The *Journal of Pharmaceutical Sciences* is published monthly by the American Pharmaceutical Association at 2215 Constitution Ave., N.W., Washington, DC 20037. Second-class postage paid at Washington, D.C., and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in this journal are published on the authority of the writer over whose name they appear and are not to be regarded as necessarily expressing the policies or views of the American Pharmaceutical Association.

Offices—Editorial, Advertising, and Subscription Offices: 2215 Constitution Ave., N.W., Washington, DC 20037. Printing Offices: 20th & Northampton Streets, Easton, PA 18042.

Annual Subscriptions—United States and foreign, industrial and government institutions $50, educational institutions $50, individuals *for personal use only* $30; single copies $5. All foreign subscriptions add $5 for postage. Subscription rates are subject to change without notice. Members of the American Pharmaceutical Association may elect to receive the *Journal of Pharmaceutical Sciences* as a part of their annual $60 (foreign $65) APhA membership dues.

Claims—Missing numbers will not be supplied if dues or subscriptions are in arrears for more than 60 days or if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. The Association cannot accept responsibility for foreign delivery when its records indicate shipment has been made.

Change of Address—Members and subscribers should notify at once both the Post Office and the American Pharmaceutical Association, 2215 Constitution Ave., N.W., Washington, DC 20037, of any change of address.

THE "DUMB COPS" IMAGE

One day this past fall we were going through the daily Washington ritual of reviewing the current issue of the *Federal Register*—which is the principal means of keeping track of what is happening in the executive branch of government—when we spotted reference to a Presidential Proclamation which caught our eye. Specifically, the entry pertained to the designation of "Drug Abuse Prevention Week" and the thought struck us that this annual effort to promote means to control the problems of drug abuse was a bit later than usual this year.

Upon turning to the Proclamation in that issue of the *Federal Register*, the explanation became immediately clear. Although the Proclamation was signed by President Ford on October 18 and printed rather promptly in the *Federal Register* dated October 20, nevertheless, the week being so designated was indicated as beginning October 17. Normally, such Proclamations appear at least two weeks or so before the pertinent date and certainly not after the observance is to begin.

Those familiar with the operation of executive agencies will recognize that the tardiness here does not lie with the President, or the White House staff, or the *Federal Register* but, rather, with the particular agency having primary responsibility for the subject area. In this instance, we suspect that the fault lies with the Drug Enforcement Administration of the Department of Justice.

Whether or not DEA was responsible for this small flub, there is no question that the agency has been clearly at fault for a long string of other foul-ups and errors which, *in toto*, project the image of an inefficient, bungling agency.

When DEA was originally established some half-dozen years or so ago, a strong argument was made that responsibility for drug control involved scientific, medical, and other technical knowledge, which argues rather strongly that the agency should be placed within the U.S. Department of Health, Education, and Welfare rather than the Department of Justice. Others, however, argued vocally that drug abuse control basically is a regulatory and enforcement activity and, as such, the agency more properly should be made part of the Department of Justice where other federal investigative and police activities are primarily centralized.

In recent months, we have seen repeated instances where official notices, proposals, or finalized regulations issuing from DEA and published in the *Federal Register* have used terminology and nomenclature to describe the drugs involved which have been confusing, inconsistent, or otherwise inaccurate. In an effort to correct this problem, at our suggestion, the office of the United States Adopted Names (USAN) Council specifically communicated with the DEA and offered assistance in this regard. Not only did the DEA fail to take advantage of this offer but, in fact, actually repeated on at least two later dates the very error cited by the USAN Council office as an example of incorrect drug nomenclature being employed by the agency.

There are many dedicated and well-qualified professionals who serve in the DEA. Undoubtedly, the bureaucratic bungling of the agency such as that described above and which projects a "dumb cop" image is highly embarrassing to those professional staff members. What is particularly unfortunate, however, is that this problem is so unnecessary. It could be readily corrected if those responsible for determining general agency policy and direction were just a bit more sensitive to the need to exercise reasonable sophistication and care in the scientific and medically related aspects of their field of responsibility.

THE "DUMB COPS" IMAGE

One day this past fall we were going through the daily Washington ritual of reviewing the current issue of the *Federal Register*—which is the principal means of keeping track of what is happening in the executive branch of government—when we spotted reference to a Presidential Proclamation which caught our eye. Specifically, the entry pertained to the designation of "Drug Abuse Prevention Week" and the thought struck us that this annual effort to promote means to control the problems of drug abuse was a bit later than usual this year.

Upon turning to the Proclamation in that issue of the *Federal Register*, the explanation became immediately clear. Although the Proclamation was signed by President Ford on October 18 and printed rather promptly in the *Federal Register* dated October 20, nevertheless, the week being so designated was indicated as beginning October 17. Normally, such Proclamations appear at least two weeks or so before the pertinent date and certainly not after the observance is to begin.

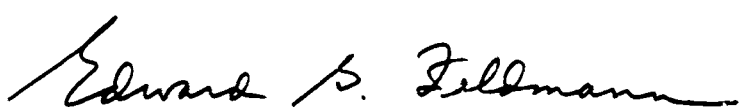
Those familiar with the operation of executive agencies will recognize that the tardiness here does not lie with the President, or the White House staff, or the *Federal Register* but, rather, with the particular agency having primary responsibility for the subject area. In this instance, we suspect that the fault lies with the Drug Enforcement Administration of the Department of Justice.

Whether or not DEA was responsible for this small flub, there is no question that the agency has been clearly at fault for a long string of other foul-ups and errors which, *in toto*, project the image of an inefficient, bungling agency.

When DEA was originally established some half-dozen years or so ago, a strong argument was made that responsibility for drug control involved scientific, medical, and other technical knowledge, which argues rather strongly that the agency should be placed within the U.S. Department of Health, Education, and Welfare rather than the Department of Justice. Others, however, argued vocally that drug abuse control basically is a regulatory and enforcement activity and, as such, the agency more properly should be made part of the Department of Justice where other federal investigative and police activities are primarily centralized.

In recent months, we have seen repeated instances where official notices, proposals, or finalized regulations issuing from DEA and published in the *Federal Register* have used terminology and nomenclature to describe the drugs involved which have been confusing, inconsistent, or otherwise inaccurate. In an effort to correct this problem, at our suggestion, the office of the United States Adopted Names (USAN) Council specifically communicated with the DEA and offered assistance in this regard. Not only did the DEA fail to take advantage of this offer but, in fact, actually repeated on at least two later dates the very error cited by the USAN Council office as an example of incorrect drug nomenclature being employed by the agency.

There are many dedicated and well-qualified professionals who serve in the DEA. Undoubtedly, the bureaucratic bungling of the agency such as that described above and which projects a "dumb cop" image is highly embarrassing to those professional staff members. What is particularly unfortunate, however, is that this problem is so unnecessary. It could be readily corrected if those responsible for determining general agency policy and direction were just a bit more sensitive to the need to exercise reasonable sophistication and care in the scientific and medically related aspects of their field of responsibility.



Drug Dosage Forms

Ecanow and Gold[1] incorrectly asserted that the Ocusert (pilocarpine) ocular therapeutic system is merely a dosage form delivery system containing a drug solution. They failed to make the distinction between a "dosage form" and a "controlled drug delivery system." The latter is a generic term for systems that go beyond conventional dosage forms in the sense that they are all specified by a drug delivery program—a predetermined rate and duration of drug delivery. The term "therapeutic system" is applied to controlled drug delivery systems that release a certain drug according to a temporal pattern designed for the therapy of a particular condition or disease state.

The therapeutic system functions according to this rate/duration program in automatic and uniform fashion. Moreover, the specification of rate and duration is based upon *in vitro* testing carried out under conditions that are predictive of the functioning of the therapeutic system *in vivo*. In contrast, a conventional dosage form is specified only by the weight or concentration of drug it contains. Thus, the distinction between dosage form and therapeutic system is clear from the labeling: the Ocusert system continuously delivers pilocarpine to the eye at either 20 or 40 μg/day for 1 week; an eyedrop solution contains pilocarpine in concentrations of 1, 2, 4, *etc.*, percent. The essential difference lies between the words "delivers" and "contains." The former labeling specifies function, and the latter only specifies general content of the bottle—not even the volume of the eyedrop is quantified.

We certainly agree with Ecanow and Gold that confusion can arise from ill-defined terminology. We propose, however, that the term "dosage form" be the broad description of pharmaceutical preparations intended for therapeutic use. This broad term encompasses various specific types of dosage forms such as tablets, capsules, suspensions, emulsions, solutions, semisolids, and controlled drug delivery systems. The drug delivery system can only be a specific entity (*e.g.*, a therapeutic system) if it is clearly distinguishable from other dosage types by definition, design, and function of the drug program.

"Dosage form delivery system," as proposed by Ecanow and Gold, would then be confined to the additional apparatus that may facilitate administration of dosage forms such as eyedroppers, syringes, and applicators. However, so restricted a meaning would create confusion and would be of dubious utility even when correctly employed.

The chemical, biological, physical, and economic characteristics of medicinal agents can be manipulated and, hence, often optimized by conversion to a salt form. Choosing the appropriate salt, however, can be a very difficult task, since each salt imparts unique properties to the parent compound.

Salt-forming agents are often chosen empirically. Of the many salts synthesized, the preferred form is selected by pharmaceutical chemists primarily on a practical basis: cost of raw materials, ease of crystallization, and percent yield. Other basic considerations include stability, hygroscopicity, and flowability of the resulting bulk drug. Unfortunately, there is no reliable way of predicting the influence of a particular salt species on the behavior of the parent compound. Furthermore, even after many salts of the same basic agent have been prepared, no efficient screening techniques exist to facilitate selection of the salt most likely to exhibit the desired pharmacokinetic, solubility, and formulation profiles.

Some decision-making models have, however, been developed to help predict salt performance. For example, Walkling and Appino (1) described two techniques, "decision analysis" and "potential problem analysis," and applied them to the selection of the most suitable derivative of an organic acid for development as a tablet. The derivatives considered were the free acid and the potassium, sodium, and calcium salts. Both techniques are based on the chemical, physical, and biological properties of these specific derivatives and offer a promising avenue for developing optimal salt forms.

Information on salts is widely dispersed throughout the pharmaceutical literature, much of which addresses the use of salt formation to prolong the release of the active component, thereby eliminating various undesirable drug properties (2–6). This review surveys literature of the last 25 years, emphasizing comparisons between the properties of different salt forms of the same compound. Included also is a discussion of potentially useful salt forms. Our purpose is twofold: to present an overview of the many different salts from which new drug candidates can be chosen and

to assemble data that will provide, for the student and practitioner alike, a rational basis for selecting a suitable salt form.

POTENTIALLY USEFUL SALTS

Salt formation is an acid–base reaction involving either a proton-transfer or neutralization reaction and is therefore controlled by factors influencing such reactions. Theoretically, every compound that exhibits acid or base characteristics can participate in salt formation. Particularly important is the relative strength of the acid or base—the acidity and basicity constants of the chemical species involved. These factors determine whether or not formation occurs and are a measure of the stability of the resulting salt.

The number of salt forms available to a chemist is large; surveys of patent literature show numerous new salts being synthesized annually. Various salts of the same compound often behave quite differently because of the physical, chemical, and thermodynamic properties they impart to the parent compound. For example, a salt's hydrophobicity and high crystal lattice energy can affect dissolution rate and, hence, bioavailability. Ideally, it would be desirable if one could predict how a pharmaceutical agent's properties would be affected by salt formation.

Tables I and II list all salts that were commercially marketed through 1974. The list was compiled from all agents listed in "Martindale The Extra Pharmacopoeia," 26th ed. (7). Table I categorizes all salt forms approved by the Food and Drug Administration (FDA), while Table II lists those not approved by the FDA but in use in other countries. (Only salts of organic compounds are considered because most drugs are organic substances.) The relative frequency with which each salt type has been used is calculated as a percentage, based on the total number of anionic or cationic salts in use through 1974. Because of simple availability and physiological reasons, the monoprotic hydrochlorides have been by far the most frequent choice of the available anionic salt-forming radicals, outnumbering the sulfates nearly six to one. For similar reasons, sodium has been the most predominant cation.

Knowledge that one salt form imparts greater water solubility, is less toxic, or slows dissolution rate would greatly benefit chemists and formulators. In some cases, such generalizations can be made. Miller and Heller (8) discussed some properties associated with specific classes of salt forms. They stated that, in general, salt combinations with monocarboxylic acids are insoluble in water and lend themselves to repository preparations, while those of dicarboxylic acids confer water solubility if one carboxylic group is left free. Pamoic acid, an aromatic dicarboxylic acid, is an exception since it is used as a means of obtaining prolonged action by forming slightly soluble salts with certain basic drugs. Saias *et al.* (9) reviewed the use of this salt form in preparing sustained-release preparations. More recently, latentiation of dihydrostreptomycin (10)

using pamoic acid resulted in the formation of a delayed-action preparation. Numerous studies using pamoate salts are dispersed throughout the literature (11–15).

Alginic acid also has been used to prepare long-acting pharmaceuticals. Streptomycin alginate was prepared (16) and shown to be effective in sustained-release preparations. A striking example of a long-acting alginate salt is that of pilocarpine. When dispersed in sterile water and dried to a solid gel, this compound was found useful in the preparation of long-acting ophthalmic dosage forms (17). While liquid preparations of the alginate and hydrochloride salts possess similar miotic activity, studies showed that solid pilocarpine alginate flakes constricted pupil size more effectively and increased the duration of miosis significantly when compared with the liquid preparations. Solid dose pilocarpine may be more uniformly available, because it diffuses more slowly through the gel matrix which holds the drug in reserve. In contrast, drops of the commonly employed solution dosage form release the dose immediately to the conjunctival fluid.

Málek *et al.* (18) devised a unique way of prolonging action through salt formation; they showed that the distribution of several antibiotics could be markedly altered by merely preparing macromolecular salts. Since macromolecules and colloidal particles have an affinity for the lymphatic system, streptomycin, neomycin, viomycin, and streptothrycin were combined with high molecular weight compounds such as polyacrylic acids, sulfonic or phosphorylated polysaccharides, and polyuronic derivatives. Parenteral administration of these compounds produced low blood levels of the antibiotic for long periods, while lymph levels were high. (In comparison, streptomycin sulfate gave high blood levels but low lymph levels.) This alteration in distribution caused the streptomycin to prolong its passage through the body, since lymphatic circulation is quite slow.

The appropriate choice of a salt form has been found to reduce toxicity. It can be rationalized that any compound associated with the normal metabolism of food and drink must be essentially nontoxic. The approach of choosing organic radicals that are readily excreted or metabolized opened up a new class of substances from which to select a salt form. For example, certain salts of the strong base choline have proven to be considerably less toxic than their parent compound. The preparation and properties of choline salts of a series of theophylline derivatives were reported (19), and it was shown that choline theophyllinate possessed a greater LD_{50} than theophylline or its other salts (20). It was postulated that this agent would be less irritating to the GI tract than aminophylline, because "its basic constituent, choline, is an almost completely nontoxic substance of actual importance to the physiologic economy." This evidence led to the preparation of choline salicylate (21) as an attempt to reduce the GI disturbances associated with salicylate administration. Clinical studies indicated that choline salicylate elicited a lower incidence of GI distress, was tolerated in higher doses, and was of greater benefit to the patient than was acetylsalicylic acid (aspirin).

Amino acids and acid vitamins also have been used as salt-forming agents. Based on the evidence that coadministration of amino acids with aminoglycoside antibiotics reduced their toxicity, a series of amino acid salts of dihydrostreptomycin was prepared (22). In all but one case, the acute toxicities of these salts were lower than the toxicity of the sulfate. The ascorbate and pantothenate also were synthesized and shown to be less toxic than the sulfate. Of the salts prepared, the ascorbate had the highest LD_{50}.

The vitamins most commonly used for forming salts exhibiting reduced toxicity are ascorbic and pantothenic acids. Keller *et al.* (23) were the first to use pantothenic acid as a means of "detoxifying" the basic streptomyces antibiotics. Parenteral administration of the pantothenates of streptomycin and dihydrostreptomycin had a significantly reduced incidence of acute neurotoxicity in cats as compared with the sulfates. Subsequent studies (24–28) supported this finding and showed that the pantothenates of neomycin and viomycin also are less toxic. The ascorbate of oleandomycin was synthesized and its pharmacological properties were reported (29). Upon intramuscular injection in rats, it produced less irritation than the phosphate.

p-Acetamidobenzoic acid, an innocuous metabolite of folic acid present in normal blood and urine, has been used in preparing salts. In particular, it yields stable salts with amines that otherwise tend to form hygroscopic products with conventional acid components (30).

Often the salt form is chosen by determining a salt

component that will pharmacologically antagonize an unfavorable property or properties exhibited by the basic agent. Salts of *N*-cyclohexylsulfamic acid are an example of the practical application of this approach. *N*-Cyclohexylsulfamic acid salts, better known as cyclamates, have a characteristic sweet, pleasing taste. Although presently under investigation by the FDA for potentially carcinogenic properties, salts incorporating this compound can render unpleasant or bitter-tasting drugs acceptable. For example, the cyclamates of dextromethorphan and chlorpheniramine exhibit greatly improved bitterness thresholds compared to commonly occurring salts (31). Furthermore, their stability in aqueous solution was described as good when maintained at a pH not greater than 4.

N-Cyclohexylsulfamic acid salts of thiamine hydrochloride and lincomycin also have been synthesized. Thiamine *N*-cyclohexylsulfamate hydrochloride was reported to have a more pleasant taste than other thiamine salts while having an equal or greater stability (32). Lincomycin cyclamate, shown to possess an enhanced thermal stability over its hydrochloride, was prepared (33) to test the hypothesis that reduced lincomycin absorption in the presence of small quantities of cyclamates was due to a simple metathetic reaction. However, this assumption was found not to be true. An extensive study of the preparation and characterization of cyclamic acid salts of several widely used classes of drugs including antihistamines, antibiotics, antitussives, myospasmolytics, and local anesthetics was reported (34, 35).

Various salts of penicillin and basic amine compounds have been formulated in an effort to produce a long-acting, nonallergenic form of penicillin. Since antihistamines appear to mitigate the symptomatology of penicillin reactions in some patients, coadministration of the two has been advocated. The preparation of the benzhydralamine salt of penicillin was an attempt to produce a repository form of penicillin with antiallergic properties (36). Blood levels achieved with this salt were comparable to those of penicillin G potassium; however, its antiallergic properties were not evaluated. In fact, the investigators noted that antihistamines can actually cause sensitization at times and stated that "despite their occasionally favorable influence on the symptoms of penicillin sensitivity, they contribute directly to the potential of drug sensitivity when co-administered with penicillin."

Silver salts of sulfanilamide, penicillin, and other antibiotics have been prepared and represent cases where the species (ions) are complementary. When aqueous solutions of the salts were applied topically to burned tissue, they yielded the combined benefits of the oligodynamic action of silver and the advantages of the antibacterial agents (37).

The use of 8-substituted xanthines, particularly the 8-substituted theophyllines, as salt-forming agents was first reported in the preparation of a series of antihistamine salts (38–41). Synthesis of these xanthine salts was an attempt to find a drug to counteract the drowsiness caused by the antihistamines with the stimulant properties of the xanthines. When an electronegative group is introduced into the xanthine molecule at the 8-position, the electron-drawing capacity of the substituent results in the creation of an acidic hydrogen at position 7. Thus, these moderately strong acidic compounds can undergo salt formation with various organic bases.

The 8-halotheophyllines were the first group of xanthines studied as potential salt-forming agents. Since the report on the preparation of the 8-chlorotheophylline salt of diphenhydramine (42), synthesis of the 8-halotheophyllinates of a number of organic bases has been attempted. The 8-chlorotheophylline salts of quinine, ephedrine, and strychnine were prepared and characterized (43). These salts were less water soluble than the corresponding free alkaloidal bases. In a similar report, the 8-chlorotheophyllinates of three synthetic narcotics, meperidine, levorphanol, and metopon, were prepared (44).

Pharmacological and clinical studies involving the 8-bromotheophylline pyrilamine salt revealed the unusual diuretic properties associated with the 8-halotheophylline portion of the compound (45, 46). This finding initiated an investigation into the preparation of a soluble 8-bromotheophylline salt of high diuretic activity. With readily available amines, over 30 salts were synthesized and screened for diuretic activity (47). When tested against theophylline salts of the same amines, the 8-bromotheophyllinates showed greater activity in every case.

With the successful formation of 8-halotheophyllinates of organic bases, Morozowich and Bope (48) proposed that, if the halogen moiety was replaced with a more electronegative substituent such as a nitro group, a more acidic compound would be formed. Presumably, more stable salts would result and precipitation of the free xanthine derivative in the stomach would be less likely to occur. On this premise, they successfully prepared pharmacologically effective 8-nitrotheophyllinates of several pharmaceutically useful bases.

Duesel *et al.* (19), in their study of choline theophyllinate, prepared the 8-chloro-, 8-bromo-, and 8-nitrotheophylline salts of choline. Oral toxicity studies in mice showed that the LD_{50} of the 8-nitrotheophyllinate was much greater than that of either 8-halotheophylline. In fact, it remained nonlethal at doses as high as 5 g.

Polygalacturonic acid, a derivative of pectin, has been used to prepare quinidine salts exhibiting reduced toxicity (49, 50). The compound possesses special demulcent properties and inhibits mucosal irritation. The rationale for use of this agent is to reduce the ionic shock to the GI mucosa resulting from the flood of irritating ions liberated by rapid dissociation of the conventional inorganic quinidine salts. Studies have shown that it is four times less toxic orally than the sulfate. This difference was attributed to the slower release of quinidine from the polygalacturonate.

Other compounds reported to be potentially useful as pharmaceutical salt forms are listed in Table III.

PHYSICOCHEMICAL STUDIES

Biological activity of a drug molecule is influenced by two factors: its chemical structure and effect at a specific site and its ability to reach—and then be removed from—the site of action. Thus, a knowledge of the physicochemical properties of a compound that influence its absorption, distribution, metabolism, and excretion is essential for a complete understanding of the onset and duration of ac-

Table III—Potentially Useful Salt Forms of Pharmaceutical Agents

Salt-Forming Agent	Compound Modified	Modification	Reference
Acetylaminoacetic acid	Doxycycline	Solubility	51
N-Acetyl-L-asparagine	Erythromycin	Solubility, activity, stability	52
N-Acetylcystine	Doxycycline	Combined effect useful in pneumonia	53
Adamantoic acid	Alkylbiguanides	Prolonged action	54
Adipic acid	Piperazine	Stability, toxicity, organoleptic properties	55
N-Alkylsulfamates	Ampicillin	Absorption (oral)	56
	Lincomycin	Solubility	57
Anthraquinone-1,5-disulfonic acid	Cephalexin	Stability, absorption	58
Arabogalactan sulfate (arabino)	Various alkaloids	Prolonged action	59, 60
Arginine	Cephalosporins	Toxicity	61
	α-Sulfobenzylpenicillin	Stability, hygroscopicity, toxicity	62
Aspartate	Erythromycin	Solubility	63
Betaine	Tetracycline	Gastric absorption	64
Bis(2-carboxychromon-5-yloxy)alkanes	7-(Aminoalkyl)theophyllines	Activity, prolonged prophylactic effect	65
Carnitine	Metformin	Toxicity	66
4-Chloro-*m*-toluenesulfonic acid	Propoxyphene	Organoleptic properties	67
Decanoate	Heptaminol	Prolonged action	68
Diacetyl sulfate	Thiamine	Stability, hygroscopicity	69
Dibenzylethylenediamine	Ampicillin	Prolonged action	70, 71
Diethylamine	Cephalosporins	Reduced pain on injection	72
Diguaiacyl phosphate	Tetracycline	Activity	73
Dioctyl sulfosuccinate	Vincamine	Organoleptic properties	74
Embonic (pamoic) acid	Kanamycin	Toxicity	75
	2-Phenyl-3-methylmorpholine	Toxicity	76
Fructose 1,6-diphosphoric acid	Tetracycline	Solubility	77
	Erythromycin	Solubility	
Glucose 1-phosphoric acid, glucose 6-phosphoric acid	Tetracycline	Solubility	77
	Erythromycin	Solubility	
L-Glutamine	Erythromycin	Solubility, activity, stability	52
Hydroxynaphthoate	Bephenium	Toxicity	78
2-(4-Imidazolyl)ethylamine	Prostaglandin	Prolonged action	79
Isobutanolamine	Theophylline	Stability	80
Lauryl sulfate	Vincamine	Organoleptic properties	81
Lysine	α-Sulfobenzylpenicillin	Toxicity, stability, hygroscopicity	62
	Cephalosporins		61
Methanesulfonic acid	Pralidoxime (2-PAM)	Solubility	82
N-Methylglucamine	α-Sulfobenzylpenicillin	Toxicity, stability, hygroscopicity	62
	Cephalosporins	Reduced pain on injection	72
N-Methylpiperazine	Phenylbutazone	Toxicity, faster onset of action	83
Morpholine	Cephalosporins	Reduced pain on injection	72
2-Naphthalenesulfonic acid	Propoxyphene	Organoleptic properties	84
Octanoate	Heptaminol	Prolonged action	68
Probenecid	Pivampicillin	Organoleptic properties	85
Tannic acid	Various amines	Prolonged action	86, 87
Theobromine acetic acid	Propoxyphene	Activity	88
3,4,5-Trimethoxybenzoate	Tetracycline	Organoleptic properties	89
	Heptaminol	Prolonged action	68
Tromethamine	Aspirin	Absorption (oral)	90
	Dinoprost (prostaglandin $F_{2\alpha}$)	Physical state	91

tion, the relative toxicity, and the possible routes of administration (2).

In a review in 1960, Miller and Holland (92) stated that "different salts of the same drug rarely differ pharmacologically; the differences are usually based on the physical properties." In a subsequent review (93), Wagner expanded upon this statement, asserting that, although the nature of the biological responses elicited by a series of salts of the same parent compound may not differ appreciably, the intensities of response may differ markedly.

The salt form is known to influence a number of physicochemical properties of the parent compound including dissolution rate, solubility, stability, and hygroscopicity. These properties, in turn, affect the availability and formulation characteristics of the drug. Consequently, the pharmaceutical industry has systematically engaged in extensive preformulation studies of the physicochemical properties of each new drug entity to determine the most suitable form for drug formulation. Published information concerning such studies, however, is sparse. Preformulation studies have been outlined, and the influence of the salt form on the volatility and hygroscopicity of an agent under investigation was discussed (94).

In one such study, methylpyridinium-2-aldoxime (pralidoxime) salts were investigated (95). This study set out to prepare a salt with water solubility adequate to allow intramuscular injection of a low volume (2–3 ml) therapeutic dose. The original compound, the methiodide, had the disadvantages of limited aqueous solubility and high potential toxicity, since its high iodide content could result in iodism. On the basis of physiological compatibility, better water solubility, favorable stability, and relatively high percentage of oxime, the chloride salt of pralidoxime was selected for therapeutic administration; it was claimed that "the anion used to form the salt can confer physical properties of importance and significance for the formulation and administration of the compound" (95).

Some physicochemical properties of a series of mineral acid salts of lidocaine also were determined (96). While the hydrochloride and hydrobromide were more hygroscopic, they were more soluble in a number of solvents than the nitrate, perchlorate, phosphate, or sulfate salts.

