is the major factor in determining duration of repellency and that there are no great differences in intrinsic repellency among the various 3-alkyl-2-oxazolidones. The sterically bulky 3-*tert*-butyl-2-oxazolidone (VI) had a repellency nearly identical to the much less bulky 3-methyl (IV) and 3-ethyl (V) derivatives. All have similar boiling points. The same is true of the 3-hexyl (IX) and 3-cyclohexyl (XII) compounds. In the alkyl-substituted 2-oxazolidone series, steric bulk and molecular shape did not appear to be major factors determining repellency.

Of interest, however, in this series is the lower protection time attained by the electronegatively substituted compounds (XV–XVII, XX, and XXI) when compared with saturated alkyl derivatives having comparable boiling points.

None of the compounds evaluated here offers a significant advantage in terms of increased protection times over topical repellents currently available. However, interesting synthetic possibilities in the area of the 3-alkyl-2-oxazolidones remain to be explored and will be the subject of future work wherein a membrane *in vitro* system will be used for initial screening rather than human subjects.

GLC Determination of Methenamine in Tablets

J. G. STROM, Jr., and H. W. JUN [x]

Abstract □ A rapid and sensitive GLC method was developed for the quantitative determination of methenamine in tablets. The method was shown to possess several advantages over the official NF assay. After dissolution of the whole tablet in absolute ethanol and addition of an internal standard (pentylenetetrazol), an aliquot was injected into the gas chromatograph for analysis. The sample was chromatographed using a stainless steel column packed with 10% OV-17 on Chromosorb W-HP. Quantitation was achieved by measuring peak heights. The simplicity, directness, extreme rapidity, and accuracy of the method represent an improvement over the official method and the other proposed assays.

Keyphrases □ Methenamine—GLC analysis, commercial tablets □ GLC—analysis, methenamine, commercial tablets □ Antibacterials, urinary—methenamine, GLC analysis, commercial tablets

Methenamine is a urinary antibacterial useful in the long-term therapy of chronic urinary tract infections. The method most often used for the determination of methenamine is based on the hydrolysis of methenamine to formaldehyde and ammonia in a strong acid solution. The formaldehyde may be volatilized by continued heating and the excess acid may be back-titrated, or the liberated formaldehyde may be determined by colorimetry. However, these assays do not differentiate between decomposed and unhydrolyzed methenamine. The NF XIII (1) method involves the back-titration procedure and may be subject to errors due to the uncertainty of complete hydrolysis.

The official NF XIV (2) method and other commonly used techniques (3–5) for the determination of methenamine are based on reaction of formaldehyde with chromotropic acid. Since the decomposition product, formaldehyde, and not the intact methenamine is the analytically available moiety, any formaldehyde released by decomposition and trapped in the tablet is determined with the drug.

Other proposed methods include complexation (6), fluorometry (7), NMR spectroscopy (8), and a 2-hydrazinobenzothiazole reaction (9). This report presents a direct method of analysis of the intact methenamine by GLC. The procedure is rapid, simple, and accurate.

EXPERIMENTAL

Apparatus—A gas chromatograph[1] equipped with a dual flame-ionization detector was used. The chromatographic column was a 3-mm (i.d.) stainless steel coiled column, 1.83 m in length, packed with 10% OV-17 on 80–100-mesh Chromosorb W-HP. The operating temperatures were 250° for the injection port, 190° (isothermal) for the column oven, and 250° for the detector. Nitrogen, with a flow rate of 60 ml/min, was the carrier gas. The flow rates of hydrogen and compressed air were adjusted to optimum sensitivity. The electrometer range was 10^{-10} amp/mv.

Materials and Reagents—Methenamine[2] and pentylenetetrazol[3] were used as received. Methenamine tablets[4,5] from two different companies were purchased in a local pharmacy. Absolute alcohol[6] USP was also used.

Analytical Calibration Curve—Six samples of methenamine[2], 105.0, 210.0, 420.0, 634.0, 845.0, and 1680.0 mg, were weighed. Each sample was placed into a 100-ml volumetric flask, and 10.0 ml of pentylenetetrazol internal standard alcoholic solution (50 mg/ml) was added and diluted to volume with absolute alcohol. Three microliters of each solution was injected into the chromatograph. The calibration curve was then obtained by plotting the known concentrations of methenamine against the corresponding peak height ratios (methenamine–pentylenetetrazol).

Tablet Analysis—Randomly selected tablets were individually wrapped inside glassine weighing paper and crushed. The powder was transferred to a 25-ml volumetric flask containing about 10 ml of absolute alcohol, shaken until dissolved, and diluted to 25 ml with absolute alcohol. Methenamine tablets contain no insoluble excipients and are totally soluble in the alcohol. Aliquots of 4.0 ml each were removed, placed into 10-ml volumetric flasks containing 1.0 ml of pentylenetetrazol internal standard solution (50 mg/ml), and diluted to 10 ml with absolute alcohol. Three-microliter samples of each tablet solution were injected into the chromatograph.

Calculations—The ratio of the peak height of the sample to the internal standard for each tablet solution was determined. The amount of methenamine per tablet was calculated from:

$$\text{mg/tablet} = \frac{R_{sa}}{R_{st}} \times \text{standard weight} \times \text{dilution factor} \quad \text{(Eq. 1)}$$

where R_{sa} is the ratio of the methenamine peak height to the internal standard peak height for the sample solution, and R_{st} is the methenamine–pentylenetetrazol peak height ratio for the known standard solution (5 mg/ml in absolute alcohol).

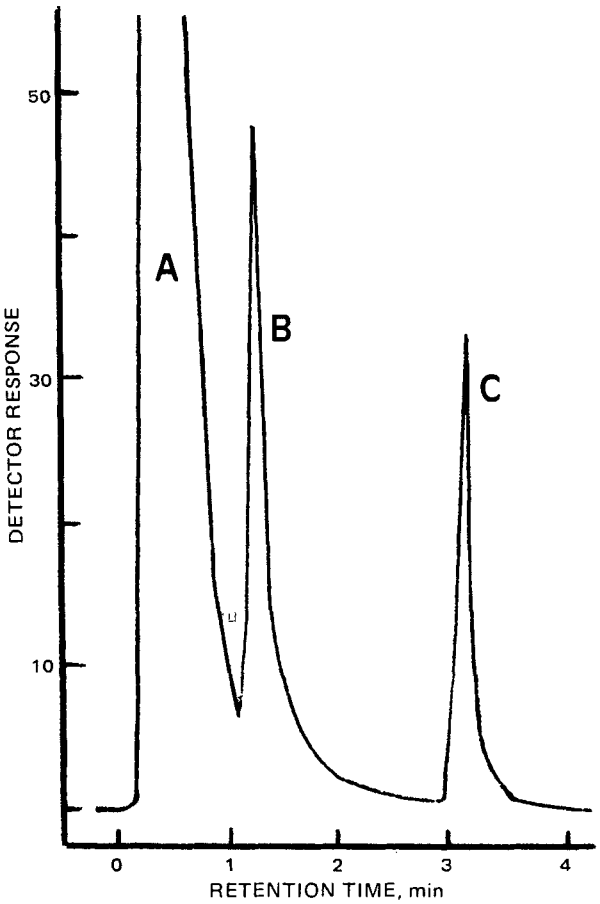

Figure 1—*GLC peaks. Key: A, solvent; B, methenamine; and C, pentylenetetrazol.*

RESULTS AND DISCUSSION

Figure 1 shows a typical gas chromatogram obtained for a tablet solution. Both the methenamine and the calibration marker, pentylenetetrazol, gave sharp, narrow, well-resolved peaks with no tailing. The retention time for each compound was relatively short, 1.2 min for methenamine and 3.0 min for pentylenetetrazol.

This analytical method was specific for intact methenamine. The retention time for formaldehyde, one of the decomposition products, was about 0.8 min. The flame-ionization detector did not respond to ammonia, the other decomposition product.

The linearity of the system was shown by analyzing various amounts of methenamine over the concentration range of 1.05–16.80 mg/ml with a constant amount of pentylenetetrazol (5 mg/ml). The correlation coefficient of the linear regression line was 0.998.

Results obtained by applying the proposed GLC method to known weights of methenamine are presented in Table I. The overall recovery for the five samples was 101.0 ± 1.85% (*SD*).

Six individual tablets from each commercial product were analyzed,

Table I—Assay Data for Known Amounts of Methenamine[a]

Amount Weighed, mg/ml	Amount Found, mg/ml	Recovery, %
3.10	3.12	100.6
3.75	3.85	102.6
4.80	4.92	102.5
5.30	5.20	98.1
5.60	5.68	101.4
	Mean recovery, %	101.1
	SD	1.85

Table III—ANOVA Table for the Assayed Weight of Methenamine Tablets

Source	*df*	*SS*	*MS*	F_0
Companies	1	20.803	20.803	2.051
Error	10	101.427	10.143	—
Total	11	122.230	—	—

and the data are summarized in Table II. The ANOVA values for the assay of the tablets, based on a one-factor analysis of variance, are given in Table III. From the *F* table (10), $F_{1,10(0.05)}$ is 4.96. The statistical analysis of the data shows that there was no detectable difference in the means of the two different commercial tablets at the 5% level of significance.

The method presented represents an improvement over the official method and over other assays for methenamine. The GLC procedure is applicable to methenamine dosage form analysis and is simple, direct, and rapid.

Comparison of Two Spectrofluorometric Procedures for Quinidine Determination in Biological Fluids

THO HUYNH-NGOC * and GERARD SIROIS ˣ

Abstract □ Different methods for the spectrofluorometric determination of quinidine in plasma and urine were studied. The alkaline washings of plasma and urine extracts remove fluorescent metabolites, as shown by TLC analysis of urine extracts, and do not lead to a significant loss of alkaloids. The spectrofluorometric assays without alkaline washings of the benzene extract averaged 18% higher than the assays with alkaline washings. Since unchanged quinidine and hydroquinidine are responsible for antiarrhythmic activity, the method with alkaline washing is more appropriate for the control of quinidinemia than are other methods. The therapeutic plasma concentration range becomes 0.8–2.5 μg/ml with this method.

Keyphrases □ Quinidine—spectrofluorometric analysis, human plasma and urine, effect of alkaline washings □ Spectrofluorometry—analysis, quinidine, human plasma and urine, effect of alkaline washings □ Antiarrhythmics—quinidine, spectrofluorometric analysis, human plasma and urine, effect of alkaline washings

Quinidine, in spite of its well-known potential toxicity, remains a useful antiarrhythmic agent. The incidence of toxic reactions gets higher with increasing plasma drug concentration. Several spectrofluorometric methods were reported (1) for the estimation of quinidine in plasma, not only to prevent toxic levels but also to ensure adequate plasma concentrations of unchanged quinidine, which is responsible for activity.

The methods currently used involve either a protein precipitation with metaphosphoric acid and a direct spectrofluorometric determination on the filtrate (2–4) or an extraction with benzene followed by a transfer of the drug to sulfuric acid for spectrofluorometric determination (5). Although benzene is the most specific extraction solvent for unchanged quinidine, Armand and Badinand (6) found that alkaline washings of benzene extracts of dog urine removed an additional amount of metabolites without reducing significantly the amount of quinidine.

The purposes of this investigation were to study the effect of alkaline washings of the benzene extract of human plasma and urine samples containing known amounts of quinidine and to compare the data obtained with and without alkaline washing of the benzene extract of plasma and urine samples of patients treated with quinidine.

EXPERIMENTAL

Materials—Commercial quinidine base[1] was used without further purification. Benzene was spectrophotometric grade. All other chemicals were analytical grade.

Spectrofluorometric Determinations of Quinidine—Heparinized blood samples[2] from patients treated with quinidine were centrifuged. The plasma samples were kept at −20° until assayed by the method of Armand and Badinand (6) with and without alkaline washing of the benzene extract. In this procedure, 1 ml of plasma is alkalinized with 1 ml of 0.1 *N* NaOH. Then 30 ml of benzene is added. The resulting mixture is vigorously shaken (30 min), and the clear benzene extract is removed and washed twice by shaking for 5 min with 10 ml of 0.1 *N* NaOH. Twenty milliliters of this washed extract is mixed with 3 ml of 0.1 *N* H_2SO_4. The mixture is shaken for 10 min, and the sulfuric acid extract is analyzed by spectrofluorometry[3].

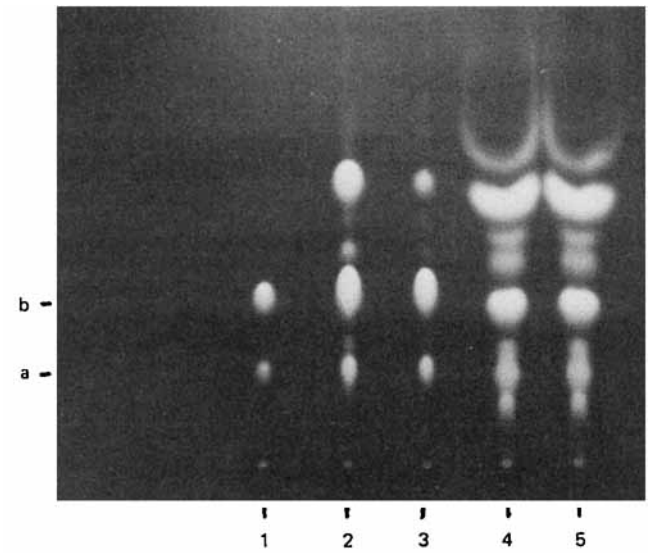

Figure 1—*Separation of hydroquinidine, quinidine, and their metabolites from urine by TLC. Key: 1, commercial quinidine containing hydroquinidine; 2, benzene extract; 3, benzene extract with alkaline washings; 4, pentanol–benzene (1:1) extract; and 5, pentanol–benzene extract with alkaline washings. Fluorescence bands for hydroquinidine and quinidine are designated by a and b, respectively (6).*

The precision and reproducibility of the alkaline washing procedure were evaluated by adding known amounts of quinidine to human plasma[2] and urine and by comparing the results obtained in the plasma with those of the protein precipitation method of Brodie and Udenfriend (2) in the same drug concentration range. The urine of one patient was also extracted with a pentanol–benzene (1:1) solvent mixture, which has been found optimal for the simultaneous extraction of quinidine, hydroquinidine, and their metabolites (7).

TLC—One urine sample from a patient receiving only quinidine was analyzed by TLC. Two 1-ml aliquots of this urine were alkalinized with 1 ml of 0.1 *N* NaOH; one was extracted with 25 ml of benzene and the other was extracted with 25 ml of pentanol–benzene (1:1). Ten milliliters of each organic extract was then washed twice with 5 ml of 0.1 *N* NaOH. Ten milliliters of the four washed and unwashed organic extracts was evaporated, and the residue was dissolved in 0.5 ml of the corresponding organic solvent.

Two hundred microliters of each resulting solution was applied on a silica gel plate[4]. Two hundred microliters of a benzene solution, containing 50 mg of commercial quinidine/liter, was also run for comparison. The chromatoplates were developed by the ascending technique with methanol (6) as the developing solvent. Fluorescent spots representing quinidine, hydroquinidine, and their metabolites were observed under UV light.

RESULTS AND DISCUSSION

The precision and reproducibility of the analytical procedure were verified by adding known amounts of commercial quinidine to human plasma and urine samples.

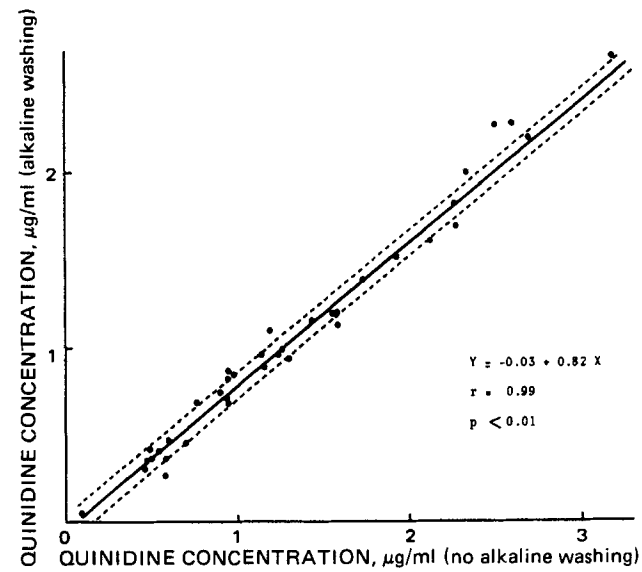

Figure 2—*Correlation of plasma quinidine concentration as measured by the method of Armand and Badinand (6) with (abscissa) and without (ordinate) alkaline washing of the benzene extract. The two dashed lines (- - -) parallel to the regression line (—) have a vertical distance from it that is equal to the standard error of estimate.*

When quinidine was added to eight plasma samples to obtain 0.1–5-µg/ml concentrations, the mean values of the percent found were 98.5 (*SD* = 4.1 and *CI*[5] = 3.4) and 100.9 (*SD* = 3.2 and *CI* = 2.6) for the protein precipitation method and benzene extraction procedure with alkaline washing, respectively. These results demonstrate that there is a good recovery of quinidine and hydroquinidine (8) with no significant loss of the alkaloids resulting from the alkaline washings of the benzene extract.

The addition of 0.1–150 µg/ml of quinidine to 14 urine samples led to a mean percent of 98.1 (*SD* = 2.5 and *CI* = 1.5) when the benzene extract was washed with an alkaline solution. The reproducibility of the extraction procedures was also checked by five measurements on the patient urine sample used for TLC analysis. The mean values of urine concentrations found in the benzene extract without and with alkaline washing were 109.75 (*SD* = 3.75 and *CI* = 4.66) and 66.43 (*SD* = 3.08 and *CI* = 3.83) µg/ml, respectively. On the other hand, mean concentration values of 182.08 (*SD* = 3.53 and *CI* = 439) and 182.92 (*SD* = 4.80 and *CI* = 5.97) µg/ml were found in the unwashed and washed pentanol–benzene (1:1) extract, respectively, of the same urine sample. In this last extraction method, the concentration of fluorescent quinidine molecules (quinidine, hydroquinidine, and their metabolites) is not reduced by the alkaline washings because of their high solubility in the pentanol–benzene solvent system.

The importance of alkaline washings of the benzene extract is illustrated in Fig. 1 where quinidine, hydroquinidine, and their metabolites were separated by TLC. In this figure, the metabolite spots have nearly completely disappeared with this treatment. This figure demonstrates also that the high quinidine concentration values obtained with the pentanol–benzene extraction solvent mixture result from fluorescent metabolites which are not removed by alkaline washing of the extract.

Thirty-seven plasma samples obtained from patients treated with quinidine were examined to test the importance of the alkaline washing. The plasma quinidine concentrations found spectrofluorometrically from washed and unwashed benzene extracts are shown in Fig. 2. As indicated by the regression line, the unwashed benzene extract assay averaged 18% higher than the washed benzene extract assay. With this additional removal of fluorescent metabolites, the quinidine therapeutic plasma concentration range would then become 0.8–2.5 µg/ml instead of 1–3 (9) or 3–7 (10) µg/ml. Since unchanged quinidine and hydroquinidine are responsible for antiarrhythmic activity (1), the procedure of Armand and Badinand (6) should be considered more appropriate than other methods for the control of quinidinemia. Furthermore, there is always the possibility in clinical practice that the rate of quinidine metabolism can be different in some patients because of physiopathological conditions or drug interactions.

[5] Confidence interval of the mean at the 0.05 level of significance.

Alkaloids of *Glaucium oxylobum* Boiss and Buhse, Population Ab-Ali

A. SHAFIEE ˣ, I. LALEZARI, and M. MAHJOUR

Abstract □ *Glaucium oxylobum* Boiss and Buhse, population Ab-Ali, was demonstrated to contain one major alkaloid, glaucine (0.7%), and two minor alkaloids, *O*-methylatheroline and predicentrine, in the aerial parts. The root also contains protopine. Glaucine and *O*-methylatheroline were detected for the first time in this species, and predicentrine was detected for the first time in the *Glaucium* genus.

Keyphrases □ *Glaucium oxylobum*—aerial parts and roots, alkaloids isolated and identified □ Alkaloids—isolated and identified in *Glaucium oxylobum* aerial parts and roots

As part of chemotaxonomic studies of Iranian wild *Papaveraceae* (1–4), the alkaloids of *Glaucium oxylobum* Boiss and Buhse[1], population Ab-Ali (a perennial wild plant scattered in Ab-Ali, located on the southern slopes of the Alborz mountains north of Tehran at about 2200 m above sea level), were isolated and identified. The height of the plant is 50–100 cm. The plant blooms from April to September. The four petals are yellow at the edge and orange at the bottom with a brown spot at the base of each petal.

EXPERIMENTAL

Plant Material—The whole aerial parts or roots were collected during May, air dried in the shade, then dried at 60° to a constant weight, and powdered so that all material possesses a mesh size not greater than 0.5 mm. The aerial parts and roots were extracted separately.

Extraction—Powdered plant material, 200 g, was moistened with 200 ml of 15% NH_4OH, stirred with 600 ml of chloroform at room temperature for 1 hr, and filtered. The extraction was repeated four times. After evaporation of the solvent, the residue was extracted with 100 ml of 5% sulfuric acid. The solution was filtered and extracted with petroleum ether (3 × 20 ml) to remove the colored material. The aqueous layer was made alkaline with 15% NH_4OH and extracted with chloroform (4 × 50 ml). Evaporation of the solvent gave 1.8 g of the crude alkaloids.

RESULTS AND DISCUSSION[2]

Chromatography of the crude alkaloids from the aerial parts [TLC, silica gel, ethyl acetate–methanol–ammonia (85:10:5)] gave glaucine (I, 1.4 g, 0.7%), mp 118–119° [lit. (5) mp 117–118°], mixed melting point with an authentic sample 117–119°. For the hydrobromide, the melting point was 239–241° (ethanol) [lit. (6) mp 241°]. The UV, IR, and NMR data of the separated alkaloid were identical with those reported previously (7, 8).

Glaucine was isolated by Bubeva-Ivanova *et al.* (9) from *Glaucium flavum* and claimed to have antitussive, spasmolytic, antiedematous, and tranquilizer effects but no depressing activity.

O-Methylatheroline (II) was obtained as a minor alkaloid, mp 224° [lit. mp 225–227° (10), 227–229° (11), and 235–236° (12)]. The IR spectrum was identical to the published spectrum for II (12), and the UV and

III: R_2 = H, R_1 = R_3 = R_4 = CH_3
IV: R_1 = H, R_2 = R_3 = R_4 = CH_3 (thaliporphine)
V: R_3 = H, R_1 = R_2 = R_4 = CH_3
VI: R_4 = H, R_1 = R_2 = R_3 = CH_3 (*N*-methyllaurotetanine)

NMR spectral data were in accord with published data (11, 13). The mass spectrum had major peaks at *m/e* 351, 336, 320, 308, and 234.

Anal.—Calc. for $C_{20}H_{17}NO_5$: C, 68.38; H, 4.84; N, 3.99. Found: C, 68.21; H, 4.93; N, 4.05.

A second minor alkaloid was an oil which could not be crystallized in various solvents. Its hydrochloride salt was a solid, mp 214–217° (methanol–ethyl acetate). As the free base, the UV spectrum showed λ_{max} (ethanol) 301 (log ϵ 4.11) and 280 (4.15) nm and λ_{min} 252 (3.73) nm; UV λ_{max} (ethanol, 2 drops of 10% NaOH): 301 and 280 nm; NMR ($CDCl_3$): δ 2.50 (s, 3H, NCH_3), 3.56 (3H, s, OCH_3), 3.88 (s, 3H, OCH_3), 3.90 (s, 3H, OCH_3), 6.56 (s, 1H, aromatic), 6.73 (s, 1H, aromatic), and 7.88 (s, 1H, aromatic) ppm. The mass spectrum had peaks at *m/e* 341 (M^+), 340 (M − 1), 326 (M − CH_3), 310 (M − OCH_3), 298 (M − CH_2=NCH_3), 165, 152, and 149.

Anal.—Calc. for $C_{20}H_{23}NO_4$: C, 70.38; H, 6.74; N, 4.11. Found: C, 70.42; H, 6.68; N, 4.02.

The UV spectrum was similar to that of dicentrine and glaucine (7); in addition, its mass spectrum fragmentation pattern was characteristic of aporphine alkaloids (14). The three singlet aromatic protons in the NMR spectrum showed that adjacent aromatic protons did not exist; in addition, the most deshielded aromatic proton must be at C_{11}. The NMR spectrum was in agreement with the four possible structures (III–VI) for this compound.

The UV spectrum in a basic solution did not show a hypsochromic shift given above, indicating that the hydroxyl was not at C-9. In addition, the spectral data for this alkaloid were different from the data for IV–VI (8, 15, 16). The UV, NMR, and IR (chloroform) spectra were identical with the spectra of predicentrine[3], which was synthesized by Charubala *et al.* (17). This alkaloid is, therefore, predicentrine. It was reported to exist also in *Ocotea macropoda*[4].

From the root of the plant, protopine was also isolated, mp 205–207° [lit. (18) mp 207°], mixed melting point with an authentic sample 205–207°. The NMR spectrum was identical with the one reported previously (19).

[1] The plant was identified by Dr. C. R. Gunn, Plant Taxonomy Laboratory, Plant Genetics and Germplasm Institute, Agricultural Research Service, Beltsville, MD 20705. A herbarium sample was deposited in the Herbarium of the College of Pharmacy, Tehran University.

[2] Melting points were taken with a Koffler hot-stage microscope and are uncorrected. UV spectra were recorded on a Varian Techtron 635 instrument. NMR spectra were taken with a Varian T-60A instrument, using tetramethylsilane as the internal standard. Mass spectra were recorded on a CH5 spectrometer at Arya-Mehr Technical University. IR spectra were obtained with a Leitz model III spectrograph.

[3] The spectra of predicentrine was provided by Professor B. R. Pai, Presidency College, Madras, India.

A literature survey (20, 21) revealed that glaucine and *O*-methylatheroline had not been found previously in *G. oxylobum* and predicentrine had not been detected in the genus *Glaucium*.

Synthesis of 5,6-Benzo-2-azabicyclo[2.2.2]octane Derivatives as Potential Benzomorphan-Type Analgesic Agents

RONALD F. BORNE [x], SAY-JONG LAW, PHILIP W. WIRTH, and JAMES C. MURPHY

Abstract □ The synthesis of two *N*-substituted 5,6-benzo-2-azabicyclo[2.2.2]octane analogs of benzomorphan-type analgesics *via* benzyne addition to appropriate *N*-substituted *N*-alkyl-2-pyridones is described. Neither derivative possessed observable analgesic activity at the doses tested.

Keyphrases □ 5,6-Benzo-2-azabicyclo[2.2.2]octanes, *N*-substituted—synthesized, analgesic activity evaluated, mice □ Structure–activity relationships—*N*-substituted 5,6-benzo-2-azabicyclo[2.2.2]octanes synthesized, analgesic activity evaluated, mice □ Analgesic activity—*N*-substituted 5,6-benzo-2-azabicyclo[2.2.2]octanes evaluated, mice

The structural features of narcotic analgesics related to morphine have been well documented (1, 2). Studies of structure–analgesic activity requirements within the benzomorphan-type analgesics have also received considerable attention. While the structural features of benzomorphans are generally incorporated in structures such as I, many analogous structures have been demonstrated to possess significant analgesic activity. For example, 2-methyl-6,7-benzomorphan (II) (3), 7-methoxy-2-methyl-B-norbenzomorphan (III) (4), and 5-methano-3-methyl-6-phenyl-1,2,3,4,5,6-hexahydro-3-benzazocine (IV) (5)

possessed analgesic potencies comparable to that of codeine.

Compounds II–IV all lack "quaternary central carbon atoms," a structural feature once thought to be essential for activity (1, 2). Additionally, II and IV lack phenolic functions, and IV contains only a one-carbon separation from the basic nitrogen and the central carbon atom. While the active benzomorphans are characterized by the presence of a basic nitrogen atom 4.1 Å from the center of an

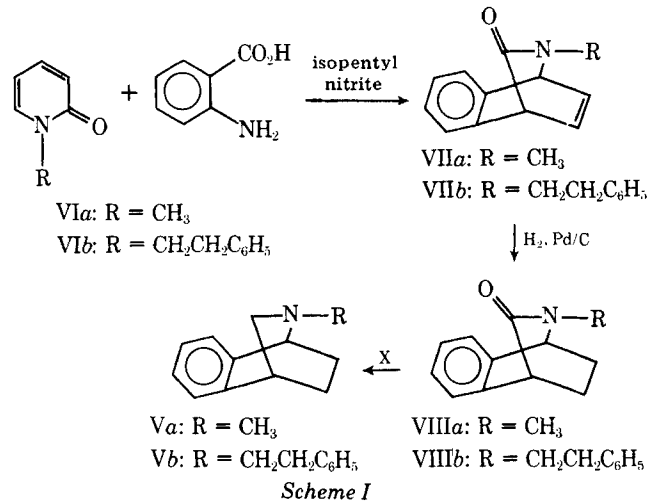


Scheme I

aromatic ring and 1.5 Å above the plane of that ring, derivatives possessing these characteristics alone proved to be inactive as analgesics (6). This discussion illustrates the flexibility of structural features for analgesic activity within the benzomorphan series.

These factors, along with interest in 2-azabicyclo[2.2.2]-octane analogs of analgesics (7), prompted the preparation and evaluation of V*a* and V*b* for analgesic and central nervous system (CNS) activity. These analogs lack a quaternary carbon atom, a phenolic function, and a two-carbon separation between the basic nitrogen and the central carbon atom but do orient the basic nitrogen 3.6 Å from the center of the aromatic ring and 1.3 Å above the plane of this ring. Additionally, these analogs may be considered as semirigid analogs of phenethylamine derivatives.

DISCUSSION

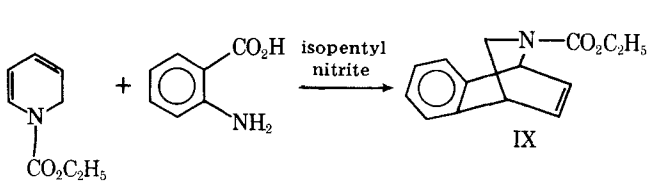
Chemistry—The synthetic approach to V*a* was essentially that previously reported (8) with some modifications (Scheme I). Benzyne was generated by the action of isopentyl nitrite on anthranilic acid in the presence of *N*-methyl-2-pyridone (VI*a*). The adduct, VII*a*, was obtained in only 10% yield. Subsequent catalytic hydrogenation gave VIII*a*, which was further reduced with sodium bis(2-methoxyethoxy)aluminum hydride (X) to give V*a*.

The synthesis of V*b* was somewhat more difficult. The synthesis of IX (Scheme II) was attempted with the anticipation that reduction, carbamate hydrolysis, and subsequent reductive alkylation with phenylacetaldehyde would give V*b*. However, condensation of benzyne with *N*-carbethoxy-1,2-dihydropyridine yielded no isolatable adduct. Thus, VI*b* was prepared by the oxidation of the quaternary salt obtained from pyridine and 2-bromoethylbenzene with potassium hydroxide and potassium ferricyanide. Condensation of this pyridone and benzyne gave only a 7% yield of VII*b*. Isolation of the diazonium salt prior to benzyne generation did not improve the yield of the adduct. Catalytic hydrogenation of VII*b* gave VIII*b* in a 92% yield. Subsequent lactam reduction gave V*b* in an overall 6% yield from VI*b*.

Pharmacology—Compounds V*a* and V*b* were evaluated for analgesic activity in mice using the D'Amour–Smith (9) tail-flick method. The toxicity of both compounds limited the maximum doses at which they could be evaluated. Both compounds failed to display analgesic activity, V*a* at 25 mg/kg and V*b* at 50 mg/kg, but produced some CNS effects.

Compound V*a* was tested at 50, 25, and 10 mg/kg. The 50-mg/kg dose was lethal to all subjects within 12 min of injection. Death was preceded by profuse salivation, Straub tail, and tremors. The 25-mg/kg dose produced tremors which lasted for about 20 min following injection. Consistent failure in tests involving muscular coordination was seen at 25 mg/kg, but spontaneous activity and reactivity were not affected. The 10-mg/kg dose produced no effects within the scope of this screen.

Compound V*b* was tested at 100, 50, and 25 mg/kg. All mice injected with 100 mg/kg died within 10 min of injection following clonic convulsions. The mice injected with 50 mg/kg showed a loss of spontaneous activity as evidenced by observer ratings and failures on the dish, pedestal, and chimney tests. Both the finger touch and tail pull tests showed a loss of reactivity. No ptosis or loss of skeletal muscle tone was observed. The pinna reflex was abolished, indicating that the effect of V*b* at 50 mg/kg may not be purely depressant. One death occurred within 24 hr at 50 mg/kg, while only marginal effects and no lethality were observed at 25 mg/kg.



Scheme II

EXPERIMENTAL[1]

2-Methyl-5,6-benzo-2-azabicyclo[2.2.2]oct-7-en-3-one (VII*a*)—A solution of anthranilic acid (20.0 g, 0.145 mole) in 125 ml of acetone was added dropwise over 1.0 hr to a refluxing solution of 15.0 g (0.137 mole) of VI*a* and 20.0 g (0.17 mole) of isopentyl nitrite in 400 ml of dichloromethane. The reaction mixture was refluxed an additional 1.0 hr and the resulting solution was washed with 2 × 200 ml of 10% hydrochloric acid and 2 × 200 ml of water. The organic phase was dried over sodium sulfate and evaporated to give a dark oil.

The oil was taken up in benzene, placed on a basic alumina column[2] (80–200 mesh, 520 g), and eluted with ether–benzene (1:1). Isopentyl alcohol eluted first, followed by the adduct, VII*a* (2.5 g, 10%); NMR: δ 3.0 (s, 3H, NCH_3), 4.8 (doublet of doublets, 1H, J = 2.5 Hz), 5.2 (doublet of doublets, 1H, J = 2.5 Hz), and 7.1–7.7 (m, 6H, olefinic and aromatic); IR (liquid film): 1680 cm^{-1} (NC=O).

2-Methyl-5,6-benzo-2-azabicyclo[2.2.2]octan-3-one (VIII*a*)—To a solution of VII*a* (4.8 g, 0.026 mole) in 100 ml of ethanol was added 10% palladium-on-charcoal (0.48 g), and the resulting mixture was hydrogenated at 3.1 kg/cm^2. The mixture was filtered through diatomaceous earth[3], and the filtrate was evaporated to give a clear oil (3.9 g, 81%); NMR: δ 2.95 (s, 3H, NCH_3), 4.0 (s, 1H, NCH), and 7.25 (s, 4H, aromatic); IR (liquid film): 1680 cm^{-1} (NC=O).

2-Methyl-5,6-benzo-2-azabicyclo[2.2.2]octane (V*a*)—A solution of VIII*a* (2.3 g, 0.012 mole) in benzene (40 ml) was added dropwise to X (14 ml of a 70% benzene solution, 0.048 mole), and the resulting solution was refluxed for 3 hr. Ethanol was added to the cooled, stirring solution until bubbling ceased. Water was added until precipitation ceased. The precipitate was removed by filtration, and the filtrate was separated into organic and aqueous phases. The aqueous phase was extracted with chloroform (2 × 30 ml); the organic extracts were combined, dried over sodium sulfate, and evaporated to give a residue.

Distillation of the residue gave an oil (1.0 g, 47%), bp 70°/0.45 mm; NMR: δ 1.27–2.5 (m, 5H, H at C-7, C-8, and C-3), 2.03 (NCH_3), 2.97 (broad, 1H, H at C-4), 3.2–3.4 (doublet of doublets, 1H, H at C-3), 3.6 (broad, 1H, H at C-1), and 7.2–7.4 (broad, 4H, aromatic); *m/e* 173 (M+) and 144 (base). The hydrochloride salt was prepared in the normal manner, mp 236.5–238.5°.

Anal.—Calc. for $C_{12}H_{16}ClN$: C, 68.72; H, 7.69; N, 6.68. Found: C, 68.63; H, 7.73; N, 6.53.

1-(2-Phenylethyl)-2-pyridone (VI*b*)—To a solution of 13.0 g (0.049 mole) of 1-(2-phenylethyl)pyridinium bromide (prepared from pyridine and 2-bromoethylbenzene, mp 123–125°) in 60 ml of water was added a solution of 65.0 g (0.2 mole) of potassium ferricyanide in 400 ml of water. After addition was complete, a yellow suspension was obtained. Benzene (125 ml) was added, and the reaction mixture was warmed to 40°. A so-

[1] All melting points were taken on a Mel-Temp apparatus and are corrected. IR spectra were obtained with a Beckman IR-33 spectrophotometer. NMR spectra were taken in deuterochloroform on a Jeolco C-60-HL spectrometer, and values are reported in parts per million (δ) from tetramethylsilane as the internal standard. Mass spectral data were obtained on a Dupont model 21-492 spectrometer. Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tenn. Sodium bis(2-methoxyethoxy)aluminum hydride (Red Al) was purchased from Aldrich Chemical Co.

[2] Fisher.

[3] Celite.

lution of potassium hydroxide (27.0 g, 0.5 mole) in 75 ml of water was added dropwise, and the resulting mixture was stirred for 2 hr.

The organic layer was separated, and the aqueous layer was extracted with benzene (2 × 75 ml). The organic phases were combined, dried over sodium sulfate, and evaporated to give a tan solid (6.5 g, 66%). Recrystallization from benzene–petroleum ether yielded colorless crystals, mp 104–106°; IR (mineral oil): 1660 cm^{-1} (C=O).

2-(2-Phenylethyl)-5,6-benzo-2-azabicyclo[2.2.2]oct-7-en-3-one (VII*b*)—A solution of anthranilic acid (61.6 g, 0.45 mole) in 500 ml of ethanol was cooled to 5°. Concentrated hydrochloric acid (35 ml) was added followed by isopentyl nitrite (85 ml). The temperature was maintained below 10° throughout addition. Ether (500 ml) was added; the resulting diazonium salt was collected by filtration, washed with anhydrous ether, and suspended in 650 ml of dichloromethane. To the suspension were added 18.3 g (0.092 mole) of VI*b* and 35.0 g (0.6 mole) of propylene oxide in 50 ml of dichloroethane. The mixture was stirred at room temperature for 1.5 hr, and the solvents were evaporated.

The residual oil was taken up in benzene, placed on a silica gel column[4] (0.05–0.20 mm, 800 g), and eluted with ether–hexane (1:1) to give 1.75 g (7%) of VII*b*, mp 124–125°; NMR: δ 2.73 (t, 2H, $CH_2C_6H_5$), 3.4–3.7 (m, 2H, NCH_2), 4.5–4.7 (doublet of doublets, 1H, H at C-4), 4.8–4.9 (doublet of doublets, 1H, H at C-1), and 6.5–7.3 (broad, 11H, olefinic and aromatic); IR (mineral oil): 1675 cm^{-1} (C=O); *m/e* 275 (M+) and 128 (base).

Anal.—Calc. for $C_{19}H_{17}NO$: C, 82.85; H, 6.23; N, 5.09. Found: C, 82.81; H, 6.26; N, 5.38.

2-(2-Phenylethyl)-5,6-benzo-2-azabicyclo[2.2.2]octan-3-one (VIII*b*)—A solution of 3.56 g (0.0129 mole) of VI*b* in 175 ml of ethanol was hydrogenated in the presence of 0.4 g of palladium-on-charcoal at 3.1 kg/cm^2 until hydrogen uptake ceased. The catalyst was removed by filtration, and the filtrate was evaporated to give a solid. The solid was recrystallized from benzene–petroleum ether to yield 3.3 g (92%) of VIII*b*, mp 127–129°; IR (KBr): 1665 cm^{-1} (C=O); *m/e* 277 (M+) and 130 (base).

Anal.—Calc. for $C_{19}H_{19}NO$: C, 82.27; H, 6.90; N, 5.05. Found: C, 82.33; H, 7.00; N, 5.01.

2-(2-Phenylethyl)-5,6-benzo-2-azabicyclo[2.2.2]octane (V*b*)—A solution of 2.18 g of VIII*b* (0.0079 mole) in 40 ml of benzene was added dropwise to X (8 ml, 0.0277 mole), and the resulting mixture was refluxed for 4 hr. The mixture was cooled, ethanol and water were added to destroy excess hydride, and the mixture was filtered. The organic phase of the filtrate was separated, and the aqueous layer was extracted with chloroform (2 × 30 ml).

The organic phases were combined, dried over sodium sulfate, and evaporated to give a residue which was chromatographed on a silica gel column[4] (0.05–0.20 mm, 45 g). Elution with ether–hexane (1:1) gave 1.85 g (89%) of V*b*; NMR: δ 1.27–2.9 (m, 9H, $NCH_2CH_2C_6H_5$ and H at C-7, C-8, and C-3), 2.9–3.1 (broad, 1H, H at C-4), 3.32–3.5 (doublet of doublets, 1H, H at C-3), 3.7–3.9 (broad, 1H, H at C-1), and 7.0–7.4 (broad, 9H, aromatic); *m/e* 263 (M+) and 172 (base). The hydrochloride salt was prepared in the normal manner, mp 142–144°.

Anal.—Calc. for $C_{19}H_{22}ClN$: C, 76.11; H, 7.40; Cl, 11.83; N, 4.67. Found: C, 76.30; H, 7.42; Cl, 11.76; N, 4.77.

Pharmacological Methods—Both V*a* and V*b* were tested for biological activity with blind screening techniques standard to this laboratory. All tests were conducted in groups of four to six male Swiss mice, 18–23 g, and were conducted according to published protocols (10, 11). This mouse assay consists of: (*a*) rating of spontaneous activity, (*b*) rating of skeletal muscle tone, (*c*) the tail pull and finger touch tests of reactivity, (*d*) the righting time test, (*e*) measurement of pinna reflex, (*f*) the test for catalepsy, (*g*) the dish test, (*h*) the pedestal test, (*i*) the traction test, (*j*) the chimney test, and (*k*) a modification of the D'Amour–Smith tail flick test for analgesia (9).

The tail-flick test was performed 30 min after intraperitoneal injection. All other tests were performed at 15 and 60 min postinjection. Sixteen standard observations of autonomic activity and abnormal behavior were made in addition to the tests listed. Appropriate vehicle and positive controls were included in the test protocols.

Polarographic Study of New Antibacterial Isoxazolium Salts: 2,3-Dialkyl-5-arylisoxazolium Perchlorates

NABIL M. OMAR ˣ and NAWAL A. EL-RABBAT

Abstract □ The polarographic reduction of new antibacterial 2,3-dialkyl-5-arylisoxazolium salts is described. The electrode process involves an irreversible two-electron transfer and is pH independent within the 6.0–10.0 range. In more acidic media, hydrogen waves are observed; at higher pH values, a chemical degradation of the isoxazolium salt proceeds. Values of the half-wave potential of the salts are dependent on the polar contribution of the 5-aryl substituents in terms of the Hammett equation. The *in vitro* minimum inhibitory concentrations of these compounds are best correlated with Hansch π-values.

Keyphrases □ Isoxazolium salts, substituted—polarographic reduction, effect of pH, polar contribution of 5-aryl substituents correlated with antibacterial activity □ Polarography—reduction, substituted isoxazolium salts, effect of pH, polar contribution of 5-aryl substituents correlated with antibacterial activity □ Antibacterial activity—substituted isoxazolium salts, correlated with polar contribution of 5-aryl substituents, polarographic reduction □ Structure–activity relationships—substituted isoxazolium salts, polar contribution of 5-aryl substituents correlated with antibacterial activity, polarographic reduction

In a search for new antimicrobial cationic agents, the synthesis and antibacterial evaluation of a series of 2,3-dialkyl-5-arylisoxazolium perchlorates (I–XIII) were undertaken (1). Since differences in the antibacterial effectiveness of these salts were roughly assigned to substituent effects, it was of interest to evaluate such effects by tracing the possible electronic contributions of the isoxazolium 2- and 5-substituents and to correlate the corresponding microbiological data with these effects.

This report describes the polarographic reduction of I–XIII and its suitability as a measure of the polar substituent effect. Correlation of the antibacterial effectiveness to the polar substituent effect and the substituent solubility effect also was attempted.

EXPERIMENTAL

Materials—Analytically pure 2,3-dimethyl- and 2-ethyl-3-methyl-5-arylisoxazolium perchlorates (I–XIII) were prepared by quaternizing the appropriate isoxazoles as reported previously (2). Double-distilled water was used for all solutions.

Reagents—A Britton–Robinson phosphate–acetate–borate buffer was used. Adjustment to the required pH value was effected by addition of 0.2 *N* carbonate-free sodium hydroxide solution (3). Potassium chloride and tetraethylammonium perchlorate were utilized as the supporting electrolytes in 0.1–1.0 *M* solutions. Octoxynol[1] (0.1% v/v) and freshly prepared gelatin (0.2% w/v) solutions were the maximum suppressors. For deoxygenation, oxygen-free nitrogen was prepared by passing commercial nitrogen through 5% (w/v) aqueous vanadous sulfate solution (4).

Instrumentation—Current–voltage curves were recorded on a suitable polarograph[2] using 25-ml H-type polarographic cells, a dropping mercury electrode, and a saturated calomel electrode. Temperature control was achieved with an ultrathermostat[3], switched at 25° (±0.1).

Capillary characteristics were: drop time, 3.0 sec; and rate of mercury flow, 3.5 mg/sec, measured at a 30.0-cm mercury column height without applied potential. Recording conditions were: full scale deflection, 0.1 μamp; applied potential, 0.0–2.0 at a rate of 200 mv/min; and shunt, $\frac{1}{200}$. A pH meter[4] fitted with a sealed calomel electrode and a shielded glass electrode was used. For the spectrophotometric monitoring, a manual spectrophotometer[5] and 1-cm thick quartz cells were employed.

Procedure—The corresponding weight of the isoxazolium salt was dissolved in an appropriate volume of 0.5 *M* potassium chloride solution (or in a selected buffer solution), 0.5–1.0 ml of the maximum suppressor solution was added, and the solution was diluted with the supporting electrolyte solution to a final concentration of 5×10^{-4} *M* depolarizer/liter. Electrolysis was conducted at 25° after deoxygenation with pure nitrogen for 10 min.

RESULTS AND DISCUSSION

A literature review revealed that data pertaining to the polarographic reduction of the isoxazolium cation are not available, although the electroactivity of other 6π-isoelectronic analogs has been established (5–7). When tested for such activity in 0.5 *M* potassium chloride solution (pH 6.60–6.75), 2,3-dimethyl-5-phenylisoxazolium perchlorate (I) afforded a single well-defined cathodic wave with a half-wave value of −1.05 v (Fig. 1). This value was not significantly affected by variations in the ionic strength of the potassium chloride solution (0.10–2.0 *M*).

The use of 0.1 *M* aqueous tetraethylammonium perchlorate solution as the supporting electrolyte brought about a negative shift in the wave ($E_{1/2}$ = −1.12 v), reflecting the relatively high electrophilicity of the isoxazolium cation relative to its isosteric pyrazolium analog. The $E_{1/2}$ of 1,2,3-trimethyl-5-phenylpyrazolium perchlorate is −1.69 v (5).

As revealed from the dependence of the limiting current values of I, both on concentration (1×10^{-3}–5×10^{-4} *M*) and on the square root of the mercury column height (20–45 cm), its reduction wave is diffusion controlled. Comparison of the wave height and slope with relevant data of the similarly investigated pyrazolium analog gives the electron transfer of I a value of $n \sim 2$ (5). Theoretical logarithmic analysis of the observed wave gave rise to a straight line; however, the slope corresponded to a nonintegral value for n ($\alpha = 0.134$, $\alpha n \neq 0.059$), thus suggesting the irreversibility of the electrode reaction (8). Based on reported electrophilic interactions of the isoxazolium cation (9), the polarographic reduction of I might be similarly expected to afford the corresponding isoxazoline (Scheme I).

With the Britton–Robinson buffer as the supporting electrolyte, no apparent change in the wave characteristics of I could be traced within pH 6.0–10.0. At lower pH values (2.0–5.5), gradual reduction of the hydrogen ion seriously precluded the observation of the isoxazolium wave, while an increase of alkalinity (10.5–11.9) brought about a remarkable fall in the wave height. The $E_{1/2}$ value was little affected by such pH variations. At pH values higher than 11.9, a continous prominent drop of the limiting current was observed.

Estimations of the actual concentration of I at such pH values by UV spectrophotometric[6] and polarographic monitoring were similar. This finding denotes a considerable instability of the isoxazolium cation at elevated pH values, probably because of a base-induced cleavage of the cation (10). Since the antibacterial effectiveness of most cationic agents

[6] The 282-nm absorption maximum of I was not affected by variations in the buffer pH.

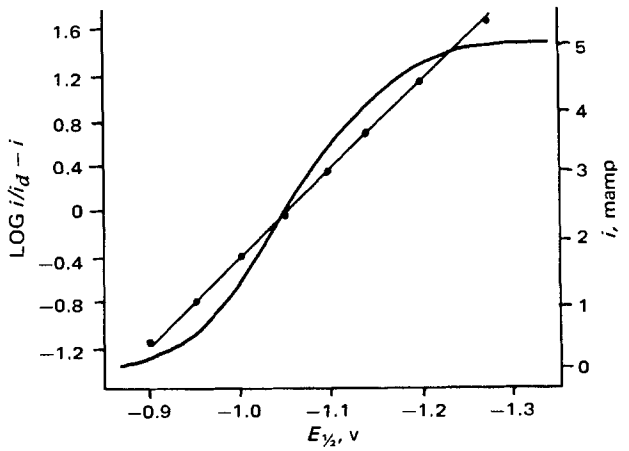

Figure 1—*Wave equation of I, 5 × 10⁻⁴ M in 0.5 M potassium chloride solution.*

is enhanced with increased pH values, further antimicrobial investigations of this series of isoxazolium salts will be carried out at pH values up to 10.0.

Polarographic reduction of II–XIII was carried out under the same conditions (Table I). Except for the two nitro derivatives, VII and XIII, comparison of the wave characteristics of the investigated salts (in 0.5 *M* potassium chloride) indicated that their electrode processes were identical to those of I. Compounds VII and XIII were reduced with the production of two waves; the first ($E_{1/2} \sim -0.68$ v) corresponded, however, to a four-electron transfer for the reduction of the nitro group (5). The second wave ($E_{1/2} \sim -1.28$ v) involved a two-electron reduction of the nitro-reduced isoxazolium cation.

The polar contribution of the 5-aryl substituents of I–XIII can be determined with the modified Hammett equation (11):

$$\Delta E_{1/2} = E_{1/2}^{x} - E_{1/2}^{0} = \sigma\rho \qquad \text{(Eq. 1)}$$

where $E_{1/2}^{x}$ and $E_{1/2}^{0}$ are the polarographic half-wave potentials of the benzene-substituted and unsubstituted derivatives of a particular series, respectively; ρ represents the reaction constant; and σ is the Hammett substituent constant. For I–VI and VIII–XII, correlation of their $E_{1/2}$ values to the corresponding 5-aryl σ-constants was fairly significant (r = 0.90 and 0.96, ρ = 0.26 and 0.28, and s = ±68 and ±46 mv for the *N*-methyl and *N*-ethyl sets, respectively).

The weak sensitivity of the polarographic reaction center of the investigated salts to the polar substituent effect was readily reflected by the relatively low values of the electrode reaction constant. Since such values are usually encountered when substituents are far away from reaction centers (12), this result would favor the representation of the isoxazolium 3-carbon for the polarographic reaction center (Scheme I).

The fact that substitution of the *N*-methyl radical for an *N*-ethyl analog did not affect the electrophilic tendency of the carrier isoxazolium cation (Table I) is explained by the electronic leveling effect of polar contributions of the *N*-methyl and *N*-ethyl moieties; σ-constants are −0.15 and −0.17, respectively (13). In contradiction to the reported polarographic data for related nitrophenyl heterocycles (5, 6), the $E_{1/2}$ values of the nitrophenylisoxazolium salts were not linearly correlated to their NHOH-substituent constant, probably due to a difference between their electrode reaction and other 5-arylisoxazolium derivatives.

Moreover, no correlations could be set up between the $E_{1/2}$ values of the investigated salts and their corresponding minimum inhibitory concentration (MIC) values. Added to the fact that VIII–XIII are more microbiologically effective than their *N*-methyl congeners (I–VII), these data suggest a weak operation of the polar contributions of both of the 2- and 5-isoxazolium substituents. In fact, the correlation of logarithmic MIC values of I–VII to the corresponding Hansch partition values of the

Micromethod for Determination of Meperidine in Plasma

M. A. EVANS [x] **and R. D. HARBISON**

Abstract □ A GLC method utilizing a flame-ionization detector is described for the analysis of meperidine in blood plasma. Meperidine is extracted with ether from plasma that has been made basic with sodium hydroxide. The ether extract is evaporated to dryness, and the residue is dissolved in carbon disulfide for GLC analysis. An internal standard, *N',N'*-diethylaminoacetyl-2,6-xylidine, is used to quantitate meperidine. The extraction efficiency from plasma is 85%, and as little as 0.05 μg of meperidine can be quantitatively determined in 1 ml of plasma.

Keyphrases □ Meperidine—GLC analysis, human plasma □ GLC—analysis, meperidine, human plasma □ Analgesics, narcotic—meperidine, GLC analysis, human plasma

Since the development (1) of a spectrophotometric analysis of meperidine[1] (I), several investigators reported procedures with greater sensitivity and specificity for plasma meperidine (2). However, some of these newer methods require several extractions (3), lack internal standard techniques (4), and demonstrate long retention times, which limit the number of samples that can be processed (5).

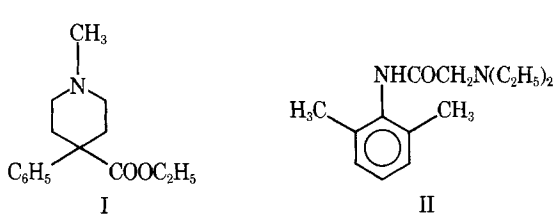
During prolonged administration of meperidine to pediatric patients, a micromethod of analysis is needed for the determination of peak plasma concentrations and the half-life of the drug. Therefore, a GLC method was developed for the rapid analysis of small amounts of meperidine in plasma using an internal standard for quantitation. The sensitivity of this method was greater than 0.05 μg/ml of plasma, and no interference was observed with peak identification. To evaluate this method, meperidine disappearance in plasma was studied in two infants following therapeutic drug administration.

EXPERIMENTAL

Apparatus—A gas chromatograph[2] equipped with a flame-ionization detector was maintained with gas flows of 20, 30, and 300 ml/min for nitrogen, hydrogen, and air, respectively. A column oven temperature of 215° was used; the injection port and detector temperatures were maintained at 240°.

Column—A glass column, 2 m × 2 mm, was packed with 3% SP 2250 on Chromosorb W, AW/DMCS[3] (80–100 mesh). The column was rinsed before packing with methanol and acetone; it was then dried and conditioned for 6 hr with a 10% solution of dimethyldichlorosilane[4] in toluene to silylate reactive sites. Following silylation, the column was again rinsed with acetone and dried.

Analytical Procedures—One milliliter of blood plasma was transferred to a 25-ml glass-stoppered centrifuge tube, mixed with the internal standard *N',N'*-diethylaminoacetyl-2,6-xylidine[5] (II) (1.0 μg/0.5 ml), made basic with 1 *N* NaOH (0.2 ml), and extracted with reagent grade ether (10 ml) by stirring on a vortex mixer (30 sec). The ether was then transferred by disposable pipet to a dry, clean, 12-ml centrifuge tube and evaporated to dryness in a water bath (45°) using nitrogen flow. The residue was redissolved in 20 μl of spectrophotometric grade carbon disulfide[6], and 1 μl was injected into the gas chromatograph.



I

II

A standard calibration curve was prepared by adding aliquots of an aqueous solution of meperidine hydrochloride to 1 ml of plasma to give a final concentration ranging from 0.05 to 0.20 μg/ml of meperidine in plasma. The internal standard (1 μg) was then added to the sample, and the analyses were made. Sixteen samples, four per concentration of meperidine, were analyzed for the determination of the standard curve. Each sample was injected in triplicate, and the determination for the entire standard was replicated once.

[^{14}C-*N*-Methyl]-meperidine hydrochloride[7] was used to estimate the extraction efficiency of meperidine from plasma by measurement of the total radioactivity in the extract[8].

RESULTS AND DISCUSSION

The GLC retention times for I and II were 1.4 and 2.5 min, respectively. A gas chromatogram from a control human plasma and plasma containing 0.1 μg of meperidine/ml with the internal standard (0.5 μg/ml) is shown in Fig. 1. Since peaks for both agents were symmetrical, quantitation was made by comparison of peak heights. Detector responses and calibration curves were linear for both compounds over the 0.05–0.20-μg/ml range. Blanks were prepared from plasma of drug-free subjects, and no peaks were observed that would interfere with the measurement of meperidine or the internal standard.

Linear regression analysis of the individual data points from the standards, plotted as the ratio of peak height of meperidine–peak height of the internal standard *versus* concentration of meperidine in plasma gave a computed slope of 1.37/μg of meperidine with a 0.01 *SE* of the

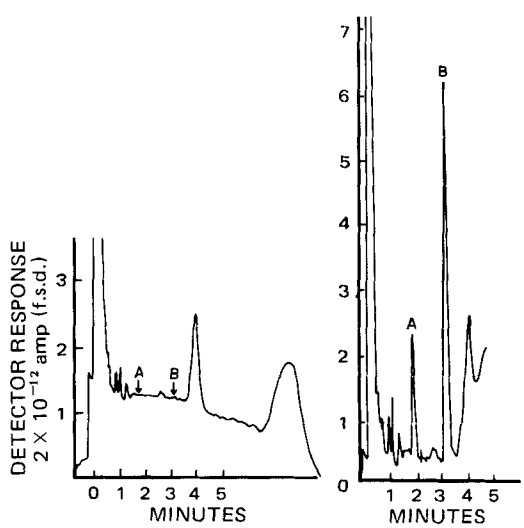


Figure 1—*Gas chromatogram of human plasma. Left: control plasma. Right: plasma containing 0.1 μg of meperidine/ml (A) and 0.5 μg of the internal standard/ml (B).*

estimate and an intercept of zero. Extraction efficiency based on results from 10 samples using ^{14}C-meperidine hydrochloride was estimated at 85%.

Results of meperidine analysis in two infants following therapeutic intravenous administration of the drug are shown in Fig. 2. Although the calculated half-life was 1.5 hr for both infants, no clear definition of biological half-life in infants can be made since only two subjects were available for complete analysis. Burns *et al.* (1) demonstrated a biological half-life of 3–4 hr in adult humans with variations up to 100%.

This rapid method of analysis may prove useful for meperidine determinations when sample size is limited and many samples must be analyzed.

Flavonoid Constituents from *Eupatorium altissimum* L. (Compositae)

R. H. DOBBERSTEIN, M. TIN-WA, H. H. S. FONG, F. A. CRANE, and N. R. FARNSWORTH [x]

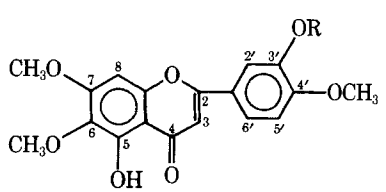
Abstract □ An aqueous ethanol extract of *Eupatorium altissimum* L. (Compositae) showed confirmed activity in the P-388 lymphocytic leukemia assay in mice, and the chloroform solubles showed both cytotoxic activity in the 9KB carcinoma of the nasopharynx cell culture assay and antitumor activity in the P-388 lymphocytic leukemia assay. Two flavones, eupatorin and 5-hydroxy-3′,4′,6,7-tetramethoxyflavone, were isolated and identified. Both were devoid of cytotoxic and antitumor activity.

Keyphrases □ *Eupatorium altissimum*—aqueous ethanol whole plant extract, two flavones isolated, cytotoxic and antitumor activity evaluated □ Flavones—isolated from *Eupatorium altissimum* aqueous ethanol whole plant extract, cytotoxic and antitumor activity evaluated □ Cytotoxic activity—evaluated in *Eupatorium altissimum* aqueous ethanol whole plant extract and isolated flavones □ Antitumor activity—evaluated in *Eupatorium altissimum* aqueous ethanol whole plant extract and isolated flavones

As part of a continuing search for antitumor compounds from plant sources, it was found that an aqueous ethanol extract of *Eupatorium altissimum* L. (Compositae) showed confirmed activity against the P-388 leukemia assay in mice and that the chloroform solubles showed both antitumor activity in the P-388 leukemia and marginal activity against the 9KB cell culture (cytotoxicity). In the only previous investigation of *E. altissimum*, a defatted ethanol extract was reported to exhibit antimicrobial activity against *Leuconostoc citrovorum* (1).

Extracts of various *Eupatorium* species have been reported to possess cytotoxic and/or antitumor activity. Cytotoxic flavonoids have been isolated from *E. semiserratum* (2–4) and *E. cuneifolium* (4); cytotoxic and antitumor sesquiterpene lactones have been isolated from *E. semiserratum* (5), *E. cuneifolium* (6, 7), *E. formosanum* (8), and *E. rotundifolium* (9–11).

In this investigation, two flavonoids were isolated from a fraction possessing cytotoxic activity. One was identified as eupatorin (I), a flavone previously isolated from *E. semiserratum* (2). The other flavonoid was verified as 5-hydroxy-3′,4′,6,7-tetramethoxyflavone (II). Although II



I: R = H

II: R = CH_3

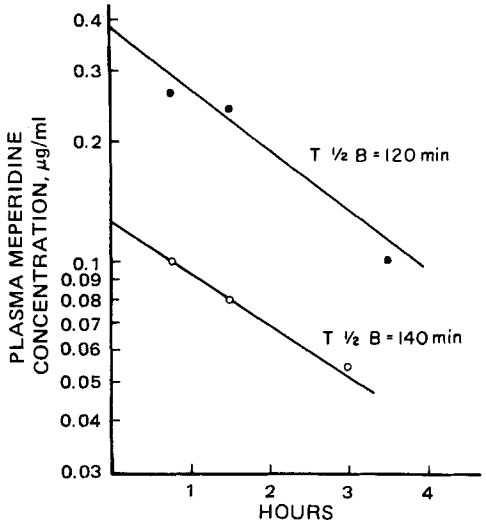


Figure 2—*Plasma concentration–time profile for meperidine in two infants following therapeutic drug administration. Sample size ranged from 0.5 to 1.5 ml of plasma.*

estimate and an intercept of zero. Extraction efficiency based on results from 10 samples using ^{14}C-meperidine hydrochloride was estimated at 85%.

Results of meperidine analysis in two infants following therapeutic intravenous administration of the drug are shown in Fig. 2. Although the calculated half-life was 1.5 hr for both infants, no clear definition of biological half-life in infants can be made since only two subjects were available for complete analysis. Burns *et al.* (1) demonstrated a biological half-life of 3–4 hr in adult humans with variations up to 100%.

This rapid method of analysis may prove useful for meperidine determinations when sample size is limited and many samples must be analyzed.

Flavonoid Constituents from *Eupatorium altissimum* L. (Compositae)

R. H. DOBBERSTEIN, M. TIN-WA, H. H. S. FONG, F. A. CRANE, and N. R. FARNSWORTH [x]

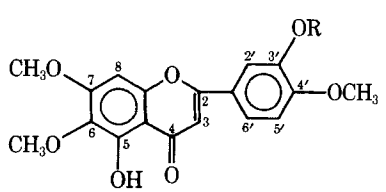
Abstract □ An aqueous ethanol extract of *Eupatorium altissimum* L. (Compositae) showed confirmed activity in the P-388 lymphocytic leukemia assay in mice, and the chloroform solubles showed both cytotoxic activity in the 9KB carcinoma of the nasopharynx cell culture assay and antitumor activity in the P-388 lymphocytic leukemia assay. Two flavones, eupatorin and 5-hydroxy-3′,4′,6,7-tetramethoxyflavone, were isolated and identified. Both were devoid of cytotoxic and antitumor activity.

Keyphrases □ *Eupatorium altissimum*—aqueous ethanol whole plant extract, two flavones isolated, cytotoxic and antitumor activity evaluated □ Flavones—isolated from *Eupatorium altissimum* aqueous ethanol whole plant extract, cytotoxic and antitumor activity evaluated □ Cytotoxic activity—evaluated in *Eupatorium altissimum* aqueous ethanol whole plant extract and isolated flavones □ Antitumor activity—evaluated in *Eupatorium altissimum* aqueous ethanol whole plant extract and isolated flavones

As part of a continuing search for antitumor compounds from plant sources, it was found that an aqueous ethanol extract of *Eupatorium altissimum* L. (Compositae) showed confirmed activity against the P-388 leukemia assay in mice and that the chloroform solubles showed both antitumor activity in the P-388 leukemia and marginal activity against the 9KB cell culture (cytotoxicity). In the only previous investigation of *E. altissimum*, a defatted ethanol extract was reported to exhibit antimicrobial activity against *Leuconostoc citrovorum* (1).

Extracts of various *Eupatorium* species have been reported to possess cytotoxic and/or antitumor activity. Cytotoxic flavonoids have been isolated from *E. semiserratum* (2–4) and *E. cuneifolium* (4); cytotoxic and antitumor sesquiterpene lactones have been isolated from *E. semiserratum* (5), *E. cuneifolium* (6, 7), *E. formosanum* (8), and *E. rotundifolium* (9–11).

In this investigation, two flavonoids were isolated from a fraction possessing cytotoxic activity. One was identified as eupatorin (I), a flavone previously isolated from *E. semiserratum* (2). The other flavonoid was verified as 5-hydroxy-3′,4′,6,7-tetramethoxyflavone (II). Although II



I: R = H

II: R = CH_3

was synthesized previously (12), it was only recently isolated from a natural source, *Salvia lavanduloides* (13). This paper reports the first isolation of these two flavones from *E. altissimum*.

EXPERIMENTAL[1]

Biological Activity—A 50% aqueous ethanol extract of *E. altissimum* was evaluated for cytotoxicity and antitumor activity[2]; it was active against the P-388 lymphocytic leukemia in mice[3] (T/C 144, 133, and 144 at 150, 100, and 66 mg/kg, respectively). The chloroform solubles, obtained by partitioning the concentrated aqueous ethanol extract between chloroform and water, possessed both cytotoxic[4] (ED_{50} = 20 μg/ml) and antitumor activity (T/C 150 and 159 at 200 and 100 mg/kg, respectively).

Extraction and Fractionation—A sample of whole plant material (5.5 kg) was continuously extracted[5] with petroleum ether (bp 30–60°) until the extract was colorless. The extract was then concentrated *in vacuo* to a viscous syrup weighing 296 g (Fraction A). The defatted plant material was air dried and then continuously extracted with methanol until the extract was nearly colorless. The methanol extract was concentrated *in vacuo* to yield 599 g of a thick dark-green syrup (Fraction B).

Fraction B was partitioned between chloroform (2 liters) and distilled water (2 liters). After two additional extractions of the aqueous layer with chloroform (2 liters), the combined chloroform fraction (Fraction C) was dried over anhydrous sodium sulfate and concentrated to dryness *in vacuo* to give a residue weighing 172 g. The aqueous phase was lyophilized to yield a residue weighing 387 g (Fraction D). A precipitate, which formed between the chloroform and water phases, was redissolved in methanol and concentrated *in vacuo* to a viscous brown syrup weighing 35 g (Fraction E).

Fraction C was partitioned between petroleum ether (bp 30–60°; 2 liters) and 20% aqueous methanol (2 liters). The petroleum ether fraction (Fraction F) was separated and concentrated *in vacuo* to a viscous green syrup weighing 32 g. The aqueous methanol phase was filtered, and a dark-green waxy material weighing 19 g (Fraction G) was collected. The filtrate was concentrated *in vacuo* to remove the methanol, diluted with distilled water (500 ml), and lyophilized to yield Fraction H (118 g).

Chromatography of Fraction H—A portion (25 g) of Fraction H was dissolved in chloroform and carefully added to the top of a chloroform slurry-packed column containing 500 g of silica gel PF_{254}[6] (Column 1). Elution was initiated with chloroform, and 20-ml fractions were collected.

The eluent was changed by the addition of increasing amounts of methanol as the fractions were monitored by TLC[7]. The fractions were combined into 24 groups on the basis of their TLC patterns.

Isolation and Characterization of Eupatorin (I)—Fraction 8 (690 mg), which was eluted from the column with chloroform–methanol (99:1), was dissolved in benzene–ethyl acetate (6:1) and rechromatographed over a column of silica gel PF_{254}. Elution was initiated with benzene–ethyl acetate (6:1), and 20-ml fractions were collected. The polarity of the eluent was increased by the addition of ethyl acetate. Finally, the column was washed with methanol. Fractions were combined into 18 groups according to their similarity following TLC[8]. Yellow crystals (I, 460 mg) spontaneously crystallized from fractions 13–15. Recrystallization from benzene–chloroform gave 245 mg of yellow needles, mp 189–190°. Additionally, a small sample (20 mg) was recrystallized from dioxane–water, mp 191–192°.

A UV spectrum of I in methanol exhibited absorptions with λ_{max} at 342 (log ε 4.50), 274 (4.35), 254 (4.32), and 243 (4.34) nm. Bands were observed in the IR spectrum (KBr) at ν_{max} 3430 (OH) and 1658 (chelated CO) cm^{-1}. These data are typical of flavones having a hydroxyl substituent at C-5 and hydroxyl or methoxyl substituents at both C-3′ and C-4′ positions (15–17). The mass spectrum showed a molecular ion at *m/e* 344 (100%), in agreement with an empirical formula of $C_{18}H_{16}O_7$. The NMR spectrum of I in dimethyl sulfoxide-d_6 was in good agreement with that reported for eupatorin (4).

The TLC, UV, IR, and mass spectral properties of I were identical with those of authentic eupatorin[9], and there was no depression of the melting point following a mixed melting-point determination. This evidence establishes the identity of I as eupatorin.

Isolation and Characterization of II—Fraction 5 (860 mg), which had been eluted from Column 1 with chloroform, was dissolved in benzene–ethyl acetate (4:1) and rechromatographed over a column of silica gel PF_{254} using benzene–ethyl acetate (4:1) as the eluent. Fractions (20 ml) were collected and combined into 13 groups on the basis of their TLC[8] similarities. Fractions 6–9 were combined and evaporated to dryness *in vacuo* (210 mg). Crystallization and recrystallization of this material from 95% ethanol yielded pale-yellow microcrystals (II, 142 mg), mp 188–189°.

The UV spectrum of II in methanol showed absorption maxima at 339 (log ε 4.49), 275 (4.32), and 242 (4.34) nm; the IR spectrum (KBr) showed bands at ν_{max} 3410 (OH) and 1660 (chelated CO) cm^{-1}. Again these data suggested a flavone nucleus having a hydroxyl substituent at C-5 and hydroxyl or methoxyl substituents at both C-3′ and C-4′ positions. The mass spectrum of II showed a molecular ion at *m/e* 358 (100%, $C_{19}H_{18}O_7$) with significant ions at *m/e* 343 (94%), 329 (22), 315 (23), 312 (25), 181 (17), and 153 (40). The NMR spectrum of II in deuterochloroform showed a 3H singlet at δ 3.92 (OCH_3), a 9H singlet at δ 4.00 (3-OCH_3), a 1H singlet at δ 6.58 (olefinic H), a 1H singlet at δ 6.61 (ArH), a 1H doublet at δ 7.01 [J = 9 Hz (ArH)], a 1H doublet at δ 7.37 [J = 2 Hz (ArH)], a 1H doublet of doublets at δ 7.64 [J = 9 Hz, J = 2 Hz (ArH)], and a 1H singlet at δ 12.76 (ArOH).

These data suggested that II was eupatorin 3′-methyl ether. Therefore, a sample of eupatorin was methylated. Eupatorin (52 mg) in methanol (100 ml) was treated with excess diazomethane (18) in ether at room temperature for 24 hr. The solvent was removed *in vacuo*, and the product, dissolved in benzene–ethyl acetate (6:1), was chromatographed over a column of silica gel PF_{254} (5 g) using benzene–ethyl acetate (6:1) as the developing solvent. The second fraction eluted (25 mg) was crystallized from 95% ethanol to give pale-yellow microcrystals (20 mg), mp 188–189°. Comparison of the TLC, UV, IR, NMR, and mass spectral properties of methylated I with those of II showed that they were identical.

Finally, an authentic sample of II[9] was shown to be identical with the isolated product in all respects. There was no depression of the melting point following a mixed melting-point determination.

DISCUSSION

As part of a program of screening plants for antitumor activity, it was observed that an aqueous ethanol extract of *E. altissimum* (Compositae) showed confirmed *in vivo* activity against the P-388 lymphocytic leukemia assay in mice. The chloroform-soluble fraction was marginally active against Eagle's 9KB carcinoma of the nasopharnyx in cell culture (cytotoxic) and active against the P-388 lymphocytic leukemia assay in mice. Compounds I and II were isolated from Fraction C. Both compounds, however, were inactive in the two test systems.

Eupatorin (I) was previously isolated from *E. semiserratum* and was reported to show cytotoxic activity (2, 4). However, the cytotoxicity of I, isolated from *E. altissimum*, could not be confirmed even after repeated testing.

Flavone II was recently isolated from *S. lavanduloides* (Labiatae) (13), representing its first reported natural occurrence. The present investigation establishes the first occurrence of this compound in the genus *Eupatorium* of the unrelated Compositae family.

Work is currently in progress to isolate and identify the compound(s) present in *E. altissimum* responsible for the antitumor activity.

[1] The plant material consisted of the whole plant of *E. altissimum* L. (Compositae), collected in Lisle, Ill., during October 1972. Identification was made by Floyd A. Swink of the Morton Arboretum, Lisle, Ill. Voucher specimens are deposited in the Herbarium of the Department of Pharmacognosy and Pharmacology, University of Illinois at the Medical Center, Chicago, IL 60612.

Melting points were determined using a Kofler hot-stage instrument and are uncorrected. Mixed melting points were determined on a Thomas-Hoover Uni-Melt apparatus. UV spectra were recorded using a Beckman model DB-G grating spectrophotometer. IR spectra were run using a Beckman model IR-18A spectrophotometer. NMR spectra were recorded on a Varian T-60A instrument at 60 MHz. Mass spectral data were obtained on a Hitachi Perkin-Elmer model RMU-6D spectrophotometer.

[2] The test methods employed were those of the Drug Research and Development Branch of the National Cancer Institute (14).

[3] An active fraction is one that exhibits a T/C of ≧125%.

[4] An active fraction is one that exhibits an ED_{50} ≦20 μg/ml.

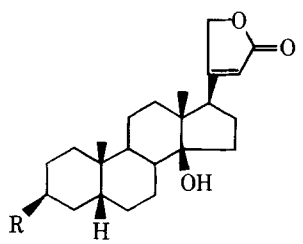
Thiocardenolides II: Synthesis and Pharmacological Evaluation of 3β-Thioacetyl-14β-hydroxy-5β-card-20(22)-enolide

HANLEY N. ABRAMSON [x], CHIAN L. HUANG, CHIU-CHUNG HO, LAWRENCE L. WALNY, and YOU-MEEI HSU

Abstract □ The synthesis of a 3β-thioacetylcardenolide is described. The thioacetate exhibited effects similar to those seen with digitoxigenin acetate on the isolated frog and guinea pig hearts at 1×10^{-7} dilution. In the intact rat heart, the lethal dose was 5 mg/kg for the thioacetate and 2.5 mg/kg for digitoxigenin acetate. The thioacetate inhibited sodium- and potassium-activated adenosine triphosphatase to the same extent as digitoxigenin, but it was somewhat less inhibitory than digitoxigenin acetate.

Keyphrases □ Thiocardenolides—3β-thioacetyl - 14β - hydroxy - 5β - card-20(22)-enolide synthesized, screened for cardiotonic activity and effect on sodium- and potassium-activated adenosine triphosphatase □ Cardiotonic activity—screened in 3β-thioacetyl-14β-hydroxy-5β-card-20(22)-enolide □ Adenosine triphosphatase, sodium and potassium activated—effect of 3β-thioacetyl-14β-hydroxy-5β-card-20(22)-enolide

The naturally occurring cardioactive steroids are widely used in the therapy of congestive heart failure and atrial arrhythmias and have low therapeutic indexes. There have been numerous efforts to synthesize and evaluate cardenolide derivatives with improved margins of safety, and the literature in this area was reviewed (1). As part of a program to replace oxygens of various cardenolides by sulfur atoms with the aim of separating the therapeutic and toxic actions of the digitalis glycosides, the synthesis and pharmacological actions of the 3β-thioacetyl analog (I) of digitoxigenin (II) are herein reported. A previous paper (2) described the preparation and biological actions of a 3β-thiocyanato analog.



I: R = $SCOCH_3$
II: R = OH
III: R = $OCOCH_3$

EXPERIMENTAL[1]

Chemistry—A solution of 584 mg (1.29 mmoles) of 3-epidigitoxigenin 3-methanesulfonate (2) and 577 mg (5.0 mmoles) of freshly recrystallized (ethanol–water) potassium thioacetate in 10 ml of dimethylformamide (freshly distilled over potassium hydroxide) was heated at 70–90° for 3 hr under dry nitrogen. The reaction mixture was poured onto ice, and the solid product was collected by filtration, dried, dissolved in chloroform,

[1] Melting points were taken on a Fisher-Johns melting-point stage and are uncorrected. UV absorption spectra were determined in 95% ethanol on a Beckman model DK2A recording spectrophotometer. IR absorption spectra were recorded in chloroform on a Beckman model 8 recording spectrophotometer. NMR spectra were determined on a Varian EM 360 spectrometer, using tetramethylsilane as the internal standard and deuterochloroform as the solvent. Microanalyses were conducted by Spang Microanalytical Laboratory, Ann Arbor, Mich. TLC was carried out using Merck silica gel G 254 (0.25-mm thick, analytical plates) or Merck silica gel PF 254 + 366 (0.75-mm thick, preparative plates). Analytical plates were visualized by charring with 5% $Ce(SO_4)_2$ in 6 *N* H_2SO_4; preparative plates were visualized under UV light.

Microanalyses were conducted by Spang Microanalytical Laboratory, Ann Arbor, Mich. TLC was carried out using Merck silica gel G 254 (0.25-mm thick, analytical plates) or Merck silica gel PF 254 + 366 (0.75-mm thick, preparative plates). Analytical plates were visualized by charring with 5% $Ce(SO_4)_2$ in 6 *N* H_2SO_4; preparative plates were visualized under UV light.

Table I—Adenosine Triphosphatase Inhibition

Compound	Adenosine Triphosphatase Activity, μmoles of Inorganic Phosphate Released/mg of Protein/hr
Control	11.45[a]
I	6.17[b]
II	6.15[b]
III	5.28[b]

[a] Average of four determinations. [b] Average of two determinations.

and filtered. After concentration to dryness, the filtrate was washed with absolute ethanol and filtered to give 378 mg of 3β-thioacetyl-14β-hydroxy-5β-card-20(22)-enolide (I), mp 198–204°.

TLC (1% methanol in chloroform) showed one major spot (R_f 0.3) with two minor products of lower R_f values. Preparative TLC (1% methanol in chloroform) gave 225 mg of a crystalline solid, mp 211–214°. Recrystallization from ethyl acetate–chloroform gave an analytical sample, mp 213–217°; IR: ν_{max} 3600 (OH), 1795 and 1750 (butenolide doublet), 1690 (SC=O), 1610 (C=C), and 730 (CS) cm^{-1}; UV: ν_{max} 219 nm (ϵ = 22,600); NMR: δ 0.88 (3H, s, 18-CH_3), 0.95 (3H, s, 19-CH_3), 2.33 [3H, s, $CH_3C(=O)S$], 4.06 (1H, broad s, 3-H), 4.95 (2H, broad s, 22-CH_2), and 5.90 (1H, s, 21-CH).

Anal.—Calc. for $C_{25}H_{36}O_4S$: C, 69.41; H, 8.39; S, 7.41. Found: C, 69.44; H, 8.45; S, 7.48.

The IR and NMR spectra indicated that the attack by thioacetate anion on the 3α-methanesulfonate occurred from the β-face of the molecule. The medium absorption band at 730 cm^{-1} (CS) stretch was consistent with the stereochemical assignment of a 3β-thioacetyl *A/B cis*-steroid (3). The epimeric 3β-thioacetyl compound would be expected to absorb at a higher frequency (755–762 cm^{-1}) (3). The broad singlet at δ 4.06 was attributed to the equatorial (α) proton at position 3, indicating that the thioacetyl substituent was axially (β) oriented (4). An axial proton at position 3 should show a peak centered considerably upfield in the δ 3.4 region (4).

Biological Evaluation—Isolated frog hearts (six preparations) were used to evaluate the cardiotonic effect of I according to Straub's method (5). Saline was used as the control, and digitoxigenin acetate (III) was used as the reference standard. The frog hearts were perfused with Frog–Ringer solutions of both compounds, and the changes in chronotropic and inotropic responses were recorded on a smoked-drum kymograph. Analytically pure samples of I were used in this and succeeding experiments.

The action of I on the isolated guinea pig heart was studied using the Langendorff preparation (6). The hearts (six preparations) were perfused with Krebs–Henseleit solutions of I, II, and III, and the inotropic changes were measured on a polygraph recorder[2].

The effect of I on the intact rat heart was studied using three animals anesthetized with pentobarbital (45 mg/kg ip). The cardiac actions were recorded on a polygraph recorder[2]. Saline was used as the control, and digitoxigenin acetate was used as the standard.

Studies of sodium- and potassium-activated adenosine triphosphatase inhibition were carried out using the enzyme obtained from guinea pig brain. The brain of a freshly decapitated guinea pig was homogenized in five volumes of an ice-cold solution (pH 6.8) containing 0.25 *M* sucrose, 5 m*M* histidine, 5 m*M* edetic acid, and 0.2% deoxycholate. The homogenate was centrifuged at 12,000×*g* for 30 min. The supernate was centrifuged at 35,000×*g* for 30 min, and the pellet was suspended in a solution (pH 7.0) containing 0.25 *M* sucrose, 5 m*M* histidine, and 1 m*M* edetic acid. This suspension was centrifuged again at 35,000×*g* for 30 min, and the pellet was resuspended in 20 ml of the same suspending solution. These procedures were carried out at 2°. The quantity of protein in the preparation was assayed by the method of Lowry *et al.* (7).

The enzyme solution (1.0 ml) was diluted to 10.0 ml with the ice-cold suspending solution. To 0.9 ml of the final solution was added 0.1 ml of a 10^{-3} *M* solution of I, II, or III in dimethylformamide and 1.0 ml of a solution containing 50 m*M* tromethamine hydrochloride buffer (pH 7.5), 5 m*M* magnesium chloride, 5 m*M* adenosine triphosphate, 100 m*M* sodium chloride, and 15 m*M* potassium chloride. The control contained the equivalent amount of dimethylformamide. After an 8-min preincubation period, the mixture was incubated at 37° for 20 min. Then 1.0 ml of 15% aqueous ice-cold trichloroacetic acid was added to terminate the reaction.

This mixture was centrifuged for 10 min. The supernate was decanted and mixed with 1.0 ml of a solution prepared by dissolving 400 mg of ferrous sulfate in 10 ml of a 1% ammonium molybdate solution in 1.15 *N* sulfuric acid. The resulting absorbance was read at 700 nm 30 min after the addition of the reagent. Reagent blanks and unincubated tests were also included. The resulting absorbance was converted into micromoles of inorganic phosphate released by comparison with a standard curve (Table I).

RESULTS AND DISCUSSION

In the isolated frog heart, I elicited a positive inotropic action at 1×10^{-8} dilution as well as at 1×10^{-7} dilution. A negative inotropic effect was seen at dilutions of 5×10^{-6} and lower. On the other hand, digitoxigenin acetate (III) demonstrated a positive inotropic response at 1×10^{-7} dilution and a negative inotropic effect at 5×10^{-5} dilution and lower.

Both I and III had similar actions on the guinea pig heart, causing a prominent inotropic response at 1×10^{-7} dilution and a negative inotropic effect at 5×10^{-5} dilution and lower. Digitoxigenin (II) exhibited a positive inotropic action at dilutions of 1×10^{-7} and 1×10^{-6} and a negative inotropic effect at 1×10^{-5} dilution and lower. At doses of 1 mg/kg, both I and III had a noticeable effect on the lead II ECG of the intact rat heart, as evidenced by decreases in the amplitudes of the T wave and the QRS complex, a prolongation of the PR interval, and a shortened QT segment. A dose of 2.5 mg/kg of III was lethal to the three rats tested; each of those receiving the same dosage of I survived. At a dosage level of 5 mg/kg of I, none of the animals survived.

The results of the interaction of I with sodium- and potassium-activated adenosine triphosphatase indicate that the inhibitory effect is approximately the same as that of digitoxigenin but less than that of digitoxigenin acetate.

It appears that the presence of a 3β-thioacetate moiety on the cardiotonic steroid nucleus does not reduce the cardioactivity associated with digitalis compounds. The results of the lethal dose study on the intact rat heart are encouraging, since they demonstrated that the thioacetyl grouping leads to decreased toxicity. This work is currently being expanded to a study of other thiocardenolides containing thiol and thioacetyl groupings at position 3β to ascertain whether such compounds may have improved margins of safety compared to those currently used in therapeutics.

Simultaneous GLC Determination of Acetaminophen, Dichloralantipyrine, and Isometheptene Mucate

FOTIOS M. PLAKOGIANNIS ˣ and AHMED M. SAAD

Abstract □ A rapid GLC assay for acetaminophen, dichloralantipyrine, and isometheptene mucate in capsules was developed. These substances are chromatographed directly, using phenyl methyl silicone gum as the stationary phase. The standard calibration curves are linear up to 14 mg/ml, with a lower limit of sensitivity of 2 mg/ml. This method is simple and rapid and does not require derivative formation.

Keyphrases □ Acetaminophen—GLC analysis in capsules with dichloralantipyrine and isometheptene mucate □ Dichloralantipyrine—GLC analysis in capsules with acetaminophen and isometheptene mucate □ Isometheptene mucate—GLC analysis in capsules with acetaminophen and dichloralantipyrine □ GLC—analyses, acetaminophen, dichloralantipyrine, and isometheptene mucate in combination capsules □ Analgesics—acetaminophen and dichloralantipyrine, GLC analysis in capsules with isometheptene mucate □ Adrenergics—isometheptene mucate, GLC analysis in capsules with acetaminophen and dichloralantipyrine

Among the reasons for the pharmaceutical popularity of acetaminophen is that it is a nonsalicylate analgesic and antipyretic. Dichloralantipyrine is also used as a hypnotic analgesic, while isometheptene is a sympathomimetic agent effective as adjunctive therapy in the treatment of peptic ulcer. A mixture of the three agents is formulated in a pharmaceutical dosage form that is effective in the relief of vascular, tension, and migraine headaches.

Acetaminophen has been assayed by spectrophotometric (1–4) and chromatographic (5–9) methods. One spectrophotometric method has been reported for the assay of dichloralantipyrine (10), but there is none for the determination of isometheptene mucate. The lack of information regarding the simultaneous determination of acetaminophen, dichloralantipyrine, and isometheptene mucate in capsules, together with the tedious extraction requirements and derivative formation required in other assays, led to this investigation.

EXPERIMENTAL

Materials—Acetaminophen[1], dichloralantipyrine[2], isometheptene mucate[3], and pure ethanol[4] (all analytical grade) were used.

Apparatus—GLC analyses were performed on a gas chromatograph[5] equipped with a dual flame-ionization detector. The column was coiled stainless steel tubing (240 cm × 3 mm i.d.) packed with 1% phenyl methyl silicone gum (OV-17) on high-performance Chromosorb WHP[6] (80–100 mesh).

Helium was used as a carrier gas at a flow rate of 25 ml/min. The flow rates of hydrogen and air were 25 and 30 ml/min, respectively. The temperature of both the injection port and the flame-ionization detector was 190°. The columns were conditioned at 200° for 24 hr before use. During analysis, the temperature was programmed as follows: 3 min of 70°, increased to 185° at 5°/min, and finally held for 5 min at 185°.

Assay Procedures—Into each of three glass-stoppered centrifuge tubes, weigh accurately 20 mg of the capsule formulation containing 325 mg of acetaminophen, 100 mg of dichloralantipyrine, and 65 mg of isometheptene mucate. Add to each tube 10 ml of a 50 μg % ethanol solution of tuaminoheptane sulfate[7]. Mix the contents of each tube for 2 min using a vortex mixer and then centrifuge for 5 min at 5000 rpm.

Transfer the ethanol solution quantitatively to another glass-stoppered tube and evaporate it in a water bath at 50° under a nitrogen stream. Redissolve the residue in 0.20 ml of pure ethanol and transfer it to a 0.2-ml injection vial[8]. Evaporate the ethanol again under nitrogen and redissolve the residue in 40 μl of pure ethanol; then cap the injection vial.

Samples of 1 μl were injected into the gas chromatograph with a 1-μl syringe[9]. Standard calibration curves were established with ethanol solutions of known concentrations (2, 4, 6, 8, 10, 12, and 14 μg/ml) of the individual drugs to be assayed. Computation was done with both peak area and peak height measurements. Reproducibility was better with the peak area than the peak height technique.

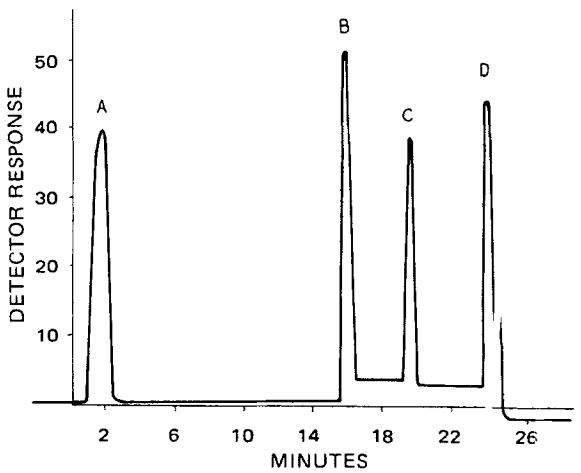

Figure 1—*Gas-liquid chromatogram. Key: A, dichloralantipyrine; B, acetaminophen; C, isometheptene; and D, tuaminoheptane sulfate (internal standard).*

RESULTS AND DISCUSSION

The standard calibration curves obtained by plotting the peak area ratio of acetaminophen, dichloralantipyrine, and isometheptene mucate *versus* their concentrations gave a straight line ($y = mx$) over the 2–14-μg/ml range with mean slope values of 0.66, 0.40, and 0.75, respectively.

Figure 1 shows a typical gas chromatogram of an acetaminophen, dichloralantipyrine, and isometheptene mucate mixture analyzed according to the described procedure. The retention times for dichloralantipyrine, acetaminophen, and isometheptene mucate were 3, 16, and 19 min, respectively; the retention time for the internal standard, tuaminoheptane sulfate, was 24 min. The overall recovery was constant from one test run to another. The results obtained with the procedure are illustrated by the examples in Table I.

The GLC determination of acetaminophen was accomplished either by measuring the unmodified drug directly (5, 6) or by converting acetaminophen to its trimethylsilyl ether or acetyl derivatives (7, 8, 11). McMartin and Street (11) reported that the reason for preparing a derivative of acetaminophen is that the unchanged drug is a highly polar compound that shows marked "tailing" during chromatography. However, there are two important disadvantages with acetaminophen de-

rivatives. They are time consuming and are readily hydrolyzed by moisture even in the presence of excess reagents.

A comparison showed that the described method is more rapid than previously described GLC methods that required preparation of a derivative (7, 8, 11). It is not more rapid than other reported methods (5, 6), but the use of the 1% OV-17 on high-performance Chromosorb WHP eliminates the tailing and, therefore, increases the efficiency and accuracy.

New Compounds: Synthesis of 2-Amino-5*H*-1,3,4-benzotriazepin-5-ones

ROBERT W. LEIBY and NED D. HEINDEL [x]

Abstract □ *N*-Methyl-2-aminobenzohydrazides, when treated with cyanogen bromide, were found to yield 2-amino-5*H*-1,3,4-benzotriazepin-5-ones.

Keyphrases □ 2-Amino-5*H*-1,3,4-benzotriazepin-5-ones—various derivatives synthesized □ Benzotriazepinones, substituted—various derivatives synthesized

Benzotriazepines as bioisosteric homologs of the well-established benzodiazepine psychotherapeutics have received considerable attention recently. Several synthetic methods and claims of sedative activity have been published (1–8) for the 1,3,4-benzotriazepine subclass, but a few earlier structural assignments (as benzotriazepines) were revised recently (9).

DISCUSSION

As a continuation of investigations on 1,4-benzodiazepin-3,5-diones derived from anthranilamides (10–12), this study reports the preparation of 2-amino-1,4-dihydro-5*H*-1,3,4-benzotriazepin-5-ones (II), a new type of 1,3,4-benzotriazepine obtained from the cyclization of anthranilohydrazides (I). By use of cyanogen bromide and a suitably methylated anthranilohydrazide, cyclization can be directed in an unambiguous fashion to the hydrobromide salts of the benzotriazepines, thus avoiding the classic pitfalls and uncertainties of structure that occur when alternative closure pathways are possible (9).

Anthranilohydrazides bearing a methyl on the amide-like nitrogen (*i.e.*, *N*-methyl-2-aminobenzohydrazides, I) were obtained by the opening of isatoic anhydride with methylhydrazine (13, 14). These hydrazides condensed instantaneously in chilled ethanol with cyanogen bromide (Scheme I) to give IIa–IIg in 36–85% yield. When the *ortho*-amino group was deactivated by conjugation to a nitro moiety, *i.e.*, If and Ig, condensation in refluxing dioxane was necessary to obtain a satisfactory yield.

The monomethylated benzotriazepines displayed four NH absorptions in the IR spectra between 3440 and 3080 cm^{-1}, while the dimethylated benzotriazepines (II, $R_2 = CH_3$) displayed only three absorptions between 3360 and 3080 cm^{-1}. Since tautomerism is possible in monomethylated compounds but not in IId, IIe, or IIg, these results may indicate a tautomeric equilibrium in the monomethyl isomers. No present structural evidence can eliminate their alternative formulation as 2-amino-3,4-dihydro-5*H*-1,3,4-benzotriazepin-5-ones.

In the PMR spectra, the N_4 methyl resonances appeared between 3.75 and 3.85 ppm; the N_1 methyl singlets were observed at 2.75–2.90 ppm. The NH resonances were variable in position, with the C_2 amino protons

EXPERIMENTAL[1]

Preparation of Anthranilohydrazides—The synthesis of hydrazides I*a*–I*g* was described previously (13, 14).

General Procedure for 2-Amino-1,4-dihydro-5*H*-1,3,4-benzotriazepin-5-one Hydrobromide Salts (II*a*–II*e*)—A solution of 0.10 mole of the requisite anthranilohydrazide (I*a*–I*e*) in 100 ml of absolute ethanol was chilled in an ice bath, and 0.10 mole of cyanogen bromide in 20 ml of ethanol was added rapidly. The solution was stirred vigorously, and almost immediately the yellow crystalline hydrobromide salt began to precipitate. The solid was collected on a filter, washed with 100 ml of cold ether, and recrystallized from ethanol (Table I).

2-Amino-4-methyl-7-nitro-1,4-dihydro-5*H* -1,3,4- benzotriazepin-5-one Hydrobromide (II*f*)—To a solution of 5.25 g (25.0 mmoles) of *N*-methyl-2-amino-5-nitrobenzohydrazide (I*f*) dissolved in refluxing dioxane was added a solution of 2.65 g (25.0 mmoles) of cyanogen bromide in dioxane. Immediately upon addition, the solution became cloudy and precipitated a yellow semisolid mass. This semisolid crystallized on cooling in an ice bath. The solid was recrystallized from acetic acid and washed with absolute ethanol and ether. The analytical product (II*f*) was obtained in 68.5% (5.40 g) yield as fine yellow needles, mp 212.0–212.5°.

2-Amino- 1,4- dimethyl-7-nitro-1,4-dihydro-5*H*-1,3,4-benzotriazepin-5-one Hydrobromide (II*g*)—A dioxane–cyanogen bromide solution was prepared from 15 ml of dioxane and 2.65 g (25.0 mmoles) of cyanogen bromide. This solution was then added to 5.61 g (25.0 mmoles) of *N*-methyl-2-methylamino-5-nitrobenzohydrazide (I*g*) dissolved in refluxing dioxane. Upon addition, the solution became blood red with concomitant precipitation of a tan solid. The crude II*g* was recrystallized from absolute ethanol (sparingly soluble), giving 6.48 g (79%), mp 246–247°.

[1] IR spectra were obtained in potassium bromide disks on a Beckman IR-33 spectrometer. A Hitachi Perkin-Elmer R20A magnetic resonance spectrometer was employed to obtain the PMR spectra. Melting points were obtained in capillaries on a Thomas Hoover apparatus and are uncorrected. Combustion analyses were obtained from Robertson Microanalytical Laboratory, Florham Park, N.J.

USP Dissolution Test I: Adequacy of Mixing

Keyphrases □ Dissolution apparatus—effect of sampling depth, temperature, and time on results □ Apparatus, dissolution—effect of sampling depth, temperature, and time on results

To the Editor:

This laboratory is presently engaged in a study aimed at characterizing the hydrodynamics (1, 2) of the USP dissolution apparatus. Phenomena have been observed akin to those reported by Withey (3) and Withey and Bowker (4), who found that "spurious results could be obtained if its sampling depth is varied." This communication assesses the seriousness of this problem and suggests a means of minimizing it.

Three pellets of pure oxalic acid dihydrate, 1.113 cm in diameter and 0.38 cm in thickness, were subjected to dissolution in a USP dissolution apparatus operated at 50 rpm in 900 ml of 0.1 *N* HCl at 25°. It was visually apparent that there was a schlieren effect; one can actually observe the discrete schlierens of oxalic acid solution move out into the liquid, sink somewhat, and then disperse. The results are shown in the lower curve in Fig. 1.

Four experiments were run in which the dissolution was carried out for 150 sec, the basket was removed, and the entire 900 ml of liquid in the dissolution vessel was assayed. This procedure was repeated at other time points, and the results are shown in the top curve in Fig. 1. Point-to-point *t*-comparisons and rank tests showed that the two sets of data differed significantly at the 99.9% confidence level.

The described tests were performed at 25°, and the sampling was carried out close to (1 cm below) the surface. The problems encountered at 25° probably would occur at 37° as well and be even more pronounced. The chosen point of sampling, of course, emphasized differences due to improper mixing. To establish the effect of temperature and sampling points, the experiments were repeated at 37° at various sampling points (Table I).

The USP description (5) states that "one of the outer ports *may* be used for insertion of a thermometer. Samples *may* be removed . . . through the other two ports." No actual dimensions or positioning details are given other than the drawing in the cited reference. Therefore, experiments were carried out (at 37°) with a setup that dimensionally matched the drawing in the USP.

Two experiments were performed (Table I). In one, a syringe was attached to the sampling tube and the dissolution was carried out with air in the dip tube (the air was there because the syringe was attached prior to the addition of liquid). This method is denoted USP-2 in Table I. In the other experiment (USP-1 in Table I), the syringe was added after the liquid was added to the vessel, so the liquid level in the dip tube matched that of the liquid in the vessel during dissolution. In this latter setup, a stagnant column of liquid will be sampled. In most sampling situations, the concentration at the sampling point will not equal the average concentration of the liquid in the vessel. If the volume of liquid is multiplied by the concentration, the amount obtained from the sampling will differ from the amount actually dissolved.

Table I—Concentrations Multiplied by Volume for Sampling at Various Points at 37° Compared with Amounts Actually Dissolved

Seconds	Position	Volume × Concentration, mg: At Sampling Point[a]	Volume × Concentration, mg: Entire Content Assayed[a]
120	0.5 cm below surface	57[a]	455
120	1 cm below surface	284[a]	455
120	2 cm above bottom	611[a]	455
120	At bottom	597	455
120	USP-1	270[a]	470
120	USP-2	398[a]	470
240	0.5 cm below surface	583[a]	796
240	1 cm below surface	753	796
240	2 cm above bottom	867[a]	796
240	At bottom	870[a]	796
240	USP-1	754[a]	839
240	USP-2	810	839

[a] Assays shown are averages of duplicate experiments. The sample standard deviation is 20 mg; on a two-way comparison, differences over 63 are significant on the 95% level.

This fact does not *per se* invalidate the test, although it places several restrictions on it, some rather severe. If the position and dimensions of the thermometer and sampling tube are defined carefully, curves can be obtained that will be reproducible. If such curves can be shown to correlate with *in vivo* data, then the test conceivably may be used as a control tool (6). However, dimensional specificity would be a necessity in such a case, as would duplication validation between apparatuses to be used.

The method denoted USP-2 in Table I gives the results closest to the actual content. It is felt that continuous monitoring by pumping liquid continuously through a flowcell comes close to this condition, since it eliminates the stagnant column of liquid in the sampling tube.

The use of a highly soluble substance (oxalic acid dihy-

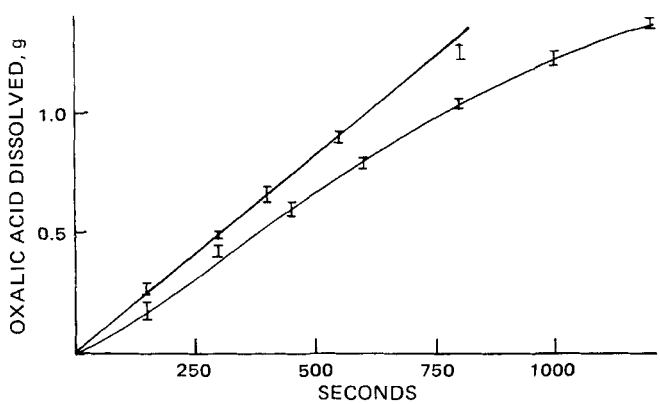

Figure 1—*Results from dissolution of oxalic acid dihydrate pellets in USP dissolution apparatus operated at 25° and 50 rpm. Key: upper curve, entire liquid mass assayed at each time point; and lower curve, samples taken 1 cm below surface.*

drate) accentuates the positional difference in concentration. The differences, furthermore, will be most pronounced in the beginning of the curve. Eventually, of course, all material will dissolve (provided the amount of liquid suffices) and molecular diffusion will provide a state of complete mixedness at very high time values.

The described phenomena were found with dissolution at higher revolutions per minute as well, although not to the same extent. They offer an added explanation of why dissolution curves are often sigmoid shaped[1], although a sigmoid shape *per se* should not be taken as a criterion for poor mixing since other factors affect curve shape.

Polymorphic and Dissolution Properties of Mercaptopurine

Keyphrases □ Mercaptopurine—polymorphic form, dissolution rate, differential thermographic and X-ray diffraction analyses □ Polymorphic form—of mercaptopurine, dissolution rate, differential thermographic and X-ray diffraction analyses □ Dissolution rate—polymorphic form of mercaptopurine, differential thermographic and X-ray diffraction analyses □ Antineoplastics—mercaptopurine, polymorphic form, dissolution rate, differential thermographic and X-ray diffraction analyses

To the Editor:

Mercaptopurine is an effective purine antagonist (1) that has significant activity against human leukemia and other neoplastic disorders. It distributes throughout the body tissues rapidly and is extensively metabolized (2). Upon oral administration, it shows erratic and incomplete absorption (3). Although the structural similarity of mercaptopurine with natural purines makes the mechanism of its absorption complicated, its dissolution rate probably affects its bioavailability in view of its low water solubility.

The purpose of this communication is to report a fast dissolving polymorphic form of mercaptopurine which can be useful in increasing the bioavailability of this compound.

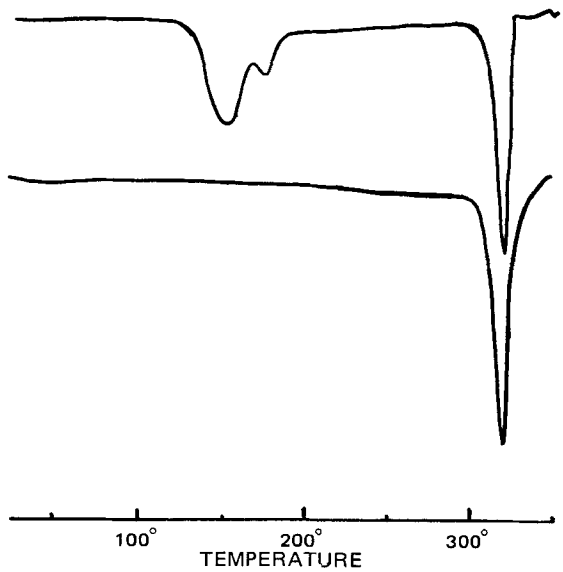

Figure 1—*Differential thermogram of original (top) and heat-treated or rerun (bottom) samples of mercaptopurine.*

The sample of mercaptopurine supplied by the manufacturer[1] yielded a differential thermogram[2] with two endothermic peaks (Fig. 1). The second peak is attributed to the melting of the compound as confirmed by a visual method[3]. The first endothermic peak can be attributed to, among other possibilities, a mercaptopurine polymorph (4). A rerun (Fig. 1) on the same sample showed only one peak corresponding to the final melting point. A similar thermogram with one peak was obtained when the sample was incubated at 225° for 20 min (4), strengthening the possibility of the polymorphic transition observed as the first endothermic peak in the original thermogram.

A sample of the high energy polymorph was prepared by incubating the original drug at 225° for 20 min; then it was subjected to X-ray diffraction analysis[4] (Fig. 2). The

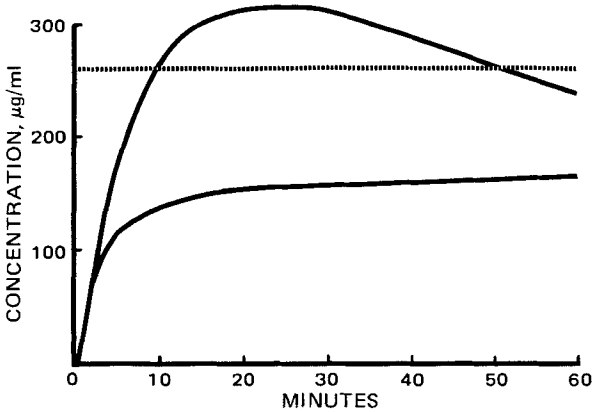

Figure 3—*Dissolution of high energy (top) and low energy (bottom) polymorphs of mercaptopurine. Broken line indicates equilibrium solubility at 37° in water.*

powder X-ray diffraction spectrum of the heat-treated sample was entirely different from that of the original compound, confirming the existence of at least two polymorphic forms. The IR spectra[5] were also different, with increased CH stretching and bending and additional CN and CC stretching and CH rocking in the heat-treated, high energy polymorphic form.

The purpose of this study was to show that a higher energy, relatively stable form of mercaptopurine can exist compared to the form of the drug used in commercial dosage forms. It is possible that the original compound may itself be composed of several polymorphic forms, especially in view of the peak splitting observed in the thermogram (Fig. 1). This aspect is currently being investigated in our laboratory.

The equilibrium solubilities of the two polymorphic forms were determined by placing excess drug in dialysis tubing[3], which was sealed, placed in an erlenmeyer flask containing 100 ml of distilled water, and equilibrated at 37° for up to 5 days. Prior studies excluded any interactions in the analysis due to leaching from the tubing.

This method allows direct sampling of the solution without filtration, which can result in significant loss due to adsorption. The solutions were analyzed spectrophotometrically[6] and gave the identical solubility value of 259.2 ± 4.3 μg/ml (mean ± *SEM*) for the two polymorphic forms. This observation, in spite of the differences in energy of the two polymorphic forms, can be attributed to the possible conversion of the high energy form to the low energy form when placed in water, a phenomenon reported for other drugs (5). However, the differences between the dissolution rates can still be observed, depending on dissolution conditions (4).

The dissolution rates of the two polymorphic forms were determined in water at 37° using a membrane filtration[7] method, which has often been shown to correlate better with *in vivo* dissolution rates and absorption (6, 7). Initial dissolution rate studies showed (Fig. 3) that the release from the high energy polymorph was twice that obtained from the low energy polymorph, resulting in supersaturation of the solution. These initial dissolution rate data (up to 20 min) showed an excellent log-linear relationship ($r > 0.98$) with corresponding rate constants of 0.25 and 0.16 min^{-1} for the high and low energy polymorphs, respectively. However, if the dissolution was continued for up to 1 hr, the high energy polymorphic form decreased in concentration, indicating precipitation and conversion to the low energy polymorph.

The effect of the nature of the medium on the dissolution rate and *in vivo* bioavailability aspects are currently being investigated in our laboratories.

Absolute Availability of Lithium

Keyphrases □ Lithium carbonate—bioavailability, calculations based on perturbation of renal clearance, commercial dosage form □ Bioavailability—lithium carbonate, calculations based on perturbation of renal clearance, commercial dosage form □ Renal clearance perturbation—calculations used to determine bioavailability of lithium carbonate, commercial dosage form □ Antidepressants—lithium carbonate, bioavailability, calculations based on perturbation of renal clearance, commercial dosage form

To the Editor:

It is generally accepted that lithium carbonate is completely absorbed when given orally to humans (1–3). This absorption, however, has not been demonstrated pharmacokinetically by comparison of oral plasma level–time curves with those obtained following intravenous dose administration, due largely to the legal and ethical considerations involved in giving this drug parenterally. It has been shown (4) that the lithium absorption rate can be influenced significantly by formulation differences between different brands. Thus, poorly formulated solid dosage forms may present a potential bioavailability problem for lithium carbonate.

Lalka and Feldman (5) recently reported an indirect method for calculating absolute bioavailability based on perturbation of renal clearance that does not require parenteral data. The purpose of this communication is to report the absolute bioavailability of one commercially

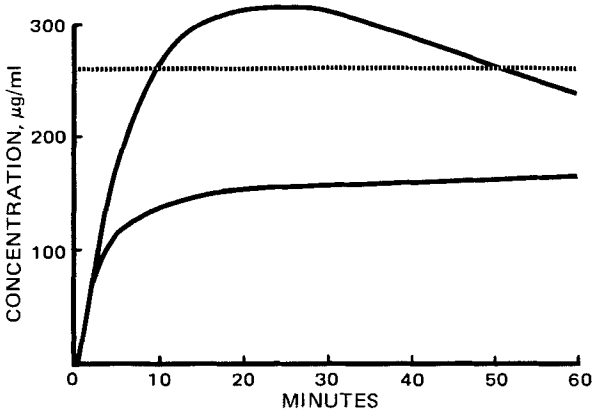

Figure 3—*Dissolution of high energy (top) and low energy (bottom) polymorphs of mercaptopurine. Broken line indicates equilibrium solubility at 37° in water.*

Absolute Availability of Lithium

Keyphrases □ Lithium carbonate—bioavailability, calculations based on perturbation of renal clearance, commercial dosage form □ Bioavailability—lithium carbonate, calculations based on perturbation of renal clearance, commercial dosage form □ Renal clearance perturbation—calculations used to determine bioavailability of lithium carbonate, commercial dosage form □ Antidepressants—lithium carbonate, bioavailability, calculations based on perturbation of renal clearance, commercial dosage form

To the Editor:

It is generally accepted that lithium carbonate is completely absorbed when given orally to humans (1–3). This absorption, however, has not been demonstrated pharmacokinetically by comparison of oral plasma level–time curves with those obtained following intravenous dose administration, due largely to the legal and ethical considerations involved in giving this drug parenterally. It has been shown (4) that the lithium absorption rate can be influenced significantly by formulation differences between different brands. Thus, poorly formulated solid dosage forms may present a potential bioavailability problem for lithium carbonate.

Lalka and Feldman (5) recently reported an indirect method for calculating absolute bioavailability based on perturbation of renal clearance that does not require parenteral data. The purpose of this communication is to report the absolute bioavailability of one commercially

Table I—Parameters Used for Calculation of Lithium Availability in Each of Four Subjects

Subject	ΔCl_R, liters/hr	AUC, mEq/liter × hr	AUC', mEq/liter × hr	F
I	0.644	3.337	4.448	1.043
II	0.516	4.823	6.805	1.037
III	0.779	3.740	5.810	0.991
IV	0.191	5.206	5.816	1.152

available dosage form of lithium carbonate using this method.

Four healthy male subjects were given one 300-mg capsule of lithium carbonate[1] under fasting conditions. Plasma concentrations were measured periodically for 30 hr. Three weeks later, the same four subjects ingested 500 mg of chlorothiazide[2] daily for 8 days. On the 8th day, they again were given a single 300-mg dose of lithium carbonate. Details of these experiments were reported elsewhere (6, 7). The coadministration of chlorothiazide and lithium led to an average reduction in renal lithium clearance of 26.5%, thus fulfilling the requirement of renal clearance perturbation (7).

The equation presented by Lalka and Feldman (5) for calculating absolute availability is:

$$F = \frac{\Delta Cl_R}{D}\left[\frac{(AUC)(AUC')}{AUC' - AUC}\right] \qquad \text{(Eq. 1)}$$

where F is the fraction of dose absorbed, ΔCl_R is the change in renal clearance that occurs as a result of changes in the experimental conditions, D is the dose administered (8.25 mEq in this case), and AUC and AUC' are the resulting areas under the plasma concentration–time curves for the two experimental conditions.

Values employed in calculating F for each subject are given in Table I along with the calculated F values. As shown, the F value for each subject is very close to unity, indicating that lithium carbonate is completely absorbed under the conditions of these experiments. Thus, we have demonstrated the applicability of this method for determining absolute availability and have shown that this particular brand of lithium carbonate is completely absorbed.

REVIEWS

Clinical Pharmacy Sourcebook. Key Articles from the American Journal of Hospital Pharmacy. Publishing Sciences Group, 162 Great Road, Acton, MA 01720, 1976. xvi + 396 pp. 22 × 28 cm. Price $20.00.

"Clinical Pharmacy Sourcebook" is, as its title indicates, a collection of carefully selected articles relating to clinical aspects of pharmacy service which have been published previously in the *American Journal of Hospital Pharmacy*. Thus, although not reflecting the entire universe of the clinically oriented pharmacy literature, the "Sourcebook" has tapped one of the most fertile sources of material on this important facet of pharmacy practice.

Stressing clinically oriented pharmacy practice rather than education, the "Sourcebook" is an excellent source of background information for pharmacy students, practicing pharmacists interested, but as yet not fully involved, in clinical practice, industrial representatives, and other health care professionals who desire to learn more about the contributions to direct patient care which can be offered by the clinically oriented pharmacist.

Readers of the "Sourcebook" will benefit also from its convenient organization. The book is divided into seven sections: Introduction; Clinical Pharmacy Services: Implementation and Administration; Clinical Pharmacy Services: The Hospitalized Patient; Clinical Pharmacy Services: The Ambulatory Patient; Clinical Pharmacy Services: Therapeutic Considerations; Clinical Pharmacy Services: Biopharmaceutics and Pharmacokinetics; and Clinical Pharmacy Services: Evaluation. This format does more than compartmentalize the material; it enables readers to select a specific area of interest such as therapeutics, develop the appropriate "mind set," and review easily a series of related articles in the area of interest selected.

In addition to the extensive number of references cited in each individual article, the "Sourcebook" contains a useful bibliography of approximately 160 selected references dealing with the clinical aspects of pharmacy practice and education. The book's index, which was computer generated from the International Pharmaceutical Abstracts Information

Table I—Parameters Used for Calculation of Lithium Availability in Each of Four Subjects

Subject	ΔCl_R, liters/hr	AUC, mEq/liter × hr	AUC', mEq/liter × hr	F
I	0.644	3.337	4.448	1.043
II	0.516	4.823	6.805	1.037
III	0.779	3.740	5.810	0.991
IV	0.191	5.206	5.816	1.152

available dosage form of lithium carbonate using this method.

Four healthy male subjects were given one 300-mg capsule of lithium carbonate[1] under fasting conditions. Plasma concentrations were measured periodically for 30 hr. Three weeks later, the same four subjects ingested 500 mg of chlorothiazide[2] daily for 8 days. On the 8th day, they again were given a single 300-mg dose of lithium carbonate. Details of these experiments were reported elsewhere (6, 7). The coadministration of chlorothiazide and lithium led to an average reduction in renal lithium clearance of 26.5%, thus fulfilling the requirement of renal clearance perturbation (7).

The equation presented by Lalka and Feldman (5) for calculating absolute availability is:

$$F = \frac{\Delta Cl_R}{D}\left[\frac{(AUC)(AUC')}{AUC' - AUC}\right] \qquad \text{(Eq. 1)}$$

where F is the fraction of dose absorbed, ΔCl_R is the change in renal clearance that occurs as a result of changes in the experimental conditions, D is the dose administered (8.25 mEq in this case), and AUC and AUC' are the resulting areas under the plasma concentration–time curves for the two experimental conditions.

Values employed in calculating F for each subject are given in Table I along with the calculated F values. As shown, the F value for each subject is very close to unity, indicating that lithium carbonate is completely absorbed under the conditions of these experiments. Thus, we have demonstrated the applicability of this method for determining absolute availability and have shown that this particular brand of lithium carbonate is completely absorbed.

Liquid Scintillation Counting. By K. D. NEAME and C. A. HOMEWOOD. Halsted, 605 Third Ave., New York, NY 10016, 1974. 180 pp. 16 × 24 cm. Price $13.75.

"Liquid Scintillation Counting" could be considered as a "McGuffey Reader" for this radiation detection technique. The book describes the elementary principles of liquid scintillation counter operation and presents information helpful in resolving fundamental practical considerations of proper operation. The authors have written a book that should be required reading for the beginning user of liquid scintillation counters.

After presenting information on radioactivity in general, the authors discuss the liquid scintillation counter, counting efficiency and quenching, and the selection and quantity of tracers to use in experimentation. With the basics covered, they then take up topics of a more applied nature. They discuss preparation of samples for counting, determination of counting efficiency for making quench correction, and double-isotope analysis. Such subjects as errors from various sources and what the user should be concerned about in correcting or evaluating them are considered. The authors omit discussion of errors that are common to all methods of analysis but cover in detail several errors peculiar to the nature of radioactivity and to its measurement by liquid counting.

The book could be considered by educators as a text in courses that teach principles of nuclear detection and the liquid scintillation method.

A Flexible Design for Health Professions Education. Edited by RICHARD M. JACOBS. Wiley, 605 Third Ave., New York, NY 10016, 1976. 260 pp. 16 × 23.5 cm.

"Flexible Design" is essential reading for anyone involved in the field of health education, particularly for those who are involved in, or are getting ready to embark on, "experiments" in new instructional techniques and/or curriculum design.

The chapters, which represent the thinking of 23 outstanding educators from the disciplines of medicine, dentistry, pharmacy, nursing, and allied health, are based on material originally presented at an invitational conference (by the same title) held in Iowa City in April 1975.

The editor's introduction succinctly states the book's purpose: "Recent trends in education, health care, and society in general have stimulated serious efforts to find alternatives to the traditional approaches to the health professions education." The volume examines how societal expectations and individual aspirations might be more effectively fulfilled outside the context of the "traditional, highly regimented and stereotyped health professions education programs"—through educational flexibility.

The 20 chapters are grouped into five parts: Basic Educational Considerations and Instructional Strategies; An Overview of Individualized Instructional Practices in the Major Health Professions, (included is the paper on "Flexible Approaches to Pharmacy Education" by L. C. Weaver and H. R. Manassee, Jr.); Planning, Implementation, and Evaluation: Case Studies; Cost of Flexibility; and Broader Dimensions of Flexibility.

The flexibility to which the work is addressed involves a personalized approach to education: individualized curricular content, individualized modes of instruction, flexible scheduling of instruction, and flexible admissions.

Several notable experiments in health professions education are elaborated upon. The authors provide excellent insights into such areas as outreach programs, individual and elective study, hospital programs, different modes of instruction, multitrack systems, independent study programs, computer-aided instruction, use of simulation, social costs, and flexible tuition.

Douglas R. Whitney's chapter on the Placement, Monitoring, and Evaluation System (PME) is important for the distinction it makes between flexible and traditional instruction in view of the demands that the flexible approach places on the system. PME is a decision-making network that collects data; a management system to hold and control data; and an output system to produce reports, documents, and summaries for use in decision making.

Alvin L. Morris, in his chapter on "Implementation," raises important questions and presents a broader perspective on the subject. He argues that: "While flexible education introduces varieties of time and methods to bring all students to the same end point, traditional education does just the opposite.

There is something disturbing about the idea of all students being the same at the end of an educational experience. Conversely, it can be argued that the identification of a wide range of achievements and achievers through traditional education has served both the students and their professions well." Dr. Morris cautions that: "Educators must be willing to reconcile their views and aspirations with those of the 'real world' where the products of the educational process must ultimately function."

"A Flexible Design for Health Professions Education" presents a balanced and timely discussion about the traditional and experimental approaches being used to educate health professionals.

Radiopharmacy. Edited by MANUEL TUBIS and WALTER WOLF. Wiley, 605 Third Ave., New York, NY 10016, 1976. 911 pp. 16 × 24 cm. Price $44.50.

This book is very pertinent and timely considering the current expansion of radiopharmacy in the curricula of schools of pharmacy both at the undergraduate and graduate levels. The editors themselves have been key figures in the development of radiopharmacy and its establishment in pharmacy education. They are eminent researchers in their own right and have assembled a highly knowledgeable group of contributors to aid them in their presentation of the subject matter. The problems of multiple-author books and variability in style and presentation occur to some extent in this text. For example, the author of Chapter 1 decided that *in vitro* tests would not be considered in the scope of the book from his vantage point, while the editors considered it pertinent and devoted Chapter 26 to a discussion of competitive binding assay procedures. This reviewer considers that the radiopharmacist does need to have an appreciation of such procedures since they will clearly become more important both clinically and industrially.

The structure of the text is orderly in the presentation of material. It is composed of six basic sections dealing with history, physics and instrumentation, biology, chemistry, radiopharmaceutics, and nuclear medicine. The organization is certainly desirable, providing the student with the background material in these various scientific areas that impinge directly on the practice of radiopharmacy. Additionally, there is an important section on regulations and legal aspects in the handling and dispensing of radiopharmaceuticals. Obviously, such information is of importance to the potential practitioner.

There is also a chapter on radionuclides in space biology and medicine by two very knowledgeable individuals. Such material will certainly gain importance with time, but presently its general application is limited and of a highly specialized nature.

In conclusion, this is a most worthwhile and highly informative text and one that will undoubtedly be widely used by those in academia for teaching purposes and by those who wish to familiarize themselves with the exciting opportunities presented by radiopharmacy. Clearly,

System's data base, is easy to use and provides the reader with fast access to the text's subject matter.

A Flexible Design for Health Professions Education. Edited by RICHARD M. JACOBS. Wiley, 605 Third Ave., New York, NY 10016, 1976. 260 pp. 16 × 23.5 cm.

"Flexible Design" is essential reading for anyone involved in the field of health education, particularly for those who are involved in, or are getting ready to embark on, "experiments" in new instructional techniques and/or curriculum design.

The chapters, which represent the thinking of 23 outstanding educators from the disciplines of medicine, dentistry, pharmacy, nursing, and allied health, are based on material originally presented at an invitational conference (by the same title) held in Iowa City in April 1975.

The editor's introduction succinctly states the book's purpose: "Recent trends in education, health care, and society in general have stimulated serious efforts to find alternatives to the traditional approaches to the health professions education." The volume examines how societal expectations and individual aspirations might be more effectively fulfilled outside the context of the "traditional, highly regimented and stereotyped health professions education programs"—through educational flexibility.

The 20 chapters are grouped into five parts: Basic Educational Considerations and Instructional Strategies; An Overview of Individualized Instructional Practices in the Major Health Professions, (included is the paper on "Flexible Approaches to Pharmacy Education" by L. C. Weaver and H. R. Manassee, Jr.); Planning, Implementation, and Evaluation: Case Studies; Cost of Flexibility; and Broader Dimensions of Flexibility.

The flexibility to which the work is addressed involves a personalized approach to education: individualized curricular content, individualized modes of instruction, flexible scheduling of instruction, and flexible admissions.

Several notable experiments in health professions education are elaborated upon. The authors provide excellent insights into such areas as outreach programs, individual and elective study, hospital programs, different modes of instruction, multitrack systems, independent study programs, computer-aided instruction, use of simulation, social costs, and flexible tuition.

Douglas R. Whitney's chapter on the Placement, Monitoring, and Evaluation System (PME) is important for the distinction it makes between flexible and traditional instruction in view of the demands that the flexible approach places on the system. PME is a decision-making network that collects data; a management system to hold and control data; and an output system to produce reports, documents, and summaries for use in decision making.

Alvin L. Morris, in his chapter on "Implementation," raises important questions and presents a broader perspective on the subject. He argues that: "While flexible education introduces varieties of time and methods to bring all students to the same end point, traditional education does just the opposite.

There is something disturbing about the idea of all students being the same at the end of an educational experience. Conversely, it can be argued that the identification of a wide range of achievements and achievers through traditional education has served both the students and their professions well." Dr. Morris cautions that: "Educators must be willing to reconcile their views and aspirations with those of the 'real world' where the products of the educational process must ultimately function."

"A Flexible Design for Health Professions Education" presents a balanced and timely discussion about the traditional and experimental approaches being used to educate health professionals.

Staff Review

Radiopharmacy. Edited by MANUEL TUBIS and WALTER WOLF. Wiley, 605 Third Ave., New York, NY 10016, 1976. 911 pp. 16 × 24 cm. Price $44.50.

This book is very pertinent and timely considering the current expansion of radiopharmacy in the curricula of schools of pharmacy both at the undergraduate and graduate levels. The editors themselves have been key figures in the development of radiopharmacy and its establishment in pharmacy education. They are eminent researchers in their own right and have assembled a highly knowledgeable group of contributors to aid them in their presentation of the subject matter. The problems of multiple-author books and variability in style and presentation occur to some extent in this text. For example, the author of Chapter 1 decided that *in vitro* tests would not be considered in the scope of the book from his vantage point, while the editors considered it pertinent and devoted Chapter 26 to a discussion of competitive binding assay procedures. This reviewer considers that the radiopharmacist does need to have an appreciation of such procedures since they will clearly become more important both clinically and industrially.

The structure of the text is orderly in the presentation of material. It is composed of six basic sections dealing with history, physics and instrumentation, biology, chemistry, radiopharmaceutics, and nuclear medicine. The organization is certainly desirable, providing the student with the background material in these various scientific areas that impinge directly on the practice of radiopharmacy. Additionally, there is an important section on regulations and legal aspects in the handling and dispensing of radiopharmaceuticals. Obviously, such information is of importance to the potential practitioner.

There is also a chapter on radionuclides in space biology and medicine by two very knowledgeable individuals. Such material will certainly gain importance with time, but presently its general application is limited and of a highly specialized nature.

In conclusion, this is a most worthwhile and highly informative text and one that will undoubtedly be widely used by those in academia for teaching purposes and by those who wish to familiarize themselves with the exciting opportunities presented by radiopharmacy. Clearly,

this book also will be well used by those engaged in research in which radionuclides are a very important factor.

The Alkaloids. Vol. 6. Edited by M. F. GRUNDON *et al.* The Chemical Society, Burlington House, London W1V 0BN, England, 1976. x + 310 pp. 13.5 × 21.5 cm. Price £19.50.

M. F. Grundon has succeeded J. E. Saxton as senior reporter for the sixth volume of this excellent series on alkaloids. This comprehensive review of the literature published between July 1974 and June 1975 follows the format established by the previous volumes.

Chapter 1 deals with biosynthesis, which continues to be an area of considerable interest. In addition to the work on various alkaloids, many biosynthetic studies are reported on secondary microbial metabolites, including gliotoxin, mycelianamide, demethyltomaymycin, actinomycin, the cytochalasins, mitomycin, rifamycin, penicillins, and prodigiosins.

The ensuing 13 chapters cover the major types of alkaloids grouped by chemical structure: pyrrolidine, piperidine, and pyridine; tropane; pyrrolizidine; indolizidine; quinolizidine; quinoline, quinazoline, and acridone; β-phenethylamine and isoquinoline; aporphinoids; indole; *Lycopodium;* diterpenoid; steroidal alkaloids of the *Apocynaceae, Buxaceae, Asclepidaceae,* and *Salamandra-Phyllobates* groups; and *Solanum* and *Veratrum* steroidal alkaloids. Included in these chapters are discussions on the isolation of new alkaloids, structure determinations, chemical synthesis, miscellaneous general chemical studies, analytical methods, and pharmacological studies, depending on the literature available concerning a particular group of alkaloids during the period reviewed.

The centers of greatest activity remain the indole and isoquinoline alkaloids. Miscellaneous alkaloids, such as the imidazole, peptide, and purine alkaloids, have not been included, with the explanation that they will be covered in Volume 7.

Like its predecessors, Volume 6 is well organized. Each chapter is thorough, yet with the conciseness necessary for such a review. That such a review is available so promptly after the time period covered is a tribute to its contributors. While it is somewhat expensive, this volume is recommended very highly for those who wish to keep up-to-date in the field of alkaloid chemistry.

Microbiology–1975. Edited by DAVID SCHLESSINGER. American Society for Microbiology, 1913 I St., N.W., Washington, DC 20006, 1975. vii + 521 pp. 17 × 25 cm. Price $16.00.

This book is a compilation of contributed articles of ASM-sponsored meetings in 1975. The title is misleading, since the book does not deal with topics that follow classical treatment of taxonomic, cultural, and biochemical aspects of microorganisms. The book addresses itself to subject matter areas of methodological and conceptual importance, intended to assist the investigator in the diagnosis and treatment of human diseases. These are provided in the form of "extensive exposures rather than an intensive high-level research." On this premise, a title such as "Recent Advances in Clinical Microbiology" or "Modern Approaches to Clinical Microbiology" or "Selected Topics of Current Interest in Clinical Microbiology" would have been more appropriate.

The book is divided into five sections, each of which is preceded by a short introductory note. Section I, Rapid Diagnostic Techniques in Clinical Microbiology, defines the extent to which new microbiological techniques that give rapid and/or automated results can be applied to clinical microbiology. It provides 14 contributed articles in 97 pages.

Section II, Pathogenic Mechanisms in Bacterial Diseases, discusses current concepts in pathogenesis of microorganisms that cause diseases in humans. It provides 43 contributed articles in 325 pages (about half of the book).

Section III, Mycotoxins, reveals basic interactions and biochemical aspects of mycotoxins in disease processes. It provides five contributed articles in 53 pages.

Section IV, New Vaccines, deals with most recent development and application of specific vaccines and immune serum globulins to the treatment of infections caused by "troublesome" organisms including *Haemophilus influenzae, Neisseria meningitidis,* and *Pseudomonas aeruginosa.* It provides four contributed articles in 17 pages.

Section V, Cell Differentiation and Communication, provides perspectives of morphogenesis in very simple organisms as they pertain to basic problems in developmental biology. It provides 11 contributed articles in 95 pages.

The contributed articles are well written and organized. Many of them show strong interactions between basic and applied concepts of microbiology. With few exceptions, *e.g.,* Considerations in Computer Data Entry by Paul D. Ellner (p. 73) and Polyvalent Vaccine and Human Globulin for Controlling *Pseudomonas aeruginosa* Infections by Mike W. Fisher (p. 416), leading references to original research articles are provided. Each article, however, includes a review, summary, and projections for future work in the specific area.

The book should find an interested audience among graduate students and microbiologists as well as health professionals in related disciplines at universities, hospital laboratories, and industry who may want to follow up on specific subjects.

Marihuana. Chemistry, Biochemistry and Cellular Effects. Edited by GABRIEL G. NAHAS, WILLIAM D. M. PATON, and JUHANA E. IDÄNPÄÄN-HEIKKILÄ. Springer-Verlag, 175 Fifth Ave., New York, NY 10010, 1976. 556 pp. 16 × 24.5 cm. Price $19.80.

This volume contains the proceedings of a Satellite Symposium on Marihuana held at Matinkylä, Finland, before the Sixth International Congress of Pharmacology in Helsinki, Finland, in the summer of 1975. The conference was held primarily to pursue scientifically the areas of marihuana toxicology developed in 1974 spring hearings before the Senate Internal Security Subcommittee of the Committee on the Judiciary (Eastland Subcommittee). Many of the original government witnesses appeared again (Nahas, Morishima, Stenchever, Heath, and Leuchtenberger), but the meeting really was much broader, attracting 43 papers and more than 126 participants and contributors.

The areas covered include marihuana chemistry, the detection and identification of cannabinoids and their metabolites, kinetics and biotransformation, biochemical and cellular effects in isolated cell systems, neurotransmitter effects, and biochemical effects on organ development. The two largest groups of papers were devoted to the chemistry of detection and metabolism and inhibitory effects in isolated cell systems. Many new hydroxylated side-chain metabolites were reported for the first time (Agurell). Parts of the Greek chronic marihuana smoking study in humans were presented, but the majority of papers dealt with animals as subjects. Unfortunately, the discussion that is much needed to help evaluate these research publications is missing. A subject index is included to aid in rapid location of items of interest. Color plates are used in two hematology papers but not for all pathology.

Dr. W. D. M. Paton's concluding state-of-the-cannabis-art summary is recommended. He successfully perceives the limitations of the neurochemical basis for explaining marihuana action, the need for *in vivo* corroboration of isolated cell system work, and the elegant chemical and biochemical studies that undergird the field.

Many of the original government witnesses appeared again (Nahas, Morishima, Stenchever, Heath, and Leuchtenberger), but the meeting really was much broader, attracting 43 papers and more than 126 participants and contributors.

The areas covered include marihuana chemistry, the detection and identification of cannabinoids and their metabolites, kinetics and biotransformation, biochemical and cellular effects in isolated cell systems, neurotransmitter effects, and biochemical effects on organ development. The two largest groups of papers were devoted to the chemistry of detection and metabolism and inhibitory effects in isolated cell systems. Many new hydroxylated side-chain metabolites were reported for the first time (Agurell). Parts of the Greek chronic marihuana smoking study in humans were presented, but the majority of papers dealt with animals as subjects. Unfortunately, the discussion that is much needed to help evaluate these research publications is missing. A subject index is included to aid in rapid location of items of interest. Color plates are used in two hematology papers but not for all pathology.

Dr. W. D. M. Paton's concluding state-of-the-cannabis-art summary is recommended. He successfully perceives the limitations of the neurochemical basis for explaining marihuana action, the need for *in vivo* corroboration of isolated cell system work, and the elegant chemical and biochemical studies that undergird the field.

"ZERO-BASED" DRUG STANDARDS

President Carter has introduced the management approach of "zero-based budgeting" in reviewing federal programs and their financing. Indeed, so much has been said and written about this concept in recent months that few of our readers are probably unfamiliar with the term and its meaning. However, a brief explanation may be useful.

Basically, in contrast to taking last year's projects and programs and simply adding to them by way of staff, budget, and so on, zero-based budget calls for a complete reassessment of each such project or program to determine if the activity itself, as well as all of its components, can be currently justified. The premise is that there is a natural tendency for activities to be initiated which in time come to outlive their usefulness, in part or in whole. In the absence of any positive step to reassess their function and value by today's perspective, they drone on indefinitely.

The thought has long been with us that some such comprehensive reassessment would be highly desirable with respect to drug standards and specifications—particularly those appearing in the official compendia. Frequently, additions or revisions are made to *United States Pharmacopeia* or *National Formulary* monographs which interrelate with other elements within the compendia.

Those responsible for the compendial revision programs generally have done a good job of making whatever modifications were necessary to avoid any outright discrepancies or contradictions. However, in the absence of a "start from scratch" review, any process that introduces changes or new material in a piecemeal fashion will result in a patchwork product to some degree.

An example or two might help to explain both what we have in mind as well as how it happens to come about.

Effective April 1 of this year, a new standard requires that certain drugs be packaged in containers meeting specified criteria of "tightness." This significant advance now provides the compendia with objective procedures to test the tightness of containers and to specify well-defined limits of performance that the containers must meet. The drugs involved are all those whose individual monographs specifically include provision for such packaging. And, a review of the USP and NF reveals that a substantial number of monographs do call for use of either "well-closed" or "tight" containers.

However, such provisions were placed in most, if not all, of these drug monographs at a time when there was no real method for evaluating container tightness. Hence, the standard was more qualitative than quantitative.

The question now arises as to whether all drugs, for which there is a tightness requirement in the pertinent monographs, actually need this degree of protection now that we have defined it and have established methodology for its determination.

Compendia officials are well aware of this situation, but there is only one way that it can be rectified. That would require a drug-by-drug, monograph-by-monograph review, complete with stability data and the like, in order to conclude that the requirement may safely be deleted from certain monographs. But this review would necessitate considerable time and effort just to "clean up" the subject; that is, there is no risk or hazard with the present situation—it simply is one that, on purely scientific grounds, probably could not be justified as necessary to the extent that it applies.

Drug identification tests are another illustration of this problem. For many years, simple qualitative tests were included in compendia monographs to confirm the identity of a specimen. For example, such a test might describe a certain color change in a solution of the sample upon addition of a certain reagent.

With the introduction and wide application of infrared spectrophotometry—especially in conjunction with a reference standard—these antiquated spot tests and color tests became superfluous in the extreme. Yet they often were not deleted because certain parties—due to limitations in available equipment or misguided nostalgia—argued for their retention.

Again, there is nothing wrong *per se* with their continued presence. However, they have outlived their usefulness and they add a lot of undesirable "clutter" to what should be a concise set of drug standards.

All of these defects could be remedied by a start from scratch review of the entire USP and NF content. In line with President Carter's approach to budget development, it appears timely to consider a zero-based review of the compendial standards, with a goal of streamlining the monographs, eliminating duplication, correcting inconsistencies, and achieving uniformity of treatment.

IMPEDING METRIC CONVERSION

For many years, this writer had served as a self-styled good will ambassador for the metric system. Whenever the subject happened to be discussed with family, friends, or professional acquaintances, we always talked up the merits of the system and the desirability of the United States converting *in toto* to its use.

Moreover, we felt very comfortable in doing so. The metric system is "the system" of the physical and biological sciences; it is "the system" of pharmacy; it is officially endorsed as "the system" by the American Pharmaceutical Association. Hence, by training, background, career, and affiliation, we were in concert with the metric theme. Indeed, we even had several occasions to participate as a witness in presenting testimony before U.S. Congressional committees which were hearing bills dealing with national conversion to the metric system.

On all these occasions, we have repeated what so many others have said in arguing the merits of such conversion; namely, we would be adopting a pure, uniform, and simple system which can be easily learned and, once learned, will remain unchanged forever.

But then some unsettling things began to happen. The first hint that all may not be quite as rosy as we thought was when the controversy arose over whether the preferred unit of volume was a "cubic centimeter" (cc) or a "milliliter" (ml). After what seemed to be a good deal of haggling, this was eventually settled with the result that much revising was necessary in style books, in texts, in calibrations on laboratory equipment, and in the labeling on numerous containers, particularly those of chemicals and drugs.

Then one day the local weather report began to give temperatures in terms of degrees celsius rather than the familiar degrees centigrade. And when we could not immediately explain the difference to our children, we suffered both embarrassment as well as a blow to our personal credibility.

We hardly had time to track this one down when we learned that the presses must be halted for our publications in order that the typesetters could scurry about changing all the "microns" to "micrometers" and the "millimicrons" to "nanometers"—along with corresponding changes in the symbols and abbreviations used in their stead.

What was happening? Why were these and other changes like them being made? Was no one else distressed and disturbed by what to us appeared to be a series of confusing, pointless, and disturbing disruptions?

Well, in the letters column of a recent issue of the American Chemical Society's publication, *Chemical and Engineering News*, we learned that there is at least one fellow sufferer. Dean W. Gibbons of Detroit wrote about his experience trying to keep up with such changes as those mentioned above, as well as a number of others including "torr" to honor Torricelli, the inventor of the barometer, and "kilopascals," presumably in honor of Pascal and his law of the pressure-volume relationship.

"There are better ways to honor our scientific forefathers than to rename familiar metric units," writes Gibbons. And he goes on to add: *"Public acceptance of the metric system will depend on whether the system is perceived as simple and logical, or regarded as a jumble of confusion. The use of long-established, descriptive units, instead of the latest fads, will aid the transition from the English to the metric system."*

His point is both well taken and well stated. Hopefully, the scientific community is more stable and sedate than the local town officials who will rename Main Street at the drop of a hat to honor—for political reasons—some celebrity or other public figure who is currently in the news.

Those of us who deal with measurement terms and their symbols on a daily basis have difficulty enough remembering which is what, and which is correct. For the general public to cope with such changes is simply asking too much. We hope that the scientists responsible for initiating such changes will recognize that they are doing a real disservice by needlessly impeding the process of metric conversion.

GI Motor Inhibition Associated with Acute Exposure to Methyl Methacrylate Vapor

MARTIN F. TANSY ˣ, JOHN S. MARTIN, SEROUYA BENHAIM, WENDELL E. LANDIN, and FRANK M. KENDALL

Abstract □ A mixture of monomeric methyl methacrylate vapor in air was delivered into the breathing air of chloralose–urethan anesthetized dogs. Fixed length exposures to 2000-ppm doses of the vapor resulted in a transient drop in arterial blood pressure and a marked inhibition of ongoing GI motor activities. Motor inhibition always continued for a variable time (~10–15 min) subsequent to the cessation of methyl methacrylate vapor administration. This inhibitory response was not blocked by bilateral vagotomy, spinal transection, splanchnectomy, or the intravenous administration of tetraethylammonium chloride. Another series of experiments determined that the administration of blood from a dog receiving methyl methacrylate vapor produced GI motor inhibition in another dog not connected to the experimental gas mixture. Therefore, it is concluded that, aside from any reflex effects produced, methyl methacrylate vapor in sufficient concentration probably exerts a direct inhibitory effect upon GI smooth muscle that is mediated by the cardiopulmonary systems.

Keyphrases □ Methyl methacrylate monomeric vapor—pulmonary exposure, effects on GI motor activities, dogs □ GI motor activities—effect of pulmonary exposure to monomeric methyl methacrylate vapor, dogs □ Toxicity—monomeric methyl methacrylate vapor, pulmonary exposure, effects on GI motor activities, dogs

Published experiments (1) from this laboratory previously demonstrated that short exposures of conscious rats to relatively high concentrations of methyl methacrylate vapor in air were associated with rapid declines in the amplitudes of gastric pressure events. These pressure events gradually reestablished normal patterns within 4 min of cessation of methyl methacrylate vapor exposures for 5–10 min. A similar observation was made with a single human subject during an exposure comparable to that received occupationally (1).

The second objective of these acute motility experiments (1) was to determine a possible reflex mechanism that could reasonably be inferred to mediate the inhibition of gastric motor activity associated with the acute exposure of the rat to methyl methacrylate vapor. However, the results were equivocal because cervical vagotomy does not define a reflex originating in the pulmonary apparatus having its afferent and efferent limbs in the vagus and subdiaphragmatic vagotomy cannot be performed as surely in the rat. For this surgical reason, the chloralose–urethan anesthetized dog was employed as the experimental animal after satisfying the requirement that a similar inhibitory response can be produced. Therefore, the experimental observations were extended to another species.

EXPERIMENTAL

Animals and General Procedure—Twelve adult mongrel dogs of both sexes were equilibrated for at least 3 days in the local animal facility prior to use. All experiments were undertaken after the animals had been fasted overnight but with water allowed *ad libitum*. All dogs were individually titrated to a surgical plane of anesthesia by the intravenous administration of a mixture of α-chloralose (5%, dissolved in polyethylene glycol 200) and urethan (50% in 0.9% saline). Further injections of the chloralose–urethan mixture were given when necessary.

Surgical and Recording Procedures—The femoral artery was cannulated to permit the continuous measurement of systemic blood pressure, and the ipsilateral vein was cannulated to permit administration of tetraethylammonium chloride[1] and fluids. Each animal was tracheostomized to permit monitoring of respiration, artificial respiration, and administration of methyl methacrylate vapor. On occasion, a pneumograph was used to record respiratory movements.

A midline laparotomy was then performed. Recording balloons were inserted *via* the oral route for gastric recording and retrograde *via* a stab wound in the ileum for small intestinal recording. Polygraphic control tracings were obtained before and at stated intervals after the physical and chemical stimulatory procedures in each group of dogs. In all in-

[1] Etamon, Parke, Davis.

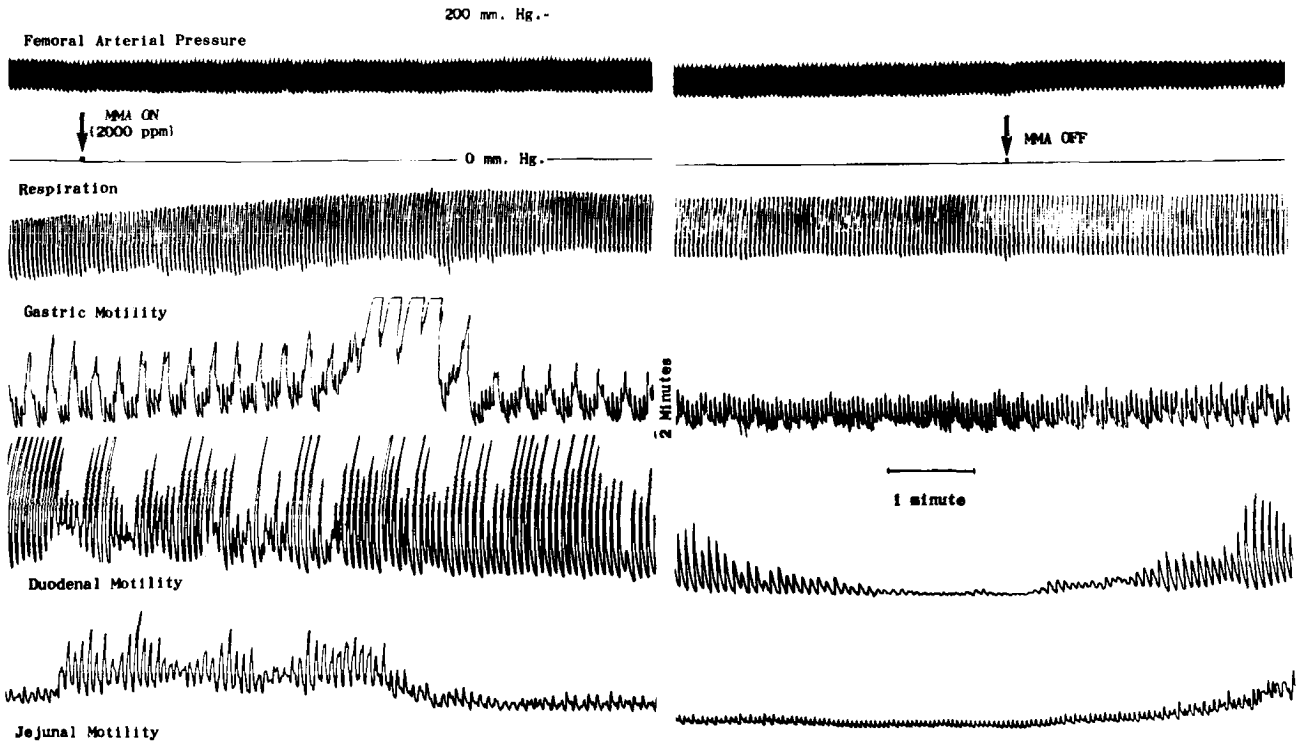

Figure 1—*Polygram of physiological parameters observed during the acute exposure of a chloralose–urethan anesthetized dog to methyl methacrylate (MMA) vapor at 2000 ppm in air. A slight, transient decline in arterial blood pressure was observed. Respiratory rate and relative tidal volume (as measured by a pneumograph) were substantially unchanged. Gastric pressure indications suggest an initial augmentation of active contractile activity followed by a decline in the active component with little effect upon tonus. Duodenal motor activity suggests a drastic decline in active contractile activity as well as a reduction in tonus. The jejunum fortuitously began a bout of contractile activity just before the exposure commenced. Both the active and tonus components of this activity were inhibited during exposure.*

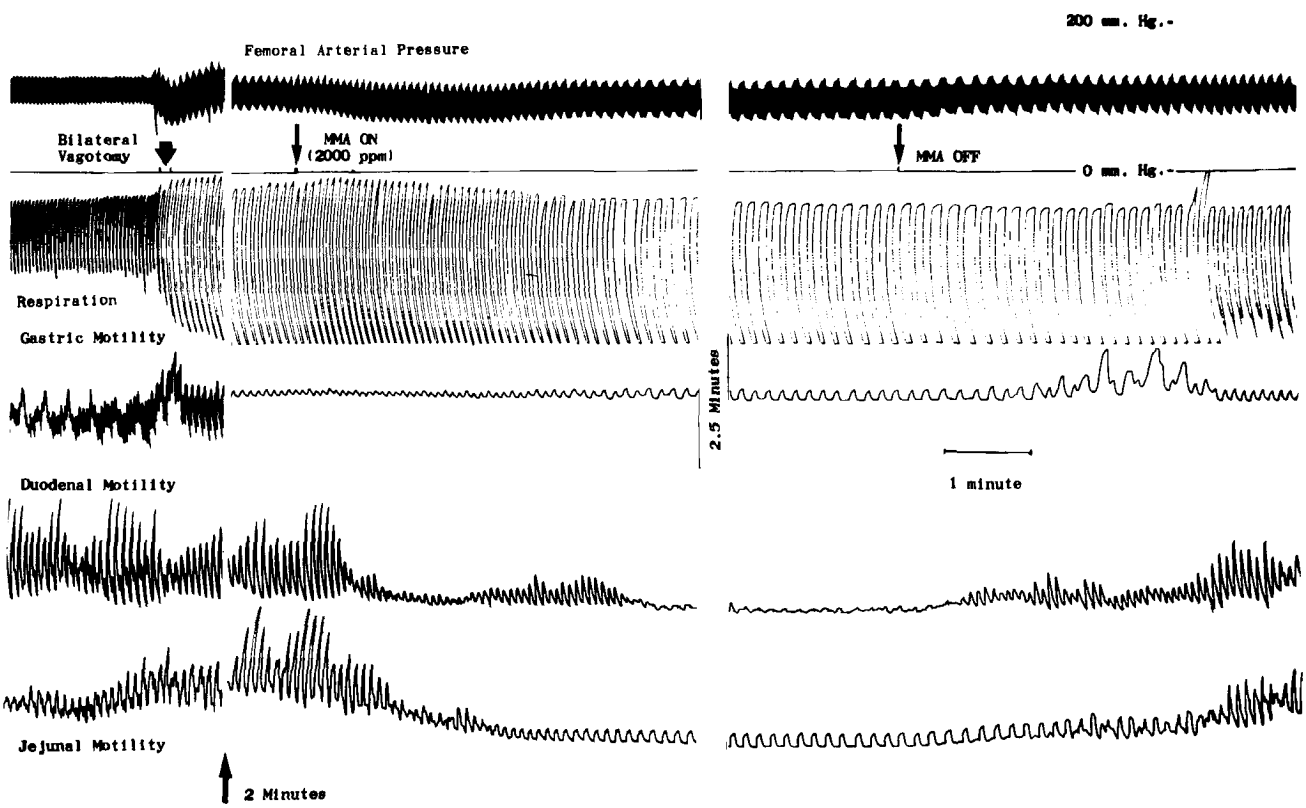

Figure 2—*Continuation of the experiment depicted in Fig. 1. Both vagi were severed, and the gas exposure was repeated. Gastric, duodenal, and jejunal motor activities continued to be inhibited during exposure. The transient depression in arterial blood pressure was more evident in magnitude and duration during the exposure to 2000 ppm of methyl methacrylate (MMA) vapor in air.*

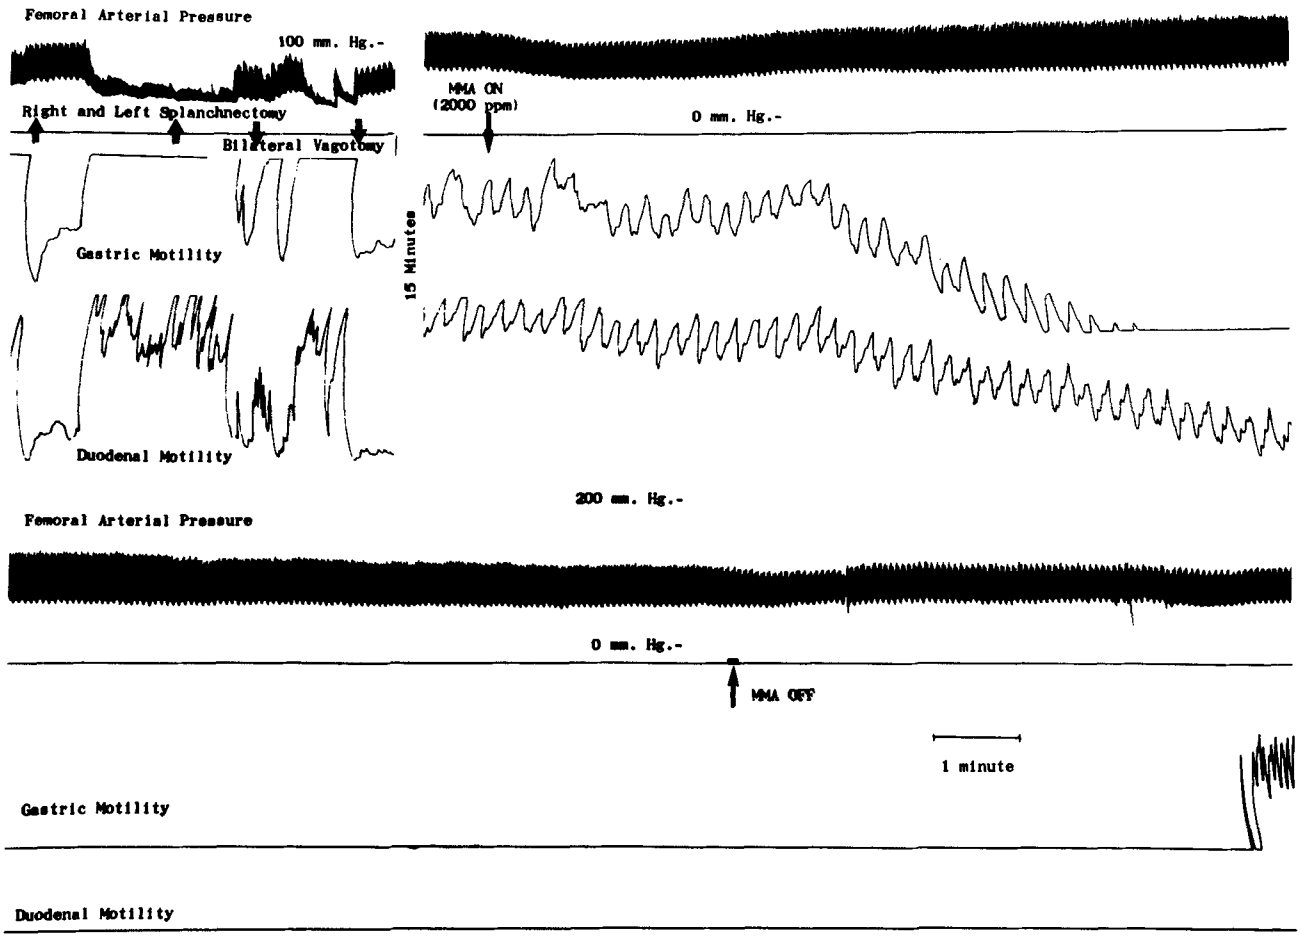

Figure 3—*Effects of acute exposure to 2000 ppm of methyl methacrylate (MMA) vapor in air following bilateral vagotomy and splanchnectomy (top panel) in a chloralose–urethan anesthetized dog. The active and tonus components of gastric and duodenal motor activities were severely inhibited (top of lower panels). Arterial blood pressure was transiently affected.*

stances, the designation of intestinal pressure records as signifying a particular type of motility response is justified on the basis of a visual observation that such a response occurred concurrently with the recorded pressure events.

Vapor Administration and Analyses—The methyl methacrylate monomer[2] used contained 10 ppm of the monoethyl ether of hydroquinone as an inhibitor. During all methyl methacrylate vapor administrations, the dogs were ventilated at a fixed minute volume of 4–6 liters. Pilot experiments were performed to determine empirically a rate of methyl methacrylate vapor introduction that would consistently produce the motor effects desired. Once this rate was determined, samples of the resulting gas mixture were analyzed by GLC[3] and the average measured concentration was assumed to be constant throughout the balance of the experiments. In view of the minute volume, it was assumed that the methyl methacrylate vapor rapidly disappeared from the respirator system when the supply of methyl methacrylate vapor was turned off.

RESULTS AND DISCUSSION

For all practical purposes, each animal was used for at least one control run prior to the performance of any procedure not already outlined. Figure 1 represents a typical polygram produced by such a run. Gastric antral pressure amplitudes became depressed during exposure. In all cases, a transient but vigorous bout of gastric contraction appeared shortly after the first introduction of methyl methacrylate vapor. This effect never occurred more than once. Gastric antral pressure activity became depressed during exposure and gradually approached control values after cessation of exposure. Small intestinal pressure amplitudes also were depressed.

The rate of onset of inhibition was not apparently a necessary function of the observed organs. In this polygram, it can be seen that the duodenum exhibited a higher degree of contractile activity during the control period. In this case, degradation of duodenal activity followed a longer time course than that of jejunum activity, which became quiescent much sooner. The latency of the inhibitory response was generally proportional to the degree of pressure activity produced by the organ prior to administration of methyl methacrylate vapor.

Figure 2 shows the responses of the previous animal to methyl methacrylate vapor following subdiaphragmatic vagotomy. A short administration of methyl methacrylate vapor quickly reduced intestinal pressure activity, which remained depressed for the duration of the exposure. In this particular experiment, the motor activity of the gastric antrum had not recovered from the transient effects of vagotomy by the time that this exposure was performed. In this record, only the onset of the return of antral motor activity is apparent. Subsequently, this activity returned and was inhibited by further methyl methacrylate exposures. There appeared to be a transient fall in arterial blood pressure in the vagotomized animal following the start of methyl methacrylate vapor administration.

Figure 3 depicts polygrams obtained from a mechanically ventilated, splanchnectomized, vagectomized dog anesthetized with chloralose–urethan. These recordings depict the time course of arterial blood pressure and gastric and duodenal motor activities. The left portion of the top panel shows the artifacts produced by sectioning of the splanchnic nerves and vagi. Methyl methacrylate vapor was introduced into the air supply, and motor activities were abruptly reduced, primarily in terms of loss of tonus. Contractile events were not seen because the pens bottomed in the channel stops. Within 7–8 min after cessation of exposure, gastric tone abruptly reappeared.

The polygrams shown in Fig. 4 were obtained as a continuation of the

[2] Rohm and Haas.

[3] The column was 1.5-m × 0.3-cm (5-ft × 0.125-in.) o.d. stainless steel, packed with 20% Carbowax 20M, coated onto 80–100-mesh Chromosorb W. The chromatographic conditions were: column oven (starting) temperature, 100°; injection port temperature, 200°; detector temperature, 200°; helium pressure, 68 psi; helium flow, 30 ml/min; hydrogen pressure, 20 psi; air pressure, 20 psi; attenuation, 32×10^{-11}; recorder sensitivity, 1 mv; and sample size, 1 ml.

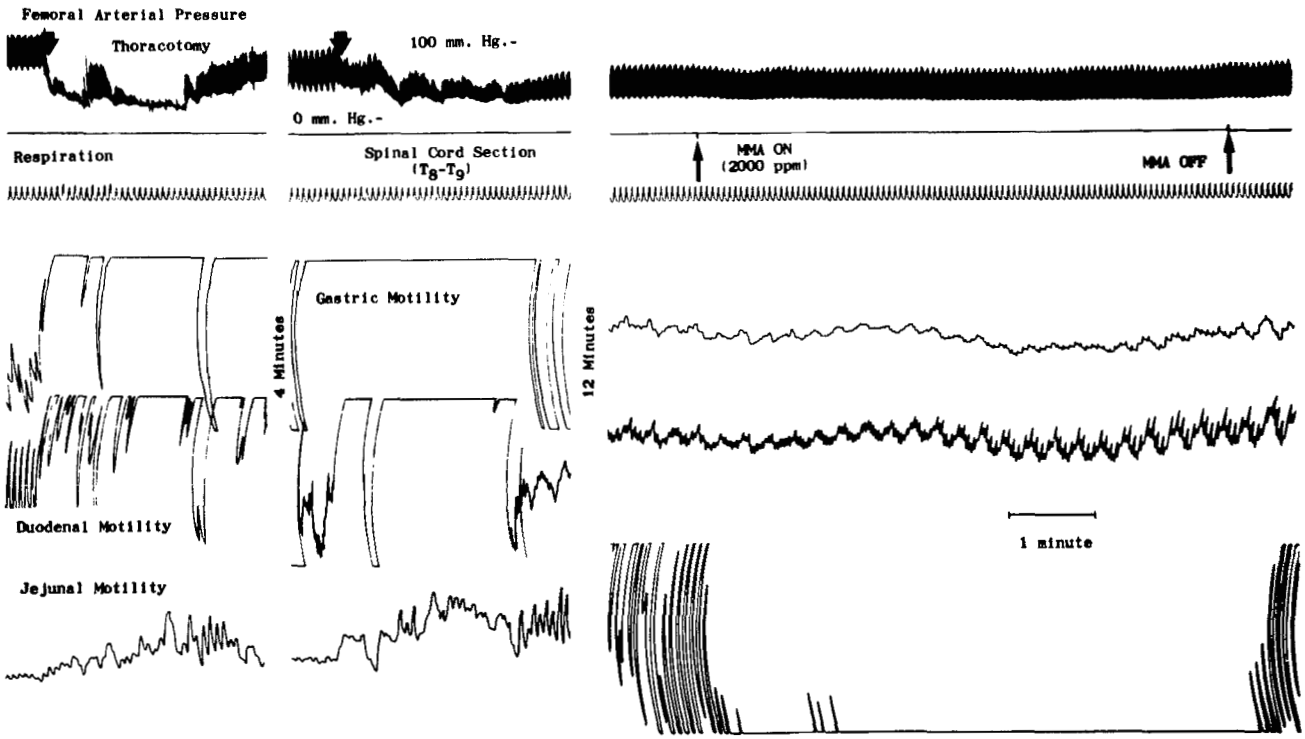

Figure 4—*Continuation of the experiment depicted in Fig. 3. Following recovery from the previous exposure, the dog was ventilated mechanically, a thoracotomy was performed, and the spinal cord was severed at the T_8–T_9 level. Tonus components of gastric and duodenal motor activities were slightly depressed. No remarkable changes in active contractile activity were apparent, because there was very little in evidence at the start of exposure. In contrast, the high amplitude jejunal activity present was abruptly abolished and spontaneously restored at the cessation of vapor exposure. A slight depressor effect on arterial blood pressure was seen.*

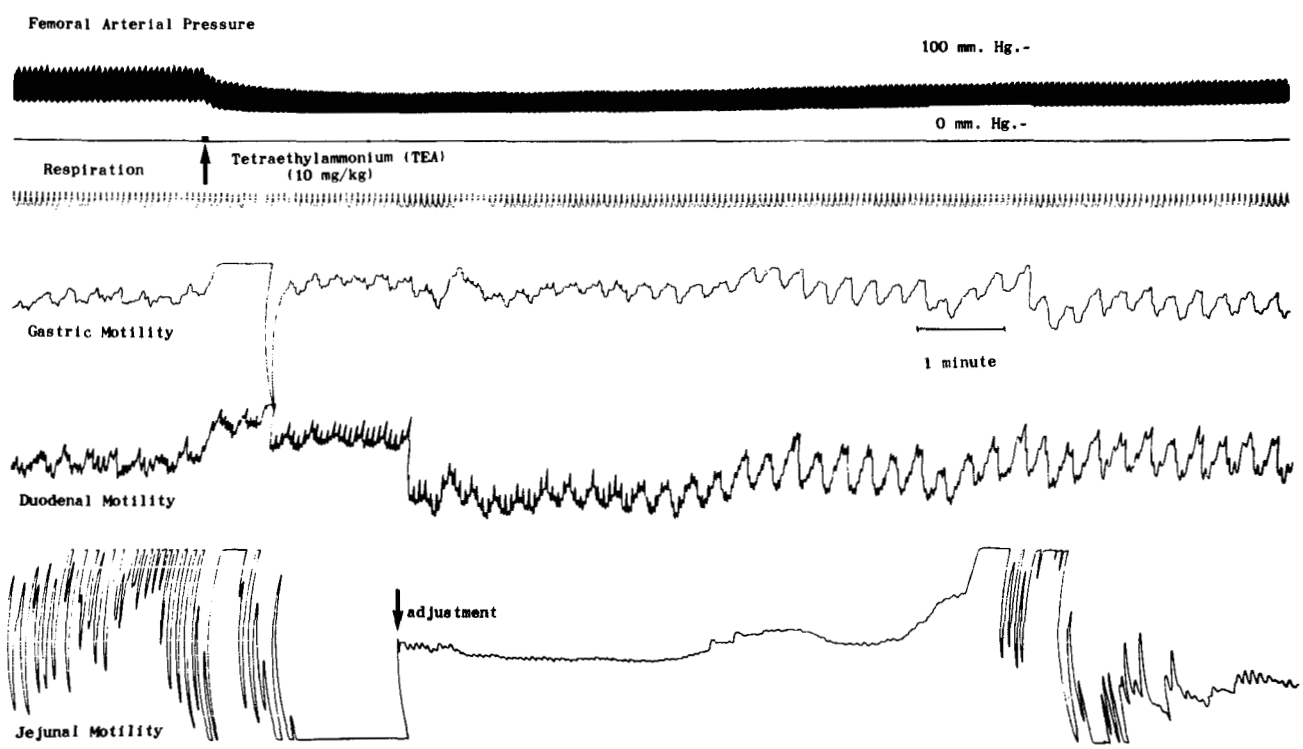

Figure 5—*Continuation of the experiment depicted in Figs. 3 and 4 following recovery from the previous exposure with a dog that has been bilaterally vagotomized, splanchnectomized, and spinally transected. Administration of the ganglionic blocking agent tetraethylammonium chloride (10 mg/kg) was associated with a decline in arterial mean and pulse pressures, a transient decline in duodenal active and tonus contractile components, and little effect upon gastric pressure activity. Jejunal contractile activity was inhibited. The baseline for jejunal pressure activity was reset to determine the effects of tetraethylammonium chloride on the active component.*

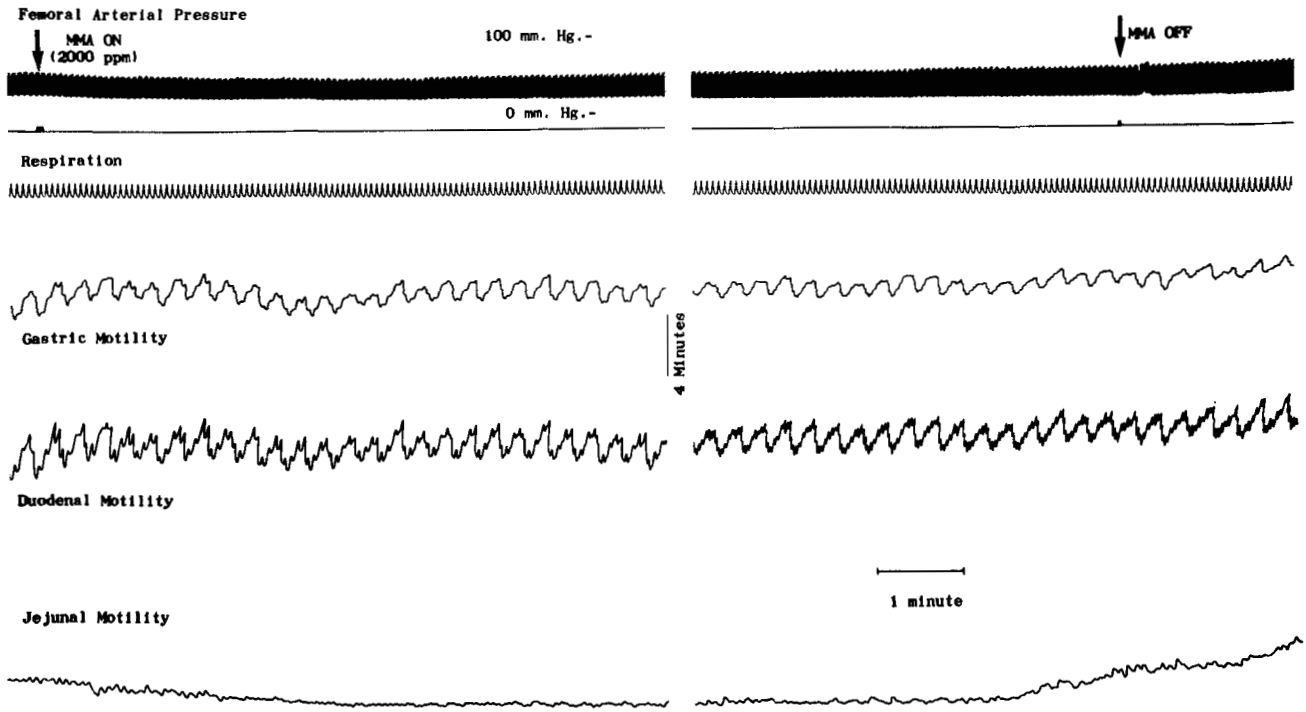

Figure 6—*Continuation of the experiment depicted in Figs. 3–5 following a recovery period from the previous procedures. At this point, reexposure to 2000 ppm of methyl methacrylate (MMA) vapor in air resulted in a slight decline in mean arterial blood pressure and a definite reduction in jejunal tonus.*

observations made during the experiment depicted in Fig. 3. In this record, relative respiratory motion and jejunal motor activities are included. The left and center panels depict the artifacts produced by retraction of the open chest and transection of the spinal cord between T_8 and T_9. During methyl methacrylate administration, gastric antral and duodenal motor activities were only slightly affected but jejunal tonus was drastically reduced.