Dissolution Rate—The dissolution rate of a pharmaceutical agent is of major importance to the formulator. In many cases, particularly with poorly soluble drugs, this characteristic best reflects the bioavailability of the com-

pound. As a rule, a pharmaceutical salt exhibits a higher dissolution rate than the corresponding conjugate acid or base at an equal pH, even though they may have the same equilibrium solubility. The explanation for this result lies in the processes that control dissolution.

Dissolution can be described by a diffusion layer model[1] in terms of an equation developed by Nernst and Brunner (97):

$$\frac{dW}{dt} = \frac{DS}{h}(C_s - C) \qquad \text{(Eq. 1)}$$

where W is the mass of the solute dissolved at time t, dW/dt is the rate of mass transfer per unit time, D is the solute molecule diffusion coefficient, S is the surface area of the dissolving solid, h is the diffusion layer thickness, C is the concentration of the drug in the bulk solution at time t, and C_s is the saturation solubility of the solute in the diffusion layer.

The driving force for dissolution in Eq. 1 is the difference between the saturation solubility of the drug and the concentration of the drug in the bulk fluid. If the drug is not rapidly absorbed after it dissolves, then C, the concentration in the bulk solution, approaches C_s and the dissolution rate is retarded. When this occurs, absorption is "absorption rate" limited (or "membrane transport" limited). If the absorption rate is rapid (or if the absorption mass transfer coefficient is much larger than DS/h of Eq. 1), however, C becomes negligible compared to C_s and dissolution occurs under "sink" conditions. Absorption is then said to be dissolution rate limited, which is what occurs with most poorly soluble drugs. In either case, an increase in C_s, as in salt formation, increases dissolution.

Salts often speed dissolution by effectively acting as their own buffers to alter the pH of the diffusion layer, thus increasing the solubility of the parent compound, C_s, in that layer over its inherent solubility at the pH of the dissolution medium. Hence, dissolution is controlled by solubility in the diffusion layer which, in turn, is determined by the pH of that layer. The influence of K_{sp} on the solubility term, C_s, and dissolution rate, should an accumulation of ions be allowed to occur, will be treated later.

Nelson (98), in a study of theophylline salts, was the first to show the correlation between diffusion layer pH and dissolution rate. The major impact that this study had on the pharmaceutical sciences was its conclusion that, if other factors remained constant, the dissolution rate of a compound determined the rate of buildup of blood levels with time and the maximum levels obtained. Those salts of the acidic theophylline with high diffusion layer pH's had greater *in vitro* dissolution rates than those exhibiting a lower diffusion layer pH. And, indeed, the rank order of dissolution rates correlated well with clinically determined blood levels. Presumably, the higher pH in the diffusion layer retards hydrolysis of the salt, thereby maintaining the anionic charge of the theophyllinate ion. This report led to many additional studies which illustrate the influence of the salt form on dissolution and the beneficial effects of changing nonionized drugs into salts.

Juncher and Raaschou (99) demonstrated that the rank order of peak blood levels of penicillin V, obtained upon administration of three different salts and the free acid, was the same as the rank order of their rates of dissolution *in vitro*. While the investigators ascribed these differences to the solubility properties of the salts, their experiments actually compared dissolution rates, not solubilities. The relative order of dissolution rates and mean maximal blood levels was: potassium salt > calcium salt > free acid > benzathine salt.

Nelson (100) determined dissolution rates for several weak acids and their sodium salts in media whose pH's represented GI fluids. In all cases, the sodium salt dissolved more rapidly than the free acid. This finding resolved the misconception that absorption of drugs is related only to solubility in the appropriate medium; rather, solubility affects absorption only to the extent that it affects dissolution rate. Absorption of drugs is a dynamic process, and the ultimate solubility of a drug in fluid at absorption sites is of limited consequence since absorption prevents the attainment of saturated solutions. Therefore, dissolution rate, more than solubility, influences absorption since it is a preceding process.

In two subsequent studies, Nelson and coworkers further illustrated the effects of changing nonionized drugs into salts. A report concerning tolbutamide (101), a weak acid, showed that the initial dissolution rate of tolbutamide sodium was approximately 5000 times more rapid than the free acid in acidic media and 300 times more rapid in neutral media. This difference, measured *in vitro*, reflected the differences observed between the free acid and the salt when administered to human subjects. Oral administration of tolbutamide sodium produced an immediate drop in blood sugar comparable to that produced by intravenous injection of the salt, while the slowly dissolving tolbutamide produced a smooth, sustained fall in blood sugar (102).

Correlation of urinary excretion rates and dissolution rates of tetracycline and some of its acid salts also was demonstrated by Nelson (103). The salts that exhibited greater *in vitro* dissolution rates showed greater urinary excretion rates, indicating more rapid absorption.

Benet (104), in a discussion of the biopharmaceutical basis for drug design, referred to the influence of the salt form on dissolution. He compared the dissolution rates of tetracycline and tolbutamide and their salts, as reported in the studies previously cited, and explained why the rates differ at the pH's exhibited by physiological fluids.

Although salt formation usually increases the dissolution rate of a drug, studies with aluminum acetylsalicylate (105, 106), warfarin sodium (107), and benzphetamine pamoate (108) showed that administration of the salt *slowed* dissolution of the drug and subsequent absorption compared to the nonionized form. This decrease appeared to result from precipitation of an insoluble particle or film on the surface of the tablet. Such a phenomenon decreases the effective surface area and prevents deaggregation of the particles. Theoretical considerations of the processes controlling dissolution of an acid salt of a base (108) and the sodium salt of a weak acid (109, 110) in reactive media have been discussed.

Tablet processing and various formulation factors can decrease the dissolution rate of a salt in human gastric juice over its nonionized form (111). Granulation and tableting caused the dissolution rate of phenobarbital sodium to

[1] The authors recognize the existence of other models; this one was chosen simply for illustrative purposes.

decrease but had the opposite effect on phenobarbital. Therefore, as a tablet dosage form, the dissolution rate of the sodium salt was slower than that of the free acid. These results were attributed to differences in the disintegrating properties of the tablets; in some instances, rapid dissolution may in fact be a problem for very soluble drugs.

Others have illustrated a phenomenon that decreases the dissolution rate of a salt below that of its nonionized form. Lin *et al.* (112) studied the relationship between salts and biological activity by dissolving three salts and the free base of an experimental antihypertensive in water, 0.1 *N* HCl, and pH 7.2 phosphate buffer. The dissolution rate of the monohydrochloride salt was lower than that of the free base in 0.1 *N* HCl and higher than the free base in both water and phosphate buffer. These authors ascribed this variation to the common ion effect and substantiated it experimentally. Although the biological activity of the monohydrochloride was greater than that of the free base, the implications of altered absorption characteristics on the activity of any other hydrochloride salt in GI fluids must be considered. Similar results also were reported for hydrochloride salts of some tetracyclines (113).

Some consideration must be given to the influence of salt formation on oral toxicity, which often reflects the relationship between the *in vivo* dissolution rate and the appearance of drug in the circulation (114, 115). Morozowich *et al.* (114) showed that the relative toxicities of a series of salts of a drug reflect the rate of absorption, providing the salt-forming agents themselves are relatively nontoxic. They stated that "when absorption is rate-limited by dissolution of the salt in the gastrointestinal tract, as will be the case with slowly soluble salts, the toxicity of a slowly dissolving salt will most probably be lower than that of a more rapidly dissolving salt." The implications of salt formation on toxicology will be discussed under *Toxicological Considerations.*

Several reviews dealt with the influence of the dissolution rate on drug availability and, in particular, salt effects (116, 117). Other reports illustrating the influence of salts and salt form on dissolution rate are listed in Table IV.

Solubility—Knowledge of the solubility characteristics of a pharmaceutical agent is essential, because solubility is usually an important factor in the pharmacokinetic profile, the chemical stability, and, ultimately, the formulation of the drug. As discussed previously, it is certainly a primary factor in controlling dissolution rates. The solubility of a compound depends basically upon the physical and chemical properties of the solute; *e.g.*, a lower melting point for a compound within a series reflects a decreased lattice energy, which would suggest a higher solubility. Solubility depends as well upon such elements as temperature, pressure, solvent properties (such as resulting pH), and, to a lesser extent, the state of subdivision of the solute.

An important solvent property which is often overlooked involves the common ion effect; in particular, hydrochloride salts of drugs often exhibit less than desirable solubility in gastric juice because of the abundance of chloride ions. The equilibrium involved is shown in Scheme I.

$$DH^+Cl^-_{(solid)} \overset{K_{sp}}{\rightleftharpoons} (DH^+)_{aq} + (Cl^-)_{aq}$$

Scheme I

Salt formation is perhaps one of the first approaches considered as a means of increasing a compound's water solubility. As with dissolution rates, however, salt formation does not always confer greater solubility. Liberally dispersed throughout the pharmaceutical literature are studies that compare the solubilities of different salt forms of the same compound with those of its free acid or base (Table IV). Selection of the salt form exhibiting the desired solubility properties is critical, since these properties often dictate the formulation characteristics of the drug.

Phase solubility techniques were used to study the formation of complex salts of triamterene (127). The results indicated that the organic acid salts of basic drugs, such as amines, were more soluble in water than the corresponding inorganic (halide) salts. This consideration is important in the synthesis and selection of a salt form that will exhibit enhanced bioavailability and desirable formulation characteristics.

The hydrogen-ion concentration can significantly affect the solubility of a salt. Anderson (128) discussed the influence of pH on the solubility of pharmaceuticals. Mathematical relationships between pH and solubility of therapeutically useful weak acids and bases and their salts were given along with some considerations in the formulation of solutions of these particular agents.

An extensive study on the solubility interrelationships of the hydrochloride and free base of two pharmaceutically useful amines was reported (129). Mathematical equations describing the total solubility at an arbitrary pH in terms of the independent solubilities of the hydrochloride and free base species and the dissociation constant of the salt were derived and fitted to experimental data with good results. This report elucidated the point that, while the solubility of the amine hydrochloride generally sets the maximum obtainable concentration for a given amine, the solubility of the free base and the pKa determine the maximum pH at which formulation as a solution is possible (assuming that the desired concentration exceeds the free base solubility). Shifting the pH–solubility profile to higher pH values for formulation purposes may require increasing the solubility of the free base. This increase might be accomplished by using an appropriate cosolvent. Since the dissociation characteristics of carboxylic acids and other acidic organic species are similar to those of organic hydrochlorides, it is expected that the pH–solubility profiles

of these organic acids, although reversed, can be characterized theoretically using the same treatment.

Several reports showed that the structure of an organic salt-forming radical influences the solubility of the resulting salt. The water solubilities of 16 salts (carboxylates, sulfates, sulfamates, and phosphates) of the weak base erythromycin were dependent on the size of the alkyl group of the acid (130). In a study with *N*-alkylsulfamates of lincomycin (66), a similar phenomenon was observed: solubility of these salts decreased as the size of the alkyl group attached to the acidic function increased.

Senior (131), in a study on the formulation and properties of the antibacterial chlorhexidine, determined the water solubilities of 35 salts and the free base. He found that inorganic salts had remarkably low solubilities while those of the lower aliphatic acids proved to be somewhat more soluble. Hydroxylation of the acid increased solubility, since salt formation with polyhydroxy acids, particularly the sugar acids, conferred extensive water solubility to the molecule.

Several investigators reported the influence of the solubility of a drug on its formulation and subsequent availability from the dosage form. In a discussion of the preparation and formulation of epinephrine salts in an aerosol system using liquefied gas propellants, Sciarra *et al.* (132) pointed out that the solubility characteristics of the agent are important in two respects. First, the solubility of the therapeutically active ingredient in the various propellants is an important consideration if the product is to be used for either local action in the lungs or systemic therapy. Second, the solubility of the drug in extracellular fluids plays an important role in selection of the compound. The bitartrate, malate, maleate, and fumarate salts of epinephrine were prepared and subjected to solubility and stability studies. While all salts had similar partition coefficients, the solubility of the maleate in several propellants and its stability in formulated aerosols made it the drug form of choice.

Ephedrine hydrochloride was more rapidly released than the free base from theobroma oil suppositories containing different surfactants (133). This enhanced rate of release (dialysis) was ascribed primarily to the greater aqueous solubility of the hydrochloride, which solubilized faster from the oil-in-water emulsion, whereas the ephedrine alkaloid base tended to remain behind in the oil phase.

The solubility of the active ingredient in ointment bases can dramatically influence its diffusion properties. A study of salicylic acid and its sodium salt showed that the diffusion of both was very low from hydrophobic bases, whereas the solubility of the drug significantly affected the diffusion from hydrophilic bases. The more soluble sodium salicylate diffused much faster from these latter bases than did salicylic acid (134).

Additional references on the relationship of salt form and solubility are listed in Table V.

Organoleptic Properties—Modern medicine requires that a pharmaceutical formulation be efficacious, safe, stable, and acceptable to the patient. Of primary importance in the development of oral dosage forms is taste acceptability. This factor presents no major problems when the drug is to be administered as a tablet or a capsule and swallowed as a unit but is clearly a prominent factor in patient acceptability when it is to be administered as a liquid, chewable tablet, or lozenge.

Since taste is a chemical sense, a substance must be dissolved if it is to elicit a taste sensation—either by taking it as a solution or by its dissolving in the saliva. Therefore, one method used to minimize undesirable organoleptic properties of pharmaceuticals involves the preparation of a poorly soluble salt form of the drug such that the saturation concentration is less than the taste threshold.

Erythromycin estolate (lauryl sulfate) has approximately one-twelfth the solubility of the free base, is tasteless, and is useful in the formulation of oral suspensions (144). A study on erythromycin salts showed that the bitterness level was dependent on two properties: (*a*) the water solubility of the salt, which is dependent on the size of the alkyl group attached to the acid function; and (*b*) the strength of the acid used to form the salt, *i.e.*, the stability of the salt (130). The stearyl sulfamate salt possessed the most desirable organoleptic properties.

Many problems concerned with formulation and stability of topical and oral pharmaceuticals containing bacitracin have been overcome by incorporating bacitracin into the formulation as its zinc salt. One distinct advantage over the parent compound is its lack of taste, caused by its relative insolubility. Thus, it is the preferred drug form for preparations where taste is a factor (145). Taste panel evaluations of the comparative bitterness of bacitracin zinc and bacitracin indicate that the taste of the zinc salt is more easily masked and that the presence of a bitterness-masking adjuvant, such as sucrose, increases the bitterness threshold ratio differences between the two compounds even further (146).

Propoxyphene napsylate, nearly water insoluble, is only slightly bitter to the taste as compared to the highly water-soluble hydrochloride (147) and can be readily formulated into a flavored aqueous suspension. The taste of these suspensions can be improved significantly by the addition of a common ion (sodium or calcium napsylate) to depress solubility further.

A newer approach to the improvement of drug palatability has been to form insoluble salts with ion-exchange resins. Several investigators described and tested the practical application of this method (148–150). Spross *et al.* (149) outlined the conditions necessary for improving the palatability of a drug by adsorbing it onto an ion-exchange resin without appreciably modifying its pharmacological effects. They found that: (*a*) the degree of drug release from the ion-exchange adsorbate depends on the

equivalent quotient between the electrolytes in the surrounding fluid and the ionic drugs, (*b*) the amount of ions is far less in the saliva than in the gastric juice (the temporary electrolyte contents can be estimated at 0.05 mEq in the saliva and at 10 mEq in the gastric juice), and (*c*) the exchange rates should allow the equilibria to be attained within a fairly short period. Insoluble drug resinates formed between dextran gel[2] cation exchangers and several basic drugs were in many cases much more pleasant tasting than their parent compounds. Furthermore, release of the drug from the ion-exchange adsorbate was quite rapid and complete under conditions prevailing in the GI tract.

Similar findings were reported using a polymethacrylic acid ion-exchange resin (150). In addition, coating the adsorbate particles with a 4:1 ethylcellulose–hydroxypropyl methylcellulose mixture further reduced bitterness. While *in vitro* release from the uncoated resinate was rapid and complete, release from coated adsorbates varied with the extent of coating.

Another approach to improving the taste properties of pharmaceutical agents is to prepare a pleasant-tasting soluble salt of a poor-tasting parent drug. This approach often can be very difficult, however, since solubilization of the parent compound usually imparts its unpleasant taste to the preparation. Nevertheless, some success has been reported using the artificial sweeteners cyclamate sodium and saccharin.

As described earlier, formation of *N*-cyclohexylsulfamate salts of several drug substances has produced better tasting derivatives with enhanced solubility properties (31, 32). The physicochemical and toxicological properties of benzalkonium saccharinate and a series of saccharinates of other quaternary ammonium compounds were reported (151). While conventional quaternary ammonium compounds have a very bitter taste, their saccharin analogs are sweet.

Potassium salts frequently possess an unpleasant taste and a metallic aftertaste. The palatability of some potassium salts in flavored vehicles was reported (152); while the salts had similar taste thresholds at effective therapeutic levels, all potassium salts exhibited inferior palatability.

Table III includes several samples of other salts that exhibit an improved taste relative to their free acid or base forms.

Stability—The chemical and physical stability of a pharmaceutical must be known, because it can influence the choice of dosage form, the manufacturing and packaging, and the therapeutic efficacy of the final preparation. Systematic determination of the thermal stability, solution stability (at various pH's), and light sensitivity of a drug and its derivatives, both alone and in the presence of common additives, provides essential input toward selecting the most suitable derivative and dosage form.

Depending on the route of degradation, different salt forms impart different stability characteristics to the parent drug by various mechanisms. Most commonly used are sparingly soluble salts which, when used in the formulation of suspensions, reduce the amount of drug in solution and, hence, its degradation. Differences in hygroscopicity of several salts influence the stability of the drug in the dry state. In some cases, the salt-forming radical itself enhances the stability of the parent agent.

The stability of penicillin G and its salts has been widely studied due to the drug's therapeutic importance and its characteristic instability. Schwartz and Buckwalter (153) described some of the stability characteristics of this antibiotic, stating that, with present techniques, a solution of penicillin cannot be made stable for more than 2 weeks, even at refrigerator temperatures. They also discussed the use of suspensions of sparingly soluble amine salts in aqueous vehicles as a means of "allowing marketing of a 'ready-made' penicillin product." Procaine, benzathine, and hydrabamine salts are marketed, and their acceptable stability as aqueous suspensions is based mainly on their insolubility and the minimization of degradation in solution.

A theoretical treatment of the solubility of these salts was presented in which equations were derived for calculating the solubility as a function of pH and the pH of minimum solubility (154, 155). These equations are based on the mass action law and its relationship to the ionization constants of the amine and the penicillin and the solubility of the salt in water. Since the salt in solution is partially dissociated, further suppression of the solubility may be achieved by the common ion effect. Swintosky *et al.* (156) demonstrated this effect with penicillin G procaine by adding procaine hydrochloride to the preparation and further enhancing its stability. The 8-chlorotheophylline salt (or complex) of penicillin G was reported to be water soluble, yet stable in solution (157). Since 8-chlorotheophylline is acidic, it has been postulated that a buffer effect could account for the stabilization of this "salt."

While penicillin G procaine is more stable in aqueous vehicles, it is less thermally stable than the sodium or potassium salts, decomposing if heated much above 60°. The sodium and potassium salts are known to withstand heating up to 100° for 4 days with little loss in potency (158). This behavior might well be due to differences in melting points—*viz.*, 106° for penicillin G procaine and ~215° dec. for the potassium salt.

Since hydrolysis of penicillin is dependent on moisture content, preparations in which moisture is rigorously excluded are quite stable in the dry state. A study on the effect of moisture on penicillin salts found the calcium salt to be less hygroscopic than the sodium salt and, hence, more stable in moist atmospheres (159). Similarly, penicillin G potassium is also much less hygroscopic than penicillin G sodium and has become the preferred form for marketing in the dry state (160).

Several studies reported the relative stabilities of thiamine salts, particularly the hydrochloride and the mononitrate (161–163). The mononitrate is observed to be less hygroscopic and is accordingly much less water soluble than the hydrochloride. Investigations of various preparations including compressed tablets, multivitamin capsules, and dry-filled vitamin B complex capsules at various temperatures showed that the mononitrate was more stable than the hydrochloride (164, 165). The stabilities of numerous thiamine salts were studied in aqueous solution and in dry powder preparations with various excipients (166, 167). In aqueous solution, the resulting pH was the chief factor controlling hydrolysis and oxidative decomposition of thiamine salts; their stability as powder

[2] Sephadex.

preparations was related to their aqueous solubility, with the sparingly soluble salts being more stable (and presumably less hygroscopic).

An orally administered drug must be stable in acidic solution because it generally must pass intact through the acidic environment of the stomach if it is to exhibit therapeutic blood levels. The advantage of erythromycin estolate over the free base lies in its low solubility in gastric juice, which enables it to be administered with food without any decrease in attained blood levels. The salt is more stable in the stomach because it remains undissolved. Therefore, it retains its potency even when exposed to acidic environments for extended periods (144).

In a study on the preparation and characterization of lincomycin cyclamate (33), it was noted that the cyclamate salt had an enhanced thermal stability over the hydrochloride. In a subsequent report (168), differential thermal analysis and thermogravimetric analysis showed that while the hydrochloride easily undergoes thermal degradation, the cyclamate anion confers a considerably greater thermal stability on the lincomycin moiety.

Mullins and Macek (169) showed that the physical and chemical stability of the calcium salt of novobiocin makes it the form of choice for the formulation of a liquid preparation of the antibiotic. The amorphous calcium novobiocin salt proved to be tasteless, yet fully biologically active and perfectly stable in aqueous suspension. Neither the sodium salt nor the free acid is suitable; the sodium salt cannot be formulated in a liquid due to its chemical instability, while the crystalline free acid is not absorbed from the GI tract. Amorphous novobiocin is absorbed but is metastable in solution and slowly converts to the unabsorbed crystalline form.

Other reports of alterations in stability characteristics due to salt formation are listed in Table VI.

Miscellaneous Properties—The salt form has been reported to influence other physicochemical properties of a drug substance. Studies illustrating the effect of the salt-forming radical on surface tension, deaggregation behavior, and ion-pair extraction have appeared.

The influence of the anion on the absorption processes of two charged species, dextromethorphan and tetracycline, was studied in the rat stomach (186, 187). A linear relationship existed between the rate of absorption from buffer solutions of the anions under investigation and their surface tensions. Thus, the absorption process was related to the surface activity of the various salts and not to their lipid solubilities. This change of surface activity with the buffer (or salt) species is similar to the results reported in a study of the surface activity of various phenothiazine salts (188).

The antibacterial chlorhexidine possesses surface activity. A study of the colloidal properties of some chlorhexidine salts showed that the counterion can affect the critical micelle concentration of a surface-active agent, and this effect was usually associated with a change in micellar size (189).

The deaggregation behavior of a relatively insoluble acid and its sodium salt was studied, and deaggregation was postulated to be a possible rate-limiting step in the absorption of a drug from a dosage form (190). While no direct comparisons of the two forms were made, inspection of the data shows that the deaggregation rate of the salt was considerably more rapid than that of the free acid in equivalent dosage forms. Therefore, if absorption is dependent on the dissolution rate, which in turn is dependent on the deaggregation rate, the salt should produce the highest and earliest blood levels. On the other hand, it is possible that hygroscopic (and deliquescent) salts can absorb atmospheric moisture, cause a sticky surface, and inhibit deaggregation.

Higuchi and coworkers presented an extensive study on the physicochemical basis of the ion-pair extraction of pharmaceutical amines. Distribution ratios of dextromethorphan (191) and chlorpheniramine (192) between an organic layer and water were highly dependent on the concentration and nature of the anion present. Less hydrophilic anions yielded more readily extractable ion-pairs. A study of the thermodynamic properties, enthalpy, free energy, and entropy, involved in the extraction equilibria of dextromethorphan ion-pairs indicated that the entropy change associated with transfer of the different anions between phases is the main controlling factor in the extraction process (193).

BIOAVAILABILITY

Most drugs prescribed in the United States are administered in solid and polyphasic dosage forms. Consequently, dissolution of the drug must precede the absorption process. The simplest model that adequately describes this process is shown in Scheme II.

$$\text{solid drug} \xrightarrow[1]{\text{dissolution}} \text{dissolved drug} \xrightarrow[2]{\text{absorption}} \text{drug in circulation}$$

Scheme II

Since the dissolution rate is generally slow for drugs with poor solubility, Step 1 is frequently rate limiting in the overall absorption process. As a result, the onset, intensity, duration of pharmacological activity, and, hence, bioavailability are affected by changes in dissolution rate. As discussed previously, administering a salt of the parent drug often proves to be an effective means of altering dissolution rate and absorption.

Formulation Effects—Choice of the salt form of a drug may have a pronounced effect on the formulation of the parent compound. For example, Fenton and Warren (194) found there was no release of medicament from proflavine cream BPC, a water-in-oil emulsion containing 0.1% proflavine as the hemisulfate salt. They also investigated the release of various salts of proflavine with aliphatic carboxylic acids from water-in-oil cream emulsions. Salts formed with the water-soluble, oil-insoluble "lower" acids, such as formic and acetic acids, showed very poor release from a water-in-oil cream. The "higher" acid salts (*e.g.*, *n*-valeric, caproic, cyclohexanecarboxylic, and caprylic) all showed increased diffusion from similar emulsions since these salts are soluble in both water and oil. Their release was even greater from oil-in-water emulsions, however, in agreement with their preferential oil solubility. The *n*-valerate salt provided the most effective water-in-oil cream. The primary factor responsible for diffusion of proflavine from a water-in-oil cream is the low hydrophilic–lipophilic balance conveyed to the salt by the acid. This finding illustrates the desirability of carefully selecting the salt anion of a cationic drug in lieu of the nature of the dosage form.

Studies of the effect of formulation on the bioavailability of warfarin sodium relative to warfarin yielded interesting results (107, 195). Absorption of warfarin upon administration of the sodium salt as a lactose-base tablet was no better than that from a similar formulation of the free acid. In fact, absorption was further depressed when the salt was formulated with starch instead of lactose. Later results indicated that the *in vitro* water dissolution rate of a warfarin sodium tablet was 350 times that of a slowly dissolving warfarin tablet formulation, yet the latter exhibited rapid and complete absorption *in vivo*. The virtual insolubility of warfarin in acidic gastric fluids precluded its absorption from the stomach. However, the strongly acidic medium was necessary for tablet disintegration, which, in turn, was critical for absorption. Following initial exposure to 0.1 *N* HCl, *in vitro* dissolution of the warfarin tablet in pH 7.4 buffer was 14 times faster than that of the sodium salt, a result that explained the otherwise contradictory *in vivo* blood level data. Therefore, absorption was ultimately dependent upon gastric emptying rate and gastric pH, as long as the formulation disintegrated properly in the stomach.

The rectal absorption of aspirin, aspirin aluminum, and calcium carbaspirin from several suppository bases was studied in dogs (196). The absorption of aspirin aluminum from either cocoa butter or a polyethylene glycol base was poor. While the maximum salicylate levels produced by aspirin and calcium carbaspirin from the cocoa butter base occurred at a later time than from the other bases studied, minimal plasma levels were exhibited by a polysorbate 61 base formulation. The highest peak and largest area under the blood level curve were seen with calcium carbaspirin in a vegetable fatty acid glyceride base. The poor absorption of aspirin aluminum from suppositories was not unexpected since it is poorly soluble. Furthermore, as pointed out for aspirin aluminum tablets (105, 106), an insoluble aluminum compound may form on the surface of the dissolving drug, further impeding its dissolution rate and bioavailability.

Additional references on bioavailability and formulation effects are given in Table VII.