Further observations were then conducted utilizing the by now surgically denervated viscera. The polygram in Fig. 5 shows the observed effects of tetraethylammonium chloride administration, which produced

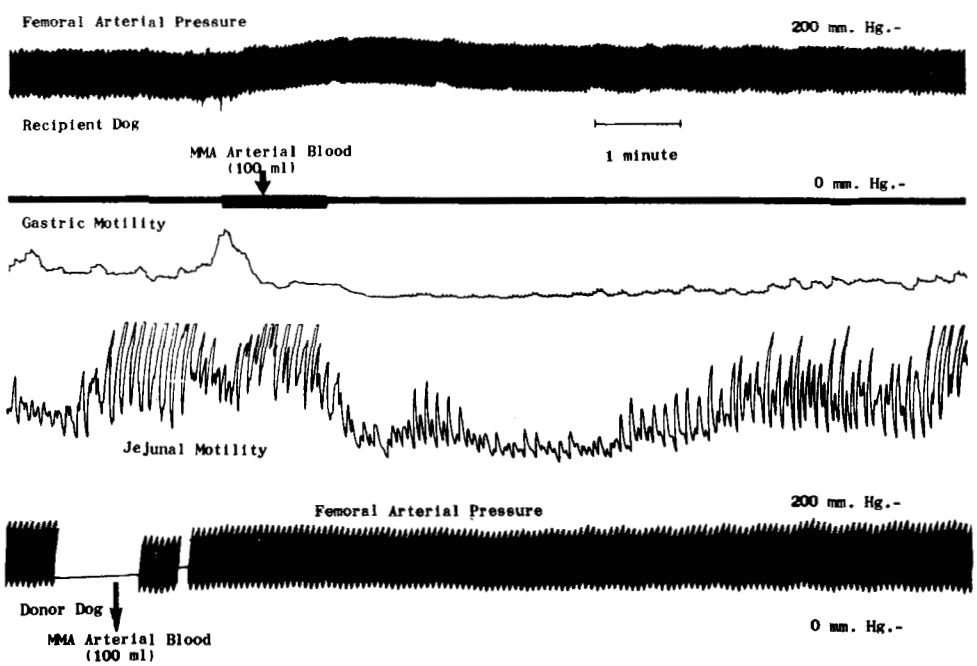

Figure 7—*Parallel polygrams obtained from chloralose–urethan anesthetized dogs. The donor dog (lower trace) was continuously exposed to 2000 ppm of methyl methacrylate (MMA) vapor in air for about 1 hr before these records were made. Arterial blood (100 ml) was obtained from the arterial pressure cannula of the exposed dog and rapidly infused into the femoral vein of the unexposed recipient dog (top traces). Gastric tonus of the recipient was depressed, but no inference can be drawn concerning an effect upon the active component of gastric activity which was not present at this time. The active and tonic components of jejunal activity were both depressed transiently in the recipient. The increase in mean arterial blood pressure of the recipient was most likely due to the hypervolemia produced by the infusion of 100 ml of whole blood, which would tend to obscure any transient decline due to the methyl methacrylate content of the donor blood.*

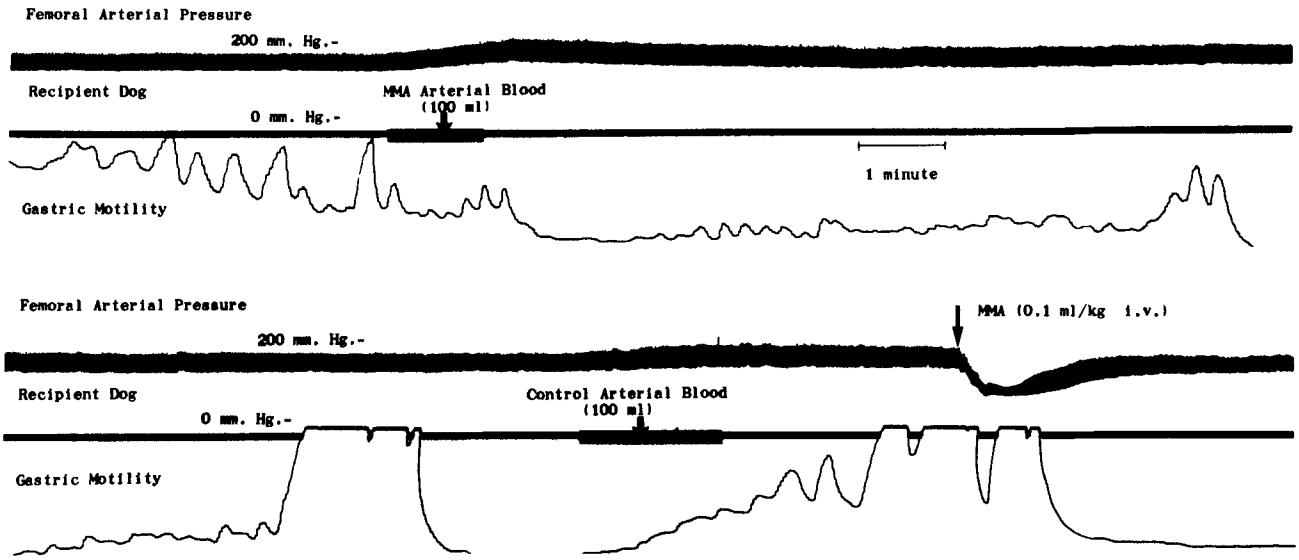

Figure 8—*Gastric contractile activity and arterial blood pressure events produced in a chloralose–urethan anesthetized dog following the infusion of 100 ml of whole blood from a donor dog (continuation of the experiment depicted in Fig. 7). In the top traces, the active and tonic gastric contractile activity of the recipient dog were depressed when 100 ml of whole blood, obtained during the exposure to 2000 ppm of methyl methacrylate (MMA) vapor in air, was infused via a femoral vein. The same experiment was repeated in the lower traces, where 100 ml of donor blood, obtained prior to methyl methacrylate exposure, was infused into the venous system of the recipient. Gastric contractile activity appeared to be normal following the infusion of blood from the donor prior to methyl methacrylate exposure, but recipient gastric motor activity was depressed following infusion from the methyl methacrylate exposed donor. At the end of the lower trace, the reactivity of the recipient was verified by the results of an intravenous administration of 0.1 mg/kg of the methyl methacrylate monomer. Gastric contractile activity was abolished and femoral arterial blood pressure was sharply, but transiently, affected.*

a transient fall in duodenal tonus and jejunal tonus and contractile activity. In this recording, the baseline of the jejunal pressure channel was reset to permit observation of the resulting motor activity, which was minimal.

Figure 6, a continuation of the record of Fig. 5, shows that the administration of methyl methacrylate vapor following ganglionic blockade with tetraethylammonium chloride was principally associated with a further depression of jejunal tonus and the by now minimal jejunal contractile activity. Jejunal tonus began to appear prior to the cessation of methyl methacrylate vapor administration.

A series of observations were then conducted simultaneously in real time utilizing four chloralose–urethan anesthetized dogs. These dogs had been subjected to identical surgical procedures: tracheostomies, arterial and venous cannulation, gastric antral recording balloons (oral route), and duodenal recording balloons (retrograde from the ileum). The purpose of these observations was to test the hypothesis that the motor effects associated with methyl methacrylate vapor administration could not be mediated in part by the circulation. Accordingly, methyl methacrylate vapor was only administered to one of each pair of dogs, and an arterial blood sample from the exposed (donor) dog was infused into the femoral vein of the nonexposed (recipient) dog. During these procedures, the monitored parameters were recorded graphically upon the same strip chart.

Figure 7 shows the time course of events in the recipient (top traces) and the donor (lower trace only) during these experiments. During the span of this record, the donor dog was continuously exposed to 2000 ppm of methyl methacrylate vapor *via* the breathing system. The top traces show that the slow infusion of 100 ml of donor blood resulted in a decrease in gastric and duodenal tonus and contractile activity. These activities gradually returned to control levels.

Figure 8 shows a continuation of the observations of the gastric antral activity of the recipient dog. Antral activity and tonus were reduced following intravenous administration of another sample of exposed donor blood (top traces). The lower traces show that recipient gastric activity was unchanged when an equal volume of donor blood, drawn during the control period prior to methyl methacrylate exposure, was infused.

Cardiovascular activity was monitored on a routine basis to indicate the general viability of the preparation and the responsiveness following certain procedures and as a general indication of cardiovascular toxicity. The time rate of the GI motor phenomena is unfortunately too low to permit adequate recording of faster cardiovascular phenomena without producing records of unusable length. As a result, the cardiovascular data are unsuitable for acquiring data for dynamic analysis. However, the records do show that direct administration of methyl methacrylate produced a decreased pulse pressure and probably a reflex tachycardia. These effects could be accounted for by two possible mechanisms: a direct toxic increase in arterial compliance and a direct toxic decrease in myocardial contractility. If, indeed, the general toxic effect of this agent resides in an inhibition of active contractile force, a further examination of the cardiovascular effects appears to be warranted.

The remainder of the foregoing data may be interpreted as follows. The acute studies indicated that the administration of methyl methacrylate is associated with a depression of tonus and contractile activity of the canine gastric antrum and proximal small bowel. Regardless of the presence or absence of visceral innervation, this effect had a latency on the order of 10 min when the agent was administered in vapor form. This latency was very short when either blood from an exposed dog or liquid methyl methacrylate was introduced intravenously. Although it was not included previously, a short latency was observed when the agent was administered intravenously to a surgically and chemically denervated preparation. Thus, the short latency might be indicative of a reflex response. However, the manifestation of the same effect in the denervated preparation, while not excluding the possibility that some reflex effects are produced, makes a reflex explanation for the observed response unlikely.

Inasmuch as this laboratory (2) and others (3) have observed that the monomer vapor depresses the spontaneous motor activity of intestinal strips *in vitro*, it may be concluded that methyl methacrylate vapor probably exerts a direct inhibitory effect upon GI smooth muscle and that the cardiopulmonary system is capable of mediating this effect when exposure is by inhalation.

Disposition of Sulfonamides in Food-Producing Animals IV: Pharmacokinetics of Sulfamethazine in Cattle following Administration of an Intravenous Dose and Three Oral Dosage Forms

RICHARD F. BEVILL [*x], LEWIS W. DITTERT [‡], and DAVID W. A. BOURNE [‡]

Abstract □ The plasma and urine data obtained following intravenous administration of sulfamethazine to cattle were fit to a one-compartment pharmacokinetic model with a half-life of elimination of 9 hr and a volume of distribution of 0.35 liter/kg. Sulfamethazine was eliminated by excretion of unchanged sulfamethazine (18%) into urine and by formation of three metabolites subsequently excreted into urine. Sulfamethazine also was administered as a solution, a rapid-release bolus, and a sustained-release bolus. The change in the urinary metabolic pattern with different routes of administration suggested that first-pass metabolism was occurring during the absorption process. The absorption half-life was 6 hr. The absorption process for the two solid boluses kinetically appeared to include a dissolution step.

Keyphrases □ Sulfamethazine—absorption, metabolism, and excretion, various dosage forms compared, cattle □ Sulfonamides—sulfamethazine, absorption, metabolism, and excretion, various dosage forms compared, cattle □ Absorption—sulfamethazine, various dosage forms compared, cattle □ Metabolism—sulfamethazine, various dosage forms compared, cattle □ Excretion—sulfamethazine, various dosage forms compared, cattle □ Pharmacokinetics—sulfamethazine, various dosage forms compared, cattle □ Antibacterials—sulfamethazine, absorption, metabolism, and excretion, various dosage forms compared, cattle

Sulfamethazine is used extensively in veterinary medicine for the treatment of various infections in food-producing animals. Commercially available oral dosage forms for large animals include a solution, a bolus of the sodium salt, and a sustained-release bolus of the free acid. The comparative bioavailabilities and plasma concentration–time profiles of these dosage forms in large animals have not been reported.

The present study investigated the rate and extent of sulfamethazine absorption from three oral dosage forms compared with an intravenous solution of sulfamethazine sodium in 1-year-old cross-bred heifer feeder calves.

EXPERIMENTAL

Intravenous Administration—Three Hereford × Angus heifers, 1 year old, were weighed, fitted with urinary retention catheters[1] attached to 4-liter plastic collection bottles, and assigned to individual slot-floored metabolism cages 3 days prior to dosing. The weights of Animals 1, 2, and 3 were 235, 226, and 245 kg, respectively. Good quality grass hay and water were provided *ad libitum* during acclimatization and postdosing periods. A concentrate mixture, formulated from shelled corn and linseed meal and containing 12% protein, was limit fed to each animal during the study.

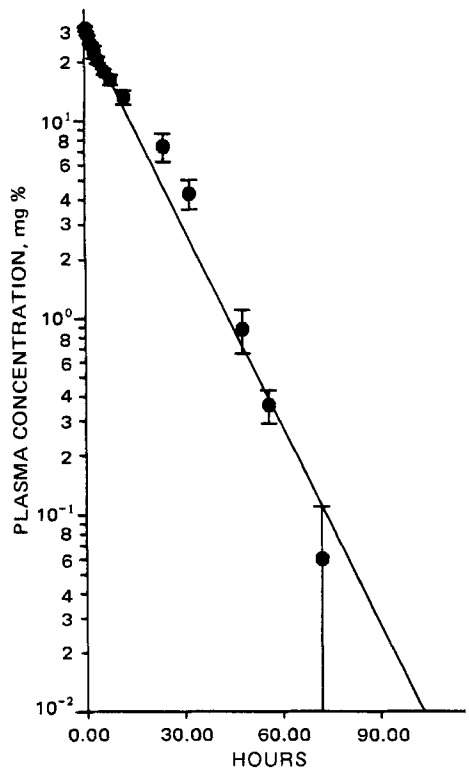

Figure 1—*Semilog plot of average plasma sulfamethazine concentration* (±SD) versus *time following intravenous administration of sulfamethazine sodium (107 mg/kg) to three calves. Points were experimentally observed, and the line was calculated by iterative least-squares fitting to a one-compartment model* ($t_{1/2}$ = *9 hr*, V_D = *0.35 liter/kg*).

A dose of 107 mg/kg (¾ gr/lb) of sulfamethazine as a 12.5% solution of sulfamethazine sodium[2] was rapidly injected *via* the right jugular vein in each animal. All blood specimens were collected from the left jugular vein by serial venipuncture using disposable plastic syringes prerinsed with a 1% solution of heparin sodium in normal saline.

Blood and urine specimens were collected at 0, 0.5, 1, 2, 3, 4, 6, 8, 12, 24, 32, 48, 56, and 72 hr following drug administration. The volume of urine collected over each interval was recorded, and a clean collection

Disposition of Sulfonamides in Food-Producing Animals IV: Pharmacokinetics of Sulfamethazine in Cattle following Administration of an Intravenous Dose and Three Oral Dosage Forms

RICHARD F. BEVILL [*x], LEWIS W. DITTERT [‡], and DAVID W. A. BOURNE [‡]

Abstract □ The plasma and urine data obtained following intravenous administration of sulfamethazine to cattle were fit to a one-compartment pharmacokinetic model with a half-life of elimination of 9 hr and a volume of distribution of 0.35 liter/kg. Sulfamethazine was eliminated by excretion of unchanged sulfamethazine (18%) into urine and by formation of three metabolites subsequently excreted into urine. Sulfamethazine also was administered as a solution, a rapid-release bolus, and a sustained-release bolus. The change in the urinary metabolic pattern with different routes of administration suggested that first-pass metabolism was occurring during the absorption process. The absorption half-life was 6 hr. The absorption process for the two solid boluses kinetically appeared to include a dissolution step.

Keyphrases □ Sulfamethazine—absorption, metabolism, and excretion, various dosage forms compared, cattle □ Sulfonamides—sulfamethazine, absorption, metabolism, and excretion, various dosage forms compared, cattle □ Absorption—sulfamethazine, various dosage forms compared, cattle □ Metabolism—sulfamethazine, various dosage forms compared, cattle □ Excretion—sulfamethazine, various dosage forms compared, cattle □ Pharmacokinetics—sulfamethazine, various dosage forms compared, cattle □ Antibacterials—sulfamethazine, absorption, metabolism, and excretion, various dosage forms compared, cattle

Sulfamethazine is used extensively in veterinary medicine for the treatment of various infections in food-producing animals. Commercially available oral dosage forms for large animals include a solution, a bolus of the sodium salt, and a sustained-release bolus of the free acid. The comparative bioavailabilities and plasma concentration–time profiles of these dosage forms in large animals have not been reported.

The present study investigated the rate and extent of sulfamethazine absorption from three oral dosage forms compared with an intravenous solution of sulfamethazine sodium in 1-year-old cross-bred heifer feeder calves.

EXPERIMENTAL

Intravenous Administration—Three Hereford × Angus heifers, 1 year old, were weighed, fitted with urinary retention catheters[1] attached to 4-liter plastic collection bottles, and assigned to individual slot-floored metabolism cages 3 days prior to dosing. The weights of Animals 1, 2, and 3 were 235, 226, and 245 kg, respectively. Good quality grass hay and water were provided *ad libitum* during acclimatization and postdosing periods. A concentrate mixture, formulated from shelled corn and linseed meal and containing 12% protein, was limit fed to each animal during the study.

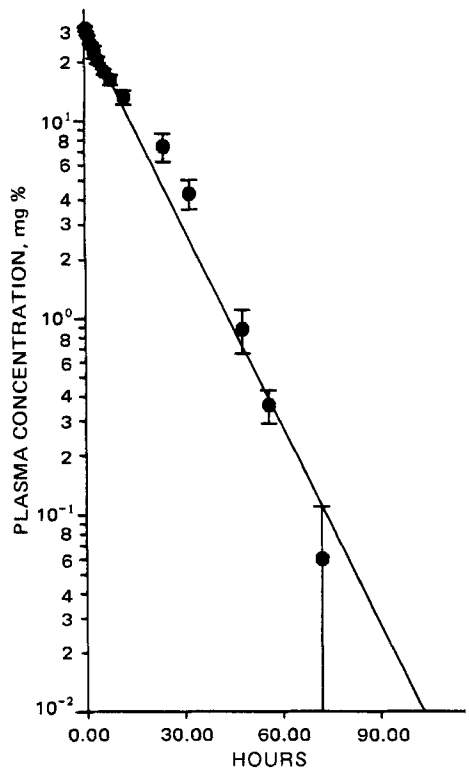

Figure 1—*Semilog plot of average plasma sulfamethazine concentration* (±SD) versus *time following intravenous administration of sulfamethazine sodium (107 mg/kg) to three calves. Points were experimentally observed, and the line was calculated by iterative least-squares fitting to a one-compartment model* ($t_{1/2}$ = *9 hr*, V_D = *0.35 liter/kg*).

A dose of 107 mg/kg (¾ gr/lb) of sulfamethazine as a 12.5% solution of sulfamethazine sodium[2] was rapidly injected *via* the right jugular vein in each animal. All blood specimens were collected from the left jugular vein by serial venipuncture using disposable plastic syringes prerinsed with a 1% solution of heparin sodium in normal saline.

Blood and urine specimens were collected at 0, 0.5, 1, 2, 3, 4, 6, 8, 12, 24, 32, 48, 56, and 72 hr following drug administration. The volume of urine collected over each interval was recorded, and a clean collection

72.0	0.06

bottle was substituted at each collection time. Urine specimens were stored in plastic bottles at −10° until assayed. Within 1 hr of collection, the blood specimens were centrifuged at 3000 rpm for 10 min; plasma was harvested and stored in screw-capped glass tubes at −10° until assayed. All assays were completed within 1 week of specimen collection.

Oral Solution Administration—The three calves were allowed to rest for 21 days between the intravenous and oral solution administrations. Three days prior to dosing, they were reweighed (1 = 232 kg, 2 = 232 kg, and 3 = 250 kg), refitted with urinary retention catheters, and reassigned to individual metabolism cages. The animals were fed and watered as previously described, except that hay and grain were withheld for 24 hr prior to drug administration to avoid regurgitation of the rumen contents and drug during the dosing procedure.

A dose of 107 mg/kg (¾ gr/lb) of sulfamethazine as a 12.5% solution of sulfamethazine sodium was administered to each animal *via* a stomach tube.

Plasma and urine specimens were collected, stored, and assayed as previously described at 0, 1, 4, 5, 7, 9, 12, 24, 32, 48, 56, 72, 96, 120, and 140 hr following drug administration.

Oral Rapid-Release Bolus Administration—The three calves were allowed to rest for 30 days between oral solution and oral bolus administrations. Three days prior to dosing, they were reweighed (1 = 255 kg, 2 = 264 kg, and 3 = 273 kg), refitted with urinary retention catheters, and reassigned to individual metabolism cages. The animals were fed and watered as described for the oral solution administration.

Two boluses[3] containing a total of 30 g of sulfamethazine sodium (27.8 g of sulfamethazine) were administered to each animal using a balling gun. The dose was similar on a milligram per kilogram basis to the dose used in the intravenous and oral solution studies. Slight variations in the milligram per kilogram doses for each animal were tolerated so that intact boluses could be administered.

Plasma and urine specimens were collected, stored, and assayed as previously described at 0, 1, 2, 3, 4, 6, 8, 12, 24, 32, 48, 56, 72, 80, 96, 104, 120, and 144 hr following drug administration.

Oral Sustained-Release Bolus Administration—The three calves were allowed to rest for 30 days between oral rapid-release bolus and oral sustained-release bolus administrations. Three days prior to dosing, they were reweighed (1 = 255 kg, 2 = 268 kg, and 3 = 289 kg), refitted with urinary retention catheters, and reassigned to individual metabolism cages. The animals were fed and watered as described for the oral solution administration.

Three sustained-release boluses[4] containing a total of 67.5 g of sulfamethazine were administered to each animal using a balling gun. The 67.5-g dose was higher than the doses used in the other studies so as to produce comparable plasma sulfamethazine levels. Slight variations in the milligram per kilogram doses for each animal were tolerated so that intact boluses could be administered.

Plasma and urine specimens were collected, stored, and assayed as previously described at 0, 1, 3, 5, 7, 9, 12, 15, 24, 30, 36, 48, 60, 72, 84, 96, 108, 120, 144, and 168 hr following drug administration.

Analytical Methods—All assays were carried out using the methods described previously (1).

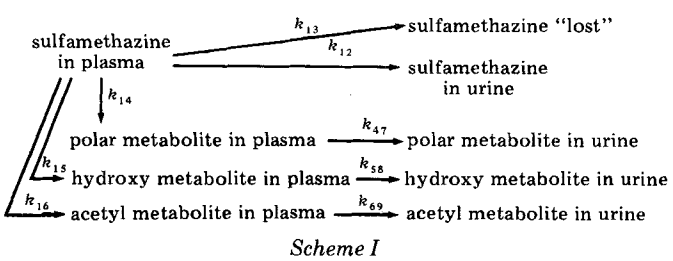
RESULTS AND DISCUSSION

Average plasma sulfamethazine concentrations following intravenous administration of 107-mg/kg doses of sulfamethazine to calves are presented in Table I and plotted in Fig. 1. Average plasma sulfamethazine concentrations following oral administration of a solution of sulfamethazine sodium, a rapid-release bolus of sulfamethazine sodium, and a sustained-release bolus of sulfamethazine are presented in Tables II, III, and IV, respectively, and plotted in Fig. 2. The cumulative amounts of sulfamethazine and its metabolites excreted in urine following the intravenous and oral administrations of sulfamethazine are presented in Tables V–VIII and plotted in Figs. 3 and 4.

The plasma sulfamethazine *versus* time curve obtained following intravenous administration (Fig. 1) appears to be monoexponential, suggesting that a one-compartment pharmacokinetic model is sufficient to describe the time course of sulfamethazine in cattle. Analysis of urine following sulfamethazine administration indicated the presence of unchanged sulfamethazine and three metabolites: the acetyl and hydroxy derivatives and a polar metabolite[5]. If the formations of all three metabolites in plasma are assumed to follow first-order kinetics and the eliminations of sulfamethazine and the three metabolites from plasma are assumed to follow first-order kinetics, Scheme I describes the time course of sulfamethazine and its metabolites in the plasma and urine of cattle.

The value of the overall elimination rate constant, $k_{el} = k_{12} + k_{13} + k_{14} + k_{15} + k_{16} = 0.0774\ hr^{-1}$, was calculated by weighted iterative least-squares fitting (2) to the plasma concentration–time data obtained following intravenous administration. This calculation also estimated a volume of distribution of 0.35 liter/kg. Values of the individual rate constants, k_{12}, k_{13}, k_{14}, k_{15}, and k_{16}, were estimated from the value of k_{el} and the ratios of the total amounts of unchanged sulfamethazine and the three metabolites excreted in urine over the 0–72-hr period after drug administration. Values of the rate constants for the elimination of the metabolites, acetyl (k_{69}), hydroxy (k_{58}), and polar (k_{47}), were estimated from the urinary excretion data for these metabolites.

With all of these values as initial estimates, a least-squares fit of the model shown in Scheme I to the urine–time data for unchanged sulfamethazine and the metabolites (Table V) was obtained using the SAAM 23 program (2) and a digital computer[6]. The final calculated values ($\pm SD$) for the parameters of Scheme I are shown in Table IX. These values were used to generate the calculated lines in Figs. 1 and 3. The good fits of the calculated lines to the experimental data points suggest that the one-compartment pharmacokinetic model is sufficient to describe the disposition and elimination of sulfamethazine in cattle and that the formations and eliminations of the metabolites are first-order processes at the dosage levels studied. The one-compartment model shown in Scheme I and the final calculated parameter values shown in Table IX were subsequently used in analyzing the results obtained following oral administrations.



Scheme I

[5] Determination of the exact structures of the hydroxy and polar metabolites will be the subject of a future publication.

The relative absorptions of the oral dosage forms of sulfamethazine (Table X) were calculated by comparing the total amount of drug (unchanged drug plus metabolites) excreted in urine following oral administration with the total amount excreted following intravenous administration. The results suggest that the oral solution and the oral rapid-release bolus are relatively efficiently absorbed but that the oral sustained-release bolus is not. This calculation does not take into account that there may be relatively more metabolism following oral administration of any dosage form compared with intravenous administration as a result of greater exposure of the drug to the enzymes of the gut and liver.

A more accurate estimate of the therapeutic potential of the various oral dosage forms is given by their systemic availabilities (3), which were calculated by comparing the total amount of unchanged drug excreted in urine following oral administration with that following intravenous administration (Table X). This calculation measures delivery of active drug to the blood and reflects the different metabolic patterns observed following oral and intravenous administrations. The results suggest that the oral solution and oral rapid-release bolus are relatively efficient at delivering active drug to the blood whereas the oral sustained-release bolus is not. Although the sustained-release bolus does not appear to be an efficient dosage form from the standpoint of relative absorption or systemic availability, inspection of its plasma concentration–time curve (Fig. 2) shows that it maintains plasma concentrations above the mini-

mum therapeutic level (5 mg %) (4) for at least 70 hr. This time is more than twice as long as that with the rapid-release bolus and the solution and probably represents a therapeutic advantage.

The different metabolic patterns of sulfamethazine following intravenous and oral administrations may be seen by comparing Figs. 3 and 4 and Tables V and VI. Figure 3 and Table V show that the major excretion product following intravenous administration was unchanged sulfamethazine, which amounted to 18% of the dose. On the other hand, the major excretion product following administration of the oral solution (Fig. 4 and Table VI) was the acetyl metabolite of sulfamethazine, amounting to more than 25% of the dose. The fraction of the dose excreted as the hydroxy metabolite also increased from 12.5% following intravenous administration to 15.8% following oral administration. Thus, a significant part of the reduction in systemic availability observed with the oral dosage forms of sulfamethazine apparently can be attributed to increased metabolism during movement from the rumen to peripheral plasma.

The kinetics of sulfamethazine absorption following oral administration of sulfamethazine sodium in solution were investigated using the method of Wagner and Nelson (5). The percentage of the dose remaining to be absorbed at each time was calculated from the plasma level data using the value of k_{el} obtained in the intravenous study. A semilog plot of the percent of the dose remaining to be absorbed *versus* time appeared to be linear, indicating that sulfamethazine absorption from solution in cattle is a first-order process with a half-life of about 6 hr (k_a = 0.115 hr^{-1}).

This value of k_a was used as an initial estimate for calculating the final value of the absorption rate constant by least-squares fitting to the plasma concentration *versus* time data using the SAAM 23 program (2).

The value of the overall elimination rate constant was set equal to the value obtained in the intravenous study. This calculation yielded an absorption rate constant of 0.113 hr^{-1}.

To account for the different metabolic patterns of sulfamethazine following intravenous and oral administrations, a kinetic model was tested where the absorption process consisted of simultaneous transfer of sulfamethazine from solution in the rumen to sulfamethazine in plasma and to the three metabolites in plasma (Scheme II). The remainder of the model, *i.e.*, that describing disposition and elimination of sulfamethazine and its metabolites in plasma, was identical to Scheme I. The values of the rate constants of Scheme I obtained by fitting the plasma and urine data from the intravenous study were used as initial estimates in the least-squares fitting of the oral data.

Initial estimates of $k_{10,1}$, $k_{10,4}$, $k_{10,5}$, and $k_{10,6}$ were calculated by mass balance from the urinary excretion–time data. In fitting the oral data, the following constraints were employed: the value of k_{el} was fixed at the value obtained from the intravenous study, and the value of $k_a = (k_{10,1}$

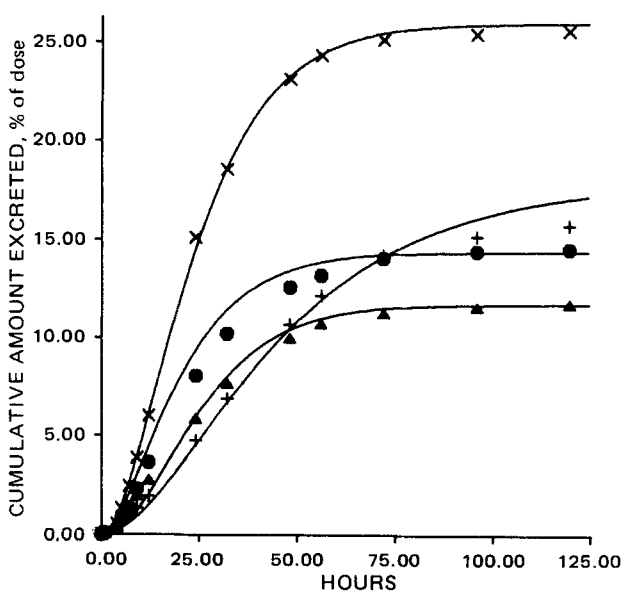

Figure 4—*Plot of average cumulative amount of unchanged sulfamethazine* (●) *and its polar* (▲), *hydroxy* (+), *and acetyl* (×) *metabolites excreted in urine* versus *time following oral administration of sulfamethazine sodium in solution (107 mg/kg) to three calves. Scheme II

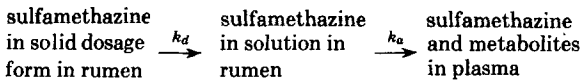

Scheme III

$+ k_{10,4} + k_{10,5} + k_{10,6}$) was fixed at the value obtained by iterative fitting of the plasma concentration–time data. The values of $k_{10,1}$, $k_{10,4}$, $k_{10,5}$, $k_{10,6}$, k_{47}, k_{58}, and k_{69} were then calculated by least-squares fitting to the data for unchanged sulfamethazine and metabolites in urine (Table VI). The results of this calculation are shown in Table XI. The calculated lines of Fig. 4 were generated using the parameter values in Table XI and appear to fit the experimental points well.

The kinetics of sulfamethazine absorption following administration of the oral rapid-release bolus of sulfamethazine sodium and the oral sustained-release bolus of sulfamethazine were investigated by the method of Wagner and Nelson (5) using the value of k_{el} obtained in the intravenous study. In both cases, the semilog plot of the percent of dose remaining to be absorbed *versus* time appeared to be biexponential. This finding suggested that the absorption process consisted of two successive first-order processes, the initial process being dissolution of the drug and the second process being absorption of the dissolved drug from the rumen (Scheme III).

An estimate of the *in vivo* dissolution rate constant, k_d, was obtained from the semilog plot of percent of dose remaining to be absorbed *versus* time. The value of k_{el} obtained in the intravenous study and the value of k_a obtained in the oral solution study were then used to calculate values for the *in vivo* dissolution rate constants for the rapid-release bolus and the sustained-release bolus by iterative least-squares fitting to the plasma concentration–time data using the SAAM 23 program (2). The values of k_{el}, k_d, and k_a calculated from the plasma data were then fixed; values for $k_{10,1}$, $k_{10,4}$, $k_{10,5}$, $k_{10,6}$, k_{47}, k_{58}, and k_{69} were calculated by least-squares iterative fitting to urine data for unchanged sulfamethazine and its metabolites (Tables VII and VIII). The results of these calculations are shown in Table XI.

The calculated dissolution rate for the sustained-release bolus is much slower than that for the rapid-release bolus. This reduced dissolution rate appears to be effective in reducing the rate of appearance of sulfamethazine in plasma and also in maintaining effective plasma sulfamethazine levels for longer times. Peak plasma levels following administration of the sustained-release bolus were about 75% of those following oral administration of the solution or the rapid-release bolus. The sustained-release bolus, although less efficient (less bioavailable) than the other oral dosage forms (Table X), maintained plasma concentrations of active drug above the minimum effective concentration (5 mg %) (4) for above twice as long as the other dosage forms.

Apparently, a compromise must be considered in designing a "best" oral dosage form of sulfamethazine for cattle. If longer dosing intervals and smoother plasma levels are important factors in sulfamethazine therapy, then the lower bioavailability of the sustained-release dosage form becomes less important than its prolonged release, and this dosage form is preferable. However, if the dosing interval can be shorter and the higher peak plasma levels do not cause increased toxicity, the more completely absorbed rapid-release bolus dosage form (82% relative absorption) may be preferred to either the incompletely absorbed sustained-release dosage form (46%) or the less convenient solution dosage form (99%).

Determination of Aqueous Solubility and pKa Values of Estrogens

A. R. HURWITZ ˣ and S. T. LIU

Abstract □ Reported estrone pKa and solubility data show wide variation. Improved experimental procedures were designed and used to obtain reproducible results. The pKa values for several estrogens and related compounds also were determined to assess the effects of structural differences on ionization. No evidence was obtained for long-range D to A ring electronic transmission affecting pKa. Significant differences in pKa values resulted only when conjugated unsaturation was added into the B ring of estrone or estradiol. The aqueous solubilities of estrone and 17α-estradiol were 0.8 and 3.9 μg/ml, respectively, at 25°.

Keyphrases □ Estrogens, various—aqueous solubilities, pKa values, effects of structural differences on ionization □ Solubility, aqueous—various estrogens, effects of structural differences on ionization □ pKa values—various estrogens, effects of structural differences on ionization □ Ionization—various estrogens, effects of structural differences □ Structure-activity relationships—various estrogens, aqueous solubilities and pKa values

Estrogen steroids undergo ionization in alkaline solution. Differences in the UV spectra of the ionized and neutral species of these compounds provide a suitable method for determining ionization constants (1). Previously, the spectrophotometric method was used to study the ionization constants of five estrogens (2). The same technique was also used in determining the pKa value differences between 17β-estradiol and six other estrogens (3). Considerable differences were claimed to exist between the ionization constants of the estrogens studied (2, 3). The results were explained in terms of long-range interaction and conjugation effects. Recent investigations (4, 5) of the ionization constants of 10 phenolic steroids also claimed that the character of the substitutions in the D ring would greatly affect the ionization constant of the C-3 hydroxyl group.

Reported observed ionization constant values for estrone ranged from 9.36 to 11.0 (2–7). This discrepancy may be due to differences in experimental conditions. In the present work, the thermodynamic ionization constants of nine phenolic steroids were studied spectrophotometrically. The ionization of 5,6,7,8-tetrahydro-2-naphthol also was investigated for comparison. A solubility method was employed to determine the ionization constant of equilenin. Aqueous solubility values of estrone, estradiol, equilin, and equilenin also were determined by either UV or GLC methods.

EXPERIMENTAL

Reagents—Estrone[1], 17α-estradiol[1], equilin[1], equilenin[1], 17α-dihydroequilin[1], 17β-dihydroequilenin[1], ethinyl estradiol[1], estriol[2], 1,3,5(10),6-estratetraen-3-ol-17-one (6-dehydroestrone)[2], and 5,6,7,8-tetrahydro-2-naphthol[3] were used with no prior treatment. Standard buffer solutions[4] of pH 9 and 10 were used for calibration of the glass electrode.

Apparatus—UV spectra were obtained with a recording spectrophotometer[5], and the pH was measured with a digital pH meter[6]. GLC analyses were performed on a gas chromatograph with flame-ionization detection[7], and the data were recorded with a recorder with a disk integrator[8].

Solubility Determination—Excess solid material was introduced into 200 ml of distilled water in a 250-ml jacketed beaker. The experiments were carried out at 25 ± 0.02° under nitrogen. Suspensions were magnetically stirred for at least 4 hr to allow the solution to reach equilibrium. Although 4 hr of such vigorous stirring was adequate to achieve equilibrium, several samples were stirred up to 24 hr. An aliquot of the suspension was filtered through a 0.2-μm filter membrane[9]. To prevent error due to possible filtration adsorption losses[10], at least 25 ml of suspension was first passed through the membrane. Additional suspension was collected for GLC analysis.

For GLC analysis, 5 ml of filtrate and a known amount of testosterone standard were mixed and evaporated to dryness under nitrogen. To the residue were added 15 ml of pyridine and 65 ml of *N,O*-bis(trimethylsilyl)trifluoroacetamide plus 1% trimethylchlorosilane[11]. The tube was immediately capped and mixed thoroughly on a vortex mixer[12]. The derivatized sample was injected onto a column packed with 2% DEGS on 100–120-mesh Gas Chrom Q. Analyses were performed under conditions described previously (8).

Equilenin was analyzed also by a UV method. Equilenin solubility was determined as a function of pH. The solution pH was adjusted with 0.1 *N* sodium hydroxide or 0.1 *N* hydrochloric acid, and the final pH was measured at the time of filtration. The filtrate pH was adjusted to 11.5 with 0.1 *N* sodium hydroxide. The solution concentration was determined from the absorbance at 245 nm with the molar absorptivity ($\epsilon = 5.22 \times 10^4$) for the ionized form.

Solutions for Spectrophotometric Determinations—While solution concentrations were higher than 2.0×10^{-5} *M* in previous investigations (2, 4, 5), relatively low concentrations, ranging from 2.4×10^{-6} to 1.5×10^{-5} *M* depending on the compound solubility, were used in this study. These concentrations gave either stable unsaturated or slightly oversaturated metastable solutions. The slightly oversaturated solutions were checked by UV to determine their turbidity. All solutions were stable without precipitation during the time of measurement.

Stock solutions of estrogens, 3.0×10^{-3} *M*, were prepared by dissolving weighed amounts in 100 ml of pure ethanol. Aliquots of 0.12–0.5 ml were then diluted to 100 ml with distilled water. During the dilution process, the stock solution was added dropwise with stirring to prevent localized precipitation. The solution pH was adjusted with 0.1 *N* hydrochloric acid or 0.1 *N* sodium hydroxide. The UV spectrum of the solution was recorded immediately after a stable pH reading was obtained. Spectrophotometric determinations were carried out at room temperature, 23 ± 2°.

Experimental pKa—Three distinct absorption spectra were observed for the compounds. Figure 1 shows the UV spectra of 17α-estradiol at different pH conditions. In acid solution, the molar absorptivity at the 278-nm absorption peak was 1.81×10^3 cm^{-1} *M*$^{-1}$. Two absorption peaks at 238 ($\epsilon = 9.07 \times 10^3$ cm^{-1} *M*$^{-1}$) and 296 (2.67×10^3) nm were found in alkaline solution. Other compounds with similar absorption spectra included estrone, estriol, equilin, 17α-dihydroequilin, ethinyl estradiol, and 5,6,7,8-tetrahydro-2-naphthol; they had corresponding molar absorptivities in acid solution at 278 nm of 1.85×10^3, 1.84×10^3, 1.81×10^3, 1.93×10^3, 1.89×10^3, and 2.00×10^3 cm^{-1} *M*$^{-1}$, respectively.

In alkaline solution, the molar absorptivities at the two absorption peaks were 9.26×10^3 and 2.76×10^3 cm^{-1} *M*$^{-1}$ for estrone, 9.20×10^3

and 2.73 × 10^3 cm^{-1} M^{-1} for estriol, 8.93 × 10^3 and 2.56 × 10^3 cm^{-1} M^{-1} for equilin, 8.80 × 10^3 and 2.65 × 10^3 cm^{-1} M^{-1} for 17α-dihydroequilin, 9.00 × 10^3 and 2.72 × 10^3 cm^{-1} M^{-1} for ethinyl estradiol, and 7.33 × 10^3 and 2.75 × 10^3 cm^{-1} M^{-1} for 5,6,7,8-tetrahydro-2-naphthol. Figures 2 and 3 show the UV spectrum of 1,3,5(10),6-estratetraen-3-ol-17-one and equilenin, respectively. From these figures, the influence on the UV spectra of the addition of one or two conjugated double bonds in the B ring can be seen. In contrast, equilin, having a nonconjugated double bond in the B ring, gave the same absorption spectrum as estrone.

The absorption maxima for 1,3,5(10),6-estratetraen-3-ol-17-one was at 235 (ε = 3.08 × 10^4 cm^{-1} M^{-1}) and 325 (2.58 × 10^3) nm in alkaline solution and at 215 (ε = 2.29 × 10^4 cm^{-1} M^{-1}), 261 (7.17 × 10^3), 271 (5.83 × 10^3), and 331 (2.50 × 10^3) nm in acid solution. Equilenin had maxima at 242 (ε = 5.22 × 10^4 cm^{-1} M^{-1}), 274 (6.80 × 10^3), 285 (7.47 × 10^3), 295 (4.53 × 10^3), and 355 (3.13 × 10^3) nm for the ionized form and at 228 (ε = 5.47 × 10^4 cm^{-1} M^{-1}), 269 (4.53 × 10^3), 280 (5.33 × 10^3), 292 (4.00 × 10^3), and 338 (2.47 × 10^3) nm for the neutral species.

Wavelengths selected for the pKa determinations were 240, 248, 295, and 300 nm for estrone, 17α-estradiol, estriol, ethinyl estradiol, 5,6,7,8-tetrahydro-2-naphthol, equilin, and 17α-dihydroequilin; 235 and 248 nm for 1,3,5(10),6-estratetraen-3-ol-17-one; 230, 240, and 250 nm for equilenin; and 355 and 370 nm for 17β-dihydroequilenin. All experiments were carried out using 5-cm cells, except for equilenin and 5,6,7,8-tetrahydro-2-naphthol where 2-cm cells were used.

RESULTS AND DISCUSSION

Solubility Determinations—Several studies reported the solubilities of estrone and estradiol in organic solvents (9) and aqueous solutions containing amino acids (10) or surfactants (11). However, few solubility values for estrogens in pure water are available. It was important to determine estrogen aqueous solubilities first in order to choose suitable concentration ranges for the spectrophotometric pKa determination. The improper choice of concentration may result in serious interference due to precipitation. A solubility value of 1.17 × 10^{-4} *M* was reported (12) for estrone in pure water. However, precipitation resulted when a concentrated estrone–ethanol solution was diluted in pure water to 1.5 × 10^{-5} *M*. This finding clearly indicated that the solubility of estrone in pure water is much less than 1.17 × 10^{-4} *M*.

Solubility determinations were made for estrone, 17α-estradiol, equilin, equilenin, 17α-dihydroequilin, 17α-dihydroequilenin, estriol, and ethinyl estradiol. No detectable difference in solubility values was observed for samples stirred for 4 or 24 hr. Satisfactory agreement between the UV and GLC results was found for equilenin. The experimental variation was within ±5%. Solubility values for estrone and 17α-estradiol determined by UV were about 20% to more than 50% higher than values obtained by GLC. This result indicated that these two compounds contained trace impurities of either high absorbance or relatively high solubility. Results of the GLC determinations of solubilities are shown in Table I.

The aqueous solubility observed for 17α-estradiol, 1.43 × 10^{-5} *M*, was in agreement with a literature value (1.40 × 10^{-5} *M*) obtained in 0.02 *M*

Table I—Solubility Values of Some Estrogens

Compound	Solvent	Solubility μg/ml	Solubility *M*
Estrone	Water	0.8	2.96 × 10^{-6}
17α-Estradiol	Water	3.9	1.43 × 10^{-5}

[a] Cell length = 5 cm; concentration = 1.50×10^{-5} *M*.

sodium chloride solution (10). Experimental results show that estradiol is more soluble than estrone in pure water. Other investigations also revealed that estradiol has higher solubility in aqueous solutions containing surfactant materials (11). From the estrogen compounds examined, it would be expected that corresponding compounds would show a similar range of solubilities.

Spectrophotometric Determination of pKa Values—The thermodynamic ionization constant is expressed by $HA \rightleftharpoons H^+ + A^-$ and:

$$K_a = \frac{A_{H^+}[A^-]f_1}{[HA]} \quad \text{(Eq. 1)}$$

where A_{H^+} is the activity of hydrogen ion, f_1 is the activity coefficient of univalent ion, and $[A^-]$ and $[HA]$ represent the concentration of ionic and neutral species of the estrogen, respectively. At the low concentrations used, the activity coefficient, f_1, should approach 1. The following equation was employed to determine the ionization constant:

$$pKa = pH - \log\frac{[A^-]}{[HA]} = pH - \log\frac{A - A_a}{A_b - A} \quad \text{(Eq. 2)}$$

where A is the absorbance of a solution at a specific pH. The corresponding absorbances of the same concentration solution in alkaline and acid solution are A_b and A_a. The advantage of calculation with Eq. 2 and comparison of solutions at the same concentration was that the possible error due to the dilution process could be reduced. The present study was carried out in very dilute solution without salt or buffer reagents to eliminate f_1 in Eq. 1.

In previous studies, usually only one wavelength was used experimentally. However, more than one wavelength was used in the present study. Typical results for the pKa determination of 17α-estradiol are shown in Table II. Absorbance at 240 nm was about three times higher than that at 295 nm. Excellent agreement was obtained between the pKa values determined at different wavelengths. The reproducibility of these results illustrated the reliability of the present procedure. The pKa of 17α-estradiol obtained was 10.46 ± 0.03 *SD*.

A summary of the pKa values of the compounds studied is given in Table III. 17α-Estradiol, estriol, and ethinyl estradiol showed pKa values of 10.38–10.46, which were slightly higher than 10.34 observed for estrone. The difference in the pKa value between estradiol and estrone was 0.12, in good agreement with the value of 0.10 reported previously (3). The thermodynamic pKa values of estrone and 17α-estradiol observed in the present study were quite close to the apparent pKa of 10.26 for estrone and of 10.30 for estradiol reported by Egorova *et al.* (4, 5). Since these latter studies were done in buffered solutions, the slightly lower apparent pKa value reported may be due to neglected correction of the activity coefficient.

Kirdani and Burgett (2) used a spectral technique to study the ionization of five estrogens and reported a pKa value 10.91 for estrone. However, this high value resulted from certain errors in their calculations. Recalculation of their data gave a value of 10.10, close to their reported values of 10.08 for 17β-estradiol and 10.10 for 17α-estradiol.

Other reported pKa values include 11.0 for estrone determined by a back-titration technique (6) and 9.36 for estrone and 9.11 for estriol in methanol solution (7) determined by a conductiometric titration method. The great discrepancy in reported values may result from different experimental conditions. Since the present experiments were made at relatively low concentrations, possible interference due to precipitation can be eliminated. In contrast, most of the previous studies were made at quite high supersaturated conditions. For example, Egorova *et al.* (4, 5) and Kirdani and Burgett (2) employed concentrations from 3.0×10^{-5} to 8.8×10^{-5} *M*. As mentioned before, the metastable supersaturation limit of estrone in pure water is less than 1.5×10^{-5} *M*. Therefore, it would be quite difficult to prepare clear solutions, free from precipitation, at such a high concentration. The unavoidable colloidal precipitation that would result would cause serious error in the pKa determination. Furthermore, only one wavelength, 300 nm, was used (2) in the determination of the pKa values of estrone and estradiol. Due to the low absorbance at this wavelength, any interference would cause a large error in the measurements. The advantages of using stable, low concentration solutions and different wavelengths were illustrated by the good agreement obtained for pKa value determinations.

Table III—pKa Values of Several Estrogens and Related Compounds

Compound	Number of Determinations	Concentration, *M*	pKa	Literature pKa
Estrone	5	7.5×10^{-6}	10.34 ± 0.05	10.91 (2), 10.26 (4, 5)
	2	5.4×10^{-6}	—	—

1-Naphthol	—	—	—	9.30 (1) (20°)
2-Naphthol	—	—	—	9.63 (1) (20°)

[a] The material used also contained 17β-dihydroequilin. Determinations were made at 370 nm to prevent interference.

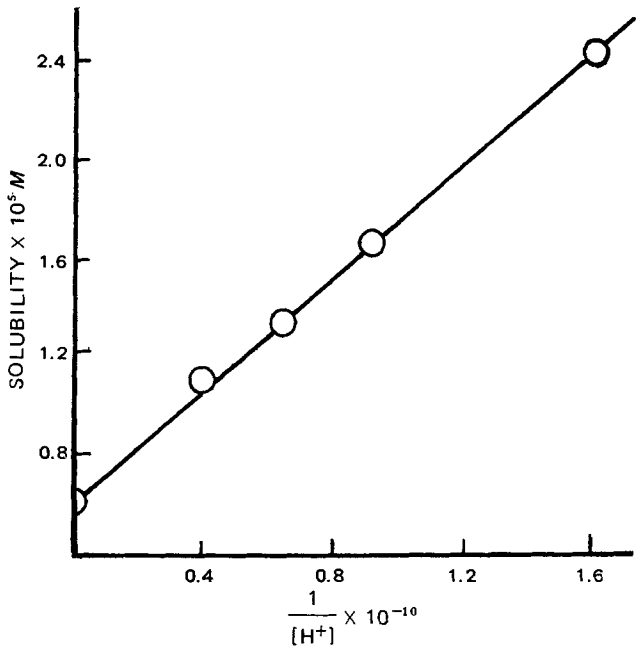

Figure 4—*Plot of solubility* versus *the reciprocal of the hydrogen-ion concentration for equilenin.*

In previous studies (2–5), small pKa value differences between estrone and estradiol were explained in terms of long-range D to A ring transmission effects. While conformational or steric transmission effects have important consequences in some reaction systems, it is not likely that electronic transmission affecting pKa occurs for estrone and estradiol. The experimental data obtained show small differences in pKa values. However, these differences apparently fall within anticipated experimental reproducibility ranges. No significant effect on pKa values occurred when the C-17 substituent was varied between carbonyl and hydroxyl for three pairs of compounds. Values for estrone, 17α-estradiol, ethinyl estradiol, and estriol ranged from 10.34 to 10.46. Where an unconjugated double bond was present in the B ring, as in equilin and 17α-dihydroequilin, pKa values were 10.26 and 10.29, respectively. When a single double bond in the B ring was in conjugation with the A ring, as in 1,3,5(10),6-estratetraen-3-ol-17-one, the pKa value observed was 10.17. For fully unsaturated B ring compounds such as equilenin and 17β-dihydroequilenin, pKa values were 9.75 and 9.77, respectively.

The acidity of the estrogens was increased by introduction of one or more double bonds in the B ring. The pKa values of estrone and related derivatives followed the order estrone > equilin > 1,3,5(10),6-estratetraen-3-ol-17-one > equilenin. The conjugated double bond in 1,3,5(10),6-estratetraen-3-ol-17-one had a greater effect in increasing acidity than the nonconjugated double bond in the B ring of equilin. Among the compounds examined, the fully conjugated B ring of equilenin produced the most profound effect in reduced pKa value. The pKa of equilenin was 0.59 unit lower than that of estrone. Similar inductive effects were found among estradiol, 17α-dihydroequilin, and 17β-dihydroequilenin.

Literature pKa values of phenol and some simple derivatives are listed in Table III for comparison. Comparison of the pKa values of 5,6,7,8-tetrahydro-2-naphthol and phenol shows that the attachment of a saturated B ring at the *meta*- and *para*-positions caused an increase in pKa of 0.5 unit. By contrast, a fully unsaturated naphthol such as 1-naphthol or 2-naphthol showed an increased acidity greater than that of phenol. The results with the more complicated estrogens were consistent with these general observations.

Solubility Method Determination of Equilenin pKa—The phenolic steroids studied are quite insoluble weak acids. Solubility changes as a function of pH provide a useful method for determining the ionization constants of these compounds. Equilenin was chosen for the comparison of pKa determination methods. Solubility values of equilenin at different pH values are listed in Table I. It was expected that a sharp increase in solubility would occur at pH values near or greater than the pKa value. Solubility values, S, can be expressed for the present experimental conditions by:

$$S = [HA] + [A^-] = [HA] + \frac{K_a[HA]}{[H^+]} \qquad \text{(Eq. 3)}$$

where [HA] is the intrinsic solubility of the neutral or undissociated species of equilenin. A linear relationship was found between S and $1/[H^+]$, as shown in Fig. 4. A value of [HA] can be obtained either from the intercept of this plot or by direct measurement in acid solution. The value for [HA] obtained from direct measurement was 5.71×10^{-6} M, which was close to that obtained from the intercept, 6.10×10^{-6} M. Linear regression was employed to determine the slope of the plot. The association constant was calculated from the equation: slope = $K_a \times [HA] = 1.13 \times 10^{-15}$. The pKa thus obtained was 9.72, in excellent agreement with the value obtained by spectrophotometric determination.

This solubility technique could also be applied in the determination of the ionization constants of other phenolic steroids. However, if a spectrophotometric method is employed for analysis, special precautions must be taken to avoid possible interference by impurities.

Acetylacroninium Salts as Soluble Prodrugs of the Antineoplastic Agent Acronine

D. W. A. BOURNE *§, T. HIGUCHI ‡, and A. J. REPTA ‡x

Abstract □ The low aqueous solubility of acronine (~2 mg/liter) has been overcome by identification of quaternary prodrug salts exhibiting apparent molar solubilities two to five orders of magnitude greater than acronine. The synthesis and kinetics of hydrolysis of the various prodrug acetylacroninium salts were studied, and the half-life for hydrolysis under conditions approximating the *in vivo* situation was estimated to be about 5 min. Such rapid reversion, together with the greatly increased solubility, appears to qualify the prodrug for intravenous use.

Keyphrases □ Acronine—quaternary salts of acetyl derivative synthesized as prodrugs for intravenous use, solubilities and kinetics of hydrolysis studied □ Acetylacroninium salts—synthesized as prodrugs for intravenous use, solubilities and kinetics of hydrolysis studied □ Prodrugs, potential—quaternary salts of acetyl derivative of acronine synthesized for intravenous use, solubilities and kinetics of hydrolysis studied □ Antineoplastic agents—acronine, quaternary salts of acetyl derivative synthesized as prodrugs for intravenous use, solubilities and kinetics of hydrolysis studied

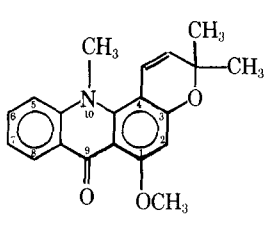
Acronine (I), a derivative of 1,3-dihydroxy-9-acridanone[1], was first isolated in 1948 (2, 3). Later, the compound was found to exhibit activity (4) against various rodent tumor system cultures when administered as an aqueous suspension by different routes. However, the extremely low solubility of acronine (2–3 mg/liter[2]) has presented problems in the clinical evaluation of the drug administered orally as a capsule[3].

A suitable intravenous formulation of acronine would obviate problems associated with the GI absorption of the nearly insoluble drug. However, the problem of low solubility, together with the estimated adult human dose of 100 mg[3], presented a significant barrier to intravenous use.

BACKGROUND

A coprecipitate of acronine with povidone (5) was about 15 times as water soluble as acronine alone, and the cytotoxic activity of acronine in the coprecipitate was about twice that of acronine itself. This study (5) demonstrated that increased solubility yielded improved drug activity, but the coprecipitate approach did not appear capable of producing the concentration increases necessary for a suitable intravenous dosage form.

The objective of the present study was to identify physical and/or chemical approaches for the solubilization of acronine in vehicle systems suitable for intravenous administration. Various approaches were considered including complexation, simple salt formation, and mixed solvent systems. Most approaches were ruled out due to the physicochemical properties of acronine (*e.g.*, its weakly basic nature) and/or the insufficient increase in solubility expected.



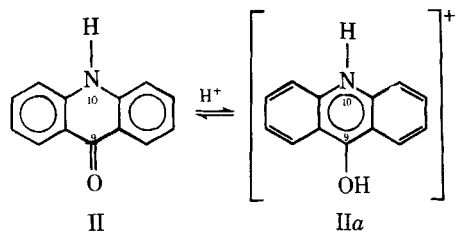
I

It was concluded that the required solubility increase would best be accomplished through the identification of a chemically derived prodrug of acronine. This report deals with the identification, synthesis, and properties of a derivative of acronine. It presumably satisfies the increased solubility requirement and yet lies within those constraints (6, 7) inherent in a satisfactory prodrug.

Acronine, mol. wt. 321.3, pKa (protonated form) 1.6, mp 176–178°, has solubilities at 25° of 3.2, 27.5, and 3×10^{-4} g/100 ml in acetone, chloroform, and water, respectively. The low aqueous solubility of acronine is probably due to its very hydrophobic nature rather than to strong interactions among molecules in the crystalline state. Therefore, a prodrug with greatly increased hydrophilic character (8, 9) might afford the greatest probability for attaining the desired solubility increase (~1 mg/ml).

Compound I contains no functional groups that could be derivatized to yield a soluble prodrug that would rapidly revert to I following intravenous administration. However, the apparent solubility of I in aqueous hydrochloric acid was >1 mg/ml at pH ~0. Although the pharmaceutical use of such a highly acidic solution is impractical, this observed solubility of acroninium chloride suggested that the presence of a formal charge on the acronine molecule might yield an increased solubility of the magnitude desired.

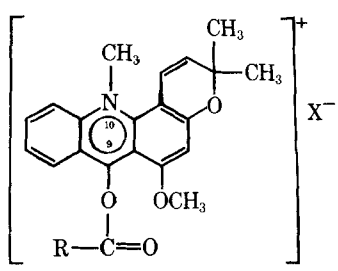
Evaluation of the reported acid–base behavior of 9-acridanone (II, Scheme I) indicates that protonation of that weak base occurs at the carbonyl oxygen (10), resulting in a fully aromatic 9-acridanonium ion (II*a*) where the positive charge resides on the nitrogen. Since acronine is structurally similar to 9-acridanone, an equilibrium similar to that shown in Scheme I may be found for acronine under strongly acid conditions. The existence of such an equilibrium suggests that the carbonyl oxygen of acronine might react under suitable conditions to form an ether or ester derivative at the 9-position.



II IIa

Scheme I

A derivative such as I*a* is a quaternary salt analogous to the protonated form of acronine and would be worthy of evaluation as a soluble prodrug of acronine, since its ester linkage might be more rapidly cleaved (6) to yield the parent drug than would the corresponding ethers. Various acetylacroninium salts (I*a*, R = methyl) were chosen as the desired candidates for initial evaluation. The anions expected to influence solubility were chosen from the more common strong inorganic acids.



I*a*

[1] All species discussed that contain the acridine skeleton are treated as derivatives of acridine. Therefore, the numbering system employed is that most widely used for acridine (1) and not acronine (3,12-dihydro-6-methoxy-3,3,12-trimethyl-7*H*-pyrano[2,3-c]acridin-7-one).

RESULTS AND DISCUSSION

Preparation and Characterization of Prodrug Salts—Acetylacroninium perchlorate was synthesized by heating a suspension of acroninium perchlorate in acetic anhydride[4] at ~100° for a short period and then cooling to room temperature. The acetylacroninium perchlorate formed was isolated as a burgundy-colored crystalline solid after the reaction filtrate was diluted with cold ether.

The solid material contained ~80% of acetylacroninium perchlorate; the remaining ~20% of the sample consisted of I and the perchlorate salt of I. Attempts to purify the samples (relative to acetylacroninium perchlorate content) were unsuccessful due to the instability of the compound. Since the impurities did not present a major problem in the evaluation of approximate solubilities and stability properties, extensive efforts to obtain high purity samples of acetylacroninium perchlorate did not appear justified.

The assignment of the structure of the acetylacroninium species was based on NMR and IR spectra and the fact that the compound hydrolyzed rapidly to yield acronine.

Solubility of Salts—Following the characterization of acetylacroninium perchlorate, the chloride, sulfate, phosphate, and bromide salts were prepared. These salts were appreciably less stable and less pure than the perchlorate salt. Because of the rather rapid hydrolysis of the acetylacroninium ion, it was not possible to obtain equilibrium data on the solubility of the various salts. However, approximate values were obtained by shaking excess quantities of the solid samples with 0.05 *M* phosphate buffer (pH 7.0) for several minutes, filtering, and allowing the filtrates to stand at 22° until hydrolysis of the acetylacroninium ion was complete. The acronine content of each filtrate was then determined spectrophotometrically. The salt solubilities, expressed as acronine content in grams per 100 ml, were: perchlorate, 0.025–0.030; sulfate, 0.15–0.2; bromide, 0.6–0.8; chloride, 1.2–1.5; and phosphate, 1.2–2.0. Since the aqueous equilibrium solubility of acronine was less than 1% of that observed for the various acetylacroninium salts, the acronine content of the filtrate was essentially completely attributable to the salt itself. Although considerable error was inherent in such determinations, the results appeared meaningful.

The solubility of the chloride salt was about the same as that of the phosphate salt, possibly because of the *in situ* formation of the phosphate salt under these conditions.

A comparison of the solubility values of the salts with those of acronine (about 2–3 mg/liter) demonstrated that even the perchlorate salt, which was the least soluble, exhibited about a 100-fold greater solubility than acronine; the more soluble chloride and phosphate salts were about 10,000 times more soluble than free acronine. Therefore, the use of any acetylacroninium salt would yield at least the minimum required increase in solubility necessary to formulate a parenteral solution of reasonable volume. However, it was yet to be determined whether these salts would be otherwise suitable for use in such solutions. Therefore, the hydrolysis of the acetylacroninium salts was studied.

Hydrolysis of Prodrug—When near-saturated aqueous solutions of the acetylacroninium salts were prepared and allowed to stand, a precipitate of acronine formed. Additionally, when aqueous solutions of the salts were prepared and examined by TLC [benzene–acetone (1:1) on silica gel] at various times, two spots were observed initially: a yellow spot (R_f 0.76) and a purple or wine-colored spot (R_f 0.17) corresponding to acronine and the prodrug, respectively. In several hours, the wine-colored spot disappeared completely and the acronine spot was enlarged, indicating a rapid and complete reversion of the acetylacroninium perchlorate (wine-colored spot) to acronine.

The rate at which the acetylacroninium perchlorate was hydrolyzed to yield acronine was studied quantitatively in pH 0–11 aqueous solutions. A plot (Fig. 1) of the logarithm of the observed half-life *versus* pH data indicated that the hydrolytic rate was pH independent at pH <8. The data for pH ≥2.6 were obtained in various buffers at 3×10^{-3} to 5×10^{-2} *M*. From these and other data[5], it appeared that the hydrolytic rate was relatively unaffected by various buffer components at low concentrations and that the spontaneous rate of hydrolysis under such conditions occurred with a half-life of about 20–25 min. At pH >8, however, there appeared to be hydroxide-ion catalysis, as evidenced by a negative slope of approximately unity at pH >9.

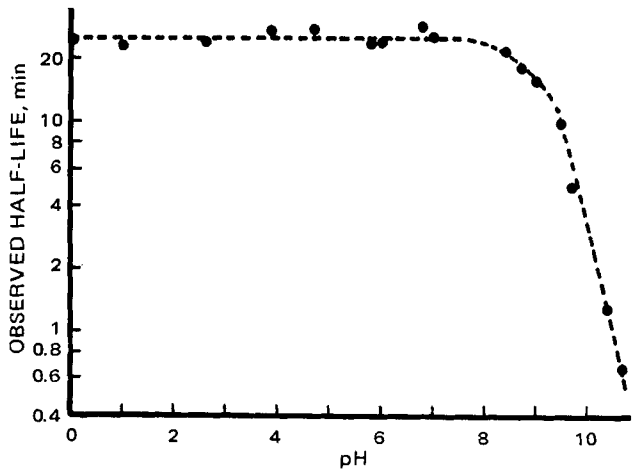

Figure 1—*Plot of observed half-life for the hydrolysis of acetylacroninium perchlorate at 25.4° in various buffers.*

The hydrolysis rate of the prodrug in pH 6.9 phosphate buffer (0.1 *M*) was also studied at 15, 25, and 30°; these data were used to construct an Eyring plot. From the slope and intercept of that plot were determined the enthalpy of activation (19.5 kcal/mole) and the entropy of activation (−16 cal/mole degree), respectively. On the basis of the temperature study data, it was estimated that the half-life for hydrolysis at body temperature of 37° would be about 5 min or even less if enzymatic enhancement (6) occurred *in vivo*.

Some studies of the influence of both the ionic strength of aqueous buffers and the dielectric constant of a mixed aqueous–organic solvent on the hydrolysis rate of acetylacroninium perchlorate were also carried out. When the ionic strength of an aqueous phosphate buffer (0.1 *M*, pH 7) was varied fivefold from 0.02 to 0.1 *M*, no significant difference was observed for the hydrolysis rate of the prodrug at 25°. However, when the hydrolytic rate of the acetylacroninium salt was followed in solutions prepared by mixing given volumes of acetone with a phosphate buffer (pH 7.0, 0.05 *M*, I = 0.1 *M*), the rate increased nearly linearly with the percent (v/v) acetone from 0 to 60%. The observed half-life of the reactions over that range of acetone concentration decreased from about 23 to 10 min.

These data suggested that the decrease in the dielectric constant when going from simply aqueous media to increasing concentrations of acetone enhanced the reaction rate. Since the reaction was hydrolytic, the rate was also a function of the water concentration. Therefore, the decrease in the water concentration at increased acetone concentrations perhaps accounted for the fact that little or no difference in the hydrolytic rate was observed in solutions containing 60 and 80% acetone in water.

When the hydrolytic rates of the other prepared salts were studied in phosphate buffer (pH 7, 0.05 *M*, I = 0.1), none differed significantly from that of the perchlorate. These latter results were not unexpected, since all prepared salts probably were completely dissociated in dilute aqueous solution and, therefore, the hydrolysis of the acetylacroninium ion should have been independent of the anion.

Applications—On the basis of these studies, it appears that the acylacroninium salts may be suitable for use as prodrugs of acronine. The major feature of the quaternary salts is the greatly enhanced solubility coupled with their rapid reversion to the parent alkaloid under conditions approximately like those encountered *in vivo*.

The information presented here together with data on the acetylacroninium perchlorate salt served as the basis for the formulation of an experimental intravenous prodrug formulation of acronine (11).

EXPERIMENTAL

Materials—Acronine[6] was used as obtained, mp 175–177° [lit. (3) mp 174–176°] and homogeneous by TLC [benzene–acetone (2:1) on silica gel[7]], R_f 0.45. All other chemicals were reagent grade. Water was distilled from acid permanganate solution in an all-glass still.

Procedures—*Acroninium Salts*—The simple acroninium salts were prepared by dissolving acronine (5 g) in acetone (175 ml) and adding 4

[4] When reactions were attempted using acetyl chloride as the acetylating agent under conditions similar to these described here, insignificant quantities of the prodrug salt were obtained.

[5] Changes in the acetate buffer concentration (pH 4.6) from 0.1 to 0.5 *M* decreased the half-life for hydrolysis by only approximately 5 min.

[7] Polygram Sil G/uv, Brinkmann Instruments.

ml of the appropriate aqueous acid. The acid solutions used were 37% (w/w) hydrochloric, 71% (w/w) perchloric, 53% (w/w) phosphoric, and 50% (w/w) hydrobromic acids. Upon mixing, the respective salts precipitated as bright red-orange solids. All but the phosphate were isolated at room temperature. The phosphate salt required cooling (~0°) to obtain good yields. The yield of all salts was 95% or better. All acroninium salts melted with decomposition as follows: perchlorate, 245–255°; chloride, 158–160°; bromide, 188–190°; sulfate, 158–160°; and phosphate, 182–184°.

Acetylacroninium Salts—Each acetylacroninium salt was prepared by heating the corresponding acroninium salt (~1 g) with acetic anhydride (~20 ml) at 100° for 10–15 min in a suitable flask fitted with a water-cooled condenser and calcium chloride-filled drying tube. The reaction mixture was then cooled to room temperature. Undissolved acroninium salt was removed by filtration, and the filtrate was quickly added to cold (~0°) ether (~200 ml). The acetylacroninium salt readily separated as a fluffy purple solid. This solid was immediately separated by filtration, rinsed with cold ether (50 ml), dried, and stored in a desiccator.

Solid acetylacroninium perchlorate was quite stable and could be stored at room temperature in a desiccator over calcium chloride for months with little or no change. However, the other salts were extremely hygroscopic and thus unstable due to hydrolysis. Therefore, these salts were stored in a desiccator cooled with solid carbon dioxide. The chloride salt was so hygroscopic that all handling procedures were carried out in a dry box under a nitrogen atmosphere.

Characterization of Acetylacroninium Salts—The characterization of acetylacroninium perchlorate was based primarily on spectral data and chemical behavior. The IR[8] spectra of acetylacroninium perchlorate and acroninium perchlorate (as potassium bromide pellets) were qualitatively quite similar, except for strong carbonyl absorption at 1790 cm^{-1} for the acetylacroninium salt. Absorption at that wave number was completely absent in the simple acroninium salt. The absorption at 1790 cm^{-1} was attributed to the carbonyl absorption (12) of the acetyl group.

The NMR[9] spectrum of the acetylacroninium perchlorate (in formamide and in dimethyl sulfoxide-d_6) exhibited a sharp singlet at δ 2.65, which integrated for about three protons and was consistent (13) with an acetate ester of the type Ia. Upon standing in such solutions, the absorption at δ 2.65 decreased and a new singlet appeared at δ 2.08. Since acetic acid also produced a sharp singlet at δ 2.08 when added to either of the solvents, it was concluded that acetic acid was being produced in the NMR tube as a result of the hydrolysis of the ester linkage. While ester hydrolysis was fairly rapid initially in the NMR studies, the rate decreased with time, apparently due to consumption of the limited amounts of water present in such solvents.

Another observation was that the *gem*-dimethyl protons of acetylacroninium perchlorate absorbed at δ 1.70 while those of acronine absorbed at δ 1.47. The hydrolysis of the ester (as already described) resulted in a decrease in the δ 1.70 peak and the corresponding appearance of a peak at δ 1.47.

When an aqueous solution of acetylacroninium perchlorate was freshly prepared, it was deep burgundy in color. Upon standing, the color became yellow and a yellow precipitate formed. This precipitate was identified as acronine. The hydrolysis was also followed by TLC as described under *Results and Discussion*.

In view of the impurity of the samples obtained, elemental analysis data were not considered meaningful, although agreement with theory was good. On the basis of all of these data, the characterization of acetylacroninium perchlorate as having Structure Ia (R = methyl) seemed conclusive.

The other acetylacroninium salts were characterized mainly on the basis that color, spectral characteristics, and chemical behavior were essentially identical to those of the perchlorate salt.

Composition of Acetylacroninium Salt Samples—Acetylacroninium perchlorate samples were dissolved in acetone and subjected to TLC [benzene–acetone (2:1) on silica gel]. Three spots were observed directly: an orange spot at the origin corresponding to authentic acroninium perchlorate, a yellow spot at R_f 0.45 corresponding to authentic acronine, and a purple spot at R_f 0.05 due to the acetylacroninium salt. No other spots were observed using iodine or UV light.

When a TLC sample of acetic acid–acetone (1:5) on silica gel was used, only two spots were observed at R_f 0.77 and 0.25. The yellow spot at 0.77 arose when both acronine and acroninium perchlorate were used[10]. The spot at R_f 0.25 was purple, corresponding to the acetylacroninium salt. When the other acetylacroninium salts were studied using the acetic acid–acetone TLC system, they behaved almost identically. On the basis of these data, the sample appeared to consist of only the prodrug salts, the corresponding acroninium salt, and acronine.

An estimate of the acetylacroninium salt present in the prepared sample was made from the NMR spectra in formamide. The ratio of the peak height at δ 1.70 to that at δ 1.47, corresponding to the *gem*-dimethyl proton in the acetylacroninium salt and acronine, respectively, was used as a simple indication of the composition. Since decomposition occurred in these solutions, it was necessary to follow the ratio as a function of time and extrapolate back to the time at which the solution was prepared. The prodrug appeared to comprise about 80% of the acetylacroninium perchlorate-containing samples. The content of the acetylacroninium salt in the other samples, such as the chloride and phosphate, was only 50–60%.

Kinetic Measurements—The hydrolysis of the acetylacroninium salts was studied spectrophotometrically[11] (520 nm) by following the disappearance of the absorption peak due to the acetylacroninium ion. The reaction mixtures were prepared by shaking a sample of the salt ($\simeq$2 mg) for about 1 min with the buffer solution[12] (10 ml). This reaction mixture was then rapidly filtered through a sintered-glass funnel of a medium or coarse pore size and diluted to 40 ml with additional buffer solution.

A portion of this solution was transferred to a quartz spectrophotometer cell. The buffer solution was used as the reference solution. Cells with 10-cm pathlengths were selected so that dilute reaction mixtures could be used and, therefore, followed spectrophotometrically for longer times. The use of larger cells was necessary because, as the reaction proceeded, the reaction solutions became supersaturated with acronine and precipitation often occurred before an absorbance value could be obtained at the completion of the reaction.

Since acronine does not absorb energy at 520 nm, the spectrophotometer was balanced carefully against air prior to initiation of the reaction; a final absorbance value (at the end of the reaction) of zero was used in the calculation of the reaction rate constant. Some sufficiently dilute solutions that did not show precipitation were found to be first order in ester concentration over three to four half-lives.

Solubility Determination of Acronine and Acroninium Salts—Acronine solubility in various solvent systems was determined by shaking excess acronine with the solvent at room temperature ($\simeq$22°) until equilibration was reached ($\simeq$24 hr). The filtered solutions, after suitable dilution with water and adjustment to pH 7, were then assayed spectrophotometrically for acronine at 277 nm ($\log \epsilon = 4.60$).

Since the acroninium salts were hydrolyzed quickly in water, determination of equilibrium solubility values for these substances was not practical. The "estimated solubility" of the salts was taken as the amount of ester dissolved (expressed as acronine content) after 2 min of constant agitation of excess sample in buffer at 22°. The resulting solution was quickly filtered through a sintered-glass funnel or filter[13]. The filtrate was allowed to stand overnight to ensure the complete hydrolysis of the ester and then was diluted with methanol to dissolve the precipitated acronine. The resulting solution was assayed spectrophotometrically for acronine (277 nm, $\log \epsilon = 4.60$).

Microencapsulation of Phenobarbital by Spray Polycondensation

C. VOELLMY, P. SPEISER ˣ, and M. SOLIVA

Abstract □ A new method for the microencapsulation of solids is described. It is based on the polycondensation of amphiphilic and, thus, tensioactive precondensates on a melamine–formaldehyde base on the surface of suspended particles during spray drying. A film-forming agent, preferably one that reacts chemically with the resin, is indispensable for spray drying and also for the formation of an efficient membrane around the drug particles. The resulting microcapsules are essentially spherical and have, after appropriate curing, a sustained-release effect *in vitro*. The factors that most influence the formation and properties of the microcapsules are the composition (qualitative and quantitative), pH, and viscosity of the suspension.

Keyphrases □ Phenobarbital—microencapsulation by spray polycondensation, effect of composition, pH, and viscosity □ Microencapsulation—of solids by spray polycondensation, effect of composition, pH, and viscosity □ Spray polycondensation—microencapsulation of solids, effect of composition, pH, and viscosity □ Technology, pharmaceutical—microencapsulation of solids by spray polycondensation, effect of composition, pH, and viscosity

Microencapsulation can be defined as a method to provide solid particles or liquid droplets with an individual coat, thereby modifying their physical, chemical, and physiological characteristics. This effect is useful for separating reactive or incompatible components, covering disagreeable odors and tastes of substances, and converting liquids into solids.

In pharmacy, microencapsulation is used to improve the stability and handling properties of drugs and to prepare controlled-release products. Release may be accomplished by rupture (mechanical or after swelling) or diffusion through the intact or swollen wall. The size of microcapsules generally ranges from several microns to about 200 μm (1).

Various specific technological aspects and limitations of microencapsulation have been studied (2, 3), as have the different variables that influence microcapsule formation. In most cases, the microcapsules were prepared by simple coacervation (4–9). The aim of this work was to gain insight into the possibilities and limitations of a new microencapsulation method; the influence of some important technological variables on the properties of the microcapsules was studied.

THEORETICAL

Spray drying is used to separate the microcapsules from the vehicle (8, 10) or to prepare microcapsules in a single operation (11, 12). The procedure is, in principle, as follows. After dissolving the coating material in a preferably aqueous medium and dispersing the core material in it, the dispersion is spray dried. The core material is thereby microencapsulated in its original state.

Clearly, different products are obtained when a true solution of coating material and drug is spray dried. The active substance is in an X-ray amorphous state and shows crystallinity only when the drug–polymer ratio is increased (13, 14).

The fundamentals of spray polycondensation were presented previously (15, 16). One processes a dispersion of core material that contains in the continuous phase aminoplast monomers or aminoplast precondensates of relatively low molecular weight in addition to other coating material (film-forming agents) and the catalyst. The resin-forming monomers and precondensates play an essential role. In contrast to the monomers, the reactive tensides (17–19) exhibit pronounced tensioactive properties. They are derived from hexamethylolmelamine whose hydroxymethyl groups are substituted partly with hydrophilic polyglycol ethers and partly with lipophilic alcohols (usually C_4–C_{18}), forming low molecular weight precondensates. Due to their physicochemical properties, they are adsorbed selectively at the surface of the inner phase of the dispersion.

The insoluble polymer microcapsule is formed upon spray drying at 150–200° by vaporization of water and simultaneous polycondensation of the monomers and the precondensates by acid catalysis. Details of the basic chemical reactions can be found in textbooks (20). The quality of the shell can be improved by the use of a film-forming agent that reacts chemically with the monomers and also by curing.

EXPERIMENTAL

Materials—Phenobarbital[1], with a mean particle size of 30–35 μm, was chosen as the model drug. As a film-forming agent, polyvinyl alcohol[2]

Microencapsulation of Phenobarbital by Spray Polycondensation

C. VOELLMY, P. SPEISER ˣ, and M. SOLIVA

Abstract □ A new method for the microencapsulation of solids is described. It is based on the polycondensation of amphiphilic and, thus, tensioactive precondensates on a melamine–formaldehyde base on the surface of suspended particles during spray drying. A film-forming agent, preferably one that reacts chemically with the resin, is indispensable for spray drying and also for the formation of an efficient membrane around the drug particles. The resulting microcapsules are essentially spherical and have, after appropriate curing, a sustained-release effect *in vitro*. The factors that most influence the formation and properties of the microcapsules are the composition (qualitative and quantitative), pH, and viscosity of the suspension.

Keyphrases □ Phenobarbital—microencapsulation by spray polycondensation, effect of composition, pH, and viscosity □ Microencapsulation—of solids by spray polycondensation, effect of composition, pH, and viscosity □ Spray polycondensation—microencapsulation of solids, effect of composition, pH, and viscosity □ Technology, pharmaceutical—microencapsulation of solids by spray polycondensation, effect of composition, pH, and viscosity

Microencapsulation can be defined as a method to provide solid particles or liquid droplets with an individual coat, thereby modifying their physical, chemical, and physiological characteristics. This effect is useful for separating reactive or incompatible components, covering disagreeable odors and tastes of substances, and converting liquids into solids.

In pharmacy, microencapsulation is used to improve the stability and handling properties of drugs and to prepare controlled-release products. Release may be accomplished by rupture (mechanical or after swelling) or diffusion through the intact or swollen wall. The size of microcapsules generally ranges from several microns to about 200 μm (1).

Various specific technological aspects and limitations of microencapsulation have been studied (2, 3), as have the different variables that influence microcapsule formation. In most cases, the microcapsules were prepared by simple coacervation (4–9). The aim of this work was to gain insight into the possibilities and limitations of a new microencapsulation method; the influence of some important technological variables on the properties of the microcapsules was studied.

THEORETICAL

Spray drying is used to separate the microcapsules from the vehicle (8, 10) or to prepare microcapsules in a single operation (11, 12). The procedure is, in principle, as follows. After dissolving the coating material in a preferably aqueous medium and dispersing the core material in it, the dispersion is spray dried. The core material is thereby microencapsulated in its original state.

Clearly, different products are obtained when a true solution of coating material and drug is spray dried. The active substance is in an X-ray amorphous state and shows crystallinity only when the drug–polymer ratio is increased (13, 14).

The fundamentals of spray polycondensation were presented previously (15, 16). One processes a dispersion of core material that contains in the continuous phase aminoplast monomers or aminoplast precondensates of relatively low molecular weight in addition to other coating material (film-forming agents) and the catalyst. The resin-forming monomers and precondensates play an essential role. In contrast to the monomers, the reactive tensides (17–19) exhibit pronounced tensioactive properties. They are derived from hexamethylolmelamine whose hydroxymethyl groups are substituted partly with hydrophilic polyglycol ethers and partly with lipophilic alcohols (usually C_4–C_{18}), forming low molecular weight precondensates. Due to their physicochemical properties, they are adsorbed selectively at the surface of the inner phase of the dispersion.

The insoluble polymer microcapsule is formed upon spray drying at 150–200° by vaporization of water and simultaneous polycondensation of the monomers and the precondensates by acid catalysis. Details of the basic chemical reactions can be found in textbooks (20). The quality of the shell can be improved by the use of a film-forming agent that reacts chemically with the monomers and also by curing.

[a] Refers to total quantity of moles of reactive tenside and monomer. [b] No curing. [c] Curing for 1 hr at 100°.

(mol. wt. ~34,000) was used. As monomers, hexamethylolmelamine hexamethyl ether[3] (I), trimethylolmelamine trimethyl ether[3] (II), and dimethylolurea dimethyl ether[3] (III) were used as well as a cationic reactive tenside on a melamine–formaldehyde base[4] (IV). Hydrochloric acid (1 N) was added as a catalyst.

Microcapsule Preparation—After dissolving the polyvinyl alcohol, the monomers, and the precondensate in distilled water, the pH was adjusted[5] with hydrochloric acid. Unless specified otherwise, a pH of 2.5 was used. The phenobarbital was homogeneously dispersed with a high-speed stirrer[6] and immediately spray dried[7]. The following conditions were used: inlet temperature, 220°; outlet temperature, 90°; spray-disk speed, about 30,000 rpm; and feed rate, 1 liter/hr[8].

After spray drying, the product that adhered to the wall was brushed off and collected. The yield of microcapsules in the cyclone was low due to the small dimensions of the spray drier. Unless otherwise indicated, curing was performed in a drying oven under standard conditions (1 hr at 100°).

Microcapsule Evaluation—*Phenobarbital Content*—A 60–100-mg sample was accurately weighed into a 100.0-ml volumetric flask. Then about 50 ml of 0.1 N NaOH solution was added, and the suspension was treated with ultrasound[9] for about 90 sec. The microcapsules were thereby ruptured, and the drug dissolved. Then 0.1 N NaOH solution was again added to give 100.0 ml, and a 1.0-ml sample was withdrawn through a G 3 sintered-glass plate. After appropriate dilution, phenobarbital was assayed spectrophotometrically[10] at 256 nm. All samples were analyzed in duplicate.

Release Studies—Phosphate buffer solution (200 ml, pH 7.2, μ = 0.2, 0.1% polysorbate 80) in a 400-ml beaker was maintained at 37° and stirred at a constant rate of 133 rpm[11]. The length of the stirring rod[12] was approximately 6 cm and its diameter was 1.1 cm. The sample containing 50.0 mg of phenobarbital was placed on a small sieve (mesh size approximately 0.75 mm) laid on the beaker. Scratching the sieve caused the powder to fall into the liquid without forming clumps (time t = 0). Filtered[13] 1-ml samples were removed after 1, 2, 4, 8, 16, *etc.*, min until about 90% of the core material was released. The samples were assayed as specified. The release rate studies were carried out in duplicate.

RESULTS AND DISCUSSION

Evaluation of Release Data—For the characterization and comparison of microcapsules prepared under different conditions, it is useful to express the release results by a representative constant.

In some cases, the release pattern follows a first-order mechanism (21). Other investigators suggested a linearization of release curves of different dosage forms by using the Weibull function (22). It was found that the calculation of the linear regression of:

$$y = K^* t^n \quad \text{(Eq. 1)}$$

where y is the percent drug released at time t and K^* is a constant, yielded an exponent, n, in the range of about 0.5. The release rate constant K was calculated by linear regression of:

$$y = Kt^{1/2} \quad \text{(Eq. 2)}$$

The fit of the experimental results with the calculated points was satisfactory, and the statistical linearity was significant for most cases.

Effect of Resin-Forming Agent on Microcapsules—No satisfactory microcapsules resulted with the exclusive use of either I or reactive tenside IV. In the former case, agglomerates of irregular shape and size, which can hardly be regarded as microcapsules, were produced (Fig. 1). In the latter case, the core material was completely coated by spherical microcapsules (Fig. 2) in which no defective coats could be discerned. However, these products were highly hydrophilic (but insoluble in water, acetone, alcohols, dimethylformamide, *etc.*) without any noteworthy sustained-release effect even after curing.

Spray polycondensation with mixtures of I and IV in different ratios was performed; the compositions and dissolution rate constants are given in Table I. The shape of the microcapsules of Batches 800–805 was spherical. Due to the low amount of reactive tenside, Batches 806 and

[a] Curing for 1 hr at 100°.

807 tended toward the structures shown in Fig. 1. In all cases, the release rate was high ($t_{75\%} < 10$ min) for the original products. This property differed distinctly after curing, depending on the ratio between I and IV. It was lowest when the fraction of IV was 0.25–0.75 based on the total amount of I and IV, as in Batches 802, 805, and 806.

To obtain products that best met the expectations (*i.e.*, spherical microcapsules with slow release effect and relatively low amount of reactive tenside used), a IV to I ratio of 1:1 was chosen for the subsequent experiments.

The excessive permeability of the original product could be explained by the relatively low molecular weight of the resin. The results demonstrate that curing distinctly reduced the permeability only of products containing I. The comparatively small molecular size of I probably formed a more intimate network than when using reactive tenside alone. A mechanism similar to steric hindrance can be assumed. Methanol evaporates when the ether groups of I are broken up; with reactive tenside, large and much less volatile molecules that could impede cross-linking are separated.

Effect of Curing Conditions on Release Properties—As already stated, curing is necessary to attain slow release microcapsules. It was found by microscopical examination that the morphology of the products was not affected by this process. The influence of the curing conditions on the release rate constant is shown in Fig. 3. The permeability of the products can only be reduced to a certain degree, characteristic for the respective formulation. The chemical reactions occurring during this process are, among others, the formation of methylene bridges by liberation of formaldehyde (organoleptic identification; see also Ref. 20) and the dehydration of resin and polyvinyl alcohol. The latter is characterized

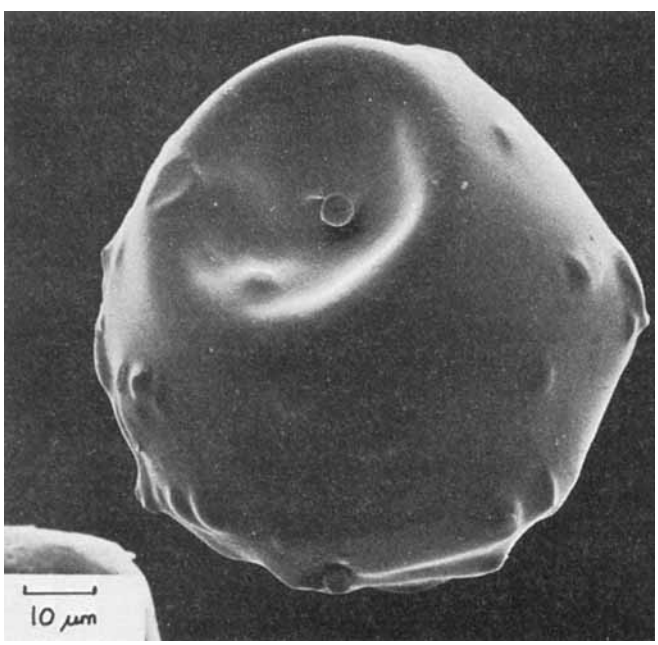

Figure 2—*Typical microcapsule manufactured using reactive tenside IV. Active substance is entirely coated.*

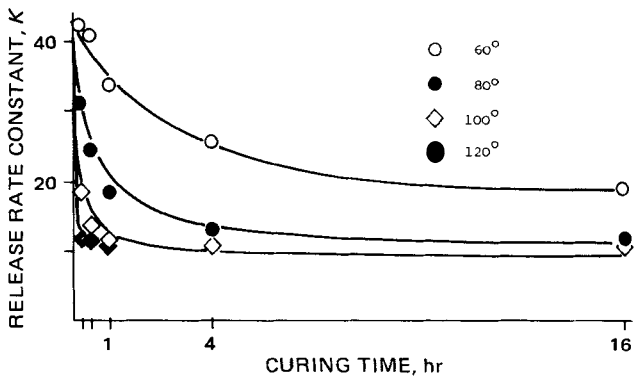

Figure 3—*Effect of curing conditions on release rate constant of Batch 805 (composition given in Table I).*

by a discoloration to yellow of the originally white product at 120° and after more than 4 hr at 100° (23).

Effect of Monomers of Low Tensioactivity on Release Properties—The composition and release rate constants are shown in Table II. The distinct differences in the release rate of the products depending on the chemical nature of the monomer used can be explained by the fact that I has more potential cross-linking sites than II and the latter has more than III. The consequence is a wall structure with a more or less intimate network which is primarily responsible for the different permeabilities. Microscopically (scanning electron microscope), no differences in the surface structure could be discerned.

Effect of pH on Release Properties—Polycondensation is catalyzed by acid pH. Consequently, pH influences the quality of the coat. The suspensions adjusted to different pH values were immediately spray dried and cured. The batches showed no morphological differences. The results of the release studies (Fig. 4) reflect the basic importance of this factor. The effect of pH on the release of phenobarbital was distinct and was not suppressed by the obligatory curing process.

A suspension with pH 1.5 could not be processed because it gelled in a few minutes; at higher pH values, gelling was observed only after several hours or days.

Effect of Viscosity on Microcapsules—Suspensions with identical compositions diluted with water to polyvinyl alcohol concentrations of 2, 4, 8, and 12% exhibited Newtonian flow[14]. The microcapsules resulting from the two high viscosity suspensions were spherical. The low viscosity suspensions, however, yielded products with irregular shapes similar to those shown in Fig. 1. The respective release patterns are shown in Fig. 5.

Viscosity is known to be an important factor in spray drying technology (24). Its influence on the formation and properties of the microcapsules is also demonstrated by the following experiment. A suspension with 16% polyvinyl alcohol does not yield discrete microcapsules but rather long and fine insoluble threads. It is obvious that in this case the water vaporizes before discrete droplets are formed by spraying; *i.e.*, the atomization of the dispersion is impeded by the high viscosity.

Effect of Resin to Polyvinyl Alcohol Ratio on Microcapsules—

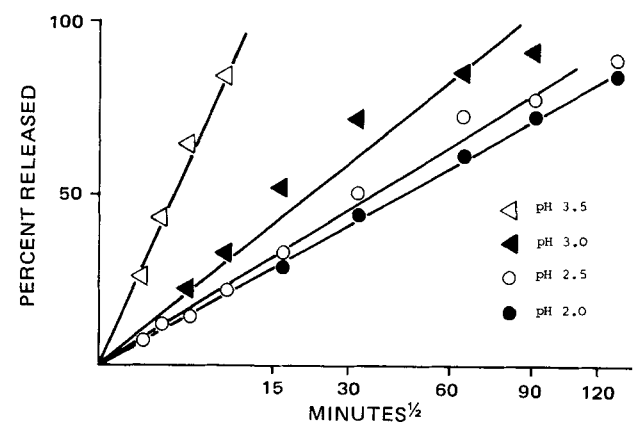

Figure 4—*Effect of pH on release rate.*

[14] Measured with a Epprecht Rheomat, Contraves, Zürich, Switzerland.

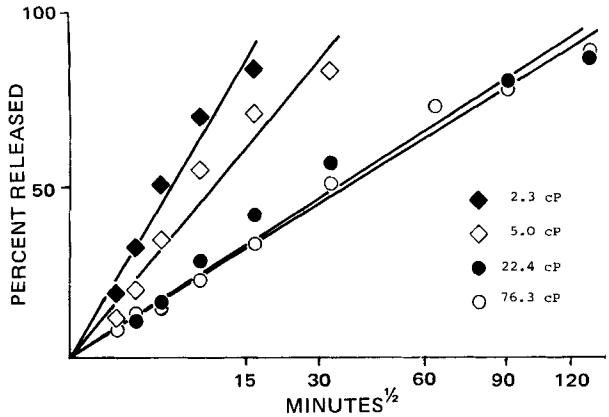

Figure 5—*Effect of viscosity on release rate.*

The composition of the batches, their respective release rate constants, and the evaluation of the results are shown in Fig. 6. In the evaluation of the results, the composition of the formulation with the maximum sustained release as well as its expected value for K was calculated. The following polynomial equation was computed after having found by analysis of variance that the regression of second order was adequate:

$$y = 33.084 - 6.133x_1 - 63.380x_2 + 25.251x_1^2 + 64.400x_2^2 - 43.796x_1x_2 \quad \text{(Eq. 3)}$$

where y is the dissolution rate constant, x_1 is the level of factor Compounds I and IV, and x_2 is the level of factor polyvinyl alcohol.

The coordinates x_{1s} and x_{2s} (Fig. 6) for the stationary point were computed by partial differentiation and setting the results equal to zero. By setting these values into the polynomial equation, the expected value for K, a true minimum, was calculated. The comparison of the computed and experimentally found values demonstrated a good fit when it was considered that the confidence limits were relatively large due to the not unimportant residual term in the analysis of variance.

The coordinates of the stationary point were within the experimental field. Thus, no significant improvement of the sustained-release effect could be expected by investigating further levels of these factors. The quality of the coat was largely determined by an interaction of the factors investigated. The slope of the ellipse in Fig. 6 and the results of the statistical analysis, however, indicated that the variable polyvinyl alcohol was somewhat more critical in its influence on the release rate constant.

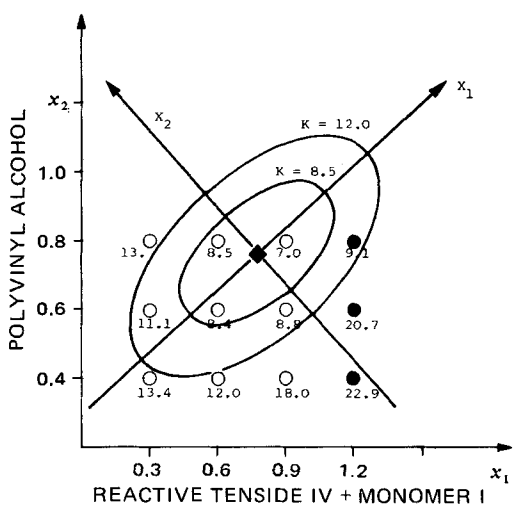

Figure 6—*Contour plot for release rate constants* K = *12.0 and 8.5. The numbers inserted give the experimental* K; x_1 *and* x_2 *are relative amounts of reactive tenside IV + monomer I and polyvinylalcohol, respectively. The relative amount of phenobarbital is unity. The polyvinyl alcohol concentration is 8%. GLC Determination of Acetohexamide and Hydroxyhexamide in Biological Fluids

J. W. KLEBER [x], J. A. GALLOWAY, and B. E. RODDA

Abstract □ A sensitive and specific GLC assay was developed for acetohexamide and hydroxyhexamide, its major metabolite, in plasma and urine. The assay uses tolbutamide as a mass internal standard. Compounds are extracted from acidified plasma or urine with toluene, converted to methylated derivatives with dimethyl sulfate, and measured by GLC using a flame-ionization detector. With GLC–mass spectrometry, the compounds measured are the *N*-methylsulfonamides resulting from GLC pyrolysis. Plasma and urine data are presented from a bioavailability study to demonstrate the utility of this method.

Keyphrases □ Acetohexamide—GLC analysis, human plasma and urine □ Hydroxyhexamide—GLC analysis, human plasma and urine □ GLC—analyses, acetohexamide and hydroxyhexamide, human plasma and urine □ Antidiabetic agents—acetohexamide, GLC analysis, human plasma and urine

Earlier methods for the determination of plasma concentrations of acetohexamide utilized isotope dilution analysis (1–3), the Spingler (4) method, or the Toolan–Wagner (5) procedure. None of these methods is sufficiently sensitive or suitable for the assay of the multiple samples needed in a bioavailability study, nor do they permit the assay of acetohexamide and hydroxyhexamide in urine.

The earliest GLC method for the determination of hypoglycemic sulfonylureas (6) involved conversion of tolbutamide and chlorpropamide to their *N*-methylated derivatives by treatment with dimethyl sulfate. Difficulty in consistently reproducing this work was reported (7, 8), and similar difficulties were experienced in this laboratory. Prescott and Redman (9) later described a method for the GLC estimation of tolbutamide and chlorpropamide, which served as the basis for the present determination of acetohexamide and hydroxyhexamide in plasma and urine.

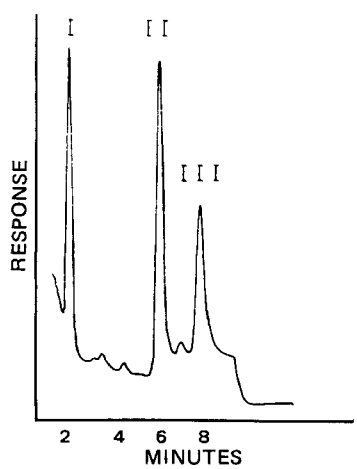

Figure 1—*Gas–liquid chromatograph of extract of plasma spiked with 10 μg of tolbutamide (I)/ml and 20 μg of acetohexamide (II) and hydroxyhexamide (III)/ml.*

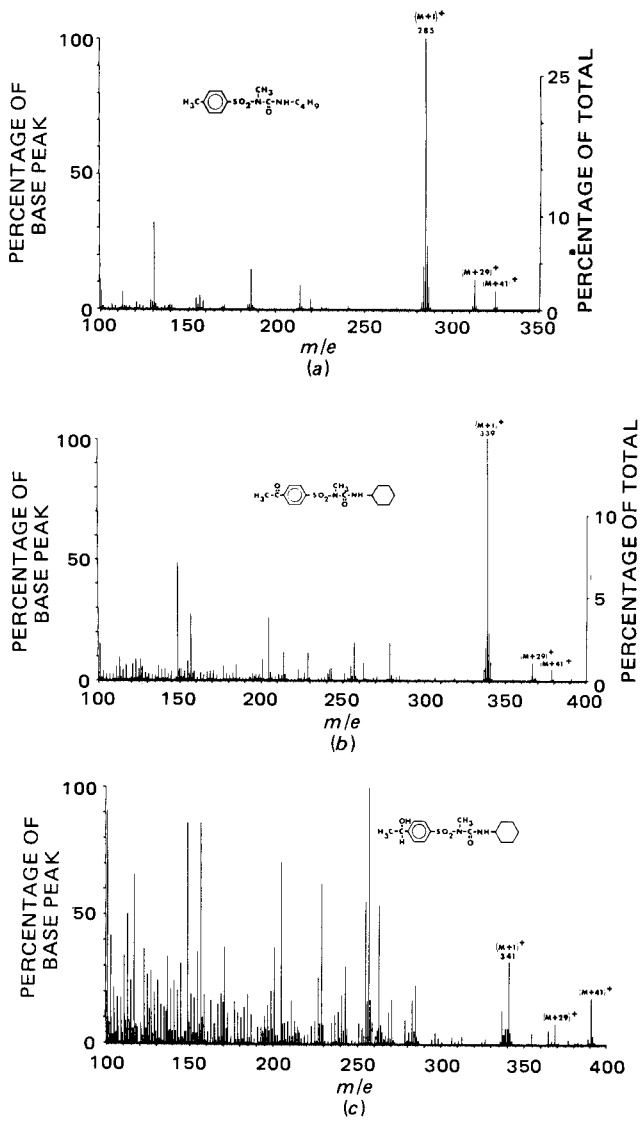

Figure 2—*Chemical ionization mass spectra of* N*-methyl derivatives of tolbutamide* (a), *acetohexamide* (b), *and hydroxyhexamide* (c).

EXPERIMENTAL

Reagents—Acetohexamide, hydroxyhexamide, and tolbutamide were synthesized[1]; tolbutamide was used as the mass internal standard for GLC analysis. All solvents were analytical reagent quality except hexane[2], which was distilled in glass. Commercially available GLC packing material, 0.5% PEG 20M on Gas Chrom Q[3] (80–100 mesh), and the methylating reagent dimethyl sulfate[4] were used.

Apparatus—The basic instrument was a gas–liquid chromatograph[5] with dual-column capability, equipped with a flame-ionization detector

and 1-mv recorder[6]. Disposable 15-ml centrifuge tubes[7] were used for the extraction procedure; previously siliconized, tapered 15-ml glass centrifuge tubes[8] were used for the methylation step and hexane evaporation[9].

Chromatographic Conditions—The gas chromatograph was operated in the dual-column mode. The two glass columns, 0.61 m × 3 mm i.d., were operated initially at 190° with a programmed 5°/min increase to 240° during analyses. The recorder was operated at a chart speed of 0.63 cm/min, the detector temperature was 260°, and the oxygen and hydrogen flow rates were 90 ml/min. Helium carrier gas (flow rate of 90 ml/min) was filtered through a molecular sieve preconditioned overnight at 240° with dry nitrogen.

Under these conditions, the following retention times were observed: *N*-methyl-*p*-toluenesulfonamide, 90 sec; *N*-methyl-*p*-acetylbenzenesulfonamide, 300 sec; and *p*-(1-hydroxyethyl)-*N*-methylbenzenesulfonamide, 480 sec. When using the instrument in the dual-column mode, a satisfactory baseline was obtained as the oven was heated.

Procedure—The 15-ml tapered centrifuge tubes were washed with chromic acid cleaning solution, rinsed with water, dried, and siliconized with a 1% solution of dimethyldichlorosilane in toluene[10]. Standard solutions of acetohexamide and hydroxyhexamide were added to 1 ml of blank plasma or urine to give calibration concentrations of 0, 5, 10, 20, and 40 μg of each drug/ml. To each tube were added 20 μl (10 μg) of the mass internal standard solution and 1 ml of 1.0 *N* HCl. The mixture was vortexed to ensure uniform distribution, and 5 ml of toluene was then added[11] to each tube.

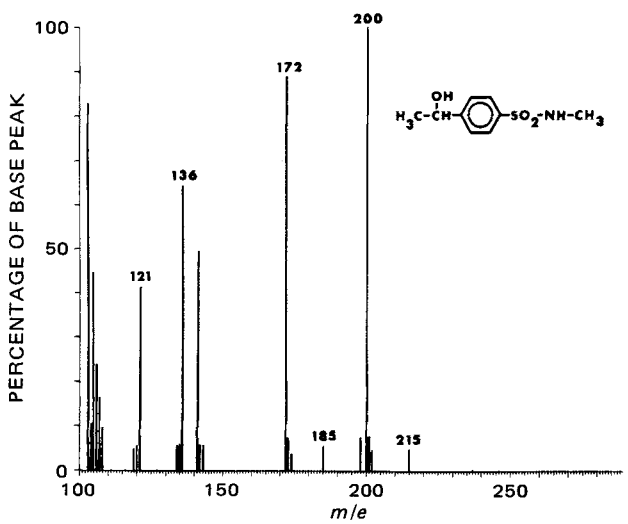

Figure 4—*Electron-impact mass spectrum of* p-(*1-hydroxyethyl*)-N-*methylbenzenesulfonamide obtained after GLC.*

The samples were shaken for 2 min and then centrifuged at 2000 rpm for 4 min. The upper organic phase was transferred to a conical screw-capped centrifuge tube containing 1 ml of 7.5% aqueous potassium carbonate solution, and the samples were again shaken and centrifuged. The toluene was aspirated and discarded. To the aqueous phase were added 1 ml of methanol and 0.1 ml of dimethyl sulfate. Then the tubes were loosely capped and placed in a water bath at 60° for 10 min.

After cooling, 1 ml of 1 *M* acetate buffer (pH 5.2) was added. The methylated sulfonylureas were extracted with 5 ml of *n*-hexane, which was transferred to a 15-ml siliconized, tapered centrifuge tube. The hexane was evaporated to dryness at 50° under a gentle stream of dry nitrogen. Dissolution of the residue in 25 μl of carbon disulfide–chloroform (1:1) was aided by vortex mixing, and 2 μl of each sample solution was then injected onto the GLC column (Fig. 1).

Following chromatography of the calibration standards, peak height ratios[12] of the *N*-methylsulfonamides to the *N*-methyl-*p*-toluenesulfonamide mass internal standard were calculated. These ratios, plotted against concentrations of acetohexamide and hydroxyhexamide in the 5.0–40.0-μg/ml range, gave straight lines passing through the origin (r = 1.0). Mean slope values of 0.080 ± 0.005 and 0.043 ± 0.004 were obtained for acetohexamide and hydroxyhexamide, respectively.

Chemical ionization mass spectra[13] of the *N*-methylated derivatives of tolbutamide, acetohexamide, and hydroxyhexamide were obtained before GLC; those of the respective *N*-methylated sulfonamides were determined after chromatography.

A bioavailability study was conducted to compare acetohexamide tablets[14] and to demonstrate the utility of this method. Tablets from three different lots[15], plus a placebo tablet to estimate basal response, were administered to eight subjects in a four-way crossover study. Each subject fasted for 8 hr before receiving a therapeutic dose of 1.5 tablets, 750 mg, of acetohexamide. Blood samples were drawn at −1, 0, 1, 2, 3, 4, 6, and 8 hr after administration, and urine was collected for the 0–8-hr period. In addition to the determination of acetohexamide and hydrox-

yhexamide concentrations in blood and urine, blood glucose (10) and serum insulin (11) concentrations were measured.

Dissolution of the acetohexamide tablets was determined by the method in USP XIX.

RESULTS AND DISCUSSION

To estimate the precision and accuracy of the procedure, plasma samples with known amounts of acetohexamide and hydroxyhexamide were assayed; the results are presented in Table I.

The chemical ionization mass spectra by which the structures of the *N*-methylated sulfonylureas were identified are shown in Fig. 2. When these compounds were chromatographed using the described conditions, they were quantitatively pyrolyzed to the respective *N*-methylsulfonamides. The GLC–mass spectra for *N*-methyl-*p*-toluenesulfonamide and *N*-methyl-*p*-acetylbenzenesulfonamide are shown in Fig. 3. *p*-(1-Hydroxyethyl)-*N*-methylbenzenesulfonamide did not elute from the column under the conditions used and was investigated by GLC–electron-impact mass spectrometry[16]. The fragmentation pattern shown in Fig. 4 is consistent with that expected for the *N*-methyl-substituted pyrolysis product of *N*-methylhydroxyhexamide.

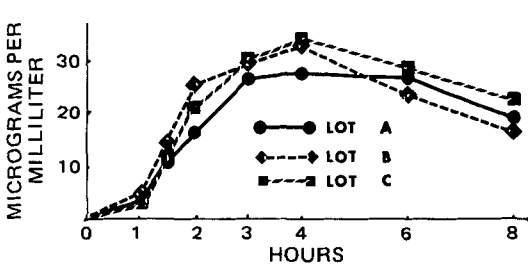

Figure 6—*Mean plasma concentrations of hydroxyhexamide after administration of 750 mg of acetohexamide to eight subjects.*

[16] Using an LKB 9000S GC–mass spectrometer with column and conditions used in this procedure.

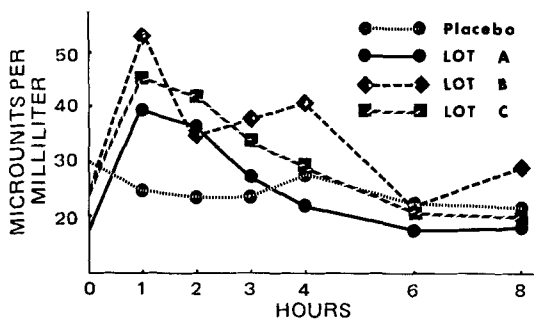

Figure 7—*Mean insulin levels in serum after administration of 750 mg of acetohexamide to eight subjects.*

Dissolution profiles are shown in Table II; all lots met the USP XIX dissolution requirement. Although Lot B appeared to have more rapid dissolution, the variability was such that all lots were judged to have relatively similar dissolution patterns.

The average plasma concentration–time curves observed for acetohexamide and hydroxyhexamide are given in Figs. 5 and 6, respectively. Recovery of drug and metabolite in the 0–8-hr urines is shown in Table III, and mean serum insulin and blood glucose responses associated with these three tablet formulations are shown in Figs. 7 and 8. The three lots were compared with respect to the area under the plasma concentration–time curves (*AUC*) and the peak plasma concentration responses for both acetohexamide and hydroxyhexamide. Analysis of variance suggested a lower bioavailability of acetohexamide for Lot A than for B or C. While it is difficult to be certain why Lot A appeared poorer than the other lots, the formulation used in preparing Lot A tablets was different from that used for Lots B and C, and Lot A tablets were approximately 30 months old at the time of this study while the other lots were only 2 months old.

The physiological responses (elevation of serum insulin and lowering of blood glucose) may more truly reflect the bioavailability of acetohexamide from the three tablet formulations, because the metabolite, hydroxyhexamide, is not only physiologically active but also has a more prolonged effect than the parent drug. Since no substantial differences were found in the plasma concentrations of hydroxyhexamide from these tablet lots, the physiological responses may more closely reflect the plasma metabolite concentrations or a combination of the plasma concentrations of drug and metabolite.

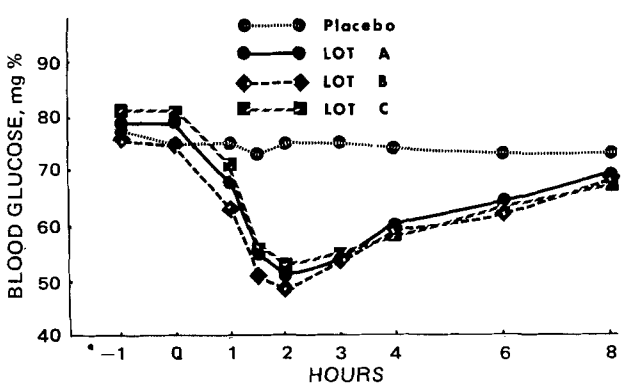

Figure 8—*Mean blood glucose responses after administration of 750 mg of acetohexamide to eight subjects.*

Quantitative Analysis of Degradation Products in Pilocarpine Hydrochloride Ophthalmic Formulations

GEORGE A. NEVILLE [*x], FARIZA B. HASAN [‡], and IAN C. P. SMITH [‡]

Abstract □ The presence of isopilocarpine, an epimer of pilocarpine, and of pilocarpinic acid, a hydrolytic degradation product of pilocarpine, was established and all three substances were assayed in various commercial ophthalmic formulations of pilocarpine hydrochloride by ^{13}C-Fourier transform spectroscopy. Assay was based upon integrated intensities of selected resonances from any formulation calibrated against the intensity of tetramethylammonium bromide, used as a common external reference. The normalized intensities were then related to those of a reference solution of pilocarpine hydrochloride, thereby eliminating any factor arising from variability of ^{13}C-relaxation times. The ^{13}C-resonance for the *N*-methyl group, being common to all products, provides a convenient basis for the assay of the total alkaloid content whereas the C-8 resonances are best suited for assaying residual pilocarpine and its degradation products. This procedure, estimated as accurate to ±5%, constitutes the first comprehensive analytical method to differentiate between pilocarpine and its degradation products.

Keyphrases □ Pilocarpine hydrochloride—and degradation products, ^{13}C-NMR analysis, commercial ophthalmic formulations □ Isopilocarpine—^{13}C-NMR analysis in commercial ophthalmic formulations of pilocarpine hydrochloride □ Pilocarpinic acid—^{13}C-NMR analysis in commercial ophthalmic formulations of pilocarpine hydrochloride □ ^{13}C-NMR spectroscopy—analysis, pilocarpine hydrochloride and degradation products, commercial ophthalmic formulations □ Ophthalmic formulations, commercial—^{13}C-NMR analysis of pilocarpine hydrochloride and degradation products

No satisfactory methodology[1] is available for the analysis of the degradation products, isopilocarpine (II) and pilocarpinic acid[2] (III), in aqueous formulations of pilocarpine (I). The analysis of such impurities has received little attention because of: (*a*) their apparent relatively low concentrations in pilocarpine formulations, (*b*) the great difficulty in effecting any separation, and (*c*) the difficulty in realizing unequivocal characterization. However, numerous procedures for the determination of pilocarpine, including colorimetric, volumetric, polarimetric, and polarographic (3, 4), have been developed.

All commonly used procedures for the assay of pilocarpine have drawbacks (5). A common deficiency is the inability to distinguish between the parent alkaloid and its degradation products. For example, various colorimetric methods use the ferric hydroxamate reaction in aqueous (4, 6) or alcoholic (7) media, the sodium nitroprusside reaction (8), the hydrogen peroxide dichromate reaction (9), and the phosphomolybdic acid reaction (10). Although none of these colorimetric procedures excludes the contribution from degradation products from the total assay,

[a] Percent concentration as read from labeled formulation. [b] Density of concentrated (freeze-dried) sample of formulation in deuterium oxide. [c] To measure the intensities of the small peaks due to isopilocarpine and pilocarpinic acid, the C-8 peak intensities were integrated separately on one intensity scale; integration of the C-14 and IV peak intensities was performed on a different, common scale.

new, similar colorimetric procedures with the same limitations continue to appear.

A recently reported procedure based on the oxidative cleavage of pilocarpine by benzoyl peroxide and colorimetric estimations of the formaldehyde formed after additions of chromotropic acid (11) is alleged to hold some advantage in obviating interferences present in the USP hydroxylamine hydrochloride method for pilocarpine formulations. However, this new procedure probably will account for every substance having the *N*-methyl group (degradation products included) in a pilocarpine solution.

Dissatisfaction with traditional methods prompted the development of rather sophisticated chemical procedures for the indirect assay of pilocarpine and associated impurities. One such procedure employs phase solubility analysis of slightly soluble picrate salts in aqueous buffered solutions (12), but it is assumed that the reference pilocarpine samples are pure and that no chemical alteration occurs upon dissolution. A kinetic method for analyzing microgram quantities of pilocarpine in aqueous solution is based on the catalytic activity of the imidazole portion of the alkaloids on the hydrolysis of 2,4-dinitrophenyl acetate (12). The catalytic constants obtained for pilocarpine, pilocarpinic acid, isopilocarpinic acid, *etc.*, like the rate constants for the same substances obtained in related kinetic studies of the hydrolysis of pilocarpine (13, 14), may be based upon false assumptions regarding the constitution of pilocarpine reference solutions.

From a detailed study of the hydrolysis and epimerization of pilocarpine in aqueous solutions with changing pH using ^{13}C-NMR spectroscopy (15), an unequivocal basis for the characterization of aqueous solutions of pilocarpine and isopilocarpine was reported. The purpose of this paper is to discuss the application of ^{13}C-NMR spectroscopy to the assay of pilocarpine formulations for the content of pilocarpine and its degradation products.

EXPERIMENTAL

Procedure—^{13}C-Fourier transform NMR spectra were obtained[3] from various concentrated formulations of pilocarpine using 10-mm o.d. tubes and operating at 30°. The samples were scanned over 4000 Hz, and chemical shifts were measured in parts per million downfield from a tetramethylsilane external reference. The noise–signal ratio was kept at a constant minimum for each sample. Comparisons of the spectra obtained from commercial formulations with those of reference solutions of pilocarpine and isopilocarpine with varying pH (15) allowed the determination of the ratio of pilocarpine, isopilocarpine, and the corresponding hydroxy acids in the samples.

The spectra used for the calculations were obtained by using 4K data points, an acquisition time of 0.5 sec, a pulse angle of 30°, and no pulse delay. To check the accuracy of the observed intensities, spectra of two samples, 4% A and 4% E, were obtained using 8K data points within a 2000-Hz spectral width, an acquisition time of 2 sec, and a pulse delay of 1 sec. These conditions eliminated any error due to insufficient data points and to differences in relaxation times in the spectra. The results from these spectra were in good agreement (±5% of the measured values) with the results obtained by the more rapid method.

A known pipetted volume of each formulation was reduced to dryness by freeze drying. The residue was dissolved in deuterium oxide and carefully transferred, together with washings, to a volumetric flask (3.0 or 5.0 ml). The final concentration of pilocarpine was usually kept close to 20%; however, more dilution was sometimes necessary to dissolve the residue completely due to the presence of buffering agents and other preservatives. Table I lists the original and prepared pilocarpine concentrations for the various formulations.

For the quantitation of components in the pilocarpine formulations, a solution (2.04 *M*) of tetramethylammonium bromide in deuterium oxide was used for calibration. First, ^{13}C-NMR spectra of a solution (reference standard) of pilocarpine hydrochloride (0.159 *M*) in deuterium oxide were obtained in an NMR tube in which a coaxial inner tube containing the calibration solution of tetramethylammonium bromide had been inserted (Fig. 1). From the resulting proton-decoupled spectra, correlations were made between the peak intensities of the tetramethylammonium carbon resonances and the peak intensities for selected carbon resonances of pilocarpine and their respective solution concentrations. The same coaxial tube of tetramethylammonium bromide solution was then inserted in each formulation analyzed to calibrate them in terms of a common standard. A typical spectrum is shown in Fig. 2.

The following ophthalmic formulations of pilocarpine hydrochloride were examined: 4% A (expiration date December 1972), 3% A (expiration date February 1973), 2% A (expiration date September 1973), 1% A (expiration date December 1972), 6% B (expiration date February 1974), 4% B (expiration date June 1974), 4% C (no expiration date), 2% D (no expiration date), and 4% E (expiration date December 1975). Pilocarpine hydrochloride[4] (mp 204–205°) and tetramethylammonium bromide[5] were used for calibration.

Formulations and Calculations—The integrated intensity of any ^{13}C-NMR resonance from the reference solution of pilocarpine hydrochloride = P_n (where n refers to the carbon numbering position); the intensity of the ^{13}C-peak for tetramethylammonium bromide (IV) calibration solution (2.04 *M*) observed in the reference solution = S; the ratio of any pilocarpine peak intensity to peak IV intensity = P_n/S; the concentration of reference pilocarpine solution, P_R, per unit concentration

[3] Varian CFT-20 spectrometer.

[4] BDH.

[5] Eastman, White Label.

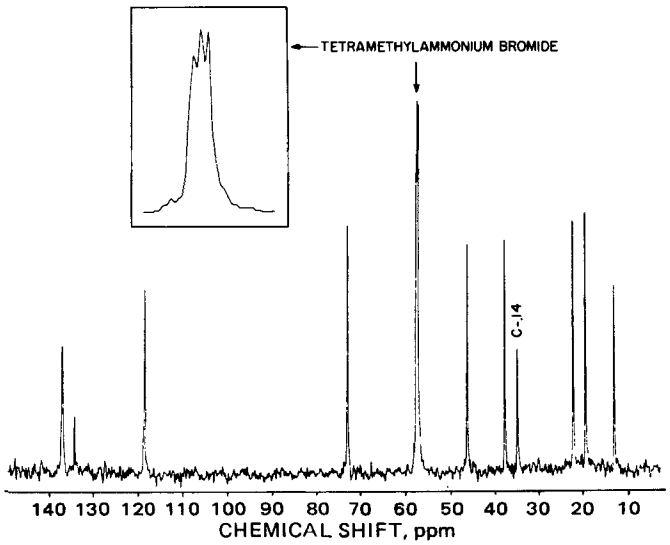

Figure 1—^{13}C-*NMR spectrum of pilocarpine hydrochloride (0.159* M*) in deuterium oxide with tetramethylammonium bromide (2.04* M*) in deuterium oxide as the external standard.*

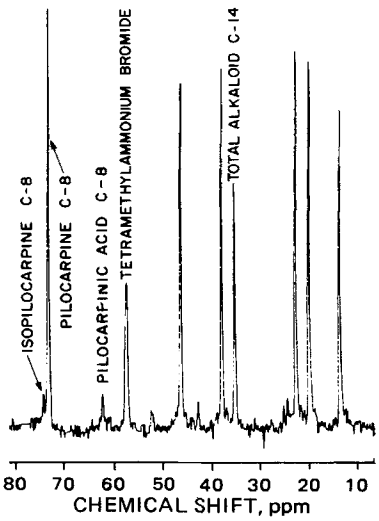

Figure 2—^{13}C-*NMR spectrum of freeze-dried sample from 6% B with tetramethylammonium bromide (2.04* M*) in deuterium oxide as the external standard.*

of IV calibration solution = $[P_R]/[IV] = 0.159/2.04 = 0.078$; and the normalized concentration of reference pilocarpine solution per normalized unit intensity, N, of any pilocarpine resonance peak = $[P_R]/[IV] \times S/P_n$. Thus, for any pilocarpine formulation, the total molar concentration, M_t, of all components having the N-methyl group may be expressed as follows:

$$M_t = \frac{\text{intensity of C-14 peak}}{\text{intensity of internal peak IV}} \times [IV] \times N \text{ (moles/liter)} \quad \text{(Eq. 1)}$$

The percent concentration (% total alkaloid) is:

$$C_t = \frac{M_t \times \text{mol. wt. of pilocarpine hydrochloride}}{1000 \text{ (ml)} \times \text{solution density (g/ml)}} \times 100 \quad \text{(Eq. 2)}$$

The calculated original concentration C_0, of pilocarpine hydrochloride in any formulation is C_t/F, where the concentration factor is:

$$F = \frac{\text{volume of labeled formulation pipetted}}{\text{final volume of concentrated formulation}} \quad \text{(Eq. 3)}$$

For a particular sample, 3% A, the total concentration of the species that contains the imidazole ring was calculated using Eqs. 1–3. From the known concentrations of the standard solutions of pilocarpine hydrochloride (0.159 *M*) and IV (2.04 *M*) and their peak intensities [16 and 117, respectively (Table I)], $N = 0.57$, $M_t = 0.81$ mole/liter, $C_t = 17.8$ moles/liter, $F = 6.7$, and $C_0 = 2.7\%$.

From the intensities of the C-8 peaks for pilocarpine, isopilocarpine, and the corresponding hydroxy acids in any particular sample, the relative quantities of the different species were calculated as follows:

$$\text{total intensity of C-8 resonances} = I_t = I_1 + I_2 + I_3 \ldots + I_n \quad \text{(Eq. 4)}$$

where $I_n = I_1$, I_2, *etc.*, C-8 intensities for pilocarpine, isopilocarpine, *etc.*

The ratio of any C-8 resonance to total C-8 intensity = I_n/I_t, and the percent species n in solution = $I_n/I_t \times C_0$. Therefore, for 3% A (Table I), pilocarpine = 2.4%, isopilocarpine = 0.1%, and pilocarpinic acid = 0.1%. Similar calculations were performed for each formulation (Table I).

RESULTS AND DISCUSSION

The results of ^{13}C-NMR analysis of pilocarpine formulations are summarized in Table II. Little change in pH resulted from the concentration of any formulation, and the small changes are ascribed to effects arising from the concentration of other formulating agents such as hydroxypropyl methylcellulose (0.33%), benzalkonium chloride (0.01%), edetate disodium (0.01%), potassium chloride (0.25%), boric acid (0.413%), and sodium carbonate (0.006%) present in a 2% pilocarpine hydrochloride formulation. The estimated amount of pilocarpine hydrochloride (percent) after concentration (Table I) was calculated from known changes in volume; usually, 20 ml reduced to 3.0 ml. However, in some instances the final volume had to be increased to keep all components of a formulation in solution. Formulations D and E were particularly troublesome for reconstitution of their components in deuterium oxide; consequently, their analyses were restricted to less concentrated solutions.

Baeschlin *et al.* (16) first utilized proton NMR spectroscopy to differentiate between pilocarpine hydrochloride in deuterium oxide and the lactone-cleaved sodium pilocarpinate in 2 *N* NaOD. Knowledge of these spectral features was then used to interpret the spectral changes observed when a formulation of pilocarpine hydrochloride (0.14 g) in deuterium oxide (2 ml) at pH 6.1, containing monobasic potassium phosphate (0.056 g) and dibasic sodium phosphate dihydrate (0.04 g), was heated at 70° for 240 hr. The gradual diminution of a multiplet at 0.4 ppm, attributed to the γ-methylene protons of the lactone ring, with the simultaneous development of a more complex multiplet at 1.1 ppm (not assigned) during prolonged heating of the formulations was attributed to hydrolysis (lactone ring cleavage) of pilocarpine. From comparison of the integrals from these multiplets, it was reported that 70% pilocarpine remained intact and that 28% of an "open form" was generated after 240 hr at 70°.

From inspection of the published spectra (16), most of the spectral change can be accounted for by isomerization to isopilocarpine, because obvious development of an additional methyl triplet can be seen on the high field side of the 3.7-ppm triplet for the methyl group of the ethyl substituent of pilocarpine. The recognition that the spectra reveal evidence for appreciable isomerization of pilocarpine also discounts the value of the colorimetric method designed by Brochmann-Hanssen *et al.* (17), with which the proton NMR method was compared because it also cannot distinguish between isopilocarpine and lactone-cleaved products.

Nunes and Brochmann-Hanssen (14) were the first to report that when pilocarpine and isopilocarpine are hydrolyzed in alkaline solution, the NMR triplets of the terminal methyl group of the ethyl substituents are shifted upfield to 1.31 ppm for both epimers and that the chemical shifts differ by 0.1 ppm for the two epimers. Nunes and Brochmann-Hanssen considered that integration of the methyl triplets due to pilocarpinate and isopilocarpinate, recorded with a 10-fold scale expansion and a 1.0-ppm offset, provided the best means of quantitating epimerization. For the best utilization of this method at 100 MHz, it is necessary to use a curve resolver for the expanded spectra (14). In addition, the assay-based integration of methyl triplets is limited to alkaline solutions and cannot be utilized under acidic or nearly neutral conditions where the chemical shifts for the methyl triplets of isopilocarpine and pilocarpine coincide.

Recently, a liquid chromatographic procedure was published for the simultaneous determination of pilocarpine and isopilocarpine in pharmaceutical preparations (1). This procedure involves separation of the isomers on an ion-exchange column followed by detection by UV absorption in the 217-nm region. The conditions used (1), *i.e.*, the buffered mobile phase was adjusted to pH 9, might lead to isomerization and hydrolysis of pilocarpine, as indicated by ^{13}C-NMR spectroscopic studies of the behavior of pilocarpine with varying pH (15). This concern for possible analytical modification of the sample by the chromatographic

procedure is especially pertinent when long retention times are involved.

While Urbànyi *et al.* (1) did not describe the determination of pilocarpinic acid, Weber[6] chromatographically determined this acid by treating a second aliquot of the ophthalmic solution with acid (pH <1) to convert pilocarpinic acid to pilocarpine. In contrast, the NMR spectroscopic technique permits pilocarpine, isopilocarpine, and pilocarpinic acid to be characterized and assayed simultaneously in the presence of one another and in the presence of excipients commonly found in commercial pilocarpine solutions.

In a detailed ^{13}C-NMR study of the hydrolysis and epimerization of pilocarpine in aqueous solution of varying pH (15), it was shown that the C-8 resonances[7] afford a particularly good spectral basis for distinguishing among pilocarpine, isopilocarpine, and pilocarpinic acid. In this study, this understanding was applied in the development of an assay procedure based on the relative intensities of the C-8 resonances for these compounds calibrated against the intensity of the ^{13}C-resonance from a known concentration of tetramethylammonium bromide.

Tetramethylammonium bromide (IV) was selected because its ^{13}C-resonance is well removed from any resonance of pilocarpine and the other compounds (Fig. 1). The insert in Fig. 1 reveals the triplet character for the resonance of IV due to quadrupole coupling by nitrogen; thus, the intensity of the resonance of IV was taken as the sum of the three integrated component intensities. Figure 2 illustrates the spectral features of a pilocarpine formulation, showing the C-8 resonances for pilocarpine, isopilocarpine, pilocarpinic acid, and IV.

Because the C-14 resonance for the *N*-methyl moiety has a common frequency for all components of a pilocarpine solution at any pH, its intensity can be used as a measure of the total alkaloid content of any pilocarpine formulation. The intensities of the C-8 resonances, however, cannot be compared directly with the C-14 resonances, because the ^{13}C-relaxation time for the C-14 is markedly different from that for C-8, as may be seen from inspection of the relative intensities in Fig. 2.

To calculate either the percentage composition or the total alkaloid content of any formulation, it is necessary to circumvent the difference in relaxation characteristics by relating any particular resonance intensity to the intensity of the common calibration resonance, IV. The ratio of intensities so obtained is then multiplied by a normalizing factor, *N*, calculated to relate the intensity of reference IV in terms of the intensity of any resonance of a reference solution of pilocarpine hydrochloride of known concentration. The details of these formulations together with sample calculations are outlined under *Experimental.*

The results of the analysis of a range of pilocarpine formulations having various labeled concentrations of drug and expiration dates are summarized in Table II. The samples were procured from various pharmacies in 1972 and were then stored at room temperature and protected from light. In most instances, no isopilocarpine was detected; where it was detected, it generally did not exceed 5% of the labeled pilocarpine content. In one instance, B (6%) showed degradation to 7% isopilocarpine and 7% pilocarpinic acid which was surprising in view of its more recent expiration date compared to most samples. However, this formulation apparently was the only one containing phenylmercuric nitrate as well as benzalkonium chloride as preservatives. One formulation, 4% E, showed a new resonance at 70.25 ppm, attributed to a ring carbon of povidone, an ingredient not found in the other formulations.

The calculated total alkaloid content agreed well with the labeled content of pilocarpine hydrochloride in each instance. Low results obtained by a colorimetric method for the determination of pilocarpine in ophthalmic solutions were attributed (18) to pilocarpine–methylcellulose interaction. In no case was there any evidence of interference with the ^{13}C-NMR method by methylcellulose, hydroxypropyl methylcellulose, or hydroxyethylcellulose.

In summary, this ^{13}C-NMR spectroscopic assay constitutes the first reported unequivocal and comprehensive method for analyzing degradation products of pilocarpine, isopilocarpine, and pilocarpinic acid, as well as unchanged pilocarpine, in pilocarpine formulations. This method provides for the differentiation and characterization *in situ* of products as well as their convenient assay utilizing resonance intensities treated in such a way as to avoid the limitation imposed upon ^{13}C-NMR spectroscopy for quantitation due to marked variability in relaxation times. The assay, as described, provides the percentage composition within ±5%.

[6] J. D. Weber, Food and Drug Administration, Washington, D.C., personal communication.

[7] By definition, the C-8 resonances arise from the γ-methylene carbon atom of the γ-lactone ring of pilocarpine, isopilocarpine, *etc.*

Structure–Activity Studies Using Valence Molecular Connectivity

LOWELL H. HALL *ˣ and LEMONT B. KIER ‡

Abstract □ The extension of the molecular connectivity concept to the treatment of heteroatom molecules affords an opportunity to examine structure–activity relationships in a wide variety of molecule series that possess biological activity. Four series are described in this report. The correlations found indicate that molecular connectivity is an extremely useful descriptor of structure in studying drug molecule structure–activity relationships.

Keyphrases □ Molecular connectivity index—related to structure–activity relationships, various types of molecules □ Structure–activity relationships—various types of molecules, related to molecular connectivity index □ Topological indexes—molecular connectivity index, related to structure–activity relationships, various types of molecules

Recently (1, 2), the extension of molecular connectivity to the treatment of heteroatom molecules was described. By considering the valence electrons, whether bonded or nonbonded, an atom connectivity term, δ^v, for multiply bonded carbon atoms or heteroatoms was assigned.

The work presented in this paper tests the ability of δ^v to describe the atomic connectivity in heteroatoms so that the molecular connectivity indexes bear some relationship to structure influencing biological properties.

DISCUSSION

The simple prescription for assigning δ^v is $Z^v - h_i$, where Z^v is the number of valence electrons and h_i is the number of attached hydrogens. For alcohols, ethers, primary amines, and pyridine, the δ^v values for the heteroatoms are 5, 6, 3, and 5, respectively. The δ^v values for heteroatoms are shown in Table I.

Since halogen atoms have an identical number of valence electrons, this prescription yields identical values of δ^v. It is necessary to derive empirical values of δ^v for the halogens by calibrating them to a physical property. The molar refraction was chosen for this assignment (1, 2) (Table I).

Table I—Valence Delta, δ^v, Values for Heteroatoms

Atom	δ^v	Atom	δ^v
—NH_2	3	—OH	5
—NH—	4	—O—	6
	5	—C=O	6
—C≡N	5	Furan O	6
—C=NH	4	O=N—O	6
Pyridine N	5	H_2O	4
Nitro N	6	H_3O+	3
NH_3	2	F	(−)20
NH_4^+	1	Cl	0.690
	6	Br	0.254
=NH_2^+	3	I	0.085

The use of δ^v thus permits the calculation of a valence chi term of the first order, $^1\chi^v$, by the expression:

$$^1\chi^v = \sum (\delta_i^v \delta_j^v)^{-1/2} \qquad \text{(Eq. 1)}$$

The $^1\chi^v$ terms provide a further structural description of heteroatom molecules, eliminating the redundancies found when simple connectivity values are used. The refinement permits the close correlation of chi terms with physical properties such as boiling point, solubility, and molar refraction (1, 2).

Cytochrome Conversion by Phenols—The conversion of cytochrome P-450 to P-420 in the rabbit liver by a series of phenols was reported (3). An analysis of these molecules using $^1\chi^v$ reveals the following relationship to the minimum active concentration (−log *c*), p*C*:

$$pC = 0.816\ (\pm 0.105)\,^1\chi^v - 0.789\ (\pm 0.329) \qquad \text{(Eq. 2)}$$

$$r = 0.914 \quad s = 0.291 \quad n = 14$$

The calculated and observed values are listed in Table II.

The inclusion of the Hammett sigma value for each substituent in a multiple regression with $^1\chi^v$ does not improve the relationship. The re-

sults are interesting in that a single term, $^1\chi^v$, is capable of producing a fairly good correlation with biological potency. This is accomplished in a group of molecules containing oxygen, nitrogen, chlorine, bromine, and iodine in three different ring positions and singly as well as multiply substituted. The $^1\chi^v$ term thus encodes within it sufficient structural information to describe the salient features influencing biological activity.

From a mechanistic point of view, it might be concluded that the electronic influence of the substituent on the ring or on the phenolic hydroxyl group is not the critical process. The substituent itself must be participating in a characteristic way in some critical event leading to the activity.

Sweet-Tasting Nitroanilines—A series of substituted nitroanilines was reported to possess sweet taste potency of up to 4000 times the level of sucrose (4). Kier studied these and other sweet-tasting molecules and predicted that the substituent is a third member of the pharmacophore that may participate in a dispersion interaction (5).

The connectivity indexes $^1\chi$ and $^1\chi^v$ were calculated for these molecules and compared with the log of the relative (molar) sweetness to sucrose (Table III). The relationship is:

$$\log RS = 0.350\ (\pm 0.160)^1\chi + 0.694\ (\pm 0.153)^1\chi^v - 3.856\ (\pm 0.689) \quad \text{(Eq. 3)}$$

$$r = 0.953 \quad s = 0.222 \quad n = 9$$

In this case, the structural characteristics influencing the receptor role of the substituent are best quantified by the combination of the simple connectivity, $^1\chi$, and the valence connectivity, $^1\chi^v$, terms. The correlation is quite good and is of potential value in drug design.

Inhibition of *Aspergillus niger*—A group of substituted benzyl alcohols exhibited an inhibitory influence on the mold *A. niger* (6). The potency of these molecules is expressed as log $1/c$ for the minimum inhibitory concentration (Table IV).

Calculation of the $^1\chi^v$ values for each molecule reveals a fair correlation with log $1/c$ (0.890). The electronic influence of the substituents on the ring might be an additional structural factor influencing the activity. Accordingly, the use of the Hammett sigma term is suggested as a second term in a multiple regression analysis. The correlation improves in this case:

$$\log 1/c = 0.990\ (\pm 0.106)^1\chi^v + 0.656\ (\pm 0.197)\sigma - 1.268\ (\pm 0.361) \quad \text{(Eq. 4)}$$

$$r = 0.937 \quad s = 0.286 \quad n = 19$$

An inspection of other chi terms reveals that the fourth-order term, $^4\chi_P{}^v$, described previously (7), gives a significantly improved correlation along with σ:

$$\log 1/c = 1.987^4\chi_P{}^v + 0.507\sigma + 0.365 \quad \text{(Eq. 5)}$$

$$r = 0.962 \quad s = 0.217 \quad n = 19$$

These results indicate that both a connectivity structural characteristic and an electronic influence contribute to the activity within the series. Furthermore, the superiority of the $^4\chi_P{}^v$ term over the first-order term, $^1\chi^v$, is of interest. The $^4\chi_P{}^v$ term describes the important connectivity feature in a superior manner, resulting in a fine correlation.

Toxicity of Diethyl Phenyl Phosphates—A series of ring-substituted diethyl phenyl phosphates was toxic to the housefly (8) (Table V). An analysis using molecular connectivity and the Hammett sigma term reveals a very good correlation with the toxic concentration, pC, according to:

$$pC = 2.512\ (\pm 0.184)\sigma + 0.382\ (\pm 0.154)^1\chi^v - 1.350\ (\pm 0.420) \quad \text{(Eq. 6)}$$

$$r = 0.975 \quad s = 0.295 \quad n = 13$$

The predicted results are shown in Table V.

Equation 6 reveals that both a connectivity feature and an electronic influence play important roles in the activity of these molecules. The wide

diversity of groups is a severe challenge for the connectivity concept, and the good correlation is testimony to the ability of the method to describe structural characteristics important in this case.

SUMMARY

These studies reveal the contribution that molecular connectivity may make in structure–activity studies. Recent advances made in this method, namely the treatment of heteroatoms (1) and the development of extended connectivity terms (7), make possible the consideration of a wide variety of molecules typically found in drug studies. Most importantly, molecular connectivity, as developed to this point, is capable of revealing good relationships with biological activities (9–13). It is expected that this method of structural analysis will find wide application in structure–activity studies.

Furthermore, the method of molecular connectivity relates molecular structure directly to biological activity. No intermediate physical properties are required for satisfactory correlation. The medicinal chemist's intuition concerning structure and activity can be applied directly and quantitatively to drug studies. The demonstrated ability to handle a variety of heteroatoms greatly strengthens the method of molecular connectivity.

Bioavailability of Digoxin–Hydroquinone Complex: A New Oral Digoxin Formulation

FELIX BOCHNER *§, DAVID H. HUFFMAN ‡, DANNY D. SHEN *, and DANIEL L. AZARNOFF *x

Abstract □ A new oral digoxin formulation, a digoxin–hydroquinone complex (99% dissolution at 5 min), was evaluated in 12 healthy human volunteers with reference to bioavailability and extent and time of peak serum digoxin levels. This preparation was compared with a commercial digoxin tablet (26% dissolution at 5 min), digoxin elixir, and a parenteral digoxin solution. Bioavailability was assessed by the 24-hr area under the serum digoxin–time curve and 48-hr digoxin excretion in urine. The bioavailability of the complex was similar to that of the elixir but not statistically different from that of the tablet. The tablet was less bioavailable than the elixir. There was less interindividual variation in bioavailability with the complex than with the elixir. Peak serum digoxin levels were higher with the complex than the tablet and were achieved more quickly.

Keyphrases □ Digoxin—bioavailability of complex with hydroquinone compared to other digoxin dosage forms, humans □ Bioavailability—digoxin–hydroquinone complex compared to other digoxin dosage forms, humans □ Complexes—digoxin–hydroquinone, bioavailability compared to other digoxin dosage forms, humans □ Dosage forms, various—digoxin and digoxin–hydroquinone complex, bioavailability compared, humans □ Cardiotonic agents—digoxin–hydroquinone complex, bioavailability compared to other digoxin dosage forms, humans

The bioavailability of oral digoxin preparations has been studied recently (1–11), and several studies (4–10) showed that the bioavailability of solid digoxin dosage forms correlated with the dissolution rate but not the disintegration rate (11). This finding led to the assertion that existing *in vitro* dissolution tests are adequate for predicting commercial digoxin tablet bioavailability. Other investigations (12–16), however, demonstrated that the *in vitro* dissolution rate of commercial digoxin tablets need not correlate with bioavailability, since tablets that did not meet USP XVIII dissolution specifications showed *in vivo* bioavailability characteristics comparable to tablets that did. Thus, the relationship between bioavailability and dissolution rate appears to be unresolved.

The main cause of the unsatisfactory dissolution of digoxin tablets is related primarily to digoxin's low water solubility. Although improved formulation technology has resulted in significant improvement, an intrinsically more soluble form of digoxin should enhance dissolution. Higuchi and Ikeda (17) recently developed such a form by complexing digoxin and hydroquinone. This approach utilizes the concept of free energy of dissolution of molecular complexes (18). The digoxin–hydroquinone[1] complex is more readily soluble than digoxin itself, and total dissolution of digoxin occurs within 5 min (17).

This paper reports a comparison of the bioavailability in humans of the complex with that of a digoxin tablet[2] of

satisfactory dissolution and bioavailability, a digoxin elixir[3], and an intravenous injection[4].

EXPERIMENTAL

Subjects—Twelve healthy volunteers[5], seven female and five male, ages 22–41 years (median 31), were studied. There was no evidence of cardiac, hepatic, renal, GI, or hematopoietic disease from the history, physical examination, ECG, complete blood count, creatinine clearance, urinalysis, and bilirubin, alkaline phosphatase, glutamic-pyruvic transaminase, and thyroxine levels.

Drug Administration—The volunteers abstained from drugs, including alcohol, for at least 48 hr prior to each dosing period. The dosage form was administered between 7 and 8 am after an overnight fast of at least 10 hr. During the first 4 hr after drug administration, the subjects were not allowed to eat or to lie down. They were allowed to drink water at a maximum rate of 100 ml/hr.

In a random sequence with at least 2-week intervals, the individuals received each of the following dosage forms: (*a*) two 0.329-mg tablets of digoxin–hydroquinone complex[1] (equivalent to 0.5 mg of digoxin), (*b*) two 0.25-mg digoxin tablets[2], (*c*) 0.5 mg of digoxin elixir[3], and (*d*) 0.5 mg of digoxin intravenous injection[4]. The oral dosage forms were given with 200 ml of water. The parenteral digoxin was injected intravenously over 2–3 min, followed by 200 ml of water orally.

Specimen Collection and Assay—Blood (10 ml) for digoxin estimation was obtained from an antecubital vein with an indwelling catheter[6] at 0, 0.25, 0.50, 0.75, 1.0, 1.5, 2, 3, 4, 6, 8, 10, and 24 hr following an oral dose. Additional early samples were collected at 0.05, 0.1, 0.17, and 0.33 hr following the intravenous dose. Serum was separated from blood and frozen until assayed for digoxin by radioimmunoassay (19). The coefficients of variation of high and low internal standards analyzed daily were 5.3 and 6.4%, respectively.

Complete daily urine collections were obtained for 48 hr following dosing. Each 24-hr urine collection was thoroughly mixed, the volume was determined, and an aliquot was frozen until assayed by a modification of a reported method (20). Each sample also was assayed for creatinine content to aid in the assessment of the completeness of the urine collections.

Analysis—Bioavailability of the various preparations was determined by comparing the 24-hr area under the serum digoxin–time curve ($AUC_{0\rightarrow24}$) following intravenous administration to that following the oral dosage forms, *i.e.*:

$$\frac{(AUC_{0\rightarrow24})_{oral}}{(AUC_{0\rightarrow24})_{iv}} \times 100\%$$

The *AUC* was computed[7] by the trapezoidal rule. Furthermore, the 48-hr excretion of digoxin in urine following intravenous administration was compared to that following the oral dosage forms (20).

The time taken to achieve peak serum digoxin concentrations and the peak concentrations were obtained from the serum concentration profiles. Statistical significance was determined by a two-way analysis of variance (ANOVA). Differences between the individual groups were determined by Duncan's multiple range test (21, 22).

Table II—Time to Achieve Peak Plasma Digoxin Concentration (Hours)

Multiple Range Analysis

Complex *versus* tablet	$p < 0.005$
Complex *versus* elixir	$p < 0.2$
Tablet *versus* elixir	$p < 0.005$

RESULTS

Dissolution Rate Tests—The dissolution of the complex was 99% complete within 5 min whereas that of the tablets was 26% at 5 min, 61% at 15 min, 74% at 30 min, and 88% at 60 min. All commercial dosage forms met USP specifications.

Bioavailability—The $AUC_{0\rightarrow24}$, time to achieve peak plasma digoxin levels, and peak digoxin levels are presented in Tables I–III. Based on the *AUC* values, the bioavailabilities of the complex, tablet, and elixir were 59.1 (40–83.2), 51.6 (30.4–77.3), and 64.5% (39.4–87.3%), respectively, compared to the intravenous dosage form. The bioavailability of the complex and the tablets was not significantly different ($p < 0.08$), but all oral preparations differed significantly from intravenous digoxin. The elixir was more available than the tablets ($p < 0.005$), but the tablet and the elixir did not differ significantly ($p < 0.2$).

The 48-hr excretion of digoxin in urine following the various dosage forms is given in Table IV. The intravenous form differed significantly from all oral formulations. The complex did not differ significantly from the tablet ($p > 0.3$) or the elixir ($p > 0.1$), although the elixir was different

Multiple Range Analysis

Complex *versus* tablet	$p > 0.3$
Complex *versus* intravenous injection	$p < 0.005$
Complex *versus* elixir	$p > 0.1$
Tablet *versus* intravenous injection	$p < 0.005$
Tablet *versus* elixir	$p < 0.01$
Intravenous injection *versus* elixir	$p < 0.005$

from the tablet ($p < 0.01$). If a 10% difference is assumed to be significant, the complex had greater bioavailability than the tablet in six subjects, the two preparations behaved equally in five subjects, and the tablet was more available than the complex in one individual.

Peak Time and Peak Concentration—The peak concentration and the time required to achieve it are presented in Tables II and III. A mean peak value of 2.79 ± 1.13 ng/ml was achieved in 0.83 ± 0.29 hr with the complex; 1.73 ± 0.73 ng/ml was achieved in 1.31 ± 0.69 hr with the tablet, and 3.27 ± 0.91 ng/ml was achieved in 0.68 ± 0.22 hr with the elixir. Compared to the tablet, both the complex ($p < 0.005$) and the elixir ($p < 0.05$) achieved significantly higher peak digoxin levels and in a shorter time (complex, $p < 0.005$; elixir, $p < 0.005$).

DISCUSSION

The bioavailability of oral liquid dosage forms has, in general, been shown to be greater than that of tablet forms (3, 20, 23). Although the bioavailability (based on comparison of *AUC*'s) of the complex, a digoxin preparation of very rapid dissolution, was not statistically different from that of the elixir, it also was not statistically different from that of a solid dosage form. This discrepancy may be related to the fact that the volunteers showed large intersubject variations in the bioavailability of various preparations (Table I).

A considerable variance from the mean $AUC_{0\rightarrow 24}$ and urine digoxin excretion was observed in subjects receiving the complex, but an even greater variance occurred with the tablet. Thus, the complex appeared to be less erratically absorbed than the tablet, which may be advantageous when administered on a chronic basis. The bioavailability of the oral preparations was lower in this study than in a previous one (20), where the elixir was 84.5% absorbed (*cf.*, 64.5% in this study) and a rapid dissolution tablet was 77.8% absorbed (*cf.*, 59.6% in this study). However, the $AUC_{0\rightarrow 24}$ (25.1) following intravenous digoxin agreed closely with values obtained in two other studies, one following single-dose digoxin (25.9) (20) and the other in a steady-state study (22.9) (23). In three subjects (Subjects 1, 4, and 5), the 48-hr excretion of digoxin in urine following intravenous administration was less than that following one of the oral preparations. There is no ready explanation for this finding, except inadequate urine collections by these volunteers; low creatinine excretion in urine confirmed this suspicion.

The complex produced a higher peak serum digoxin level earlier than the tablet. This characteristic may not be desirable, although there is no evidence (24, 25) to suggest that the peak digoxin concentration during absorption and distribution is related to toxicity. The rapid achievement of the higher peak level is similar to that attained with the elixir, which also has not been reported to be associated with more toxicity than a solid dosage form. On the other hand, steady-state serum digoxin concentrations do correlate with therapeutic and toxic responses in patients (26).

The absorption of incompletely absorbed drugs has more inter- and intraindividual variability than that of completely absorbed drugs (23, 27, 28). This variation may have harmful effects in humans if the drug has a narrow therapeutic index, such as digoxin. Considerable data (4–10) demonstrate a direct correlation between the dissolution rate of digoxin tablets and their bioavailability. This relationship is further supported by the observation that various digoxin solutions are more bioavailable than solid dosage forms (3, 20, 23).

The particle size of digoxin in relation to bioavailability was examined (29), and particles below 3.7 μm in size produced better availability than did particles above 12 μm. However, another study (9) found that the bioavailability of a digoxin elixir was not greater than that of digoxin tablets whose dissolution rate exceeded 85% in 1 hr. A recent study (30) compared the availability of a digoxin solution in capsules with tablets that were 97 and 78% dissolved in 1 hr. However, the tablet dissolution rate was not given. The solution in capsules performed better than the tablets, whose availability did not differ despite different *in vitro* dissolution rates. This latter finding is in accord with information obtained in other studies (13–16) and supports the finding of this study that dissolution rates above a certain point may not be associated with increased digoxin absorption. However, in these and other studies (4–10), oral preparations were compared only to each other, whereas in this study the bioavailability of oral digoxin was compared to other oral forms as well as to the intravenous form. Thus, absolute bioavailability cannot be ascertained in most other studies.

It appears, therefore, that the dissolution rate of digoxin tablets may not be the only limiting factor in their incomplete absorption and that the current method of dissolution testing does not discriminate satisfactorily. Digoxin is prescribed for chronic therapy. Single-dose studies may not assess the bioavailability of the dosage forms accurately during chronic use. The results in this single-dose study warrant the further evaluation of the chronic administration of the complex. Steady-state bioavailability studies of digoxin have been reported (23).

The principle of complexing a drug with substances such as hydroquinone to enhance dissolution might be applied to other medications whose absorption is erratic following poor *in vivo* dissolution.

Time-Dependent Kinetics I: Exponential Autoinduction of Carbamazepine in Monkeys

WILLIAM H. PITLICK * and RENÉ H. LEVY ˣ

Abstract □ The pharmacokinetics of carbamazepine were studied during a week-long infusion of the drug in 60% polyethylene glycol 400 solution in three rhesus monkeys. Serum concentrations approached steady state within 8–16 hr and then rapidly declined, within 72 hr, to a new asymptotic level approximately 46% of the maximum steady-state concentration. Serum concentrations remained at that level during the rest of the experimental period. The decline from the maximum value to the asymptotic steady state was exponential. It is postulated that the decline in the steady-state concentration is due to autoinduction by carbamazepine of its own metabolism.

Keyphrases □ Time-dependent pharmacokinetics—carbamazepine, 1-week infusion, monkeys □ Carbamazepine—time-dependent pharmacokinetics, 1-week infusion, monkeys □ Pharmacokinetics, time dependent—carbamazepine, 1-week infusion, monkeys □ Analgesics—carbamazepine, time-dependent pharmacokinetics, 1-week infusion, monkeys

Over the past 15 years, awareness of the various facets of dose dependency in drug disposition has increased. As a result, experimental designs of pharmacokinetic investigations often include studies at several dose levels. Examples of dose dependency in absorption, distribution, and elimination have been reported. However, the concept of *time dependency* in pharmacokinetics is still undefined.

BACKGROUND

Studies in this laboratory involving animals and humans clearly indicated that time dependency is a multifaceted phenomenon, at least as complex as dose dependency. Several types of time dependency exist, and this series of papers will provide examples. Carbamazepine is the drug of choice for the treatment of trigeminal neuralgia (1) and was recently approved for use as an anticonvulsant in adults (2). Single-dose intravenous and oral studies in monkeys indicated that the drug has a short biological half-life (1–2 hr) and that chronic oral administration during its efficacy testing in epileptic monkeys would be impractical (3, 4). Consequently, a continuous mode of administration such as constant-rate intravenous infusion in chronically catherized monkeys was considered.

Short-term infusion studies indicated that carbamazepine exhibits dose-dependent kinetics (5, 6). Infusion rates between 8.5 and 40 mg/hr yielded steady-state concentrations of carbamazepine between 2.0 and 5.8 μg/ml (6). However, the increase in steady-state concentration was more than proportional to the increase in infusion rate, and the time required to reach one-half of the steady-state level was not constant. A model with zero-order input and one capacity-limited elimination pathway was adequate to describe the pharmacokinetic behavior of the drug (6).

Time-Dependent Kinetics I: Exponential Autoinduction of Carbamazepine in Monkeys

WILLIAM H. PITLICK * and RENÉ H. LEVY ˣ

Abstract □ The pharmacokinetics of carbamazepine were studied during a week-long infusion of the drug in 60% polyethylene glycol 400 solution in three rhesus monkeys. Serum concentrations approached steady state within 8–16 hr and then rapidly declined, within 72 hr, to a new asymptotic level approximately 46% of the maximum steady-state concentration. Serum concentrations remained at that level during the rest of the experimental period. The decline from the maximum value to the asymptotic steady state was exponential. It is postulated that the decline in the steady-state concentration is due to autoinduction by carbamazepine of its own metabolism.

Keyphrases □ Time-dependent pharmacokinetics—carbamazepine, 1-week infusion, monkeys □ Carbamazepine—time-dependent pharmacokinetics, 1-week infusion, monkeys □ Pharmacokinetics, time dependent—carbamazepine, 1-week infusion, monkeys □ Analgesics—carbamazepine, time-dependent pharmacokinetics, 1-week infusion, monkeys

Over the past 15 years, awareness of the various facets of dose dependency in drug disposition has increased. As a result, experimental designs of pharmacokinetic investigations often include studies at several dose levels. Examples of dose dependency in absorption, distribution, and elimination have been reported. However, the concept of *time dependency* in pharmacokinetics is still undefined.

BACKGROUND

Studies in this laboratory involving animals and humans clearly indicated that time dependency is a multifaceted phenomenon, at least as complex as dose dependency. Several types of time dependency exist, and this series of papers will provide examples. Carbamazepine is the drug of choice for the treatment of trigeminal neuralgia (1) and was recently approved for use as an anticonvulsant in adults (2). Single-dose intravenous and oral studies in monkeys indicated that the drug has a short biological half-life (1–2 hr) and that chronic oral administration during its efficacy testing in epileptic monkeys would be impractical (3, 4). Consequently, a continuous mode of administration such as constant-rate intravenous infusion in chronically catherized monkeys was considered.

Short-term infusion studies indicated that carbamazepine exhibits dose-dependent kinetics (5, 6). Infusion rates between 8.5 and 40 mg/hr yielded steady-state concentrations of carbamazepine between 2.0 and 5.8 μg/ml (6). However, the increase in steady-state concentration was more than proportional to the increase in infusion rate, and the time required to reach one-half of the steady-state level was not constant. A model with zero-order input and one capacity-limited elimination pathway was adequate to describe the pharmacokinetic behavior of the drug (6).

Table I—Data Obtained from Three Monkeys following Infusion of Carbamazepine at a Constant Rate during 1 Week

Monkey	R_0, mg/hr	Initial Steady-State Concentration, C_0*, μg/ml	Lag Time, θ, hr	Final Steady-State Concentration, C_∞*, μg/ml	Apparent Total Body Clearance		Induction Half-Life, hr
					Initial, liters/hr	Final, liters/hr	
1	17.3	4.10	16	2.04	4.2	8.5	5.8
2	16.0	4.32	12	1.84	3.7	8.6	11.6
3	9.0	2.86	16	1.29	3.1	6.9	7.6

The present investigation was undertaken to define infusion schedules and involved continuous infusion of the drug during 7 days. The steady-state levels of carbamazepine decreased during long-term constant rate infusion. Thus, carbamazepine appears to be the first example of a drug exhibiting simultaneously two types of nonlinearities, dose and time dependency. Furthermore, the long-term constant rate infusion approach used allowed a characterization of the kinetics of autoinduction. These findings provide an experimental basis for the development of nonlinear pharmacokinetic models involving time dependency.

EXPERIMENTAL

Materials—Carbamazepine[1] in polyethylene glycol 400–water (60:40) at 8 mg/ml was used for intravenous infusions.

Animals—Three healthy, male, chaired rhesus (*Macaca mulatta*) monkeys, 3.5–4.5 kg, with chronic jugular and femoral catheters were used. The patency of the catheters was assured by a slow continuous saline infusion into each catheter. The animals were maintained on monkey chow and fresh fruit.

Procedures—Carbamazepine was infused at a constant rate for 1 week. The intravenous infusion was accomplished by pumping the drug solution from a 100-ml calibrated reservoir[2] into the femoral vein catheter through an appropriate chamber attached to a calibrated peristaltic pump[3]. Infusion rates ranged between 9.0 and 17.3 mg/hr (Table I).

Samples of 1.5 ml of blood were drawn from the jugular catheter into a 5-ml plastic disposable syringe through a three-way stopcock attached to the catheter. Each sample was transferred to a nonheparinized tube, allowed to clot, and centrifuged at 2000 rpm for extraction immediately or frozen until assayed. Following the collection of each sample, the catheter was flushed with 1.5 ml of saline.

Twenty to 22 samples were collected over 1 week, the majority of the samples being taken in the first 48 hr. Twenty-four-hour urine collections were taken during the infusion studies. Serum and urine samples of carbamazepine were assayed using a GLC method presented previously (7).

RESULTS AND DISCUSSION

Serum concentration–time plots for Monkeys 1 and 2 are shown in Figs. 1 and 2, respectively. Serum concentrations approached an initial steady state, C_0*, within 8–16 hr and then fell off to a new asymptotic level, C_∞*, which was reached within 72 hr after the start of the infusion. There was no further decline from this final steady state during the rest of the experimental period. The serum concentrations observed within the first 12 hr were within 10% of the levels predicted from short-term infusion studies (6), as shown by the dotted lines in Figs. 1 and 2.

On the average, the final steady-state concentrations represented 46% (42–50%) of the maximum levels seen within the first 8–16 hr (Table I). This decrease corresponded to a twofold increase in apparent total body clearance (Table I). In all animals, the decline in steady-state concentrations from 12 hr onward was remarkable from two aspects: (*a*) the decline began somewhat abruptly, after a lag time (θ) of 12–16 hr, and (*b*) the decline in levels during a continuous infusion at a constant rate appeared to be an exponential process (Figs. 1 and 2). Semilogarithmic plots of the serum concentration data after the lag time, log ($C - C_\infty$*) *versus* ($t - \theta$), appeared linear (Fig. 3). An induction rate constant, K_I, and a corresponding half-life of induction, $T_{I\,1/2}$, can be measured to characterize the decreases in concentration at times larger than θ. The values of $T_{I\,1/2}$ obtained for these monkeys ranged between 5.8 and 11.6 hr. Serum concentrations at times larger than θ could then be fitted to the equation:

$$C = C_\infty^* + (C_0^* - C_\infty^*)\, e^{-K_I(t-\theta)} \qquad \text{(Eq. 1)}$$

A good agreement was observed between experimental data points and the fitted lines (continuous lines in Figs. 1 and 2).

No unchanged carbamazepine could be measured in the 24-hr urine samples. This finding was consistent with an earlier report that less than 1% of single intravenous and oral doses could be recovered as unchanged carbamazepine in urine (3).

Many drugs and chemicals affect the activity of drug-metabolizing enzymes in the liver microsomes. A large amount of evidence indicates that an increase in activity could be due to the increased synthesis of microsomal protein (8). In addition, a period of time follows treatment before the effect is apparent, and this time delay corresponds to known rates of protein synthesis (8). Carbamazepine has affected the half-lives of other drugs (9–12). A reduction in the half-life of doxycycline from 15 to 8 hr was reported in patients receiving carbamazepine (10). Carbamazepine also caused a decrease in the elimination half-life of phenytoin in patients (11). Likewise, a reduction in the half-lives of phenytoin and carbamazepine in monkeys pretreated with carbamazepine was reported (12). The effect of carbamazepine on the metabolism of several drugs is considered to be due to an induction of the drug-metabolizing enzyme systems in the liver. Other studies in this laboratory (excretion of *d*-

glucaric acid) indicated that the observed autoinduction in steady-state plasma levels was probably due to enzyme induction.

Carbamazepine, in and of itself, is capable of stimulating its own metabolism in rhesus monkeys. Drug interaction studies with carbamazepine in other monkeys showed that the autoinduction phenomenon was consistently reproducible[4]. The possible role played by the solvent (polyethylene glycol 400) in the observed phenomenon was considered. Other anticonvulsants (ethosuximide, clonazepam, and dipropylacetic acid) were infused intravenously in rhesus monkeys with the same solvent for 1–2 weeks, and no index of autoinduction was observed[4]. In addition, Ronfeld and Benet (12) showed that the intravenous kinetics of phenytoin in rhesus monkeys were not altered after prolonged intravenous infusion of polyethylene glycol 400.

Several questions remain to be evaluated, particularly the relationship between the induction effect and the dosing regimen (dose or infusion rate and duration of infusion) of the inducing agent. It is not known whether the levels of carbamazepine achieved prior to induction (2.9–4.3 μg/ml) represent minimum or maximum inducing levels. However, it appears that the duration of infusion used in this study was long enough to permit an analysis of the time course of induction.

A significant feature of the present results is that the decrease in the steady-state concentration during autoinduction was exponential. In view of this relatively simple kinetic pattern, the phenomenon of autoinduction becomes quantifiable and, as such, predictable. Thus, it should be possible to design a pharmacokinetic model that will allow the calculation of dosage regimens that can maintain steady-state plasma concentrations of carbamazepine and overcome the phenomenon of autoinduction.

A one-compartment pharmacokinetic model with an exponentially increasing first-order elimination rate "constant" was proposed to explain the decreases in maximum and minimum serum levels of carbamazepine in human volunteers during a 3-week treatment (13). However, such a model would not be appropriate in the present study since short-term infusion studies (5, 6) indicated that the kinetics of carbamazepine in monkeys were dose dependent. A pharmacokinetic model involving simultaneous dose and time dependency is currently being investigated to account for the present results as well as additional chronic infusion data.

Time-Dependent Kinetics II: Diurnal Oscillations in Steady-State Plasma Ethosuximide Levels in Rhesus Monkeys

INDRAVADAN H. PATEL, RENÉ H. LEVY ˣ, and JOAN S. LOCKARD

Abstract □ Morning steady-state (9 am) plasma levels were significantly higher than the corresponding evening (5 pm) plasma levels during a 3-week zero-order infusion of ethosuximide to six monkeys. These differences could not be explained by experimental variables such as GLC assay and infusion pump. Circadian periodicity in steady-state plasma levels was investigated in three monkeys over 4 months under controlled experimental conditions: blood sampling at 2-hr intervals for 26 hr, 1 day/week; fixed lighting, feeding, and noise schedules; and electroencephalogram monitoring. The plasma concentration–time curves showed two minima in the 12 noon–2 pm and 8 pm–12 midnight periods, and the later involved the largest percent change in plasma levels (4–8%). The plasma concentration–time data were subjected to cross-correlation analysis, which indicated a circadian rhythm in steady-state plasma levels with a period of 24–26 hr.

Keyphrases □ Time-dependent kinetics—ethosuximide, circadian rhythm in steady-state plasma levels, monkeys □ Ethosuximide—circadian rhythm in steady-state plasma levels, monkeys □ Pharmacokinetics—ethosuximide, circadian rhythm in steady-state plasma levels, monkeys □ Circadian rhythm—in steady-state plasma levels of ethosuximide, monkeys □ Anticonvulsants—ethosuximide, circadian rhythm in steady-state plasma levels, monkeys

Time dependency in pharmacokinetics involves several types of phenomena. Previous studies dealt with the self-induced decreases in steady-state concentrations of carbamazepine during chronic administration of the drug to humans (1) and monkeys (2). More recently, the terms "cronodisponibilita" (3) (equivalent to chronoavailability) and "chronopharmacokinetics" (4) have been coined to stress the importance of temporal changes in bioavailability and pharmacokinetics, respectively.

Diurnal variations in excretion rates of several acidic and basic drugs (*e.g.*, salicylate, sulfasymazine, and amphetamine) were reported (5–7). In several instances, these variations could be explained on the basis of circadian rhythms in kidney functions (8–11). Diurnal fluctuations in plasma levels of dipyridamole could be related to circadian changes in GI absorption (12).

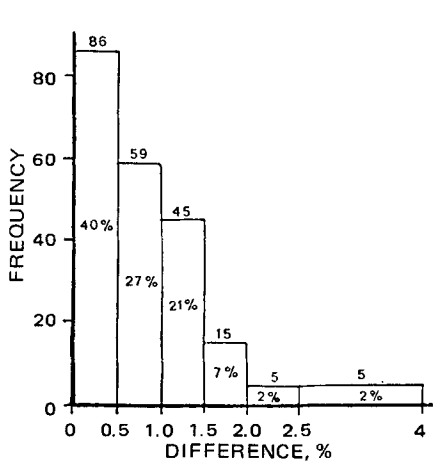

Figure 1—*Plot of frequency* versus *difference (percent) between duplicate assay determinations.*

In a previous study (13) designed to test for time dependency in elimination kinetics of ethosuximide in monkeys, the drug was chronically infused for 22 days to six animals. Morning (9 am) plasma concentrations were consistently higher than evening (5 pm) concentrations, and the presence of circadian rhythm in steady-state plasma levels was suspected. The present study was undertaken to elucidate this phenomenon under more rigorously controlled experimental and, particularly, environmental conditions. These conditions included frequent blood sampling (2-hr intervals); duplicate GLC assays; infusion pump monitoring; fixed lighting, feeding, and noise schedules; and electroencephalogram (EEG) monitoring (sleep staging).

EXPERIMENTAL

Experimental Subjects—Three chronically catheterized male rhesus monkeys (Animals 903, 923, and 983) were used. These monkeys were previously used to determine the pharmacokinetics of ethosuximide under single-dose and chronic dosing conditions (13, 14).

EEG Monitoring—Screw electrodes[1], 3 mm, were bilaterally implanted in the mastoid, occipital, central, and inferior lateral orbital regions of the skull. The left mastoid electrode served as a reference electrode. Electroculograms were recorded for each eye with respect to the reference electrode. Electromyograms were recorded from the temporal muscles. Electroencephalograms (EEG) were monitored from the right central electrode to the left mastoid electrode.

All leads were crimped to a miniature 16-pin socket, and the assembly was fixed to the skull with 3-mm screws[1] and cranioplastic fluid[2]. A chronic, shielded, flexible cable connected the leads of the socket assembly to the four-channel EEG machine[3].

The sleep stages were determined from the EEG data using a previously described procedure (15).

Environmental Conditions—The animals were housed in a room with glass windows and diurnal lighting (light during "day" period, 6 am–6 pm; dark during "night" period, 6 pm–6 am). They were fed twice a day, at 6 am (monkey chow) and 5:30 pm (monkey chow and fresh fruit). The glass windows were covered to prevent penetration of external light. The jugular and femoral catheters, as well as the EEG cable of each animal, were carried to an adjacent room through holes drilled in the glass window.

Infusion of drug solutions, blood sampling, and EEG monitoring were performed in the adjacent room. Continuous 24-hr music (moderately high volume, 6 am–6 pm; low volume, 6 pm–6 am) aided in the masking of external noise during the study. Activities in the monkey room and the adjacent room were kept to a minimum.

Experimental Protocol—The animals received a continuous zero-order infusion[4] of ethosuximide in normal saline over 4 months (infusion rate, 3.72–4.74 mg/hr; steady-state plasma concentration, 30–55 μg/ml). Plasma samples of 0.4 ml were collected 1 day/week at 2-hr intervals for 26 hr for 5 weeks. Fractions of 0.1 ml of the plasma samples were assayed for ethosuximide in duplicate using the GLC assay of Dill *et al.* (16). Only

Mean	26.79	25.41	0.01	52.54	50.37	0.01	82.76	79.09	0.01

[a] Paired t-test. [b] Each concentration value represents a mean of six to eight determinations, excluding the concentrations obtained during the first 24 hr of each stage. [c] Not significant at $p = 0.05$.

3 weeks of data for Animal 983 could be obtained because of technical difficulties with the catheters.

Continuous EEG monitoring was performed from 10 am to 10 am or from 10 pm to 6 am with and without blood sampling.

RESULTS

Preliminary Observations—Previously (13), it was pointed out that morning steady-state plasma concentrations of ethosuximide were consistently higher than the corresponding evening concentrations during a three-stage zero-order infusion of the drug to six monkeys. A statistical evaluation of the differences between morning and evening concentrations was performed (Table I). The differences between morning and evening plasma concentrations ranged from 3.8 to 7.7% in Stage 1, from 0.4 to 8.1% in Stage 2, and from 0.2 to 7.8% in Stage 3. These differences were significant in the majority of animals in each stage. However, these differences were of a small magnitude and could be explained by fluctuations in several experimental variables (*e.g.*, drug assay and infusion pump). Thus, it became necessary to evaluate the potential contribution of these experimental factors to the observed differences in plasma concentrations.

The precision of the GLC assay was calculated from duplicate determinations of approximately 200 plasma samples (concentration range of 30–55 μg/ml), and a frequency plot was constructed from these data (Fig. 1). The percent difference was less than 1% in 67% of the cases, 1–2% in 28% of the cases, and 2–4% in the remaining instances. These results indicated that the GLC procedure can establish differences in plasma concentrations of 4–7%. Furthermore, morning and evening plasma samples were always assayed simultaneously (within the same run). Since assay error would tend to be random, it could not explain the observed systematic differences between morning and evening plasma concentrations.

Fluctuations in the voltage of the electrical line could influence the operational pump voltage, rotational speed, and, consequently, delivery rate. The delivery rates of two infusion pumps were determined by recording the volume delivered between 9 am and 5 pm and between 5 pm and 9 am for 5–10 consecutive days. These measurements utilized six different pump chambers. In three instances, delivery rates increased during the 5 pm–9 am period (0.3–0.7%); in the other three, they decreased (0.5–2.4%). There were no significant differences between the delivery rates of the 9 am–5 pm and 5 pm–9 am periods in five of six cases.

These experiments suggested that experimental variables such as infusion pump and drug assay did not contribute to the observed fluctuations in steady-state plasma levels. However, the sampling schedule employed in the previous study (13) was limited. Therefore, additional studies were undertaken where steady-state plasma levels were obtained at 2-hr intervals over 26 hr under rigorously controlled experimental conditions.

EEG–Time and Plasma Concentration–Time Data—EEG data were collected to determine the sleeping behavior of monkeys during day and night periods. The data indicated that the animals were awake during most of the day periods and slept an appreciable portion of the night periods (Fig. 2 and Table II).

Typical diurnal variations in steady-state plasma levels for Animals 903, 923, and 983 during a single sampling period are represented in Figs. 3A–5A. The observed oscillations were reproducible within a given animal over 3–5 weeks. Consequently, plasma concentrations were averaged, and plots of mean percent change in plasma level (using the 8 am concentration as a reference value) as a function of time were constructed (Figs. 3B–5B). Certain features were present in the profiles of all animals: a decline from 8 am to 2–4 pm, a small rise or plateau between 4 and 6 pm, and a steady decline until 8 pm–12 midnight followed by a steady rise until 8–10 am (next day). Thus, in each plot, there appeared to be two minima, in the 12 noon–2 pm and 8 pm–12 midnight time periods. However, the minimum occurring during the night period involved the largest percent change in plasma levels (4–8%).

The evidence suggesting a circadian rhythm in steady-state plasma levels can be summarized as follows:

1. The earlier multistage infusion studies (13) indicated that the pattern of oscillations in plasma levels was similar on several consecutive days (up to 3 weeks).
2. The percent change in plasma concentration–time profiles obtained in the present study defined the actual time course of steady-state plasma levels within a 26-hr period.
3. The concentrations observed in the 8–10 am period on 2 consecutive days were quite close.
4. The time course of steady-state plasma levels within a 26-hr period was reproducible on successive weeks (on the same day of the week).

Several techniques (moving variate analysis, Fourier analysis, auto- and cross-correlation, and cosinor analysis) are available to estimate the

[a] Plasma samples were collected over 22 hr. Mean values obtained at 24 and 26 hr were substituted for the missing values.

parameters of a periodic function, namely, period and amplitude (17–24). However, a literature review failed to demonstrate applications of these analyses to blood level data of exogenous compounds such as drugs. In the present study, an attempt was made to analyze the observed data by cross-correlation analysis (22).

In view of the relatively small oscillations in plasma levels found in this study, the cross-correlation method was first evaluated with generated data using the equation $y = a + b\cos(cX)$. The following input values were used: period = 24 hr, amplitude = 5%, sampling interval = 2 hr, and observation timespan = 26 hr. The method yielded values of the period within 2% and values of the amplitude within 14% of the input values even with 1–4% random error in the data. These results indicated that the cross-correlation method could be applied to the experimental observations.

Sets of plasma concentration–time data of individual animals, as well as the mean set of data of each animal, were subjected to the cross-correlation analysis (Table III). The mean periods obtained from individual sets of data were 28.0, 24.8, and 28.5 hr for Animals 903, 923, and 983, respectively. The corresponding periods obtained from mean plasma concentration–time data were 25.5, 25.5, and 24.5 hr. These values are close to the circadian period (24 hr) and provide further support for the hypothesis of a circadian rhythm in steady-state plasma levels.

DISCUSSION

The present study revealed diurnal fluctuations (circadian periodicity) in steady-state plasma levels of ethosuximide in monkeys. An analysis of the possible causes for fluctuations in plasma levels during zero-order infusion suggested a circadian rhythm in total body clearance. Diurnal variations in the volume of distribution, renal excretion, and/or metabolism could explain the observed periodicity in plasma levels.

Circadian variations in the excretion rates of several drugs (*e.g.*, salicylate, sulfasymazine, and amphetamine) have been reported in humans and were believed to be associated with the diurnal urinary pH rhythm (5–7). It is not known whether such a circadian rhythm in urine pH exists in monkeys. However, even if such a cycle exists, it should include urine pH values close to 9 to influence the urinary excretion of ethosuximide (pKa = 9.4). In the present study, it was not possible to determine the existence of a circadian rhythm in the excretion rate of ethosuximide,

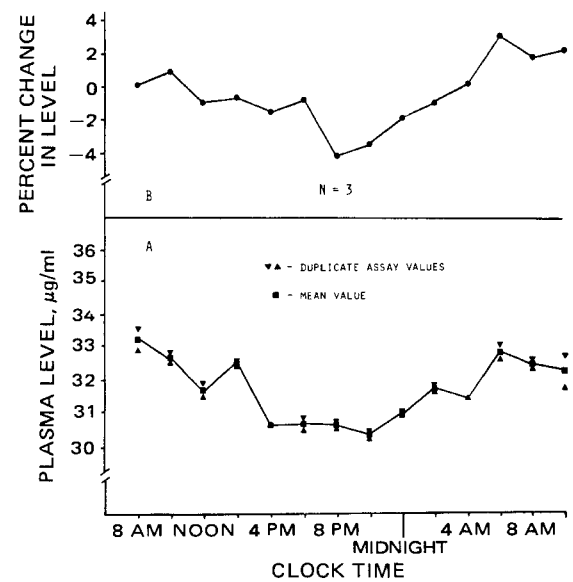

Figure 5—*Plots of typical diurnal changes in steady-state plasma levels observed during a given sampling period (A) and mean (±SD) percent changes in plasma levels* versus *time (B) for Animal 983.*

primarily because of the additional technical problems (trauma and infection) posed by chronic urethral catheters.

Circadian variations in the rates of *in vitro* metabolism of drugs (hexobarbital, aminopyrine, *p*-nitroanisole, and 4-dimethylaminoazobenzene) have been documented (25–32). However, whenever a circadian rhythm in metabolism has been reported, it has usually been associated with an oxidative metabolic process (33). Ethosuximide is metabolized to a significant extent (60–65%) in monkeys (13, 14, 34), and all known metabolic pathways (in rats, monkeys, and humans) involve oxidative processes (35–38). Thus, the possibility of circadian variations in the activities of hepatic drug-metabolizing enzymes in monkeys is not unrealistic.

This study shows that the phenomenon of circadian rhythm in steady-state levels is real. Although the extent of oscillations reported here is limited, ongoing studies show that other anticonvulsants (valproic acid and clonazepam) exhibit diurnal oscillations in plasma levels likely to have therapeutic consequences.

Diffusion Model for Drug Release from Suspensions I: Theoretical Considerations

JAMES W. AYRES * and F. TOM LINDSTROM ‡x

Abstract □ A new mathematical model based on physicochemical principles is presented; it does not require a "diffusion layer" for the release of a suspended drug from a semisolid vehicle. This general model has wide range application to systems where release is controlled by the diffusion rate or dissolution rate of a drug. The appropriate mathematical relationships are derived and evaluated. Theoretical drug concentration distributions in the vehicle and a membrane and the predicted cumulative drug mass uptake by blood under specified conditions are presented. The dissolution rate of solid drug in the vehicle markedly influences predicted drug release using the model presented. It is anticipated that the model will stimulate further research to confirm or reject the assumption that the dissolution rate may be slow enough to be important in the systems studied.

Keyphrases □ Diffusion—suspended drug in semisolid vehicle, mathematical model based on physicochemical principles □ Dissolution—suspended drug in semisolid vehicle, mathematical model based on physicochemical principles □ Pharmacokinetic models—diffusion and dissolution of suspended drug in semisolid vehicle □ Drug release—from suspensions, diffusion model based on physicochemical principles □ Suspensions—drug release, diffusion model based on physicochemical principles

Many physical models for diffusion from solutions were defined and the appropriate mathematical equations were presented in standard texts (1–3). The release of drug from a topically applied ointment was considered (4) when the drug was initially uniformly dissolved in a homogeneous base and the rate-controlling step was in either the applied phase or the skin. The theoretical analysis of drug diffusion through emulsion systems was extensively studied and reported (5–8).

Physical models for diffusion of drug from suspension systems were also reported (4, 5, 9). In one case, the suspension was considered as a potential barrier to drug diffusion (5); in others (4, 9), the suspended drug was considered a source of drug supply.

The most widely accepted theory for dissolution rates was proposed by Noyes and Whitney in 1897 and subsequently modified to include the stagnant or unstirred diffusion layer concept of Nernst and Brunner. These and other theories for dissolution models were reviewed previously (10–12).

The purposes of this study were to describe dissolution and diffusion for a suspended drug in a semisolid vehicle in terms of the molecular rates of escape from, and the return to, a particle surface; to present a mathematical model (a set of nonlinear diffusion equations) for the mass transport of the drug through the suspension and a permeable barrier system to a perfect sink; and to solve the appropriate linearized equations for a general least upper bound case as well as for several specific cases.

Consideration is given to the condition where dissolution is either very slow or very fast with respect to diffusion in the continuous phase of the suspension as well as where dissolution and diffusion occur at about the same rate. Special emphasis is placed on the condition of slow dissolution and fast diffusion, because this case is not treated in the literature and the need for such equations has been stated (13).

MODEL DEVELOPMENT

Suppose that the ointment–skin–blood system can be approximated by the system shown in Fig. 1. The barrier enclosing the ointment on three sides penetrates the skin only as a means of illustrating that the drug is required to move perpendicular to the membrane in this model. Assume that there is a uniformly distributed source (at time $t = 0$) in the region $-L_1 \leq x < 0$ and that this source operates in the following way. In any plane sheet of thickness Δx and cross-section area A (cm^2) in Medium I ($-L_1 \leq x < 0$), the time rate of change of the source mass is equal to the difference between the mass dissolution rate and the crystallization rate. Or:

$$\frac{\partial[\rho_s A\, \Delta x \epsilon(x,t)]}{\partial t} = -K_{dis} A_s(x,t) C_{sol} + K_{cry} A_s(x,t) C_1(x,t) \quad \text{(Eq. 1)}$$

where:

C_{sol} = solvent concentration (grams per milliliter)
ρ_s = crystal or powder density (grams per milliliter)
K_{dis} = dissolution rate constant (centimeters per second)
K_{cry} = crystallization rate constant (centimeters per second)
$A_s(x,t)$ = effective source (crystal) surface area at (x, t) (square centimeters)
$\epsilon(x,t)$ = volume fraction measure of source (milliliters per milliliter)

These relationships between dissolution and crystallization provide a general model and are developed from standard theories of velocity of adsorption and desorption (14) as well as crystallization and dissolution (15). In addition, the coefficients K_{dis} and K_{cry} are assumed to be temperature and activation energy dependent in the sense of their definitions as stated by Szinai and Hunt (16). The volume fraction measure of the source ϵ simply measures how much of the source is left at point (x, t).

Again using the ideas of Rowler (15), let $A_s(x,t) = \kappa A\, \Delta x[\epsilon(x,t)]^{2/3}$, where κ is a surface area to volume constant.

Putting all these hypotheses together yields for the time rate of change of the source mass in the incremental volume $A\, \Delta x$:

$$\frac{\partial \epsilon}{\partial t} = -\frac{K_{dis}\kappa}{\rho_s}\epsilon^{2/3} C_{sol} + \frac{K_{cry}\kappa}{\rho_s}\epsilon^{2/3} C_1 \quad \text{(Eq. 2)}$$

Suppose that at time $t = 0$, $C_1(x,0) = C_s$, the saturation concentration for the free ointment phase drug distribution. Also, let $\epsilon(x,0) = \epsilon_0$, a prescribed positive constant volume fraction. Then, assuming uniform equilibrium conditions between the dissolution and crystallization pro-

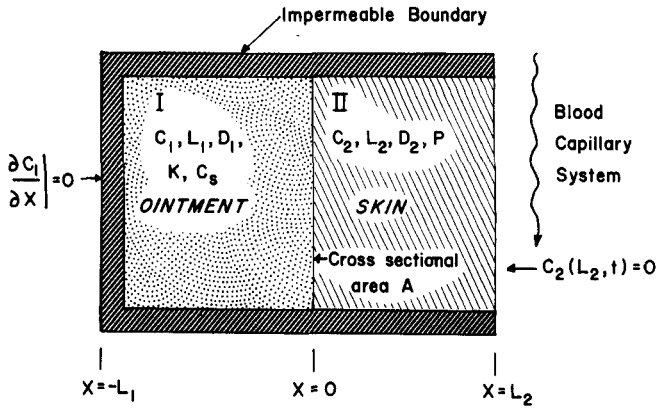

Figure 1—*Model geometry approximating the transport system.*

cesses at time $t = 0$, *i.e.*, $(\partial\epsilon/\partial t)|_{t=0} = 0$, results in:

$$K_{dis}C_{sol} = K_{cry}C_s \qquad \text{(Eq. 3)}$$

and:

$$\frac{\partial \epsilon}{\partial t} = -\frac{\kappa}{\rho_s}\epsilon^{2/3}K_{cry}(C_s - C_1) \qquad \text{(Eq. 4)}$$

This expression may be rewritten as:

$$\frac{\partial(\epsilon^{1/3} - \epsilon_0{}^{1/3})}{\partial t} = -\frac{\kappa}{3\rho_s}K_{cry}(C_s - C_1) \qquad \text{(Eq. 5)}$$

which can be integrated to yield:

$$\epsilon(x, t) = \left\{\epsilon_0{}^{1/3} - \frac{\kappa}{3\rho_s}K_{cry}\int_0^t [C_s - C_1(x, \tau)]d\tau\right\}^3 \qquad \text{(Eq. 6)}$$

The free or solution phase mass balance in the plane sheet then admits the equation[1]:

$$A\,\Delta x\frac{\partial C_1}{\partial t} = -D_1 A\frac{\partial C_1}{\partial x}\bigg|_{x-\Delta x/2} + D_1 A\frac{\partial C_1}{\partial x}\bigg|_{x+\Delta x/2} - \frac{\partial[\rho_s A\,\Delta x\epsilon(x, t)]}{\partial t} \qquad \text{(Eq. 7)}$$

or, in words, the net instantaneous free drug mass gain in the sheet is equal to the mass flux in minus the mass flux out plus the source mass flux into the solution phase from the suspended phase. Substitution for $\rho_s A\,\Delta x[\partial\epsilon(x, t)/\partial t]$ from Eq. 4 into Eq. 7, with subsequent passage to the limit as $\Delta x \to 0$, yields the solution phase concentration distribution rule in Medium I:

$$\frac{\partial C_1}{\partial t} = D_1\frac{\partial^2 C_1}{\partial x^2} + K(C_s - C_1)\left\{1 - \frac{K}{3\rho_s\epsilon_0}\int_0^t [C_s - C_1(x, \tau)]d\tau\right\}^2 \qquad \text{(Eq. 8)}$$

for $t > 0$ and $-L_1 < x < 0$ with K defined as:

$$K = \kappa K_{cry}\epsilon_0{}^{2/3} \qquad \text{(Eq. 9)}$$

Based upon mass balance considerations at time $t = 0$, it is not too difficult to show that:

$$\epsilon_0 = \frac{\frac{M_{DT}}{AL_1} - C_s}{\rho_s - C_s} \qquad \text{(Eq. 10)}$$

for $C_s \leq (M_{DT}/AL_1) \leq \rho_s$, where M_{DT} is equal to the total drug mass in the solution plus suspended phases at time $t = 0$, and AL_1 is the total volume of the ointment slab.

While Eq. 8 incorporates the realistic ideas of source area changes with time and a decreasing local solvent concentration with an increasing local free phase drug concentration, it is nonlinear and thus out of the realm of classical linear problem solution methods such as integral transforms and eigenfunction expansion.

The analysis presented later in this paper concerns a linear approximation to Eq. 8 valid for small values of time[2].

Since all physical parameters of the dissolution process are positive and $C_s - C_1(x, t) \geq 0$ for all (x, t) such that $-L_1 < x < 0$ and $t > 0$, the source function defined in Eq. 8 is a strictly monotone decreasing function of increasing time t, making the local source term less important; *i.e.*, locally, the source contributes less and less to the overall drug distribution process as time goes on. Hence, setting the source function term equal to 1.0 for all $t > 0$ and $-L_1 < x < 0$, as is done in the remainder of this paper, generates an upper bound on the actual physical process. That is, the assumption is made that the free phase drug concentration distribution in the ointment slab obeys the linearized distribution rule:

$$\frac{\partial C_1}{\partial t} = D_1\frac{\partial^2 C_1}{\partial x^2} + K(C_s - C_1) \qquad -L_1 < x < 0 \qquad t > 0 \qquad \text{(Eq. 11)}$$

By proceeding formally in an analogous manner in Medium II, the solution phase concentration distribution rule can be shown to be:

$$\frac{\partial C_2}{\partial t} = D_2\frac{\partial^2 C_2}{\partial x^2} \qquad t > 0 \qquad 0 < x < L_2 \qquad \text{(Eq. 12)}$$

The following initial conditions are assumed:

$$C_1(x, 0+) = C_s \qquad -L_1 \leq x < 0 \qquad \text{(Eq. 13)}$$

and:

$$C_2(x, 0+) = 0 \qquad 0 < x < L_2 \qquad \text{(Eq. 14)}$$

and the following boundary conditions are assumed:

$$C_1(0, t) = PC_2(0, t) \qquad t > 0 \qquad \text{(Eq. 15)}$$

$$D_1\frac{\partial C_1(0, t)}{\partial x} = D_2\frac{\partial C_2(0, t)}{\partial x} \qquad t > 0 \qquad \text{(Eq. 16)}$$

$$\frac{\partial C_1}{\partial x}\bigg|_{x=-L_1} = 0 \qquad t \geq 0 \qquad \text{(Eq. 17)}$$

and:

$$C_2(L_2, t) = 0 \qquad t \geq 0 \qquad \text{(Eq. 18)}$$

The coefficients D_1 and D_2 are assumed to be constant in this model and are, respectively, the solution phase diffusion coefficients in Media I and II (square centimeters per second), while P is the equilibrium coefficient of partition between solution concentrations in Media I and II. The authors were unable to find this particular mass transport system or its heat conduction analog listed in the literature or in standard references (1, 2, 17, 18). Churchill (19) considered a similar problem and used Laplace transform techniques, which led to a solution of the system by operational methods[3].

A paper (20) important to this discussion reported the conduction of heat in a semi-infinite solid of two different materials.

Laplace transform techniques lead to the following forms for the solution phase drug concentration distributions. In Medium I (ointment):

$$C_1(x, t) = C_s - C_s\frac{\cosh\left[(L_1 + x)\sqrt{\frac{K}{D_1}}\right]}{\cosh\left(L_1\sqrt{\frac{K}{D_1}}\right) + P\sqrt{\frac{KD_1L_2{}^2}{D_2{}^2}}\sinh\left(L_1\sqrt{\frac{K}{D_1}}\right)} + C_s\sum_{n=1}^{\infty}\frac{\sin(2\beta_n)\cosh\left(\frac{L_1 + x}{L_2}\sqrt{\frac{D_2}{D_1}}\sqrt{\frac{K}{D_2}L_2{}^2 - \beta_n{}^2}\right)\exp[-(\beta_n{}^2D_2t/L_2{}^2)]}{\beta_n\Delta_n\cosh\left(\frac{L_1}{L_2}\sqrt{\frac{D_2}{D_1}}\sqrt{\frac{K}{D_2}L_2{}^2 - \beta_n{}^2}\right)} \qquad \text{(Eq. 19)}$$

for $-L_1 \leq x < 0$ and $t > 0$. In Medium II:

$$C_2(x, t) = C_s\frac{\sqrt{\frac{KD_1L_2{}^2}{D_2{}^2}}\left(1 - \frac{x}{L_2}\right)\sinh\left(L_1\sqrt{\frac{K}{D_1}}\right)}{\cosh\left(L_1\sqrt{\frac{K}{D_1}}\right) + P\sqrt{\frac{KD_1L_2{}^2}{D_2{}^2}}\sinh\left(L_1\sqrt{\frac{K}{D_1}}\right)} + \frac{2C_s}{P}\sum_{n=1}^{\infty}\frac{\cos\beta_n\sin\left[\beta_n\left(1 - \frac{x}{L_2}\right)\right]\exp[-(\beta_n{}^2D_2t/L_2{}^2)]}{\beta_n\Delta_n} \qquad \text{(Eq. 20)}$$

where β_n is the nth zero of the transcendental equations:

$$\cot\beta + \frac{P\sqrt{\frac{D_1}{D_2}}\sqrt{\frac{K}{D_2}L_2{}^2 - \beta^2}}{\beta}\tanh\left(\frac{L_1}{L_2}\sqrt{\frac{D_2}{D_1}}\sqrt{\frac{K}{D_2}L_2{}^2 - \beta^2}\right) = 0 \qquad \text{(Eq. 21)}$$

for $0 < \beta \leq L_2\sqrt{K/D_2}$, and:

$$\cot\beta - \frac{P\sqrt{\frac{D_1}{D_2}}\sqrt{\beta^2 - \frac{K}{D_2}L_2{}^2}}{\beta}\tan\left(\frac{L_1}{L_2}\sqrt{\frac{D_2}{D_1}}\sqrt{\beta^2 - \frac{K}{D_2}L_2{}^2}\right) = 0 \qquad \text{(Eq. 22)}$$

[1] The reviewer correctly pointed out that, as $\epsilon \to 0$, D_1 will be a variable of position and time and Medium I will probably undergo contraction. While these assumptions will be dealt with in future work, they are not included in this first approximation model.

[2] The full numerical analysis will be the subject of a later paper in this series.

[3] The solution procedure is to be published elsewhere.

for $\beta \geqq L_2\sqrt{K/D_2}$, and where:

$$\Delta_n = 1 + P\frac{L_1}{L_2}\sin^2\beta_n\left[1 - \sqrt{\frac{D_1}{D_2}}\tanh^2\left(\frac{L_1}{L_2}\sqrt{\frac{D_2}{D_1}}\sqrt{\frac{K}{D_2}L_2^2 - \beta_n^2}\right)\right] + P\sqrt{\frac{D_1}{D_2}}\frac{KL_2^2}{\beta_n^2 D_2}\frac{\sin^2\beta_n \tanh\left(\frac{L_1}{L_2}\sqrt{\frac{D_2}{D_1}}\sqrt{\frac{K}{D_2}L_2^2 - \beta_n^2}\right)}{\sqrt{\frac{K}{D_2}L_2^2 - \beta_n^2}} \quad \text{(Eq. 23)}$$

While the concentration distributions (formal solutions) are important for some work, two other important formulas to obtain are the cumulative drug mass taken up by the receptor phase (blood in some cases), $M_{but}(t)$, and the cumulative mass loss from the ointment, $M_1(t)$. These two drug mass distribution functions are defined as:

$$M_{but}(t) = \int_0^t \left(-D_2 A \left.\frac{\partial C_2}{\partial x}\right|_{x=L_2}\right) d\tau \quad \text{(Eq. 24)}$$

and:

$$M_1(t) = \int_0^t \left(-D_1 A \left.\frac{\partial C_1}{\partial x}\right|_{x=0}\right) d\tau \quad \text{(Eq. 25)}$$

Performing the indicated partial differentiations with subsequent evaluations of these results at $x = L_2$ and $x = 0$, respectively, obtains (after some algebra and use of Eqs. 19–22):

$$M_{but}(t) = AC_s\sqrt{KD_1}t\frac{\sinh\left(L_1\sqrt{\frac{K}{D_1}}\right)}{\cosh\left(L_1\sqrt{\frac{K}{D_1}}\right) + P\sqrt{\frac{KD_1L_2^2}{D_2^2}}\sinh\left(L_1\sqrt{\frac{K}{D_1}}\right)} + \frac{2AL_2C_s}{P}\sum_{n=1}^{\infty}\frac{\cos\beta_n\{1 - \exp[-(\beta_n^2 D_2 t/L_2^2)]\}}{\beta_n^2\Delta_n} \quad \text{(Eq. 26)}$$

and:

$$M_1(t) = AC_s\sqrt{KD_1}t\frac{\sinh\left(L_1\sqrt{\frac{K}{D_1}}\right)}{\cosh\left(L_1\sqrt{\frac{K}{D_1}}\right) + P\frac{L_2}{L_1}\sqrt{KD_1}\sinh\left(L_1\sqrt{\frac{K}{D_1}}\right)} + \frac{2AL_2C_s}{P}\sum_{n=1}^{\infty}\frac{\cos^2\beta_n}{\beta_n^2\Delta_n}[1 - \exp(-\beta_n^2 D_2 t/L_2^2)] \quad \text{(Eq. 27)}$$

Uniform convergence of the resulting series is confirmed by an analysis similar to that mentioned by Churchill (19).

Before pursuing an in-depth study of these least upper bounding distributions for published literature values of the transport parameters, a brief discussion is included for the following asymptotic forms to which the relative cumulative receptor phase uptake, $\mu_{but}(t) = M_{but}(t)/M_0$, and/or the cumulative drug mass loss from the ointment, μ_1, converge in the limit of small and large K values.

For finite D_1 and D_2 values, $0 \leq K \leq 0.25\,(D_1/L_1^2)$, $t \geqq (4L_2^2/\beta_1^2 D_2)$, and $M_0 = AL_1C_s$:

$$\mu_{but}(t) \sim \frac{Kt}{1 + KP\frac{L_1L_2}{D_2}} + 2\left(\frac{L_2}{L_1}\right)\frac{\cos\beta_1}{P\beta_1^2\Delta_1} \quad \text{(Eq. 28)}$$

and:

$$\mu_1(t) \sim \frac{Kt}{1 + KP\frac{L_1L_2}{D_2}} + 2\left(\frac{L_2}{L_1}\right)\frac{\cos^2\beta_1}{P\beta_1^2\Delta_1} \quad \text{(Eq. 29)}$$

Again for finite D_1 and D_2 values, $K \geqq 25\,(D_1/L_1^2)$, $t \geqq (4L_2^2/\beta_1^2 D_2)$, and $M_0 = AL_1C_s$:

$$\mu_{but}(t) \sim \frac{\sqrt{KD_1}}{L_1}\frac{t}{1 + P\frac{L_2}{D_2}\sqrt{KD_1}} + 2\frac{L_2}{L_1}\frac{\cos\beta_1}{P\beta_1^2\Delta_1} \quad \text{(Eq. 30)}$$

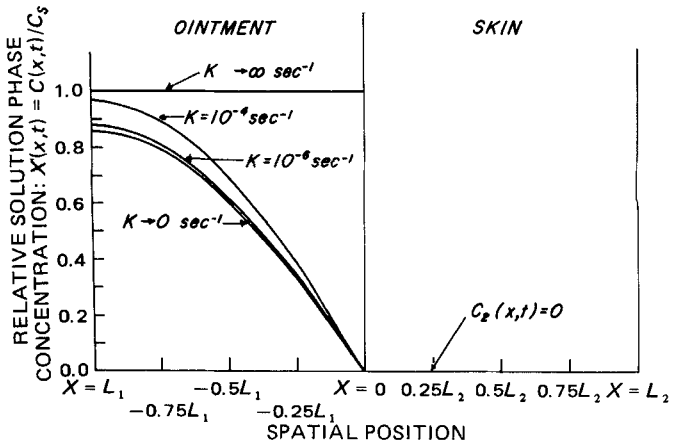

Figure 2—*Plots of relative solution phase drug concentration distribution in the ointment and the skin when* $D_2 \to \infty$ *and time* t = 600 *sec* ($D_1 = 10^{-9}$ *cm²/sec).*

and:

$$\mu_1(t) \sim \frac{\sqrt{KD_1}}{L_1}\frac{t}{1 + P\frac{L_2}{D_2}\sqrt{KD_1}} + 2\frac{L_2}{L_1}\frac{\cos^2\beta_1}{P\beta_1^2\Delta_1} \quad \text{(Eq. 31)}$$

An ointment–drug–stirred water system represents the extreme case of large D_2. Mathematically, if $D_2 \to \infty$, the perfect sink at $x = L_2$ becomes operable throughout the entire skin region; *i.e.*, there is no barrier to overcome. The practical situation might be the topical application of a product containing drug suspended in a vehicle directly to the capillary system exposed due to skin abrasion. Thus, in the limit as $D_2 \to \infty$, $K \geqq 25\,(D_1/L_1^2)$, and $t \geqq 5/[(9\pi^2 D_1/4L_1^2) + K]$, the relative receptor phase uptake of drug mass, μ_{but}, is:

$$\mu_{but} \sim \frac{\sqrt{D_1K}}{L_1}t + \frac{1}{2L_1}\sqrt{\frac{D_1}{K}} \quad \text{(Eq. 32)}$$

RESULTS AND DISCUSSION

Since the main purpose of formulating this mathematical model is to aid in understanding the passive diffusion process (one type of mass transport process) of a drug from a suspension dosage form through the dermal layer to the blood capillary bed, attention is now turned to an evaluation of the equations of the model itself.

The drug cortisone was chosen as an example of a commonly used drug in an ointment form, and a literature search revealed the following estimates for the model parameters. For the partition coefficient and average skin diffusion coefficient:

$$P = \frac{K_{hex}}{K_{skin}} = \frac{0.28}{8.5} = \frac{1}{30} \quad \text{(Eq. 33)}$$

and:

$$D_2 = 10^{-12}\ \text{cm}^2/\text{sec} \quad \text{(Eq. 34)}$$

respectively (21). From a diffusion path length viewpoint, the effective composite layer through which substances must diffuse to enter the bloodstream was estimated to be about 200 μm (21). However, the main skin barrier in most cases of percutaneous absorption is the stratum corneum, reported to be about 10 μm in depth. Since the thickness of the stratum corneum varies with its location on the body, a thickness of 20 μm for L_2 is used in Fig. 2 as a first approximation of the main skin barrier. Variable pathways of diffusion and differing diffusion rates through appendages in the skin (21) are not considered, since Medium II in Fig. 2 is assumed to be homogeneous in the model, although skin is, in reality, a heterogeneous system. This "artificial" membrane, although not an exact equivalent of skin, is used as an approximation in solving the model.

Let it be assumed that a thinly applied ointment or salve is also around 20 μm in thickness. Thus, $L_1 = 2 \times 10^{-3}$ cm. The authors were unable to find any specific diffusion coefficient data on cortisone in different lipophilic bases. However, the value of $D_1 = 10^{-9}$ cm²/sec was finally chosen, since it is less than the average value for diffusion of steroids in aqueous solution and greater than diffusion through the skin barrier. The knowledge that the vehicle composition can influence the release (22)

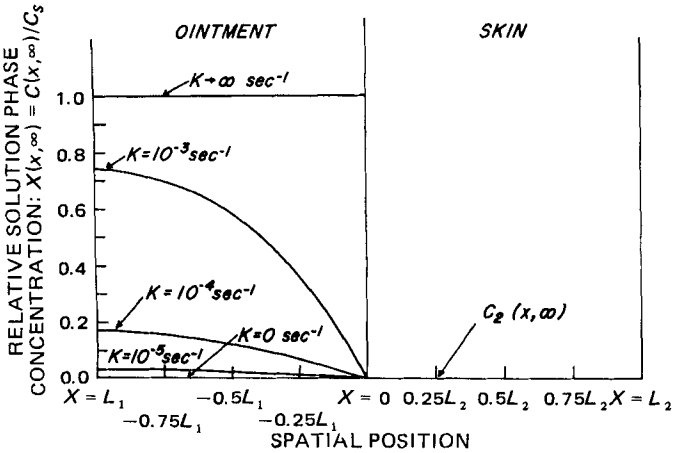

Figure 3—*Plots of relative solution phase drug concentration distribution in the ointment and the skin when* $D_2 \to \infty$ *and time* $t \to \infty$, i.e., *"steady state"* ($D_1 = 10^{-9}$ *cm*^{2}*/sec).*

and physiological response (23) for some steroids makes this value a reasonable estimate.

Finally, the dissolution rate constant K, for which the authors were unable to find any specific values for cortisone in semisolid vehicles, is used as an active parameter. For the remainder of this paper, K is simply assigned order of magnitude values.

Substitution of these parameter values into the appropriate equations, *e.g.*, Eqs. 19, 20, and 26, allows the drug concentration distributions in the solution phases of both media to be estimated at any time after drug application. In addition, the drug mass uptake as a function of time also can be calculated. The discussion of these distributions is carried out starting with the extreme cases ($D_1 \to \infty$, $D_2 \to \infty$, or any subcase thereof) and progressing toward the most general situation, namely, an evaluation of Eqs. 19, 20, and 26.

Extreme Case $D_2 \to \infty$—It is assumed that mass transport through the skin is carried out infinitely fast, as would approximately be the case for some *in vitro* studies or if there is no skin covering the capillary bed and the dosage form is applied directly to the capillary bed. Evaluation of the limiting forms of Eqs. 19, 20, and 26 gives the concentration distributions shown in Figs. 3 and 4 and the relative cumulative drug mass uptake by the blood shown in Fig. 5, respectively. This type of mass transport system may be an example of ointment or salve applied directly to an open wound or abrasion.

Mathematically, the perfect sink boundary condition $C_2(L_2, t) = 0$ is moved left to $C_1(0, t) = 0$ (Fig. 2). Also, as $K \to \infty$, the solution phase concentration phase distribution in Medium I (the ointment) tends to stay at saturation concentrations, C_s, as expected. The distribution curves shown in Fig. 3 are all for one fixed time, $t = 600$ sec, after ointment application. The long time or steady-state concentration distributions to which $C_1(x, t)$ converges for the various K values chosen in this work are shown in Fig. 3.

The cumulative mass of drug taken up by the blood for this special case is shown in Fig. 4. If $K = 0$, then only the finite amount of original solution phase drug in the ointment can be taken up by the blood, because this quantity is the only drug mass available to be taken up. However, if $K > 0$, then the blood uptake of drug distribution over time is seen. The abscissa in all time plots is the square root of time.

This time scale was chosen because it compresses the abscissa, allowing a greater time period to be shown on the graph, and because some models of diffusion[4] have resulted in equations where the total amount of drug transferred from the donor phase is linearly dependent on time$^{1/2}$.

While still operating under the assumption that $D_2 \to \infty$, the asymptotic form (Eq. 32) can be used for the relative cumulative blood uptake of drug mass, μ_{but}. Suppose that $K \geq 25\ (D_1/L_1^2)$ ($= 6.25 \times 10^{-3}$ sec^{-1} based on D_1 and L_1 used for Figs. 2–4) and time t is such that:

$$t \geq t_{min} = 5 \Big/ \left(\frac{9\pi^2 D_1}{4L_1^2} + K\right) \qquad \text{(Eq. 35)}$$

This time would be variable for Figs. 2–4, depending on the value of K. The t_{min} would be 42.3 sec for $K = 10^{-2}$ sec^{-1}. Then the asymptotic form

[4] A comparison among different diffusion models for the predicted release of drug is included in Part II of this series (24).

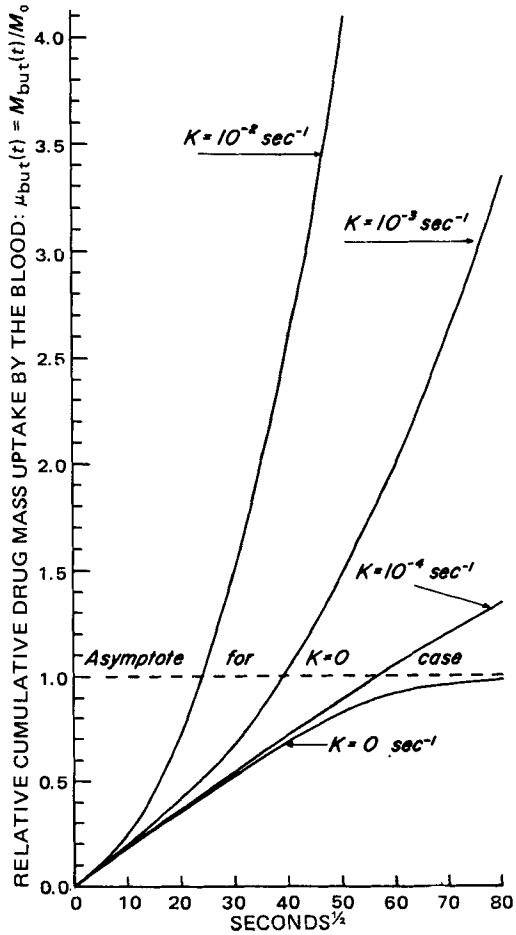

Figure 4—*Plots of relative cumulative drug mass uptake by the blood,* $\mu_{but}(t) = M_{but}(t)/M_0$, $M_0 = AL_1C_s$, *for* $D_2 \to \infty$. *The ordinate is linear while the abscissa is the square root of time with each curve carrying its respective* K *value* ($D_1 = 10^{-9}$ *cm*^{2}*/sec).*

for μ_{but} (Eq. 32) demonstrates directly that under these conditions μ_{but} is proportional to the total drug mass, M_{DT}, to the one-third power, close to agreement with the classical model for drug release from ointments (9). Since:

$$K = \kappa K_{cry} \epsilon_0^{2/3} \qquad \text{(Eq. 36)}$$

and:

$$\epsilon_0 = \left(\frac{M_{DT}}{AL_1} - C_s\right) \Big/ (\rho_s - C_s) \qquad \text{(Eq. 37)}$$

K is directly proportional to $M_{DT}^{2/3}$ and, hence, $\mu_{but} \propto M_{DT}^{1/3}$. Note, however, that the amount of drug taken up by the receptor phase is only predicted to be proportional to the cube root of the total drug mass when the restrictions on K and t are satisfied.

Recasting the classical equation into the notation of the proposed model gives:

$$\mu_H = \frac{\sqrt{D_1 t \left(2\frac{M_{DT}}{M_0} - 1\right)}}{L_1} \qquad \text{(Eq. 38)}$$

where the subscript H stands for the classical model (9).

The major difference between μ_{but} and μ_H is that μ_{but} is proportional to t for large values of time while μ_H is proportional to $t^{1/2}$ for all time values. Furthermore, in the case of small values of time, μ_H is proportional to $t^{1/2}$ while the asymptotic form for μ_{but} for small time can easily be shown to be root t like in this linearized model; that is:

$$\mu_{but} \sim \frac{2\sqrt{D_1 t}}{L_1}\left[1 + \frac{Kt}{3} - O(Kt)^2\right] \qquad \text{(Eq. 39)}$$

where the O notation of Heaviside has been used to collect all higher order terms.

No matter which of these equations is assumed to describe the drug release phenomenon, they are all invalid for values of time $t > t_{C_s}$, the

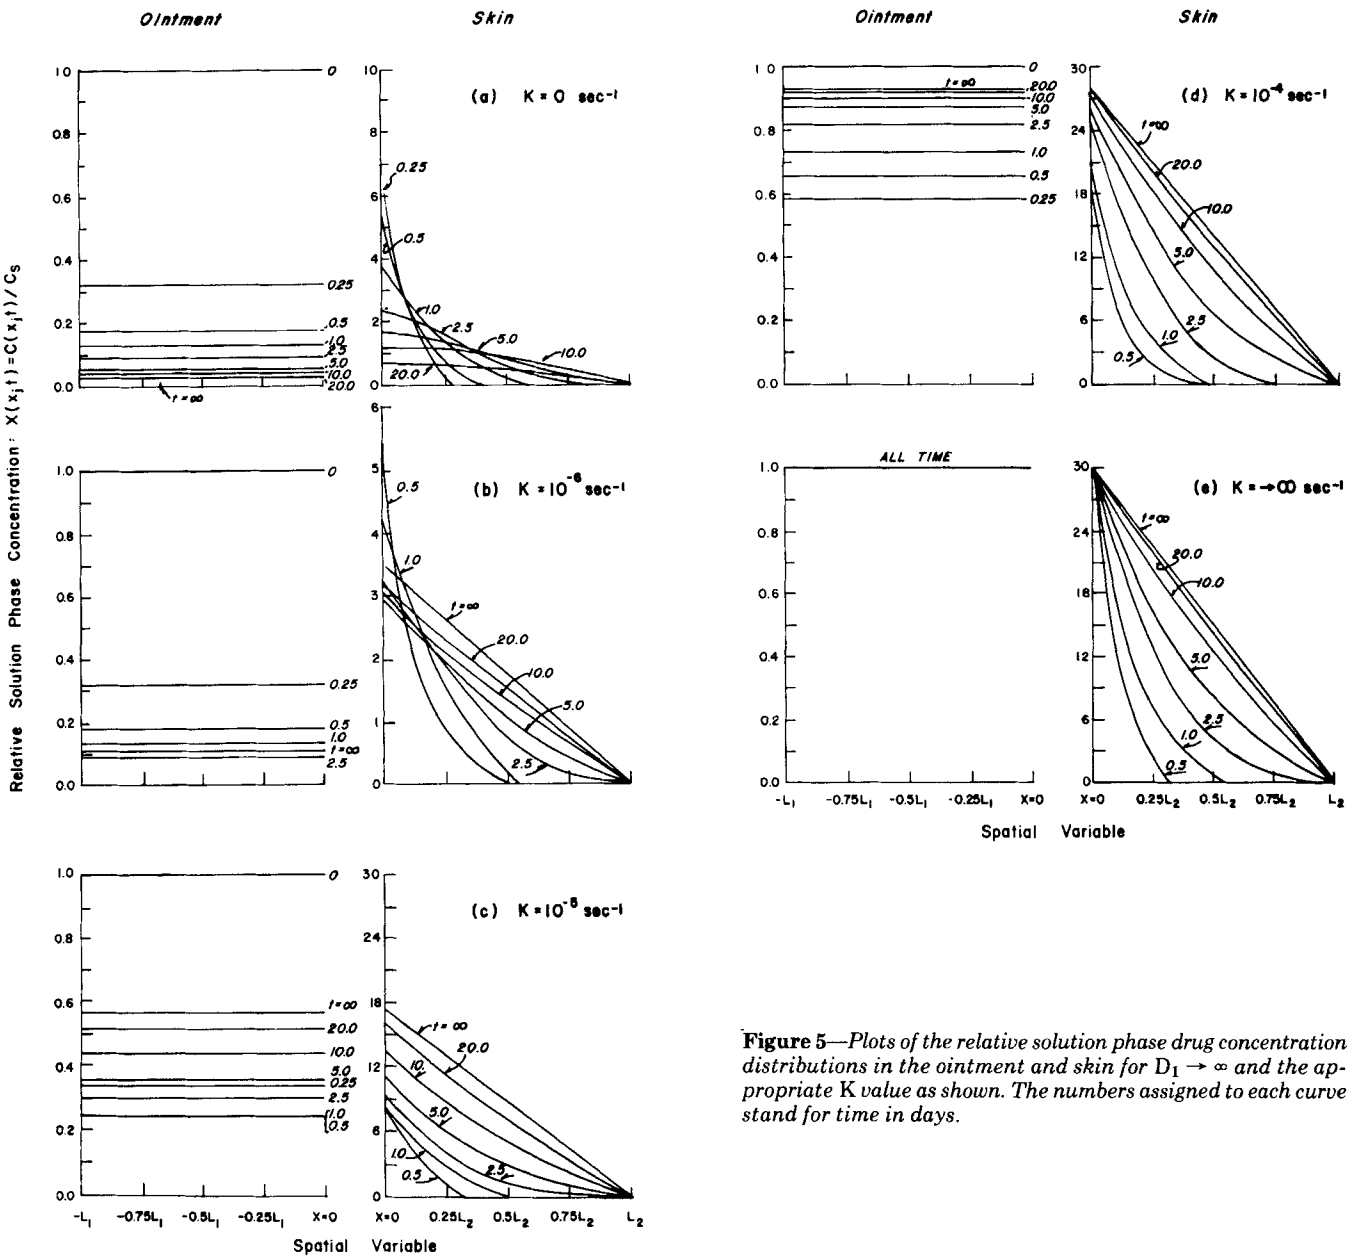

Figure 5—*Plots of the relative solution phase drug concentration distributions in the ointment and skin for* $D_1 \to \infty$ *and the appropriate* K *value as shown. The numbers assigned to each curve stand for time in days.*

exhaustion of source time. The analytical expressions derived here for the cumulative drug mass uptake by the blood are only useful for estimation purposes, since they are actually upper bounding distributions for realistic release situations.

A cursory look at preliminary numerical analysis data for the more realistic model (Eq. 8), *i.e.*, if the source function is *not* constrained at 1.0 but is free to vary in the natural way, shows that, depending upon the magnitude of K, the cumulative relative drug mass uptake by the blood distribution begins to flatten out considerably before t_{C_s} is reached. The preliminary data also show that, for any fixed value of time $t > 0$, μ_{but}, when looked upon as a function of M_{DT}, increases monotonically but nonlinearly toward an asymptotic bounding curve. That is, the release does not continue to be proportional to $(M_{DT})^{1/3}$ at all times, as predicted by Eq. 32, but a maximum release rate is predicted by Eq. 8 with increasing M_{DT}, as reported experimentally (13).

Finally, it should be seen that even in the upper bounding case (Eq. 32), when the crystal or powder density increases, as would be the case in using a finer grind of powder, *i.e.*, a larger surface area to volume ratio, κ increases. Moreover, since μ_{but} is proportional to $\kappa^{1/2}$ (for time t sufficiently large), μ_{but} increases with the increasing surface area of the suspended drug. This increase in the drug release rate with an increasing surface area to volume ratio (smaller suspended particles) has been observed experimentally (13, 24, 25).

For this special case ($D_2 \to \infty$), it can be seen that the relative cumulative blood uptake of drug mass, μ_{but}, is: (*a*) rather linearly dependent upon total drug mass for small time t, (*b*) almost proportional to $t^{1/2}$ for small t, (*c*) linearly dependent upon t for t large, (*d*) proportional to $(M_{DT})^{1/3}$ for large M_{DT} and moderate to large values of time t, and (*e*) increasing accordingly as the surface area to volume ratio of the suspended drug increases for both small and large time values. Another physical factor affecting the release rate is the Arrhenius-type temperature dependence of K_{dis} and K_{cry}; *i.e.*, as T (absolute temperature) goes up, the release rate increases.

Extreme Case $D_1 \to \infty$—This case corresponds to having the transport rate-limiting step occurring in the skin, which is a diffusion barrier-type process. The solution phase concentration distributions are given by limiting forms of Eqs. 19 and 20. The large D_1 limiting form of Eq. 26 is evaluated to demonstrate the cumulative drug mass uptake by the blood. Other special subcases ($K = 0$ and $K \to \infty$) are included here for reference purposes.

Before any actual evaluation of the limiting forms of Eqs. 19, 20, and 26 can be made, the first several zeros, β_n, of the associated transcendental equation (limiting form of Eqs. 21 and 22) must be found for the parameter values of interest. The first 12 zeros for the various values of K and the other designated parameters are listed in Table I.

When using the β values in Table I, the solution phase concentration phase distributions are obtained by evaluating the appropriate distribution equations. Figure 5 was prepared as an aid in understanding the

[a]This set of zeros follows from setting $K = 0$, yielding the well-known form $\beta \tan \beta - (L_2/PL_1) = 0$.

effect of varying the dissolution rate coefficient K upon the overall system. The distribution curves in Fig. 5 clearly show that as K sequences in value from $K = 0$ to $K \to \infty$, the solution phase concentration in the skin builds up in time toward the well-known constant negative gradient situation. The magnitude of the slope of the "steady-state" distribution clearly depends upon the value of K. Linear ordinates and abscissa axes are used throughout Fig. 5. The much larger ordinate numbers for Medium II (the skin) are simply a reflection of P being a 30:1 ratio of skin to ointment; *i.e.*, the drug cortisone likes to be in the solution phase in the skin much better than in the ointment vehicle for the conditions described.

Initially (small times, $t < \frac{1}{4}$ day), drug is lost rapidly from the ointment to the surface layers of the skin. Indeed, if $K = 0$ (Fig. 5*a*), then about 87% of the total "available" drug has been lost from the ointment by the end of Day 1 and resides in the outermost region of the skin. Since there is no dissolution from the suspension when $K = 0$, the only available drug is that in the solution phase initially. With the blood capillary system supposedly forming a perfect sink for the drug, both C_1 and $C_2 \to 0$ as time $t \to \infty$.

In cases where $K > 0$, a finite steady state in the skin is easily observable as time $t \to \infty$. At small times, the same apparent rapid loss of drug from the ointment to the skin is seen. However, as time progresses, some drug released by the ointment at previous times is being replaced by the finite dissolution rate process occurring in the suspension (Medium I).

Another interesting phenomenon that occurs as K increases is the generation of a "deficit" zone in the solution phase of the ointment. The drug in the ointment appears to be lost to the skin too rapidly to be replaced by the dissolution from the suspension until a certain solution phase concentration balance between the drug concentration in the solution phase of the ointment and the solution phase in the skin is reached (Figs. 5*b*–5*d*). The time at which this turning point occurs is dependent on K, as expected. The magnitude of the initial drop and the subsequent return to a long time or steady-state level are also dependent on K.

With the cumulative drug mass uptake by the blood distributions (Fig. 6), it is much easier to see why there is little drug mass transmitted to the blood until after time $t = 4$ days. In fact, it is easy to show that if the drug solution phase concentration at the boundary $x = 0$ remains constant at the relative concentration of 1.0 in the ointment (30.0 on the surface of the skin), it takes at least 3.5 days for the concentration at a point 20 μm from this barrier to reach 1% of the surface concentration. A clear indication of the barrier or rate-limiting action of the skin for this particular drug is seen by a careful study of Figs. 5 and 6. The buildup of drug in Medium II (the skin), which is predicted by this model and shown in Fig. 5, is in agreement with the recognized fact that the stratum corneum is a reservoir for drugs (26).

The cumulative drug mass uptake by the blood (Fig. 6) is bounded above for the case $K = 0$ by the asymptote $M_0 = C_s A L_1$. The same reason for this asymptote holds as in the previously discussed limiting case, $D_2 \to \infty$ and D_1 remaining finite. For values of $K > 0$, the drug mass delivered to the blood increases rapidly for values of time t greater than 9 days (77.76×10^4 sec).

Figure 7 demonstrates the relative cumulative drug mass loss from the ointment, $\mu_1(t) = [M_1(t)/M_0]$ (based upon the limiting form of Eq. 27).

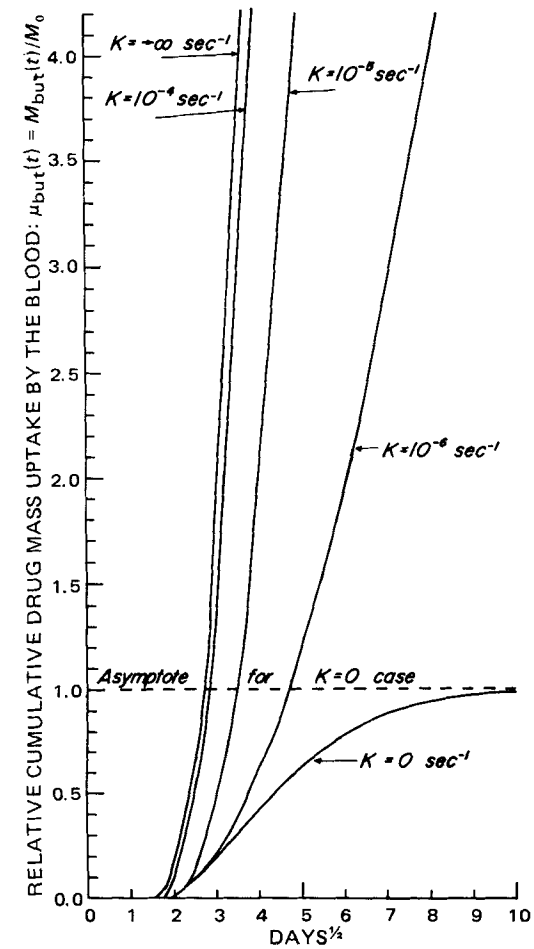

Figure 6—*Plots of the relative cumulative drug mass uptake by the blood, $\mu_{but}(t)$ (see Fig. 4), for $D_1 \to \infty$ and the appropriate K value as shown. The ordinate is linear in drug mass units, M_0, while the abscissa is the square root of time.*

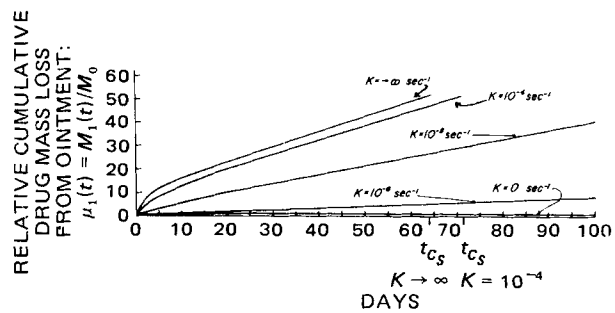

Figure 7—*Plots of the relative cumulative drug mass loss from the ointment under the assumption $D_1 \to \infty$. Both ordinate and abscissa are linear scales. The curves carry their appropriate K values.*

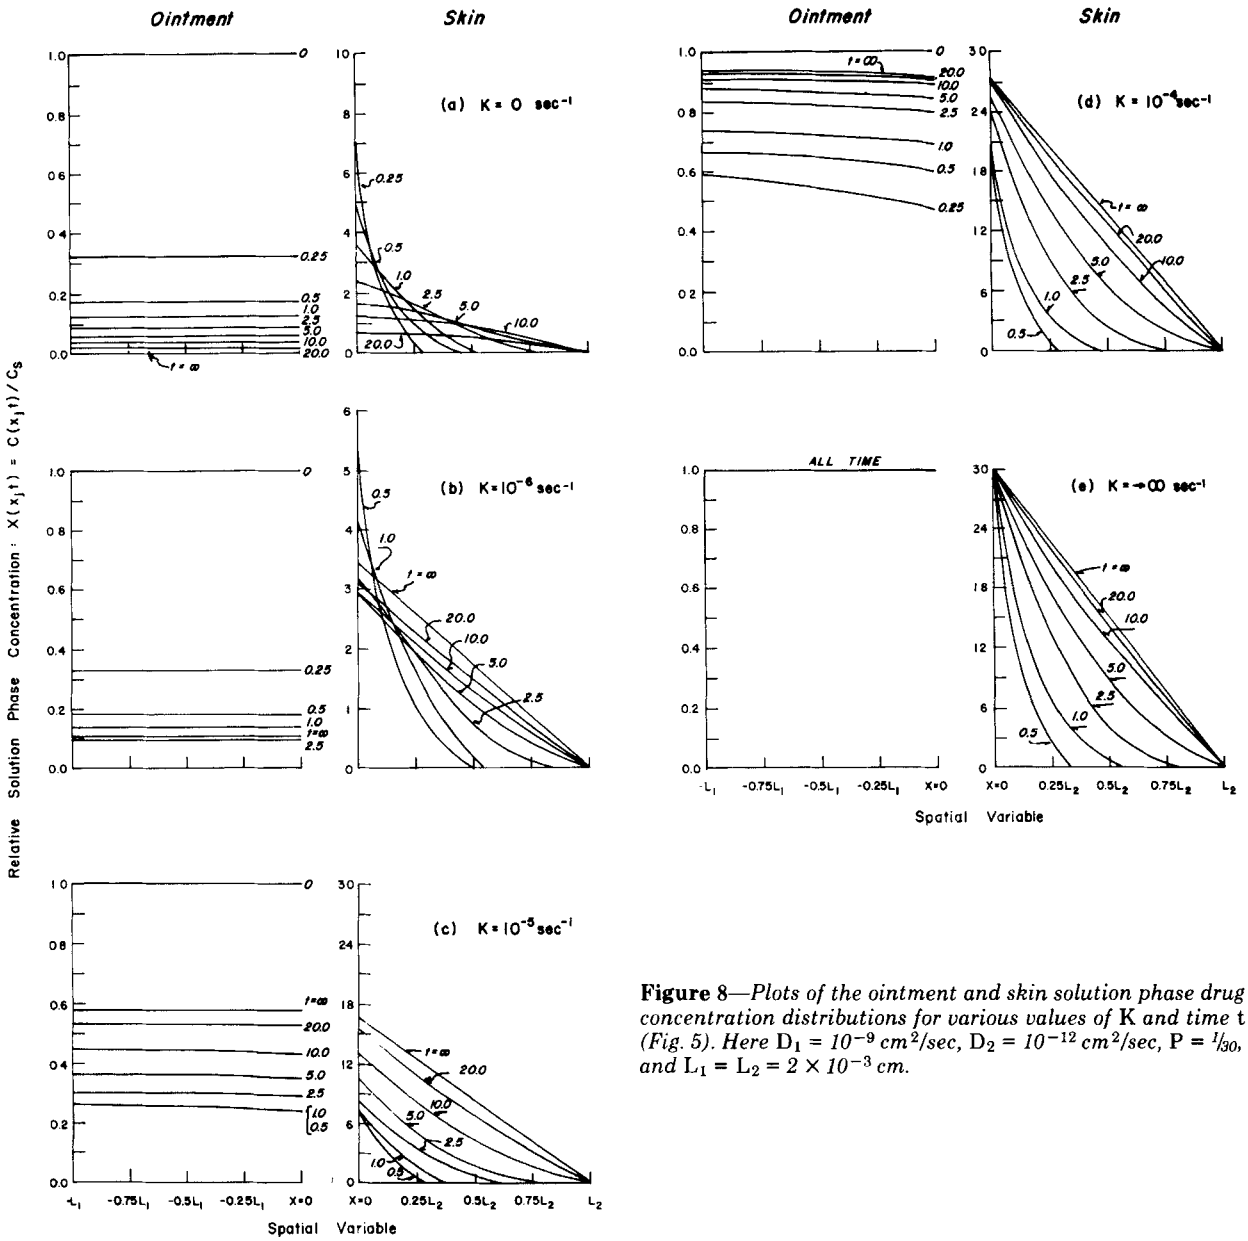

Figure 8—*Plots of the ointment and skin solution phase drug concentration distributions for various values of* K *and time* t *(Fig. 5). Here* $D_1 = 10^{-9}$ *cm²/sec,* $D_2 = 10^{-12}$ *cm²/sec,* P = 1/30, *and* $L_1 = L_2 = 2 \times 10^{-3}$ *cm.*

The scales on this plot are both linear. Suppose, for example, that at time $t = 0$ there exist 50 initial M_0 units of drug in the suspended phase of the ointment and one M_0 unit of drug in the solution phase of the ointment for a total of 51 M_0 units of drug mass. Under the hypothesis of $D_1 \to \infty$, with all other parameters as previously stated, the time t_{C_s} (the time at which 50 M_0 units of drug mass have been lost from the ointment) is easily seen to be 65 days for $K \to \infty$ sec^{-1}, 69 days for $K = 10^{-4}$ sec^{-1}, and > 100 days for $0 < K < 10^{-5}$ sec^{-1}.

If a smaller value of the total initial drug mass is used, then the appropriate values of t_{C_s} can be read off the graphs shown in Fig. 7. The curves in Fig. 7 are peculiar to $D_2 = 10^{-12}$ cm^2/sec. If some other value of D_2 is used, then the relative cumulative mass loss distributions also would be different from those shown in Fig. 7.

General Case D_1 and D_2 Both Finite—As in the special cases, a set of zeros, β_n, associated with the particular transcendental Eqs. 21 and 22 must be obtained. The first 12 zeros of the general case for these transcendental equation(s) for the parameter values $D_1 = 10^{-9}$ cm^2/sec, $D_2 = 10^{-12}$ cm^2/sec, $L_1 = L_2 = 2 \times 10^{-3}$ cm, $P = 1/30$, and several orders of magnitude values of K are listed in Table II.

A careful comparison of the β_n values in Table II with those (for a corresponding K value) in Table I reveals that one should not expect any major differences in the solution phase concentration distributions in either the ointment or the skin (Fig. 2). In fact, an order of magnitude sequence of D_1 values with D_2 fixed at $D_2 = 10^{-12}$ cm^2/sec, *e.g.*, ($D_1 =$: $10^{-9}, 10^{-8}, 10^{-7}, \ldots$), gives essentially no differences between the solution phase concentration distributions for these D_1 values and those obtained under the special case $D_1 \to \infty$. This fact follows from the physical reasoning that, as $D_1 \to \gg D_2$, diffusion across the skin barrier becomes the rate-limiting process. However, if D_2 is about the same order of magnitude as the D_1 value ($D_1 = 10^{-9}$ cm^2/sec), then considerable differences would arise between the general case $D_2 \cong D_1 = 10^{-9}$ cm^2/sec and the special case $D_2 = 10^{-9}$ cm^2/sec and $D_1 \to \infty$.

Figures 8 and 9 summarize the solution phase concentration distributions in the ointment and the skin and the cumulative drug mass blood uptake, respectively. The close similarity of the distributions shown in Figs. 8 and 9 with those in Figs. 5 and 6 is expected as explained. Table III shows some selected values of $\chi_1(x, t)$ and $\chi_1(x, t) = C_1(x, t)/C_s$ and the relative solution phase concentration distribution for several values of (x, t) and K. Note that the slope

$$\left.\frac{\partial \chi_1}{\partial x}\right|_{\substack{-L_1<x<0 \\ t>0}}$$

is almost zero. Only in the case considered, $K = 10^{-4}$ sec^{-1}, does even a shallow gradient exist at small negative x values and small values of time. Somewhere between $K = 10^{-5}$ sec^{-1} and $K \to \infty$ sec^{-1} for small time values, the gradient has a finite maximum value. The spatial position of this maximum gradient lies on the boundary $x = 0$; the exact time at which this maximum occurs is primarily of academic interest and is beyond the scope of this paper.

Table II—Set of First 12 Zeros of the Transcendental Expressions:

$$\beta \cot \beta + P\sqrt{\frac{D_1}{D_2}}\sqrt{\frac{K}{D_2}L_2^2-\beta^2}\tanh\left(\frac{L_1}{L_2}\sqrt{\frac{D_2}{D_1}}\sqrt{\frac{K}{D_2}L_2^2-\beta^2}\right)=0,\ 0<\beta\leqq L_2\sqrt{\frac{K}{D_2}}$$

$$\beta \cot \beta - P\sqrt{\frac{D_1}{D_2}}\sqrt{\beta^2-\frac{K}{D_2}L_2^2}\tan\left(\frac{L_1}{L_2}\sqrt{\frac{D_2}{D_1}}\sqrt{\beta^2-\frac{K}{D_2}L_2^2}\right)=0,\ \beta>L_2\sqrt{\frac{K}{D_2}}$$

12	35.0008	35.0010	35.0031	35.0243	35.2785	37.6991

[a] This set of zeros follows from setting $K = 0$, yielding the transcendental equation:

$$\cot \beta - P\sqrt{\frac{D_1}{D_2}}\tan\left(\frac{L_1}{L_2}\sqrt{\frac{D_2}{D_1}}\beta\right)=0$$

The model developed in this report is based on parameters known or anticipated to affect drug release. Therefore, for semisolids containing suspensions for topical application, the following are predicted to affect drug release and uptake: (*a*) powder density or particle size, (*b*) partition coefficient between the vehicle and the receptor phase, (*c*) solubility of the drug in the vehicle, (*d*) area of application, (*e*) viscosity of the vehicle (affects the diffusion coefficient), (*f*) temperature (affects release and would be different for semisolids applied rectally compared to semisolids applied to the forearm), and, (*g*) total time the material remains in contact with the receptor phase.

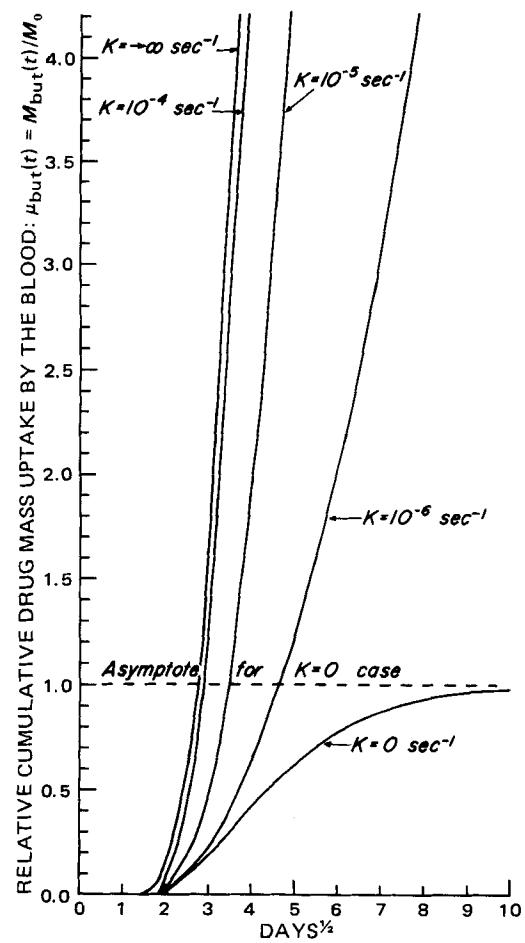

Figure 9—*Plots of the relative drug mass uptake by the blood, $\mu_{but}(t)$, versus the square root of time for the general case (Fig. 8).*

CONCLUSIONS

A general model system for the mass transport of drug in a suspension through the suspension and a permeable barrier to a perfect sink was presented. The appropriate equations for a general case and several specific cases were solved and evaluated. Drug distribution in a vehicle and a membrane and the cumulative drug mass uptake by a receptor phase were all related to the dissolution rate of the drug in the vehicle and diffusion through the vehicle and membrane for specified model conditions. If dissolution is essentially nonexistent during the time considered, then a suspension system behaves as a solution with respect to drug release. Where dissolution of the suspended drug into a semisolid vehicle is slower than diffusion, the rate of dissolution markedly influences the rate of drug release from the vehicle.

The classical model (9) for drug release from suspensions is simple to apply and describes drug release in many systems. It should certainly be used where the model requirements are satisfied. The system presented

here is more complex and results in equations that are not simple and do not predict a simple relationship between drug release and time, particle size, or drug concentration. This model should be considered if its assumptions appear to be met and if experimental data are not described by the classical model.

The model presented here probably will provide some insight into the formulation of suspensions for application to the skin or mucous membranes. The equations presented are only valid for systems that satisfy the requirements of the model. Parameters other than dissolution rate that can affect drug release and parameter interrelationships will be investigated and discussed in a subsequent publication based on the model presented here.

Diffusion Model for Drug Release from Suspensions II: Release to a Perfect Sink

F. TOM LINDSTROM *x and JAMES W. AYRES ‡

Abstract □ Numerical mathematical methods are applied to a diffusion model based on physicochemical principles to predict drug release from suspensions of drug in semisolid vehicles. The predicted mass of drug released *versus* time curves using this model are in agreement with some reported experimental data but differ from predictions using the classical model for semisolid suspensions. The differences are discussed in relation to the drug dissolution rate and diffusion rate in the vehicle.

Keyphrases □ Diffusion—suspended drug in semisolid vehicle, mathematical model based on physicochemical principles □ Dissolution—suspended drug in semisolid vehicle, mathematical model based on physicochemical principles □ Pharmacokinetic models—diffusion and dissolution of suspended drug in semisolid vehicle □ Drug release—from suspensions, diffusion model based on physicochemical principles □ Suspensions—drug release, diffusion model based on physicochemical principles

Previously (1), the complete theoretical development of a general nonlinear mass transport model was presented. Thus, this paper simply gives the nonlinear mass transport equations that incorporate local drug dissolution mechanics as already reported. The case under consideration is the mass transfer of drug out of an ointment vehicle containing dissolved and suspended drug when the semisolid is in immediate contact with a perfect sink (Fig. 1). A typical "real world" case where these conditions can exist

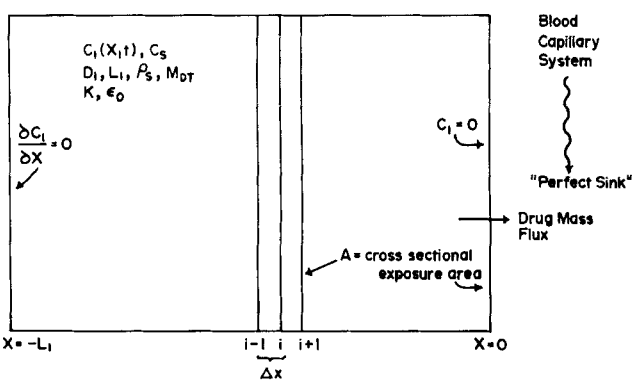

Figure 1—*Schematic of the model system for drug release directly to a perfect sink.*

here is more complex and results in equations that are not simple and do not predict a simple relationship between drug release and time, particle size, or drug concentration. This model should be considered if its assumptions appear to be met and if experimental data are not described by the classical model.

The model presented here probably will provide some insight into the formulation of suspensions for application to the skin or mucous membranes. The equations presented are only valid for systems that satisfy the requirements of the model. Parameters other than dissolution rate that can affect drug release and parameter interrelationships will be investigated and discussed in a subsequent publication based on the model presented here.

[a] $D = 6 \times 10^{-8}$ cm^2/min, $L = 2 \times 10^{-3}$ cm, $C_s = 100$ μg/cm^3, $\rho_s = 1.0$ g/cm^3, and $\Delta t = 0.5$ min.

would be the application of ointment directly to an exposed capillary bed when the skin has been abraded.

This model also simulates certain laboratory experiments where a drug suspended in a semisolid is in direct contact with a large, well-stirred, uniform temperature receptor phase for a period of time. Drug release from suspension experiments have been carried out in this manner (2–4). This case was solved previously (1) using classical nonnumerical mathematical methods. This paper explores the predicted drug release from such systems obtained by numerical analysis of the system simulated in Fig. 1.

MASS TRANSPORT MODEL

The heart of the mass transport model for drug movement in the solution phase in an ointment base (1) is:

$$\frac{\partial C_1}{\partial t} = D_1 \frac{\partial^2 C_1}{\partial x^2} + K(C_s - C_1)\left(\epsilon_0^{1/3} - \frac{K}{3\rho_s}\int_0^t [C_s - C_1(x,\tau)]\,d\tau\right)^2 \quad \text{(Eq. 1)}$$

where:

C_1 = solution phase drug concentration distribution (grams per cubic centimeter)
D_1 = solution phase drug diffusion coefficient (square centimeters per minute)
C_s = solution phase drug saturation concentration (grams per cubic centimeter)
ρ_s = suspended phase drug density (powder density) (grams per cubic centimeter)
ϵ_0 = initial volume fraction of ointment that is suspended drug (cubic centimeter per cubic centimeter) and equals:

$$\left(\frac{M_{DT}}{AL_1} - C_s\right) \Big/ (\rho_s - C_s) \qquad C_s \leqq \frac{M_{DT}}{AL_1} \leqq \rho_s$$

M_{DT} = total drug mass in ointment sample (free and suspended) (grams)
A = exposure surface area of ointment (square centimeters) (Fig. 1)
L_1 = ointment slab thickness
$K = \kappa K_{cry}$, where K is the overall dissolution rate constant (min^{-1}), the product of the crystal surface area to volume constant and the energy-dependent reverse dissolution rate or crystallization rate constant K_{cry}. A more complete explanation of these terms is found in Ref. 1.

The subscripts (suppressed for the remainder of this paper) simply denote that a particular parameter or dependent variable belongs to the ointment portion of the model (Fig. 1).

The concentration distributions $C(x, t)$ can be obtained by solving the numerical analog of Eq. 1 subject to a no flux–perfect sink set of boundary conditions. The simulated system (Fig. 1) can be described mathematically as:

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} + K(C_s - C)\left(\epsilon_0^{1/3} - \frac{K}{3\rho_s}\int_0^t [C_s - C(x,\tau)]\,d\tau\right)^2 \quad \text{(Eq. 2)}$$

The initial conditions are:

$$C(x, +0) = C_s \qquad -L \leqq x < 0 \quad \text{(Eq. 3)}$$

The boundary conditions are:

$$\left.\frac{\partial C}{\partial x}\right|_{x=-L} = 0 \qquad \text{no flux boundary, } t > 0 \quad \text{(Eq. 4)}$$

$$C(0, t) = 0 \qquad \text{perfect sink, } t > 0 \quad \text{(Eq. 5)}$$

Since the system of mass transport (Eqs. 2–5) is nonlinear and the parameter values (especially K) may be large, the more classical math-

[a] $D = 6 \times 10^{-8}$ cm^2/min, $L = 2 \times 10^{-3}$ cm, $C_S = 100$ μg/cm^3, $\rho_S = 1.0$ g/cm^3, and $\Delta t = 0.5$ min.

ematical methods such as perturbations (regular in this case) are not applicable. Thus, it is necessary to consider numerical methods for obtaining the close approximation concentration distributions. The exact numerical method used is that of backward finite differences, where the global error involved at any point in time and space always remains bounded and goes as $O(\Delta x^2 + \Delta t)$. The details of sectioning the ointment slab up into N discrete, but adjoining, compartments (analogous to N discrete, but intimately connected, well-mixed chemical reactors) are contained in the *Appendix*.

RESULTS AND DISCUSSION

The model drug–vehicle system chosen was cortisone powder suspended in a semisolid vehicle that is not soluble in the receptor sink. Thus, the following parameter data estimates are available (1): $N = 10$ compartments, $\Delta x = L/N$, $D = 6 \times 10^{-8}$ cm^2/min, $L = 2 \times 10^{-3}$ cm, $C_s = 100$ μg/cm^3, $\rho_s = 1.0$ g/cm^3, K is variable, $0 \leqq \kappa < \infty$ min^{-1}, and ϵ_0 is variable ($0 \leqq \epsilon_0 < 1$).

Since the relative cumulative drug mass release (grams) at any time t after the release process has begun is defined as (1):

$$\mu(t) = \frac{\int_0^t \left\{ -AD \left. \frac{\partial C}{\partial x} \right|_{x=0} \right\} d\tau}{M_0} \qquad \text{(Eq. 6)}$$

and $M_0 = ALC_s$, the actual formula used in calculating the relative cumulative drug mass release from the ointment is:

$$\mu(t) = -\frac{D}{L} \int_0^t \left\{ \left. \frac{\partial \eta}{\partial x} \right|_{x=0} \right\} d\tau \qquad \text{(Eq. 7)}$$

where $\eta(x, t) = C(x, t)/C_s$, and the partial derivative in Eq. 7 is replaced by a sufficiently high order (2 or higher) numerical approximation so that $O(\Delta x^2)$ is always retained (see *Appendix* for details).

For the finite sequence $\epsilon_0 = 0.025$, 0.05, 0.1, 0.2, and 0.4, the relative cumulative drug mass release, $\mu(t)$, as a function of time (minutes) over the interval 0–24 hr is summarized in Tables I–V. Note that $\epsilon_0 = 0.025$ is equivalent to a concentration of 2.5% drug in the semisolid and would give a maximum $\mu(t)$ value of 250. In like manner, the other ϵ_0 values follow suit and the maximum $\mu(t)$ for $\epsilon_0 = 0.4$ would be 4000.

Several important effects on the cumulative relative drug mass loss distribution can be observed by study of the distributions in Tables I–V. In the true case of no dissolution of drug in the vehicle ($K = 0$), there is no release of drug since none dissolves. This model assumes a C_s of 100 μg/cm^3; therefore, this total amount is predicted to be released when $K = 0$, since no more drug can dissolve to replace the released drug. Each 100 μg/cm^3 gives a relative release of 1.0; if the numerical approximation is exact, $\mu(t) = 1.00$ for the case $K = 0$ as $t \rightarrow$ large.

However, since the numerical simulation is actually formed from a truncated Taylor series, it is not exact but does remain close to the exact value as time $\rightarrow$ large (*i.e.*, the error remains bounded in time). For low overall dissolution rate constants, $0 \leqq K \leqq 0.1$ min^{-1} (the choice of 0.1 is, of course, dependent on D and L), the cumulative drug mass loss is quite slow and becomes linear with time after about 120 min (Tables I–IV, bottom three curves in Fig. 2). The exact value of time where this more or less zero-order type of drug release commences can be seen from the tables to be close to 120 min regardless of the initial total drug mass (ϵ_0). This type of phenomenon is expected for such low values of K, because the rate-limiting step in this region of K values is clearly dissolution. The drug simply cannot go into solution fast enough to replace what has been transported toward the boundary ($x = 0$) by diffusion when $D = 6 \times 10^{-8}$ cm^2/min.

In the highest case of $\epsilon_0 = 0.4$ (40% of the ointment slab consists of suspended drug initially), it can be calculated that as $t \rightarrow \infty$, $\mu(t) \rightarrow 4000$ for the example presented here. At the end of 24 hr, less than 1.0% of the total drug has been released due to the slow dissolution.

For values of K in the range $0.1 \leqq K \leqq 100.0$ min^{-1}, a substantial increase in the cumulative relative drug mass release distribution is seen compared to $K \leqq 0.1$ min^{-1}. This region (again dependent upon D and L) contains those values of K where the dissolution and diffusion processes are somewhat comparable and neither one is clearly the rate-limiting step. In this region of K values (over the first 24 hr anyway), the distributions are somewhat linear (Fig. 2) in time after a similar initial curvilinear buildup, as was observed for K in $0 \leqq K \leqq 0.1$ min^{-1}. The maximum cumulative drug release at 24 hr ($\epsilon_0 = 0.4$) is about 6%.

1440	1.05	7.84	39.07	116.68	241.33	310.21	322.50	323.85

[a] $D = 6 \times 10^{-8}$ cm^2/min, $L = 2 \times 10^{-3}$ cm, $C_s = 100$ μg/cm^3, $\rho_s = 1.0$ g/cm^3, and $\Delta t = 0.5$ min.

In the region $100 \leqq K < \infty$ min^{-1} (∞ = 10,000 for Tables I–V), diffusion is the rate-limiting step. When diffusion is the rate-limiting process, the model predicts the following very interesting "moving source" phenomenon, which is in good agreement with literature data for release of medroxyprogesterone acetate from a cylindrical silicone polymer (5). Notice that under the columns labeled K = 10,000 min^{-1}, the relative cumulative drug mass distribution initially has a zero-order (Fig. 3) type of buildup ($0 < t < 60$ min). Then (especially at low ϵ_0 values), the release becomes non-zero order as the suspended drug in the surface layer [first compartment adjacent to the boundary ($x = 0$) in the numerical scheme] becomes exhausted and a type of diffusion layer or ointment boundary is created by the portion of the semisolid vehicle that is now drug free.

Initially, under high K values, a large burst of drug is obtained from the surface layer of ointment only. The other deeper regions in the ointment slab have essentially not yet begun to feel any concentration gradient in the local regions and are thus, for all practical purposes, just sitting still in time. However, as time goes on and the surface layer (first compartment) is exhausted of its suspended drug, the second layer (second compartment) begins to contribute drug by diffusion of dissolved drug and by sending suspended drug into solution. But this newly dissolved drug must diffuse through a thin permeable slab of ointment, the empty first compartment which is now devoid of any suspended drug, to the boundary $x = 0$.

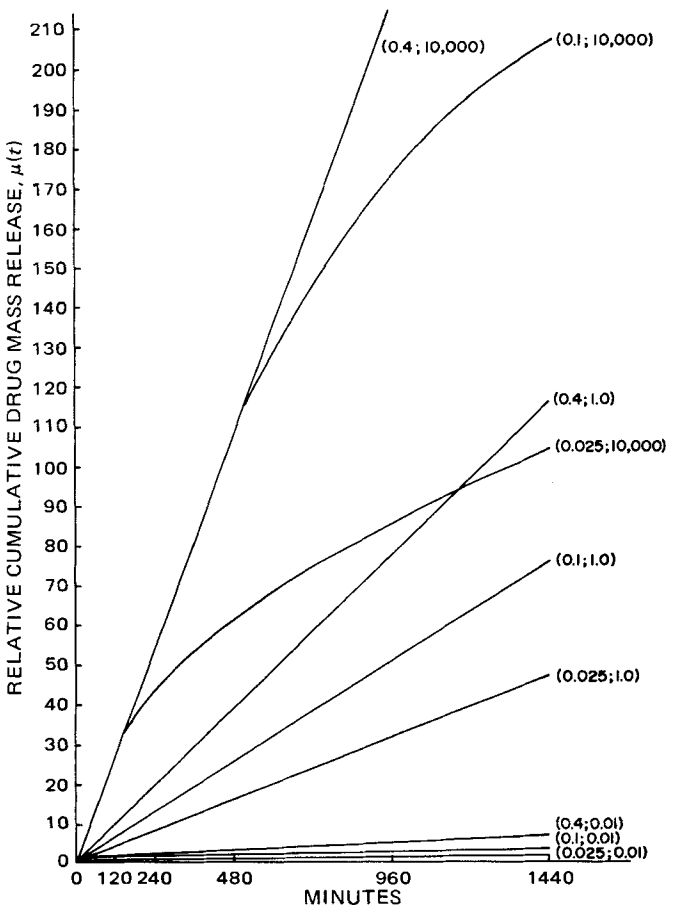

Figure 2—*Relationship between relative cumulative mass loss* μ(t) versus *time* t *in minutes for three different* ϵ_0 *values and three* K *values for each* ϵ_0 *value. The combinations are characterized via the order pair designation* (ϵ_0 = —; K = —).

As time goes on, the second layer is also depleted of its suspended drug and the third compartment begins to contribute. Now drug coming from the third compartment must diffuse through the first two compartments. This sequence is repeated in time until the entire ointment slab is devoid of all suspended and free drug under the hypothesis of this model. The net effect of these large values of K is to produce a moving source of suspended drug, very much like an earlier model (6) in which diffusion is the rate-limiting step.

From Table VI, it can be seen that after 24 hr the first four compartments are nearly exhausted of their initially suspended drug mass (K large) in the case of ϵ_0 being a 2.5% suspension, whereas only the first compartment is extensively depleted when ϵ_0 = 40%. This moving source phenomenon is the reason for the extreme curvilinearity in the case of ϵ_0 small and almost complete linearity for 24 hr for ϵ_0 large (Fig. 3).

Although the current model is in agreement with an earlier model (6) with respect to a moving source when dissolution is very rapid, the models predict different cumulative drug mass release *versus* time curves. The classical model (6) results in Eq. 8 to relate the amount and rate of release of drug suspended in an ointment vehicle to time and variables of the system (when $C_s \ll A$):

$$Q = S\sqrt{2ADC_s t} \qquad \text{(Eq. 8)}$$

where Q = amount of drug released at time t, S = surface area of exposure, A = concentration of drug (units per cubic centimeter), C_s = solubility of drug (units per cubic centimeter) in the vehicle, D = diffusion constant of the drug in the vehicle, and t = time.

Equation 8 predicts that the amount of drug released would be proportional to the square root of the total drug present. The model presented here predicts a limiting or upper bounding distribution (for large K values) as ϵ_0 increases (Fig. 3). Obviously, ϵ_0 cannot be increased beyond 1.0. However, it appears from the tables that ϵ_0 = 40% is probably close to the upper bounding distribution. This upper limit distribution is important and was observed experimentally (7).

Other experimental data indicate that the release of drug from a sus-

[a] Relative amounts obtained for μ and μ_H using Eq. 7 and converting Eq. 8 to a form (1) that also predicts relative cumulative drug mass release at time t, namely, $\mu_H = \sqrt{2Dt}/L\ \sqrt{\rho\epsilon_0/C_S}$ or $\mu_H = Q/LC_S$.

pension in a semisolid is not always proportional to the square root of drug concentration and the ratio changes with time. Examples are sulfacetamide in hydrogenated cottonseed oil with surfactant and sulfathiazole in hydrogenated cottonseed oil (8). Salicylic acid suspended in several different vehicles was not released as predicted by Eq. 8, possibly due to an inadequate dissolution rate of the suspended particles (9). Release of suspended benzocaine from white petrolatum was not proportional to the square root of concentration for each sample obtained over the time period investigated (10).

Introduction of a membrane between the vehicle and the receptor phase, when the membrane is not rate limiting for release (as occurred in some experiments), would not change the relationship predicted by the model for Eq. 8 between concentration and amount released, although a lag time may be evident. A matrix–boundary diffusion layer model (5, 11, 12) was proposed to explain some cases where the release is not proportional to the square root of concentration. Such models incorporate the realistic assumption of a desorptive phenomenon occurring at the semisolid–receptor phase interface. This assumption is compatible with the model presented here and will be considered in a future publication.

The differences in predicted relative cumulative drug mass release using Eqs. 7 and 8 are shown in Table VII and Fig. 4. In the range of rapid dissolution for increasing drug concentrations, the model presented predicts little effect on the amount of drug released at short times and a limiting upper bound for drug release at longer times. In contrast, the classical model predicts a large effect at short times for increasing drug concentrations. The predicted effect at short times is highly dependent on the parameter constants being used and will vary for each drug–vehicle system. An upper bound, however, is predicted for all systems by the current model and not by the classical model.

The apparent linearity of μ *versus* $\sqrt{t}$ in Fig. 4 is due to computer time limitations. If this numerical simulation were plotted for 10 or 20 days consecutively, a pronounced negative curvature, especially at smaller ϵ_0 values, would clearly be seen at longer times. This negative curvature has no place in the theory of heat and mass transfer when simple $\sqrt{t}$ behavior is assumed. However, the negative curvature is a well-known phenomenon in heat and mass transfer theory when the complete Fourier series representation is given to the drug concentration distribution $C(x, t)$ across the ointment slab, $-L \leqq x < 0$.

The previous discussion was obtained from a rather good (as evidenced by the column labeled $K = 0$) numerical simulation of the transport model under the hypothesis that $D = 6 \times 10^{-8}$ cm^2/min and $L = 20$ μm. When these parameter values are changed for systems other than the one presented here, a new set of drug mass release distribution tables over the same range of K values can be easily obtained[1].

Since this scheme is numerical, it is instructive to consider the effects of changes in the mesh size, Δx, and time step size, Δt, on the distributions, $\mu(t)$. Since it is difficult to generate a large set of tables for the

[a] $D = 6 \times 10^{-6}$ cm^2/min, $L = 2 \times 10^{-3}$ cm, $C_S = 100$ μg/cm^3, and $\rho_S = 1.0$ g/cm^3.

various ϵ_0 *versus* K combinations for selected values of Δx and Δt while still retaining the total ointment thickness, L, and run time $t = 1440$ min, the cases of $\Delta t = 1$ min and $\Delta t = 0.25$ min for $\epsilon_0 = 0.1$ and $N = 10$ were chosen for evaluation. In accordance with theory (13), when N increases and Δx and Δt decrease, the order of the error goes down rapidly. Hence, the approximation becomes better and better.

Although this paper does not attempt to give an exact error analysis for the model presented, Tables III, VIII, and IX illustrate the accuracy and error stability of the numerical simulator used to approximate the solution to the complete nonlinear mass transport system. Tables VIII, III, and IX reflect the values $\Delta t = 0.25$, 0.5, and 1.0 min, respectively. All have the common parameter values used earlier. Examination of the tables shows that not only does the error remain bounded in all cases, as theory says it should (13), but also that the percentage difference between values for corresponding K values decreases with increasing time when Tables III and VIII are compared and when Tables VIII and IX are compared. The worst error occurs at early times and small K values ($0 \leqq K \leqq 0.1$). This finding is justified, however, by the error analysis (13) for parabolic-type partial differentio-integral equations of the type adapted for the transport model.

The value of Δt throughout this paper is 0.5 min. This value is the geometric mean of the two values 1.0 and 0.25, although the main reason for choosing 0.5 min is simply that it gives reasonably accurate μ values coupled with ease of computation.

SUMMARY

A numerical method was used to solve the equations associated with a new model for the release of suspended drug from a semisolid vehicle to an infinite sink. Evaluation of the method through the consideration of increasing t values shows the mathematics to be stable and bounded in the scheme presented. The model predicts a curvilinear relationship between the amount of drug released and the amount of drug present and the time elapsed other than time$^{1/2}$.

The release pattern may or may not appear linear with time or time$^{1/2}$ if release is evaluated over short time intervals. Use of such linear relationships to project drug release at earlier or later times than those actually evaluated may introduce considerable error with respect to the actual amount released.

APPENDIX

Consider the following nonlinear parabolic integro-differential problem for mass transport of drug in an ointment–perfect sink system:

$$\frac{\partial \eta}{\partial t} = D\frac{\partial^2 \eta}{\partial x^2} + K(1-\eta)\left(\epsilon_0^{1/3} - \frac{KC_s}{3\rho_s}\int_0^t [1-\eta(x,\tau)]\,d\tau\right)^2 \quad \text{(Eq. A1)}$$

for all (x, t) in $\{(-L_1 < x < 0) \times (t > 0)\}$ subject to the initial conditions:

$$\eta(x, +0) = 1.0 \qquad -L_1 \leqslant x > 0 \quad \text{(Eq. A2)}$$

and boundary conditions:

$$\left.\frac{\partial \eta}{\partial x}\right|_{x=-L_1} = 0 \qquad t > 0 \quad \text{(Eq. A3}a\text{)}$$

and:

$$\eta(0, t) = 0 \qquad t > 0 \quad \text{(Eq. A3}b\text{)}$$

and $\eta(x, t) = C(x, t)/C_s$. Note that D, K, ϵ_0, ρ_s, C_s, and L_1 are all positive parameters.

By using a reported scheme (13), the time derivative $\partial\eta/\partial t$ can be replaced by a backward in time difference quotient:

$$\left.\frac{\partial \eta}{\partial t}\right|_{t_{n+1}} \doteq \frac{\eta^{(n+1)} - \eta^{(n)}}{\Delta t} \quad \text{(Eq. A4)}$$

while the space derivative is approximated by a space-centered difference quotient:

$$\frac{\partial^2 \eta}{\partial x^2} \doteq \frac{1}{\Delta x^2}(\eta_{i-1} - 2\eta_i + \eta_{i+1}) \quad \text{(Eq. A5)}$$

and the integral term is evaluated backward in time by the trapezoidal rule. Note that $\Delta x = L_1/N$ and Δt is chosen arbitrarily small but positive. The $\eta_i^{(n)}$ notation used for the remainder of the paper means simply this:

$$\eta_i^{(n)} = \eta(x_i, t_n) = \eta(i\Delta x, n\Delta t)$$
$$i = 0, 1, 2, \ldots, N \qquad n = 0, 1, 2, \ldots \qquad \text{(Eq. A6)}$$

The space, time, and integral operators have been approximated in such a way that an implicit, irreducible, diagonal dominant linear system must be solved at each time step. The resulting iterative scheme is not only unconditionally stable but has been shown (13) to produce an approximating solution which converges uniformly to the true solution as Δx and $\Delta t \to 0$.

Define:

$$I_i^{(n)} = \left(\epsilon_0^{1/3} - \frac{KC_s}{3\rho_s}\int_0^{t_n}[1 - \eta_i(\tau)]\,d\tau\right)^2 \qquad \text{(Eq. A7)}$$

For computer computation, define:

$$J_i^{(n)} = \int_0^{t_n}[1 - \eta_i(\tau)]\,d\tau \qquad \text{(Eq. A8)}$$

By using the trapezoid rule, which retains $O(\Delta t)^2$ globally:

$$J_i^{(n)} = J_i^{(n-1)} + \frac{\Delta t}{2}\{2 - [\eta_i^{(n)} + \eta_i^{(n-1)}]\} \qquad \text{(Eq. A9)}$$

with $J_i^{(0)} = 0$ and $i = 0, 1, 2, \ldots, N$. Hence:

$$I_i^{(n)} = \left[\epsilon_0^{1/3} - \frac{KC_s}{3\rho_s}J_i^{(n)}\right]^2 \qquad \text{(Eq. A10)}$$

Putting all parts together gives the numerical scheme (tridiagonal system):

$$\frac{\eta_i^{(n+1)} - \eta_i^{(n)}}{\Delta t} = \frac{D}{\Delta x^2}\left[\eta_{i-1}^{(n+1)} - 2\eta_i^{(n+1)} + \eta_{i+1}^{(n+1)}\right] + K[1 - \eta_i^{(n+1)}]I_i^{(n)} \qquad \text{(Eq. A11)}$$

where $i = 1, 2, 3, \ldots, N-1$. The boundary conditions (no flux boundary) at $x = -L_1$, which corresponds to $i = 0$ in the "bookkeeping" of this numerical scheme, is approximated as:

$$\left.\frac{\partial\eta^{(n+1)}}{\partial x}\right|_{x=-L_1} \doteq \frac{1}{2\Delta x}[-3\eta_0^{(n+1)} + 4\eta_1^{(n+1)} - \eta_2^{(n+1)}] \qquad \text{(Eq. A12)}$$

where the $O(\Delta x^2)$ accuracy is preserved *via* this approximation. Since the boundary condition requires $(\partial\eta/\partial x)|_{x=-L_1} = 0$ for all $t \geq 0$, then:

$$\eta_0^{(n+1)} = \frac{4}{3}\eta_1^{(n+1)} - \frac{1}{3}\eta_2^{(n+1)} \qquad \text{(Eq. A13)}$$

This equation, together with the boundary condition at $i = N$ ($x = 0$), $\eta_N^{(n+1)} = 0$, and $n = 0, 1, 2, \ldots$, and Eq. A11 give, after some algebra, the tridiagonal system (interative):

$$\begin{aligned}
a_{11}\eta_1^{(n+1)} + a_{12}\eta_2^{(n+1)} + 0\eta_3^{(n+1)} + \ldots + 0\eta_{N-1}^{(n+1)} &= \eta_1^{(n)} + K\Delta t I_i^{(n)} \\
a_{21}\eta_1^{(n+1)} + a_{22}\eta_2^{(n+1)} + a_{21}\eta_3^{(n+1)} + 0\eta_4^{(n+1)} + \ldots + 0\eta_{N-1}^{(n+1)} &= \eta_2^{(n)} + K\Delta t I_2^{(n)} \\
&\vdots \quad \vdots \quad \vdots \\
0\eta_1^{(n+1)} + \ldots + a_{21}\eta_{N-2}^{(n+1)} + a_{N-1,N-1}\eta_{N-1}^{(n+1)} &= \eta_{N-1}^{(n)} + K\Delta t I_{N-1}^{(n)}
\end{aligned} \qquad \text{(Eq. A14)}$$

where:

$$a_{11} = 1 + \frac{2}{3}\frac{D\Delta t}{\Delta x^2} + K\Delta t I_1^{(n)}$$
$$a_{12} = -\frac{2}{3}\frac{D\Delta t}{\Delta x^2}$$
$$a_{21} = -\frac{D\Delta t}{\Delta x^2}$$
$$a_{ii} = 1 + \frac{D\Delta t}{\Delta x^2} + K\Delta t I_i^{(n)},\ i = 2, 3, 4, \ldots, N-1$$

Hence, by iteration with the matrix system:

$$A^{(n)}\eta^{(n+1)} = \eta^{(n)} + K\Delta t\,\mathbf{I}^{(n)} \qquad \text{(Eq. A15)}$$

the relative concentration distribution $\eta^{(n+1)} = [\eta_0^{(n+1)}, \eta_1^{(n+1)}, \eta_2^{(n+1)} \ldots \eta_N^{(n+1)}]^1$, is obtained in terms of the previous time level relative concentration distribution and any new drug which has come into solution in the intervening time.

It remains now to calculate $\mu_1(t)$, the relative cumulative drug mass loss from the ointment system. Since $\mu_1(t)$ is defined as:

$$\mu_1(t) = \frac{\int_0^t\left\{-DA\left.\frac{\partial C}{\partial x}\right|_{x=0}\right\}}{AL_1C_s}d\tau = -\frac{D}{L_1}\int_0^t\left.\frac{\partial\eta}{\partial x}\right|_{x=0}d\tau \qquad \text{(Eq. A16)}$$

the space derivative at the right-hand boundary $x = 0$ is replaced by the numerical approximation which preserves the $O(\Delta x^2)$ accuracy locally and globally in time:

$$\left.\frac{\partial\eta}{\partial x}\right|_{x=0} \doteq \frac{1}{2\Delta x}[\eta_{N-2} - 4\eta_{N-1} + 3\eta_N] \qquad \text{(Eq. A17)}$$

Under the assumption that there is a perfect sink condition operating at all times at the ointment–sink boundary, $x = 0$, $\eta_N^{(n)} = 0$, and $n = 1, 2, \ldots$. Hence, substituting for this space derivative approximation and again using the trapezoid rule for numerical quadrature in time yield:

$$\mu^{(n+1)} = \frac{D}{2\Delta x L_1}I_2^{(n+1)} \qquad \text{(Eq. A18)}$$

where:

$$I_2^{(n+1)} = I_2^{(n)} + \frac{\Delta t}{2}\{4[\eta_{N-1}^{(n+1)} + \eta_{N-1}^{(n)}] - [\eta_{N-2}^{(n+1)} + \eta_{N-2}^{(n)}]\} \qquad \text{(Eq. A19)}$$

with $I_2^{(0)} = 0$.

Equations A9, A10, A13, and A14 constitute the numerical simulation for the relative solution phase drug concentration at any point in time, while Eqs. A18 and A19 are used to obtain the relative cumulative drug mass release from the ointment slab at time $t \geq 0$.

Polymorphism of Phenylbutazone: Properties and Compressional Behavior of Crystals

H. G. IBRAHIM ˣ, F. PISANO, and A. BRUNO

Abstract □ Data from X-ray diffraction, thermal analysis, IR spectroscopy, and solubility studies were used for the identification and characterization of four crystalline modifications of phenylbutazone. The thermal behavior of the polymorphs under different treatment conditions also was investigated. Compression of the thermodynamically unstable forms, at a compression force of 1590–2040 kg, induced polymorphic changes in the crystals. Similar changes also were produced through grinding. The apparent equilibrium solubilities of polymorphs were determined, as was the dissolution of the polymorphs as compressed disks in an aqueous medium. The small effective surface area possessed by one polymorph resulted in slow dissolution.

Keyphrases □ Phenylbutazone—four polymorphic forms identified, thermal and compressional behavior and solubilities compared □ Polymorphism—phenylbutazone, four crystalline forms identified, thermal and compressional behavior and solubilities compared □ Thermal behavior—four polymorphic forms of phenylbutazone compared □ Compressional behavior—four polymorphic forms of phenylbutazone compared □ Solubility—four polymorphic forms of phenylbutazone compared □ Antirheumatic agents—phenylbutazone, four polymorphic forms identified, thermal and compressional behavior and solubilities compared

Different polymorphs are known to possess different physical properties. From a practical point of view, solubility, surface tension, density, crystal shape, and hardness are the most significant differences. The bioavailability of a drug as well as the chemical and physical stability of a solid compound in a particular dosage form can be modified by presenting the drug in the appropriate crystal form (1, 2). This approach, of course, requires a thorough knowledge of the properties and behavior of the different crystalline modifications.

While several reports discussed the bioavailability of drugs that can exist in more than one crystalline modification (3, 4), little information is available on the role of polymorphism and crystal habit in solid dosage form and powder technology. The orientation of crystals during a packing or compression process is influenced by the dominant faces in the crystal and, therefore, by crystal habit. Using data from X-ray powder diffraction, Shell (5) described crystal habit as it relates to a good or poor tableting performance.

Polymorphous transformations at high pressures occur in some inorganic and organic substances (6, 7). The possibility of phase transitions with pressure during tableting and their effects on dissolution rates and availability of drugs have not been adequately investigated, probably because of the general contention that tableting pressures will not induce phase transformations. Nevertheless, such phase changes during compression are conceivable and would occur at individual points of contact between particles where local pressures are extremely large (pressure being force per unit area). These pressures probably would promote transitions toward structures of higher coordination and higher density.

The present work reports on polymorphism in phenylbutazone and provides information regarding the feasibility of crystalline structural changes under tableting conditions.

EXPERIMENTAL

Crystal Forms—Cyclohexane (Form II), *n*-heptane (III), 2-propanol (IV), and isobutyl alcohol (I) were used as crystallization solvents for the polymorphs. All solvents were analytical grade. A single batch of commercial phenylbutazone[1] was used. The techniques of crystallization of the different polymorphs from the different solvents were essentially the same. An adequate amount of the drug was added to the warm solvent, and the resultant saturated solution was allowed to cool.

For the preparation of Form IV, water was added to the 2-propanol solution until the cloud point. Then the solution was warmed again and allowed to cool. The separated crystals were filtered off using a sintered-glass funnel and then dried under vacuum.

Polymorph Characterization—*Differential Scanning Calorimetry*—The thermograms of the different crystalline modifications were recorded on a thermal analyzer[2] equipped with a differential scanning calorimetry cell. Indium (99.99% purity) was used to check instrument calibration. The thermal behavior of the four polymorphs was studied at different heating rates and under different conditions of sample treatment; *i.e.*, crystals were heated in an open pan, covered pan, or as a crimped sample.

Heating rates of 2 and 5°/min and, to a much lesser extent, 10°/min promoted solid–solid transformation. To minimize such transformation, the samples routinely were heated throughout the investigation at 20°/min. Phase transition temperatures obtained from the thermograms were corrected for the nonlinear response of the chromel–alumel thermocouple.

IR Spectroscopy—A double-beam IR spectrophotometer[3] was used for recording the spectra of the polymorphs. Grinding, as will be shown later, induced polymorphic changes in the samples. Since the sample must be sufficiently ground to obtain a good mineral oil[4] mull, this technique and the potassium bromide disk technique were considered unsuitable for handling such grinding-sensitive material. For this reason, attenuated total reflectance, using a TR-9 ATR unit with a 45° KRS-5 (thallous bromide–iodide) crystal, was employed to record the IR spectra. An adhesive tape technique similar to that used by Kang *et al.* (8) was utilized in preparing the samples for IR analysis.

X-Ray Analysis—X-ray diffraction patterns were recorded using an X-ray diffractometer with K_α radiation[5]. The settings used with the instrument were: 1° beam slit, 0.2° detector slit, copper tube-K_α radiation, and nickel filter.

Dissolution and Solubility Studies—All dissolution studies were conducted in a 0.067 *M* aqueous phosphate buffer of pH 6.95. The apparatus used in the dissolution rate determinations was similar to that described by Wood *et al.* (9). Approximately 100 mg of the crystals was compressed[6] into a disk in an 8-mm stainless steel tablet die at approximately 1590 kg. The tablet die, with one face of the compressed disk exposed and in plane with the die surface, was placed in a plastic holder. The tablet assembly was rotated in 500 ml of dissolution medium at 50 rpm. The drug concentration in solution was continuously monitored by circulating the solution into a spectrophotometer[7] and continuously measuring the absorbance at 264 nm.

For the determination of the equilibrium solubility, an excess quantity of the crystals was shaken with 100 ml of the buffer solution in an erlen-

meyer flask immersed in a water bath thermostated to ±0.02°. No attempt was made to control the particle size of the crystals. At specific time intervals, 5 ml of the solution was withdrawn with a pipet fitted with a glass wool plug. Aliquots of 1 ml were withdrawn from the filtered solution and appropriately diluted, and the absorbance was measured spectrophotometrically at 264 nm.

Scanning Electron Microscopy—Compressed disks prepared in the same manner as those used for dissolution rate determinations were used for the scanning electron microscopy investigation[8]. The disks were flushed with air, and the photomicrographs were taken at magnifications ranging from 200 to 10,000×.

RESULTS AND DISCUSSION

Four crystalline modifications of phenylbutazone were obtained by the crystallization technique described and identified using data from X-ray diffraction, thermal analysis, and IR spectroscopy. Figure 1 shows the X-ray diffraction patterns of Forms I, II, III, and IV prepared from isobutyl alcohol, cyclohexane, *n*-heptane, and 2-propanol–water, respectively. Distinct differences are apparent and are attributed to differences in the arrangements of the molecules in the crystal lattices of the polymorphs.

The IR absorption spectra of the various forms showed recognizable differences in the detailed structure and intensities of some major absorption bands. Differences in the carbonyl stretching vibration region, specifically from 1760 to 1700 cm^{-1}, and in the 750–650-cm^{-1} region were peculiar for each form and could be used for the characterization and identification of the different crystalline phases. Differences in the ketone

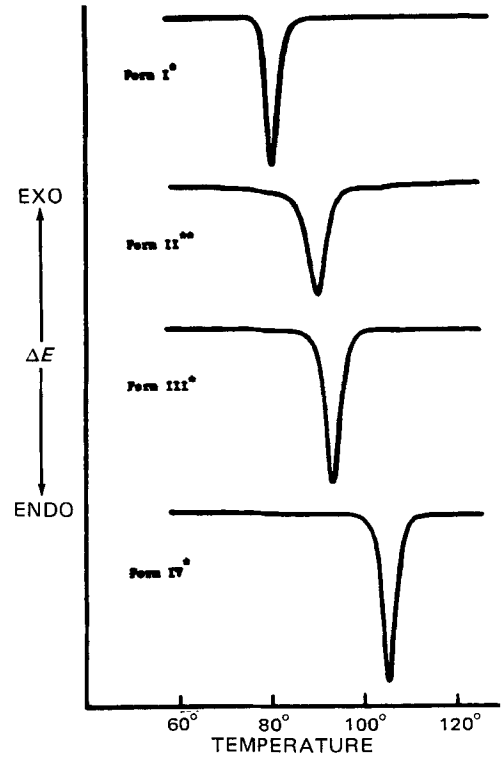

Figure 2—*Thermograms of the different crystal modifications at a heating rate of 20°/min. Key: *, crimped sample; and **, crystals heated in a covered pan with no pressure applied.*

skeletal vibration region (1350–1000 cm^{-1}) could also be attributed to differences in crystal structures. No attempt was made, however, to associate these differences with the modes of association of the molecules in the crystal lattice. The possibility of a solvate formation was excluded

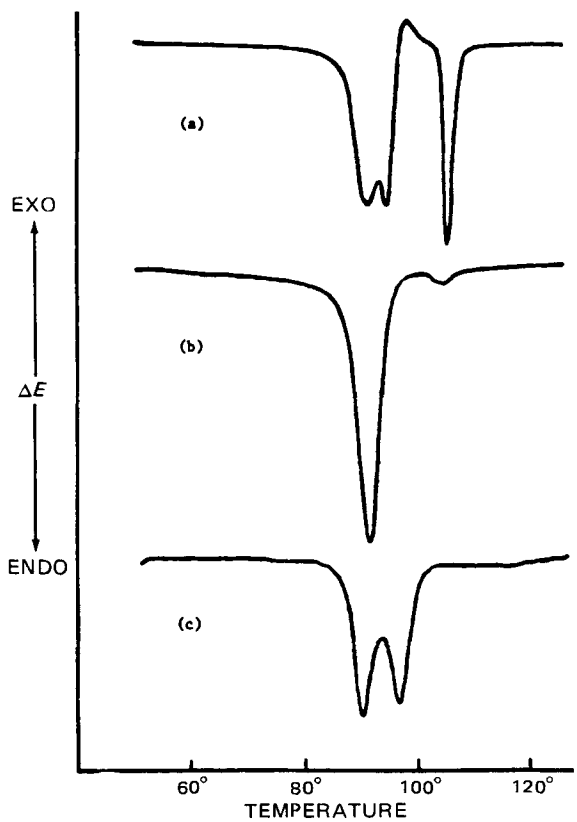

Figure 3—*Thermograms of polymorph II under different conditions of sample treatment. Key: (a), open pan; (b), covered pan; and (c), crimped sample.*

on the basis that both IR spectra and thermal analysis did not show any trace of the solvents used in the crystallization processes.

Differential scanning thermograms of I–IV are depicted in Fig. 2. In all instances, a lowering of 0.5–1° was noted in the recorded transition temperatures if the sample was crimped as compared to determinations in an open or covered pan. This decrease probably resulted from better thermal contact between the sample and the aluminum pan. Thermograms obtained for Forms III and IV were independent of the conditions of sample packing, whereas those of Forms I and II showed various phase changes depending on whether the heating was conducted in an open pan or a covered pan or whether the sample was crimped before heating.

The thermal behavior of Form II under different conditions of sample treatment is illustrated in Fig. 3. Samples heated in an open pan showed a noticeable solid–solid transformation and crystallization from melt. These effects are evident from the two endothermic peaks at 94 and 105° and the exotherm at 98° in the upper thermogram. The covered and crimped samples did not show any apparent crystallization from melt, probably because of the reduced thermal gradient within the sample.

The thermogram of the crimped sample in Fig. 3 is qualitatively in agreement with the middle thermogram in Fig. 4, where a small portion of a compressed disk of Form II was heated in a covered pan. Correlation between the two thermograms indicates that the appearance of an endotherm at 97–98° (which could possibly correspond to another form that has not been isolated as individual crystals yet) was caused by the compression pressure used in preparing the disk or even in crimping the sample.

Form IV, when heated up to 120°, cooled either naturally or with liquid nitrogen, and then subjected to thermal analysis, showed an endothermic peak at 97–98° instead of the original melting peak at 105°. On the other hand, slow controlled cooling of the melt resulted in the regeneration of the original crystals, *i.e.*, Form IV. Grinding of the rapidly cooled mass, as judged from the thermal behavior of the ground material, induced transformation to the most stable form, IV. Also, water caused such polymorphic changes when the rapidly cooled mass was kept in contact with aqueous buffer solutions. Despite the recorded differences in the X-ray diffraction patterns of the solidified mass and Forms III and IV, judgment on the authenticity of these differences should be made with great care because of the influence of the preferred orientations of the crystals in the solidified mass.

In a recent report concerning a nonclassical dissolution behavior of

phenylbutazone, Stella (10) noted the existence of three crystalline phases of the compound. Melting points of 86, 96, and 106° were the only information provided about the polymorphs. The reported melting point of 96° is close to the melting point of 97–98° obtained for the rapidly cooled mass. So far, attempts to obtain phenylbutazone as individual

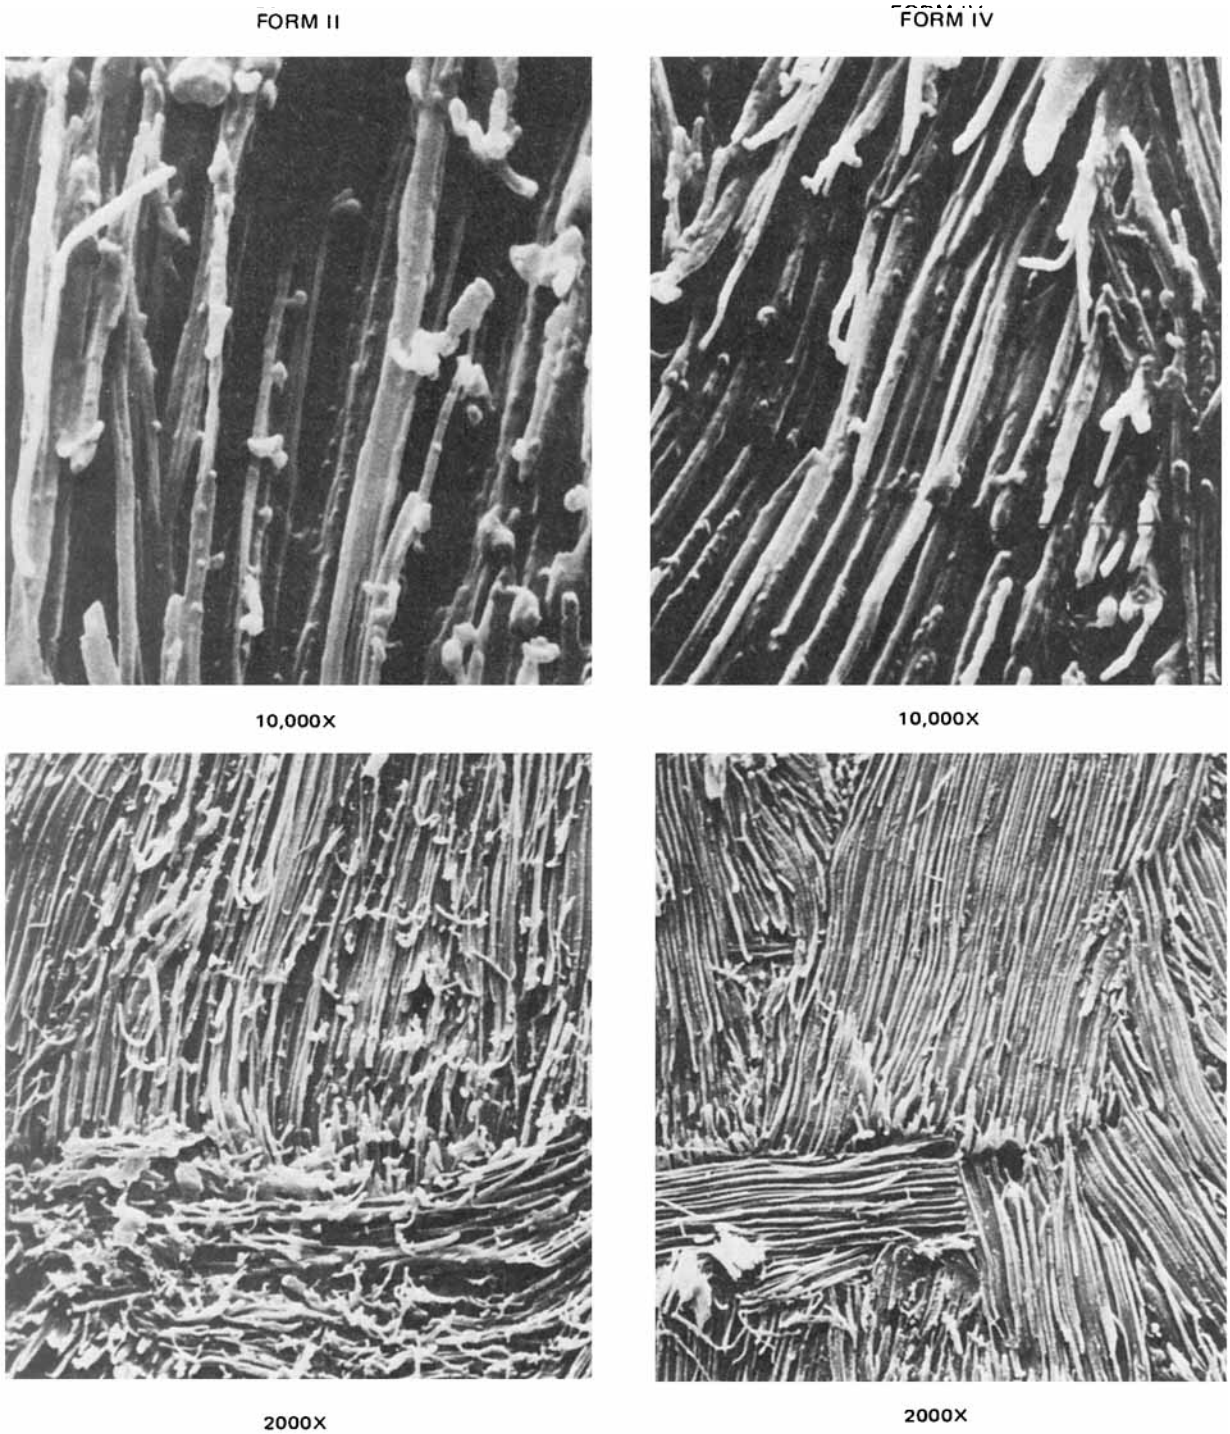

Figure 7—*Scanning electron photomicrographs of compressed disks of Forms II and IV.*

crystals with melting and spectral characteristics similar to those of the rapidly cooled mass, *e.g.*, by crystallization, have failed.

Similarly, Form I exhibited various transitions when heated under different conditions of sample treatment (Table I). Apparently, Form I is not as sensitive to crimping pressure as is Form II; however, heating of Form I in a covered pan induced solid–solid transformation to Form II.

Figure 4 shows thermograms obtained by heating a small portion of disks of Forms I–III, previously prepared by compacting approximately 100 mg of the crystals in an 8-mm die at 1590–2040 kg. Form III, during compression, was transformed to the most stable modification, Form IV. Forms I and II gave thermodynamically unstable phases, *i.e.*, Form II and a polymorphic species melting at 97–98°, respectively. Grinding of Forms I–III in a mortar induced polymorphic changes analogous to those observed when the respective crystal forms were compressed into disks. While compression of Form II into a disk consistently produced a polymorphic species melting at 97–98°, mortar grinding sometimes resulted in Form IV instead.

In view of the observed results, it is likely that similar effects on the crystals were produced by the shear stresses dominating in the mortar assembly and the shear stresses operative during compression and decompression of the disks. The notion of an active ingredient undergoing polymorphic changes during compression was discussed previously (11, 12). The variation and apparent increase in the dissolution rate of unlubricated sulfathiazole disks with pressure, as reported by Milosovich (13), were interpreted by Nogami *et al.* (14) to be caused by a change in the crystalline form. The effects of such polymorphic transformations on the dissolution rates as determined from compressed disks as well as from tablets containing transformation-labile ingredients are important to recognize. In fact, the determined dissolution rates vary depending

Table I—Phase Transitions in Form I when Heated under Different Conditions of Sample Treatment

Covered pan	80°, 90°	—
Crimped sample	80°	—

on the type and proportions of the polymorphic species produced during compact preparation. This variation might affect drug bioavailability in an unpredictable and undesirable manner.

The dissolution profiles of the four crystal modifications (Fig. 5) show differences in solubilities and physical stabilities of the various forms in the aqueous medium. The apparent equilibrium solubilities (Table II) correspond in value to the peak solubilities as determined from the dissolution profiles. Form I gave the highest solubility in the aqueous buffer solution and was the fastest to achieve the degree of supersaturation necessary for the nucleation process. Apparent slower nucleation and crystal growth processes were associated with Form III compared to Forms I and II (Fig. 5). Since the degree of supersaturation achieved in a system containing Form III was much less than that in a system containing Form I or II, a much smaller driving force for the crystal growth process existed. Transformation of Forms I–III to the most stable modification, Form IV, at the end of the dissolution experiment was confirmed by IR and thermal analysis.

Solubility measurements at different temperatures were used to obtain information concerning enthalpy and entropy of transition from Form I to Form IV. The thermodynamic background of the relationship between polymorphism and solubility was extensively reviewed (15). A straight-line relationship between the logarithm of the solubility ratio of the two forms and the reciprocal of the absolute temperature was obtained, and the extrapolation of the line to a solubility ratio of unity corresponded to a transition temperature of 74.1°. The calculated enthalpy and entropy of transition were −1613 cal/mole and −4.6 eu, respectively. The observed entropy difference between phenylbutazone Forms I and IV suggests differences in the molecular association in the crystalline lattice of the two forms.

A comparison between the dissolution rates of the different crystal modifications is shown in Fig. 6. Because of the crystal changes that took place during the compression of Forms I–III into disks, the respective dissolution rates of the three forms are apparent rather than intrinsic dissolution rates. Unexpectedly, the dissolution rate of Form II was consistently lower than that of the most stable modification, IV. This low dissolution behavior persisted even for compressed disks prepared from 50% mixtures of II and IV and of II and I. The slopes of the concentration–time curves for the dissolution of such disks were of intermediate values between those of II and IV.

If a transport-controlled dissolution from the disk surface is assumed, the dissolution curves in Fig. 6 should adhere to the Noyes–Whitney equation and, in the initial stages of dissolution, the relationship between concentration in solution and time could be given by:

$$\frac{dC}{dt} = \frac{D}{Vh} AC_s \qquad \text{(Eq. 1)}$$

where D is the diffusion coefficient, h is the thickness of the diffusion layer, A is the surface area, and C_s is the saturated solubility of the crystalline solid in the medium. The volume of the dissolution medium, V, was kept constant by using 500 ml of the medium in each experiment. The four polymorphs should have the same values of D and h irrespective of the crystal form, and the increase in the slopes of the straight lines in Fig. 6 should follow the order reflected in their saturated solubilities. The latter holds true only when the area exposed to dissolution is the same for the four polymorphs. In view of the obtained results, it is likely that the physical characteristics of phenylbutazone Form II crystals are such that, upon compression, they produce disks with a smaller effective surface area compared to those of Form IV, even though the same conditions are maintained carefully during compression.

Table II—Differential Scanning Transition Temperatures and Peak Solubilities of the Different Polymorphs

Form	Solvent of Crystallization	Transition Temperature	Peak Solubility[a], mg/100 ml
I	Isobutyl alcohol	80°	288.7
II	Cyclohexane	90°	279.9
III	*n*-Heptane	93°	233.6
IV	2-Propanol–water	105°	213.0

[a] Solubility in phosphate buffer, pH 6.95, at 36°.

A qualitative assessment of the surfaces of compressed disks of Forms II and IV was sought through the use of the scanning electron microscope. Photomicrographs (Fig. 7) indicate differences in the surface characteristics of the disks. Also, it can be inferred from the pictures that the extent of corrugation per unit area of the surfaces differed. Although it is too difficult to describe differences in surface area in a quantitative manner, these differences reflect that crystals of different forms behave differently under compression. This fact could, at least in part, account for the observed anomaly in the dissolution rates of compressed disks of Form II compared to Form IV.

Antipyretic Testing of Commercial Aspirin Formulations in Rats

J. J. LOUX *x, P. D. DePALMA *, R. Z. EBY ‡, and S. L. YANKELL *§

Abstract □ Four commercial aspirin formulations and aspirin powder USP were assayed in yeast-fevered rats for antipyretic activity. Tablets allowed to disintegrate spontaneously prior to dosing yielded aggregates of various sizes which failed to produce uniform patterns of antipyresis. When tested at smaller, more uniform particle sizes of total product, consistent, statistically significant antipyresis was observed with no significant variation among formulations. The ED_{50} values and parallel line assays were homogeneous.

Keyphrases □ Aspirin—four commercial formulations evaluated for antipyretic activity, compared to powder, effect of particle size, rats □ Antipyretic activity—aspirin, four commercial formulations evaluated and compared to powder, effect of particle size, rats □ Particle size—effect on antipyretic activity of aspirin, four commercial formulations evaluated and compared to powder, rats

Previously, this laboratory reported a method for obtaining statistically significant antipyresis in yeast-fevered rats utilizing low doses of aspirin (1). Since the aspirin tested was the pure chemical (white, crystalline powder, USP), those results provided little information on the pharmacological effects of commercial formulations. Thus, experiments were conducted, utilizing the same basic methodology, in which several commercially available products were assayed for their comparative antipyretic activity. Since it was anticipated that differences in activity might be realized with the various products, an attempt also was made to determine what factor(s) might be responsible for such variances.

EXPERIMENTAL

Male albino Charles River rats, 200–250 g, were used. Fever was induced by 20 ml/kg of a 20% aqueous suspension of brewer's yeast[1], which was injected subcutaneously in the back below the nape of the neck. The animals were then fasted for the duration of the experiment (approximately 24 hr). Water was available *ad libitum*.

Temperatures[2] were taken with a lubricated[3] thermistor probe[4] inserted approximately 4 cm into the rectum for 45 sec. Rectal temperatures were taken 24 hr after the yeast injection to determine the pyretic response to yeast. This response ranged between 1.25 and 2.0° above the normal nonfevered control value of 36.40°. No marked variability was encountered. These temperatures, taken 24 hr after yeast administration and 30 min prior to drug administration on fevered animals, served as the predrug controls.

Study 1—Eight animals were used per dose for each compound studied, with eight animals serving as controls. The following were tested: Formulation 1, an aspirin tablet[5]; Formulation 2, a generic aspirin tablet[6]; Formulation 3, a buffered aspirin tablet[7]; Formulation 4, an effervescent aspirin tablet[8]; and Formulation 5, aspirin powder USP[9] as the positive control.

All preparations were tested at equal doses in terms of aspirin content, determined from the "Handbook of Non-Prescription Drugs" (2), label statements, and multiple weighings of groups of 10 tablets.

All preparations except the effervescent one were allowed to disintegrate spontaneously in 0.5% tragacanth; water was employed for the effervescent preparation. Disintegration was considered complete when the respective test preparations had fallen apart into small particles, usually in 5 min or less. After the stock bottles were manually shaken, a stirring bar[10] was added to each. The bottles remained on magnetic stirring plates throughout the animal dosing. Doses employed were 18.75, 37.50, 75, and 150 mg/kg po at a dose volume of 10 ml/kg. Control animals received 0.5% tragacanth at 10 ml/kg. Antipyretic activity was measured at 15, 30, 60, 120, 180, and 240 min after administration.

Study 2—The data from Study 1 indicated variable antipyretic activity among the test formulations. Thus, in this study the following variables were controlled carefully.

Differences in Aspirin Content, Tablet to Tablet—Groups of 10 tablets were ground, and an aliquot was taken of the resulting powder.

Particle Size—All preparations were further extensively ground to a uniform fine particle size in a mortar prior to suspension in the vehicle. With standard USP XVIII sieves (3), it was determined that all products assayed in Study 2, prior to suspension in a vehicle, had a particle-size composition of which 60% passed a 60-mesh, 20% passed an 80-mesh, and 20% passed a 100-mesh sieve.

Dilutions—All doses of a given formulation were prepared by serial dilutions of the respective formulation.

Pyretic Response—The pyretic response to yeast injections was controlled by not using any animal that did not demonstrate a minimum 1.5° elevation in rectal temperature.

Experimenters—The entire study was performed by the same experimenter to eliminate any variability between technical personnel.

The time action study in Study 1 showed that the peak antipyretic activity of aspirin occurred between 1 and 2 hr. The tight, within-group variability in Study 2 along with the steep slope seen in a preliminary dose range study suggested that only four animals per dose were needed. This modification was introduced based on complete statistical analysis of the data. Previous unreported work in this laboratory has repeatedly demonstrated that control yeast responding animals maintain a long pyretic response (up to 4 or 5 hr).

Each of the five preparations was tested at the following doses in terms of aspirin content: 18.75, 37.50, 75, and 150 mg/kg po. Two animals were tested at each dose of each preparation on 2 consecutive days. Thus, any day-to-day variability effect was balanced over all preparations to yield unbiased comparisons. The antipyretic activity assay was measured at 60 and 120 min.

The data were analyzed for the presence of statistically significant antipyretic activity, and ED_{50} values with 95% confidence limits were calculated by paired analysis (4). The ED_{50} refers to the dose of test compound (milligrams per kilogram) that reduced the rectal temperature in treated fevered rats to 50% of the response observed in the fevered nontreated control groups. "Significant antipyretic activity" indicates statistical significance at p values of <0.05. Parallel-line bioassay was performed to test deviation from linearity and parallelism (5).

RESULTS

Study 1—The data from Study 1 indicated that all compounds tested produced effective antipyresis for the duration of the study (4 hr). The time to peak effect was between 2 and 3 hr. Controls did not vary significantly over the 4-hr test period.

Since all preparations were tested at equivalent doses of aspirin, an attempt was made statistically to prepare comparative dose–response

Controls	—	37.85°	0.13°	0.05°	0.04°	0.06°	0.16°	0.15°

curves. However, significant variations were present that precluded fitting linear and parallel lines to the data. As an alternative, the 1- and 2-hr postdrug responses to the highest dose tested were compared and ranked according to effectiveness. This approach showed that Formulation 5 was the most effective, closely followed by Formulation 1. These agents did not differ from each other. The remaining formulations were statistically less effective, with Formulation 2 better than Formulation 3. Formulation 4 was the least effective. Table I presents the mean antipyretic responses for each dose of the five test formulations at each time period.

Study 2—The mean antipyretic responses for each dose of the five test formulations at each time period are presented in Table II. The ED_{50} values with 95% confidence limits are presented in Table III for both the 2- and 3-hr data. Statistically significant antipyresis was observed for all formulations. The ED_{50} values ranged between 17.2 and 22.7 mg/kg. All responses were linear and parallel. No significant variation was observed between any two formulations. The statistical evaluation of the 2-hr data is presented in Table IV.

The test of validity showed that deviations from parallelism and from linearity were not significant. Thus, relative potencies and 95% confidence limits were calculated. The relative potencies were very near 1.0 (*i.e.*, equality) with 95% confidence limits that bracket 1.0. There was no significant difference in potency between any of these preparations.

DISCUSSION

The initial study (1) described the criteria for significant antipyresis; *i.e.*, the test substance must reduce the pyretic response induced by yeast to 50% of the value obtained for the controls. The pyretic control value in this study was 1.86° above the value before yeast administration, which indicated a satisfactory response to the pyretic agent. All test formulations allowed to disintegrate spontaneously prior to testing exhibited effective antipyretic responses (Table I). However, the study indicated wide variability; some preparations exhibited poor activity at doses as high as 75 mg/kg while another demonstrated good activity at half that dose.

Examination of these data for the time course of activity also demonstrated variability in that one preparation effected favorable activity at 30 min with 75 mg/kg whereas another preparation required 120 min to exhibit similar activity at the same dose. Since it had previously been determined that the ED_{50} for aspirin was 10.3 (1.8–23) mg/kg, the lack of significant antipyresis at doses up to 75 mg/kg in this portion of the study was questioned. However, these results were not entirely unexpected. Apparently, one may not assume that equal doses of the same compounds (in terms of active ingredient) will produce the same degree of pharmacological effect. The results clearly indicate that the behavior of several commercial preparations of aspirin was variable when tested under similar experimental conditions.

Some factors contributing to the variability in drug response include nonuniformity of dose among the test preparations (6), disintegration

Table III—ED_{50} and Relative Potency of Test Formulations

Formulation	ED_{50} (95% Confidence Limits), mg/kg	Relative Potency (95% Confidence Limits)

and dissolution characteristics of the various preparations (7), additives that alter the absorptive processes in the GI tract (8), particle size (9, 10), fasted *versus* nonfasted subjects (7), and normal *versus* febrile (disease) states (11). In these studies, nonuniformity of dose was controlled by testing all preparations at equivalent aspirin doses. The disintegration parameter was controlled by allowing complete disintegration of tablets prior to dosing the animal. Since it has been pointed out that the amounts of buffering agents contained in analgesic products are probably insufficient in quantity to affect drug action or gastric pH (8, 12), this parameter was considered insignificant. Finally, all animals were fasted and febrile. However, one parameter was not controlled: particle size.

The particle size of a drug influences dissolution or disintegration rates of tablets (9) and absorption from the GI tract (10, 13). Study 2 attempted, in part, to control particle size more closely. In this second study, in which testing parameters were more tightly controlled, the data obtained indicated statistically significant antipyresis for all test preparations, and no statistical or pharmacological differences could be determined among the various test preparations.

Relatively few reports have been published wherein an attempt was made to ascertain the variability of pharmacological response relative to controlled particle sizes. One report (11) detailed the variability of responses not only due to different particle sizes but also due to differences in dissolution rates and absorption rates, all of which are interdependent. An interesting factor was noted, *i.e.*, that the plasma concentration and time course activity of aspirin not only differs with the particle size of aspirin crystals but also differs between febrile and normal rabbits; febrile rabbits obtain faster, higher, and longer blood levels than the nonfevered controls.

Additionally, data reported (11) for the antipyretic activity of various aspirin preparations of different particle sizes in fevered rabbits correlate with the present data for fevered rats dosed with random particle-size aspirin. Itami *et al.* (11) concluded that the data supported the theory that as the particle size of aspirin decreases, antipyretic activity is more pronounced and more rapid in onset. Study 2 results also supported this theory, particularly at low dose levels where the antipyretic activity (Table II) was markedly different than the activity of the larger sized aggregates (Table I).

On the other hand, the favorable improvement in the physical properties of aspirin crystals may be reversed when subjected to the tableting process (9), a factor that also could compromise much of the pharmacological benefits derived from smaller crystal size. Thus, the recent suggestion (14) that aspirin tablets be crushed or chewed to a fine powder prior to being swallowed merits some attention.

Effect of Temperature and Relative Humidity on Nitrazepam Stability in Solid State

D. GENTON and U. W. KESSELRING ˣ

Abstract □ The decomposition of a 1% dilution of nitrazepam in microcrystalline cellulose was established by quantitative determination of the two main breakdown products, 2-amino-5-nitrobenzophenone and 3-amino-6-nitro-4-phenyl-2(1*H*)-quinolone, using *in situ* diffuse reflectance measurements on thin-layer chromatograms. The decomposition and formation rate constants of nitrazepam and of the breakdown products, respectively, were determined at four temperatures and six relative humidities. By means of a three-parameter regression equation, it was possible to correlate quantitatively the decomposition constant of nitrazepam to both temperature and relative humidity.

and dissolution characteristics of the various preparations (7), additives that alter the absorptive processes in the GI tract (8), particle size (9, 10), fasted *versus* nonfasted subjects (7), and normal *versus* febrile (disease) states (11). In these studies, nonuniformity of dose was controlled by testing all preparations at equivalent aspirin doses. The disintegration parameter was controlled by allowing complete disintegration of tablets prior to dosing the animal. Since it has been pointed out that the amounts of buffering agents contained in analgesic products are probably insufficient in quantity to affect drug action or gastric pH (8, 12), this parameter was considered insignificant. Finally, all animals were fasted and febrile. However, one parameter was not controlled: particle size.

The particle size of a drug influences dissolution or disintegration rates of tablets (9) and absorption from the GI tract (10, 13). Study 2 attempted, in part, to control particle size more closely. In this second study, in which testing parameters were more tightly controlled, the data obtained indicated statistically significant antipyresis for all test preparations, and no statistical or pharmacological differences could be determined among the various test preparations.

Relatively few reports have been published wherein an attempt was made to ascertain the variability of pharmacological response relative to controlled particle sizes. One report (11) detailed the variability of responses not only due to different particle sizes but also due to differences in dissolution rates and absorption rates, all of which are interdependent. An interesting factor was noted, *i.e.*, that the plasma concentration and time course activity of aspirin not only differs with the particle size of aspirin crystals but also differs between febrile and normal rabbits; febrile rabbits obtain faster, higher, and longer blood levels than the nonfevered controls.

Additionally, data reported (11) for the antipyretic activity of various aspirin preparations of different particle sizes in fevered rabbits correlate with the present data for fevered rats dosed with random particle-size aspirin. Itami *et al.* (11) concluded that the data supported the theory that as the particle size of aspirin decreases, antipyretic activity is more pronounced and more rapid in onset. Study 2 results also supported this theory, particularly at low dose levels where the antipyretic activity (Table II) was markedly different than the activity of the larger sized aggregates (Table I).

On the other hand, the favorable improvement in the physical properties of aspirin crystals may be reversed when subjected to the tableting process (9), a factor that also could compromise much of the pharmacological benefits derived from smaller crystal size. Thus, the recent suggestion (14) that aspirin tablets be crushed or chewed to a fine powder prior to being swallowed merits some attention.

The corresponding standard deviations are ±0.6, ±0.1, ±1.4, and ±1.3° for 42.5, 55.0, 73.8, and 83.4°, respectively. [b] Precision was better than ±2% using a SINAequiHygroscope type eZFBA-PP, Sina AG, Zurich, Switzerland.

the separate and combined influences of temperature and humidity on the decomposition of a 1% dilution of nitrazepam in microcrystalline cellulose.

EXPERIMENTAL

Compounds—Nitrazepam[1] (1,3-dihydro-7-nitro-5-phenyl-2*H*-1,4-benzodiazepin-2-one) (I), 2-amino-5-nitrobenzophenone[1] (II), 3-amino-6-nitro-4-phenyl-2(1*H*)-quinolone[1] (III), and microcrystalline cellulose[2] were used as received. All reagents were of analytical grade or Pharm. Helv. VI quality.

Sample Storage Conditions—Individual samples of about 300 mg of microcrystalline cellulose containing 1.00% nitrazepam were stored as described previously (3) at relative humidities of about 30, 40, 50, 60, 70, and 80% (4) and at around 40, 55, 70, and 85° (Table I).

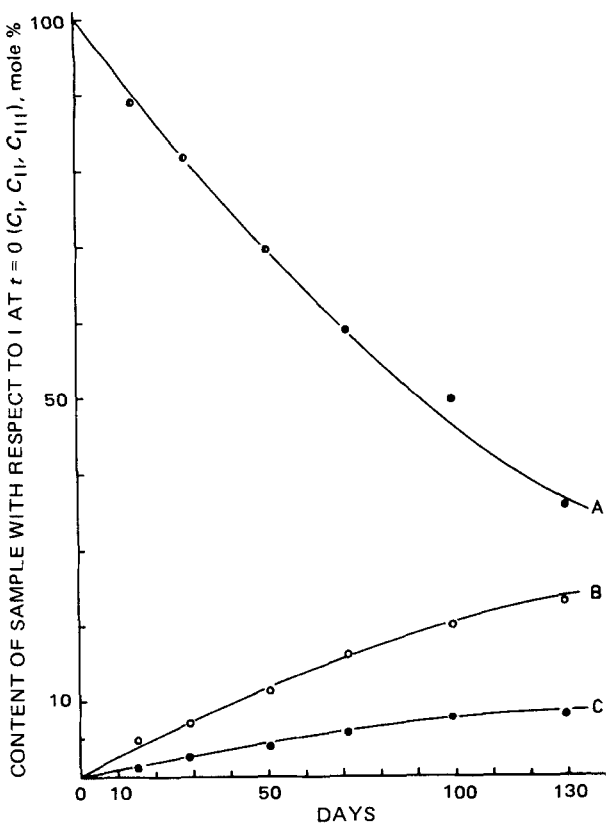

Figure 1—*Nitrazepam stability at 38.1% relative humidity and 83.4°. Key: A, decomposition of I; B, formation of II; and C, formation of III.*

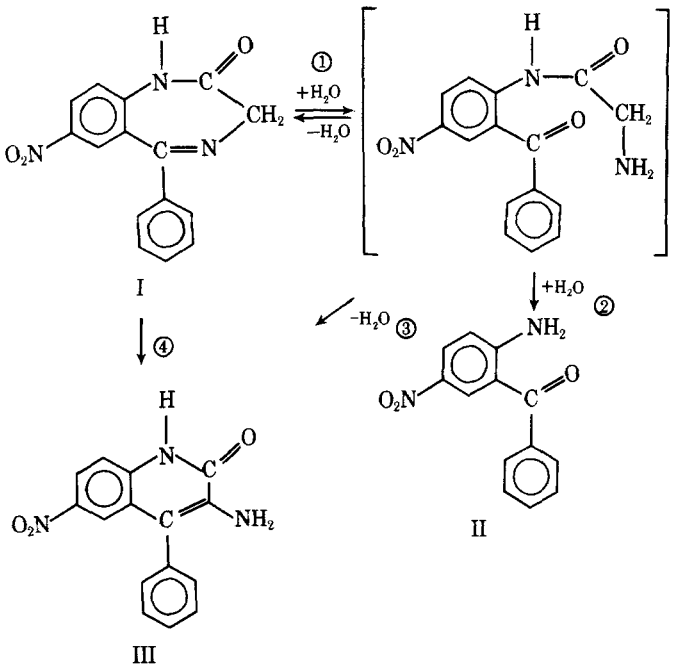
[1] F. Hoffmann–La Roche & Co. SA., Basel, Switzerland.
[2] Avicel PH-101, Interchemie, Zurich, Switzerland.



Scheme I

Quantitative Analysis—The quantitative analysis consisted essentially of extraction of I–III with methanol, their separation by TLC, and their quantitative determination by *in situ* diffuse reflectance measurements.

Extraction—Methanol, 3.00 ml, was added to the sample and vigorously shaken for 10 min. After the microcrystalline cellulose formed a deposit, the liquid layer was collected and centrifuged for 5 min. The clear solution, transferred to a hermetically sealable test tube, constituted the sample solution and eventually was diluted for quantitative determination, depending on the degree of decomposition.

Separation by TLC—The stationary phase was 0.40-mm kieselgel GF_{254}[3]-coated plates, dried for 12 hr at room temperature and activated just before use at 105° for 10 min. The mobile phase was benzene–ethyl acetate–acetic acid (60:36:4). The chamber saturation time was 1 hr, and the development time was 1 hr for the whole plate (about 18 cm).

Standard solutions, which were stable for about 6 months if stored away from light and at 4°, were at concentrations of 0.04–0.26, 0.02–0.10, and 0.02–0.10 mg/ml in methanol for I, II, and III, respectively.

One plate was used for the assay of each substance. With a precision syringe, seven spots (five standards and two samples) of 5 μl, one every 2.5 cm, were applied in increasing order of standard concentration with the samples placed third and fifth. The developed chromatograms were dried for 40 min in a cold air stream. The spots were located by visualizing with UV light at 254 nm.

Quantitative Evaluation—The spots were quantitatively evaluated by diffuse reflectance measurements[4] at 265, 365, and 295 nm for I, II, and III, respectively. The instrument conditions were: diaphragm opening, 12 mm; amplification, 10/10/I/A; scanning speed of the chromatogram, 3 cm/min; and chart flow (log scale), 10 cm/min. The peak surfaces, determined by direct integration[5], were linearly related to concentration in the ranges of 0–1.3 μg for I and 0–0.5 μg for II and III.

Kinetics (5)—The following decomposition scheme, reported previously (6–8) and confirmed by this work, shows the main decomposition routes of nitrazepam in the solid state under the influence of temperature and humidity (Scheme I). The bimolecular reactions 1 and 2 are acid–base catalyzed and depend on the amount of water available. The main decomposition product is II in aqueous solution and III in the solid state, with the II–III ratio depending on the availability of water (6). For low water concentrations, reactions 2 and 3 are competitive with preferential formation, especially in the solid state, of the quinolone derivative. The isomerization reaction 4 occurs only around and above the fusion temperature.

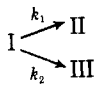
[a] y_0 = y-intercept (*cf.*, Eq. 4); theoretically zero. [b] r^2 = coefficient of determination. [c] y_0 = y-intercept (*cf.*, Eq. 5); theoretically zero.

Nitrazepam (I) decomposes in two pseudo-first-order parallel reactions to II and III according to Scheme II:



Scheme II

and:

$$C_I = C_{I_0}e^{-Kt} \quad \text{(Eq. 1)}$$

$$\log C_I = 0.4343Kt + \log C_{I_0} \quad \text{(Eq. 2)}$$

$$K = k_1 + k_2 \quad \text{(Eq. 3)}$$

$$C_{II} = \frac{k_1}{K} C_{I_0}(1 - e^{-Kt}) \quad \text{(Eq. 4)}$$

$$C_{III} = \frac{k_2}{K} C_{I_0}(1 - e^{-Kt}) \quad \text{(Eq. 5)}$$

where k_1 = formation constant of II, k_2 = formation constant of III, K = decomposition constant of I, C = mole percent content of the sample with respect to I at time t, and C_{I_0} = mole content of I at time t = 0 (=100%).

The value of K is obtained from the slope of the regression line calculated through Eq. 2. The obtained K values are used in Eqs. 4 and 5, whose corresponding regression lines reveal k_1 and k_2.

[a] n = number of experimental points. [b] r^2 = coefficient of determination.

RESULTS

Substances II and III are the only important decomposition products of I; both have to be followed to establish the decomposition kinetics of I (Figs. 1 and 2). Substances II and III were considered stable, although a few unidentified compounds (seemingly breakdown products of II and III) were observed in samples stored at 73.8 and 83.4° and high humidities. The appearance of these unidentified products was automatically detected on the chromatograms and helped establish the time limits for the system for the calculation of rate constants.

At 83.4°, the instability of II and III was such that only the disappearance constant K could be calculated (Tables II and III). For temperatures up to 83.4° and relative humidities up to 70%, the rate constants

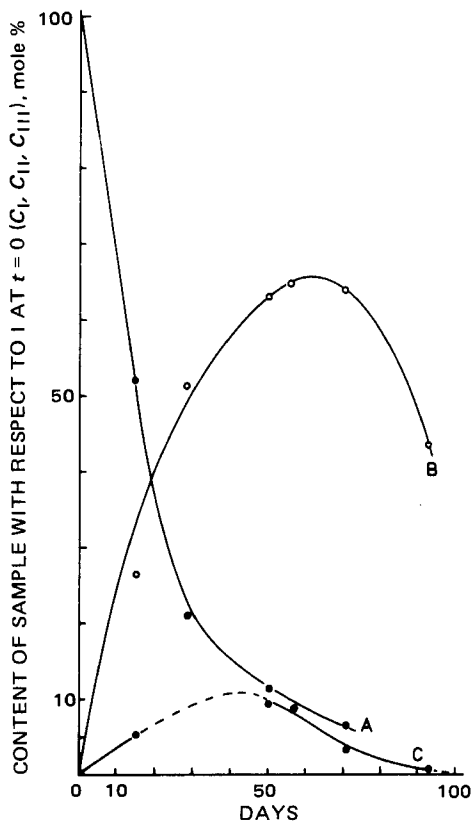

Figure 2—*Nitrazepam stability at 83.8% relative humidity and 83.4°. Key: A, decomposition of I; B, formation and decomposition of II; and C, formation and decomposition of III.*

Table IV—Regression Line Parameters for Logarithm $K \times 10^5$ as a Function of Relative Humidity

Temperature	42.5°	55.0°	73.8°	83.4°
Slope	0.03838	0.03718	0.04052	0.02492
Confidence interval, $p = 0.05$	0.00393	0.00960	0.00749	0.00348
y-Intercept	−1.0437	−0.5316	0.08549	1.9849
Confidence interval, $p = 0.05$	0.2141	0.5193	0.3917	0.1819
Coefficient of determination	0.988	0.980	0.990	0.994

followed an exponential pattern proportional to relative humidity. At 80% relative humidity, they diminished significantly. At about 75% relative humidity, an instability maximum was apparent at all temperatures (Fig. 3).

The parameters defining the regression equations relating log K, for a given temperature, to relative humidities are summarized in Table IV.

The slope values, discarding the result for 83.4°, were all within the confidence interval of each other. Therefore, if the straight lines are considered to be parallel with a slope equal to the mean value of the observed slopes at the three temperatures, then:

$$\log K \times 10^5 = 0.03869\% \text{ relative humidity} + A \qquad \text{(Eq. 6)}$$

where A represents a constant depending on temperature. Its values are obtained by putting the mean $\bar{x}, \bar{y}$ values of the regression lines for 42.5, 55.0, and 73.8° in Eq. 6. This approach yields $A = -1.0602$, -0.6105, and 0.1785 for the three temperatures, respectively. Treating the variation of A as a linear function of the reciprocal temperature, one obtains an Arrhenius-like relationship:

$$A = -4.3576 \times 10^3 \frac{1}{T} + 12.7207 \qquad \text{(Eq. 7)}$$

If Eqs. 6 and 7 represent truly straight lines, the decomposition constants of nitrazepam must be linearly related to both relative humidity and the reciprocal absolute temperature, in which case one might as well calculate directly the equation of the corresponding regression plane:

$$X_1 = a + bX_2 + cX_3 \qquad \text{(Eq. 8)}$$

where $X_1 = \log K \times 10^5$, $X_2 = 10^3\ T^{-1}$ (K), X_3 = relative humidity (percent), a = constant depending on the system, b = partial regression coefficient of log K on T^{-1} (relative humidity = constant), and c = partial regression coefficient of log K on relative humidity (T = constant).

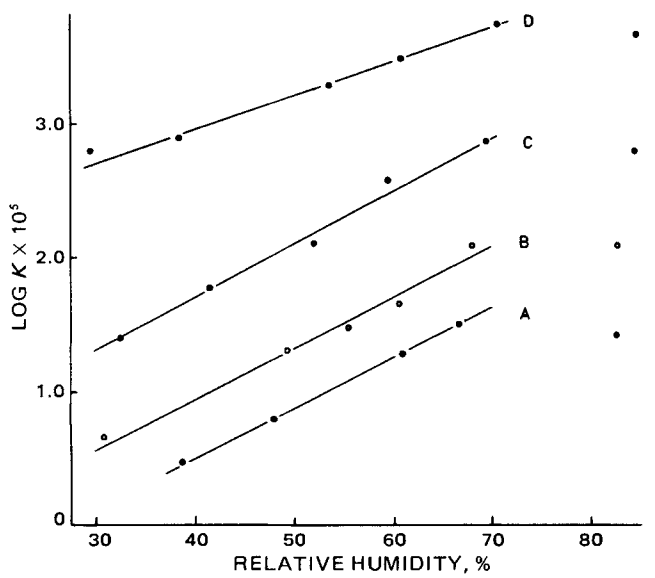

Figure 3—*Logarithm of the nitrazepam decomposition constant,* K, *as a function of relative humidity at various temperatures. Key: A, 42.5°; B, 55.0°; C, 73.8°; and D, 83.4°.*

Table V—Values of $t_{0.9}$ for Various Climatic Conditions

Climatic Condition	log $K \times 10^5$	$K \times 10^5$	$t_{0.9}$, years
North of Europe 18°; 50% relative humidity	−0.331	0.46	62.8
Central Europe 20°; 65% relative humidity	0.353	2.25	12.9
Tropical climate 30°; 70% relative humidity	1.040	11.0	2.7

The coefficients a, b, and c are found by solving the following system of equations (9):

$$\sum X_1 = aN + b\sum X_2 + c\sum X_3 \qquad \text{(Eq. 9)}$$

$$\sum X_1X_2 = a\sum X_2 + b\sum X_2^2 + c\sum X_2X_3 \qquad \text{(Eq. 10)}$$

$$\sum X_1X_3 = a\sum X_3 + b\sum X_2X_3 + c\sum X_3^2 \qquad \text{(Eq. 11)}$$

where N represents the number of storage conditions defined by temperature and relative humidity. Thus, the final result is obtained for all storage conditions where $T < 75°$ and relative humidity <80% (N = 14):

$$X_1 = 12.783 - 4.3804X_2 + 0.03877X_3 \qquad \text{(Eq. 12)}$$

or:

$$\log K \times 10^5 = 12.783 - 4.3804 \times 10^3T^{-1} + 0.03877\ (\%\text{ relative humidity}) \qquad \text{(Eq. 13)}$$

with a regression coefficient of $R_{1.23} = 0.995$. Figure 4 represents the plane corresponding to Eq. 13. Extrapolation with respect to T and interpolation with respect to relative humidity of the plane regression equation yields K for any other desired climatic condition. Therefore, the time interval $t_{0.9}$, after which only 90% of the initial nitrazepam concentration is left, may be calculated (Table V).

DISCUSSION

The presented results do not suggest adherence to any published model. In particular, the rate of disappearance of nitrazepam in a 1% dilution in microcrystalline cellulose apparently does not follow a sigmoid decomposition pattern like aspirin (10), and it does not reach an equilibrium level like thiamine hydrochloride in microcrystalline cellulose (11). Although this latter compound displays an instability maximum at a water content of about 5%, no comparison can be made with the instability maximum shown for the nitrazepam system at 75% relative humidity; no relationship between water content and relative humidity has yet been established, and thiamine hydrochloride is water soluble

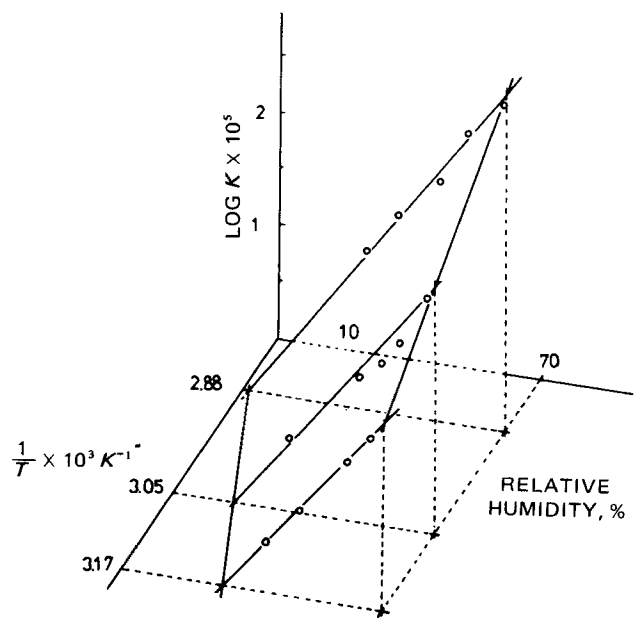

Figure 4—*Variation of log* K *as a function of relative humidity and reciprocal temperature.*

but nitrazepam is not. Kinetically limiting factors could be different in the two systems.

Nevertheless, there is now enough evidence to conclude that the rate of decomposition of pure and compound drugs in the solid state may be influenced as much by water as by temperature and that it is possible to relate the decomposition constants simply and simultaneously to temperature and to a term reflecting the influence of water. Relative humidity seems to be a good way to deal with this problem; combined with temperature, it can characterize climatic conditions and allows establishment of the corresponding $t_{0.9}$ values directly from experimental results.

GI Drug Absorption in Rats Exposed to Cobalt-60 γ-Radiation III: *In Situ* Intestinal Absorption

MICHAEL E. BRADY [*] and WILLIAM L. HAYTON [x]

Abstract □ The absorption rate of sulfanilamide, bretylium tosylate, sulfisoxazole acetyl, and riboflavin from the *in situ* small intestine was studied in rats exposed to 850 rad of cobalt-60 γ-radiation. Compared to absorption from the intestine of sham-irradiated animals, the absorption rate of sulfanilamide declined following irradiation. It declined to a minimum that was 65% of the control value at 4 days postirradiation before it began to return toward the control value. The reduced absorption rate of sulfanilamide in irradiated animals was accompanied by, and appeared to result from, a reduction in the absorption rate of water from the intestinal drug solution. The sulfisoxazole acetyl absorption rate was reduced compared to the control rate at both 1 and 5 days postirradiation. While this reduced absorption rate at 5 days postirradiation may have resulted from a reduced absorption rate of water, postirradiation water absorption rates at 1 day were similar in irradiated and control animals. The absorption rates of bretylium and riboflavin were not affected by exposure of animals to radiation 1 or 5 days previously. The permeability of the small intestinal epithelium to the drugs studied appeared to be reduced slightly following its exposure to ionizing radiation. The reduced permeability is apparently an indirect effect of the reduced absorption rate of water.

Keyphrases □ Absorption, GI—sulfanilamide, bretylium tosylate, sulfisoxazole acetyl, and riboflavin, effect of γ-radiation on rate, rats □ Radiation, gamma—effect on rate of GI absorption of sulfanilamide, bretylium tosylate, sulfisoxazole acetyl, and riboflavin, rats □ Sulfanilamide—GI absorption, effect of γ-radiation on rate, rats □ Bretylium tosylate—GI absorption, effect of γ-radiation on rate, rats □ Sulfisoxazole acetyl—GI absorption, effect of γ-radiation on rate, rats □ Riboflavin—GI absorption, effect of γ-radiation on rate, rats

The bioavailability of drugs administered orally was altered in rats exposed to 850 rad of γ-radiation (1, 2). The alterations in bioavailability in irradiated animals compared to controls appeared to result primarily from a pronounced reduction in the gastric emptying rate. The effects of irradiation on bioavailability depended upon the physicochemical properties of the drug, the dosage form, and the time postirradiation at which the drug was administered.

While reduced gastric emptying appeared to be the principal mechanism by which irradiation of the gut altered bioavailability, damage resulting from irradiation of the intestine (3, 4) can also affect the absorption of orally administered drugs by alteration of the permeability of the intestinal epithelium. In irradiated rats, the apparent decrease in the absorption rate of sulfanilamide from the *in situ* intestine (5) and the altered permeability of the *in vitro* intestine to several drugs (6, 7) indicate that the permeability of the intestinal epithelium may be altered directly by its exposure to ionizing radiation. The purpose of this study was to explore further the effects of prior whole body exposure to 850 rad of γ-radiation on the apparent permeability of the *in situ* rat intestine to drugs.

EXPERIMENTAL

Materials—The chemicals and reagents used were described previously (1).

Intestinal Absorption Rate—Male Sprague–Dawley rats, 170–250 g, were either irradiated or sham-irradiated by a procedure described previously (1). At various times following irradiation, equal numbers of irradiated and sham-irradiated animals were fasted overnight, anesthetized with 1.3 g of ethyl carbamate/kg, and prepared surgically for the determination of the drug absorption rate from 7.0 ml of a solution instilled into the cannulated small intestine (8, 9). The drugs[1], at initial

[1] The following drugs were used: sulfisoxazole acetyl, Hoffmann–La Roche, Nutley, N.J.; bretylium tosylate, Burroughs Wellcome Co., Research Triangle Park, N.C.; 2-^{14}C-*d*-riboflavin, Amersham/Searle, Arlington Heights, Ill.; and sulfanilamide, Sigma Chemical Co., Irvington, N.Y.

but nitrazepam is not. Kinetically limiting factors could be different in the two systems.

Nevertheless, there is now enough evidence to conclude that the rate of decomposition of pure and compound drugs in the solid state may be influenced as much by water as by temperature and that it is possible to relate the decomposition constants simply and simultaneously to temperature and to a term reflecting the influence of water. Relative humidity seems to be a good way to deal with this problem; combined with temperature, it can characterize climatic conditions and allows establishment of the corresponding $t_{0.9}$ values directly from experimental results.

concentrations determined by assay sensitivity and drug solubility, were dissolved in 67 m*M* sodium phosphate buffer made isotonic with sodium chloride. The volume of the drug solution in the intestine was maintained at 7.0 ml by addition of 0.9% NaCl solution immediately prior to removal of each sample.

The rectal temperature of each animal was monitored[2] throughout the experiment and maintained at 37° by a rheostatically controlled heating pad. At the conclusion of each experiment, the following data were recorded: the volume of water absorbed[3], the pH of the intestinal drug solution, and the length of intestine perfused.

Absorption rate constants were estimated from the slopes of lines fitted by least squares to plots of the logarithm of drug concentration in the intestinal drug solution *versus* time. Each rate constant was corrected for the loss of drug due to sampling[4], and absorption half-lives were calculated from the corrected value of the rate constant.

Analytical Methods—To separate sulfisoxazole acetyl from sulfisoxazole present due to hydrolysis, samples of intestinal perfusate were made alkaline by addition of 0.6 *M* pH 8.0 sodium phosphate solution and extracted with chloroform. Sulfisoxazole acetyl in the chloroform layer was determined by spectrophotometry[5] at 278 nm. Methods for the determination of the other drugs and radioactivity were described previously (1). Tonicity (osmolality) was measured by dew point depression using an osmometer[6].

RESULTS AND DISCUSSION

A preliminary study showed that the absorption rate of sulfanilamide from the *in situ* rat intestine decreased to a minimum at 4–5 days following exposure of the animals to 850 rad of γ-radiation (Fig. 1). Therefore, additional experiments were performed at 4 days postirradiation (5), and the results showed a statistically significant decrease in the rate of sulfanilamide absorption in irradiated animals compared to controls (Table I). The reduced absorption rate could not be attributed to differences in the length of the intestine perfused nor to differences in the intestinal perfusate pH (Table I). The decrease in the apparent permeability of the intestinal mucosa to sulfanilamide at 4 days postirradiation did not affect significantly the overall *in vivo* rate or extent of absorption of sulfanilamide, since the slow step in its absorption tended to be gastric emptying (2).

The decreased rate of sulfanilamide absorption from the intestine of irradiated animals was accompanied by a similar decrease in the absorption rate of water from the intestine (Fig. 1 and Table I). The water absorption rate affects the rate of intestinal drug absorption directly due to a solvent drag effect (10–12). To examine the role of water absorption in the reduced rate of sulfanilamide absorption, the rate of water absorption from the *in situ* intestine was varied by altering the sodium chloride concentration in the intestinal perfusate (Table II). The ab-

sorption rate of sulfanilamide was significantly greater from a hypotonic than from a hypertonic perfusate (Fig. 2).

In nonirradiated animals, there was a linear relationship between the sulfanilamide absorption rate constant and the water absorption rate (Fig. 3). This relationship was similar to that reported for several other drugs (10–12). When the mean absorption rate constant of sulfanilamide in irradiated animals was plotted at the corresponding rate of water absorption, it was nearly on the line (Fig. 3). Thus, the reduction in the absorption rate constant of sulfanilamide in irradiated animals at 4 days postirradiation apparently resulted indirectly from a reduction in the water absorption rate and not from a direct alteration in the permeability of the intestinal mucosa to the drug. The possibility remains, however, that the rates of absorption of both water and sulfanilamide depend on a third factor affected by radiation.

Irradiation did not appear to alter the permeability of the intestinal epithelium to bretylium (Table I). No measurable absorption of bretylium occurred at 1 or 5 days postirradiation (Fig. 4). The initial relatively rapid decline in the fraction of bretylium remaining in the drug solution (Fig. 4) was possibly due to binding of the drug to the surface of the epithelial mucosa (13).

In a previous study (1), poor absorption of orally administered bretylium was demonstrated by low recovery of the drug in the urine of irradiated and sham-irradiated rats. The data reported here indicate that epithelial permeability is the rate-controlling step that limits both the rate and extent of drug absorption. In addition, this study indicates that the barrier properties of the intestinal epithelium to the transfer of positively charged compounds are not altered by prior exposure of the intestine to radiation.

Sulfisoxazole acetyl, a highly lipid-soluble drug, disappeared rapidly

Tonicity, mOsm/kg	Absorption Rate Constant[b,c], min^{-1}	Volume of Water Absorbed[c,d], ml/hr	Gut Length[c], cm	Final pH of Drug Solution[c,e]
232	0.0497 ± 0.00299[f]	8.7 ± 1.4[f]	88.5 ± 4.80	6.6 ± 0.10
314 (Isotonic)	0.0410 ± 0.00518	3.2 ± 1.4	90.0 ± 6.30	6.3 ± 0.12
548	0.0258 ± 0.00236[f]	−3.5 ± 2.7[f]	88.5 ± 2.65	6.7 ± 0.08

[a] Initial concentration 60 μg/ml. [b] Corrected for loss of drug due to sampling. [c] Mean of four or more animals ± *SD*. [d] This volume is the difference between the volume of 0.9% NaCl solution added to maintain the volume of the drug solution constant and the volume of drug solution removed as samples. [e] Initial pH was 6.8, except for isotonic solutions where the pH was 6.5. [f] Significantly different ($p < 0.02$) from the isotonic value.

from the intestinal drug solution (Fig. 5). While the analytical method was specific for sulfisoxazole acetyl, deacetylation may have occurred simultaneously with absorption. When sulfisoxazole acetyl was incubated with intestinal epithelium, hydrolysis was accelerated compared to control studies in which the incubation medium did not contain intestinal epithelium (14). Thus, the rapid rate of disappearance of sulfisoxazole acetyl from the intestinal drug solution may reflect both rapid absorption and hydrolysis (15, 16).

Prior exposure of animals to 850 rad of γ-radiation reduced slightly, but significantly, the apparent absorption rate constant for sulfisoxazole acetyl at both 1 and 5 days (Table I). The reduction in the absorption rate of sulfisoxazole acetyl in irradiated animals was not due to a reduction in the length of intestine perfused nor to differences in the drug solution pH (Table I). Nor did a reduced rate of water absorption account entirely for the reduced rate of sulfisoxazole acetyl absorption in irradiated animals, since the water absorption rate at 1 day postirradiation was similar in irradiated and control animals (Table I).

Sulfisoxazole acetyl may penetrate the intestinal epithelium from solution so rapidly that blood flow to the intestine is the rate-controlling step in its absorption. Exposure to radiation reduced the rate of blood flow to the intestine of rats (17) and dogs (18) exposed 2–3 days previously. Absorption limited by blood flow was demonstrated for other rapidly absorbed drugs from the perfused *in situ* rat intestine (12, 19). The reduction in the sulfisoxazole acetyl absorption rate observed here was not clinically significant, since the intestinal absorption rate of the drug was still very high in irradiated animals.

Riboflavin disappeared slowly from the intestinal drug solution (Fig. 6). The absorption rate of the vitamin was not significantly different from that of the control at 1 or 5 days postirradiation (Table I). The initial rapid decline in the riboflavin concentration in the intestinal solution was similar to that observed for bretylium (Fig. 4) and may be attributed to binding of riboflavin to the intestinal mucosa rather than to absorption. In irradiated animals, the volume of water absorbed was lower than in sham-irradiated animals at 1 and 5 days postirradiation. The reduced rate of water absorption was not accompanied by a corresponding decrease in the rate of riboflavin absorption (Table I).

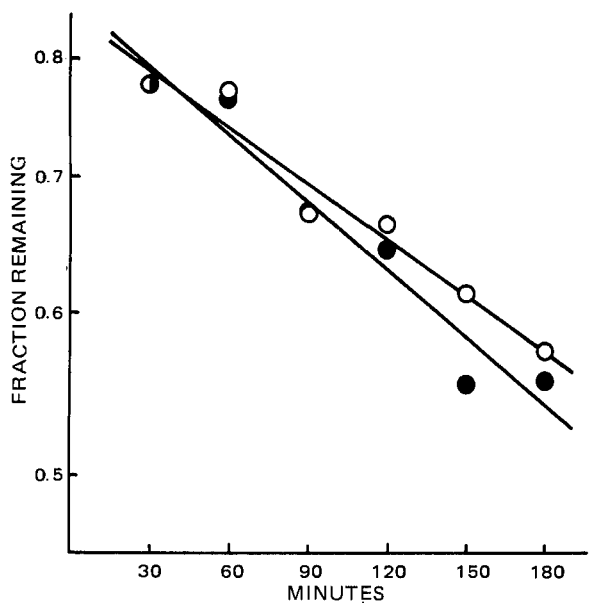

Figure 6—*Effect of 850 rad of γ-radiation on the absorption of riboflavin (initial concentration of 20 μg/ml) from the* in situ *rat intestine at 5 days postirradiation. Key: ●, irradiated; and ○, sham irradiated. Each point represents the mean of at least five animals.*

In general, prior irradiation of the small intestine tends to reduce its apparent permeability to drugs in an indirect manner by reducing the rate of water absorption by the intestine. In addition, the drug absorption rate may be reduced following irradiation due to a reduction in mesenteric blood flow, particularly for rapidly absorbed drugs. The magnitude of the observed radiation-induced reduction in the intestinal absorption rate was relatively small. If such a reduction in absorptive capacity occurred in humans following radiation therapy, it would not be clinically significant, although higher doses of radiation might have a more pronounced effect on intestinal drug absorption.

High-Performance Liquid Chromatographic Determination of Chlordiazepoxide and Major Related Impurities in Pharmaceuticals

A. G. BUTTERFIELD ˣ, F. F. MATSUI, S. J. SMITH, and R. W. SEARS

Abstract □ A rapid, precise, forward-phase (adsorption) high-performance liquid chromatographic procedure is presented for the determination of chlordiazepoxide and two common impurities, 7-chloro-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepin-2-one 4-oxide and 2-amino-5-chlorobenzophenone, in commercial formulations and for the determination of the benzophenone in the chlordiazepoxide drug substance. The method involves simultaneous quantitation of chlordiazepoxide and the 1,3-dihydro impurity, followed by quantitation of the benzophenone from a separate sample extract using a second mobile phase. A single microparticulate silica gel column is used throughout. Nitrazepam and *o*-dinitrobenzene are the internal standards. Quantitation is by peak area using a computing integrator, except that the peak due to the benzophenone is quantitated by peak height. The described procedure is of equivalent precision, but superior accuracy, to the BP 1973 spectrophotometric procedure for the analysis of chlordiazepoxide in chlordiazepoxide formulations. Quantitation of the 1,3-dihydro and the benzophenone impurities at levels as low as 6.3 and 0.9 ng, respectively, is demonstrated.