Absorption Alteration—Several years ago, clinicians claimed that certain salts of theophylline were therapeutically preferable to other salts or to the free acid (202–204). For example, Schluger *et al.* (204) found higher blood theophylline levels after administering uncoated tablets of theophylline ethylenediamine than were observed with enteric-coated tablets of choline theophyllinate. These results were at variance with the *in vivo* work of Gagliani *et al.* (202), who found that the oral ingestion of choline theophyllinate produced significantly higher blood levels than the ethylenediamine salt. This apparent discrepancy could be explained by the formulation effects of tablet coating, *etc.*, which was not discussed in the work of Gagliani *et al.* In another study, a slightly more rapid rise in blood concentration and a greater area under the curve were observed with theophylline isopropanolamine than with theophylline ethylenediamine (203). It was suggested that the difference was a result of the greater water solubility of the isopropanolamine salt.

The *in vitro* dissolution rates of the choline and isopropanolamine salts of theophylline have been observed to be three to five times greater than the ethylenediamine salt, depending on the dissolution medium (98). It has been suggested that these differences in dissolution rate are consistent with, and offer an explanation for, the clinical results.

In a comparative study of the absorption of ampicillin trihydrate and ampicillin potassium following oral administration (205), the potassium salt yielded 37% higher peak levels and a larger area under the curve. Only 36% of the administered ampicillin trihydrate was absorbed while 53% of the potassium salt was absorbed. Determining the percentage of each drug eliminated in the urine showed that 39% was eliminated following administration of the trihydrate and 52% from the potassium salt. The entire difference between the two drug forms was accounted for in the initial 4 hr postadministration.

Several studies compared blood levels obtained with erythromycin and its salts and esters. Erythromycin estolate produced blood levels that were severalfold higher than those obtained with erythromycin base or erythromycin stearate (206–208). These differences were found to persist in the fasting as well as nonfasting subjects (207), indicating that food did not appreciably alter the absorption of erythromycin estolate when given under single or

multiple dosing (207). This finding is explained by the fact that this salt is acid stable and alkaline dissociable, permitting its passage through the acid of the stomach both in fasting and nonfasting subjects (209). Accordingly, the antibacterial activity remained essentially the same when this form of erythromycin was given, regardless of the state of fasting of the subject (209).

On first inspection, the higher serum levels attained with erythromycin estolate suggest that the salt form is more readily absorbed. Also critical to efficacy, however, is the volume of distribution of the drug, since extensive binding to plasma proteins can render a drug unavailable for activity at the biophase. Therefore, the significance of blood level data greatly depends on the measure of the free or unbound fraction of total antibiotics in the blood, which more directly indicates probable therapeutic benefit.

Wiegand and Chun (210) showed that, despite the higher blood levels attained with erythromycin estolate (after correction for half-life differences), the stearate salt produced seven times more free drug in serum than did the estolate salt. This finding explained the higher total tissue levels observed on administration of the stearate. They attributed the difference to a greater serum protein binding of the intact erythromycin estolate, proving that its higher serum levels did not necessarily reflect more efficient absorption.

Marked differences have been observed following oral administration of various salts of penicillin. Penicillin G potassium has been compared with penicillin G benzathine (benzethacil) (211, 212), penicillin G hydrabamine (213), penicillin V (214), penicillin G procaine (212), and penicillin G ammonium (215). As anticipated, penicillin G potassium produced higher and earlier blood levels than penicillin G benzathine (211, 212). Furthermore, tablets of penicillin G potassium buffered with sodium citrate yielded higher peak levels than unbuffered penicillin G potassium. While the absorption of buffered tablets was apparently not significantly affected by food intake, the unbuffered tablets yielded lower average levels and irregular absorption under similar conditions.

When penicillin G potassium was compared with penicillin G hydrabamine (213), a less soluble salt, blood levels similar to those produced by penicillin G benzathine were observed. When equivalent doses were administered, the penicillemia that occurred with penicillin G hydrabamine was only one-third or one-fourth as great and was of shorter duration than that produced by penicillin G potassium.

Budolfsen *et al.* (212) found that peak concentrations of penicillin G potassium were three to four times those obtained with penicillin G procaine and five to six times those of penicillin G benzathine, indicating a more rapid rate of absorption. The therapeutic action was related to the maximum concentration attained, but it also depended on the persistence of penicillemia, which was greater with penicillin G potassium than with the other two compounds. The authors suggested that the lower blood levels attained with the relatively insoluble penicillin G benzathine were caused by its destruction in the GI tract prior to absorption. This suggestion seems unlikely, however, since the drug should not degrade very rapidly as an undissolved suspension.

Because of its superior stability in gastric juice, penicillin V produces higher blood penicillin levels than corresponding doses of penicillin G. As a result, extensive investigations have been conducted with various salts of penicillin V (99, 214–220). For instance, tablets, capsules, and oral suspensions of penicillin V acid produced significantly higher blood concentrations than comparable penicillin G preparations (214). In the same study, the average serum levels produced by the benzathine salt of penicillin V were significantly higher than comparable doses of penicillin G benzathine for the first 4 hr but lower thereafter, again illustrating the value of using an insoluble salt to prolong blood levels of an acid-unstable compound. In another study (215), penicillin V acid was shown to produce higher and more prolonged plasma concentrations than either penicillin G potassium or ammonium, whose properties were comparable.

Plasma levels were correlated with dissolution rates of various forms of penicillin V (99). As solid dosage forms, the readily soluble potassium and calcium salts produced earlier and higher blood levels in fasting subjects than either the free acid or its benzathine salt. On the other hand, when the potassium and benzathine salts were administered orally as solutions, absorption was the same, implying that the poor solubility of the benzathine salt was responsible for the inferior blood levels obtained from its solid dosage forms. Other studies found that, while the potassium salt is 40% better absorbed than the free acid in fasting subjects, both forms produce therapeutic levels when administered with food (218).

Experiments with fistulated dogs indicated that penicillin V is absorbed primarily from the stomach. Therefore, it is not surprising that the potassium salt should show higher blood levels on oral administration since it is the most soluble salt in gastric pH (216). In accordance with this observation, it was also reported that the benzathine salt exhibited higher serum levels in patients with gastric achlorhydria (pernicious anemia) than in patients with normal gastric function (219). Differences in gastric emptying time may also explain this result.

Several studies compared the absorption of tetracycline and its salts (103, 221, 222). For example, serum concentrations in dogs and humans showed that a phosphate complex salt of tetracycline was absorbed more rapidly and gave higher blood levels during the first 6–8 hr than did tetracycline hydrochloride (221). The total amount of drug absorbed was about twice as great with the former compound.

Another study (222) suggested that tetracycline base produced higher blood levels than tetracycline hydrochloride. However, a subsequent investigation (223) showed that, in the absence of adjuvants or fillers, tetracycline hydrochloride and tetracycline base were absorbed equally well. Results obtained in this same study indicated that tetracycline hydrochloride encapsulated with citric acid produced higher serum concentrations than tetracycline hydrochloride mixed with hexametaphosphate or the phosphate complex salt of tetracycline.

In a study comparing urinary excretion rates and *in vitro* dissolution, the absorption of tetracycline and tetracycline phenolsulfonaphthaleinate was rate limited by their dissolution rates, whereas tetracycline hydrochloride absorption was rate limited by the absorption process itself (103).

Several lincomycin salts were studied for their comparative availability (224). In particular, the blood levels obtained with the relatively water-insoluble hexadecylsulfamate salt were compared to those of the hydrochloride following oral administration. Higher and extended whole blood and serum concentrations were obtained in mice, rats, and dogs with the hexadecylsulfamate. However, subcutaneously administered lincomycin did not produce significantly different fractions absorbed, regardless of which salt was administered. It is not known whether the greater area under the curve with oral administration of lincomycin hexadecylsulfamate is due to greater absorption from the GI tract, slower renal clearance, or greater enterohepatic circulations.

Salts of streptomycin, neomycin, viomycin, and streptothrycin have been formed with: (*a*) polyacrylic acids, (*b*) sulfonic or phosphorylated polysaccharides, and (*c*) natural polycarboxyl acids from a series of polyuronic substances and polysaccharide derivatives containing carboxyl groups (18). The report indicated that these salts were absorbed from the injection locus primarily by the lymph system. Blood levels from the salts were generally lower but were maintained for a longer time than the equivalent amount of antibiotic alone, and higher concentrations of longer duration may actually be produced in the lymphatic drainage.

The influence of salt formation on the onset and duration of pharmacological activity also was illustrated with tolbutamide and several of its salts (101). Following oral administration, the sodium salt produced a rapid decrease in blood sugar level followed by a rapid recovery. By contrast, the free acid of tolbutamide caused a slow and prolonged drop in blood sugar level, a preferred effect since the chance of hypoglycemic shock would be lessened. This finding also illustrates the often overriding influence of the actual disease state on the choice of drug form.

Additional references on the implications of salt formation on absorption are listed in Table VIII.

Pharmacokinetics—Because of the various new properties that are usually imposed on a compound by salt formation, the pharmacokinetics of the drug necessarily change as a function of these properties.

For example, a pharmacokinetic evaluation comparing ampicillin sodium and potassium with ampicillin trihydrate was performed after oral administration to beagle dogs (243). The absorption rate constants of the sodium and potassium salts, which were similar, proved significantly greater than the rate constant of ampicillin trihydrate, resulting in earlier, higher peak concentrations with two to three times higher serum concentrations during the 1st hr. Yet, any differences between the fraction absorbed for the three products were not statistically significant. Apparently, although dissolution of the ampicillin trihydrate was the rate-limiting step in its absorption, the overall extent of bioavailability remained unaffected.

An interesting study of the biliary excretion of erythromycin base and erythromycin estolate was reported (244). The biliary excretion of erythromycin base was high, while that of erythromycin estolate was much lower; preferential secretion of erythromycin in the bile could partially account for the lower serum levels exhibited by the base. However, the proportion of the ingested dose secreted in the bile was small, and the total amounts involved were not sufficient to account entirely for the differences in serum concentrations attained. Undoubtedly, the protein binding studies of Wiegand and Chun (210) (discussed under *Absorption Alteration*) more satisfactorily explain the difference in serum concentrations.

Often, salt formation can be used to modify drug absorption and dose tolerance favorably. For example, aminosalicylic acid exhibits a short half-life and, therefore, requires large and frequent doses which may cause gastric irritation. Consequently, different chemical forms such as salts have been prepared (119, 245–247) to reduce the incidence of gastric irritation, increase absorption, and prolong blood levels.

Aminosalicylic acid is an interesting example in other ways; considerable confusion about this drug exists because many fail to recognize its nonlinear pharmacokinetics. Several definitive studies were reported regarding the absorption of the acid and its sodium, potassium, and calcium salts from solution, suspension, and tablet formulations (245, 246). Comparison of the relative bioavailabilities of aminosalicylic acid suspended in water and its salts dissolved in water showed that, while differences in rate of absorption were found to exist, absorption of both the acid and its salts was essentially complete. Absorption of the free acid from tablets reached only 77% of the dose, whereas that of the tableted salts was rapid and complete.

Regardless of formulation, the area under the plasma concentration–time curve of unmetabolized drug from free acid administration was less than that for the salts. This result was attributed to concentration-dependent metabolism during absorption: when the rate of absorption is high, the metabolic processes become saturated and more unmetabolized drug remains in the blood; conversely,

GENERAL PHARMACY

Pharmacological Effect—Chlorpromazine hydrochloride and quaternary chlorpromazine chloride were investigated with respect to their effects on the central nervous system (CNS) (253). The quaternized compound was less potent and more toxic in rodents than the parent tertiary compound.

Naloxone, an effective opiate antagonist, is generally used as the hydrochloride salt; however, the drug has a very short duration of action. The mucate salt was prepared to extend its duration of action, since mucic acid is only slightly soluble in water (254). In a test on the blocking of morphine activity in mice, however, the mucate salt did not differ in duration from the hydrochloride. These investigators assumed the same receptor site for naloxone as for morphine and, since Heron's (232) work suggested that the receptor had a greater affinity for morphine mucate than for the free base, it also should have a greater affinity for naloxone mucate. The results disproved this hypothesis. Furthermore, this theory implies that intact salt reaches the receptor, which is highly unlikely, regardless of whether the drug is administered as a solution or as a suspension.

A series of salts of 9-aminoacridine and its derivatives was prepared and screened for antifungal and antibacterial activity (255–257). By using salts of fatty acids, the antifungal action was found to parallel the length of the carbon chain of the anion, with maximal activity occurring with acridine caproate, undecylate, and undecylenate (where undecylenic acid also exhibits some intrinsic antifungal activity) (255). This result appears reasonable, because these salts would be more lipid soluble and could be expected to pass through the cell wall of the infecting organism more readily, probably as an ion-pair.

The efficacy of bases or salts as topical anesthetics for relieving cutaneous itch, burning, and pain in unbroken skin has also been examined (258). In these experiments, itching and pricking were induced by an alternating current of low amperage and voltage applied to the skin or by exposure of the skin to UV light. Interestingly, aqueous solutions of salts of the local anesthetics did not alleviate itching or burning in any of the subjects, although saturated solutions of their bases in a mixture of water, 40% alcohol, and 10% glycerol were claimed to be effective. Such transport phenomena across the stratum corneum are often dependent on the polarity of the drug and vehicle and on the binding of the drug to keratin.

Dialysis—Dialysis through a cellophane membrane of the hydrochloride or sodium salts has been studied with several drugs (270). In many cases, it appeared that the ionic form of the drug was bound to the membrane whereas the nonionized form was not. Ephedrine hydrochloride presented an interesting example, however, since it dialyzed considerably faster than its corresponding base. It was theorized that the chloride ion dialyzed rapidly, enhancing the rate of dialysis of the ephedrine ion. Accordingly, when chloride ion was present on both sides of the membrane, the observed rate of dialysis for the ephedrine ion was comparable to the ephedrine base.

The diffusion of sodium chloride through a lipoprotein interface was very slow, especially if calcium chloride was present on both sides of the interface (271). In the presence of low concentrations of choline chloride or carbamylcholine chloride, the diffusion of sodium chloride is more rapid. Apparently, choline salts are able to increase the permeability of the lipoprotein to salts, which may relate to the physiological action of choline salts.

Miscellaneous—Release rates were determined for aminophylline, ephedrine alkaloid, and ephedrine hydrochloride from theobroma oil suppositories containing nonionic surfactants (133). While surfactants with hydrophilic–lipophilic balance (HLB) values less than 11 only minimally affected release rate, rates increased with surfactants of HLB values greater than 11. Under optimal conditions, aminophylline was faster than ephedrine hydrochloride which, in turn, was superior to the ephedrine base.

Willis and Banker (272) reported on the formation of polymer–drug salts as an approach to the physicochemical design of dosage forms. Poly(methyl vinyl ether/maleic

anhydride) salts of methapyrilene were prepared and tested with the free base for *in vitro* dissolution and dialysis. Their dissolution and dialysis rates were not appreciably different from the free drug or its hydrochloride salt. Various poly(methyl vinyl ether/maleic anhydride) hemiester salts of methapyrilene exhibited substantially slower release than the polymer ether salts, hydrochloride salt, or free base forms. Polymer–drug salts thus appear to have promise.

A series of metallic salts of edetic (ethylenediaminetetraacetic) acid were tested *in vitro* to determine their effect on blood coagulation (273). The results showed that only the dipotassium and disodium salts had any effect on coagulation. It was theorized that the lack of anticoagulant activity resulted from an almost complete suppression of ionization of the heavy metal salts.

Interesting research regarding the angina-preventive effect of some chromone-2-carboxylate salts showed a direct correlation between biological activity and pKa of the salt-forming amines (274).

Lin *et al.* (112) investigated the relationship between salt form and biological activity of a given antihypertensive. While the intrinsic dissolution rates of the dihydrochloride and disulfate salts were many fold greater than the monohydrochloride, the hypotensive potencies of the salts did not differ significantly from one another in an anesthetized dog study. Yet, when administered to renal hypertensive dogs, the dihydrochloride and disulfate salts produced greater hypotensive effects than did the monohydrochloride.

TOXICOLOGICAL CONSIDERATIONS

Toxicity of Salt Ion—Any discussion regarding the toxicity of salts of a drug must consider the pharmacological properties of the cation or anion used to form the salt as well as those of the free drug, since any of these may produce toxic effects. The toxicology of several ions that are commonly used to form salts and that are relevant to this review were discussed in depth (275).

Toxicity from ingestion of calcium salts of drugs is rare. If hypercalcemia occurs, however, calcium deposits in the kidney can bring on a reduction of renal function. The principal toxic effects of lithium also involve the kidneys. When small amounts of lithium are taken, no apparent damage occurs; yet large amounts of the metal can lead to irreversible damage. An apparent correlation was observed between lithium dosage and sodium intake (276). When lithium dosage was low or sodium intake was high, rats were able to excrete all lithium given and sustained a reversible polyuria. Conversely, if large amounts of lithium were administered to the rats or if their sodium intake was lowered, they incurred irreversible kidney damage. Ammonium ion, although it serves a major role in maintenance of the acid–base balance of the body, can be toxic in high concentrations and initiate CNS derangements.

Sulfate ions given orally tend to be minimally absorbed and may act as a laxative. The nitrate ion is irritating to the GI tract, causing nausea and gastric distress. Also, intestinal bacteria may convert the nitrate ion to nitrite which oxidizes hemoglobin to methemoglobin. The citrate ion, an intermediary in carbohydrate metabolism, can form a soluble complex with calcium which is poorly dissociable and rarely causes any toxic reactions. While tartrate ions are usually absorbed minimally from the GI tract, high concentrations reaching the circulation can cause renal damage.

Acetate and lactate ions are normal metabolites and appear to be well tolerated in relatively large amounts. Iodide and bromide ions can produce conditions known as iodism and bromidism, respectively. Bromide intoxication occurs quite frequently, since bromides are used as ingredients in some nonprescription preparations (277–280). Bromide is slowly excreted by the kidney (its half-life is 12 days) and tends to accumulate when taken for prolonged periods or when used by patients with decreased renal function (277).

Toxicity of Salt Form—Provided the salt-forming agents are nontoxic, the relative toxicities of a series of salts of a compound are often observed to reflect directly their absorption rates. For example, the toxicities of dibromide, dichloride, diiodide, and dimethylsulfate salts of quinapyramine[3], a trypanocidal drug, were determined (238). The sparingly soluble halogen salts were much less toxic subcutaneously or intramuscularly than the freely soluble dimethylsulfate, yet all salts showed about equal toxicity upon intravenous administration. The difference in toxicities obviously resulted from rapid absorption of the methylsulfate compared to the slowly absorbed, poorly soluble halogen salts. Similar reasoning has been used to explain the acute oral toxicity of propoxyphene hydrochloride in rodents, which is twice that of equimolar doses of the napsylate salt (281).

Several salts of benzphetamine and etryptamine were prepared as potential sustained-release formulations (114). The water solubility, *in vitro* dissolution rates at pH 1.0 and 7.2, and the median lethal times (LT_{50}) were determined for each salt. Both the LT_{50} and LD_{50} (determined on only a few salts) increased as the *in vitro* dissolution rate at pH 7.2 decreased. While dissolution at pH 1.0 did not correlate well with toxicity, the LT_{50}'s were inversely related to the square root of the dissolution rates at pH 7.2.

Toxicity studies comparing iopanoic acid, a cholecystographic contrast medium, with its sodium salt (115) showed that the salt form has 10-fold greater toxicity. The LD_{50}'s of the free acid and the salt were 22 and 2.32 g/kg, respectively. It was postulated that the free acid precipitated from the sodium salt upon its reaction with gastric hydrochloric acid. The fine, amorphous particles of precipitated acid had a greatly increased surface area and, therefore, dissolved more rapidly than even fine crystals of the free acid. The faster and more complete drug absorption then resulted in increased toxicity.

Salts exhibiting greater water solubility than their parent compounds or less soluble salts are not always more toxic. For example, various inorganic and organic ions were used to prepare salts of methyl pyridinium-2-aldoxime that would have greater water solubility and would eliminate undesirable side effects due to the iodide ion (95). Even though the aqueous solubility of the majority of these salts was many times greater than the iodide, their toxicity on a molar basis was not significantly different, with the exception of the dihydrogen phosphate salt which was 15%

[3] Aritrycide.

more toxic. Further research with oximes revealed that other salts are also toxic (282).

GI bleeding is a common toxic effect of aspirin for a large percentage of the population. Consequently, a search was initiated for an aspirin derivative that would not induce GI blood loss (283). All compounds prepared, however, including the sodium and calcium salts, caused GI hemorrhage with a severity similar to aspirin.

Polyene antibiotics are potent antifungal agents but bear considerable toxicity. Even though the methyl ester hydrochlorides of these compounds are more soluble, they retain almost all of their antifungal activity and, more significantly, show a uniform decrease in toxicity compared to their parent compounds (284).

Additional references on toxicological considerations of salt formation are given in Table XI.

CONCLUSIONS

Salt formation is a means of altering the physical, chemical, and biological characteristics of a drug without modifying its chemical structure. Clearly, the salt form can have a dramatic influence on the overall properties of the parent compound. At present, selecting a salt form that exhibits the desired combination of properties is a difficult semiempirical choice. Pharmaceutical scientists now recognize these facts and are beginning to study the effects of different salt forms on the physicochemical properties, bioavailability, and toxicity of drug substances.

Although now only a few generalizations are available to predict the effect of particular salt forms on the characteristics of a drug, perhaps in time it will be possible to evolve increasingly more powerful generalizations regarding the effect of a salt on the properties of its parent compound. In addition, we predict that polymer–drug salts will have a revolutionary effect on future trends in drug therapy, particularly in the areas of reducing drug toxicity and in controlling the release profile of novel drug delivery systems.

Separation and Analysis of Δ^9-Tetrahydrocannabinol in Biological Fluids by High-Pressure Liquid Chromatography and GLC

EDWARD R. GARRETT [x] and C. ANTHONY HUNT *

Abstract □ High-pressure liquid chromatographic (HPLC) systems were developed to separate quantitatively Δ^9-tetrahydrocannabinol from heptane-extractable lipoidal and other endogenous substances in biological fluids. These substances interfered with the quantitation by flame-ionization GLC of the unmodified compound and by electron-capture GLC of the pentafluorobenzoyl derivative. Reversed-phase HPLC elution, with 47% acetonitrile in water, and normal-phase HPLC with 25% chloroform in heptane separated Δ^9-tetrahydrocannabinol from 11-hydroxy-Δ^9-tetrahydrocannabinol and other monohydroxylated tetrahydrocannabinols. These systems also purified stock solutions of Δ^9-tetrahydrocannabinol from accompanying contaminants. The various monohydroxylated tetrahydrocannabinols were resolved from each other in the normal phase, 80% chloroform in heptane. The Δ^8- and Δ^9-tetrahydrocannabinols were separable in the normal phase with 5% tetrahydrofuran in hexane. The GLC analysis of pentafluorobenzoylated Δ^9-tetrahydrocannabinol had a sensitivity of 1 ng/ml of plasma, with an estimated 5% standard error with the developed extraction and GLC procedures. Radiochemical analysis of the HPLC-separated fraction had a sensitivity of 0.2 ng/ml of plasma, with an estimated 2% standard error. There was no significant difference between the liquid scintillation and electron-capture GLC assays of the HPLC-separated Δ^9-tetrahydrocannabinol obtained from the plasma of dogs administered the drug. Radiolabeled compounds can be added to plasma samples as internal standards to determine the recovery efficiencies of the several procedures in the analysis of unlabeled tetrahydrocannabinol.

Keyphrases □ Δ^9-Tetrahydrocannabinol—GLC and high-pressure liquid chromatographic analyses, biological fluids □ GLC—analysis, Δ^9-tetrahydrocannabinol in biological fluids □ High-pressure liquid chromatography—analysis, Δ^9-tetrahydrocannabinol in biological fluids

A GLC method for tetrahydrocannabinol in biological fluids was developed previously (1) and used electron-capture detection of the derived pentafluorobenzoylated tetrahydrocannabinol. It could readily detect 0.5 ng of tetrahydrocannabinol added to a 5.0-ml blood sample from a fasting dog. This sensitivity was only obtained when it was realized that tetrahydrocannabinol bound extensively (15–40%) to glass (1, 2) and rubber stoppers (2) and that the time-dependent degree of adsorption could be minimized by prior treatment of all glassware with an organic solution of a silyl reagent[1]. In the case of organic solutions, the tetrahydrocannabinol could be reincorporated from the glass into solution by vigorous shaking prior to any sampling.

The method's validity was demonstrated in the fasting dog with a low fat diet. Plasma levels down to 1 ng/ml of blood from 5-ml blood samples were monitored for 12 hr after the administration of 0.1 mg of pure tetrahydrocannabinol/kg (1). However, when the same method was applied to nonfasting animals, a significant increase in the GLC background from interfering plasma constituents was observed, particularly within 4 hr of feeding a previously fasted animal. The resultant minimal detectable quantity unfortunately increased to 5–10 ng/ml when a 5-ml blood sample was taken.

Since pharmacokinetic studies were contemplated in both dogs and humans over longer periods so that fasting would be impractical, such interferences were anticipated that would lower the analytical sensitivity. Thus, it was necessary to devise suitable separation and cleanup procedures prior to analysis to improve the sensitivity.

High-pressure liquid chromatography (HPLC) provided a powerful method of separation of drugs from their potential metabolites and from endogenous substances in biological fluids. While the classical on-line monitoring devices such as refractive index or UV spectrophotometry were too insensitive for direct assay at the plasma levels anticipated, the separated collected pertinent fractions were analyzed by analytical methods that provided the proper sensitivities. This paper presents HPLC techniques to separate tetrahydrocannabinol from various cannabinoids and interfering endogenous materials of biological fluids with subsequent analysis by various appropriate methods.

EXPERIMENTAL

Materials—Δ^9-Tetrahydrocannabinol[2], cannabinol[3], cannabidiol[4], 11-hydroxy-Δ^9-tetrahydrocannabinol[5], 8α-hydroxy-Δ^9-tetrahydrocannabinol[6], 8β-hydroxy-Δ^9-tetrahydrocannabinol[7], ^{3}H-11-hydroxy-Δ^9-tetrahydrocannabinol[8], and ^{14}C-Δ^9-tetrahydrocannabinol[9] were used.

Liquid Scintillation—Two different instruments were used. In one system[10], two of three channels were set specifically to read tritium and carbon-14. In the other system[11], all three channels were used. All samples were counted for 10 min with a blank inserted at the start of every 50 samples.

The degree of quench of each sample was estimated from the channel ratios of the sample and from known standards. When quench was indicated, it was calculated after addition of a ^{14}C-toluene or tritiated water standard. All samples were allowed to adapt to the dark, and this adaptation was checked by recounting selected samples.

[1] Rinsing glass for 30 min with a 1% (v/v) solution of Sil-Prep (Applied Sciences Laboratories, State College, PA 16801) in dichloromethane reduced adsorption to less than 5%. This rinsing was followed by a solvent rinse of dichloromethane and drying.

GLC—A gas chromatograph[12], fitted with both ^{63}Ni- and flame-ionization detectors, was used. Detectors were maintained between 270 and 285°. The ^{63}Ni-detector had a separate nitrogen gas flow of 35 ml/min, and the glass columns were 30 cm or 1.8 m (6 ft) long (2.0 mm i.d.). The conditions were: column, 210–230°; injection port, 245°; 3% OV-225 on 100–120-mesh Gas Chrom Q or 3% OV-17 on 100–120-mesh Gas Chrom Q; nitrogen gas flow, 35–45 ml/min; standing current (^{63}Ni), 60–90% at 2×10^{-9}; and background noise, 2–3% at 1×10^{-10}.

HPLC—A chromatograph[13], equipped with a 6000-psi constant-flow pump, a 254-nm UV detector, and a differential refractometer detector, was used. The columns were either a low polarity 0.61-m (2-ft) × 0.3-cm (0.125-in.) Bondapak-C_{18} Corasil [with a $(CH_2)_{17}CH_3$ surface functionality], designed for reversed-phase chromatography, or a high polarity 30-cm μ-Porasil (with a SiOSiOH surface functionality), designed for normal-phase chromatography. All on-column injections were made under constant-flow conditions. Special high quality solvents[14] were used.

Extraction of ^{14}C-Δ^9-Tetrahydrocannabinol from Plasma—A 2-ml plasma sample containing the ^{14}C-Δ^9-tetrahydrocannabinol was transferred to a silylated 50-ml glass centrifuge tube. The pH was adjusted between 9.5 and 11.0 by addition of 0.1 *N* Na_2CO_3 (0.2–0.5 ml) prepared from water purified by HPLC using a clean Bondapak-C_{18} Corasil column. The final volume was adjusted to 2.5 ml by addition of water, and 15 ml of heptane[14] containing 1.5% isoamyl alcohol[14] was added. The tube was stoppered[15], shaken for 15 min, and centrifuged. It was not necessary to denature the plasma protein as described previously (1).

An aliquot (5–14 ml) of the organic layer to be used for HPLC was transferred to a glass centrifuge tube, and a second aliquot (0.5–1.0 ml) was transferred to a 20-ml glass liquid scintillation vial. Both vial and tube contents were dried under a stream of nitrogen in a water bath (50°).

Six milliliters of scintillation solution[16] was added to the vial contents, and the sample was analyzed by liquid scintillation spectroscopy. Samples with low counts (less than 400 cpm) were counted twice and averaged.

HPLC Separation of Δ^9-Tetrahydrocannabinol—The sides of the 5-ml tube were rinsed with 100 μl of ethanol, and the contents were dried again. The residue was dissolved in 15–21 μl of ethanol, and an aliquot (10–14 μl) was used for separation of Δ^9-tetrahydrocannabinol by the normal-phase HPLC system, which used a 20–25% chloroform in heptane solvent system at a constant flow rate (either 1.0 or 1.5 ml/min). The tetrahydrocannabinol fraction was collected over the predetermined collection range in a 5-ml tube and dried. The residue was dissolved in 0.5 ml of ethanol and stored in a freezer until time for derivatization and analysis by GLC with electron-capture detection.

After one to three injections of plasma extracts, it was necessary to remove from the column those components of the extract that had high affinities with the packing material. When normal-phase HPLC was used, the solvent system was changed to heptane, 4 ml of 10% heptane in tetrahydrofuran was injected, the flow rate was adjusted to 2 ml/min, and the heptane was replaced after 3 min by the original solvent system. No further injections were made until the system operated for 10 min at the original specifications.

The HPLC system was checked for reproducibility in collecting fractions of administered tetrahydrocannabinol prior to a series of injections on a given day. Known amounts of HPLC-purified ^{14}C-Δ^9-tetrahydrocannabinol were dissolved in 21 μl of ethanol, and 14 μl was injected in the chromatograph. The remainder of each sample was counted for total carbon-14. At the beginning of each series of HPLC collections, two reference standards of approximately 5 and 500 ng, each originally dissolved in 21 μl and of equal activity, were injected and collected as stated to assure that the collection range used was proper.

The collected fractions were counted for total carbon-14, and the collection efficiency was considered as the fraction injected recovered. It was shown previously (1) that Δ^9-tetrahydrocannabinol did not degrade significantly under the mild conditions of these analytical procedures (1–3). All glassware was silylated as described (1). It is possible to analyze eight samples/day, including the determination of the reproducibility of the HPLC system.

Derivatization of Samples for Sensitive Electron-Capture Detection (1)—Prior to GLC analysis, each stored sample was dried under a stream of nitrogen in a water bath (50°). One hour was a satisfactory drying time. The residue was dissolved in 0.1 ml of dry benzene. A 100 *M* excess of pyridine in benzene was added to the benzene solution of Δ^9-tetrahydrocannabinol. A 100 *M* excess of pentafluorobenzoyl chloride[17] in 5–20 μl of benzene was also added. The amounts were estimated from the known amount of radiolabeled tetrahydrocannabinol in the heptane extract. The tube was stoppered and allowed to stand for 15 min, and 100 μl of 0.1 *M* Na_2CO_3 was added. The mixture was shaken for 1 min on a vortex shaker and centrifuged.

The aqueous layer was removed, 200 μl of benzene was added, and the tube was centrifuged again. An aliquot, approximately 250 μl, of the benzene layer was transferred to a 5-ml centrifuge tube and dried under nitrogen in a water bath. The residue was dissolved in an appropriate volume, 0.2–2.0 ml, of toluene, usually containing 50 pg of cannabidiol pentafluorobenzoate (the internal standard)/ml. The optimum amount of internal standard to give an area ratio with tetrahydrocannabinol pentafluorobenzoate of about unity was predicted from the radiolabeled tetrahydrocannabinol concentration in the heptane extract of plasma. Aliquots of 0.5–1.5 μl of this final solution were analyzed by GLC.

Preparation of Internal Standard—Cannabidiol for use as the GLC internal standard was purified by injecting 1 mg into the normal-phase HPLC system with a 20% chloroform in heptane eluant. The central third of the peak was collected, dried, and dissolved in 10 ml of dry benzene. The concentration of the solution was determined by flame-ionization GLC (2, 3). Cannabidiol pentafluorobenzoate was prepared by adding 2 μl each of pyridine and pentafluorobenzoyl chloride to 1 ml of this solution. After 5 min, 1 ml of 0.1 *M* Na_2CO_3 was added, the solution was shaken for 1 min, and the organic layer was transferred to a 5-ml tube and dried.

The stable residue was dissolved in dry toluene to yield 50–500 pg/ml when needed for use as an internal standard. A given volume of this solution was analyzed by electron-capture GLC, and the area under the peak was determined. This approach provided a measure of the volume of internal standard solution necessary to add to the tetrahydrocannabinol sample to be analyzed to obtain the proper area ratio even without an exact knowledge of the internal standard concentration.

Preparation of Calibration Curves—Calibration curves of peak area ratios of drug to internal standard *versus* plasma concentration for monitoring plasma levels of tetrahydrocannabinol in pharmacokinetic studies were usually prepared from duplicate 2-ml plasma samples containing 1, 5, 10, 50, and 100 ng of ^{14}C-labeled or unlabeled Δ^9-tetrahydrocannabinol. After heptane extraction of the samples, normal-phase HPLC and electron-capture GLC assay of the derivatized material was effected.

The amount in the plasma sample could also be calculated from a calibration curve of the ratios of the peak area of the tetrahydrocannabinol pentafluorobenzoate prepared from pure tetrahydrocannabinol in toluene to that of the cannabidiol pentafluorobenzoate when the dilution, reconstitution, and separate efficiencies of the extraction and HPLC elution procedures were taken into account. The extraction efficiency was established for each batch of plasma by adding known amounts of ^{14}C-Δ^9-tetrahydrocannabinol to 2 ml of plasma and determining the fraction of the label recovered after extraction in 15 ml of heptane.

The HPLC eluant of the labeled Δ^9-tetrahydrocannabinol fraction was also collected in vials (20 ml), dried, and analyzed for total carbon-14, using liquid scintillation spectroscopy. The amount of tetrahydrocannabinol present was calculated from the known dilutions, reconstitutions, and evaluated efficiencies of the extraction and HPLC elution procedures.

Purification of Δ^9-Tetrahydrocannabinol by HPLC—Aliquots of the stock ^{14}C-Δ^9-tetrahydrocannabinol solutions were analyzed for radiolabel purity by HPLC with a reversed-phase column, using a 45 or 51% acetonitrile–water solvent system at a constant pressure below 3000 psi at a flow rate of 1.5 ml/min, or with the normal-phase column, using a 20 or 25% chloroform–heptane solvent system at a flow rate of 2.5 ml/min. The eluate was monitored for UV absorbance at 254 nm and collected in volumetric tubes at 0.5- or 1-ml intervals.

Each fraction was analyzed by GLC and by liquid scintillation counting for total carbon-14; its activity, corrected for background, was plotted against the cumulative volume for that fraction, defined as the volume eluted at a time after injection minus the "dead volume" of the system. The pooled volumes containing the separated ^{14}C-Δ^9-tetrahydro-

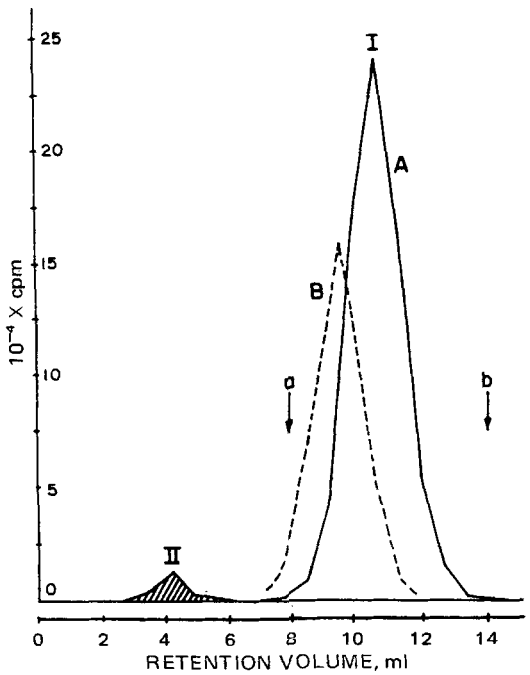

Figure 1—*Reversed-phase HPLC of stock* ^{14}C-Δ^9-*tetrahydrocannabinol. The total radioactivity per eluate fraction was plotted* versus *retention volume (curve A). Peak I is* ^{14}C-Δ^9-*tetrahydrocannabinol, and peak II is an unknown radioactive contaminant. Curve B is a plot of the mean UV detector response (arbitrary units)* versus *retention volume and is displaced relative to A by the solvent volume between the detector and the collection point. Collection between volumes* a *and* b *(peak retention volume ± 30%) for curve B recovered 92.5% of the radioactivity in this case. The column was Bondapack* C_{18}*; the eluant was 45% acetonitrile in water at 1.5 ml/min. Each fraction was corrected for background counts per minute.*

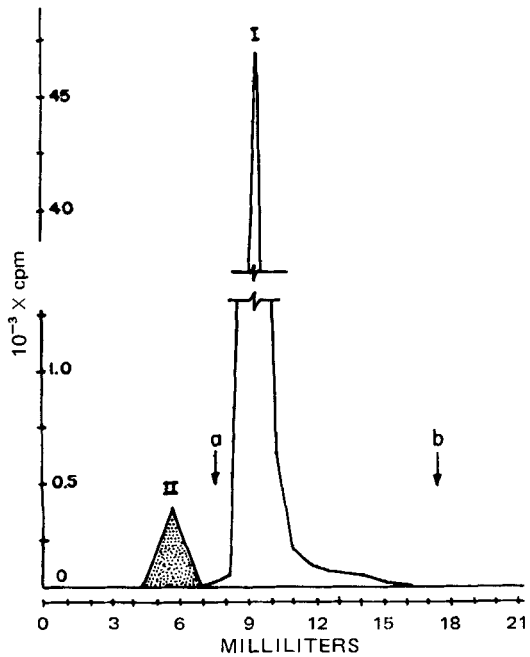

Figure 2—*Normal-phase HPLC of stock* ^{14}C-Δ^9-*tetrahydrocannabinol. The total activity per eluate fraction was plotted* versus *milliliters of eluate. Peak I is* ^{14}C-Δ^9-*tetrahydrocannabinol, and peak II is an unknown radioactive contaminant. Collection between volumes* a *and* b *recovered 97.5% of the radioactivity in this case. The column was μ-Porasil; the eluant was 20% chloroform in heptane at 2.5 ml/min. Each fraction was corrected for background counts per minute.*

cannabinol (peak I, Figs. 1 and 2), as evidenced by the observed single peak, contained the material used in the quantification of the efficiencies of the various separation and analytical methods.

Quantitation of Efficiency of HPLC Separation of Δ^9-Tetrahydrocannabinol—The described procedure was repeated on this purified material after the collected eluates containing the Δ^9-tetrahydrocannabinol fraction were dried under nitrogen at 50° and reconstituted in absolute ethanol to yield 2×10^4 cpm/μl. The fractions collected were analyzed for total carbon-14. Thus, a collection range for tetrahydrocannabinol was established that would contain at least 98% of the recoverable label. The eluates within this established collection range were analyzed for total carbon-14 when various aliquots of the purified ^{14}C-tetrahydrocannabinol in ethanol were injected on the two HPLC systems (Tables I and II). The effect of varying percentages of acetonitrile in the eluting solvent for the reversed phase was also studied (Fig. 3 and Table I). Similarly, an authentic sample of ^{3}H-11-hydroxy-Δ^9-tetrahydrocannabinol was purified, and its collection range for 98% recovery was determined for reversed-phase HPLC (Fig. 3).

The HPLC-purified ^{14}C-Δ^9-tetrahydrocannabinol, in known various amounts, was added to aliquots of fresh dog plasma to determine the efficiency of HPLC drug recovery from plasma. The tetrahydrocannabinol was extracted, the pertinent fraction of drug was collected on the HPLC system used, and the total carbon-14 activity of each collection was determined. A 45% acetonitrile–water solvent system was used in the reversed phase; a 20% chloroform–heptane solvent system was used in the normal phase.

As stated previously, it was necessary to remove components of the plasma extract that had high affinities with the packing material of the column after one to three injections of plasma. The cleanup procedure for normal-phase HPLC was given previously. When reversed-phase HPLC was used, 4 ml of 10% methanol in acetonitrile was injected or the eluant was changed to 100% acetonitrile, the flow rate was adjusted to 1 ml/min, and the flow rate was increased after 5 min to 3 ml/min for 3 min.

A 2-ml plasma sample was spiked with 400 ng of unlabeled Δ^9-tetrahydrocannabinol and 400 ng of 11-hydroxy-Δ^9-tetrahydrocannabinol, extracted, and prepared for HPLC. The sample was injected on

the reversed-phase HPLC system, and the eluate was collected over the range for a 51% acetonitrile–water solvent system that would collect both compounds. The collected fraction was dried under nitrogen in a water bath (50°), reconstituted in 50 μl of chloroform, and analyzed by GLC, using flame ionization as previously described (2, 3).

Variability in Extraction, HPLC, and Electron-Capture GLC Analytical Procedures for Δ^9-Tetrahydrocannabinol in Plasma—The total error and the sources of error for such analyses were evaluated

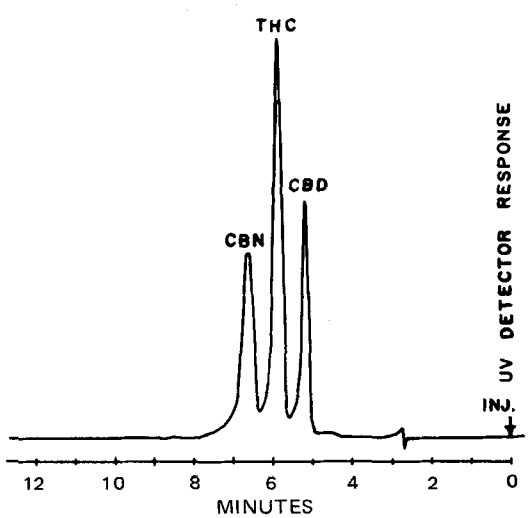

Figure 4—*Normal-phase HPLC separation of cannabinoids. The UV detector response (arbitrary units) was plotted* versus *retention time after injection (inj.) of a mixture of cannabidiol (CBD), Δ^9-tetrahydrocannabinol (THC), and cannabinol (CBN). The amounts of Δ^9-tetrahydrocannabinol and cannabidiol injected were approximately twice the amount of the cannabinol. The column was μ-Porasil; the eluant was 20% chloroform in heptane at 1.5 ml/min.*

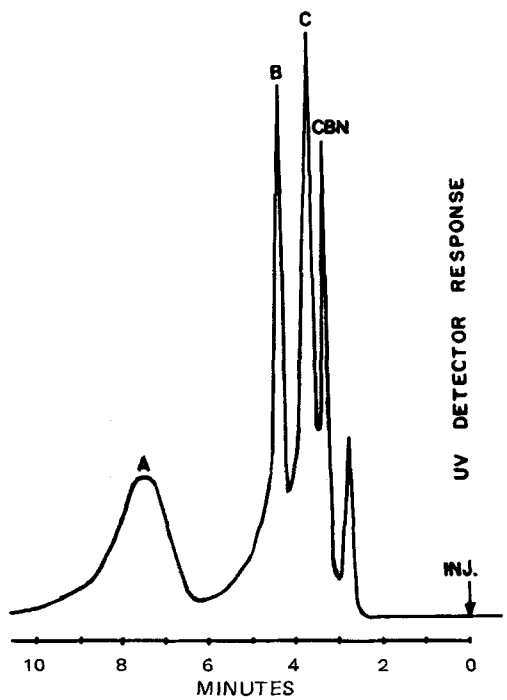

Figure 5—*Normal-phase HPLC separation of Δ^9-tetrahydrocannabinol metabolites. The UV detector response (arbitrary units) was plotted* versus *retention time after injection (inj.) of a mixture of cannabinol (CBN), 11-hydroxy-Δ^9-tetrahydrocannabinol (C), 8α-hydroxy-Δ^9-tetrahydrocannabinol (B), and 8β-hydroxy-Δ^9-tetrahydrocannabinol (A). The column was μ-Porasil; the eluant was 80% chloroform in heptane at 1.5 ml/min.*

for the overall analytical scheme in three separate experiments.

1. Each of three 9-ml plasma samples was spiked with 2.25, 22.5, or 225 ng of ^{14}C-Δ^9-tetrahydrocannabinol. Four 2-ml aliquots were removed from each sample, the tetrahydrocannabinol was extracted from each, and 14 of the 15 ml of the heptane extract was dried and analyzed for total carbon-14.

2. Three 9-ml plasma samples were prepared and extracted as already described. The tetrahydrocannabinol in the dried heptane extract was separated by normal-phase HPLC, and the tetrahydrocannabinol fraction was collected directly in counting vials and analyzed for total carbon-14.

3. Three 9-ml plasma samples were prepared as described, extracted, and separated by HPLC (normal phase). The proper eluant fraction was analyzed by GLC.

These three studies were carried out on different days and used fresh plasma from different dogs.

HPLC Separation of Δ^9-Tetrahydrocannabinol from Selected Cannabinoids and Metabolites—Normal-phase HPLC (20% chloroform in heptane) was tested for the degree of separation obtainable between cannabinol, cannabidiol, and tetrahydrocannabinol by injection of an aliquot of a mixture of the three cannabinoids at a flow rate of 1.5 ml/min. The compounds were monitored by UV detection. When an aliquot of a mixture of cannabinol and three monohydroxylated metabolites of tetrahydrocannabinol, 8α-hydroxy-Δ^9-tetrahydrocannabinol, 8β-hydroxy-Δ^9-tetrahydrocannabinol, and 11-hydroxy-Δ^9-tetrahydrocannabinol, was injected into the same HPLC system, no peaks for the three monohydroxy compounds were observed prior to 15 min. Thus, this system widely separated Δ^9-tetrahydrocannabinol, with its retention volume of 9 ml (Fig. 2), from these compounds. HPLC was obtained for the three metabolites in an 80% chloroform–heptane solvent system at a 1.5-ml/min flow rate. Δ^9-Tetrahydrocannabinol had a retention value equivalent to cannabinol in this system.

RESULTS AND DISCUSSION

Purification and Reproducibility of Collection from Injected Ethanolic Solutions of Δ^9-Tetrahydrocannabinol on HPLC—The ^{14}C-Δ^9-tetrahydrocannabinol used was reportedly[18] free of radiolabeled

[18] National Institutes of Health, personal communication in reference to Contract HSM-42-71-108.

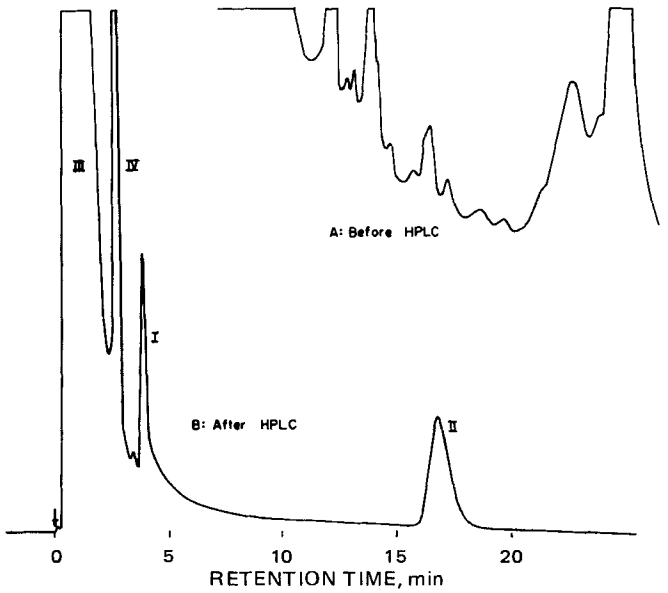

Figure 6—*Gas–liquid chromatograms (flame-ionization detection) of an extract of 2 ml of plasma containing Δ^9-tetrahydrocannabinol, I (200 ng/ml), and 11-hydroxy-Δ^9-tetrahydrocannabinol, II (200 ng/ml), before (A) and after (B) reversed-phase HPLC separation of both cannabinoids over a range of predetermined collection volumes (Fig. 1). One microliter of 18 μl of extract was injected into the gas chromatograph prior to HPLC (A). Ten microliters of 18 μl of the extract was injected into the liquid chromatograph, the collected fraction was reconstituted in 10 μl of chloroform, and 1 μl was injected into the gas chromatograph (B). Peak III is the solvent; peak IV is an unknown from plasma. For HPLC, the column was Corasil C_{18}; the eluant was 51% acetonitrile in water at 1.5 ml/min. For GLC, the column was 1.5 m (5 ft) × 2 mm, 1.9% OV-225 at 245°, with a nitrogen flow of 24 ml/min. An attenuation of 8×10^{-12} was used for both chromatograms. The initial baselines and injection times for both chromatograms are superimposed for comparison.*

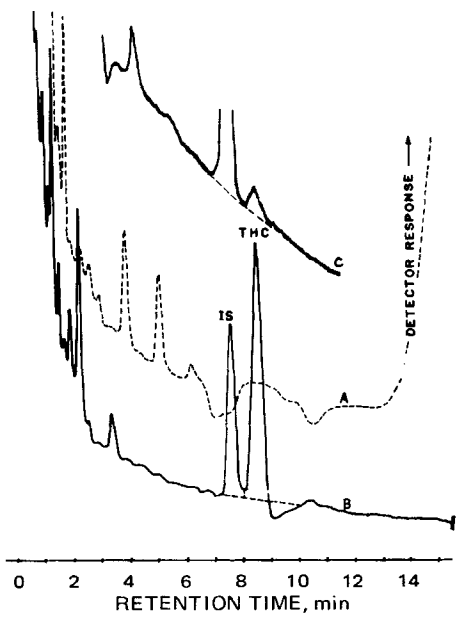

Figure 7—*GLC (electron-capture) analysis of derivatized samples. The chromatograms represent: (A) the injection of 1 of 300 μl from a derivatized extract of 2 ml of blank plasma without HPLC purification; (B) the injection of 1 of 200 μl of the final solution of derivatized compound, which was 70% of the total amount extracted from 2 ml of dog plasma containing 200 ng of Δ^9-tetrahydrocannabinol/ml, with extraction and normal-phase HPLC collection efficiencies of 91 and 95%, respectively; and (C) the injection of 1 of 200 μl from a derivatized extract of 2 ml of plasma containing 1.3 ng of Δ^9-tetrahydrocannabinol/ml. All other factors were the same as for chromatogram B. The peaks for the internal standard, cannabidiol pentafluorobenzoate (IS), and Δ^9-tetrahydrocannabinol pentafluorobenzoate (THC) are appropriately labeled. Typical estimated baselines are shown. The GLC conditions were: 1.8-m (6-ft) OV-17 column, 225°; detector, 280°; injector, 255°; nitrogen flow, 45 ml/min; and attenuations, 4×10^{-9} (A and B) and 8×10^{-10} (C).*

contaminants by TLC. However, reversed-phase HPLC (Fig. 1) revealed the presence of a labeled contaminant. The major peak, I, contained Δ^9-tetrahydrocannabinol (>96%) and Δ^8-tetrahydrocannabinol (≃3%), quantified by flame-ionization GLC (2, 3). A labeled contaminant was also found (Fig. 2) with a normal-phase column. The contaminant eluted prior to Δ^9-tetrahydrocannabinol in both cases. Since the more polar compounds elute first on reversed-phase HPLC whereas the least polar compounds elute first on normal-phase HPLC, the contaminants observed in the two systems probably were not the same. The contaminants were not analyzed further.

When the tetrahydrocannabinol under peak I (Figs. 1 and 2) was collected, dried, reconstituted in ethanol, and reanalyzed on the same HPLC system, only the single peak I was observed. All of the stock Δ^9-tetrahydrocannabinol used underwent this purification procedure. The percent of the total injected radioactivity under peak I recovered was 97.6 ± 0.7% (*SEM*) (Table I) in the reversed-phase system for the ranges of volumes collected (Figs. 1 and 3) and 96.3 ± 1.0% (Table II) for 1–1000 ng injected in the normal-phase system at a retention volume of 9.7 ml within the collection range of 7.3–16.2 ml (Fig. 2).

The fact that the retention volume of peak I and the appropriate collection ranges for 98% recovery of injected labeled tetrahydrocannabinol were sensitive to solvent composition (Fig. 3) necessitated the prior establishment of an appropriate collection range for each newly prepared batch of solvent by radiochemical analysis of the collected HPLC fractions of previously purified ^{14}C-Δ^9-tetrahydrocannabinol. The retention volume and the appropriate collection range increased with decreasing solvent polarity (less percent acetonitrile) due to peak spreading (Fig. 3).

The quality of the water used in the eluting solvent, acetonitrile–water, in reversed-phase HPLC was an important factor in maintaining the reproducibility of the percent radioactivity recovered for a given collection range. The UV detector clearly indicated that adsorbed contaminants in impure water could be eluted from a previously used column by 100% acetonitrile, a less polar solvent than the used mixed eluant. Additional evidence of these contaminants was demonstrated when the GLC background varied significantly when distilled water from various sources was collected after reversed-phase chromatography, extracted as if Δ^9-tetrahydrocannabinol were present, then treated by the derivatization procedure, and analyzed by electron-capture GLC.

HPLC Separation of Δ^9-Tetrahydrocannabinol from Selected Cannabinoids and Metabolites—Δ^9-Tetrahydrocannabinol, cannabinol, and cannabidiol were resolved by the normal-phase HPLC system (Fig. 4). If 98% of the Δ^9-tetrahydrocannabinol were to be collected after normal-phase HPLC in this system, the chosen range (Fig. 2) would also collect cannabinol and cannabidiol. The retention volumes of cannabinol and cannabidiol relative to Δ^9-tetrahydrocannabinol increased as the percent of chloroform in heptane increased.