Keyphrases □ Chlordiazepoxide—and related impurities, high-performance liquid chromatographic analysis, commercial formulations □ High-performance liquid chromatographic analysis—chlordiazepoxide and related impurities, commercial formulations □ Tranquilizers—chlordiazepoxide and related impurities, high-performance liquid chromatographic analysis, commercial formulations

Pharmacopeial specifications for the tranquilizer chlordiazepoxide [7-chloro-2-(methylamino)-5-phenyl-3*H*-1,4-benzodiazepine 4-oxide] and its hydrochloride salt (I) include limit tests for the impurities 7-chloro-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepin-2-one 4-oxide (II) and 2-amino-5-chlorobenzophenone (III) (1–3). These specifications allow a maximum of 0.1% of II and 0.01% (1, 2) or 0.05% (3) of III in the chlordiazepoxide drug substance. Specifications for capsules containing the hydrochloride salt permit a maximum of 3.0 and 0.1% for II and III, respectively (1, 3); tablets prepared with chlordiazepoxide base may contain up to 4.0% of II and 0.1% of III (2).

Numerous procedures have been reported for the quantitation of chlordiazepoxide in pharmaceuticals and biological fluids (1–9). However, none of these methods describes the quantitation of all three compounds. Spectrophotometric methods, such as those described in the pharmacopeias (1–3), are not specific for I since II exhibits a similar absorption spectrum. GLC has been used to quantitate I (8), but attempts in this laboratory to develop a GLC analysis for I–III were unsuccessful because of poor peak shape, lack of separation of I and II, long analysis times, sample decomposition, and/or poor precision.

High-performance liquid chromatography (HPLC) has been used extensively for the analysis of drugs in pharmaceuticals (10–14), including the qualitative (15) and quantitative (16) analysis of benzodiazepines. Chlordiazepoxide, but not II or III, has been quantitatively analyzed by HPLC (17).

This report describes a rapid, two-part HPLC method for the analysis of I–III in chlordiazepoxide formulations and for the analysis of III in I drug substance.

EXPERIMENTAL

Materials—Chlordiazepoxide hydrochloride[1] [tested to conform to USP (1) specifications], nitrazepam[1], and *o*-dinitrobenzene[2] were used as received. Compound II was prepared by controlled alkaline hydrolysis of I, recrystallized from ethanol–hexane, and dried at 56° *in vacuo* (mp 231–234°). Purity was established chromatographically (TLC and HPLC) by comparison to USP reference standard material[3]. Compound III[2] was recrystallized twice from ethanol and dried *in vacuo* at 61° (mp 97–98°). Reagent grade tetrahydrofuran[4] was distilled from ferrous sulfate[4] and stored over molecular sieves[5] under nitrogen. All other solvents and reagents were analytical reagent grade, except *n*-hexane[6] which was UV grade.

Apparatus—A liquid chromatograph[7], fitted with a septumless injection port[7], a fixed wavelength UV detector[7] (254 nm), and a computing integrator[8], was used. The detector was attenuated to 0.04 absorbance unit full scale (aufs) throughout. The column (25 × 0.216 cm i.d.), packed with 5-μm diameter silica gel[9] using a balanced density slurry technique similar to that described by Majors (18), was operated at ambient temperature and a flow rate of 60 ml/hr.

Mobile Phases—For the quantitation of I and II, System A, 5% ammoniacal ethanol and 30% tetrahydrofuran in *n*-hexane, was used. Ammoniacal ethanol (10% v/v) was prepared from concentrated ammonium hydroxide and absolute ethanol.

For the quantitation of III, System B, 25% tetrahydrofuran in *n*-hexane, was used.

Mobile phases were prepared as required, degassed (reflux, 5 min), and stored in the solvent reservoirs of the instrument.

Stock Solutions—*Nitrazepam (IV) Internal Standard Solution*—Approximately 15 mg of IV, accurately weighed, was transferred to a 500-ml volumetric flask, dissolved, and brought to volume with ethyl acetate (final concentration of 30 μg/ml).

o-Dinitrobenzene (V) Internal Standard Solution—Approximately 25 mg of V, accurately weighed, was transferred to a 500-ml volumetric flask, dissolved in a minimum of ethanol, and brought to volume with *n*-hexane (final concentration of 50 μg/ml).

Standard Solution of I—Approximately 25 mg of I, accurately weighed, was transferred to a 100-ml volumetric flask, dissolved, and brought to volume with 0.1 *N* aqueous hydrochloric acid (final concentration of 250 μg/ml).

Standard Solution of II—Approximately 20 mg of II, accurately weighed, was transferred to a 200-ml volumetric flask, dissolved, and brought to volume with ethyl acetate (final concentration of 100 μg/ml).

Standard Solution of III—Approximately 20 mg of III, accurately weighed, was transferred to a 200-ml volumetric flask, dissolved, and brought to volume with *n*-hexane. Then 10.0 ml of this solution was transferred to a 50-ml volumetric flask and brought to volume with *n*-hexane (final concentration of 20 μg/ml).

All stock solutions and sample preparations were protected from light by wrapping the tubes or flasks with aluminum foil.

Standard Curves for I and II—Five standard solutions were prepared to contain between 200 and 400 μg of I/ml in 0.1 *N* aqueous hydrochloric acid. Similarly, five solutions were prepared to contain between 1.7 and 300 μg of II/ml in ethyl acetate. Ten milliliters of the highest concentration solution of I and 1.0 ml of the highest concentration solution of II were pipetted into a 30-ml screw-capped tube[10] along with 1.0 ml of concentrated ammonium hydroxide and 12.5 ml of IV internal standard solution. The other standard solutions were prepared in the corresponding manner. The five tubes were tumbled on a rotator[11] at 30 rpm for 30 min and then centrifuged[12] at 2000 rpm for 10 min. Duplicate 5-μl aliquots of the supernatant ethyl acetate layer were chromatographed using mobile phase System A.

Linearity Curve for III—Six solutions were prepared to contain between 1.0 and 35 μg of III/ml in *n*-hexane. Aliquots of 1.0 ml of each solution were pipetted into individual 5-ml volumetric flasks along with 3.0 ml of V internal standard solution. The solutions were diluted to volume with *n*-hexane, and duplicate 5-μl aliquots of each solution were chromatographed using mobile phase System B.

Daily Calibration Standards—For the determination of I and II, 10.0 ml of I standard solution, 1.0 ml of II standard solution, 1.0 ml of concentrated ammonium hydroxide, and 12.5 ml of IV internal standard solution were pipetted into a 30-ml screw-capped tube. The tube was tumbled at 30 rpm for 30 min and then centrifuged at 2000 rpm for 10 min. Duplicate 5-μl aliquots of the ethyl acetate layer were chromatographed using mobile phase System A.

For the determination of III, 15.0 ml of 0.1 *N* hydrochloric acid, 1.0 ml of III standard solution, and 3.0 ml of V internal standard solution were pipetted into a 30-ml screw-capped tube. The tube was tumbled at 30 rpm for 1 hr and then centrifuged at 2000 rpm for 10 min. Duplicate 5-μl aliquots of the *n*-hexane layer were chromatographed using mobile phase System B.

Analysis of Pharmaceuticals—*Determination of I and II*—Powdered tablet or capsule contents equivalent to 25 mg of chlordiazepoxide hydrochloride or to 20 mg of chlordiazepoxide base, accurately weighed, were transferred to a 100-ml volumetric flask along with 60 ml of 0.1 *N* hydrochloric acid. The stoppered flask was shaken[13] vigorously for 1 hr, brought to volume with 0.1 *N* hydrochloric acid, mixed well, and filtered[14] with the aid of suction.

Ten milliliters of the filtrate, 1.0 ml of ammonium hydroxide, 1.0 ml of ethyl acetate, and 12.5 ml of IV internal standard solution were transferred to a 30-ml screw-capped tube. The tube was tumbled on a rotator for 30 min at 30 rpm and centrifuged at 2000 rpm for 10 min. Duplicate 5-μl aliquots of the supernatant ethyl acetate layer were chromatographed using mobile phase System A.

Determination of III—Powdered tablets or capsule contents equivalent to 25 mg of chlordiazepoxide hydrochloride or to 20 mg of chlordiazepoxide base, accurately weighed, were transferred to a 30-ml screw-capped tube. Then 15.0 ml of 0.1 *N* hydrochloric acid, 1.0 ml of *n*-hexane, and 3.0 ml of V internal standard solution were added. The tubes were tumbled on a rotator for 1 hr at 30 rpm and centrifuged at 2000 rpm for 10 min. Duplicate 5-μl aliquots of the *n*-hexane layer were chromatographed using mobile phase System B.

Calculations—The slopes of the calibration curves, S_C, determined each time the mobile phase was replenished, were calculated from:

$$S_C = N_S C_I / N_I C_S \qquad \text{(Eq. 1)}$$

where N_S is the number of integrator counts for I or II or the peak height for III, N_I is the number of integrator counts for the internal standard, C_I is the concentration of the internal standard, and C_S is the concentration of the test compound I, II, or III.

The amount of each component found, expressed as a percentage of the label claim of chlordiazepoxide hydrochloride, was calculated from:

$$\% \text{ label claim} = \frac{N_S C_I F}{N_I S_C M_I} \qquad \text{(Eq. 2)}$$

where M_I is the theoretical weight of I injected (based on label claim), and F is a scaling factor (13,500 for I and II, 400 for III).

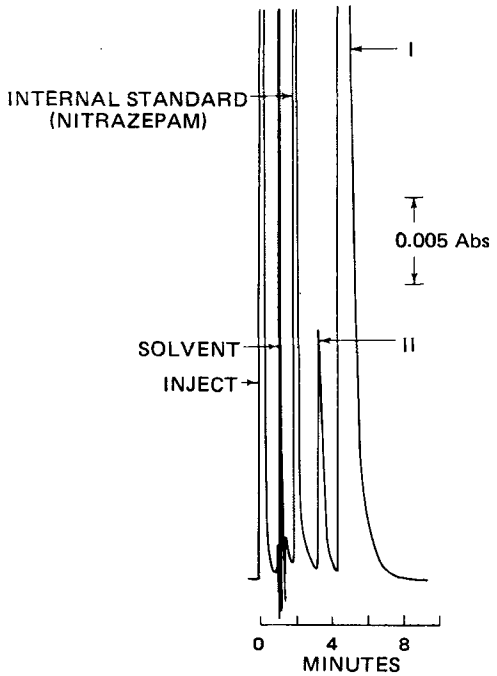

Figure 1—*High-performance liquid chromatogram of a standard solution containing 0.223 mg of chlordiazepoxide hydrochloride/ml, 7.06 μg of II/ml, and 33.0 μg of nitrazepam/ml (internal standard) using mobile phase System A.*

RESULTS AND DISCUSSION

Evaluation of Chromatographic Systems—Liquid–solid (adsorption) and bonded-phase chromatography are the modes of HPLC most applicable to the analysis of chlordiazepoxide and related impurities. Due to availability, cost, simplicity, stability, and column efficiency, liquid–solid chromatography, using a column packed with microparticulate silica gel, was chosen.

Various isocratic and gradient mobile phase systems were tried before the systems described were chosen. Attempts to find an isocratic mobile phase that eluted III behind the solvent front while eluting I and II within a reasonable time were unsuccessful because of the large relative differences in polarity among the three compounds. The inclusion of tetrahydrofuran in mobile phase System A was necessary to elute II before I. Also, III could not be detected at the low levels required (<0.01% in I) while maintaining the amount of I within the linear range of the system. The first problem was overcome by using a gradient system, but this approach had several disadvantages: lower precision, major baseline shifts during the gradient run, and longer total time due to a long column re-equilibration time. The sensitivity problem could possibly have been overcome by using a two-injection technique (overload the column with I to quantitate III and proceed normally to quantitate I and II). However, it was decided that this approach, combined with a gradient mobile phase system, would be less precise and offer little, if any, timesaving over the use of two separate isocratic systems for the analysis of III and for I and II. This latter approach allows optimum partition and chromatographic conditions to provide maximum peak size and minimum chromatograph time for all compounds.

Figure 1 shows a chromatogram obtained when the contents of a chlordiazepoxide hydrochloride capsule were analyzed for I and II using the described procedure. The internal standard, nitrazepam, and I and II were well resolved in less than 8 min. The peaks tailed somewhat, despite the basic mobile phase, but this tailing did not affect quantitation.

Figure 2 shows a chromatogram obtained when a 5-μl aliquot of a calibration standard, containing 4 μg/ml of III, was analyzed using mobile phase System B. The peaks for III and the internal standard, *o*-dinitrobenzene, were well resolved and eluted in less than 6 min.

Linearity and Standard Curves—A plot of peak area *versus* the amount of I injected was linear over the concentration range of 40–300 μg/ml[15] (0.2–1.5 μg/injection).

[15] Compound I was dissolved in 0.3% ammonium hydroxide in absolute ethanol (v/v).

Table I—Analysis of Synthetic Solutions of I and II

Sample	I			II		
	Calculated, μg/ml	Found, μg/ml	Recovery, %	Calculated, μg/ml	Found, μg/ml	Recovery, %

2	192	193	100.4	5.9	6.0	101.7
3	180	183	101.5	2.9	2.9	100.0
4	244	245	100.4	7.3	7.1	97.3
5	211	211	100.2	20.3	20.6	101.5
Mean recovery, %			100.3			99.8
RSD, %			±1.0			±2.6

A standard curve for I, covering the concentration range of 150–300 μg/ml (0.75–1.50 μg/injection) was linear with a slope of 1.37 ± 0.02 and a negligible intercept (0.005). By using the sample preparation procedure described, this standard curve is applicable to samples containing 80–160% of the theoretical weight of I (25 mg).

Duplicate calibration standards were prepared daily and injected periodically to determine the slope of the standard curve. The slope varied by less than 1% on any given day and by less than 3% over the study. Since the current value of the slope was experimentally determined and used in the calculations, small variations in the slope did not affect the accuracy of the procedure.

An identical procedure was followed for the determination of II. A plot of peak area *versus* the amount injected was linear to 140 μg/ml (0.7 μg/injection). A standard curve over the range of 1.2–20 μg/ml (0.006–0.1 μg/injection), the equivalent of 0.7–11% of the theoretical weight of I (25 mg), was linear with a slope of 1.10 ± 0.01 and a negligible intercept (0.0003). Duplicate calibration standards were used to check the slope of the standard curve, as for I.

A standard curve was not used for the analysis of III. Instead, linearity, partition, and calibration standard data were combined to show that the slope obtained from subsequent calibration standard data alone allowed III to be determined directly.

A plot of the ratio of peak height to internal standard counts *versus* the amount of III injected was linear between 1 and 35 ng/injection and passed through the origin. This range represented, using the sample preparation scheme described under *Experimental*, levels of III between 0.003 and 0.11% of the theoretical amount of I (25 mg).

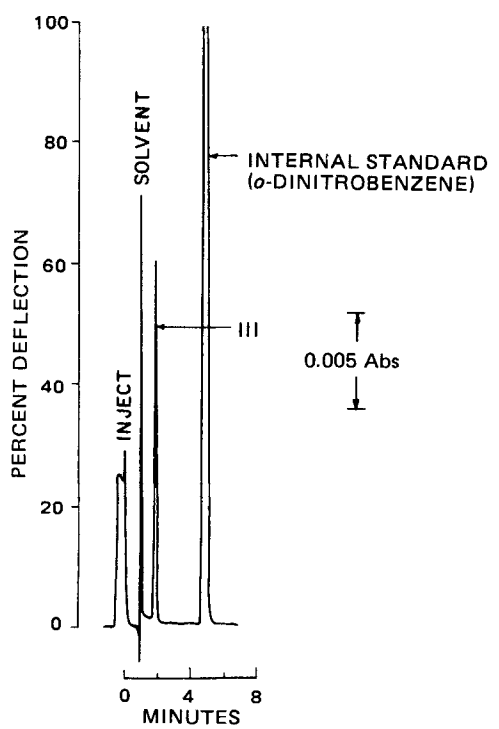

Figure 2—*High-performance liquid chromatogram of a standard solution containing 4.0 μg of III/ml and 56.0 μg of o-dinitrobenzene/ml (internal standard) using mobile phase System B.*

Sample Preparation—The times necessary for constant and complete extraction and partition of I and II from formulations were determined in two stages. Time for extraction into 0.1 *N* hydrochloric acid was determined by shaking capsule composite samples for 30, 60, and 90 min. The samples were then made alkaline and partitioned into ethyl acetate, as described, for 60 min. When the ethyl acetate layer was analyzed for I and II, levels in the samples extracted for 60 and 90 min were identical but somewhat higher than in the sample extracted for 30 min. With a 60-min extraction, the time for constant partition was determined by tumbling capsule composite samples, as described, for various times up to 60 min. No change in the peak heights for I or II were noted after 20 min.

Quantitative partition of I and II from hydrochloric acid (made basic) into ethyl acetate was demonstrated by chromatographing both layers of a capsule composite sample tumbled for 30 min. Also, when the described procedure was applied to capsule composite samples equivalent to 10, 20, and 30 mg of I, the ratio of concentrations for I and for II in the three samples was 1:2:3 in both cases.

To determine the time required to attain equilibrium in the partition of II, capsule composite samples in 0.1 *N* hydrochloric acid were tumbled with *n*-hexane, as described, for various times up to 90 min. No change in the size of the peak for III, obtained by chromatographing 5-μl aliquots of the *n*-hexane layer using mobile phase System B, was observed after 40 min.

When both layers of a calibration standard were analyzed for the internal standard (*o*-dinitrobenzene) and III, both compounds were partitioned quantitatively into the *n*-hexane layer (<99:1 concentration ratio). In addition, when the described extraction procedure was applied to capsule composite samples equivalent to 10, 20, and 30 mg of I, the concentrations of III were in the ratio 1:2:3. These data indicated complete and constant partition of III under the described conditions.

Compounds I and II did not interfere with the analysis of III since no peaks were observed for I or II when 5-μl aliquots of the *n*-hexane layer of a capsule composite sample, prepared using the procedure described for the determination of III, were chromatographed using mobile phase System A.

Quantitation—Compounds I and II were quantitated using peak area; however, quantitation of III was more precise using peak height. Since the internal standard peak was integrated in both cases, the assay for III was based on the peak height to peak area ratio and the assay for I and II was based on peak area ratios.

Reproducibility of the chromatographic system was shown by chromatographing six 5-μl aliquots of a calibration standard containing 0.19 mg of I/ml and 0.006 mg of II/ml (0.95 and 0.02 μg/injection, respectively)

Table II—Analysis of Synthetic Solutions of III

Sample	Calculated, μg/ml	Found, μg/ml	Recovery, %
1	0.179	0.178	99.6

RSD, %			±1.5

Table III—Analysis of Chlordiazepoxide Formulations for I and II by HPLC and Spectrophotometric[a] Methods

Sample	Type	HPLC			Spectrophotometric, "I"[b], %
		I[b], %	II[b], %	Total[b], %	
A	Tablet, base	98.0	0.73	98.7	98.8
B	Capsule, hydrochloride	97.3	0.81	98.1	98.1
C	Capsule, hydrochloride	96.6	4.12	100.7	101.2
D	Capsule, hydrochloride	91.5	5.62	97.4	96.4
E	Tablet, hydrochloride	87.1	8.54	95.7	95.7

[a] Reference 3. [b] Percent of label claim amount of chlordiazepoxide *or* chlordiazepoxide hydrochloride.

along with the 0.03-mg/ml nitrazepam internal standard. The relative standard deviations of the peak area ratios were 0.32% for I and 2.7% for II. The analogous figure for III at a level of 0.0036 mg/ml (0.018 μg/injection) was 2.3%.

Calibration standards, stored in the dark at 4° between analyses, were analyzed for I, II, and III on each of 5 consecutive days; the relative standard deviations were 1.1, 2.7, and 2.5%, respectively. While the standards appeared to be stable for at least 1 week at 4°, fresh calibration standards were prepared daily to check the slopes of the calibration curves.

The minimum detectable amounts of II and III under the conditions described were 1 and 0.2 ng/injection, respectively. The lowest levels actually quantitated were 6.3 and 0.9 ng/injection, respectively. Under the extraction conditions described, these amounts of II and III represented 0.7 and 0.0003%, respectively, of the label claim of I.

Analysis of Solutions of Known Concentration—Five solutions of I and II, prepared in the same manner as the calibration standard solutions, were analyzed using the described procedure. Table I shows that the mean recoveries for I and II were 100.2 and 99.8% with relative standard deviations of 1.0 and 2.6%, respectively.

Similarly, eight solutions were prepared to contain known concentrations of III (0.18–32 μg/ml) in the same way as solutions used for the determination of linearity. Table II shows that the mean recovery was 99.3% with a relative standard deviation of 1.5%. For this assay, only the calibration standard used to determine the slope of the standard curve was prepared in the same way as for linearity samples. For the analysis of pharmaceuticals, the procedure described in *Experimental* was used.

Analysis of Pharmaceuticals—Five formulations of chlordiazepoxide or chlordiazepoxide hydrochloride, capsules or tablets, were analyzed by the BP spectrophotometric procedure (3) and by the described HPLC procedure for I and II. Aliquots of the same tablet or capsule composite were analyzed in each case. The spectrophotometric method is nonspecific, since both I and II exhibit absorbance maxima at 308 nm, the wavelength used in the assay. It was not surprising, therefore, that the sum of the levels of I and II determined by the HPLC procedure agreed closely with the level of I determined by the spectrophotometric method (Table III). The level of II exceeded the allowed limit in three cases; however, the samples assayed were several years old and were not representative of current formulations.

The precision of the procedure for the determination of I and II in formulations was determined by analyzing Sample B (Table III) five times. Percent relative standard deviations of 0.2 and 1.8% were measured for I and II, respectively.

Five formulations of chlordiazepoxide or chlordiazepoxide hydrochloride were analyzed for III using the described procedure (Table IV). Very low levels of III were encountered; in all cases, these levels were well within the allowable limits. Results for Formulation E (Tables III and IV) showed that a high level of II did not necessarily imply a high level of III. The other four samples listed in Table IV were selected to contain the highest levels of III from over 30 screened by the appropriate TLC limit test (1–3). The precision of the procedure for the determination of III in formulations was shown by analyzing Sample F five times. A percent relative standard deviation of 1.4% was measured.

Table IV—Analysis of Chlordiazepoxide Formulations for III by HPLC[a]

Sample	Type	III[b], %
E	Tablet, hydrochloride	0.030
F	Capsule, hydrochloride	0.015
G	Capsule, hydrochloride	0.009
H	Capsule, hydrochloride	0.006
I	Capsule, hydrochloride	0.015

[a] Using mobile phase System B. [b] Percent of label claim amount of chlordiazepoxide hydrochloride.

Five samples of chlordiazepoxide or chlordiazepoxide hydrochloride drug substance also were analyzed for III. In all cases, levels below the quantifiable limit of 0.003% were found, well below the allowable limits of 0.01%.

The described method is applicable to both tablets and capsules and both the free base and hydrochloride salt forms of chlordiazepoxide. Interference from excipients was not experienced. The method could be adapted to the analysis of single 5- or 10-mg tablets or capsules by reducing the volumes used for extraction and may be used as described for single 25-mg tablets or capsules.

Pharmacokinetics of Methsuximide and a Major Metabolite in Dogs

MICHAEL R. DOBRINSKA * and PETER G. WELLING ˣ

Abstract □ The pharmacokinetics of methsuximide and its major metabolite 2-methyl-2-phenylsuccinimide were studied in dogs after single intravenous doses. Plasma methsuximide levels were described by a two-compartment open model, and those of the metabolite were described by a one-compartment open model. An expression was derived that describes both methsuximide and metabolite plasma levels after methsuximide administration. Excellent fits were obtained between observed data and those predicted from the model. The metabolite accounted for 40% of the overall elimination of methsuximide, and the half-life of the metabolite (15 hr) was much greater than that of the parent drug (1–3.5 hr). The results suggest that pharmacological effects after methsuximide administration may be due primarily to the metabolite, which may accumulate in the body during repeated doses.

Keyphrases □ Methsuximide and metabolite—pharmacokinetics in dogs after single intravenous doses, GLC analysis in plasma □ Pharmacokinetics—methsuximide and metabolite, after single intravenous doses in dogs □ GLC—analysis, methsuximide and metabolite, dog plasma □ Anticonvulsants—methsuximide and metabolite, pharmacokinetics in dogs after single intravenous doses, GLC analysis in plasma

Methsuximide is a succinimide derivative useful in the treatment of petit mal epilepsy (1–4). In rats, it is distributed rapidly into most major tissues and organs (5). Metabolism studies in rats, guinea pigs, dogs, and humans (6–8) indicate not only that methsuximide is metabolized extensively but also that a prime biotransformation route is *N*-demethylation, leading to 2-methyl-2-phenylsuccinimide, which is pharmacologically active (2, 5, 9). There is evidence that this metabolite is cleared slowly from the body relative to the parent drug (10–12). This phenomenon is not uncommon; several other antiepileptic drugs undergo *N*-demethylation to yield slowly cleared, active metabolites (13).

The *N*-demethylated metabolite may be responsible for the therapeutic activity of methsuximide. Plasma levels of methsuximide and the metabolite were measured by mass fragmentography in 17 patients receiving chronic methsuximide therapy (11). Plasma metabolite levels exceeded those of the parent drug by 700-fold. However, this number reflects the extremely low methsuximide concentrations that the assay was capable of detecting. Metabolite levels of less than 10 μg/ml were judged ineffective, while levels in excess of 40 μg/ml were toxic.

As exemplified in a recent case report (12), special caution must be exercised in the management of a methsuximide overdose. After ingestion of 10 g of methsuximide, the time course of toxicity was biphasic. The initial phase of toxicity was attributed to the high circulating level of the parent drug. After a period of improvement, the patient regressed into an extended, profound coma. This second phase of toxicity was attributed to the sustained, high concentrations of the metabolite in plasma, which were about 20 times those of the parent drug.

A primary objective of this study was to obtain the pharmacokinetic profiles in the dog of both methsuximide and the metabolite after single intravenous doses. By combining the individual models, it was then possible to quantitate the rate and extent to which methsuximide was biotransformed into the metabolite after single doses of the parent drug. This report also describes an improved, sensitive, and fast GLC assay for the simultaneous measurement of methsuximide and its metabolite in plasma.

EXPERIMENTAL

Pure samples of methsuximide[1], phensuximide[1], and 2-methyl-2-phenylsuccinimide[2] were the racemic forms. Two male beagle dogs were used; Dog A weighed 14 kg and Dog B weighed 17.5 kg. The dogs had free access to water at all times, but food was withheld 12 hr prior to an experiment.

Due to the limited water solubility of methsuximide (10), the intravenous dosage form, used in all experiments, consisted of 250 mg of methsuximide dissolved in 5 ml of an aqueous solution of 75% propylene glycol. For consistency, the metabolite was also administered in this dosage form.

Procedure—Each dog was placed in a restraining apparatus with its limbs held secure by pediatric limb restraints. A vein infusion set[3] was positioned in each of the two front limbs. One set was used to administer 5 ml iv (250 mg) of the drug solution by rapid injection (120 sec or less) and was then immediately flushed with 10 ml of normal saline solution to ensure quantitative delivery of the dose. This set was then removed. The other infusion set was used to collect multiple samples at short intervals during the 1st hr of the experiment. The set was kept open by filling with heparin sodium solution, 10 units/ml, between samples.

Blood samples (5 ml) were collected in vacuum tubes[4] at 0, 2–5, 10, 15, 30, 45, 60, and 120 min and then at longer time intervals up to 48 hr. After 3 hr, the infusion set was removed and the dog was freed from the restraints. Blood samples after this time were obtained by direct venipuncture. When the set was used, the blood collection procedure was to withdraw 5 ml of the heparin-diluted blood, draw the 5-ml blood sample, inject 5 ml of saline, reinject the diluted blood, and refill the set with about 1 ml of the dilute heparin solution. The blood samples were centrifuged, and the plasma was deep frozen until analyzed, usually within 1 week.

To eliminate the possibility of drug-related changes in the pharmacokinetic parameters, the minimum time between experiments on the same dog was 1 month.

Assay—The assay was a modification of that of Kinkel *et al.* (10). One milliliter of plasma, or blank plasma containing known quantities of methsuximide and metabolite, was pipetted into a 13-ml glass-stoppered centrifuge tube and acidified with 0.5 ml of 0.5 *N* hydrochloric acid. Five milliliters of chloroform[5] was added, and the tubes were shaken horizontally on a flat-bed shaker for 15 min and then centrifuged[6]. A 4-ml aliquot of the chloroform layer was transferred to clean tubes, and 1 ml of phensuximide solution (6 μg/ml in chloroform) was added as an external standard. The chloroform was evaporated to dryness carefully in a 40° water bath under a gentle stream of nitrogen. The residue was immediately redissolved in about 100 μl of carbon disulfide[7], and the samples were analyzed by GLC.

The gas chromatograph[8], equipped with flame-ionization detectors, was run isothermally using a U-shaped glass column (1.8 m × 2 mm i.d.) packed with 3% OV-17 on 100–120-mesh Gas Chrom Q[9]. The temperatures employed were: column, 175°; flame-ionization detector, 200°; and

Table I—Summary of Experiments

Experiment	Dog	Compound Administered, Dose and Route
A	A[a]	Methsuximide, 250 mg iv
B	B	Methsuximide, 250 mg iv
C	B	Methsuximide, 250 mg iv
D	B	2-Methyl-2-phenylsuccinimide, 250 mg iv
E	B	2-Methyl-2-phenylsuccinimide, 250 mg iv

[a] Dog A had some difficulty adapting to the restraining apparatus and was replaced by Dog B.

injection block, 210°. The electrometer settings varied between 8 and 64 $\times 10^{-11}$ amp. Sample volume, introduced by the on-column injection technique, was 3 μl; the recorder chart speed was 38 cm/hr.

The flame gases were hydrogen and compressed air, and their flow rates were systematically adjusted until maximum flame-ionization detector response to the compounds was obtained at 20 and 200 ml/min, respectively. The carrier gas was nitrogen, and its optimal flow rate of 20 ml/min was obtained from an experimentally determined Van Deemter plot (14). Under the conditions used, the column had 321 and 435 theoretical plates/30.5 cm for methsuximide and the metabolite, respectively.

Compounds were quantitated using peak height ratios. This method was faster than, and as accurate as, peak area determination by disk integration or planimetry. The assay method was sensitive to plasma compound concentrations of 0.5 μg/ml.

Standard curves, run in triplicate on separate days, were constructed from the assay results of blank dog plasma containing known quantities of methsuximide and the metabolite at 10 concentrations over the range of 0.5–25.0 μg/ml. The standard curves were checked at the time of assay of unknowns by including in each run a blank plasma sample containing 10 μg of methsuximide and the metabolite; recoveries were 93 ± 3 (*SD*) and 88 ± 5%, respectively.

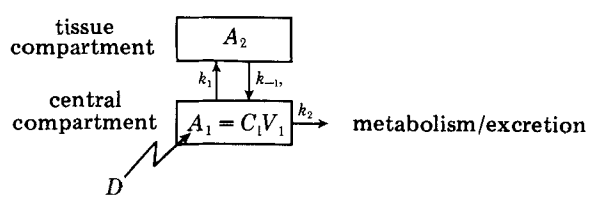
The experiments conducted are summarized in Table I.

Pharmacokinetic Analysis—Plasma level data were fitted to the appropriate pharmacokinetic equations by graphical methods (15). Improved estimates of pharmacokinetic parameters, including confidence limits and coefficients of determination, were obtained using the iterative nonlinear least-squares program NREG on a digital computer[10] as described previously (16).

RESULTS AND DISCUSSION

Assay—Carbon disulfide was substituted for chloroform as the final solvent for injection into the gas chromatograph, because flame-ionization detectors respond poorly to carbon disulfide and compound peaks are obtained from a flat baseline. Chromatograms obtained by the two methods are compared in Fig. 1. Although evaporation of chloroform solutions was reported to result in drug losses (10), no loss of methsuximide or metabolite was observed. The entire chromatogram was obtained within 6 min of injection.

Pharmacokinetic Model for Methsuximide—The decline in plasma methsuximide levels in Experiments A, B, and C was biphasic. A typical plasma profile from Experiment B is shown in Fig. 2. Therefore, these data were analyzed in terms of the two-compartment open model (17) as depicted in Scheme I. This model describes the instantaneous introduction of an intravenous dose, D, of drug into a rapidly accessible central or plasma compartment having an apparent distribution volume, V_1, and equilibration of this compartment with a less readily accessible tissue compartment. The quantities A_1 and A_2 refer to the amounts of unchanged drug in the central and tissue compartments, respectively. The disposition first-order rate constants k_1 and k_{-1} govern the transfer of drug between the compartments, while k_2 is the first-order rate constant representing loss of drug from the central compartment by all routes except k_1.



Scheme I

[10] Univac 1118.

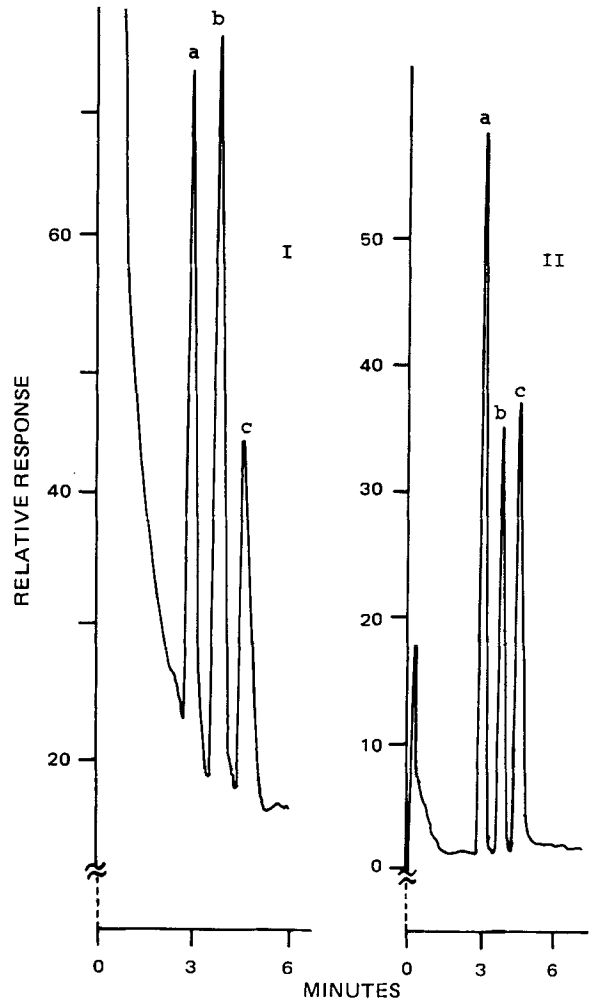


Figure 1—*Representative GLC chromatograms using chloroform (I) and carbon disulfide (II) as solvents. The lettered peaks and their retention times are:* (a) *methsuximide, 191 sec;* (b) *phensuximide external standard, 239 sec; and* (c) *2-methyl-2-phenylsuccinimide, 281 sec. Curves I and II are different plasma samples run at different chart speeds.*

Equation 1 describes the plasma drug concentration *versus* time profile appropriate to this model (17):

$$C_1 = \frac{D}{V_1(\alpha - \beta)}\left[(\alpha - k_{-1})\,e^{-\alpha t} + (k_{-1} - \beta)e^{-\beta t}\right] \qquad \text{(Eq. 1)}$$

where:

$$\begin{matrix}\alpha \\ \beta\end{matrix} = \tfrac{1}{2}\{(k_1 + k_{-1} + k_2) \pm [(k_1 + k_{-1} + k_2)^2 - 4k_{-1}k_2]^{1/2}\} \qquad \text{(Eq. 2)}$$

The composite rate constant β is the slope of the postdistributive log-linear phase of loss of drug from the body multiplied by −2.303, and α is the log-linear slope multiplied by −2.303 obtained by the method of curve stripping (17).

The broken line in Fig. 2 represents the computer fit to unweighted data. Low concentrations were consistently underestimated by the computer. Since NREG is a least-squares fitting routine, a small relative error in the higher concentrations contributes more to the sums of squares than an equivalent error in the lower concentration range. Thus, to make all concentrations contribute equally, data points were weighted by the reciprocal of their concentrations. This weighting scheme improved the curve fitting in all cases (solid line in Fig. 2) and was used in all nonlinear regression procedures.

Table II gives the computer-estimated parameters for Experiments A, B, and C. The distribution characteristics of methsuximide (k_1, k_{-1}, α, V_1, and T/P) differed between the two dogs, although they were of similar order of magnitude. There was more rapid equilibration of drug between compartments in Dog B (α, k_1, and k_{-1}), while Dog A had a

Table II—Pharmacokinetic Parameters after Intravenous Administration of Methsuximide to the Dog

Parameter[a]	Experiment A	Experiment B	Experiment C
k_1, hr^{-1}	2.80 (0.32–5.29)[b]	3.61 (1.02–6.32)	1.86 (0.074–3.65)
k_{-1}, hr^{-1}	1.47 (0.69–2.26)	3.40 (1.89–4.91)	3.28 (0.73–5.82)
k_2, hr^{-1}	0.63 (0.35–0.91)	1.67 (1.21–2.13)	0.84 (0.70–0.97)
D/V_1, mg/liter	23.3 (12.9–33.7)	18.5 (13.4–23.6)	11.1 (9.6–12.6)
D, mg	250	250	250
V_1, liters	10.7	13.5	22.5
α, hr^{-1}	4.71	8.03	5.48
β, hr^{-1}	0.20	0.71	0.50
$t_{1/2}$, hr	3.47	0.98	1.39
T/P[c]	2.20	1.36	0.67
R^2[d]	0.9930	0.9977	0.9972

[a] First four parameters are primary while the balance are derived. [b] The 95% confidence limits. [c] Amount of drug in the tissue compartment to that in the plasma compartment at equilibrium (17). [d] Coefficient of determination, $(\Sigma obs^2 - \Sigma dev^2)/\Sigma obs^2$.

greater amount of drug in the tissue compartment at equilibrium (T/P). The elimination characteristics (k_2, β, and $t_{1/2}$) also differed between the dogs, with Dog A eliminating and/or metabolizing methsuximide more slowly than Dog B.

The rate constant k_2 reflects excretion and metabolism of methsuximide. Since the metabolite was determined in all methsuximide experiments, it was possible to separate k_2 into components representing (*a*) formation of 2-methyl-2-phenylsuccinimide and (*b*) excretion of unchanged methsuximide and/or formation of any other metabolites. Before the metabolite data could be incorporated into Scheme I, its apparent distribution volume and individual pharmacokinetic model had to be obtained by intravenous administration of the pure metabolite.

Pharmacokinetic Model for Metabolite—Figures 3 and 4 are semilogarithmic plots of the data from Experiments D and E after intravenous metabolite administration (250 mg). Since the initial data points did not show sufficient curvilinearity to justify two-compartment model kinetics, the one-compartment open model (Scheme II) was used. The symbolism used in this model for the metabolite is equivalent to that used in Scheme I for unchanged drug.

The plasma metabolite level *versus* time profiles are described by:

$$C_m = \frac{D}{V_3} e^{-k_3 t} \qquad \text{(Eq. 3)}$$

so that, when plotted semilogarithmically, the concentration axis intercept is D/V_3 while the slope is $-k_3/2.303$. The solid lines in Figs. 3 and 4 are the lines of best fit as determined by linear regression analysis[11].

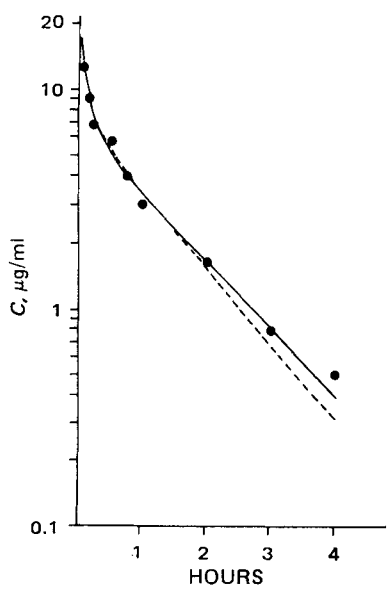

Figure 2—*Semilogarithmic plot of methsuximide concentration* versus *time data from Experiment B. The computer-determined equations of best fit using unweighted data* (- - -) *and data weighted by 1/C* (—) *are* $C_1 = 12.1e^{-9.95t} + 7.7e^{-0.81t}$ *and* $C_1 = 11.7e^{-8.03t} + 6.8e^{-0.71t}$, *respectively. See text for explanation.*

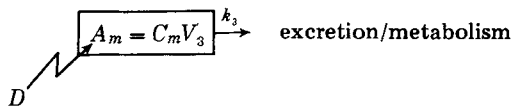


Scheme II

Table III summarizes the regression-determined parameters of Scheme II.

The elimination rate constant k_3, representing excretion or further metabolism, was identical in both experiments and the biological half-life, $t_{1/2}$, was about seven times greater than that of the parent drug (*cf.*, Table II). The apparent distribution volumes of the two compounds were similar.

Since the models and pharmacokinetic parameters for methsuximide and its major metabolite in plasma were obtained independently, it was possible to develop a model to quantitate the rate and extent of formation of the metabolite after an intravenous dose of methsuximide.

Pharmacokinetics of Methsuximide Including Metabolite Formation—Scheme III depicts the model describing intravenous administration of methsuximide with subsequent formation of the metabolite. In Scheme III, D is the amount of methsuximide administered intravenously, k_1 and k_{-1} are as previously defined, k_{el} is the first-order rate constant describing excretion and metabolism of methsuximide to compounds other than 2-methyl-2-phenylsuccinimide, k_f is the first-order rate constant describing formation of the metabolite, and k_3 is the first-order rate constant representing excretion and/or further metabolism of 2-methyl-2-phenylsuccinimide. The remaining symbols are as in Schemes I and II.

The differential equations for the rate of change of C_1 and C_m, with time, can be solved to yield Eqs. 1 and 4:

$$C_m = \frac{WDk_f}{V_3}\left\{\left[\frac{k_{-1}-\alpha}{(k_3-\alpha)(\beta-\alpha)}\right]e^{-\alpha t} + \left[\frac{k_{-1}-\beta}{(k_3-\beta)(\alpha-\beta)}\right]e^{-\beta t} + \left[\frac{k_{-1}-k_3}{(\beta-k_3)(\alpha-k_3)}\right]e^{-k_3 t}\right\} \qquad \text{(Eq. 4)}$$

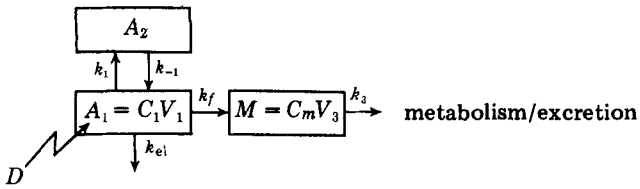
Since all concentrations are expressed on a mass per volume basis, the factor W, the molecular weight ratio of the metabolite to the parent drug (189/203), is required in Eq. 4.

The composite rate constants α and β are now defined by Eq. 5. The significance of these constants is the same as that in Eq. 2. However, in Eq. 5, k_2 from Eq. 2 is separated into $k_{el} + k_f$:

$$\begin{matrix}\alpha \\ \beta\end{matrix} = \tfrac{1}{2}\{(k_1 + k_{-1} + k_{el} + k_f) \pm [(k_1 + k_{-1} + k_{el} + k_f)^2 - 4(k_{-1}k_f + k_{el}k_{-1})]^{1/2}\} \qquad \text{(Eq. 5)}$$

Table III—Metabolite Pharmacokinetic Parameters after Intravenous Administration to the Dog

Parameter	Experiment D	Experiment E
D, mg	250	250
V_3, liters	14.6	11.8
D/V_3, mg/liter	17.1	21.1
k_3, hr^{-1}	0.047	0.047
$t_{1/2}$, hr	14.7	14.7



Scheme III

Figures 5 and 6 give the experimental data for methsuximide and the metabolite in Experiments B and C. Experiment A had to be terminated early, and the metabolite was followed over a time period less than its half-life (14.7 hr). Thus, this experiment could not be used to test the validity of the model in Scheme III.

Initial estimates of the parameters are needed for the computer analysis of the data in terms of Scheme III, but stripping of triexponential curves (Eq. 4) is an inaccurate procedure (18). However, initial estimates of α, β, k_1, and k_{-1} can be obtained from the computer values obtained from methsuximide alone (Table II). The estimate of k_3 can be obtained in two ways; it can be estimated from the independent metabolite experiments or from Eq. 4. Since it is already established that $\alpha > \beta > k_3$, after a certain time Eq. 4 will become essentially monoexponential and the resulting log-linear slope will equal $-k_3/2.303$. The volume V_3 can be estimated as the average volume obtained in Experiments D and E, and an estimate of k_f can be obtained by area analysis. Equations 1 and 4 can be integrated between the limits of zero and infinite time to yield Eqs. 6 and 7, respectively:

$$\text{area } C_1 = \frac{Dk_{-1}}{V_1\alpha\beta} \qquad \text{(Eq. 6)}$$

$$\text{area } C_m = \frac{Wk_fk_{-1}D}{V_3k_3\alpha\beta} \qquad \text{(Eq. 7)}$$

Combining Eqs. 6 and 7 and solving for k_f yield:

$$k_f = \frac{V_3k_3}{WV_1}\frac{\text{area } C_m}{\text{area } C_1} \qquad \text{(Eq. 8)}$$

The areas under the methsuximide and metabolite curves, area C_1 and area C_m, respectively, were determined using the trapezoidal rule; the areas from the time of the terminal data points to time infinity were calculated (17). The remaining parameter, k_{el}, was determined from:

$$k_{el} = \frac{\alpha\beta - k_{-1}k_f}{k_{-1}} \qquad \text{(Eq. 9)}$$

obtained directly from Eq. 5.

Table IV—Pharmacokinetic Parameters for Methsuximide and Metabolite after Intravenous Doses of Methsuximide

Parameter[a]	Experiment B	Experiment C
k_1, hr^{-1}	3.84 (0.52–7.17)[b]	0.71 (0.20–1.23)
k_{-1}, hr^{-1}	3.80 (1.92–5.68)	1.14 (0.26–2.02)
k_{el}, hr^{-1}	1.01 (0.69–1.33)	0.50 (0.42–0.58)
k_f, hr^{-1}	0.77 (0.54–1.00)	0.28 (0.24–0.31)
k_3, hr^{-1} (F)[c]	0.047	0.047
D/V_1, mg/liter	18.9 (12.8–25.0)	10.4 (9.3–11.5)
D/V_3, mg/liter (F)	18.9	18.9
V_1, liters	13.2	24.0
V_3, liters	13.2	13.2
α, hr^{-1}	8.64	2.24
β, hr^{-1}	0.78	0.40
$t_{1/2}$, hr (methsuximide)	0.9	1.7
$t_{1/2}$, hr (metabolite)	14.7	14.7
R^2 (methsuximide)	0.9979	0.9937
R^2 (metabolite)	0.9919	0.9914
R^2 (overall)	0.9950	0.9928

[a] First seven parameters are primary while the balance are derived. [b] The 95% confidence limits. [c] Indicates parameter was fixed in the regression analysis.

The methsuximide and metabolite data from Experiments B and C were simultaneously fitted to Eqs. 1 and 4. Since high correlations existed between some parameters, it was necessary to fix two of the seven primary parameters so that they would not contribute to the nonlinear regression analysis. Since V_3 was determined accurately in Experiments D and E and since identical values of k_3 were obtained by both initial estimate methods, these parameters were fixed. This procedure significantly reduced not only the correlations but also the 95% confidence limits of the parameters.

The computer parameter values are given in Table IV. The solid curves in Figs. 5 and 6 are the computer fits to the data. These figures and the R^2 values in Table IV indicate that Scheme III excellently describes the experimental data.

The simultaneous fitting only slightly changed the methsuximide parameters obtained in the absence of metabolite data (*cf.*, Table II).

Of particular interest is the relative importance of the rate of biotransformation of methsuximide to the metabolite, k_f, compared to the overall methsuximide elimination rate constant, $k_{el} + k_f$. This metabolic step accounted for 43 and 36% of the overall elimination of methsuximide in Experiments B and C, respectively. The large value of k_f together with the small k_3 led to sustained, high metabolite concentrations. This fact

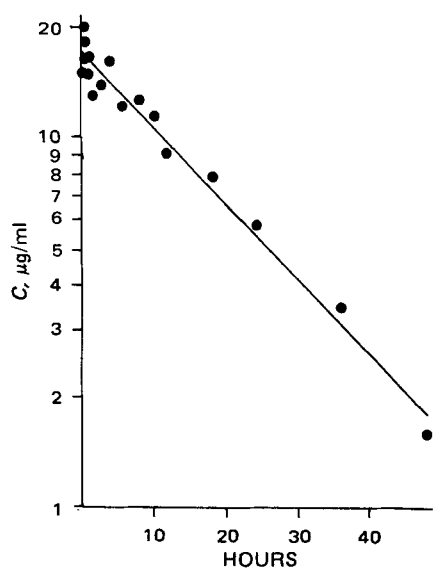


Figure 3—*Semilogarithmic plot of 2-methyl-2-phenylsuccinimide concentration* versus *time data from Experiment D after intravenous injection of this metabolite in the dog. The solid line was determined by linear regression analysis, the equation of which, including the 95% confidence limits, was log* $C_m = -0.0205(\pm 0.0015)t + 1.2326(\pm 0.0261)$.

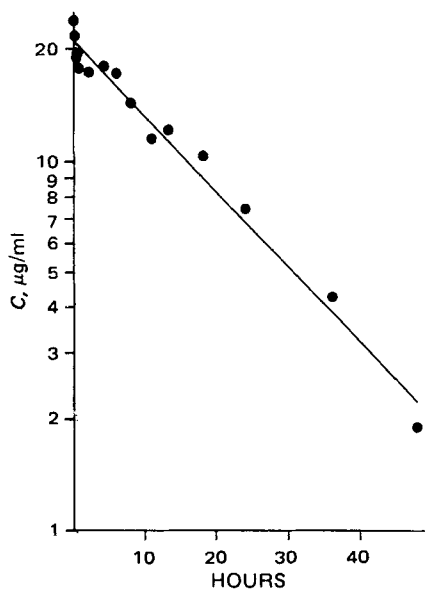

Figure 4—*Semilogarithmic plot of 2-methyl-2-phenylsuccinimide concentration* versus *time data from Experiment E after intravenous injection of this metabolite in the dog. The solid line was determined by linear regression analysis, the equation of which, including the 95% confidence limits, was log* $C_m = -0.0203(\pm 0.0017)t + 1.3245(\pm 0.0314)$.

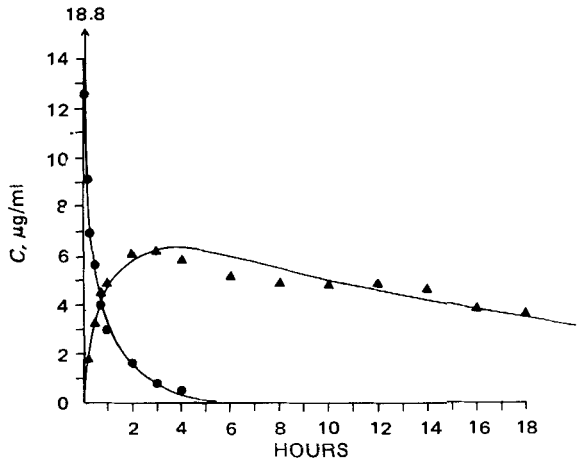

Figure 5—*Methsuximide and 2-methyl-2-phenylsuccinimide plasma level* versus *time profiles after a 250-mg intravenous injection of methsuximide (Experiment B). The computer-determined equations were: methsuximide* (●), $C_1 = 11.6e^{-8.64t} + 7.2e^{-0.78t}$; *and the metabolite* (▲), $C_m = -1.0e^{-8.64t} - 7.1e^{-0.78t} + 8.1e^{-0.047t}$.

lends support to the underlying assumption in this study that the dog is a suitable model for the pharmacokinetics of methsuximide in humans, since it has been shown that metabolite levels are also high and sustained in an overdose patient (12).

Multiple dosing of methsuximide results in induction of drug-metabolizing enzymes (10, 19). Thus, after multiple dosing, it might be expected that the metabolic step studied here would be increasingly important, both from a therapeutic and toxicological point of view. It cannot be discounted, however, that the metabolite may itself be responsible for some or all of the hepatic enzyme induction seen after repeated methsuximide doses.

Methsuximide is available for human use only as an oral dosage form. Since this drug is cleared from the body primarily by metabolism (7), the "first-pass effect," reported by Gibaldi *et al.* (20), may be an important phenomenon in methsuximide therapy. In light of the discussed enzyme induction and a possible first-pass effect, the pharmacological activity of methsuximide in humans may be due primarily to 2-methyl-2-phenylsuccinimide.

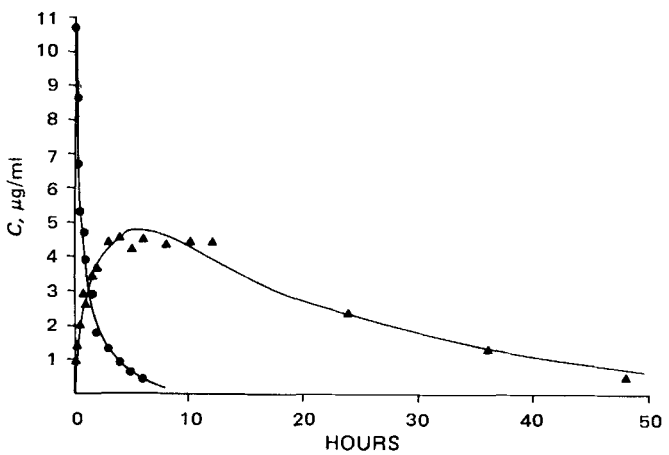

Figure 6—*Methsuximide and 2-methyl-2-phenylsuccinimide plasma level* versus *time profiles after a 250-mg intravenous injection of methsuximide (Experiment C). The computer-determined equations were: methsuximide* (●), $C_1 = 6.2e^{-2.24t} + 4.2e^{-0.40t}$; *and the metabolite* (▲), $C_m = -1.4e^{-2.24t} - 5.6e^{-0.40t} + 7.0e^{-0.047t}$.

Stable Nonaqueous Pentobarbital Sodium Solutions for Use in Laboratory Animals

SAUL BORODKIN ˣ, LOWELL MACY, GEORGE THOMPSON, and RONALD SCHMITS

Abstract □ The degradation kinetics of pentobarbital sodium in propylene glycol-based solutions were studied along with the *in vivo* effects in laboratory animals. The degradation rate constant was directly proportional to the water concentration in propylene glycol–water solvent systems. An activation energy of 23.4 kcal/mole was obtained in propylene glycol–water (1:1). Pentobarbital sodium solutions in anhydrous propylene glycol and 9:1 mixtures of propylene glycol with ethanol, glycerin, or dimethylacetamide gave relatively slow degradation rates at 100°, with all projected 25° $t_{99\%}$ values greater than 4.5 years. Intravenous administration of pentobarbital sodium in various anhydrous propylene glycol-based vehicles to rats produced no hemolysis or gross organ damage that would interfere with pathological evaluations. Results of an intraperitoneal sleeptime study indicated that pentobarbital sodium produced consistent hypnotic effects when administered as an aqueous solution or in anhydrous propylene glycol-based vehicles.

Keyphrases □ Pentobarbital sodium—degradation kinetics in propylene glycol-based solutions, *in vivo* effects in laboratory animals □ Degradation kinetics—pentobarbital sodium in propylene glycol-based solutions, *in vivo* effects in laboratory animals □ Stability—pentobarbital sodium in propylene glycol-based solutions, *in vivo* effects in laboratory animals □ Hypnotics—pentobarbital sodium, degradation kinetics in propylene glycol-based solutions, *in vivo* effects in laboratory animals

Pentobarbital has been recommended frequently as a drug of choice for producing euthanasia in laboratory animals whenever its use will not interfere with experimental results (1). In the dog, the maximum lethal dose is generally considered to be about 50 mg/kg. It is also widely used intraperitoneally to induce anesthesia in small laboratory animals.

A major concern in the use of injectable pentobarbital sodium products is the chemical instability in aqueous solutions (2, 3). At the high pH level necessary to maintain pentobarbital sodium in solution, the degradation rate is fast enough to cause crystallization of the water-insoluble degradation product within several months at room temperature. The use of vehicles containing 20–60% propylene glycol in water to overcome the stability problem was reported (4, 5), but detailed kinetic and toxicological data were not included. However, the utility of propylene glycol in parenteral products is well established (6).

This paper describes studies on propylene glycol-based solutions of pentobarbital sodium intended for parenteral use in producing euthanasia or anesthesia in laboratory animals. High temperature kinetic studies established the degradation rate reduction in the propylene glycol-based vehicles. The effects of water concentration and other solvents on the degradation rate also were evaluated. Additionally, acute intravenous toxicity and intraperitoneal sleeptime studies were conducted in rats to evaluate the drug availability and pathological changes associated with propylene glycol-based formulations.

EXPERIMENTAL

Kinetic Procedure—Solutions were prepared by dissolving sufficient pentobarbital sodium in the desired solvent to give a concentration of 50 mg/ml. The solution was then divided into several 10-ml ampuls, which were sealed and placed in a mechanical convection oven[1] maintained at a constant temperature ±0.2°. Periodically, ampuls were removed and assayed for the remaining pentobarbital sodium concentration.

Approximately 15 assays were obtained in each kinetic study, with each assay obtained from a separate ampul. All data were treated statistically, using linear regression analyses to establish rate constants and confidence intervals (7).

Assay—A differential UV method, similar to that reported by Tishler *et al.* (8) for phenobarbital degradation, was used to assay the remaining pentobarbital sodium. The sample was diluted in 1.0 *N* NH_4OH to a concentration of 4–20 μg/ml of pentobarbital sodium, and a UV spectrum from 220 to 300 nm was obtained[2]. An additional sample was diluted similarly in 0.1 *N* HCl, and a UV spectrum was obtained.

The difference in acidic and basic absorbances at 240 nm was used to determine the drug concentration. A standard curve obtained with this method, using concentrations of 4, 8, 12, 16, and 20 μg/ml, showed a slope of 0.03598 with an intercept of 0.0089 and a correlation coefficient of 0.9999.

Acute Intravenous Toxicity Studies—Forty-four male Sprague–Dawley rats[3], 160–180 g (7–8 weeks old), were divided into 11 treatment groups of four each. All animals were housed individually in stainless steel hanging cages with ambient temperature maintained at 22–24°. Food[4] and water were supplied *ad libitum*.

4:0	0.04 ± 0.33	16,100

[a] Relationship between k_1 and percent water yields a correlation coefficient of 0.999 by linear regression analysis.

Table II—Effect of Temperature on Rate Constants Obtained from a Pentobarbital Sodium Solution in Propylene Glycol–Water (1:1)

Temperature	$k_1 \times 10^3$, hr^{-1} ± 95% Confidence Interval	$t_{1/2}$, hr
100°	4.07 ± 0.63	170
90°	1.61 ± 0.16	430
80°	0.683 ± 0.064	1016
70°	0.252 ± 0.049	2750

mg/ml), the five corresponding vehicles (0.5 ml/kg), or 100 mg/kg of a pentobarbital sodium aqueous solution (positive control) were administered to each group intravenously by the tail vein. In the drug-treated animals, euthanasia was produced by the intravenous administration of the pentobarbital sodium; these rats were evaluated for gross anatomical changes. Vehicle-treated rats were placed in a carbon dioxide chamber immediately after injection as a means of inducing euthanasia for evaluation of pathological changes associated with vehicle treatment. Immediately after death, all animals were necropsied; observations were made for gross pathological changes in the heart, liver, lungs, kidneys, spleen, and brain.

Intraperitoneal Sleeptime Studies—Eighty-five male Sprague–Dawley rats[3], 160–180 g (7–8 weeks old), were divided into six groups of 10 rats and five groups of five rats each. Pentobarbital sodium doses of 25 mg/kg in five different formulations and an aqueous solution (200 mg/ml) were administered to each group of 10 rats by the intraperitoneal route. The corresponding formulation vehicles without drug were administered to the five remaining groups of five rats using volumes equivalent to those used for the drug-treated rats (0.125 ml/kg). Sleeptime was defined as the time interval from loss to restoration of the righting reflex. The righting reflex was considered recovered when the animal erected itself three times within 30 sec.

RESULTS AND DISCUSSION

Degradation Kinetics—In all cases, the degradation of pentobarbital sodium followed first-order kinetics with the logarithm of drug concentration remaining linear with time. Garrett *et al.* (3) demonstrated first-order kinetics in hydrolysis studies with barbiturates, including pentobarbital, under neutral and alkaline conditions. Since the rate constant is independent of the initial concentration in first-order kinetics, the values obtained using 50 mg/ml (in most experiments) would be applicable to any other pentobarbital sodium concentration.

Table III—Degradation Rate Constants for Pentobarbital Sodium at 100° in Nonaqueous Solvent Systems

Solvent[a]	$k_1 \times 10^4$, hr^{-1} ± 95% Confidence Interval	Maximum $k_1 \times 10^4$ hr^{-1}	Minimum Projected $t_{99\%}$ at 25°, years[b]

[a] Type 2 glass and butyl rubber closures. [b] All assay values for stability samples are means from two vials, one maintained in an upright position and the other inverted. Initial values are from a single assay.

Propylene Glycol–Water Ratio—Kinetic experiments were run at 100° using various ratios of propylene glycol–water as the solvent to assess the magnitude of the degradation rate reduction with increasing proportions of propylene glycol (Fig. 1 and Table I). The data clearly show the decrease in the hydrolysis rate constant with an increased percentage of propylene glycol in the solvent. In fact, the rate constant appeared to be approximately proportional to the water concentration in the solvent, a condition consistent with a consideration of water as a first-order reactant in the hydrolysis. In anhydrous propylene glycol, the calculated rate constant was extremely low, with the statistical maximum still less than one-fifth of the rate constant in 75% propylene glycol.

Temperature Effect—Table II summarizes the kinetic results obtained at four temperatures with a 50-mg/ml pentobarbital sodium solution in propylene glycol–water (1:1). When the data were fitted to the Arrhenius relationship by plotting the logarithm of the rate constant *versus* the reciprocal of absolute temperature, excellent linearity was obtained, with a calculated activation energy of 23.4 kcal/mole (Fig. 2).

Table V—Acute Intravenous Toxicity[a] and Intraperitoneal Sleeptime in Rats

Pentobarbital Sodium Concentration, mg/ml	Solvent System[b]	Sleeptime Duration, min[c]
200	Water	45.7 ± 4.5
200	Propylene glycol	49.5 ± 6.1
0	Propylene glycol	0
200	10% Dimethylacetamide in propylene glycol	51.6 ± 8.9
0	10% Dimethylacetamide in propylene glycol	0
200	20% Dimethylacetamide in propylene glycol	51.2 ± 8.6
0	20% Dimethylacetamide in propylene glycol	0
200	10% Glycerin in propylene glycol	46.6 ± 7.2
0	10% Glycerin in propylene glycol	0

0	10% Ethanol in propylene glycol	0

[a] No gross pathology was found based on observations of four rats using 0.5 ml/kg of solution, equivalent to a pentobarbital sodium dose of 100 mg/kg. [b] Percentage refers to grams per 100 ml of solution. [c] Values represent mean ± 1 *SD* from 10 rats treated with drug-containing solutions and five rats treated with vehicles. All doses were 0.125 ml/kg, equivalent to 25 mg/kg of pentobarbital sodium, except with propylene glycol vehicle where 0.5 ml/kg was used.

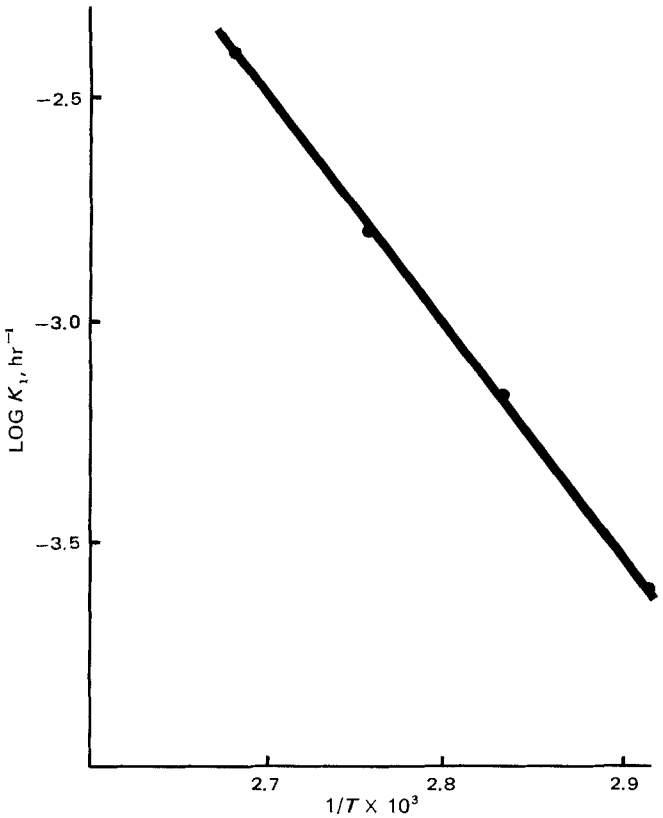

Figure 2—*Linear relationship between log* k_1 *and the reciprocal of absolute temperature in the hydrolysis of pentobarbital sodium in propylene glycol–water (1:1) using initial concentrations of 50 mg/ml. Energy of activation = 23,400 ± 1700 (p = 0.05) cal/mole; correlation coefficient = 0.9997.*

Extrapolation of this relationship to 25° yielded a rate constant of 1.42×10^{-6} hr^{-1}, a value 3.49×10^{-4} times the magnitude of the rate constant at 100°. When using this extrapolated constant, the calculated time for 1% pentobarbital sodium degradation in propylene glycol–water (1:1) at 25° would be 295 days; the time for 10% degradation would be 8.49 years.

Other Solvents—Degradation rates were determined at 100° for solutions containing 50 mg/ml of pentobarbital sodium and 10% ethanol, glycerin, or dimethylacetamide in propylene glycol (Table III). The glycerin-containing solvent gave the fastest degradation rate, while the pure propylene glycol system appeared to be the most stable. However, all anhydrous formulations showed substantially more stability than the propylene glycol–water solvent systems studied.

Based on the energy of activation determined with propylene glycol–water (1:1), the listed anhydrous solvents have projected minimum $t_{99\%}$ values (time for 1% degradation) at 25° of at least 4.68 years. As a comparison, the projected 25° $t_{99\%}$ values in water and propylene glycol–water (1:1) are 0.37 and 0.81 year, respectively. Actual stability assays on formulations based on the anhydrous systems showed no significant degradation, even after 19 months at 40° (Table IV).

Acute Intravenous Toxicity—Five anhydrous propylene glycol-based formulations containing 200 mg/ml of pentobarbital sodium were tested for acute intravenous toxicity in rats along with the corresponding vehicles (Table V). The pentobarbital sodium dose was 100 mg/kg, equivalent to 0.5 ml of formulation/kg. No drug-related pathological changes occurred in the organs of rats treated intravenously with the various pentobarbital sodium solutions or their corresponding vehicles. In all cases, organs were grossly normal. Thus, it may be concluded that the use of these solutions to produce euthanasia should not interfere with pathological evaluations or interpretations in rats.

Intraperitoneal Sleeptime—Sleeptimes induced by the various pentobarbital sodium solutions varied from 44.0 to 51.6 min (Table V). The values were not statistically different. The lack of statistically significant differences in the mean sleeptime durations indicated that the use of anhydrous propylene glycol-based vehicles did *not* affect pentobarbital sodium bioavailability. None of the vehicles (without drug) produced hypnotic effects in rats.

Bactericidal Properties of Quaternary Ammonium Compounds in Dispersed Systems

G. J. BALEY *, G. E. PECK x, and G. S. BANKER

Abstract □ Alkyltrimethylammonium bromides of selected chain length were synthesized and characterized with respect to their bactericidal properties. A partitioning method was developed, and the aqueous phases of the partitioned systems were evaluated for their antibacterial activity against *Staphylococcus aureus*. The relationships between the quaternary ammonium compound chain length and the aliphatic alcohol chain length were determined. The effect of selected hydrocarbons on the bactericidal effectiveness of the systems was studied. Cream systems corresponding to the partitioned systems were prepared and evaluated against *S. aureus*. The relationship between the aqueous phase concentration of the bactericidal agent was studied, and a correlation was shown between the bactericidal activity of the partitioned systems and cream systems.

Keyphrases □ Quaternary ammonium bromides, various—synthesized, bactericidal activity determined in simple partition systems, compared to cream systems □ Alkyltrimethylammonium bromides, various—synthesized, bactericidal activity determined in simple partition systems, compared to cream systems □ Bactericidal agents—various alkyltrimethylammonium bromides synthesized, activity determined in simple partition systems, compared to cream systems

In earlier studies (1), the partition coefficient of a series of quaternary ammonium compounds in selected aliphatic alcohols and hydrocarbons was evaluated and correlated to the physical stability of cream systems corresponding to the partitioned systems. In this study, the relationship between partitioning properties of selected quaternary ammonium compounds and their bactericidal properties in dispersed systems was evaluated.

The bactericidal effectiveness of a topical cream depends primarily on the inherent bactericidal properties of the bactericidal agent and its concentration in the aqueous phase of the system. The concentration in the aqueous phase depends upon the partition coefficient of the compound between the aqueous phase and the oil phase of the emulsion.

The partition coefficient of a solute is the ratio of the concentration of the agent in the oil phase divided by the concentration of the agent in the aqueous phase. The antimicrobial activities of antibacterials in oil-in-water systems were dependent on their aqueous phase concentration (2, 3), and another study (4) showed that the activity of solubilized iodine preparations was controlled by the concentration of iodine in the aqueous phase. In other reports, partition coefficients were used in the design of pharmaceutical dosage forms (5) and partitioning was related to preservative activity in emulsions (6).

Partitioning data were investigated relative to the preservation of multidose parenterals (7). An attempt was made to correlate partition coefficients, chemical structure, and solvent nature in dosage form design (8). Recent studies considered the availability of antimicrobial agents from emulsion systems and high petrolatum-based ointments (9, 10). Recently, the interaction of quaternary ammonium bactericides with biological materials was studied to understand their use (11, 12).

The purpose of this study was to correlate the partition characteristics of quaternary ammonium compounds with their bactericidal properties in simple partition and cream systems.

EXPERIMENTAL

The apparatus, materials, partitioned systems, and cream systems, including their method of manufacture, were described previously (1).

Test Culture—The Gram-positive bacteria, *Staphylococcus aureus*[1] (FDA 209, ATCC 6538), was maintained on nutrient agar, grown in nutrient broth, and tested in "Letheen" broth (13).

Preparation of Dilution—A 1% stock solution of the synthesized quaternary ammonium compounds was prepared in sterile distilled water. The final dilutions were made from the stock solution, directly into the medication tubes.

A 1:15 dilution of the aqueous phase from each partition study was prepared, and final dilutions were made directly into the medication tubes.

A 1:30 or greater dilution of each cream was prepared in sterile distilled water. The tube containing the cream dilution was shaken on a vortex mixer[2] until the contents appeared to be dispersed evenly. The phases were allowed to separate for 1 hr, after which a sample of the lower phase was removed with a 15.2-cm (6-in.), 18-gauge needle attached to a 10-ml syringe[3]. Final dilutions were made directly into the medication tubes.

Antibacterial Test Conditions—The critical kill dilution of each system was determined using the AOAC phenol coefficient method (14). The critical kill dilution is the highest dilution killing the test organism in 10 min but not in 5 min. Tests were conducted at 37° in a water bath, and results were read after 48 hr.

RESULTS AND DISCUSSION

Bactericidal Testing—The critical kill dilution (CKD) of each of the four synthesized quaternary ammonium compounds in distilled water was determined; the results are shown in Table I along with a comparison of reported data (15). In aqueous solution, the cetyl derivative was the most effective bactericidally, followed by stearyl-, myristyl-, and lauryltrimethylammonium bromides, respectively.

Ferguson (16) suggested that the toxicities of substances should be compared on the basis of their chemical potentials in the aqueous phase. Ecanow and Siegel (17) suggested that an extension of this concept may be applied to surfactants using the critical micelle concentration (CMC) as a standard state rather than a saturated solution as suggested by Ferguson. The thermodynamic activity and, therefore, the biological activity should be equal to a constant percent of the CMC of the drug.

The activities shown in Table II were calculated by obtaining the ratio of the test critical kill dilution divided by the CMC for each quaternary ammonium compound. The difference between the activities of the various compounds is relatively small, except for the stearyl derivative

[1] Also known as *Micrococcus pyogenes* var. *aureus*.
[2] Scientific Products, Evanston, Ill.
[3] Multifit (Luer-Lok), Becton Dickinson and Co., Rutherford, N.J.

Table II—Activity of Synthesized Quaternary Ammonium Compounds

Alkyl Group	CKD, *M*	CMC, *M*	Activity, CKD/CMC, *M*
Lauryl	4.63×10^{-7}	1.8×10^{-2}	2.57×10^{-5}
Myristyl	5.96×10^{-8}	3.6×10^{-3}	1.65×10^{-5}
Cetyl	3.03×10^{-8}	1.0×10^{-3}	3.03×10^{-5}
Stearyl	5.95×10^{-8}	3.3×10^{-4}	2.58×10^{-4}

which has an activity approximately 10-fold larger than the other three compounds.

On the other hand, a comparison indicated a 60-fold difference between the largest and smallest CMC values of the four quaternary ammonium compounds. Thus, Ferguson's principle appears to apply to the compounds studied, since the activities are in the same order of magnitude and substantiate the hypothesis that the bactericidal activity is the result of some nonspecific physical activity in contrast to the involvement of a specific chemical mechanism.

The equilibrated aqueous phases from the partitioning systems were evaluated for their critical kill dilutions. In the following experimental data, two critical kill dilutions are listed: an experimental and a corrected value. The experimental value is based on the actual dilution of the aqueous phase that was prepared to meet the critical kill dilution requirement. The corrected critical kill dilution takes into account the weight of the partitioned alcohol phase, which was not removed and evaluated; consequently, this value represents the total initial oil-in-water system. If the total nonaqueous phase was completely inert and acted only to dilute the aqueous phase, the corrected critical kill dilution would correspond to the experimental critical kill dilution for the whole cream formula.

The corrected critical kill dilution was calculated by substituting into the following equation:

$$\text{corrected CKD} = \frac{(\text{experimental CKD}) \times (\text{total weight of system})}{\text{weight of aqueous phase}} \quad \text{(Eq. 1)}$$

The relationships between quaternary ammonium compound chain length and aliphatic alcohol chain length were studied for the selected systems. Various systems were evaluated in which a hydrocarbon was included, and the change in bactericidal effectiveness was noted.

The lauryl-, myristyl-, cetyl-, and stearyltrimethylammonium bromides, at initial concentrations of 0.418, 0.452, 0.492, and 0.535%, respectively (corresponding to about 1.0 mEq/75.0 g), were each evaluated after equilibration with lauryl, myristyl, cetyl, and stearyl alcohols (15% each) against *S. aureus*. The relationships among the concentration of the quaternary ammonium compound in the aqueous phase, the quaternary ammonium compound chain length, the chain length of the aliphatic alcohol, and their effect on the critical kill dilution of the system are given in Table III.

The cetyl and stearyl quaternary ammonium compounds were ineffective as bactericidal agents, showing a corrected critical kill dilution of less than 1–13 with each alcohol. The poor killing properties may be related to the low concentration of quaternary ammonium compound present in the aqueous phase. The myristyl derivative was the most effective quaternary ammonium compound in the homologous series, even

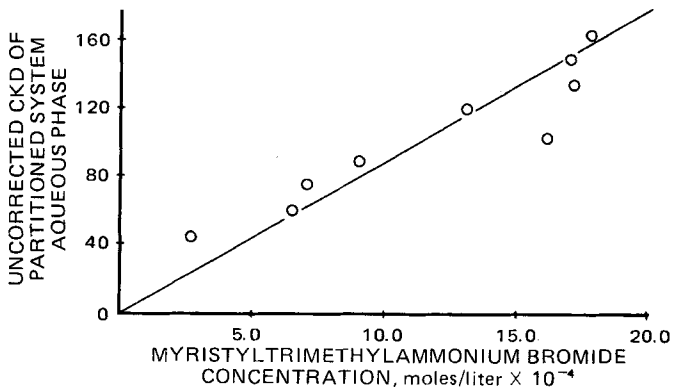

Figure 1—*Relationship between myristyltrimethylammonium bromide aqueous phase concentration and the uncorrected critical kill dilution of the aqueous phase.*

though the lauryl derivative was present in a greater concentration in each system. In the partitioning studies, the bactericidal properties of the quaternary ammonium compounds were a function of both their inherent bactericidal properties and their concentration in the aqueous phase. The myristyl quaternary ammonium compound, as a result of its intrinsic critical kill dilution, possessed the greatest bactericidal effectiveness for the concentration present in the aqueous phase.

Effect of Hydrocarbons—The critical kill dilutions for the lauryl, myristyl, and cetyl quaternary ammonium compounds in cetyl and stearyl alcohols were evaluated (Table IV) in systems that contained no hydrocarbon, 15% mineral oil, or 15% white petrolatum. The critical kill dilutions obtained appeared to be related to the inherent activity and the concentration of quaternary ammonium compound remaining in the aqueous phase of the partitioned systems.

The stearyl alcohol base systems were bactericidally more effective than the corresponding cetyl alcohol systems, due probably to the higher concentration of quaternary ammonium compound present in the aqueous phase. Both mineral oil and white petrolatum enhanced the critical kill dilution by decreasing the equilibrium partition distribution coefficient (1), thus making more quaternary ammonium compound available for bactericidal action.

The myristyltrimethylammonium bromide systems, without exception, were bactericidally more effective than either the lauryl or cetyl systems when combined with the same aliphatic alcohol and hydrocarbon. The greater activity of the myristyl compound was related to both its concentration in the aqueous phase and to its inherent bactericidal properties.

Effect of Percent Hydrocarbon—The effects of the percent hydrocarbon on the critical kill dilution of the myristyl quaternary ammonium compound in 15% cetyl or stearyl alcohol were evaluated (Table V). As the concentration of the hydrocarbon increased, the critical kill dilution of the system against *S. aureus* also increased. The addition of white petrolatum appeared to have a greater influence on increasing the critical kill dilution of a system than the corresponding percent mineral oil. The superiority of white petrolatum at increasing the critical kill dilution appeared to be related to the increase in the concentration of the myristyl compound remaining in the aqueous phase.

Relationship between Quaternary Ammonium Compound Concentration and Critical Kill Dilution—A relationship between the

antibacterial agent concentration in the aqueous phase of an emulsion and the critical kill dilution of the emulsion has been suggested (2–8). It was observed throughout the study that the critical kill dilution of the aqueous phase was related to the aqueous phase concentration of quaternary ammonium compound determined in the partitioning studies. The concentration of the myristyl quaternary ammonium compound derivative in each partition study for which critical kill dilution data were available was averaged for each experimental critical kill dilution value, irrespective of the alcohol or additive present (Fig. 1). The average aqueous phase myristyl quaternary ammonium concentration was plotted against the uncorrected critical kill dilution of the systems. The uncorrected critical kill dilutions were employed because only the relationship between the critical kill dilution and concentration was being observed. This plot substantiates the hypothesis that the critical kill dilution is related to the concentration of quaternary ammonium compound in the aqueous phase.

Critical Kill Dilution Evaluation of Creams—The critical kill dilutions of creams prepared with the lauryl, myristyl, and cetyl quaternary ammonium compounds in cetyl and stearyl alcohols with 15% hydrocarbon were evaluated (Table VI). In general, the same critical kill dilution pattern was observed for the creams as for the corresponding partitioned systems (Table IV). The stearyl alcohol base creams with each quaternary ammonium compound were more effective than creams prepared with cetyl alcohol, except for the cetyl quaternary ammonium compound containing cream with 15% mineral oil. The increased effectiveness of the stearyl alcohol base creams may again be related to larger concentrations of quaternary ammonium compound in the aqueous phase, as was suggested in the partitioning studies.

The myristyl quaternary ammonium compound was the most effective compound in the series, while the lauryl compound showed one-fifth to two-thirds the effectiveness of myristyltrimethylammonium bromide. The reason the cetyl derivative was slightly less effective than the myristyl compound was probably related again to the lower concentration in the aqueous phase of the cream system—not to inherent bactericidal properties.

The inclusion of either 15% mineral oil or 15% white petrolatum increased the critical kill dilution of the cream, which again appeared to correlate with the increased aqueous phase concentration observed in the partitioning studies. Even more significant was the fact that the addition of white petrolatum to the formula permitted the preparation of systems exhibiting *both* acceptable bactericidal effectiveness and satis-

Table VI—Critical Kill Dilution Evaluation of Creams Prepared with and without 15% Hydrocarbon against *S. aureus*

Aliphatic Alcohol (15%)	Alkyl Group	No Hydrocarbon	15% Mineral Oil	15% White Petrolatum
Cetyl	Lauryl	45	30	60
	Myristyl	60	90	150
	Cetyl	<30	60	30
Stearyl	Lauryl	60	30	60
	Myristyl	120	150	180
	Cetyl	30	30	60

Table VII—Critical Kill Dilution Evaluation of Creams Prepared with and without Various Percent Hydrocarbons against *S. aureus*

Aliphatic Alcohol (15%)	Hydrocarbon, %	Mineral Oil	White Petrolatum
Cetyl	0	60	60
	5	75	120
	10	75	135
	15	90	150
	20	105	—
Stearyl	0	120	120
	5	135	150
	10	135	180
	15	150	180
	20	165	—

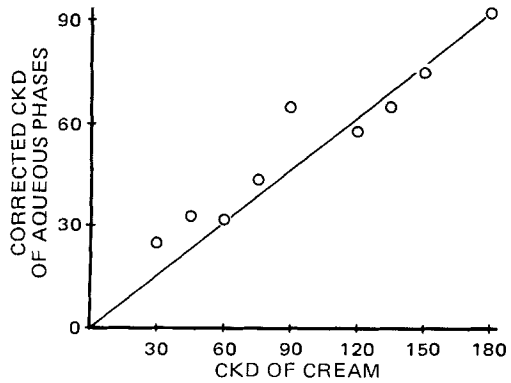

Figure 2—*Relationship between the critical kill dilutions of cream systems and the corrected critical kill dilutions of the partitioned aqueous phases.*

factory emulsion stability. A satisfactory combination of these two properties was not possible in the cream systems containing no hydrocarbon or 15% mineral oil.

Effect of Percent Hydrocarbon—The effect of the concentration of hydrocarbon on the critical kill dilution of creams emulsified with the myristyl quaternary ammonium compound and containing either cetyl or stearyl alcohol was evaluated (Table VII). The critical kill dilutions of the creams were similar in rank order to those observed in the critical kill dilution evaluation of the partitioned systems. The critical kill dilutions increased with increasing hydrocarbon concentration, with the stearyl alcohol creams being more effective than the corresponding cetyl alcohol base creams.

The white petrolatum creams showed a larger increase in critical kill dilution compared to the creams containing mineral oil of the same concentration. The increase may again be attributed to the greater concentration of quaternary ammonium compound present in the aqueous phase of the white petrolatum creams.

The relationship between the critical kill dilution of a cream and its corresponding aqueous phase was observed throughout the previous study. Figure 2 compares the relationship by pairing the corrected critical kill dilutions for the partitioned aqueous phases with the corresponding cream formula. The critical kill dilutions of the creams were ranked, and the corresponding corrected critical kill dilutions of the corresponding aqueous phases were averaged. From the data obtained, it appeared that on the average a cream was about twice as effective as the corresponding partitioned aqueous phase. The correlation technique appears to offer a method of correlating the bactericidal effectiveness of a cream and *in vitro* conditions, such as in the partitioning studies. The result also indicates that the nonaqueous phase also possesses antibacterial activity; otherwise, the slope of the plot would equal unity.

Determination of Solasodine in Fruits of *Solanum* Species

LEHEL TELEK

Abstract □ A potentiometric nonaqueous titration procedure was developed for the quantitative determination of solasodine in fruits of the *Solanum* species. The steroid glycoalkaloids were extracted from freshly harvested fruits with 2% acetic acid and methanol. After hydrolysis, the common aglycone solasodine was extracted with benzene. An aliquot was mixed with an equal volume of acetone and titrated potentiometrically with 0.005 *N* perchloric acid in dioxane, using glass and silver electrodes for the determination.

Determination of Solasodine in Fruits of *Solanum* Species

LEHEL TELEK

Abstract □ A potentiometric nonaqueous titration procedure was developed for the quantitative determination of solasodine in fruits of the *Solanum* species. The steroid glycoalkaloids were extracted from freshly harvested fruits with 2% acetic acid and methanol. After hydrolysis, the common aglycone solasodine was extracted with benzene. An aliquot was mixed with an equal volume of acetone and titrated potentiometrically with 0.005 *N* perchloric acid in dioxane, using glass and silver electrodes for the determination.

Keyphrases □ Solasodine—potentiometric analysis in fruits of *Solanum* species □ *Solanum* species—potentiometric analysis of solasodine in fruits □ Potentiometry—analysis, solasodine in fruits of *Solanum* species □ Steroids—solasodine, potentiometric analysis in fruits of *Solanum* species

The consumption of pharmacologically active steroids is increasing significantly (1). The use of steroidal contraceptives will spread with the pressing need for birth control. In the growing demand for raw materials, solasodine is the most competitive in supplementing diosgenin in the partial synthesis of steroid hormones (2). The special

advantages of solasodine are that all manufacturing processes based on diosgenin apply to it without any changes (3) and that its plant sources, some *Solanum* species, are easy to cultivate in the temperate zone.

Schreiber (4) reviewed the *Solanum* species that contain steroid glycoalkaloids in various plant parts. *S. laciniatum* Ait. is utilized industrially, and it is extensively cultivated in the Soviet Union (5) and New Zealand (6). In numerous *Solanum* species, the active ingredient is concentrated in their fruits. In Puerto Rico, *S. mammosum* L. and *S. khasianum* C. B. Clarke were studied as potential plant sources of steroid hormones[1].

In agronomic and plant biochemical research, a fast, reliable method was required for quantitative determination of solasodine in fruits of the *Solanum* species. Published procedures for the determination of solasodine in dried leaves of *S. laciniatum* include preparative gravimetry (7), colorimetry (8–11), titration in nonaqueous media (12, 13), and potentiometric titration in aqueous media (14). However, none of these methods is suitable for analyzing *Solanum* fruits.

The present report describes the direct quantitative determination of solasodine in fresh fruits, without drying, from the *Solanum* species grown in Puerto Rico in 1970 and 1971.

EXPERIMENTAL

Apparatus—An automatic system was used for the titrations[2]. A glass electrode[3] and a laboratory-made silver electrode, consisting of a folded silver strip 6.4 mm wide, 10 cm long, and 0.16 mm thick[4], were used. The sample was mixed using a magnetic stirrer and a 12.5-mm polytef[5]-coated stirring bar.

Reagents—Reagent grade acetic acid, benzene, methanol, and acetone were used without purification. Reagent grade dioxane was purified by the method of Chatten *et al.* (15) to eliminate browning with perchloric acid.

The 0.005 *N* perchloric acid titrant was prepared by dissolving 5 ml of 72% perchloric acid (reagent grade) in 100 ml of dioxane. From this 0.5 *N* $HClO_4$ stock solution, 5 ml was made up to 500 ml with purified dioxane. The perchloric acid titrant was standardized with atropine base[6] as a reference standard, which was purified by recrystallization from acetone and dried at 103°; its purity was checked by TLC (16).

Procedures—The fruits of *S. mammosum* and *S. khasianum* were harvested as soon as they reached a transition green-to-yellow color and were immediately extracted.

Extraction—Each of four or five fruits of *S. mammosum* or 20–25 fruits of *S. khasianum* of the same degree of maturity, collected from a single plant, was cut into four pieces with a sharp knife in a petri dish. The pieces were homogenized in a blender until they formed a thick, uniform slurry. The knife and dish were wiped with a small filter paper, which was added to the blender. From the homogenate, about a 10-g sample was weighed into a tared dish for determining the moisture content by drying to constant weight at 103°.

The glycoalkaloids were extracted by weighing 50 g of the homogenate in a beaker, transferring it quantitatively into a homogenizer[7] with 100 ml of 2% aqueous acetic acid, and mixing for 5 min. The slurry was centrifuged for 10 min, the supernate was decanted into an erlenmeyer flask, and the centrifuged solids were reblended and reextracted with 100 ml of methanol. After centrifugation, the methanol extract was combined with the acetic acid extract and again centrifuged. The clear solution was transferred into a 250-ml volumetric flask and diluted to volume with methanol.

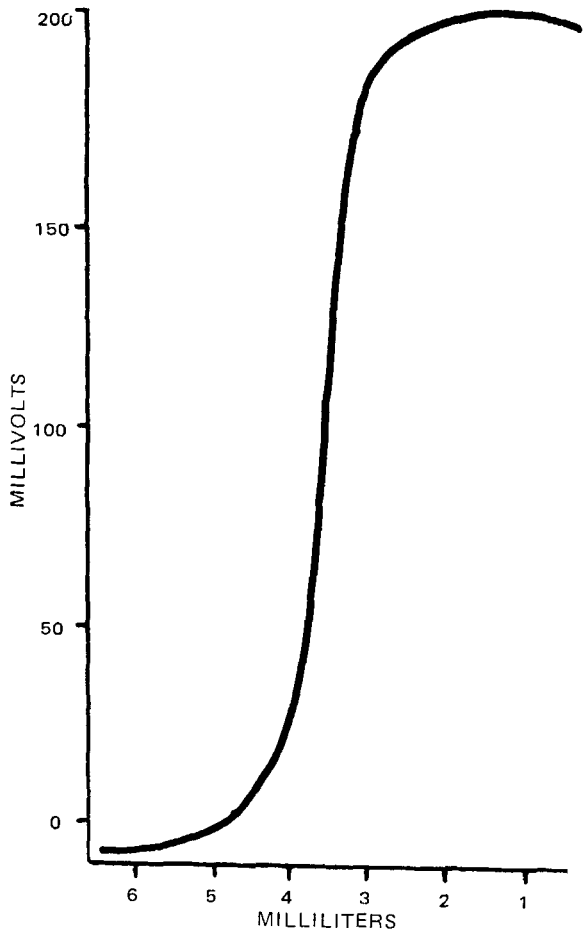

Figure 1—*Titration curve of solasodine.*

Hydrolysis—Duplicate 50-ml aliquots of the extracts were measured into 125-ml erlenmeyer flasks equipped with glass-tube condensers. Concentrated hydrochloric acid (5 ml) was added, and the mixture was heated in a boiling water bath for 2 hr. After cooling, 20 ml of 25% aqueous sodium hydroxide was added, and the mixture was heated in a water bath for 1 hr. After cooling, the content of the flask was transferred quantitatively into a separator and extracted with 25, 15, and 10 ml of benzene, consecutively. The pooled benzene extracts were dried with anhydrous sodium sulfate, transferred into a 50-ml volumetric flask, and brought to volume with benzene.

Twenty-five milliliters of the benzene extract was pipetted into the titration vessel, and 25 ml of reagent grade acetone was added. The extract was stirred at medium speed with a polytef stirring bar. The titration was monitored with a recorder by setting the electrode potential amplifier to the 100-mv scale and the recorder speed to 12.7 cm/min. Initially, the titrant was added rapidly; but as the first derivative curve began to appear, the rate of addition of titrant was decreased.

The percent of solasodine was calculated from:

$$\text{solasodine (\%)} = \frac{VF2.069 \times 100}{W_d} \qquad \text{(Eq. 1)}$$

where V = milliliters of titrant, F = normality factor of titrant, 2.069 = milliequivalents of solasodine, and W_d = weight of sample calculated as dry weight:

$$W_d = W_f - (W_f \times \%M) \qquad \text{(Eq. 2)}$$

where W_f = weight of fresh sample and $\%M$ = moisture content of fresh sample.

RESULTS AND DISCUSSION

Previously published analytical methods were developed for the evaluation of the solasodine content of dried and milled leaves of *S. la-*

Recrystallized	*S. khasianum*	Potentiometric	99.8 ± 0.4	10
Purified (preparative TLC)	*S. mammosum*	Potentiometric	100 ± 0.3	3
Purified (preparative TLC)	*S. mammosum*	Color indicator[b]	100 ± 0.4	2

[a] Every sample was heated to 105° for 2 hr before analysis. [b] From Ref. 13.

ciniatum. To achieve homogeneity of the sample, 250 g of dried leaves had to be milled through a fine mesh screen. The efficiency of extraction was inversely proportional to the particle size (17). To obtain a homogeneous sample using previous methods, serious problems would have been encountered. The steroid glycoalkaloids are not uniformly distributed in the fruit. The sap around the seed is very rich in the active principle, whereas the skin and seeds contain little or none.

It is difficult to dry a whole fruit quickly, and slow drying may cause decomposition. Moreover, the dried fruit cannot be minced because the high glycoalkaloid-containing sap tends to burn on the blades of the mill. Homogenization of fresh fruits yielded the best results. Extraction of freshly harvested fruits with weak acids and the subsequent precipitation of pectinous substances by methanol resulted in transparent yellow-colored solutions, free of suspended solids. The *Solanum* glycoalkaloids were removed quantitatively from the fruits.

In previously reported methods, the glycoalkaloids were isolated prior to hydrolysis. This step was unnecessary in the present procedure. After acid hydrolysis of the fruit extract, the solasodine was extracted with benzene from the hydrolysate.

Other methods suggested colorimetric techniques for determining solasodine based on its reaction with amphi-indicators such as methyl orange and tropaeoline 000 (8). However, these procedures are feasible only with purified compounds or colorless sample solutions.

The widely used gravimetric method, based on the weighing of a dried precipitate of solasodine hydrochloride, is not specific for solasodine and is subject to interference by inorganic coprecipitates.

The nonaqueous titration of secondary amines of alkaloids with 0.001 *N* *p*-toluenesulfonic acid, using dimethyl yellow as an indicator, is well established (18). It was applied (12, 13) to determine solasodine in leaves of *S. laciniatum*. When this method was applied to the colored fruit extracts, it was practically impossible to detect the transition color of the dimethyl yellow indicator. The chloroform solution of solasodine was also unstable, and the normality of *p*-toluenesulfonic acid in chloroform changed on standing.

Potentiometric determination of the end-point of the chloroform solutions of extracts of *Solanum* fruit titrated with *p*-toluenesulfonic acid also gave erratic results. Fritz and Burgett (19) titrated amines in acetone, using perchloric acid in dioxane as the titrant. When solasodine was titrated by this method, using calomel and glass electrodes, the resulting curves changed after each titration. By replacing the calomel electrode with a small strip of silver foil, titration of benzene extracts mixed with equal volumes of acetone gave good results. The titration curve and its first derivative curve are shown in Figs. 1 and 2.

The curves of purified solasodine and plant extracts were reproducible after repeated titrations. As a check of the procedure, the peak of the first derivative curve correlated well with the transition color of the added dimethyl yellow indicator when titrating colorless solutions of solasodine samples.

Fritz (20) recommended potassium acid phthalate in glacial acetic acid solution as a reference for standardization of perchloric acid in dioxane solution, using methyl violet as the indicator. The observation of the transition color of this indicator is very subjective, and potentiometric end-point determination of this system with glass and silver electrodes was unsuccessful.

Therefore, atropine was chosen for a reference standard. The purity of atropine was checked by TLC and by titration using the method of Gyenes (18). The titration of atropine base in benzene and acetone solution with perchloric acid in dioxane gave a curve similar to that of solasodine, and the first derivative curve showed a sharp end-point. The transition color of the dimethyl yellow indicator appeared exactly when the recorder reached the maximum of the first derivative curve.

The variable speed command module of the titration apparatus permitted the rapid addition of the bulk of the titrant; as the end-point was approached, the addition could be suitably slowed down. In this way, error due to temperature fluctuations could be minimized (21).

Titrations of crude, recrystallized, and chromatographically purified solasodine samples gave precise results. Titration of crystalline solasodine by the method of Bite (13) yielded the same result as that with the potentiometric determination (Table I).

The merits of this described method are illustrated in Table II. For the method development experiments, a composite sample was prepared of randomly picked yellow-green fruits of *S. mammosum* of different shapes. With the described extraction procedure of fresh samples, the average deviation in six assays was only 1.89% when the end-point was determined potentiometrically. However, when the methyl yellow indicator was used for the end-point determination, the average deviation of the results of four measurements was 18.4%. This deviation was further increased when the analytical samples were prepared by soxhlet extraction of dried and milled fruit (22). The titration of dark-colored samples was difficult using the methyl yellow indicator, and the average

Figure 2—*First derivative curve of solasodine.*

Table II—Analysis of a Composite Sample of Yellow-Green Fruits of *S. mammosum* for Method Development

Moisture Content[a], %	Extraction Method[b]	End-Point Indication	Solasodine Content, %	Number of Determinations
80.8	I	Potentiometric	1.06 ± 0.02	6
80.8	I	Color indicator[c]	0.98 ± 0.18	4
Dried	II	Potentiometric	0.94 ± 0.06	4
Dried	II	Color indicator[c]	0.92 ± 0.32	4
Previously extracted[d]	I	Potentiometric	2.04 ± 0.04	4

[a] Determined by drying to constant weight at 105°. [b] Extraction Method I is as outlined in this paper; Method II uses dried fruit and methanol extraction (22). [c] From Ref. 13. [d] Crystalline solasodine, 0.2 g, was added to 10 g of extracted sample.

Table III—Analyses of Fruits of *S. khasianum* and *S. mammosum*[a]

Fruit	Color	Shape	Moisture Content[b], %	Solasodine Content, %
S. khasianum	Green	Round	76.8	0.82 ± 0.04
S. khasianum	Yellow	Round	80.4	1.12 ± 0.06
S. mammosum	Yellow-green	Pear	79.1	1.05 ± 0.04
S. mammosum	Yellow-green	Round	81.9	0.99 ± 0.02
S. mammosum	Yellow-green	Pear with nipples	80.2	0.91 ± 0.03

[a] In all cases, the extraction method used was the one described in this report, and the end-point was determined potentiometrically (n = 3). [b] Determined by drying to constant weight at 105°

error of four titrations was 34.8%. Titrating the same sample with potentiometric end-point detection gave an average deviation of 6.4% in four measurements.

The recovery of added crystalline solasodine to an exhaustively extracted *S. mammosum* sample was quantitative within the experimental error of 2%, demonstrating the reliability of the extraction procedure outlined in this report.

Table III summarizes the results of solasodine determinations performed according to this procedure. Freshly harvested fruits of *S. khasianum* at different ripening stages and fruits of *S. mammosum* of different shapes were analyzed. Experimental errors were at the level previously experienced in the method development assays.

These analyses of *S. mammosum* and *S. khasianum* samples yielded more realistic values than those reported in the literature. Perez-Medina *et al.* (22) found 3.5–4% glycoalkaloids in *S. mammosum*. Maiti and Mathew (23) found 5% solasodine in *S. khasianum*. These investigators used the gravimetric method, and their results showed large variations and unusually high values when compared to solasodine levels found in other *Solanum* species. The present analyses showed alkaloid contents of 0.82–1.12% for these plants (Table III).

The easy operation of the titrating apparatus and the recorded end-point determination method should permit technicians to analyze single samples with sufficient accuracy for field evaluations.

Antimicrobial Action of Compound 48/80 against Protozoa, Bacteria, and Fungi

J. F. LENNEY *x, W. A. SIDDIQUI ‡, J. V. SCHNELL ‡, E. FURUSAWA *, and G. W. READ *

Abstract □ Compound 48/80 inhibited the growth of protozoa, bacteria, and fungi but had no effect on the multiplication of viruses. All susceptible organisms were inhibited by 10 μg/ml of crude compound 48/80, and some were inhibited by as little as 0.1 μg/ml. Against *Tetrahymena pyriformis*, this drug was seven times more potent than quinine. Separation of compound 48/80 into different fractions indicated that some antimicrobial activity could be separated from the histamine-liberating activity. It was found that compound 48/80 is not surface active at 500 μg/ml.

Keyphrases □ Compound 48/80—antimicrobial activity evaluated in protozoa, bacteria, fungi, and viruses □ Antimicrobial activity—compound 48/80 evaluated in protozoa, bacteria, fungi, and viruses □ Phenethylamine polymers—compound 48/80, antimicrobial activity evaluated in protozoa, bacteria, fungi, and viruses □ Polymers of phenethylamine—compound 48/80, antimicrobial activity evaluated in protozoa, bacteria, fungi, and viruses

In 1949, a family of polymers that lowered blood pressure was synthesized from *p*-methoxyphenethylmethylamine and formaldehyde (1). It was proposed that the products were various polymers of phenethylamine and that the most potent oligomer in the mixture was possibly the trimer. A widely distributed batch of this product was

Table III—Analyses of Fruits of *S. khasianum* and *S. mammosum*[a]

Fruit	Color	Shape	Moisture Content[b], %	Solasodine Content, %
S. khasianum	Green	Round	76.8	0.82 ± 0.04
S. khasianum	Yellow	Round	80.4	1.12 ± 0.06
S. mammosum	Yellow-green	Pear	79.1	1.05 ± 0.04
S. mammosum	Yellow-green	Round	81.9	0.99 ± 0.02
S. mammosum	Yellow-green	Pear with nipples	80.2	0.91 ± 0.03

[a] In all cases, the extraction method used was the one described in this report, and the end-point was determined potentiometrically (n = 3). [b] Determined by drying to constant weight at 105°

error of four titrations was 34.8%. Titrating the same sample with potentiometric end-point detection gave an average deviation of 6.4% in four measurements.

The recovery of added crystalline solasodine to an exhaustively extracted *S. mammosum* sample was quantitative within the experimental error of 2%, demonstrating the reliability of the extraction procedure outlined in this report.

Table III summarizes the results of solasodine determinations performed according to this procedure. Freshly harvested fruits of *S. khasianum* at different ripening stages and fruits of *S. mammosum* of different shapes were analyzed. Experimental errors were at the level previously experienced in the method development assays.

These analyses of *S. mammosum* and *S. khasianum* samples yielded more realistic values than those reported in the literature. Perez-Medina *et al.* (22) found 3.5–4% glycoalkaloids in *S. mammosum*. Maiti and Mathew (23) found 5% solasodine in *S. khasianum*. These investigators used the gravimetric method, and their results showed large variations and unusually high values when compared to solasodine levels found in other *Solanum* species. The present analyses showed alkaloid contents of 0.82–1.12% for these plants (Table III).

The easy operation of the titrating apparatus and the recorded end-point determination method should permit technicians to analyze single samples with sufficient accuracy for field evaluations.

Antimicrobial Action of Compound 48/80 against Protozoa, Bacteria, and Fungi

J. F. LENNEY *x, W. A. SIDDIQUI ‡, J. V. SCHNELL ‡, E. FURUSAWA *, and G. W. READ *

Abstract □ Compound 48/80 inhibited the growth of protozoa, bacteria, and fungi but had no effect on the multiplication of viruses. All susceptible organisms were inhibited by 10 μg/ml of crude compound 48/80, and some were inhibited by as little as 0.1 μg/ml. Against *Tetrahymena pyriformis*, this drug was seven times more potent than quinine. Separation of compound 48/80 into different fractions indicated that some antimicrobial activity could be separated from the histamine-liberating activity. It was found that compound 48/80 is not surface active at 500 μg/ml.

Keyphrases □ Compound 48/80—antimicrobial activity evaluated in protozoa, bacteria, fungi, and viruses □ Antimicrobial activity—compound 48/80 evaluated in protozoa, bacteria, fungi, and viruses □ Phenethylamine polymers—compound 48/80, antimicrobial activity evaluated in protozoa, bacteria, fungi, and viruses □ Polymers of phenethylamine—compound 48/80, antimicrobial activity evaluated in protozoa, bacteria, fungi, and viruses

In 1949, a family of polymers that lowered blood pressure was synthesized from *p*-methoxyphenethylmethylamine and formaldehyde (1). It was proposed that the products were various polymers of phenethylamine and that the most potent oligomer in the mixture was possibly the trimer. A widely distributed batch of this product was

identified by its code name "BW 48-80," which subsequently led to the adoption of the name "compound 48/80." Later, the dimeric and trimeric oligomers were synthesized by an alternative route and found to be inactive (2, 3). In 1972, dialysis and gel filtration were used to obtain evidence that the molecular size of the hypotensive constituents ranged from the tetramer to the octamer (4).

One study (5) reported that compound 48/80 caused the release of histamine and that this was the mechanism by which it lowered blood pressure. Since then, compound 48/80 has often been used as a tool to study the mechanism of mast cell degranulation and the pharmacological effects of the potent agents released from these cells. It is difficult to separate the direct effects of compound 48/80 from its indirect effects caused by the release of these agents, but several reports described actions for compound 48/80 that may not be related to mast cell degranulation: inhibition of the action of acetylcholine (6), central nervous system effects (7), ganglionic blockade (8), competitive inhibition of agonists that produce smooth muscle contraction (9), inhibition of skeletal muscle contraction (10), release of creatine phosphokinase from muscle (11), inhibition of viral-induced giant cell formation (12), and stimulation of tumor growth (13, 14). However, apparently no one has reported an antimicrobial action for compound 48/80.

The effects of compound 48/80 on the growth of protozoa, bacteria, fungi, and viruses were measured, and it was found that compound 48/80 is a moderately potent antimicrobial agent against all of these groups except the viruses. The relation between the antimicrobial activity and the histamine-liberating activity of this drug was also studied. A preliminary account of this work has been presented (15).

EXPERIMENTAL

Protozoa—*Tetrahymena pyriformis* GL (ATCC 30006) was grown in flasks containing Hogg's medium (1% proteose peptone, 0.1% K_2HPO_4, 0.1% dextrose, and 0.1% sodium acetate) on a rotary shaker at 27°. Growth was measured at intervals by counting cells that were freshly killed by dilution with 2.5% formaldehyde in 0.5% saline. In addition to compound 48/80 and its monomer, histamine diphosphate[1], diphenhydramine hydrochloride[2], and quinine hydrochloride[3] were tested for their effects on the growth of *Tetrahymena*.

Two strains of *Plasmodium falciparum* were employed: chloroquine resistant (FVO, Vietnam-Oak Knoll) and chloroquine sensitive (FUP, Uganda-Palo Alto). *P. falciparum*-infected blood was taken from Aotus monkeys and diluted with normal blood to obtain approximately 2% parasitemia. These diluted cultures were then incubated *in vitro* using a rocker dilution technique with a modified Harvard medium (16). The infections were synchronous, and experiments were begun with a majority of asexual parasites in the "ring" stage. At intervals, 100 or more parasites from each blood sample were examined microscopically and classified according to their maturation to trophozoite, schizont, or segmenter stages.

Fungi—Cultures of *Saccharomyces cerevisiae* (ATCC 7754) were grown at 30° in shake flasks containing 2% AC broth[4] on a rotary shaker. At intervals, aliquots of the cultures were diluted with water, and the transmittance of the yeast suspension was read at 755 nm. *Aspergillus niger* (ATCC 1004) was grown by the same procedure; however, growth was measured by weighing the dried mycelium, which was harvested by filtration through preweighed filter paper disks.

Bacteria—*Klebsiella pneumoniae* (ATCC 13883) and *Staphylococcus albus* (ATCC 3004) were grown in SMA broth, *Pediococcus cerevisiae* (ATCC 8081) and *Streptococcus faecalis* (ATCC 8042) were grown in Citrovorum factor assay medium[4] supplemented with 0.1 μg of calcium leucovorin/ml, and *Lactobacillus casei* (ATCC 7469) was grown in folic acid medium[4] supplemented with 0.1 μg of folic acid/ml. Cultures were incubated at 37°, and growth was followed by measuring the transmittance of the culture at 660 nm.

Viruses—Encephalomyocarditis (ATCC VR-129), vesicular stomatitis (ATCC VR-158), and vaccinia (ATCC VR-156) viruses were grown in KB cells at 37° in medium 199 supplemented with 2% calf serum (17). The concentration of the viruses in each inoculum was 100 times that necessary to infect 50% of the cells (100 $TCID_{50}$). The inoculum and compound 48/80 were added to the medium at the same time. Viral growth was followed microscopically by noting the degree of cytopathic effect caused by virus multiplication.

Gel Filtration—Compound 48/80 was fractionated in a 111 × 1.5-cm column of Sephadex G-25 medium[5]. A solution of 0.03 *N* acetic acid adjusted to pH 3.0 with hydrochloric acid was passed through the column at a flow rate of 12 ml/hr. Ten-milligram samples dissolved in 1 ml of acetic acid solution were placed on the column. The effluent was continuously monitored at 280 nm, and 8.5-ml fractions were collected.

Blood Pressure—Wistar male rats (300–600 g) were anesthetized with pentobarbital sodium[6] (50 mg/kg) and monitored on a polygraph[7]. Arterial pressure was measured with a liquid-pressure transducer[8] connected by a cannula to the right femoral artery. Heparin sodium[9] (10 mg/kg) and the fractions to be assayed were given through a cannula inserted into the right femoral vein. In each animal, the blood pressure was noted just before the infusion and again 5 min later. A dose–response curve was prepared for compound 48/80. The column fractions were analyzed in quadruplicate, and their potencies were expressed in terms of equivalent micrograms of compound 48/80 by reference to the dose–response curve.

Surface Activity—Test solutions were passed through a drop counter at a rate of approximately 15 drops/min. The volume obtained from 4000 drops provided a measure of drop size and, therefore, of surface tension. Benzalkonium chloride (0.01%) and other surfactants produced a volume that was 40–60% of the volume obtained with pure water.

RESULTS

The effects of compound 48/80 on the growth of microorganisms are presented in Table I. The growth of each protozoan, fungal, and bacterial species tested was inhibited, but there was no effect on the viruses used. The most sensitive species was *Staph. albus*, which did not grow at all in medium containing 2.5 μg of compound 48/80/ml. *L. casei* was also very sensitive, with 0.1 μg/ml causing a 37% inhibition of growth. The least sensitive of the affected organisms were *K. pneumoniae* and *A. niger*. In every case where the main reactant (*p*-methoxyphenethylmethylamine) for the synthesis of compound 48/80 was tested, it had no effect or was far less effective than an equal amount of compound 48/80.

Also shown in Table I are the effects of quinine, histamine, and diphenhydramine on the growth of *T. pyriformis*. Quinine and the antihistamine inhibited growth, whereas histamine had no significant effect. Quinine was about one-seventh as active as compound 48/80. Low levels of compound 48/80 had a static effect on *T. pyriformis* rather than a killing effect. After 24 hr of growth inhibition, dilution of the medium allowed growth to resume.

In separate experiments, compound 48/80 was about as active as pyrimethamine in inhibiting the maturation of *P. falciparum*, but it was only 10% as active as chloroquine. Compound 48/80 was more active against the chloroquine-sensitive strain of *Plasmodium* than it was against the chloroquine-resistant strain.

The activities of the fractions of compound 48/80 prepared by chromatography on Sephadex G-25 are shown in Fig. 1. The fractions that were the most potent histamine liberators also contained most of the antimicrobial activity. However, some fractions possessed antimicrobial activity but no hypotensive activity. When these fractions were tested against *P. falciparum*, all were active, including peaks 1, 2, and 3. Each fraction was more active against the chloroquine-sensitive strain of this protozoan than against the chloroquine-resistant strain.

In a preliminary experiment, peak 5 from the Sephadex G-25 column effluent was further purified by rechromatography on G-25 and then was

chromatographed on paper as previously described (4). The four resulting components were eluted from the paper and then analyzed for hypotensive activity and for activity against *L. casei*. One component displayed hypotensive activity only, another showed antibacterial activity only, and the other two components were inactive.

In another preliminary experiment, repurified peak 5 was chromatographed on a Bio Gel P-4[10] column. Four peaks were obtained in the effluent, representing compounds that were evidently separated by adsorption effects. As in the case of the paper chromatography, one peak showed hypotensive activity only, another had antibacterial activity only, and the other two were inactive.

Since compound 48/80 contains ionized nitrogen atoms, its antimicrobial and histamine-liberating activities were compared with those of a typical quaternary ammonium detergent. Benzalkonium chloride[11] was 100 times more potent than compound 48/80 as a hemolytic agent and 10 times more potent as an antimicrobial agent against yeast. However, benzalkonium chloride was one-third as potent as compound 48/80 as a histamine-releasing agent when tested *versus* mast cells *in vitro* and was only 1% as potent as a hypotensive agent. Detergents liberate histamine from mast cells by disrupting the plasma membrane, whereas compound 48/80 liberates histamine by a selective, noncytolytic action (18). The drop size procedure showed that compound 48/80 has no surface activity at 500 μg/ml; therefore, its antimicrobial activity is not attributable to surface activity or detergency.

DISCUSSION

The data show that compound 48/80 has a broad spectrum of activity in inhibiting the growth of microorganisms. In this respect, it resembles cationic detergents; however, the results indicate that compound 48/80 does not display the hemolytic and surface activities of a detergent. Although compound 48/80 is only moderately potent as an antimicrobial agent, it is not a pure substance; Fig. 1 shows that some components are inactive or are only weakly active. Thus, it is possible that the mixture may contain some very potent compounds.

In addition, since the assays were performed in the presence of growth media, complex formation with medium components may have reduced the concentration of free antimicrobial agent. (Each nitrogen atom of the polymer bears a positive charge.) Since different media were used for the growth of different organisms, the percentage of compound 48/80 complexed (if any) may have varied from one organism to another. Therefore, the relative sensitivities observed may be approximate. However, the salient point is that compound 48/80 inhibited the growth of all bacterial, fungal, and protozoal cultures tested.

Compound 48/80 (at 2–10 μg/ml) blocks the division of fertilized sea urchin (*Tripneustes gratilla*) eggs[12]. In KB cells and in sea urchin eggs, compound 48/80 alters the appearance of the cytoplasm and the shape of the nucleus. Evidently, compound 48/80 inhibits the division of a wide variety of cells, possibly by a similar mechanism.

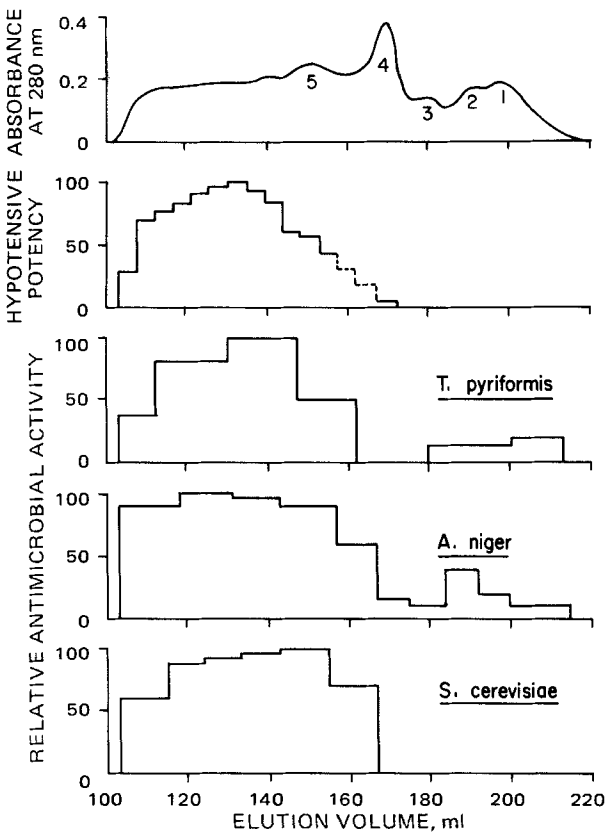

Figure 1—*Histamine-liberating and antimicrobial activities of fractions of compound 48/80. Compound 48/80 was fractionated by chromatography on Sephadex G-25 as previously described (4). The top curve is the tracing produced by a UV monitor. In the other four charts, the most potent fraction was assigned an activity of 100%.*

There are several indications that the histamine-liberating and antimicrobial activities of compound 48/80 may reside in different constituents of this mixture. Figure 1 shows that some antimicrobial activity was separated from the hypotensive fractions by chromatography on Sephadex G-25. A similar partial separation was achieved as measured by activity against *P. falciparum*. When peak 5 (Fig. 1) was separated into four components by chromatography on paper or on Bio Gel P-4, preliminary data indicated that a separation of the two activities had been effected. The fact that peak 5 contained at least four different compounds, all of approximately the same molecular size, suggests that the reaction for the synthesis of compound 48/80 may be more complex than previously assumed.

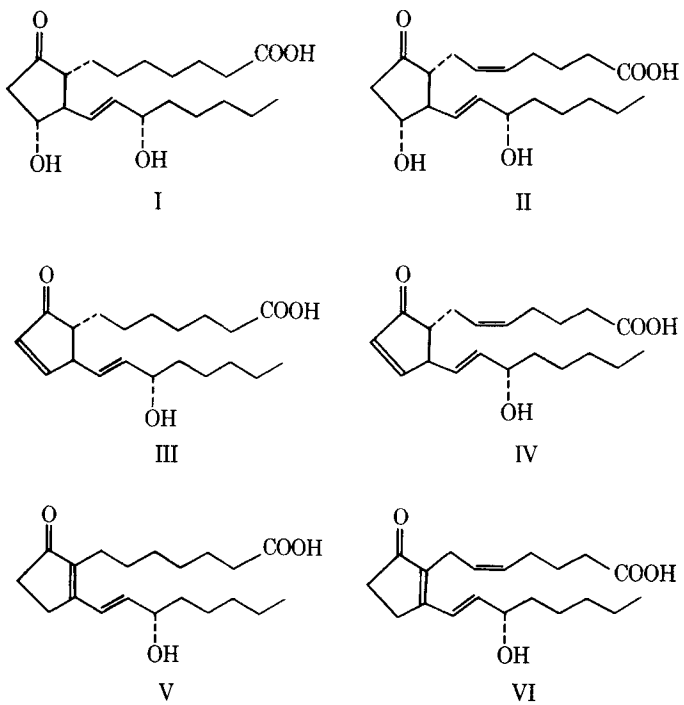
Utilization of Cyclodextrin Complexation for Separation of E, A, and B Prostaglandins by Ion-Exchange Liquid Chromatography

K. UEKAMA [x], F. HIRAYAMA, K. IKEDA *, and K. INABA [‡]

Abstract □ Application of cyclodextrin complexation to the separation of E-, A-, and B-type prostaglandins by ion-exchange liquid chromatography is demonstrated. The addition of α- or β-cyclodextrin into the mobile phase on an anion-exchange support decreased the retention times of the prostaglandins significantly because of soluble complex formation. Chromatographic separation behavior is discussed on the basis of the stability of the inclusion complex. A rapid and sensitive method for the separation and quantification of the prostaglandins, using β-cyclodextrin in the mobile phase, is described.

Keyphrases □ Prostaglandins—ion-exchange liquid chromatographic analysis after cyclodextrin complexation, prepared samples □ Cyclodextrin complexation—with various prostaglandins, ion-exchange liquid chromatographic analysis, prepared samples □ Ion-exchange liquid chromatography—analysis, various prostaglandins after cyclodextrin complexation, prepared samples □ Complexes—various prostaglandins with cyclodextrins, ion-exchange liquid chromatographic analysis, prepared samples

The prostaglandins are essentially long chain unsaturated fatty acids containing a substituted cyclopentane ring system. The β-hydroxyketo moiety of E-type prostaglandins (I and II[1]) is susceptible to dehydration in acidic or alkaline conditions to form A-type prostaglandins (III and IV[2]), which are isomerized consecutively to form the corresponding B-type prostaglandins (V and VI[3]) in alkaline conditions (1, 2). The A- and B-type prostaglandins are isomeric compounds, differing only in the position of the double bond in the cyclopentanone ring.



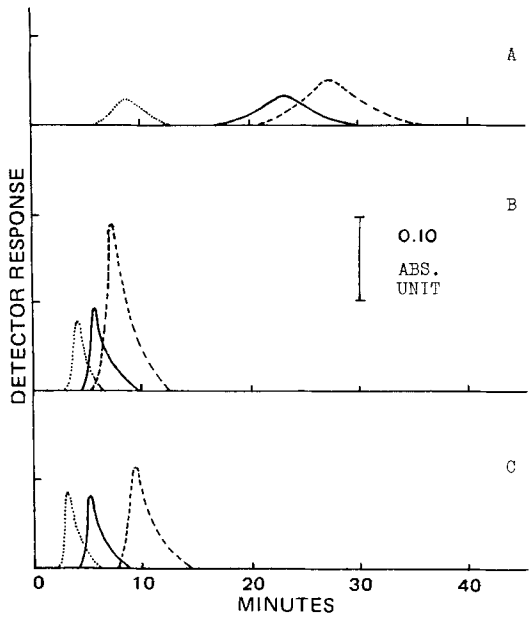


Figure 1—*Liquid chromatograms of I (20 μg), III (2.67 μg), and V (3.32 μg) on an anion-exchange column in the absence and presence of cyclodextrin in the mobile phase. Chromatographic conditions were: mobile phase, 0.1 M sodium phosphate buffer (pH 6.0, ionic strength 0.2); flow rate, 0.5 ml/min; and detection, 210, 221, and 282 nm for I, III, and V, respectively. Key: A, without cyclodextrin; B, with 0.5% α-cyclodextrin; C, with 0.5% β-cyclodextrin; ·····, I; —, III; and - - - -, V.*

High-performance liquid chromatography (HPLC) allows the direct analysis of closely related prostaglandins without protective derivatization (3). However, because the prostaglandins are hydrophobic, they generally exhibit long retention times with undesirable separation behavior on anion-exchange supports using an aqueous mobile phase. Therefore, a more rapid and sensitive HPLC method is required for the separation and detection of the prostaglandin isomers.

α- and β-Cyclodextrins form inclusion complexes with various drug molecules in water (4–9). The relatively hydrophobic environment of the cyclodextrin cavity is expected to attract the prostaglandins. A preliminary study indicated that I, III, and V formed soluble complexes with α- and β-cyclodextrins in water, which were stable in the neutral pH region (10).

The present paper deals with the application of cyclo-

[2] III is prostaglandin A_1 [(13*E*,15*S*)-15-hydroxy-9-oxoprosta-10,13-dien-1-oic acid], and IV is prostaglandin A_2 [(5*Z*,13*E*,15*S*)-15-hydroxy-9-oxoprosta-5,10,13-trien-1-oic acid].

[3] V is prostaglandin B_1 [(13*E*,15*S*)-15-hydroxy-9-oxoprosta-8(12),13-dien-1-oic acid], and VI is prostaglandin B_2 [(5*Z*,13*E*,15*S*)-15-hydroxy-9-oxoprosta-5,8(12),13-trien-1-oic acid].

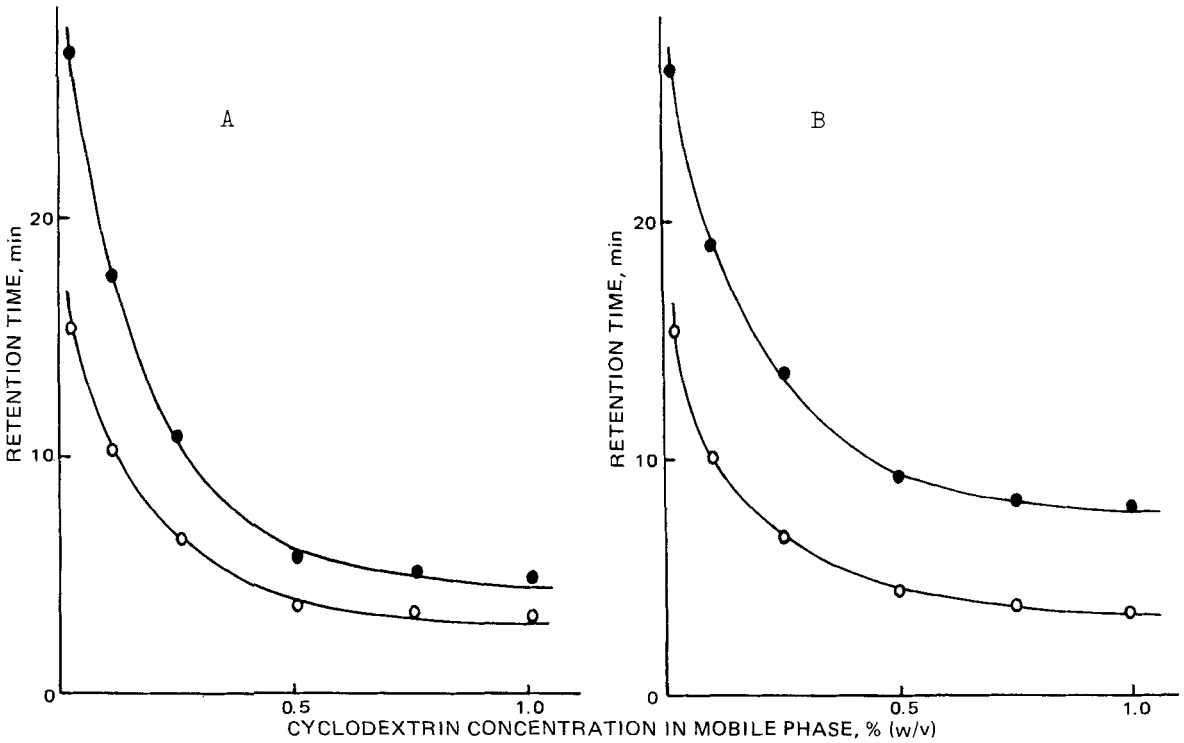

Figure 2—*Effects of cyclodextrin concentration on the retention times of III and V. Chromatographic conditions were the same as in Fig. 1. Key: A, α-cyclodextrin system; B, β-cyclodextrin system;* ○, *III; and* ●, *V.*

dextrin complexation to the separation of these prostaglandins by ion-exchange HPLC. α- or β-Cyclodextrin was added to the mobile phase on a strong anion-exchange support. To increase the detection sensitivity, A and B prostaglandins were monitored at their UV maximum wavelengths by a spectrophotometer equipped with a multiwavelength scanner. Furthermore, the concentration of cyclodextrin, pH, ionic strength, and solvent composition in the mobile phase were investigated to optimize resolution. The developed method is rapid, sensitive, and precise for the separation and quantification of the prostaglandins.

EXPERIMENTAL

Apparatus—The liquid chromatograph was equipped with a pump[4] (700 kg/cm^2 maximum), a double-beam spectrophotometric detector with a programmable multiwavelength scanner[5], an injection port[6], a microflowcell unit[7], and a strip-chart four-pen recorder[8].

Chromatographic Conditions—A 500 × 2.3-mm i.d. stainless steel column, packed with a strong anion-exchange pellicular support[9], was operated at a flow rate of 0.5 ml/min (about 1100 psi), unless otherwise stated. The pH and ionic strength of the mobile phase, phosphate buffer, were adjusted with 0.1 *M* phosphoric acid, 0.1 *M* sodium hydroxide, and sodium chloride.

Quantitative Analysis—Stock solutions of E, A, and B prostaglandins were prepared at concentrations of 6.63, 2.13, and 1.53 mg/ml in ethanol, respectively. A 2-μl aliquot of the sample was injected quantitatively with a 10-μl syringe[10]. The column temperature was ambient, and the chart speed of the recorder was 10 mm/min at a range of 0.2 absorbance unit full scale (aufs). Quantification was accomplished by the measurement of peak height. The retention time was measured as the elapsed time between injection and attainment of the chromatographic peak maximum.

Materials—α- and β-Cyclodextrins[11] and prostaglandins I–VI[12] were used as supplied. All other materials and solvents were reagent grade, and deionized, double-distilled water was used.

Solubility Studies—Solubility studies were carried out according to Higuchi and Lach (11). Excess amounts of the prostaglandins were added to aqueous α- or β-cyclodextrin solutions and were shaken at 25 ± 0.1°. After equilibration was attained, an aliquot was centrifuged and pipetted through a cotton filter. A 0.5-ml aliquot of the sample solution was extracted with 5 ml of ether from acidified media, and 2 ml of the ether phase was evaporated to dryness.

With I and III, the residues were converted to V by the treatment of 0.1 *M* sodium hydroxide solution at 80° for 1 hr (12). After cooling to room temperature, the resultant V was diluted suitably with 0.1 *M* sodium phosphate buffer (pH 7.0) and then subjected to UV spectrophotometry at 282 nm. With V, the residue was dissolved directly in a suitable amount of 0.1 *M* sodium phosphate buffer (pH 7.0) and subjected to UV spectrophotometry at 282 nm.

No appreciable degradations of I and III were confirmed during equilibration. The presence of cyclodextrin did not interfere in the spectrophotometric assay.

The stability constants for complexes were calculated from the phase diagrams obtained according to Higuchi and Lach (11).

Apparent Partition Coefficients—Solutions of E, A, and B prostaglandins (6.0×10^{-5} *M*) were prepared in chloroform, previously saturated with 0.1 *M* phosphate buffer (pH 6.0). These solutions were added to buffer solutions in suitable volume ratios and shaken at 25 ± 0.1° for 1 hr. After separation by centrifugation, an aliquot of the aqueous phase was assayed by the procedure described under *Solubility Studies*. The partition coefficient was defined as the ratio of the equilibrium concentration in the organic phase to that in the aqueous phase.

RESULTS AND DISCUSSION

Effects of Cyclodextrins on Retention Times of Prostaglandins—Figure 1 shows typical liquid chromatograms of I, III, and V on an anion-exchange support in the absence and presence of α- or β-cyclodextrin. The aqueous mobile phase was sodium phosphate buffer, since phosphate anions do not interfere with the inclusion complexation of cyclodextrins (13). A simple phosphate buffer gave long retention times

with marked tailing, particularly for A and B prostaglandins. This result may have been due to the highly hydrophobic nature of the prostaglandins, as expected from their partition coefficients (Table I). When α- or β-cyclodextrin was added to the phosphate buffer, the retention times of the prostaglandins decreased significantly. The resolution of II, IV, and VI was somewhat better than that of I, III, and V (Table I).

Figure 2 shows that an increase in α- or β-cyclodextrin concentrations shortened the retention times of III and V. This result may be ascribed to the increase in the solubility of prostaglandins by complexation with cyclodextrins.

Solubility studies clearly indicated that prostaglandins form soluble complexes with α- and β-cyclodextrins in water (Fig. 3). Stability constants were calculated on the basis of 1:1 complexation from the straight-line portion of solubility diagrams (Table II).

Complexation of the prostaglandins with cyclodextrins was also studied by UV, circular dichroism, and ^{13}C-NMR spectrometry (10), where the importance of the spatial relationship between the guest and host molecules was suggested. For example, the small spectral changes observed for the β-cyclodextrin–V system may indicate that the inclusion of V in β-cyclodextrin of a larger cavity is loose compared to that of α-cyclodextrin and this is responsible for the magnitude of the stability constant in Table II.

The magnitude of the stability constants corresponds to the change in the retention times of the prostaglandins due to the presence of cyclodextrins. β-Cyclodextrin gave better resolution of the prostaglandin peaks compared to α-cyclodextrin, particularly for A and B prostaglandins. The insufficient separation of the peaks observed for α-cyclodextrin systems may reflect the smaller difference in the stability constants of A and B prostaglandins as compared to β-cyclodextrin systems. Use of β-cyclodextrin in the mobile phase (concentration of more than 0.5% w/v) yielded rapid separation of the A and B prostaglandins in anion-exchange HPLC (Fig. 2B).

Separation and Detection of A and B Prostaglandins—Morozowich (3) employed ion-exchange HPLC for the separation of IV and VI, followed by UV (254 nm) detection. The detector response of these

compounds, however, is expected to be quite low at 254 nm, as predicted from their molar absorption coefficients (Fig. 4).

The suitable selection of the detection wavelength would provide optimum resolution with higher sensitivity. In this study, A and B prostaglandins were monitored at their UV maximum wavelengths, using a programmable multiwavelength scanner connected to a double-beam spectrophotometer and multipen recorder. The multiwavelength scanner[13] was mapped continuously through a given set of detection wavelengths, and UV absorption data were taken at the desired wavelengths throughout the entire chromatogram.

Figure 5 shows liquid chromatograms of the mixtures of III and V, where their absorbances were monitored at 221, 254, and 282 nm. This method was also applicable to the separation and detection of IV and VI, using the β-cyclodextrin solution as the mobile phase; the resolution was somewhat better than that of III and V. These results indicate that use of the multiwavelength scanner as the detection system is a significant improvement in the separation and quantification of lower levels of prostaglandins compared to ordinary 254 nm detection.

Variations in pH, ionic strength, and solvent composition in the mobile phase were investigated to determine the best operating conditions. Figure 6 shows the effect of pH on the retention times of III and V, where the concentration of cyclodextrin (0.5%) and ionic strength (0.2) were fixed. No attempts were made at pH > 8, since III is susceptible to isomerization at room temperature. The pH–retention time profile showed the general chromatographic behavior of weak acids: the higher the pH, the faster the elution because of ionization of the acids. A lower pH of the eluent gave somewhat better resolution, but this advantage was offset by the longer retention time.

Figure 7 shows the effects of the variations of ionic strength on the retention times of III and V, where the pH and concentration of cyclodextrin were fixed. The mobility of the prostaglandins was increased significantly with an increasing sodium chloride concentration owing to a salting-out effect (14). These results indicate that use of higher pH and greater electrolyte concentration is preferable for the faster elution of prostaglandins.

Retention time also decreased with increasing concentrations of organic solvents such as methanol, ethanol, and acetonitrile in the mobile phase. The presence of higher organic solvent concentrations (about 10% v/v), however, led to undesirable separation behavior, particularly for the α-cyclodextrin systems. This result may be due to the fact that the effective concentration of cyclodextrin decreases with increasing organic solvent because of the interference of inclusion complexation with prostaglandins. The smaller size of the α-cyclodextrin cavity may be particularly susceptible to competitive complexation by solvent as compared with β-cyclodextrin. Combination of β-cyclodextrin with a small amount of organic solvent (less than 5%) as the mobile phase is suggested for the elution of the prostaglandins.

Quantification of Prostaglandins—Linearity of the chromatographic conditions was evaluated by running standard mixtures of various concentrations against their corresponding peak heights. The mobile phase was 0.1 *M* sodium phosphate buffer (pH 6.0 and ionic strength 0.2) containing 0.5% β-cyclodextrin. A linear response was obtained for E, A,

[13] The scanning rate and time interval between data points were 100 nm/sec and 2 sec, respectively.

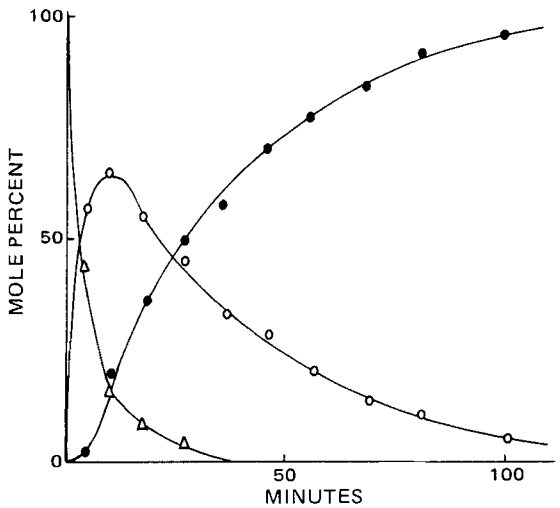

Figure 8—*Reaction profile of base-catalyzed conversion of I to III and V. A solution of I (0.863 mg/ml) in 0.05* M *sodium hydroxide at 30° under a nitrogen stream was periodically subjected to HPLC by direct injection of the alkaline mixture (pH 12.7) sample (4 μl) onto the column. Chromatographic conditions were the same as in Fig. 5. Key: △, I; ○, III; and ●, V.*

and B prostaglandins over concentration ranges of 0–30, 0–5, and 0–3 μg, respectively. In all cases, the correlation coefficient for the linear regression lines was 0.999. The minimum detection quantities of E, A, and B prostaglandins (followed at 210, 221, and 282 nm, respectively) were 150, 30, and 25 ng, respectively, when injected at a recorder range setting of 0.05 aufs.

The developed HPLC system is expected to have great utility in kinetic studies of the degradation of E and A prostaglandins. For example, Fig. 8 shows the reaction profile of base-catalyzed conversion of I to III and V. The rate constants of dehydration (0.267 min^{-1}) and isomerization (0.027 min^{-1}) were obtained by the direct analysis of the reaction species.

The described results were more rapid and sensitive than literature methods.

Determination of Meclizine Hydrochloride by Ion-Pair Extraction with Methyl Orange

F. S. HOM ˣ and W. R. EBERT

Abstract □ A method, based on ion-pair extraction, is described for the quantification of meclizine hydrochloride in various pharmaceutical dosage forms, for content uniformity determination, and for concentration monitoring in dissolution and bioavailability studies. Methyl orange, dissolved in pH 2.8 MacIlvaine buffer, gave excellent recovery of meclizine after its isolation from aqueous solutions of gelatin, urine, and blood serum. The chloroform-extracted molecular species appeared to be a 1:1 ion-pair. Beer's law was obeyed for a wide concentration range. Because the extracted species seemed well defined and stable and since a surface or an interphase adsorption phenomenon was not a problem, the reported method is considered sensitive, accurate, precise, rapid, and simple.

Keyphrases □ Meclizine hydrochloride—spectrophotometric analysis using ion-pair extraction with methyl orange, pharmaceutical dosage forms and biological fluids □ Ion-pairs—meclizine hydrochloride–methyl orange, spectrophotometric analysis, pharmaceutical dosage forms and biological fluids □ Spectrophotometry—analysis, meclizine hydrochloride using ion-pair extraction with methyl orange, pharmaceutical dosage forms and biological fluids □ Antiemetics—meclizine hydrochloride, spectrophotometric analysis using ion-pair extraction with methyl orange, pharmaceutical dosage forms and biological fluids

Meclizine hydrochloride USP (1), an antiemetic, has been used in the management of motion sickness for many years. All available methods cited by Wong *et al.* (2), including the official ones (1), that are used for the determination of meclizine are not suitable or convenient for the rapid assay of numerous small quantities of the drug

samples. For the Wong *et al.* (2) GLC method to be applicable to the present case, the small amounts of the isolated drug must be concentrated to a small volume, which is inconvenient.

Narrod *et al.* (3) used a modification of a literature method (4) in their study of the metabolism of meclizine in the rat. Their modified technique apparently worked well, but they experienced extraction and recovery problems. Similar analytical problems prompted the study of the chloroform extraction of meclizine from aqueous solutions (5) and the development of the present method.

EXPERIMENTAL

Apparatus—A spectrophotometer[1], matched 1-cm cells, a pH meter[2], and a rotating bottle (6) or the NF *in vitro* test apparatus (7) were used.

Reagents—USP meclizine hydrochloride reference standard, meclizine hydrochloride[3], type B gelatin[4], 25-mg meclizine hydrochloride tablets[5] and capsules[6], and analytical reagent grades of methyl orange[7], chloroform, citric acid monohydrate, dibasic sodium phosphate dodecahydrate, potassium chloride, anhydrous sodium sulfate, hydrochloric acid, and sodium hydroxide were used as received.

Methyl Orange Solution—Dissolve 250 mg of methyl orange and dilute to 1 liter with distilled water.

McIlvaine Buffer (8)—For Stock Solution A (0.2 *M*), dissolve 71.63 g of dibasic sodium phosphate dodecahydrate and dilute to 1 liter with distilled water. For Stock Solution B (0.1 *M*), dissolve 21.01 g of citric acid monohydrate and dilute to 1 liter with distilled water. To prepare pH 2.8 buffer, transfer 158 ml of Stock Solution A into a 1-liter volumetric flask and dilute to volume with Stock Solution B. Mix well and check and adjust pH, if necessary, with more Stock Solution A or B. Do not contaminate the pH 2.8 buffer solution with chloride ions from the electrode.

Reagent Solution—Dilute 100 ml of methyl orange solution to 1 liter with pH 2.8 buffer solution and mix well.

Standard Preparation—Dissolve 25 mg of USP meclizine hydrochloride reference standard, accurately weighed, by warming on a steam bath, if necessary, and dilute with 0.1 *N* HCl to volume in a 200-ml volumetric flask. Further dilute 10.0 ml with 0.1 *N* HCl to volume in a 200-ml volumetric flask.

Sample Preparation—Dissolve a sufficient sample equivalent to 25 mg of meclizine hydrochloride in 0.1 *N* HCl by warming on a steam bath, if necessary, so that the final solution contains a concentration of about 6.25 μg/ml. Adjust the pH of the solution with hydrochloric acid to a value of 1 or less.

Procedure—Concomitantly pipet 25.0-ml aliquots of standard and sample solutions into respective separators. Extract with 25 ml of chloroform by shaking for about 1 min. Allow the phases to separate and discard the aqueous layer. Wash the chloroform phase with 25 ml of 1 *N* NaOH by shaking for about 1 min and collect the chloroform layer into a 25-ml volumetric flask. Add more chloroform through the separator, if necessary, to bring to volume and mix well. Pipet 10.0-ml aliquots of the chloroform solutions into clean dry separators and use 10.0 ml of chloroform for the reagent blank. Add 20 ml of reagent solution to each. Shake each separator for about 1 min and allow the phases to separate.

Determine the absorbance of the chloroform extract at 422 nm *versus* the reagent blank in a suitable spectrophotometer after drying the extract with 1 g of anhydrous sodium sulfate. Calculate the amount of meclizine hydrochloride, in milligrams, in the sample by using:

$$\text{mg/sample} = \frac{4CA_u}{A_s} \qquad \text{(Eq. 1)}$$

where A_u and A_s are the absorbance values of the sample and standard, respectively; and C is the concentration of the standard solution in micrograms per milliliter.

RESULTS AND DISCUSSION

It was necessary to study the effects of pH, various ions, and buffer systems to find an optimum condition for the chloroform extraction of meclizine with methyl orange (5). Figure 1 shows the percent meclizine extracted into chloroform from a citric acid–sodium phosphate–sodium hydroxide system as a function of pH (from basic to acidic). The open circles represent the total amounts of meclizine extracted into the chloroform layer, and the closed circles represent that portion extracted as the methyl orange ion-pair.

Absorbance reading at the 422-nm wavelength of the original chloroform extract from a given pH value only showed the amount of meclizine extracted as the methyl orange ion-pair (closed circles). The amount of meclizine extracted other than as the methyl orange ion-pair was visualized by a subsequent treatment of the original chloroform extract with an excess of reagent solution. The absorbance reading of the resulting chloroform layer represents the total meclizine extracted (open circles). The difference in the two curves between pH values of 4 and 10 is meclizine extracted possibly as the free base or as other ion-pairs. The shapes of the two curves indicate an apparent anomalous behavior because meclizine, an amine, should be extracted into chloroform rapidly and completely at the higher pH values but is not, probably because of the insolubility of meclizine in water (9).

This observed behavior is not reversible: if the system is made basic again, the meclizine remains in the chloroform layer. Apparently the rapid addition of alkali causes the meclizine in solution to form a colloidal suspension in water, making the complete chloroform extraction difficult and slow. Therefore, the observed difficulty may be a physical interphase phenomenon rather than a chemical one. To circumvent this difficulty, a method based on the chloroform extraction at pH 2.8, where all of the meclizine is extracted in the form of methyl orange ion-pairs, was developed.

Figure 2 is a plot of absorbance of the chloroform extract at 422 nm as a function of the methyl orange concentration with a constant 2×10^{-5} *M* meclizine in the aqueous layer. The extrapolation of the linear portions of the curve gives an intersect at about the 2×10^{-5} *M* methyl orange point, indicating an apparent 1:1 ion-pair of methyl orange to meclizine. However, a molar ratio greater than 1 must be used for the complete meclizine extraction, as indicated by the curve leveling off slowly after the intersect.

Figure 3 shows the molar absorptivity at 422 nm as a function of the methyl orange to meclizine molar ratio. As can be seen, a value of about 4 or greater is required before a constant molar absorptivity of about 2.91×10^4 is obtained. Unfortunately, Narrod *et al.* (3) did not give a value for this comparison. However, Chatten and Okamura (10) listed molar absorptivities for eight methyl orange ion-pairs ranging from 2.36 to 3.24×10^4. Their mean was 2.81 with a standard deviation of 0.33×10^4, which is close to the present value of about 2.91×10^4.

A typical Beer's law plot of absorbance at 422 nm *versus* meclizine concentration is linear if the methyl orange to meclizine molar ratio is 4 or greater and the system is freed of ions or molecules that can also form ion-pairs with meclizine or methyl orange. Figure 4 shows the effect of the chloride ion on the percent recovery of meclizine as the methyl orange ion-pair. The chloride ion competes with methyl orange to form an ion-pair with meclizine. For this reason, meclizine is converted to the free base to eliminate interfering ions before it is allowed to form the ion-pair with methyl orange.

Since this is an acid–dye method, color change could be a problem; however, the methyl orange–meclizine ion-pair in chloroform at these concentration levels was stable for 6 hr or longer, provided the chloroform was kept from evaporating. Methyl orange in the range from 2.95 to 29.5 mg/liter when dissolved in pH 2.8 McIlvaine buffer was stable for 2 weeks or longer, as shown by the constancy of the absorbance at 505 nm *versus* time in days. One fault with this reagent solution is that it supports mold growth. However, the reagent solution may be filtered and washed with chloroform before use. The absorbance of the reagent blank is zero or near zero and is unique for a colorimetric method of this type. Another property worth pointing out is surface or interphase adsorption. This phenomenon is a common source of difficulty in this type of analytical technique but is not a problem in the present method.

The extraction interphase is clean to the naked eye, perhaps the result of the use of rather dilute solutions. Glassware shows no sign of surface adsorption; consequently, special cleaning and handling are not necessary. Since methyl orange in solution exists in several forms, one has the choice of which form to use for the final absorbance reading. The cationic form has about a 30% advantage in sensitivity over the anionic form. However, use of the cationic form for the final absorbance reading requires an extra step in the procedure. For most purposes, this additional sensitivity is not necessary or worth the added effort. All recovery results reported were made on the anionic form of methyl orange.

Precision and Accuracy—Table I lists the replicate recovery results of 100 μg of meclizine hydrochloride from 20-ml solutions of water, 0.125% type B gelatin, and 50% urine. The mean recovery was from 97.0 to 100.2% of theory with a less than 1% *RSD*. Table II shows the replicate recovery results of 20 μg of meclizine hydrochloride from 20-ml solutions of water, 0.125% type B gelatin, 50% urine, and 10% blood serum. The mean recovery was from 98.5 to 99.5% of theory with a relative standard deviation of 2.5% or less. Gelatin binding of meclizine may have been the reason for the lower recovery in both cases. Table III summarizes the results on content uniformity determination of meclizine hydrochloride from 25-mg

Table I—Recovery Results of 100 μg of Meclizine Hydrochloride from 20-ml Solutions

	Wafer	0.125% Gelatin	50% Urine

solid gelatin capsules and 25-mg tablets. The mean recovery was 100.4 and 106.0% of labeled claim with relative standard deviations of 1.6 and 4.0%, respectively.

Figure 5 shows the dissolution of meclizine hydrochloride from a 25-mg solid gelatin capsule in simulated gastric fluid (without pepsin) at 37° using the rotating-bottle method (6,7). The initial portion of the curve represents the dissolution of the drug from the shell. When the shell dissolved, the slope of the curve changed from the dissolution of meclizine hydrochloride in the lesser concentrated shell to the more concentrated core. The core completely dissolved after about 20 min and the curve leveled off.

Recording pH Method of Characterizing Composition and Monitoring Dissolution Profile of an Anhydride–Acid Copolymer and Its Salt Derivatives

YEHCHUN MO, GARNET E. PECK, ALLEN HEYD, and GILBERT S. BANKER [x]

Abstract □ A sensitive potentiometric monitoring method was developed that permits the continuous measurement of the dissolution profiles of methyl vinyl ether–maleic anhydride–acid copolymers and salt derivatives. Three distinct rate periods were observed in the dissolution of the anhydride copolymer. The relative dissolution rate of the anhydride copolymer, expressed as percent anhydride dissolved, was independent of sample weight over the weight range studied. The acid form of the copolymer showed only one dissolution rate period, with dissolution being very rapid. The rapid initial pH decrease observed during the first stage of dissolution for a series of anhydride–acid copolymer powder samples correlated closely with the anhydride–acid ratio, permitting chemical characterization of the copolymer functionality simultaneously with the analysis of dissolution profiles. Similarly, the extent of copolymer alkaline salt conversion was inversely proportional to the initial maximum pH increase observed during the first stage of dissolution of these salts. Mechanisms of dissolution of copolymer powder materials are discussed and compared to the dissolution of compressed disks and films reported previously.

Recording pH Method of Characterizing Composition and Monitoring Dissolution Profile of an Anhydride–Acid Copolymer and Its Salt Derivatives

YEHCHUN MO, GARNET E. PECK, ALLEN HEYD, and GILBERT S. BANKER [x]

Abstract □ A sensitive potentiometric monitoring method was developed that permits the continuous measurement of the dissolution profiles of methyl vinyl ether–maleic anhydride–acid copolymers and salt derivatives. Three distinct rate periods were observed in the dissolution of the anhydride copolymer. The relative dissolution rate of the anhydride copolymer, expressed as percent anhydride dissolved, was independent of sample weight over the weight range studied. The acid form of the copolymer showed only one dissolution rate period, with dissolution being very rapid. The rapid initial pH decrease observed during the first stage of dissolution for a series of anhydride–acid copolymer powder samples correlated closely with the anhydride–acid ratio, permitting chemical characterization of the copolymer functionality simultaneously with the analysis of dissolution profiles. Similarly, the extent of copolymer alkaline salt conversion was inversely proportional to the initial maximum pH increase observed during the first stage of dissolution of these salts. Mechanisms of dissolution of copolymer powder materials are discussed and compared to the dissolution of compressed disks and films reported previously.

Keyphrases □ Maleic anhydride–acid copolymers—with methyl vinyl ether, potentiometric characterization of composition and measurement of dissolution profiles □ Methyl vinyl ether–maleic anhydride–acid copolymers—potentiometric characterization of composition and measurement of dissolution profiles □ Copolymers—methyl vinyl ether–maleic anhydride–acid, potentiometric characterization of composition and measurement of dissolution profiles □ Potentiometry—characterization of composition and measurement of dissolution profiles of methyl vinyl ether–maleic anhydride–acid copolymers □ Dissolution—methyl vinyl ether–maleic anhydride–acid copolymers, potentiometric measurement of profiles

Alkyl, aryl, and alkyl vinyl ether–maleic anhydride copolymers, their hydrolyzed acids, and various ester derivatives have been recommended for various pharmaceutical applications, including use as thickeners, suspension and emulsion stabilizers, topical product and cosmetic vehicles, complexing agents of iodine and other antiseptics, controlled-release matrixes, and protective, delayed-, or controlled-release coatings (1–4). Styrene,

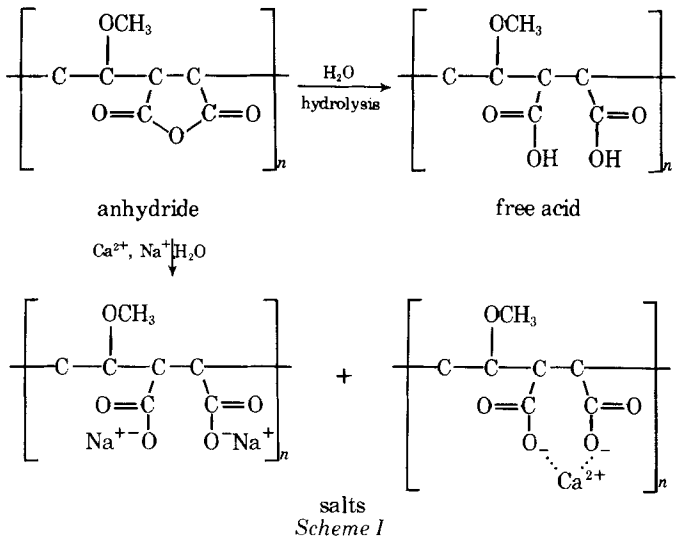
ethylene, and various alkyl vinyl ether–maleic anhydride copolymers were studied extensively as delayed and enteric coatings (5–11), and some are now used commercially. Due to the reported low toxicity of this polymer class and its increasing acceptance in cosmetic and food applications, the importance and use of these materials in drug products probably will expand.

The dissolution of alkyl vinyl ether–maleic anhydride copolymers and ester derivatives from compressed disk and film structures, using an immersion refractometry method, was reported (12). Previously, Heyd *et al.* (13, 14) discussed the immersion refractometry method, studied the dissolution of a series of ethylene maleic anhydride and acid copolymers, and examined the surface phenomena associated with polymer dissolution. The dissolution of the anhydride copolymer as a compressed disk went through an induction period comprised of a lag time (no solute in solution), a stabilization period (rate of dissolution was nonlinear), and then a linear dissolution rate period (14). These periods were subsequently related to solvent penetration into the compressed disk and initial polymer swelling (the lag time), the formation of a hydrated layer on the disk surface and the attainment of a maximum hydrated layer thickness (the stabilization period), and a constant dissolution rate (polymer chain diffusion out of the hydrated layer probably being the rate-limiting step). Woodruff *et al.* (12) examined the effect of the degree of alkyl esterification of the alkyl vinyl ether–maleic acid copolymer and the effect of alkyl chain length of the ether substituent on dissolution properties of compressed disks. The dissolution of film structures was also characterized, and the effect of formulation factors such as the presence and concentration of plasticizers was examined.

While immersion refractometry provides a simple method of following polymer dissolution, it does not readily lend itself to continuous monitoring procedures. The method is also most applicable to polymer structures (compressed disks, matrixes, and films), but it lacks sensitivity at low polymer concentrations and has been of limited use in evaluating the dissolution characteristics of powdered polymer samples. This investigation was undertaken to develop a continuous dissolution monitoring method for anhydride–acid copolymers utilizing standard laboratory equipment. Additional objectives were to study powdered polymer materials, to examine the effect of the anhydride–acid ratio and the extent of alkaline salt formation on copolymer dissolution characteristics, and to find additional methods of characterizing these copolymers as to the anhydride–acid ratio or the extent of salt formation.



Scheme I

EXPERIMENTAL

Materials—The free acid of the copolymer[1] (mol. wt. 1,125,000) of methyl vinyl ether and maleic anhydride (Scheme I) was prepared by completely dissolving the anhydride copolymer [assayed purity = 99.9% using potentiometric method (12)] in water to produce the totally hydrolyzed free acid, which was then lyophilized to a white dry powder. The alkaline salt of this copolymer was produced in an aqueous solution, and the resultant copolymer salt was dried utilizing lyophilization. All copolymer samples were subjected to a sieve treatment, and the fraction of each sample in the 60–100-mesh cut (150–250 μm) was used.

Continuous Potentiometric Monitoring Apparatus—Figure 1 outlines the setup for the continuous potentiometric monitoring apparatus. The changing pH of the test solution (A) was monitored continuously using a calomel–glass combination electrode[2] (E) connected to a pH meter[3] (P) equipped with a 25.4-cm chart recorder[4]. Double-deionized water (50 ml) was pipetted into the thin-walled beaker (T), which was then fitted into the double-walled chamber (D). Water, at a constant temperature (37 ± 1°) controlled by a thermostat[5] (W), was circulated through the double-walled chamber to maintain the test solution at a constant temperature. For each test, the electrode (E) was introduced into the test solution to a fixed depth of 2 cm below the surface of solution.

A 2 × 1-cm "floating" stirring bar[6] (F), equipped with baffles (B), was placed in the bottom of the beaker and operated at a constant stirring rate (455 ± 10 rpm), which was verified with a strobe light. The floating stirring bar was used to avoid the grinding or the milling of the undissolved copolymer particles by the normal stirring operation; the baffles served to furnish a more smooth and homogeneous agitation as well as a more stable reading on the pH meter. A plastic cover (C) was placed on the top of the beaker to reduce evaporation and to avoid contamination during a prolonged dissolution monitoring process.

The pH meter was calibrated with standard pH buffer solutions. The recording chart of the recorder was adjusted to give a full scale of 5 (pH 2.0–7.0) or 10 (pH 2.0–12.0) pH units for the dissolution study of the anhydride or the alkaline salt copolymer sample, respectively.

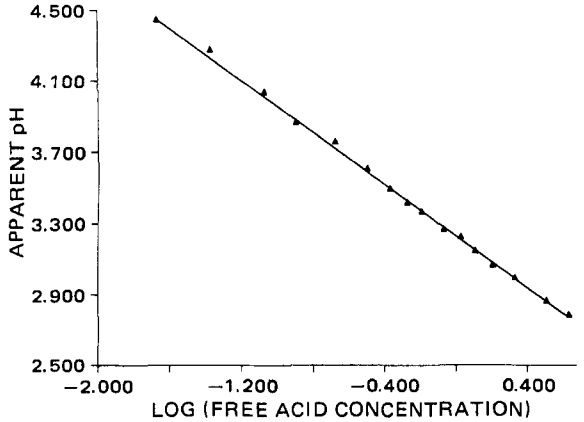

Figure 2—*Correlation of apparent pH values and logarithm values of the corresponding free acid concentrations of the copolymer standard solutions. Linear regression analysis produced a correlation coefficient of 0.998 over a concentration range of the free acid between 0.02 and 4.5 mg/ml.*

Quantitative Standardization of Copolymer Free Acid Solution—A copolymer free acid solution with an approximate concentration of 4.5 mg/ml was accurately prepared and potentiometrically titrated with a 0.1 *N* NaOH standard solution to determine its concentration quantitatively. An automatic titration system was used[7]. The free acid concentration was calculated as:

$$C_2\,(\text{mg/ml}) = \frac{174 \times N_1 \times V_1\,(\text{ml})}{V_2\,(\text{ml})} \qquad \text{(Eq. 1)}$$

where N_1 and V_1 are the normality and the amount of the sodium hydroxide standard solution consumed, respectively, and V_2 is the volume of the free acid sample solution.

RESULTS AND DISCUSSION

Correlation of Apparent pH Values with Copolymer Free Acid Concentrations in Aqueous Solutions—A series of standard copolymer free acid solutions (0.02–4.5 mg/ml) was prepared by diluting the standardized free acid solution with double-deionized water. The apparent pH value of 50 ml of each free acid solution was measured using the continuous pH-monitoring apparatus (Fig. 1) as described under *Experimental.* A linear calibration curve (r = 0.998) was observed when the measured apparent pH values of the free acid solutions were plotted against the logarithm of the corresponding concentrations (Fig. 2). The pH–concentration relationship may be expressed as:

$$\text{pH} = 3.2393 - 0.7382 \times \log\,(\text{free acid concentration}) \qquad \text{(Eq. 2)}$$

This finding coincides with the assumption (15) that the pH value of a dilute solution of a weak acid linearly correlates with the logarithm of its respective concentration:

$$\text{pH} = 0.5 \times \text{pKa} - 0.5 \times \log\,(\text{concentration}) \qquad \text{(Eq. 3)}$$

where the concentration is expressed in moles per liter. The value of the slope, 0.7382, obtained from Eq. 2 is different from the value of 0.5 of Eq. 3, because Eq. 2 expresses the concentration–pH relationship for a polyprotonic solution while Eq. 3 describes this relationship for a simple monomeric solution. For the polyacid aqueous solution, a modified form of the Henderson–Hasselbalch equation (16) was used:

$$\text{pH} = \text{pKa} - n \log \frac{(1-d)}{d} \qquad \text{(Eq. 4)}$$

where d is the degree of dissociation, pKa is the apparent dissociation constant, and n is a constant for a given set of conditions.

pH Dissolution Profile for Anhydride Copolymer—A carefully weighed sample of 100 mg of the anhydride copolymer, with a particle-size distribution ranging from 60 to 100 mesh, was added to a dissolution medium of 50 ml of double-deionized water in the sample beaker of the continuous pH-monitoring apparatus, maintained as described under *Experimental.* The pH value of the dissolution medium was continuously recorded on the recording chart (1 pH unit = 5.08-cm scale) over 10 hr (Fig. 3).

The observed decreasing pH value was due to the increased concentration of the free acid produced in the dissolution medium as the dissolution process proceeded. An initial abrupt decrease in the apparent pH value was followed by a slow and general decrease in pH until a plateau was reached, indicating that the dissolution process was complete.

Characterization of Dissolution Process of Anhydride Copolymer—The pH profile (Fig. 3) obtained by continuously monitoring the formation of the free acid in the dissolution medium was then trans-

formed into a dissolution profile (Fig. 4). This profile correlated the formation of the free acid with the dissolution time by substituting the recorded pH values into the calibration equation (Eq. 2). The resultant dissolution profile was used to investigate the dissolution process of the anhydride copolymer powder.

Two possible mechanisms for the anhydride copolymer dissolution process are proposed, Schemes II and III. Scheme III is a more likely route for the copolymer dissolution process, where the hydrolysis reaction is the rate-limiting step.

anhydride copolymer (solid) —slow dissolution→ anhydride copolymer (in solution) —fast hydrolysis→ copolymer free acid (in solution)

Scheme II

anhydride copolymer (solid) —slow hydrolysis→ copolymer free acid (solid) —fast dissolution→ copolymer free acid (in solution)

Scheme III

Essentially, three different periods are observed for the dissolution process of the anhydride copolymer with respect to the formation of the free acid (Fig. 4). Period I, the initial lag period (0–180 min), is attributed to the slow process of wetting and penetration by the water molecules. Period II, an accelerating rate period, may be reflecting the hydration and swelling of the particles as well as the autocatalytic nature of the hydrolysis reaction in which the increased hydrogen-ion concentration accelerates the hydrolysis process (17). Period III is an apparent zero-order dissolution process.

The dissolution profile of the anhydride copolymer powder material correlated with reported dissolution studies of the polymer free acid film (14) and the compressed copolymer disk (12). In these studies, a similar lag time or induction period followed by an apparent zero-order dissolution process was observed.

The three different rate periods were further characterized by relating

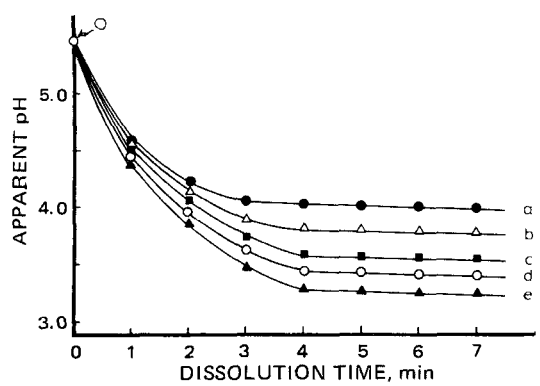

Figure 7—*Comparisons of initial dissolution profiles of copolymer anhydride–free acid mixtures. Key (anhydride–free acid ratio): a, 90:10; b, 80:20; c, 60:40; d, 40:60; and e, 0:100.*

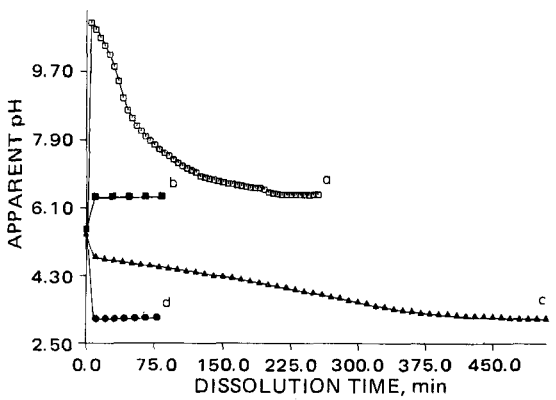

Figure 8—*Overall dissolution profiles observed for the copolymer anhydride, free acid, and salt. Key: a, mixture of the copolymer and the free alkaline salts; b, pure reacted copolymer salt; c, pure anhydride copolymer; and d, pure copolymer free acid.*

the calculated value of the initial rate of free acid formation with the dissolution time (Fig. 5). Initially, a slow dissolution rate was observed for Period I, followed by a rapidly increasing rate for Period II. The dissolution rate then reached a plateau and exhibited a constant and maximum value.

When 100-, 75-, 50-, and 30-mg powder samples of the anhydride copolymer were subjected to the dissolution test, nearly identical relative dissolution profiles were observed (Fig. 6). This result indicates that the dissolution process is essentially independent of the concentration of polymer already in solution over the concentration range studied. Figure 6 also indicates a high order of reproducibility for these recorded profiles.

Dissolution as Function of Anhydride–Free Acid Ratio—Fifty milligrams of each of a series of copolymer sample mixtures, composed of different anhydride–free acid compositions, was evaluated for dissolution characteristics as described under *Experimental.* As indicated in Fig. 7, samples containing different anhydride–free acid ratios exhibited different initial pH profiles. These profiles showed abruptly decreasing pH readings at the very beginning of the dissolution processes, followed by a much more gradual decrease in the pH values after the first 5 min (Figs. 3 and 7). In a separate experiment, the copolymer free acid completely dissolved within 5 min to give a concentration of 1.0 mg/ml.

The more abrupt drop in initial pH readings is attributed to the presence of the free acid (Fig. 8). Therefore, it is possible to determine the composition of the free acid in this mixed acid–anhydride polymer system by substituting the apparent pH reading of the dissolution medium recorded at the end of the first 5 min of the dissolution process into the calibration equation (Eq. 2) and solving for the free acid concentration. Thus, this method can be applied to the analysis of the acid–anhydride functionality of this type of polymer system. Only a very small amount of the copolymer anhydride was converted into the free acid during the first 5 min (Fig. 4). The amount of the copolymer anhydride

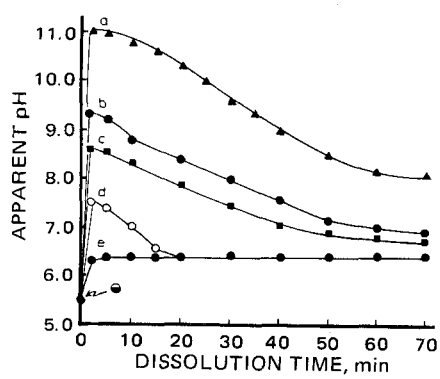

Figure 9—*Comparisons of dissolution profiles of copolymer mixtures of different anhydride–salt compositions. The half-open circle (◒) shows pH reading (5.50) prior to addition of samples. Key (anhydride–salt ratio): a, 80:20; b, 35:65; c, 25:75; d, 10:90; and e, 0:100. All samples contained identical content (29%) of alkaline salts, including both free (unreacted) and reacted salts. All profiles reached a similar plateau pH reading of 6.45 ± 0.05 toward the end of the dissolution processes.*

Table I—Correlation of the Anhydride–Salt Derivatives Ratio with the Maximum Dissolution pH Value and the Total Dissolution Time

Anhydride–Salt Derivatives Ratio[a]	Maximum pH	Total Dissolution Time, min
100/0	11.2 ± 0.1	210 ± 10
80/20	11.0 ± 0.1	180 ± 10
70/30	10.6 ± 0.1	165 ± 10
55/45	10.20 ± 0.05	140 ± 10
45/55	9.75 ± 0.05	115 ± 10
35/65	9.25 ± 0.05	95 ± 5
25/75	8.60 ± 0.05	85 ± 5
15/85	8.00 ± 0.05	55 ± 5
10/90	7.55 ± 0.05	17 ± 2
0/100	6.45 ± 0.05	1.5 ± 0.5

[a] Sample weight = 50 mg; dissolution medium = 50 ml; all samples were prepared in physical mixtures.

in a mixed anhydride–acid system is given by:

$$\text{copolymer anhydride (mg)} = 50\text{ mg} - \text{free acid concentration (mg/ml)} \times 50\text{ ml} \quad \text{(Eq. 5)}$$

Sample mixtures with higher free acid contents showed the greater initial pH drop.

Dissolution as a Function of Anhydride–Salt Ratio—When 50 mg of each anhydride–salt mixture was used for the dissolution study as discussed under *Experimental*, different characteristic dissolution profiles were recorded (Fig. 9). Free alkaline salts of calcium hydroxide and sodium carbonate were added to each sample mixture to maintain fixed salt concentrations. The profile of each sample abruptly rose from an initial reading of pH 5.5 to a maximum, after which the pH gradually decreased. The samples with a higher copolymer salt content exhibited a shorter dissolution process. In other words, the dissolution process of the anhydride copolymer was dramatically facilitated in the presence of alkaline salts (Fig. 8). One could, therefore, construct two working curves, correlating both the maximum pH readings and the total dissolution time values with the anhydride–acid salt ratios (Table I), to determine the anhydride–acid salt composition of an unknown sample mixture.

Four different dissolution profiles, representing the dissolution processes of the salt-catalyzed anhydride (a), the 100% totally reacted copolymer salt (b), the pure anhydride copolymer (c), and the pure copolymer free acid (d), are compared in Fig. 8. The copolymer sample that exhibited more polar functional groups as indicated by higher calculated hydrophilic–lipophilic balance (HLB) numbers (18) exhibited a faster dissolution process in aqueous solutions (Table II).

Table II—Correlation of the Total Dissolution Time and the Calculated HLB Number

Sample[a]	Total Dissolution Time, min[b]	HLB Number[c]
Copolymer salt	2	38.6
Pure copolymer free acid	5	9.8
Mixture of anhydride copolymer and free alkaline salts	210	—
Pure anhydride	540	7.3

[a] A 50-mg sample dissolved in 50 ml aqueous solution. [b] Determined as the time required to reach the plateau of the dissolution profile, which was recorded by the continuous pH-monitoring apparatus as described in the text. [c] Values were calculated for each repeating unit (Scheme I) of the copolymers using the reported HLB group numbers (7); (COO^-Na^+) or (COO^-Ca^+) = 20; (COOH) = 2.1; (—O—) = 1.3; (OCH_3) = 0.5; (C=O) = 0.2; and (CH) or (HCH) = 0.475. The HLB number (summation of group numbers) = +7.

Benzoyl Peroxide Stability in Pharmaceutical Gel Preparations

JAMES N. BOLLINGER ˣ, DELMA LEWIS, and VICTOR M. MENDEZ

Abstract □ The storage stability of benzoyl peroxide in the presence of both individual and combined pharmaceutical gel ingredients was investigated. Benzoyl peroxide was quite unstable in the presence of nucleophilic agents and certain acidic substances. At both 30 and 40° storage temperatures, benzoyl peroxide was destroyed rapidly (within 1 month) in the presence of ethanol and acidic chelating agents. The substitution of acetone for ethanol, the elimination of chelating agents, and the addition of sodium hydroxide to gel preparations markedly reduced degradation.

Keyphrases □ Benzoyl peroxide—stability in pharmaceutical gels, effect of temperature, pH, and various gel ingredients □ Stability—benzoyl peroxide in pharmaceutical gels, effect of temperature, pH, and various gel ingredients □ Gels—stability of benzoyl peroxide, effect of temperature, pH, and various gel ingredients □ Keratolytics—benzoyl peroxide, stability in pharmaceutical gels, effect of temperature, pH, and various gel ingredients

Benzoyl peroxide pharmaceutical preparations are widely used in the treatment of acne. However, due to the inherent chemical nature of benzoyl peroxide, degradation of these preparations is often encountered in storage. The purpose of this investigation, therefore, was to evaluate various parameters regarding the storage stability of benzoyl peroxide in pharmaceutical gel formulations.

BACKGROUND

A survey of existing products showed that most formulations contain either 5 or 10% benzoyl peroxide. The thickening agents commonly employed in the formation of the gels are carboxypolymethylene and hydroxypropyl methylcellulose. The stability of the gels formed with carboxypolymethylene is regulated by the addition of alkaline neutralizers such as sodium hydroxide, bis(2-propanol)amine, and triethanolamine. The stability of gels formulated with hydroxypropyl methylcellulose is usually enhanced by the addition of silicates.

Other gel components include the polyoxyethylene lauryl ether surfactants, which aid in the solubility of components in the gels themselves and enhance the contact of benzoyl peroxide with the skin. The latter effect probably is also enhanced by the presence of organic solvents.

Gels often contain various glycols such as glycerol, ethylene glycol, and propylene glycol. They serve several purposes including solvent action and humectant properties. The final major substance present is water, which may have a chelating agent added such as edetate disodium or citric acid.

Gels also may contain sodium lauryl sulfate, fragrances, and color, but these were not evaluated in this study.

Preliminary studies in this laboratory[1] indicated that certain ingredients in gels may influence the chemical stability of benzoyl peroxide—namely, that the benzoyl peroxide concentration is, with time, lowered due to its reactivity with the other ingredients. Original studies (1) on stability showed that, when heated, benzoyl peroxide, either in pure form or in nonpolar solvents, decomposed to yield carbon dioxide, biphenyl, phenyl benzoate, and benzene.

In the presence of alcohols, benzoyl peroxide decomposed to carbon dioxide, benzoic acid, and alcohol esters of benzoic acid (2). In the presence of acetic acid, it decomposed to form carbon dioxide, benzoic acid, phenylbenzoic acid, benzene, biphenyl, and phthalic acids (3). Since benzoyl peroxide is both a UV and a thermal free radical precursor, the resultant free radicals can interact with most molecules that, through electron shifts, are easily induced to possess reactive unshared electrons, such as certain alcohols, sulfhydryl compounds, alkanes, alkenes, and aromatic compounds.

The purpose of this study was not to identify reaction products but to evaluate the decomposition of benzoyl peroxide with respect to whether any ingredient used in the gel preparations enhances its degradation.

EXPERIMENTAL

Formulations—As shown in Table I, experimental test formulations were made to evaluate the stability of benzoyl peroxides as influenced by thickening agents, alkaline neutralizers, surfactants, solvents, chelating agents, and temperature. Except for the alkaline neutralizers, all ingredients were added on a gram-weight basis. The ingredients were added together and thoroughly mixed to a uniform gel using a high speed, high shear mixer. The benzoyl peroxide suspension was prepared by adding water and micropulverizing the mixture into a milky, stable suspension.

The final concentration of the ingredients, including benzoyl peroxide, was adjusted prior to the final mixing through the addition of weighed amounts of water; neutralization and pH adjustments were made during the final mixing using approximately 5–10 ml of a 10% solution of the amines and 5–7 ml of a 10% NaOH solution. A zero-time analysis of benzoyl peroxide was performed in triplicate by titrimetric means (4) on each final test sample batch.

Experimental Protocol—The 22 gel formulations (Table I) were individually evaluated in triplicate at zero time and after storage for 30, 60, and 90 days at both 30 and 40°. Approximately 2.5 g of the test gel was placed in tared glass vials and sealed with polyethylene- or polycarbonate–polyethylene-lined screw caps. Each vial was then reweighed and stored in the dark in either the 30 or 40° oven. Therefore, 18 samples were prepared for each test of the 22 gel formulations; an additional vial containing 20 g of the gel was used to evaluate pH changes.

The concentration of benzoyl peroxide was determined as indicated by employing the recently developed titrimetric procedure (4, 5), using acetone extractions with potassium iodide–thiosulfate titrations in the presence of phenyl sulfide.

Sample weight losses due to storage were determined gravimetrically for each sample. Hydrogen-ion concentrations were determined using glass electrodes and a digital readout pH meter.

GLC[2] and GLC–mass spectrometry[3] were employed to identify any unusual reaction products.

RESULTS AND DISCUSSION

Figures 1–7 graphically depict the mean percentage loss of benzoyl peroxide as influenced by the various ingredients and combination of ingredients used in the gels.

The first six test samples were stored in glass vials with polyethylene caps; at the 40° test temperature, several samples stored with these caps lost substantial weight (10–20%) due to heat softening of the caps and subsequent solvent leakage. Subsequent analysis indicated, however, that this loss had no influence on the stability of benzoyl peroxide. Loss in sample weight usually ranged from 1 to 3% of the original weight.

Influence of Alkaline Neutralizers in Carboxypolymethylene Gel—These gel systems contained 1.75% carboxypolymethylene, 10% benzoyl peroxide, and enough triethanolamine, bis(2-propanol)amine, or sodium hydroxide solution to bring the pH to approximately 5. As shown in Fig. 1*a*, at 30° there was practically no breakdown of benzoyl peroxide over 90 days in any of these test samples. At 40° (Fig. 1*b*) and after 60 days, a 5–10% loss in benzoyl peroxide occurred. After 90 days at this temperature, the breakdown or loss was 20% in the presence of bis(2-propanol)amine, 10% with triethanolamine, and 5% with sodium hydroxide. The pH of the 40° samples over 90 days dropped approximately from 5 to 4.5.

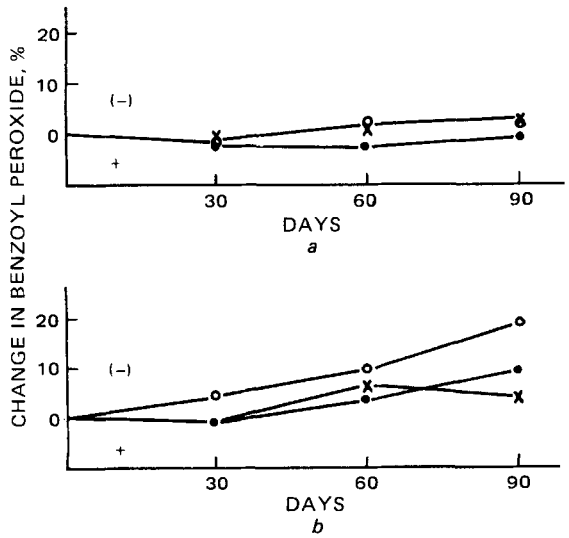

Figure 1—*Influence of alkaline neutralizers in carboxypolymethylene gel on the stability of benzoyl peroxide. Each gel consisted of carboxypolymethylene, benzoyl peroxide, and water. Alkaline neutralizers included triethanolamine (●), sodium hydroxide (×), and bis(2-propanol)amine (○). Key:* a, *storage at 30°; and* b, *storage at 40°.*

Influence of Organic Solvents—As shown in Fig. 2, two solvents, ethanol and acetone, were evaluated regarding their effect on benzoyl peroxide stability. The remainder of the preparation consisted of 10% benzoyl peroxide, 1.75% carboxypolymethylene, and both triethanolamine and sodium hydroxide as the polymer neutralizing-thickening agents.

At 30° (Fig. 2*a*), samples containing ethanol displayed 2–5% losses in benzoyl peroxide after 60 days. By 90 days, the samples containing ethanol and triethanolamine showed benzoyl peroxide losses of about 12%; those containing ethanol and sodium hydroxide had a 4% mean loss. None of the samples containing acetone showed measurable losses in benzoyl peroxide.

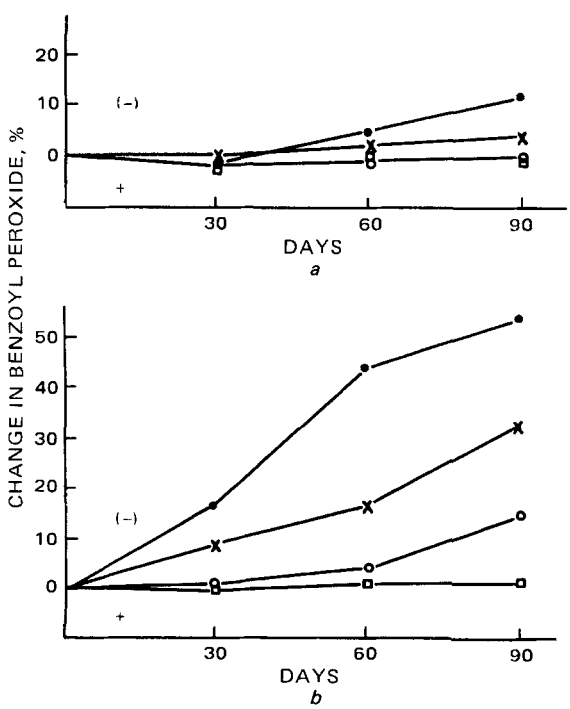

Figure 2—*Influence of organic solvents on benzoyl peroxide stability. Each gel mixture consisted of carboxypolymethylene, benzoyl peroxide, and water. Variants to the system included ethanol and triethanolamine (●), ethanol and sodium hydroxide (×), acetone and triethanolamine (○), and acetone and sodium hydroxide (□). Key:* a, *storage at 30°; and* b, *storage at 40°.*

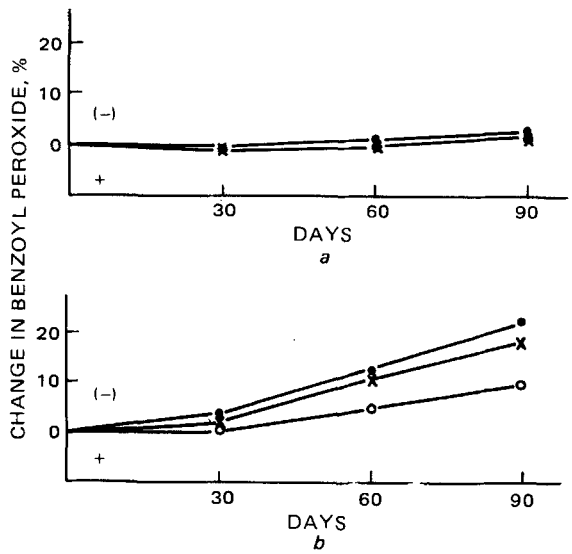

Figure 3—*Influence of surfactant and humectant on the stability of benzoyl peroxide. Each gel mixture consisted of carboxypolymethylene, benzoyl peroxide, and water. Variants to the system included polyoxyethylene 23 lauryl ether (●), polyoxyethylene 4 lauryl ether (×), and propylene glycol (○). Key:* a, *storage at 30°; and* b, *storage at 40°.*

These same effects were accentuated at the 40° storage temperature. By 90 days, the ethanol–triethanolamine samples sustained a 50% loss in benzoyl peroxide, the ethanol–sodium hydroxide samples had a 33% loss, and the acetone–triethanolamine-containing samples had a 15% loss. Samples containing acetone–sodium hydroxide showed no loss in benzoyl peroxide (Fig. 2*b*).

Indicative of the breakdown of the benzoyl peroxide was a marked pH change (*e.g.*, from a pH of 5 to ~3.5 in the ethanol–triethanolamine samples). After 90 days at 40°, samples containing ethanol–sodium hydroxide showed a decomposition of about 33% and the pH did not drop (from pH 5.0 to 4.2) as markedly.

Influence of Surfactant and Humectant—As shown in Fig. 3, neither the polyoxyethylene lauryl ethers nor propylene glycol appeared to influence the decomposition of benzoyl peroxide appreciably. After 90 days at 30°, there was no decomposition whatsoever; after 90 days at 40°, the decomposition of benzoyl peroxide was 20% in the presence of polyoxyethylene lauryl ethers as compared to 10% with propylene glycol.

Influence of Chelating Agents—These test systems contained all of the gel ingredients (Table I, Samples 11–16). The components held constant included carboxypolymethylene, polyoxyethylene lauryl ether, and propylene glycol. The ingredients that were varied included the solvents (ethanol and acetone), the neutralizers (sodium hydroxide and triethanolamine), and the chelating agents (edetate disodium and citric acid). It was not anticipated that any effect would be seen due to the chelating agents; however, as shown in Figs. 4 and 5, this assumption was erroneous.

Figure 4 graphically shows the influence of ethanol, triethanolamine, citric acid, and edetate disodium on the stability of benzoyl peroxide. The large decomposition of benzoyl peroxide (50–60%) at 30° after 90 days of storage (Fig. 4*a*) indicates that the chelating agents, citric acid and edetate disodium, somehow influenced the breakdown of benzoyl peroxide. The use of sodium hydroxide in this test system reduced the decomposition of benzoyl peroxide by more than 75% when compared to triethanolamine. The 15% level of decomposition noted in the sodium hydroxide-containing system was only slightly higher than that in the ethanol–sodium hydroxide system (5%) without chelating agents.

Figure 4*b* (40° test of the same mixtures) shows 90–100% destruction of benzoyl peroxide by 60 days, further indicating some form of catalytic activity due to the presence of chelating agents. The results were similar to the 30° test system discussed previously in that sodium hydroxide markedly delayed the decomposition of benzoyl peroxide during the initial 30 days.

Additional information on the effects of the solvent *versus* chelating agents can be seen in Fig. 5*a*. In these test systems, acetone was substituted for ethanol as the solvent. After 90 days at 30°, there was only a 10% decomposition in the acetone–triethanolamine–citric acid samples as

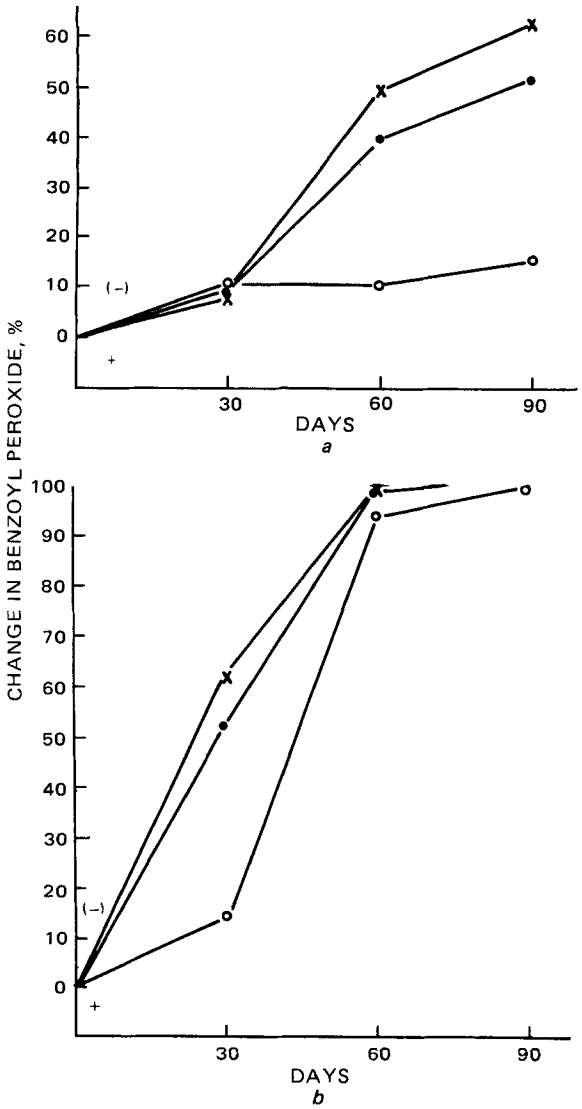

Figure 4—*Influence of ethanol in the presence of chelating agents on the stability of benzoyl peroxide. Each gel system contained carboxypolymethylene, benzoyl peroxide, ethanol, polyoxyethylene 23 lauryl ether, propylene glycol, and water. Variants in the system included triethanolamine and edetate disodium (●), triethanolamine and citric acid (×), and sodium hydroxide and edetate disodium (○). Key:* a, *storage at 30°; and* b, *storage at 40°.*

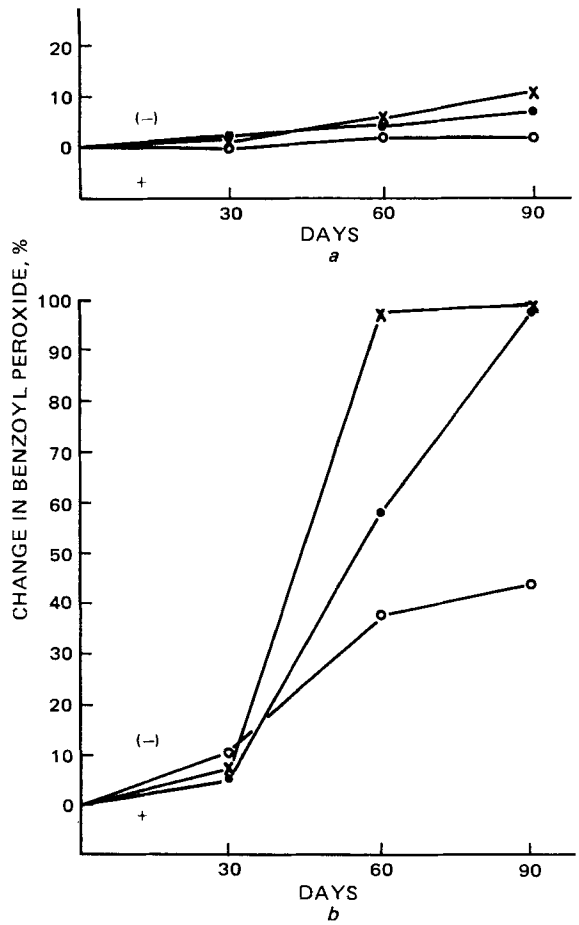

Figure 5—*Influence of acetone in the presence of chelating agents on the stability of benzoyl peroxide. Each test system consisted of the same ingredients as in Fig. 4, except that ethanol was replaced with acetone. Variants to the system included triethanolamine and edetate disodium (●), triethanolamine and citric acid (×), and sodium hydroxide and edetate disodium (○). Key:* a, *storage at 30°; and* b, *storage at 40°.*

compared to a 60% decomposition when ethanol was used in the same system. With the acetone–triethanolamine–edetate disodium system, there was a 7% decomposition of benzoyl peroxide but virtually no (<2%) decomposition in the acetone–sodium hydroxide–edetate disodium system.

Increasing the test storage temperature to 40° (Fig. 5*b*), however, induced the decomposition of benzoyl peroxide. During the initial 30 days of storage at this temperature, little decomposition occurred in any acetone sample; however, in the triethanolamine–citric acid–acetone system, there was 100% destruction of benzoyl peroxide by 60 days. It took 90 days to destroy benzoyl peroxide completely in the triethanolamine–edetate disodium–acetone system; with the sodium hydroxide–edetate disodium–acetone samples, only 45% destruction occurred after storage at 40° for 90 days.

These data indicate that the presence of chelating agents greatly enhanced the breakdown of benzoyl peroxide in the presence of ethanol. The partial decomposition noted in the presence of acetone and chelating agents at the higher temperatures was probably related to alcohol groups and other free-radical potentiating groups and not to acetone itself.

A GLC analysis of these samples indicated that the ethanol-containing preparations contained an additional reaction by-product. Both comparative GLC and GLC–mass spectrometry analysis showed this product to be ethyl benzoate.

Influence of Hydroxypropyl Methylcellulose and Silicate—Samples 16–22 (Table I) contained hydroxypropyl methylcellulose and magnesium aluminum silicate as the thickening agents instead of carboxypolymethylene. As opposed to gel thickened with carboxypolymethylene (pH 5), these samples were stored at pH 6 and 8. The results of these tests are shown in Figs. 6 and 7. The exception to the use of complete formulations was that one group of samples, prepared and stored at pH 6 and 8, contained only benzoyl peroxide, hydroxypropyl methylcellulose, silicate, and sodium hydroxide.

The ethanol-containing samples were the only ones to show appreciable (30%) decomposition of benzoyl peroxide after storage for 90 days at 40° (Figs. 6 and 7). Whether the test samples were initially stored at pH 8 or 6 had no influence on the degree of breakdown. The pH of the samples stored at pH 6 dropped approximately 1.7 units and that of the samples stored at pH 8 dropped approximately 3.7 units, to yield an average pH for all samples of 4.3 regardless of whether the samples contained acetone, ethanol, or no solvents. The effects of the catalytic activity of the chelating agents was not as evident in this gel system. However, since sodium hydroxide was used to adjust the pH, the breakdown of benzoyl peroxide would not be expected to be as great as if triethanolamine had been employed.

Influence of Temperature *versus* Gel Ingredients—An evaluation of the data showed that the storage temperature had only an indirect influence on the stability of benzoyl peroxide. Even at storage temperatures of 40° (104°F), little degradation (1–3%) occurred if no free-radical propagating-type molecules were present in the mixture. Molecules that enhanced the free-radical propagation-type reactions included hydroxyl-containing molecules, primarily ethanol, and, indirectly, the chelating agents.

The fact that neutralization of the gel with sodium hydroxide markedly reduced degradation of benzoyl peroxide in the presence of ethanol and

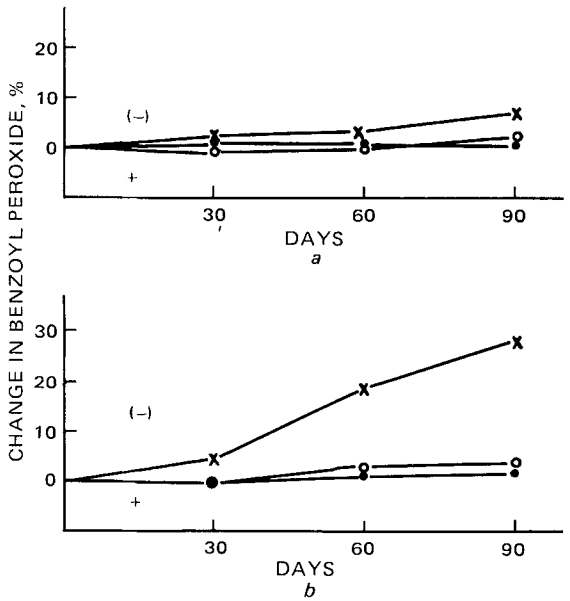

Figure 6—*Influence of hydroxypropyl methylcellulose and magnesium aluminum silicate gel system on the stability of benzoyl peroxide. The formulation contained benzoyl peroxide, sodium hydroxide, polyoxyethylene 23 lauryl ether, propylene glycol, edetate disodium, hydroxypropyl methylcellulose, magnesium aluminum silicates, and water. Variants to the system were: no solvent or chelating agent (●), ethanol as the solvent (×), and acetone as the solvent (○). Initial storage pH was 6.0. Key:* a, *storage at 30°; and* b, *storage at 40°.*

the chelating agents indicated that it interfered with the formation and entrance of ethanol radicals into the reaction. However, once the neutralization effect on the solvents is lost or lowered through either reaction with existing carboxyl groups or the thermal formation of benzoic acid (6), the entrance of free-radical propagating solvents such as ethanol into the reaction becomes increasingly unhindered. Acetone cannot readily, if at all, enter into free-radical reactions due to its electrochemical makeup. One might predict, based on data obtained in this study, that the polyoxyethylene lauryl ethers, glycols, carboxypolymethylene, and hydroxypropyl methylcellulose, in that order, can enter (on a limited basis) into a free-radical propagation-type reaction.

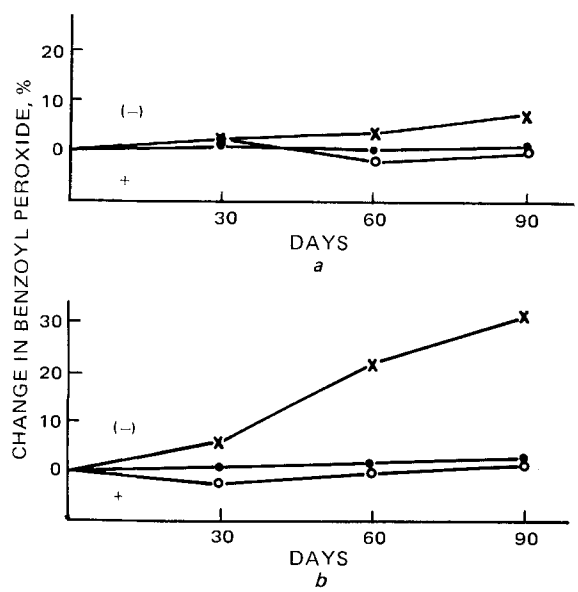

Figure 7—*Influence of pH on the storage stability of benzoyl peroxide in the hydroxypropyl methylcellulose–magnesium aluminum silicate gel. Basic gel system was the same as in Fig. 6, except that the samples were initially stored at a pH of 8. Variants were: no solvent or chelating agent (●), ethanol solvent (×), and acetone solvent (○). Key:* a, *storage at 30°; and* b, *storage at 40°.*

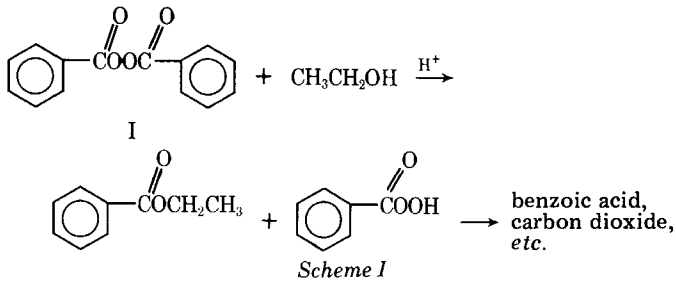
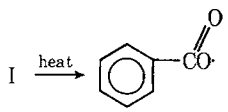


Scheme I



Scheme II

SUMMARY

The results of this investigation showed that triethanolamine, bis(2-propanol)amine, sodium hydroxide, carboxypolymethylene, hydroxypropyl methylcellulose, magnesium aluminum silicate, propylene glycol, the polyoxyethylene lauryl ethers, and acetone, individually, do not appreciably influence the storage stability of benzoyl peroxide (I). However, ethanol alone and, to a larger extent, in the presence of chelating agents and the carboxypolymethylene gel and, to a lesser degree, hydroxypropyl methylcellulose–silicate gel markedly enhanced the breakdown of benzoyl peroxide. The most pronounced degradation (100% within 30 days of storage at 30°) occurred in the presence of carboxypolymethylene, ethanol, and either edetate disodium or citric acid.

This latter phenomenon is thought to be due to the reaction shown in Scheme I. Classically, in the presence of heat, for example, benzoyl peroxide is thought to react as shown in Scheme II. However, the results of this investigation indicate that the Scheme II reaction did not occur to an appreciable extent even at the 40° storage temperature. Therefore, the partial degradation that occurred in the acetone samples containing the acidic chelating agents probably was due to some other alcohol or free-radical propagating groups, since acetone itself cannot be expected to react readily with benzoyl peroxide. In the absence of the chelating agents, for example, samples containing acetone were quite stable. In addition, the gel preparations containing sodium hydroxide as the neutralizing agent were far more stable than those containing triethanolamine, and the latter samples were slightly more stable than those containing bis(2-propanol)amine. These data indicate that sodium hydroxide hinders the formation of "solvent" radicals (*i.e.*, $CH_3CH_2O\cdot + \cdot H$), thus slowing the propagation of benzoyl peroxide decomposition.

In general, the results of this investigation demonstrated that the stability of benzoyl peroxide in pharmaceutical gel preparations is strongly influenced by the chemical makeup of the formulations and, secondarily, by the storage temperature due to increased reactivity.

Spectrophotometry as a Tool for Assaying Endotoxins

NARBIK A. KARAMIAN *x and PAUL F. WATERS ‡

Abstract □ A spectrophotometric method is reported for assaying endotoxins over a wide concentration range, including low parts per billion levels. Five solutions of endotoxins, *Escherichia coli* 0127:B8, *Escherichia coli* 055:B5, *Salmonella abortus-equi*, *Salmonella enteritidis*, and *Shigella flexneri*, were examined. Each exhibited an absorption maximum at 259 nm, but the absorptivities differed in each case. Thus, rigorous quantification requires that the identity of the endotoxin be known. The UV absorbance and the statistical data for the standard curves for three groups of standard solutions are presented. The absorbance for each group was linear with concentration within acceptable limits.

Keyphrases □ Endotoxins, various—UV spectrophotometric analysis, prepared solutions, wide concentration range □ UV spectrophotometry—analysis, various endotoxins, prepared solutions, wide concentration range □ Pyrogens, various—UV spectrophotometric analysis, prepared solutions, wide concentration range □ Bacterial endotoxins, various—UV spectrophotometric analysis, prepared solutions, wide concentration range

Pyrogens are generally endotoxins produced by microorganisms growing in water or aqueous solutions. They cause inflammation and general fever when injected intravenously. They are colloidal in nature and persist even after the organisms that produced them are destroyed by sterilization.

Neither the mode(s) of their activity nor their structures are known (1). However, in Gram-negative bacteria, the glycopeptide basal layer usually is covered with a lipopolysaccharide constituting 20–30% of the cell wall. Lipopolysaccharides, components of the whole somatic antigen, with molecular weights of 10^6–10^7, exhibit endotoxin activity. It is difficult to construct a molecular model for a lipopolysaccharide that would adequately explain the shapes revealed by electron microscopy (2).

BACKGROUND

Endotoxins of high antigenic activity have been extracted from bacteria by using one of the recognized published procedures. The modified (3) Boivin trichloroacetic acid procedure (4) and the trypsin digestion method (5) produce bacterial endotoxins possessing properties adequate for most immunological and pathological studies. If more highly purified material is needed, the endotoxins are prepared by the phenol extraction procedure (6). The purified endotoxins are comparatively stable in the solid form but may become inactivated in solution by hydrolysis (7, 8).

Parenteral solutions are examined for pyrogens by using rabbits as test animals according to the USP procedure (9). This procedure was adopted in the early 1940's when the need for an official pyrogen test was first recognized.

Many attempts have been made to quantify the pyrogen test. One such procedure related solutions having less than 10,000 bacteria/liter to nonpyrogenicity (10). However, this procedure did not detect pyrogens at all unless viable bacteria were present in the sample. In 1971, a specific *in vitro* assay method, the "*Limulus* amebocyte lysate test," was developed. This test has a sensitivity level of 0.001–0.005 mg of pyrogen/ml of human plasma (11).

Although the test will normally detect a low level of endotoxins, it has not been used widely with sufficient confidence to replace the present rabbit test, primarily because there is a borderline region in the gelation process where the analyst must rely heavily on visual judgment. Furthermore, the gel-forming reaction is quite delicate and is irreversibly terminated with improper care.

Another disadvantage of the test lies in the production of the lysate itself. The lysate has been prepared by several different methods (11–15), and each study used different endotoxin references. At present, there is no universally adopted procedure or reference substance for this test.

A spectrophotometric approach was used in this research project, and an analytical method was developed that allows the detection of pyrogens from known sources below the 10-ppb level.

EXPERIMENTAL

Reagents and Equipment—A spectrophotometer[1] was used for measuring the absorbance of endotoxin solutions over a concentration range of 10–10,000 ppb. The endotoxins[2] used were: lipopolysaccharide *Escherichia coli* 0127:B8, lipopolysaccharide *Escherichia coli* 055:B5, lipopolysaccharide *Salmonella abortus-equi*, lipopolysaccharide *Salmonella enteritidis*, and lipopolysaccharide *Shigella flexneri*. All endotoxins were commercially prepared by a reported extraction method (6) and were shipped in powder form in vials that had to be kept refrigerated.

Endotoxin-free sterile double-distilled water was prepared in a still designed and constructed for that purpose (16).

Procedure—Stock solutions containing 50 ppm of endotoxin were prepared by dissolving 50 mg of each endotoxin in 1 liter of endotoxin-free sterile double-distilled water. The stock solutions were diluted to 7.5 ppm with endotoxin-free sterile double-distilled water, and the absorption curve of each was determined in a 10-cm cell.

To examine the linearity of the absorption *versus* concentration curve, a 1-liter solution of the five endotoxins containing a total of 50 ppm was prepared by mixing 200 ml of each 50-ppm endotoxin solution in a 1-liter volumetric flask. This solution was kept refrigerated at 10°. It was diluted to prepare a series of solutions for making the standard curve.

The solutions covered concentrations from 10 to 10,000 ppb. They were divided into three groups: (1) concentrations of 10, 25, and 50 ppb; (2) concentrations of 50–1000 ppb; and (3) concentrations of 500–10,000 ppb.

The measurements were made as follows. Aliquots of the stock solution, containing 50 ppm of the five mixed endotoxins, were diluted with endotoxin-free sterile double-distilled water to produce the desired concentrations. Each data point represents 49 readings of the absorbance

[a] Two independent groups of investigators at the National Institutes of Health tested the endotoxin mixture by both the rabbit and the *Limulus* amebocyte lysate methods, and each reported positive biological responses above 1.5 ppb. [b] Mean of 49 individual instrument readings expressed to the limit of the readability of the instrument. [c] $\hat{A} = A_0 + bC$, where $\hat{A}$ is the absorbance predicted from the fitted line, A_0 is the intercept of the fitted line, b is the slope, and C is the concentration of endotoxin mixture in parts per billion. [d] Standard deviation of each concentration.

for the solution of a given concentration. These readings were obtained in the following manner. For each concentration, the cell was filled seven separate times from a given prepared solution, and seven different readings were recorded for each filling by successively removing and then replacing the cell in the instrument. Each recorded reading was corrected by the absorbance of the blank, 0.0019 unit, measured with endotoxin-free sterile double-distilled water in each cell. The absorbance of the blank is ascribed to imperfect matching of the two 10-cm cells used.

RESULTS

The absorption curves for *E. coli* 0127:B8, *E. coli* 055:B5, *S. abortus-equi*, *S. enteritidis*, and *Sh. flexneri*, each at a concentration of 7.5 ppm, along with a mixture of the five endotoxins containing equal weights of each for a final total concentration of 7.5 ppm, are shown in Fig. 1. Each point represents the mean of two measurements made on a single solution without refilling the cell. Fresh solutions of each endotoxin were prepared, and the absorbance measurements were repeated. Essentially the same results as those reported here were observed. The absorption maxima for all endotoxins were practically the same—259 nm. The maximum for the mixture was at 258 nm.

The data for the determination of the standard curves are presented in Table I along with statistical information resulting from a regression analysis performed on the data from each of the three groups.

The regression equations for Groups 1, 2, and 3, respectively, are:

$$\hat{A} = 1.277 \times 10^{-3} + 1.248 \times 10^{-4} C \qquad r = 0.986 \qquad s = 3.5 \times 10^{-4} \quad \text{(Eq. 1)}$$

$$\hat{A} = 5.389 \times 10^{-3} + 5.518 \times 10^{-5} C \qquad r = 0.999 \qquad s = 5.1 \times 10^{-4} \quad \text{(Eq. 2)}$$

$$\hat{A} = 3.075 \times 10^{-3} + 5.602 \times 10^{-5} C \qquad r = 0.9998 \qquad s = 3.3 \times 10^{-3} \quad \text{(Eq. 3)}$$

where C is concentration, $\hat{A}$ is absorbance, r is the associated correlation coefficient, and s is the standard deviation about the regression.

The high concentrations show that within each group the absorbance is well approximated by a straight line, thereby indicating that Beer's law is approximately obeyed within each region. However, the high correlations are somewhat misleading. There were 49 observations at each concentration, and a lack of fit sum of squares is significant for each group. For practical purposes, the small, but significant, lack of fit does not seem important (17).

If all data from 10 to 10,000 ppb are represented by a single continuous curve, the linearity relationship between the absorbance and the concentration does not hold and Beer's law is not obeyed strictly, nor does it have to so long as the measurement regimen is reproducible. The reason(s) for this departure and the positive absorbance reading at 0 ppb are not known. It can be emphasized that endotoxins are macromolecules with molecular weights of 10^6–10^7. If portions of the molecular structure are polyelectrolytic, configurational changes can accompany dilution; these changes are accentuated at extremely low concentrations where unfolding might uncover more absorptive moieties. Disaggregation accompanying dilution could also be a possible cause of the increased slope in the low concentration region. Neither of these possibilities was proved in this work.

Scrupulous care must be exercised in handling glassware, cells, and solutions to achieve the precision reported. The data accumulated thus far are limited and, in the strictest sense, the method must be said to apply only to those bacterial endotoxins actually studied here. However, the endotoxins used were from an assortment of bacteria, and the results obtained hopefully presage wide applicability for the method[3].

GLC Determination of Free Triclocarban in Blood

D. R. HOAR [x] and M. H. BOWEN *

Abstract □ A method is presented for the quantitative determination of free triclocarban in rat or human blood. The procedure involves the extraction from blood with acetone, a TLC cleanup, derivatization with *N,O*-bis(trimethylsilyl)acetamide, and GLC using an electron-capture detector. GLC–mass spectral analysis confirmed that the structure of the derivative was a bis(trimethylsilyl) molecule with one group on a nitrogen and the second group attached to the enol tautomer. The method is sensitive to 25 ng (12.5 μg/liter of blood). Recoveries of added triclocarban in the 12.5–50-μg/liter range were between 80 and 90%.

Keyphrases □ Triclocarban—GLC analysis, rat and human blood □ GLC—analysis, triclocarban, rat and human blood □ Disinfectants—triclocarban, GLC analysis, rat and human blood

The bacteriostatic agent triclocarban[1] is used exclusively in bar soaps. It is effective against both Gram-positive bacteria (*e.g.*, staphylococci) and fungi (1, 2). Its chemistry and antimicrobial properties were described previously (3). At the present time, the only methods for the determination of triclocarban are based on UV absorption (4) or HPLC[2]. Neither of these methods approaches the 10-μg/liter sensitivity of the GLC methods developed for the study of hexachlorophene (5) and triclosan[3] absorption.

A direct GLC measurement of triclocarban (4) was unsuccessful because of its low volatility. A method is now presented for the quantitative determination of free triclocarban in human and rat blood following derivatization. The procedure involves extraction from blood with acetone, a cleanup procedure by TLC, conversion to a trimethylsilyl derivative, and analysis by GLC using an electron-capture detector.

EXPERIMENTAL

Reagents—The following were used: triclocarban (>99% purity), acetone (analar grade), toluene (analar), ether (analar), acetonitrile (analar), and *N,O*-bis(trimethylsilyl)acetamide[4] (vacuum distilled).

Apparatus—GLC[5] was conducted on a glass column (1.5 m × 4 mm i.d.) containing 1.5% phenyl methyl silicone[6] and 1.95% trifluoropropyl methyl silicone[7] on 100–120-mesh Supelcon AW-DMCS[8].

All newly prepared columns were conditioned at 240° for 16 hr and then deactivated with 5 μl of hexamethyldisilazane. During analysis, the column and the detector were maintained at 210 and 300°, respectively. Nitrogen was used both as the carrier gas at 75 ml/min and as the purge gas to the ^{63}Ni-electron-capture detector at 25 ml/min.

GLC–Mass Spectrometry[9]—Combined GLC–mass spectrometry of the triclocarban derivative was conducted on a glass column (1.5 m × 4 mm i.d.) containing 3% methyl silicone[10] (OV-1) on 100–120-mesh Diatomite CLQ.

TLC—TLC was conducted on 250-μm silica gel GF plates[11] which had been prewashed overnight in a developing solvent [ether–toluene (1:4)]. After development, the separated bands were visualized by irradiation with a short wavelength (254 nm) UV lamp.

Calculation—The peak height for the trimethylsilyl derivative was measured and compared to a calibration curve prepared each day from known concentrations of triclocarban.

Assay Procedure—A 2.0-ml aliquot of whole blood (stored with edetate dipotassium dihydrate as an anticoagulant) was extracted twice by shaking with 10 ml of acetone. The mixture was centrifuged for 5 min at 1200×*g* after each extraction, and the solvent layers were removed. The combined extracts were placed in a warm water bath and concentrated to approximately 0.2 ml by a nitrogen stream. The concentrated extract was then applied to a silica gel GF plate as a narrow band. At least three aliquots of a standard solution containing 1 μg of triclocarban were spotted onto the plate, and the plate was developed for 10 cm and then allowed to dry at ambient temperature.

A 2-cm wide band of silica gel between the standards, located by irradiation with UV light, was scraped into a 10-ml tube and twice extracted with 10 ml of acetonitrile. The solvent was separated by centrifugation for 5 min at 1200×*g*, and the extracts were combined. The solution was placed on the water bath and concentrated to approximately 5 ml with nitrogen. This solution was transferred to a 10-ml tapered tube and blown to dryness. A 50-μl aliquot of *N,O*-bis(trimethylsilyl)acetamide was added to the residue, the tube was stoppered and placed in a water bath at 60° for 10 min, and a 5-μl aliquot was injected into the chromatograph.

RESULTS AND DISCUSSION

The structure of triclocarban suggests that the germicide might not be particularly well suited to direct GLC analysis. This compound was not eluted from nonpolar stationary phases even at high temperatures. Silylation gave a derivative that could be chromatographed at 210° on a mixed silicone column. Under these conditions, the derivative had a retention time of 7.8 min (Fig. 1).

Elucidation of Derivative Structure—The structure of the derivative was characterized by combined GLC–mass spectrometry. The mass spectrum (Fig. 2) corresponding to the peak from the flame-ionization detector gave significant fragments at *m/e* 458/460/462 (M, molecular ion), 386/388/390 (M − 72, loss of C_3H_8Si), 296/298/300 (further loss of C_3H_9Si + OH), and 73 (C_3H_9Si ion). This pattern confirms that the

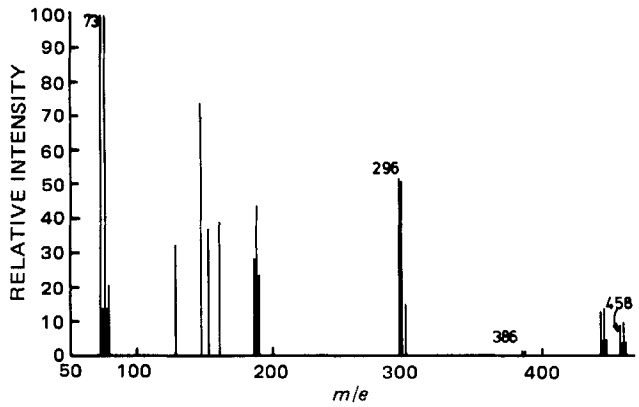

Figure 2—*Mass spectrum* (m/e *50–500*) *of the bis(trimethylsilyl) derivative of triclocarban.*

compound was a bis(trimethylsilyl) derivative. The relevant ions each displayed the characteristic trichloro isotope cluster. These particular ions show that only one nitrogen has a trimethylsilyl group while the second trimethylsilyl group is on the enol tautomer.

Examination of the spectra taken at intervals as the peak eluted showed that the ratio of *m/e* 458 to 386 decreased. This finding suggested that the derivative was capable of breaking down to the mono(trimethylsilyl) compound.

It was reported (6) that the drug rafoxanide[12] forms a similar bis(trimethylsilyl) derivative on a phenolic group and a secondary amide group. This derivative was shown to react with active sites on a chromatographic packing, exchanging one of its trimethylsilyl groups for a hydrogen atom to form a mono derivative. This effect was very small when carefully deactivated columns were used. Since electron-capture GLC of standard solutions gave only one peak, the column used for the GLC–mass spectral analysis may not have been completely deactivated.

This phenomenon of silyl donation was not completely unexpected since the amide structure of the derivative is similar to that of the silylating reagent. Therefore, it is important to maintain excess reagent to obtain a quantitative conversion to the bis(trimethylsilyl) derivative and to ensure that the column is completely deactivated. The optimum conditions of derivatization were determined to be 10 min and 60° with *N,O*-bis(trimethylsilyl)acetamide acting as the solvent as well as the derivatizing agent. A linear response was obtained over the range of 5–100 ng of triclocarban.

TLC of Blood Extracts—Ether–toluene (1:4), in which the R_f of triclocarban was 0.4, was by far the most effective solvent system. It separated triclocarban from interfering bands in the blood extract which were concentrated at the origin or solvent front.

Various solvents were evaluated for their ability to extract triclocarban from silica gel TLC plates. It was reported previously (7) that it is frequently necessary to use a solvent with a much greater polarity than the developing solvent. This suggestion was only partly relevant since, although acetonitrile gave 90% recovery, the more polar methanol gave only 41% recovery.

Recovery Experiments—A duplicate series of aliquots containing 25, 50, and 100 ng of triclocarban was blown to dryness in 10-ml tubes. Aliquots (2.0 ml) of whole blood were added to one series of tubes, and the samples were shaken and then analyzed by the described procedure. The second series of standards was taken up in 0.2 ml of acetone and put through the TLC cleanup procedure and the derivatization. The recoveries of these samples relative to a series of standard solutions that had only been concentrated and derivatized are given in Table I.

[12] Rafoxanide is generic name for 3′-chloro-4′-(*p*-chlorophenoxy)-2-hydroxy-3,5-diiodobenzanilide.

Table I—Recovery of Free Triclocarban Added to Whole Blood

Amount Added to Blood, ng	Amount through Cleanup, ng	Mean Recovery, %	*SD*
100	—	82	±4
—	100	80	±4
50	—	82	±6
—	50	86	±5
25	—	89	±15
—	25	90	±0

The results in Table I show that the recoveries of free triclocarban from whole blood in the 12.5–50-μg/liter range were between 80 and 90%. The results from the standard solutions that had been through only the cleanup procedure and derivatization were in good agreement with the recoveries from the blood samples. These results showed that the losses were occurring during the elution from the TLC plate rather than during the extraction from blood. This finding was confirmed by spotting aliquots containing 50 ng of triclocarban onto a TLC plate, allowing the spots to dry, scraping off the silica gel, and eluting with acetonitrile without developing the plate. The mean recovery was 90%.

Since the sensitivity of this method is comparable to methods used for other germicides, it should be applicable to studies on the absorption and metabolism of triclocarban. The metabolic pathway may be hydroxylation followed by conjugation with glucuronic acid or sulfate (8). Therefore, it is possible that this derivatization method may be applicable to the determination both of the amount and nature of the metabolite(s).

Effect of Surfactants on Absorption through Membranes V: Concentration-Dependent Effect of a Bile Salt (Sodium Deoxycholate) on Absorption of a Poorly Absorbable Drug, Phenolsulfonphthalein, in Humans

M. WAFIK GOUDA *x, NAWAL KHALAFALAH ‡, and SAID A. KHALIL ‡

Abstract □ The effect of administration of 600- and 300-mg doses of sodium deoxycholate 1 hr before phenolsulfonphthalein solution is reported. The 600-mg dose caused a decrease in drug bioavailability as measured by the total amount excreted in 24 hr. The 300-mg dose caused an increase in the initial phenolsulfonphthalein absorption rate, suggesting a direct action of the bile salt on membrane permeability. The decrease in absorption upon administration of 600 mg was attributed to micellar entrapment of the drug molecule.

Keyphrases □ Sodium deoxycholate—effect of preadministration on absorption and excretion of phenolsulfonphthalein, humans □ Phenolsulfonphthalein—absorption and excretion, effect of preadministration of sodium deoxycholate, humans □ Absorption—phenolsulfonphthalein, effect of preadministration of sodium deoxycholate, humans □ Excretion—phenolsulfonphthalein, effect of preadministration of sodium deoxycholate, humans □ Bile salts—sodium deoxycholate, effect of preadministration on absorption and excretion of phenolsulfonphthalein, humans

Bile salts, an important class of surface-active agents, play a significant role in the intestinal absorption of lipids (1, 2) and lipid-soluble vitamins. Several reports (3–6) indicated that bile salts influence drug absorption. Most accumulated data were derived from animal studies. Data obtained from human studies are limited. An increase in the urinary recovery of riboflavin in humans was reported when a 600-mg dose of sodium deoxycholate was administered 0.5 hr prior to the oral ingestion of the vitamin (7).

Sodium deoxycholate enhanced the absorption of phenolsulfonphthalein, a poorly absorbable drug, in the rat (4). The aim of the present study was to determine if a similar effect occurs in humans.

EXPERIMENTAL

The study was designed in a crossover fashion. The urinary excretion of phenolsulfonphthalein was determined following the administration of Treatments A, B, and C (Table I). Ten healthy volunteers (capable of informed consent) participated in Treatments A and B, and seven of these volunteers participated in Treatment C. Doses were administered at weekly intervals to fasting subjects. Fluid and food intake, as well as the analysis of the urine samples, was carried out as previously described (8).

RESULTS AND DISCUSSION

Administration of 600 mg of sodium deoxycholate 1 hr before phenolsulfonphthalein solution did not result in a significant change in the amount of the dye excreted in 1 hr. However, the total amount excreted in 24 hr was significantly less than the control (Table II). Administration of 300 mg of the bile salt increased significantly the amount of phenolsulfonphthalein excreted in 1 hr, while the total amount of the dye excreted in 24 hr was not significantly different from the control. The time course of phenolsulfonphthalein excretion following the various treatments is shown in Fig. 1. The average data in the figure are a good reflection of the individual results.

The increase in the initial rate of absorption (1-hr urinary excretion data, Table II) following the administration of 300 mg of sodium deoxycholate suggests a direct action of the bile salt on the membrane permeability, in agreement with other studies in animals (4, 5) and humans (7). Data in Table II and Fig. 1 indicate that 600 mg of sodium deoxycholate did not significantly affect the initial phenolsulfonphthalein absorption rate. Previous studies with bile salts indicated that the change in membrane permeability did not increase with an increase in the surfactant concentration (9). A minimum concentration of bile salt was usually sufficient to produce a maximum effect on membrane permeability. Hence, the higher dose of sodium deoxycholate was expected to produce a similar, but not necessarily greater, effect on the initial phenolsulfonphthalein absorption rate as that of the lower dose.

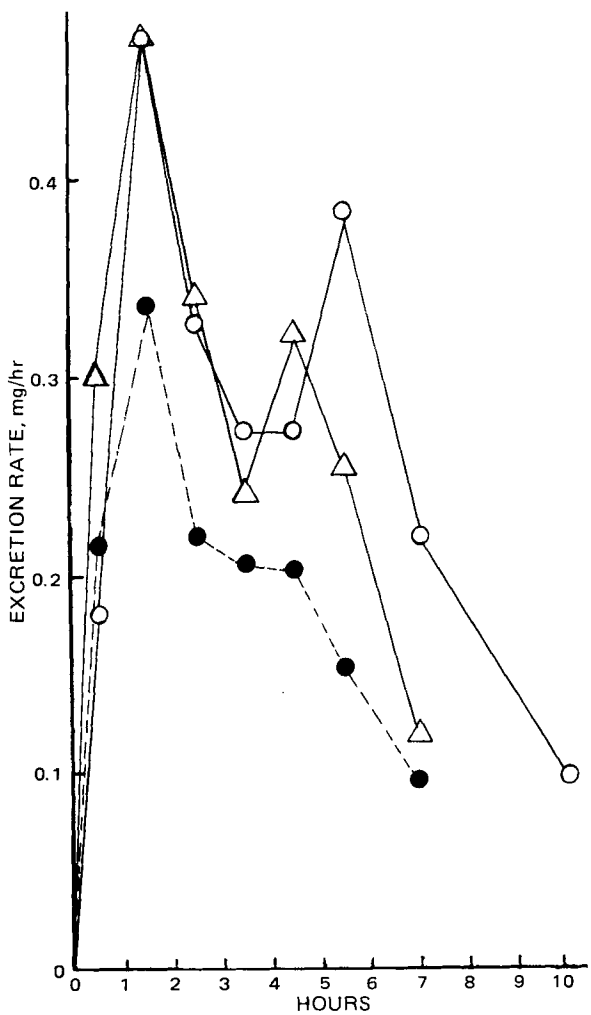

Figure 1—*Mean urinary excretion rates of phenolsulfonphthalein after oral administration of 20 mg in solution. Key: ○, control (average of 10 subjects); ●, pretreatment with 600 mg of sodium deoxycholate (average of 10 subjects); and △, pretreatment with 300 mg of sodium deoxycholate (average of seven subjects).*

Table I—Regimen of Treatments Administered to Human Volunteers

Hours	Treatment A	Treatment B	Treatment C
−1	100 ml of water	600 mg of sodium deoxycholate[a] with 100 ml of water	300 mg of sodium deoxycholate[a] with 100 ml of water
−0.5	100 ml of water in all treatments		
0	20 mg of phenolsulfonphthalein[b] dissolved in 50 ml of water[c] in all treatments		
1, 2, 3, 4, 5, 6, 8, 12, 24	Collection of urine in all treatments		

[a] Sodium deoxycholate (Mann Research Lab., New York, N.Y.) was administered in hard gelatin capsules, each containing 300 mg. [b] Nutritional Biochemical Corp., Cleveland, Ohio. [c] Contains 20 mg of sodium bicarbonate to aid the solubility of phenolsulfonphthalein.

The results obtained with Treatment B are not in agreement with this expectation and suggest that the direct effect of the bile salt on the membrane must have been masked by an opposing effect tending to decrease phenolsulfonphthalein absorption. The 24-hr urinary excretion data (Table II) give the same picture of two opposing effects of the bile salt on phenolsulfonphthalein absorption and provide evidence that the decrease in drug absorption becomes significant with the increase in the sodium deoxycholate concentration.

The decrease in the total excretion of phenolsulfonphthalein upon administration of 600 mg of the bile salt is believed to be the result of micellar solubilization. Entrapment of the dye in the micelles of sodium deoxycholate, with the resultant loss in thermodynamic activity, is expected to result in decreased absorption. Phenolsulfonphthalein was previously shown (5) to be a candidate for entrapment in the micelles of other bile salts. The concentration of bile salts in human intestinal content was reported (10) to be slightly above their critical micellar concentration. Therefore, it is expected that administration of both 300 and 600 mg of sodium deoxycholate will result in a micellar solution in the intestinal tract.

It seems that a direct membrane effect, resulting in potentiation of the initial rate of absorption, predominates at the lower dose, while more micelles entrap more drug at the higher dose, resulting in decreased absorption. The excretion pattern (Fig. 1) suggests this possibility. Higher concentrations of surfactants (3) including bile salts (11) decreased drug absorption. Although none of the volunteers reported experiencing a laxative effect, the possibility that the 600-mg dose of the bile salt resulted in an increased GI motility, and hence decreased absorption, cannot be ruled out. The delay in gastric emptying, suggested (7) as one possible explanation of the increased bioavailability of riboflavin after administration of a similar dose of the same bile salt, was not evident in the present study (Fig. 1).

The data of the present study and of Mayersohn *et al.* (7) suggest that, depending on the drug and its absorption mechanism, bile salts could decrease as well as increase drug absorption.

Uptake of Acetazolamide by Human Erythrocytes *In Vitro*

SYLVIA M. WALLACE [x] and SIDNEY RIEGELMAN

Abstract □ The binding of acetazolamide to human erythrocytes was studied *in vitro*. Blood and plasma samples were analyzed by electron-capture GLC. At 37°, drug equilibrated between plasma and erythrocytes in approximately 40 min. The effect of plasma concentration on the steady-state level of drug within the erythrocytes was examined. Erythrocyte accumulation of acetazolamide appeared to be a composite of two processes: a nonlinear, saturable process and a linear, diffusion-controlled process. By appropriate linear transformation of the data, estimates of the erythrocyte binding capacity and the dissociation constant for the drug were obtained.

Keyphrases □ Acetazolamide—*in vitro* binding to human erythrocytes, effect of plasma drug concentration on steady-state level within erythrocytes □ Binding—acetazolamide to human erythrocytes *in vitro*, effect of plasma drug concentration on steady-state level within erythrocytes □ Erythrocytes, human—binding of acetazolamide *in vitro*, effect of plasma drug concentration on steady-state level within erythrocytes □ Plasma drug concentration—effect on steady-state level of acetazolamide within human erythrocytes □ Carbonic anhydrase inhibitors—*in vitro* binding to human erythrocytes, effect of plasma drug concentration on steady-state level within erythrocytes

The erythrocyte compartment of the blood is often dismissed as an insignificant consideration in pharmacokinetics. Blood and plasma levels are often merely *assumed* to be equivalent terms. However, many drugs accumulate significantly in erythrocytes. Concentrations of salicylate (1), phenobarbital (1), phenytoin (2), chlorpromazine (3), and chlorthalidone (4) within the erythrocyte are all in excess of the free drug concentration in the plasma. The nature of the interaction and accumulation is unknown and probably varies, and the significance of these interactions in the overall pharmacokinetics of the drugs has not been determined.

After a single oral dose of acetazolamide to humans, concentration–time profiles of the drug in erythrocytes and plasma were significantly different[1]. Twenty-four hours after the dose, erythrocyte levels were four times greater than plasma levels. This accumulation was previously attributed to binding to erythrocyte carbonic anhydrase (5). Although Maren *et al.* (6) reported that erythrocyte uptake appears to have two components—one diffusible, *i.e.*, lost by washing, and the other bound—the extent and strength of binding have not been determined.

In vivo, in a dynamic situation, a single event such as erythrocyte uptake is difficult to isolate from the multiplicity of kinetic events occurring. Therefore, to determine the strength and capacity of acetazolamide binding, erythrocyte uptake of the drug was studied *in vitro* in a closed system.

EXPERIMENTAL

Time Course to Equilibration—Acetazolamide was added to whole human blood[2] and warmed to 37°, and the mixture was swirled gently on a water bath[3]. Aliquots were withdrawn at 10, 20, 40, 60, and 120 min and centrifuged[4] for 1 min to separate the plasma.

Equilibrium Studies—Whole blood containing varying concentrations of acetazolamide was incubated for 1 hr at 37° with gentle swirling. Aliquots (50 μl) of blood were withdrawn for analysis, and the remainder was centrifuged[5] for 15 min at 1500 rpm. Plasma and blood were analyzed, and the erythrocyte concentration was calculated from the difference using the hematocrit. The free drug concentration in the plasma was determined in plasma water samples obtained by microultrafiltration (7). Results of individual representative experiments are illustrated in Figs. 1–4.

Similar experiments were conducted using a synthetic blood medium consisting of erythrocytes washed three times with isotonic Sorenson's phosphate buffer (pH 7.4) and reconstituted to a hematocrit of approximately 0.5 with the buffer. To determine if washing erythrocytes altered acetazolamide uptake, erythrocytes washed three times with buffer were reconstituted with plasma and the results were compared to those obtained with whole blood.

GLC Analysis—Acetazolamide was determined in plasma and blood by GLC using a ^{63}Ni-electron-capture detector[6]. Samples were processed and chromatographed on a glass column packed with 3% OV-17 coated on Gas Chrom Q[7] (100–120 mesh).

RESULTS AND DISCUSSION

After addition of acetazolamide to whole blood *in vitro*, equilibration of acetazolamide between plasma and erythrocytes did not occur instantaneously. Steady state was established 40 min later (Fig. 1). *In vivo*, in subjects administered a single oral dose of acetazolamide, erythrocyte levels reached peak concentrations 1–2 hr after plasma levels. Presumably, this lag time *in vivo* reflects the equilibration time noted *in vitro*.

Uptake of acetazolamide by the erythrocytes is concentration dependent. Although a distinct plateau is not reached if the erythrocyte concentration of acetazolamide at equilibrium is plotted against the plasma concentration, the graph is curvilinear (Fig. 2). The ratio of the erythrocyte–plasma concentration decreases as the plasma concentration increases.

For example, at a hematocrit of 0.5 and plasma concentration of 1.6 μg/ml (blood concentration of 5 μg/ml), the erythrocyte–plasma ratio was 5.2:1. However, at a plasma concentration of 23.2 μg/ml (blood concentration of 30 μg/ml), the ratio was 1.6:1. Thus, over a wide range of plasma concentrations, the erythrocyte–plasma ratio cannot be characterized by a single value. As in the case of plasma protein binding of drugs, for a given percentage bound to have any significance, the total plasma concentration must be known.

Since erythrocyte uptake of acetazolamide is concentration dependent, it is assumed to be partially composed of a saturable process. The total erythrocyte concentration can be expressed as:

$$RBC_{total} = RBC_b + RBC_f \qquad \text{(Eq. 1)}$$

At equilibrium, the diffusible free drug concentration, RBC_f, within the erythrocytes is assumed to be equal to the concentration of free drug in the plasma, C_f; therefore:

$$RBC_b = RBC_{total} - C_f \qquad \text{(Eq. 2)}$$

The total uptake curve is a sum of two processes: a linear, presumably diffusion-controlled process such that RBC_f is equal to C_f and a nonlinear, saturable binding process such that the relationship of RBC_b to

[7] Applied Science Laboratories, State College, Pa.

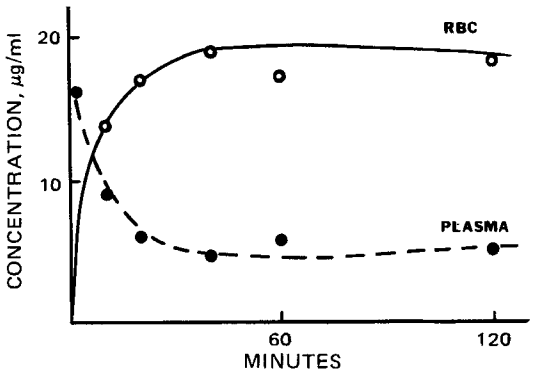

Figure 1—*Time course of erythrocyte (RBC) uptake of acetazolamide at a total blood concentration of 10 μg/ml. (All drug was assumed to be present initially in plasma.)*

C_f changes with the free concentration (Fig. 3). The curve for RBC_b is obtained by subtracting the values for RBC_f from the experimental curve, RBC_{total}.

The bound concentration, RBC_b, as calculated from Eq. 2, can also be expressed in terms of the law of mass action for the reversible macromolecule–ligand interaction:

$$RBC_b = \frac{nMk_aC_f}{1 + k_aC_f} \qquad \text{(Eq. 3)}$$

Since the macromolecule concentration is unknown, only the product of the number of binding sites, n, and the macromolecule concentration, M, can be calculated. However, the product nM is a useful parameter, because it represents the maximum binding capacity of the protein.

Linear transformation (8) of Eq. 3 yields:

$$\frac{RBC_b}{C_f} = nMk_a - k_aRBC_b \qquad \text{(Eq. 4)}$$

Thus, for a plot of RBC_b/C_f *versus* RBC_b, the absolute value of the slope is the association constant, k_a, and the intercept on the abscissa, the maximum binding capacity, nM (Fig. 4). The dissociation constant, k_d, is the reciprocal of the association constant.

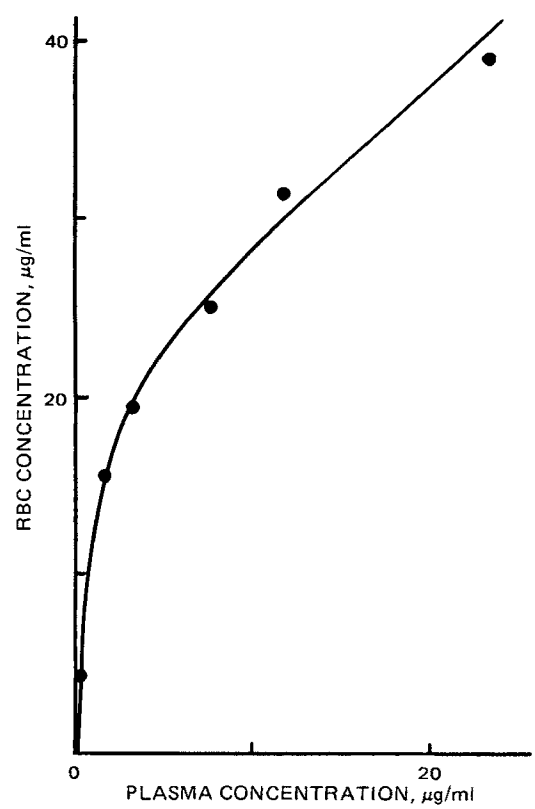

Figure 2—*Erythrocyte concentration of acetazolamide at equilibrium as a function of the total plasma concentration.*

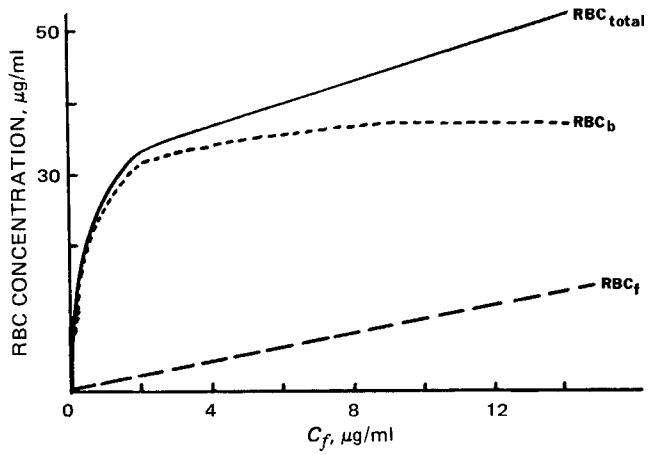

Figure 3—*Total (RBC_{total}, obtained experimentally), bound (RBC_b), and free (RBC_f) erythrocyte concentrations of acetazolamide as a function of the free drug concentration in plasma (C_f).*

Thus, to determine binding parameters for acetazolamide and erythrocytes, blood, total plasma, and free plasma concentrations were determined at equilibrium. Since greater than 90% of acetazolamide in plasma is bound to plasma protein (7), plasma ultrafiltrates were obtained to measure the freely diffusible drug in whole blood. By using a synthetic blood medium of erythrocytes suspended in isotonic buffer, the free drug concentration can be measured directly in the protein-free supernate. Washing the erythrocytes with isotonic buffer in the process of preparing the suspension does not alter the uptake of the drug. Uptake of acetazolamide from the plasma by untreated erythrocytes and by those washed with buffer is essentially the same (Fig. 4).

The concentration bound by erythrocytes was calculated by subtracting the unbound plasma concentration from the total erythrocyte concentration. Data were linearized according to Eq. 4, and the binding parameters were calculated by least-squares linear regression analysis (Fig. 4).

Blood samples varied in their maximum binding capacity and dissociation constant for acetazolamide (Table I). However, the values were in the same range as those reported (9) for human erythrocyte carbonic anhydrase B, *i.e.*, a molar concentration of 136 μM (30 μg/ml) and an inhibitory constant (K_i for acetazolamide) of 1 μM (0.22 μg/ml). These data strengthen the hypothesis (5) that the accumulation of the drug within the erythrocytes is due to binding to intracellular carbonic anhydrase.

Because blood samples varied not only in their erythrocyte binding but also in their plasma protein binding of acetazolamide, the plasma concentration at which erythrocyte binding sites become saturated cannot be closely defined. Lehmann *et al.* (9) suggested that inhibition of erythrocyte carbonic anhydrase may induce some of the side effects of acetazolamide therapy. However, attempts to delineate a maximum tolerable plasma level of drug sufficient to saturate erythrocyte enzyme may be thwarted by the large individual variation in binding parameters. Determination of the erythrocyte binding capacity for acetazolamide may

Direct Analysis of Salicylic Acid in Keratolytic Plaster by Gas–Solid Chromatography

PAK H. KO

Abstract □ A rapid gas–solid chromatographic method is reported for the direct analysis of salicylic acid in keratolytic plaster. The method requires no preseparation or derivatization and takes about 14 min. Since it requires only 2–7 mg of sample, it can determine the salicylic acid concentration in a particular area of plaster. The analyzing column is packed with porous polymer beads of 2,6-diphenyl-1,4-phenylene oxide. An automatic solid sampling system is used in connection with the gas chromatograph employing dual flame-ionization detectors. The average recovery of salicylic acid in synthetic samples containing 400–2700 μg was 100.6 ± 1.6%. The average correlation coefficient of the peak area against the standard was +0.9995 ± 0.0003 for samples in the 300–3000-μg range.

Keyphrases □ Salicylic acid—gas–solid chromatographic analysis, commercial plaster pads □ Gas–solid chromatography—analysis, salicylic acid in commercial plaster pads □ Keratolytics—salicylic acid, gas–solid chromatographic analysis in commercial plaster pads

The 40% salicylic acid (I) keratolytic plaster is a uniform mixture of I in a suitable base spread on a backing material such as paper or cloth. The USP (1) requires the plaster mass to contain not less than 90.0% and not more than 110.0% of the labeled amount of I.

To check for uniform distribution of I and for specification compliance, a specific method that does not require a fairly large sample is needed. Since the USP method (1) requires more than 1 g of the plaster base, excluding the backing material, it lacks the sensitivity desired for the type of product[1] with considerably less than 10 mg of the plaster base in a small disk. Furthermore, the USP method is very lengthy.

BACKGROUND

Literature methods for the determination of I that are based on measurement of UV absorption (2–4), color intensity of its ferric chelate (5, 6), fluorescence (7, 8), and alkalimetric titration (9) either required extensive separation manipulations or gave unsatisfactory results due to interference by the excipients in the plaster base.

Several investigators reported the use of GLC for the determination of I in pharmaceuticals and biological media (10–14). However, the methyl ester and methyl ether derivatives (11, 12) or the trimethylsilyl derivative (13, 14) of I had to be prepared before GLC analysis for sufficient volatility; otherwise, severe tailing occurred (10).

Because of the low solubility of the plaster base in most common solvents, methods requiring additional steps to extract I prior to GLC determination or other functional group analyses are less desirable than a direct method by which I in a plaster base can be analyzed without preseparation.

A direct method by gas–solid chromatography (GSC) for determining underivatized I with three other ingredients in a mixture was reported previously (15). This paper reports a rapid and specific GSC method using the same column (15) for the direct determination of I in the plaster base of callus pads without preliminary separation or derivatization.

Direct Analysis of Salicylic Acid in Keratolytic Plaster by Gas–Solid Chromatography

PAK H. KO

Abstract □ A rapid gas–solid chromatographic method is reported for the direct analysis of salicylic acid in keratolytic plaster. The method requires no preseparation or derivatization and takes about 14 min. Since it requires only 2–7 mg of sample, it can determine the salicylic acid concentration in a particular area of plaster. The analyzing column is packed with porous polymer beads of 2,6-diphenyl-1,4-phenylene oxide. An automatic solid sampling system is used in connection with the gas chromatograph employing dual flame-ionization detectors. The average recovery of salicylic acid in synthetic samples containing 400–2700 μg was 100.6 ± 1.6%. The average correlation coefficient of the peak area against the standard was +0.9995 ± 0.0003 for samples in the 300–3000-μg range.

Keyphrases □ Salicylic acid—gas–solid chromatographic analysis, commercial plaster pads □ Gas–solid chromatography—analysis, salicylic acid in commercial plaster pads □ Keratolytics—salicylic acid, gas–solid chromatographic analysis in commercial plaster pads

The 40% salicylic acid (I) keratolytic plaster is a uniform mixture of I in a suitable base spread on a backing material such as paper or cloth. The USP (1) requires the plaster mass to contain not less than 90.0% and not more than 110.0% of the labeled amount of I.

To check for uniform distribution of I and for specification compliance, a specific method that does not require a fairly large sample is needed. Since the USP method (1) requires more than 1 g of the plaster base, excluding the backing material, it lacks the sensitivity desired for the type of product[1] with considerably less than 10 mg of the plaster base in a small disk. Furthermore, the USP method is very lengthy.

BACKGROUND

Literature methods for the determination of I that are based on measurement of UV absorption (2–4), color intensity of its ferric chelate (5, 6), fluorescence (7, 8), and alkalimetric titration (9) either required extensive separation manipulations or gave unsatisfactory results due to interference by the excipients in the plaster base.

Several investigators reported the use of GLC for the determination of I in pharmaceuticals and biological media (10–14). However, the methyl ester and methyl ether derivatives (11, 12) or the trimethylsilyl derivative (13, 14) of I had to be prepared before GLC analysis for sufficient volatility; otherwise, severe tailing occurred (10).

Because of the low solubility of the plaster base in most common solvents, methods requiring additional steps to extract I prior to GLC determination or other functional group analyses are less desirable than a direct method by which I in a plaster base can be analyzed without preseparation.

A direct method by gas–solid chromatography (GSC) for determining underivatized I with three other ingredients in a mixture was reported previously (15). This paper reports a rapid and specific GSC method using the same column (15) for the direct determination of I in the plaster base of callus pads without preliminary separation or derivatization.

0.41	2713	2783	102.6
			100.6 ± 1.6

EXPERIMENTAL

Standard—USP grade salicylic acid[2] was used.

GSC Column—A pair of 1.8-m × 0.32-cm o.d. stainless steel columns were packed with 60–80-mesh porous polymer beads of 2,6-diphenyl-1,4-phenylene oxide[3]. Newly packed columns were conditioned at 260° with helium carrier gas flow for 1 hr before use.

Apparatus—The GSC analyses were performed on a gas chromatograph[4] equipped with dual flame-ionization detectors. An automatic capsule sampling system[5] was fitted over the head of the analyzing column. A digital integrator[6] was used to analyze the signals from the flame-ionization detector. The interfacing mechanism was modified to link the integrator, the chromatograph, and the programmer of the automatic capsule sampling system, which were made by different manufacturers. An electronic microbalance[7] for weighing standards and samples, special aluminum capsules[8] for holding standards and samples, and a capsule cold-welding accessory[9] for sealing aluminum capsules containing standards and samples were used.

The chromatography conditions were: injection port, 280°; interface, 290°; column, initially 180° and (after the capsule is punctured) immediately programmed at 16°/min to the upper limit of 245° and maintained at the upper limit for 8 min; helium gas flow, 30 ml/min; detector hydrogen, 40 ml/min; and detector air, 500 ml/min.

Calibration Curve—Standard I samples were weighed into tared aluminum capsules to prepare a calibration curve with the range of 300–3000 μg. The capsules were sealed immediately. The samples were analyzed according to the suggested experimental condition using the gas chromatograph and the automatic sampling system. Specific information pertaining to the use of the automatic sampling system was given elsewhere[10].

The area of the I peak by each standard, as printed out by the digital integrator, was used to establish the calibration curve of area *versus* mass of I for the day's work. The least-squares linear regression method was perferred for showing the calibration.

Analysis of Samples—Samples of plaster base containing I were scraped from the backing cloth with a thin spatula and weighed in tared capsules. The size of the sample was chosen depending on the concentration of the I in the product in order to conform to the range of the calibration curve. The samples were analyzed in the same manner as the standards. The sample's peak area counts were used directly to calculate the I content in the samples according to the slope and intercept obtained by the least-squares linear regression analysis of the calibration runs.

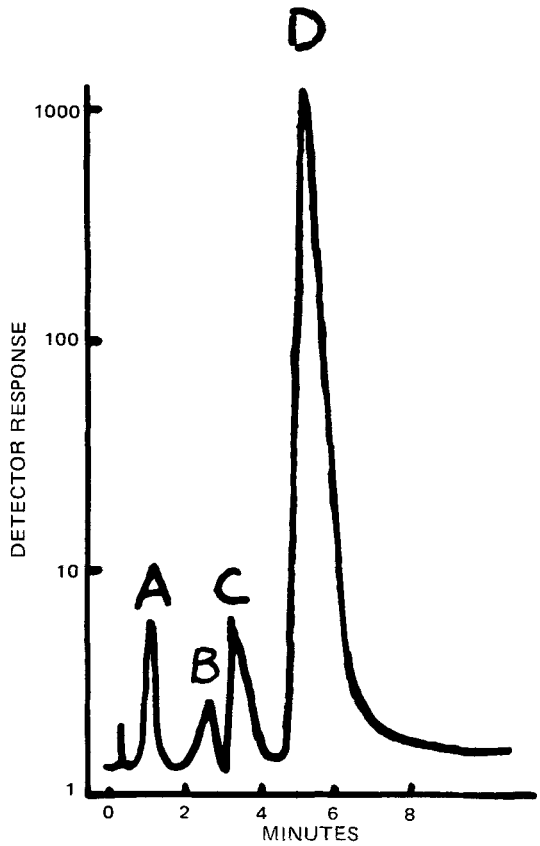

Figure 1—*Gas–solid chromatogram of keratolytic plaster. Key: A, B, and C, unidentified volatile ingredients; and D, salicylic acid.*

RESULTS AND DISCUSSION

Experimental results showed that underivatized solid I can be determined by this new method.

GSC Analysis Time Requirement—Complete elution of I was within 7 min from the time of injection, the time when the sample capsule was conveyed to the vaporizer port behind the trap door. A hollow thorn pierced the capsule, and the helium gas swept the sample vapors through the hollow thorn into the analyzing column. The complete cycle of temperature programming and cooling for the next sample required 14 min.

Calibration Curve Linearity and Sample Size Limitation—The correlation coefficients from various days were determined, and a mean value of +0.9995 was obtained with a standard deviation of 0.0003. Calibration routinely consisted of 15–29 individually weighed standards covering the range of 300–3000 μg of I, and the calibration curves obtained were linear.

When the I mass was less than 300 μg, the chromatographic response (peak area per unit weight of I) became slightly smaller. The cause for deviation has not been determined at this time. Therefore, sample sizes were adjusted to avoid having less than 300 μg of I. Samples with I content much higher than 3000 μg also were avoided because the volume in the aluminum capsule was limited. When the plaster base sample was too big and not enough empty space was available in the capsule, the gummy base material clogged the capillary of the thorn and blocked the carrier gas and the sample vapors from entering the column. Besides avoiding excessively large samples, a way to alleviate the clogging problem is to wrap the plaster base samples in small pieces of porous tissue paper before inserting samples into the capsules.

Continuous Calibration—Although experience showed no significant fluctuation of flame-ionization detector response during runs, slight changes of response were occasionally observed after shutdowns and startups of the instruments.

Since this method uses the I peak area for quantitation and the flame-ionization detector response is affected by the ratio of air and hydrogen, this laboratory routinely monitors the flame-ionization detector response during the span of analyses, usually for several days and nights, by intermittently analyzing known I standards along with unknown samples to ascertain the calibration validity.

Method Accuracy—Table I shows the amounts of I added and those recovered in the synthetic samples containing different ratios of placebo plaster base. The average recovery of I, covering the range of 400–2700 μg of I/sample, was 100.6 ± 1.6%. The accuracy of the method was maintained even when the I concentration was below the formula's theoretical level.

Advantages of Direct Solid Analysis—Because the plaster base samples were directly analyzed without preseparation such as extractions and filtrations, mechanical loss of I was avoided. The proposed method is superior to the methyl ester–methyl ether and trimethylsilyl GLC methods because multiple derivatives of I may be formed upon derivatization (11–14), which may lead to errors. With this method, interferences from solvents and derivatizing agents were totally eliminated.

Since all nonvolatile components in the plaster base were retained in the aluminum capsule and kept from contacting the column, there was essentially no contamination of the packing material. This undoubtedly contributed to the reproducible performance of the column, which has been used to analyze more than 1000 samples but shows no sign of deterioration.

No significant interference is caused by the other volatile ingredients for analysis of I using this method. Figure 1 shows a typical chromatogram (recorded in log scale of the digital integrator) for the analysis of I in a keratolytic plaster, illustrating the separation of I from the other impurities and the general elution characteristics of I.

Stability of Phenylbutazone in Presence of Pharmaceutical Colors

ROSALIND BAUGH, R. T. CALVERT, and J. T. FELL ˣ

Abstract □ The degradation of phenylbutazone was studied in the presence of lakes suitable for coloring the sugar coats of phenylbutazone tablets. The drug was degraded, in light, in the presence of erythrosine sodium. The degradation probably proceeds *via* singlet oxygen generated by the light-excited dye. The degradation may be important in some quality control procedures and can lead, for example, to unusual results in dissolution rate testing.

Keyphrases □ Phenylbutazone—stability in presence of various pharmaceutical colors, effect of light □ Stability—phenylbutazone in presence of various pharmaceutical colors, effect of light □ Colors, various pharmaceutical—effect on stability of phenylbutazone, effect of light □ Antirheumatic agents—phenylbutazone, stability in presence of various pharmaceutical colors, effect of light

Colors are used in pharmaceutical dosage forms for their aesthetic appeal and as an aid to identification. Coated tablets are frequently colored, and lakes are becoming increasingly popular for this purpose because they offer advantages in the speed of application and cover uniformity. The stability of pharmaceutical dyes and lakes was assessed (1, 2), but little attention has been paid to the possible interactions between colors and drugs.

Amaranth (FD&C Red No. 2 lake), erythrosine sodium (FD&C Red No. 3 lake), tartrazine (FD&C Yellow No. 5 lake), and FD&C Yellow No. 6 lake may be used in combination to give a color suitable for incorporation in the sugar coats of phenylbutazone tablets. This report is concerned with the interaction between these lakes and phenylbutazone.

EXPERIMENTAL

Materials—Amaranth lake[1], erythrosine sodium lake[1], tartrazine lake[1], and FD&C Yellow No. 6 lake[1] (sunset yellow) were obtained as separate powders and as a mixture in syrup[1]. Phenylbutazone[2] was of BP quality, and soluble erythrosine sodium[3] and methylene blue[3] were of reagent grade.

Irradiation of Samples—Suspensions or solutions of the materials in phosphate buffer (pH 7.4) were prepared and stored in subdued light. The test mixtures were exposed, in 1-cm quartz cells, to unfiltered light from a 300-w projector bulb situated 50 cm from the cell. Measurements of the liquid temperature during runs indicated no heating effect by the light beam. Due to the fine particle size of the lakes, sedimentation problems did not arise during the experiment.

Rate constant, min^{-1}	~0	~0	0.016	~0	0.017	0.019	0.091	0.155	0.195	0.062	~0	~0	~0

[a] Dye content = 40%.

At various intervals, the cell was removed from the beam, and the phenylbutazone concentration was measured spectrophotometrically at 264 nm. Corrections were applied for absorbance due to the lake. Interference from the degradation products of phenylbutazone was accounted for by measuring absorbance at the absorption peak of the degradation product (235 nm) and applying the simultaneous equations suggested by Beckstead *et al.* (3).

Identity of Degradation Products—Identification of the degradation products was accomplished by TLC using the method of Awang *et al.* (4). The use of silica gel–kieselguhr plates buffered at pH 6 prevented on-plate oxidation. As a further precaution, the plates were dried under nitrogen.

Dissolution Rates—Dissolution rates were measured by the method of Barrett and Fell (5). Coated phenylbutazone tablets were allowed to dissolve in 1 liter of phosphate buffer (pH 7.4) maintained at 37° and stirred at 70 rpm with a three-blade stirrer. Samples were removed at suitable intervals and filtered through membrane filters[4] (0.45 μm) mounted in special adaptors[4], and the phenylbutazone concentration was determined spectrophotometrically. The filtration procedure removed the majority of the lake.

RESULTS AND DISCUSSION

The concentration of phenylbutazone in solution (0.001% w/v) was monitored on exposure to light and to light in the presence of the lake mixture (0.0009% w/v). Rate constants for the degradation of phenylbutazone under these conditions were calculated from semilogarithmic plots derived from the original data shown in Fig. 1 (Table I). Comparative data for the changes of phenylbutazone concentration in the dark and in the dark in the presence of the lake mixture also are shown in Table I.

The rate constants indicate that phenylbutazone was stable in solution on illumination and in the dark and in the dark when mixed with the lakes. However, illumination of the phenylbutazone plus the lake mixture led to rapid phenylbutazone decomposition.

The effect of the individual lakes in approximately the same concentration as in the lake mixture on the degradation of phenybutazone was examined, and the resulting rate constants are given in Table I. Only erythrosine sodium lake caused measurable degradation of the phenylbutazone, the rate increasing with increasing lake concentration (Fig. 2 and Table I). This effect was also found with a solution of erythrosine sodium (0.00078% w/v), but a slower rate of degradation was noted than with an equivalent lake concentration (Table I), possibly due to a surface catalytic effect.

Only one degradation product could be isolated on TLC (4) from the phenylbutazone–erythrosine sodium mixture after illumination. It was identified as 1,2-diphenyl-4-*n*-butyl-4-hydroxypyrazolidine-3,5-dione

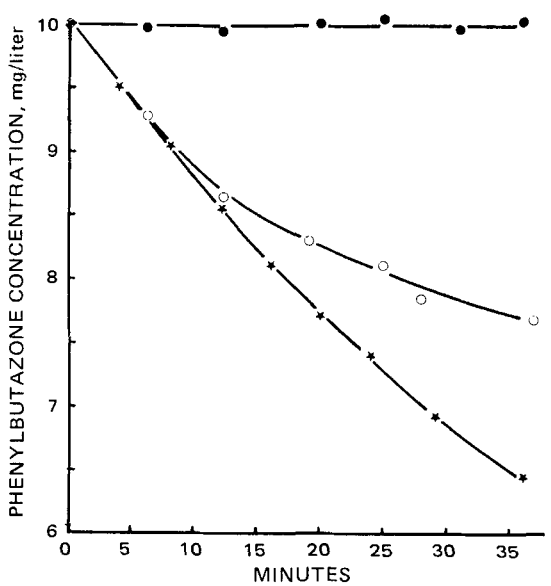

Figure 1—*Effect of the lake mixture on the degradation of 0.001% phenylbutazone solution under various conditions. Key: ★, phenylbutazone plus lake mixture in the light; ○, phenylbutazone plus lake mixture in the light after bubbling with nitrogen prior to irradiation; and ●, phenylbutazone plus lake mixture in the dark. Similar plots were obtained for phenylbutazone alone in the light and phenylbutazone plus other lake mixture components in the light.*

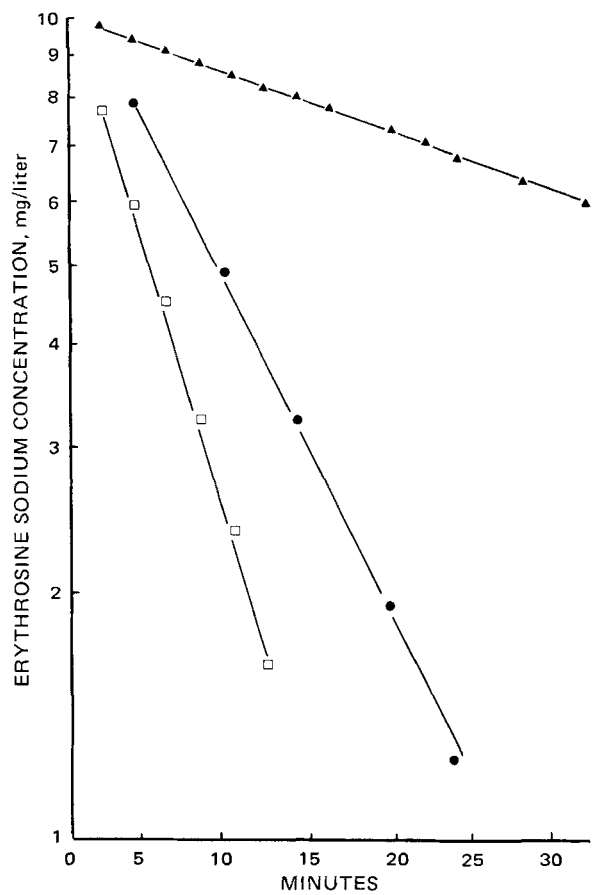

Figure 2—*Effect of erythrosine sodium lake concentration on the degradation of 0.001% phenylbutazone solution exposed to unfiltered light. Key: ▲, 1.23 mg/liter; ●, 4.90 mg/liter; and □, 9.80 mg/liter.*

[4] Millipore filters in Swinnex adaptors, Millipore Ltd., London, England.

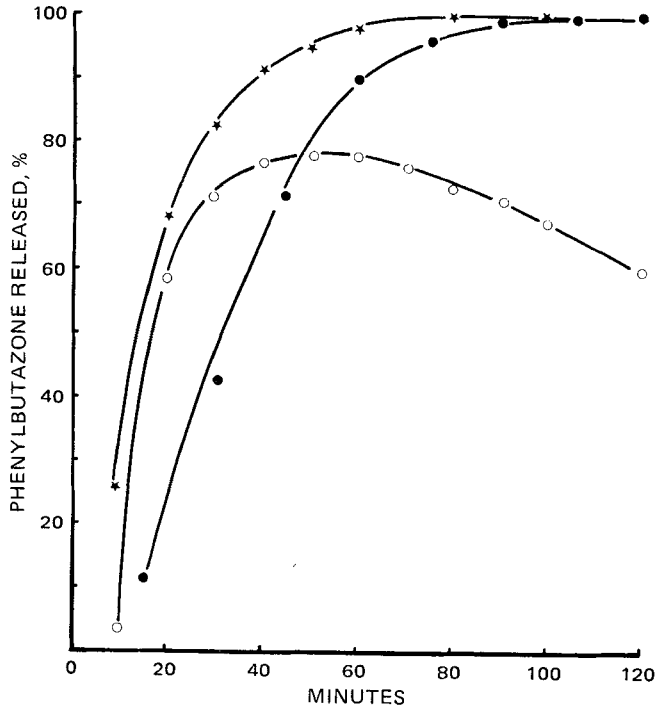

Figure 3—*Release rate of phenylbutazone from coated tablets containing erythrosine sodium in the light (○) and dark (★) or ponceau 4R in the light and dark (●).*

by comparison of R_f values on TLC with an authentic sample. This product is a known degradation product of phenylbutazone and is formed by oxidation (4). Illumination of phenylbutazone solution in the presence of the lake mixture after flushing the liquid with nitrogen markedly decreased the degradation rate of phenylbutazone (Fig. 1). This finding suggests that a mechanism involving oxygen is involved in the dye-catalyzed degradation of phenylbutazone on illumination.

Reactions involving dyes as photosensitizers are often mediated by singlet oxygen (6). A possible mechanism is suggested in Scheme I, where D = dye and R = oxidizable material. This mechanism involves the excitation of the dye into its triplet state by the light. The dye in the triplet state may return to the ground state with release of energy or may transfer the energy to ground-state triplet oxygen, generating singlet oxygen. The singlet oxygen may return to the ground state or attack oxidizable material present, in this case, phenylbutazone.

$$D + h\nu \rightarrow {}^3D^*$$
$$^3D^* \rightarrow D + h\nu'$$
$$^3D^* + {}^3O_2 \rightarrow D + {}^1O_2^*$$
$$^1O_2^* \rightarrow {}^3O_2$$
$$R + {}^1O_2^* \rightarrow RO_2$$

Scheme I

Further support for the suggestion that this scheme operates during the degradation of phenylbutazone by erythrosine sodium came from experiments in which methylene blue (10^{-7} *M*), a known generator of singlet oxygen, was substituted for erythrosine sodium and exposed to identical conditions. The phenylbutazone was degraded to the same degradation product as was produced with erythrosine sodium (first-order rate constant = 0.0282 min^{-1}).

The importance of this reaction lies in procedures where the drug, in solution, is brought into contact with erythrosine sodium in the presence of light, as in quality control procedures such as assays or dissolution rate testing. Figure 3 shows the results from the dissolution rate testing of coated phenylbutazone tablets. In one case, the color in the sugar coating contained erythrosine sodium; in the other, the erythrosine sodium had been replaced by ponceau 4R and the proportions of the other lakes had been altered to obtain an identical color. The tablets were not prepared from the same batch of cores, but comparison can be made between the types of dissolution profiles rather than absolute values.

The testing was carried out under normal laboratory lighting conditions, consisting of natural light from windows and artificial light from fluorescent fittings, and in the dark. When the tablet coat contained erythrosine sodium, the concentration of phenylbutazone in the beaker fell after a certain time due to degradation in the light in the manner described. Equivalent tests run in the dark showed no degradation, and the concentration of phenylbutazone rose to 100%. For tablets with the reformulated color, the drug dissolved and reached 100% in solution both in the dark and in the light, indicating that no degradation had occurred.

If tests are carried out in the light on tablets containing erythrosine sodium in the sugar coat and samples are taken only before the phenylbutazone concentration starts to fall, a falsely low dissolution rate will be indicated due to the competing reactions of dissolution and degradation.

High-Pressure Liquid Chromatographic Analysis of Polythiazide in Pharmaceutical Tablet Formulations

C. K. WONG, D. Y. J. TSAU, D. M. COHEN ˣ, and K. P. MUNNELLY

Abstract □ A high-pressure liquid chromatographic method was developed for the quantitative determination of polythiazide in pharmaceutical tablet formulations after extraction of the powdered tablets with a water–acetonitrile solvent. Analysis is accomplished by comparison of peak areas after chromatography.

Keyphrases □ Polythiazide—high-pressure liquid chromatographic analysis, pharmaceutical formulations □ High-pressure liquid chromatography—analysis, polythiazide in pharmaceutical formulations □ Diuretics—polythiazide, high-pressure liquid chromatographic analysis in pharmaceutical formulations □ Antihypertensives—polythiazide, high-pressure liquid chromatographic analysis in pharmaceutical formulations

Polythiazide {6-chloro-3,4-dihydro-2-methyl - 3 - [[(2,2,2-trifluoroethyl)thio]methyl] -2*H*- 1,2,4- benzothiadiazine-7-sulfonamide 1,1-dioxide}, an orally effective, nonmercurial diuretic and antihypertensive agent, is supplied as a tablet, alone and in combination with reserpine (1). Methods for the determination of polythiazide include TLC (2), spectrophotometry (3–5), column chromatography (6), and polarography (7, 8). However, these methods do not have the rapidity, simplicity, sensitivity, and accuracy of the high-pressure liquid chromatographic (HPLC) methodology.

Recently, a quantitative HPLC method for polythiazide involving reversed-phase partition chromatography was published (9). This method utilized a Bondapak phenyl/Corasil column[1], methanol–water (35:65 v/v) as the mobile phase, and peak height quantitation. The system, however, does not appear optimum since the absolute recovery of added polythiazide was reported as 106%, and baseline separation was not achieved between vanillin, a formulation excipient, and polythiazide, and polythiazide and the reported internal standard, quinoline. The subject of this report is the development of a simple, direct, extremely rapid, and precise HPLC procedure for the quantitation of polythiazide in several pharmaceutical tablet formulations.

EXPERIMENTAL

Apparatus—A high-pressure liquid chromatograph[2], operated at ambient temperature, was equipped with a UV detector for monitoring the column effluent at 254 nm. The column[3] was 25-cm × 4.6-mm (i.d.) stainless steel packed with Partisil 10-ODS. An electronic computing integrator[4] was used to obtain peak areas. A 10-μl loop injection valve[5] was used to introduce samples into the chromatographic system.

Reagents—Polythiazide NF reference standard was dried in vacuum at 60° for 2 hr. Reagent ACS grade acetonitrile[6] and distilled water were used in preparing the mobile phase.

Mobile Phase—Add 20 ml of distilled water to 980 ml of acetonitrile and shake vigorously. Degas prior to use.

Standard Solution—Accurately weigh approximately 50 mg of polythiazide reference standard, transfer quantitatively to a 250-ml volumetric flask, and dissolve in and dilute to volume with the mobile phase.

Sample Solution—Accurately weigh and finely powder 20 polythiazide tablets. Transfer an accurately weighed portion of the powder, equivalent to about 2 mg of polythiazide, to a glass-stoppered 30-ml centrifuge tube. Add 10 ml of the mobile phase, shake for 30 min, centrifuge, and filter the supernate through a 1-μm membrane filter[7]. Use the filtered supernate for analysis.

Chromatography—Condition the column for 24 hr with the mobile phase at a flow rate of 0.5 ml/min. This procedure is necessary for new columns; conditioning is not required for previously used columns. Inject 10 μl of the standard solution and adjust either the pressure or flow rate so that the polythiazide exhibits a retention time of about 3 min.

The approximate chromatographic conditions are a flow rate of 1 ml/min (at an inlet pressure of 300 psig), a chart speed of 1.3 cm (0.5 in.)/min, and a detector sensitivity of 0.32 absorbance unit full-scale (aufs). Data acquisition parameters for the electronic computing integrator were optimized according to the manufacturer's instructions.

For the analysis of a sample, two 10-μl aliquots of the standard solution are injected followed by two 10-μl injections of the sample solution. The peak areas obtained or peak heights may be used for the calculations.

RESULTS AND DISCUSSION

Initial studies concerned the selection of an appropriate column for the separation and quantitation of polythiazide. The adsorption mode of chromatography was investigated using a silica gel-type column[8]. With methanol as the mobile phase, a sharp and symmetrical peak was observed for polythiazide. As additional injections of polythiazide were made onto the column, peak broadening and finally peak splitting were observed. This phenomenon may be attributed either to a nonuniform adsorption of polythiazide on the column or to elution of residual polythiazide retained on the column from previous injections.

		2	98.7	99.1
		3	101.2	101.7
	2	1	99.4	100.0
		2	100.9	100.6
		3	100.2	99.9
	3	1	101.8	102.2
		2	101.8	102.1
		3	101.1	102.1
Average = 100.6% (95% confidence limits of 99.8–101.4%)				

[a] Contained 2 mg of polythiazide and 0.25 mg of reserpine.

The addition of water to the methanolic mobile phase (50% v/v) produced a sharp and reproducible peak for polythiazide. However, the detector response was not linear and an interference was observed from some tablet excipients. Due to the problems encountered, adsorption chromatography was not investigated further.

Reversed-phase partition chromatography with a Partisil 10-ODS column was then investigated. With methanol as the mobile phase, the observed peak for polythiazide was sharp and the response was linear. However, vanillin, a tablet excipient, was not resolved from polythiazide. The addition of water to the methanolic mobile phase up to 50% (v/v) resulted in no observed improvement in resolution.

Because of vanillin's known solubility in methanol, acetonitrile was substituted for methanol in the mobile phase. A sharp peak was observed for polythiazide while no peak was observed for vanillin; it appeared to be retained by the column. However, continued injections of a polythiazide–vanillin solution resulted in tailing of the polythiazide peak, which may be attributed to the retained vanillin acting as a partition substrate. The addition of methanol (2:98 v/v) to the acetonitrile mobile phase resulted in elution of the vanillin while maintaining adequate resolution for polythiazide. However, continued injections of solutions prepared from spiked tablet placeboes resulted in peak broadening for polythiazide and decreased resolution between polythiazide and vanillin.

Table II—Estimates of Precision for Determination of Polythiazide in Pharmaceutical Tablet Formulations by HPLC

Weights per Day	Injections per Weight	Estimates of Precision[a], % 2 mg	4 mg	Combination[b]
1	1	±3.0	±2.6	±2.3
1	2	±2.6	±2.5	±2.2
2	2	±2.3	±2.2	±1.8
3	2	±2.2	±2.2	±1.6
Injection to injection within a weight		±2.0	±1.0	±0.7

[a] Ninety-five percent of the individual results or averages of two, four, or six results will not vary from each other by more than the percentages quoted. These estimates include variability due to days, weights, and injections. The estimates of precision for injection to injection within a weight exclude variability due to days and weights. [b] Contained 2 mg of polythiazide and 0.25 mg of reserpine.

Table III—Comparison of HPLC and Compendial Methods for Determination of Polythiazide in Pharmaceutical Tablet Formulations

Formulation	Day	Sample	Analysis, mg/Tablet HPLC	Spectrophotometric	TLC
2 mg	1	1	2.07	2.07	1.97
		2	2.07	2.09	1.96
		3	2.05	2.10	1.95
	2	1	2.09	2.05	2.00
		2	2.09	2.09	2.00
		3	2.08	2.05	1.97
	Average		2.08	2.08	1.98
4 mg	1	1	4.18	3.96	4.06
		2	4.18	4.03	3.99
		3	4.22	3.87	4.03
	2	1	4.18	4.12	3.99
		2	4.18	4.12	3.96
		3	4.22	4.18	4.03
	Average		4.18	4.06	4.03
Combination[a]	1	1	2.07	2.12	2.05
		2	2.07	2.12	1.99
		3	2.09	2.11	2.01
	2	1	2.06	2.07	1.97
		2	2.06	2.10	1.95
		3	2.06	2.10	1.97
	Average		2.07	2.10	1.99

[a] Contained 2 mg of polythiazide and 0.25 mg of reserpine.

The addition of water to the mobile phase was investigated and, after evaluating various combinations of acetonitrile, methanol, and water, optimum separation and column stability were obtained with a water–acetonitrile (2:98 v/v) system. With this system, baseline separation was obtained between polythiazide and vanillin and tablet placeboes did not interfere. Reserpine was retained on the column, and peak broadening or changing of retention time was not observed, indicating long-term column stability. The detector response for polythiazide was linear up to a concentration of 300 μg/ml when dissolved in the mobile phase. In addition, the column could be regenerated with water, the retained reserpine being washed off under this condition. A typical chromatogram of polythiazide is shown in Fig. 1.

The accuracy and precision of the HPLC method were determined by the following experiments. Three weights of the placeboes for the 2- and 4-mg tablets and 2-mg combination with 0.25 mg of reserpine, in which known quantities of polythiazide were added, were assayed each day for 3 consecutive days. The average percent recoveries of polythiazide were 100.8, 99.9, and 100.6, respectively (Table I).

Estimates of precision (Table II) were obtained using the analysis of variance statistical technique. Ninety-five percent of the individual results will not vary from each other (*i.e.*, from the mean) by more than ±3.0, ±2.6, and ±2.3% for the 2- and 4-mg tablets and 2-mg combination with reserpine, respectively. The standard errors for the average of two injections per sample were ±1.3, ±1.3, and ±1.1% for the 2- and 4-mg tablets and 2-mg combination with reserpine, respectively.

The proposed HPLC method was compared to the compendial TLC and colorimetric assays (2), and the results (Table III) were in agreement. All samples were within the requirements of NF XIV for polythiazide tablet formulations by HPLC methodology (2). Because of the speed, accuracy, and precision of the proposed procedure, it represents an alternative to present compendial and published methodologies.

Quantitative High-Pressure Liquid Chromatographic Determination of Thimerosal in Pharmaceutical Formulations

CHERNG-CHYI FU and MURRAY J. SIBLEY [x]

Abstract □ A quantitative high-pressure liquid chromatographic method using an anion-exchange resin column and an aqueous perchlorate solution as the mobile phase is employed for the determination of thimerosal in pharmaceutical formulations. With a liquid formulation containing large amounts of edetate disodium, calcium chloride is used for complexation to eliminate the interference from edetate disodium.

Keyphrases □ Thimerosal—high-pressure liquid chromatographic analysis, pharmaceutical formulations □ High-pressure liquid chromatography—analysis, thimerosal in pharmaceutical formulations

Thimerosal is an organomercurial chemical with antibacterial activity. It is used as an antiseptic for applications such as skin disinfection, urethral irrigation, and preservation of ophthalmic formulations (1). Compendial analytical methods using atomic absorption spectroscopy lack specificity (2). Another analytical method employing colorimetry of a dithizone complex (3) is tedious, and the presence of metal ions in the reagents causes interference.

Described here is a high-pressure liquid chromatographic (HPLC) analysis of thimerosal using an anion-exchange resin column with buffered sodium perchlorate as the mobile phase. The method is specific and simple.

EXPERIMENTAL

Apparatus—A high-pressure liquid chromatograph[1] equipped with a pump (7000 psig maximum), dual-channel UV detectors at 254 and 280 nm, and a 3 × 500-mm stainless steel column packed with anion-exchange resin[2] was used.

Reagents—The mobile phase was 0.35% perchloric acid[3] in 0.001 *M* dibasic sodium phosphate with pH adjusted to 7.0 with 1 *N* sodium hydroxide.

Standard Solution—Dissolve 8, 10, and 12 mg of thimerosal, separately, in purified water and dilute to 1 liter. These solutions represent thimerosal concentrations of 0.0008, 0.001, and 0.0012%, respectively.

Sample Solution—Dilute the sample solutions with purified water to make a final thimerosal concentration of 0.001%.

Chromatographic Separation—The procedure is run at ambient temperature, and the solvent flow is 1.6 ml/min. The UV monitor is set at 254 nm with a sensitivity of 0.02 absorbance unit. The samples and standards are injected with a 30-μl loop. The concentration of thimerosal is calculated from a standard curve using peak area (*i.e.*, height times width at half-height) for quantitation.

[1] Spectra Physics isocratic model 3500B, Santa Clara, Calif.
[2] Vydac, Applied Science Laboratories, State College, Pa.
[3] J. T. Baker Chemical Co., Phillipsburg, N.J.

RESULTS AND DISCUSSION

A typical chromatogram of thimerosal is shown in Fig. 1*a*. The chromatogram of one sample was complete in less than 5 min. Areas were used for the calculation of thimerosal concentration. Linear response over the concentration range from 0 to 15 μg/ml was obtained.

Table I shows the results using both the HPLC and the dithizone complex colorimetric methods. A solution containing edetate disodium, a common ingredient in ophthalmic formulations, and thimerosal in the ratio of less than 10:1 was separated and analyzed by this method without further sample treatment. However, an overlap of peaks was observed if a formulation contained edetate disodium and thimerosal in a ratio of more than 10:1. In such cases, calcium chloride was added to the sample solution to suppress the edetate disodium peak. With this step, complete separation and analysis of thimerosal were obtained.

Figure 1*b* illustrates a typical chromatogram of a sample solution containing 0.02% edetate disodium and 0.001% thimerosal. Figure 1*c* shows the chromatogram of the sample solution after treating with calcium chloride (to each 5 ml of sample solution was added 0.1 ml of 2%

calcium chloride solution). The amount of calcium chloride added to the sample solution depended on the actual amount of edetate disodium present. Since the complexation of edetate disodium with metal ions is pH dependent, one must adjust the sample solution pH to between 6.8 and 7.4 to obtain the best results.

Sex Differences in Drug Evaluations

NANCY J. HORROM [x] and CLINTON C. BROWN

Abstract □ Twenty normal, nonobese subjects (10 male and 10 female) were administered a battery of seven psychomotor tests as well as affect checklists and physiological measurements on 6 alternate days. Subjects performed the entire battery predrug and at 45, 90, and 135 min postdrug. Fenfluramine, dextroamphetamine, two combined doses of the drugs, and a placebo were given in a double-blind, repeated measures design. Findings revealed significant sex-based differences in initial performance on five of the seven psychomotor tasks and in two physiological measures, with males performing at higher levels than females. Additionally, sex differences in postdrug changes were found in three psychomotor and two physiological measures, with females evidencing greater change scores than males.

Keyphrases □ Fenfluramine—alone and combined with dextroamphetamine, sex-based differences in psychomotor and physiological effects, humans □ Dextroamphetamine—alone and combined with fenfluramine, sex-based differences in psychomotor and physiological effects, humans □ Psychomotor effects—fenfluramine and dextroamphetamine, alone and in combination, sex-based differences, humans □ Physiological effects—fenfluramine and dextroamphetamine, alone and in combination, sex-based differences, humans □ Sex-based differences—fenfluramine and dextroamphetamine, alone and in combination, psychomotor and physiological effects, humans

Fenfluramine is an anorexic agent structurally similar to dextroamphetamine; however, it does not produce central nervous system (CNS) activation with respect to measures of sleep (1) or psychomotor performance (2). The mood elevation, euphoria, and lift produced by dextroamphetamine are well documented (3–5); fenfluramine, however, appears to have sedative properties (2, 4, 6). There is some evidence that fenfluramine may block the CNS stimulant effects of dextroamphetamine (7).

As with most psychopharmacological investigations, sex-based differences in drug reactivity were not explored in the studies cited (8). A chance assignment of subjects in a study to be reported elsewhere provided a comparison of pre- and postdrug performance and mood differences between the sexes given identical treatments. Based upon a preliminary analysis, it was hypothesized that males would have higher levels of performance on psychomotor tests than would females and that sex differences would occur in the pattern of drug reactivity.

EXPERIMENTAL

Twenty subjects (10 male and 10 female, age range of 21–30, $\bar{X}$ = 23.7) were recruited by newspaper advertisements and screened by psychiatric interview and psychological test (16 PF) (9). Informed consent was obtained and subjects were paid for their participation. Subjects were asked to abstain from all medication and alcohol and to maintain normal diet and sleeping habits during the 2-week testing period.

Subjects were tested at the same time of day (11:30 am–5:00 pm) on 6 alternate days. The 1st day was primarily for practice and familiarization with the tests, and this day's data were subsequently discarded. On each of the remaining 5 test days, the subject performed the entire test battery of psychomotor, perceptual, physiological, and affect evaluations prior to receiving medication and at 45, 90, and 135 min postmedication (exceptions noted in test descriptions).

Five treatments were used: (*a*) placebo (lactose), (*b*) fenfluramine alone (60 mg), (*c*) dextroamphetamine alone (10 mg), (*d*) a low combination (60 mg of fenfluramine plus 10 mg of dextroamphetamine), and (*e*) a high combination (90 mg of fenfluramine plus 10 mg of dextroamphetamine).

Each of the five conditions appeared equally on each test day, and subjects were randomly assigned to a treatment sequence upon acceptance. Postdrug measures were compared against the predrug baseline for each subject on each test day to minimize practice and potential day-of-week effects. Both the subject and experimenter were unaware of the contents of the identically appearing capsules. In the five treatment groups representing orders of administration of placebo and four drug conditions, males and females appeared in the ratios of 1:1, 0:1, 3:1, and 1:3. This approach provided the opportunity for an evaluation of study results with sex as a main factor.

The test battery included various psychomotor tasks, several physiological measures, and self-report mood evaluative forms. Psychomotor tests have been shown to be sensitive to various drug effects (8, 10) and were used previously in this laboratory (2).

Physiological Measures—Pulse rate, oral temperature, blood pressure, and salivary output were taken daily prior to drug administration and at 200 min postdrug; pupil size was measured predrug and at 45, 90, and 135 min postdrug. Additionally, the Lorr outpatient mood scale

calcium chloride solution). The amount of calcium chloride added to the sample solution depended on the actual amount of edetate disodium present. Since the complexation of edetate disodium with metal ions is pH dependent, one must adjust the sample solution pH to between 6.8 and 7.4 to obtain the best results.

Sex Differences in Drug Evaluations

NANCY J. HORROM [x] and CLINTON C. BROWN

Abstract □ Twenty normal, nonobese subjects (10 male and 10 female) were administered a battery of seven psychomotor tests as well as affect checklists and physiological measurements on 6 alternate days. Subjects performed the entire battery predrug and at 45, 90, and 135 min postdrug. Fenfluramine, dextroamphetamine, two combined doses of the drugs, and a placebo were given in a double-blind, repeated measures design. Findings revealed significant sex-based differences in initial performance on five of the seven psychomotor tasks and in two physiological measures, with males performing at higher levels than females. Additionally, sex differences in postdrug changes were found in three psychomotor and two physiological measures, with females evidencing greater change scores than males.

Keyphrases □ Fenfluramine—alone and combined with dextroamphetamine, sex-based differences in psychomotor and physiological effects, humans □ Dextroamphetamine—alone and combined with fenfluramine, sex-based differences in psychomotor and physiological effects, humans □ Psychomotor effects—fenfluramine and dextroamphetamine, alone and in combination, sex-based differences, humans □ Physiological effects—fenfluramine and dextroamphetamine, alone and in combination, sex-based differences, humans □ Sex-based differences—fenfluramine and dextroamphetamine, alone and in combination, psychomotor and physiological effects, humans

Fenfluramine is an anorexic agent structurally similar to dextroamphetamine; however, it does not produce central nervous system (CNS) activation with respect to measures of sleep (1) or psychomotor performance (2). The mood elevation, euphoria, and lift produced by dextroamphetamine are well documented (3–5); fenfluramine, however, appears to have sedative properties (2, 4, 6). There is some evidence that fenfluramine may block the CNS stimulant effects of dextroamphetamine (7).

As with most psychopharmacological investigations, sex-based differences in drug reactivity were not explored in the studies cited (8). A chance assignment of subjects in a study to be reported elsewhere provided a comparison of pre- and postdrug performance and mood differences between the sexes given identical treatments. Based upon a preliminary analysis, it was hypothesized that males would have higher levels of performance on psychomotor tests than would females and that sex differences would occur in the pattern of drug reactivity.

EXPERIMENTAL

Twenty subjects (10 male and 10 female, age range of 21–30, $\bar{X}$ = 23.7) were recruited by newspaper advertisements and screened by psychiatric interview and psychological test (16 PF) (9). Informed consent was obtained and subjects were paid for their participation. Subjects were asked to abstain from all medication and alcohol and to maintain normal diet and sleeping habits during the 2-week testing period.

Subjects were tested at the same time of day (11:30 am–5:00 pm) on 6 alternate days. The 1st day was primarily for practice and familiarization with the tests, and this day's data were subsequently discarded. On each of the remaining 5 test days, the subject performed the entire test battery of psychomotor, perceptual, physiological, and affect evaluations prior to receiving medication and at 45, 90, and 135 min postmedication (exceptions noted in test descriptions).

Five treatments were used: (*a*) placebo (lactose), (*b*) fenfluramine alone (60 mg), (*c*) dextroamphetamine alone (10 mg), (*d*) a low combination (60 mg of fenfluramine plus 10 mg of dextroamphetamine), and (*e*) a high combination (90 mg of fenfluramine plus 10 mg of dextroamphetamine).

Each of the five conditions appeared equally on each test day, and subjects were randomly assigned to a treatment sequence upon acceptance. Postdrug measures were compared against the predrug baseline for each subject on each test day to minimize practice and potential day-of-week effects. Both the subject and experimenter were unaware of the contents of the identically appearing capsules. In the five treatment groups representing orders of administration of placebo and four drug conditions, males and females appeared in the ratios of 1:1, 0:1, 3:1, and 1:3. This approach provided the opportunity for an evaluation of study results with sex as a main factor.

The test battery included various psychomotor tasks, several physiological measures, and self-report mood evaluative forms. Psychomotor tests have been shown to be sensitive to various drug effects (8, 10) and were used previously in this laboratory (2).

Physiological Measures—Pulse rate, oral temperature, blood pressure, and salivary output were taken daily prior to drug administration and at 200 min postdrug; pupil size was measured predrug and at 45, 90, and 135 min postdrug. Additionally, the Lorr outpatient mood scale

Temperature	Mean	98.08	97.72	1.91	0.05
	SD	0.14	0.13		

(LOMS) and an adjective checklist were completed 160 min postmedication.

Psychomotor Performance Measures—*Tapping Rate*—The subject was instructed to tap as rapidly as possible with the forefinger of the preferred hand on a standard telegraph key for 1 min. The score was the number of taps.

Cross-Out Rate—The subject was required to make a slash through each X on a 21.6 × 28-cm sheet of paper with X's and O's in random order typed in continuous double-spaced rows. The score was the number of X's crossed out.

Reaction Time—The subject was instructed to react as quickly as possible to a signal light mounted on the response key 30.5 cm from the subject's hand by pressing the key at the appearance of the light. Twenty-five trials with randomized intertrial intervals were presented during 2 min. The score was the average reaction time in milliseconds.

Steadiness—The subject was given a pistol handle connected to a light metal rod 0.63 cm in diameter and 91.4 cm long, the end of which was placed in the center of a hole 1.2 cm in diameter. Contact between the rod and the hole produced an audible tone and activated a timer. The task was to hold the rod, with the elbow locked, in the center of the hole without touching the side for 60 sec. The score was time in milliseconds that the rod touched the side.

Number Path—The subject was instructed to connect the numbers one through 30 interspersed over a paper. The score was the number reached after 30 sec (11).

Card Sorting—The subject was required to sort four decks of playing cards into suits by placing them face down into the four divisions of a sorting bin. The score was the number of cards sorted.

Handwriting—The subject was asked to copy a standard paragraph on a piece of paper 21.6 × 28 cm. The score was the area in centimeters squared covered by the handwriting (12).

RESULTS

Male and female groups did not differ significantly on height–weight ratio, age, or 16 PF profiles.

Data were gathered across subjects and days with each subject serving as his or her own control. An analysis was undertaken to determine differences between sexes with regard to the baseline level of performance of the tests and differences in drug-modified performance.

Five of seven psychomotor tests, three physiological measures, and four LOMS factors revealed one or the other type of sex-based difference.

Predrug Sex Differences—Differences in the initial level of daily task performance between men and women were assessed by a t for correlated means (Table I). Significant pretreatment sex differences were found for five of the seven psychomotor tasks. In each case, the magnitude of male performance exceeded that of females. Males tapped more times in a minute, sorted more cards, reacted more quickly to a stimulus, were steadier, and covered a larger area with their handwriting than did females. Men also displayed a lower temperature and a higher systolic blood pressure.

Since the Lorr outpatient mood scale (LOMS) was given only once, 160 min postmedication, those ratings reflect a combination of drug-induced and predrug mood states. Males rated themselves significantly higher in total affect, energy level, "anger," and "cheerfulness" than did females.

Sex Differences in Drug Reactivity—Difference scores were obtained by subtracting each subject's predrug score from the scores obtained at 45, 90, and 135 min postdrug. A three-way analysis of variance (repeated measures) was employed on these difference scores, followed by t tests where significance was found. Sex appeared as a significant main factor in three psychomotor tasks and two physiological measures. In each case, females had greater change scores than did males (Table II).

Table II—Postdrug Change Scores for Males and Females

Test		Female	Male	F
Tapping rate	Mean	13.73	5.99	5.36[a]
	SD	3.23	1.89	
Card sorting	Mean	4.48	1.73	8.87[b]

	SD	1.92	1.15	
Pulse	Mean	0.28	−4.96	7.60[b]
	SD	1.32	1.94	

[a] Significant at 0.05. [b] Significant at 0.01.

Females had a significantly greater increase in card sorting, tapping rate, and steadiness after drugs than males had. Additionally, females showed greater changes in the physiological measures of systolic blood pressure and pulse rate. Although the systolic blood pressure of *both* males and females increased from pre- to postdrug, females increased significantly more than males. The differences in pulse rate change between the two sexes also achieved significance; while the pulse rate of women subjects increased after drugs, that of male subjects decreased.

DISCUSSION

These results suggest that there are significant sex-based differences in the initial performance of certain psychomotor tasks. Five of the seven psychomotor tasks used revealed significantly higher initial levels of test performance for males than for females. The rate of change in performance, *i.e.*, drug reactivity, following drugs may be partially determined by the sex of the subject. In this study, females had a greater change after drugs than did males.

The observed differences in certain physiological measures (pulse, blood pressure, and temperature) both pre- and postdrug may point to metabolic differences between males and females. Although there was no significant difference between the ratio of height to weight between males and females, the females were on the average 9.07 kg lighter than the males. This factor, along with probable differences in the proportion of fat and muscle, may contribute both to predrug differences as well as differences in reactivity. Further study of male–female reactivity to drugs and situational changes is definitely indicated.

The data from the Lorr outpatient mood scale, which showed that males rated themselves higher in affect, also need to be explored further. Since the design of the study had subjects completing the scale only after medication, it could not be determined if this sex difference was due to drug reactions, procedural factors, or basic difference between male and female awareness of and/or reporting of different feelings.

In the performance of the simple psychomotor tasks, the males excelled initially while the females showed greater postdrug changes. The effect of learning on the postdrug performance must be considered. Women have been shown to excel in performance of simple overlearned tasks (13). Postdrug increases in performance may be partially attributed to relearning occurring during the predrug testing.

The factor of sex of the experimenter may account for some differences between male and female subject performance. Studies have shown that subjects perform at a higher rate when the experimenter is of the opposite sex (14, 15). All subjects in this study were tested by the same female experimenter.

Sex-based differences in the performance of psychomotor tasks both initially and following drug treatment point out the need to consider the sex of the subject as an important factor in evaluating drug effects. Averaging the performance of an equal number of male and female subjects does not ensure results that can be generalized to both or, possibly, either sex. It may be inappropriate to generalize psychopharmacological research findings to the general population if only one sex has been used in the testing. Further study is indicated to determine if measurements other than psychomotor performance also show strong sex-based differences.

Mathematical Description of Solute Velocities during Dissolution from a Horizontal Surface

ALLEN CHAO [*], CHONG-KOOK KIM, DANE O. KILDSIG [x], and PAUL A. KRAMER

Abstract □ A mathematical analysis of solute flow in a descending column following dissolution is presented. The acceleration of a solute particle from zero velocity, when it is in the solid phase, to its final equilibrium descending velocity was analyzed. The maximum velocity for *N*-(3-methylphenyl)acetamide developed essentially at the solid–liquid interface, contradicting the postulate of a microsize diffusional layer. The possibility of a diffusional layer existing for solids of lower solubility than *N*-(3-methylphenyl)acetamide is discussed.

Keyphrases □ Solute velocities—in descending column during dissolution from a horizontal surface, mathematical analysis □ Velocities, solute—in descending column during dissolution from a horizontal surface, mathematical analysis □ Dissolution—from a horizontal surface, mathematical analysis of solute velocities in descending column

Studies utilizing a descending column model to investigate the dissolution of a solid showed that convective transport of solute rather than molecular diffusion is the primary means of mass transfer for such a model (1, 2). Interfacial effects such as solvent penetration, wetting, and solvation of the solid seem to control the rate of mass transfer when dissolution from the solid surface occurs in the descending direction. Under such conditions, one would not anticipate the presence of a finite "diffusion layer." Calculations based on measurements of the rate of movement of a solute front in a descending dissolution column (1) are presented here to show that steady-state velocities are established within microseconds and essentially begin at the interface, thus eliminating the possibility of a microsize diffusion layer.

THEORY AND DISCUSSION

The velocity of solute flow in a vertical dissolution column was determined from observations of the movement of the solute front down the column (1). Since a linear relationship was observed between the solvent front location and time, the velocity appears to be independent of time. There must, however, be a time-variant laminar flow velocity profile, on a molecular basis, for molecules in the bulk fluid stream at times close to zero. A molecule in the solid phase obviously has a zero-velocity component contributing to its flow down the column.

Following the solvation step in a dissolution process, the solvated solute molecule descends from rest in a stationary fluid under the action of gravity. The molecule first accelerates as it would in a vacuum; but unlike the situation in a vacuum, its acceleration is retarded due to friction with the surrounding solvent medium. As the frictional force increases with an increase in velocity, this force eventually reaches a value equal to that of the gravitational force. From that point on, the two forces are balanced and the molecule continues to fall at a constant velocity. The exponentially increasing velocity of such a molecule descending from rest under the influence of gravity represents an interesting first-order system, because the dynamics are defined completely by the steady-state velocity and the time constant for the approach to steady state can be predicted from this velocity.

Consider the fall of a solvated solute molecule through an aqueous medium when the solvated solute and solvent differ in density and viscosity. Under the action of gravity, the downward force, F, acting on the molecule depends on the relative magnitudes of the forces of gravity and buoyancy. The gravitational force, F_w, acts on the molecule even when it is at rest and remains constant during the entire period of descent. The buoyancy, F_b, is dependent on the solvent medium. From Newton's second law of motion:

$$F = F_w - F_b \qquad \text{(Eq. 1a)}$$

$$F = (\rho - \rho_0)gV \qquad \text{(Eq. 1b)}$$

Mathematical Description of Solute Velocities during Dissolution from a Horizontal Surface

ALLEN CHAO [*], CHONG-KOOK KIM, DANE O. KILDSIG [x], and PAUL A. KRAMER

Abstract □ A mathematical analysis of solute flow in a descending column following dissolution is presented. The acceleration of a solute particle from zero velocity, when it is in the solid phase, to its final equilibrium descending velocity was analyzed. The maximum velocity for *N*-(3-methylphenyl)acetamide developed essentially at the solid–liquid interface, contradicting the postulate of a microsize diffusional layer. The possibility of a diffusional layer existing for solids of lower solubility than *N*-(3-methylphenyl)acetamide is discussed.

Keyphrases □ Solute velocities—in descending column during dissolution from a horizontal surface, mathematical analysis □ Velocities, solute—in descending column during dissolution from a horizontal surface, mathematical analysis □ Dissolution—from a horizontal surface, mathematical analysis of solute velocities in descending column

Studies utilizing a descending column model to investigate the dissolution of a solid showed that convective transport of solute rather than molecular diffusion is the primary means of mass transfer for such a model (1, 2). Interfacial effects such as solvent penetration, wetting, and solvation of the solid seem to control the rate of mass transfer when dissolution from the solid surface occurs in the descending direction. Under such conditions, one would not anticipate the presence of a finite "diffusion layer." Calculations based on measurements of the rate of movement of a solute front in a descending dissolution column (1) are presented here to show that steady-state velocities are established within microseconds and essentially begin at the interface, thus eliminating the possibility of a microsize diffusion layer.

THEORY AND DISCUSSION

The velocity of solute flow in a vertical dissolution column was determined from observations of the movement of the solute front down the column (1). Since a linear relationship was observed between the solvent front location and time, the velocity appears to be independent of time. There must, however, be a time-variant laminar flow velocity profile, on a molecular basis, for molecules in the bulk fluid stream at times close to zero. A molecule in the solid phase obviously has a zero-velocity component contributing to its flow down the column.

Following the solvation step in a dissolution process, the solvated solute molecule descends from rest in a stationary fluid under the action of gravity. The molecule first accelerates as it would in a vacuum; but unlike the situation in a vacuum, its acceleration is retarded due to friction with the surrounding solvent medium. As the frictional force increases with an increase in velocity, this force eventually reaches a value equal to that of the gravitational force. From that point on, the two forces are balanced and the molecule continues to fall at a constant velocity. The exponentially increasing velocity of such a molecule descending from rest under the influence of gravity represents an interesting first-order system, because the dynamics are defined completely by the steady-state velocity and the time constant for the approach to steady state can be predicted from this velocity.

Consider the fall of a solvated solute molecule through an aqueous medium when the solvated solute and solvent differ in density and viscosity. Under the action of gravity, the downward force, F, acting on the molecule depends on the relative magnitudes of the forces of gravity and buoyancy. The gravitational force, F_w, acts on the molecule even when it is at rest and remains constant during the entire period of descent. The buoyancy, F_b, is dependent on the solvent medium. From Newton's second law of motion:

$$F = F_w - F_b \qquad \text{(Eq. 1a)}$$

$$F = (\rho - \rho_0)gV \qquad \text{(Eq. 1b)}$$

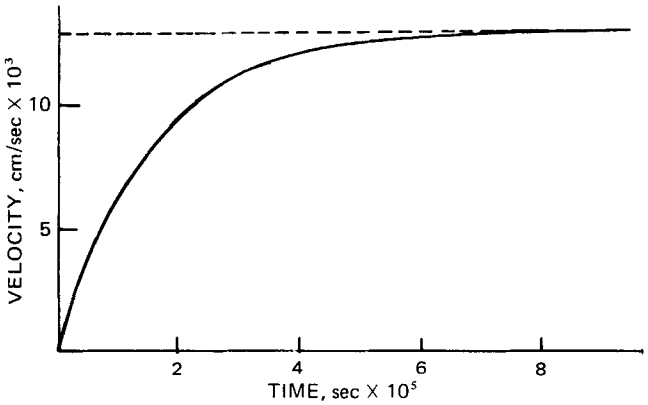

Figure 1—*Plot of velocity* versus *time for I using Eq. 9. The dashed line is the limiting maximum velocity:* v_{max} = *0.013 cm/sec.*

where g is the gravitational acceleration; ρ and ρ_0 are the densities of solvated solute and solvent, respectively; and V is the volume of the solvated solute molecule. The force F_w in Eq. 1*a* is the downward force of gravity acting on the solute molecule in the stationary medium. The term $\rho_0 gV$ represents the buoyancy effect. Although it is difficult to determine the volume of a molecule with an irregular shape, shape is an important factor contributing to the forces acting on a falling molecule. For the sake of simplicity, the solvated molecules are assumed to be spherical. If D is the diameter of a molecule, then:

$$V = \frac{\pi D^3}{6} \qquad \text{(Eq. 2)}$$

Substituting Eq. 2 into Eq. 1*b* yields:

$$F = \frac{\pi D^3 g}{6}(\rho - \rho_0) \qquad \text{(Eq. 3)}$$

The force resisting motion is generally referred to as the drag, R. It is assumed that its magnitude is a function of the diameter of the molecule, its velocity, v, and the viscosity of the surrounding fluid. On the basis of these assumptions, Stokes derived an equation for flow resistance in laminar flow systems (3):

$$R = KD\eta v \qquad \text{(Eq. 4)}$$

where η is the dynamic viscosity of the solvent medium, K is a shape factor for the solute and has been determined experimentally for a number of shapes, and v is velocity. For a spherical object, K has a value of 3π, so Eq. 4 takes the form:

$$R = 3\pi D\eta v \qquad \text{(Eq. 5)}$$

The net driving force, DF, acting on a molecule is:

$$DF = F - R \qquad \text{(Eq. 6)}$$

From Newton's law (3):

$$DF = \frac{F}{g}(dv/dt) \qquad \text{(Eq. 7}a\text{)}$$

$$DF = \frac{\pi D^3}{6}(\rho - \rho_0)dv/dt \qquad \text{(Eq. 7}b\text{)}$$

Substituting Eqs. 3, 5, and 7*b* into Eq. 6 yields:

$$\frac{\pi D^3}{6}(\rho - \rho_0)dv/dt = \frac{\pi D^3 g}{6}(\rho - \rho_0) - 3\pi D\eta v \qquad \text{(Eq. 8)}$$

I	4.1	2.8	1.3
Benzamide	12.5	4.0	4.2

[a] From Ref. 4.

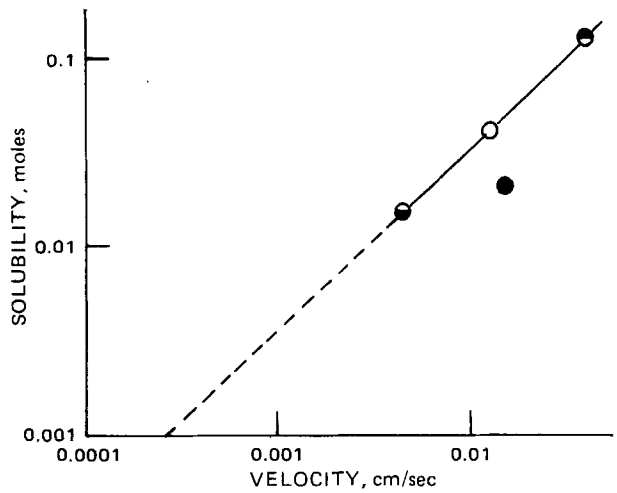

Figure 2—*Logarithmic plot of solubility* versus *velocity of flow. Key:* ○, *I;* ◓, *benzamide;* ◒, *phenacetin; and* ●, *salicylamide.*

By letting $v = 0$ at $t = 0$ since the molecules are initially at rest, the solution of Eq. 8 becomes:

$$v = \frac{D^2 g(\rho - \rho_0)}{18\eta}\left[1 - e^{-(18\eta/D^2)(\rho-\rho_0)t}\right] \qquad \text{(Eq. 9)}$$

As time increases, v approaches a constant limiting velocity, v_{max}, where:

$$v_{max} = \frac{D^2 g(\rho - \rho_0)}{18\eta} \qquad \text{(Eq. 10)}$$

In the descending dissolution of *N*-(3-methylphenyl)acetamide (I) in water, a v_{max} of 0.013 cm/sec was observed (1). A graph of the velocity of flow, v, as a function of time can be constructed according to Eq. 9 (Fig. 1). The descending molecules start at rest, exponentially gain velocity due to the effects of gravity, and reach their limiting velocity in an extremely short period (about 80 μsec).

The distance from the solid surface at which the maximum velocity is first attained is of particular interest. Since the solute velocity increases from 0 to 0.013 cm/sec, it is conceivable that diffusional velocities exist in the approximately 50-μm region usually described by diffusion layer theory. Equation 9 may be written as:

$$dx/dt = v_{max}\left[1 - e^{-(g/V_{max})t}\right] \qquad \text{(Eq. 11)}$$

where $v = dx/dt$ = the change in distance x with time for a solute front moving in the x direction. The solution of this equation for x with the initial condition $x = 0$ at $t = 0$ is:

$$x = v_{max}\left\{t + \frac{V_{max}}{g}\left[e^{-(g/V_{max})t}\right] - \frac{V_{max}}{g}\right\} \qquad \text{(Eq. 12)}$$

The solution of Eq. 12 at $t = 80$ μsec is 9.26×10^{-7} cm. As might be expected from the short time required, the maximum velocity for I is established essentially at the interface, contradicting any postulate of a microsize diffusional layer.

Since the steady-state velocity in the descending column is related to the solubility of the solid (Table I), the question arises as to the possibility of a diffusional layer existing for solids of a lower solubility than I. By using the solubility and descending solute front velocity values reported (2–4) for the solids I, benzamide, phenacetin, and salicylamide, a logarithmic plot of solubility *versus* velocity was constructed (Fig. 2) and an extrapolation was made to lower velocities. Since the velocity of solute flow down the column is related to the density difference between the solution at the interface and the bulk solution and since this density difference should, in general, decrease with the decreasing solubility of the solid, the extrapolation in Fig. 2 should reasonably reflect solute velocities at low solubilities.

The diffusional velocity of I can be estimated from reported ascending dissolution experiments (examining a true diffusion process) (1). When using the I diffusion coefficient of 1.25×10^{-5} cm^2/sec as representative of most solutes and a 60-min time period, a diffusion velocity of 2×10^{-4} cm/sec was obtained. The extrapolation in Fig. 2 indicated that velocities in the diffusional range are reached when the solubility falls below 0.001

M. Variations from Fig. 2 occur due to the fact that not all solids and their resulting solutions have the same density and convective velocity. For example, salicylamide has a lower solubility than I but a higher solution mass transfer velocity.

Finally, it must be stressed that a diffusional mass transfer step does not mean a diffusion-controlled mechanism for dissolution. While the dissolution of solids having solubilities below 0.001 M appears to be diffusion controlled, this does not mean that the interfacial rate is now fast compared to the diffusion rate. Certainly, the rate of interaction at the solid–liquid interface decreases as the solubility decreases, as indicated by the data in Table I showing that the effective interfacial concentration decreases with decreasing solubility. This phenomenon is not likely to change at even lower solubilities. Consequently, regardless of solubility or the approach to diffusional mass transfer, the interfacial rate will remain slower than the diffusion rate and dissolution must be considered as an interfacially controlled process.

GLC–Mass Spectral Analysis of Psilocin and Psilocybin

DAVID B. REPKE ˣ, DALE THOMAS LESLIE *, DANIEL M. MANDELL ‡, and NICHOLAS G. KISH §

Abstract □ With the combined technique of GLC–mass spectrometry, psilocin and psilocybin, two hallucinogenic indoles, were analyzed as their trimethylsilyl derivatives. The method was applied to these two components in an extract of *Psilocybe cubensis* (Earle) Sing.

Keyphrases □ Psilocin—GLC–mass spectral analysis in extract of mushroom *Psilocybe cubensis* □ Psilocybin—GLC–mass spectral analysis in extract of mushroom *Psilocybe cubensis* □ GLC–mass spectrometry—analysis, psilocin and psilocybin in extract of mushroom *Psilocybe cubensis* □ Hallucinogenics—psilocin and psilocybin, GLC–mass spectral analysis in extract of mushroom *Psilocybe cubensis*

Psilocin and psilocybin, two hallucinogenic principles found in certain agarics (1), have aroused considerable interest since their isolation and characterization in the late 1950's (2, 3). The mushrooms in which they occur have been known and revered in southern Mexico for centuries. Their rediscovery in 1939 (4) and their subsequent study (5, 6) and popularization ultimately led to legislation to control their use (7).

BACKGROUND

Psilocin (3-[2-(dimethylamino)ethyl]indol-4-ol) and psilocybin, its dihydrogen phosphate ester, are unique in nature as indoles having a 4-substituent and a phosphate group. Both qualitative and quantitative methods have been utilized for their analysis. Paper chromatography (2) and TLC (8) have been used in conjunction with colorimetric reagents as well as UV spectroscopy. When pure samples are available, IR spectrometry can be used (9). Mass spectrometry (10) has been relied upon for identification of these compounds in various pharmaceutical preparations. Various fluorescence and phosphorescence techniques (11) as well as other emission spectral techniques (12) have also been used.

In an investigation of the genus *Psilocybe* and related genera, the need for a sensitive and accurate quantitative method for the analysis of psilocin and psilocybin became apparent. This method would have to be applicable to extracts of minute amounts of scarce herbarium material and vegetative mycelium obtained from liquid culture.

Previously, GLC was applied to the analysis of psilocin (13) and psilocybin (14), both as the free bases and their trimethylsilyl derivatives. GLC–mass spectrometry has been successfully applied to the bis(trimethylsilyl) derivative of bufotenine, the 5-hydroxy positional isomer of psilocin (15).

The possibility of utilizing GLC for the separation of organic molecules containing a phosphate group was suggested by work with trimethylsilyl derivatives of ribonucleotides (16).

EXPERIMENTAL[1]

Fifty milligrams of freeze-dried pileus tissue of *P. cubensis*[2] was ground to a fine powder with sand and transferred to a screw-capped vial. Methanol (5 ml) was added, and the tube was shaken at room temperature for 24 hr. The mixture was filtered, and the solid was washed with 5 ml of methanol. The filtrate was concentrated *in vacuo* to 0.5 ml, transferred to a 1.0-ml vial[3], and concentrated to dryness in a nitrogen stream. All traces of solvent were removed by evacuation on the oil pump. In an anhydrous nitrogen atmosphere, 100 μl of bis(trimethylsilyl)trifluoroacetamide[4] was added to the vial, which was then closed with a septum-lined aluminum seal[5].

The vial was heated at 140° for 15 min. Prolonged reaction periods (up to 2.5 hr) showed that this length of time was sufficient for quantitative

[1] GLC was carried out using a Hewlett-Packard model 402 gas chromatograph equipped with hydrogen flame-ionization detectors. The column used was a 1.6-m × 2.8-mm i.d. glass U-tube with 1.5% SE-30 on 100–120-mesh Chromosorb W. Chromatography conditions were: injection block, 220°; detector, 280°; oven, temperature programmed from 150 to 250° at 7.5°/min; chart speed, 0.64 cm/min; and helium carrier gas, 50 ml/min. TLC utilized glass plates with 0.25-mm layers of silica gel GF using 1-propanol–5% ammonium hydroxide (5:2) (17).

GLC–mass spectrometry was carried out with a Finnigan model 9500 gas chromatograph coupled to a Finnigan model 3100 D quadrupole mass spectrometer through a single-stage glass jet separator. A System/250 data system (Systems Industries) was used to control the mass spectrometer and acquire data. The mass spectrometer parameters were: interface temperature, 200–225°; transfer line, 150–175°; manifold temperature, 100°; and ion source potential, 70 ev. Two sets of chromatography conditions were employed: (*a*) essentially the same as those listed for GLC, and (*b*) a 0.75-m × 2-mm i.d. glass U-tube with 3% OV-101 on 100–120-mesh Gas Chrom Q temperature programmed from 200 to 275° at 10°/min with a helium flow rate of 20 ml/min.

[2] Carpophores of *Psilocybe cubensis* (Earle) Singer (= *Stropharia cubensis* Earle) (Strophariaceae) were obtained by aseptic cultivation of a strain of this fungus on sterile horse manure. The strain was isolated from pileus tissue of a fresh carpophore of *P. cubensis* collected Aug. 31, 1974, in Huautla de Jimenez, Oaxaca, Mexico, and was maintained on malt extract agar. The origin and maintenance of the culture and the production of fruiting bodies were similar to those reported previously (5, 6, 18). Carpophores were authoritatively identified by Dr. Gastón Guzmán, Escuela Nacional de Ciencias Biológicas (ENCB), I.P.N., Mexico, D.F., Mexico. Herbarium material is on deposit at the ENCB herbarium and the University of Michigan herbarium as LESLIE 1902 and at the Institute for Fermentation herbarium, Osaka, Japan, as IFO-H 11703. Subcultures are on deposit at the Institute for Fermentation (IFO 30176) and the Centraalbureau vorr Schimmelcultures, Baarn, The Netherlands (CBS 134.76).

derivatization. The resulting solution was cooled to room temperature, and 1.0-μl aliquots were used for subsequent analyses. Reference standards of psilocin and psilocybin were derivatized in the same manner, and quantitation was performed using an external standard of bis(trimethylsilyl)psilocin following the general method described by Gudzinowicz (19). The silanized solutions were stable for several weeks when stored at 4° under anhydrous conditions.

RESULTS AND DISCUSSION

Under the temperature-programmed chromatography conditions described (SE-30), the retention times for bis(trimethylsilyl)psilocin (I) and tris(trimethylsilyl)psilocybin (II) were 8.45 and 13.10 min, respectively. These two compounds were clearly separated from other components in the natural extract. Comparison with the external standard showed the concentrations to be 0.420% psilocin and 0.168% psilocybin. These values are not inconsistent with the total yields obtained by Heim and Hofmann (20) from various cultivated strains of *P. cubensis*. However, in the present analysis, the ratio of psilocin to psilocybin consistently exceeded 1, in contrast to the isolated yields of each compound reported by Heim and Hofmann (20). The present results were confirmed by TLC. The difference in these results might be attributed to the decomposition of psilocin during isolation procedures.

While the mass spectrum of I both as the standard and from the natural extract could be recorded easily, the mass spectrum of II could not be obtained with the longer SE-30 column. However, the conditions utilized with the OV-101 column proved rewarding, and a satisfactory spectrum was recorded. Under these conditions, II was eluted in 3.6 min.

The mass spectrum of I exhibited peaks at *m/e* 348 (M^+) (relative intensity 4%), 333 (1), 291 (6), 290 (21), 75 (3), 73 (39), and 58 (100). The mass spectrum of II showed peaks at *m/e* 500 (M^+) (1%), 485 (1), 442 (6), 77 (9), 75 (15), 73 (47), and 58 (100). While these two spectra are relatively simple in appearance, they are consistent with known fragmentation patterns of this type of compound. The parent peak at *m/e* 348 in I indicates the presence of two trimethylsilyl groups. As expected for 3-indolylethylamines, the significant fragments at *m/e* 290 and *m/e* 58 arise by fission of the bond beta to the nitrogen in the dimethylaminoethyl side chain (21). The M − 15 peak at *m/e* 333 and the peaks at *m/e* 75 and 73 are consistent with known fragmentations of trimethylsilyl ethers (22). The parent peak in the spectrum of II at *m/e* 500, the β-bond fission fragment at *m/e* 442 (M − 58), and the M − 15 peak at *m/e* 485 are evidence for the presence of three trimethylsilyl groups. Again, the peak at *m/e* 58 due to β-bond fission is the most prominent. The mass spectrum of the eluted psilocybin derivative confirms the stability of the silanized molecule under the instrumental conditions used.

Analyses by this method are routinely performed using 5–20 mg of dried fungal tissue.

High-Pressure Liquid Chromatographic Separation of 5,6-*cis*- and *trans*-Prostaglandin A_2

DENNIS J. WEBER

Abstract □ A high-pressure liquid chromatographic procedure capable of separating the *cis*- and *trans*-isomers of prostaglandin A_2 is described.

Keyphrases □ Prostaglandin A_2—high-pressure liquid chromatographic analysis, *cis*- and *trans*-isomers □ High-pressure liquid chromatography—analysis, *cis*- and *trans*-prostaglandin A_2

Prostaglandin A_2 (I) normally has the *cis*-configuration at the 5,6-double bond. However, extracts from the gorgonian *Plexaura homomalla*, a soft coral found in the Caribbean area, contained significant amounts of 5,6-*trans*-prostaglandin A_2 (II) (1). Therefore, a procedure capable of separating the *cis*- and *trans*-isomers in prostaglandin samples is needed.

A recent paper (2) described the high-pressure liquid

derivatization. The resulting solution was cooled to room temperature, and 1.0-μl aliquots were used for subsequent analyses. Reference standards of psilocin and psilocybin were derivatized in the same manner, and quantitation was performed using an external standard of bis(trimethylsilyl)psilocin following the general method described by Gudzinowicz (19). The silanized solutions were stable for several weeks when stored at 4° under anhydrous conditions.

RESULTS AND DISCUSSION

Under the temperature-programmed chromatography conditions described (SE-30), the retention times for bis(trimethylsilyl)psilocin (I) and tris(trimethylsilyl)psilocybin (II) were 8.45 and 13.10 min, respectively. These two compounds were clearly separated from other components in the natural extract. Comparison with the external standard showed the concentrations to be 0.420% psilocin and 0.168% psilocybin. These values are not inconsistent with the total yields obtained by Heim and Hofmann (20) from various cultivated strains of *P. cubensis*. However, in the present analysis, the ratio of psilocin to psilocybin consistently exceeded 1, in contrast to the isolated yields of each compound reported by Heim and Hofmann (20). The present results were confirmed by TLC. The difference in these results might be attributed to the decomposition of psilocin during isolation procedures.

While the mass spectrum of I both as the standard and from the natural extract could be recorded easily, the mass spectrum of II could not be obtained with the longer SE-30 column. However, the conditions utilized with the OV-101 column proved rewarding, and a satisfactory spectrum was recorded. Under these conditions, II was eluted in 3.6 min.

The mass spectrum of I exhibited peaks at *m/e* 348 (M^+) (relative intensity 4%), 333 (1), 291 (6), 290 (21), 75 (3), 73 (39), and 58 (100). The mass spectrum of II showed peaks at *m/e* 500 (M^+) (1%), 485 (1), 442 (6), 77 (9), 75 (15), 73 (47), and 58 (100). While these two spectra are relatively simple in appearance, they are consistent with known fragmentation patterns of this type of compound. The parent peak at *m/e* 348 in I indicates the presence of two trimethylsilyl groups. As expected for 3-indolylethylamines, the significant fragments at *m/e* 290 and *m/e* 58 arise by fission of the bond beta to the nitrogen in the dimethylaminoethyl side chain (21). The M − 15 peak at *m/e* 333 and the peaks at *m/e* 75 and 73 are consistent with known fragmentations of trimethylsilyl ethers (22). The parent peak in the spectrum of II at *m/e* 500, the β-bond fission fragment at *m/e* 442 (M − 58), and the M − 15 peak at *m/e* 485 are evidence for the presence of three trimethylsilyl groups. Again, the peak at *m/e* 58 due to β-bond fission is the most prominent. The mass spectrum of the eluted psilocybin derivative confirms the stability of the silanized molecule under the instrumental conditions used.

Analyses by this method are routinely performed using 5–20 mg of dried fungal tissue.

High-Pressure Liquid Chromatographic Separation of 5,6-*cis*- and *trans*-Prostaglandin A_2

DENNIS J. WEBER

Abstract □ A high-pressure liquid chromatographic procedure capable of separating the *cis*- and *trans*-isomers of prostaglandin A_2 is described.

Keyphrases □ Prostaglandin A_2—high-pressure liquid chromatographic analysis, *cis*- and *trans*-isomers □ High-pressure liquid chromatography—analysis, *cis*- and *trans*-prostaglandin A_2

Prostaglandin A_2 (I) normally has the *cis*-configuration at the 5,6-double bond. However, extracts from the gorgonian *Plexaura homomalla*, a soft coral found in the Caribbean area, contained significant amounts of 5,6-*trans*-prostaglandin A_2 (II) (1). Therefore, a procedure capable of separating the *cis*- and *trans*-isomers in prostaglandin samples is needed.

A recent paper (2) described the high-pressure liquid

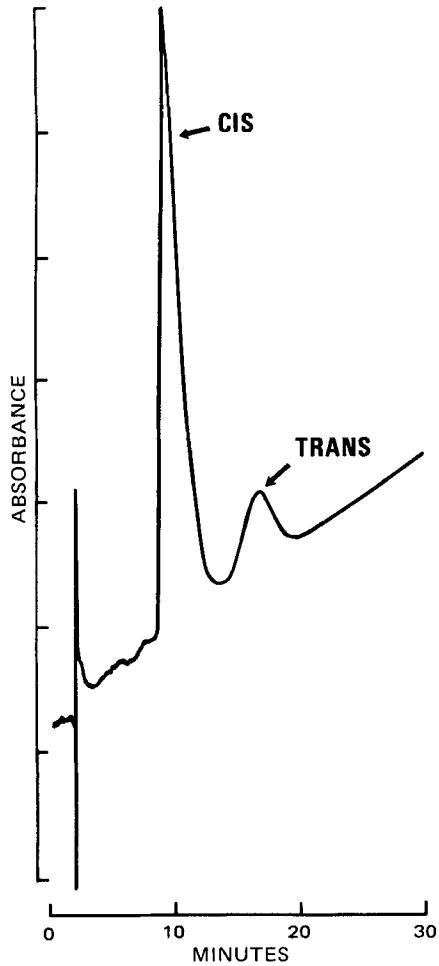

Figure 1—*Chromatogram of I and II methyl esters.*

chromatographic (HPLC) separation of a large number of prostaglandin *p*-nitrophenacyl esters using a microparticulate silica column. The partial separation of 5,6-*cis*- and *trans*-isomers of dinoprostone (III) and dinoprost (IV) was described, but no mention was made of the separation of prostaglandin A_2 or prostaglandin B_2 *cis*- and *trans*-isomers.

The separation of alkenes from saturated hydrocarbons (3, 4) and the resolution of *cis–trans*-isomers using silver-ion complexes are well-known procedures (5). The thermodynamics of alkene–silver-ion complexes in water show (6) that, although the enthalpy change favors formation, the entropy change is large and negative and causes the complex to be quite weak. Thus, temperatures near 25° are required for appreciable complexation. This low temperature requirement is easily satisfied by HPLC.

EXPERIMENTAL

Reagents and Samples—All solvents were distilled-in-glass quality[1], except water which was deionized. The anhydrous silver perchlorate[2] was used as received. The prostaglandin methyl esters[3] were used as received and stored as the methanol solutions.

Apparatus—The liquid chromatograph[4] was equipped with a 1-m column packed with 37-μm superficially porous beads with a bonded stationary phase of octadecylsilyl groups. Detection was by UV absorption at 254 nm. The mobile phase was 0.5 *M* $AgClO_4$ dissolved in methanol–water (20:80). The instrument was operated at 900 psi and room temperature. The sample concentrations were between 0.5 and 4 mg/ml, and 1–3-μl injections were used.

Because of the corrosive effect of the aqueous silver perchlorate on the copper drain tubing and on the brass pressure backup plate in the main pump, extensive plumbing changes were necessary. All copper drain tubing and brass fittings were replaced by perfluoropolyethylene tubing or stainless steel. The brass pressure backup plate was replaced by one made from ceramic-filled plastic.

The UV spectra were recorded on a recording spectrophotometer[5].

Mass spectra were taken on a high-resolution mass spectrometer[6] using an ionization potential of 70 v and direct probe sampling. Samples were prepared by evaporating an aliquot to dryness and reacting with reagent[7] to form the 15-trimethylsilyl derivative. Mass spectral samples from chromatographic cuts were obtained by running the aqueous chromatographic effluent into a flask containing about 10 ml of methylene chloride overlaid with about 3 ml of water. After each collection, the flask was immediately shaken to extract the prostaglandin into the organic phase. The phases were separated, and the methylene chloride fraction was washed with about 3 ml of water. The organic layer was taken to dryness and treated with derivatizing reagent as before.

Table I—Principal Ions in Mass Spectra of the 15-Trimethylsilyl Derivatives of I, II, and V Methyl Esters

Ion	*m/e* 15-Trimethylsilyl I and II Methyl Esters	*m/e* 15-Trimethylsilyl V Methyl Ester

Table II—Comparison of Retention Times of 5,6-*cis*- and *trans*-Prostaglandin B_2 and Prostaglandin A_2 Methyl Esters

Compound	Retention Time, min
I Methyl ester	8.9
II Methyl ester	17.0
5,6-*cis*-V Methyl ester	16.4
5,6-*trans*-V Methyl ester	15.8

RESULTS AND DISCUSSION

Separation of I and II—Separation of I methyl ester from II methyl ester was achieved using a reversed-phase column[8] and a mobile phase of 0.5 *M* $AgClO_4$ in methanol–water (20:80). An example of the separation is shown in Fig. 1.

The retention times of the *cis*- and *trans*-isomers were 8.9 and 17.0 min, respectively. The *cis*-isomer eluted before the *trans*-isomer, because the complexation took place in the mobile phase and the stability constant of the silver–*cis*-isomer complex was greater (5). The relative sizes of the peaks were correct, since samples of I usually contained less than 15% of the *trans*-isomer.

An authentic sample of II methyl ester gave a single peak with a retention time of 17 min, which agreed very well with the peak assigned to the *trans*-isomer in Fig. 1.

Table III—Molar Absorptivities of Prostaglandin B_2 and Prostaglandin A_2 Methyl Esters

	Solvent 1[a]			Solvent 2[b]		
	λ_{max}	$\epsilon\lambda_{max}$	ϵ_{254}	λ_{max}	$\epsilon\lambda_{max}$	ϵ_{254}
Prostaglandin B_2	278	23,700	10,500	282	23,700	7560
Prostaglandin A_2	217	9,970	1,040	—[c]	—[c]	1520

[a] Solvent is methanol. [b] Solvent is 0.5 *M* $AgClO_4$ in methanol–water (20:80). [c] Data were not collectable due to solvent absorbance below 238 nm.

The possibility that the second, smaller peak of Fig. 1 was not the *trans*-isomer but an on-column degradation product of I methyl ester was checked by injecting a large amount, about 50 μg of the *cis–trans*-mixture, collecting the peak representing the *cis*-isomer, and reinjecting it. The reinjected material gave only one peak, and its retention time was the same as that for the *cis*-peak of the original mixture. Therefore, the chromatographic conditions had no apparent effect on the chemical stability of the samples and the peaks seen were not artifacts of the separation process.

A further check on the validity of the separation was carried out by injection of a biosynthetically produced I methyl ester. The material contains only the *cis*-isomer. Chromatographic analysis gave only one peak with a retention time of 9.2 min, in good agreement with the retention time of the *cis*-isomer in the mixture.

Mass Spectra of I and II Methyl Esters—The mass spectra of the pure biosynthetic I and pure II methyl esters were identical to each other and to the spectra of samples obtained by chromatographic cuts of elution curves. This finding is good evidence that the 8.9- and 17-min peaks differ only by a 5,6-*cis–trans*-relationship, since other prostaglandin A_2 methyl ester isomers or derivatives would be expected to give different mass spectra. The principal mass ions of the 15-trimethylsilyl derivative of I and II methyl esters are shown in Table I.

Chromatography of 5,6-*cis*- and *trans*-Prostaglandin B_2 Methyl Esters—Since I is often contaminated with prostaglandin B_2 (V), it was necessary to determine if the retention times of 5,6-*cis*- and *trans*-V methyl esters would interfere with the I or II methyl ester peak. Samples of the V methyl ester isomers[3] were chromatographed, and their retention times were close to each other and to the retention time of the II methyl ester (Table II).

Mass Spectra of V Methyl Esters—A chromatographic cut of 5,6-*cis*-V methyl ester was collected and submitted for mass spectral analysis as the trimethylsilyl derivative. Comparison with the mass spectra of the silylated unchromatographed 5,6-*cis*- and *trans*-V methyl esters showed no difference, indicating that the chromatographic process had no deleterious effect and that the samples of *cis*- and *trans*-V esters had the expected identical mass spectra. The principal mass ions of the 5,6-*cis–trans*-V methyl ester trimethylsilyl derivative are given in Table I. The 190 and 199 peaks in the prostaglandin A_2 series and the 247 peak in the prostaglandin B_2 series may be diagnostic of the differences among I, II, and V methyl esters.

UV Spectra of 5,6-*cis*- and *trans*-V, I, and II Methyl Esters—Additional evidence for the identity of the 5,6-*cis*- and *trans*-V, I, and II methyl esters was obtained from the UV spectra in methanol. The two samples of 5,6-*cis*- and *trans*-V methyl esters showed a peak at 278 nm and no evidence of a peak at 217 nm, indicating that neither sample contained any appreciable amount of I or II methyl ester. Conversely, the UV spectrum of II methyl ester, which had the same chromatographic retention time as the V isomers, indicated that the sample contained less than 5% of the V isomer. Approximately the same amount of V isomer was found in the biosynthetic I methyl ester.

The mass spectra and UV absorption data indicate that the assumed structures of the samples are correct. Therefore, the coincidence of the retention times of the *cis*- and *trans*-V methyl esters with the II methyl ester was real and not an artifact.

The UV spectra of V methyl ester in methanol–water (20:80), which was 0.5 *M* in silver perchlorate, showed a slight shift to a longer wavelength at the λ_{max} and no change in the molar absorptivity at the absorption maximum when compared to the spectrum in methanol. This finding indicates that the complexation of Ag^+ with I, II, and V methyl esters does not drastically change the chromophores. The molar absorptivities at the λ_{max} and at 254 nm are given in Table III.

Quantification of 5,6-*trans*-V Methyl Ester—An assay for the fraction of prostaglandin A_2 with the 5,6-*trans*-configuration is possible using the described procedure, but a reliable source of I methyl ester uncontaminated with the *trans*-isomer is needed to construct a calibration curve using a particular instrument and set of conditions. The 5,6-*cis*-isomer content can be found from HPLC data, and the sum of 5,6-*cis*- and 5,6-*trans*-isomers can be obtained from UV data. Therefore, the desired result can be calculated.

Possible Relationship of Structure to Lack of Separation of 5,6-*cis*- and *trans*-V Methyl Esters—A possible explanation as to why I and II methyl esters, but not the esters of 5,6-*cis*- and *trans*-V, can be separated in this system can be found in the differences in structure of prostaglandins B_2 and A_2. In prostaglandin A_2, the two side chains are *trans* to each other about the 8,12-bond. Thus, there is little or no interference of the lower side chain (C-13–C-20) with the approach of a silver ion to the 5,6-double bond. However, in prostaglandin B_2, the 8,12-double bond forces the side chains to be coplanar at the points of ring attachment. This orientation could result in a serious interference by the C-13–C-20 side chain with the approach of a silver ion to the 5,6-unsaturation. If no complexation occurs, there can be no separation of 5,6-*cis*- and *trans*-V esters, as is observed.

Novel Method for Determination of Partition Coefficients of Penicillins and Cephalosporins by High-Pressure Liquid Chromatography

TSUKINAKA YAMANA ˣ, AKIRA TSUJI, ETSUKO MIYAMOTO, and OSAMU KUBO

Abstract □ Newly defined lipophilic indexes, log k', of a series of penicillins and cephalosporins were rapidly and reliably determined by reversed-phase high-pressure liquid chromatography (HPLC) on bonded octadecylsilane supports. The log k' values obtained from their retention times exhibited a linear relationship with methanol concentration (v/v %) in the mobile phase. The extrapolated log k' values to zero and those at 30% correlated well with the partition coefficients, log P, in 1-octanol–water and with R_m values from TLC. This HPLC technique provided some new log P and R_m values for highly ionizable β-lactam antibiotics. The HPLC method for the determination of partition coefficients of drugs has some advantages and is a useful alternative for the determination of log P and R_m.

Keyphrases □ Penicillins, various—high-pressure liquid chromatographic determination of lipophilic indexes, correlated to partition coefficients □ Cephalosporins, various—high-pressure liquid chromatographic determination of lipophilic indexes, correlated to partition coefficients □ High-pressure liquid chromatography—determination of lipophilic indexes of various penicillins and cephalosporins, correlated to partition coefficients □ Lipophilic indexes—log k' of various penicillins and cephalosporins determined by high-pressure liquid chromatography, correlated to partition coefficients □ Partition coefficients—various penicillins and cephalosporins, correlated to lipophilic indexes determined by high-pressure liquid chromatography □ Antibacterials—various penicillins and cephalosporins, high-pressure liquid chromatographic determination of lipophilic indexes, correlated to partition coefficients

Considerable effort has been expended to correlate biological properties of penicillins (1–7) and cephalosporins (5) with their partition coefficients. While the most useful and widely accepted lipophilic index is the logarithm of the partition coefficient, log P, determined in a 1-octanol–water system (8), such a measurement for penicillin molecules often presents practical difficulties because of their high instability in the acidic pH region near the pKa (~2.7). The log P values determined with a rapid pH-stat technique (9) seem to be the most accurate and reliable. Unfortunately, in spite of this technique, it is difficult to determine or compare the true log P values for β-lactam antibiotics because of two or more ionizable substituents in their side chains (*e.g.*, carbenicillin and sulbenicillin) and because of the zwitterion itself (*e.g.*, cyclacillin, ampicillin, amoxicillin, cephaloridine, cephaloglycin, cephalexin, and cephradine).

The R_m values, which are alternative lipophilic indexes, were determined from reversed-phase TLC for some penicillins (10) and cephalosporins (11). Recently, R_m values of penicillins were determined in another TLC system (9), but a difference between the actual pH on the plate and that of the mobile phase was observed (9). This pH difference is undesirable for acids such as β-lactam antibiotics, because the R_m values, in order to be an expression of the true partition coefficients, have to be corrected according to their degree of ionization at the mobile phase pH.

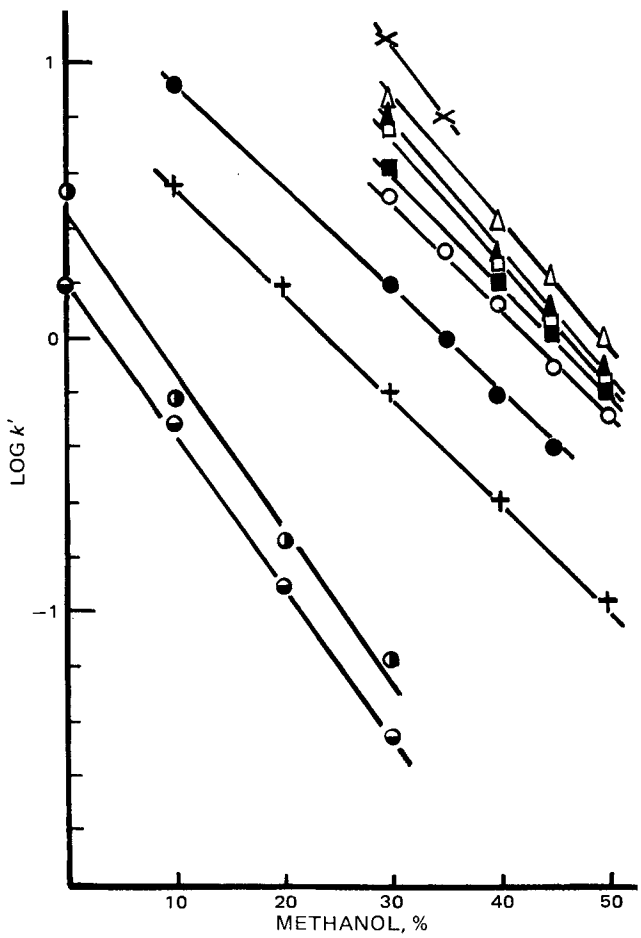

Figure 1—*Relationship between log* k' *values of penicillins and methanol concentration (v/v %) in the mobile phase. The compounds are numbered as in Table I. Key:* ×, *1;* △, *2;* ▲, *3;* □, *4;* ■, *7;* ○, *8;* ●, *9;* +, *11;* ◑, *12; and* ◒, *13.*

This paper reports a novel and useful method for the determination of partition coefficients of these β-lactam antibiotics by high-pressure liquid chromatography (HPLC). With the reversed-phase HPLC method developed recently (12), the lipophilic index, log k', can be defined as follows:

$$\log k' = \log [(t_R - t_0)/t_0] \quad \text{(Eq. 1)}$$

where t_R is the retention time of a retained peak, and t_0 is the retention time of an unretained peak. The term log k' is considered to be analogous to R_m.

[a] Log k' was defined in the text. A 2.1-mm × 25-cm stainless steel column was packed with Zorbax-ODS and eluted with 0.035 M NH_4Cl aqueous methanol solution of pH 7.4 at 150 kg/cm² and ambient temperature. [b] Extrapolated log k' value to 0% methanol from Fig. 1. [c] Data from Ref. 9, except those for Compounds 1, 3, and 15, which are averages of the values determined by employing the pKa values of 2.72 for Compounds 1 and 3 and of 2.22 for Compound 15 at four or more different pH's at 37° in this laboratory. [d] Calculated from corresponding Eqs. 2–4, except those for Compounds 5, 6, 10, and 14–19, which were calculated from Eqs. 5–7. [e] The R_m value determined at pH 4.0 (9); cellulose was the solid support, and 1-octanol was the stationary phase. [f] The R_m value determined at pH 7.4 (10, 11); silica gel was the solid support, and silicone oil was the stationary phase. [g] Calculated from Eq. 4 for the penicillins except Compounds 5, 6, and 10. Calculated from Eq. 7 for Compounds 5, 6, 10, and cephalosporins.

sodium[2] (900 μg/mg), floxacillin sodium[3] (893 μg/mg), cloxacillin sodium[2] (907 μg/mg), oxacillin sodium[4] (840 μg/mg), propicillin potassium[5] (993 μg/mg), phenethicillin potassium[2] (1444 units/mg), penicillin V potassium[2] (1490 units/mg), penicillin G potassium[2] (1600 units/mg), cyclacillin[5] (999 μg/mg), ampicillin sodium[5] (955 μg/mg), amoxicillin[3] (844 μg/mg), sulbenicillin disodium[5] (878 μg/mg), cephaloridine[6] (971 μg/mg), cephalothin sodium[6] (930 μg/mg), cephaloglycin[6] (864 μg/mg), cephalexin[6] (925 μg/mg), cephradine[7] (962 μg/mg), and cefazolin sodium[3] were used as supplied. Other chemicals[8] were of reagent grade and were used without further purification.

Procedures—A liquid chromatograph[9] equipped with a UV detector operating at 254 nm was used for HPLC. The stationary phase was totally porous silica gel bonded chemically with octadecyl chains prepacked into a 25-cm stainless steel column, 2.1 mm i.d.[10]. The mobile phase was a 0.035 M ammonium chloride–aqueous methanol solution adjusted to pH 7.4; ammonium salt was added to block the active silanol sites and to maintain the ionic strength. The instrument was operated at ambient temperature and 150 kg/cm². Solutions of penicillins and cephalosporins were prepared in the concentration range between 5×10^{-3} and 1×10^{-2} M. A 5-μl quantity of sample was injected into the column.

RESULTS AND DISCUSSION

Log k' values of the sample compounds were calculated from their t_R values by the application of Eq. 1, where the retention time of formamide was used for the t_0 value. The methanol concentration of the mobile phase was varied to obtain peaks with a reasonable retention time.

For the tested penicillins, plots of log k' *versus* methanol concentration (v/v %) showed a reasonable linear relationship (Fig. 1). Table I lists the log $k'_{(0\%)}$ values extrapolated to 0% methanol. The relationship between log $k'_{(0\%)}$ and the other reported lipophilic indexes (log P or R_m) (9, 10) is expressed by Eqs. 2–4 for penicillins and cephalosporins:

$$\log P_{octanol} = 1.03 \log k'_{(0\%)} + 0.38$$
$$n = 7 \quad r = 0.992 \quad s = 0.061 \qquad \text{(Eq. 2)}$$

$$R_{m\,octanol} = 1.07 \log k'_{(0\%)} - 2.10$$
$$n = 5 \quad r = 0.988 \quad s = 0.066 \qquad \text{(Eq. 3)}$$

$$R_{m\,silicone} = 1.12 \log k'_{(0\%)} - 0.95$$
$$n = 6 \quad r = 0.999 \quad s = 0.030 \qquad \text{(Eq. 4)}$$

where n, r, and s are number of experiments, correlation coefficient, and standard deviation, respectively. These equations show that log P and R_m in 1-octanol–water and silicone oil–water systems are satisfactorily correlated with log $k'_{(0\%)}$ values.

The slopes of Eqs. 2–4 are close to unity, which indicates that log $k'_{(0\%)}$ values should be regarded as those for the standard system in partition between a stationary phase and a mobile phase. However, such an extrapolation technique appears to be tedious and unreliable for highly lipophilic compounds, since one must extrapolate from a higher methanol concentration range. From the practical point of view, therefore, it would be desirable if log k' values at a suitable composition of the mobile phase could be used as an expression of the lipophilic character of the test compounds. For the present reference system, the log k' values at 30% methanol were selected because the 30% methanol concentration in the mobile phase provided a log $k'_{(30\%)}$ value in the range of maximum accuracy for most β-lactam antibiotics. The log $k'_{(30\%)}$ values (Table I) are considerably sensitive to the lipophilic balance of the substituents on the nucleus of penicillins and cephalosporins. Good correlations between log $k'_{(30\%)}$ values and log P or R_m are shown in Eqs. 5–7:

$$\log P_{octanol} = 1.74 \log k'_{(30\%)} + 1.21$$
$$n = 10 \quad r = 0.979 \quad s = 0.123 \qquad \text{(Eq. 5)}$$

$$R_{m\,octanol} = 1.45 \log k'_{(30\%)} - 1.02$$
$$n = 7 \quad r = 0.941 \quad s = 0.123 \qquad \text{(Eq. 6)}$$

$$R_{m\,silicone} = 1.23 \log k'_{(30\%)} + 0.39$$
$$n = 10 \quad r = 0.971 \quad s = 0.116 \qquad \text{(Eq. 7)}$$

The log P and R_m values calculated from Eqs. 2–7 with the corresponding log $k'_{(0\%)}$ or log $k'_{(30\%)}$ values are recorded in Table I. The results apparently confirm the usefulness of the log k' values as another expression of the lipophilic character and/or the conversion parameter for estimating unknown partition coefficients such as log P or Hansch π values (13) of β-lactam antibiotics.