The monohydroxylated metabolites had large retention volumes (>15 ml) on the normal-phase column when 20–25% chloroform in heptane was the solvent (Fig. 2) and could be completely separated from tetrahydrocannabinol on this system. They were resolved from each other with a more polar solvent, 80% chloroform in heptane (Fig. 5).

Δ^9-Tetrahydrocannabinol and 11-hydroxy-Δ^9-tetrahydrocannabinol were quantitatively separable on the reversed-phase HPLC system at 47% (or less) acetonitrile in water (Fig. 3). The collection efficiencies in the ranges given were 98% of the recoverable radioactivities of ^{3}H-11-hydroxy-Δ^9-tetrahydrocannabinol and ^{14}C-Δ^9-tetrahydrocannabinol.

Both Δ^8- and Δ^9-tetrahydrocannabinols were not readily resolvable in any of these systems. However, an HPLC system that readily resolved and separated these two compounds was 5% tetrahydrofuran in hexane on the normal-phase column at 0.5 ml/min, with retention volumes of 8.15 and 8.45 ml, respectively. The tetrahydrocannabinols collected under peak I (Figs. 1 and 2) could be further separated by this system.

Effect of HPLC Separation on GLC Analysis of Δ^9-Tetrahydrocannabinol in Plasma—An equal amount of Δ^9-tetrahydrocannabinol and 11-hydroxy-Δ^9-tetrahydrocannabinol in 2 ml of dog plasma was extracted and separated from a majority of the extracted components by reversed-phase HPLC. The reduction in potential contaminants from plasma observable on GLC was demonstrated by flame-ionization GLC analysis (2, 3) both before and after the HPLC treatment (Fig. 6).

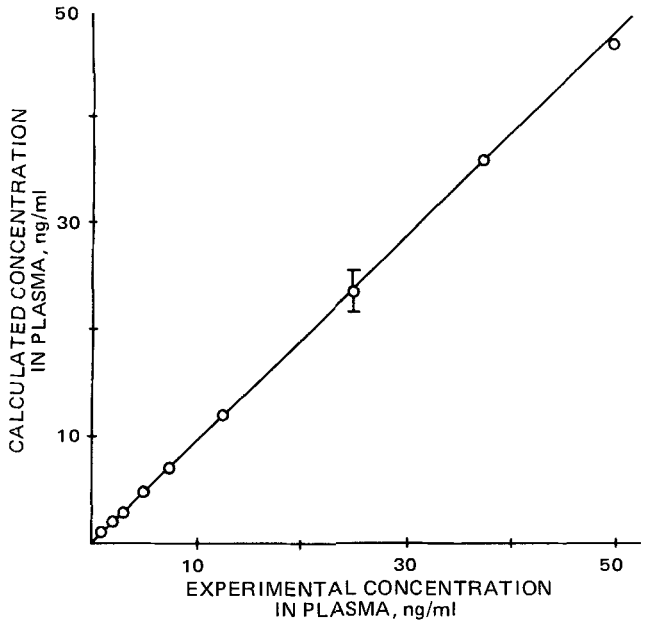

Figure 8—*Recovery of ^{14}C-Δ^9-tetrahydrocannabinol calculated as concentration in plasma corrected for an extraction efficiency of 91% against the experimentally prepared concentrations. The drug was extracted from plasma and collected over the proper volume range (Table I and Fig. 1) after reversed-phase HPLC with a 45% acetonitrile–water eluant. The collection was analyzed by liquid scintillation. The slope, 0.957, is the HPLC collection efficiency for Δ^9-tetrahydrocannabinol and was typical of the values obtained. The vertical bar is the range for ±1 SD (n = 4).*

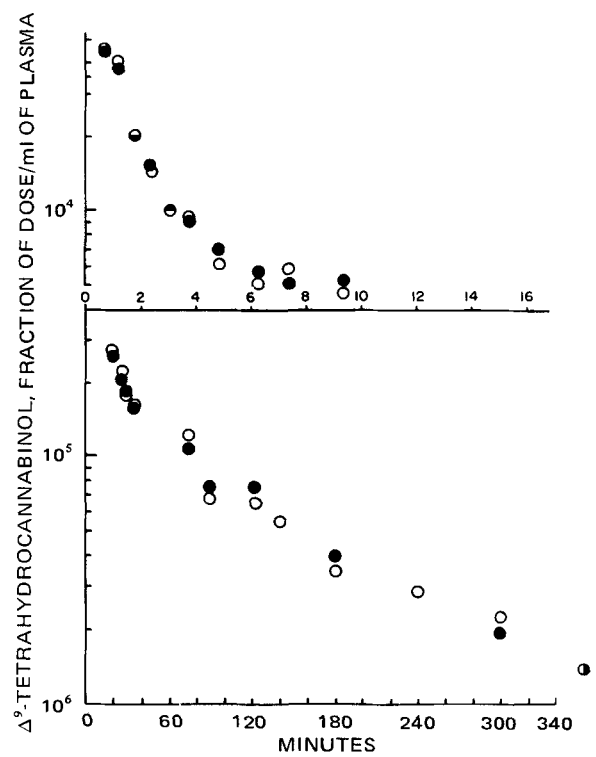

Figure 9—*Semilogarithmic plots of fraction of the Δ^9-tetrahydrocannabinol, 0.1-mg/kg dose/ml of plasma, against time for Dog A plotted from the liquid scintillation analysis of the total carbon-14 collected as Δ^9-tetrahydrocannabinol on normal-phase HPLC (○) and from the electron-capture GLC of the derivatized HPLC collected fraction (●). The values were corrected for the fractions of extracts and total collection range used.*

Normal-phase HPLC with 20% chloroform in heptane could separate Δ^9-tetrahydrocannabinol from monohydroxylated metabolites and 11-hydroxy-Δ^9-tetrahydrocannabinol. However, a minor overlap could be avoided by collecting the tetrahydrocannabinol in a slightly narrower volume range. The prior heptane extraction of alkalinized plasma separated these nonpolar constituents from any acidic metabolite. This separation of plasma extracts and normal-phase HPLC collection of volumes in the appropriate range resulted in a substantial reduction in GLC background from plasma components for derivatized Δ^9-tetrahydrocannabinol analyzed with electron-capture detection, as shown by a comparison of curves A and B or A and C in Fig. 7.

Plasma samples obtained from dogs administered Δ^9-tetrahydrocannabinol solutions intravenously were analyzed by electron-capture GLC in accordance with the modified procedures described here, including extraction, normal-phase HPLC separation, and derivatization, but no internal standard was added. These procedures would have included any cannabinol or cannabidiol in the HPLC collection volume range (Figs. 2 and 4) used. However, no peaks were seen at the retention times of cannabinol or cannabidiol pentafluorobenzoate, and no significant amounts of cannabinol or cannabidiol could be detected as metabolites of Δ^9-tetrahydrocannabinol in the dog. Thus, either compound, when purified, should serve as an appropriate internal standard in pharmacokinetic studies. However, since cannabinol has been reported as a minor metabolite (4–6), cannabidiol pentafluorobenzoate was chosen as the internal standard. Cannabinol is known to be a contaminant of degraded Δ^9-tetrahydrocannabinol (3).

The presented GLC methodology differed from the prior studies (1) in that the short 30-cm column of 3% OV-225 was supplanted by a longer OV-17-packed column to be consistent with the data in the literature accumulated for the resolution of the cannabinols (7–9).

Efficiency, Reproducibility, and Sensitivity of Radiochemical and Electron-Capture Assay of ^{14}C-Δ^9-Tetrahydrocannabinol in Dog Plasma—The heptane extraction efficiency from plasma was highly reproducible (Table III) over a wide range of plasma concentrations, 90.6 ± 0.7% (*SEM*).

The recovery of Δ^9-tetrahydrocannabinol from the heptane extract of dog plasma by normal-phase HPLC was reproducible (Table III) over the range of plasma concentrations studied. Equivalent overall recoveries (Table II) were obtained by both radiochemical analysis (83.7 ± 1.8% *SE*) and electron-capture GLC analysis (84.0 ± 4.9% *SE*) of the derivatized tetrahydrocannabinol (Fig. 7). Both methods permitted estimation of

Table III—Percent Recoveries[a] of ^{14}C-Δ^9-Tetrahydrocannabinol in the Heptane Extract of Plasma and in the Collection of the Proper Fraction of the Heptane Extract Separated by HPLC and the Overall Recovery after Both Extraction and HPLC Collection as Monitored by Both Electron-Capture GLC and Scintillation Analysis

^{14}C-Δ^9-Tetrahydrocannabinol[b], ng/2 ml of Plasma	Extracted by Heptane, %, Scintillation	Extract HPLC Collected[c], %		Overall Recovery[d], %	
		Scintillation	GLC	Scintillation	GLC
2.25	90.2 ± 4.7	93	92	84 ± 8	83 ± 32
22.5	90.8 ± 2.6	88	97	80 ± 6	88 ± 12
225	90.9 ± 8.5	97	89	88 ± 4	81 ± 7
Overall average ± *SE*	90.6 ± 0.7	92	93	84 ± 2	84 ± 5

[a] Given as the mean from four separate plasma samples ± *SD*. The scintillation analysis of recovered radioactivity was performed on a different set of four studies and on a different day than the electron-capture GLC analysis of the derivatized HPLC collection. [b] 142.47 cpm/ng. Two milliliters of plasma was extracted with 15 ml of heptane, and 14 ml was analyzed for total carbon-14. [c] Quotient divided by the extraction efficiency (0.91). Additional studies were conducted for 26 ng of ^{14}C-Δ^9-tetrahydrocannabinol/2 ml of plasma on 2 other days for four samples each, and the percents recovered on HPLC from the extract were 94 ± 4 and 92 ± 3% (*SE*), respectively. [d] Quotient of amount recovered corrected for volumes of extract used and amount added, which is the product of the extraction efficiency and the collection efficiency.

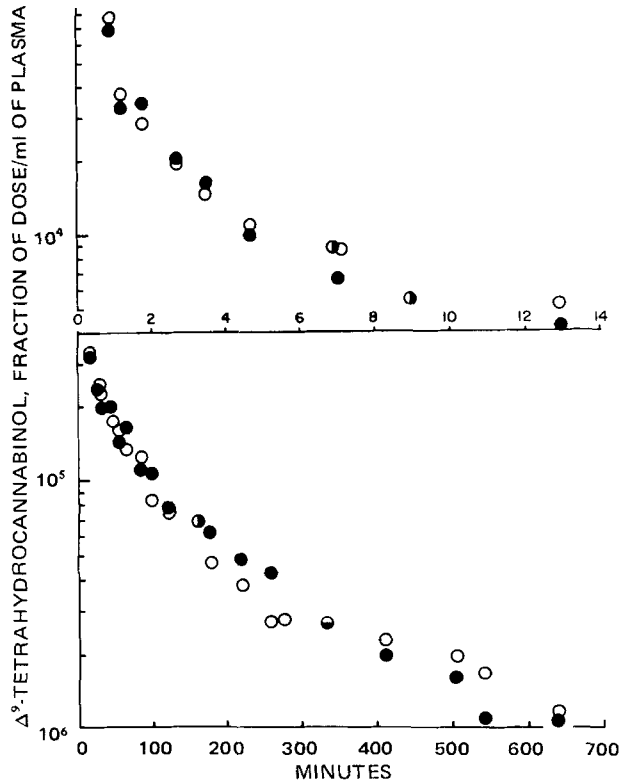

Figure 10—*Semilogarithmic plots of fraction of the Δ⁹-tetrahydrocannabinol, 2.0-mg/kg dose/ml of plasma, against time for Dog A plotted from the liquid scintillation analysis of the total carbon-14 collected as Δ⁹-tetrahydrocannabinol on normal-phase HPLC (○) and from the electron-capture GLC of the derivatized HPLC collected fraction (●). The values were corrected for the fractions of extracts and total collection range used.*

a 92.5% recovery of the amount in the heptane extract injected on normal-phase HPLC and collected in the chosen range.

The normal HPLC collection range was chosen to be slightly smaller than in the studies on ethanolic solutions of Δ⁹-tetrahydrocannabinol (Fig. 2 and Table II) since the procedure had to be modified to separate tetrahydrocannabinol from possible monohydroxylated or 11-hydroxy-Δ⁹-tetrahydrocannabinol metabolites in plasma. A slight overlap of their HPLC peak areas with Δ⁹-tetrahydrocannabinol would have occurred with the larger collection ranges.

A similar study of the reproducibility of collection of ^{14}C-Δ⁹-tetrahydrocannabinol in plasma assayed by liquid scintillation after extraction and reversed-phase HPLC was also conducted. The amounts recovered were proportional to the amounts injected (Fig. 8), and the HPLC recovery efficiency of the drug in the heptane extract was 95.7%.

Equivalency of Radiochemical Analyses of ^{14}C-Δ⁹-Tetrahydrocannabinol and GLC Electron-Capture Detection of Derivatized Material after Normal-Phase HPLC in Dog Plasma during Pharmacokinetic Studies—The plasma of a dog intravenously administered solutions of ^{14}C-Δ⁹-tetrahydrocannabinol was monitored with time after heptane extraction by both radiochemical analysis and electron-capture GLC of the derivative of the appropriately collected eluate fraction from normal-phase HPLC. Typical plots of the time course of the results from both methods are given in Figs. 9 and 10.

The procedures for GLC analysis gave a lower limit for quantitative analysis of tetrahydrocannabinol in plasma of approximately 1 ng/ml from twice the standard deviation (0.32 ng) obtained for the amount of tetrahydrocannabinol recovered from 2.25 ng in 2 ml of plasma (Table II). Similarly, the procedure for radiochemical analysis gave a lower limit of approximately 0.2 ng/ml from twice the standard deviation (0.084 ng). A statistical analysis of the apparent differences between the tetrahydrocannabinol assays at a given time from both analytical methods (Figs. 9 and 10) showed no significance. This finding demonstrated that all of the recovered radioactivity from the HPLC separation procedure could be assigned to the Δ⁹-tetrahydrocannabinol assayed specifically by electron-capture GLC. Thus, no significant amounts of radiolabeled metabolites were in the collected HPLC fractions.

It can be concluded that Δ⁹-tetrahydrocannabinol can be extracted from plasma and other biological fluids and that it can be separated on HPLC from the simultaneously extracted biologically endogenous materials and metabolites that would interfere with a chosen highly sensitive analytical method such as GLC. It is not necessary to collect all of the material to be analyzed; assurance that a reproducible or known fraction of the total material injected on HPLC is recovered is all that is necessary, since it is directly proportional to the total drug concentration. If unlabeled Δ⁹-tetrahydrocannabinol in a solution of plasma were analyzed, the calculated recovery of known amounts of labeled Δ⁹-tetrahydrocannabinol added either to plasma prior to extraction or to the heptane extract subsequent to extraction would permit calculation of the extraction and/or HPLC collection efficiencies for that particular biological sample. These known efficiencies would permit the calculation of the original plasma concentrations. If ^{14}C-Δ⁹-tetrahydrocannabinol were used in pharmacokinetic studies, extracted, and separated liquid chromatographically, ^{3}H-tetrahydrocannabinol could be used as the appropriate internal standard to monitor the recovery efficiencies.

Kinetics of Indomethacin Degradation I: Presence of Alkali

B. R. HAJRATWALA ˣ and J. E. DAWSON

Abstract □ The kinetics of indomethacin degradation were followed in alkaline aqueous solutions at various temperatures between 20.1 and 40.7°. The apparent first-order rate constants were evaluated from log absorbance *versus* time plots at λ_{max} 318 nm. The primary salt effect was positive. The rate constant–hydroxide-ion concentration profile was linear with a positive slope, suggesting the following rate law: $k_{obs} = k_1 [OH^-]$. The experimental data fit the proposed reaction of degradation, $I^- + OH^- \xrightarrow{k_1}$ products, where I^- = monodissociated indomethacin species. Activation energies and other related parameters were calculated from Arrhenius-type plots.

Keyphrases □ Indomethacin—degradation in alkaline aqueous solutions, various temperatures, kinetics, effect of ionic strength □ Degradation—indomethacin in alkaline aqueous solutions, various temperatures, kinetics, effect of ionic strength □ Kinetics—degradation of indomethacin in alkaline aqueous solutions, various temperatures, effect of ionic strength □ Anti-inflammatory agents—indomethacin, degradation in alkaline aqueous solutions, various temperatures, kinetics

Indomethacin [1-(4-chlorobenzoyl)-5-methoxy-2-methylindole-3-acetic acid, I] is a relatively new (1, 2) anti-inflammatory agent; it is not related to salicylates but is an acid. It is stable in neutral or slightly acidic media but is decomposed by strong alkali (3). Its physical properties, *e.g.*, solubility (4), polymorphism (5), and release rates from suppository bases (6, 7), have been reported, but its degradation kinetics have not.

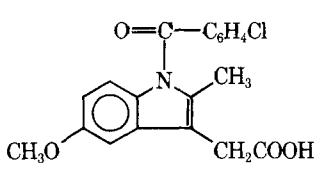
The purposes of this investigation were to study the degradation of indomethacin in alkali, to establish the order of reaction, to study the effect of ionic strength, and to obtain an Arrhenius-type plot.

EXPERIMENTAL

Materials—All materials, including indomethacin[1], sodium hydroxide, and sodium chloride, were analytically pure grade. All-glass double-distilled water was used throughout.

Kinetic Studies—An accurately weighed quantity (~100 mg) of indomethacin was dissolved in 30 ml of 95% ethanol, and the volume was adjusted to 50 ml with water at 25°. The indomethacin solution, 0.1 *N* sodium hydroxide, and water were all kept at the temperature of the study. Mixtures of the indomethacin solution (2 ml), varying quantities of 0.1 *N* sodium hydroxide, and water to a final volume of 100 ml were immediately transferred to a quartz cell kept in a constant-temperature cell holder[2]. The initial concentration of indomethacin in the reaction cell was approximately 1.1×10^{-4} *M*.

Absorbance (against an appropriate blank) was recorded as a function of time at λ_{max} 318 nm. The pH was measured at the beginning and end of each run, and no significant change in pH was found. The absorbance data obtained were used to construct semilogarithmic plots of the function $(A_t - A_\infty)$ *versus* time, where A_t is the observed absorbance at time t, and A_∞ is the observed equilibrium absorbance value. Such plots are illustrated in Fig. 1, where the degradation behavior is observed to follow first-order kinetics. The apparent first-order rate constants, k_{obs} (Table I), were calculated using regression analysis (10 or more points). Correlation coefficients were between −0.993 and −0.999.



I

Effect of Ionic Strength—The effect of ionic strength was investigated at 25.8° in 0.005 *M* hydroxide-ion concentration adjusted to the ionic strengths of 0.045, 0.165, 0.505, and 1.00 and in 0.01 *M* hydroxide-ion concentration adjusted to the ionic strengths of 0.05, 0.17, 0.51, and 1.00. The ionic strength was adjusted by addition of sodium chloride (Fig. 2).

Effect of Hydroxide-Ion Concentration and Temperature—The study was carried out in various concentrations of hydroxide ion at 20.1, 25.8, 30.3, 35.1, and 40.7°.

Determination of pKa of Indomethacin—About 100 mg of indomethacin, accurately weighed, was dissolved in ethanol, and the volume was made up to 100 ml with water. The solutions were titrated potentiometrically (8) with 0.1 *M* KOH at 30°. The pKa's were calculated on a specially written Fortran program[3], using both Debye and Guntelberg activity coefficients (9). The difference between the pKa values calculated by the two methods was in all cases less than 0.002 unit. The pKa's reported are an average of 13 data points, with a range of ±0.05 unit.

RESULTS AND DISCUSSION

Figure 2 shows the effect of ionic strength. At both hydroxide-ion concentrations, there was a positive ionic strength effect with the slope of the line less than 1. At 0.005 and 0.01 *M* hydroxide-ion concentrations, the slopes of the line were 0.168 and 0.077, respectively. Since even model pharmaceutical systems by necessity are in concentration ranges above 0.01 ionic strength, it is not unusual to study pharmaceuticals at high ionic strength (10–12). This positive ionic strength effect suggests that the reaction of ions of like sign plays a role in the mechanism of indomethacin degradation (13).

Figure 3 shows the effect of varying hydroxide-ion concentrations on indomethacin degradation at various temperatures. The rate constant–hydroxide-ion concentration profile suggests a simple

[a] Duplicate values are in parentheses.

mechanism. The reaction shown in Scheme I, where I^- is the monodissociated species of indomethacin, would give a rate constant–hydroxide-ion concentration profile that fits the experimental points well.

$$I^- + OH^- \xrightarrow{k_1} \text{products}$$
Scheme I

The overall velocity of the reaction is given by:

$$\frac{d[I]_T}{dt} = k_1[I^-][OH^-] \quad \text{(Eq. 1)}$$

and:

$$[I]_T = [I] + [I^-] \quad \text{(Eq. 2)}$$

where I = undissociated indomethacin species. The brackets signify molar concentrations of the appropriate species. Because of the overall first-order character of the reaction:

$$-\frac{d[I]_T}{dt} = k_{obs}[I]_T \quad \text{(Eq. 3)}$$

and:

$$K_a = \frac{K_w[I^-]}{[I][OH^-]} \quad \text{(Eq. 4)}$$

Combining these equations and substituting in Eq. 1 yield:

$$k_{obs} = \frac{k_1K_a[OH^-]^2}{[OH^-]K_a + K_w} \quad \text{(Eq. 5)}$$

The pKa for indomethacin was 6.02, 5.69, and 5.45 at 30° in 70, 60, and 50% ethanol in water, respectively. It was necessary to determine the pKa of indomethacin in the presence of ethanol because of its low solubility in water. Increasing concentrations of ethanol increase the pKa of weak acids, *e.g.*, sulfathiazole (14, 15), phenobarbital (16), and ascorbic acid (17). For the present study, for a weak acid such as indomethacin, $[OH^-]K_a \gg K_w$, where K_w is the ionic product for water. Thus, Eq. 5 reduces to:

$$k_{obs} = k_1[OH^-] \quad \text{(Eq. 6)}$$

Table II shows the values for k_1 at various temperatures together with standard errors of estimate and correlation coefficients.

The good agreement of the experimental data with Eq. 6 does not prove that Scheme I is correct but justifies its proposal. In considering the effect of hydroxide-ion concentration on the degradation of indomethacin in aqueous solution, Schemes I–VI are possible.

$$I^- + H^+ \xrightarrow{k_2} \text{products}$$
Scheme II

$$I^- \xrightarrow{k_3} \text{products}$$
Scheme III

$$I + OH^- \xrightarrow{k_4} \text{products}$$
Scheme IV

$$I + H^+ \xrightarrow{k_5} \text{products}$$
Scheme V

$$I \xrightarrow{k_6} \text{products}$$
Scheme VI

Schemes II and VI and III and IV are kinetically indistinguishable. On the basis of experimental results, Schemes II and V cannot be considered. If Schemes II (or VI) and V hold, the observed rate con-

stant would be inversely proportional to the hydroxide-ion concentration. If Scheme III (or IV) holds, the observed rate constant would be independent of the hydroxide-ion concentration. Thus, only Scheme I can be proposed.

The effect of temperature on the reaction rate can be expressed using the Arrhenius equation. As shown in Fig. 4, plots of log *k versus* $1/T$ yield a straight-line relationship at all hydroxide-ion concentrations used. Table III shows the activation energy values and other parameters calculated. The parallel slopes of the Arrhenius-type plots indicate that the mechanism of degradation is identical at all hydroxide-ion concentrations used.

Scattered Isergonic Profiles

JAMES J. ZIMMERMAN

Abstract □ Equations were developed for the geometric analysis of scatter in isergonic profiles as a function of vertical ($\Delta\Delta H$), horizontal ($\Delta\Delta S$), and perpendicular (d) distances from the error line. Sigma (σ^-) correlates with each of these quantities of the test series to produce statistics (F and r) identical to those for correlation with ΔG. The vertical distances, $\Delta\Delta H$, are shown to be identical to the substituent effect, $\delta\Delta G$; thus, it is concluded that the Hepler approach of implicating a solvation mechanism on the basis of ρ–σ correlations for these distances is not warranted. The uncertainty of points on the isergonic profile for the test series was determined using the joint confidence region ("error contour") approach. Statistical limits of the contour lengths overlapped extremely between members of the test series. To eliminate such overlap for series showing small ranges in substituent effects, extremely precise rate data would be required with N (number of data points) = 4 or 5 for the Arrhenius fits. A comparison between d values and the perpendicular half-widths ($w/2$) of the error contours resulted in $d > w/2$ for each member of the test series (excluding H), proving that scatter in the profile could not result from experimental error. A further comparison between differences in d, Δd, from suggested β lines for solvation and $w/2$ values showed that a β range as large as 45° could be included in the error contour widths of the test series. Since the average reaction temperature, $\overline{T}$, fell within this range, solvation effects could not be distinguished statistically from error effects.

Keyphrases □ Solvation isergonic profiles—geometric analysis of scatter as a function of vertical, horizontal, and perpendicular distances from error line □ Isergonic profiles, solvation—geometric analysis of scatter as a function of vertical, horizontal, and perpendicular distances from error line □ Reaction mechanisms—solvation isergonic profiles, geometric analysis of scatter as a function of vertical, horizontal, and perpendicular distances from error line

Attempts to demonstrate the usefulness of entropy–enthalpy (ΔH *versus* ΔS) profiles in augmenting the mechanistic descriptions of chemical reactions have been well documented (1). Recent publications attempted to extend them to enzyme reactions (2) and protein–small molecule interactions in general (3).

In many cases, ΔH *versus* ΔS profiles are linear; the slope of such profiles for either rate or equilibrium data yields β_i[1], the isergonic[2] temperature (1, 2), in accordance with:

$$\delta\Delta H = \beta_i\delta\Delta S \qquad \text{(Eq. 1)}$$

where δ = the Leffler–Grunwald operator for substituent or medium effects. The linearity of such profiles tends to confirm a common reaction mechanism for the members of a congeneric series, and the numerical value of β_i is potentially associated with a known reaction mechanism. Thus, a value of $\beta_i \simeq 280$°K is customarily associated with an aqueous solvation mechanism for a series (4).

Hepler (5) showed that Eq. 1 is one relationship obtained from an exact thermodynamic analysis of the Hammett equation (Eq. 2) when ΔH and ΔS are temperature independent:

$$\log (k_x/k_H) = \rho\sigma \qquad \text{(Eq. 2)}$$

where ρ = reaction constant, σ = substituent constant, and x and H refer to substituted and parent derivatives, respectively. As a result, congeneric series that obey Eq. 2 should also obey Eq. 1. However, some reaction series follow the Hammett relationship but their ΔH *versus* ΔS profiles are nonlinear or scattered (1). A rational explanation for the behavior of such series was discussed previously in terms of multiple interaction mechanisms and related compensation phenomena (1, 5).

THEORETICAL

Leffler–Grunwald Analysis of Scattered Isergonic Profiles—According to Leffler and Grunwald (1), the scatter in ΔH *versus* ΔS profiles may be explained in terms of multiple contributions to the observed enthalpies and entropies. For a model based on a two-interaction mechanism, the enthalpy and entropy expressions are given by:

$$\delta\Delta H = \delta\Delta H' + \delta\Delta H'' \qquad \text{(Eq. 3)}$$

$$\delta\Delta S = \delta\Delta S' + \delta\Delta S'' \qquad \text{(Eq. 4)}$$

where the superscripts, ′ and ″, refer to two different but additive types of substituent contributions (*e.g.*, resonance, inductive, steric, or solvation effects). These two contributions to the observed enthalpy and entropy would vary independently of one another for any given reaction series. Therefore, a plot of ΔH *versus* ΔS would not be expected to be linear. For the same reason, a plot of the Hammett equation (Eq. 2) would not be expected to be linear under these conditions.