For the determination of partition coefficients, Huber *et al.* (14) established a liquid–liquid chromatographic method; the HPLC method was recently proposed (12) as a useful alternative to the often tedious 1-octanol–water partition measurements. The HPLC method (12) is recommended for partition study of any compound because: (*a*) it is fast (*e.g.*, typical compounds can be eluted in less than 10 min) and repro-

Rapid GLC Determination of Ibuprofen in Serum

D. J. HOFFMAN

Abstract □ A rapid procedure for the determination of ibuprofen in human serum was developed using a single extraction with carbon tetrachloride after deproteinization with perchloric acid. The internal standard, 3-methyl-3-phenylbutyric acid, was added directly to the serum. Gas chromatograms were free of interfering peaks. Calibration curves (0–40 μg/ml) were linear with a sensitivity of 0.5 μg of ibuprofen/ml of serum. Relative standard deviations ranged from 1.1 to 25%.

Keyphrases □ Ibuprofen—GLC analysis, human serum □ GLC—analysis, ibuprofen in human serum □ Anti-inflammatory agents—ibuprofen, GLC analysis in human serum

Ibuprofen is a 2-phenylalkylcarboxylic acid derivative possessing potent anti-inflammatory, antipyretic, and analgesic properties (1–3). Recently, a GLC method for determining ibuprofen in human plasma was reported (4). The assay involved an extraction into benzene, followed by evaporation of the extract to dryness and subsequent derivatization of ibuprofen to the methyl ester. A rapid GLC method for the anticonvulsant valproic acid in serum utilized the underivatized acid and a 5% FFAP column (5). By using similar conditions, a GLC method was developed for the assay of serum ibuprofen levels. This method is rapid and precise and does not require derivative formation.

EXPERIMENTAL

Reagents—Reagent grade perchloric acid[1] and carbon tetrachloride[2] were used without further purification. Ibuprofen and 3-methyl-3-phenylbutyric acid were used as supplied[3].

Instrumentation—The GLC analyses were performed on a gas chromatograph[4] equipped with an automatic sampler[5], computing integrator[6], and flame-ionization detector. The chromatograph was fitted with a 1.83-m (6-ft) U-shaped glass column (2 mm i.d.) packed with 5% FFAP[7] on Gas Chrom W (HP), 80–100 mesh[8]. The column was conditioned before use at 255° for 15 hr with a carrier gas (nitrogen[9]) at a flow rate of 30 ml/min.

The chromatographic conditions were: carrier gas, 35 ml/min; air, 260 ml/min; hydrogen, 37 ml/min; injection port and detector temperatures, 250°; and oven temperature, 220°. The attenuation of the computing integrator was ×8, and the electrometer[10] range was 10^2. Under these conditions, the internal standard and ibuprofen had retention times of 2.9 and 4.3 min, respectively (Fig. 1).

Assay—*Preparation of Standards*—A 2-mg/ml stock solution of ibuprofen was prepared by dissolving 100 mg of ibuprofen in a 50-ml volumetric flask with 2 ml of 0.5 *N* NaOH and adjusting to 50 ml with distilled water. A working serum ibuprofen standard at 40 μg/ml was prepared by adding 1.0 ml of the stock solution to a 50-ml volumetric flask and adjusting to volume with commercial human serum[11]. Other serum standards were prepared from serial dilutions (with serum) of the 40-μg/ml serum standard.

The internal standard stock solution (2 mg/ml) was prepared by dissolving 100 mg of 3-methyl-3-phenylbutyric acid in a 50-ml volumetric flask with 2 ml of 0.5 *N* NaOH and adjusting to 50 ml with distilled water. A working internal standard solution (100 μg/ml) was prepared by diluting 5 ml of the internal standard stock solution to 100 ml with distilled water.

Extraction Procedure—To a 15-ml conical glass centrifuge tube were added 0.5 ml of the internal standard solution, 1.0 ml of serum, and 0.5 ml of 10% perchloric acid. After vigorous mixing[12], 0.4 ml of carbon tetrachloride was added, followed again by vigorous mixing for 15 sec. The

40.0	1.18 ± 0.024	2.0

[a] Mean ± *SD* of four determinations at each concentration.

sample was centrifuged for 10 min at 2500 rpm, and the clear upper aqueous layer was discarded by aspiration. The lower carbon tetrachloride layer was transferred to a microvial[13] using a disposable pipet[14]. After the microvial was capped, a 5-μl aliquot was injected into the GLC using an automatic sampler.

Calculations—A calibration curve was constructed by plotting peak area ratios (ibuprofen/internal standard) against the serum ibuprofen concentration. All calibration curves were linear and passed through the origin. Unknowns were automatically calculated by a computing integrator, programmed with the slope of a least-squares calibration curve. A least-squares regression line from the values in Table I yielded parameters of 0.0293, −0.0085, and 0.999 for the slope, *y*-intercept, and correlation coefficient, respectively.

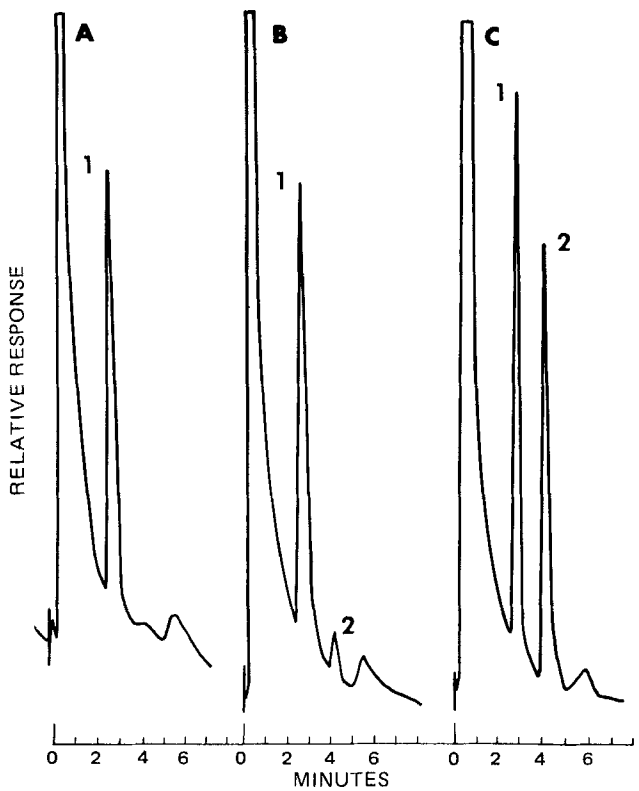

Figure 1—*GLC tracings of extracted serum samples. Key: A, serum blank with internal standard; B, serum containing ibuprofen at 5 μg/ml; C, serum containing ibuprofen at 40 μg/ml; 1, internal standard; and 2, ibuprofen.*

0.5	0.6	+20.0
10.0	10.2	+2.0
2.5	2.8	+12.0
30.0	31.4	+4.7
40.0	39.1	−2.2

[a] Serum spiked with ibuprofen at the indicated concentrations.

RESULTS AND DISCUSSION

Figure 1 shows a chromatogram of an extract from 1 ml of serum spiked with ibuprofen. Peak shapes were good with only a small amount of tailing. Ibuprofen and the internal standard were well resolved from coextractives.

The precision of the assay is shown in Table I. Relative standard deviations ranged from 1.1 to 25.0%. Assay sensitivity was 0.5 μg/ml for a 1-ml sample volume, the lowest concentration of ibuprofen in serum that was accurately detected and integrated by the instrumentation used. The accuracy of this assay was estimated by analyzing eight spiked serum unknowns under blind conditions. These results (Table II) show excellent accuracy at 5 μg/ml and above. Satisfactory accuracy (12–20% error) was achieved at low ibuprofen concentrations (2.5 and 0.5 μg/ml).

Ibuprofen in serum can be assayed by this method in less than one-half the time required by a derivatization method (4). By using those recovery data as an estimate of assay precision, a relative standard deviation of 7.0% was calculated for standards between 2 and 80 μg/ml. The average relative standard deviation of this method is 3.4% (excluding the 0.5-μg/ml concentration). Both methods have a sensitivity of 0.5 μg of ibuprofen/ml.

This assay provides the precision and accuracy needed for pharmacokinetic and bioavailability studies in humans where serum ibuprofen concentrations range from 0.5 to 30 μg/ml.

Liquid Chromatography in Pharmaceutical Analysis VII: Determination of Dantrolene Sodium in Biological Fluids

S. J. SAXENA, I. L. HONIGBERG ˣ, J. T. STEWART, and J. J. VALLNER

Abstract □ Dantrolene sodium can be determined in plasma and urine samples by high-pressure liquid chromatography without interference from its two major metabolites, the hydroxy and acetamido compounds. The minimum detectability of the drug using this procedure is 8 ng. The complete assay including extraction, evaporation, and separation steps can be performed in approximately 70 min with an accuracy of 1–3%.

Keyphrases □ Dantrolene sodium—high-pressure liquid chromatographic analysis, biological fluids □ High-pressure liquid chromatography—analysis, dantrolene sodium, biological fluids □ Relaxants, skeletal muscle—dantrolene sodium, high-pressure liquid chromatographic analysis, biological fluids

Dantrolene sodium, 1-[[5-(*p*-nitrophenyl)furfurylidene]amino]hydantoin sodium salt hydrate, first reported by Snyder *et al.* (1), is a peripherally acting skeletal muscle relaxant indicated in controlling the manifestations of clinical spasticity resulting from serious chronic disorders such as spinal cord injury, stroke, cerebral palsy, and multiple sclerosis (2).

Analytical methods previously reported for dantrolene sodium include spectrophotofluorometry (3, 4), differential pulse polarography (5), and a qualitative colorimetric procedure (6). In continuing efforts to apply high-pressure liquid chromatography (HPLC) in pharmaceutical analysis (7–9), an HPLC procedure for the determination of dantrolene sodium in a dosage form was reported (9). This procedure has been adapted to the determination of dantrolene sodium in human plasma and urine in the presence of its two major metabolites, the hydroxy and acetamido compounds (5, 10).

The HPLC procedure described here separates and simultaneously quantitates the drug with no interference from the metabolites. The fluorometric and the polarographic methods require a differential analytical technique to measure the metabolites in the presence of the drug. The complete HPLC assay can be performed in approximately 70 min, including denaturing the proteins, extraction of the drug and its metabolites, chromatographic separation, and quantification. Biological determinations by HPLC were compared with the spectrophotofluorometric method. A preliminary *in vitro* experiment to determine the amount of dantrolene sodium bound to blood cells was also performed.

EXPERIMENTAL

Reagents and Chemicals—Micronized dantrolene sodium[1] powder was used. Reagent grade solvents and chemicals were used as received; solvents constituting the mobile phase, carbon tetrachloride and dimethylformamide, were filtered through a 0.5-μm filter[2] prior to use. The pH of a 0.5 *M* aqueous solution of dimethylformamide was consistently 6.8 ± 0.1.

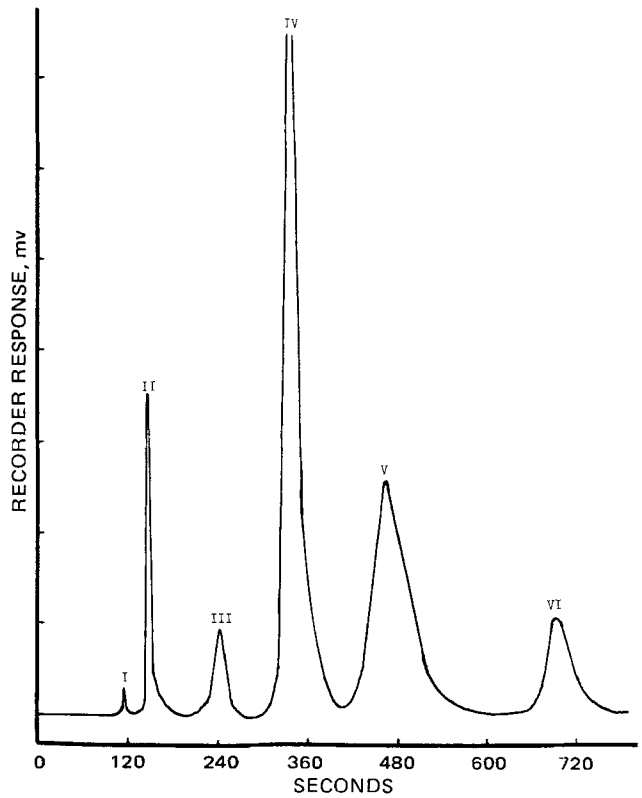

Figure 1—*Illustrative liquid chromatogram of dantrolene, its known metabolites, and furil (internal standard) in butanol–chloroform at a flow rate of 2.0 ml/min. The mobile phase was carbon tetrachloride–dimethylformamide (90:10). Key: I, solvent front; II, furil; III, impurity in dantrolene sodium; IV, dantrolene; V, hydroxy metabolite; and VI, acetamido metabolite.*

Mobile Phase—Carbon tetrachloride–dimethylformamide (90:10) was used as the mobile phase. The mixture was degassed before use.

Internal Standard Solution—Powdered furil[3] was dissolved in 1-butanol–chloroform (30:70) to give a stock internal standard solution of 400 μg/ml. This solution was filtered through a 0.5-μm filter[4] prior to use.

Standard Solution for Calibration Curve—A stock solution of dantrolene sodium (5 μg/ml) was prepared by dissolving powdered dantrolene sodium in 0.9% sodium chloride solution.

Calibration Curve—Into individual 60-ml separators were placed accurately pipetted volumes of 1.0, 2.0, 3.0, and 4.0 ml of the dantrolene sodium stock solution. The volume of each solution was adjusted to 7.0 ml with 0.9% sodium chloride solution. Then 40 ml of water-saturated 1-butanol–chloroform (30:70) and 2 ml of 0.1 *N* HCl were added. The solutions were shaken to partition the dantrolene acid into the organic layer. Then solid ammonium sulfate, about 1 g/ml of aqueous solution, was added in small portions to each solution and gently shaken for 5 min.

The solutions were set aside for 5 min, and then the organic layer (lower) was collected. The aqueous layer was shaken with another 40 ml of 1-butanol–chloroform, and the wash was combined with the previous

Table I—Calibration Data for Standard Drug Solutions

Initial Concentration of Dantrolene Sodium, μg/ml	Observed Results[a]
0.7143	2.0689 ± 0.0114
1.4286	3.9922 ± 0.0595
2.1429	6.1423 ± 0.0318
2.8571	8.0774 ± 0.0974
Slope = 0.4035	
Intercept = 0.0263	
$r \pm s_{yx}$[b] = 0.9998 ± 0.0495	

[a] D/IS ratio is based on three replicate injections of standard solution. Table value shows the mean ± *SD*. D/IS is the ratio of the integrated area of the drug at some concentration to the integrated area of furil at 50 μg/ml. [b] *r* is the correlation coefficient calculated from linear regression analysis, and s_{yx} is the sample standard deviation, also from regression analysis.

organic layer. The combined organic layer was evaporated to dryness in a hot water bath (~70°) under a stream of nitrogen. The residue was dissolved in 500 μl of 1-butanol–chloroform, and 500 μl of the internal standard solution was added. The solution was then filtered through a 0.5-μm filter, and 40 μl was injected into the liquid chromatograph.

Dantrolene Sodium in Human Plasma and Urine—To 3.0 ml of biological fluid was added 10 μg of dantrolene sodium. This solution was treated in the same manner as the standard solutions described under *Calibration Curve*. A control blank using 0.9% sodium chloride solution instead of the biological fluid was also included. Replicate injections of 40 μl were made for each sample.

***In Vitro* Binding of Dantrolene Sodium to Whole Blood Cells**—Dantrolene sodium (10 μg) was added to each of three 5-ml samples of whole blood; these samples were gently shaken and set aside for equilibration at room temperature for 5 min. The samples were then centrifuged at 1000 rpm for 20 min. The supernatant plasma from each tube was transferred to separate separators. A volume of 0.9% sodium chloride solution equal to the volume of the plasma removed was added to each packed cell sample, and the mixture was shaken gently and centrifuged again at 1000 rpm for 20 min.

The supernates from each tube were transferred to the respective separators, and the wash procedure was repeated once again. The plasma and washings in each separator were extracted and analyzed in the same manner as outlined under *Dantrolene Sodium in Human Plasma and Urine*. Injections of 40 μl were made.

Chromatographic Conditions—A liquid chromatograph equipped with a pump[5], a variable wavelength detector[6], an integrator with a digital printout[7], and a column containing a porous silica packing[8] was used. The degassed mobile phase was pumped through the column at 2.0 ml/min (1800 psig) at room temperature (23 ± 2°) until a stable baseline was obtained. Replicate 40-μl injections of samples and standard solutions were made using a 100-μl syringe[9]. A record of drug elution from the column as peaks on a chromatogram was provided by a chart recorder. The peaks were detected at 375 nm. The solute was measured by digital integration of the peak area in each case.

Determination of Dantrolene Sodium by Fluorescence—Spiked samples of urine and blood plasma, each containing 10 μg of dantrolene sodium, were assayed by a previously reported fluorometric method (9). The extraction procedure was identical to the one used for analysis by HPLC except that the final residue, after evaporation, was diluted to 10 ml with 1-butanol–chloroform (30:70). The fluorescence of each solution was measured in a spectrophotofluorometer[10] with the following operating parameters: excitation and emission slit widths, 5 nm; sensitivity, 3.0; excitation wavelength, 395 nm; and emission wavelength, 575 nm.

With the fine sensitivity control, the recorder was set to read full scale (100 units) for a 1-butanol–chloroform solution obtained from a 0.9% sodium chloride control containing 10 μg of dantrolene sodium, which was carried through the same extraction procedure as the biological fluids. Measurements for the biological fluid extracts were made relative to this arbitrary setting.

Table II—Determination of Dantrolene Sodium in Human Plasma and Urine

Sample	Amount of Dantrolene Sodium Added, μg	HPLC, % Found[a]	Fluorometric, % Found[a]
Urine	10	91.27 ± 0.47[b]	90.94 ± 1.32[b]
Plasma	10	82.67 ± 1.09	81.68 ± 0.92

[a] Based on triplicate determinations of three individual samples. [b] Confidence limits at $p = 0.05$.

RESULTS AND DISCUSSION

Dantrolene sodium is converted to dantrolene acid in acidic media and can be extracted into an organic solvent (9). In biological fluids, an additional protein precipitation step was necessary. Precipitation was accomplished by the use of 1 g of ammonium sulfate/ml of aqueous solution. In addition, the smaller concentrations of dantrolene sodium in biological fluids necessitated the concentration of the organic extract from biological fluids prior to the HPLC analysis.

Dantrolene was eluted within 6 min (Fig. 1). Figure 1 illustrates the elution and separation of the two major metabolites of dantrolene, the hydroxy and acetamido compounds. These metabolites were well-separated from the parent drug and internal standard. The presence of the metabolites had no significant effect on the ratio of the drug to the internal standard (D/IS), even when present in equal concentrations. All components were detectable at the 375-nm wavelength used in this procedure. Figure 2 shows a typical chromatogram for dantrolene sodium from a spiked plasma sample.

The area under the curve for each peak on the chromatogram was digitally integrated. The D/IS ratio was calculated for each dantrolene concentration. A linear regression analysis of the data at the four standard concentrations of dantrolene sodium gave the results shown in Table I.

To determine the percent accuracy of the procedure, two known concentrations of dantrolene sodium were treated as unknowns and their

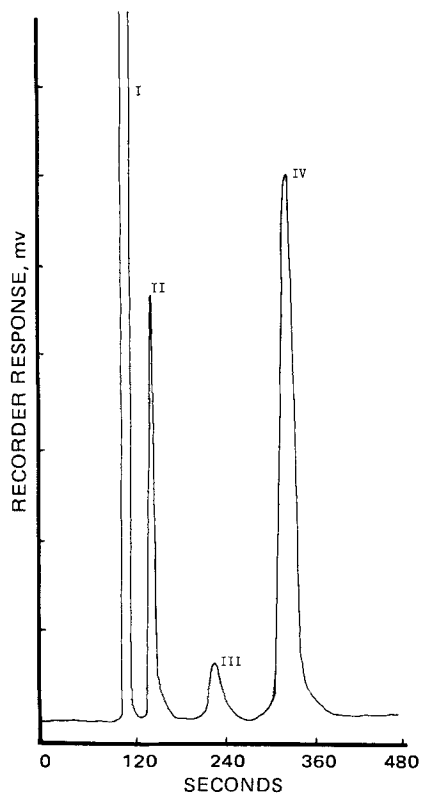

Figure 2—*Liquid chromatogram of dantrolene from a spiked plasma sample of dantrolene sodium at a flow rate of 2.0 ml/min. The mobile phase was carbon tetrachloride–dimethylformamide (90:10). Key: I, unidentified plasma components at solvent front; II, furil (internal standard); III, impurity in dantrolene sodium; and IV, dantrolene.*

Table III—Recovery Data of Dantrolene Sodium[a]

Sample	D/IS Ratio[b]	Recovery[c], %
Water	4.0368 ± 0.2148	99.4
Plasma	3.3620 ± 0.1916	82.7
Whole blood	2.7903 ± 0.0312	68.5

[a] Ten micrograms of dantrolene sodium was added to each sample. [b] Based on triplicate injections of three individual samples. [c] Calculated from linear regression analysis data.

concentrations were calculated from the constants (slope and intercept) obtained from the linear regression analysis. The concentration was calculated from the equation: D/IS = (slope × concentration) + intercept, using a programmable calculator[11]. Accuracy was 1–3% for the overall procedure.

The results for the spiked biological samples obtained from HPLC and fluorometry are shown in Table II. There was no significant difference between the values obtained by the two techniques at $p = 0.01$.

Recovery data of dantrolene sodium from water, plasma, and whole blood are shown in Table III. Extraction of the drug from spiked plasma accounted for approximately 82% of the added dantrolene. In the whole blood investigations, about 31.5% of the drug was not found in the plasma portion. Blood cells may account for about 15% binding of the dantrolene.

In summary, this procedure is useful for the determination of drug in the presence of its two major metabolites with a minimum detectability of 8 ng.

Polynitro Aromatic Compounds in Analytical Chemistry I: Reaction with Ouabain and Digitoxin

L. B. BURNS, R. J. STEDMAN, and M. M. TUCKERMAN [x]

Abstract □ By the use of NMR spectroscopy, the highly colored reaction products formed by ouabain or digitoxin with 1,3,5-trinitrobenzene or 2,4,6-trinitroanisole in the presence of alkali (as used for the determination of these glycosides) are shown to be Meisenheimer complexes. The complexes are produced by attachment of a carbon of the butenolide ring to an aromatic carbon of the nitro compound with formation of a charge-delocalized cyclohexadienate anion.

Keyphrases □ Nitro aromatic compounds—1,3,5-trinitrobenzene and 2,4,6-trinitroanisole, NMR spectral characterization of products □ Ouabain—reaction with 1,3,5-trinitrobenzene or 2,4,6-trinitroanisole, NMR spectral characterization of products □ Digitoxin—reaction with 1,3,5-trinitrobenzene or 2,4,6-trinitroanisole, NMR spectral characterization of products □ NMR spectroscopy—characterization of products of reaction of ouabain and digitoxin with 1,3,5-trinitrobenzene or 2,4,6-trinitroanisole □ Cardiotonic agents—ouabain and digitoxin, reaction with 1,3,5-trinitrobenzene or 2,4,6-trinitroanisole, NMR spectral characterization of products

The most recent review article on the chemical estimation of ouabain and digitoxin was published in 1949 by Canbäck (1). In 1950, the same author (2) reported further results on the reaction of these cardiotonic glycosides with dinitro aromatic compounds in the presence of alkali. Canbäck attributed the intense color produced to the transfer of a proton from the butenolide ring of the glycoside to a ring carbon of the nitro compound. Later, Kimura (3) investigated the reaction between digitoxin and picric acid and proposed that the colored product resulted from the addition of the butenolide ring to one of the two unsubstituted carbons of the picric acid.

In the present work, NMR studies established that ouabain and digitoxin give Meisenheimer complexes (charge-delocalized cyclohexadienate anions) with both 1,3,5-trinitrobenzene and 2,4,6-trinitroanisole in dimethyl sulfoxide as the solvent. Comparison of the visible spectra of the products with those of materials produced in aqueous methanol (which more nearly approximates the normal assay medium) suggested that the colored components are the same in the two cases.

EXPERIMENTAL[1]

Visible Spectra—Approximately 3×10^{-5} *M* solutions of ouabain and digitoxin were used in a 1-cm cell. Excess 2,4,6-trinitroanisole and sodium hydroxide were added, and the spectra were measured against a reagent blank. The positions of the absorption maxima were: ouabain–trini-

[1] Visible spectra were obtained using a Cary model 15 UV-visible spectrophotometer. NMR spectra were run on a Jeolco MH-60-II spectrometer.

Table I—Chemical Shifts (δ) of Protons of Trinitrobenzene and Trinitroanisole in Dimethyl Sulfoxide-d_6 as Affected by Base, Ouabain, and Digitoxin

Nitro Compound	Glycoside	Base	Chemical Shifts of Lowest Field Protons	Chemical Shift of Methoxyl Protons
Trinitrobenzene	None	None	9.04	—
Trinitrobenzene	None	Sodium hydroxide	7.68, 5.61[a,b]	—
Trinitrobenzene	Ouabain	None	9.04	—
Trinitrobenzene	Ouabain	Sodium hydroxide	8.17, 6.07[a,b]	—
Trinitrobenzene	Digitoxin	None	9.07	—
Trinitrobenzene	Digitoxin	Sodium hydroxide	8.23, 6.10[a,b]	—
Trinitroanisole	None	None	9.00	4.07
Trinitroanisole	None	Sodium hydroxide	8.56[a]	3.13
Trinitroanisole	Ouabain	None	9.00	4.07
Trinitroanisole	Ouabain	Sodium hydroxide	8.56[a]	3.30[c]
Trinitroanisole	Digitoxin	None	9.00	4.07
Trinitroanisole	Digitoxin	Sodium hydroxide	8.56[a]	3.30[c]

[a] Spectra also showed aromatic protons of the unchanged nitro compound. [b] Integrated areas of these peaks were in the ratio of 2:1. [c] Area around δ 3.30 was obscured by water peak unless concentration was carefully controlled. A solvent interaction peak at δ 3.13 also was present.

troanisole–base, λ_{max} 536 (aqueous methanol) and 545 (dimethyl sulfoxide) nm; and digitoxin–trinitroanisole–base, λ_{max} 536 (aqueous methanol) and 545 (dimethyl sulfoxide) nm.

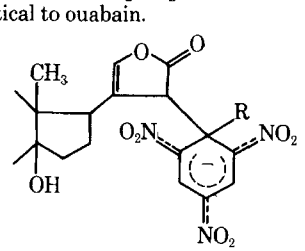
NMR Spectra—The spectra of the nitro aromatic compounds were obtained in dimethyl sulfoxide-d_6, and then ouabain or digitoxin (presumably in excess) was added until the signals of the glycoside became visible. The colored products were formed by adding a small amount of sodium hydroxide in deuterium oxide, and the spectra were determined again (Table I). A reagent blank spectrum was obtained from a mixture of all components except the glycoside.

RESULTS AND DISCUSSION

The visible absorption peak developed by both glycosides with trinitroanisole in dimethyl sulfoxide was only 9 nm displaced from its position in aqueous methanol. Therefore, the colored complex in dimethyl sulfoxide probably has the same structure as that in aqueous methanol and corresponds to the species used in the chemical assay. Therefore, the NMR studies in dimethyl sulfoxide should help to elucidate the nature of the assay reaction.

The NMR spectra clearly showed that the nitro compounds did not undergo any reaction in the absence of base. Interpretation is complicated by the observation that there was complexation between the solvent and the aromatic nitro compound in the absence of a glycoside. Thus, the singlet from 1,3,5-trinitrobenzene at δ 9.04 in dimethyl sulfoxide alone was replaced by a pair of signals at δ 7.68 and 5.61 on the addition of base. When ouabain was present, the two new signals appeared at δ 8.17 and 6.07; clearly, a different complex was formed from that provided by the solvent.

The positions of the new peaks and their 2:1 intensity ratio were consistent with their representing the two protons on sp^2 hybridized carbon and the one proton on sp^3 hybridized carbon in a Meisenheimer complex (I) (4–11). Both peaks were moved upfield because of the loss of aromaticity of the ring. The chemical shift of the one-proton peak at δ 6.07 was consistent only with attachment of the new ligand at one unsubstituted carbon of the trinitrobenzene ring. Digitoxin with trinitrobenzene gave results almost identical to ouabain.



I: R = H or OCH_3

In the reactions of the glycosides with trinitroanisole and base, only one new low field peak, at δ 8.56, was seen. This finding strongly suggests attachment of the glycoside at the methoxylated carbon of the nitro compound. Since solvent and base gave a new peak also at δ 8.56, it could be argued that only solvent was involved in the complexation. However, the position of the trinitroanisole methoxyl peak proved that complexation with the glycosides was occurring; in the absence of the glycosides, it appeared at δ 3.13. When either glycoside was present, it was found at δ 3.30.

In summary, the evidence supports the view that the colored complexes formed by ouabain or digitoxin with the trinitroaromatic compounds in the presence of base may be formulated as Structure I. The butenolide ring is shown with its double bond shifted and the carbon next to the carbonyl group as the position reactive toward the nitro aromatic ring (2, 3). The present work does not provide any additional evidence about the condition of the butenolide ring.

In Vitro Estimates of Topical Bioavailability

Keyphrases □ Bioavailability, topical—quantitative skin model assuming inactive stratum corneum and viable, enzyme-containing epidermis □ Topical bioavailability—quantitative skin model assuming inactive stratum corneum and viable, enzyme-containing epidermis □ Metabolism, drug—topically applied, quantitative skin model assuming inactive stratum corneum and viable, enzyme-containing epidermis □ Absorption, percutaneous—quantitative skin model assuming inactive stratum corneum and viable, enzyme-containing epidermis □ Diffusion, drug—quantitative skin model assuming inactive stratum corneum and viable, enzyme-containing epidermis

To the Editor:

Many disease conditions of the skin are due to pathogens or aberrant metabolism of the epithelial layer. Cold sores, for example, are caused by the Herpes simplex type I virus (1) which forms intraepithelial vesicles as a result of successive rounds of infection and proliferation. Psoriasis, on the other hand, is due to the uncontrolled proliferation of the basal epithelial cells. This abnormal growth probably results from a metabolic defect of the basal cells.

Since the epidermis is the most metabolically active layer of the skin (2, 3), any topical dosage form that delivers active drug components to intraepithelial sites should be formulated realizing that the skin is an active metabolizing barrier. In the past, the passive permeability properties of the stratum corneum were shown to constitute the major diffusional resistance of the skin (4). Several studies (5–7) also examined the *in vivo* percutaneous absorption of topical dosage forms. However, since urine was usually assayed as the main excretory route of the drug, the degree of cutaneous metabolism could not be clearly established because the metabolism of other tissues was included in the data. In one human skin study on the *in vivo* catabolism of hydrocortisone (7), the conclusion drawn on the basis of urine data was that hydrocortisone was probably rapidly metabolized in the skin, thus becoming physiologically inactive before it reached its site of action.

Direct evidence of the cutaneous metabolism of adrenal steroids (8) and hydrocortisone (9) was obtained *in vitro* by incubating viable human skin in a medium containing the steroid and assaying the medium by chromatographic methods. In another study (10), the cutaneous conversion of fluorouracil (I) to 5-fluoro-2′-deoxyuridine 5′-monophosphate (II) was verified *in vitro*. The intraepithelial metabolism of I was important to verify, since II is considered to be the drug form with antitumor activity. Thus a "prodrug," I, penetrated the stratum corneum (II, being more polar, would be expected to penetrate less effectively) and was converted by the enzymes of the epithelial cells into II, the active drug form.

These considerations emphasize the need for a quantitative model of the skin that can assess the metabolic barrier of the skin concurrent with cutaneous transport. One model, which treats the skin as a bilayer (11), assumes that the stratum corneum is inactive metabolically and that the epidermis contains a homogeneous distribution of enzymes. Some preliminary experimental results based on the model are discussed here. It is hoped that these and future studies will provide the experimental framework for evaluating this and more complex models of the viable epidermis.

In this system, the viable epidermis contains an enzyme, adenosine deaminase, which can convert the antiviral drug vidarabine (9-β-D-arabinofuranosyladenine) (III) into 9-β-D-arabinofuranosylhypoxanthine (IV). Skin from a 3-month-old hairless mouse[1] containing both the dermis and epidermis was removed and placed between two 3-ml chambers of a dialysis cell[2] (Fig. 1). Both the stratum corneum and the dermis side of the diffusion chamber could be used as the donor compartment for III in Dulbecco's phosphate-buffered saline (12). Five-microliter samples were taken at different times using a disposable microliter pipet[3], spotted onto TLC plates[4], and developed in chloroform–methanol–3% acetic acid (3:2:1) (13). Both III and IV were assayed.

When this solution was placed on the stratum corneum side of the diffusion cell and saline was placed on the receptor side, no metabolism of III was observed on the epidermis side and no label was found on the dermis side for time intervals up to 24 hr. Similarly, when the dermis side was used as the donor compartment, no drug penetrated into the receptor compartment. However, in this latter situation, rapid metabolism was observed in the donor compartment; 50% of the original III was in the hypoxanthine form after 2 hr (Fig. 2).

One problem arose when the dermis side of the skin was used as the donor compartment. If samples from the donor compartment were taken at different times, stored in holding vials, and assayed 12 hr later, the amount of metabolism observed was greater than that found if the samples were assayed immediately. Evidently, adenosine deaminase, the enzyme that metabolized III, was leaching out of the skin into the donor compartment. Thus, the amount of metabolized drug in the donor compartment

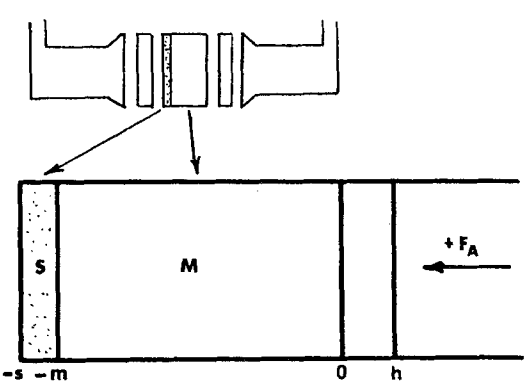

Figure 1—*Impermeable stratum corneum. Drug A moves in the negative* x *direction, first penetrating the aqueous diffusion* ($0 \leq x \leq h$) *and then the metabolizing epidermis* (M) *located at* $-m \leq x \leq 0$. *The stratum corneum* (S), located at $-s \leq x \leq -m$, *does not permit passage of A through it.*

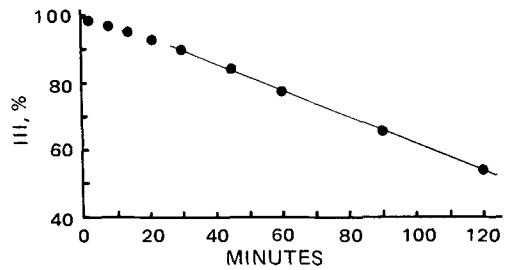

Figure 2—*Determination of* F_A. *Percent of III in the bulk solution was assayed with respect to time; the steady-state slope,* dC/dt, *was computed from the last five points. This value, −0.227, was corrected for bulk metabolism from Fig. 4 and was computed from* $F_A = (V/A)(dC/dt)$, *where* $V = 2.0\ cm^2$ *and* $A = 1.54\ cm^2$.

reflected not only the epidermal component but also a bulk phase metabolism due to leached enzyme. To correct for this bulk metabolism, a separate study was conducted.

Hairless mouse skin was prepared as already described, but only buffered saline was placed in both chambers of the diffusion cell. At 30-min intervals up to 2 hr, samples were taken from the dermis compartment. Compound III was immediately added to each sample, which was then assayed as a function of time for III metabolism. Figure 3 shows that the amount of enzyme in the bulk phase continuously increased with time. The slope of each curve was plotted in Fig. 4 as a function of sampling time to determine whether a linear relationship existed. Figure 4 shows that the slopes are highly linear with time so that:

$$\frac{dC_X(t)}{dt} = kt \qquad \text{(Eq. 1)}$$

or:

$$C_X(t) = C_X(0) + \frac{k}{2}t^2 \qquad \text{(Eq. 2)}$$

where C_X represents an upper bound to the amount of product, X, formed in the bulk aqueous phase, and k is the slope of the dC_X/dt *versus* time plot. The reason that $C_X(t)$ is an upper bound and not the actual amount of

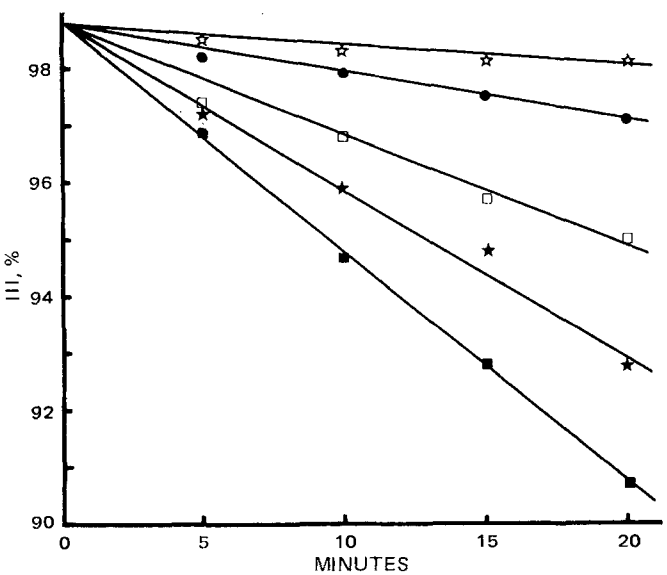

Figure 3—*Bulk phase metabolism. Metabolism of III in the bulk aqueous phase by enzymes leached out of the epidermal side of the diffusion cell at 5 (☆), 30 (●), 60 (□), 90 (★), and 120 (■) min. Solid lines were determined from linear regression fit forced through 98.8% purity for III.*

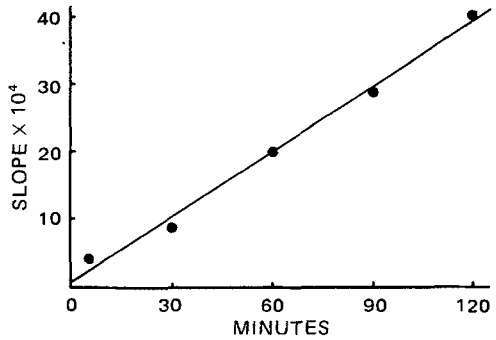

Figure 4—*Linearity of bulk phase metabolism slopes. Slopes determined from Fig. 3 are plotted against time to determine linearity. Linear regression gives an intercept of* $9.06 \times 10^{-5}\ min^{-1}$, *a slope of* $3.20 \times 10^{-5}\ min^{-2}$, *and a correlation coefficient of 0.996.*

product formed in the experiment of Fig. 2 is that the initial rate of enzyme reaction is usually faster than the reaction rate at later times. If the plots of Fig. 3 remained linear for times up to 2 hr, then $C_X(t)$ would represent the actual concentration of product formed, which would be reflected in Fig. 2. From Fig. 4, $k = 3.20 \times 10^{-5}\ min^{-2}$; therefore, at 20 min, $(k/2)t^2 = 0.0064$. The plots of Figs. 2 and 3 are linear up to 20 min, so that the flux determination from Fig. 2 can be corrected for bulk metabolism.

The model equation (11) that determines the loss of III from the bulk solution is:

$$\frac{1}{\kappa} = C_1 \tanh \kappa m \qquad \text{(Eq. 3)}$$

where:

$$C_1 = D_A\left[\frac{C_A(h)}{-F_A} - \frac{1}{P_{aqA}}\right] \qquad \text{(Eq. 4)}$$

and:

$$\kappa = \sqrt{\frac{k_m}{D_A}} \qquad \text{(Eq. 5)}$$

where m is the thickness of the skin sample, D_A is the diffusion coefficient of III in the skin, $C_A(h)$ is the concentration of III in the bulk solution, P_{aqA} is the permeability of III in the aqueous diffusion layer, and F_A is the flux of III into the skin. Since the flux of III from the bulk solution into the skin is considered negative, $-F_A$ is positive:

$$F_A = \frac{V}{A}\frac{dC_A}{dt} \qquad \text{(Eq. 6)}$$

where V is the volume of the bulk phase, and A is the area of the skin.

The initial flux of III can be estimated from Fig. 2 by using the steady-state slope of the last five points and correcting for the bulk metabolism using $(k/2)t^2$. The corrected slope is −0.227, so that F_A is 4.92×10^{-3}

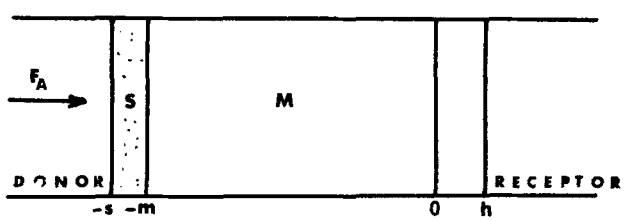

Figure 5—*Permeable stratum corneum. Drug A moves from left to right in the positive flux direction, first penetrating the stratum corneum* (S) *located at* $-s \leq x \leq -m$, *then the metabolizing epidermis* (M) *located at* $-m \leq x \leq 0$, *and then the aqueous diffusion layer at* $0 \leq x \leq h$.

amount/cm^2 sec, where $V = 2.0$ cm^3 and $A = 1.54$ cm^2. Because the full thick skin used also contained some subcutaneous tissue and dermis, there appeared to be a lag time of about 5 min (Fig. 1).

Using the value for F_A, we can compute that $C_A(h)/-F_A = 2.03 \times 10^4$ sec/cm, where $V = 2.0$ cm^3 and $A = 1.54$ cm^2. A reasonable upper limit for P_{aqA} might be estimated as $P_{aqA} \doteq 5 \times 10^{-4}$ cm/sec, which corresponds to a 200-μm aqueous diffusion layer with a diffusion coefficient for III of 10^{-5} cm^2/sec. When assuming a III epidermal diffusivity of 10^{-6} cm^2/sec, $C_1 \doteq 1.8 \times 10^{-2}$ cm.

Finally, plotting each side of Eq. 3 *versus* κ for an epidermis of 300 μm, we find that $\kappa = 82$ or $k_m \doteq 6.7 \times 10^{-3}$ sec^{-1} from the intersection of the two curves. This calculation for the linear enzyme parameter, k_m, assumed some typical values for the diffusion coefficient of III in the epidermis and aqueous diffusion layer and the thicknesses of these layers. Experiments are planned to determine these parameters directly. In addition, the validity of assuming a first-order enzyme reaction must be investigated.

The determination of the metabolic parameter, κ, can be used to predict to what degree metabolism affects the bioavailability of the drug when it is administered topically. Figure 5 shows an *in vitro* situation relevant to the clinical application of a topical dosage form. The drug passes from the topical vehicle through the stratum corneum, S, into the metabolizing epidermis, M, and then through the aqueous diffusion layer into the receptor compartment. Suppose that there is a virus lesion halfway through the epidermal layer of 100 μm. How might drug bioavailability be affected by the fact that the epidermis metabolizes the drug?

For the application of a topical drug, the relevant equations (11) are:

$$C_{AM}(x) = -\frac{P_{SA}(P_{aqA}\sinh\kappa S - D_A\kappa\cosh\kappa X)C_A(-s)}{D_A\kappa(P_{SA}+P_{aqA})\cosh\kappa M + [P_{SA}P_{aqA}+(D_A\kappa)^2]\sinh\kappa M} \quad \text{(Eq. 7)}$$

and:

$$C_{A0}(x) = -\frac{\left(\frac{1}{D_A/X}-\frac{1}{P_{aqA}}\right)C(-s)}{\frac{1}{P_{aqA}}+\frac{1}{P_{SA}}+\frac{1}{D_A/m}} \quad \text{(Eq. 8)}$$

where $C_A(-s)$ is the concentration of III in the vehicle at the stratum corneum boundary; $C_{AM}(x)$ and $C_{A0}(x)$ are the concentrations of III at the distance X for a metabolizing and a nonmetabolizing epidermis, respectively; and P_{SA} is the III permeability of the stratum corneum. For P_{SA} values of 10^{-6} and 10^{-7} cm/sec and for the computed κ:

$$\frac{C_{AM}(-m/2)}{C_{A0}(-m/2)} = 0.181 \quad \text{(Eq. 9)}$$

$$\frac{C_{AM}(-m/2)}{C_{A0}(-m/2)} = 0.183 \quad \text{(Eq. 10)}$$

These results show that, for a metabolizing membrane, the bioavailability of III due to metabolism does not depend strongly on the stratum corneum permeability and that the concentration of the active drug, III, is only 18% of the level that would have existed at the site of the lesion (halfway through the epidermis) had there been no metabolism.

Antineoplastic Agents L: Isolation and Characterization of Sphyrnastatins 1 and 2 from the Hammerhead Shark *Sphyrna lewini*

Keyphrases □ *Sphyrna lewini*—hammerhead shark, potential antineoplastic constituents isolated from body fluids, muscle tissue, and liver, identified □ Sphyrnastatins—isolated from hammerhead shark, preliminary evaluation of antineoplastic activity □ Antineoplastic activity—preliminary evaluation of sphyrnastatins isolated from hammerhead shark □ Marine antineoplastic agents, potential—sphyrnastatins isolated from hammerhead shark

To the Editor:

Hammerhead sharks of the Sphyrnidae family (cartilaginous fishes of the class Chondrichthyes) have inhabited the oceans for 181–350 million years (1) and represent a most successful evolutionary achievement. Sharks are rarely affected by diseases (2) and, to our knowledge, hammerhead sharks have not been found with cancer. In 1966, we began a long-term study (3) of marine animals for the purpose of developing cancer chemotherapeutic drugs (4). Early in this investigation, it was found that extracts of certain marine vertebrates exhibited a confirmed level of activity against the National Cancer Institute's PS (murine lymphocytic leukemia) screening system.

amount/cm^2 sec, where $V = 2.0$ cm^3 and $A = 1.54$ cm^2. Because the full thick skin used also contained some subcutaneous tissue and dermis, there appeared to be a lag time of about 5 min (Fig. 1).

Using the value for F_A, we can compute that $C_A(h)/-F_A = 2.03 \times 10^4$ sec/cm, where $V = 2.0$ cm^3 and $A = 1.54$ cm^2. Antineoplastic Agents L: Isolation and Characterization of Sphyrnastatins 1 and 2 from the Hammerhead Shark *Sphyrna lewini*

Keyphrases □ *Sphyrna lewini*—hammerhead shark, potential antineoplastic constituents isolated from body fluids, muscle tissue, and liver, identified □ Sphyrnastatins—isolated from hammerhead shark, preliminary evaluation of antineoplastic activity □ Antineoplastic activity—preliminary evaluation of sphyrnastatins isolated from hammerhead shark □ Marine antineoplastic agents, potential—sphyrnastatins isolated from hammerhead shark

To the Editor:

Hammerhead sharks of the Sphyrnidae family (cartilaginous fishes of the class Chondrichthyes) have inhabited the oceans for 181–350 million years (1) and represent a most successful evolutionary achievement. Sharks are rarely affected by diseases (2) and, to our knowledge, hammerhead sharks have not been found with cancer. In 1966, we began a long-term study (3) of marine animals for the purpose of developing cancer chemotherapeutic drugs (4). Early in this investigation, it was found that extracts of certain marine vertebrates exhibited a confirmed level of activity against the National Cancer Institute's PS (murine lymphocytic leukemia) screening system.

Now we wish to report the first[1] isolation and characterization of a shark anticancer constituent. The hammerhead shark, *Sphyrna lewini*[2], was found to produce two new antineoplastic agents designated sphyrnastatin 1 and sphyrnastatin 2. These anticancer components were isolated from the blood (and other body fluids), the fins (and other muscle tissue), and the liver.

In a typical isolation sequence, the water extract of blood and body fluids was first chromatographed on macroreticular resin[3]. The aqueous fraction (20 → 13.5 g) was next subjected to gel[4] permeation chromatography (10 × 100-cm column). Following elution with 3.25 liters of water, the PS inhibitory fraction (0.6 g from 5.0 g) was finally purified by chromatographic separation[5] (5 × 69-cm column and elution with a mixture of 0.05 *M* tromethamine and 0.1 *M* potassium chloride). The two highest molecular weight fractions (0.076 and 0.34 g) represented the antineoplastic components.

Sphyrnastatins 1 and 2, isolated by this procedure, were glycoproteins [~22 and 26% carbohydrate, respectively (6)] with apparent molecular weights (7) of at least 40×10^6. Amino acid analyses indicated a minimum protein segment of 274 amino acid units for sphyrnastatin 1 and 380 amino acid units for sphyrnastatin 2. Upon preliminary biological evaluation, the sphyrnastatins produced a 30–40% (at 11–13 mg/kg) life extension in mice inoculated with the PS leukemia. More extensive antineoplastic evaluation of sphyrnastatins 1 and 2 in the National Cancer Institute's exploratory screening systems is in progress. Presently, we are attempting to isolate other shark and marine vertebrate anticancer constituents.

Perhaps the sphyrnastatins and other high molecular weight antineoplastic substances (4) act by stimulating the immune system to more effective action against invading neoplastic disease. If this hypothesis is valid, then immunotherapy approaches to cancer treatment with, for example, BCG might better be considered as just another facet of cancer chemotherapy.

BOOKS

REVIEWS

Drug Metabolism: Chemical and Biochemical Aspects. By BERNARD TESTA and PETER JENNER. Dekker, 270 Madison Ave., New York, NY 10016, 1976. xii + 500 pp. 18.5 × 26 cm. Price $47.50.

This is the fourth volume in the new "Drug and Pharmaceutical Sciences" series of textbooks and monographs edited by James Swarbrick. As stated by the editor, the purpose of the series is "to enable the pharmacist, and others in the health sciences field, to stay abreast of the changing trends, advances and innovations associated with drugs and the body of knowledge that has come to be known as the pharmaceutical sciences." According to the authors, the purpose of this volume is "to create a fundamental awareness of the basis of drug metabolic processes to those entering the subject or to those who have worked at higher levels of *in vivo* organization." Both purposes have been admirably met with this volume.

As promised in the title, the authors treat both the chemical and biochemical aspects of drug metabolism. The book is divided into these two major sections, with 60% of the text devoted to chemical considerations.

The five chapters devoted to chemical aspects include the major chapter of the book, phase I (biotransformation of chemical groupings) reactions, and a somewhat shorter chapter, phase II (conjugation) reactions. Together, these two chapters account for nearly one-half the total text. Having detailed the specific chemical reactions of drug metabolism, these chapters are brought together and placed in perspective in the third chapter of this section by presenting schematic views of the metabolism of 15 selected drugs. This is followed by a chapter concerning the stereochemical aspects of drug metabolism, a topic recently reviewed in some depth by the authors. The final chapter of this section deals with the influence of physiochemical factors on drug metabolism. This very short chapter (five pages) perhaps should have been expanded or eliminated.

The biochemical aspects of drug metabolism, primarily at the enzymatic level, are presented in four chapters of approximately equal length. The first describes the basic biochemical nature of the drug-metabolizing enzyme systems responsible for phase I and phase II reactions. The effects

BOOKS

REVIEWS

Drug Metabolism: Chemical and Biochemical Aspects. By BERNARD TESTA and PETER JENNER. Dekker, 270 Madison Ave., New York, NY 10016, 1976. xii + 500 pp. 18.5 × 26 cm. Price $47.50.

This is the fourth volume in the new "Drug and Pharmaceutical Sciences" series of textbooks and monographs edited by James Swarbrick. As stated by the editor, the purpose of the series is "to enable the pharmacist, and others in the health sciences field, to stay abreast of the changing trends, advances and innovations associated with drugs and the body of knowledge that has come to be known as the pharmaceutical sciences." According to the authors, the purpose of this volume is "to create a fundamental awareness of the basis of drug metabolic processes to those entering the subject or to those who have worked at higher levels of *in vivo* organization." Both purposes have been admirably met with this volume.

As promised in the title, the authors treat both the chemical and biochemical aspects of drug metabolism. The book is divided into these two major sections, with 60% of the text devoted to chemical considerations.

The five chapters devoted to chemical aspects include the major chapter of the book, phase I (biotransformation of chemical groupings) reactions, and a somewhat shorter chapter, phase II (conjugation) reactions. Together, these two chapters account for nearly one-half the total text. Having detailed the specific chemical reactions of drug metabolism, these chapters are brought together and placed in perspective in the third chapter of this section by presenting schematic views of the metabolism of 15 selected drugs. This is followed by a chapter concerning the stereochemical aspects of drug metabolism, a topic recently reviewed in some depth by the authors. The final chapter of this section deals with the influence of physiochemical factors on drug metabolism. This very short chapter (five pages) perhaps should have been expanded or eliminated.

The biochemical aspects of drug metabolism, primarily at the enzymatic level, are presented in four chapters of approximately equal length. The first describes the basic biochemical nature of the drug-metabolizing enzyme systems responsible for phase I and phase II reactions. The effects

of inducers and inhibitors of these enzymatic systems and the mechanisms of actions involved are treated in the next chapter. The third chapter of this section deals with the physiological factors influencing drug metabolism, including species, strain, sex, and age. The final chapter of the section, and the book, is devoted to a comparison of the biochemical aspects of extrahepatic drug metabolism.

This book deals with "drug metabolism" in the sense of biotransformation, not in the sense of the overall fate, of drugs. Commendably, it has not been diluted with pharmacokinetics, methodology, or extensive physiology. The authors selected, organized and wrote the material in such a manner that the text is entirely readable and instructive, yet valuable for reference. The many references are grouped so that pertinent ones usually are no more than five pages, and never more than 20 pages, away. The subject and author indexes should be useful. This book fills a need in the field for a definitive text relating the chemical and biochemical aspects of drug metabolism.

This reviewer highly recommends the book to anyone engaged in drug metabolism activities; it should be particularly valuable to those entering the field and to those whose experience has been primarily with *in vivo* systems. Unfortunately, its rather high price may prevent many from having a personal copy.

Clinical Chemistry. Principles and Procedures. 4th Ed. By JOSEPH S. ANNINO and ROGER W. GIESE. Little, Brown, 34 Beacon St., Boston, MA 02106, 1976. 412 pp. 16 × 24 cm. Price $15.00.

The fourth edition of this book reflects the rapid growth in the field of clinical chemistry. Part I, which details fundamental information on basic analytical techniques, includes chapters on automation, separation techniques, and radioimmunoassay for the first time. In addition, quality control and spectrophotometry have been expanded and a section on atomic absorption has been added to the chapter dealing with emission spectrophotometry. The overall treatment in Part I is very basic and quite brief; however, most of the important techniques are appropriately referenced.

The majority of this book (Part II) is devoted to descriptions of analytical methods for most of the tests performed in a modern clinical chemistry laboratory. The authors attempted to limit the material presented to one or two established methods for each test, and specific automated procedures are omitted entirely. In addition to the experimental details, most chapters contain a brief discussion of the principle of the method as well as limitations and clinical significance of the results. A concise survey of other current methods with references is also included. One notable weakness is the expanded section on drugs and poisons. It is still quite short and details procedures that are useful in toxicology but not sensitive enough for therapeutic monitoring.

This book is generally well written and appears to be most useful as an inexpensive, concise reference source for the nonclinical chemist who requires access to the principles and details of a variety of clinical chemistry procedures.

Pharmacokinetics of Psychoactive Drugs: Blood Levels and Clinical Response. Edited by LOUIS A. GOTTSCHALK and SIDNEY MERLIS. Wiley, 605 Third Ave., New York, NY 10016, 1976. 255 pp. 16 × 23.5 cm. Price $20.00.

At the annual meeting of the American College of Neuropsychopharmacology held in December 1974 in Puerto Rico, a series of papers was presented at the first study group dealing with pharmacokinetics and clinical response. This book represents an organized compilation of those papers.

The book contains 16 chapters divided into two main sections: Methodological Problems and Approaches (six chapters, 114 pp) and Pharmacological–Clinical Response (10 chapters, 136 pp). A major contribution of the book is the emphasis on the critical evaluation of measurement techniques, analytical as well as behavioral. Particularly noteworthy are Chapters 4 and 6. Chapter 4 includes a limited quality control study (five laboratories) of the determination of chlorpromazine and three metabolites, and Chapter 6 involves comparisons of three types of psychological measurement procedures. The second section of the book illustrates well the challenges of establishing relationships between blood level and clinical response with predictive capabilities.

The references at the end of each chapter are generally adequate. Since the book is the result of contributions at a scientific meeting, the reader should expect a certain amount of discontinuity in content and style. However, the book illustrates the state of the art in this highly interdisciplinary field of research and represents the first attempt to draw attention to several problem areas.

Alicyclic Chemistry. Vol. 4. Edited by W. PARKER *et al.* The Chemical Society, Burlington House, London W1V OBN, England, 1976. 511 pp. 14 × 22 cm. Price $75.75.

The present volume is organized identically to Volume 2 [reviewed in *J. Pharm. Sci.*, **64**, 2032 (1975)], which dealt with the literature of alicyclic chemistry published during 1972. Four large chapters cover three- and four-membered rings, five- and six-membered rings (and related fused systems), medium- and large-ring compounds, and bridged carbocyclics. Each chapter is extensively subdivided and deals with ring characteristics of the systems, methods of synthesis, and reactions. The format is the same as in the earlier volumes. The general comments made by this reviewer about Volume 2 are equally applicable here.

As in all areas of chemistry (all science), the sheer quantity of information available each year continues to grow exponentially. For example, the number of publications dealing with three- and four-membered rings alone increased by 35% in 1974 over the previous year.

Each chapter in this book is prepared by different authors (reporters), with W. Parker serving as the senior reporter for this and previous volumes. Finally, I think it is fair to state that the price of this volume (obtainable through the American Chemical Society) is simply exorbitant. The price in England is considerably less (£27.50). This price differential is hard to understand.

Drug Treatment. Principles and Practice of Clinical Pharmacology and Therapeutics. Edited by GRAEME S. AVERY. Publishing Sciences Group, 162 Great Neck Rd., Acton, MA 01720, 1976. 1048 pp. 18.5 × 27 cm. Price $25.00.

This text is composed of 28 chapters authored by 53 contributors from around the world. It is arranged in three sections: clinical pharmacology, therapeutics, and a section of five appendixes containing mostly tables of data on physiochemical and pharmacokinetic properties of drugs, adverse reactions to drugs, drug interactions, selection of systemic antibacterial agents, and a guide to dosage in renal failure.

Each chapter begins with a synopsis of important principles which itemizes generalities that should be understood and retained as residual information even after the smaller nitty-gritty facts in each chapter fade from one's mind.

The specific aim of the book is to aid the clinician in selecting a drug

of inducers and inhibitors of these enzymatic systems and the mechanisms of actions involved are treated in the next chapter. The third chapter of this section deals with the physiological factors influencing drug metabolism, including species, strain, sex, and age. The final chapter of the section, and the book, is devoted to a comparison of the biochemical aspects of extrahepatic drug metabolism.

This book deals with "drug metabolism" in the sense of biotransformation, not in the sense of the overall fate, of drugs. Each chapter is extensively subdivided and deals with ring characteristics of the systems, methods of synthesis, and reactions. The format is the same as in the earlier volumes. The general comments made by this reviewer about Volume 2 are equally applicable here.

As in all areas of chemistry (all science), the sheer quantity of information available each year continues to grow exponentially. For example, the number of publications dealing with three- and four-membered rings alone increased by 35% in 1974 over the previous year.

Each chapter in this book is prepared by different authors (reporters), with W. Parker serving as the senior reporter for this and previous volumes. Finally, I think it is fair to state that the price of this volume (obtainable through the American Chemical Society) is simply exorbitant. The price in England is considerably less (£27.50). This price differential is hard to understand.

Drug Treatment. Principles and Practice of Clinical Pharmacology and Therapeutics. Edited by GRAEME S. AVERY. Publishing Sciences Group, 162 Great Neck Rd., Acton, MA 01720, 1976. 1048 pp. 18.5 × 27 cm. Price $25.00.

This text is composed of 28 chapters authored by 53 contributors from around the world. It is arranged in three sections: clinical pharmacology, therapeutics, and a section of five appendixes containing mostly tables of data on physiochemical and pharmacokinetic properties of drugs, adverse reactions to drugs, drug interactions, selection of systemic antibacterial agents, and a guide to dosage in renal failure.

Each chapter begins with a synopsis of important principles which itemizes generalities that should be understood and retained as residual information even after the smaller nitty-gritty facts in each chapter fade from one's mind.

The specific aim of the book is to aid the clinician in selecting a drug

and dose schedule by making it clear that one should first pay strict attention to the patient's particular disease conditions because these invariably affect the responses of the agents chosen. In this regard, it must be stated that no other text to date has done as good a job as this one. It truly succeeds as a bridge between classic pharmacology texts and those limited to therapeutics and medicine.

Through a close reading of any chapter, one is made aware of clinical pharmacology as it should be delineated; *i.e.*, as an area of concentration that deals with the understanding of the action of current drugs in patients with diseases, rather than simply the evaluation of new entities as they are synthesized and brought to the clinic for initial trials.

The handling of the reference material for books, tables, and figures is accomplished in such a way that if one is interested it can be found, but the descriptive material is not continuously interrupted with names, sources, and dates.

This work is recommended for anyone involved with the applied aspects of pharmacology including physicians, pharmacologists, pharmacists, and allied health professionals. It will make an excellent contribution to the literature and certainly fills a void that has developed as pharmacology and therapeutics have emerged as the foundations for a thorough understanding of the clinical implications of drug usage.

Terpenoids and Steroids, Vol. 6. Edited by K. H. OVERTON *et al.* The Chemical Society, Burlington House, London W1V OBN, England, 1976. 363 pp. 15 × 22 cm. Price £20.50. (Available from Special Issues Sales, American Chemical Society, 1155 Sixteenth Street, N.W., Washington, DC 20036.)

This is the sixth volume on terpenoids and steroids in a valuable series first published 5 years ago. The aim of each series of Specialist Periodical Reports is to provide a systematic, comprehensive, and critical review of progress in the major areas of chemical research. The various series, which now total 35, are being published annually or bienially on such topics as Environmental Chemistry; Biosynthesis; Foreign Compound Metabolism in Mammals; The Alkaloids; Carbohydrate Chemistry; Amino-acids, Peptides, and Proteins; and Photochemistry.

This volume does not contain a subject index but is organized in a systematic manner which facilitates finding any information being sought. The six pages in the Table of Contents outline this volume in detail. The chapters are divided into many sections, which are identified in boldface type in the text as well as in the Table of Contents. These sections are further divided into subsections. Chapter titles are found at the top of every second page of the text. The author index of 3500 names is helpful to those following the research of a given individual.

This review is illustrated with drawings of 2100 chemical structures. It is documented with 1850 references, most of which are listed at the bottom of the first page of each chapter where cited.

Part I, which covers the terpenoids, is divided into chapters including Monoterpenoids, Sesquiterpenoids, Diterpenoids, Triterpenoids, Carotenoids and Polyterpenoids, and Biosynthesis of Terpenoids and Steroids. Part II, which covers steroids, is divided into two large chapters entitled Steroid Properties and Reactions, and Steroid Synthesis. No compilation of references to review articles on subjects related to terpenoids or steroids is included in this volume as in previous volumes.

The chapter on Steroid Properties and Reactions is divided into sections based upon more common functional groups, a section on Compounds of Nitrogen and Sulfur, and sections on such important subjects as Photochemical Reactions, Molecular Rearrangements, and Functionalization of Non-activated Positions. The chapter on Steroid Synthesis is divided into the following sections: Total Synthesis, Halogenosteroids, Oestranes, Androstanes, Pregnanes, Seco-steroids, Cholestane and Analogues, Steroidal Insect and Plant Hormones, Steroidal Alkaloids, Sapogenins, Cardenolides, and Bufadienolides.

The editor and 11 reporters who prepared this volume are to be commended for maintaining the high standards set by the previous volumes in this series. Everyone interested in the chemistry of terpenoids and/or steroids should have access to this volume and others in the series. They are great timesavers and sources of new ideas. I highly recommend this series.

Progress in Toxicology. Special Topics. Vol. 2. By GERHARD ZBINDEN. Springer-Verlag, 175 Fifth Ave., New York, NY 10010, 1976. 117 pp. 18 × 26 cm. Price $7.40.

The cuisine of Zbinden's second book on special topics in toxicology is based on experience, sound reasoning, good common sense, a pinch of humor, and clear expression of realistic idealism. Is toxicology really too serious a matter to be left to the toxicologists? Read the book and answer the question yourself. Then read "How Safe is Safe?," available from the National Academy of Sciences. In a rather brief but informative manner, Zbinden covers in 93 pages (not including references and index) some of the most important problems confronting toxicology and related sciences but in a rather unusual manner. For example, he relates his son's experience with a gum ball machine, indicating that his son may put in two nickels and get nothing but doesn't give up until he finds out why or gets his two nickels back! "Why then does a negative response to a drug not elicit from us a similar anger?" More attention is paid to side-effects than negative medication responses. Zbinden then goes on to demonstrate the role of urinary pH as a factor in accelerated drug excretion and negative medication responses.

He discusses percutaneous drug permeation, hyperglycemia, the glutathione story, a new disease (pseudolupus), drug-induced lipidosis, the magnitude of drug combinations, drug interactions, and the growing problem (?) of health hazards from colors. In his discussion of food, drug, and cosmetic colors, he points out that the number of colors permitted in foods varies from country to country; *i.e.*, Australia permits seven synthetic and six natural dyes, and the United Kingdom permits 22 and 23, respectively. All other countries are somewhere inbetween. In this section, Zbinden also deletes expletives!

I personally enjoy reading anything that Zbinden writes (in English!) and don't hesitate to recommend this book to all concerned with toxicity, toxicology, and human health. I hope that Zbinden continues to write because what he says affords sound advice for those dealing with the naive.

IMPEDING METRIC CONVERSION

For many years, this writer had served as a self-styled good will ambassador for the metric system. Whenever the subject happened to be discussed with family, friends, or professional acquaintances, we always talked up the merits of the system and the desirability of the United States converting *in toto* to its use.

Moreover, we felt very comfortable in doing so. The metric system is "the system" of the physical and biological sciences; it is "the system" of pharmacy; it is officially endorsed as "the system" by the American Pharmaceutical Association. Hence, by training, background, career, and affiliation, we were in concert with the metric theme. Indeed, we even had several occasions to participate as a witness in presenting testimony before U.S. Congressional committees which were hearing bills dealing with national conversion to the metric system.

On all these occasions, we have repeated what so many others have said in arguing the merits of such conversion; namely, we would be adopting a pure, uniform, and simple system which can be easily learned and, once learned, will remain unchanged forever.

But then some unsettling things began to happen. The first hint that all may not be quite as rosy as we thought was when the controversy arose over whether the preferred unit of volume was a "cubic centimeter" (cc) or a "milliliter" (ml). After what seemed to be a good deal of haggling, this was eventually settled with the result that much revising was necessary in style books, in texts, in calibrations on laboratory equipment, and in the labeling on numerous containers, particularly those of chemicals and drugs.

Then one day the local weather report began to give temperatures in terms of degrees celsius rather than the familiar degrees centigrade. And when we could not immediately explain the difference to our children, we suffered both embarrassment as well as a blow to our personal credibility.

We hardly had time to track this one down when we learned that the presses must be halted for our publications in order that the typesetters could scurry about changing all the "microns" to "micrometers" and the "millimicrons" to "nanometers"—along with corresponding changes in the symbols and abbreviations used in their stead.

What was happening? Why were these and other changes like them being made? Was no one else distressed and disturbed by what to us appeared to be a series of confusing, pointless, and disturbing disruptions?

Well, in the letters column of a recent issue of the American Chemical Society's publication, *Chemical and Engineering News*, we learned that there is at least one fellow sufferer. Dean W. Gibbons of Detroit wrote about his experience trying to keep up with such changes as those mentioned above, as well as a number of others including "torr" to honor Torricelli, the inventor of the barometer, and "kilopascals," presumably in honor of Pascal and his law of the pressure-volume relationship.

"There are better ways to honor our scientific forefathers than to rename familiar metric units," writes Gibbons. And he goes on to add: *"Public acceptance of the metric system will depend on whether the system is perceived as simple and logical, or regarded as a jumble of confusion. The use of long-established, descriptive units, instead of the latest fads, will aid the transition from the English to the metric system."*

His point is both well taken and well stated. Hopefully, the scientific community is more stable and sedate than the local town officials who will rename Main Street at the drop of a hat to honor—for political reasons—some celebrity or other public figure who is currently in the news.

Those of us who deal with measurement terms and their symbols on a daily basis have difficulty enough remembering which is what, and which is correct. For the general public to cope with such changes is simply asking too much. We hope that the scientists responsible for initiating such changes will recognize that they are doing a real disservice by needlessly impeding the process of metric conversion.

HAS JUSTICE BEEN SERVED?

As this column is being written, the "blue ribbon" investigative body known as the HEW Review Panel on New Drug Regulation is in the last stages of winding down its two-year plus period of existence. At least, it appears to be approaching its final demise. The group has had a long history of twelfth-hour reprieves and extensions, each coming when the Panel's life previously seemed to be terminating.

From its inception, this Review Panel has been one of the most puzzling and curious activities to hit the Washington scene in a long time.

Its formation was originally announced by former HEW Secretary Caspar W. Weinberger on March 28, 1975, principally for the purpose of reviewing the allegations by a group of disgruntled Food and Drug Administration employees of FDA misconduct in the area of approval of New Drug Applications. These dissidents had publicly charged that NDA review procedures were improperly administered by agency officials sympathetic to the drug industry, and that any efforts by FDA staff members to be objective were met with abuse, retaliation, and harassment.

If such charges had been made by only a couple of employees, they might have been dismissed as nothing more than commonplace employee disenchantment and exaggeration. However, at least a score of medical scientists openly voiced such grievances. Hence, a full investigation was in order.

But immediately, even at its inception, the Panel got off to a peculiar start. Rather than confining its purpose to a review of the allegations of the dissident employees, the Panel embarked upon a broad scale review of the entire FDA operation, the entire concept of the drug approval process, the complete philosophy of FDA objectives and management, and more. The charge given the Panel was sufficiently broad that the Panel—rightly or wrongly—chose to interpret it as so sweeping as to encompass every aspect of FDA activity, involvement, and responsibility.

Subsequently, the Panel has had a turbulent and rocky history—within its own operation, in its relation with the HEW hierarchy, and in its purposeful adversary stance *versus* the FDA.

Its original Chairman drastically dissented from the views of the Panel majority and then resigned. The initial Executive Secretary resigned because of discord with the Panel, and several successors followed in as many months. Testimony presented during Panel hearings ranged from the bizarre to the incredulous and included a "true confessions" inside view of daily conduct in the FDA's Bureau of Drugs. Staff written reports were prepared in secret, circulated confidentially, discussed in open session, and then rejected by the Panel. The FDA Commissioner was obliged to prepare a defense in the form of a report running thirteen chapters and several hundred pages and which, in turn, was subjected by the Panel to a page-by-page, point-by-point dissection and rejection. A 765-page report prepared by the Panel's special legal counsel included a recommendation for both criminal and disciplinary actions against several former and present FDA officials.

But despite its sordid operation, the Panel has worked and produced. Full meetings have been held on a regular monthly basis, lengthy interim reports have been issued on each of the many subjects reviewed by the Panel, related documents such as announcements and meeting minutes have flowed promptly and consistently from the staff office, and a series of meaningful recommendations has ultimately emanated from the Panel's deliberations.

But now that the whole operation is about to conclude, we asked ourselves: Was it all worthwhile? What was accomplished? Were the complaints of the employees which triggered the entire operation adequately dealt with and satisfactorily resolved?

In all candor, we find it hard to say. And, judging by the ambivalence of virtually all other press reports we have read relating to the Panel, it appears that other observers of the Washington scene are experiencing similar difficulty in making judgments.

In many respects, this Review Panel operation reminds us of the various President Kennedy assassination inquiries which have been similarly intense, controversial, and, yet, unfulfilling in that few real answers have been provided. In fact, whatever satisfaction has been realized is probably the result of the catharsis effect derived from engaging in this lengthy and abrasive inquiry. Only time and history will ultimately determine if the result was worth the effort.

HAS JUSTICE BEEN SERVED?

As this column is being written, the "blue ribbon" investigative body known as the HEW Review Panel on New Drug Regulation is in the last stages of winding down its two-year plus period of existence. At least, it appears to be approaching its final demise. The group has had a long history of twelfth-hour reprieves and extensions, each coming when the Panel's life previously seemed to be terminating.

From its inception, this Review Panel has been one of the most puzzling and curious activities to hit the Washington scene in a long time.

Its formation was originally announced by former HEW Secretary Caspar W. Weinberger on March 28, 1975, principally for the purpose of reviewing the allegations by a group of disgruntled Food and Drug Administration employees of FDA misconduct in the area of approval of New Drug Applications. These dissidents had publicly charged that NDA review procedures were improperly administered by agency officials sympathetic to the drug industry, and that any efforts by FDA staff members to be objective were met with abuse, retaliation, and harassment.

If such charges had been made by only a couple of employees, they might have been dismissed as nothing more than commonplace employee disenchantment and exaggeration. However, at least a score of medical scientists openly voiced such grievances. Hence, a full investigation was in order.

But immediately, even at its inception, the Panel got off to a peculiar start. Rather than confining its purpose to a review of the allegations of the dissident employees, the Panel embarked upon a broad scale review of the entire FDA operation, the entire concept of the drug approval process, the complete philosophy of FDA objectives and management, and more. The charge given the Panel was sufficiently broad that the Panel—rightly or wrongly—chose to interpret it as so sweeping as to encompass every aspect of FDA activity, involvement, and responsibility.

Subsequently, the Panel has had a turbulent and rocky history—within its own operation, in its relation with the HEW hierarchy, and in its purposeful adversary stance *versus* the FDA.

Its original Chairman drastically dissented from the views of the Panel majority and then resigned. The initial Executive Secretary resigned because of discord with the Panel, and several successors followed in as many months. Testimony presented during Panel hearings ranged from the bizarre to the incredulous and included a "true confessions" inside view of daily conduct in the FDA's Bureau of Drugs. Staff written reports were prepared in secret, circulated confidentially, discussed in open session, and then rejected by the Panel. The FDA Commissioner was obliged to prepare a defense in the form of a report running thirteen chapters and several hundred pages and which, in turn, was subjected by the Panel to a page-by-page, point-by-point dissection and rejection. A 765-page report prepared by the Panel's special legal counsel included a recommendation for both criminal and disciplinary actions against several former and present FDA officials.

But despite its sordid operation, the Panel has worked and produced. Full meetings have been held on a regular monthly basis, lengthy interim reports have been issued on each of the many subjects reviewed by the Panel, related documents such as announcements and meeting minutes have flowed promptly and consistently from the staff office, and a series of meaningful recommendations has ultimately emanated from the Panel's deliberations.

But now that the whole operation is about to conclude, we asked ourselves: Was it all worthwhile? What was accomplished? Were the complaints of the employees which triggered the entire operation adequately dealt with and satisfactorily resolved?

In all candor, we find it hard to say. And, judging by the ambivalence of virtually all other press reports we have read relating to the Panel, it appears that other observers of the Washington scene are experiencing similar difficulty in making judgments.

In many respects, this Review Panel operation reminds us of the various President Kennedy assassination inquiries which have been similarly intense, controversial, and, yet, unfulfilling in that few real answers have been provided. In fact, whatever satisfaction has been realized is probably the result of the catharsis effect derived from engaging in this lengthy and abrasive inquiry. Only time and history will ultimately determine if the result was worth the effort.

New Method for Characterizing Dissolution Properties of Drug Powders

PETER VENG PEDERSEN

Abstract □ Various multiparticulate dissolution models that assume a log-normal particle-size distribution are fitted by nonlinear least-squares regression to data from the dissolution of micronized glyburide. Estimates of parameters describing the effective initial particle-size distribution are obtained, together with estimates of the specific dissolution rate parameter. A dissolution equation based on an ideal, untruncated, log-normal distribution, with the single particles dissolving according to the Hixson–Crowell cube root law, is the best model. The dissolution behavior of glyburide can be well described by this model in terms of the specific dissolution rate parameter and one other parameter accounting for the distribution effect. The estimation of these two parameters represents a more exact way of describing the dissolution characteristics of drug powders than previous approaches. The method should be of interest in the quality control of drugs that may cause bioavailability problems because of dissolution rate-limited absorption.

Keyphrases □ Dissolution—micronized glyburide, various multiparticulate models fit to data, rate and size distribution parameters evaluated □ Powders—micronized glyburide, various multiparticulate models fit to dissolution data, rate and size distribution parameters evaluated □ Glyburide, micronized—dissolution, various multiparticulate models fit to data, rate and size distribution parameters evaluated

The dissolution behavior of a multiparticulate system is determined by the single-particle dissolution behavior and the particle-size distribution (1, 2). Dissolution profiles have been related to the initial particle-size distribution (3, 4). However, the mathematical models used to account for the size distribution effect were not exact but were based on empirical approximations.

A previous paper (5) showed good agreement between the theoretical dissolution profile based on a rigorous mathematical treatment and dissolution data for tolbutamide. The present paper evaluates some kinetic models for multiparticulate dissolution by fitting them to data from the dissolution of micronized glyburide. This method represents a new and better approach for characterizing the dissolution behavior of powders by evaluating both rate and size distribution parameters. The method should be of value in quality control measurements of slightly soluble pure drugs that can cause bioavailability problems.

THEORY

Consider a multiparticulate dissolution where the single particles dissolve according to the Hixson–Crowell (6) cube root law or the Niebergall *et al.* (7) square root law, which can be written in a common form as:

$$w^{1/m} = w_0^{1/m} - k_m t \qquad \text{(Eq. 1)}$$

where $m = 3$ for the cube root law and $m = 2$ for the square root law[1].

Let the initial effective particle diameters, a_0, be log normally distributed, *i.e.*, have a frequency distribution that is well approximated by the following density distribution (2):

$$\mu(\ln a_0) = \frac{N(\ln a_0,\mu,\sigma)}{\int_{\ln a_0=\mu-i\sigma}^{\ln a_0=\mu+j\sigma} N(\ln a_0,\mu,\sigma)d\ln a_0} \qquad \text{(Eq. 2)}$$

for $\mu - i\sigma \leq \ln a_0 \leq \mu + j\sigma$ where i and j are the lower and upper truncation parameters (Fig. 1), and N is the normal density function defined by:

$$N(x,\mu,\sigma) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2} \qquad \text{(Eq. 3)}$$

The dissolution of such a multiparticulate powder is described by (2):

$$\frac{W}{W_0} = \sum_{n=0}^{m} \binom{m}{n} (-K_m t)^{(m-n)} \times \frac{F\left(\frac{T_2-\mu}{\sigma} - \frac{3n\sigma}{m}\right) - F\left(\frac{T_1-\mu}{\sigma} - \frac{3n\sigma}{m}\right)}{F(j-3\sigma) - F(-i-3\sigma)} e^{3(n-m)\{\mu+3(n+m)\sigma^2/2m\}/m} \qquad \text{(Eq. 4)}$$

[1] The positive constants k_3 ($m = 3$) and k_2 ($m = 2$) are used for simplicity to replace the coefficients of time that contain quantities such as density, the diffusion coefficient, and the shape factor, which are considered constant.

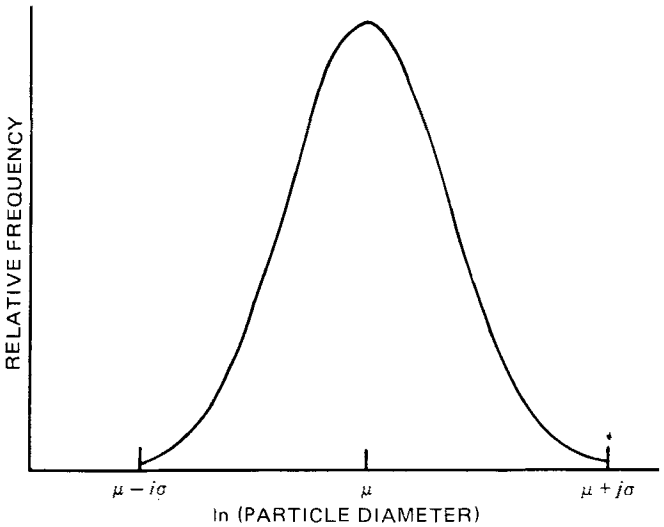

Figure 1—*Illustration of the initial (t = 0) particle-size distribution parameters, μ, σ, i, and j, of a log-normal powder. The approximating distribution function shown is defined in Eq. 2. The initial diameters, a_0, are diameters of hypothetical spherical particles that approximate the dissolution behavior of the real nonspherical particles. The dimensionless distribution shape parameters, i, j, and σ, can be estimated from the dissolution profile (Figs. 3–6) by nonlinear least-squares regression analysis (Table I). The scale parameter, μ, cannot be determined.*

where W/W_0 is the fraction of undissolved powder at time t, F is the cumulative standard normal distribution function defined by:

$$F(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{x} e^{-x^2/2}\, dx \qquad \text{(Eq. 5)}$$

T_1 and T_2 are given by:

$$T_1 = \mu - i\sigma \qquad \text{for } \frac{m}{3}\ln(K_m t) < \mu - i\sigma \qquad \text{(Eq. 6)}$$

$$T_1 = \frac{m}{3}\ln(K_m t) \qquad \text{for } \frac{m}{3}\ln(K_m t) \geq \mu - i\sigma \qquad \text{(Eq. 7)}$$

$$T_2 = \mu + j\sigma \qquad \text{for } \frac{m}{3}\ln(K_m t) < \mu + j\sigma \qquad \text{(Eq. 8)}$$

$$T_2 = \frac{m}{3}\ln(K_m t) \qquad \text{for } \frac{m}{3}\ln(K_m t) \geq \mu + j\sigma \qquad \text{(Eq. 9)}$$

and:

$$\binom{m}{n} = \frac{m!}{(m-n)!n!} \qquad \text{(Eq. 10)}$$

If the particles are spherical, K_m is related to k_m by:

$$K_m = (6/\rho\pi)^{1/m} k_m \qquad \text{(Eq. 11)}$$

Equation 4 appears to contain five parameters, namely, σ, i, j, μ, and K_m, which define the dissolution profile (W/W_0 *versus* time). However, an attempt to obtain least-squares estimates of all five parameters from W/W_0 *versus* time data may fail, because μ and K_m can be fused into a single rate parameter:

$$K_m^* = e^{-3\mu/m} K_m \qquad \text{(Eq. 12)}$$

which will be called the specific dissolution rate parameter.

The uniqueness of these four parameters, σ, i, j, and K_m^*, in defining the dissolution profile can be seen by substituting $K_m = e^{3\mu/m}K_m^*$ into Eq. 4, resulting in total cancellation of μ, in full agreement with the theory discussed previously (2):

$$\frac{W}{W_0} = \sum_{n=0}^{m} \binom{m}{n} (-K_m^* t)^{(m-n)} \frac{F\left(j - \frac{3n\sigma}{m}\right) - A}{F(j - 3\sigma) - F(-i - 3\sigma)} e^{2[(n/m)^2 - 1]\sigma^2/9} \qquad \text{(Eq. 13)}$$

where:

$$A = F\left(-i - \frac{3n\sigma}{m}\right) \qquad \text{for } t < \frac{1}{K_m^*} e^{-3i\sigma/m} \qquad \text{(Eq. 14)}$$

and:

$$A = F\left[\frac{m}{3\sigma}\ln(K_m^* t) - \frac{3n\sigma}{m}\right] \qquad \text{for } \frac{1}{K_m^*} e^{3j\sigma/m} > t > \frac{1}{K_m^*} e^{-3i\sigma/m} \qquad \text{(Eq. 15)}$$

and:

$$\frac{W}{W_0} = 0 \qquad \text{for } t \geq \frac{1}{K_m^*} e^{3j\sigma/m} \qquad \text{(Eq. 16)}$$

The continuously recording flow-through dissolution apparatus used provides dissolution rate data. The fraction undissolved, W/W_0, *versus* time can be obtained by integrating these data (5). The parameters σ, i, j, and K_m^* can then be estimated by nonlinear least-squares regression analysis using Eq. 13. However, the integrated data contain integration errors. The integration also tends to "smooth" the original data, so estimates of the variability of the parameters will be less reliable than if the original rate data were used. Therefore, it is useful to derive an expression for the release rate to estimate the four parameters directly from the original (rate) data.

By applying Eq. 13*a* of Ref. 1, the following equation (similar to Eq. A2 in the same reference) is obtained:

$$\frac{W}{W_0} = \frac{\int_{R_1}^{R_2} (x^{3/m} - K_m t)^m x^{-1} N(\ln x, \mu, \sigma)\, dx}{\int_{d_0}^{D_0} x^2 N(\ln x, \mu, \sigma)\, dx} \qquad \text{(Eq. 17)}$$

where:

$$d_0 = e^{\mu - i\sigma} \qquad \text{(Eq. 18)}$$

$$D_0 = e^{\mu + j\sigma} \qquad \text{(Eq. 19)}$$

$$R_1 = d_0 \qquad \text{for } K_m t < d_0^{3/m} \qquad \text{(Eq. 20)}$$

$$R_1 = (K_m t)^{m/3} \qquad \text{for } K_m t \geq d_0^{3/m} \qquad \text{(Eq. 21)}$$

$$R_2 = D_0 \qquad \text{for } K_m t < D_0^{3/m} \qquad \text{(Eq. 22)}$$

$$R_2 = (K_m t)^{m/3} \qquad \text{for } K_m t \geq D_0^{3/m} \qquad \text{(Eq. 23)}$$

An expression for the dissolution rate of drug, $Q = -dW/dt$, can now be found by differentiating Eq. 17 with respect to time (using Leibnitz's rule). For abbreviation, let B denote the (constant) denominator of Eq. 17; differentiation then gives:

$$\frac{B}{W_0} Q = mK_m \int_{R_1}^{R_2} (x^{3/m} - Kt)^{(m-1)} x^{-1} N(\ln x, \mu, \sigma)\, dx - (R_2^{3/m} - K_m t)^m R_2^{-1} N(\ln R_2, \mu, \sigma) \frac{dR_2}{dt} + (R_1^{3/m} - K_m t)^m R_1^{-1} N(\ln R_1, \mu, \sigma) \frac{dR_1}{dt} \qquad \text{(Eq. 24a)}$$

Before the critical time[2], $R_1 = d_0$ and $R_2 = D_0$, so $dR_1/dt = dR_2 dt = 0$ and the last two terms of the right-hand side of Eq. 24*a* vanish. After the critical time, dR_2/dt is still zero, but $R_1 = (K_m t)^{m/3}$ (according to Eq. 21). Thus, the last term also vanishes because:

$$R_1^{3/m} - K_m t = [(K_m t)^{m/3}]^{3/m} - K_m t = 0 \qquad \text{(Eq. 24b)}$$

Equation 24*a* can be simplified to:

$$Q = mK_m W_0 \frac{\int_{R_1}^{R_2} (x^{3/m} - K_m t)^{(m-1)} x^{-1} N(\ln x, \mu, \sigma)\, dx}{\int_{d_0}^{D_0} x^2 N(\ln x, \mu, \sigma)\, dx} \qquad \text{(Eq. 25)}$$

The term $(x^{3/m} - K_m t)^{(m-1)} x^{-1}$ under the integral sign can be expanded:

$$(x^{3/m} - K_m t)^{(m-1)} x^{-1} = x - 2K_3 t + (K_3 t)^2 x^{-1} \qquad \text{(for } m = 3\text{)} \qquad \text{(Eq. 26)}$$

$$(x^{3/m} - K_m t)^{(m-1)} x^{-1} = x^{1/2} - K_2 t x^{-1} \qquad \text{(for } m = 2\text{)} \qquad \text{(Eq. 27)}$$

and a formula given previously (Eq. A3 of Ref. 1) can be applied to express the integrals in Eq. 25 in terms of the function F (Eq. 5). This process leads to the following expression for Q that can be evaluated more readily

[2] The critical time is the time when the first particles start disappearing in the dissolution process, *i.e.*, $t = (1/K_m)e^{3/m(\mu - i\sigma)}$.

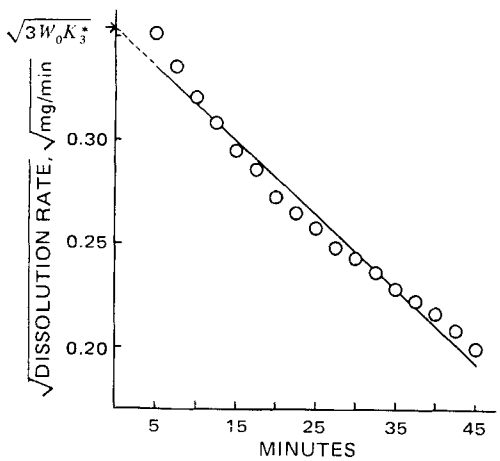

Figure 2—*Illustration of a graphic method for obtaining an initial estimate of the specific dissolution rate parameter, K_m^*, from rate data from the dissolution of 5 mg of micronized glyburide. Equation 39 predicts a linear relationship between $\sqrt{Q}$ and t for a monodisperse powder in which the single particles dissolve according to the cube root law (Eq. 1, m = 3). The deviation from linearity in the graph is caused by the particle-size distribution effect.*

and exactly than Eq. 25:

$$Q = mK_mW_0 \sum_{n=0}^{(m-1)} \binom{m-1}{n} (-K_mt)^{(m-n-1)} \times \frac{F\left(\frac{T_2-\mu}{\sigma} - \frac{3n\sigma}{m}\right) - F\left(\frac{T_1-\mu}{\sigma} - \frac{3n\sigma}{m}\right)}{F(j-3\sigma) - F(-i-3\sigma)} e^{3(n-m)[\mu+3(n+m)\sigma^2/2m]/m} \quad \text{(Eq. 28)}$$

where T_1 and T_2 are as defined previously (Eqs. 6–9).

This expression for the dissolution rate, Q, contains five parameters (σ, i, j, μ, and K_m). However, as before (Eq. 13), only four parameters (σ, i, j, and K_m^*) are needed to define uniquely the dissolution rate profile:

$$Q = mK_m^*W_0 \sum_{n=0}^{(m-1)} \binom{m-1}{n} (-K_m^*t)^{(m-n-1)} \times \frac{F\left(j - \frac{3n\sigma}{m}\right) - A}{F(j-3\sigma) - F(-i-3\sigma)} e^{9[(n/m)^2-1]\sigma^2/2} \quad \text{(Eq. 29)}$$

This equation is the differential form of Eq. 13.

The quantity A is as defined previously (Eqs. 14 and 15) and $Q = 0$ for $t \geq (1/K_m^*)\, e^{3j\sigma/m}$. This expression is valuable since it allows the effective initial particle-size distribution parameters, σ, i, and j, to be determined together with the specific dissolution rate parameter, K_m^*, by nonlinear regression analysis of the dissolution rate profile (dW/dt *versus* time).

It is also of interest to investigate how well the dissolution behavior can be described if the particle-size distribution is considered ideal, *i.e.*, if $i = j = \infty$. With $F(\infty) = 1$ and $F(-\infty) = 0$, Eq. 29 becomes, for an ideal distribution:

$$Q = mK_m^*W_0 \sum_{n=0}^{(m-1)} \binom{m-1}{n} (-K_m^*t)^{(m-n-1)} \times \left\{1 - F\left[\frac{m}{3\sigma}\ln(K_m^*t) - \frac{3n\sigma}{m}\right]\right\} e^{9[(n/m)^2-1]\sigma^2/2} \quad \text{(Eq. 30)}$$

If the distribution is considered ideal at the lower end ($i = \infty$) but truncated at the higher end, the expression becomes:

$$Q = mK_m^*W_0 \sum_{n=0}^{(m-1)} \binom{m-1}{n} (-K_m^*t)^{(m-n-1)} \times \frac{F\left(j - \frac{3n\sigma}{m}\right) - F\left[\frac{m}{3\sigma}\ln(K_m^*t) - \frac{3n\sigma}{m}\right]}{F(j-3\sigma)} e^{9[(n/m)^2-1]\sigma^2/2} \quad \text{(Eq. 31)}$$

and if it is considered truncated at the lower end but not at the higher end ($j = \infty$):

$$Q = mK_m^*W_0 \sum_{n=0}^{(m-1)} \binom{m-1}{n} (-K_m^*t)^{(m-n-1)} \times \frac{1-A}{1-F(-i-3\sigma)} e^{9[(n/m)^2-1]\sigma^2/2} \quad \text{(Eq. 32)}$$

Discussion of the limiting case where the particle-size distribution is infinitely narrow, *i.e.*, $\sigma = 0$, allows a better understanding of the specific dissolution rate parameter, K_m^*. It also provides a method of obtaining a suitable initial estimate of this parameter to use in nonlinear curve fitting.

When $\sigma = i = j = 0$, Eq. 29 becomes:

$$Q = mK_m^*W_0 \sum_{n=0}^{(m-1)} \binom{m-1}{n} (-K_m^*t)^{(m-n-1)} \quad \text{(Eq. 33)}$$

which can be written more simply as:

$$Q = -\frac{dW}{dt} = mK_m^*W_0(1 - K_m^*t)^{(m-1)} \quad \text{(Eq. 34)}$$

which, after integration, can be written:

$$\left(\frac{W}{W_0}\right)^{1/m} = 1 - K_m^*t \quad \text{(Eq. 35)}$$

As expected, since there is no size distribution effect (2), this equation predicts that the powder will dissolve strictly according to the cube root or square root law.

When the powder is monodisperse, $\mu = \ln a_0$ and Eq. 12 becomes:

$$K_m^* = e^{-(3/m)\ln a_0}K_m = a_0^{-3/m}K_m \quad \text{(Eq. 36)}$$

Equations 11 and 36 then give, for spherical particles[3]:

$$K_m^* = a_0^{-3/m}(6/\rho\pi)^{1/m}k_m = w_0^{-1/m}k_m \quad \text{(Eq. 37)}$$

When $k_m = w_0^{1/m} K_m^*$ (from Eq. 37) is inserted in Eq. 1:

$$\left(\frac{w}{w_0}\right)^{1/m} = 1 - K_m^*t \quad \text{(Eq. 38)}$$

A comparison of Eqs. 38 and 35 shows that, for a monodisperse powder, the specific dissolution rate parameter, K_m^*, is common to both multiparticulate (Eq. 35) and single-particle dissolutions (Eq. 38). It has the dimension of time^{-1} for both single-particle models ($m = 2$ and 3).

Equation 34 can be written:

$$Q^{1/(m-1)} = (mW_0K_m^*)^{1/(m-1)} - (mW_0)^{1/(m-1)}(K_m^*)^{m/(m-1)}t \quad \text{(Eq. 39)}$$

This equation can be used to obtain an initial estimate of K_m^* from the linear regression of $Q^{1/(m-1)}$ on t. In this way, the intercept value, $(mW_0K_m^*)^{1/(m-1)}$ ($t = 0$), divided by $(mW_0)^{1/(m-1)}$ gives $K_m^{*\,1/(m-1)}$ (Fig. 2).

EXPERIMENTAL

The high precision, flow-through, continuously recording dissolution apparatus used for the dissolution tests was described previously (5). Various amounts of micronized glyburide[4] were exposed in the dissolution cell to pH 7.25 phosphate buffer ($I = 0.05$) at a flow rate of 0.568 ml/sec (~ 0.149-cm/sec linear flow rate) and at a temperature of 37.5 ± 0.2°. Values of absorbance were read from the chart recording at 2.5-min intervals. The dissolution rate, Q, was then given as (volumetric flow rate) × (absorbance)/(absorption coefficient).

The accuracy of the rate data was checked by integration. The amount released, calculated in this way, agreed to within ±5% with the amount remaining in the dissolution cell at the end of the experiment (which was about 10% of the initial amount). The lower and upper limits for the nonlinear regression parameters used in the curve fitting were chosen as: σ = 0–1, K_m^* = 0–0.1, i = 0–10, and j = 0–10. The initial estimate for the rate parameter, K_m^*, was obtained graphically (Eq. 41 and Fig. 2).

RESULTS AND DISCUSSION

For a monodisperse powder, Eq. 39 predicts a linear relationship between $\sqrt{Q}$ and t when the single particles dissolve according to the cube root model ($m = 3$) and a linear relationship between Q and t when they dissolve according to the square root model ($m = 2$).

Significant deviations from linearity were observed when dissolution rate data for micronized glyburide were plotted in either of these ways (Figs. 2–6). Such deviations arise if the powder is not monodisperse or if the single particles do not dissolve according to the single-particle model (Eq. 1).

Under an electron microscope, the micronized glyburide used appeared to be considerably polydisperse. Therefore, the observed deviation from

[3] The derivation is also valid for nonspherical particles if the concept of spherical approximations (8) applies.

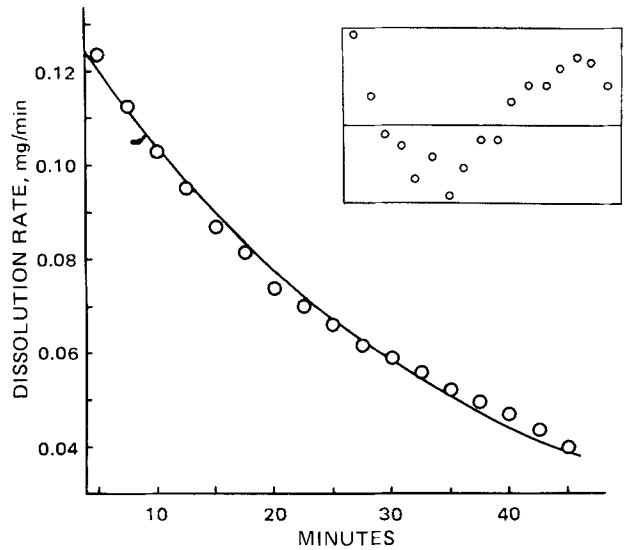

Figure 3—*Least-squares fit of the multiparticulate dissolution model (Eq. 30,* m = *3) to rate data from the dissolution of 5 mg of micronized glyburide. The model assumes that the effective initial particle-size distribution can be approximated by an ideal log-normal distribution* (i = j = ∞, *Fig. 1) and that the single particles dissolve according to the cube root model (Eq. 1,* m = *3). The inset graph shows a plot of the residuals* versus *time in arbitrary units.*

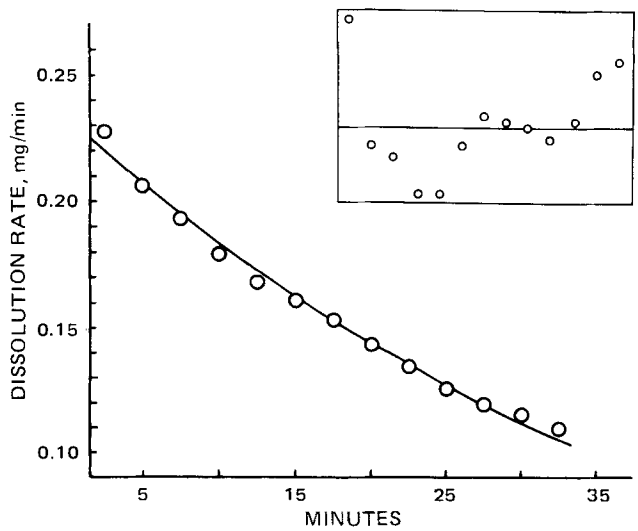

Figure 5—*Least-squares fit of the multiparticulate dissolution model (Eq. 30,* m = *3) to rate data from the dissolution of 10 mg of micronized glyburide. The model assumes that the effective initial particle-size distribution can be approximated by an ideal log-normal distribution* (i = j = ∞, *Fig. 1) and that the single particles dissolve according to the cube root model (Eq. 1,* m = *3). The inset graph shows a plot of the residuals* versus *time in arbitrary units.*

linearity in the rate plots can be explained as a particle-size distribution effect if Eq. 1 is assumed to be valid. However, the rate data can also be explained by other single-particle dissolution models in combination with a size distribution effect. Conclusions about the validity of a single-particle model can only be made when the size distribution effect is taken into account.

In a previous study (5) dealing with the dissolution of 60–85-mesh fraction tolbutamide in relation to its particle-size distribution, the dissolution of the single particles accorded well with the cube root model and nearly as well with the square root model. The distribution effect could be evaluated for tolbutamide because of the regular form of its particles. This was not possible for the much smaller micronized glyburide particles, which had very irregular shapes.

Effective Particle-Size Distribution—Spherical particles are assumed for the multiparticulate dissolution equations presented. Such particles are usually not encountered in pharmaceutical systems. However, the dissolution of a nonspherical particle can, in most cases, be well approximated by the dissolution of a hypothetical spherical particle (8), particularly under conditions of isotropic dissolution.

A previous paper showed how an equivalent spherical diameter can be calculated from the geometry of simple crystal forms (8). In this way, it is possible to obtain an effective particle-size distribution, *i.e.*, the shape of the distribution of hypothetical spherical particles that approximates the dissolution behavior of the real particles. For tolbutamide, the effective distribution was approximately log-normal (5). Because of the irregular particle shapes, it was not possible to make *a priori* conclusions about the effective particle-size distribution for glyburide. In these investigations, the distribution was assumed to be log-normal, consistent with previous results (5) and the fact that powders often have log-normal particle-size distribution (9, 10). Therefore, the distribution in Fig. 1 il-

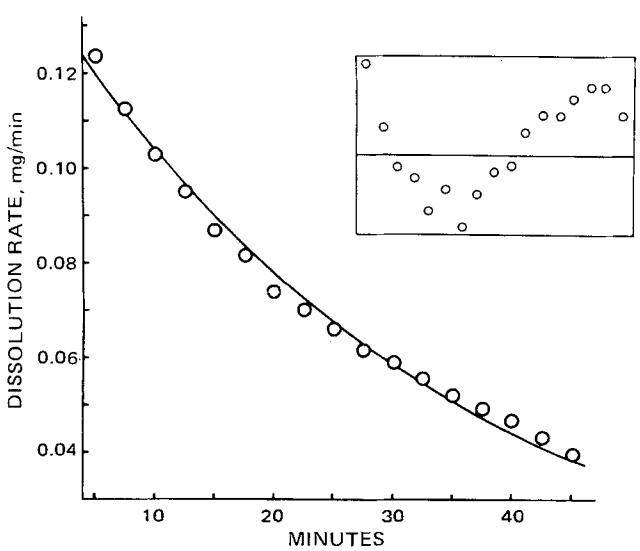

Figure 4—*Least-squares fit of the multiparticulate dissolution model (Eq. 29,* m = *3) to rate data from the dissolution of 5 mg of micronized glyburide. The model assumes that the effective initial particle-size distribution can be approximated by a log-normal distribution truncated at both ends (Fig. 1) and that the single particles dissolve according to the cube root model (Eq. 1,* m = *3). The inset graph shows a plot of the residuals* versus *time in arbitrary units.*

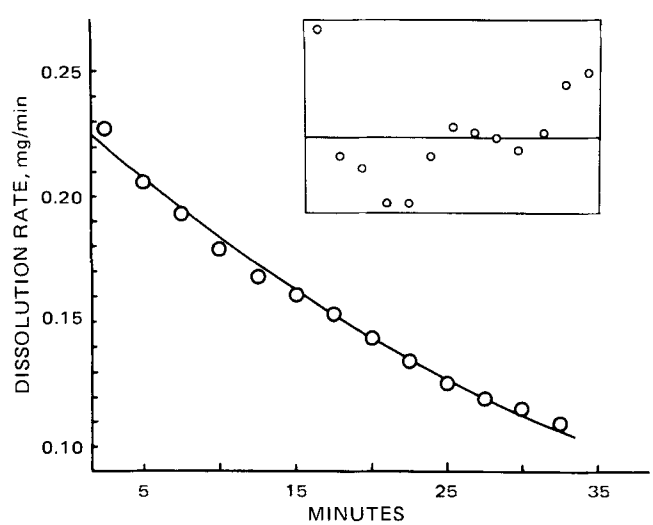

Figure 6—*Least-squares fit of the multiparticulate dissolution kinetic model (Eq. 29,* m = *3) to rate data from the dissolution of 10 mg of micronized glyburide. The model assumes that the effective initial particle-size distribution can be approximated by a log-normal distribution truncated at both ends (Fig. 1) and that the single particles dissolve according to the cube root model (Eq. 1,* m = *3). The inset graph shows a plot of the residuals* versus *time in arbitrary units.*

Table I—Least-Squares Estimates of Rate and Distribution Parameters Obtained from Nonlinear Regression Analysis of Data from the Dissolution of Micronized Glyburide, Using Various Models for Multiparticulate Dissolution Kinetics[a]

W_0, mg	Parameter	Square Root Model ($m = 2$)			Cube Root Model ($m = 3$)		
		Eq. 30[b]	Eq. 31[c]	Eq. 29[d]	Eq. 30[b]	Eq. 31[c]	Eq. 29[d]
5	K_m^*, min^{-1}	0.02858 (6.39)	0.02858 (5.12)	0.02859 (6.51)	0.02367 (4.55)	0.02367 (4.44)	0.02449 (3.96)
	σ	0.4759 (2.93)	0.4760 (2.70)	0.4760 (3.28)	0.6184 (2.47)	0.6184 (2.11)	0.6315 (1.71)

	j	∞	5.299	5.655	∞	9.807	4.172
	r[e]	0.9935	0.9935	0.9935	0.9952	0.9952	0.9954
10	K_m^*, min^{-1}	0.02633 (7.18)	0.02633 (10.6)	0.02633 (9.35)	0.02147 (9.45)	0.02147 (4.74)	0.02176 (4.03)
	σ	0.4955 (3.20)	0.4956 (7.24)	0.4955 (5.14)	0.6374 (3.29)	0.6374 (2.03)	0.6446 (1.89)
	i	∞	∞	8.912	∞	∞	4.577
	j	∞	5.299	6.732	∞	7.060	4.200
	r[e]	0.9938	0.9938	0.9938	0.9957	0.9957	0.9958

[a] Values in parentheses are relative standard deviations (percent). [b] Initial size distribution is considered ideal ($i = j = \infty$, Fig. 1). [c] Initial size distribution is truncated at the upper end ($i = \infty$, $j < \infty$, Fig. 1). [d] Initial size distribution is truncated at both ends (Fig. 1). [e] Correlation coefficient.

lustrates a log-normal approximation to the effective particle-size distribution. The initial particle diameters, a_0 (Eq. 2), are the diameters of the hypothetical spherical particles that approximate the dissolution of the real nonspherical particles.

If the lower and upper truncation parameters, i or j, are finite, the log-distribution is said to be truncated; otherwise, it is ideal.

Regression Parameters—In a discussion of size distribution effects in multiparticulate dissolution, it was pointed out that the intrinsic dissolution profile does not depend on the actual size of the particles (a_0) but on the shape of their distribution (2). For the same reason, it is not possible to determine by regression analysis the scale parameter, μ, as might be erroneously expected from the appearance of Eq. 28. If, in fact, this equation is used to obtain least-squares estimates of μ and K_m, these values would not be unique. Any other of the infinite combinations of the two parameters that give the same value of K_m^* (Eq. 12) will, according to Eq. 13, result in the same fit (for the same values of σ, i, and j). Therefore, the regression analysis can only provide estimates of the dimensionless distribution parameters σ, i, and j, which define the shape of the initial distribution, and K_m^*. The scale or position of the distribution, given by μ, is hidden in the specific dissolution rate parameter, K_m^* (Eq. 12).

Curve Fitting—Equation 29 was fitted by least squares to dissolution rate data from dissolution of 5 and 10 mg of micronized glyburide[5]. The fitting was done using FUNFIT, an interactive time-sharing program for general nonlinear regression, written by the author[6].

The estimates obtained for the truncation parameters, i and j (Table I, Eq. 29), were all larger than 2 and usually exceeded 4, indicating that the effective initial particle-size distribution (Fig. 1) was close to ideal. It was shown earlier that the effect on the dissolution profile of the lower truncation parameter, i, is negligible (1). Simulation studies also show that the influence of an increase in the upper truncation parameter, j, becomes insignificant when j is larger than 2. Therefore, it is expected from the values of i and j obtained using Eq. 29 that the simpler model, Eq. 30, which assumes an ideal distribution ($i = j = \infty$), should fit the same data nearly as well.

The values in Table I and the curves fitted in Figs. 3–6 confirm this expectation. There does not seem to be any significant difference in the K_m^*, σ, or r values for the two models. The residual plots in Figs. 3–6 also seem to be very similar. Equation 31 (upper truncation) and Eq. 32 (lower truncation) also gave similar results (and, therefore, they have not been included).

Choice of Mathematical Model—In agreement with the general principles of mathematical modeling, Eq. 30 should be considered as the model that best describes the dissolution of the micronized glyburide. It is the simplest of the models, containing only the two parameters K_m^* and σ, and fits the dissolution data just as well as the other models that contain more parameters (i and j).

It also is clear (Table I) that the multiparticulate dissolution model based on the cube root model (Eq. 1, $m = 3$) agrees best with the dissolution data for either a truncated or ideal distribution using either 5 or 10 mg of powder (Table I). Of the eight multiparticulate models investigated, it can be concluded that the following equation:

$$\frac{dW}{dt} = -3K_3^* W_0 \sum_{n=0}^{2} \binom{2}{n} (-K_3^* t)^{(2-n)} \times \left\{1 - F\left[\frac{1}{\sigma}\ln(K_3^* t) - n\sigma\right]\right\} e^{(n^2-9)\sigma^2/2} \quad \text{(Eq. 40)}$$

which can be written in integrated form as:

$$\frac{W}{W_0} = \sum_{n=0}^{3} \binom{3}{n} (-K_3^* t)^{(3-n)} \times \left\{1 - F\left[\frac{1}{\sigma}\ln(K_3^* t) - n\sigma\right]\right\} e^{(n^2-9)\sigma^2/2} \quad \text{(Eq. 41)}$$

best describes the dissolution kinetics of the micronized glyburide. Either of these two equations uniquely characterizes the dissolution behavior in terms of the rate parameter, K_3^*, and the distribution parameter, σ.

It appears from the residual plots in Figs. 3–6 that there is a serial correlation between the residuals. The Durbin–Watson statistic indicates ($\alpha < 0.05$) that this correlation is significant (11). Systematic deviation can be caused by nonrandom experimental errors. It can also be caused by a significant departure from the assumed single-particle dissolution model (Eq. 1) or by a deviation from log-normality. The residual values are, however, so small in relation to the accuracy of the experimental technique that the correlation seems of little importance.

The specific dissolution rate parameter, K_3^*, theoretically should be independent of the initial amount used, W_0, but this condition was only approximately true. Values of the rate parameter, K_m^*, obtained for $W_0 = 10$ mg were consistently lower than for $W_0 = 5$ mg (Table I). The dissolution models consider dissolution under complete sink conditions, *i.e.*, conditions where there is no interaction between the dissolving particles. When using 10 mg of the very fine powder, it was not possible to load the dissolution cell with a single "layer" of particles in such a way that dissolved drug from any particle did not pass over other particles. The slightly larger K_m^* values observed when less powder was used in the cell agree with an expected smaller particle interaction.

Characterization and Quality Control of Drug Powders—Previous approaches to characterizing the dissolution properties of drug powders have been based on equations describing monodisperse systems. The so-called "dissolution rate constant" sometimes evaluated using such equations will often not characterize the dissolution behavior because the size distribution effect is not taken into account. This is particularly true for pharmaceutical systems, since these systems frequently involve fine, highly polydisperse powders.

The use of nonlinear regression analysis to evaluate the specific dissolution rate parameter, K_m^*, and the distribution parameter, σ, represents a more exact and meaningful approach.

The properties of K_m^* make its interpretation particularly useful. These properties are best understood in relation to the concepts of time scaling and the intrinsic dissolution profile (2) from which the following conclusion can be made:

If K_m^* is changed by a factor α, then the time for complete dissolution, or the time for any particular fraction to dissolve, is changed by a factor of $1/\alpha$[7].

The distribution parameter, σ, is a single measure of how polydisperse

[5] The initial data point(s) ($t = 0$ and 2.5 min) was not considered in the curve fitting because of irregularities due to initial adjustments of the solvent flow rate.

[6] The program is available on tape from the author together with a listing of the subroutines specifying the multiparticulate models (Eqs. 29–31).

[7] For example, if it takes x min for a powder to dissolve, *e.g.*, 30% for a given K_m^* value, then it will take the powder $x/2$ min to dissolve to the same extent if the value of K_m^* is doubled (see Fig. 1 in Ref. 2).

a powder is, or more exactly, how much the dissolution behavior deviates from what would be expected if the powder were completely monodisperse. A value close to zero characterizes a nearly monodisperse powder, while higher values indicate increasing "degrees of dispersion." Probably, the most important property of σ is that it is a measure of how long it takes the last fraction of a polydisperse powder to dissolve. For example, it is seen from Eq. 16 that the time for complete dissolution increases exponentially with σ. For this reason, a significant correlation probably exists between σ and systemic availability for very slightly soluble drugs that exhibit low systemic availability due to dissolution rate-limited absorption. Research in this area should be of considerable pharmaceutical interest.

Although the multiparticulate dissolution model (Eqs. 40 and 41) defining K_m^* and σ may seem complex, the interpretation of these parameters is simple and they can be readily obtained. The experimental technique used requires a high precision, flow-through dissolution apparatus that is easy to standardize [*e.g.*, the apparatus described in Ref. 5 or other suitable flow-through system (12)] in combination with a nonlinear regression program.

The method could well become established as a routine procedure in quality control, and further investigation could result in improved standards for drug dissolution.

Sensitive Assay Procedure for Ethambutol Hydrochloride *via* Charge Transfer Complex Formation

HENRY S. I. TAN ˣ, ERIC D. GERLACH, and ANTHONY S. DIMATTIO

Abstract □ The charge transfer complex formation between ethambutol and iodine was investigated and utilized as the basis for a sensitive spectrophotometric procedure for ethambutol and its dosage forms. The solutions exhibited blue-shifted iodine bands at 293 and 360 nm. A Job's plot of corrected absorbance against the mole ratio of ethambutol to iodine indicated a 1:2 drug–iodine ratio. At 293 nm, the absorbance was linear (r = 0.9998) over the 0.25–15-μg/ml concentration range, but the concentration range for best accuracy is 1.6–5.8 μg/ml. The method can be applied successfully to the analysis of commercially available ethambutol tablets.

Keyphrases □ Ethambutol—spectrophotometric analysis using charge transfer complex formation, prepared samples and commercial tablets □ Spectrophotometry—analysis using charge transfer complex formation, ethambutol in prepared samples and commercial tablets □ Charge transfer complex formation—spectrophotometric analysis of ethambutol in prepared samples and commercial tablets □ Antibacterials—ethambutol, spectrophotometric analysis using charge transfer complex formation, prepared samples and commercial tablets

Ethambutol is a new antitubercular drug included in USP XIX (1). Being a relatively new drug, few procedures have been reported for its determination as a drug substance or in commercial dosage forms. The official assay procedure involves a nonaqueous titration with perchloric acid titrant (1).

Quantitative analyses of small quantities of ethambutol have been based on the chelation properties of the drug with copper in aqueous or nonaqueous media (2, 3). A reineckate method and an acid–dye technique using bromthymol blue were also reported (4, 5). However, these procedures are not feasible for the analysis of microquantities of the drug in biological fluids.

Amines and alcohols are lone-pair (n) electron donors and can interact strongly with sacrificial electron acceptors such as iodine to form charge transfer complexes (6). Recently, a study on charge transfer complexes of iodine with alkaloids was reported (7). This paper reports the charge transfer complex formation of ethambutol with iodine and its application to drug assay.

EXPERIMENTAL

Apparatus—A UV–visible double-beam spectrophotometer[1] with 1-cm cells and dynode voltage of 500 v (slit width 0.80–0.85 mm) and an analytical balance[2] were used.

Materials and Reagents—Ethambutol hydrochloride[3] and 8×10^{-4} M iodine[4] (resublimed) in anhydrous chloroform[4] were used. Other reagents were analytical grade.

Ethambutol Base—Ethambutol hydrochloride (1 g) was dissolved

[3] Lederle Laboratories, Pearl River, N.Y.
[4] Fisher Scientific Co., Pittsburgh, Pa.

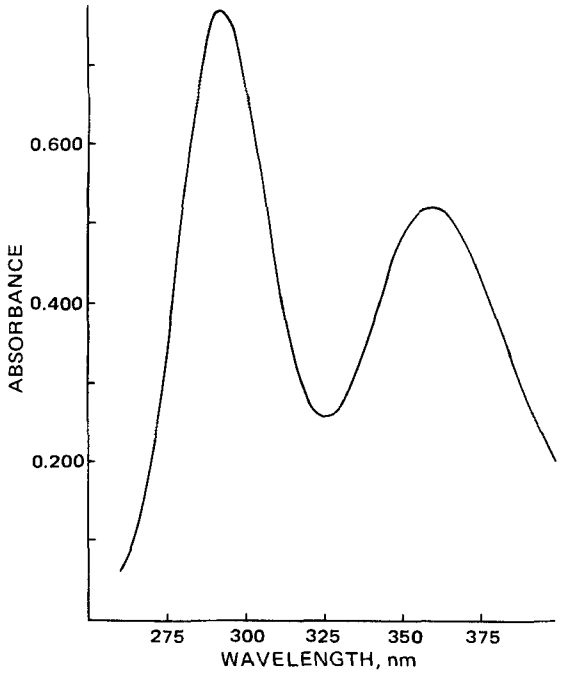

Figure 1—*Absorption spectrum of ethambutol–iodine complex.*

in 50 ml of aqueous sodium hydroxide solution (1:12) and extracted with five 30-ml portions of chloroform. The chloroform extracts were combined, dried with anhydrous sodium sulfate, and filtered, and the filtrate was evaporated to dryness under nitrogen. Recrystallization of the residue (yield 98.9%) from chloroform–hexane afforded white needles (mp 87–88°).

Standard Curve—A 25.0-mg portion of ethambutol base was weighed accurately and dissolved in 100.0 ml of anhydrous chloroform. Further dilutions were then made to prepare standard solutions containing 2.5–150 μg of ethambutol/ml. One milliliter of this solution was utilized for complex formation with the iodine reagent as described under *Assay Procedure for Ethambutol Hydrochloride,* beginning with: "Pipet 1.0 ml of this solution into a 10-ml volumetric flask . . . ."

Assay Procedure for Ethambutol Hydrochloride—*Powder*—Weigh accurately about 50.0 mg of ethambutol hydrochloride and transfer into a 60-ml separator. Dissolve the powder in 3 ml of sodium hydroxide solution (1:12) and extract with five 15-ml portions of anhydrous chloroform. Combine the chloroform extracts, dry them with anhydrous sodium sulfate (5 min), and filter through dry filter paper into a 100-ml volumetric flask. Rinse the sodium sulfate and filter with anhydrous chloroform, and use the washings to dilute the bulk solution to volume.

Measure 5.0 ml (buret or pipet) into a 50-ml volumetric flask and dilute to volume with anhydrous chloroform. Pipet 1.0 ml of this solution into a 10-ml volumetric flask, add 5.0 ml of iodine reagent, and dilute to volume with anhydrous chloroform. Allow the solution to stand in the dark for no less than 1 hr and measure the absorbance at 293 nm against a blank. Determine the concentration of ethambutol from the calibration curve or from the regression equation.

Tablets—Weigh and finely powder 20 ethambutol hydrochloride tablets. Transfer an accurately weighed portion of the powder, equivalent to about 50 mg of ethambutol hydrochloride, to a 60-ml separator. Then add 3 ml of sodium hydroxide solution (1:12) and proceed as described for the powder, beginning with: "extract with five 15-ml portions of anhydrous chloroform . . . ."

Stoichiometric Relationship—Master solutions of iodine (1.67×10^{-4} *M*) and ethambutol base (1.67×10^{-4} *M*) in anhydrous chloroform were prepared. A series of 10-ml quantities of mixtures containing a total of 10 ml of the master solution of ethambutol base and iodine in different complementary proportions (from 0:10 to 10:0 inclusive) were made up in 10-ml volumetric flasks. After the flasks were allowed to stand in a water bath at 25° for 60 min, absorbances were measured at 293 nm.

Association Constant and Molar Absorptivity—Ethambutol base solutions in anhydrous chloroform were prepared (1.5, 3.0, and 6.0×10^{-4} *M*), and these solutions and an iodine solution in anhydrous chloroform (8×10^{-5} *M*) were placed in a water bath at 25° for 30 min. Five milliliters of the iodine solution was mixed with the same volume of each ethambutol solution. After quick mixing, the absorbance of each solution was determined immediately at 293 nm.

Table I—Effect of Time on Absorbance of Ethambutol–Iodine Complex

Minutes after Mixing	Absorbance (293 nm)
0	0.823
10	0.930
20	0.923
30	0.917
40	0.908
50	0.896
60	0.881
70	0.880
80	0.879
90	0.880
120	0.878

RESULTS AND DISCUSSION

Charge transfer complex formation is distinguished from other slow oxidation or substitution reactions of iodine with amines by being practically instantaneous, analogous to ionic reactions. Upon reaction of ethambutol with a chloroform solution of iodine, the violet color of iodine is changed immediately to yellowish purple or yellow, depending on the amount of ethambutol present. Further confirmation of the charge transfer nature of the complex was obtained by extracting the drug from the complex by shaking with aqueous hydrochloric acid, whereby the violet color of iodine was restored in the chloroform layer. The regeneration of the drug from the charge transfer complex is easy, since the binding energy of charge transfer complexes is usually small; addition of a solvent of relatively high polarity causes complete decomposition (8).

Therefore, the chloroform used must be checked for its suitability. With some spectrograde samples of chloroform, no complex was formed, as evidenced by a lack of absorbance in the wavelength region studied. This result was due presumably to relatively high concentrations of water. Unfortunately, the water content levels in these spectrograde brands of chloroform were not furnished by the manufacturers. *Anhydrous* chloroform[4], which contains the same amount of ethanol preservative but a low water content of 0.02%, was suitable as a medium for the ethambutol–iodine complex formation.

The absorption spectrum of iodine in chloroform showed only one peak, with a maximum absorption at 515 nm. However, the charge transfer complex with ethambutol exhibited blue-shifted iodine bands at 293 and 360 nm, with the first peak being more intense than the second (Fig. 1). The absorption at these wavelengths is due solely to the complex because ethambutol itself is nonabsorbing.

Although the complex was formed rapidly, constant absorbance readings were obtained only after no less than 1 hr of standing in the dark (Table I). The readings remained constant for at least 1 additional hr.

At 293 nm, a linear relationship ($r = 0.9998$) was obtained between absorbance and concentration over the 0.25–15-μg/ml range. The regression equation[5] of the line was $A_{293} = 0.1648C - 0.0079$, where A_{293} is the absorbance at 293 nm, and C is the concentration of ethambutol base expressed in micrograms per milliliter. Conversion to the concentration (micrograms per milliliter) of ethambutol hydrochloride can be obtained by multiplying C by 1.357. The standard deviations ($n = 3$) of the slope and y-intercept were 4.1×10^{-3} and 5.5×10^{-3}, respectively.

The Ringbom plot (9) indicates that the concentration range for best accuracy is 1.6–5.8 μg of ethambutol base/ml in the final test solution (Fig. 2). Deviations from linearity in the Beer–Lambert plot result when the concentrations of donor and acceptor differ in magnitude (8, p. 171). For this reason, the concentration of iodine reagent was kept at the same order of magnitude as that of the ethambutol.

The determination of the mole ratio of reactants in the complex is based on the method of continuous variation (10). The plot (Fig. 3) shows a 1:2 molar ratio of ethambutol–iodine in the complex. No attempts were made to predict the orientation of the donor and acceptor moieties in the charge transfer complex.

In analogy to equations for the equilibria involved in a 1:1 charge

[5] Wang computer 700C and plotting output writer 2202.

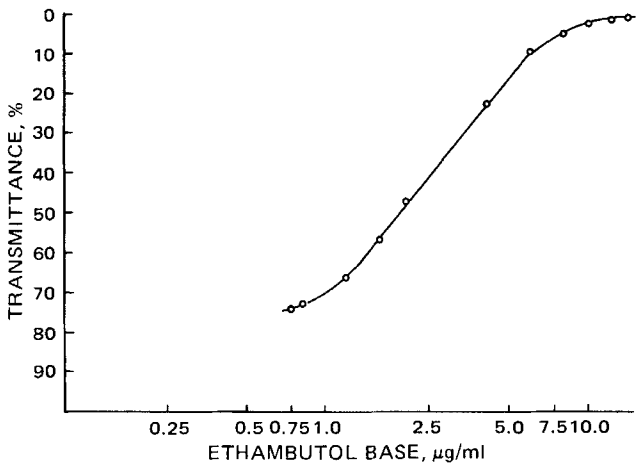

Figure 2—*Ringbom plot of ethambutol–iodine complex.*

transfer complex formation (8, 11, 12), it can be postulated that for a 1:2 ethambutol–iodine ratio the reaction for the equilibrium involved is shown in Scheme I:

$$E + 2I_2 \rightleftarrows E \cdot 2I_2$$

Scheme I

where E stands for ethambutol. Based on this equilibrium reaction, the association constant, K, for the complex $E \cdot 2I_2$ can be easily derived:

$$K = \frac{[E \cdot 2I_2]}{[E][I_2]^2} \qquad \text{(Eq. 1}a\text{)}$$

$$K = \frac{[E \cdot 2I_2]}{([E]_0 - [E \cdot 2I_2])([I]_0 - [E \cdot 2I_2])^2} \qquad \text{(Eq. 1}b\text{)}$$

where $[E]_0$ and $[I]_0$ indicate the total, *i.e.*, free and complexed, concentrations of ethambutol and iodine, respectively. Then:

$$\frac{1}{K} = \frac{[E]_0[I]_0^2}{[E \cdot 2I_2]} + [E \cdot 2I_2]([E]_0 + 2[I]_0) - [E \cdot 2I_2]^2 - [I]_0(2[E]_0 + [I]_0) \qquad \text{(Eq. 2)}$$

Since the absorbance, A, at 293 nm is due entirely to the complex, which obeys the Beer–Lambert law, in a 1-cm cell:

$$[E \cdot 2I_2] = \frac{A}{\epsilon} \qquad \text{(Eq. 3)}$$

where ϵ is the molar absorptivity of the complex. Substituting Eq. 3 into Eq. 2 yields:

$$\frac{1}{K} = \frac{[E]_0[I]_0^2\epsilon}{A} + \frac{A([E]_0 + 2[I]_0)}{\epsilon} - \frac{A^2}{\epsilon^2} - [I]_0(2[E]_0 + [I]_0) \qquad \text{(Eq. 4)}$$

Equation 4 contains two unknowns, K and ϵ. If two equations like Eq. 4 are set up, each representing different experimental trials (*i.e.*, $[E]_0$ and $[E]_0'$ and A and A'), an analytical solution can be derived specifically for ϵ. Because this expression was awkward to use, a graphical procedure was developed.

Evaluation of Eq. 4, which is a nonhomogeneous polynomial of the third order, by substituting random values of ϵ for a given set of experimental data generates corresponding values of K^{-1}. The values of K^{-1} and ϵ for *each* given set of experimental data are plotted. The intersect of the curves yields the association constant and molar absorptivity of the system. The results (Fig. 4) show that the association constant, K, for the ethambutol–iodine complex is $2.07 \pm 0.22 \times 10^8$ and that the molar absorptivity is $6.10 \pm 0.15 \times 10^3$.

The reproducibility of the procedure was determined by running 13 replicate samples, each containing 4.1 μg of ethambutol base/ml in the final test solution. At this concentration level, the relative standard deviation was 0.0112 (Table II).

Table III shows the accuracy of the proposed method. Recovery studies were performed on five different amounts of ethambutol hydrochloride,

GLC Determination of Lasalocid and Its Bromo Analog as Their Silyl Derivatives

GERALD MANIUS and V. VISWANATHAN [x]

Abstract □ A GLC method is presented for the determination of lasalocid and its bromo analog. The method is based on the quantitative trimethylsilylation of the compounds without any molecular cleavage, followed by chromatography on a nonpolar silicone column. Silylation was carried out directly without any extraction or prior cleanup, despite the complexity of the dosage forms. This procedure was used for the assay of pure substances, pellets, premixes, experimental ampul solutions, and mycelial filter cakes. The results were in good agreement with data obtained by microbiological procedures.

Keyphrases □ Lasalocid and bromo analog—GLC analysis, various preparations and dosage forms □ GLC—analysis, lasalocid and bromo analog, various preparations and dosage forms □ Coccidiostatic antibacterials—lasalocid and bromo analog, GLC analysis, various preparations and dosage forms

The isolation of lasalocid (I), an antibiotic, was reported by Berger *et al.* (1). The structural configuration and the existence of four homologs for this antibiotic were described subsequently (2–4). Recently, a microbiological cylinder-plate assay (5) and a spectrofluorometric procedure for the determination of lasalocid in premixes (6) were reported. A GLC procedure also was reported in which the antibiotic was assayed after thermal degradation to yield the retroaldol ketone (7).

The bioassay procedure is a good indicator of the mi-

GLC Determination of Lasalocid and Its Bromo Analog as Their Silyl Derivatives

GERALD MANIUS and V. VISWANATHAN [x]

Abstract □ A GLC method is presented for the determination of lasalocid and its bromo analog. The method is based on the quantitative trimethylsilylation of the compounds without any molecular cleavage, followed by chromatography on a nonpolar silicone column. Silylation was carried out directly without any extraction or prior cleanup, despite the complexity of the dosage forms. This procedure was used for the assay of pure substances, pellets, premixes, experimental ampul solutions, and mycelial filter cakes. The results were in good agreement with data obtained by microbiological procedures.

Keyphrases □ Lasalocid and bromo analog—GLC analysis, various preparations and dosage forms □ GLC—analysis, lasalocid and bromo analog, various preparations and dosage forms □ Coccidiostatic antibacterials—lasalocid and bromo analog, GLC analysis, various preparations and dosage forms

The isolation of lasalocid (I), an antibiotic, was reported by Berger *et al.* (1). The structural configuration and the existence of four homologs for this antibiotic were described subsequently (2–4). Recently, a microbiological cylinder-plate assay (5) and a spectrofluorometric procedure for the determination of lasalocid in premixes (6) were reported. A GLC procedure also was reported in which the antibiotic was assayed after thermal degradation to yield the retroaldol ketone (7).

The bioassay procedure is a good indicator of the mi-

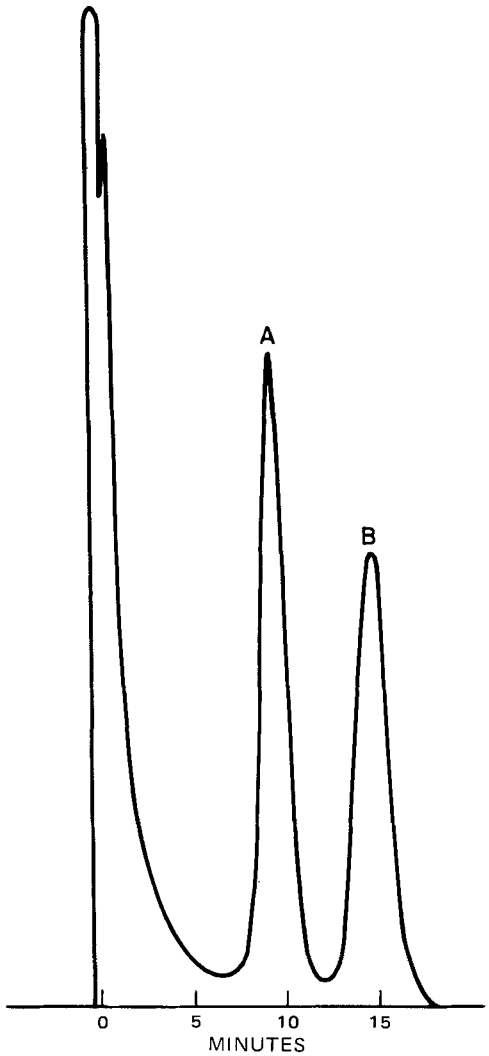

Figure 1—*Chromatogram of I (A) and II (B) trimethylsilyl derivatives.*

crobiological activity of the antibiotic. However, it is generally subject to interference from other antibiotics or biologically active degradation products and is very time consuming. Chemical methods such as the spectrofluorometric procedure require extraction and cleanup of the samples prior to analysis. GLC of the thermolysis product of lasalocid was reported to be quantitative; however, the degradation product of the antibiotic was assayed rather than the intact compound to establish sample purity. In most analytical applications, this approach is considered unsatisfactory, particularly for the assay of finished products for clinical use.

During this investigation, emphasis was placed on developing a specific assay procedure for the antibiotic in various dosage forms within a reasonably short time and with minimal sample preparation. Chromatographing the intact molecule in the form of a stable derivative appeared suitable, since this method would offer several advantages such as specificity for the antibiotic and the ability to resolve and quantitate the active ingredient in the presence of decomposition products and substances that interfere in other methods. In addition, a suitable derivative of the antibiotic would lend itself easily to confirmatory tests such as mass spectrometry when the intact antibiotic must be detected in complex media. Trimethylsilylation of the

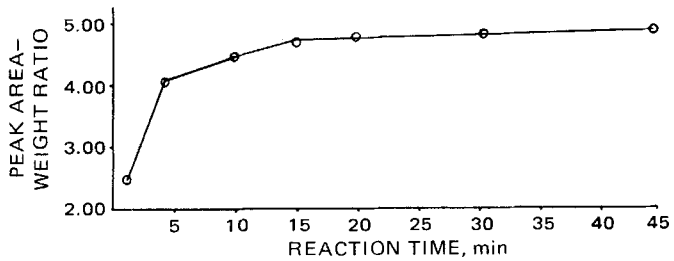

Figure 2—*Completeness of silylation reaction.*

carboxyl and secondary alcohol functions of the antibiotic was chosen, since this approach was used successfully for the assay of other antibiotics such as chloramphenicol, penicillin, erythromycin, neomycin, and lincomycin (8–14).

EXPERIMENTAL

Apparatus—A gas chromatograph equipped with a hydrogen flame-ionization detector was used. The chromatographic column was type 304 stainless steel, 61 cm in length and 3.2 mm o.d., fitted for on-column injections. The packing was 3% methyl silicone fluid on acid-washed, silane-treated diatomite support, which was sieved to specification before and after liquid phase coating. Data acquisition and quantitation were carried out using a computer system. All injections were made using a 10-μl syringe.

Reagents—*N,O*-Bis(trimethylsilyl)acetamide, *N*-trimethylsilylimidazole, trimethylchlorosilane, and tetrahydrofuran (reagent grade) were used as received. For the silylation reaction, a 3:3:2 (v/v) mixture of *N,O*-bis(trimethylsilyl)acetamide, *N*-trimethylsilylimidazole, and trimethylchlorosilane was made. To protect the stability of the reagent, mixtures were prepared fresh in small quantities and stored in tightly sealed containers under refrigeration.

Operational Parameters—For the chromatography of lasalocid and its bromo analog (II), the temperatures were: column, 260°, isothermal; injector port, 260°; and detector, 290°. The flow rate for the nitrogen carrier gas was 30 ml/min; the flow rates of hydrogen and air to the detector were set at 30 and 300 ml/min, respectively. The injection volume was 5 μl, and the attenuation was nominally set at 64× at a range setting of 10^{-11} amp/mv. Under these conditions, the trimethylsilyl derivatives of I and II eluted at retention times of 10 and 15 min, respectively.

Preparation of Solutions for Assay—*Reference Standard*—Approximately 20 mg of I or II reference material was accurately weighed into a 10-ml volumetric flask. One milliliter of the silylating reagent mixture was added, and the flask was capped and allowed to stand at ambient temperature for a minimum of 30 min. After the reaction was completed, the solution was diluted to 10 ml with tetrahydrofuran.

Sample Solutions—Pure substances were prepared in the same manner as the reference standard preparation. For premix pellets, final premixes, or mycelial cake materials, samples equivalent to approximately 20 mg of active ingredient were weighed into a 10-ml volumetric flask, silylated for 30 min or longer, and diluted as described. Small, accurately measured quantities of experimental ampul solutions equivalent to 2.0 mg of I were transferred into small vials, 2–3 drops of anhydrous methanol were added, and the mixture was evaporated to dryness under mild heat with a stream of nitrogen and reacted with exactly 1.0 ml of silylating reagent prior to chromatography.

Precautions were taken to exclude excessive heat, moisture, and metallic contact during the standard and sample preparations.

Ia

Prior to analyzing the samples, the chromatographic column was conditioned by making several 5.0-μl injections of appropriate reference standard solution until a constant response was obtained. The calculations were carried out in a conventional manner using standard and sample peak areas.

RESULTS AND DISCUSSION

Chemical Stability—High temperature causes cleavage of I at an apparent weak point (Ia) due to hydrogen bonding stress between the hydroxyl and carbonyl groups. Westley *et al.* (7) utilized this thermal degradation as the basis of a GLC assay wherein the retroaldol ketone formed during the degradation was assayed rather than the intact antibiotic.

Even though these authors utilized an injector port at 300° as an "on-site" pyrolytic chamber, experiments indicated that I in solutions would degrade with relative ease at a much lower temperature range. Due to the inherent nature of the compound to undergo cleavage at high temperatures, derivatization methods to chromatograph the intact molecule had to be carried out under ambient conditions. Attempts to silylate the compound at elevated temperatures did indeed result in multiple peaks, indicating degradation.

Silylation—*N,O*-Bis(trimethylsilyl)acetamide silylated the free acid to some extent at ambient temperatures but had no effect on the sodium salt of lasalocid (III). The addition of trimethylchlorosilane had the twofold effect of freeing I from its sodium chelate by acting as a Lewis acid and catalyzing the formation of more silylated derivative. This reagent combination, however, required 12 hr or longer to produce a quantitatively silylated product. The resulting derivative was unstable on standing (indicated by shoulder peaks), particularly after dilution with solvent, probably due to dissociation of the trimethylsilyl group from hindered sites.

The addition of the third ingredient, *N*-trimethylsilylimidazole, enhanced the reaction considerably. This reagent has the distinct advantage

Sample	GLC Method, %	Alternative Method, %
I free acid	91.9	92.0[a]
I free acid	95.6	94.5[a]
II free acid	98.9	99.0[a]
III	89.8	88.8[b]
III	91.5	89.5[b]
III	90.8	89.5[b]

[a] Titration. [b] Microbiological.

of silylating the hindered hydroxyl groups due to its superior ability to accommodate a negative charge in the transition state (15). It also may act as a synergistic catalyst in the presence of trimethylchlorosilane to enhance the silylation of all active sites. The quantities of excess reagent present in sample solutions effectively prevented any dissociation of trimethylsilyl groups. The prepared solutions were stable during chromatography, as indicated by reproducible, well-resolved peaks for I and II derivatives (Fig. 1).

A time study was carried out on the silylation reaction at ambient temperature, and derivative formation reached equilibrium in about 30 min (Fig. 2). A time range of 30–45 min was satisfactory for the silylation of I in dosage forms. Due to the very reactive nature of the reagent mixture, contact with metallic surfaces such as aluminum cap liners was avoided throughout the study. Excess moisture in samples also was removed with mild heat and nitrogen prior to silylation to prevent an exothermic reaction with the reagent. Samples of I derivatives were subjected to GLC–mass spectrometric analysis, and the results confirmed the anticipated trimethylsilyl substitution of all carboxyl and alcohol functions, with the molecular ion observed at *m/e* 878.

Detector Response—The response of the flame-ionization detector to I and II derivatives was linear over a wide range. The II derivative was also chromatographed using scandium electron-capture detection, and the minimum detectable level was approximately 30 ng *versus* 300 ng for hydrogen flame-ionization detection.

An ideal internal standard could not be found, mainly due to solubility and elution characteristics associated with high molecular weight compounds. The external standard method used in the study yielded reproducible results.

Assay Results—A statistical analysis was carried out on the assay of III; the relative standard deviation was ±1.4%, significantly better than what is generally feasible in any microbiological assay method (Table I). Several samples of I and II pure substances also were assayed by this method, and the results were in good agreement with data obtained using other analytical techniques (Table II).

The procedure was used for the simultaneous assay of meglumine and active ingredients in I and II complexes with meglumine. The results were useful in establishing the molar concentrations of each component, depending upon the purity of materials used. However, the results could not be compared to other methods, since available chemical methodology was not reproducible for the assay of both chemical moieties of the complex (Table III). Other complex dosage forms such as ampuls (containing propylene glycol, preservative, and water), pellets, and feed premixes also were assayed with no special sample preparation. The chromatographic peak was free from interference, and the results are listed in Table IV.

All reported results are averages of duplicate determinations.

Specificity—During the assay of meglumine complexes, the chromatographic run was carried out at an initial column temperature of 160° for the elution of the meglumine trimethylsilyl derivative peak. Subse-

Table III—Assay of Experimental I and II Complexes with Meglumine

Sample	Percent Active by GLC	Percent Theory	Meglumine Percent by GLC	Meglumine Percent Theory[a]
I–monomeglumine	75.3	78	20.3	22

I–dimeglumine	52.1	62	36.3	38
II–dimeglumine	64.8	65	35.6	35
II–dimeglumine	61.4	65	38.6	35

[a] Percent theory was calculated using molar ratios. Variations from the theoretical results were due to the presence of residual crystallization solvents, excess meglumine, and technical grade drug in the complexes.

Table IV—Assay of I in Other Matrixes

Sample	GLC Assay	Theoretical
Ampul solution 1	16.2 mg/2 ml[a]	20 mg/2 ml
Ampul solution 2	18.4 mg/2 ml[a]	20 mg/2 ml
Ampul solution 3	21.2 mg/2 ml	20 mg/2 ml
Premix pellets	2.53%	2.5%
Premix 1	14.8%	15.0%
Premix 2	16.1%	17.3%
Premix 3	16.4%	16.5%
Premix 4	16.2%	17.3%
Mycelial cake 1	6.3%	NA[b]
Mycelial cake 2	6.5%	NA
Mycelial cake 3	5.0%	NA
Mycelial cake 4[c] 1.1% excess	7.6%	7.4

[a] Decomposition of I in solution was indicated by the presence of an unknown GLC peak. [b] NA = not available. [c] Sample 1 to which had been added 1.1% of active ingredient to get an indication of recovery.

quently, the column temperature was raised to 260° to elute the I or II derivative peaks.

If any retroaldol ketone (known thermal degradation product) is present in the samples, it also would be silylated, resulting in a well-resolved peak suitable for quantitation. Samples of I and II complexes with meglumine were experimentally spiked with known amounts of retroaldol ketone and chromatographed after silylation. When the column temperature was programmed from 100 to 300°, trimethylsilyl derivatives of retroaldol ketone, meglumine, I, and II eluted at retention times of 7.5, 15, 30, and 35 min, respectively, clearly indicating the specificity and capability of the method for the assay of the antibiotic in multicomponent systems.

Furthermore, the I derivative peak area was approximately twice that of the retroaldol ketone when equal concentrations of I were subjected to the GLC–thermolysis method and the silylation procedure. This enhancement in peak response would be an added advantage in the analysis of low levels of I as a trimethylsilyl derivative.

The method presented has been applied to the assay of I in various solid and liquid preparations. It is specific for the antibiotic and does not require any extraction or pretreatment of the samples as in other reported methods.

New Synthesis of 1,4,2-Dioxazoles and Their Pharmacological Properties

NED D. HEINDEL[*x], WILLIAM P. FIVES[*], and RICHARD A. CARRANO[‡§]

Abstract □ A series of 3-substituted 5-methoxycarbonyl-5-methoxycarbonylmethyl-1,4,2-dioxazoles was prepared by addition of hydroxamic acids to acetylene esters. Eleven of these previously unknown compounds were submitted to general pharmacological screening, and several displayed modest CNS depressant activity.

Keyphrases □ 1,4,2-Dioxazoles, substituted—synthesis, general pharmacological screening □ CNS activity—substituted 1,4,2-dioxazoles screened □ Structure-activity relationships—substituted 1,4,2-dioxazoles, general pharmacological screening

Most reported 1,4,2-dioxazoles are derived from the condensation of hydroxamic acids with phosgene (1, 2) or diethylacetals (3). Newer routes include a 1,3-dipolar addition method involving ketones and nitrile oxides (4) and a ring expansion of 2-acyloxaziridines (5). Except for some claims of antifungal activity in the 5-oxo derivatives (6) and of antibacterial potency in 5-benzenesulfonamido-substituted 1,4,2-dioxazoles (7), the possible pharmacological utility of this family of heterocyclics is still unknown.

CHEMISTRY

Reports from these laboratories noted the general utility of acetylenic esters in the synthesis of heterocyclic compounds generated by double nucleophilic additions to the same alkyne carbon (8, 9). In a similar fashion, hydroxamic acids, presumably in their enol tautomers (I) (10), reacted with dimethyl acetylenedicarboxylate (II*a*) and/or methyl propiolate (II*b*) (Schemes I and II) to produce high yields of 3-substituted 5-methoxycarbonyl-5-methoxycarbonylmethyl-1,4,2-dioxazoles (III*a*–III*j* and IV, Table I). In view of the paucity of information available on this heterocyclic family and the unique nature of this particular subclass, the general biological responses are now reported.

Available spectral evidence supported the assigned dioxazole structure.

Table IV—Assay of I in Other Matrixes

Sample	GLC Assay	Theoretical
Ampul solution 1	16.2 mg/2 ml[a]	20 mg/2 ml
Ampul solution 2	18.4 mg/2 ml[a]	20 mg/2 ml
Ampul solution 3	21.2 mg/2 ml	20 mg/2 ml
Premix pellets	2.53%	2.5%
Premix 1	14.8%	15.0%
Premix 2	16.1%	17.3%
Premix 3	16.4%	16.5%
Premix 4	16.2%	17.3%
Mycelial cake 1	6.3%	NA[b]
Mycelial cake 2	6.5%	NA
Mycelial cake 3	5.0%	NA
Mycelial cake 4[c] 1.1% excess	7.6%	7.4

[a] Decomposition of I in solution was indicated by the presence of an unknown GLC peak. [b] NA = not available. [c] Sample 1 to which had been added 1.1% of active ingredient to get an indication of recovery.

quently, the column temperature was raised to 260° to elute the I or II derivative peaks.

If any retroaldol ketone (known thermal degradation product) is present in the samples, it also would be silylated, resulting in a well-resolved peak suitable for quantitation. Samples of I and II complexes with meglumine were experimentally spiked with known amounts of retroaldol ketone and chromatographed after silylation. When the column temperature was programmed from 100 to 300°, trimethylsilyl derivatives of retroaldol ketone, meglumine, I, and II eluted at retention times of 7.5, 15, 30, and 35 min, respectively, clearly indicating the specificity and capability of the method for the assay of the antibiotic in multicomponent systems.

Furthermore, the I derivative peak area was approximately twice that of the retroaldol ketone when equal concentrations of I were subjected to the GLC–thermolysis method and the silylation procedure. This enhancement in peak response would be an added advantage in the analysis of low levels of I as a trimethylsilyl derivative.

The method presented has been applied to the assay of I in various solid and liquid preparations. It is specific for the antibiotic and does not require any extraction or pretreatment of the samples as in other reported methods.

New Synthesis of 1,4,2-Dioxazoles and Their Pharmacological Properties

NED D. HEINDEL[*x], WILLIAM P. FIVES[*], and RICHARD A. CARRANO[‡§]

Abstract □ A series of 3-substituted 5-methoxycarbonyl-5-methoxycarbonylmethyl-1,4,2-dioxazoles was prepared by addition of hydroxamic acids to acetylene esters. Eleven of these previously unknown compounds were submitted to general pharmacological screening, and several displayed modest CNS depressant activity.

Keyphrases □ 1,4,2-Dioxazoles, substituted—synthesis, general pharmacological screening □ CNS activity—substituted 1,4,2-dioxazoles screened □ Structure-activity relationships—substituted 1,4,2-dioxazoles, general pharmacological screening

Most reported 1,4,2-dioxazoles are derived from the condensation of hydroxamic acids with phosgene (1, 2) or diethylacetals (3). Newer routes include a 1,3-dipolar addition method involving ketones and nitrile oxides (4) and a ring expansion of 2-acyloxaziridines (5). Except for some claims of antifungal activity in the 5-oxo derivatives (6) and of antibacterial potency in 5-benzenesulfonamido-substituted 1,4,2-dioxazoles (7), the possible pharmacological utility of this family of heterocyclics is still unknown.

CHEMISTRY

Reports from these laboratories noted the general utility of acetylenic esters in the synthesis of heterocyclic compounds generated by double nucleophilic additions to the same alkyne carbon (8, 9). In a similar fashion, hydroxamic acids, presumably in their enol tautomers (I) (10), reacted with dimethyl acetylenedicarboxylate (II*a*) and/or methyl propiolate (II*b*) (Schemes I and II) to produce high yields of 3-substituted 5-methoxycarbonyl-5-methoxycarbonylmethyl-1,4,2-dioxazoles (III*a*–III*j* and IV, Table I). In view of the paucity of information available on this heterocyclic family and the unique nature of this particular subclass, the general biological responses are now reported.

Available spectral evidence supported the assigned dioxazole structure.

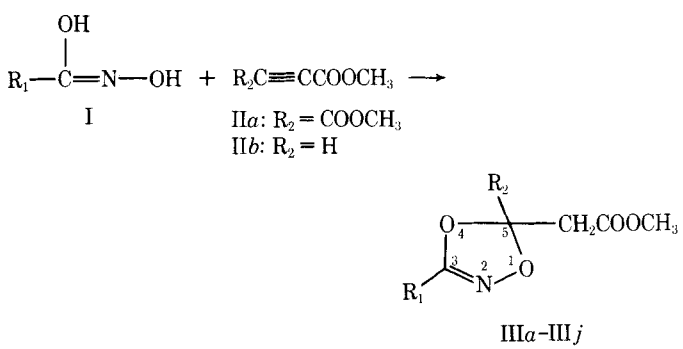
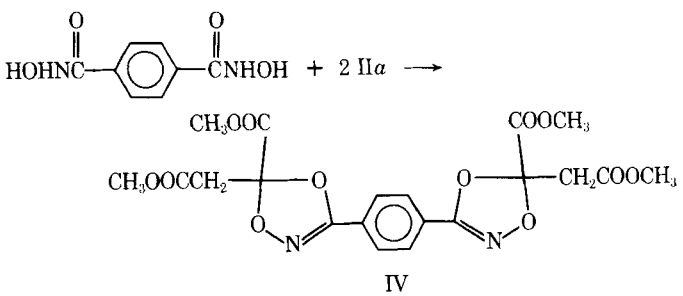
In the IR spectrum, all NH and OH absorptions of the starting hydroxamic acid disappeared and the saturated ester carbonyls appeared between 1732 and 1752 cm^{-1}. The PMR spectrum revealed the ester methoxys between δ 3.65 and 3.86 ppm and, more significantly, the pendent methylene group by its characteristic geminally coupled *AB* quartet (J = 17 Hz) at δ 3.20 ± 0.20 ppm. This appearance of magnetically nonequivalent methylene protons adjacent to an asymmetric center is well known (11). Furthermore, the mass spectra of all 1,4,2-dioxazoles derived from dimethyl acetylenedicarboxylate showed the expected parent ion and fragments at P − 73 (loss of CH_2COOCH_3) and P − 59 (loss of $COOCH_3$), clearly indicating the nature of the two ester moieties attached at C-5 of the 1,4,2-dioxazoles.



Scheme I



Scheme II

In accord with numerous citations in the patent literature claiming pyrolysis of 1,4,2-dioxazoles as a route to isocyanates (12, 13), distillation of the prepared liquid dioxazoles often produced a fraction containing the corresponding isocyanate (absorption at 2250 ± 15 cm^{-1}). Two dioxazoles (III*d* and III*h*) suffered such extensive thermal decomposition on refluxing that they could not be distilled. For these two particular materials, an extraction purification procedure was developed which yielded analytically pure product. This technique was also applicable to most other liquid dioxazoles.

Table I reports boiling points for the substances that could be vacuum distilled and refractive indexes for the dioxazoles purified by the extraction method. If an analytically pure product could be obtained by either route, then both boiling points and refractive index values are cited.

PHARMACOLOGY

General Rat Screening—All compounds were tested and the results were analyzed according to the methods described by Malone and Carrano (14) and employed previously (15). Nonfasted albino rats, 180–210 g, were used; injections were made intraperitoneally.

General Central Nervous System (CNS) Testing in Mice—Motor function and neurotoxicity were tested at 200 mg/kg ip by measuring the inability of trained animals to walk a rotating wooden rod (28 mm diameter at 6 rpm) for 1 min. Six 18–22-g nonfasted albino mice were used per group; dosing was done intraperitoneally. The animals were tested at 0, 15, 30, 60, 90, 120, 150, and 180 min postinjection.

If there was no neurotoxicity at 200 mg/kg ip, then that dose was used for subsequent work in the antistrychnine, antipentylenetetrazol, antielectroshock, and antioxotremorine tests. In these tests, the experimental drug was injected intraperitoneally into groups of six 18–22-g nonfasted albino mice; at 30 min postinjection, strychnine sulfate (1.1 mg/kg sc), pentylenetetrazol (70 mg/kg sc), oxotremorine (350 μg/kg sc), or a 50-amp, 0.2-sec shock was administered to each animal. The animals were observed for 30 min for tonic extensor seizures in the antistrychnine test and for clonic seizures in the antipentylenetetrazol test. In the antielectroshock test, they were observed for hindlimb tonic extensor seizures. In the antioxotremorine test, tremors were subjectively rated per

animal on a scale of 0–3 and the total response for the entire group was calculated and compared to that of a control group.

In each test, a group of animals receiving 0.9% NaCl (5 ml/kg) was run simultaneously with the experimental groups. In the acetylcholine writhing test, mice were injected orally with the experimental agent; 30 min later, they were challenged with 7.0 mg/kg ip of acetylcholine bromide. The number of animals in the experimental group that elicited a writhing response within 2 min was compared to a control group receiving 0.9% NaCl.

Selected drugs were tested for their ability to inhibit aggression induced in pairs of mice by subjecting them to an interrupted direct current foot shock of 0.8 mamp for 2 min.

Acute Anti-Inflammatory–Analgesic Testing—Nonfasted albino rats, 160–180 g, equally divided between sexes were used. The experimental drugs were administered orally. A modified Randall–Selitto (16) method was used; immediately following administration of the drug, 0.1 ml of a 1% carrageenan suspension was injected into the subplantar area of the right hindpaw, and the control foot volume was recorded by volume displacement. The control analgesic response was then estimated by placing the injected paw between two grooved disks, which were slowly forced together *via* air pressure. The amount of pressure required to cause the animal to vocalize or attempt to bite the disks was recorded. The analgesic response was again estimated at 45 min postinjection, and foot volume was measured at 4 hr postinjection. A control group that received 0.9% NaCl in place of the experimental drug was tested simultaneously.

RESULTS AND DISCUSSION

Table II lists the important observations in the general rat screening. The maximum sublethal dose is the highest dose administered at which no death occurred. Since no doses were made over 1.0 g/kg, the maximum sublethal dose was assumed to be greater than 1.0 g/kg in cases where there was no death at this dosage.

Also presented in Table II are scores that represent the extent of general autonomic nervous system (ANS) and general CNS depressant (CNSD) activity. The absolute values of these ANS and CNSD scores are not comparable. The significant symptomatology of the candidate dioxazoles is given. These data were subjected to a computer-matching operation against a library of 27 reference drugs. The symptomatology and ANS/CNSD scores for the drugs selected for comparison were reported previously (15).

Compounds III*a*, III*g*, and IV produced significant CNS depression in rats. The symptomatology exhibited by these drugs suggests that they have activity similar to tranquilizers, muscle relaxants, anticonvulsants, and other CNS depressants. On the basis of computerized matching, III*g* showed a particular similarity to chlorpromazine and chlordiazepoxide. Apparently, only the dioxazoles with phenyl moieties (lacking polar substituents such as methoxy, nitro, and bromo) attached directly to the hetero ring or in the α-position (*i.e.*, III*g*) displayed the depressant activity. The two pendent ester groupings are apparently necessary, since III*a* was one of the most active compounds tested while III*j* gave evidence of only very modest activity. On the basis of the primary rat screening, III*a*, III*g*, and IV were submitted for further evaluation in the CNS battery. The percent protection at the rotarod ED_{50} was evaluated.

Here again the benzyl derivative, III*g*, displayed the highest percentage protection (36%) against shock-induced aggression and did exhibit some antioxotremorine activity (14%). All compounds were tested at a considerably more elevated dose, 200 mg/kg ip, than the comparison drugs, and none was judged sufficiently active to warrant further study. Chlordiazepoxide hydrochloride, for example, at a dose of 32 mg/kg ip, provides 100% protection against shock-induced aggression and 75% protection in the antioxotremorine assay.

Some protection against acetylcholine writhing was observed with III*a* and IV, 33% in both cases, but they were rejected for advanced studies because of the elevated doses required (300 mg/kg po) and the lack of significant anti-inflammatory–analgesic activity in the Randall–Selitto assay (16).

Since both III*i* and III*j* displayed significant scores in the autonomic category of the general rat screen (Table II), they were selected for cardiovascular measurements in the anesthetized cat. Both compounds produced moderate to extreme transient falls in blood pressure at 1–25 mg/kg iv. Heart rate was not affected dramatically. Both drugs produced some potentiation of the responses to norepinephrine, a decrease in the pulse pressure response to isoproterenol, and an inhibition of the response to 1,1-dimethyl-4-phenylpiperazinium iodide. However, none of these actions was considered significant enough to merit further investigation.

Table II—*In Vivo* Rat Screening Data for 1,4,2-Dioxazoles

Compound[a]	ANS Score	CNSD Score	Significant Symptomatology
III*a*	0.53	4.78	Decreased body tone, body weight
III*b*	0	0	None
III*c*	2.01	1.23	Miosis, piloerection
III*d*	1.48	2.16	Miosis, piloerection, decreased body tone
III*e*	1.27	0	Miosis, piloerection, decreased body weight, fearfulness
III*g*[b]	1.06	11.88	Decreased motor activity, ataxia, decreased respiratory rate, piloerection, decreased rotarod ability, decreased body tone
III*i*	4.87	0.62	Miosis, decreased body weight
III*f*	0.74	2.93	Decreased motor activity, piloerection, increased body tone
III*j*	4.97	0.77	Miosis
IV	3.70	10.49	Decreased motor activity, ataxia, miosis, piloerection, decreased body weight, decreased body tone, decreased rotarod ability
III*h*	0.42	1.08	Decreased body weight

[a] The maximum sublethal dose was greater than 1000 mg/kg ip. [b] Similar to chlordiazepoxide and chlorpromazine.

In general, these 1,4,2-dioxazoles were water-insoluble viscous liquids that were difficult to manipulate and administer in the animal studies. Gross necropsy of rats at 48 hr after intraperitoneal injection revealed the presence of some unabsorbed drug in the peritoneal cavity.

EXPERIMENTAL[1]

Hydroxamic Acids—The required hydroxamic acids were either commercially available or prepared from the corresponding ester and hydroxylamine according to published procedures (17–22).

Compounds III*a*–III*i*—An equimolar mixture of the required hydroxamic acid and dimethyl acetylenedicarboxylate was prepared in anhydrous methanol at a concentration of 100 mmoles/100 ml of solvent. The solution was refluxed for 30–60 min and then allowed to stir at room temperature for 24 hr. Concentration *in vacuo* produced an oil, which solidified in the case of III*b* (recrystallized from methanol, mp 50–51°, 90%) but remained liquid in the other examples. Purification was effected by either fractional vacuum distillation or by the following solvent extraction procedure.

The oily dioxazole was dissolved in a minimum of carbon tetrachloride and washed four times with 50-ml portions of cold distilled water. The carbon tetrachloride layer was dried with magnesium sulfate and evaporated under vacuum with minimal heating to yield the product as a clear oil. Refractive indexes (n_D^{21}), yields, and analytical data are given in Table I for those dioxazoles purified by this method. If no refractive index is given, the purification was by vacuum distillation.

Compound III*j*—A solution of 73.0 mmoles of benzohydroxamic acid and methyl propiolate in 75 ml of methanol was heated at reflux for 24 hr, evaporated *in vacuo*, and purified by the solvent extraction procedure to return a 76% yield. The oil could also be vacuum distilled.

Compound IV—A methanol solution of 51.0 mmoles of terephthalohydroxamic acid, 102 mmoles of dimethyl acetylenedicarboxylate, and 200 ml of methanol was stirred at room temperature for 48 hr, during which time a white precipitate appeared. The reaction mixture was filtered, concentrated, and chilled to produce an additional crystal crop; the crude product was recrystallized from methanol to afford 14.2 g (58%) of white microneedles, mp 112–114° (Table I).

[1]Melting points were determined with a Fisher-Johns apparatus and are not corrected. IR spectra were obtained as hydrocarbon mulls or neat on a Perkin-Elmer model 257 spectrophotometer. PMR spectra were determined on a Hitachi Perkin-Elmer model R20A spectrometer in deuterochloroform, using tetramethylsilane as the internal reference.

Plasma Isosorbide Dinitrate Concentrations in Human Subjects after Administration of Standard and Sustained-Release Formulations

D. F. ASSINDER, L. F. CHASSEAUD[x], and T. TAYLOR

Abstract □ After sublingual administration of 5 mg of isosorbide dinitrate, mean plasma concentrations (± *SD*) peaked (8.9 ± 3.1 ng/ml) at 15 min after dosing and declined with a half-life of 30 min. After oral administration of 5 mg, mean concentrations peaked (3.1 ± 0.7 ng/ml) at 30 min and declined with a half-life of 40 min. After oral administration of 20 mg in a sustained-release tablet, mean concentrations initially peaked (1.4 ± 1.2 ng/ml) at 40 min, declining to 0.9 ± 0.5 ng/ml after 8 hr. Mean concentrations were maintained above half the mean peak level during 10 hr. Because of probable rapid first-pass metabolism, the bioavailability of isosorbide dinitrate after administration of the oral dose of the standard tablet was 58% of that from the sublingual dose, and the bioavailability from the sustained-release tablet was 47% of that from the sublingual dose of the standard tablet. The time course of mean plasma concentration data could be described by a one-compartment model; but a more complex model, taking the pass effect into account, probably is needed for a better description of the pharmacokinetics of isosorbide dinitrate.

Keyphrases □ Isosorbide dinitrate—pharmacokinetics, oral and sublingual administration compared, standard and sustained-release tablets compared, humans □ Pharmacokinetics—isosorbide dinitrate, oral and sublingual administration compared, standard and sustained-release tablets compared, humans □ Vasodilators—isosorbide dinitrate, pharmacokinetics, oral and sublingual administration compared, standard and sustained-release tablets compared, humans

The vasodilator isosorbide dinitrate has been in use for many years (1–9), but little has been reported regarding its pharmacokinetics in humans because, in part, of the difficulty in measuring small amounts of the drug in blood. Using a GLC method (10), peak plasma concentrations ranging between 10.5 and 34.5 ng/ml in different subjects were measured at 6 min following a 1.25-mg sublingual dose of isosorbide dinitrate. More detailed studies involving the oral administration of 5.4 mg of ^{14}C-isosorbide dinitrate (11) showed that peak levels of unchanged drug of about 5 ng/ml could be expected (12). However, higher concentrations of the respective mononitrate metabolites were present (12).

Isosorbide dinitrate and other organic nitrates are rapidly metabolized by the glutathione *S*-transferases (13, 14). From studies in animals, Needleman *et al.* (15) concluded that after oral administration of any one of the various organic nitrates, such as isosorbide dinitrate, essentially

Plasma Isosorbide Dinitrate Concentrations in Human Subjects after Administration of Standard and Sustained-Release Formulations

D. F. ASSINDER, L. F. CHASSEAUD[x], and T. TAYLOR

Abstract □ After sublingual administration of 5 mg of isosorbide dinitrate, mean plasma concentrations (± *SD*) peaked (8.9 ± 3.1 ng/ml) at 15 min after dosing and declined with a half-life of 30 min. After oral administration of 5 mg, mean concentrations peaked (3.1 ± 0.7 ng/ml) at 30 min and declined with a half-life of 40 min. After oral administration of 20 mg in a sustained-release tablet, mean concentrations initially peaked (1.4 ± 1.2 ng/ml) at 40 min, declining to 0.9 ± 0.5 ng/ml after 8 hr. Mean concentrations were maintained above half the mean peak level during 10 hr. Because of probable rapid first-pass metabolism, the bioavailability of isosorbide dinitrate after administration of the oral dose of the standard tablet was 58% of that from the sublingual dose, and the bioavailability from the sustained-release tablet was 47% of that from the sublingual dose of the standard tablet. The time course of mean plasma concentration data could be described by a one-compartment model; but a more complex model, taking the pass effect into account, probably is needed for a better description of the pharmacokinetics of isosorbide dinitrate.

Keyphrases □ Isosorbide dinitrate—pharmacokinetics, oral and sublingual administration compared, standard and sustained-release tablets compared, humans □ Pharmacokinetics—isosorbide dinitrate, oral and sublingual administration compared, standard and sustained-release tablets compared, humans □ Vasodilators—isosorbide dinitrate, pharmacokinetics, oral and sublingual administration compared, standard and sustained-release tablets compared, humans

The vasodilator isosorbide dinitrate has been in use for many years (1–9), but little has been reported regarding its pharmacokinetics in humans because, in part, of the difficulty in measuring small amounts of the drug in blood. Using a GLC method (10), peak plasma concentrations ranging between 10.5 and 34.5 ng/ml in different subjects were measured at 6 min following a 1.25-mg sublingual dose of isosorbide dinitrate. More detailed studies involving the oral administration of 5.4 mg of ^{14}C-isosorbide dinitrate (11) showed that peak levels of unchanged drug of about 5 ng/ml could be expected (12). However, higher concentrations of the respective mononitrate metabolites were present (12).

Isosorbide dinitrate and other organic nitrates are rapidly metabolized by the glutathione *S*-transferases (13, 14). From studies in animals, Needleman *et al.* (15) concluded that after oral administration of any one of the various organic nitrates, such as isosorbide dinitrate, essentially

none of the parent compound was present in the circulation to relax vascular smooth muscle. Previous work (11), however, showed that, in humans, orally administered isosorbide dinitrate does reach the peripheral circulation intact. Additional evidence is now presented, obtained from studies of standard and sustained-release formulations of the drug.

EXPERIMENTAL

Materials—Standard tablets[1] of isosorbide dinitrate for oral or sublingual administration each contained 5 mg of drug. Sustained-release tablets[1] for oral administration each contained 20 mg.

Drug Administration—Six male subjects[2], 22–39 years old and 57–89 kg, were given one tablet of each formulation of isosorbide dinitrate according to a randomized complete crossover treatment schedule, with about 1 week between dosing.

Following an overnight fast, the oral doses were taken with 100 ml of water and the sublingual doses were retained under the tongue until completely dissolved but were not swallowed deliberately. The subjects fasted for 4 hr following the dose. Blood samples were regularly withdrawn by venipuncture from the antecubital veins into heparinized tubes, and the plasma was immediately separated by centrifugation for rapid analysis.

The blood pressure of each subject was monitored for the first 2 hr after dosing. Decreases in blood pressure occurred after administration of all three formulations but particularly after the sublingual form. The subjects were under continual medical supervision.

Measurement of Drug—Concentrations of isosorbide dinitrate in plasma were measured by GLC using electron-capture detection by a modification[3] of the method of Rosseel and Bogaert (10). Glycerol trinitrate was used as the internal standard; under the conditions employed, it and isosorbide dinitrate were eluted as symmetrical peaks with retention times of 2 and 6 min, respectively. The limit of detection of isosorbide dinitrate in plasma was 0.5 ng/ml. The standard curves were prepared from known amounts of isosorbide dinitrate added to control plasma.

RESULTS

Plasma Concentrations—Fifteen minutes after administration of the standard tablet as a sublingual 5-mg dose, the peak of mean concentrations (±*SD*) was 8.9 ± 3.1 ng/ml (Table I and Fig. 1). Mean concentrations thereafter declined rapidly to 0.8 ± 0.3 ng/ml after 2 hr and were below the limit of detection (<0.5 ng/ml) at 4 hr after dosing. After administration of the standard tablet as an oral 5-mg dose, a peak of mean concentrations of 3.1 ± 0.7 ng/ml was reached at 30 min (Table I and Fig. 1). Mean concentrations declined to 0.7 ± 0.2 ng/ml at 2 hr and were below the limits of detection at 4 hr after dosing. After administration of 20 mg of isosorbide dinitrate as the sustained-release tablet, an initial peak of mean concentrations of 1.4 ± 1.2 ng/ml occurred at 40 min; concentrations remained at about this level during 1–6 hr (Table I and Fig. 1). Thereafter, mean concentrations declined to the limits of detection at about 12 hr after dosing.

After oral or sublingual doses, peak concentrations in individual subjects varied more than twofold. After administration of the 20-mg sustained-release tablet, at least two peak levels in the plasmas of five of the six subjects were measured (Table I). The first peak occurred at 1.5 hr after administration (0.9–3.1 ng/ml), and the second occurred between 4 and 6 hr (1.4–3.0 ng/ml). Three peak levels in the plasma of Subject 4 were measured: at 40 min, 2.2 ng/ml; at 2 hr, 2.1 ng/ml; and at 6 hr, 3.0 ng/ml. Plasma concentrations were maintained at a plateau during approximately 40 min–8 hr after dosing, and the average plateau (steady-state) plasma concentration during this time was 1.4 ng/ml (range of 1.3–1.9 ng/ml). Mean concentrations were maintained above a value of half the average plateau level during 10 hr after dosing; *i.e.*, the mean half-peak value duration time for this formulation was approximately 10 hr. In contrast, the mean half-peak value duration time for the oral dose of the standard tablet was approximately 1 hr, and the ratio, R_Δ, of the half-peak value duration times was 10. The R_c of peak mean concentrations after administration of the sustained-release tablet and the oral dose standard tablet was 1.4/3.1 = 0.45. The retard quotient (R_Δ, R_c) was (10.0, 0.45) for this pair of formulations; therefore, the *in vivo* performance of the sustained-release formulation was fairly good (16).

Table I—Plasma Isosorbide Dinitrate Concentrations (Nanograms per Milliliter ± *SD*, *n* = 6)

Minutes	Route of Administration: Sublingual	Oral	Oral Sustained Release
5	4.2 ± 2.2	—	—
10	8.7 ± 3.8	—	—
15	8.9 ± 3.1	2.4 ± 0.7	0.6 ± 0.5
30	6.5 ± 2.0	3.1 ± 0.7	1.0 ± 1.0
45	4.7 ± 1.5	2.6 ± 0.6	1.4 ± 1.2
60	3.3 ± 1.2	2.0 ± 0.6	1.3 ± 0.7
90	1.7 ± 0.5	1.1 ± 0.3	1.4 ± 0.5
120	0.8 ± 0.3	0.7 ± 0.2	1.4 ± 0.6
240	ND[a]	ND	1.3 ± 0.5
360	ND	ND	1.9 ± 0.8
480	—	—	0.9 ± 0.5
720	—	—	ND[b]

[a] ND = not detected (<0.5 ng/ml). [b] Concentrations (1.6 ng/ml) detected in one subject only.

Bioavailability—The bioavailability from the drug formulations was compared indirectly from the peak plasma concentrations and their times of occurrence. The first peak levels after administration of the sustained-release tablet were much lower (mean 1.8 ± 0.8 ng/ml) and occurred later (78 min) than those after administration of the sublingual dose (9.7 ± 2.1 ng/ml at 12.5 min) or the oral dose (3.3 ± 0.6 ng/ml at 27.5 min) (Table II and Fig. 1). The rates of bioavailability were obviously lowest after administration of the sustained-release tablet, and rates after administration of the oral dose were lower than those after administration of the sublingual dose of the standard tablet.

The extent of bioavailability was estimated by comparing the areas under the plasma concentration–time relationships (Fig. 1), taking the sublingual dose of the standard tablet as a reference. With the sublingual and oral doses of the standard tablet, plasma concentrations were below

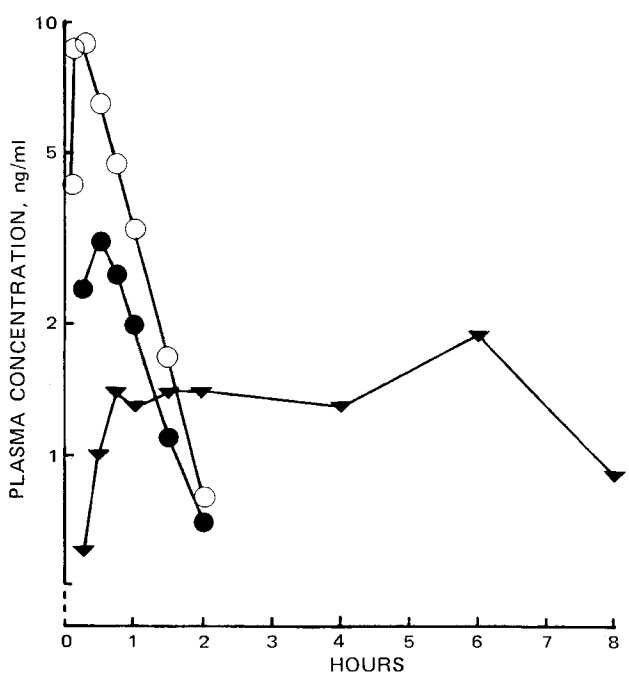

Figure 1—*Mean plasma concentrations of unchanged drug after administration of different formulations of isosorbide dinitrate to human subjects. Key:* ○, *5 mg sublingual;* ●, *5 mg oral; and* ▼, *20 mg oral sustained release.*

3	6.9	15	4.1	30	1.7	120–240
4	9.6	10	3.4	15 and 30	2.2	40
5	10.0	10	2.2	30	1.3	30–60
6	15.0	15	3.3	30	0.9	60–90
Mean (±*SD*)	9.7 (±2.1)	12.5	3.3 (±0.6)	27.5	1.8 (±0.8)	78

[a] Initial peak level after administration of the sustained-release tablet containing 20 mg of drug. Several peak levels occurred in plasma of individual subjects.

the limits of detection 4 hr after administration, and areas to 4 hr were equivalent to "areas to infinite time," which are proportional to the fraction of the dose absorbed. With the sustained-release tablet, plasma concentrations were relatively high at the last time of sampling in one subject (12 hr), and comparison of areas to this time may have slightly underestimated the bioavailability from the formulation.

Measured areas under the concentration–time relationships were corrected for dose–body weight variations because unequal doses were administered (Table III). The ratios of corrected areas, with the area after administration of the sublingual dose as reference, provided an estimate of the relative fraction of the dose absorbed into the peripheral circulation and, hence, the bioavailability of isosorbide dinitrate from the standard tablet, oral dose, and the sustained-release tablet. The mean bioavailability from the standard tablet after oral administration was 58% of that from the standard tablet after sublingual administration. So calculated, the mean bioavailability of isosorbide dinitrate from the sustained-release tablet was 47% of that from the sublingual dose of the standard tablet. However, since comparison of areas to 12 hr after administration of the sustained-release tablet may have led to an underestimation of bioavailability, it was likely that a similar fraction of the dose was absorbed from both the sustained-release tablet and the standard tablet after oral administration.

Pharmacokinetics—The half-lives of drug elimination were calculated by least-squares regression analysis of $\log_e$ (concentration) against time from data points on the terminal linear section of the curve (Fig. 1). After sublingual doses, more than 96% of the total variance was accounted for by the regression, and half-lives were adequately estimated from the data. These half-lives were similar in individual subjects, with a mean of 0.5 hr (range of 0.47–0.53 hr; Fig. 1). After oral doses of the standard tablet, more than 93% of the variance was accounted for by the regression, and half-lives were again adequately estimated from the data. The mean half-life after these doses was 0.67 hr, with a wider range (0.47–1.05 hr) than after administration of the sublingual dose. A more prolonged absorptive phase after oral doses may have prolonged the half-lives after oral doses, although the difference in mean half-life after administration by these two routes was not statistically significant ($p > 0.05$).

Inspection of the mean plasma concentrations (Fig. 1) indicated that the data might be fitted to a one-compartment model (17). Accordingly, the rate constants for absorption were calculated by the method of Saunders and Natunen (18) assuming a one-compartment model. After sublingual and oral doses, the mean concentration–time relationships were described by the equations:

$$C_{\text{sublingual}} = 12.25(-e^{-0.2877t} + e^{-0.0229t}) \quad \text{(Eq. 1)}$$

$$C_{\text{oral}} = 5.40(-e^{-0.1093t} + e^{-0.0171t}) \quad \text{(Eq. 2)}$$

respectively. The calculated parameters of the model are given in Table IV; it was assumed that the dose was completely absorbed by the sublingual route and that 58% of the dose was absorbed after oral administration (see *Bioavailability* section).

This model requires a very large "unphysiological" volume of distribution and a high plasma clearance of 10 liters/min. The volume of distribution calculated from the mean data after oral administration (626 liters) was, however, larger than that calculated from data after sublingual administration (443 liters). After oral administration, the volume of distribution, V_D, was calculated for individual subjects both from the model parameters and from the expression V_D = clearance/k_e (where k_e is the elimination rate constant); good agreement was found between the two methods of calculation. The *in vivo* release rate of drug from the sustained-release tablet was calculated to be 1.2 mg/hr.

If the bioavailability of the drug from the sustained-release formulation was similar to that from the standard tablet after oral administration (see *Bioavailability* section), *i.e.*, 58% of the dose was absorbed, then the sustained-release tablet would be expected to supply drug over approximately 10 hr. Inspection of Fig. 1 indicated that plasma concentrations were maintained during 1–8 hr after dosing, in reasonable agreement with the calculated release rate.

Table III—Areas[a] under the Plasma Concentration–Time Relationship to 4 hr after Administration of Sublingual and Oral Doses of the Standard Tablet and to 12 hr after Administration of the Sustained-Release Tablet

Subject	Sublingual	Oral	Oral Sustained Release
1	71.6	62.2	59.0
2	132.7	75.5	50.9
3	87.3	53.9	38.0
4	86.2	59.2	59.2
5	129.7	62.0	44.7
6	190.3	46.0	27.3
Mean (±*SD*)	116.3 (±44.0)	59.8 (±9.8)	46.5 (±12.5)

[a] Corrected for dose–body weight variations. Units of ng × hr/ml/mg/kg.

DISCUSSION

Plasma concentrations of isosorbide dinitrate observed after oral doses (Table I) were in fairly good agreement with those measured using radiotracer methods (11). Concentrations observed after sublingual doses were somewhat lower than those reported by others (10). The plasma half-life of isosorbide dinitrate is short, probably too short to support the role of the drug as a relatively long-acting vasodilator. The pharmacologically active metabolites (19, 20), the two isosorbide mononitrates, also might contribute to drug action. These studies showed (Fig. 1) that the use of a sustained-release formulation may prolong the plasma drug concentrations and, probably, the pharmacological action.

Table IV—Parameters of a One-Compartment Open Model for the Pharmacokinetics of Isosorbide Dinitrate[a]

Parameter	Route of Administration	
	Sublingual	Oral
Absorption rate constant, min^{-1}	0.2877	0.1093
Absorption half-life, min	2.4	6.3
Elimination rate constant, min^{-1}	0.0229	0.0171
Elimination half-life, min	30.3	40.4
Volume of distribution, liters	443	626
Plasma clearance, liters/min	10.15	10.70

[a] Calculated from mean concentration data.

The one-compartment model appeared to describe adequately the data obtained after oral administration, but calculation of the absorption rate constant failed in computing with some sets of data from individual subjects after sublingual administration. It was likely, therefore, that after the absorption phase, a very rapid distribution phase preceded the linear elimination phase of the concentration–time relationships but that there were insufficient early sampling times to allow its detection. A simple one-compartment model, therefore, is probably not adequate to describe the pharmacokinetics of isosorbide dinitrate.

Moreover, isosorbide dinitrate is absorbed completely from the GI tract after oral doses (12). Although the reduced bioavailability of isosorbide dinitrate from the standard tablet after oral administration could have been formulation related, the decreased bioavailability after oral doses probably was due to rapid metabolism by the liver after absorption into the hepatoportal system, the drug being subjected to a considerable first-pass effect as occurs for certain other drugs (21–23). Rapid metabolism also explains the very large volumes of distribution and clearances of isosorbide dinitrate by applying a simple one-compartment model to the data. An adequate model of the pharmacokinetics of isosorbide dinitrate must include a pass effect and can be constructed only from a more intensive study of plasma concentrations of the drug and its metabolites after different routes of administration.

Systems Approach to Vaginal Delivery of Drugs IV: Methodology for Determination of Membrane Surface pH

S. HWANG, E. OWADA, L. SUHARDJA, N. F. H. HO, G. L. FLYNN, and W. I. HIGUCHI [x]

Abstract □ A physical model including a diffusional layer in series with the membrane was developed for studying the possible differences between the pH at the membrane surface and that in the bulk solution. Both the membrane-secreted substances (acids and bases) and buffer constituents in the bulk solutions are assumed to contribute to the surface pH. Equations derived for this situation, together with experimental determinations of the acidic dissociation constant of the secreted material, the total secretion flux, the flux of total secreted acidic species, and the diffusional layer thickness, allow estimates to be made of the pH at the membrane surface. With the rabbit vagina, the membrane surface pH was close to that of the bulk solution in most cases. These results were supported by the fact that the absorption of 1-alkanoic acids in pH 2.2 phosphate buffers was relatively constant over the buffer concentration range of 0.003–0.1 *M* phosphate.

Keyphrases □ Drug delivery, vaginal—membrane surface pH determined, compared to bulk solution pH, rabbits □ pH—membrane surface compared to bulk solution, vaginal drug delivery model, rabbits □ Vaginal drug delivery—model, membrane surface pH determined, compared to bulk solution pH, rabbits

The objectives of the present investigations were to develop suitable methodology in an appropriate animal system to obtain firm baseline data on vaginal absorption, to delineate the general barrier properties of the vaginal mucosa, and to develop quantitative integrated models describing both the release of drug from vaginal devices and the subsequent drug absorption.

The first paper (1) in this series described a method for evaluating drug absorption in the vagina, using the rabbit doe as a prototype animal. A rib-cage-type cell, which provided a closed absorptive compartment in the vaginal tract, was designed and surgically implanted in the rabbit. Drug absorption was determined by perfusing the drug solution through this system and following the time changes in drug concentration in the system. The study showed that the method generally affords good precision

The one-compartment model appeared to describe adequately the data obtained after oral administration, but calculation of the absorption rate constant failed in computing with some sets of data from individual subjects after sublingual administration. It was likely, therefore, that after the absorption phase, a very rapid distribution phase preceded the linear elimination phase of the concentration–time relationships but that there were insufficient early sampling times to allow its detection. A simple one-compartment model, therefore, is probably not adequate to describe the pharmacokinetics of isosorbide dinitrate.

Moreover, isosorbide dinitrate is absorbed completely from the GI tract after oral doses (12). Although the reduced bioavailability of isosorbide dinitrate from the standard tablet after oral administration could have been formulation related, the decreased bioavailability after oral doses probably was due to rapid metabolism by the liver after absorption into the hepatoportal system, the drug being subjected to a considerable first-pass effect as occurs for certain other drugs (21–23). Rapid metabolism also explains the very large volumes of distribution and clearances of isosorbide dinitrate by applying a simple one-compartment model to the data. An adequate model of the pharmacokinetics of isosorbide dinitrate must include a pass effect and can be constructed only from a more intensive study of plasma concentrations of the drug and its metabolites after different routes of administration.

Systems Approach to Vaginal Delivery of Drugs IV: Methodology for Determination of Membrane Surface pH

S. HWANG, E. OWADA, L. SUHARDJA, N. F. H. HO, G. L. FLYNN, and W. I. HIGUCHI [x]

Abstract □ A physical model including a diffusional layer in series with the membrane was developed for studying the possible differences between the pH at the membrane surface and that in the bulk solution. Both the membrane-secreted substances (acids and bases) and buffer constituents in the bulk solutions are assumed to contribute to the surface pH. Equations derived for this situation, together with experimental determinations of the acidic dissociation constant of the secreted material, the total secretion flux, the flux of total secreted acidic species, and the diffusional layer thickness, allow estimates to be made of the pH at the membrane surface. With the rabbit vagina, the membrane surface pH was close to that of the bulk solution in most cases. These results were supported by the fact that the absorption of 1-alkanoic acids in pH 2.2 phosphate buffers was relatively constant over the buffer concentration range of 0.003–0.1 *M* phosphate.

Keyphrases □ Drug delivery, vaginal—membrane surface pH determined, compared to bulk solution pH, rabbits □ pH—membrane surface compared to bulk solution, vaginal drug delivery model, rabbits □ Vaginal drug delivery—model, membrane surface pH determined, compared to bulk solution pH, rabbits

The objectives of the present investigations were to develop suitable methodology in an appropriate animal system to obtain firm baseline data on vaginal absorption, to delineate the general barrier properties of the vaginal mucosa, and to develop quantitative integrated models describing both the release of drug from vaginal devices and the subsequent drug absorption.

The first paper (1) in this series described a method for evaluating drug absorption in the vagina, using the rabbit doe as a prototype animal. A rib-cage-type cell, which provided a closed absorptive compartment in the vaginal tract, was designed and surgically implanted in the rabbit. Drug absorption was determined by perfusing the drug solution through this system and following the time changes in drug concentration in the system. The study showed that the method generally affords good precision

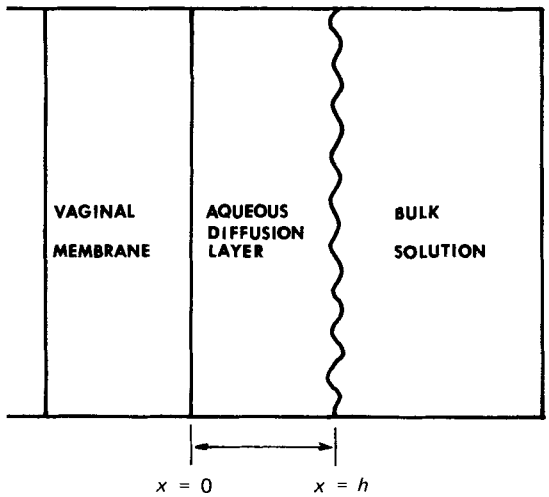

Figure 1—*Physical model for consideration of surface pH. Aqueous diffusion layer is in series with the membrane.*

and should provide a sound basis for meeting the objectives of this research.

The second paper (2) reported the results of the investigation of a physical model for the vaginal absorption barrier, utilizing experimental data on the absorption of the 1-alkanols from methanol to 1-octanol. The analysis of the data showed that experimental results were in reasonably good agreement with the model in which the absorption barrier consists of an aqueous diffusion layer in series with a membrane having two parallel pathways for solute transport—a lipoidal pathway and an aqueous pore pathway.

In the next phase, which is to explore the vaginal absorption behavior of ionizing solutes, it became apparent that an understanding of the membrane surface pH was necessary before a rational study of any physical model for the absorption of weakly ionized drugs (*e.g.*, weak acids and weak bases) could be undertaken. Therefore, the purposes of this study were to develop a method for evaluating the surface pH and to employ it to assess the possible importance of surface pH in analyzing the 1-alkanoic acid vaginal absorption data with the physical models.

THEORY

A schematic diagram of the physical model is shown in Fig. 1. There are the simultaneous fluxes of secretions from the membrane surface across the aqueous diffusion layer and fluxes of the buffer species in the aqueous diffusion layer.

It is assumed that the buffer species (*e.g.*, phosphate) are essentially conserved within the vagina, *i.e.*, there is little or no absorption of buffer species.

It is assumed that the membrane secretes two species, H_2X and HX^-, of a substance by some undefined mechanism. As shown later, the measured acid dissociation constant(s) of H_2X is very close to that for carbonic acid; therefore, H_2X and HX^- might be H_2CO_3 and HCO_3^-, respectively. However, it is unnecessary to specify the exact chemical nature of the secreted material in surface pH (pH_s) analysis.

For the present discussion, assume that phosphate is the buffer in the bulk solution and consider the bulk pH range of 2–8. Then the following six equations (steady state) may be written for the diffusion and chemical equilibrium reaction occurring in th aqueous diffusion layer:

$$K_1 = \frac{(H_2P)(H)}{(H_3P)} \quad \text{(Eq. 1)}$$

$$K_2 = \frac{(HP)(H)}{(H_2P)} \quad \text{(Eq. 2)}$$

$$K_X = \frac{(HX)(H)}{(H_2X)} \quad \text{(Eq. 3)}$$

$$D_{H_3P}\frac{d(H_3P)}{dx} + D_{H_2P}\frac{d(H_2P)}{dx} + D_{HP}\frac{d(HP)}{dx} + D_P\frac{d(P)}{dx} = 0 \quad \text{(Eq. 4)}$$

$$J_{TX} = D_{H_2X}\frac{d(H_2X)}{dx} + D_{HX}\frac{d(HX)}{dx} \quad \text{(Eq. 5)}$$

$$J_{TA} = D\frac{d(H_3P)}{dx} + D_{H_2P}\frac{d(H_2P)}{dx} + D_{HP}\frac{d(HP)}{dx} + D_H\frac{d(H)}{dx} + D_{H_2X}\frac{d(H_2X)}{dx} \quad \text{(Eq. 6)}$$

where (H_3P), (H_2P), (HP), and (P) = concentrations of phosphate buffer species, with the valence of the ions omitted for convenience; (H_2X) and (HX) = concentrations of secretion species of a diprotic acid, with the valence of the ions omitted for convenience; (H) = hydrogen-ion concentration; D = aqueous diffusion coefficient; K = dissociation constant; J_{TX} = total flux of the secretion buffer species per unit surface area; and J_{TA} = total flux of acidic species including drug solution buffer species and hydrogen ions per unit surface area.

The integration of Eqs. 4–6 yields:

$$(H_3P)_s + (H_2P)_s + (HP)_s + (P)_s = (H_3P)_b + (H_2P)_b + (HP)_b + (P)_b \quad \text{(Eq. 7)}$$

$$J_{TX} = \frac{D}{h}[(H_2X)_s - (H_2X)_b + (HX)_s - (HX)_b] \quad \text{(Eq. 8)}$$

$$J_{TA} = \frac{D}{h}[3(H_3P)_s - 3(H_3P)_b + 2(H_2P)_s - 2(H_2P)_b + (HP)_s - (HP)_b + (H_2X)_s - (H_2X)_b + (H)_s - R(H)_b] \quad \text{(Eq. 9)}$$

where h = effective thickness of the aqueous diffusion layer, and s and b = subscripts denoting the membrane surface and the bulk solution boundaries, respectively.

The aqueous diffusion coefficients of all buffer species have been taken to be equal to D, except for the hydrogen ions for which $R = D_H/D$. At low pH, <8, $(P)_b$ and $(P)_s$ are negligible. Then Eq. 7 is reduced to:

$$(H_3P)_s + (H_2P)_s + (HP)_s = (H_3P)_b + (H_2P)_b + (HP)_b \quad \text{(Eq. 10)}$$

Combining Eqs. 9 and 10 yields:

$$J_{TA} = \frac{D}{h}[2(H_3P)_s - 2(H_3P)_b + (H_2P)_s - (H_2P)_b + (H_2X)_s - (H_2X)_b + R(H)_s - R(H)_b] \quad \text{(Eq. 11)}$$

Equations 1–3, 8, 10, and 11 represent six independent equations. All bulk concentrations are known. The effective diffusion layer thickness, h, is 0.035 cm, as previously determined (2) from the alcohol absorption studies. The diffusion coefficients are taken to be 1×10^{-5} cm^2/sec, and R is in the order of 8 under swamping electrolyte conditions (3). The parameters K_X, J_{TX}, and J_{TA} are experimentally determined. Thus, there are six unknowns: $(H_3P)_s$, $(H_2P)_s$, $(P)_s$, $(H_2X)_s$, $(HX)_s$, and $(H)_s$. The J_{TX} and J_{TA} are determined for the experimental situations in which the phosphate buffer is perfused in the rabbit vagina. Subsequently, the surface concentrations of all buffer species and the hydrogen-ion concentration can be calculated. All of these results are examined in the light of the experimental aliphatic carboxylic acid absorption rates and bulk pH values.

EXPERIMENTAL

Materials and Apparatus—^{14}C-Labeled hexanoic acid[1] and tritium-labeled methanol[2] were used without further purification. The radioactivity of the sample was determined by a liquid scintillation counter[3], using a cocktail prepared as described previously (2). The pH was measured by a pH meter[4].

Absorption Procedure and Perfusion System—The absorption procedure and perfusion system were the same as described previously (2). Mature female New Zealand White rabbits, 3.5–5.5 kg, were used. The perfusion system consisted of a reservoir and a rib-cage cell surgically

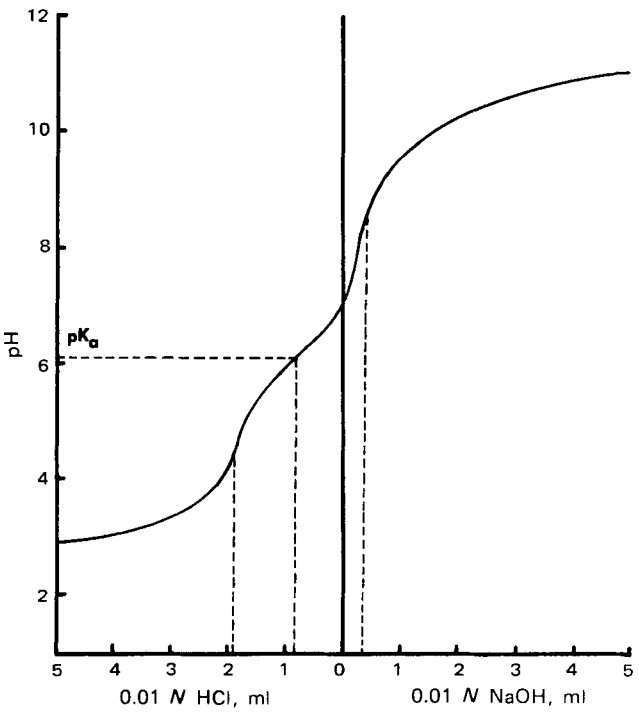

Figure 2—*Titration curve of the saline solution that was circulated in the rabbit vagina for 1 hr.*

implanted in the vagina. The entire path was made of glass and stainless steel, except a short connection [about a 2.54-cm (1-in.) polyethylene tube] between the rib-cage cell and the circuit.

Experiments were scheduled beginning 2 days after the surgical implantation of the rib-cage cell. Two or three experiments were carried out on each day, but the total time interval of an experiment did not exceed 2 hr. The rabbit was anesthetized with pentobarbital sodium (25 mg/kg), and the perfusion system was connected through the fenestra rotunda. The vagina was washed with normal saline solution for about 5 min at 35 ml/min and then with the buffer solution to be used in the experiment. Finally, the drug solution in the reservoir was introduced to the circuit, and the sample was taken periodically at 10-min intervals. The pH was measured before each sample was taken.

Determination of Acid Dissociation Constant, K_X, for Secreted Material—Thirty-five milliliters of 0.9% sodium chloride solution was circulated in the rabbit vagina for 1 hr. Two 10-ml samples were taken. One was titrated with 0.01 *N* NaOH and the other with 0.01 *N* HCl.

Determination of H_2X and HX^- Secretion Rates, J_{TX}—Thirty-five milliliters of phosphate buffer (0.001, 0.003, or 0.01 *M*) or 0.9% sodium chloride was circulated as usual in the system for 23, 43, and 63 min. The

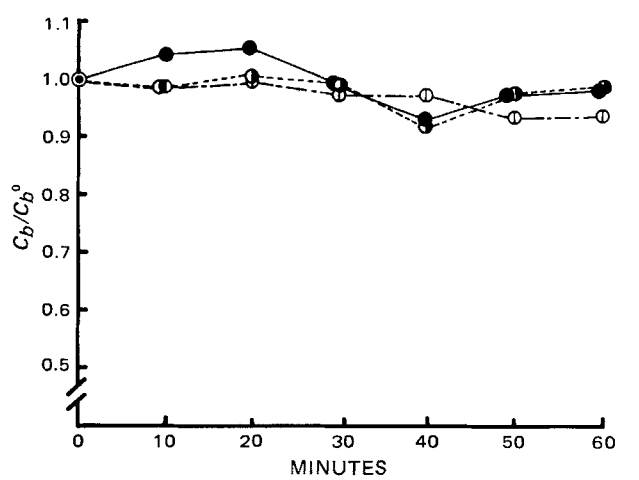

Figure 3—*Plots of phosphate concentration as a function of time. The* C_b *and* C_b^0 *represent the phosphate concentration at time* t *and 0, respectively. Key:* ●, *100 mM;* ◑, *10 mM; and* ⊙, *3 mM.*

Table I—Results of Typical Secretion Rate Determinations at Different Time Intervals

Solution Used	Secretion Rate, μEq/min/cm²		
	23 min	43 min	63 min
0.9% NaCl	0.13	0.11	0.10
3 m*M* Phosphate isotonic buffer (initial pH 3.0)	0.07	0.12	0.08

solutions were then titrated to determine the total acid and base content. The total phosphate concentration was determined by a colorimetric method (4). The difference between the total acid/base of the solution and the total acid/base calculated for the phosphate buffer was attributed to secretions.

Determination of Total Acid Flux, J_{TA}—Let *B* and *C* be the initial amounts of the acidic and basic species of the buffer (at pH close to 3, these will be H_3PO_4 and $H_2PO_4^-$, respectively). Let *Y* and *Z* be the amounts of H_2X and HX^-, respectively, secreted in the time interval, *t*. Then the reaction shown in Scheme I takes place at time *t*:

$$\underset{(B-\delta)}{H_3PO_4} + \underset{(Z-\delta)}{HX^-} \rightleftharpoons \underset{(C+\delta)}{H_2PO_4^-} + \underset{(Y+\delta)}{H_2X}$$

Scheme I

where δ is the amount of reaction taking place. Since the pH of the solution is known at time *t*:

$$K_X = \frac{(H)(Z-\delta)}{(Y+\delta)} \qquad \text{(Eq. 12)}$$

$$K_1 = \frac{(H)(C+\delta)}{(B-\delta)} \qquad \text{(Eq. 13)}$$

where (H) is the hydrogen-ion concentration, K_X is the acid dissociation constant for the secreted material, and K_1 is the first dissociation constant for phosphoric acid. The value of δ is determined by Eq. 13 because *B* and *C* are both known. Thus, *Y* (and *Z*) may be determined from Eq. 12 and the fact that $Y + Z$ is known from the J_{TX} determination discussed previously. The total acid flux, J_{TA}, can then be calculated from *Y*, *t*, and *A*, the surface area of the vaginal membrane, by:

$$J_{TA} = \frac{Y}{tA} \qquad \text{(Eq. 14)}$$

RESULTS AND DISCUSSION

A typical titration curve of the vaginal secretion obtained by perfusing normal saline solution in the vagina for 60 min is shown in Fig. 2. From five experiments, the effective pKa was 6.3 ± 0.1. These data also were used to estimate a second pKa of around 10. These pKa values are close to those for carbonic acid.

The absorption of the phosphate species over the concentration range of 0.003–0.10 *M* at pH 3 was insignificant during 1 hr (Fig. 3). Therefore, it was concluded that the total phosphate is essentially conserved within the usual experimental period.

The secretion rates were relatively constant during the experiments (Table I). The titratable secreted acid was essentially zero, and this value was determined by Eqs. 12 and 13.

The surface pH for the phosphate buffer at bulk pH 2 and 3 could then be calculated (Table II). The surface pH was not greatly different from the bulk pH in these instances over the buffer concentration range of 0.001–0.1 *M*. These results were supported by 1-hexanoic acid absorption studies where the absorption rate at pH 2.1 was independent of the buffer concentration (Fig. 4).

For most membrane transport studies of weak electrolytes conducted

Table II—Calculated Surface pH as a Function of Bulk pH and Total Phosphate Concentration

Bulk pH	Surface pH at Various Concentrations of Total Phosphate		
	100 m*M*	10 m*M*	1 m*M*
2.0	2.0	2.0	2.0
3.0	3.1	3.2	3.3

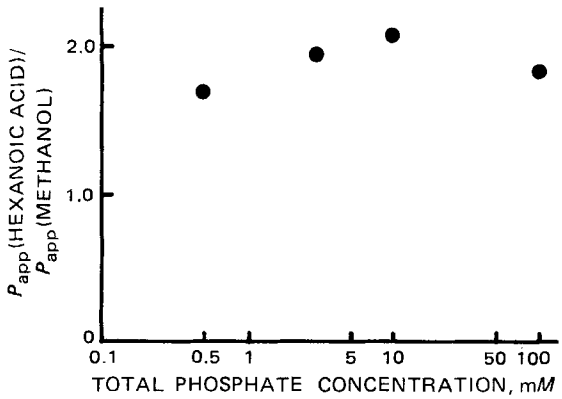

Figure 4—*Plot of the normalized permeability coefficient, P_{app} (hexanoic acid)/P_{app} (methanol), as a function of buffer concentration. The P_{app} is the apparent permeability coefficient.*

in these laboratories, the pH at the membrane surface was assumed to be the same as the pH in the bulk solution. This assumption has now been shown to be a reasonable approximation when the lumenal solution possesses a minimal modest buffer capacity in the case of the rabbit vagina because the rate of secretion (acids or bases) from the membrane is relatively small. In contrast, Desai (5) showed that the surface pH is significantly different from the bulk lumenal pH in *in situ* intestinal absorption experiments with *n*-butyric acid in the rat jejunum. In these studies with the rat intestine, wide ranges of initial buffer pH's (4.5–9.5), buffer capacities, and hydrodynamic conditions were employed in which the flux of buffer secretions across the aqueous diffusion layer was significant and the prevailing surface pH influenced the absorption of *n*-butyric acid.

Systems Approach to Vaginal Delivery of Drugs V: *In Situ* Vaginal Absorption of 1-Alkanoic Acids

S. HWANG, E. OWADA, L. SUHARDJA, N. F. H. HO, G. L. FLYNN, and W. I. HIGUCHI [x]

Abstract □ The vaginal absorption of a homologous series of ionizable compounds, the 1-alkanoic acids, was studied using a perfusion method with a rib-cage cell surgically implanted in the rabbit vagina. The absorption rates of these compounds followed first-order kinetics. The physical model previously used for the 1-alkanols, but accounting for the pKa and pH effects in the present case, was employed in the analysis of the carboxylic acid data. The aqueous diffusion layer thickness was 0.031 cm. The permeability coefficient for the lipoidal pathway increased 3.5-fold per methylene group. Both values agree reasonably well with those obtained in the alcohol study.

Keyphrases □ Drug delivery, vaginal—*in situ* absorption of 1-alkanoic acids, rabbits □ Absorption, vaginal—1-alkanoic acids, rabbits □ Acids, 1-alkanoic—vaginal absorption, rabbits

The first paper (1) of this series described a methodology for studying the absorption of solutes in the rabbit vagina. A rib-cage cell is implanted in the rabbit vagina, and an appropriate perfusion system is used. The absorption of a homologous series of 1-alkanols was studied (2) employing this technique. The data were analyzed by a physical model that involves a diffusion layer in series with a membrane consisting of two parallel pathways—a lipoidal and an aqueous pore pathway. Most recently (3), it was found that the surface pH of the rabbit vaginal membrane under experimental conditions was well approximated by the pH of the lumenal solution.

The general perfusion technique has now been used to study the permeability behavior of a homologous series of 1-alkanoic acids in the rabbit vaginal membrane. These compounds were expected to exhibit a lumen solution pH dependence for absorption and a chain length dependence. The same physical model as was used (2) with the 1-alkanols appeared to describe adequately the primary features of the absorption behavior of the 1-alkanoic acids in the rabbit vagina.

EXPERIMENTAL

Animals—Mature female New Zealand White rabbits, 3.5–5.0 kg, were maintained in a temperature-controlled animal room (25°) with free access to water and a regular diet.

Materials—^{14}C-Labeled acetic[1], butyric[1], octanoic[1], hexanoic[2], and decanoic[2] acids, ^{3}H-labeled polyethylene glycol[1] (mol. wt. ~4000), and ^{3}H-labeled methanol were used without further purification. Buffers of 0.1 *M* phosphate at pH 3, 6, and 8 were prepared (Table I).

[a] Adjusted to isotonic by adding sodium chloride.

Perfusion System and Absorption Study Procedure—The perfusion system, as described previously (1, 2), consisted of an outside solution reservoir and a rib-cage cell surgically implanted in the vaginal tract. The entire perfusion path was made of glass tubing and stainless steel, except the short portion [about a 2.54-cm (1-in.) polyethylene tube] between the rib-cage cell and the fenestra rotunda. The rib-cage cell provided an interior volume of 8.1 cm^3 and a geometrical surface area of 22.5 cm^2. It was inserted through the wall of the upper part of the vaginal tract after an appropriate incision.

The procedure for an absorption experiment was essentially the same as described previously (2). Experiments were started 2 days after surgical implantation of the cell. For each rabbit, experiments were conducted on each day successively for 5 or 6 days. The rabbit was anesthetized with pentobarbital sodium, 25 mg/kg, and the perfusion system was connected through the fenestra rotunda. The vagina was first washed with normal saline solution for about 5 min at a flow rate of 35 ml/min and then for an additional 2 min with the buffer solution to be used in the experiment.

In all experiments (except that with polyethylene glycol 4000), ^3H-labeled methanol was run as a reference together with the acid of interest. After the vagina was washed with buffer, the drug solution was introduced by turning the three-way switch. The drug solution became well mixed with the buffer in the whole system after about 3 min (1). Then a zero-time sample was taken, and the experiment was continued for 1 hr during which samples were taken periodically and analyzed for both activities with a liquid scintillation counter[3] employing a dioxane cocktail[4].

RESULTS AND DISCUSSION

Water Flux in Rabbit Vagina—^3H-Labeled polyethylene glycol 4000 was used as a marker to determine the water flux with the three buffer systems (Table I) in the rabbit vagina. Three rabbits were used for each buffer. The water flux was not significant within the 1-hr experiment (Fig. 1 and Table II).

Permeability Coefficient of Methanol ($P_{app}^{methanol}$) with Three Buffers—Nine rabbits were equally divided into three groups for studying the permeability coefficient of methanol in the three buffers (pH 3, 6, and 8). Five experiments were carried out on 5 successive days for every rabbit (Table III). No significant differences in the permeability coefficient of methanol were found among the three buffers.

	2.47 ± 0.30	1.31 ± 0.22	1.59 ± 0.43
Mean ± *SD*	2.00 ± 0.77	1.55 ± 0.63	1.53 ± 0.05

Absorption of 1-Alkanoic Acids—The absorption of the acids (from acetic to decanoic) was studied at pH 3, 6, and 8 in the same buffers. Three rabbits were used for each pH, and all acids were studied in each rabbit at the assigned pH. The order of the experiments was different for each rabbit in each pH group, but the same order combination was used for each pH group.

The data were plotted as log (C_b/C_b^0) *versus* time, where C_b^0 is the drug concentration at time zero. Without exception, the plots were linear for all acids (Fig. 2). This first-order pattern could be expressed by:

$$\frac{dC_b}{dt} = -K_u C_b \qquad \text{(Eq. 1)}$$

and:

$$K_u = P_{app}\left(\frac{A}{V}\right) \qquad \text{(Eq. 2)}$$

where C_b is the concentration of the drug in the bulk, K_u is the first-order rate constant, A is the effective surface area of the vaginal tract, V is the volume of the perfusion solution, and P_{app} is the apparent permeability coefficient.

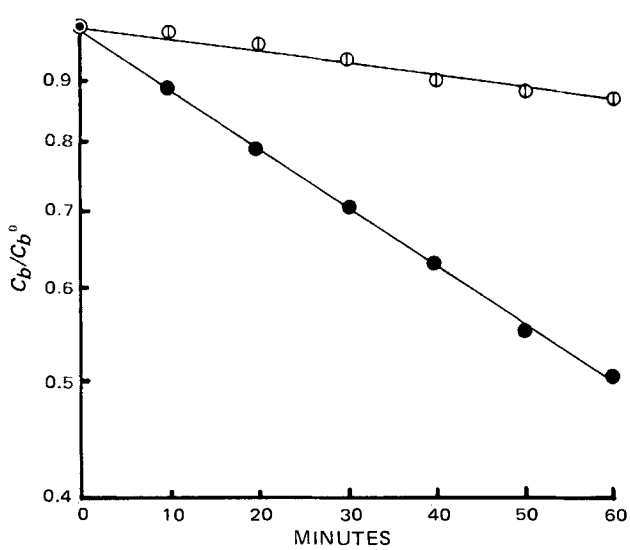

Figure 2—*Semilogarithmic plot of the acid concentration in solution as a function of time. Key: ⊙, acetic acid, pH 8; and ●, hexanoic acid, pH 3.*

Table IV—($P_{app} \pm SD$) × 10^4 cm/sec at Three Different pH Values[a]

Acid	pH 3	pH 6	pH 8
Acetic	2.39 ± 1.40	1.07 ± 0.20	0.49 ± 0.15
Butyric	3.31 ± 1.91	2.89 ± 0.95	0.48 ± 0.04
Hexanoic	3.68 ± 1.18	3.57 ± 0.59	1.15 ± 0.17
Octanoic	3.92 ± 1.48	3.57 ± 0.93	1.87 ± 0.18
Decanoic	—	—	1.89 ± 0.32

[a] Each value is a mean of three experiments involving three different rabbits.

The permeability coefficients of acids at various pH values calculated by Eq. 2 are summarized in Table IV. The ratio of $P_{app}/P_{app}^{methanol}$ is summarized in Table V. (The data for decanoic acid at pH 3 and 6 are not presented, because solute losses to the perfusion system were large for this compound under these conditions.) The relative standard deviations for the ratio were generally less than for the permeability coefficient itself, showing the value of having the reference solute, methanol, run simultaneously with the acid.

Figure 3 is a plot of the mean ratio as a function of the carbon number for the acids. For pH 3 and 6, the ratio reached a plateau between butyric and hexanoic acids. For pH 8, the ratio increased from acetic to decanoic acid.

Proposed Physical Model and Analysis of Acid Data—As previously reported (2), the rabbit vaginal absorption barrier may be considered to consist of two barriers in series, an effective aqueous barrier and a principal membrane barrier, with two parallel pathways: a lipoidal pathway and an aqueous pore pathway. The model is schematically illustrated in Fig. 4. Mathematically, the apparent permeability, $P_{app}(n,\text{pH})$, can be expressed as a function of the permeability coefficient for the aqueous barrier, $P_{aq}(n)$, and of the permeability coefficient for the membrane $P_m(n,\text{pH})$, where n is the number of carbon atoms in the compound of interest:

$$P_{app}(n,\text{pH}) = \frac{1}{\frac{1}{P_{aq}(n)} + \frac{1}{P_m(n,\text{pH})}} \qquad \text{(Eq. 3)}$$

The value of $P_{aq}(n)$ is assumed to be equal to $D_{aq}(n)/h$, where $D_{aq}(n)$ is the diffusion coefficient of the compound and h is the effective diffusion layer thickness. The Stokes–Einstein relationship was used to account for the difference in D_{aq} for the different compounds in the homologous series.

By assuming that the ionic form of the acid cannot be transported through the lipid pathway and that the undissociated acid molecule can go through both the pore and the lipid pathways, $P_m(n,\text{pH})$ can be expressed as a function of the fraction of undissociated acid, X, the permeability coefficient of the lipid pathway, P_l, and the permeability coefficient of the pore pathway, P_p:

$$P_m(n) = XP_l(n) + P_p(n) \qquad \text{(Eq. 4)}$$

$$X = \frac{(H)_s}{K_a(n) + (H)_s} \qquad \text{(Eq. 5)}$$

where $(H)_s$ is the membrane surface ($x = 0$) hydrogen-ion concentration, and $K_a(n)$ is the dissociation constant of the acid. The surface hydrogen-ion concentration in these experiments should be well approximated by the bulk hydrogen concentration, (H) (3).

Following the concept of incremental partition coefficient (4, 5) yields:

$$P_l(n) = P_l^0 \times 10^{\pi n} \qquad \text{(Eq. 6)}$$

where P_l^0 is the permeability coefficient of the lipoidal pathway for the hypothetical acid with zero carbon atoms.

The term $P_p(n)$ is a function of the diameter of the pore and the molecular size and shape of the permeant and its diffusion coefficient. However, it is assumed to be a constant in the present calculations since this approximation does not significantly affect our considerations. Thus, Eq. 3 may be rewritten as:

$$P_{app}(n,\text{pH}) = \frac{1}{\left[\frac{MV(n)}{125}\right]^{1/3}\frac{h}{D(6)} + \frac{1}{\frac{(H)}{K_a + (H)}P_l^0\,10^{\pi n} + P_p}} \qquad \text{(Eq. 7)}$$

where $MV(n)$ is the molar volume of the acid with n carbon atoms, 125 is the molar volume of hexanoic acid[5], and $D(6)$ is the diffusion coefficient of hexanoic acid at 37°[6].

By using the proposed model, the following assessments were made.

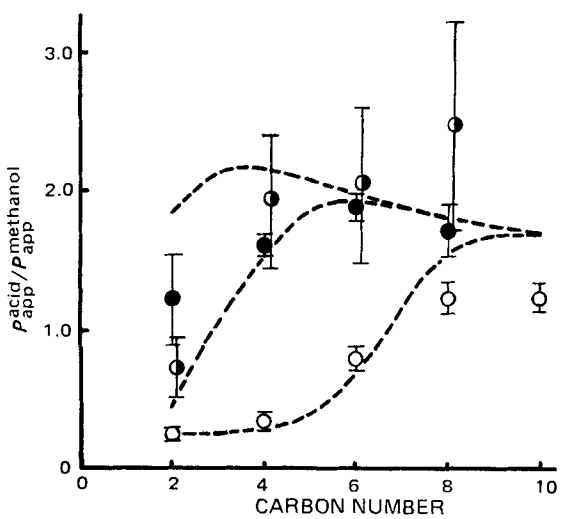

Figure 3—*Effect of carbon number on the normalized permeability coefficient,* $P_{app}^{acid}/P_{app}^{methanol}$, *at pH 3 (●), 6 (◑), and 8 (○).*

Table V—$P_{app}^{acid}/P^{methanol} \pm SD$ at Three Different pH Values[a]

Acid	pH 3	pH 6	pH 8
Acetic	1.22 ± 0.33	0.73 ± 0.23	0.25 ± 0.04
Butyric	1.62 ± 0.08	1.94 ± 0.48	0.34 ± 0.06
Hexanoic	1.89 ± 0.10	2.06 ± 0.56	0.81 ± 0.09
Octanoic	1.74 ± 0.18	2.49 ± 0.75	1.24 ± 0.12
Decanoic	—	—	1.26 0.10

[a] Each value is the mean of three experiments involving different rabbits.

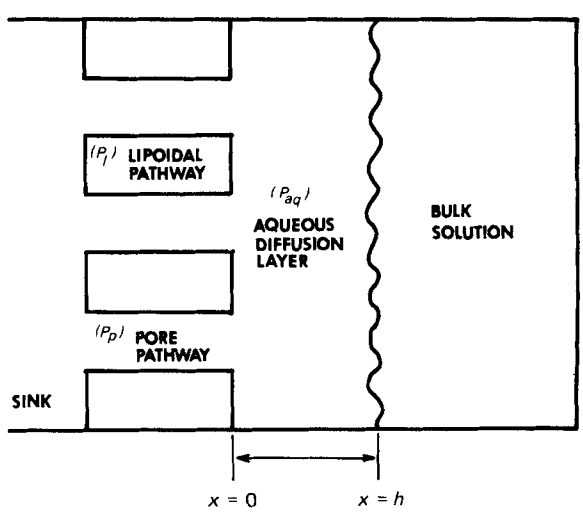

Figure 4—*Schematic model of the vaginal membrane as a transport barrier. Aqueous diffusion layer is in series with the membrane consisting of parallel lipoidal and aqueous pore pathways.*

[5] Hexanoic acid was arbitrarily chosen as a reference to allow for the Stokes–Einstein molar volume dependence for the diffusivity.

[6] It is calculated from the 25° value (6) by the Stokes–Einstein equation.

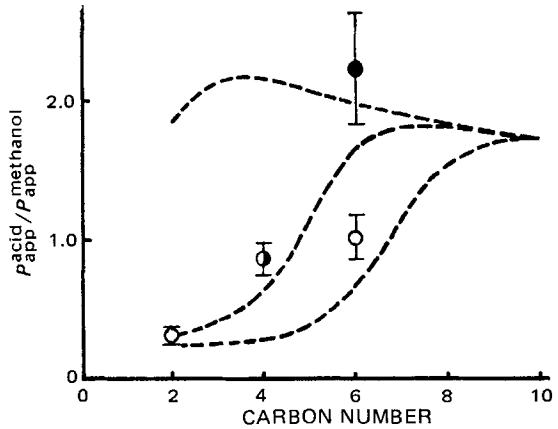

Figure 5—*Further test of the model. Theoretical curves are based on the results in Fig. 3. Key:* ●, *pH 3;* ◑, *pH 7; and* ○, *pH 8.*

At pH 3 and 6, the absorption rates for all acids (except acetic) were mainly controlled by the aqueous diffusion layer. At pH 8, the absorption rates of the lower acids were mainly controlled by the membrane. More specifically, both acetic and butyric acids were controlled by the pore pathway.

The best fit theoretical curves of $P_{app}/P_{app}^{methanol}$ *versus* n were deduced using Eq. 6 and by varying the parameters P_p, P_1^0, π, and h. A $P_{app}^{methanol}$ value of $(1.69 \pm 0.55) \times 10^{-4}$ cm/sec was used. This value, as mentioned earlier, was based on experiments with nine rabbits. The best fit set of curves is shown in Fig. 3, and these curves were based on the best parameter values $P_p = 4.6 \times 10^{-5}$ cm/sec, $P_1^0 = 6.8 \times 10^{-5}$ cm/sec, $\pi = 0.55$, and $h = 0.031$ cm.

The principal features of the proposed model are consistent with the experimental data (Fig. 3). The rather large standard deviations with the animal experiments preclude making a strong statement about the general quantitative validity of the proposed model. However, the π value of 0.55 ± 0.10 and the h value of 0.031 cm are believed to be physically significant.

Further Test of Model—Following the initial studies (Fig. 3), it was decided to pursue another study of limited scope to test the model. According to the theoretical predictions (Fig. 3), butyric acid at pH 7 was expected to be in a sensitive region of the $(P_{app}/P_{app}^{methanol})$ *versus* carbon number curve. Thus, an experiment involving butyric acid at pH 7 was expected to be a good further test of the model. Accordingly, a set of experiments involving three rabbits was designed and performed. Results of the new experiments were in good agreement with the predictions of the model based on the previous experiments (Fig. 5); these results were uniformly slightly higher but essentially within the experimental variations. Table VI shows that if only the results of the new experiments are used in the calculations with the model, a π value of 0.55 ± 0.06 is obtained, in excellent agreement with π values found with the first set of experiments (Fig. 3).

Table VI—Apparent Permeability Coefficient for the Acids and the Values of π for Three Rabbits

Acid	$P_{app} \times 10^4$ cm/sec		
Hexanoic acid, pH 3	4.69	6.24	6.71
Acetic acid, pH 8	0.46	0.50	0.54
Hexanoic acid, pH 8	1.13	1.64	1.97
Butyric acid, pH 7	1.05	1.32	1.32
Calculated π	0.50	0.54	0.62

Table VII—Physical Model Constants for the Aliphatic Acids and the Alcohols

Constant	Acid	Alcohol
P_p	4.6×10^{-5} cm/sec	1.9×10^{-4} cm/sec
P_1^0	6.8×10^{-5} cm/sec	1.5×10^{-6} cm/sec
h	0.031 cm	0.035 cm
π	0.55 ± 0.10	0.40 ± 0.15

Comparison of Results of Aliphatic Alcohols and Carboxylic Acids—These results with the acids compared favorably with those obtained with the alcohols. A summary of all physical constants for both series is presented in Table VII. The diffusion layer thickness, h, and the methylene group incremental constant, π, were in good agreement between these two homologous series. However, the permeability coefficient of the aqueous pore, P_p, for acids was significantly smaller than that for alcohols. This finding suggests two possibilities:

1. The "aqueous" pore phase may not be truly aqueous but somewhat semipolar in character and itself have a modest π value associated with it, or the aqueous pore may be negatively charged so that anions have more difficulty in being transported *via* this pathway.
2. As discussed previously (2), there may be an effective third parallel pathway in the membrane which may be characterized as being "lipoidal" but have a π value significantly less than that for the primary lipoidal pathway. This pathway may allow polar neutral species (*e.g.*, methanol) to go through with relative ease compared to ions like acetate or butyrate.

The methylene group incremental constant, π, had values close to that for the partition coefficient obtained in the 1-octanol–water system, $\pi = 0.5$, as reported by Hansch and Anderson (7). However, the difference in P_1^0 values between acid and alcohol was much larger than that expected by extrapolation of the octanol–water data for the alcohols and the fatty acids (8). Therefore, as might be expected, the similarity between the lipoidal pathway in rabbit vagina and octanol is not total.

Simplified Method to Study Stability of Pharmaceutical Preparations

A. K. AMIRJAHED

Abstract □ Data simulating zero-, first-, and simple second- and third-order kinetic reactions are employed at four elevated temperatures. The existence of a linear relationship is established between the logarithm of $t_{0.9}$ (the time required for the concentration of the reactant remaining to decompose to reach 90% of its original value) and the reciprocal of the corresponding temperature in absolute degrees. The independence of the result from the order of the reaction is reconfirmed using literature data. The application of the linear relationship to predict the shelflife of dosage forms is discussed.

Keyphrases □ Stability—pharmaceutical preparations, linear relationship between log $t_{0.9}$ and reciprocal of absolute temperature related to shelflife □ Shelflife—pharmaceutical preparations, predicted using linear relationship between log $t_{0.9}$ and reciprocal of absolute temperature

The classical method of determining the shelflife of a pharmaceutical preparation was to store it under conditions similar to those of the normal market and to study its stability for the expected period of storage in the market. If the preparation was unstable and was subsequently modified, the same time-consuming process had to be repeated for the modified form (1). Later, high temperature accelerated stability studies were employed to predict the shelflife of the drug in a considerably shorter time. The application of such kinetic studies dates back to 1950 for consumer products in the food (2) and pharmaceutical (3, 4) industries.

BACKGROUND

In general, accelerated stability studies involve the determination of the concentration of drug remaining to decompose as a function of time. The concentration or a function of it is linearized with respect to time. The effect of relatively high temperatures on the slope of these straight lines (the specific rate constants) is determined and utilized for the preparation of an Arrhenius plot. Prediction of the time required for the drug to decompose to 90% of its original concentration at 25°—the shelflife—is based on the Arrhenius plot.

Many factors have to be investigated in such a study (5) including pH, moisture, light, oxidation, chelation, solubility, excipients, trace metals, compatibility, closures, containers, and sterilization. Other variables are the solvent, dielectric constant, ionic strength, substrate pKa, substrate reactive groups, nucleophiles, acids, and bases (4). All such studies employ the proper experimental design, a reliable assay procedure, and the appropriate statistical evaluation of the results. From the findings, the formulator determines a set of conditions that best keep the quality, purity, identity, and strength of the drug (6). Numerous articles and reviews deal with different aspects of such studies (4, 6–12). To ensure the safety and efficacy of medicaments, accelerated stability studies are now an essential part of the activities of the pharmaceutical formulator and the hospital and clinical pharmacist.

Most investigators emphasize the determination of the exact kinetic path followed by the degrading drug compound. However, some ignored such exact determinations and obtained shelflife predictions using reference decomposition models based on kinetic concepts (3) in an attempt to reduce the length of time required for stability studies. Clark and Hudson (13) suggested the use of a stability chart and explained it for first-order reactions. An experimental design and its proper statistical analysis were constructed to predict shelflife when imprecise assay methods have to be employed (14). The design provides for the minimum number of time–temperature combinations that can be used.

For first-order degradation, a stability chart was developed utilizing the Arrhenius equation, the specific rate of degradation at two elevated temperatures, and the heat of activation (15). The overall first-order rate of hydrolysis of procaine solutions was studied, and a linear relationship was found between the logarithm of the half-lives and the reciprocal of the corresponding temperatures in absolute degrees (16). As a corollary to the half-life concept, the time taken for the drug to decompose to 90% of its original concentration can be designated as $t_{0.9}$. The linear relationship between log $t_{0.9}$ and the reciprocal of the corresponding temperature in absolute degrees may be employed in the prediction of room temperature stability in a first-order reaction (6). The relationship between $t_{0.9}$ and the first-order specific rate constant was studied (17), and this concept was used for the prediction of stability of parenteral solutions from considerations of first-order reaction kinetics (18).

Lordi and Scott (15) indicated that, at less than 10% degradation and within the limits of the experimental error involved in stability studies, it is not possible to distinguish between first-, zero-, and simple second-order kinetics using curve-fitting techniques. Consequently, they felt confident that assuming first-order kinetics in their work should result

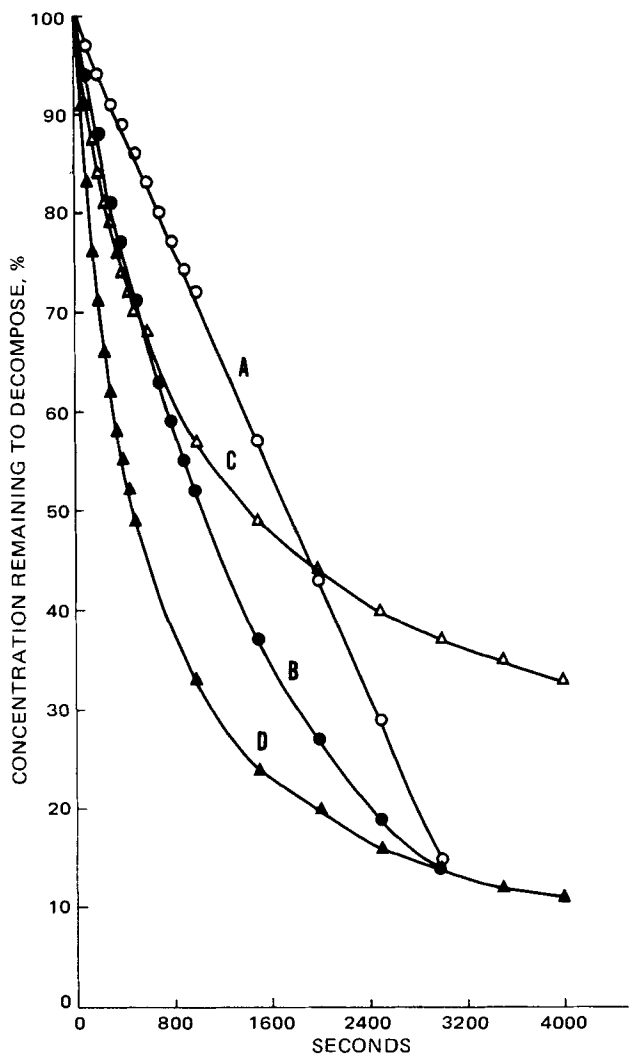

Figure 1—*Representative simulated concentration* versus *time data for zero-, first-, and simple second- and third-order reactions. Key: A, zero order; B, first order; C, third order; and D, second order.*

in minimum error in the absence of a knowledge of the actual order of reaction.

The purpose of the present study was to investigate: (*a*) the presence of a linear relationship between log $t_{0.9}$ and the reciprocal of the corresponding temperature in absolute degrees regardless of the order of reaction and (*b*) the applicability of the results to the prediction of shelflife.

EXPERIMENTAL

In the first phase of this investigation, simulated concentration *versus* time data for zero-, first-, and simple second- and third-order reactions containing ±0.4–2% experimental error in the concentration terms were utilized (Fig. 1). Regression analysis of the data provided the formulas of the straight lines reported in Tables I–IV. For the different temperatures in each reaction order, the time required for the concentration to decrease to 90% of its value at zero time was determined from the respective straight-line equations. The logarithms of these values (log $t_{0.9}$) were plotted against the reciprocal of the corresponding temperatures in absolute degrees (Fig. 2).

Regression analysis provided the equations of the observed straight lines reported in Table V. The predicted $t_{0.9}$ at room temperature or the time required for the hypothetical substance to degrade at 25° to 90% of its original value was determined by substitution of the reciprocal of room temperature (in absolute degrees) multiplied by 10^3 for the independent variable. These values are also reported in Table V.

In the second phase of the investigation, available literature data were utilized to calculate log $t_{0.9}$ values. Standard kinetic equations for the particular order of reaction stated in the source were used for these calculations. The log $t_{0.9}$ values were plotted on the ordinate against the reciprocal of the corresponding temperatures (in absolute degrees multipled by 10^3 or 10^4) on the abscissa. The formula of the resultant straight line was obtained through least-squares regression analysis.

A simple substitution of the proper form of the room temperature similar to that performed in the first phase of the investigation provided the predicted value of $t_{0.9}$ at room temperature. This $t_{0.9}$ value was utilized in calculating the specific rate constant for the reaction at 25° (k_n). The k_n was subsequently compared with the equivalent specific rate constant value (k_0) reported in the source. The two specific rate constants are reported in Tables VI–VIII.

The literature sources were selected from kinetic studies reported since 1936. Many such studies could not be used in this particular investigation; only those that clearly indicated the order of reaction and provided enough data at different temperatures suitable for application of the standard kinetic equations were employed.

RESULTS AND DISCUSSION

The nature and experimental error of the simulated data of Tables I–IV are representative of studies performed on simple degradation reactions. The number of concentration *versus* time data points (15–18) is also a practical and reasonable sample. Since kinetic studies utilizing greater than four elevated temperatures are not very common, four temperatures of 40, 50, 60, and 70° were selected as an acceptable range. Furthermore, there were two replicates for each temperature, providing a better basis for the determination of error. The values of the coefficients of correlation were all significant at least at the 95% level of probability.

Each set of data (concentration *versus* time pairs for a certain order

[a] All values of the coefficient of correlation are significant at the 5% level of probability. [b] The k_n is the specific rate constant at 25° calculated from $t_{0.9}$ at 25°. The $t_{0.9}$ was predicted using the appropriate straight-line equation. [c] The k_0 is the specific rate constant reported in the reference.

of reaction and a specific temperature) provided one of the reported straight lines (Tables I–IV) and one $t_{0.9}$ value, so a total of eight log $t_{0.9}$ values was available for each order of reaction. Four elevated temperatures were employed for the same order, and each two of the log $t_{0.9}$ values corresponded to a different elevated temperature. The observed relationship between the log $t_{0.9}$ values and the reciprocal of the temperatures in absolute degrees was linear in all of the different orders of reaction (Fig. 2).

The slope, intercept, and coefficient of correlation for each line are reported in Table V. The coefficients of correlation were significant at least at the 1% level of probability. The linear relationship was used to predict the $t_{0.9}$ for the particular reaction at room temperature. In accelerated stability studies of pharmaceutical dosage forms, this time is the desired shelflife.

The establishment of the existence of the linear relationship between the log $t_{0.9}$ and the reciprocal of the absolute temperature regardless of the order of reaction led to the second phase of the investigation in which available data from selected literature sources were used to provide the same linear relationship (Tables VI–VIII). By utilizing the linear relationship, the specific rate constant at room temperature was calculated for the particular reaction. This calculated specific rate constant was compared with the specific rate constant for 25° reported in the source, using the Student t test (19). The difference between the two was not significant.

The existence of a linear relationship between the log $t_{0.9}$ and the reciprocal of the absolute temperature independent of the order of reaction is demonstrated by the simulated and experimental data. In practice, therefore, one may maintain the degradation reaction at several high temperatures, carrying on concentration determinations at predetermined time intervals. A plot of concentration remaining to decompose (on the ordinate) against time (on the abscissa) is constructed for each elevated temperature. The time taken for the concentration to decrease to 90% of the original value is read, and its logarithm is plotted against the reciprocal of the corresponding temperature in absolute degrees. The shelflife at the desirable temperature is predicted from the observed straight line. Before this new method is fully and solely employed, however, it should be applied to available data from a dosage form for which the shelflife has already been determined by other more elaborate means. Such a precaution will be of assistance in evaluating the accuracy of the simple technique.

The k and x of the general kinetic formula $-dC/dt = kC^x$ (C = concentration remaining to decompose, x = order of reaction, and k = specific reaction rate constant) can be determined using a suitable computer and program. The log k values (dependent variable Y) plotted against the reciprocal of the corresponding temperatures in absolute degrees (independent variable x) will provide an Arrhenius plot (based on $k = Ae^{-E_a/RT}$) from which the k value at room temperature can be predicted. Knowing the x and the predicted k, one can then calculate the $t_{0.9}$ at room temperature.

The present method does not depend on the x and k values, thus

Table VII—First-Order Reactions: Straight Lines Obtained When the Logarithm of the $t_{0.9}$ Values (Dependent Variable Y) Calculated from Data Reported in the Literature Is Plotted against the Reciprocal of the Corresponding Temperatures in Absolute Degrees [Independent Variable $X = (1/T) \times 10^3$]

minimizing the time and effort involved in accelerated stability studies without sacrificing scientific rigor. This approach is of particular advantage to small laboratories and hospital pharmacy manufacturing units where a suitable computer and program may not be available. The procedure is applicable only where the degradation reaction is a thermal process in which the use of an Arrhenius plot is justified.

The physicochemical properties of the particular medicinal substance and the possibilities available to the formulator dictate the range of elevated temperatures employed. The statistical reliability of the result can be increased by using a greater number of elevated temperatures. The reliability is also increased if the lower end of the temperature range is as close to the room temperature as possible. The accuracy of the result is indeed greater if the number of log $t_{0.9}$ and $1/T$ pairs is preferably about eight to 12. The procurement and analysis of the samples need not be carried beyond the point at which the concentration remaining to decompose becomes less than 80% of its original value. This possibility is particularly helpful in cases where the product of degradation is insoluble in the reaction mixture vehicle.

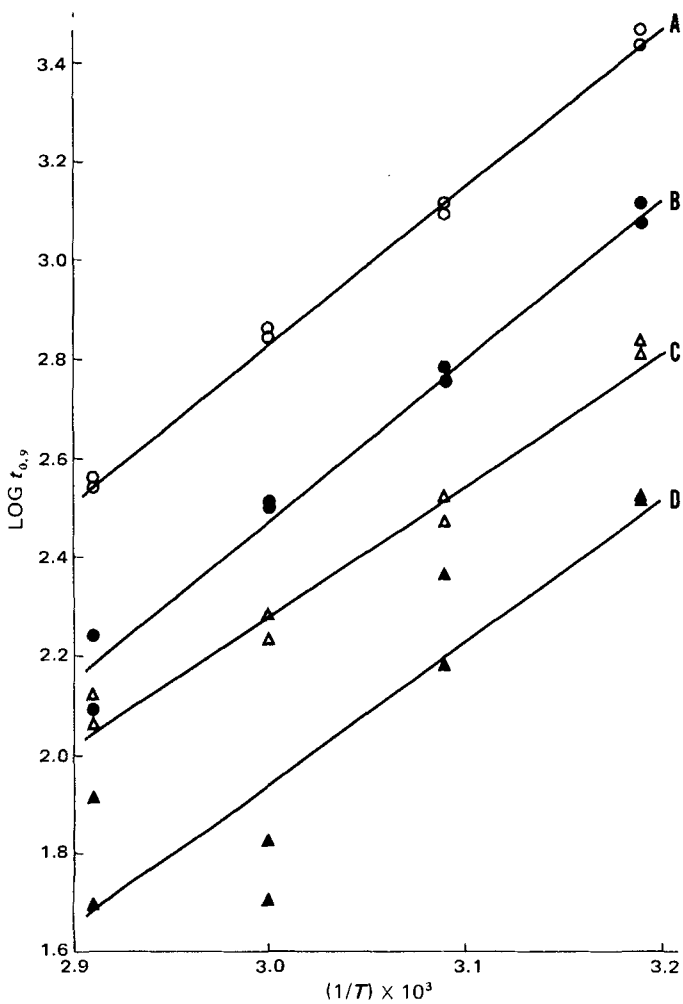

Figure 2—*Log $t_{0.9}$ values obtained from the simulated data and plotted against the reciprocal of corresponding temperatures (T in absolute degrees). Key: A, zero order; B, first order; C, third order; and D, second order.*

Simple GLC Determination of Ethylene Oxide and Its Reaction Products in Drugs and Formulations

P. A. HARTMAN and P. B. BOWMAN ˣ

Abstract □ Convenient rapid GLC methods for the estimation of residual ethylene oxide, ethylene chlorohydrin, and ethylene glycol in ethylene oxide-sterilized bulk drugs and formulations prepared therefrom are described. Ethylene oxide was chromatographed using a porous polymer column; ethylene chlorohydrin and ethylene glycol were chromatographed using either polyethylene glycol 400 or a porous polymer column. All three residuals were determined from the same sample preparation for each type of drug or formulation examined. Recoveries of each of the three residuals were greater than 95% for all samples examined. Detection limits, at moderate electrometer sensitivities, were 2 μg/g or ml for ethylene oxide and ethylene chlorohydrin and 5 μg/g or ml for ethylene glycol. The most likely interferences are discussed.

Keyphrases □ Ethylene oxide—and reaction products, GLC analysis, sterilized bulk drugs and formulations □ GLC—analysis, ethylene oxide and reaction products in sterilized bulk drugs and formulations □ Sterilizers—ethylene oxide and reaction products, GLC analysis in bulk drugs and formulations

The determination of residual levels of ethylene oxide and its reaction products, ethylene chlorohydrin and ethylene glycol, has received a great deal of attention. However, most work has dealt with the estimation of the residual levels in plastic medical devices and foods (1, 2).

Essentially all recently published procedures depended on GLC for separation and quantitation. Differences in the methods were primarily in the sample preparations (3). Natural and synthetic polymers have the capacity to absorb large quantities of ethylene oxide, and various methods have been proposed to measure accurately ethylene oxide, ethylene chlorohydrin, and ethylene glycol in these materials (4). However, drugs and pharmaceutical formulations have received scant attention. A GLC procedure was described for the determination of residual ethylene oxide in steroids that involved distillation and thermal conductivity detection (5).

Recent work centered on the use of porous polymer packings (Chromosorb 101 or Porapak) for ethylene oxide and of polyethylene glycols for ethylene chlorohydrin and ethylene glycol.

To test large numbers of samples, a method was desired that would require minimal sample preparation and analyst time without compromising the requirements for quantitative results. Since the measurement of residual levels is more of a limits test than a precise quantitation for a potency measurement, simple sample preparations and minimum chromatographic time were desired. In this paper, procedures for water-insoluble bulk drugs, aqueous suspensions, aqueous solutions, and ointments are described. For each material or formulation discussed, a single sample preparation was suitable for the quantitation of ethylene oxide, ethylene chlorohydrin, and ethylene glycol.

For quantitation of ethylene oxide, a Porapak R column was employed; a polyethylene glycol 400 column was used for the other two compounds. The use of the two columns was advantageous, since both were operated at the same temperature. With a dual-column dual-electrometer instrument, all three residuals could be determined simultaneously.

EXPERIMENTAL

Instrument—A gas chromatograph[1] equipped with a flame-ionization detector and U-shaped glass columns, 180 cm × 3 mm i.d., was used. The column packings used were Porapak R[2] (80–100 mesh) for ethylene oxide determinations and 15% Carbowax 400 on 80–100-mesh Gas Chrom Q[3] for ethylene chlorohydrin and ethylene glycol measurements. The carrier gas was helium at a flow rate of approximately 60 ml/min, with hydrogen and air flows adjusted for maximum flame response.

The oven temperature was approximately 110° for both columns. A Porapak R column at 170° was also used for ethylene chlorohydrin and ethylene glycol. The flash heater and the detector were operated about 10 and 30° above the column temperature, respectively. The instrument sensitivity was range 10 and attenuation 1, 2, or 4, depending upon sample concentration.

Reagents and Chemicals—Distilled water, hexane[4], ethylene oxide[5] (liquid), ethylene chlorohydrin[5], and ethylene glycol[6] were used. The hexane was washed with distilled water prior to use.

Reference Preparations—The ethylene oxide reference solution was prepared by diluting an ethylene oxide stock solution with distilled water to a concentration of 30 μg/ml. The stock solution of ethylene oxide was prepared by adding about 0.5 ml of liquid ethylene oxide to a 50-ml volumetric flask containing about 25 ml of distilled water. The flask was weighed before and after addition of the ethylene oxide; the increase in weight was the amount of ethylene oxide dissolved. The ethylene oxide solution was diluted to volume and mixed prior to dilution.

A combined ethylene chlorohydrin and ethylene glycol reference solution was prepared by dilution of a stock solution containing both compounds to a concentration of 30 μg/ml each. The stock solution was

prepared by combining about 0.3 g each, accurately weighed, of ethylene chlorohydrin and ethylene glycol in a 100-ml volumetric flask and diluting to volume with distilled water.

Sample Preparations—Aqueous solutions were chromatographed directly. Aqueous suspensions were centrifuged, and portions of the clear supernates were removed for chromatography.

One-gram samples of water-insoluble bulk drugs were placed in disposable vials, and 4.0 ml of distilled water was added. The samples were mixed thoroughly with a vortex mixer and shaken vigorously for at least 5 min. The samples were centrifuged, and portions of the clear supernates were withdrawn for chromatography.

Three-gram samples of ointments were placed into 35-ml centrifuge tubes and dissolved in 6.0 ml of water-washed hexane. Exactly 3.0 ml of distilled water was added, and the samples were mixed for 5 min with a vortex mixer and centrifuged. The upper organic layer was removed by aspiration, and the lower aqueous layer was retained for chromatography. A 3.0-ml portion of the ethylene oxide reference solution was washed with 6.0 ml of water-washed hexane before chromatography in this case.

Equal aliquots, usually 6.0 μl, of the sample preparations and the appropriate reference preparations were chromatographed using the specified conditions. It was necessary to equilibrate the columns by injecting two or three aliquots of the reference solutions prior to each day's analyses. Peak heights were determined directly from the chromatograms.

Calculations—The level of each residual, ethylene oxide, ethylene chlorohydrin, and ethylene glycol, was calculated by a peak height comparison with the corresponding reference.

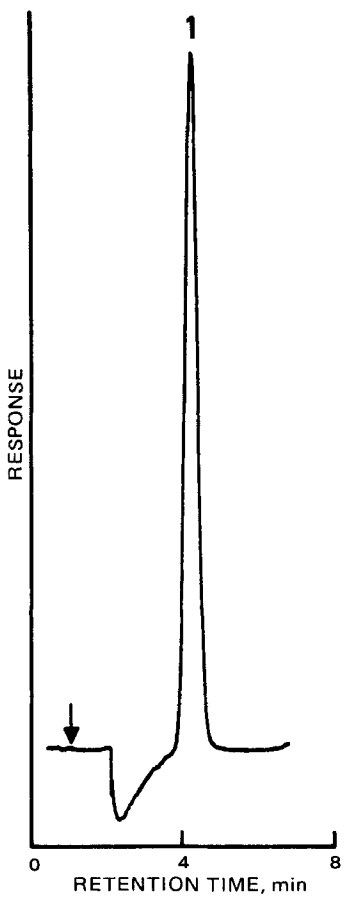

Figure 1—*Chromatogram of 40 μg/ml of ethylene oxide (1) added to an aqueous suspension of a steroid (Porapak R column). The arrow indicates the point of injection.*

RESULTS AND DISCUSSION

GLC—A representative chromatogram for ethylene oxide is shown in Fig. 1. Although water should not give a response in the flame-ionization detector, an apparent solvent front was observed, probably due to pertubation of flows by injection and vaporization. The shape of this solvent front varied from one sample type to another. Chromatographic response was linear over the 2–80-μg/ml range. The limit of detection was about 2 μg/ml for ethylene oxide.

Under the standard chromatographic conditions, ethylene oxide was not resolved from methanol. Methanol is a common recrystallization solvent for steroids and could be present in residual amounts. If a significant ethylene oxide response was observed, chromatography at 70° resolved the methanol. At a column temperature of 70°, ethylene oxide and methanol had retention times of 7 and 8 min, respectively. Acetone, another common recrystallization solvent, also was detected in some cases. This peak, which had a retention time of about 13 min at 110°, did not interfere with the ethylene oxide determination but did require extended chromatography time. No other interferences were observed.

Either of two sets of chromatographic conditions was used for the simultaneous determination of ethylene chlorohydrin and ethylene glycol. Typical chromatograms for the Carbowax 400 and Porapak R columns are shown in Figs. 2 and 3, respectively. Chromatographic response was linear for both columns over the 2–110-μg/ml range for ethylene chlorohydrin and the 5–200-μg/ml range for ethylene glycol. Limits of detection were estimated to be 2 μg/ml for ethylene chlorohydrin and 5 μg/ml for ethylene glycol.

Chromatography on the Carbowax 400 column was preferred over the Porapak R column because fewer extraneous peaks were observed and

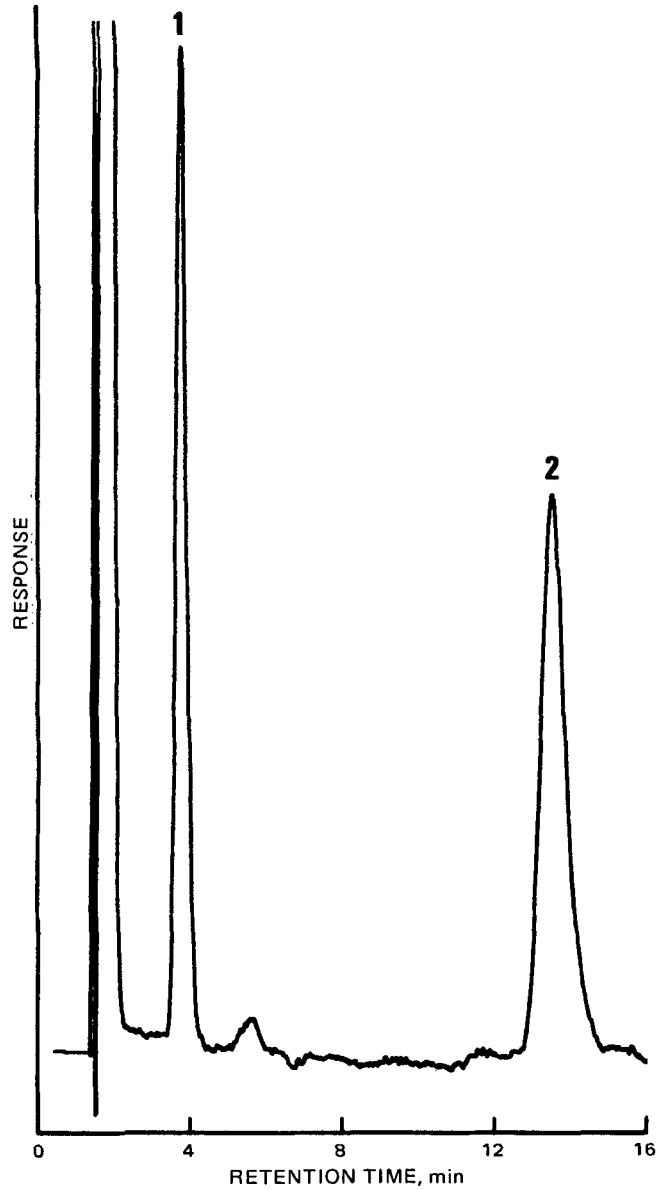

Figure 2—*Chromatogram of ethylene chlorohydrin and ethylene glycol added to an aqueous suspension of a steroid (polyethylene glycol 400 column). Key: 1, ethylene chlorohydrin (63 μg/ml); and 2, ethylene glycol (63 μg/ml).*

the resolution and shape of the peaks were superior. The Carbowax column was tried first in all cases. However, some aqueous suspensions and solutions were formulated with benzyl alcohol as a preservative, and the large benzyl alcohol peak masked the ethylene glycol peak when the Carbowax column was used. The retention time of benzyl alcohol on the Porapak R column was about 90 min at 170°, thus permitting several samples to be run before the benzyl alcohol eluted. It was necessary to chromatograph two or three aliquots of the reference solutions to establish a reproducible response, probably due to on-column adsorption of these compounds.

A buildup of components from the various sample formulations on the column packings was observed after extended use and caused a deterioration of the chromatographic performance. Original column efficiency was restored by replacing the front 4–5 cm of column packing and allowing the column to reequilibrate for at least 16 hr.

No attempt was made to identify extraneous peaks (other than those previously discussed) because they were always resolved from the peaks of interest. As a precautionary measure, the hexane was washed with distilled water prior to use to eliminate impurities that interfered.

Recovery—Recovery data were obtained for each of the 12 bulk drugs, 16 aqueous suspensions and solutions, and 11 ointments studied. Various spiking techniques were used to add three different levels each of ethylene oxide, ethylene chlorohydrin, and ethylene glycol to separate samples of every sample type studied.

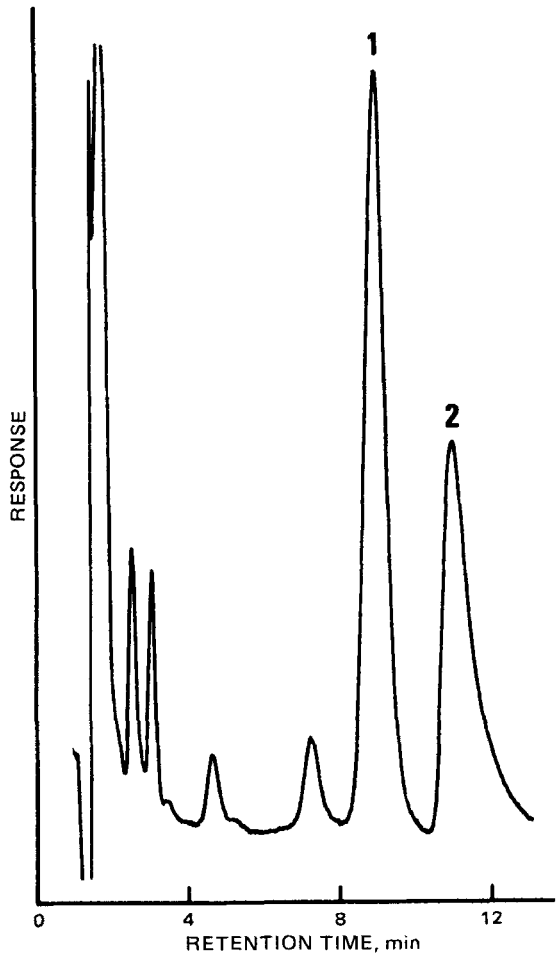

Figure 3—*Chromatogram of ethylene chlorohydrin and ethylene glycol added to a sterile infusion solution of a steroid (Porapak R column). Key: 1, ethylene chlorohydrin (61 μg/ml); and 2, ethylene glycol (62 μg/ml). Excipient peaks are not identified, and the benzyl alcohol peak is not shown.*

For bulk drugs, recovery samples were simulated by equilibrating aqueous solutions of the residuals with samples of non-ethylene-oxide-treated bulk drugs. The vortex mixer produced a homogeneous mixture of the bulk drug powder and the aqueous phase. This mixture was separated by centrifugation, and the clear supernates were chromatographed. Adler (5) found that the retention of ethylene oxide on steroids is due to sorption on the surface of the individual drug particles. Since ethylene oxide is highly water soluble and the drugs tested were generally micronized, the removal of this residual from the drug should have been highly efficient.

Aqueous suspensions and solutions for the recovery studies were prepared using vehicles containing non-ethylene-oxide-treated materials. Microliter aliquots of concentrated solutions of the residuals were added to produce the desired concentrations. The samples were mixed, centrifuged if necessary, and chromatographed under the appropriate conditions.

Recovery for the ointments was demonstrated by extracting hexane solutions of a nonsterilized formulation with aqueous solutions containing the residuals.

Typical recovery data are presented in Table I. In most cases, the recovery for individual samples was greater than 90%. The average recovery for each formulation or bulk material was greater than 95%. Due to the significant solubility of ethylene oxide in hexane, it was necessary to wash the ethylene oxide reference solution with hexane prior to analysis of ointments. Thus, the recoveries reported for ethylene oxide are actually apparent recovery.

The reference solutions were quite stable. The combined ethylene chlorohydrin and ethylene glycol reference preparation was retained for several weeks with no noticeable change in concentration. The ethylene

oxide reference solution was stable for about 1 week when prepared in distilled water. However, a change in pH or contamination with inorganic halide would induce rapid conversion of the ethylene oxide to ethylene glycol or ethylene halohydrin. The same concern existed for the sample preparations. Therefore, samples were always chromatographed on the same day that they were prepared.

Precision—Reproducibility of the chromatographic response was about 2% in each case, determined by replicate injections of reference solutions. The variation in results for actual samples was about 5%.

Simplicity—The measurement of the levels of residual ethylene oxide, ethylene chlorohydrin, and ethylene glycol present in pharmaceutical preparations is more of a limits test than a precise quantitation for potency determination. Thus, it is desirable to use rapid, simple, sensitive, and fairly accurate methods for these measurements. The procedures as described satisfy these requirements.

The sample preparation was as simple as possible. All three residuals were extracted simultaneously by a single aqueous extraction.

The chromatographic systems were ideal. Two columns in one dual column instrument provided the necessary instrumentation for estimating all three residuals without changing oven temperature.

Chromatographic time was held to a minimum. Since the highest precision was not required, internal standards were not employed which minimized chromatographic time and permitted a single sample preparation to be employed for all three residuals. Water proved to be the ideal solvent. It provided the highest extraction efficiency, yet did not respond in the flame-ionization detector. If an organic solvent had been required, it would probably have eluted after ethylene oxide and time would have been lost waiting for a large solvent peak to clear the column. With water, this delay was eliminated.

These procedures are versatile and applicable to a large number of aqueous suspensions, aqueous solutions, ointments, and water-insoluble bulk drugs.

Enzymatic Activity of Pig Heart Mitochondrial Malate Dehydrogenase Monomolecular Films by Surface Exchange Technique

A. W. MALICK [*] and N. D. WEINER [x]

Abstract □ A technique for studying the catalytic activity of enzymes spread as a film at an air–water interface, by exchanging the subphase under the film to remove unspread enzyme molecules, was developed, and its effectiveness was studied using surface-spread mitochondrial malate dehydrogenase. Mitochondrial malate dehydrogenase formed stable films which gave reproducible π–A curves. The enzyme activity was measured by the oxidation rate of reduced nicotinamide adenine dinucleotide (NADH) in the presence of the substrate oxalacetic acid. Oxalacetic acid and NADH were injected into the subphase. The catalytic activity of the enzyme was dependent on the surface pressure of the film. The maximum catalytic activity was observed at a surface pressure of 4.4 dynes/cm. The activity was higher at intermediate surface pressures than at very low or very high surface pressures. A high bulk catalytic activity was observed in the unstable region, *i.e.*, at a high degree of compression, of the film. The catalytic activity of the surface-spread enzyme was only a fraction of an equivalent amount of enzyme in solution.

Keyphrases □ Catalytic activity—enzymes spread as a monomolecular film at an air–water interface, surface exchange technique developed □ Enzymes—mitochondrial malate dehydrogenase, spread as a monomolecular film at an air–water interface, surface exchange technique developed □ Malate dehydrogenase, mitochondrial—spread as a monomolecular film at an air–water interface, surface exchange technique developed □ Films, monomolecular—of enzymes at an air–water interface, surface exchange technique developed □ Surface exchange technique—enzymes spread as a monomolecular film at an air–water interface

Monomolecular films offer a useful model system for studying the behavior of membrane components at an air–water interface (1). The application of monomolecular films to the study of interactions that may occur at the membranes of cells and cell organelles is a flexible and versatile system whereby numerous effects can be observed. The relative simplicity of this system permits analysis and understanding of the effects that often cannot be observed in the extremely complex environment of living systems.

BACKGROUND

Modification of the film can be employed to gain further insight into cellular function. Since membrane-bound enzymes are situated at interfaces, it must be assumed that they are in a partially unfolded state and that the side chains are oriented in relation to the interface. Monolayer studies also afford a method to study the conformational change effects of proteins by monitoring the surface pressure, since the orientation of the side chains of surface-spread protein would be expected to vary with the surface pressure of the film. A dependence of the catalytic activity on surface pressure was reported for catalase and acetylcholinesterase films (2). The activity of surface-spread trypsin was dependent on the surface concentration of the enzyme (3).

Estimation of catalytic activity of surface-spread enzymes presents unique difficulties, because the fraction of the enzyme that escapes into the bulk phase must first be removed. Previously (4), an apparatus and technique for studying monomolecular films were reported; the subphase can be exchanged without disturbing the film, thereby removing any dissolved contaminants in the bulk phase. Data were presented to demonstrate the utility of this system for studying protein monolayers and its applicability to the study of ion-exchange properties of phospholipid monolayers.

In this study, the subphase exchange technique was used to investigate the enzymatic behavior of surface-spread pig heart mitochondrial malate

oxide reference solution was stable for about 1 week when prepared in distilled water. However, a change in pH or contamination with inorganic halide would induce rapid conversion of the ethylene oxide to ethylene glycol or ethylene halohydrin. The same concern existed for the sample preparations. Therefore, samples were always chromatographed on the same day that they were prepared.

Precision—Reproducibility of the chromatographic response was about 2% in each case, determined by replicate injections of reference solutions. The variation in results for actual samples was about 5%.

Monomolecular films offer a useful model system for studying the behavior of membrane components at an air–water interface (1). The application of monomolecular films to the study of interactions that may occur at the membranes of cells and cell organelles is a flexible and versatile system whereby numerous effects can be observed. The relative simplicity of this system permits analysis and understanding of the effects that often cannot be observed in the extremely complex environment of living systems.

BACKGROUND

Modification of the film can be employed to gain further insight into cellular function. Since membrane-bound enzymes are situated at interfaces, it must be assumed that they are in a partially unfolded state and that the side chains are oriented in relation to the interface. Monolayer studies also afford a method to study the conformational change effects of proteins by monitoring the surface pressure, since the orientation of the side chains of surface-spread protein would be expected to vary with the surface pressure of the film. A dependence of the catalytic activity on surface pressure was reported for catalase and acetylcholinesterase films (2). The activity of surface-spread trypsin was dependent on the surface concentration of the enzyme (3).

Estimation of catalytic activity of surface-spread enzymes presents unique difficulties, because the fraction of the enzyme that escapes into the bulk phase must first be removed. Previously (4), an apparatus and technique for studying monomolecular films were reported; the subphase can be exchanged without disturbing the film, thereby removing any dissolved contaminants in the bulk phase. Data were presented to demonstrate the utility of this system for studying protein monolayers and its applicability to the study of ion-exchange properties of phospholipid monolayers.

In this study, the subphase exchange technique was used to investigate the enzymatic behavior of surface-spread pig heart mitochondrial malate

dehydrogenase. Mitochondrial malate dehydrogenase, an enzyme of the tricarboxylic acid cycle, catalyzes the oxidation of L-malate to oxalacetate (5). This enzyme requires relatively drastic isolation procedures, including an acetone-dried powder preparation of tissues and an ethanol fractionation (6). The difficulty in its isolation suggests that the enzyme is firmly bound to the mitochondrial framework. Aqueous solutions of mitochondrial malate dehydrogenase are quite unstable, and most of the catalytic activity is lost on standing for a few hours at room temperature (7). This instability of the enzyme is associated with the removal of the enzyme from its bound state, which also suggests that it is situated at a biological interface.

A previous article (4) discussed film studies of pig heart mitochondrial malate dehydrogenase at an air–water interface with and without subphase exchange. Malate dehydrogenase forms stable films, which give reproducible surface pressure–surface area (π–A) curves. Films of malate dehydrogenase that were formed using different amounts of this enzyme were studied after the buffered subphase was changed with a buffer solution of the same composition. The exchange of this subphase had no effect on the π–A plots of any malate dehydrogenase film studied.

The purposes of this phase of the study were to investigate the applicability of the subphase exchange technique for studying the catalytic activity of surface-spread malate dehydrogenase and to determine the effect of surface pressure on catalytic activity.

EXPERIMENTAL

Materials—Malate dehydrogenase[1] (porcine heart) was supplied as a suspension in 70% saturated ammonium sulfate solution. Oxalacetic acid[2] (*cis*-enol) and nicotinamide adenine dinucleotide, reduced[1] (NADH), 90%, were used to measure the activity of the enzyme. The inorganic chemicals used, all reagent grade, were checked for surface impurities. The water used was first deionized by passing distilled water through a mixed resin bed of a demineralizer[3] and then distilled twice from an all-glass still. All buffer solutions were passed through a column of activated charcoal.

Surface tension measurements were made by the Wilhelmy plate method (8), using a thin roughened platinum plate suspended from a torsion balance. The film balance[4] consisted of a 500-ml capacity Langmuir-type polytef[5] trough equipped with a polytef movable barrier and two ribbon screw polytef stirrers running along the two long edges of the trough. The stirring system was designed so that the motion at reasonable speeds did not disturb the film. For all experiments, the temperature of the trough was maintained at 27 ± 2° by circulating water from a bath in a jacket surrounding the trough.

Monolayer Methods—The apparatus and procedure for subphase exchange and for determining π–A isotherms for protein monolayers spread at the air–water interface were described previously (4). The π–A isotherms of proteins were obtained by film compression after the protein was spread by the Trurnit (9) method. Compression was initiated 25 min after the protein was spread, which allowed enough time for equilibration and subphase exchange. In the exchange process, 900 ml of subphase was exchanged (trough capacity = 500 ml) with a phosphate buffer solution of the same composition as the subphase.

Spreading solutions of malate dehydrogenase were prepared by diluting a suspension of malate dehydrogenase with sufficient 0.1 *M* phosphate buffer (pH 7.4) to yield a concentration of 1.36 mg/ml. The subphase in the surface balance trough also consisted of 0.1 *M* phosphate buffer (pH 7.4). The pH value of 7.4 was chosen because the highest activity of malate dehydrogenase occurs in the physiological range of pH 7.3–7.5 (10). Different volumes of spreading solution of the same concentration of enzyme were delivered to spread films of different protein surface concentrations. For each experiment, a fresh spreading solution of malate dehydrogenase was prepared.

To determine the amount of enzyme adsorbed at the air–water interface after subphase exchange, films were removed by negative pressure using a narrow glass tube and then analyzed for protein content by a modification of the Lowry (11) technique.

Enzyme Activity Methods—For enzyme activity studies, a fresh solution of oxalacetic acid was prepared for each experiment by dissolving 50 mg of oxalacetic acid in 50 ml of pH 7.4 phosphate buffer and adjusting to pH 7.2–7.4. The solution was stored at 0°. Solutions of NADH were prepared by dissolving 112 mg of NADH in 50 ml of the pH 7.4 phosphate buffer immediately before use. This solution was never frozen.

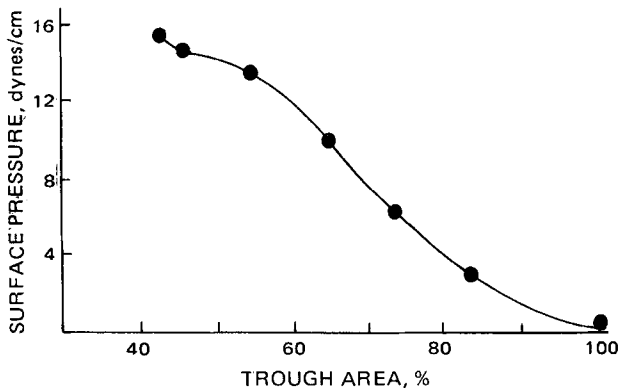

Figure 1—*The π–A curves of mitochondrial malate dehydrogenase films of 0.081 mg of enzyme spread on pH 7.4 phosphate buffer and the subphase was exchanged with 900 ml of buffered solution.*

The malate dehydrogenase film was first spread by the method described previously. Five minutes after the protein had been spread, the subphase exchange was started and continued for 15 min. In the process, 900 ml of the subphase was exchanged. After the exchange, the polytef barrier of the surface balance was moved to a position that gave the desired surface pressure at which the activity of the enzyme was to be measured.

Following compression, 40 ml of the NADH solution was injected under the film with two glass syringes attached to stainless steel needles previously placed at the midline of the trough 10 cm from each edge in the trough. Two injections were used instead of one to obtain a quicker mixing of the injected solution with the subphase. Injections were made at a slow, steady rate to avoid any disturbance of the film. The injection of air bubbles was also avoided.

Soon after injection of the NADH solution, the stirrers were started. The stirrer speed, at which there was no disturbance at the surface, was kept constant for all experiments. Seven minutes after the injection of NADH solution, oxalacetic acid solution was injected through the two syringes to initiate the reaction. The time at which the contents of the first syringe of oxalacetic acid solution was injected was taken as time zero for the reaction.

As soon as the oxalacetic acid solution was injected, a 4-ml sample of the subphase was pulled through one needle. Additional 4-ml samples were then pulled at specific intervals for UV analysis[6] at 340 nm. The UV absorbance of the subphase solution was independent of the part of the trough from which the sample was withdrawn. Throughout the experiment, the needles remained in place and the stirring was continued. The activity of the enzyme was measured spectrophotometrically by virtue of disappearance of NADH based on the characteristic absorption of NADH at 340 nm.

The slope of the absorbance–time curve, representing the rate of enzyme-induced oxidation of NADH to NAD, was used as a measure of malate dehydrogenase activity. Plots of NADH absorbance *versus* time were linear, and results were reproducible. Slopes were calculated using a linear regression computer program.

RESULTS AND DISCUSSION

The malate dehydrogenase films were spread on pH 7.4 phosphate buffer, and the subphase was exchanged with a buffer solution of the same composition. In all experiments, malate dehydrogenase formed stable films which gave reproducible π–A curves.

Figure 1 shows the π–A curve of 0.081 mg of malate dehydrogenase spread on buffer solution with the subphase exchanged. The π–A plot shows an inflection point at 15 dynes/cm. Beyond the inflection point, *i.e.*, at smaller surface areas, the film became less compressible and also less reproducible. This concentration of protein was chosen because it allowed observation of the catalytic activity of the enzyme film essentially from the gaseous state up to the point where the film became unstable, using the same trough without changing the amount of protein spread. The concentration of malate dehydrogenase at the surface must be

constant because the π–A plots using different concentrations of this protein are parallel but not superimposable (4). The π–A curves of higher malate dehydrogenase concentration films are condensed relative to those of lower concentrations.

Figure 2 shows some catalytic activity data of the surface-spread malate dehydrogenase. The plots of NADH absorbance *versus* time were linear and reproducible. The slopes of these plots were taken as a measure of malate dehydrogenase activity. The reactions were followed for about 20 min.

To investigate the effect of surface pressure on enzyme activity, compression of the enzyme film was necessary. The movement of the polytef barrier to compress the film resulted in a proportional decrease in area available to the enzyme at the surface. Since the reaction was carried out under zero-order saturated conditions, the available surface area of the enzyme at any given surface pressure should not have affected the reaction rate. To be certain that this was the case, different amounts of malate dehydrogenase were spread at the surface and the catalytic activity was studied at different available areas of the surface.

Figure 2 and Table I show the catalytic activity of different amounts of protein. Since the surface pressure of all films in this phase of the study was about zero, all of these films were gaseous in nature. First, 0.08 mg of protein was applied to the surface at full trough area and the enzyme activity of this film was recorded. The catalytic activity of 0.04 mg of enzyme spread at full trough area was then observed. In another experiment, 0.04 mg of enzyme was spread at full trough area and the area was then reduced to one-half the original trough area. The catalytic activity of this system was then studied. Similarly, the catalytic activity of 0.06 mg of enzyme was studied at full trough area and then after reduction to three-quarters trough area.

Table I shows that the activity of 0.04 mg of the enzyme, both at full trough area and at one-half trough area, was one-half of the catalytic activity observed for 0.08 mg of the enzyme. Similarly, the activity of 0.06 mg of the enzyme was about three-quarters of the activity observed for 0.08 mg of the enzyme both at full and three-quarters trough areas. These results indicate that the surface area available to the enzyme did not affect the catalytic activity when 0.08 mg or less of protein was spread as long as the surface pressure remained constant, *i.e.*, no conformational changes occurred. Thus, any changes of enzyme activity observed with compression of the film can be safely attributed to the change in surface pressure, *i.e.*, the conformational changes of the enzyme molecules associated with the change in surface pressure.

The orientation of the side chains of the surface-spread protein in relation to the surface may vary with the surface pressure (2). At film pressures close to zero, the side chains may lie flat in the surface. If the pressure is increased, the polar groups would be oriented into the aqueous phase while the nonpolar groups would be oriented toward the air phase. Therefore, it should be possible to vary the orientation of the protein molecules in a film by applying surface pressures of varying magnitudes.

Table I—Enzyme Activity of Malate Dehydrogenase Films

Amount of Enzyme Spread, mg	Surface Area Available to Enzyme	Enzyme Activity[a], Arbitrary Units
0.08	Full trough	2.2
0.06	Full trough	1.62
	Three-quarters trough	1.5
0.04	Full trough	0.98

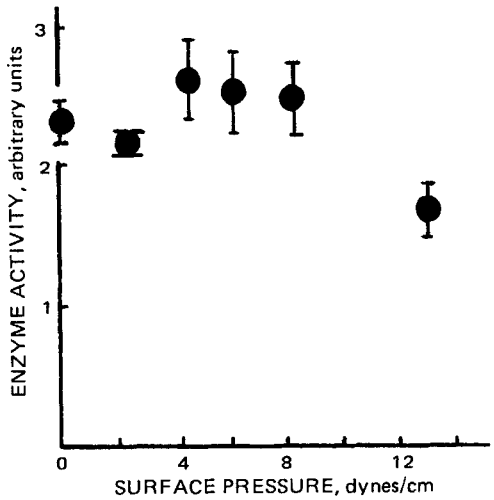

Figure 3—*Catalytic activity of mitochondrial malate dehydrogenase* versus *surface pressure plot of malate dehydrogenase films.*

In all subsequent experiments in this study, the same amount of enzyme, 0.081 mg, was spread each time. The concentration of the spreading solution was also kept constant.

Figure 3 shows the catalytic activity of surface-spread malate dehydrogenase at different surface pressures. A dependence of catalytic activity was observed with surface pressure. At intermediate film pressures, the activity of the enzyme was higher than at very low or very high surface pressures. The maximum activity was noted at 4.4 dynes/cm, and very small changes in catalytic activity were observed at surface pressures between 4 and 8 dynes/cm. Although not shown in Fig. 3, at a surface pressure of 18 dynes/cm, a point beyond the inflection point of malate dehydrogenase film (Fig. 1), a high bulk catalytic activity was observed.

The film studies of the enzyme showed that the π–A plots were not reproducible beyond 15 dynes/cm. This finding suggests that the enzyme film at this pressure becomes unstable and that some enzyme leaves the surface and diffuses to the bulk. This idea is borne out by the observation of significant catalytic activity in the subphase at a high surface pressure (18 dynes/cm).

These results show that the catalytic activity of malate dehydrogenase films is dependent on the surface pressure and, in turn, on the conformation of the enzyme molecules and suggest a mechanism by which the activity of enzymes may be regulated in membranes. A dependence of catalytic activity on surface pressure also was reported for surface-spread acetylcholinesterase and catalase (2). With acetylcholinesterase, maximum activity was attained at a surface pressure of 10 dynes/cm and decreased at both lower and higher pressures.

The results of the surface protein content analysis show that when 0.081 mg of enzyme was spread, 29.6% of the original protein spread was found at the surface after subphase exchange. This loss would be expected since, when a solution of protein is applied at the interface, some protein unfolds and anchors at the surface while the remainder escapes into the bulk in globular form. The amount of protein escaping to the bulk would be dependent on, among other factors, the amount of protein originally applied to the surface. When acetylcholinesterase was applied to the surface, 44–74% of the original protein applied anchored at the surface (2). In another study (3), 80% of the trypsin applied to the surface was lost to the subphase.

An amount of malate dehydrogenase equivalent to that present at the surface after exchange was used to compare enzyme activity in the bulk with that of surface-spread enzyme under similar conditions; *i.e.*, the final concentrations of the enzyme, oxalacetic acid, and NADH were kept the same as in the activity studies of the film. The enzyme activity at the surface was equal to 13% of the activity of the same amount of the enzyme in solution.

The loss of activity of enzyme adsorbed at an air–water interface has been shown by a number of workers. Catalase retained about 22% catalytic activity on adsorption at the air–water interface (12). The catalytic

activity was dependent on the surface pressure of a film of acetylcholinesterase, and the maximum activity observed was at a surface pressure of 10 dynes/cm (2). This activity was equal to 29% of the activity of the same amount of enzyme in solution. The fraction of the retained enzyme activity on adsorption at an air–water interface in the case of trypsin varied from 0.125 to 0.35, depending on the surface concentration of the enzyme (3).

This study demonstrated the effectiveness of the subphase exchange technique for investigating the catalytic activity of enzymes spread at an air–water interface, without interference of bulk reaction. Future reports will discuss the effects of various lipids on the catalytic activity of surface-spread malate dehydrogenase.

Kinetics and Mechanisms of Hydrolysis of 1,4-Benzodiazepines III: Nitrazepam

WESLEY W. HAN *, GERALD J. YAKATAN ˣ, and DALE D. MANESS

Abstract □ The hydrolysis of nitrazepam involves a two-step sequential mechanism. The intermediate is the ring-opened compound resulting from scission of the azomethine bond. The final products are glycine and 2-amino-5-nitrobenzophenone. Recyclization of the intermediate to nitrazepam occurs at pH values above the pKa of the intermediate, in the pH region where the amino group of the intermediate is not protonated. As opposed to chlordiazepoxide and oxazepam, the initial hydrolysis step occurs at the 4,5-bond, not at the 1,2-amide linkage. This difference is attributed to a preferential activation for hydrolysis of the azomethine linkage by the nitro group. The hydrolysis involves an uncatalyzed reaction, specific acid–base catalysis, and general acid–base catalysis for acetate and phosphate buffers.

Keyphrases □ 1,4-Benzodiazepines—nitrazepam, kinetics and mechanisms of hydrolysis □ Nitrazepam—kinetics and mechanisms of hydrolysis □ Hydrolysis—nitrazepam, kinetics and mechanisms □ Anticonvulsants—nitrazepam, kinetics and mechanisms of hydrolysis

Nitrazepam, 1,3-dihydro-7-nitro-5-phenyl-2*H*-1,4-benzodiazepin-2-one, belongs to the 1,4-benzodiazepine class of tranquilizing agents. This compound is centrally active (1), surpassing diazepam, a popular benzodiazepine, in anticonvulsant activity (2).

Preceding publications (3, 4) in this series reported the hydrolysis kinetics of 7-chloro-1,4-benzodiazepines. The present study concerned the hydrolysis of the 7-nitro analog, nitrazepam.

EXPERIMENTAL

Materials—Compound purity was verified by TLC. Nitrazepam[1] and 2-amino-5-nitrobenzophenone[1] were used as received.

Buffer Solutions—All buffer solutions were made with deionized, distilled water. They were adjusted to an ionic strength of 1.0 with sodium chloride, except in ionic strength effect studies where they were adjusted to ionic strengths other than 1. The pH at the temperature of the runs was measured with a digital pH meter[2] equipped with high temperature electrodes.

The buffer systems used were: pH 1.0–3.0, hydrochloric acid; pH 3.2–5.6, acetate; pH 6.4–7.4, phosphate; pH 7.9–9.5, borate; and pH 10.1–11, sodium hydroxide.

Kinetic Measurements—The kinetic studies of the hydrolysis of nitrazepam were followed spectrophotometrically. Details of the specific procedures were given previously (3) and are summarized as follows.

A stock solution of nitrazepam (6.3×10^{-3} *M*) in ethanol was diluted in an appropriate buffer to a final concentration for the kinetic run of 2.4×10^{-5} *M*. The reaction flasks (light protected) were maintained in a constant-temperature oil bath[3] controlled within 0.1° at selected temperatures between 70 and 85°. Samples were withdrawn at suitable time intervals and cooled to room temperature by quenching in an ice water bath. Visible and UV spectrophotometric measurements were made with a double-beam spectrophotometer[4].

Isolation and Identification—Thin-layer chromatograms were made on 20 × 20-cm glass plates coated with a 250-μm layer of silica gel GF_{254}. After lyophilization, the samples were dissolved in chloroform, spotted, and developed in a closed tank for approximately 1 hr with dioxane–benzene–hexane–7.4 *M* NH_4OH (45:50:70:5). The solvent front was allowed to travel 17 cm from the origin. After drying, the plates were visualized using a short wavelength UV lamp and then sprayed with ninhydrin aerosol (0.5%) to produce visible spots. Nitrazepam, 2-amino-5-nitrobenzophenone, and glycine were spotted as reference standards. An intermediate was isolated by preparative TLC and characterized by its IR[5], NMR[6], and high-resolution mass[7] spectra.

RESULTS AND DISCUSSION

Spectral Changes and Rate Constant Determinations—The kinetics of hydrolysis of nitrazepam were monitored by following the change in absorbance, A, of the visible and/or UV chromophore as a function of time. The pKa values for nitrazepam are 3.2 and 10.8 (5). No pKa was found for 2-amino-5-nitrobenzophenone in the pH region of the present study. For pH values below the pKa of 3.2, two apparent reaction steps were observed. The first was characterized by an absorbance decrease at λ_{max} 278 nm with isosbestic points at 252 and 315 nm. The second showed an absorbance decrease at λ_{max} 265 nm with the formation of a new absorbance band with λ_{max} 364 nm.

For pH values intermediate to pKa_1 and pKa_2, only one reaction step was observed spectrally. The spectral changes were similar to those observed for the second hydrolysis step for pH values below pKa_1. For pH values above pKa_2, the single reaction step observed was characterized by a red shift from λ_{max} 364 to 380 nm. The spectrum at the time infinity point was identical to the spectrum of 2-amino-5-nitrobenzophenone throughout the entire pH region.

The logarithms of the difference in the final absorbance, A_∞, and the absorbance at any time, A_t, at the desired wavelength were plotted against time. The apparent first-order rate constants were calculated from the slopes of the linear segment according to:

$$\ln(A_t - A_\infty) = \ln(A_0 - A_\infty) - kt \qquad \text{(Eq. 1)}$$

where A_0 is the absorbance at zero time, and k is the apparent first-order rate constant. Absorbance changes in the visible region (370 nm) were used to calculate the apparent first-order rate constants for all pH values above the first pKa. For pH values below pKa_1, plots made according to Eq. 1 were biphasic, indicative of a two-step hydrolytic reaction in this pH region. For these data, the "feathering" technique was utilized to determine the sequential apparent first-order rate constants for the first and second reaction steps. Typical first-order plots for the hydrolysis of nitrazepam are shown in Fig. 1. The rate constants derived from these plots are presented in Table I.

Based on the observed spectral and kinetic behavior of nitrazepam (I), a two-step sequential hydrolysis pathway could be proposed (Scheme I). A reversible first-step hydrolytic ring opening of the benzodiazepine nucleus is followed by a second hydrolytic step, leading to the formation of glycine and a substituted benzophenone derivative.

Log k–pH Profiles—The log k–pH profile for nitrazepam was constructed at 75° with the data in Table I. For pH values below pKa_1, the first reaction step can be described by:

$$k_{obs} = k_{H_2O} f_{NH} \qquad \text{(Eq. 2)}$$

or by its kinetic equivalent:

$$k_{obs} = k_H[H^+]f_N \qquad \text{(Eq. 3)}$$

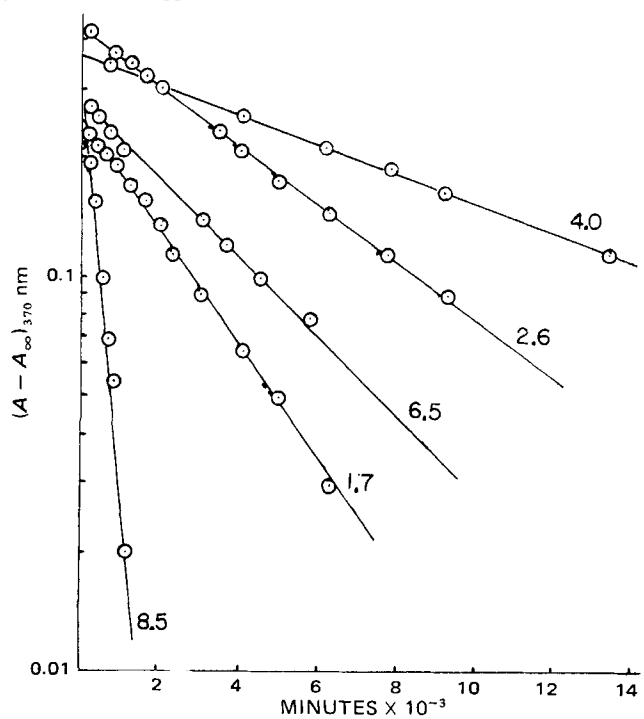

Figure 1—*Typical apparent first-order plots for the hydrolysis of 10^{-5} M nitrazepam as a function of pH.*

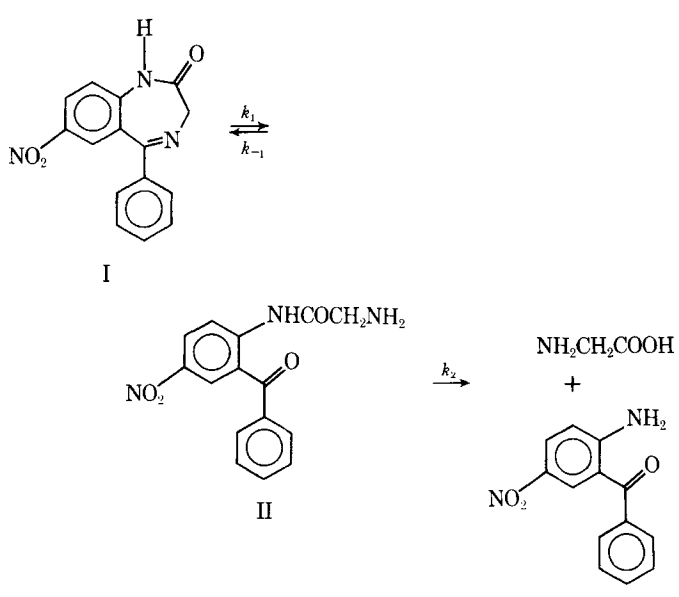


Scheme I

Table II—Apparent First-Order Rate Constants, 10^4 k (in Minutes^{-1}) for Hydrolysis of Nitrazepam at Various Buffer Concentrations

pH	Total Buffer Concentration in 1X	1X	2X	3X	4X	k_0
4.74	[CH_3COOH][CH_3COO^-] 0.100	0.63	0.74	1.0	1.17	0.41
6.37	[$H_2PO_4^-$][HPO_4^{2-}] 0.066	2.52	3.08	3.42	3.56	2.2

The terms f_{NH} and f_N are the fractions existing as protonated and deprotonated nitrazepam, respectively.

The rate constants that provided the best fit are $k_{H_2O} = 0.054$ min^{-1} and $k_H = 54$ min^{-1} M^{-1}. The kinetic pKa at 75° was 3.0, in agreement with the reported pKa_1 of nitrazepam at room temperature.

The log k–pH profile for the second reaction step exhibited five distinct components. At low pH values, the kinetics indicated hydrogen-ion catalysis on the protonated intermediate H_2S, followed by water attack on the neutral intermediate, HS. Uncatalyzed hydrolysis on the neutral intermediate, or the kinetic equivalent of hydroxide-ion attack on the protonated species, was observed over the neutral pH region.

The hydrolysis kinetics of nitrazepam in the basic pH region indicated hydroxide-ion catalysis on the double deprotonated intermediate, S, followed by water attack on the deprotonated species or its kinetic equivalent of hydroxide-ion catalysis on the neutral species. The apparent first-order rate constant at any pH can be quantitatively described by:

$$k_{obs} = k_H[H^+]f_{H_2S} + k_{H'}[H^+]f_{HS} + k_{H_2O}f_{HS} + k_{OH}[OH]f_{HS} + k_{OH'}[OH^-]f_S \quad \text{(Eq. 4)}$$

or the following substituted kinetic equivalents:

$$k_{H'}[H^+]f_{HS} = k_{H_2O}'f_{H_2S} \quad \text{(Eq. 5)}$$

$$k_{H_2O}f_{HS} = k_{OH''}[OH^-]f_{H_2S} \quad \text{(Eq. 6)}$$

$$k_{OH'}[OH^-]f_{HS} = k_{H_2O}''f_S \quad \text{(Eq. 7)}$$

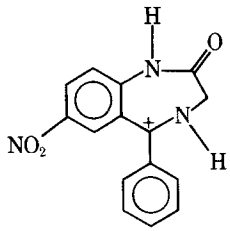
The bimolecular rate constants that provided the best fit are $k_H = 0.0088$ min^{-1} M^{-1}, $k_{H'} = 1.88$ min^{-1} M^{-1}, $k_{H_2O} = 0.00015$ min^{-1}, $k_{OH} = 1.52 \times 10^5$ min^{-1} M^{-1}, and $k_{OH'} = 247$ min^{-1} M^{-1}.

From the log k–pH profile, the two kinetic pKa's were calculated as 4.1 and 8.8 and were assigned to the amino nitrogen and the amide group of the intermediate, respectively. The experimental data points with the theoretical curves calculated from Eqs. 2 and 4 are shown in Fig. 2.

Isolation and Identification—Samples withdrawn at appropriate times were subjected to TLC analysis. At pH values below the pKa_1 of nitrazepam, TLC showed an increase in intensity of the yellow 2-amino-5-nitrobenzophenone spot (R_f 0.43) and a decrease in the relative intensity of the nitrazepam spot (R_f 0.22). A compound (R_f 0.17) appeared transiently and was attributed to a reaction intermediate. For pH values above the pKa_1 of nitrazepam, no intermediate was observed by TLC. The spectral changes in this pH region also demonstrated a single isosbestic point, indicative of a one-to-one transformation.

The intermediate was isolated as a yellow solid by preparative TLC. Mass spectrometric analysis of the intermediate demonstrated a possible molecular ion at 18 mass units above the molecular weight of nitrazepam. A compound with this molecular weight could result from hydrolysis of either the 1,2-amide bond or the 4,5-azomethine bond. The NMR spectrum did not show a characteristic carboxylic acid absorption. Since the acid group would result from heterolysis of the amide, the structure resulting from hydrolysis of the azomethine bond was tentatively assigned as II in Scheme I.

Corroborating evidence for this structural assignment was obtained by studying the reversibility of the reaction leading to II. Prior reports (6, 7) showed that, in 1,4-benzodiazepin-2-one hydrolysis, the recyclization of the protonated opened-ring intermediate resulting from scission of the 1,2-amide linkage is quite facile. Additionally, the deprotonated form does not undergo recyclization (3). The opposite was found for recyclization of intermediate II. When heated at 75° for 5 min, the intermediate was shown spectrally to revert to nitrazepam at pH values greater than 5. At pH values below the first pKa of the intermediate, no recyclization was indicated. Indeed, at the higher pH values, II was not observable by either TLC or spectral measurements. If the intermediate is of the benzophenone structure (II), then protonation of the primary amine at pH values below 4 would decrease its nucleophilicity. This, in turn, would decrease the rate of recyclization, in agreement with the experimental results showing rapid recyclization only at pH values above 5.



IV

Hydrolytic Mechanisms—The preceding kinetic and TLC data are mechanistically interpretable according to Scheme I. The first hydrolytic reaction step is only reversible at pH values above the pKa_1 of the intermediate. Initially, the 4,5-bond is hydrolyzed, leading to the ring-opened compound, intermediate II. Although models show that this bond is sterically hindered to nucleophilic attack relative to the amide bond, protonation of the azomethine nitrogen should electronically favor attack at the 5-position. This conclusion is based on possible resonance contribution shown as Structure IV.

However, the 7-chloro-1,4-benzodiazepines chlordiazepoxide (3) and oxazepam (4), also capable of 4-nitrogen protonation to lead to a positive charge resident on the 5-position by resonance, show initial 1,2-bond hydrolysis preferentially. The difference noted between these 7-substituted analogs can be interpreted using the Hammett relationship:

$$\log k/k_0 = \sigma\rho \quad \text{(Eq. 8)}$$

where k and k_0 are the rate constants for hydrolysis of the substituted and unsubstituted compounds, respectively; σ measures the electron-attracting ability of the substituents; and ρ is a parameter defined by the reaction type. The σ values for chloro and nitro substituents are σ_{Cl}^m 0.37 and $\sigma_{NO_2}^m$ 0.71 for *meta*-substitution and σ_{Cl}^p 0.23 and $\sigma_{NO_2}^p$ 0.78 for *para*-substitution (8). Upon substitution of these values into Eq. 8, the Hammett relationship can be written as:

$$\log (k_{Cl}^p/k_{Cl}^m) = -0.14\rho \quad \text{(Eq. 9)}$$

where k_{Cl}^p and k_{Cl}^m are the rate constants for the hydrolysis of *p*- and *m*-chloro-substituted positions, respectively. The equation indicates that the *m*-chloro-substituted position is less reactive than the *p*-chloro-substituted position, assuming a negative ρ value due to electronic requirements for acid-catalyzed hydrolysis. Thus, initial 1,2-bond hydrolysis would be favored. For the 7-nitro compound, the Hammett equation operable is:

$$\log (k_{NO_2}^p/k_{NO_2}^m) = 0.07\rho \quad \text{(Eq. 10)}$$

The *meta*-position (azomethine) hydrolysis would be slightly favored, again assuming a negative ρ.

Stability Parameters—To provide a complete profile of the stability of nitrazepam, hydrolysis kinetics as a function of buffer concentration, ionic strength, and temperature were investigated. Buffer catalysis was studied according to the relationship:

$$k_{obs} = k_0 + \left(\frac{k_{HA}[H^+]}{K_a} + k_A\right)[A^-] \quad \text{(Eq. 11)}$$

where K_a is the dissociation constant for the buffer species, k_0 is the hydrolysis rate constant in absence of buffer catalysis, and k_{HA} and k_A are the rate constants for buffer catalysis of the acid buffer species, HA, and its conjugate base, A^-, respectively. Buffer effects were investigated by changing the original buffer concentration fourfold in a gradient manner. Table II gives the results of these studies on the rate constants

Table III—Apparent First-Order Rate Constants, 10^4 k (in Minutes^{-1}) for Hydrolysis of Nitrazepam at Various Ionic Strengths.

k_1	1418.0	1166.5	599.5	550.3	17.0	22.0	16.3	−7.0	22.3
k_2	14.0	12.2	9.0	6.6	12.5	11.0	11.8	−38.9	25.5

for hydrolysis of nitrazepam. Both acetate and phosphate buffers catalyzed the hydrolysis.

The kinetics of hydrolysis were carried out for different ionic strengths from 0.1 to 1.0 at pH 0.98 and 4.80. The apparent first-order rate constants are given in Table III. No significant ionic strength effect was observed for the k_1 step at pH 0.98 and the k_2 step at pH 4.80. A positive ionic strength effect was observed for the k_2 step at pH 0.98. The use of the Bronsted–Bjerrum equation together with the extended Debye–Huckel equation yields:

$$\log k = \log k_0 + 2QZ_AZ_B \sqrt{\mu}/(1 + \sqrt{\mu}) \qquad \text{(Eq. 12)}$$

where k is the apparent first-order rate constant, k_0 is the rate constant at zero ionic strength, Q is a constant equal to 0.557 (9) at 80°, Z_A and Z_B are the charges of the reacting molecules, and μ is the ionic strength. The ionic strength effect plot for k_2 of pH 0.98 shows a Q value of 0.37. This result suggests that the hydrolysis at pH 0.98 involves a reaction between molecules of like univalent charge.

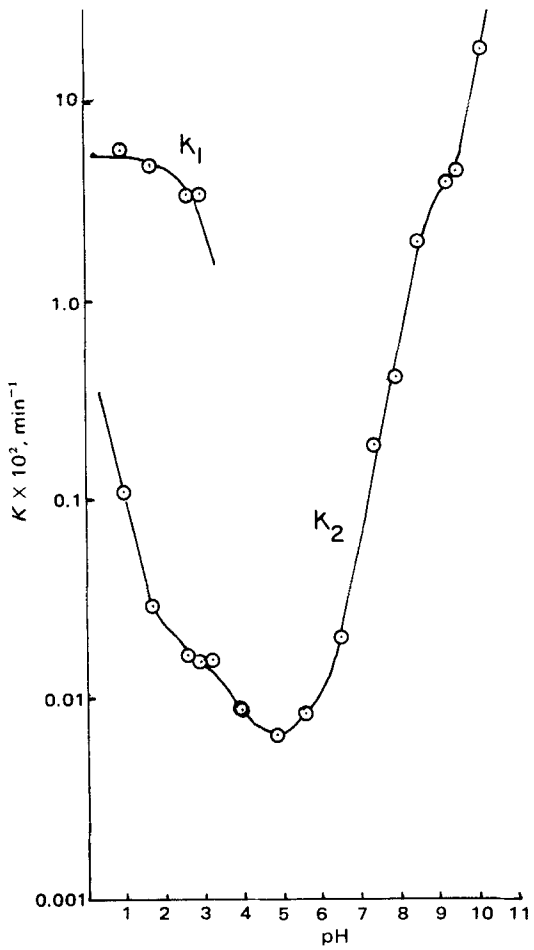

Figure 2—*Log* k–*pH profile for the hydrolysis of* 10^{-5} M *nitrazepam at 75°,* μ = *1.0. The* k_1 *and* k_2 *refer to the first and second reaction steps, respectively.*

The Arrhenius parameters for the hydrolysis of nitrazepam were obtained from the slope and intercept of a plot of the logarithm of the apparent first-order rate constant, k, *versus* the reciprocal of the absolute temperature, T, shown by:

$$\ln k = \ln P - E_a/RT \qquad \text{(Eq. 13)}$$

where R is the gas constant equal to 1.987 cal deg^{-1} mole^{-1}; ln P is related to the entropy of activation, ΔS_a, by:

$$\Delta S_a = R[\ln P - \ln (KT/h) - 1] \qquad \text{(Eq. 14)}$$

where h and K are the Planck and Boltzman constants, respectively; and E_a is related to the enthalpy of activation of the hydrolysis, ΔH_a, by:

$$\Delta H_a = E_a - RT \qquad \text{(Eq. 15)}$$

The Arrhenius parameters for the hydrolysis of nitrazepam at pH 0.93 are given in Table IV. These values will allow stability prediction in this pH region where degradation is rapid.

GLC Determinations of Plasma Acenocoumarol Levels

K. K. MIDHA ˣ and J. K. COOPER

Abstract □ A method for the quantitative estimation of acenocoumarol in plasma is described. Plasma containing acenocoumarol, to which a known amount of γ-oxo derivative of phenylbutazone is added as an internal standard, is acidified and extracted with ethylene dichloride. The drug and the internal standard are then back-extracted into alkali, which, in turn, is acidified and reextracted with ethylene dichloride. The organic extract is evaporated and treated with an ethereal solution of diazomethane (100 μl). The reacted mixture is evaporated, and the residue is dissolved in 25 μl of carbon disulfide. Aliquots (2–3 μl) are injected into a gas chromatograph equipped with a flame-ionization detector. The methyl derivatives of acenocoumarol and the internal standard give sharp, well-separated, symmetrical peaks. The method is of sufficient sensitivity to determine 0.25 μg/ml of the drug in plasma with a relative standard deviation of 4%.

Keyphrases □ Acenocoumarol—GLC analysis, human and dog plasma □ GLC—analysis, acenocoumarol, human and dog plasma □ Anticoagulants—acenocoumarol, GLC analysis, human and dog plasma

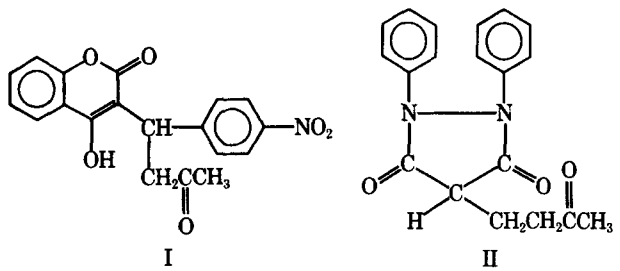
Acenocoumarol (I) is an oral anticoagulant with an onset of action similar to that of dicumarol. It is structurally related to warfarin, both drugs belonging to the coumarin class. Although GLC procedures for the quantitative determination of warfarin (1, 2) and phenprocoumon (3) and a high-pressure liquid chromatographic (HPLC) procedure for quantitating warfarin (4) from plasma have been reported, no GLC or HPLC procedures for quantitating acenocoumarol from biological fluids have been described.

The chromatographic behavior of I and its trimethylsilyl ether derivative was investigated using an aluminum column packed with silicone gum rubber on dimethyldichlorosilane-treated, flux-calcined diatomite support (5). However, this procedure was not applied to plasma level determinations. To facilitate study of the pharmacokinetics and potential interactions after single- and multiple-dose oral administration of I, a sensitive and apparently specific GLC procedure was developed for the measurement of the intact drug in plasma.

EXPERIMENTAL

Reagents—Ethylene dichloride[1] and ether[2] were glass distilled prior to use. Stock solutions containing 100 μg of I[3]/ml were prepared daily in 0.1 *N* NaOH and stored in the dark at 4°. Appropriate dilutions (0.25–4.0 μg/ml) were made immediately before use. Aqueous solutions containing 100 μg/ml of the internal standard, the γ-oxo derivative of phenylbutazone[4] (II), were prepared weekly in 0.1 *N* NaOH and diluted daily to 15 μg/ml with distilled water. An ethereal solution of diazomethane was synthesized from *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide[5].

Plasma Level Study—Acenocoumarol was administered orally in gelatin capsules to two dogs. One dog, 35 kg, received 1 mg/kg of I; a second dog, 30 kg, was given 0.5 mg/kg of I. Blood samples (10 ml) were withdrawn from the cephalic vein of each dog, using heparinized evacuated tubes[6], at 14 appropriate time intervals for 96 hr. The blood samples



I II

were centrifuged, and the plasma was transferred to another tube before storage at −15°.

Extraction of Acenocoumarol—To a 2-ml human or canine plasma sample ("spiked" or from dosed animals) in a glass-stoppered centrifuge tube[7] (50 ml) were added 1 ml of the internal standard solution (II, 15 μg), 3 ml of 3 *N* HCl, and 20 ml of ethylene dichloride. The samples were stoppered and extracted by shaking at an angle of 30° for 30 min at 180 cpm on a flat-bed shaker[8]. After centrifugation at 3000 rpm for 10 min, the aqueous layer was removed by aspiration; 18 ml of the organic phase was then transferred into another glass-stoppered centrifuge tube[7] (50 ml) containing 10 ml of 1 *N* NaOH.

The extraction was repeated (shaking for 15 min and centrifuging for 10 min), and 9 ml of the aqueous phase was transferred to another glass-stoppered tube[7] (50 ml) containing 3 ml of 5 *N* HCl. The tube was

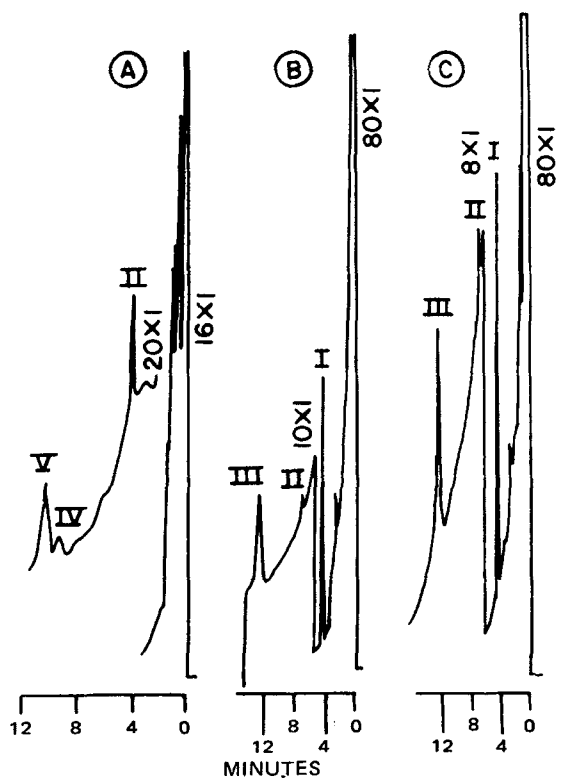


Figure 1—*Gas chromatograms of human plasma. Key: A, control plasma; B, plasma containing 1.0 μg/ml of I and 7.5 μg/ml of II; and C, plasma (7 hr) from a dog given 1 mg of I/kg po containing I (1.24 μg/ml) and II (7.5 μg/ml). Peak I is methylated II, and peak III is methylated I. Peaks II, IV, and V are due to endogenous materials in plasma.*

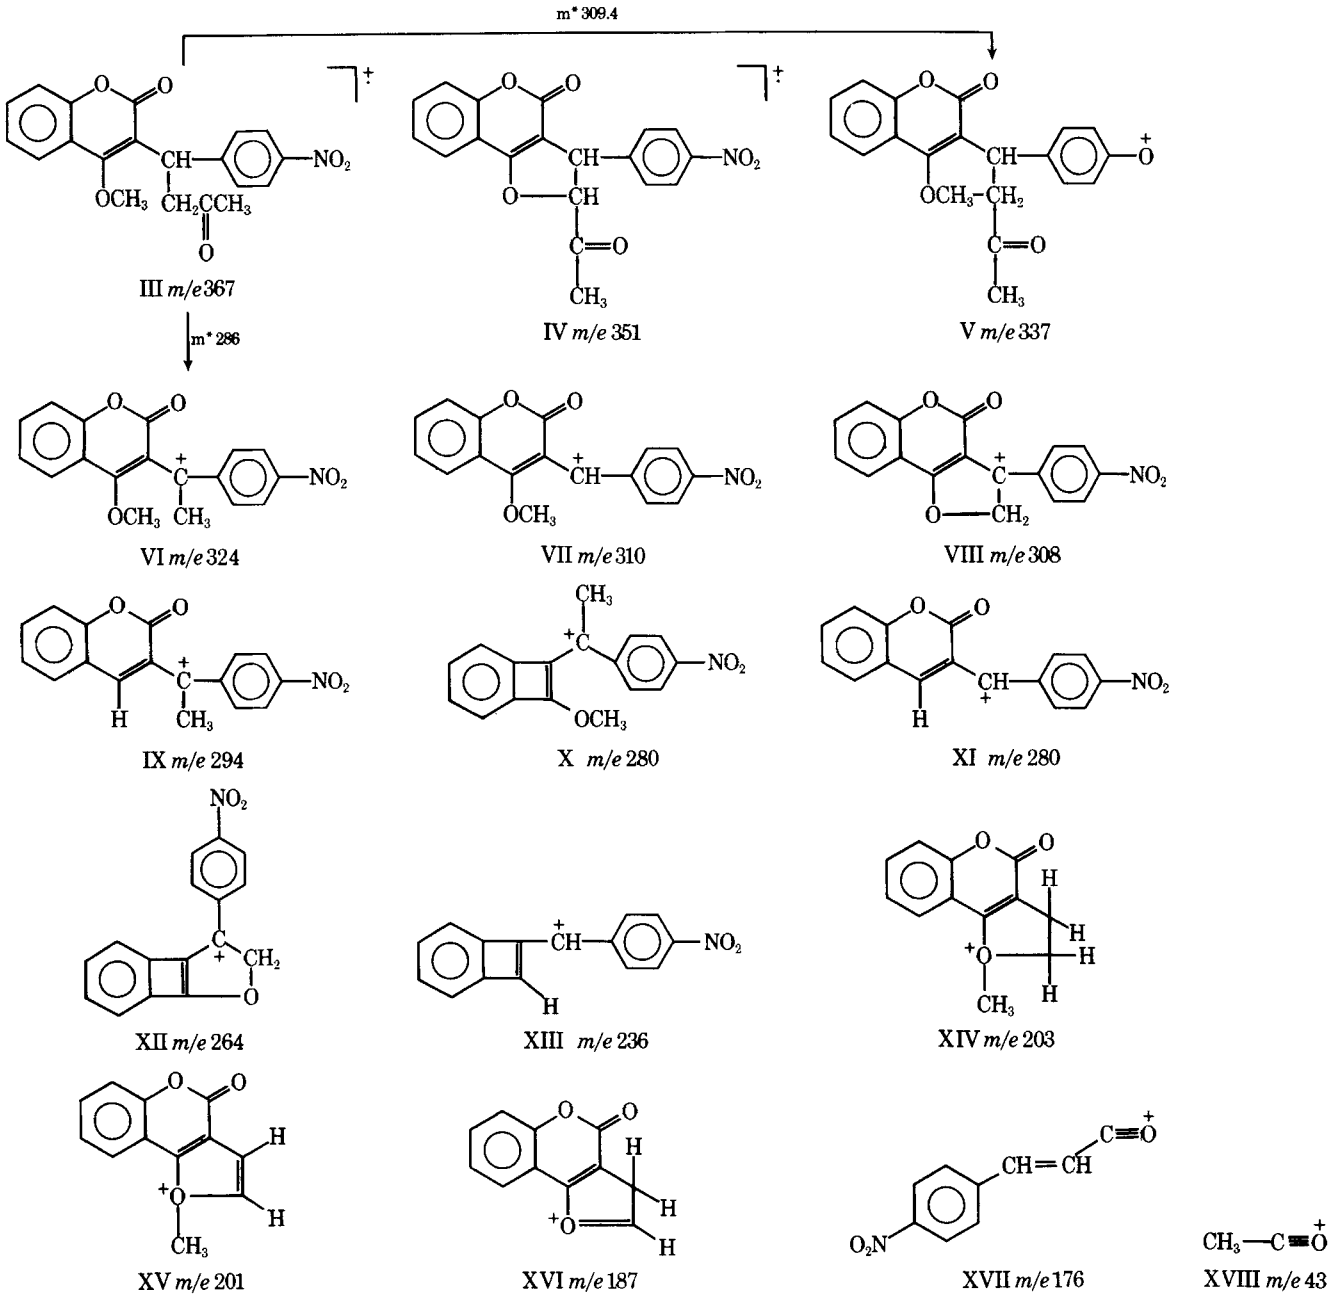

Scheme I

swirled gently, and the extraction was carried out with another 20 ml of ethylene dichloride for 20 min. The aqueous layer was removed by aspiration, and 18 ml of the organic phase was transferred to a glass-stoppered centrifuge tube[7] (50 ml).

The organic extract was evaporated[9] at 85° under a stream of dry nitrogen to a volume of approximately 4 ml. A crystal of anhydrous calcium chloride[7] was added, and the tube was swirled gently. The extract was transferred quantitatively into a custom-made evaporating tube (6) containing a small antibumping granule[10] and evaporated as before to dryness.

The tube was then allowed to cool to room temperature, and the residue was dissolved in 100 μl of ethereal diazomethane by mixing[11] for 30 sec. After the solution was left to incubate for 10 min, it was evaporated to dryness at room temperature. The evaporated extract was dissolved in 25 μl of carbon disulfide by mixing[11] for 30 sec, and aliquots (2–3 μl) were then injected into the gas chromatograph.

GLC—A gas chromatograph[12] equipped with a flame-ionization detector was employed. The column was a spiral glass tube[12], 180 × 0.25 cm i.d., packed with 3% phenyl methyl dimethyl silicone[13] coated on acid-washed, dimethylchlorosilane-treated, 80–100-mesh, high performance, flux-calcined diatomite support[14].

The column was conditioned by maintaining the column at 340° for 18 hr with a low nitrogen flow. In use, the injection port, detector, and column oven temperatures were 300, 310, and 285°, respectively. The nitrogen carrier gas was maintained at a flow rate of 70 ml/min. Hydrogen and compressed air flow rates were adjusted to give maximum response.

Calculations—Peak height ratios were calculated by dividing the height of the peak due to methylated I (7.1 min) by that of methylated II (2.6 min). Calibration curves were constructed from the results of

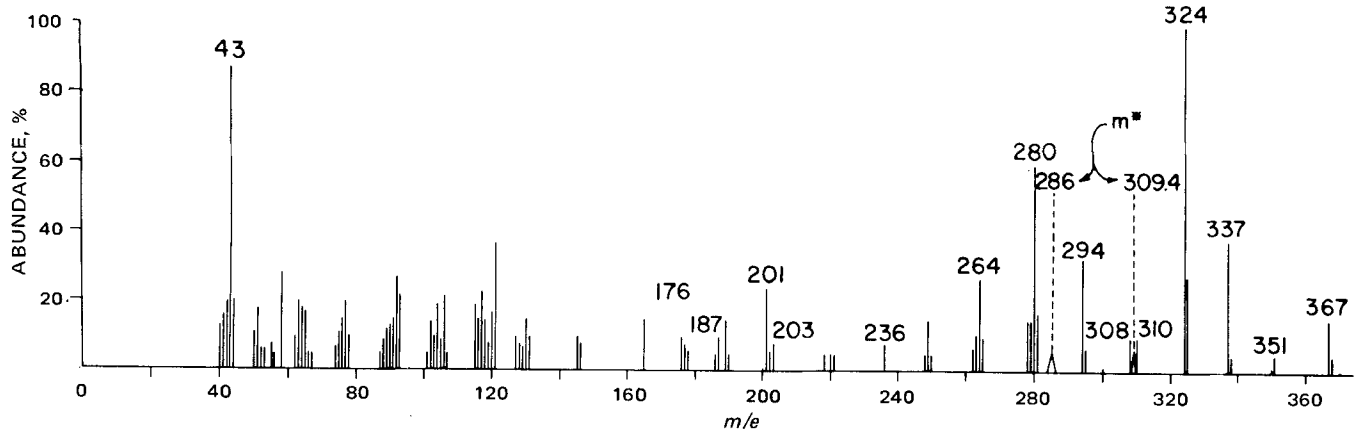

Figure 2—*GLC–mass spectrum (normalized) of methylated acenocoumarol.*

spiked control plasma samples by plotting the peak height ratios against the concentration of I (micrograms per milliliter of plasma).

RESULTS AND DISCUSSION

Methylation of I with diazomethane gave one peak on GLC analysis with a retention time of 7.1 min (peak III, Fig. 1B). Methylation of II with diazomethane also gave one peak on GLC with a retention time of 2.6 min (peak I, Fig. 1B). Combined GLC–mass spectrometric[15] analysis was carried out on the compound giving rise to peak III (Fig. 1B).

The mass spectrum (Fig. 2) showed a molecular ion at *m/e* 367 and abundant ions at *m/e* 351, 337, 324, 310, 308, 294, 280, 264, 236, 203, 201, 187, 176, and 43. Structures III–XVIII (Scheme I) are postulated for these ions. These fragmentations are in agreement with those reported for warfarin (2, 7) and phenprocoumon (3, 8, 9) and suggest that the methylated derivative of I has the structure 3-(α-acetonyl-*p*-nitrobenzyl)-4-methoxycoumarin. Combined GLC–mass spectral evidence for the structure of the internal standard (peak I, Fig. 1B, retention time of 2.6 min) indicated it to be 1,2-diphenyl-4-methyl-4-(2-butanone)-3,5-dioxopyrazoline (molecular ion at *m/e* 336 and other diagnostic ions at *m/e* 321, 308, 293, 279, 264, 202, 177, 160, 119, 77, 51, and 43).

Attempts to prepare a methyl derivative of I by the safer flash-heater methylation technique using trimethylanilinium hydroxide were unsuccessful. However, ethereal diazomethane was effective in the methylation of I and other coumarin derivatives such as phenprocoumon[16] and warfarin[17], the later two being investigated as possible internal standards for the assay of I. These derivatives gave sharp well-defined GLC peaks; however, phenprocoumon and warfarin could not be employed as internal standards because their methyl derivatives eluted too close to the solvent front. Since methylated II [a metabolite of phenylbutazone in humans (10)] gave a single GLC peak with the desired retention time and had similar partition characteristics to I, it was chosen as an internal standard for the assay of I.

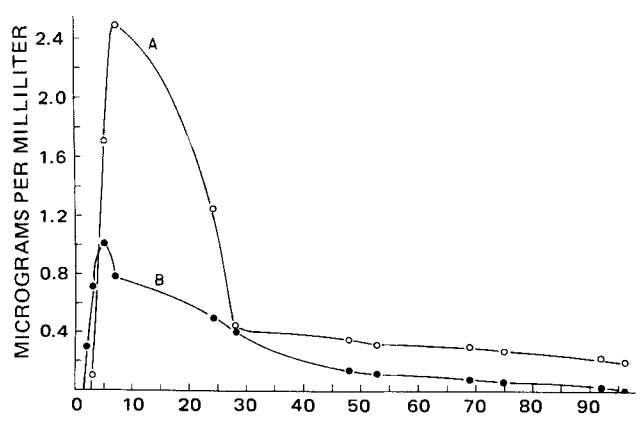

Figure 3—*Plasma profiles of acenocoumarol. Key: Dog A (35 kg), 1.0 mg/kg po; and Dog B (30 kg), 0.5 mg/kg po.*

Several other liquid phases such as saturated hydrocarbon lubricant[18], methyl silicone gum[19], phenyl methyl silicone fluid[20], and phenyl methyl dimethyl silicone fluid[21] were tested, but the peak for methylated I under these conditions was either not sharp or had interference from plasma constituents. When carbon disulfide was employed as the injection solvent, it rendered a very small solvent peak. Untreated plasma extracts were much less stable than those reacted immediately after extraction. The plasma extracts that had been reacted with diazomethane were stable up to 12 hr at room temperature.

Figure 1A shows a typical chromatogram obtained by processing fresh blank plasma from humans as described under *Experimental.* Extraneous peaks II, IV, and V were observed in chromatograms of all human plasma samples, but IV and V were not present in chromatograms of dog plasma samples. A chromatogram obtained when the method was applied to spiked plasma containing 1.0 μg of I/ml and 7.5 μg of II/ml is shown in Fig. 1B. Extraneous peaks II, IV, and V did not interfere with the peak from the internal standard (peak I, retention time of 2.6 min) or acenocoumarol (peak III, retention time of 7.1 min). Figure 1C shows a chromatogram obtained from a 7-hr sample (1 ml) of a 35-kg dog which received an extemporaneously prepared gelatin capsule containing 35 mg of I.

The overall recoveries of I and II from plasma were 99.90 ± 1.25 and 47.42 ± 1.64%, respectively (Table I). The accuracy and precision of the GLC assay are demonstrated in Table II. Results are based on at least five determinations of each acenocoumarol concentration (0.25–4.0 μg/ml), treated as described under *Experimental.* The overall relative standard deviation was 3.12%. The calibration curve obtained by plotting the peak height ratio of methylated I/II *versus* the concentration of I was linear ($y = mx$) over the concentration range of 0.25–4.0 μg of I/ml of plasma. A mean slope value of 0.0492 ± 0.0006 ($p = 0.05$; $r^2 = 0.998$) was obtained. The peak height ratio of the drug and the internal standard was used as the index of detector performance and overall efficiency of the analytical procedure.

The application of the method to plasma level determinations in dogs is demonstrated in Fig. 3. This figure shows the plasma profiles over 96 hr for Dogs A (35 kg) and B (30 kg), which received 1 and 0.5 mg/kg, respectively, of I orally in extemporaneously prepared capsules. The specificity of the analytical procedure was determined by pooling the remaining plasma from dosed dogs, extracting and derivatizing it as described under *Experimental.* A GLC–mass spectrum of the compound giving rise to the resultant peak for I was obtained and compared with that of authentic methylated I. No ions other than those for methylated I were observed in the mass spectrum of the peak from pooled plasma samples, indicating virtually no interference.

The described GLC procedure is sensitive for the determination of acenocoumarol, and large plasma samples are not required. It also offers

Binding of Codeine, Morphine, and Methadone to Human Serum Proteins

JOSEPH JUDIS

Abstract □ The binding properties of codeine, morphine (as representative opium alkaloids), and methadone (a synthetic pharmacologically similar compound) were studied with selected human serum proteins. The methodology involved equilibrium and dynamic dialysis using ^3H- and/or ^{14}C-labeled compounds. For estimation of the percent binding with equilibrium dialysis, concentrations of the ligand used were approximately therapeutic blood levels and another concentration 30–60 times higher. The percent binding to whole human serum ranged from about 20% for morphine to almost 60% for methadone. Of the human serum proteins investigated, the highest percent binding was found with albumin, except for methadone for which it was β-globulin III. The affinity for other serum proteins varied with the ligand. In studies with albumin using dynamic dialysis, the plots of nubar divided by free concentration *versus* nubar were similar for all three ligands studied and had positive slopes, unlike those reported for acidic compounds for which the slope is always negative. In studies of binding of one ligand in the presence of another, significant competition was demonstrated, suggesting that the same binding sites were involved.

Keyphrases □ Codeine—binding to human serum proteins □ Morphine—binding to human serum proteins □ Methadone—binding to human serum proteins □ Binding, protein—codeine, morphine, and methadone to human serum □ Protein binding—codeine, morphine, and methadone to human serum □ Analgesics, narcotic—codeine, morphine, and methadone, binding to human serum proteins □ Alkaloids, opium—codeine, morphine, and methadone, binding to human serum proteins

The binding of drugs to serum proteins is well established as a parameter in pharmacological and therapeutic activities of medicinal agents (1). Several reviews treated the methodology for studying protein binding and summarized the vast number of substances already investigated (2–5). Of the hundreds of compounds studied, the vast majority are acidic or nonpolar; few studies have

For estimation of the percent binding with equilibrium dialysis, concentrations of the ligand used were approximately therapeutic blood levels and another concentration 30–60 times higher. The percent binding to whole human serum ranged from about 20% for morphine to almost 60% for methadone. Of the human serum proteins investigated, the highest percent binding was found with albumin, except for methadone for which it was β-globulin III. The affinity for other serum proteins varied with the ligand. In studies with albumin using dynamic dialysis, the plots of nubar divided by free concentration *versus* nubar were similar for all three ligands studied and had positive slopes, unlike those reported for acidic compounds for which the slope is always negative. In studies of binding of one ligand in the presence of another, significant competition was demonstrated, suggesting that the same binding sites were involved.

Keyphrases □ Codeine—binding to human serum proteins □ Morphine—binding to human serum proteins □ Methadone—binding to human serum proteins □ Binding, protein—codeine, morphine, and methadone to human serum □ Protein binding—codeine, morphine, and methadone to human serum □ Analgesics, narcotic—codeine, morphine, and methadone, binding to human serum proteins □ Alkaloids, opium—codeine, morphine, and methadone, binding to human serum proteins

The binding of drugs to serum proteins is well established as a parameter in pharmacological and therapeutic activities of medicinal agents (1). Several reviews treated the methodology for studying protein binding and summarized the vast number of substances already investigated (2–5). Of the hundreds of compounds studied, the vast majority are acidic or nonpolar; few studies have

[a] The number of moles of ligand added to each system is indicated as the concentration. Values in parentheses are standard deviations.

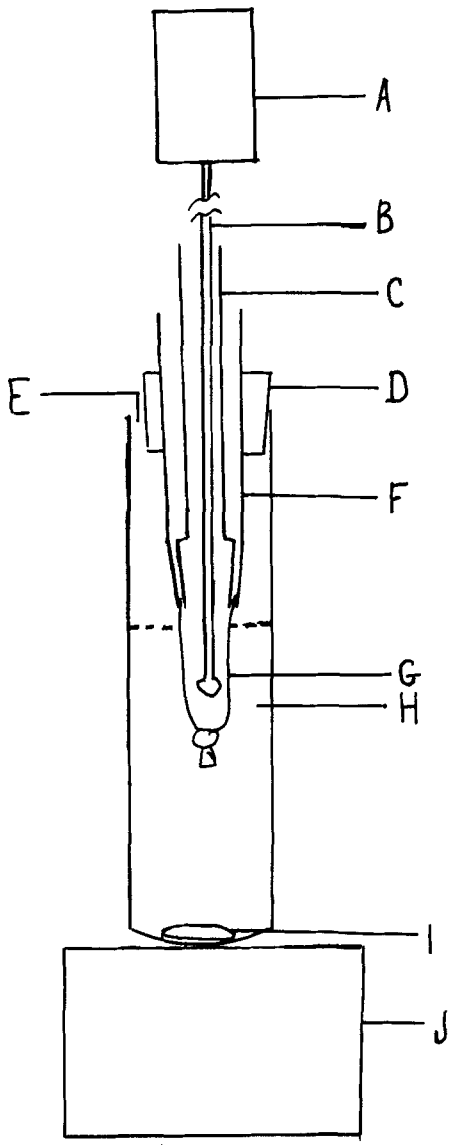

Figure 1—*Diagram of the apparatus used for dynamic equilibrium dialysis. Key: A, stirring motor; B, stirring rod; C, inner tube; D, rubber stopper; E, slot for withdrawing and adding buffer; F, middle tube; G, dialysis bag; H, 100 ml of buffer; I, stirring bar; and J, magnetic stirrer.*

concerned the serum protein binding properties of alkaloids and other basic organic compounds.

Only a handful of reports treated such widely used compounds as opium alkaloids or methadone. Morphine and methadone were shown to bind to serum proteins on the basis of decreased analgesic qualities resulting when the compounds were dissolved in serum prior to injection as compared to aqueous solutions (6). Several studies (7, 8) demonstrated the binding of morphine and methadone to human serum albumin and the binding of methadone to γ-globulin (9), but these studies involved nothing more quantitative than percent binding figures. In addition, the binding of morphine to α_1-globulin was demonstrated using electrophoresis (10), and the binding of papaverine to plasma proteins also was reported (11).

In view of the paucity of investigations of human serum protein binding of alkaloids, studies were conducted using codeine and morphine, as naturally occurring alkaloids, and methadone, as a synthetic organic base with pharmacological properties similar to the other two.

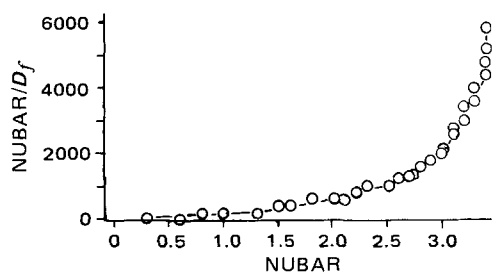

Figure 2—*Binding of codeine to human serum albumin determined by dynamic equilibrium dialysis. The plot is of nubar divided by free concentration* versus *nubar. A total of 3.368 × 10^{-5} mole of codeine was added at the beginning of the run, and the albumin concentration in the bag was 5.797 × 10^{-4}* M.

Table II—Binding of Methadone, Morphine, and Codeine to Various Human Serum Proteins[a] (Ranking in Order by Percent Binding)

	Methadone		Morphine		Codeine	
	9.3 × 10^{-8} Mole[b]	3.3 × 10^{-6} Mole	5.5 × 10^{-8} Mole	3.6 × 10^{-6} Mole	5.6 × 10^{-8} Mole	3.4 × 10^{-6} Mole
Rank 1	HS	HS	HS	HS	HS	ALB
Rank 2	B-III	ALB	ALB	ALB	ALB	HS
Rank 3	ALB	B-III	B-III	G-II	AG4	AG4
Rank 4	AG4	G-II	AG4	AG4	AG1	G-II
Rank 5	AG1	AG1	G-II	AG1	B-III	AG1
Rank 6	G-II	AG4	AG1	B-III	G-II	B-III

[a] Abbreviations for serum proteins are as follows: HS = human serum, ALB = human serum albumin, AG1 = α-globulin IV-1, AG4 = α-globulin IV-4, G-II = γ-globulin II, and B-III = β-globulin III. [b] Total concentration of ligand in cell.

EXPERIMENTAL

Materials—[^{14}C-*N*-Methyl]codeine hydrochloride[1], [^{14}C-*N*-methyl]morphine hydrochloride[1], and 1-^{3}H-*l*-methadone hydrobromide[2] had specific activities of 54, 57, and 135 mCi/mmole, respectively. Crystalline human serum albumin[3] and the other human serum proteins[3] were used as received. A liquid scintillation phosphor solution[4] was used in all radioactivity determinations. All other chemicals were reagent grade.

Methods—Equilibrium dialysis was employed for the estimation of the percent binding to specific proteins. However, to obtain more data efficiently for Scatchard-type plots, the dynamic equilibrium procedure was used. The procedure for the determination of protein binding using equilibrium dialysis was identical with that described previously (12, 13). All components of the system were dissolved in pH 7, 0.67 *M* phosphate

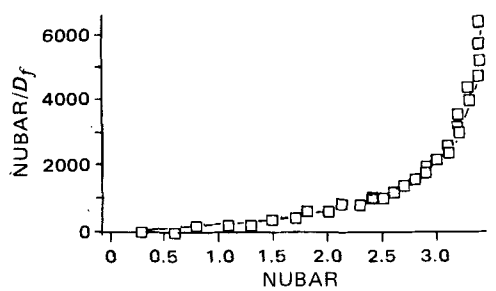

Figure 3—*Binding of morphine to human serum albumin determined by dynamic equilibrium dialysis. The plot is of nubar divided by free concentration* versus *nubar. A total of 3.527 × 10^{-5} mole of morphine was added at the beginning of the run, and the albumin concentration in the bag was 5.797 × 10^{-4}* M.

buffer and incubated on a shaker in a 37° water bath for 24 hr, previously shown to be adequate for reaching equilibrium.

The dynamic equilibrium procedure used was a modification (14) of the Meyer and Guttman (15) procedure. The basic apparatus (Fig. 1) consisted of a collodion bag apparatus[5] modified by the attachment of dialysis tubing[6] (3.32 cm flat width), tied off at one end and held in the

ground-glass joint at the end of the inner tubes of the collodion bag apparatus at the other end. The dialysis tubing was soaked overnight in phosphate buffer prior to use and cut to hold a volume of 5 ml.

Buffer was added through a slot cut in the rubber stopper at the top of the apparatus, and the contents of the bag were stirred with a motor-driven glass stirring rod. Incubation was at room temperature (24 ± 2°). The buffer was stirred with a polytef[7]-coated stirring bar driven by a magnetic stirrer. At the start of a run, protein and ligand solutions (total volume of 5 ml) were added to the bag and 100 ml of pH 7, 0.067 *M* phosphate buffer was added to the apparatus. At 30-min intervals for 3 hr, 50 ml of buffer was withdrawn with a syringe and replaced by 50 ml of fresh buffer.

Radioactivity was determined[8] in an aliquot of the withdrawn buffer. The amount of radioactivity added to the bag initially was determined from an aliquot of the stock solution of radioisotope and the counts per minute in the bag calculated for each sampling time. Free ligand counts per minute in the bag at each sampling time was calculated using the equation given by Meyer and Guttman (15) and the computer program developed by Dearden and Tomlinson (14). From the knowledge of the total and free concentrations of ligand, bound concentrations could be calculated; from the equation relating free concentrations and times of sampling, bound concentrations for intermediate time intervals could be calculated. Approximate estimates of binding parameters were calculated using the method of Sandberg *et al.* (16).

RESULTS AND DISCUSSION

Codeine, morphine, and methadone bound to the several human serum proteins to varying extents (Table I). The lower concentrations of the

[a] A total of 1.75×10^{-5} mole of morphine added to the dialysis bag.

ligands were approximately those indicated in the literature as therapeutic levels[9] (8, 17–20). When the concentrations were increased by a factor of 30–60, the percent binding did change, generally decreasing. When the ligands were arranged according to the percent binding in decreasing order, the greatest binding occurred with whole human serum with one exception (Table II) and with albumin next except for methadone at the lower concentration and codeine at the higher concentration. Otherwise, the order was different for the three ligands.

The conventional binding curves, Scatchard plots (2, 3, 21) in which moles bound per mole of protein (nubar) divided by free ligand concentration (D_f) is plotted against nubar, are shown in Figs. 2–4. For most ligands studied previously (22–27), the Scatchard plot curve has a negative slope and is a straight line unless more than one type of binding site is involved. In the latter situation, a curve is found. The plots in Figs. 2–4 all have positive slopes and are curves, indicating more than one type of binding site.

Positive slopes have been interpreted to indicate possible cooperativity (28) and do not lend themselves to the analyses generally performed with typical Scatchard curves in terms of the calculation of binding parameters. However, to obtain approximate estimates of the binding parameters, the Sandberg *et al.* (16) method was used. This method involves plots of bound concentration of ligand divided by free concentration *versus* bound concentration (Figs. 5–7). The y-intercept is equal to nKP, the x-intercept is equal to n, and the slope is equal to K (n refers to the number of binding sites, K refers to the association constant, and P refers to the molar protein concentration). Each curve had three distinct segments, and each segment was treated as a separate curve for calculation (Table III).

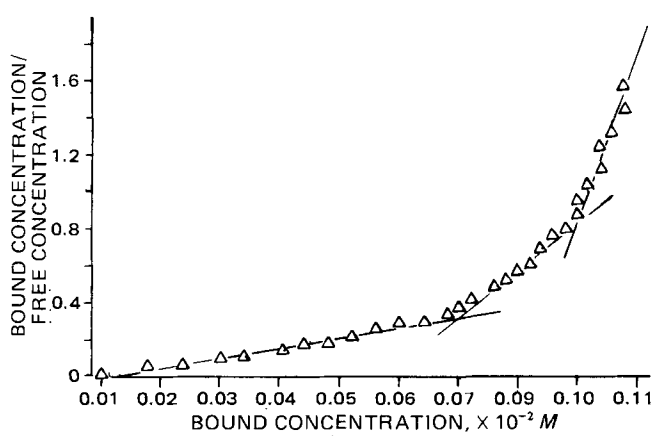

Figure 7—*Binding of methadone to human serum albumin determined by dynamic equilibrium dialysis. The plot is of bound concentration divided by free concentration* versus *bound concentration; amounts of albumin and methadone are the same as for Fig. 4.*

As an approach to determining whether the three ligands bind to the same sites on albumin, binding of one ligand was determined in the presence of another. Unlabeled morphine decreased significantly the binding of ^{14}C-codeine (Table IV), and codeine interfered with the binding of ^{14}C-morphine (Table V). Both codeine and morphine interfered with the binding of ^{3}H-methadone to human serum albumin (Tables VI and VII).

Codeine, morphine, and methadone apparently do bind significantly to human serum proteins, with all of the implications in terms of pharmacological action of drugs (1). Binding to albumin is greatest generally for the three ligands, which is characteristic of many molecules. The three compounds yielded binding plots (nubar divided by D_f *versus* nubar) that are clearly distinct from those of many anionic and nonpolar compounds. The curves for codeine, morphine, and methadone have positive slopes, and this feature may be characteristic of alkaloids and organic bases in general. The same types of plots were obtained in this laboratory in preliminary experiments with amphetamine, histamine, atropine, and epinephrine with human serum albumin as the protein. A curve with a positive slope (same type of plot) was found by Powis (29) in studies of the binding of tetracycline to albumin.

[9] Data on therapeutic serum levels for codeine were obtained from Carl W. Sigel, Burroughs Wellcome Co., Research Triangle Park, N.C.

Pharmacokinetics of β-Methyldigoxin in Healthy Humans IV: Comparisons of Radioimmunoassays, Total Radioactivity, and Specific Assays of β-Methyldigoxin and Digoxin in Plasma

EDWARD R. GARRETT ˣ and PETER H. HINDERLING *

Abstract □ A modified radioimmunoassay, using the displacement of the ^{125}I-digoxin derivative bound to antiserum, is presented. It permitted the monitoring of plasma for total glycosides up to 144 hr after oral and intravenous administrations of 0.3 and 0.6 mg of ^{3}H-β-methyldigoxin to healthy humans. In a specific plasma, the radioimmunoassay response of β-methyldigoxin was 86 ± 3% that of digoxin. Radioimmunoassay of plasma was highly correlated with liquid scintillation spectrometric analysis of total radioactivity, and plots of various studies showed intercepts not significantly different than zero. However, radioimmunoassay underestimated the radiolabeled plasma concentration by 12–38% and was dependent on the individual plasma. Since total radioactivity and radioimmunoassay can be expressed as a linear sum of the ^{3}H-digoxin and ^{3}H-β-methyldigoxin plasma concentrations, plots of ratios of total radioactivity to ^{3}H-digoxin concentration against ratios of ^{3}H-β-methyldigoxin to ^{3}H-digoxin plasma concentration were statistically evaluated to determine the specific activities of both glycosides in the two assays. The contributions of ^{3}H-β-methyldigoxin and its metabolite ^{3}H-digoxin were equivalent in liquid scintillation spectrometry, but the former ranged from 65 to 87% of the potency of the latter in the various radioimmunoassay studies. There was a significant difference in the estimated specific antigenicity of β-methyldigoxin at higher and lower plasma concentration ratios of β-methyldigoxin to digoxin, where the specific antigenicity was less at the higher ratios.

Keyphrases □ β-Methyldigoxin—oral and intravenous, pharmacokinetics, radioimmunoassay compared to radiochemical spectrometric assays, human plasma □ Pharmacokinetics—β-methyldigoxin, oral and intravenous, radioimmunoassay compared to radiochemical spectrometric assays, human plasma □ Radioimmunoassay—β-methyldigoxin, pharmacokinetic study after oral and intravenous administration, compared to radiochemical spectrometric assays, human plasma □ Cardiac glycosides—β-methyldigoxin, oral and intravenous, pharmacokinetics, radioimmunoassay compared to radiochemical spectrometric assays, human plasma

Radioimmunoassay has been applied to measure glycoside concentrations in biological fluids after administration of therapeutic dosages of digoxin and β-methyldigoxin (1–4). This radioimmunoassay of glycosides should be compared with other established methods, such as liquid scintillation spectrophotometry of labeled glycosides, to monitor total radioactivity or the specifically assigned radioactivity of separated parent drug and metabolites. Such comparisons should elucidate the specificity of such procedures.

Recent studies with radioimmuno- and ^{86}Rb-uptake assays investigated the mutual relationships between digoxin and its metabolites and quantified the fractional contributions of parent drug and metabolites (2, 5) to total activity. It was suggested that all cardioactive metabolites of digoxin and digitoxin also contribute to the total antigenicity and total uptake inhibition in the radioimmuno- and ^{86}Rb-uptake assays, respectively (2, 6). Potency differences were reported for different glycoside metabolites and derivatives in the radioimmunoassay (2). Equipotency can be assumed for the parent drug and metabolites when total radioactivity is monitored by liquid scintillation spectrophotometry.

This paper compares the radioimmunoassay and total and specific radioactivity methods used to monitor the glycoside ^{3}H-β-methyldigoxin (7, 8), which is about 50% metabolized, mainly to digoxin (7–9).

EXPERIMENTAL

Equipment—An automated-control γ-scintillation spectrometer[1] was used for determining the activity of the ^{125}I-digoxin derivative after addition to plasma in the radioimmunoassay procedure.

Materials and Methods—The ^{125}I-digoxin derivative, digoxin standard, buffer components, and antiserum used for the radioimmunoassay were obtained from the commercially available kit[2].

Pharmacokinetics of β-Methyldigoxin in Healthy Humans IV: Comparisons of Radioimmunoassays, Total Radioactivity, and Specific Assays of β-Methyldigoxin and Digoxin in Plasma

EDWARD R. GARRETT ˣ and PETER H. HINDERLING *

Abstract □ A modified radioimmunoassay, using the displacement of the ^{125}I-digoxin derivative bound to antiserum, is presented. It permitted the monitoring of plasma for total glycosides up to 144 hr after oral and intravenous administrations of 0.3 and 0.6 mg of ^{3}H-β-methyldigoxin to healthy humans. In a specific plasma, the radioimmunoassay response of β-methyldigoxin was 86 ± 3% that of digoxin. Radioimmunoassay of plasma was highly correlated with liquid scintillation spectrometric analysis of total radioactivity, and plots of various studies showed intercepts not significantly different than zero. However, radioimmunoassay underestimated the radiolabeled plasma concentration by 12–38% and was dependent on the individual plasma. Since total radioactivity and radioimmunoassay can be expressed as a linear sum of the ^{3}H-digoxin and ^{3}H-β-methyldigoxin plasma concentrations, plots of ratios of total radioactivity to ^{3}H-digoxin concentration against ratios of ^{3}H-β-methyldigoxin to ^{3}H-digoxin plasma concentration were statistically evaluated to determine the specific activities of both glycosides in the two assays. The contributions of ^{3}H-β-methyldigoxin and its metabolite ^{3}H-digoxin were equivalent in liquid scintillation spectrometry, but the former ranged from 65 to 87% of the potency of the latter in the various radioimmunoassay studies. There was a significant difference in the estimated specific antigenicity of β-methyldigoxin at higher and lower plasma concentration ratios of β-methyldigoxin to digoxin, where the specific antigenicity was less at the higher ratios.

Keyphrases □ β-Methyldigoxin—oral and intravenous, pharmacokinetics, radioimmunoassay compared to radiochemical spectrometric assays, human plasma □ Pharmacokinetics—β-methyldigoxin, oral and intravenous, radioimmunoassay compared to radiochemical spectrometric assays, human plasma □ Radioimmunoassay—β-methyldigoxin, pharmacokinetic study after oral and intravenous administration, compared to radiochemical spectrometric assays, human plasma □ Cardiac glycosides—β-methyldigoxin, oral and intravenous, pharmacokinetics, radioimmunoassay compared to radiochemical spectrometric assays, human plasma

Radioimmunoassay has been applied to measure glycoside concentrations in biological fluids after administration of therapeutic dosages of digoxin and β-methyldigoxin (1–4). This radioimmunoassay of glycosides should be compared with other established methods, such as liquid scintillation spectrophotometry of labeled glycosides, to monitor total radioactivity or the specifically assigned radioactivity of separated parent drug and metabolites. Such comparisons should elucidate the specificity of such procedures.