On the other hand, when each of the two mechanisms is isergonically related (*i.e.*, $\delta\Delta H' = \beta'\delta\Delta S'$ and $\delta\Delta H'' = \beta''\delta\Delta S''$):

$$\delta\Delta H = \beta'\delta\Delta S' + \beta''\delta\Delta S'' \qquad \text{(Eq. 5)}$$

$$\delta\Delta S = \delta\Delta H'/\beta' + \delta\Delta H''/\beta'' \qquad \text{(Eq. 6)}$$

$$\delta\Delta G = [\beta' - T]\delta\Delta S' + [\beta'' - T]\delta\Delta S'' = [1 - (T/\beta')]\delta\Delta H' + [1 - (T/\beta'')]\delta\Delta H'' \qquad \text{(Eq. 7)}$$

From Eq. 7 it is apparent that for reactions run at $T = \beta'$ or $T = \beta''$, the free energy expression will be simpler by one interaction mechanism. The same, however, is not true for the observed enthalpy and entropy expressions (Eqs. 5 and 6), which remain complex independent of T when $\beta' \neq \beta''$ or $\beta' \gg \beta''$. In practice, then, it is possible to obtain linear Hammett plots even when the ΔH *versus* ΔS profile is scattered, provided that the reaction temperature is close to β' or β''.

Hepler Analysis of Scattered Isergonic Profiles—Hepler (4, 5) proposed a two-interaction model, which simplifies Eqs. 3 and 4 and permits the linearization of a scattered ΔH *versus* ΔS plot. According to the Hepler scheme, the prime and double-prime superscripts of Eqs. 3 and 4 refer to internal and external contributions of substituents, respectively. The internal contributions represent substituent interactions with the reaction center, and the environmental contributions represent substituent interactions with the solvent. By assuming an isergonic relationship for the environmental contributions and a negligible contribution from the internal entropy, Eq. 8 may be derived from Eqs. 3 and 4:

$$\delta\Delta H = \delta\Delta H' + \beta''\delta\Delta S \qquad \text{(Eq. 8)}$$

where β'' is the isergonic temperature for the solvation effect. The $\delta\Delta H'$ quantity, corresponding to the internal enthalpy contribution, may now be calculated from Eq. 8 using the experimentally observed values of $\delta\Delta H$ and $\delta\Delta S$ and letting $\beta'' = \overline{T}$, the average temperature for the determinations[3] (5, 6). The free energy expression for the Hepler scheme is given by:

$$\delta\Delta G = \delta\Delta H' + (\beta'' - T)\delta\Delta S \qquad \text{(Eq. 9)}$$

[1] The slope = $R\beta_i$ when Arrhenius parameters E_a and ln A are used for rate data.

[2] The general term isergonic is used here to include both isokinetic and isoequilibrium phenomena (Ref. 2).

[3] The reviewer of this manuscript appropriately commented that the Hepler scheme with 270° < β < 320° is specifically applicable to water and similar solvents. In other solvent systems, β'' for solvation may not necessarily approximate $\overline{T}$.

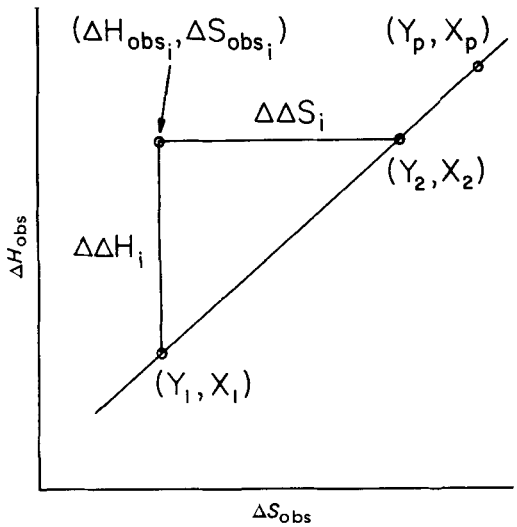

Figure 1—*Diagram showing the vertical* ($\Delta\Delta H_i$) *and horizontal* ($\Delta\Delta S_i$) *distances of point* (ΔH_{obs_i}, ΔS_{obs_i}) *from the error line,* $Y_i = \overline{T}X_i + b$.

Since thermodynamic parameters for reactions are normally reported for the average temperature of determination and since β'' equals $\overline{T}$ or follows it closely, the second term in Eq. 9 will equal zero in most cases; the calculated values of $\delta\Delta H'$ will equal $\delta\Delta G$. It is not surprising, therefore, that calculated $\delta\Delta H'$ values are linear in σ for series that obey the Hammett relationship (Eq. 2) (4, 7, 8).

Vertical and Horizontal Distances from Error Line—While the Hepler model is satisfying from a mechanistic point of view, the method has two serious drawbacks. First, $\overline{T}$ for the solvation effect is also equal to the error slope for any isergonic relationship. Second, the calculation of $\delta\Delta H'$ from Eq. 8 is identical to the method used in calculating $\delta\Delta G$ values for scatter about any isergonic line. Therefore, it is possible to obtain results identical to those of Hepler's without referring to a solvation mechanism merely by calculating the deviation in enthalpy or entropy from the error slope, $\overline{T}$.

The equations for an analysis based on distances from the error line may be formulated by reference to Fig. 1. The equation of the error line with a slope equal to $\overline{T}$ and drawn through the coordinates of the parent point (Y_p, X_p) is given by:

$$Y_i = \overline{T}X_i + b \qquad \text{(Eq. 10)}$$

where $b = \Delta H_{obs_p} - \overline{T}\Delta S_{obs_p}$ = free energy of parent compound, and Y_i and X_i represent ΔH_{obs} and ΔS_{obs} values for a given compound projected to the error line. The vertical distance of the observed point in the figure from the error line is given by the difference in ΔH_{obs_i} and Y_1 according to:

$$\Delta\Delta H_i = \Delta H_{obs_i} - \overline{T}\Delta S_{obs_i} - b \qquad \text{(Eq. 11)}$$

In a similar manner, the horizontal distance of the observed point from the error line is obtained as the difference between S_{obs_i} and X_2, which is equal to:

$$\Delta\Delta S_i = \Delta S_{obs_i} - (\Delta H_{obs_i}/\overline{T}) + b/\overline{T} \qquad \text{(Eq. 12)}$$

The corresponding free energy terms for the observed values calculated from the distances to the error line are obtained by substituting Eqs. 11 and 12 into the Gibbs free energy expression to obtain:

$$\Delta G_{obs_i} = \Delta\Delta H_i + b \qquad \text{(Eq. 13)}$$

and:

$$\Delta G_{obs_i} = -\overline{T}\Delta\Delta S_i + b \qquad \text{(Eq. 14)}$$

The values of $\Delta\Delta H_i$ of Eq. 11 and $\delta\Delta H'$ of Eq. 8 differ only by the constant b, which is equal to the free energy contribution of the parent compound. Furthermore, from Eqs. 13 and 14, it can be seen that the expression for ΔG_{obs_i} is given as a sum of two free energy terms: one for the parent compound (b) and one for the substituent ($\Delta\Delta H_i$ or $-\overline{T}\Delta\Delta S_i$). The vertical distance, $\Delta\Delta H_i$, or its counterpart on the horizontal axis, $-\overline{T}\Delta\Delta S_i$, simply yields the free energy contribution of the substituent symbolized by $\delta\Delta G$. Thus, series that obey the Hammett relationship (Eq. 2) will necessarily yield $\Delta\Delta H_i$ values that correlate with σ.

Lengths of Error Contours and Perpendicular Distances from β Line—The decision of whether to include any given member of a congeneric series within the classification of an assigned β value is arrived at by determining the error associated with that member on an isergonic profile. As stressed previously (1, 6), however, the uncertainty of any point on such a profile is not given by a rectangle with dimensions in standard errors for that point but instead by a region referred to as the error contour. The standard errors of ΔH and ΔS are appropriate when discussing either one of these two quantities independently of the other; but when both are considered jointly as in isergonic profiles, the correct uncertainty function is the joint confidence region (9). This region takes the shape of a highly eccentric ellipse when the variances of the two considered quantities differ widely and are strongly correlated. Such is the case for the least-squares estimates of the slope and intercept of Arrhenius plots from which ΔH and ΔS are derived.

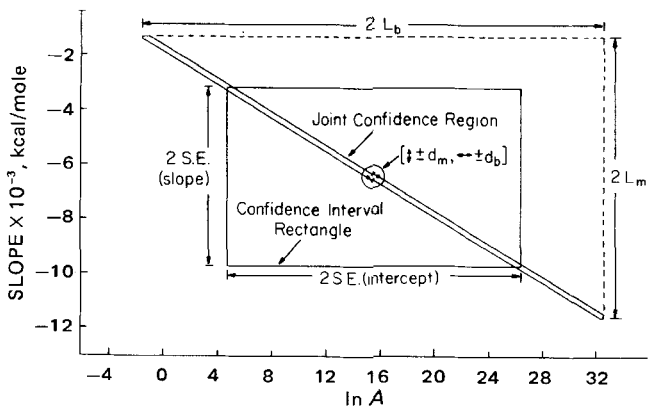

Figure 2—*Comparison of the joint confidence region (error contour) and confidence interval rectangle associated with the slope and intercept of the Arrhenius fit for the alkaline hydrolysis of phenyl benzoate.*

Mandel and Linnig (10) pointed out that a negative correlation exists between the errors in slope and intercept whenever the x values of the original data are positive. As a consequence, the upper part of the error ellipse tilts toward the ordinate in a plot of slope *versus* intercept[4]. The boundaries of this ellipse are determined by the standard error of estimate, s, for the least-squares analysis and by the $(F \text{ ratio})^{1/2}$ for the desired confidence level. Thus, at any desired confidence level, only values of the slope and intercept that fall within the boundaries of the ellipse are allowed on the basis of observed experimental error.

Mandel and Linnig (10) simplified the plotting of joint confidence regions by deriving a function that closely approximates the error ellipse from three sets of parallel tangents. These parallel lines can be plotted on graph paper with the aid of four constants (L_m, L_b, d_m, and d_b) describing the error function (see *Appendix* for equations). This method of ellipse construction was used to plot the joint error region associated with the slope and intercept of the Arrhenius fit for the alkaline hydrolyses of phenyl benzoates at 20, 30, and 35° (8). Figure 2 illustrates the extreme eccentricity of the error ellipse for this type of data as compared with the larger rectangular area based in the standrd errors of the slope and intercept.

Two important features arise out of the error ellipse analysis as applied to the interpretation of isergonic profiles. First, the lengths of the error regions determine whether two or more points lying along an isergonic line are potentially interchanged as a result of experimental error. Second, the widths, w, or thicknesses of the error regions determine which points of an isergonic profile belong to a given interaction line with slope = β. Both of these features can be utilized by plotting all individual error contours on an isergonic profile and then observing their distribution relative to either the least-squares line drawn through the data or the error line with a slope of $\overline{T}$.

Since the process of plotting error contours on graph paper is tedious and time consuming, even for the Mandel–Linnig projections, an alternative method for providing the same information is desirable. A comparison of the contour lengths projected along a given β line is easily accomplished by computing the value of (slope $\pm$ L_m) for each point and then visually inspecting the calculated limits for overlap between any

[4] A plot of $\Delta H^{\neq}$ *versus* $\Delta S^{\neq}$ for these data would yield an error ellipse with a positive slope because of the change in sign that occurs in converting the slope to $\Delta H^{\neq}$.

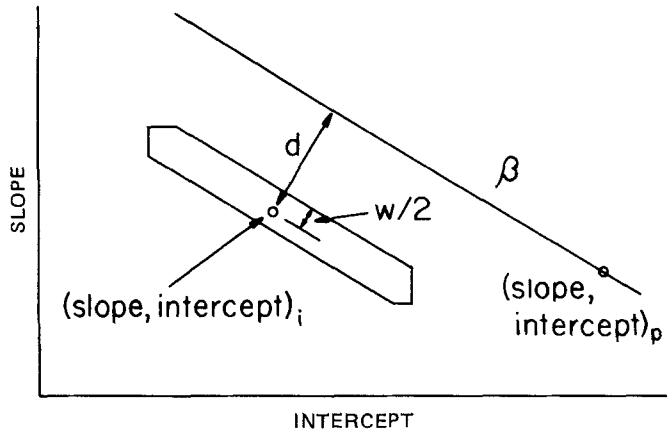

Figure 3—*Diagram showing the perpendicular distances* d (*distance from center of error ellipse to β line drawn through parent point*) *and* w/2 (*distance from center to ellipse boundary*).

points. These limits should not overlap if one wishes to gain statistical confidence in the relative positioning of points along the line.

The use of contour widths to interpret isergonic data requires a comparison between the perpendicular half-widths, $w/2$, of the contours and the respective perpendicular distances, d, from a given β line (Fig. 3). These distances may be calculated from Eq. 15 which, in general, gives the perpendicular distance, p, of any point from a given line (11):

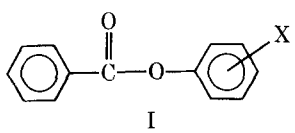
$$p = (AX_i + BY_i + C)/(A^2 + B^2)^{1/2} \qquad \text{(Eq. 15)}$$

where X_i and Y_i are the coordinates of the point and where the equation for the line is given by $AX + BY + C = 0$, with X and Y representing the coordinates for a point on the line. The coefficients A, B, and C may be expressed in terms of the more usual slope–intercept form for a line, $Y = mX + b$, as follows: $A = -m$, $B = 1$, and $C = -b = -(Y - mX)$. For calculating the distance, d, in Fig. 3 from the line drawn through the parent point, these coefficients take on the values $A = -\beta$, $B = 1$, and $C = -[\text{slope}_p - \beta\ (\text{intercept}_p)]$. For calculating the distance, $w/2$, in the figure from the contour limit extending through a point with coordinates of $(\text{slope}_i + dm_i$ and $\text{intercept}_i)$, the coefficients take on the values $A = -L_m/L_b$, $B = 1$, and $C = -[(\text{slope}_i + dm_i) - L_m/L_b(\text{intercept}_i)]$[5]. A comparison between the values of d and $w/2$ for each point indicates whether the point belongs to the particular β line in question. Thus, a point may be rejected at the confidence level of its error contour when $d > w/2$.

RESULTS AND DISCUSSION

The data chosen for analysis are those of Washkuhn *et al.* (8) for the alkaline hydrolysis of 3- or 4-substituted phenyl benzoates (I), where X = 4-CH_3, H, 4-F, 4-Cl, 3-CN, 4-CN, or 4-NO_2. This congeneric series obeys the Hammett relationship (Eq. 2) but shows a scattered ΔH *versus* ΔS profile. Therefore, it is suitable for analysis using the equations given previously. The second-order rate constants, k_{OH}, for the series were reported as a function of temperature at 20, 25, 30, and 35° determined in 50% (v/v) acetonitrile–0.02 *M* phosphate buffer.

Activation Parameters—A preliminary graphical plot of the data showed a large systemic deviation of the rate constant at 25° for each member of the series. These displaced data points were tested for exclusion from further data analysis by determining the significance probability of the t value under such conditions (12). In all cases, the significance levels were considerably greater than 0.05, justifying a rejection of the null hypothesis. From these results and because of the large upward systemic displacement of each point, data at 25° were not included in calculating the parameters given in Table I. The slopes and intercepts of the Arrhenius plots based on data at 20, 30, and 35° were significant at least at the 0.05 level, except the intercept for the parent compound which was significant at the 0.10 level.



I

[5] From the *Appendix*, $L_m/L_b = (N/\Sigma X^2)^{1/2} = [N/\Sigma(1/T)^2]^{1/2}$ while $\overline{T} = (\Sigma T)/N$. The difference between these two quantities, however, is small ($\simeq$0.3°K) for the usual 20° temperature range used in collecting Arrhenius data.

Table I—Activation Parameters for the Alkaline Hydrolysis of Substituted Phenyl Benzoates[a]

Substituent (σ^-)[b]	$\Delta G^{\neq}$, kcal/mole	$\Delta H^{\neq}$, kcal/mole	$\Delta S^{\neq}$, cal/mole-deg
4-CH_3 (−0.17)	21.3	10.9	−34.8
H (0.00)	21.1	12.1	−29.7
4-F (0.062)	20.7	11.0	−32.4
4-Cl (0.226)	20.6	11.8	−29.3
3-CN (0.678)	19.9	10.3	−31.9
4-CN (1.00)	19.6	10.5	−30.2
4-NO_2 (1.27)	19.4	11.6	−25.8

[a] Activation parameters are based upon an initial linear least-squares fit of raw data (at 20, 30, and 35°) from Ref. 8 to the Arrhenius equation, where $\Delta H^{\neq} = E_a - RT$, $\Delta S^{\neq} = R\ [\ln k\overline{T} - \ln (k\overline{T}/h) + \Delta H^{\neq}/R\overline{T}]$, $\Delta G^{\neq} = \Delta H^{\neq} - \overline{T}\Delta S^{\neq}$ (before rounding off), and $\overline{T} = (\Sigma T)/N = 301.3$°K. [b] Values of σ^-, the Hammett constant for substituted phenols, were taken from Table 2-17 of Ref. 13.

Linear free energy and isergonic correlations for activation parameters of the phenyl benzoate series are given in Table II. Of the three parameters, only $\Delta G^{\neq}$ is a linear function of σ^- (Eq. 16). Furthermore, Eq. 19 shows that the isergonic profile is highly scattered. From the Leffler–Grunwald analysis given previously, nonlinearity observed with Eqs. 17–19 could be viewed in terms of multiple contributions to the observed enthalpies (Eqs. 3 and 4). When more than one mechanism contributes to ΔH, ΔS, or both, the separate contributions would not be expected to correlate with the same substituent parameter in either ΔH or ΔS, nor would a proportionality of effects be expected to exist between the mechanisms. Hence, the isergonic profile would be scattered.

Vertical and Horizontal Distances from β Line—The vertical ($\Delta\Delta H^{\neq}$) and horizontal ($\Delta\Delta S^{\neq}$) distances from the error slope (β = 301.3°) for the individual points on the isergonic profile (Table III) were calculated from the observed activation enthalpies and entropies before rounding off, using Eqs. 11 and 12, respectively. The vertical distance of each substituent from the error line is identical to its substituent effect, $\delta\Delta G^{\neq}$, in agreement with Eq. 13. Similarly, on the horizontal scale, $\delta\Delta G^{\neq}$ may be obtained as the product of $\Delta\Delta S^{\neq}$ times $-\overline{T}$, which is in agreement with Eq. 14.

Linear free energy correlations for the vertical and horizontal distances are presented in Table IV. For β = 301.3°, the resulting F ratios and correlation coefficients, r, are identical to those of Eq. 16 in Table II, demonstrating the redundancy between $\Delta G^{\neq}$, $\Delta\Delta H^{\neq}$, and $\Delta\Delta S^{\neq}$ as parameters for correlation with σ^-. Correlations based on $\Delta\Delta H^{\neq}$ and $\Delta\Delta S^{\neq}$ simply do not add any new information to the previously determined substituent effect based on $\Delta G^{\dagger}$ (Eq. 16).

Table IV also gives correlations for $\Delta\Delta H^{\neq}$ *versus* σ^- when β is varied using the values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ at 301.3°. The analysis demonstrates the effect upon F and r when β equals some value other than the error slope, $\overline{T}$. When β varies between 0 and 600°K, the correlation coefficient takes on values between −0.215 and −0.910, with a maximum appearing at β = 325°. For β = 0°, the resulting $\Delta\Delta H^{\neq}$ values equal $\delta\Delta H^{\neq}$; the resulting F and r values for the correlation are identical to those for Eq. 17 (Table II) based on $\Delta H^{\neq}$.

Values of β between 280 and 325° closely approximate the limits of β

Table II—Correlations for Activation Parameters[a]

Regression Equations[b] (n = 7)	S	F	r	Equation Number
$\Delta G^{\neq} = -1.33\sigma + 21.0$	0.136	175	−0.986	16
$\Delta H^{\neq} = -0.268\sigma + 11.3$	0.733	0	−0.215	17
$\Delta S^{\neq} = 3.53\sigma - 32.1$	2.27	4	−0.684	18
$\Delta H^{\neq} = 134\Delta S^{\neq} + 15{,}300$	625.0	2	−0.554	19

[a] n = number of data points used in linear least-squares fit; S = standard error of estimate; r = correlation coefficient; and F = F ratio (at the 90 and 95% confidence levels, F = 4.06 and 6.61, respectively, for 1,5 degrees of freedom). [b] Equations 16 and 17 are expressed in kcal/mole, Eq. 18 is expressed in cal/mole-deg, and Eq. 19 is expressed in cal/mole.

4-CN	−1450	−1450	4.813
4-NO_2	−1669	−1669	5.538

[a] $\delta\Delta G = \Delta G_X^{\neq} - \Delta G_H^{\neq}$; $\Delta\Delta H^{\neq}$ and $\Delta\Delta S^{\neq}$ were calculated using Eqs. 11 and 12, respectively.

for aqueous solvation effects in phenols as suggested by Hepler ($270° < \beta < 320°$) (4). Within this range of β, the value of r for the $\Delta\Delta H^{\neq}$ *versus* σ^- correlations is observed to change only very slightly, and deviations in the slopes from $\overline{T}$ are not statistically significant even at the 50% level. Alternatively, it may be stated that values of β between 280 and 325°K for a proposed solvation mechanism could not be distinguished statistically from $\overline{T}$ falling within this temperature region.

Lengths of Error Contours—The constants L_m, L_b, d_m, and d_b were calculated for each member of the series, using the method of Mandel and Linnig (10) outlined in the *Appendix*. Based upon the values of L_m and the slope values for Arrhenius fits to the data, limits for lengths of error contours are given in Table V for the 90% confidence level. A visual inspection of these limits shows that each member of the series is overlapped to some extent by every other member of the series. If the individual data points for the present series fell upon a single isergonic line, $\beta = \overline{T}$, the result could only be attributed to experimental error.

The extreme overlap of error contours for this series is a function of: (*a*) the small number of data points, N, available for the Arrhenius fits; (*b*) the experimental error as reflected by S^2 (error variance); and (*c*) the narrow range of slope values (0.9 kcal/mole), which produces small differences between the individual members. The first two factors are included in the constant, K (Eq. A5), which determines the length of the error contour. If S^2 is maintained at the same level, simply increasing N for the Arrhenius fits would considerably reduce the lengths of the contours. Thus, lengths would be decreased by a factor of $[(F_{df} = 1)/(F_{df} = x)]^{1/2}$ for each additional increase in N above $N = 3$. For $N = 4$ and $N = 5$, the contour lengths decrease by factors of 2.35 and 3.01, respectively, at the 90% confidence level. For the present series, however, these decreases in contour lengths are not sufficient to eliminate their overlap because of the small differences between the slopes. Extremely precise data yielding very small values of S^2 would be required to remove the overlap.

Perpendicular Distances from β Line—As discussed under *Theoretical*, perpendicular distances represented by d and $w/2$ may be utilized to determine whether the individual members of a series belong to a given β line. These values for the present series are given in Table VI for variations in β and in significance levels. The perpendicular distances for the members of the series from the error line ($d_{301.3}$) is greater than their respective contour widths ($w/2$) measured perpendicularly to the contour boundary (Table VI). This comparison is good at both the 90 and 95% confidence levels. A similar comparison between d values measured from β = 280° and 325° and their respective $w/2$ values produces the same results.

Table IV—Correlations for Distances from the β-Line

β	Slope	Intercept	F	r
	Vertical Distances[a] ($\Delta\Delta H^{\neq}$ *versus* σ^-)			
0	−268	−839	0	−0.215
280	−1260	−153	118	−0.979

325	2.19	0.0674	211	0.988
600	2.00	0.528	24	0.910

[a] The intercepts for vertical and horizontal distances are expressed in calories per mole and calories per mole-degree, respectively.

Table V—Limits for Lengths of Error Contours at 90% Confidence Level[a]

Substituent	Slope + L_m, kcal/mole	Slope − L_m, kcal/mole
4-CH_3	−4.64	−6.89
H (none)	−1.26	−11.6
4-F	−3.22	−8.44
4-Cl	−2.35	−10.1
3-CN	−3.23	−7.74
4-CN	−2.57	−8.60
4-NO_2	−4.55	−7.76

[a] Slope = $-(E_a/R)$, obtained from a linear least-squares fit of the data (at 20, 30, and 35°) to the Arrhenius equation. The L_m values were calculated from Eq. A1 (see *Appendix*). The F ratio = 49.5 for 2,1 degrees of freedom at the 0.90 level.

From the comparisons based on a β line of 301.3°, it is certain that the points do not fall along the error line or that the distribution of points on the isergonic profile is strongly affected by the correlation of error producing this line. The influence of a heavily weighted error slope would force the distribution of points along a slope of $\beta = \overline{T}$. This is not the case here since, from the previous $\Delta H^{\neq}$ *versus* $\Delta S^{\neq}$ correlation (Eq. 19), β = 134° and $r = -0.554$. Pure error would produce a perfect correlation between $\Delta H^{\neq}$ and $\Delta S^{\neq}$, with the resultant slope being equal to $\overline{T}$.

The Δd values given in Table VI provide a means of determining whether β = 301.3° is different from either β = 280° or β = 325°, the latter being close to the suggested limits for solvation effects in phenols (4). A comparison of either Δ^1 or Δ^2 (differences in d from either side of the error line) with the respective $w/2$ values for the 95% confidence level shows that the differences, Δd, fall within the error range of the perpendicular contour widths, $w/2$. The comparisons are approximately as good at the 90% confidence level. These results indicate that β = 301.3° cannot be distinguished from β = 280 or 325°.

The d values for each substituent at a given value of β follow a trend resembling its substituent effect (Table VI). Correlations between d and σ^- for values of β ranging between 0 and 600° are given in Table IV. The values of F and r obtained over the range of β for these correlations are identical to those values obtained for the correlation between $\Delta\Delta H^{\neq}$ and σ^- (Table IV). While a comparison between values of d and $w/2$ aids in the classification of β values, the absolute values of d identically parallel substituent effects ($\delta\Delta G^{\neq}$) and, therefore, provide no new information about substituent effects for the series.

CONCLUSIONS

The present analysis shows that the geometric distances of data points on an isergic profile, calculated either in the vertical ($\Delta\Delta H$), horizontal ($\Delta\Delta S$), or perpendicular (d) distances from the error slope, do not add any new information to a substituent effect analysis already based on ΔG. The vertical distances, $\Delta\Delta H$, are identical to the substituent effect $\delta\Delta G$; for series that obey the Hammett relationship (Eq. 2), these distances must correlate with σ^- regardless of the implication of a solvation mechanism. Thus, the use of the Hepler method (Eq. 8) to demonstrate a solvation effect in the scattered isergonic profile for series I would not be warranted. This conclusion does not deny the existence of a solvation mechanism for the series but does seriously question the Hepler approach for implicating the mechanism.

Statistically, the use of the joint confidence region (error contour) is the soundest way of analyzing the distribution of points on an isergonic profile. The method is simple and should routinely accompany such profiles appearing in the literature. The limits of the error contour lengths provide evidence of overlap between members of the series and, hence, dictate statistical uncertainty along the line. For series such as I, which do not show a wide variation in substituent effects, extremely precise rate data with N = 4 or 5 would be required to eliminate overlap between contours.