Recent studies with radioimmuno- and ^{86}Rb-uptake assays investigated the mutual relationships between digoxin and its metabolites and quantified the fractional contributions of parent drug and metabolites (2, 5) to total activity. It was suggested that all cardioactive metabolites of digoxin and digitoxin also contribute to the total antigenicity and total uptake inhibition in the radioimmuno- and ^{86}Rb-uptake assays, respectively (2, 6). Potency differences were reported for different glycoside metabolites and derivatives in the radioimmunoassay (2). Equipotency can be assumed for the parent drug and metabolites when total radioactivity is monitored by liquid scintillation spectrophotometry.

This paper compares the radioimmunoassay and total and specific radioactivity methods used to monitor the glycoside ^{3}H-β-methyldigoxin (7, 8), which is about 50% metabolized, mainly to digoxin (7–9).

EXPERIMENTAL

Equipment—An automated-control γ-scintillation spectrometer[1] was used for determining the activity of the ^{125}I-digoxin derivative after addition to plasma in the radioimmunoassay procedure.

Materials and Methods—The ^{125}I-digoxin derivative, digoxin standard, buffer components, and antiserum used for the radioimmunoassay were obtained from the commercially available kit[2].

Table I—Influence of Plasma Volume on Radioimmunoassay Efficiency[a]

Plasma Volume in 1 ml of Phosphate Buffer, μl	Replicate Measured Digoxin Concentrations by Radioimmunoassay, dpm/ml
50	1091, 1206
100	1183, 1218
200	1203, 1335
500	1162, 1248

[a] There was no statistically significant influence of the size of the assayed plasma on the radioimmunoassay ($F = 0.0052$; $df = 3, 4$; $p > 0.9$).

The seven volunteers received 0.3 and 0.6 mg of β-methyldigoxin orally and intravenously. Plasma glycoside concentrations were assayed by radioimmunoassay in five subjects (A, B, C, D, and G) (7, 8, 10) at the following times: 0, 1.5, 2, 2.5, 3.5, 7, 10, 15, 45, 60, and 90 min and 2, 3, 5, 7, 9, 11, 15, 20, 24, 36, 48, 60, 72, 84, 96, 120, and 144 hr after intravenous administration. Samples were assayed at the same times after oral administration except for 1.5, 2.5, and 3.5 min.

The methods and procedures for measurement of total plasma radioactivity and the radioactivity assignments to the separated drug and metabolite were described previously (7). The commercially available kit was modified in accordance with Stoll *et al.* (2) so that the wide glycoside concentration ranges found in plasma up to 144 hr after administration could be monitored by radioimmunoassay. The ^{125}I-digoxin derivative, rather than the ^{3}H-digoxin derivative, was used since the administered β-methyldigoxin was tritium labeled. This change alleviated the problem of quenching and led to increased sensitivity (11).

All plasma samples of a particular study were assayed at the same time. Individual calibration curves used the particular volunteer's blank plasma to which known concentrations of standard digoxin solutions were added.

Isotonic pH 7.4 phosphate buffer (1.0 ml) was added to 50–500 μl of plasma containing unknown concentrations of digoxin and/or β-methyldigoxin standard. Tracer, 10 μl, and 10 μl of antiserum were added to the mixtures. The mixtures were gently vortexed and incubated for 2 hr at 25° and then for an additional 16 hr at 4°. Equilibration was undoubtedly effected in the first 0.5 hr at room temperature but certainly was achieved by this procedure. The subsequent time under refrigeration was only to inhibit bacterial growth. Dextran-coated charcoal, 500 μl, was squirted into each mixture. Subsequently, at no more than 5 min, the samples were centrifuged at 1500 rpm for 10 min. The clear supernates were decanted and transferred to γ-counting tubes for measurement.

The influence of varied plasma volumes on the assay was studied since contradictions were reported (2, 12). Plasma blanks of 50, 100, 200, and 500 μl were spiked with digoxin standard so that the ultimate digoxin concentrations would be 2.0 ng/ml after dilution with phosphate buffer to the same 1.00-ml volume. Duplicate radioimmunoassays were performed (Table I), and no statistically significant difference was observed with decreasing fractions of plasma in the final solution.

Both the ^{3}H-digoxin and the ^{125}I-digoxin derivative radioimmunoassays were originally designed to measure unknown digoxin concentrations. However, these assays are not specific for digoxin but also respond to digoxin metabolites (2) and digoxin derivatives such as β-methyldigoxin (3, 4).

Since β-methyldigoxin is metabolized, mainly to digoxin (5, 9), the individual antigenic potencies of β-methyldigoxin and digoxin were evaluated in the radioimmunoassay over a significant concentration range. Plasma aliquots were spiked with either β-methyldigoxin or digoxin standards to give concentrations of 0.4, 1.0, 2.0, 3.0, 4.0, 5.0, and 10.0 ng/ml. Controls with blank plasma were run at the same time.

RESULTS AND DISCUSSION

Typical semilogarithmic plots of total plasma glycoside concentrations as determined by total radioactivity as measured by liquid scintillation spectrophotometry and by "total antigenicity," *i.e.*, the total antigenic effect resulting from the sum of antigenic effective glycosides, as measured by radioimmunoassay are given against time for intravenous and oral administrations (Fig. 1) of β-methyldigoxin. Both methods of analysis permitted the measurement of plasma glycoside concentrations from 40.0 to 0.2 ng/ml.

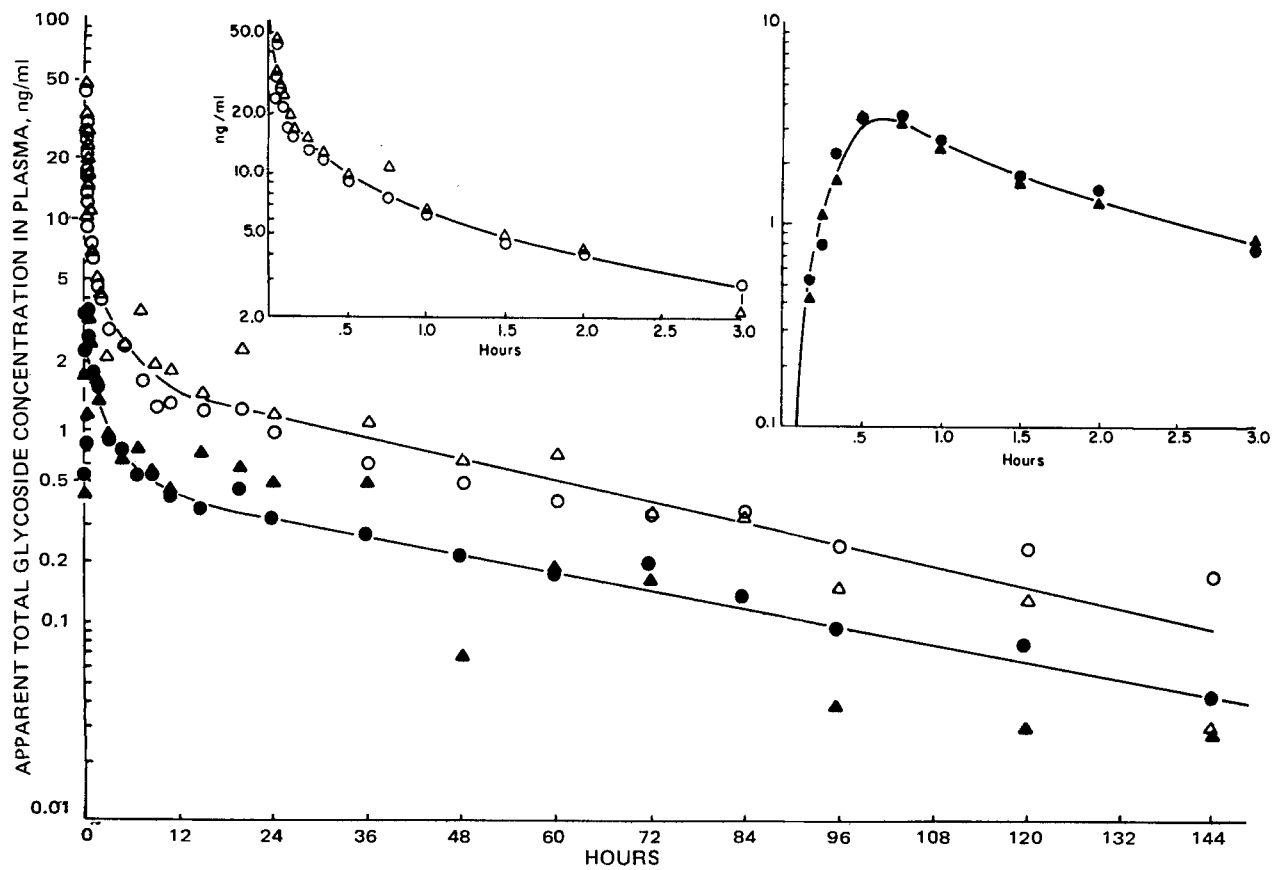

Figure 1—*Typical semilogarithmic plots of plasma concentrations of total glycosides against time by radioimmunoassay (▲, Subject B, 0.3-mg po dose; and △, Subject G, 0.6-mg iv dose) and liquid scintillation spectrometry (●, Subject B, 0.3-mg po dose; and ○, Subject G, 0.6-mg iv dose) after β-methyldigoxin administration. The insets expand the time axis over the initial period.*

Correlation of Plasma Concentrations of Glycosides by Radioimmunoassay and Liquid Scintillation Spectrophotometry of Total Radioactivity—Highly significant linear correlations existed between concentrations assayed by radioimmunoassay (RIA) and liquid scintillation spectrophotometry (LSC):

$$\text{RIA} = m\text{LSC} + b \qquad \text{(Eq. 1)}$$

The parameters of Eq. 1 and their variability are given in Table II for all studies conducted. Typical plots are given in Fig. 2.

The intercepts, b, in all cases were not significantly different from zero. The slopes, m, were significantly different among subjects and frequently within subjects, indicating that an individual plasma factor contributed to the variability in the radioimmunoassay response and that this plasma factor may vary within the individual.

In all cases except for Subject G, the slopes were significantly less than unity and indicated that the radioimmunoassay as established was not equivalent to the assay by liquid scintillation spectrophotometry. Radioimmunoassay alone would underestimate the radiolabeled material by 12–38% with Subject G excluded.

The radioimmunoassay was calibrated for digoxin by plotting the percent of added tracer bound to the antiserum against the added digoxin concentrations. Equivalent amounts of β-methyldigoxin were assayed at the same seven concentration levels between 0.40 and 10 ng/ml, and the experimental assay values were determined as digoxin-equivalent responses. β-Methyldigoxin was only 86% as responsive as digoxin in the plasma used for the radioimmunoassay (Table III).

Both of these compounds compete with ^{125}I-digoxin for binding sites. Since varying ratios of digoxin (DIG) and β-methyldigoxin (BMD) in plasma were assayed simultaneously, the presence of one could have modified the separate response of the other. Since:

$$\text{RIA} = m_R\text{BMD} + b_R\text{DIG} \qquad \text{(Eq. 2)}$$

it is possible that the factor m_R is not constant but varies as a function of the digoxin concentration.

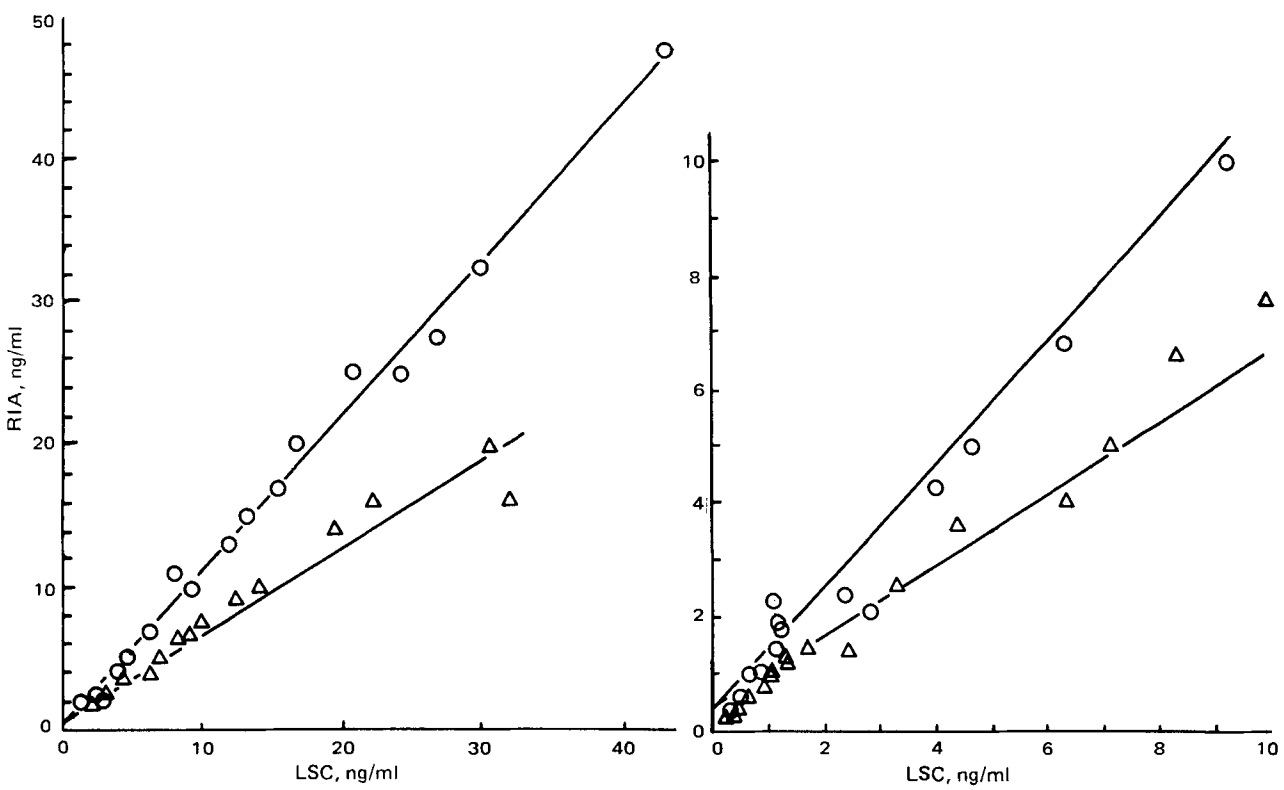

Figure 2—*Typical regressions of assays of total glycosides in plasma by radioimmunoassay (RIA) against assays by liquid scintillation spectrometry (LSC) for Subjects B (△) and G (○) given 0.6 mg iv of β-methyldigoxin. The lines drawn over the shorter range are the best fit over the longer range.*

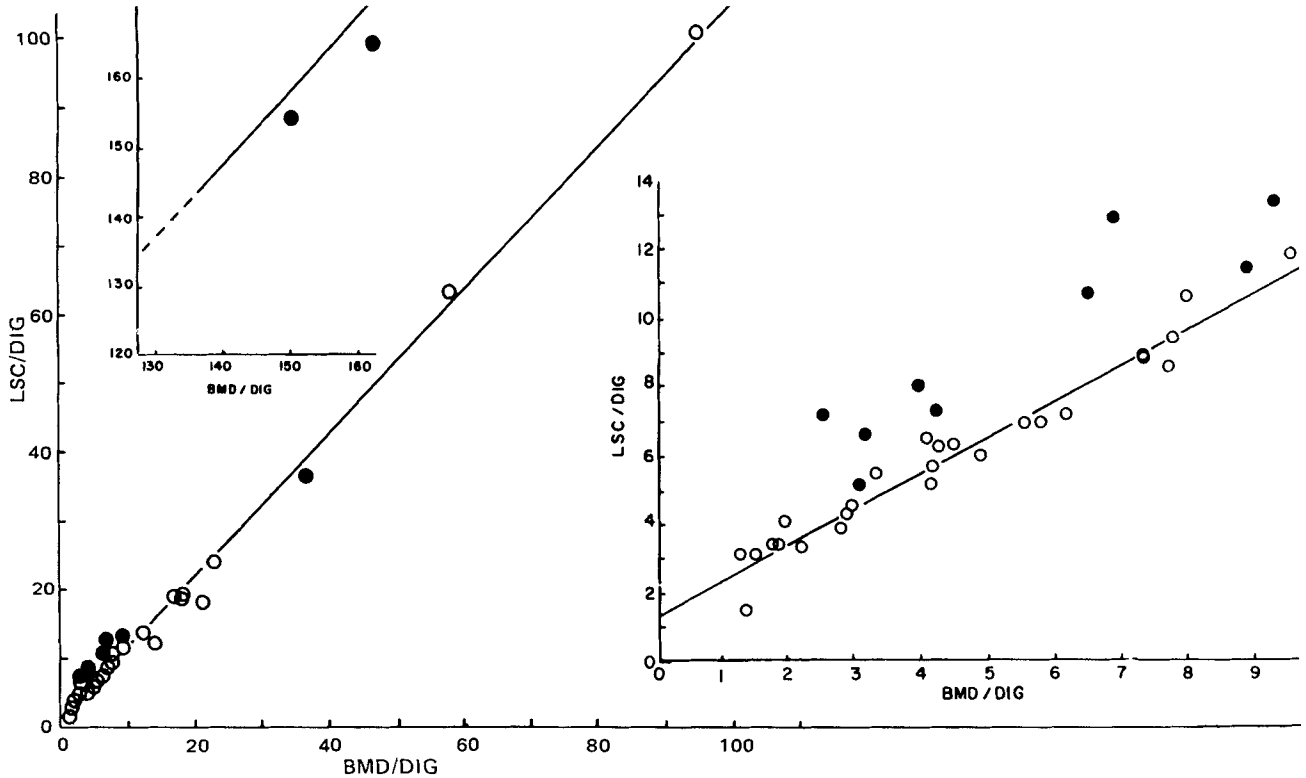

Figure 3—*Plots of the ratios of total glycoside plasma concentration by liquid scintillation spectrometry (LSC) to the plasma digoxin concentration (DIG) against the plasma concentration ratios of β-methyldigoxin (BMD) to digoxin (DIG) for the pooled available data from all subjects, oral and intravenous. The left inset shows the extrapolated regression line of best fit. The right inset is for the BMD/DIG range of 0–10 fitted separately. The dark symbols are for the data from Subject A, 0.6 mg po of β-methyldigoxin, which were excluded in fitting the shown regression line.*

It is also possible that the radiolabeled β-methyldigoxin metabolites or digoxin metabolites were monitored in the plasma by the liquid scintillation spectrometry but did not respond to the radioimmunoassay. However, studies on the TLC-separated β-methyldigoxin and digoxin from plasma did not show any significant amounts of other metabolites in plasma (7, 8).

Relative Potencies of β-Methyldigoxin and Digoxin in Several Plasma Assays after β-Methyldigoxin Administration—Total radioactivity (LSC) in a plasma aliquot can be expressed as the linear sum of the individual radioactivities of labeled β-methyldigoxin and digoxin:

$$\text{LSC} = m_L\text{BMD} + b_L\text{DIG} \qquad \text{(Eq. 3)}$$

where m_L and b_L reflect the relative potencies of β-methyldigoxin and digoxin, respectively, in the liquid scintillation spectrometric assay. The "total antigenicity" by the radioimmunoassay also can be expressed as a similar linear sum (Eq. 2) of the partial antigenicities.

Equation 3 can be rearranged to:

$$\text{LSC/DIG} = m_L\text{BMD/DIG} + b_L \qquad \text{(Eq. 4)}$$

and typical plots of one ratio against the other are given in Fig. 2 and for the pooled data in Fig. 3. Statistical evaluations of the regressions for the available studies are given in Table IV. As anticipated, the parameters m_L and b_L were not significantly different from unity, and the contributions of digoxin and β-methyldigoxin to the total radioactivity were equivalent except for b_L for Subject A at the 0.6-mg po dose. The anomalous discrepancy in this intercept is obvious from the plotted solid symbols in Fig. 3, where the regression line was fitted to the pooled data with the data from this particular study excluded. There were no significant differences between the parameters for β-methyldigoxin (Table IV). Plots of LSC/BMD *versus* DIG/BMD gave similar information; the intercepts, m_L, were unity in all studies.

Similarly, Eq. 2 can be rearranged to:

$$\text{RIA/DIG} = m_R\text{BMD/DIG} + b_R \qquad \text{(Eq. 5)}$$

Table IV—Typical Linear Regressions of Ratios of Plasma Concentrations of Glycosides by Liquid Scintillation Spectrometry (LSC) and by Radioimmunoassay (RIA) to Plasma Digoxin Concentration (DIG) against the Ratios of Concentrations of β-Methyldigoxin (BMD) to Digoxin (DIG) in Human Plasma: LSC/DIG = m_LBMD/DIG + b_L; RIA/DIG = m_RBMD/DIG + b_R

Subject	Dose, mg	Mode of Administration	Range, BMD/DIG	n^a	$m_L \pm SE$	$b_L \pm SE$	$r_L{}^b$	$m_R{}^c \pm SE$	$b_R \pm SE$	$r_R{}^b$
A	0.6	Intravenous	1.4–23	11	0.930 ± 0.052	1.12 ± 0.73	0.986	0.870 ± 0.035 (0.80–0.90)	1.31 ± 0.49	0.994

B	0.6	Intravenous	1.9–95	11	1.050 ± 0.006	1.32 ± 0.20	1.000	0.706 ± 0.018 (0.70)	1.62 ± 0.62	0.997
C	0.3	Oral	2.8–21	7	1.013 ± 0.032	1.16 ± 0.30	0.998	0.649 ± 0.036 (0.67)	2.3 ± 0.34	0.993
Pooled	0.3, 0.6	Oral, intravenous	1.4–165	49	1.012 ± 0.010	1.87 ± 0.36	0.998	0.829 ± 0.017	1.04 ± 0.52	0.991
Pooled[d]	0.3, 0.6	Oral, intravenous	1.4–165	40	1.016 ± 0.010	1.39 ± 0.39	0.998	0.716 ± 0.014	1.76 ± 0.30	0.994
Pooled[d]	0.3, 0.6	Oral, intravenous	1.4–10	26	1.052 ± 0.046	1.23 ± 0.23	0.978	0.825 ± 0.082	0.981 ± 0.41	0.903

[a] Numbers of pairs. [b] Respective correlation coefficients. [c] Parenthetical values are estimates of m_R from the intercepts of plots of RIA/BMD *versus* DIG/BMD. When given as a range, the initial data were too scattered by this plotting method to conclude anything other than that the value lay within this range. Similar plots of LSC/BMD *versus* DIG/BMD were conclusive of intercepts, m_R, of unity in all cases. [d] Data of Subject A at the 0.6-mg po doses were excluded because of an anomalous intercept, b_L.

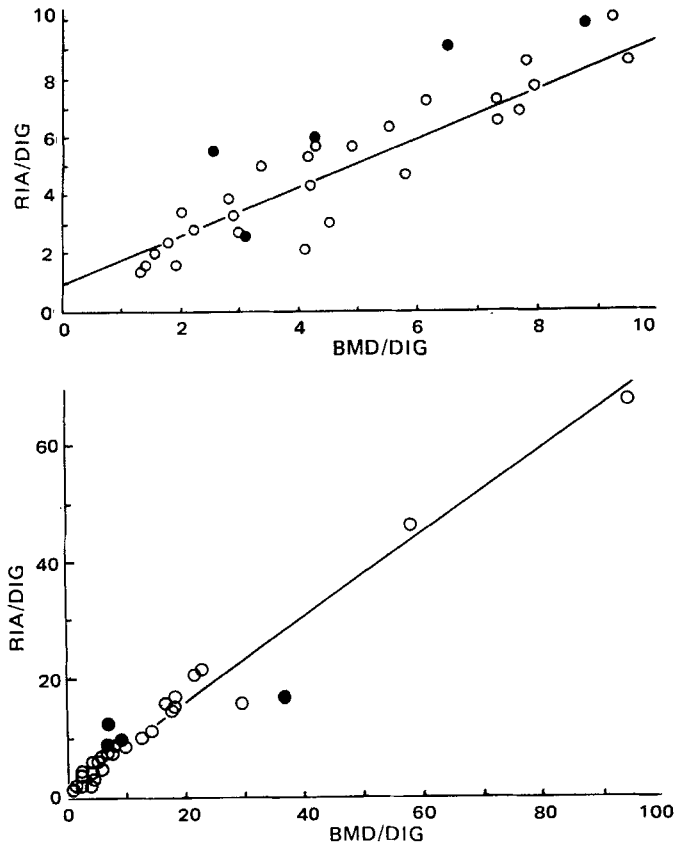

Figure 4—*Plots of the ratios of total glycoside plasma concentration by radioimmunoassay (RIA) to the plasma digoxin concentration (DIG) against the plasma concentration ratios of β-methyldigoxin (BMD) to digoxin (DIG) for the pooled available data from all subjects, oral and intravenous. The dark symbols are for the data from Subject A, 0.6 mg po of β-methyldigoxin, which were excluded in fitting the shown regression lines. Both ranges were fitted separately.*

and plots of the pooled data over several BMD/DIG ranges are given in Fig. 4. The regression lines were fitted for the particular ranges given where the anomalous data of Subject A at the 0.6-mg po dose were excluded. The statistical evaluations of the regressions for the pooled data over several ranges and for the available specific studies are given in Table IV. There were no significant differences among the various intercepts, b_R, which were not significantly different from unity. This result was a measure of the individual "antigenicity" of digoxin in the assay and was anticipated since the radioimmunoassay was calibrated for digoxin. However, individual m_R values, measures of antigenic potency of β-methyldigoxin in the assay, were significantly different for the separate studies. This finding was consistent with the previously discussed results for the regressions of RIA *versus* LSC (Table II).

The m_R values were significantly less than unity for the separate studies and for the pooled data of all available studies, consistent with the fact that the specific antigenicity of β-methyldigoxin was less than that of digoxin (Table III). The separate regressions for different ranges of β-methyldigoxin to digoxin ratios, BMD/DIG, showed significantly different slopes when the anomalous oral study for Subject A was excluded. The slope, 0.72 ± 0.014, for the longer range (1.4–165) or higher relative β-methyldigoxin concentrations was significantly less than the m_R = 0.03 ± 0.08 for the shorter range (1.4–10), indicative of higher specific potency for β-methyldigoxin in the presence of relatively large amounts of digoxin. This finding tends to confirm the previously stated possibility that the presence of one glycoside may modify the radioimmunoassay response of the other. Similar values for m_R were obtained (Table III) from the intercepts of RIA/BMD plots against DIG/BMD.

In summary, it can be stated that an *a priori* assumption of radioimmunoassay equivalency of glycosides with their derivatives and their cardioactive metabolites is unwarranted. The fundamental basis of a radioimmunoassay demands a competition for binding sites, and minor functional changes in a molecule can affect the binding constants. An assumption that the specific potency of an agonist in the presence of others is not modified by changes in their relative concentration is also unwarranted. These factors are further perturbed by interactions peculiar to an individual plasma.

UV Spectrophotometric Determination of Aminophylline, Amobarbital, and Ephedrine Hydrochloride in an Antiasthma Capsule Preparation

FABRIZIO De FABRIZIO

Abstract □ A simple and rapid procedure for the determination of aminophylline, amobarbital, and ephedrine hydrochloride in a capsule preparation is described. Aminophylline and amobarbital are determined simultaneously using differential UV spectrophotometry; ephedrine hydrochloride is determined separately after elution from an alginic acid column with 0.1 *N* hydrochloric acid.

Keyphrases □ Aminophylline—UV spectrophotometric analysis, commercial capsule in combination with amobarbital and ephedrine hydrochloride □ Amobarbital—UV spectrophotometric analysis, commercial capsule in combination with aminophylline and ephedrine hydrochloride □ Ephedrine hydrochloride—UV spectrophotometric analysis, commercial capsule in combination with aminophylline and amobarbital □ UV spectrophotometry—analyses, aminophylline, amobarbital, and ephedrine hydrochloride in combination commercial capsule

The combination of aminophylline, ephedrine hydrochloride, and barbituric acid derivatives is frequently encountered in commercial and clinical preparations and in research situations. Procedures for the determination of these active ingredients alone or in combination in tablets, capsules, or syrups include gravimetric (1), titrimetric (2), spectrophotometric (3, 4), GLC (5), and IR (6) measurements.

The National Formulary (7) describes a method for the analysis of theophylline, phenobarbital, and ephedrine hydrochloride in a tablet formulation; the active components are separated using column partition chromatography and liquid–liquid extraction, followed by UV spectrophotometric determination of the isolated ingredients. However, this NF procedure is tedious and requires much care to obtain good results; the various steps are the largest sources of both systematic and random errors. Therefore, this work was planned to propose a uniform methodology that would reduce sample manipulation.

EXPERIMENTAL

Apparatus—A recording spectrophotometer[1] with matched 1- and 4-cm cells was used. The glass column was 50 × 2 cm and had a fine regulatory needle valve stopcock with a polytef insert[2].

Reagents—The following were used: alginic acid[3] cation-exchange resin, 40–100 mesh; 2 *N* hydrochloric acid in water; 0.1 *N* hydrochloric acid in water; 0.02 *N* sodium hydroxide in water; 50% ethanol in water; and 50% ethanol in 4% (v/v) acetic acid.

Standard Solutions—The following were used: ephedrine hydrochloride, 0.136 mg/ml in 0.1 *N* hydrochloric acid; aminophylline, 0.7 mg/ml in 50% ethanol in 0.4% (v/v) acetic acid; and amobarbital, 0.136 mg/ml in 50% ethanol in 0.4% (v/v) acetic acid. All standards were USP XVI, NF XIII, or BP 1973 quality[4].

Column Preparation—A slurry of about 4 g of alginic acid, previously soaked in water for 4 hr, was transferred to a chromatographic column and allowed to settle. The column was eluted with 2 *N* hydrochloric acid until the eluate gave an absorbance less than 0.005 between 230 and 330 nm. It was then washed with distilled water until the eluate was neutral to the litmus solution. Finally, a small pledget of glass wool was added to the column. After 20 ml of 50% ethanol in water was passed through the column, alginic acid was slightly tamped.

Sample Treatment—The average weight of not less than 20 capsules[5] was determined. An accurately weighed portion of powder, equivalent to about 67 mg of ephedrine hydrochloride, was transferred to a 50-ml volumetric flask, and 50% ethanol–acetic acid solution was added to the mark. A magnetic stirring bar was slipped into the flask, and the mixture was stirred for 10 min and then centrifuged for 2 min.

Determination—*Aminophylline and Amobarbital*—Pipet a 10-ml aliquot of the centrifuged sample onto the prepared alginic acid column. Place a 100-ml volumetric flask beneath the column and start collecting the eluate at a rate of 1 ml/min. Then add 50 ml of 50% ethanol (in water) in small portions, letting each drain through the column before successive additions. Remove the flask and dilute to volume with the same solvent. This solution contains aminophylline and amobarbital.

Transfer a 2-ml aliquot of the solution into each of two 50-ml volumetric flasks. Adjust the solution in one flask to pH 4 and the other to pH 10 by adding 0.02 *N* sodium hydroxide; then dilute to 50 ml with distilled water. Using the pH 4 solution as the reference and the pH 10 solution in the sample position, measure the absorbance at 285.5 and 240 nm (1-cm cells). Calculate the concentration of aminophylline and amobarbital in the tablets by determining the absorptivities at 285.5 and

240 nm of both aminophylline and amobarbital standard solutions, taken individually, diluted as the sample, and adjusted to pH 4 (blank) and 10 (sample).

Ephedrine Hydrochloride—Wash the column with 20 ml of distilled water divided into two portions. Elute the column with 0.1 *N* hydrochloric acid at a rate of 2 ml/min, discarding the first 7 ml of the liquid. Collect the eluate in a volumetric flask to the 100-ml mark. Scan the sample and standard solutions between 330 and 230 nm, using 4-cm cells, against 0.1 *N* hydrochloric acid as the reference. Determine the absorptivity at the maximum (about 257 nm) for the ephedrine hydrochloride standard and calculate its concentration in the sample solution.

RESULTS AND DISCUSSION

A prepared column containing alginic acid retained ephedrine hydrochloride from an ethanolic solution and allowed aminophylline and amobarbital to pass through as washings. Subsequently, ephedrine hydrochloride was eluted with 0.1 *N* hydrochloric acid and determined spectrophotometrically at 257 nm. Aminophylline and amobarbital were volumetrically collected and quantitatively determined by UV differential spectrophotometry at 240 (maximum for amobarbital) and 285.5 (maximum for aminophylline) nm, using two aliquots of the same solution as the blank and sample at pH 4 and 10, respectively.

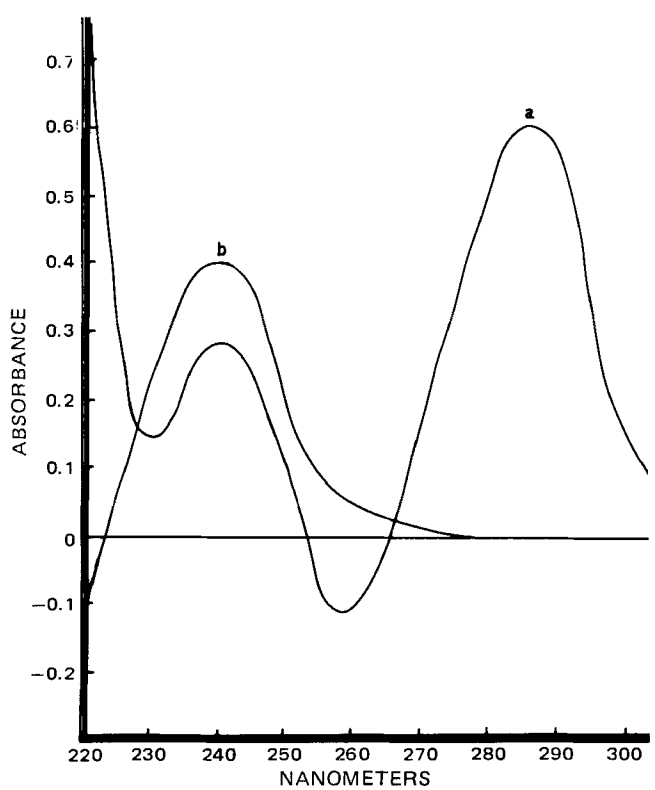

Figure 2—*Differential absorption spectra of aminophylline (a) and amobarbital (b) at pH 10.*

Synthetic mixtures of the three active ingredients in the presence of an excipient (light magnesium carbonate) were prepared and assayed by this method including the chromatographic step. Recovery results are given in Table I; analyses of commercial samples are reported in Table II.

The determination of aminophylline and amobarbital represented the main problem. An algebraic method for additive absorbances was not applicable, since the weight ratio of aminophylline to amobarbital was about 5:1. Therefore, the pH–chromophoric properties of the two compounds had to be considered. Both aminophylline and amobarbital are organic acids and have hydrogen atoms that can be ionized in alkaline media. When their absorption spectra are determined at different pH values that include molecular and ionic forms, isosbestic points are observed frequently. To find an eventual isosbestic point that might be employed as the baseline, differential absorption spectra of individually prepared solutions of aminophylline and amobarbital between pH 10 and 13 were examined.

A series of aminophylline solutions at pH 10, 11, 12, and 13 (using the same solutions at pH 4 as reference) showed two maxima at 240 and 285.5 nm and two isosbestic points at 253.5 and 263 nm. The differential curves determined at pH 11, 12, and 13 did not exhibit a significant change over those taken at pH 10, as would be expected from the pK value of aminophylline. When differential absorption spectra of amobarbital solutions were prepared following the same procedure, a gradual shift of the absorption maxima from 240 to about 254 nm was observed as the pH was increased from 10 to 13. Particular attention was focused on the absorption curves taken at pH 13, where the correlation between the isosbestic point at 253.5 nm for aminophylline and the maximum for amobarbital and the correspondence of the maximum for aminophylline at 285.5 nm with an insignificant absorbance for amobarbital seemed to be the ideal setup for the quantitative determination of the ingredients in the presence of one another.

Figure 1 illustrates the differential absorption spectra at pH 13 of three concentrations of aminophylline and three concentrations of amobarbital. Each solution contained the active ingredient in the weight ratio similar to that of the commercial preparation. However, while both compounds followed the Lambert–Beer law individually, their mixtures, over the same concentration range, did not. When these mixtures were scanned

SD, %		±0.92		±1.67

[a] Synthetic mixes were prepared by dissolving an accurately weighed amount of both compounds in 50% ethanol in 4% acetic acid in a 50-ml volumetric flask. Each mixture was treated and diluted as the sample, excluding the chromatographic step.

between 320 and 220 nm, the absorption curves showed that the maximum at 285.5 nm remained unchanged and that the maximum at 254 nm was absent. The absorption at 240 nm increased significantly in intensity with respect to that of aminophylline determined individually at the same concentration.

The cause of this deviation at pH 13 may have been that the keto–enolic equilibrium of the doubly ionized form of amobarbital with the absorption maximum at 254 nm was probably shifted by a much larger concentration of the enolized aminophylline to exhibit an absorption maximum at 240 nm (singly ionized form). To eliminate such a possible keto–enolic equilibrium effect, a new approach was followed. The differential absorption curves at pH 10, previously plotted for the separated compounds, showed that aminophylline and amobarbital exhibited fairly strong maxima at about 240 nm and that there was a wide variation between the intensities of absorption of both components at 285.5 nm. Figure 2 shows the differential absorption spectra at pH 10 of aminophylline and amobarbital. These conditions seemed to be theoretically adequate for the quantitative determination of mixtures of aminophylline and amobarbital (8).

This hypothesis was verified experimentally when mixtures of the two substances, analyzed at pH 10, gave a positive response. The results in Table III show that the procedure is both accurate and precise. Compared to the NF procedure, the proposed method significantly shortens the time required for the analysis of aminophylline, amobarbital, and ephedrine hydrochloride, thus making possible the quantitative determination of more samples per day.

Liquid Chromatography in Pharmaceutical Analysis VIII: Determination of Isoniazid and Acetyl Derivative in Plasma and Urine Samples

S. J. SAXENA, J. T. STEWART, I. L. HONIGBERG ˣ, J. G. WASHINGTON, and G. R. KEENE

Abstract □ Parameters are described for the qualitative and quantitative analysis of a mixture of isoniazid and its acetyl derivative. The compounds are chromatographed on an octadecylsilane column, using absolute methanol–distilled water (60:40) at pH 2.5 containing 0.01 *M* dioctyl sodium sulfosuccinate. The flow rate was 2.0 ml/min (2500 psig). The separation and quantification are applicable to plasma and urine samples. The determination in each biological fluid can be achieved in approximately 90 min with percentage accuracies for isoniazid of 5.25 and 7.45 and for the acetyl derivative of 4.47 and 1.56 in plasma and urine, respectively.

Keyphrases □ Isoniazid and acetyl derivative—high-pressure liquid chromatographic analyses, plasma and urine □ High-pressure liquid chromatography—analyses, isoniazid and acetyl derivative, plasma and urine □ Tuberculostatic antibacterials—isoniazid and acetyl derivative, high-pressure liquid chromatographic analyses, plasma and urine

Interest in high-pressure liquid chromatography (HPLC) for the determination of drugs and their metabolites in biological media led to the analysis of isoniazid (I) and its major metabolite, the acetyl derivative (II). Presently, I is very effective as an antituberculosis drug, and the determination of I and II is important in studies related to I disposition and metabolism. A review of analytical methodology concerning I and its metabolites is available (1).

This paper reports the HPLC separation of I and II and the application of the procedure to the quantification of these compounds in plasma and urine. The HPLC separation is effected utilizing ion-pair formation with dioctyl sodium sulfosuccinate on an octadecylsilane column. Generalities of ion-pair formation were reviewed extensively (2, 3). Some investigators (4–6) used ion-pair formation as a tool for effecting chromatographic analysis of selected organic ions. The mechanism for such a separation apparently depends upon the reversible formation of ion-pairs in the chromatographic system and the separa-

[a] Based on a typical 3-ml biological sample. [b] Data represent three replicate injections of calibration solutions; D/IS is the ratio of the integrated area of the drug at some concentration divided by the integrated area of the internal standard. [c] The r is the correlation coefficient determined from linear regression analysis, and s_{yx} is the standard error of the estimated concentration. [d] Confidence limits at $p = 0.05$.

tion of the constituents on the basis of differences in the lipophilicity of the ion-pairs formed.

The analysis of an isoniazid–pyridoxine hydrochloride dosage form, using ion-pair formation with dioctyl sodium sulfosuccinate, was recently reported (7). The chromatographic separation described herein takes approximately 10 min. The overall analysis time is approximately 90 min, which includes extraction of the drug and metabolite from the biological fluid (8) followed by HPLC separation and quantification.

EXPERIMENTAL[1]

Reagents and Chemicals—Powdered samples of I[2] and II (9) were used in the analytical procedure, and dioctyl sodium sulfosuccinate[3] was used as a component of the mobile phase. All other chemicals and solvents were commercially available and were utilized as received.

Mobile Phase—The mobile phase, consisting of absolute methanol–distilled water (60:40), was prepared fresh daily. It was made 0.01 *M* with respect to dioctyl sodium sulfosuccinate (4.4 g/liter), and its pH was adjusted to 2.5 by dropwise addition of 2 *M* sulfuric acid (<1 ml).

Internal Standard Solution—The stock internal standard solution (8 mg/10 ml) was prepared by dissolving 1-benzoyl-2-isonicotinoylhydrazine in distilled water. The substituted hydrazine was originally synthesized by Kerr *et al.* (10). It was recrystallized from water (mp 232–234°) before use.

Standard Solutions for Calibration Curves—Stock solutions of I (6 mg/10 ml) and II (8 mg/10 ml) were prepared by dissolving weighed amounts of each powder in distilled water.

Determination of Calibration Curve—*For Plasma Levels*—Into individual 60-ml separators were placed accurately pipetted volumes[4] of 0.050, 0.075, 0.100, and 0.150 ml of both I and II standard solutions. A 0.200-ml volume of the internal standard solution was added to each separator, and the volume of each solution was adjusted to 6 ml with distilled water. Then 1 ml of 0.1 *N* sodium hydroxide solution and solid ammonium sulfate, about 1 g/ml of aqueous solution, were added. The latter was added in small portions to each solution followed by gentle shaking for 5 min. Each solution was then shaken for 5 min with 40 ml of water-saturated 1-butanol–chloroform (30:70).

The layers were allowed to separate, and 30 ml of the organic layer (bottom) from each separator was transferred to clean 45-ml stoppered conical centrifuge tubes. Four milliliters of 0.1 *N* sulfuric acid was added to each tube, and the contents were shaken for 5 min. The layers were allowed to separate, with centrifugation if necessary, and a 40-μl aliquot of the acidic layer (top) was injected into the liquid chromatograph. The concentrations of both I and II were subjected to a linear regression analysis, and the slope and intercept for each component were calculated (Table I).

For Urine Levels—Into individual 60-ml separators were placed the following accurately pipetted volumes of I and II standard solutions, respectively: 0.300 and 0.700 ml, 0.400 and 1.000 ml, 0.600 and 1.20 ml, and 0.700 and 1.40 ml. A 0.800-ml quantity of the internal standard solution was added to each separator, and the volume of each mixture was adjusted to 6 ml with distilled water. The solutions were then treated in the same manner as described for plasma levels.

Determination of I and II in Human Plasma and Urine—To 3.0 ml of human plasma in a 60-ml separator were added accurately pipetted quantities of 0.100 ml of both I and II standard solutions and 0.200 ml of the internal standard solution. To 3.0 ml of human urine in another separator were added 0.400 and 0.900 ml of I and II solutions, respectively, along with 0.800 ml of the internal standard solution. Each plasma and urine sample was then treated in the same manner as described for the standard solutions. Control blanks for each biological fluid were also included. Replicate 40-μl injections were made for each sample.

Chromatographic Separation and Quantification—The degassed mobile phase was pumped through an octadecylsilane column[5] at a flow rate of 2.0 ml/min (2500 psig) at room temperature until a stable baseline was obtained. Replicate 40-μl injections of sample and standard solutions were made using a 100-μl syringe[6]. The wavelength of the UV detector was set at 266 nm. The chart recorder provided a record of drug elution from the column as peaks on a chromatogram. In all cases, the solute was measured by digital integration of the peak area[1].

RESULTS AND DISCUSSION

The analysis of the I–II mixture and the application to plasma and urine extracts necessitated the examination of three separate problems: (*a*) the development of a set of HPLC operating parameters that would separate the two compounds without peak overlap, (*b*) the detection and quantification of each compound at the level found in biological fluids, and (*c*) the contribution of extracted plasma and urine blanks to the chromatograms.

Initially, the separation was achieved on a cation-exchange column using aqueous 0.01 *M* ammonium acetate (pH 3.5) as the mobile phase. However, this procedure was rejected due to the lack of reproducible

[1] A Waters Associates liquid chromatograph (model ALC/GPC 201), equipped with an M-6000 pump, a Perkin-Elmer model LC-55 variable wavelength UV–visible detector, an Infotronics integrator (model CRS-204) with digital printout, and a Waters packed column, 4 mm i.d. × 30 cm, was used.

resolution of the compounds from different batches of resin from the same supplier and due to a loss in resolution of I and II from plasma and urine extracts.

Attempts to separate I and II using conventional reversed-phase chromatography were also unsuccessful. Studies showed that the compounds were most propitiously separated on an octadecylsilane column using absolute methanol–distilled water (60:40) at pH 2.5 with 0.01 *M* dioctyl sodium sulfosuccinate. The mobile phase had been successfully employed for the determination of a I–pyridoxine hydrochloride mixture (7) and was readily adaptable to the I–II problem. Adequate separation was achieved between I and II in this solvent mixture as evidenced by an approximate resolution (R_s) value of 2.0 (11). Furthermore, use of this mobile phase allowed 1-benzoyl-2-isonicotinoylhydrazine to be used as a suitable internal standard.

A flow rate of 2.0 ml/min (2500 psig at room temperature) was the most satisfactory, since separations could be obtained in less than 10 min. The void volume of the column was 2.8 ml. UV detection at 266 nm was employed, since both I and II give maximum absorption at this wavelength and the detector would therefore provide maximum sensitivity for the low concentration levels present in biological fluids.

The solutions used in the determination of the standard curves as well as the plasma and urine samples were extracted according to a literature procedure for I (8). To make the sample compatible with the mobile phase, the extraction method was slightly modified with the use of 0.1 *N* sulfuric acid in the reextraction step. The internal standard was added to the original samples prior to extraction to improve precision. The drug concentrations used in the preparation of the standard curves and biological samples were in the range of those reported for plasma and urine levels (1, 12). Minimum detectability of I and II utilizing the chromatographic procedure described herein was 200 and 50 ng, respectively.

Calibration curves for both plasma and urine levels of I and II were obtained as follows. Digital integration of the area under the curve for each peak on the chromatograms was performed. The ratios of I and II peak areas to the area of the internal standard were calculated for each chromatogram. A linear regression analysis of these data at the four concentrations of each component gave the slope, intercept, and correlation coefficient for the plasma and urine calibration curves (Table I).

The liquid chromatograms of I–II from the spiked plasma and urine samples are shown in Figs. 1 and 2. No interferences from blank plasma and urine samples were noted. The ratios of drug peak areas/internal standard peak areas (D/IS) were calculated for I and II. The constants (slope and intercept) shown in Table I for the linear regression equations were used to solve for drug concentration in each biological sample: [D/IS

In Vitro and *In Vivo* Considerations of a Novel Matrix-Controlled Bovine Progesterone-Releasing Intravaginal Device

V. W. WINKLER [x], S. BORODKIN, S. K. WEBEL, and J. T. MANNEBACH

Abstract □ An *in vitro* system measuring progesterone release from silicone matrixes into serum is described. Drug release followed a matrix-controlled diffusion model in which the cumulative quantity released was linear with the square root of time. A bovine intravaginal device, consisting of a steel coil coated on both sides with a progesterone silicone matrix, was used as an *in vivo* drug delivery system. *In vivo* drug release also was matrix controlled, with rates comparable to those obtained *in vitro*. However, lag times of 1.7 and 4.2 days before reaching the steady-state rate were obtained for the outer and inner surfaces, respectively. The combination of effects resulted in a pseudo-zero-order drug-releasing device in which cumulative drug released was linear with time for at least 16 days.

Keyphrases □ Progesterone—release from silicone matrixes, *in vitro* system compared to bovine intravaginal device *in vivo* □ Silicone matrixes—release of progesterone, *in vitro* system compared to bovine intravaginal device *in vivo* □ Drug delivery—progesterone from silicone matrixes, *in vitro* system compared to bovine intravaginal device *in vivo* □ Vaginal devices, bovine—progesterone in silicone matrix, compared to *in vitro* system □ Hormones—progesterone, release from silicone matrixes, *in vitro* system compared to bovine intravaginal device *in vivo*

Intravaginal devices coated with a progesterone silicone matrix were used successfully (1–3) to control the bovine estrus cycle and to synchronize estrus by regulating pituitary release of gonadotropic hormones. Estrus occurs at a predictable time upon removal of the device developed in these laboratories 9–21 days after intravaginal implantation. The drug release rate profile of this device is defined in this report through correlation of *in vitro* and *in vivo* studies.

EXPERIMENTAL

Matrix Preparation—Progesterone silicone matrixes at various drug concentrations were prepared by first mixing the required amount of micronized drug into silicone fluid 360[1] and then adding Silastic elastomer 382[1]. The mixture was blended for 30 min to ensure random distribution of drug before adding the polymerizing catalyst, stannous octanoate[1].

***In Vitro* Study**—Matrixes used in the *in vitro* studies were prepared by streaking the silicone drug mixture containing catalyst onto fiber glass cloth and allowing it to cure. A template was used to obtain a uniform thickness of 1.5 mm. The cured matrixes were cut accurately into 2 × 2-cm pieces, mounted onto stainless steel plates with medical adhesive[1], and allowed to dry for 48 hr.

Two types of *in vitro* experiments were performed. The first followed the release of progesterone as a function of time from a silicone matrix containing 6.75% drug. The second concerned the release rate as a function of drug concentration using 5, 7.5, and 10% progesterone in silicone matrixes. The 6.75% matrix was prepared from a different lot of silicone liquid and elastomer, restricting direct comparison of the two *in vitro* experiments.

In both experiments, a specified number of matrixes mounted on stainless steel were individually placed in 25 × 150-mm glass tubes. To each tube, 15 ml of sheep serum[2] and 2 drops of toluene were added to retard microbial growth. Each tube was capped with a rubber stopper, placed on a shaker, and incubated at 37°. Serum changes at the end of Days 1, 2, 3, 4, 7, 11, 15, and 18 for one set of matrixes were matched with serum changes at the end of Days 0.1, 0.2, 0.3, 0.7, 1, 1.3, 2, 2.3, 3, 4, 5, 8, 12, 15, 18, and 20 for a duplicate set of matrixes.

The progesterone released in selected mounted matrixes was determined at various scheduled times by analyzing the amount of drug re-

Table I—Comparative *In Vitro* Progesterone Release Rates from 5, 7.5, and 10% Silicone Matrixes Incubated 21 Days at 37° in Sheep Serum

Parameter	Progesterone Matrix Concentration		
	5%	7.5%	10%
Rate ($k = Q/t^{1/2}$ mg/cm day$^{1/2}$)	1.924	2.164	2.436
Confidence limit ($p < 0.05$), ±%	10.7	6.2	8.3
Extrapolated lag time, hr	5.0	4.5	5.0
Correlation coefficient (r)	0.969	0.987	0.980

maining and calculating the difference from the initial content (determined by percent progesterone of total matrix weight) of the particular mounted matrix analyzed. Since there were no significant differences in results between the two serum changing schedules and at no point did the released progesterone exceed 10% of its maximum solubility in serum, near perfect sink conditions existed throughout the experiment.

***In Vivo* Study**—Intravaginal devices were prepared by injection molding the silicone drug mixture containing catalyst around a 3.5 × 28.5 × 0.1-cm stainless steel strip set in a die such that both sides of the strip had 1.5 mm of matrix attached. The cured progesterone silicone device was then formed into a coil with a diameter of ~4 cm and a length of ~12 cm before intravaginal implantation into cows as described by Roche (1).

Devices were removed at the end of Days 2, 6, 9, 12, and 16. The silicone matrix of the inside and outside surfaces was peeled from the steel and analyzed for progesterone content. As was done in the *in vitro* studies, the progesterone released was determined by difference from the initial progesterone content of the device.

Analytical—Progesterone was extracted from the silicone matrixes by soaking in ethyl acetate, and the extracted drug was analyzed by flame-ionization GLC using bis(2-ethylhexyl) sebacate[3] as an internal standard. The column was a 0.31-cm × 1.22-m (0.125-in. × 4-ft) glass U-tube[4] containing 3% Dexsil on Chromosorb W Hp[3]. The flow rates (milliliters per minute) were: air, 300; hydrogen, 25; and nitrogen, 40. The temperatures were: injection, 250°; column, 240°; and detector, 250°.

The method described is accurate with 100% recovery on spiked samples and a coefficient of variation less than ±3%.

RESULTS AND DISCUSSION

The release rate of drugs suspended in a stationary matrix was described theoretically (4) to be a linear function of the square root of time. With the assumptions that (*a*) a quasi-steady state exists, (*b*) the drug particles are small compared to the average distance of diffusion, and (*c*) perfect sink conditions exist in the external media, the basic equation of interest for planar systems is:

$$Q = [D(2A - C_s)C_s t]^{1/2} \quad \text{(Eq. 1)}$$

where Q is the amount of drug released after time t per unit of exposed area, A is the initial drug concentration, C_s is the solubility of the drug in the matrix, and D is the effective diffusivity through the matrix.

For a given matrix system, D, A, and C_s remain constant; therefore, Eq. 1 can be expressed as:

$$Q = kt^{1/2} \quad \text{(Eq. 2)}$$

where the release rate constant:

$$k = [D(2A - C_s)C_s]^{1/2} \quad \text{(Eq. 3)}$$

Results of the first *in vitro* experiment (Fig. 1), using the 6.75% progesterone silicone matrix, dramatically demonstrate the relationship in Eq. 2, with a matrix-controlled rate constant, k, of 2.425 mg/cm^2 day$^{1/2}$ ± 4% ($p < 0.05$ and $r = 0.995$). Extrapolation to the x axis indicates a lag time of 6 hr before reaching steady state. This lag time is generally seen in systems of this type, and it has been attributed to drug release being controlled by a matrix-boundary diffusion layer model in the early stages (5).

The Higuchi equation describing matrix-controlled drug release (Eq. 1) also dictates that the rate constant should be proportional to the square root of drug concentration as long as $2A$ is much greater than C_s. This

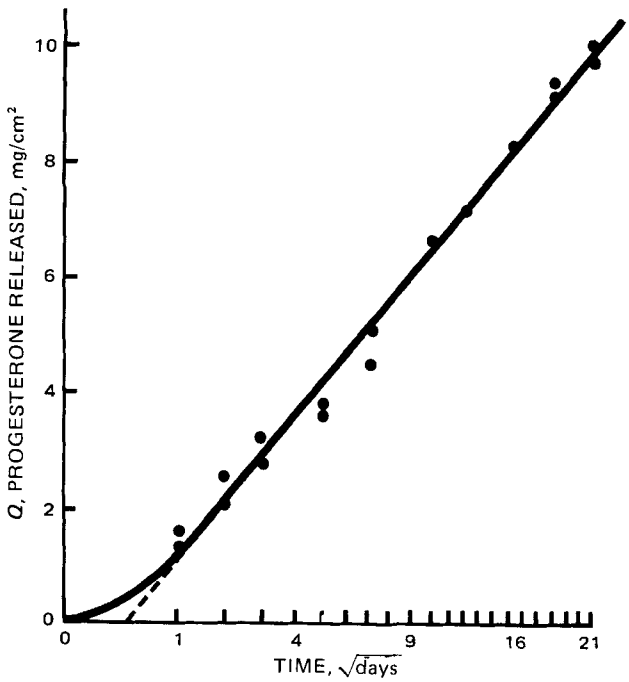

Figure 1—In vitro *progesterone release as a function of the square root of time from a silicone matrix containing 6.75% drug incubated at 37° in sheep serum. Matrix-controlled release rate* ($k = Q/t^{1/2}$ *mg/cm*^{2} *day*$^{1/2}$) *is 2.425 ± 4% (*$p < 0.05$ *and* $r = 0.995$*). Based on extrapolated intercepts, there is a 0.25-day lag time before reaching steady state.*

should be the case in the progesterone-silicone matrix system for which Roseman (6) reported a C_s value of 0.513 mg/ml. The relationship may be expressed as:

$$\frac{k_1}{k_2} = \frac{\sqrt{A_1}}{\sqrt{A_2}} \quad \text{(Eq. 4)}$$

Chien *et al.* (7) reported this relationship in a study of ethynodiol diacetate in silicone matrixes. Results of the second *in vitro* experiment, comparing progesterone release from matrixes containing 5, 7.5, and 10% drug, are shown in Table I. The rate constants show increasing values with drug concentration as predicted, although the magnitude of increase is somewhat less than that expected from Eq. 4. When using the 7.5% rate

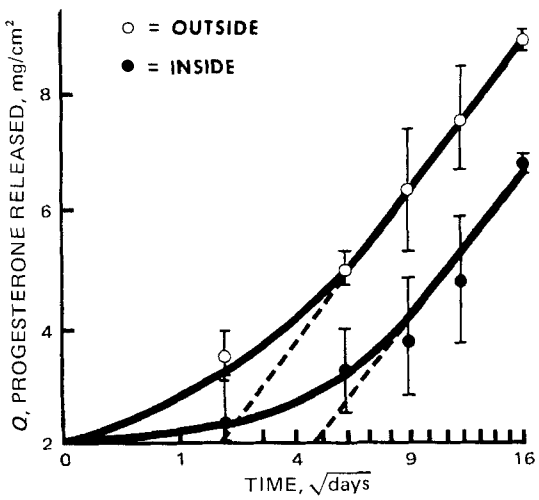

Figure 2—In vivo *cumulative progesterone release* ±SD *as a linear function of the square root of time from separate outside and inside surfaces of a silicone matrix intravaginal device containing 7.8% drug implanted in cows. The following matrix-controlled release rates (in milligrams per square centimeter day*$^{1/2}$*) were calculated from the 6-, 9-, 12-, and 16-day means shown in Table II: outside rate,* $k_o = 2.597 \pm 23\%$ ($p < 0.05$ *and* $r = 0.998$*); and inside rate,* $k_i = 2.359 \pm 87\%$ ($p < 0.05$ *and* $r = 0.959$*). Based on extrapolated intercepts, there are 1.7- and 4.2-day lag times before reaching steady state for the outside and inside surfaces, respectively.*

	Inside	4.68	5.08	4.74	—	—	—	4.83	0.21
	Total	5.77	6.12	5.89	—	—	—	5.92	0.18

[a] Negative value results from positive variation in actual progesterone content of individual implant from assumed initial progesterone content. Thus, percent drug remaining after a 2-day implantation was greater than the theoretical 7.8%. Since averages are used in determining drug release, the negative value must be included so as not to bias the final result.

as reference, the 5 and 10% rates are 108 and 97.9% of expected theory.

It is intriguing to speculate that an increase in drug concentration increases the diffusion pathway, thus decreasing the effective diffusion coefficient, D. Such a process is conceivable, because a "sponge effect" is created in the matrix as insoluble drug is removed by the matrix diffusion process. The higher the drug concentration, the more "holes" exist; consequently, there is an increased migration distance for soluble drug before passing into the external media. When using C_s at 0.513 (6), the effective diffusion coefficients are (Eq. 3) 0.0445, 0.0337, and 0.0285 cm²/day for the 5, 7.5, and 10% matrixes, respectively. The net result of such a decrease in the effective diffusion coefficients is a less than expected increase in rates with respect to increasing drug concentrations. There is no doubt, however, that the release of progesterone is matrix controlled.

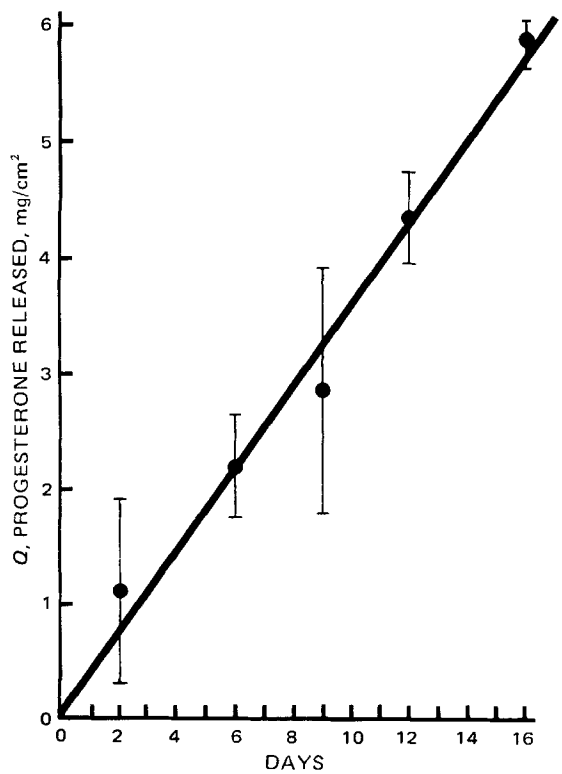

Figure 3—In vivo *cumulative progesterone release* ±SD *as a linear function of time from total outside and inside surfaces of a silicone matrix intravaginal device containing 7.8% drug implanted in cows. When using mean* Q *values shown in Table II including Day 0, the zero-order rate* (k_t = Q/t *mg/cm² day) is 0.357* ± *24%* ($p < 0.05$ *and* $r = 0.991$).

Results of the *in vivo* progesterone release from the outside and inside surfaces of 7.8% progesterone intravaginal devices implanted in cows are shown in Table II. The mean release values with respect to time (Q) are greater with less variation for the outer surface than for the inner surface of the coils at all time periods. The release rates as a function of the square root of time from the separate outside and inside surfaces are graphically shown in Fig. 2. When using the mean Q values from Days 6 through 16 in Table II, the following matrix-controlled release rates are calculated (in milligrams per square centimeter day$^{1/2}$): outside rate, $k_o = 2.597 \pm 23\%$ ($p < 0.05$ and $r = 0.998$); and inside rate, $k_i = 2.359 \pm 87\%$ ($p < 0.05$ and $r = 0.959$). These results are in excellent agreement with those obtained in the *in vitro* system and demonstrate progesterone release from the coils to be a matrix-controlled process *in vivo*.

Based on extrapolated intercepts, there are 1.7- and 4.2-day lag times before reaching steady state for the outside and inside surfaces, respectively. The shorter lag time for the outer surface accounts for its greater release values and less variation. The longer lag time for the inner surface likewise accounts for the smaller release values and greater variation. The difference between lag times may be attributed to physical phenomena such as wetting of the polymer surface, establishment of a steady-state diffusion gradient, and contact with the vaginal wall.

The most remarkable effect of the time lag difference between the two surfaces is the establishment of a pseudo-zero-order drug-releasing device. Indeed, as shown in Fig. 3, the amount of progesterone released per day is approximately uniform. When using the mean Q values including Day 0, the zero-order rate ($k_t = Q/t$ mg/cm² day) for 16 days is 0.357 ± 24% ($p < 0.05$ and $r = 0.991$). The net 16-day progesterone dose administered to the cow implanted with the described intravaginal device having a surface area of 224 cm² is 80 ± 19 mg/day ($p < 0.05$). This linear dose rate is achieved by superimposing *via* time lag the nonlinear matrix-controlled dose rate of the outer and inner surfaces of the implanted device.

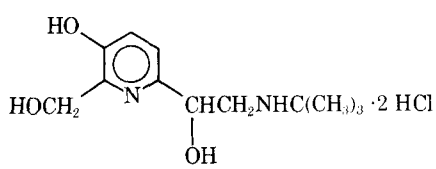
Stability of Aqueous Solutions of Pirbuterol

P. C. BANSAL * and D. C. MONKHOUSE ˣ

Abstract □ The hydrolytic degradation of pirbuterol was investigated under saturated oxygen conditions over a wide range of pH values and at different temperatures. Two of the five observed breakdown products were positively identified. The first-order decomposition rate appeared to depend on the rate constants of the four dissociated ionic species. The most stable region for the drug was pH 1–2, where the diprotonated molecule predominated; appropriate thermodynamic parameters were calculated.

Keyphrases □ Pirbuterol—aqueous solutions, stability, effect of pH and temperature □ Stability—pirbuterol, aqueous solutions, effect of pH and temperature □ Degradation, hydrolytic—pirbuterol, effect of pH and temperature □ Bronchodilators—pirbuterol, stability of aqueous solutions, effect of pH and temperature

Pirbuterol[1] (I) is a potent sympathomimetic bronchodilator that possesses high selectivity for pulmonary as opposed to cardiac adrenergic receptors. Exploratory studies indicated that satisfactory pirbuterol stability could be attained in acidic media, while degradation occurred under alkaline conditions. Since this bronchodilator will be manufactured in many liquid dosage forms (aerosol, oral spray, intravenous injection, and pediatric syrup), its solution stability profile should be well characterized and understood.



I

The stability of pirbuterol should be superior to that of the catecholamines, since intramolecular cyclization leading to indole derivatives can be excluded on mechanistic grounds. Its stability is more likely to compare with that of the more stable compounds terbutaline and phenylephrine. Upon oxidation, these compounds produce formaldehyde, which can further react with the intact molecule to form isoquinoline derivatives *via* the Pictet–Spengler reaction (1, 2).

The purpose of this study was to evaluate pirbuterol in the light of what has already been reported about structurally similar agents of contrasting stability behavior. The stability of pirbuterol's closest analog, albuterol, has not yet been reported.

EXPERIMENTAL

Quantitative TLC Assay—Pirbuterol[2] solutions (0.5–5.0 mg/ml) were spotted (5 μl) on scored precoated silica gel TLC plates[3] using capillary pipets[4]. Following each application, the pipet was rinsed with 5 μl of ethanol, which was applied to the respective spot to ensure complete transfer. Then the pipet was rinsed with the next solution to be spotted. The same pipet was used for each series. Standard samples containing known amounts of pirbuterol were spotted alternately with the unknown samples.

The chromatographic bath was prepared in a glass chamber (30 × 22 × 10 cm) by mixing 40 ml of acetic acid and 40 ml of water into 240 ml of methyl ethyl ketone. The chamber was lined on one side with filter paper, which was in contact with the mobile phase. The chamber was tightly sealed and allowed to equilibrate overnight.

After drying the applied spots thoroughly, chromatographic development was performed until the solvent front was 14–16 cm above the origin. The plates were removed from the chamber and dried in a stream of forced warm air. The reflectance of the pirbuterol spot (R_f 0.43) was measured on a double-beam spectrodensitometer[5] at 282 nm, using a slit width of 1 mm and a sensitivity of 0.4. Peak areas were measured with a computing integrator[6].

Kinetic Studies—Aqueous 5-mg/ml solutions of pirbuterol were prepared (initial pH ~3), and the pH was adjusted with 1 *N* HCl or NaOH to integral values of pH from 1 to 14. Since preliminary investigation showed that oxygen played a significant role in the degradation of pirbuterol, the oxygen tension was kept constant in the test solutions. Oxygen saturation was achieved by bubbling oxygen through each solution throughout the experiment. The apparatus used is shown in Fig. 1. Oxygen was bubbled into the solution at a rate of 6 ml/min and was allowed to escape through a condenser, which prevented loss of water vapor.

The test solution pH was adjusted periodically by the addition of 1 *N* NaOH or HCl, utilizing a pH meter equipped with an electrode[7] specially

prepared for use at high temperatures. To prevent aging and poisoning of the electrode, immersion in the actual reaction mixtures was kept to a minimum. At no time was the pH allowed to deviate more than 0.2 pH unit from the original settings. Only those solutions with pH >5 required periodic adjustment.

Temperature was controlled by immersing the solution flask into a constant-temperature oil bath. Loss of intact drug was monitored by TLC–densitometry.

Determination of Ionization Constants—The pKa's of pirbuterol were determined at 21 and 90°. A 0.25-mmole sample of drug was dissolved in freshly boiled double-distilled water and titrated with 1 *N* NaOH (carbon dioxide free). Change in pH as a function of the titrant delivered was monitored with a pH meter equipped with the high temperature electrode[7]. Confirmation of pKa's was achieved by titrating the structurally similar compounds 2,6-bis(hydroxymethyl)-3-hydroxypyridine and 2-(*tert*-butylamino)ethanol.

2-Hydroxymethyl-3-hydroxypyridine-6-carboxaldehyde (II)—An authentic sample of this compound[8] was prepared, and the structure was confirmed by NMR, IR, and elemental analyses. It exhibited an R_f value of 0.75 on the TLC system previously described.

RESULTS AND DISCUSSION

For the quantitative TLC procedure, the densitometric response for pirbuterol is linear and can be quantitated over a 0.5–5.0-mg/ml range when 5-μl spots are applied. The calibration plot (electronic peak area *versus* quantity spotted) for the assay had a correlation coefficient of 99.9% with a standard deviation of ±3.9%.

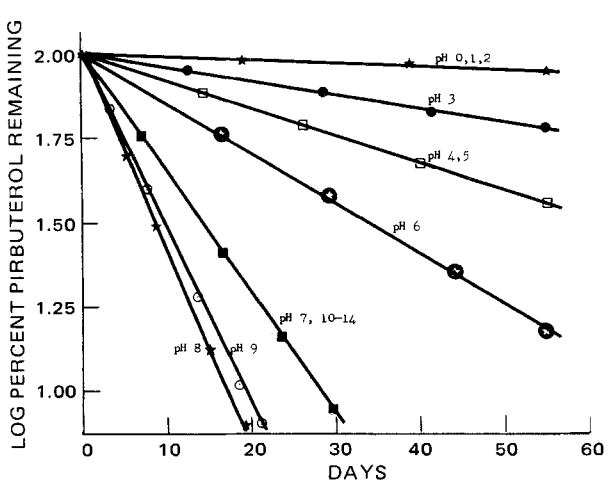

Figure 3—*First-order degradation of pirbuterol at 90° at various pH values.*

[8] CP-34,028, Pfizer Inc.

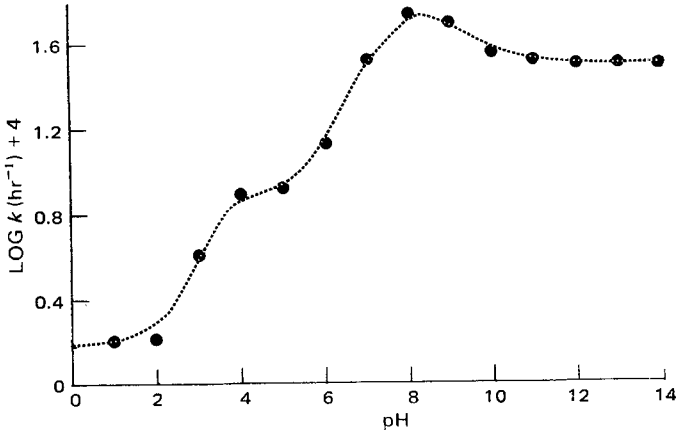

Figure 4—*The pH–rate profile of pirbuterol degradation at 90° as a function of pH.*

In the present study, the degradation of pirbuterol was investigated over a pH range of 1–14. These studies were conducted at 90° to accelerate the decomposition rates so that their measurement would be kinetically convenient. Preliminary studies indicated that the reaction rate was affected both by oxygen tension and by buffer catalysis but unaffected by ionic strength effects and light. Therefore, the study was designed so that constant oxygen tension was maintained (saturation conditions) and buffers *per se* were not used. Hence, it was assumed that only thermal phenomena and pH contributed to the rate constants obtained.

The reaction followed apparent first-order kinetics with respect to pirbuterol. Figure 2 shows that log concentration *versus* time plots were linear and parallel for each concentration studied (0.5–25 mg/ml) at pH 7. Similar results were also obtained at pH 1, 5, 8.5, and 11. The reaction was then treated as first order in pirbuterol over the entire pH range of 1–14. In Fig. 3, the log concentration of pirbuterol remaining is plotted as a function of time. The slopes of these lines were used to calculate the first-order rate constants (Table I). These log k values can be used to plot a log k–pH profile for the reaction (Fig. 4).

The pH of maximum stability was between 1 and 3. Another pH-independent region occurred between pH 10 and 14. The degradation rate

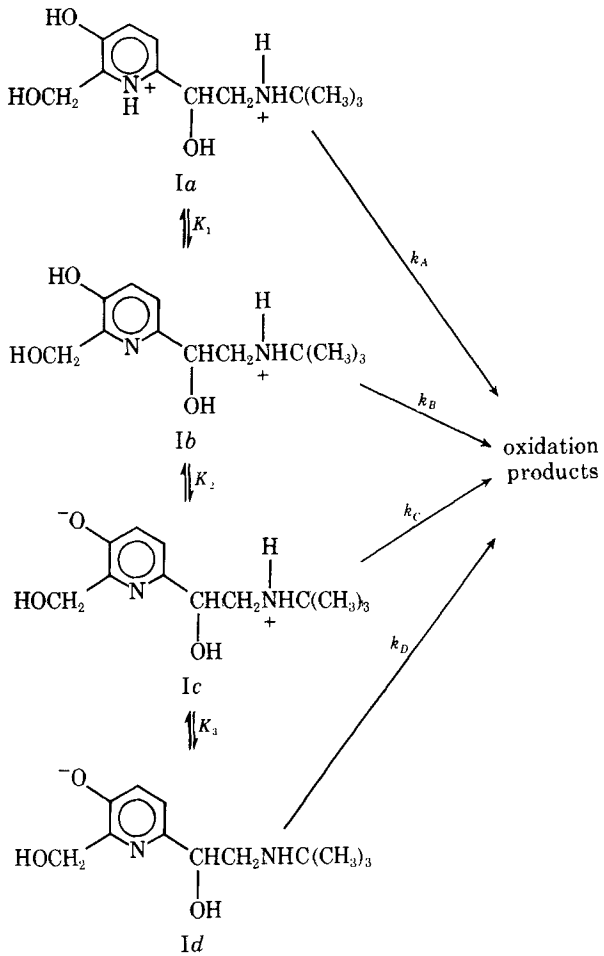
[a] Rate constants and equilibrium constants of individual species used in the rate equation for calculation of theoretical curve were: $k_A = 1.50 \times 10^{-4}\ hr^{-1}$, $k_B = 8.24 \times 10^{-4}\ hr^{-1}$, $k_C = 6.00 \times 10^{-3}\ hr^{-1}$, $k_D = 3.22 \times 10^{-3}\ hr^{-1}$, $K_1 = 7.0 \times 10^{-4}$, $K_2 = 8.0 \times 10^{-8}$, and $K_3 = 6.3 \times 10^{-10}$.

Table II—Ionization Constants of Pirbuterol

Functional Group		21°	90°
Pyridine	pKa_1 =	3.0	2.8
Pyridol	pKa_2 =	7.0	7.1
Secondary amine	pKa_3 =	10.3	9.2



Scheme I

increased with pH between 3 and 6, reaching a pseudomaximum at pH 6, after which the rate rose again until minimum stability was observed at pH 8. This unusual profile can be explained by considering the degradation rates of the various ionic species of pirbuterol whose concentrations change with pH.

Pirbuterol exists as four ionic species. Their pKa's, determined by the titration method described under *Experimental*, are listed in Table II. The equilibria involved in the total reaction are shown in Scheme I.

From these pKa values, it was possible to calculate the degree to which each functional group ionizes as the pH varies (Fig. 5). Figure 6 shows the proportions of ionic species of pirbuterol that are expected to exist in aqueous solution, adjusted to any pH, at 90° [9].

The total rate equation for Scheme I is then:

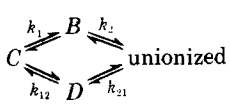
$$k_{obs} = k_A f_A + k_B f_B + k_C f_C + k_D f_D \qquad \text{(Eq. 1)}$$

where:

$$f_A = \frac{[A]}{[A] + [B] + [C] + [D]} \qquad \text{(Eq. 2)}$$

$$f_A = \frac{1}{1 + \frac{[B]}{[A]} + \frac{[C]}{[A]} + \frac{[D]}{[A]}} \qquad \text{(Eq. 3)}$$

[9] Scheme I presents a simplified picture of the ionic equilibria involved. Many more ionic species could theoretically exist (3, 4), the most likely of which would be the totally unionized form. This species would be in equilibrium with species B and D as follows:



where $K_2 = k_1 + k_2$ and $(1/K_3) = (1/k_{12}) + (1/k_{21})$. Based on the relative pKa's of the pyridol and secondary amine, the proportion of unionized species to zwitterion is expected to be very small. Therefore, the mathematical treatment of experimental data neglects the formation of unionized species.

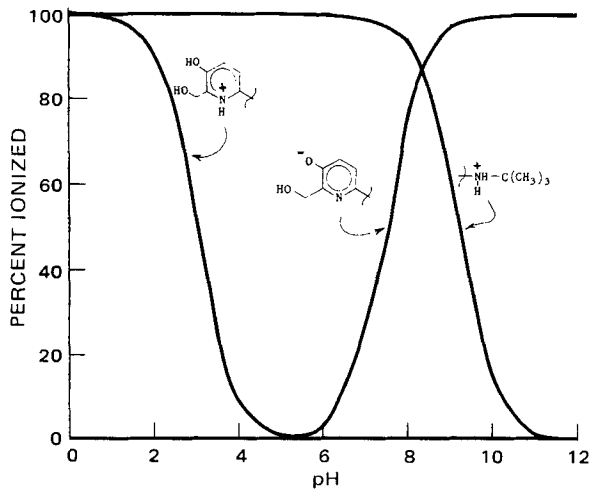


Figure 5—*Degree of ionization of pirbuterol at 90° as a function of pH.*

$$f_A = \frac{1}{1 + \frac{K_1}{[H^+]} + \frac{K_1K_2}{[H^+]^2} + \frac{K_1K_2K_3}{[H^+]^3}} \qquad \text{(Eq. 4)}$$

$$f_A = \frac{[H^+]^3}{[H^+]^3 + K_1[H^+]^2 + K_1K_2[H^+] + K_1K_2K_3} \qquad \text{(Eq. 5)}$$

Species B, C, and D can be treated similarly. Substituting the appropriate (f_i) equalities into Eq. 1 yields:

$$k_{obs} = \frac{k_A[H^+]^3 + k_BK_1[H^+]^2 + k_CK_1K_2[H^+] + k_DK_1K_2K_3}{[H^+]^3 + K_1[H^+]^2 + K_1K_2[H^+] + K_1K_2K_3} \qquad \text{(Eq. 6)}$$

In the pH 1–2 region, pirbuterol is diprotonated and $k_A \sim k_{obs}$. Similarly, in the pH 10–12 region, pirbuterol exists as the pyridinolate ion in which case $k_D \sim k_{obs}$. By using these two derived constants, k_A and k_D, Eq. 6 can be solved as two simultaneous equations at two pH's with two unknowns, k_B and k_C. The latter two rate constants were estimated and optimized in this manner (Table I), and the theoretical pH–rate profile was then plotted and compared with experimental data points (as indicated by the dashed line *versus* observed data points in Fig. 4). The goodness of fit suggests that this model is consistent with experimental data and can be used to explain the unusually shaped pH–rate profile.

The apparent energies of activation were determined at four pH's: 1, 5, 8.5, and 11. As indicated by Fig. 6, essentially one single ionic species exists at any of these pH's; therefore, the E_a's reflect the thermodynamic

III (*m/e* 297)

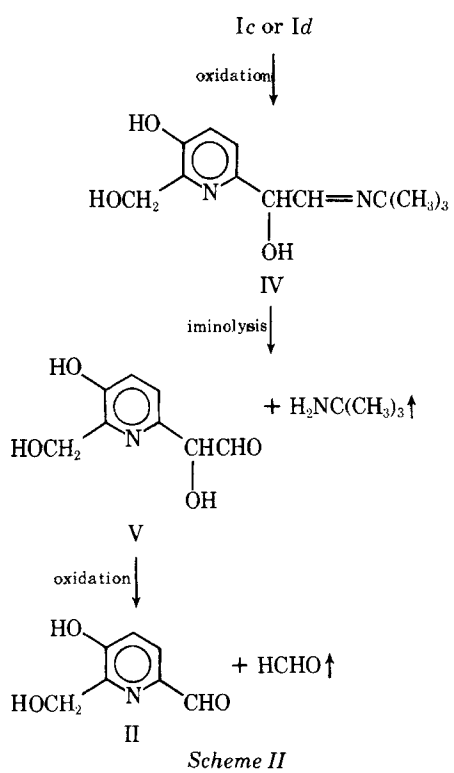
behavior of the respective pirbuterol ion present in that solution. Arrhenius plots of kinetic data collected at 70, 80, and 90° yielded the apparent activation parameters listed in Table III.

As the profile indicates, drug stability is best at pH 2[10], a major factor to be considered in the formulation of liquid products. The relatively small value of the energies of activation indicates a low sensitivity of the reaction rate to temperature. The large negative value of the entropies reflects a significant requirement in molecular orientation for the reaction to occur, presumably imposed by the large bulky *tert*-butyl moiety.

A representative TLC plate of stressed oxidative degradation of pirbuterol is shown in Fig. 7. Five degradation products were observed. The spot migrating to R_f 0.75 (pH 7–12) had a GLC retention time of 2.4 min when derivatized on-column with bis(trimethylsilyl)trifluoroacetamide plus 1% trimethylchlorosilane. The mass spectra[11] of the trimethylsilyl derivative (III) of the degradation product and of II, prepared by unambiguous synthesis, were identical. The prominent peaks in the fragmentation pattern of III (Fig. 8) are listed in Table IV.

Another product resulting from the same reaction sequence is *tert*-butylamine. During the kinetic studies, vapors from the reaction vessels were passed through a saturated aqueous picric acid solution to confirm the presence of the volatile amine. A precipitate was collected in this manner and, upon drying, was analyzed. The melting point, IR spectrum, and elemental analysis corresponded to authentic *tert*-butylamine picrate.

Scheme II is proposed to describe the degradation in solution at pH 7–12 in accordance with the data. The degradation pattern observed at low pH (Fig. 7) indicates that an entirely different mechanism is operative in acidic media. Before a pathway of degradation can be proposed, further identification of degradation products is necessary. Any such mechanism should, however, accommodate the obvious dependence of the reaction rate on the ionization of the ring functionalities.



Scheme II

[10] Because E_a's were determined over a small temperature range, extrapolation involves considerable risk. Nevertheless, room temperature data obtained so far do suggest that the $t_{1/2}$ at pH 1–2 is consistent with the predicted value of ~5 years.

Formaldehyde, produced by oxidation of the secondary alcohol (V), can react with the parent amine in a Pictet–Spengler-type reaction to produce the corresponding isoquinoline derivative in the cases of phenylephrine and, to a lesser extent, terbutaline. The parallel reaction, if observed with pirbuterol, would be represented by I (Scheme II) reacting with formaldehyde produced during the formation of II to result in the corresponding pyrido[4,3-*b*]pyridine product. Upon the addition of excess formaldehyde to a solution of pirbuterol (pH ~6), TLC revealed a spot at R_f 0.30, which did not correspond to any observed in Fig. 7. Although this product may have been the cyclized adduct, it was concluded that such a reaction did not occur to any observable extent in the degradation of pirbuterol. This conclusion is likely, since the pyridine nucleus and hydroxyl substitution of pirbuterol should differ significantly in their directing properties from those of the isoquinoline precursors.

Identification of the spots at R_f 0, 0.12, 0.51, and 0.55 has not yet been achieved. Some possible degradation routes lead to *N*-oxide formation, self-condensation, 2,2′-pyridoin compound formation, polymerization of oxidation products, and oxidation of the primary alcohol.

CONCLUSIONS

The shape of the pH–rate profile (Fig. 4) indicates that each of the four ionic species of pirbuterol oxidizes at a rate independent of the other species present. The diprotonated species appears to be most stable to oxidation, as implied by the profile where optimum stability lies at pH 1–2. In accordance with the pH–rate profile, the rank order of the individual rate constants of the species was observed to be $k_A < k_B \ll k_D$

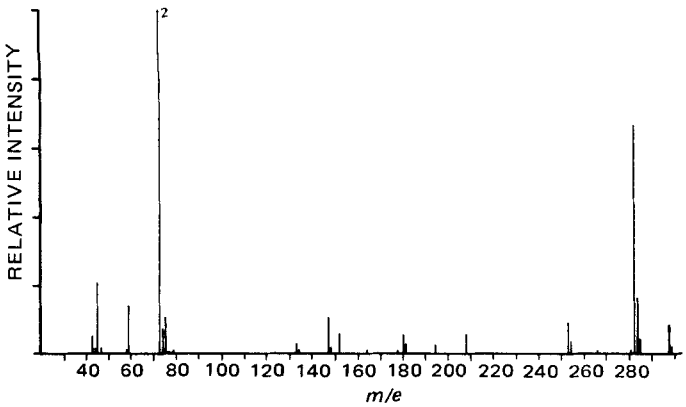

Figure 8—*Mass spectrum of the trimethylsilyl derivative of the degradation product from the oxidation of pirbuterol.*

$< k_C$. The experimental values were consistent with the derived rate equation. Arrhenius plots revealed low activation energies (~10 kcal/mole), which explain why conducting the experiments at 90° did not markedly accelerate the oxidation over that predicted (and observed) at room temperature.

Prostaglandin Monolayers II: Monomolecular Film Behavior of Dinoprost C-15 Alkyl Esters

BERNARD E. SIMS [x] and GLENFORD R. DERR

Abstract □ Monomolecular film compression–relaxation behavior was examined for select dinoprost C-15 alkyl esters. Higher homologs of the series such as palmitate and decanoate esters yielded stable expanded monolayers that exhibited minimal relaxation of surface pressure during noncompression. Their limiting molecular areas were consistent with a Hirschfelder model projection in which the prostaglandin moiety assumes a horizontal orientation at the interface with its alkyl ester chain oriented vertical to the surface plane. Shorter chain homologs such as hexanoate, valerate, butyrate, propionate, and acetate also formed expanded monolayers but exhibited increased instability with decreased alkyl chain length, as reflected in their lower surface pressure development during compression and significant relaxation of pressure during noncompression. Such instability can be tied to their increased solubility in the subphase solution and higher desorption rate from the interface.

Keyphrases □ Dinoprost C-15 alkyl esters, various—monomolecular film compression–relaxation behavior compared □ Films, monomolecular—various dinoprost C-15 alkyl esters, compression–relaxation behavior compared □ Prostaglandins—various dinoprost C-15 alkyl esters, monomolecular film compression–relaxation behavior compared

In recent years, much effort has been directed to elucidating the pharmacological and physiological properties of a new class of biological compounds termed prostaglandins (1–3). Very little attention, however, has been directed toward their possible surface-active properties, even though they have been implicated in various roles portending high surface activity (4–9).

The naturally occurring prostaglandins dinoprost ($F_{2\alpha}$), dinoprostone (E_2), A_1, and B_1 exhibited surface activity in the presence of spread insoluble monomolecular films (10). They in themselves, however, do not tend to form stable monolayers because of their high aqueous solubility. In this article, monolayer film behavior for some long chain alkyl derivatives of dinoprost that do form stable monolayers is reported. This basic and fundamental study should contribute to the limited information available on surface behavior of these ubiquitous and biologically important compounds.

The prostaglandin derivatives selected for monolayer investigation were long chain aliphatic esters of dinoprost attached at the C-15 hydroxyl group (I, R = alkyl). The numbering system generally accepted for prostaglandin-type compounds is with the upper chain carboxylic acid function as the 1-position.

EXPERIMENTAL

Materials—A TLC analysis of the synthesized[1] prostaglandin esters indicated a purity of 99+% for all compounds. Spectroscopic grade hexane–chloroform–methanol (20:2:1) was used as the spreading solvent. Subphase solutions consisted of 0.01 *M* HCl prepared with double-distilled water in an all-glass apparatus with alkaline permanganate.

Equipment—The monolayer balance consisted of a polytef[2]-covered

trough having an area of 315 cm^2 and a width of 10.5 cm. The trough was hollowed out so that water at controlled temperatures could be circulated. This entire unit was enclosed in a large metallic box for protection against dust. The barrier mechanism was driven at controlled rates by means of constant revolutions per minute motors equipped with reversible drive and a positive clutch for an instant stop.

Surface pressure was measured using the Wilhelmy plate method, utilizing a 5-cm roughened platinum plate. Mass changes were measured with an electromagnetic balance[3] and recorded[4]. The balance was housed in a large metallic box above the trough unit and was situated on an elevating stand to facilitate placement of the plate into the subphase. Since vertical movement of the plate was negligible when the self-balancing unit was used (11, 12), it was possible to minimize any errors introduced by possible contact angle change.

General Procedure—Monolayers of the prostaglandins were spread from 1.0-mg/ml solutions of the particular component dissolved in the mixed solvent system. These solutions were added to the surface of the subphase by means of a micrometer syringe[5], which delivered 20–30 μg of material at an initially high area per molecule. After 15 min was allowed for complete spreading and equilibration, the film was subjected to compression at a constant velocity, followed by a period of noncompression to observe relaxation (12–14) and/or dissolution effects.

Each subphase was used only once, and each reported isotherm was reproduced from at least three different spreadings in which areas agreed within ±0.5 Å²/molecule. All experiments were conducted at 25 ± 0.2°.

No significant increment in surface pressure development (>0.2 dyne/cm) was observed upon manual advancement of the barrier over the subphase in the absence of spread film.

RESULTS AND DISCUSSION

The monolayer isotherm obtained for dinoprost palmitate is depicted in Fig. 1. The generally expanded character of the film exhibits surface pressure development at rather high areas per molecule. The isotherm begins to rise rather steeply around 120 Å²/molecule, until collapse is observed at a surface pressure of 40 dynes/cm. During the period of noncompression (dashed lines) immediately following collapse, no relaxation behavior is observed. Such film behavior suggests that lens formation occurs at collapse and that some degree of equilibrium is established between the collapsed bulk phase and monolayer molecules (15).

A limiting area per molecule of 108 Å² can be obtained by extrapolation of the upper linear portion of the curve preceding collapse. This area per molecule agrees very closely with that obtained from a Hirschfelder molecular model projection (Fig. 2). In this molecular configuration, the basic prostaglandin moiety assumes a horizontal orientation within the plane of the surface, with the palmitate chain extended upward and vertical to the surface. The model area projections for such an orientation are approximately 115–98 Å²/molecule. Again, these values appear to be in close agreement with the actual area per molecule of 108 Å² obtained from the π–A isotherm.

A test for this postulated configuration would be to examine another dinoprost C-15 alkyl ester having a significantly different chain length. If the alkyl portion is extended out of the surface, it should not contribute to the limiting area per molecule and both compounds should approximate the same limiting area.

Figure 3 depicts film compression behavior observed for dinoprost decanoate. The π–A compression character is similar to that observed for the palmitate monolayer. The isotherm is expanded at higher areas per molecule and exhibits a relatively rapid surface pressure development at intermediate areas. Collapse occurs at approximately 40 dynes/cm, with no evidence of relaxation during the noncompression period. The limiting area obtained by extrapolation to the area axis yields a value of 103 Å²/molecule. Hence, decreasing the ester chain length by six methylene groups appears to make no major contribution to the observed limiting area per molecule. This finding strongly supports the configuration previously postulated for these prostaglandin esters at the air–solution interface.

In Fig. 4, the monolayer isotherms obtained for dinoprost hexanoate and valerate are presented. Both shorter chained esters produce generally expanded monolayers, as observed with the palmitate and decanoate films. However, the period of noncompression here is characterized by

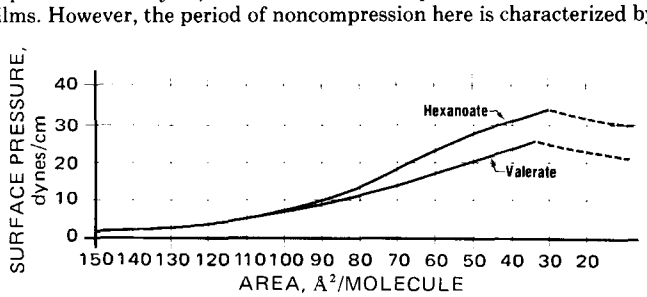

Figure 4—*Monolayer compression–relaxation isotherms generated by dinoprost hexanoate and valerate esters on 0.01 M HCl subphase at 25° and* v_0 *= 5.17 Å²/molecule-min.*

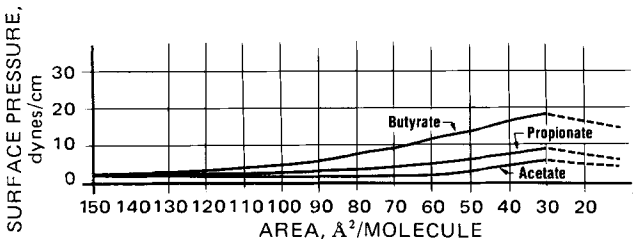

Figure 5—*Monolayer compression–relaxation isotherms generated by dinoprost butyrate, propionate, and acetate esters on 0.01* M *HCl subphase at 25° and* $v_0 = 5.17$ *Å²/molecule-min.*

significant surface pressure reduction, in contrast to the palmitate and decanoate. Another effect of chain length on the stability of these monolayers is seen in the maximum surface pressure developed during compression. The area per molecule at which compression is terminated in Fig. 4 is not a collapse area. Indeed, no collapse is observed for either film. However, under similar conditions of spreading, elapsed time before compression, and compression rate, the hexanoate film is the more stable, as evidenced by the higher surface pressure development throughout the compression sequence. At 32 Å²/molecule, where compression is terminated, the hexanoate film exhibits a maximum pressure of 35 dynes/cm compared to 26.5 dynes/cm for the valerate. The lower pressure of the valerate as well as the surface pressure reduction observed during the noncompression period can be attributed to the shorter chain length and faster dissolution rate from the interface. The hexanoate film is also somewhat soluble in the subphase but to a lesser degree.

Figure 5 presents monolayer behavior for three other members of this alkyl derivative series, butyrate, propionate, and acetate. All three esters tend to accentuate the film behavior previously observed with the hexanoate and valerate films. Monolayer stability is progressively decreased with decreasing alkyl chain length, as evidenced by reductions in surface pressure development during compression. All three compounds exhibit relaxation of surface pressure during noncompression, which appears to be tied directly to their decreased stability as a result of dissolution.

Effect of Primidone Concentration on Glass Transition Temperature and Dissolution of Solid Dispersion Systems Containing Primidone and Citric Acid

M. P. SUMMERS [x] and R. P. ENEVER

Abstract □ The glass transition temperatures of glasses containing various concentrations of primidone in citric acid were measured and found to increase as the primidone concentration increased. Dissolution studies of these systems and particle-size measurements of primidone precipitated during dissolution of devitrified glasses suggest that the increase in the dissolution rate of the devitrified systems is due to both the small size of the precipitated crystals and the excellent wettability of these systems.

Keyphrases □ Primidone—solid dispersion systems with citric acid, effect of concentration on glass transition temperature and dissolution □ Citric acid—solid dispersion systems with primidone, effect of primidone concentration on glass transition temperature and dissolution □ Glass transition temperature—primidone–citric acid solid dispersion systems, effect of primidone concentration □ Dissolution—primidone–citric acid solid dispersion systems, effect of primidone concentration □ Solid dispersion systems—primidone–citric acid, effect of primidone concentration on glass transition temperature and dissolution □ Anticonvulsants—primidone, solid dispersion systems with citric acid, effect of concentration on glass transition temperature and dissolution

The use of citric acid as a water-soluble carrier for sparingly soluble drugs was first investigated by Chiou and Riegelman (1). Recently, a study of a solid dispersion system containing primidone in citric acid was reported (2). The systems were prepared by fusing citric acid with primidone; immediately after preparation, they existed in the vitreous state. Both the viscosity of these glasses and their devitrification rate were dependent on the primidone concentration.

Dissolution studies conducted on the devitrified dispersions showed that they dissolved more rapidly than physical mixtures of primidone and citric acid. It was postulated that there was rapid depletion of citric acid from the solid dispersions, leaving a suspension of primi-

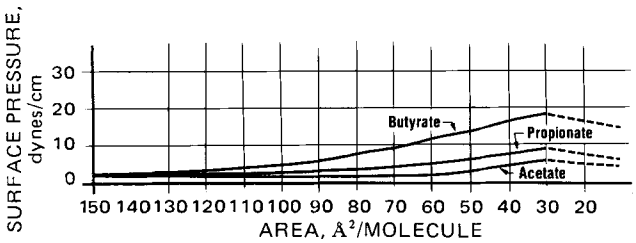

Figure 5—*Monolayer compression–relaxation isotherms generated by dinoprost butyrate, propionate, and acetate esters on 0.01* M *HCl subphase at 25° and* $v_0 = 5.17$ *Å²/molecule-min.*

significant surface pressure reduction, in contrast to the palmitate and decanoate. Another effect of chain length on the stability of these monolayers is seen in the maximum surface pressure developed during compression. The area per molecule at which compression is terminated in Fig. 4 is not a collapse area. Indeed, no collapse is observed for either film. However, under similar conditions of spreading, elapsed time before compression, and compression rate, the hexanoate film is the more stable, as evidenced by the higher surface pressure development throughout the compression sequence. At 32 Å²/molecule, where compression is terminated, the hexanoate film exhibits a maximum pressure of 35 dynes/cm compared to 26.5 dynes/cm for the valerate. The lower pressure of the valerate as well as the surface pressure reduction observed during the noncompression period can be attributed to the shorter chain length and faster dissolution rate from the interface. The hexanoate film is also somewhat soluble in the subphase but to a lesser degree.

Figure 5 presents monolayer behavior for three other members of this alkyl derivative series, butyrate, propionate, and acetate. All three esters tend to accentuate the film behavior previously observed with the hexanoate and valerate films. Monolayer stability is progressively decreased with decreasing alkyl chain length, as evidenced by reductions in surface pressure development during compression. All three compounds exhibit relaxation of surface pressure during noncompression, which appears to be tied directly to their decreased stability as a result of dissolution.

Effect of Primidone Concentration on Glass Transition Temperature and Dissolution of Solid Dispersion Systems Containing Primidone and Citric Acid

M. P. SUMMERS [x] and R. P. ENEVER

Abstract □ The glass transition temperatures of glasses containing various concentrations of primidone in citric acid were measured and found to increase as the primidone concentration increased. Dissolution studies of these systems and particle-size measurements of primidone precipitated during dissolution of devitrified glasses suggest that the increase in the dissolution rate of the devitrified systems is due to both the small size of the precipitated crystals and the excellent wettability of these systems.

Keyphrases □ Primidone—solid dispersion systems with citric acid, effect of concentration on glass transition temperature and dissolution □ Citric acid—solid dispersion systems with primidone, effect of primidone concentration on glass transition temperature and dissolution □ Glass transition temperature—primidone–citric acid solid dispersion systems, effect of primidone concentration □ Dissolution—primidone–citric acid solid dispersion systems, effect of primidone concentration □ Solid dispersion systems—primidone–citric acid, effect of primidone concentration on glass transition temperature and dissolution □ Anticonvulsants—primidone, solid dispersion systems with citric acid, effect of concentration on glass transition temperature and dissolution

The use of citric acid as a water-soluble carrier for sparingly soluble drugs was first investigated by Chiou and Riegelman (1). Recently, a study of a solid dispersion system containing primidone in citric acid was reported (2). The systems were prepared by fusing citric acid with primidone; immediately after preparation, they existed in the vitreous state. Both the viscosity of these glasses and their devitrification rate were dependent on the primidone concentration.

Dissolution studies conducted on the devitrified dispersions showed that they dissolved more rapidly than physical mixtures of primidone and citric acid. It was postulated that there was rapid depletion of citric acid from the solid dispersions, leaving a suspension of primi-

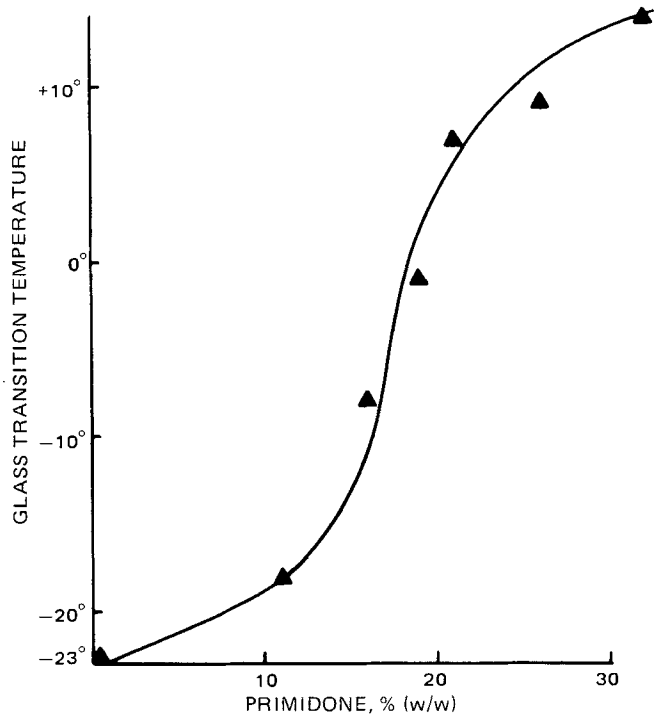

Figure 1—*Variation of the glass transition temperature with primidone concentration.*

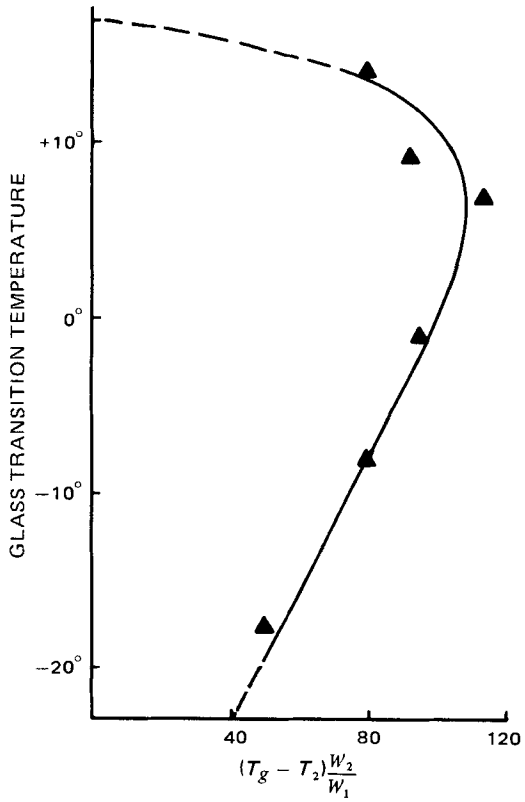

Figure 2—*Plot of the glass transition temperature against* $(T_g - T_2)$ W_2/W_1.

done crystals. The enhanced dissolution rate would then be due, in part, to the small size of these crystals.

The work now reported was conducted to examine the viscous nature of the glasses and to assess the importance of particle size of the precipitated primidone crystals on the dissolution rate of the devitrified systems.

EXPERIMENTAL

Solid Dispersion Systems—The method of preparation was described previously (2).

Glass Transition Temperatures—The glass transition temperatures, T_g, of the vitreous state of the dispersions were measured using a differential scanning calorimeter[1]. A marked shift in the baseline due to a change in the specific heat of the material indicated the transition.

Dispersions containing various concentrations of primidone in citric acid were prepared and poured directly into aluminum sample pans. An aluminum cover was placed on the sample before transferring the pan to the sample holder of the instrument. The sample holder was covered with the low temperature head containing liquid nitrogen to obtain starting temperatures of approximately −20°. A heating rate of 2°/min was used, and at least three determinations were performed on each system studied. The precision of the measurement was ±1°.

Isolation of Primidone Precipitated from Vitreous and Devitrified Dispersions—A 10-g sample of vitreous dispersion containing 16% (w/w) primidone was added to 100 ml of distilled water and shaken until the citric acid dissolved. The resulting suspension of primidone crystals was collected by filtering through a 0.45-μm membrane filter[2]. The crystals were subsequently dried at 50° overnight.

The process was repeated using 10 g of devitrified dispersion containing 16% (w/w) primidone.

The crystallinity and polymorphic form of the precipitated material were checked by X-ray diffraction[3] (2).

Dissolution Studies—Dissolution studies were performed on powdered material using the apparatus and methods previously described (2). The dissolution of 150–250-μm size samples of the following devitrified dispersions in distilled water at 37° was studied: (*a*) 700 mg of a dispersion containing 3% (w/w) primidone (21 mg of primidone), (*b*) 100 mg of a dispersion containing 21% (w/w) primidone (21 mg of primidone), (*c*) 200 mg of a dispersion containing 16% (w/w) primidone (32 mg of primidone), and (*d*) 400 mg of a dispersion containing 8% (w/w) primidone (32 mg of primidone).

The dissolution of physical mixtures produced by adding 150–250-μm size citric acid crystals to the precipitated primidone was also studied by using 200 mg of mixtures containing 16% (w/w) primidone.

Particle-Size Measurement of Primidone—The size distributions of the commercial primidone starting material and the primidone precipitated from the vitreous and devitrified dispersion systems were measured using an automated particle counter[4] fitted with a 50-μm orifice tube. The electrolyte was 0.9% (w/w) sodium chloride previously saturated with primidone at room temperature. The solution was filtered before use through a 0.45-μm membrane filter[2]. Two samples of each system were used, and two determinations were performed on each.

RESULTS AND DISCUSSION

Glass Transition Temperature of Vitreous State—The glass transition temperature may be defined as the temperature at which changes in physical properties such as specific heat and viscosity occur that indicate that the vitreous state is changing to the liquid state. Because of the differing bond lengths and bond strengths in the random structure, the point is ill defined (3, 4).

For a series of glasses containing the same constituents, at a fixed temperature above the transition points of all glasses, the glasses possessing the lowest transition temperatures will be the least viscous. Previous work with primidone–citric acid dispersions showed that the devitrification rate of the systems was dependent upon the primidone concentration and that the most rapidly devitrifying systems were the least viscous (2). The present glass transition data confirm this relationship. As Fig. 1 shows, the smaller the primidone concentration, the lower was the glass transition temperature and hence the lower was the viscosity of the system at ambient temperature.

The glass transition points of all dispersions were below ambient temperature (20°). Therefore, these systems, which previously were re-

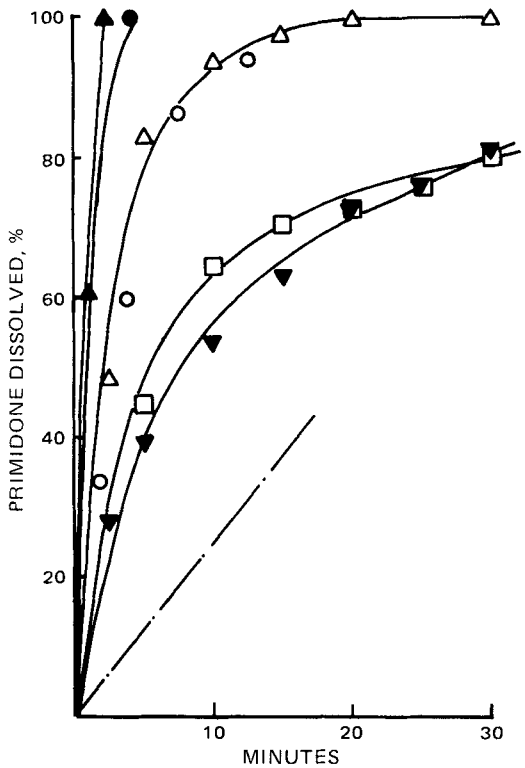

Figure 3—*Dissolution rate of primidone. Key: ▲, 3% (w/w) devitrified system; ●, 8% (w/w) devitrified system; △, 16% (w/w) devitrified system; ○, 21% (w/w) devitrified system; ▼, primidone from 16% (w/w) devitrified system (physical mixture); □, primidone from 16% (w/w) vitreous system (physical mixture); and — · —, 16% physical mixtures previously tested (2), primidone particle size of 150–250 μm.*

ferred to as glasses, are more correctly described as highly viscous supercooled liquids.

Gordon and Taylor (5) derived an equation to predict the variation of the glass transition temperature with composition for a copolymer system:

$$T_g = -k(T_g - T_2)\frac{W_2}{W_1} + T_1 \qquad \text{(Eq. 1)}$$

where T_1 and T_2 are the glass transition temperatures of pure Components 1 and 2, W_1 and W_2 are the weight fractions of the components, and k is a coefficient defined by:

$$k = \Delta B_1/\Delta B_2 \qquad \text{(Eq. 2)}$$

where ΔB is the difference between the coefficients of expansion of the vitreous and liquid states.

Equation 1 is valid provided the following relationship is obeyed (6):

$$A_{AB} = \frac{A_{AA} + A_{BB}}{2} \qquad \text{(Eq. 3)}$$

where A_{AA} and A_{BB} are the bonding energies between molecules of the individual components, and A_{AB} is the bonding energy between molecules in the mixture.

Figure 2 shows a plot of the citric acid–primidone data in accordance with Eq. 1. Since the graph is not a straight line, the system does not obey the ideal situation described by Eq. 1. Similar cases have been shown for copolymer systems (6). The bonding energy between citric acid and primidone molecules is not the arithmetic mean of the bonding energies of the pure components and may support the hypothesis previously advanced (2) that the concentration-dependent devitrification of these systems could be due to extensive formation of strong hydrogen bonds between the component molecules in the vitreous state.

Dissolution Studies of Devitrified Systems Containing Low Primidone Concentrations—Figure 3 shows a plot of the percentage primidone released against time for systems containing 3, 8, 16, and 21% (w/w) primidone. The dissolution profiles of the 16 and 21% (w/w) devitrified systems are the same as those previously published (2) and indicate that the percentage primidone released is independent of the

Table I—Particle-Size Data of Primidone Crystals

Source of Crystals	Mean Particle Diameter, μm	*SD*
3% (w/w) devitrified glass	5.2 ± 0.3	2.10
8% (w/w) devitrified glass	4.6 ± 0.2	1.91
16% (w/w) devitrified glass	4.7 ± 0.3	2.06
21% (w/w) devitrified glass	4.7 ± 0.3	1.91
32% (w/w) devitrified glass	4.5 ± 0.3	1.92
16% (w/w) glass	4.2 ± 0.2	1.95
Commercial material	6.2 ± 0.4	2.17

primidone content of the sample. However, the 3 and 8% (w/w) primidone systems do not follow this pattern, even though the quantities of primidone in the samples are equivalent to those in the 21 and 16% (w/w) systems, respectively.

Particle-Size Measurement of Precipitated Crystals—Table I shows the mean particle diameter of primidone precipitated from the solid dispersion systems, together with values for the standard deviations of the log-normal distributions. Prior to particle-size measurement, the crystals were well dispersed with an octylphenol–ethylene oxide polymer[5] so measurements were conducted on a suspension of individual particles.

The mean diameter and size distribution of the precipitated crystals did not vary significantly between systems containing different concentrations of primidone. The mean diameter of the commercial sample was, however, slightly larger than that of the precipitated crystals.

Dissolution Studies of Physical Mixtures of Precipitated Primidone and Citric Acid—The results of the dissolution studies of 16% (w/w) physical mixtures of primidone precipitated from the dispersion before and after devitrification are shown in Fig. 3. X-Ray diffraction studies confirmed that the precipitate was the crystalline Form II primidone polymorph. The data in Fig. 3 indicate that the smaller particle size of the primidone in these mixtures was responsible for an increased dissolution rate when compared with physical mixtures previously tested (containing primidone of 152–250-μm size) (2). The dissolution rates,

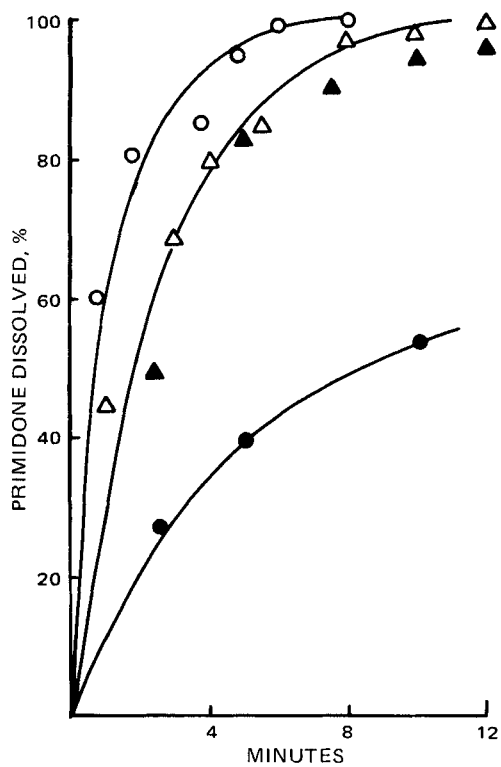

Figure 4—*Effect of dispersal with polyethylene glycol 300 on the dissolution rate of primidone. Key: ○, 16% (w/w) physical mixture (dispersed); ●, 16% (w/w) physical mixture (not dispersed); △, 16% (w/w) devitrified system (dispersed); and ▲, 16% (w/w) devitrified system (not dispersed).*

[5] Nonidet P40, British Drug Houses, Poole, Dorset, United Kingdom.

however, were not as rapid as those from the 16% (w/w) devitrified dispersion.

It is doubtful whether the increased solubility of primidone in the citric acid contained in the diffusion layer surrounding the dissolving devitrified dispersion could account for the differences in dissolution of the physical mixture and the devitrified dispersion. If it is assumed that the diffusion layer thickness is about 3×10^{-3} cm (7) and that the diffusion layer is saturated with citric acid, then calculations indicate that the maximum amount of primidone that could be in solution is 1–10% of the primidone content of the system (depending upon the primidone concentration in the dispersion). Thus, a gross excess of primidone is present in all cases.

The precipitated primidone crystals were very cohesive, and incomplete wetting could have inhibited dissolution from the physical mixtures. To test this possibility, the dissolution experiment was repeated using another 200-mg sample of the 16% (w/w) physical mixture of precipitated primidone and citric acid previously dispersed with 0.4 ml of polyethylene glycol 300[6]. A sample of the 16% (w/w) devitrified dispersion was also examined in the same manner. From the results (Fig. 4), it can be seen that the dissolution of the devitrified dispersion was not significantly affected by the addition of the polyethylene glycol. The dissolution of the physical mixture was, however, increased and was greater than that of the devitrified dispersion, even though complete dispersal of the mixture was not achieved.

These results indicate that the primidone particles precipitated during dissolution of the devitrified system remain as loose agglomerates during the dissolution process. The collection of these particles and their redispersal with polyethylene glycol in the mixture with citric acid probably result in the destruction of these agglomerates to produce individual particles. The resulting increase in the primidone surface area is responsible for the higher dissolution rate seen with these physical mixtures.

The enhanced dissolution rate of primidone in these devitrified systems (2) is thus confirmed to be due to the reduction in particle size of the primidone in the system and the improved wetting characteristics of the solid dispersion system. Nevertheless, the dissolution rate is impaired by the failure of the precipitated primidone particles to separate completely during dissolution. The enhanced dissolution rates of the 3 and 8% (w/w) devitrified glasses could be due to better particle separation during dissolution.

[6] Koch Light Laboratories, Colnbrook, Bucks, United Kingdom.

CONCLUSIONS

Interactions between primidone and citric acid occur when they are fused together, and viscous supercooled liquids are produced when the melt is cooled. The viscosity of the supercooled liquids increases with increasing primidone concentration, as reflected in an increased glass transition temperature.

During dissolution of the devitrified systems, primidone is precipitated in aggregates of fine particles. The relatively large surface area produced by this process results in the powdered devitrified dispersions (150–250-μm size) having a faster rate of dissolution than physical mixtures of primidone and citric acid of the same size.

The aggregation of primidone particles during dissolution appears to be dependent on the primidone concentration in the dispersion. At low concentrations (3% w/w), the aggregation is less than at 8–16% (w/w), resulting in a faster dissolution of primidone from the devitrified dispersion.

Phytochemical Investigation of Xanthones of *Eustoma grandiflorum* (Raf.) Shinners

GERALD SULLIVAN [x], FRANCIS D. STILES, and KARL-HEINZ A. ROSLER *

Abstract □ Six polyoxygenated xanthones were isolated from the roots of *Eustoma grandiflorum* (Raf.) Shinners collected in Texas. Structural elucidation of five of these xanthones (1-hydroxy-3,7-dimethoxyxanthone, 1-hydroxy-3,5-dimethoxyxanthone, 1-hydroxy-3,5,6,7-tetramethoxyxanthone, 1-hydroxy-3,5,6,7,8-pentamethoxyxanthone, and 1-hydroxy-3,7,8-trimethoxyxanthone) was accomplished *via* UV, IR, NMR, and mass spectrometry; traditional physical–chemical methods; or direct comparison with a prepared derivative. The sixth xanthone derivative was characterized incompletely. The pentamethoxyxanthone is a new compound and has been designated generically as eustomin. The probable occurrence of these six xanthone compounds in the plant as glycosides is reported.

Keyphrases □ *Eustoma grandiflorum*—methanol extract of roots, six polyoxygenated xanthones isolated □ Xanthones, polyoxygenated—six isolated from methanol extract of roots of *Eustoma grandiflorum* □ Hydroxyxanthones—six isolated from methanol extract of roots of *Eustoma grandiflorum*

Eustoma grandiflorum (Raf.) Shinners (Gentianaceae), a plant primarily indigenous to the southwestern portion of the United States, is commonly referred to as the catchfly-gentian, Texas bluebell, and lira de San Pedro. It has a very showy, eye-catching flower, blooming in great profusion in several areas of Texas. A prominent taproot is evident, and even a cursory examination reveals a bright yellow pigment.

The Gentianaceae family is known to produce xanthone derivatives liberally, and several have been isolated from related genera such as *Canscora, Frasera, Gentiana,* and *Swertia* (1–5). Plant extracts obtained from these genera

however, were not as rapid as those from the 16% (w/w) devitrified dispersion.

It is doubtful whether the increased solubility of primidone in the citric acid contained in the diffusion layer surrounding the dissolving devitrified dispersion could account for the differences in dissolution of the physical mixture and the devitrified dispersion. If it is assumed that the diffusion layer thickness is about 3×10^{-3} cm (7) and that the diffusion layer is saturated with citric acid, then calculations indicate that the maximum amount of primidone that could be in solution is 1–10% of the primidone content of the system (depending upon the primidone concentration in the dispersion). Thus, a gross excess of primidone is present in all cases.

The precipitated primidone crystals were very cohesive, and incomplete wetting could have inhibited dissolution from the physical mixtures. To test this possibility, the dissolution experiment was repeated using another 200-mg sample of the 16% (w/w) physical mixture of precipitated primidone and citric acid previously dispersed with 0.4 ml of polyethylene glycol 300[6]. A sample of the 16% (w/w) devitrified dispersion was also examined in the same manner. From the results (Fig. 4), it can be seen that the dissolution of the devitrified dispersion was not significantly affected by the addition of the polyethylene glycol. The dissolution of the physical mixture was, however, increased and was greater than that of the devitrified dispersion, even though complete dispersal of the mixture was not achieved.

These results indicate that the primidone particles precipitated during dissolution of the devitrified system remain as loose agglomerates during the dissolution process. The collection of these particles and their redispersal with polyethylene glycol in the mixture with citric acid probably result in the destruction of these agglomerates to produce individual particles. The resulting increase in the primidone surface area is responsible for the higher dissolution rate seen with these physical mixtures.

The enhanced dissolution rate of primidone in these devitrified systems (2) is thus confirmed to be due to the reduction in particle size of the primidone in the system and the improved wetting characteristics of the solid dispersion system. Nevertheless, the dissolution rate is impaired by the failure of the precipitated primidone particles to separate completely during dissolution. The enhanced dissolution rates of the 3 and 8% (w/w) devitrified glasses could be due to better particle separation during dissolution.

[6] Koch Light Laboratories, Colnbrook, Bucks, United Kingdom.

CONCLUSIONS

Interactions between primidone and citric acid occur when they are fused together, and viscous supercooled liquids are produced when the melt is cooled. The viscosity of the supercooled liquids increases with increasing primidone concentration, as reflected in an increased glass transition temperature.

During dissolution of the devitrified systems, primidone is precipitated in aggregates of fine particles. The relatively large surface area produced by this process results in the powdered devitrified dispersions (150–250-μm size) having a faster rate of dissolution than physical mixtures of primidone and citric acid of the same size.

The aggregation of primidone particles during dissolution appears to be dependent on the primidone concentration in the dispersion. At low concentrations (3% w/w), the aggregation is less than at 8–16% (w/w), resulting in a faster dissolution of primidone from the devitrified dispersion.

Phytochemical Investigation of Xanthones of *Eustoma grandiflorum* (Raf.) Shinners

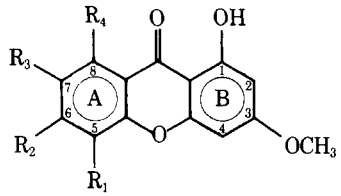
GERALD SULLIVAN [x], FRANCIS D. STILES, and KARL-HEINZ A. ROSLER *

Abstract □ Six polyoxygenated xanthones were isolated from the roots of *Eustoma grandiflorum* (Raf.) Shinners collected in Texas. Structural elucidation of five of these xanthones (1-hydroxy-3,7-dimethoxyxanthone, 1-hydroxy-3,5-dimethoxyxanthone, 1-hydroxy-3,5,6,7-tetramethoxyxanthone, 1-hydroxy-3,5,6,7,8-pentamethoxyxanthone, and 1-hydroxy-3,7,8-trimethoxyxanthone) was accomplished *via* UV, IR, NMR, and mass spectrometry; traditional physical–chemical methods; or direct comparison with a prepared derivative. The sixth xanthone derivative was characterized incompletely. The pentamethoxyxanthone is a new compound and has been designated generically as eustomin. The probable occurrence of these six xanthone compounds in the plant as glycosides is reported.

Keyphrases □ *Eustoma grandiflorum*—methanol extract of roots, six polyoxygenated xanthones isolated □ Xanthones, polyoxygenated—six isolated from methanol extract of roots of *Eustoma grandiflorum* □ Hydroxyxanthones—six isolated from methanol extract of roots of *Eustoma grandiflorum*

Eustoma grandiflorum (Raf.) Shinners (Gentianaceae), a plant primarily indigenous to the southwestern portion of the United States, is commonly referred to as the catchfly-gentian, Texas bluebell, and lira de San Pedro. It has a very showy, eye-catching flower, blooming in great profusion in several areas of Texas. A prominent taproot is evident, and even a cursory examination reveals a bright yellow pigment.

The Gentianaceae family is known to produce xanthone derivatives liberally, and several have been isolated from related genera such as *Canscora, Frasera, Gentiana,* and *Swertia* (1–5). Plant extracts obtained from these genera



I: $R_1 = R_2 = R_4 = H$, $R_3 = OCH_3$
II: $R_1 = OCH_3$, $R_2 = R_3 = R_4 = H$
III: $R_1 = R_2 = R_3 = OCH_3$, $R_4 = H$
IV: $R_1 = R_2 = R_3 = R_4 = OCH_3$
V: $R_1 = R_2 = H$, $R_3 = R_4 = OCH_3$

are used to treat various ailments including constipation, nervous debility, tuberculosis, fever, and anorexia. Since certain chemotaxonomic relationships often occur among related genera and since results of a preliminary TLC examination of the root extract were promising, it was postulated that xanthones might be present in *E. grandiflorum*.

EXPERIMENTAL

Instrumentation—All NMR spectra[1] were determined in deuterated chloroform solutions in microcells unless otherwise stated. Tetramethylsilane served as an internal standard. IR spectra[2] were determined in potassium bromide pellets. Only significant bands are quoted. All molecular weights were obtained by mass spectrometry[3]. UV spectra were determined with a double-beam spectrophotometer[4] equipped with a recorder[5]. Determinations were made in 95% ethanol unless otherwise stated.

Melting points were determined on a Koffler hot-stage microscope and are uncorrected. Sublimation was performed in a sublimation tube fitted with a cold-finger condenser under vacuum and heat. Silicone fluid[6] was used as the heating medium. Liquid chromatography[7] was performed with Porasil A (37–75 μm) as the column packing and chloroform–methanol (5:1) as the mobile phase.

Plant Material—The plant material was collected near Brenham, Washington County, Tex., in late August of 1971[8]. The air-dried roots (705 g) were ground to a coarse powder in a Wiley mill and subjected to continuous soxhlet extraction with methanol for 60 hr.

TLC—Several investigators (1–5) used TLC procedures to separate xanthones, but none of these procedures was satisfactory for this investigation. Silica gel G plates, prepared according to Stahl (6) and developed in benzene–ethyl acetate–acetic acid (90:5:5), resulted in excellent separation of xanthone constituents. Examination of the methanol extract by this procedure indicated the possible presence of five xanthone constituents. These constituents were detected visually as discrete yellow spots or by UV light whereby the spots fluoresced a rust-red color. This system was employed in all preparative work unless otherwise stated.

Hydrolysis of Root Extract—The methanol was removed under reduced pressure, and the resulting dark-reddish-black extract was treated with four 500-ml portions of 3% aqueous hydrochloric acid. Each portion was boiled over steam for 1 hr, and finally all portions were combined and allowed to cool.

Partition of Hydrolyzed Root Extract—The cooled hydrolyzed root extract was partitioned with benzene. Initial partitions were deep red in color, but repeated partitionings were carried out until a colorless benzene fraction was obtained. The aqueous portions were discarded. The benzene portions were combined, filtered, and allowed to stand at room temperature for several hours. A lemon-yellow compound precipitated from the pooled benzene fractions and was removed by gravity filtration.

Isolation of Xanthone II—The lemon-yellow precipitate from the benzene fractions was purified by column chromatography[9], employing dichloromethane as the eluting solvent. It was crystallized from methanol as yellow needles and designated Xanthone II.

Benzene Partitions—The fraction containing benzene partitions from which Xanthone II had precipitated was placed on a chromatographic column and eluted with dichloromethane. Three major fractions, A-1, A-2, and A-3, were collected.

Xanthone I from Fraction A-1—Fraction A-1 was subjected to high-pressure liquid chromatography with a mobile phase of chloroform–methanol (5:1). One yellow compound was obtained and further purified by preparative TLC. The compound was recrystallized as fluffy, pale-yellow needles from methanol and designated Xanthone I.

Xanthone III from Fraction A-2—Preparative TLC of Fraction A-2, using benzene–ethyl acetate–acetic acid (90:5:5), yielded a yellow compound. Upon recrystallization from methanol, this compound was crystallized as pale-yellow needles and labeled Xanthone III.

Xanthones IV and V from Fraction A-3a—Fraction A-3 was placed on a column and again eluted with dichloromethane, resulting in the collection of two distinct fractions, A-3a and A-3b. Fraction A-3a was subjected to preparative TLC with carbon tetrachloride–methanol (25:1) as the solvent system. Two compounds, Xanthones IV and V, were obtained as pale-yellow needles from methanol.

Xanthone VI from Fraction A-3b—This fraction was evaporated to dryness and sublimed under reduced pressure. This procedure yielded a small amount of yellow material, which was recrystallized from methanol as yellow needles and designated Xanthone VI.

RESULTS AND DISCUSSION

Preliminary examination of the methanol extract of the root material of *E. grandiflorum* by TLC initially revealed the possible presence of five xanthone constituents. These constituents exhibited R_f values of 0.93, 0.86, 0.79, 0.63, and 0.49. It was later shown that six xanthone derivatives had actually been isolated, since two compounds exhibited identical migration patterns and resided at R_f 0.63. These two xanthones were easily separated by TLC procedures with a solvent system of carbon tetrachloride–methanol (25:1). These compounds then exhibited R_f values of 0.73 and 0.65.

The structural characterization of the isolated and purified compounds is discussed in the order in which they were isolated.

1-Hydroxy-3,5-dimethoxyxanthone (II)—This compound exhibited an R_f value of 0.86 and a melting point of 174°. Its UV absorption spectrum was characteristic of a 1,3,5-trioxygenated xanthone (7). Mass spectrometry revealed the parent ion and base peak to be *m/e* 272, corresponding to a xanthone derivative containing one hydroxyl and two methoxyl functions. The compound exhibited positive ferric chloride (8) and Wilson's boric acid (9) tests and was insoluble in aqueous sodium carbonate (1)[10].

These chemical and physical data indicated the presence of a free phenolic hydroxyl *ortho* to a carbonyl and also a methoxyl group at C-3 on the xanthone nucleus. Further confirmation of the hydroxyl function *ortho* to a carbonyl was accomplished utilizing IR spectrometry, since a strong band due to carbonyl absorption occurred near 1650 cm^{-1} (7, 8). Xanthone II exhibited a significant band at 1650 cm^{-1}. Final elucidation was accomplished utilizing NMR spectroscopy. Two singlets representing six protons at 6.17 and 6.03 τ accounted for the presence of two methyl group protons. From previous NMR studies, it was shown that a xanthone having substituents at C-1 and C-3 exhibited characteristic signals. In general, a pair of doublets occurred in the 3.2–3.7 τ region. The proton on C-2 always occurred at a higher field than the proton on C-4.

Furthermore, a signal far downfield may be attributed to a hydroxyl proton on C-1 (or the equivalent C-8 position) due to a deshielding effect of the adjacent carbonyl (2, 10). Thus, two doublets at 3.68 and 3.48 τ represented two aromatic protons, one at C-2 and the other at C-4. A signal far downfield at −2.31 τ represented a hydroxyl proton on C-1. Carbons 1 and 3 must be occupied by a hydroxyl and a methoxyl function, respectively. Since all positions on ring B were accounted for, only ring

[8] The plant material utilized was identified as *Eustoma grandiflorum* (Raf.) Shinners (Gentianaceae) by Dr. B. L. Turner, Department of Botany, University of Texas at Austin. A voucher specimen [Sullivan–S. N. (Acc. No. 298773)] representing material collected for this investigation is available for inspection at the Herbarium, Department of Botany, University of Texas at Austin.
[9] All separations by column chromatography were carried out by using 100–200-mesh Bio Sil A silicic acid.
[10] All test reagents were prepared immediately prior to use.

A could contain the remaining methoxyl function. A quartet at 2.20 τ was indicative of a proton on C-8 splitting with two protons exhibiting a multiplet at 2.68–3.03 τ on C-6 and C-7 (2). Thus, the second methoxyl group was placed at C-5.

NMR: −2.31 (s, OH), 3.68 (d, 2-H), 3.48 (d, 4-H), 2.68–3.03 (m, 6,7-H), 2.20 (q, 8-H), 6.17 (s, 3,5-OCH_3), and 6.03 (s) ppm [lit. (11) NMR ($CDCl_3$): 3.69 (d, 2-H), 3.51 (d, 4-H), 2.65–3.00 (m, 6,7-H), and 2.24 (q, 8H) ppm]; UV: λ_{max} (ethanol) 354 (log ϵ 3.53), 307 (4.10), and 244 (4.49) nm [lit. (11) UV: λ_{max} (ethanol) 355 (log ϵ 3.75), 306 (4.28), and 245 (4.60) nm; (1) 308 (4.27) and 245 (4.60) nm; (12) 355 (3.66), 335 sh (3.70), 310 (4.24), and 245 (4.59) nm]; mp 174° [lit. (1) mp 173–174°; (11) 174–175°; (12) 170–171°]; IR_{max}: 1650, 1613, and 1577 cm^{-1} [lit. (11) IR (mineral oil mull): 1662, 1610, and 1575 cm^{-1}].

1-Hydroxy-3,7-dimethoxyxanthone (I)—The second compound isolated and purified exhibited an R_f value of 0.93 and a melting point of 168–169°. Mass spectrometry revealed the parent ion and base peak to be *m/e* 272. This mass again corresponds to a xanthone derivative having one hydroxyl function and two methoxyl groups. It exhibited positive Wilson's boric acid and ferric chloride tests and was insoluble in aqueous sodium carbonate. These data similarly pointed to a compound having a free phenolic hydroxyl *ortho* to a carbonyl and the presence of a methoxyl group at C-3. IR spectrometry verified the presence of an *ortho*-hydroxyl, since a major band of absorption occurred at 1645 cm^{-1}.

By utilizing NMR spectroscopy, final structural elucidation was accomplished. Two singlets representing six protons at 6.10 and 6.11 τ corresponded to two methyl group protons, while two doublets at 3.69 and 3.60 τ occurred due to a proton at C-2 and C-4, respectively. A low field signal at −2.92 τ indicated the presence of a hydroxyl proton on C-1. These assignments placed a hydroxyl and a methoxyl function on ring B, thus leaving final placement of the second methoxyl on ring A. A multiplet at 2.68 τ was attributed to single protons on C-5 and C-6, while a quartet at 2.40 τ arose from a proton splitting with those on C-5 and C-6 and was assigned to C-8. Thus, the second methoxyl substituent must be located at C-7.

NMR: −2.92 (s, OH), 3.69 (d, 2-H), 3.60 (d, 4-H), 2.68 (m, 5,6-H), 2.40 (q, 8-H), 6.10 (s, 3,7-OCH_3), and 6.11 (s) ppm [lit. (2) NMR ($CDCl_3$): −2.94 (s, OH), 3.70 (d, 2-H), 3.58 (d, 4-H), 2.68 (m, 5,6-H), and 2.41 (q, 8H) ppm]; UV: λ_{max} (ethanol) 368 (log ϵ 3.76), 307 (4.12), 260 (4.58), and 232 (4.49) nm [lit. (13) UV: λ_{max} (ethanol) 311 (log ϵ 4.2), 261 (4.7), and 239 (4.5) nm; (14) (methanol) 369 (3.83), 292 (4.39), 259 (4.59), and 231 (4.54) nm; (2) (ethanol) 396 (4.80), 308 (4.14), 259 (4.59), and 238 (4.46) nm]; mp 168–169° [lit. (2) mp 167.5–169°; (15) 167°]; IR_{max}: 1645, 1608, and 1575 cm^{-1}.

As further proof of structure, a synthesis of I (methylgentisin) was accomplished by selective methylation of commercially available gentisin[11] (1,7-dihydroxy-3-methoxyxanthone) (11). Simultaneous development of I with methylgentisin on a TLC plate gave identical spots having an R_f value of 0.93. Chemical and physical test results were identical to those obtained for I. Furthermore, spectral data were also almost identical to those obtained for I.

NMR ($CDCl_3$): −2.94 (s, OH), 3.70 (d, 2-H), 3.58 (d, 4-H), 2.68 (m, 5,6-H), 2.41 (q, 8-H), 6.08 (s, 3,7-OCH_3), and 6.11 (s) ppm; UV: λ_{max} 234, 258, 306, and 368 nm; mp 168°; IR_{max}: 1645, 1610, and 1577 cm^{-1}.

1-Hydroxy-3,5,6,7-tetramethoxyxanthone (III)—Xanthone III exhibited an R_f value of 0.79 and a melting point of 178°. Mass spectrometry indicated a parent ion and base peak at *m/e* 332, corresponding to a xanthone compound having one hydroxyl group and four methoxyl functions. Chemical and physical test results were identical to those mentioned for the previous compounds, and an IR analysis showed a major band at 1653 cm^{-1}. NMR data indicated three singlets at 5.95, 6.04, and 6.15 τ, which were assigned to four methyl group protons. Two doublets at 3.64 and 3.47 τ were assigned to protons on C-2 and C-4, respectively.

From the preceding data, it could be ascertained that all positions on ring B were fully accounted for, with one hydroxyl group on C-1 and a methoxyl group on C-3. Therefore, the three methoxyl functions left to be assigned could only be on ring A. With three of four positions on ring A being occupied, only one singlet for an aromatic proton would be expected; indeed, this signal was observed at 2.70 τ. This signal was assigned to a proton on C-8, while another singlet far downfield at −2.93 τ was assigned to the hydroxyl proton on C-1. These assignments placed the remaining three methoxyl groups at C-5, C-6, and C-7.

NMR: −2.93 (s, OH), 3.64 (d, 2-H), 3.47 (d, 4-H), 2.70 (s, 8-H), 5.95 (s, 3,5,6,7-OCH_3), 6.04 (s), and 6.15 (s) ppm [lit. (3) NMR ($CDCl_3$): 3.76 (d, 2-H), 3.60 (d, 4-H), 2.70 (s, 8-H), 6.03 (s, 3,5,6,7-OCH_3), 6.13 (s), and 6.20 (s) ppm]; UV: λ_{max} (ethanol) 364 (log ϵ 4.03), 311 (4.44), 258 (4.74), and 239 (4.64) nm [lit. (3) UV: λ_{max} (methanol) 364 (log ϵ 3.81), 312 (4.18), 258 (4.49), and 240 (4.35) nm]; mp 178°; IR_{max}: 1653, 1608, and 1582 cm^{-1}.

1-Hydroxy-3,5,6,7,8-pentamethoxyxanthone (IV)—This compound exhibited an R_f value of 0.63 with benzene–ethyl acetate–acetic acid (90:5:5) as the solvent system and an R_f value of 0.73 with carbon tetrachloride–methanol (25:1). A melting point of 108–109° was observed. Mass spectrometry indicated the parent ion and base peak to be at *m/e* 362. This mass corresponds with a xanthone derivative having one hydroxyl and five methoxyl groups. It produced positive Wilson's boric acid and ferric chloride tests and was insoluble in aqueous sodium carbonate.

The IR spectrum exhibited a major band at 1653 cm^{-1}. NMR indicated four singlets at 6.05, 5.99, 5.93, and 5.80 τ, corresponding to five methyl group protons. Doublets at 3.58 and 3.43 τ were assigned to protons on C-2 and C-4, respectively. A single signal at −3.37 τ was indicative of a hydroxyl proton located on C-1. The characteristic pattern of doublets, the singlet far downfield, and data just mentioned indicated the presence of a hydroxyl group on C-1 and a methoxyl group on C-3. Thus, all positions on ring B were accounted for, leaving only ring A to accommodate the four remaining methoxyl groups. With only four positions available for substitution, no signal downfield would be anticipated if all four positions were occupied. This was indeed the case, as no downfield signal (other than that far downfield for the hydroxyl proton on C-1) was noted. Thus, the compound in question must be 1-hydroxy-3,5,6,7,8-pentamethoxyxanthone (IV). This compound has never been reported in the literature and has been named eustomin.

NMR: −3.37 (s, OH), 3.58 (d, 2-H), 3.43 (d, 4-H), 5.80 (s, 3,5,6,7,8-OCH_3), 5.93 (s), 5.99 (s), and 6.05 (s) ppm; UV: λ_{max} (ethanol) 350 sh (log ϵ 3.71), 312 (4.27), and 255 (4.55) nm; mp 108–109°; IR_{max}: 1653, 1595, and 1590 cm^{-1}.

1-Hydroxy-3,7,8-trimethoxyxanthone (V)—The fifth compound isolated exhibited an R_f value of 0.63 with benzene–ethyl acetate–acetic acid (90:5:5) as the solvent system and an R_f value of 0.65 with carbon tetrachloride–methanol (25:1). A melting point of 150–151° was noted. Mass spectrometry showed a parent ion and base peak at *m/e* 302. This mass corresponds to a xanthone compound having one hydroxyl and three methoxyl functions. Chemical and physical tests provided results identical to those mentioned for previous compounds, while the IR spectrum indicated a major band at 1642 cm^{-1}.

NMR analysis revealed two singlets at 6.15, 6.08, and 6.00 τ, representing three methyl group protons. A singlet at −3.10 τ represented a hydroxyl proton on C-1; a peak at 3.69 τ, which arose from two overlapping doublets, was assigned to protons on C-2 and C-4. Thus, once again a 1,3-dioxygenation pattern was evident with a hydroxyl group at C-1 and a methoxyl function at C-3. Therefore, only ring A was available to accommodate the two remaining methoxyl groups. Signals assigned to protons on C-5 and C-6 exhibited peaks at 2.83 and 2.74 τ, thus leaving only positions C-7 and C-8 to accommodate the methoxyl functions.

NMR: −3.10 (s, OH), 3.69 (d, 2-H), 3.69 (d, 4-H), 2.83 (s, 5-H), 2.74 (s, 6-H), 6.00 (s, 3,7,8-OCH_3), 6.08 (s), and 6.15 (s) ppm [lit. (4) NMR ($CDCl_3$): −3.30 (s, OH), 3.69 (d, 2-H), 3.69 (d, 4-H), 2.86 (s, 5H), 2.65 (s, 6-H), 5.99 (s, 3,7,8-OCH_3), 6.07, and 6.11 ppm]; UV: λ_{max} (ethanol) 373 (log ϵ 3.62), 312 (4.13), 261 (4.52), and 241 (4.44) nm [lit. (7) UV: λ_{max} (ethanol) 380 (log ϵ 3.7), 315 (4.1), 260 (4.6), and 242 (4.6) nm; (1) (ethanol) 313 (4.16), 362 (4.42), and 242 (4.29) nm]; mp 150–151° [lit. (5) mp 148–149°]; IR_{max}: 1642, 1603, and 1570 cm^{-1}.

Xanthone VI—This compound, collected in 1–2-mg yield, was not fully characterized. It exhibited an R_f value of 0.49. It did produce positive Wilson's boric acid and ferric chloride tests and was insoluble in aqueous sodium carbonate. The mass spectrometry was variable, as was an NMR analysis, undoubtedly due to impurities. UV scans indicated major bands at 237, 261, and 375 nm; its IR spectrum showed major bands at 1653, 1610, and 1580 cm^{-1}. Its NMR spectrum revealed the presence of two methyl group protons as singlets at 6.12 and 5.95 τ. A singlet far downfield at −3.78 τ represented a hydroxyl proton adjacent to a carbonyl function. This compound apparently contained the usual 1,3-dioxygenation pattern of ring B with a methyl group(s?) on ring A.

Yields of approximately 5, 10, 5, 6, 5, and 1 mg were obtained for Xanthones I, II, III, IV, V, and VI, respectively.

Glycosidic Studies—The solvent of the methanol extract of coarsely powdered root material was evaporated under vacuum. The resulting syrupy extract was solubilized in water and exhaustively partitioned with benzene. A final partitioning with chloroform left an extract in which no free xanthones (aglycones) could be detected when spotted on TLC and

[11] K and K Laboratories, Inc., Hollywood, Calif.

developed with either benzene–ethyl acetate–acetic acid or carbon tetrachloride–methanol. The developed plate was placed in an empty developing chamber. A 50-ml beaker of concentrated hydrochloric acid was placed in the chamber and then covered. The plate was thus exposed to concentrated hydrochloric acid fumes. Exposure was continued for 30 min.

After removal from the chamber, the plate was redeveloped in the solvent systems indicated. Six xanthone compounds, which corresponded on TLC with previously isolated material, were found. Also, by hydrolyzing the root extract from which all free xanthones had been removed with 3% aqueous hydrochloric acid and partitioning with benzene, the six xanthone (aglycone) derivatives could be detected. Thus, each of the six xanthones isolated from *E. grandiflorum* may exist in the plant as glycosides as well as free aglycones.

Phytochemical investigations of the various higher plants revealed the presence of xanthones in four primary families: Gentianaceae, Guttiferae, Moraceae, and Polygalaceae. The xanthones obtained from the Gentianaceae are limited to polyoxygenated derivatives, and the variation of substituents is restricted to hydroxyl and/or methoxyl groups (16). There are, however, exceptions to this general rule, as evidenced by the occurrence of mangiferin (a C-glucoside) in *Canscora decussata* Schult (1) and the presence of certain *O*-glucosides isolated from various members of this family (10, 17).

The oxygenation patterns of xanthones derived from higher plants indicate that they are formed by a mixed shikimate–acetate pathway (18). This approach suggests that ring A and the attached carbonyl group (C-7 unit) are provided *via* the shikimic acid pathway, whereas ring B (C-6 unit) originates through the acetate–malonate polyketide route. The C-7 and C-6 units thus generated form polyhydroxybenzophenones or benzophenone-like intermediates. The next step in biogenesis involves the intramolecular transformation of these intermediates into polyoxygenated xanthones (16, 18).

Various suggestions have been presented to account for the intramolecular transformation of the intermediates into xanthones. One method, direct phenolic oxidative coupling, is regarded as particularly valid. Carpenter *et al.* (18) emphasized that the observed oxygenation patterns of naturally occurring xanthones is precisely what would be expected for a phenoxyl radical coupling process in which the newly created carbon–oxygen bond would necessarily be located either *ortho* or *para* to oxygen functions in ring A. This could account for the frequently observed cooccurrence of pairs of corresponding oxygenated xanthones, *e.g.*, 5- and 7-monooxygenated xanthones, 1,5- and 1,7-dioxyxanthones, 1,5,6- and 1,6,7-trioxyxanthones, 1,3,5- and 1,3,7-trioxyxanthones, and 1,3,5,6- and 1,3,6,7-tetraoxyxanthones.

In support of the work just described, the xanthones isolated from *E. grandiflorum* were substituted with hydroxyl and methoxyl functions only. These substitutions closely parallel those of other members of the Gentianaceae. Also, the probable presence of glycosides was noted, and this observation coincided with previous reports concerning their presence in the Gentianaceae (10, 18).

This plant appears to follow the substitution pattern of some previously mentioned xanthones that contain corresponding oxygen pairs; that is, it contains 1,3,5- and 1,3,7-trioxygenated components as evidenced in II and I, respectively. Furthermore, it is interesting in that it produces a totally oxygenated and completely methoxylated A ring in IV.

No pharmacological or microbiological work was performed on these compounds, but other investigators noted such activity in total xanthone studies (19, 20). Compound II exhibited antitubercular activity, while V showed monoamine oxidase inhibiting activity devoid of pressor effects of tyramine and lacking in high toxicity. It would be interesting to note the actions of eustomin (IV) if subjected to similar studies due to its increased methoxylation. Increasing methoxylation may or may not enhance activity; however, it would perhaps be useful to determine if this activity is or is not related to the number of methoxyl groups in a xanthone compound.

Quantitative Determination of Fenclorac in Serum

J. K. LEE ˣ, R. D. SMYTH *, A. POLK, T. HERCZEG, C. T. TSUEI, and N. H. REAVEY-CANTWELL

Abstract □ A spectrophotometric method for the analysis of fenclorac and its metabolite, 3-chloro-4-cyclohexylbenzeneglycolic acid, in human serum was developed. The parent compound represented at least 90% of the total species present in blood; the metabolite was present to the extent of about 10%, primarily in the elimination phase. The basic procedure consists of extraction of both compounds from serum, further extraction to remove interfering substances, alkaline conversion of fenclorac to the α-hydroxy acid metabolite, oxidation of this metabolite to the corresponding benzaldehyde derivative, and spectrophotometric measurement of the absorbance of the aldehyde at 252 nm. A comparison of serum concentrations obtained by this method with concentrations calculated from ^{14}C-data following oral administration of 1-^{14}C-fenclorac to eight normal adult volunteers indicated a 90% correlation between methodologies over a range of 1.4–25.5 μg of fenclorac/ml of serum.

Keyphrases □ Fenclorac and metabolite—spectrophotometric analysis, serum □ Spectrophotometry—analysis, fenclorac and metabolite in serum □ Anti-inflammatory agents—fenclorac and metabolite, spectrophotometric analysis in serum

Fenclorac (α,3-dichloro-4-cyclohexylbenzeneacetic acid) is a potent antiphlogistic, antinociceptive, and antipyretic agent (1, 2). Fenclorac is more potent than phenylbutazone or aspirin in the treatment of developing or established adjuvant arthritis and inhibition of carrageenan paw edema. Fenclorac is more potent than aspirin and indomethacin in reducing fever in rats rendered hyperthermic with brewer's yeast.

This paper describes the development of a quantitative assay for fenclorac (I) and its metabolite, 3-chloro-4-cyclohexylbenzene glycolic acid (II), in serum.

EXPERIMENTAL

Apparatus—A spectrophotometer[1], a recording spectrophotometer[2], and 1-cm quartz semimicro cells[3] were used.

Materials and Reagents—Methanol[4] (certified ACS grade), ceric ammonium sulfate dihydrate[4] (certified grade), sodium hydroxide[4] (certified ACS electrolytic pellets), chloroform[5] (spectrophotometric grade), sulfuric acid[5], hydrochloric acid[6] (analytical reagent grade), hexane[7] (distilled-in-glass UV grade), and normal human serum[8] were used as received.

Compounds I, II, 3-chloro-4-cyclohexylbenzaldehyde (III) and 1-^{14}C-carboxyl-labeled I and II were all synthesized[9].

Ceric reagent solution, 0.2 *M*, was prepared by the following procedure (3). Ceric ammonium sulfate, 126 g, was transferred to a 1-liter glass-stoppered volumetric flask containing a magnetic stirring bar. Approximately 700 ml of distilled water was added, followed by 30 ml of concentrated sulfuric acid. The mixture was stirred briefly, the volume was adjusted to 1 liter, and mixing was continued for about 2 hr. Insoluble material was allowed to settle overnight, and the clear supernate was used.

Serum Samples for Standard Curve—Standard solutions of I in serum were prepared by first mixing 3 ml of a 1.25-mg/ml methanolic solution of the diethylammonium salt of I with 97 ml of normal human serum to yield a stock serum standard equivalent to 30 μg of I/ml (factor for converting diethylammonium salt to free acid = 1.25). Dilutions of this stock serum standard were prepared to yield samples containing 2, 5, 10, 20, and 30 μg of I/ml of serum. Aliquots were dispensed into small tubes and frozen prior to use.

Analytical Procedure—The following procedure was a modification of the method of Cummins and Perry (4).

Methanol (5.0 ml) was added to a 35-ml ground-glass-stoppered conical centrifuge tube containing exactly 1.5 ml of serum sample or serum standard. The contents were mixed[10] during this addition, and the mixing was continued for another 10 sec. The tube was capped, and the contents were mixed[10] for 30 sec, followed by centrifugation for 5 min at 1500 rpm.

The methanol extract was quantitatively transferred to a second tube containing 1 ml of water, 0.2 ml of 8 *N* hydrochloric acid, and 5 ml of chloroform. The sample was mixed[10] for 1 min and centrifuged for 5 min. The lower phase (containing the chloroform extract) was quantitatively transferred to another tube containing exactly 8.5 ml of 1 *N* sodium hydroxide. The sample was again mixed for 1 min[10] and centrifuged for 5 min. Exactly 8 ml of the clear aqueous phase was transferred to a 40-ml glass-stoppered centrifuge tube, and the sample was reextracted with a second 8.5-ml aliquot of 1 *N* sodium hydroxide and centrifuged. The clear aqueous phase was transferred quantitatively to the second tube containing the first alkaline extract, and the combined extracts were mixed thoroughly.

The combined alkaline extract was heated in a boiling water bath for 15 min and then cooled to room temperature. Approximately 5 ml of hexane was added, and the sample was mixed for 30 sec[10] and centrifuged. The hexane phase was separated and discarded, and the sample was then reheated in boiling water for another 5 min to remove residual hexane.

After cooling to room temperature and acidification with 3 ml of 8 *N* hydrochloric acid, exactly 5 ml of ceric reagent was added and the contents were mixed briefly and allowed to stand for 30 min in the dark. Approximately 3 ml of 10 *N* sodium hydroxide was added, and the sample was mixed. The aqueous phase, containing the product of oxidation, was then extracted with 2.5 ml of hexane by mixing for 45 sec[10]. After centrifugation, the hexane phase was transferred to a semimicro UV cell. The absorbance was measured at 252 nm with hexane in the reference cell and then compared with the measurements obtained from the serum standard curve. Each standard curve was drawn from linear regression analysis of the individual data points.

Recovery Studies—Although II is a minor metabolite, its recovery from serum must approximate that of I so that the final extract is representative of the original serum sample.

Small aliquots of 1-^{14}C-I and/or 1-^{14}C-II were added to serum, and these samples were then carried through the assay procedure. Recoveries of carbon-14 were determined after each step, and the cumulative percent recovery was determined from these values. To minimize any effect due to volume changes upon sampling, no more than 10% of any extract was sampled for ^{14}C-analysis.

The radioactivity of all samples was determined in a liquid scintillation counter[11] using a modified Bray's solution cocktail (5). All counts were then corrected for background and quench by the external standard channels ratio method and converted to disintegrations per minute. The counting efficiency was 68%.

Extent of Oxidation—The oxidation of II, the final product obtained in the assay procedure just prior to oxidation, was studied by determining the disappearance of chloroform-extractable radioactivity from the acid medium of the ceric reaction mixture. Since the ^{14}C-label was on the carboxyl function of both I and II, its disappearance as ^{14}C-labeled carbon dioxide after oxidation served as an index of the extent of oxidation.

Identification of Oxidation Product—A serum sample containing added fenclorac and a serum sample from a subject who had received

Table I—Recovery of I and II in the Extraction Procedure

Assay Step	Recovery, %		
	I[a]	II[b]	I[c] and II[c]
Methanol extraction	89.6	81.5	91.0
Chloroform extraction	100	100	100
Alkaline extraction	76.9	88.1	83.0
Cumulative	68.9	71.8	75.5

[a] Original serum sample contained 19.6 μg/ml. [b] Original serum sample contained 23.8 μg/ml. [c] Original serum sample contained 9.8 μg of I and 11.9 μg of II/ml.

Table II—Extent of Oxidation of II to III

Component in Original Serum Sample	Percent of Sample Unoxidized	Percent Oxidized
I[a]	2.4	97.6
II[b]	0.2	99.8
I and II[c]	1.4	98.6

[a] Serum sample contained 19.6 μg of I/ml. [b] Serum sample contained 23.8 μg of II/ml. [c] Serum sample contained 9.8 μg of I and 11.9 μg of II/ml.

fenclorac were carried through the entire procedure. The UV spectra were determined on the product of oxidation and compared with the spectrum of the authentic oxidation product, III.

Correlation with Radioactivity Data—Serum samples were obtained from eight normal adult volunteers following oral administration of 200 mg of 1-^{14}C-I (specific activity of 0.317 μCi/mg). One hundred and twenty samples, representing various time intervals after the administration of the radioactive compound to the eight subjects, were assayed (15 samples/subject).

The levels of I found were compared to those levels obtained from liquid scintillation counting. Since GLC–mass spectrometry studies (6, 7) had shown that I is the major serum component along with small amounts of II, a direct correlation was made between levels obtained by this spectrophotometric method and the ^{14}C-levels.

Reproducibility—Within-day reproducibility was determined by assaying, on the same day, 10 identical serum samples containing exactly 20 μg of I/ml.

Day-to-day reproducibility was determined on a series of standard curves obtained over 3 weeks.

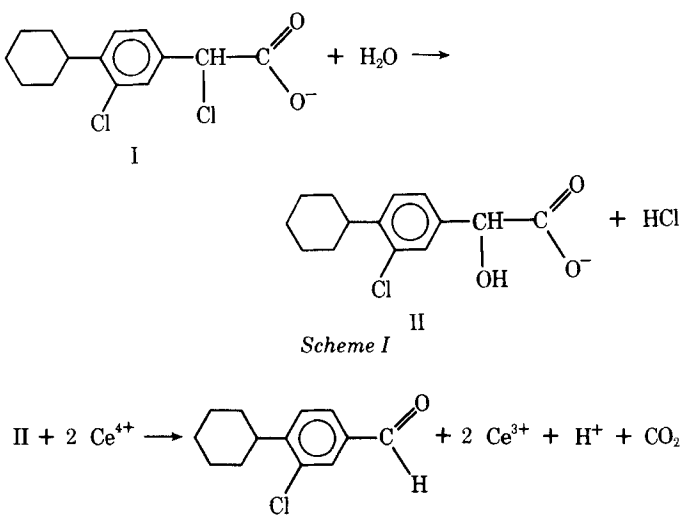
RESULTS AND DISCUSSION

The principal reactions in this assay are (*a*) the conversion of I to II (8, 9) (Scheme I), which occurs at room temperature but is greatly accelerated in an alkaline medium at elevated temperatures (100°); and (*b*) the oxidation of II by ceric sulfate (10) (Scheme II).

Although small amounts of the methyl esters of both I and II are formed in acidified methanol, base-catalyzed hydrolysis at elevated temperatures converted the esters to 3-chloro-4-cyclohexylbenzeneglycolate and eliminated any interferences (11).

Recovery Studies—The cumulative percent recovery of I and/or II from serum was equivalent up to the step immediately prior to oxidation. Therefore, if a serum sample contained I and/or II, the final extract was representative of the composition of the original serum sample. This condition is necessary when two compounds are present in the same sample and when both must be assayed simultaneously. Table I summarizes the complete recovery study.

Extent of Oxidation—Less than 2.5% of radioactivity was recovered into chloroform from the ceric reaction mixture, indicating that the oxidation was essentially quantitative after 30 min (Table II).



Scheme I

Scheme II

Identification of Oxidation Product—The product of ceric oxidation of II or extracts of serum samples from subjects who received I had the same UV spectral characteristics as the predicted product of oxidation, III (Fig. 1).

Correlation of Spectrophotometric and ^{14}C-Analyses—Linear regression analysis of serum concentrations of I determined by spectrophotometric (C_{sp}) or ^{14}C (C_{RI}) procedures indicated a 90% correlation between the two methods ($r^2 = 0.965$; $C_{sp} = 0.90C_{RI} - 0.46$) over a range of 1.4–25.5 μg of I/ml. There was no significant serum blank, and slight hemolysis in serum did not interfere.

GLC–mass spectrometric studies indicated that I was the major species present in serum after oral administration of fenclorac. Only small amounts (<10%) of II were present (6, 7). Also, due to the small difference in molecular weight between I and II (~7%), this assay gives a direct measure of the unchanged parent compound.

Figure 2 is a graphical comparison of the average values obtained on the serum samples of eight subjects by the spectrophotometric method with the ^{14}C-values obtained by liquid scintillation.

Reproducibility—The standard curves used for the radioisotope

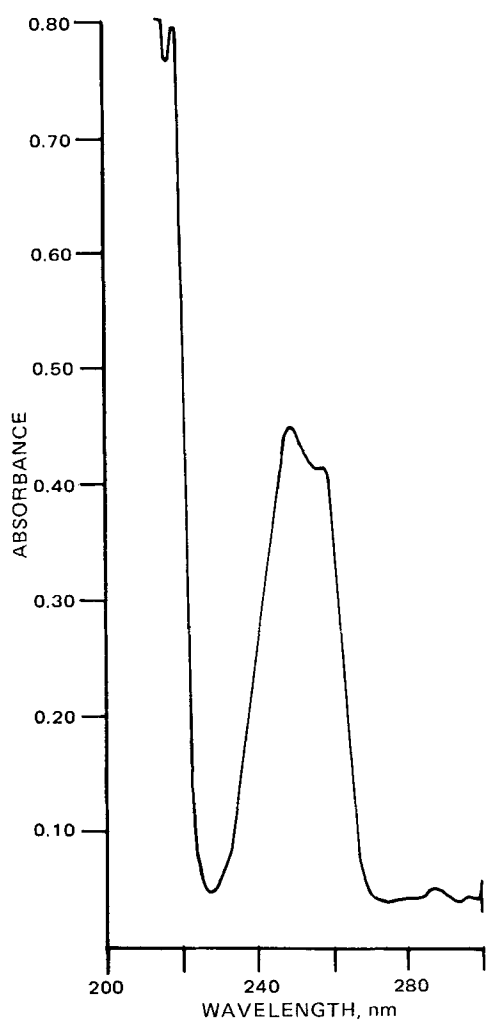


Figure 1—*UV spectrum of III in hexane.*

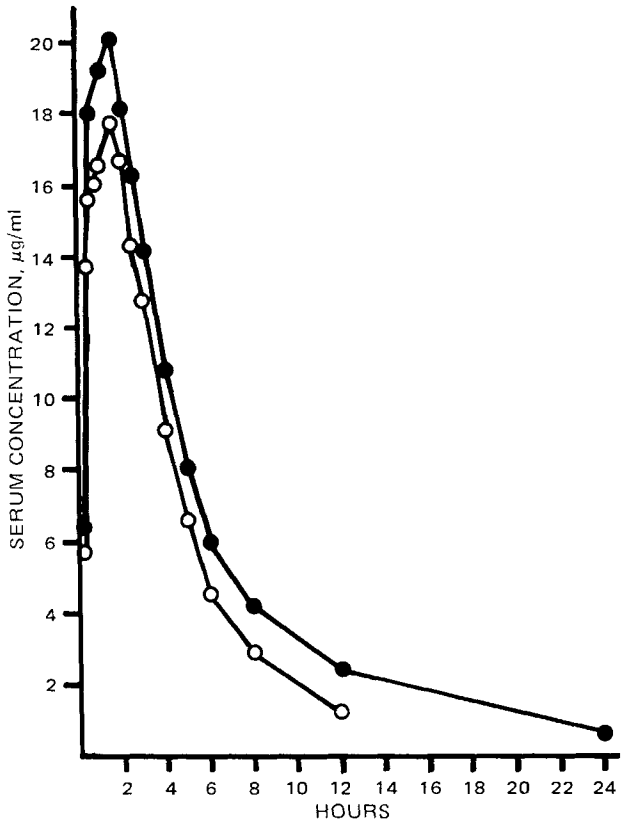

Figure 2—*Serum I concentration after oral administration of 200 mg of I in an aqueous medium. Key (mean values of eight subjects): ●, ^{14}C-assay; and ○, UV spectrophotometric assay.*

study indicated good day-to-day reproducibility on samples assayed over 3 weeks.

The composite linear regression standard curve had a y-intercept of 0.024 absorbance unit (blank), a slope of 0.018 absorbance unit/μg of I/ml, and $r^2 = 0.995$ ($y = 0.018x + 0.024$), where x is micrograms of I per milliliter of serum. The coefficient of variation was 5% with serum samples containing 2, 5, 10, 20, and 30 μg of I/ml on 12–14 determinations of each concentration over 3 weeks.

Replicate determinations of I in 10 identical serum standards, each containing 20 μg of I/ml, on the same day resulted in a coefficient of variation of 2.8% and a mean of 0.321 ± 0.009 absorbance unit at 252 nm.

Sensitivity—As mentioned previously, linear regression analysis of absorbance *versus* standard concentration data yielded a slope of 0.018 absorbance unit for 1 μg of I/ml of serum. When using 1.5 ml of serum per test, the minimum detectable quantity of I was approximately 1 μg/ml.

Quantitation of the Antimalarial Agent, Mefloquine, in Blood, Plasma, and Urine Using High-Pressure Liquid Chromatography

J. M. GRINDEL *ˣ, P. F. TILTON *, and R. D. SHAFFER ‡

Abstract □ Sensitive and specific assays are described for the quantitation of mefloquine in whole blood, plasma, and urine specimens using high-pressure liquid chromatography. Specimens were extracted with ethyl acetate and concentrated before chromatography. Whole blood and plasma extracts were chromatographed on a polar bonded phase partitioning column, and urine extracts were chromatographed on a bonded reversed-phase partitioning column. The sensitivity of the assays for mefloquine was 0.05 μg/ml of whole blood or plasma and 0.25 μg/ml of urine using 5-ml samples. The assays are suitable for studying mefloquine pharmacokinetics in humans.

a sensitive and specific nonradioactive assay.

High-pressure liquid chromatography (HPLC) is a powerful analytical technique for the quantitative analysis of pharmaceuticals in biological fluids. Due to the low vapor pressure of mefloquine, GLC was not as applicable as HPLC. Thus, HPLC was utilized to effect a specific separation and quantitation of mefloquine from whole blood, plasma, and urine specimen extracts.

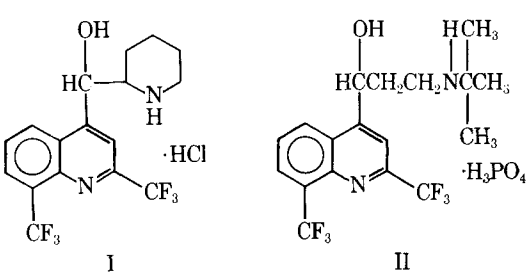
EXPERIMENTAL

Reagents—Mefloquine hydrochloride and the internal standard[2] (II) were assayed at >99 and 98% purity, respectively. All solvents used were spectroquality, and drug solutions were made with the appropriate salt form of the compound. All concentrations are expressed as the free base.

Standard Solutions—A solution of the internal standard was prepared in dioxane–methanol (7:3 v/v) (196 μg/ml). The internal standard solution was used as the solvent for the preparation of a stock solution of mefloquine (1028 μg/ml), from which dilutions were made with the internal standard solution to give solutions with concentrations of 10.2–205.6 μg of mefloquine/ml and 1.96 μg of II/ml.

Chromatographic Conditions—A high-pressure liquid chromatograph[3] equipped with a 280-nm absorbance monitor was utilized. Whole blood and plasma extracts were chromatographed on a column of 10-μm, fully porous silica, bonded with a monomolecular layer of cyanopropylsilane[4]. A mobile phase of isopropyl ether–dioxane–acetic acid (3:2 v/v + 0.5%) at 2 ml/min was used. Urine extracts were chromatographed on a column of 10-μm, fully porous silica, bonded with a monomolecular layer of octadecylsilane[5]. A mobile phase of methanol–0.1 *M* NaH_2PO_4 (3:2 v/v) at 2 ml/min was used.

General Assay Procedure—The internal standard solution (50 μl) containing 9.8 μg of II, 5 ml of whole blood, plasma, or urine, and 5 ml of pH 7.4 phosphate buffer (0.065 *M*) were placed in a 45-ml glass conical tube with a polytef[6]-lined screw cap and thoroughly mixed. Then 10 ml of ethyl acetate was added to each tube, and the samples were agitated at 100 strokes/min for 30 min on a reciprocating shaker bath[7] and centrifuged[8] at 2000 rpm for 10 min. The ethyl acetate layer was then pipetted carefully into a 45-ml glass conical tube with a polytef stopper.



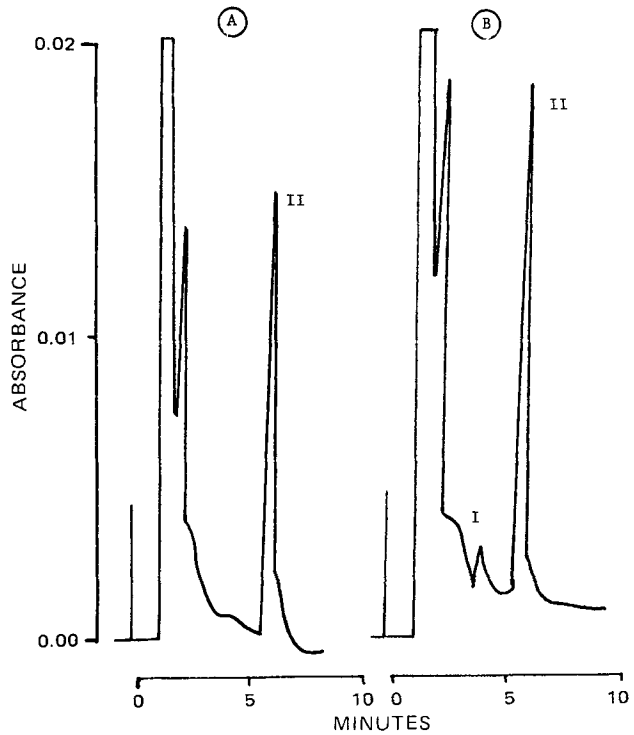


Figure 1—*Representative chromatograms of a whole blood extract containing 0.98 μg of II (A) and of a whole blood extract containing 0.05 μg of I plus 0.98 μg of II (B) after chromatography on a polar bonded phase column using isopropyl ether–dioxane–acetic acid (3:2 v/v +0.5%) as the mobile phase.*

The extraction procedure was repeated two more times, the combined ethyl acetate layers from each sample were evaporated to dryness under a gentle stream of nitrogen at 40° [9], and the residues were stored overnight in a vacuum desiccator. The sample residues were reconstituted with 500 μl of the appropriate mobile phase, and 50-μl aliquots were injected into the chromatograph. Quantitation was achieved by measuring peak area ratios for I/II and relating them to the least-squares linear regression curve of the peak area ratio for I/II *versus* the amount of mefloquine injected. Peak areas were obtained from the product of the maximum peak height (centimeters) × width at peak half-height (centimeters).

Spiked Samples—*Recovery of Mefloquine from Whole Blood*—Aliquots (25 ml) of human whole blood were spiked with a methanol solution of mefloquine (250 μg/ml) to give drug concentrations of 1.00, 0.50, and 0.10 μg/ml. The samples were thoroughly mixed for 30 min and treated as described under *General Assay Procedure*, except that the internal standard (II) was not added until the extraction was completed.

Recovery of II from Whole Blood—Aliquots (25 ml) of human whole blood were spiked with a methanol solution of II (250 μg/ml) to give drug concentrations of 1.00, 0.50, and 0.10 μg/ml. The spiked blood was thoroughly mixed for 30 min, and four 5-ml samples of each concentration level were placed in individual glass tubes along with 5 ml of pH 7.4 phosphate buffer (0.065 *M*). Each sample was extracted with 3 × 10 ml of ethyl acetate, the combined ethyl acetate extracts were evaporated under nitrogen, the residues were reconstituted with 500 μl of mobile phase, and 50-μl aliquots were injected into the chromatograph. Quan-