Leffler (6) suggested testing the randomness of the data along the isergonic line when overlap cannot be eliminated. Thus, points appearing

[a] The d and $w/2$ values were calculated using Eq. 15 and the values of the coefficients A, B, and C described in the text. [b] Δ^1 and Δ^2 refer to the differences $(d_{301.3} - d_{325})$ and $(d_{280} - d_{301.3})$, respectively. [c] CL = confidence level.

along the line in an order that also follows their σ values could still represent a real effect. A comparison between the d and $w/2$ values provides a means of determining whether the points falling along an isergonic line differ statistically from those falling along another line such as the error line. For series such as I with scattered isergonic profiles, a result of $d > w/2$ simply proves that the scatter is not the result of experimental error.

A further comparison between differences in d, Δd, from various β lines and $w/2$ values provides a means of establishing a β range for the error contour. When using suggested β lines for solvation effects, this range for series I was approximately 45°. Since the average reaction temperature, $\overline{T}$, fell within this range, it must be concluded that solvation effects could not be distinguished statistically from error effects.

APPENDIX

Equations A1–A4 give the relationships for computing the four constants (L_m, L_b, d_m, and d_b) required in constructing the joint confidence region from three sets of parallel tangents (10):

$$L_m = K(N/\Delta)^{1/2} \quad \text{(Eq. A1)}$$

$$L_b = K(Q/\Delta)^{1/2} \quad \text{(Eq. A2)}$$

$$d_m = K[2W/Q(1 + W)]^{1/2} \quad \text{(Eq. A3)}$$

$$d_b = d_m(L_b/L_m) \quad \text{(Eq. A4)}$$

Definitions of the symbols appearing in these equations are further given by Eqs. A5–A8:

$$K = (2FS^2)^{1/2} \quad \text{(Eq. A5)}$$

$$\Delta = N\sum X^2 - (\sum X)^2 \quad \text{(Eq. A6)}$$

$$Q = \sum X^2 \quad \text{(Eq. A7)}$$

$$W = (N\sum X^2)^{1/2}/\sum X \quad \text{(Eq. A8)}$$

where F = F ratio for 2 and $N - 2$ degrees of freedom at the desired confidence level, S^2 = the error variance for the least-squares analysis, N = total number of data pairs, and X = X value for data pair.

The joint confidence region is constructed within a rectangle having the dimensions of $2L_m$ for the ordinate and $2L_b$ for the abscissa, as observed in Fig. 2. A diagonal line with a negative slope running from corner to corner through the rectangle forms the major axis of the simulated ellipse, thus producing a tilt slope of L_m/L_b. Plotted values $\pm d_m$ in the ordinate direction and $\pm d_b$ in the abscissa direction from the center of the rectangle form the guide points for drawing the two sloping major ellipse boundaries (Fig. 2).

Effect of Lysine and Diethanolamine–Rutin on Blood Levels, Withdrawal Reaction, and Acute Toxicity of Ethanol in Mice

M. A. DORATO *, V. D. LYNCH, and C. O. WARD ˣ

Abstract □ The effects of L-lysine and diethanolamine–rutin on blood ethanol levels and withdrawal convulsions following a 4-day exposure to ethanol vapors were evaluated in 30–40-g male Swiss-Webster mice. The animals were exposed in groups, along with simultaneous controls, in a 34-liter dynamic Plexiglas exposure chamber. Blood was collected by retro-orbital puncture and analyzed enzymatically for ethanol. At the end of the inhalation period, convulsions on handling were scored over 24 hr. In addition, the effects of L-lysine and diethanolamine–rutin on blood ethanol levels and on acute ethanol toxicity following oral and intraperitoneal administration were evaluated. L-Lysine lowered blood ethanol levels following inhalation or oral administration of ethanol. Diethanolamine–rutin had no effect on blood ethanol levels. Both L-lysine and diethanolamine–rutin decreased the withdrawal reaction in dependent mice. L-Lysine increased the oral LD_{50} of ethanol, while diethanolamine–rutin decreased the intraperitoneal LD_{50} of ethanol.

Depletion of amino acids was reported to be characteristic in the development of delerium tremens following chronic alcohol ingestion (1). The prophylactic use of amino acids was accompanied by a high degree of success in forestalling delerium tremens in individuals whose low amino acid levels indicated their increased susceptibility (1). Specific amino acids, such as L-glutamine and L-lysine, also were effective in reducing or preventing ethanol toxicity (2–4).

BACKGROUND

Schiller (5) investigated the effects of amino acids (as a solution of protein hydrolysates[1]) on blood ethanol levels and the rate of disappearance of ethanol from the blood. The amino acids were administered intravenously and ethanol was administered orally to chronic alcoholics free of liver impairment. Ethanol-utilization curves showed that amino acids decreased blood ethanol levels and accelerated the rate of disappearance of ethanol from the blood (5). The specific amino acids in the mixture used by Schiller (5) could not be determined. Selected amino acids were effective in decreasing blood ethanol levels in dogs when administered orally simultaneously with ethanol (6). Certain amino acids possibly impede the absorption of orally administered ethanol by formation of a stable complex (7).

A significant reduction in the depressant action of ethanol (30% v/v) was reported following a 30-min pretreatment with L-lysine (2.5 g/kg ip or po) (3). The oral administration of L-lysine and ethanol resulted in the complete elimination of hypnotic effects. Administration of L-lysine and ethanol intraperitoneally resulted in a 65% reduction in ethanol sleeping time. Also, an increase in the LD_{50} of ethanol in rats was noted following treatment with L-lysine (3).

The interaction of ethanol or acetaldehyde, its major metabolite, with various biogenic amines is a possible cause of ethanol dependence following chronic administration (8–10). The presence of acetaldehyde may lead to localized increases in the concentrations of aromatic aldehydes in tissues rich in biogenic amines (9). Furthermore, these highly reactive aldehydes condense with their parent amines to yield a morphine-like benzyltetrahydroisoquinoline alkaloid (9). This effect was demonstrated *in vitro* using rat liver homogenates (8). Such condensation products were reported for dopamine (9), epinephrine, and norepinephrine (levarterenol) (10).

The coadministration of an excess reactive α-amino acid and ethanol might lead to a decrease in ethanol toxicity due to the combination of acetaldehyde with the amino acid (3).

Rutin-enhanced diethanolamine mixtures protected rats from the motor effects of ethanol, without affecting blood ethanol levels, *via* a weak agonist–antagonist action (11–13).

This study was undertaken to determine the extent to which L-lysine, a reactive α-amino acid, protects against ethanol toxicity and alters the ethanol-withdrawal reaction in dependent mice. In addition, because of the possible agonist–antagonist relationship of diethanolamine to ethanol, the effects of diethanolamine–rutin on the ethanol-withdrawal reaction and acute ethanol toxicity in mice were evaluated.

L-Lysine was chosen because of previous studies (3, 4) and because: (*a*) it has one of the fastest rates of reaction with acetaldehyde (14); (*b*) L-lysine levels of 0.57, 0.98, and 1.53 mg % were reported for patients with delerium tremens, recovered patients, and normal subjects, respectively (1); (*c*) L-lysine is the only essential α-amino acid having sufficient amino groups in nonzwitterionic form to interact with acetaldehyde (15); and (*d*) treatment with L-lysine significantly increased the LD_{50} of acetaldehyde[2].

EXPERIMENTAL

Production of Ethanol Dependence—Male Swiss-Webster mice[3], 30–40 g, were divided into four treatment groups of 10 mice each. These treatment groups were housed individually in 34-liter Plexiglas exposure chambers, along with simultaneous pH controls, for 4 days. Air was introduced into the chamber at the rate of 8 liters/min. The total air flow was split between two 1-liter erlenmeyer flasks (16); one flask contained ethanol (95%, USP) and the other remained empty. The air flow was joined again just before entering the chamber.

The relationship of air flow to chamber concentration is shown in Table I. A flowmeter in each line, between the air compressor pump and the flasks, allowed for control of the chamber ethanol levels. A chamber ethanol concentration of 11–15 mg/liter was appropriate in establishing ethanol dependence in mice over 4 days. The priming dose of ethanol (17) was not necessary if the chamber was allowed to reach equilibrium before introducing the mice (18). Therefore, the air flow through the chamber was begun approximately 20 hr before introducing the mice. During the exposure period, the chamber temperature varied from 24 to 27° and the relative humidity varied from 60 to 70%.

The test animals were removed from the chamber for a short period each day for administration of: Solution A, L-lysine[4] (20% w/v) prepared in a solution of protein hydrolysates[1], 1 g/kg po, pH 5.7; Solution B, L-lysine[4] (20% w/v) as an aqueous solution, 1 g/kg po twice daily,

Table I—Relationship of Air Flow Split between Ethanol and Air Flasks to Chamber Ethanol Concentration

Air Flow through Ethanol Flask, liters/min	Air Flow through Air Flask, liters/min	Chamber Concentration, mg/liter
0.75	7.25	11
0.88	7.12	13
1.10	6.90	15
1.30	6.70	18
1.50	6.50	22

pH 5.7; protein hydrolysate[1], 9 ml/kg po, pH 5.7; or diethanolamine–rutin[5], 4.5 ml/kg po, pH 7.4.

In addition, each animal received pyrazole (34 mg/kg ip) for the maintenance of stable blood ethanol levels (19, 20). On Day 5, the animals were removed from the ethanol environment, and convulsions on handling were evaluated according to the method of Goldstein and Pal (19) over 24 hr.

pH Controls for Amino Acid and Diethanolamine–Rutin Treatments—A pH 5.7 phosphate buffer solution was administered orally to control groups exposed to ethanol vapors simultaneously with amino acid treatment groups. The control buffer was administered in volumes equivalent to the various amino acid treatments. Another pH 7.4 phosphate buffer was administered to the control group exposed simultaneously with the diethanolamine–rutin treatment group in a volume equivalent to that of the treatment. Each animal in the control groups received pyrazole, 34 mg/kg ip. The control groups were removed from the ethanol environment, and their withdrawal scores were evaluated simultaneously with the treatment groups (19).

Environmental Control—Ten animals were introduced into the exposure chamber and kept there for 4 days. The air flow was maintained at 8 liters/min. Ethanol, however, was not introduced into the chamber. The animals were removed for short periods each day for intubation. On Day 5, the animals were removed from the chamber, and convulsions on handling were evaluated (19).

Evaluation of Blood Ethanol Levels Resulting from Inhalation of Ethanol Vapors—Blood ethanol levels were measured enzymatically. Each day during the exposure period, three animals from the treated and control groups were randomly selected for blood sampling. The blood samples were obtained by retro-orbital puncture (21–23) before the administration of any treatment or control.

A volume of 0.25 ml of blood was collected from each animal, deproteinated, and added to the enzymatic reaction mixture[6] (24). After 30 min at room temperature, the fluorescence[7] of the mixture was measured at an absorption maximum of 340 nm and an emission maximum of 458 nm. This method is based on the natural fluorescence of the reduced diphosphopyridine nucleotide formed, since ethanol is metabolized by alcohol dehydrogenase to acetaldehyde (24). The reaction is pushed toward completion by the addition of semicarbazide (25). On Day 5, five animals from each group were chosen randomly for the blood ethanol analysis.

Determination of Chamber Ethanol Concentration—The chamber ethanol concentration also was determined enzymatically (24). Each day, a 1-ml sample of chamber air was withdrawn using a gastight syringe[8]. The sample was then injected into the headspace of a vial containing 3.5 ml of the enzymatic reaction mixture[6] (25). After 30 min at room temperature, the fluorescence[7] of the reaction mixture was measured (24). The sampling port was positioned to facilitate sampling at the respiratory level of the test animals (26). The chamber ethanol concentrations resulting from various rates of flow are shown in Table I.

Evaluation of Ethanol Intoxication—Before each exposure period, the animals were trained to maintain their balance on a rotating roller (10 rpm) for 1 min (27). This simple test was used each morning during the exposure period, before any treatment was administered, as an indication of the level of intoxication, tolerance, and loss of muscle control due to ethanol inhalation.

Effect of Amino Acids and Diethanolamine–Rutin on Acute Blood Ethanol Levels—Male Swiss-Webster mice, 30–40 g, were divided into 12 treatment groups of six mice each, with appropriate pH controls. The treatments were administered, as previously indicated, for 4 days. One hour after the last treatment on Day 4, ethanol was administered, 3 g/kg ip or 6 g/kg po. One treatment group received 6 g/kg po simultaneously with the last treatment. Blood was sampled 0.5 or 1 hr after the intraperitoneal or oral administration of ethanol, respectively. Blood was obtained by retro-orbital puncture (21–23) and analyzed enzymatically for ethanol (24, 25).

Effect of Amino Acids and Diethanolamine–Rutin on 24- and 72-hr LD_{50} of Ethanol—Male Swiss-Webster mice, 30–40 g, were divided into groups of 10 and treated as previously described for 4 days. One hour after the last treatment on Day 4, ethanol was administered (40% w/v) in graded doses of 1–5 g/kg ip and 5–11 g/kg po. The LD_{50} was calculated from the number dead at 24 and 72 hr by the log-probit method of Miller and Tainter (28).

Effect of Various Treatments and Controls on Weights of Mice Exposed to Ethanol Vapor—The subjects in the treatment and control groups were weighed each day. The mean weight of each group on Day 1 was taken as the base for comparison. Weight loss during the exposure period was recorded as percent of the starting weight.

RESULTS

No difference was found between treatment and control groups in their ability to maintain balance on a rotating roller (Table II). However, each treatment group maintained their balance for a longer time than the corresponding control.

None of the treatments used decreased blood ethanol levels after intraperitoneal administration (Table III). In those groups receiving ethanol orally, only the Solution A and Solution B treatments decreased the blood ethanol levels. This result was true for pretreatment as well as simultaneous administration (Table III).

Among the groups exposed to the inhalation of ethanol vapor, only the Solution A group showed a decrease in the daily mean blood ethanol levels (Table IV). However, both the Solution A and Solution B groups had blood ethanol levels below those of controls on Days 4 and 5 (Table IV).

The evaluation of convulsions on handling (19) during the withdrawal period showed that Solution A and diethanolamine–rutin groups had reduced mean withdrawal scores (Table V). The peak withdrawal score, the mean of the three highest consecutive scores, was reduced in the Solution A, Solution B, and diethanolamine–rutin groups (Table V). All treatment and control groups had peak withdrawal scores greater than the environmental control (Table V, $p < 0.001$). Peak withdrawal development, the mean of all scores up to the highest mean score for each group, was reduced in only the Solution A and diethanolamine–rutin groups (Table V).

The 24-hr oral LD_{50} of ethanol (40% w/v) was increased by Solutions A and B and protein hydrolysate (Table VI). The 72-hr oral LD_{50} of ethanol was increased only by Solutions A and B (Table VI). None of the various amino acid treatments affected either the 24- or 72-hr intraperitoneal LD_{50} of ethanol (Table VII).

The diethanolamine–rutin treatment did not affect the 24- or 72-hr oral LD_{50} of ethanol, nor did it affect the 24-hr intraperitoneal LD_{50} (Tables VI and VII). However, diethanolamine–rutin did decrease the 72-hr intraperitoneal LD_{50} of ethanol (Table VII).

Since weight loss can indicate toxicity, the mean percent weight

loss of each treatment group was compared with the appropriate control (Table VIII). Only the diethanolamine–rutin group showed a lower mean percent weight loss. The weight loss in the diethanolamine–rutin group did not differ significantly from that resulting from pyrazole treatment alone. As expected, all groups showed weight loss when compared to the environmental control.

When the Solution A and Solution B treatments were compared, the Solution A group demonstrated a lower peak withdrawal score (0.95 ± 0.09 and 1.32 ± 0.12, respectively; $p < 0.02$). Also, simultaneous administration of ethanol (40% w/v) and amino acids orally resulted in lower blood ethanol levels for the Solution A group (3.60 ± 0.58 and 5.20 ± 0.82, respectively; $p < 0.01$). No difference in blood ethanol levels established by inhalation, nor in any other parameters except those mentioned, was noted between the Solution A and Solution B groups (Table IV).

DISCUSSION

Physical dependence on ethanol is rapidly established in rodents by inhalation techniques (16, 17, 19). To maintain adequate and stable blood ethanol levels, pyrazole, an inhibitor of alcohol dehydrogenase (20, 29), was necessary (16, 17, 19). A dose of 34 mg/kg ip (0.5 mmole/kg), rather than 68 mg/kg ip (1 mmole/kg) as previously reported (17, 19), was adequate (30). A 96-hr exposure at an ethanol concentration of 11–15 mg/liter produced a satisfactory, postalcohol, hyperexcitability reaction in mice. Beginning the air flow approximately 20 hr before introducing the animals to the chamber allowed for the elimination of a priming dose of ethanol (18).

The rotating roller test was used to evaluate the protection afforded by the various treatments against the muscular incoordination produced by ethanol (27) and to serve as an index of tolerance production. Since tolerance has been described as a homeostatic adjustment (31), a decrease followed by a gradual increase in the ability to stay on the rotating roller (10 rpm) would be expected. In fact, a rapid decline in balancing ability occurred during the first 2 days of ethanol inhalation. This decline was followed by a more gradual increase in balancing ability. Even though the mean time on the rotating roller was not significantly longer in the treated than control groups, the treated groups were consistent in maintaining balance for longer periods. This increase indicates a decrease in the intensity of ethanol effects in these groups.

Various amino acids hasten the disappearance of ethanol from the blood (5), resulting in lower blood ethanol levels. The Solution A and Solution B groups showed a decrease in blood ethanol levels following oral ethanol administration. This effect was seen with both the pretreatment with amino acids and the simultaneous administration of amino acids and ethanol. The protein hydrolysate treatment had no effect on blood ethanol levels. This result indicates the necessity of excess L-lysine (3). It was not expected that the diethanolamine–rutin treatment would affect blood ethanol levels by any route, or sequence, of administration[2], and no effect was found.

When ethanol was administered *via* inhalation, the Solution A group showed lower mean blood ethanol levels. The other treatments did not affect the mean blood ethanol levels. However, both the Solution A and the Solution B treatments lowered blood ethanol levels on Days 4 and 5. The rate of ethanol disappearance from the blood was increased by L-lysine[2] and by amino acids in general (5). An in-

crease in the rate of ethanol disappearance from the blood, developing over time, could account for the lower blood ethanol levels on the last 2 days of inhalation. This finding could also explain the lack of effect on blood ethanol levels following acute intraperitoneal administration of ethanol. The diethanolamine–rutin and protein hydrolysate treatments did not affect blood ethanol levels.

Differences in blood ethanol levels did not exist between Solutions A and B following ethanol inhalation or intraperitoneal or oral administration following a 1-hr pretreatment with the amino acid solutions. The lower blood ethanol level in the Solution A group following simultaneous oral administration with ethanol could be attributed to the additional reactive α-amino acids in the treatment.

Both Solutions A and B were expected to increase significantly the 24- and 72-hr oral LD_{50} of ethanol but not the 24- and 72-hr intraperitoneal LD_{50}. This was the case, but there was no difference between the two groups.

The diethanolamine–rutin treatment did not affect the 24- or 72-hr oral LD_{50} nor the 24-hr intraperitoneal LD_{50} of ethanol. However, the 72-hr intraperitoneal LD_{50} of ethanol was decreased by diethanolamine–rutin. Diethanolamine–rutin is a weak ethanol agonist, itself a central nervous system (CNS) depressant[2].

The protein hydrolysate treatment increased the 24-hr oral LD_{50} of ethanol. It did not, however, protect beyond this point. This result could be attributed to insufficient reactive α-amino acids, particularly L-lysine.

The acute and chronic effects of ethanol have been attributed to the augmentation, by ethanol and acetaldehyde, of tetrahydroisoquinoline alkaloid formation from biogenic amines (8, 9). It has been proposed that an increase in the steady-state level of one or more biogenic aldehydes, due to competitive inhibition of NAD-linked aldehyde dehydrogenase by acetaldehyde (9), could be responsible for the CNS effects related to ethanol (32).

L-Lysine decreases blood ethanol levels and accelerates its rate of disappearance from the blood. It also increases the LD_{50} of acetaldehyde (13) and forms a complex with acetaldehyde (3, 11). The formation of this complex could block, to some degree, the ability of acetaldehyde to inhibit NAD-linked aldehyde dehydrogenase, thereby decreasing the formation of tetrahydroisoquinoline derivatives and the pharmacological effects of ethanol. L-Lysine decreased ethanol sleeping time in rats (3). A decrease in alkaloid formation *per se* or in rate of formation could account for the decrease in the severity of the postalcohol hyperexcitability seen in dependent mice.

The Solution A treatment resulted in a decrease in mean withdrawal scores, peak withdrawal scores, and peak withdrawal development. The Solution B treatment resulted in a significant decrease in only the peak withdrawal, while treatment with protein hydrolysate had no effect. The Solution A treatment resulted in a lower peak withdrawal than did Solution B. This effect could be due to the additional reactive α-amino acids in the Solution A treatment.

Treatment with diethanolamine–rutin resulted in a reduction in mean withdrawal, peak withdrawal, and peak withdrawal development scores. However, no effect was seen on blood ethanol levels. Preliminary studies indicated a decreased rate of ethanol elimination following administration of diethanolamine–rutin[2].

Diethanolamine–rutin was proposed as a weak agonist–antagonist to ethanol[2]. However, the characteristic signs of ethanol withdrawal did not appear immediately after the administration of diethanolamine–rutin to dependent mice. Therefore, diethanolamine–rutin probably reduces the postalcohol hyperexcitability in mice by some other mechanism.

Chronic ethanol administration produced an increase in brain γ-aminobutyrate (33). Its inhibitory effects were implicated in the regulation of the depressant actions of ethanol (34, 35). A significant reduction in brain γ-aminobutyrate was reported to coincide with the maximum intensity of ethanol withdrawal scores in mice (30). The reduction in brain γ-aminobutyrate renders the subject more susceptible to postalcohol hyperexcitability (30). Since diethanolamine–rutin is also a CNS depressant[2], it too may increase brain γ-

aminobutyrate. In addition, its effect in slowing ethanol elimination from the blood[2] may cause a more gradual decline in brain γ-aminobutyrate during ethanol withdrawal, decreasing the intensity of the characteristic hyperexcitability.

Treatment with diethanolamine–rutin produced a peak withdrawal response at 5 hr, which remained constant for 3 hr. None of the other treatment groups showed a similar plateau in withdrawal responses. Possibly, brain γ-aminobutyrate was prevented from falling to levels low enough for maximal hyperexcitability to occur. Studies are in progress to determine this possibility.

SUMMARY AND CONCLUSIONS

The reactive α-amino acid, L-lysine, lowered blood ethanol levels when ethanol was administered orally or by inhalation. This decrease in blood ethanol could be the result of poor absorption or increased elimination. The withdrawal reaction, following ethanol inhalation in mice, was also reduced by L-lysine. L-Lysine possibly interferes with an acetaldehyde-mediated alkaloid formation from biogenic amines, thereby decreasing the degree of dependence on ethanol. The presence of additional reactive α-amino acids somewhat enhanced the effects of L-lysine.

Diethanolamine–rutin also reduced the ethanol withdrawal reaction in mice but had no effect on blood ethanol levels. It may prevent the fall in brain γ-aminobutyrate reported to accompany ethanol withdrawal convulsions by slowing the rate of ethanol elimination from the blood.

A relationship may exist between the formation of tetrahydroisoquinoline alkaloids and the increase in brain γ-aminobutyrate seen in ethanol-dependent mice. The increase in brain γ-aminobutyrate during ethanol administration and its subsequent decrease during withdrawal may cause postalcohol hyperexcitability in mice (30). The amino acid treatments seem to interfere with the acetaldehyde-dependent formation of these alkaloids. Diethanolamine–rutin seems to exert its effect by decreasing the rate of ethanol elimination, which then might prevent a significant decrease in brain γ-aminobutyrate during ethanol withdrawal.

Simultaneous High-Pressure Liquid Chromatographic Determination of Niacin and Niacinamide in Multivitamin Preparations: Reversed-Phase, Ion-Pairing Approach

S. PAUL SOOD *, D. P. WITTMER ‡, S. A. ISMAIEL §, and W. G. HANEY ×

Abstract □ A high-pressure liquid chromatographic procedure for the simultaneous determination of niacin and niacinamide in multivitamin preparations was developed and evaluated. Reversed-phase liquid chromatography with dioctyl sodium sulfosuccinate in the mobile phase is utilized for the analysis. The accuracy and precision of the procedure were compared with those of the currently official procedure.

Keyphrases □ Niacin and niacinamide—simultaneous analysis, reversed-phase high-pressure liquid chromatography, multivitamin preparations □ High-pressure liquid chromatography, reversed phase—simultaneous analysis, niacin and niacinamide in multivitamin preparations □ Vitamins—niacin and niacinamide, simultaneous analysis, reversed-phase high-pressure liquid chromatography, multivitamin preparations

Currently, procedures for the determination of niacin and niacinamide in multivitamin preparations suffer from several disadvantages. An involved sample workup often is required (1, 2). Niacin is either ignored entirely in the determination (3) or included in the results as "niacinamide" due to hydrolysis of the sample prior to determination (4, 5). In addition, reagents required for analysis are often caustic and unstable.

These objections have been considerably reduced in procedures (6) where a solution of the vitamin product is chromatographed, the appropriate migration zones are eluted, and the eluate is determined spectrophotometrically. However, these procedures are somewhat tedious. Therefore, a related method for the simultaneous analysis of niacin and niacinamide, utilizing reversed-phase high-pressure liquid chromatography (HPLC), was developed and evaluated.

EXPERIMENTAL

Apparatus—A liquid chromatograph[1] equipped with a high-pressure pump and an injector was used, and effluents were monitored with the 254-nm detector. Peak areas were determined using an electronic digital integrator[2]. The column[3], 30 cm × 4 mm i.d. stainless steel, was packed with totally porous silica particles of 10-μm average size, chemically bonded to a monomolecular layer of octadecyltrichlorosilane. The flow rate was 2.5 ml/min.

Materials and Reagents—Niacin and niacinamide were obtained as USP reference standards. Dioctyl sodium sulfosuccinate, camphorsulfonic acid, and sodium hexanesulfonate were obtained from commercial suppliers and used as received. Commercial multivitamin preparations were obtained from local pharmacies.

Preparation of Mobile Phase—Solvent systems were prepared by dissolving the salt (2.0×10^{-3} *M*) in distilled water (300 ml), adjusting the pH to 2.5 with 10% formic acid solution, and combining the resulting solution with methanol (300 ml). The mobile phase was deaerated prior to use by the brief application of a vacuum.

Standard Solutions—Solutions of niacinamide in pH 6.0 phosphate buffer were prepared to contain 1.0, 2.0, 3.0, 4.0, 4.5, 5.0, 5.5, and 6.0 mg/100 ml. Niacin standard solutions were prepared to contain 0.5, 1.0, 1.5, 2.0, and 2.5 mg/100 ml.

Sample Solutions—The homogenized vitamin preparation (one dosage unit) was placed in a volumetric flask (100 ml) with pH 6.0 phosphate buffer (50.0 ml) and shaken for 5 min. Buffer was added to volume, the flask was shaken, and the particulate matter was allowed to settle. The sample was filtered when required, and the first 10–15 ml of filtrate was rejected. An aliquot of the remaining filtered solution was then diluted to a concentration of 2.5 mg/100 ml based on the label claim of niacinamide or 0.75 mg/100 ml based on the label claim of niacin.

Calibration Curves and Sample Analysis—Calibration curves were prepared by mixing niacinamide standard solutions (2.0 ml) with niacin solutions (2.0 ml) and injecting an aliquot (20 μl) of the mixture into the chromatographic system. Peak areas, determined using the digital integrator, were plotted against the analyte concentration for preparation of calibration curves.

Niacinamide and niacin were determined by injecting an aliquot (20 μl) of the sample solution, determining the resulting peak areas, and referring to the previously derived calibration curves.

RESULTS AND DISCUSSION

The complex matrixes in which the water-soluble vitamins are often found make chromatographic techniques a logical choice for their routine analysis. Of the quantitative chromatographic techniques, HPLC is particularly attractive since derivatives need not be formed prior to separation so sample preparation time may be reduced significantly. However, the choice of an appropriate stationary phase is critical in maximizing this advantage.

Methods using ion-exchange resins have been employed for separating niacin (7) from other constituents of vitamin products but suffer from poor reproducibility (8) and limited column life (9). Normal-phase chromatographic systems also may be used (10), but several constituents (*e.g.*, coloring and flavoring agents and diluents) are present in multivitamin preparations that are more polar than the vitamins. Methodologies based on these systems consequently require substantial sample workup or long analysis time.

Reversed-phase chromatographic systems appear to offer significant advantages in the determination of water-soluble vitamins in multivitamin preparations. Polar diluents, fillers, *etc.*, that dissolve in an aqueous dispersion of the multivitamin product elute at or near the solvent front while lipophilic constituents, such as the oil-soluble vitamins, have very limited solubility in the aqueous dispersion. Under such conditions, retention volumes are reproducible, column lifetimes are long (11), and sample preparation time is short. The latter advantage is not only important in terms of technician time but also in the precision of the method.

In such a chromatographic system, however, niacinamide and niacin have little affinity for the lipophilic stationary phase and also move through the system with the solvent front (Table I). However, it was shown previously (12) that addition of an appropriate salt to the mobile phase results in retention of ionic analytes in the reversed-phase system. For example, anionic analytes are retained in a reversed-phase system in which a small quantity of a lipophilic qua-

Table I—Retention Characteristics of Niacinamide and Niacin

Solute[a]	Niacin[b]	Niacinamide[b]
	1.8	1.8
Sodium heptanesulfonate	3.0	2.8
Sodium camphorsulfonate	6.2	5.6
Dioctyl sodium sulfosuccinate	10.5	9.0

[a] The salt (2×10^{-3} *M*) was dissolved in distilled water (300 ml), the pH was adjusted to 2.5 with 10% formic acid solution, and methanol (300 ml) was added. [b] Retention volume in milliliters with a flow rate of 3.0 ml/min.

ternary ammonium compound is added to the mobile phase. Conversely, cationic analytes in a mobile phase containing lipophilic sulfonate salts are dramatically retained when compared to the same systems not containing these salts. The advantages of such systems over ion-exchange procedures also were discussed (12).

In the current study, the pH of the aqueous component of the mobile phase was adjusted to 2.5, at which pH the heteronitrogens of niacin and niacinamide are protonated and carboxylate ionization (of niacin) is suppressed. Addition of the appropriate sulfonate salt to the mobile phase then results in retention of both niacin and niacinamide, with niacin less strongly retained because of its greater polarity. The retention characteristics of such ionic analytes in this system appear to be explicable in terms of the rate of formation and relative lipophilicity of the ion-pair formed within the system. This technique has been referred to as the reversed-phase, ion-pairing approach to HPLC; its use here allows sample preparation time to be held to a minimum.

By using this chromatographic system (Fig. 1), standard curves were prepared daily for 10 days. The standard deviations of the slope of the curve for niacinamide and niacin were 1.57 and 1.69%, respectively. The average correlation coefficient for niacinamide calibration curves was 0.996; for niacin, it was 0.998. The average *y*-intercepts

Table III—Analysis of Niacinamide and Niacin in Multivitamin Products

				Amount Found[a]		
				Niacinamide		
Sample	Dosage Form	Labeled Components	Labeled Niacinamide, mg/Dosage Unit	USP	HPLC	Niacin[b], HPLC
1	Capsule	Nine vitamins, six minerals	100	101.6 (3.98)	94.5 (2.56)	5.4 (2.27)
2	Chewable tablet	Eight vitamins, artificial flavors, colors	10	103.4 (4.64)	97.6 (1.87)	3.2 (2.69)
3	Liquid	Eight vitamins, eight minerals, preservative, artificial flavors, colors	10	98.4 (3.60)	84.6 (2.20)	14.2 (2.90)
4	Drop	Eight vitamins	6	108.2 (3.14)	102.6 (1.94)	4.6 (2.20)
5	Capsule	Six vitamins	50	105.4 (3.90)	102.6 (2.27)	2.16 (1.86)
6	Tablet	Nine vitamins	50	99.8 (3.64)	96.4 (2.00)	5.46 (1.45)

[a] Percent of labeled amount (% *SD*); $n = 8$. [b] Expressed as percent of labeled niacinamide content.

were −3.24 integrator units for niacinamide and +4.70 integrator units for niacin. These data indicate that the procedure is amenable to use of a single-point standard.

The accuracy and precision of the proposed chromatographic procedure were investigated by analysis of laboratory-prepared samples (Table II), and results were compared with those of the USP procedure (4). In each case, the precision of the HPLC procedure was greater than that of the currently official procedure, and this result may be attributed to the less complicated sample workup required by the former. However, the two methods compared quite favorably in terms of the determination of the combined quantity of niacin and niacinamide.

Data regarding the suitability of the proposed procedure in the analysis of commercial multivitamin preparations are presented in Table III. Standard deviations of the HPLC procedure were again lower. Furthermore, niacinamide content, as determined by the proposed procedure, was less in each case. However, when the sum of niacinamide and niacin content was compared with that determined by the USP procedure, results were again comparable. Niacin was found in each sample examined, in quantities as high as 14.2% of the labeled niacinamide concentration.

This type of analysis is very attractive in terms of analysis time, since a trained technician can readily process 10 samples/hr with a minimum of active involvement. Column stability under these conditions of minimum sample preparation was a subject of concern initially. However, over 300 preparations have been processed with no change in the chromatographic characteristics of the system. This stability may be attributed in part to the small quantities of sample injected into the chromatographic system and in part to the daily flushing recommended by the column supplier.

In summary, the reversed-phase, ion-pairing approach to the simultaneous analysis of niacin and niacinamide appears to result in an accurate and precise procedure. These features, in combination with the simple sample preparation and short analysis time, should make the procedure attractive to pharmaceutical analysts. The application of this approach to the other water-soluble vitamins is currently under investigation.

Solubility Profiles and Thermodynamics of Parabens in Aliphatic Alcohols

KENNETH S. ALEXANDER *, JOHN W. MAUGER ‡, HAROLD PETERSEN, Jr. §, and ANTHONY N. PARUTA ˣ

Abstract □ The solubility of a series of compounds was determined in a wide polarity spectrum of normal aliphatic alcohols over a limited temperature range. The solutes chosen were the methyl through *n*-butyl *p*-hydroxybenzoates, several of these being useful preservatives. Solubility profiles were determined for these compounds, and the effect of temperature upon their solubility behavior was investigated. The solubility of the solutes is expressed in several concentration notations; mole fraction plots showed a variable twin peak array as a function of the dielectric constant for the solutes studied. Since heats of fusion were available and data were generated as a function of temperature, thermodynamic parameters for these systems could be calculated. The relationship of these parameters to multiple solubility peak array is discussed.

Keyphrases □ Parabens, alkyl—solubility and thermodynamics in aliphatic alcohols, effect of temperature □ Solubility—alkylparabens in aliphatic alcohols, effect of temperature □ Thermodynamics—alkylparabens in aliphatic alcohols, effect of temperature □ Alcohols, aliphatic—solvents for series of alkylparabens, effect of temperature □ Structure–activity relationships—alkylparabens, solubility and thermodynamics in aliphatic alcohols □ Antifungal agents—alkylparabens, solubility and thermodynamics in aliphatic alcohols

The effect of temperature upon the solubility of four normal alkyl *p*-hydroxybenzoates (parabens) was determined over a wide polarity spectrum of aliphatic alcohols from methanol to 1-decanol. The effect of decreasing polarity with an increase in size for the first four *n*-alkyl members for this ester series was also considered.

Previous solubility work (1–5) considered several of these compounds at ambient temperatures. It was believed that the extension of this work in pure solvents over a temperature range and polarity range would be instructive. Additionally, since several of these solutes gave multiple peak solubility isotherms, it was useful to determine if solubility was linear as a function of temperature. The temperature range used was 25–40° in four steps; the polarity range *via* dielectric constants was from 32 for methanol to eight for 1-decanol at 25°, utilizing seven in-

were −3.24 integrator units for niacinamide and +4.70 integrator units for niacin. These data indicate that the procedure is amenable to use of a single-point standard.

The accuracy and precision of the proposed chromatographic procedure were investigated by analysis of laboratory-prepared samples (Table II), and results were compared with those of the USP procedure (4). In each case, the precision of the HPLC procedure was greater than that of the currently official procedure, and this result may be attributed to the less complicated sample workup required by the former. However, the two methods compared quite favorably in terms of the determination of the combined quantity of niacin and niacinamide.

Data regarding the suitability of the proposed procedure in the analysis of commercial multivitamin preparations are presented in Table III. Standard deviations of the HPLC procedure were again lower. Furthermore, niacinamide content, as determined by the proposed procedure, was less in each case. However, when the sum of niacinamide and niacin content was compared with that determined by the USP procedure, results were again comparable. Niacin was found in each sample examined, in quantities as high as 14.2% of the labeled niacinamide concentration.

This type of analysis is very attractive in terms of analysis time, since a trained technician can readily process 10 samples/hr with a minimum of active involvement. Column stability under these conditions of minimum sample preparation was a subject of concern initially. However, over 300 preparations have been processed with no change in the chromatographic characteristics of the system. This stability may be attributed in part to the small quantities of sample injected into the chromatographic system and in part to the daily flushing recommended by the column supplier.

In summary, the reversed-phase, ion-pairing approach to the simultaneous analysis of niacin and niacinamide appears to result in an accurate and precise procedure. These features, in combination with the simple sample preparation and short analysis time, should make the procedure attractive to pharmaceutical analysts. The application of this approach to the other water-soluble vitamins is currently under investigation.

Solubility Profiles and Thermodynamics of Parabens in Aliphatic Alcohols

KENNETH S. ALEXANDER *, JOHN W. MAUGER ‡, HAROLD PETERSEN, Jr. §, and ANTHONY N. PARUTA ˣ

Abstract □ The solubility of a series of compounds was determined in a wide polarity spectrum of normal aliphatic alcohols over a limited temperature range. The solutes chosen were the methyl through *n*-butyl *p*-hydroxybenzoates, several of these being useful preservatives. Solubility profiles were determined for these compounds, and the effect of temperature upon their solubility behavior was investigated. The solubility of the solutes is expressed in several concentration notations; mole fraction plots showed a variable twin peak array as a function of the dielectric constant for the solutes studied. Since heats of fusion were available and data were generated as a function of temperature, thermodynamic parameters for these systems could be calculated. The relationship of these parameters to multiple solubility peak array is discussed.

Keyphrases □ Parabens, alkyl—solubility and thermodynamics in aliphatic alcohols, effect of temperature □ Solubility—alkylparabens in aliphatic alcohols, effect of temperature □ Thermodynamics—alkylparabens in aliphatic alcohols, effect of temperature □ Alcohols, aliphatic—solvents for series of alkylparabens, effect of temperature □ Structure–activity relationships—alkylparabens, solubility and thermodynamics in aliphatic alcohols □ Antifungal agents—alkylparabens, solubility and thermodynamics in aliphatic alcohols

The effect of temperature upon the solubility of four normal alkyl *p*-hydroxybenzoates (parabens) was determined over a wide polarity spectrum of aliphatic alcohols from methanol to 1-decanol. The effect of decreasing polarity with an increase in size for the first four *n*-alkyl members for this ester series was also considered.

Previous solubility work (1–5) considered several of these compounds at ambient temperatures. It was believed that the extension of this work in pure solvents over a temperature range and polarity range would be instructive. Additionally, since several of these solutes gave multiple peak solubility isotherms, it was useful to determine if solubility was linear as a function of temperature. The temperature range used was 25–40° in four steps; the polarity range *via* dielectric constants was from 32 for methanol to eight for 1-decanol at 25°, utilizing seven in-

dividual solvents. The Hildebrand solubility parameter (6) was applied previously (2, 3) in a study of benzoic acid and alkyl esters of *p*-hydroxybenzoic acid; these solutes also were studied in binary mixtures (4, 5, 7) consisting of dioxane–water and ethanol–water.

A rather striking dichotomy appeared in contemporary work on solubility behavior (8–14). The excellent theoretical approach undertaken by Hildebrand and coworkers (15–22), referred to as the "solubility parameter" theory, certainly has much to offer in terms of the interpretation of solubility phenomena. Extension of this theory to systems of some pharmaceutical interest was undertaken by other investigators (23, 24). Work over the last decade has shown that a dielectric constant (dielectric requirement) approach has some validity. The Hildebrand approach only accounts for a monotonic isotherm or a single solubility maximum. This approach assumes a neat and smooth variation of molecular interactions such that an analytical solution can be formulated to approximate real behavior. A symmetrical isotherm can be expected from this theory and is quite reasonable, because the summed interactions are at a mathematical condition of constant differences.

Hildebrand, continuing elegant work in this area (18), was instrumental in shifting the thrust of past work from a dielectric constant approach to a more fundamental and theoretical thermodynamic approach. It now appears that the multiple solubility peak arrays observed for various solutes qualitatively resides in the nature of the systems and quantitatively resides in the values or magnitudes of the thermodynamic functions resulting from each individual system.

Therefore, this study deals with the thermodynamic parameters for various solutes in a series of normal aliphatic alcohols. Since heats of fusion were available (16), a theoretical ideal mole fraction solubility could be determined and compared with the actual mole fraction solubility. In this manner, the activity coefficients could be determined. The solubility of these solutes as a function of temperature would allow for the experimental determination of enthalpies and entropies of solution. A thermodynamic scheme for the interpretation of solubility behavior is presented. Excess free energy functions were calculated and utilized as a basis for multipeak solubility isotherms.

EXPERIMENTAL

Equipment—The following were used: a melting-point apparatus[1], a pH meter[2], a chemical oscillometer[3], a spectrophotometer[4], a temperature controller[5], and a refractometer[6].

Materials—The chemicals utilized were ethyl *p*-hydroxybenzoate (ethylparaben) and propyl *p*-hydroxybenzoate[7] (propylparaben); methanol[8], spectrograde; butyl *p*-hydroxybenzoate[9] (butylparaben); 1-propanol[10]; ethanol[11], absolute reagent quality; 1-butanol[12], analytical reagent; 1-hexanol and 1-octanol[13]; 1-decanol[14]; certified acetone[15], 99 mole % pure; certified benzene[16], 99 mole % pure; hydrochloric acid[17], certified pure reagent; and potassium chloride[18] USP. The purity of the alcohols was established by refractive indexes and dielectric constant measurements. Melting points were determined and were within 1° of literature values.

Method—Solubility was determined by the method described previously (1). The solubility of each solute was determined at least eight times for each solvent, and average values were taken. The experimental variation in solubility was about 2.5% in replicate samples for these solutes.

RESULTS AND DISCUSSION

The solubility of a series of solutes was determined in a chemically related series of solvents at various temperatures over 25–40° (Tables I–IV).

In Fig. 1, the solubility of the solutes is plotted as milligrams per gram of solution *versus* the carbon number in the aliphatic alcohol solvent series used. Typical nonlinear curves were generated in all cases; for each solute, the highest solubility occurred in methanol and decreased in value to 1-decanol. The order of solubility was the butyl ester > propyl ester > ethyl ester > methyl ester.

In Fig. 2, the solubility of the methyl *p*-hydroxybenzoate (methylparaben) as a typical solute is plotted in milligrams per gram of solution as a function of the temperature. The solubility increased linearly over the experimental temperature range utilized.

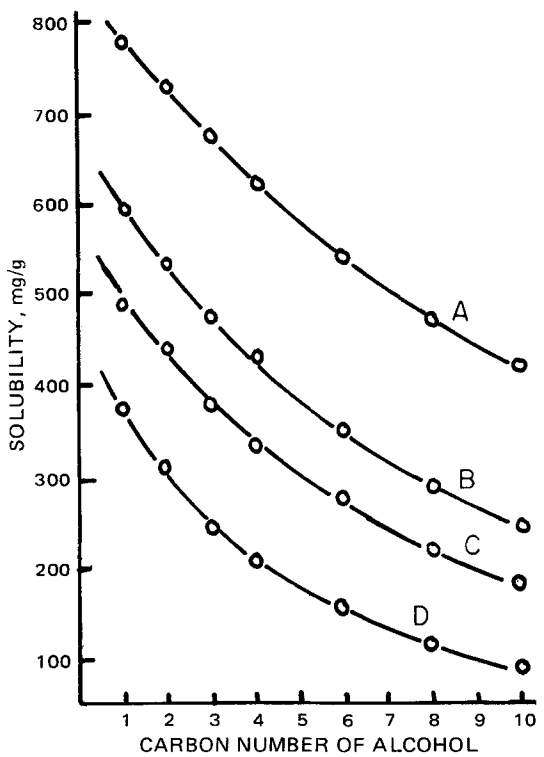

Figure 1—*Solubility of the noted substances in milligrams per gram of solution as a function of the carbon number of the alcohol used. Curve A = butyl* p*-hydroxybenzoate, curve B = propyl* p*-hydroxybenzoate, curve C = ethyl* p*-hydroxybenzoate, and curve D = methyl* p*-hydroxybenzoate.*

In Fig. 3, the solubility of methylparaben in milligrams per gram of solution is plotted as a function of the carbon number of the alcohol solvent at each of four temperatures. Nonlinear curves were observed with the typical incremental response of increased solubility with temperature.

In Fig. 4, the mole fraction solubility is plotted as a function of the dielectric constant of the solvents. For each compound, a twin peak array is observed possessing values of dielectric constants of about 10–13 and 19–22, as previously reported (1).

In Fig. 5, the mole fraction solubility profiles of methylparaben are plotted as a function of the dielectric constant of the alcohols at various temperatures. The dielectric constants vary and decrease over the 15° range of temperature used; however, these variations are about two to three units lower at 40° than at 25°. These solubility profiles are fairly consistent over this temperature range; each profile indicates a binary peak array, with the dielectric constant of maximum solubility showing fair consistency. The first maxima are found at a dielectric constant range of about 12–13.5, whereas the second maxima are found at 21–24.

It is felt that where the solubility maxima occur, these magnitudes of

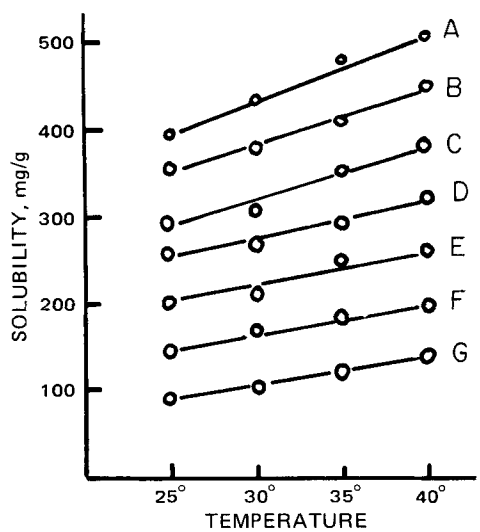

Figure 2—*Solubility of methyl* p*-hydroxybenzoate in the noted alcohol solvents as a function of temperature. Curve A = methanol, curve B = ethanol, curve C = 1-propanol, curve D = 1-butanol, curve E = 1-hexanol, curve F = 1-octanol, and curve G = 1-decanol.*

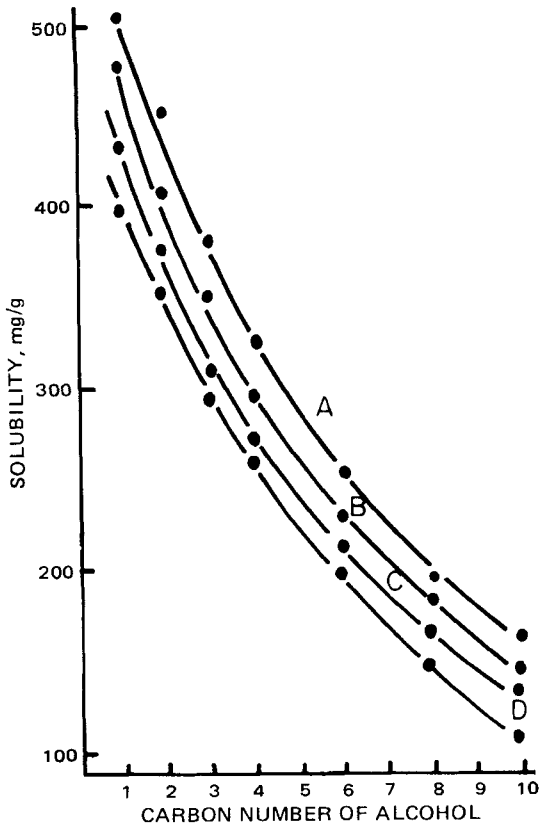

Figure 3—*Solubility of methyl* p-*hydroxybenzoate at various temperatures as a function of the carbon number of the alcohol solvents used. Curve A = 40°, curve B = 35°, curve C = 30°, and curve D = 25°.*

solubility are approaching ideal solubility values such that the excess free energy values at the maxima are approaching the ideal free energy values. It thus becomes desirable to differentiate "ideal" and "nonideal" solubility with a view of obtaining thermodynamic elements from literature

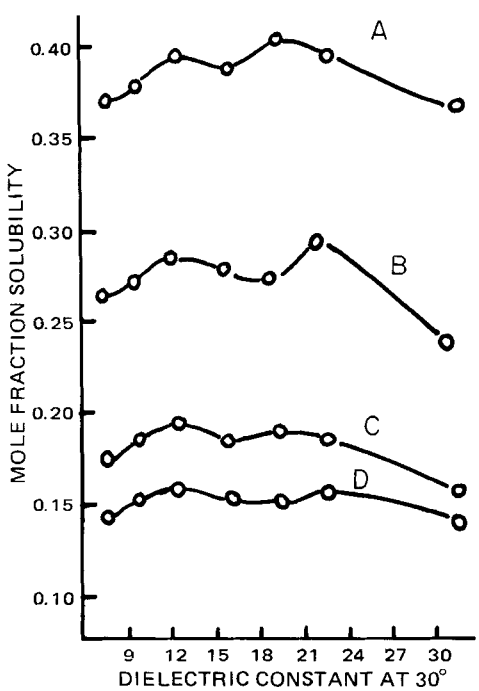

Figure 4—*Mole fraction solubility of the noted solutes as a function of the dielectric constants at 30° for the alcohol solvents used. Curve A = butyl* p-*hydroxybenzoate, curve B = propyl* p-*hydroxybenzoate, curve C = ethyl* p-*hydroxybenzoate, and curve D = methyl* p-*hydroxybenzoate.*

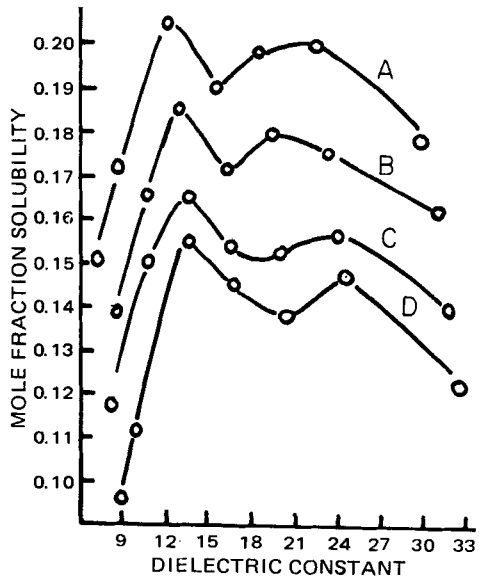

Figure 5—*Mole fraction solubility of methyl* p-*hydroxybenzoate as a function of the dielectric constants of the alcohol solvents used at four temperatures. Curve A = 40°, curve B = 35°, curve C = 30°, and curve D = 25°.*

and experimental data. Thus, ideal solubility can be calculated from ΔF_l values once the enthapy of fusion and entropy of fusion are known. These values can then be compared with those obtained experimentally. Thus, the ratio of the ideal solubility and the actual solubility can be used to determine activity coefficients for both the solute and the solvent. It is well known that the actual solubility is always less than ideal solubility. (The summation of two positive factors leads to a larger negative logarithm or a smaller X_2 value.) Thus, other determined elements, ideal solubility (X_2^i) and activity coefficients (γ_1 and γ_2), have been added to the existing list of thermodynamic elements: ΔH_f, ΔH_s, ΔS_f, and ΔS_s.

In summary, then, solubility can be expressed as a function of the energy change in the following manner: F_E (excess) = F_A (actual) − F_l (ideal) (1); therefore, as the excess energy approaches zero, the nonideal or actual solubility approaches the ideal solubility.

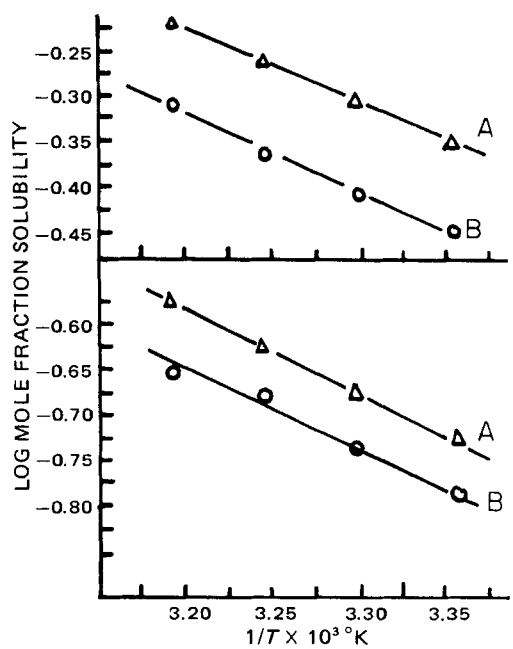

Figure 6—*Mole fraction solubility for ethyl* p-*hydroxybenzoate (lower figure) and butyl* p-*hydroxybenzoate (upper figure) as a function of reciprocal temperature (°K). The ideal curves (Δ, A) are from heat of fusion data, and the actual curves (O, B) are from experimental data.*

Table V presents literature values for the heat of fusion, ΔH_f, which were applied to calculate ideal mole fraction solubility values. The entropy of fusion, ΔS_f, presented can be obtained graphically from a plot of log X_2^i *versus* $1/T$. The ideal free energy change and the ideal mole fraction solubilities are also given for the four temperatures.

In Fig. 6, the ideal and actual mole fraction solubility for ethyl- and butylparaben are plotted *versus* reciprocal temperature. The ideal solubility, as expected, is greater than the actual solubility.

The rational activity coefficients for the solutes in a particular solvent with respect to temperature were calculated in the usual manner (Table VI). The rational activity coefficient for the solvent is given in like manner in Table VII. The error in the activity coefficients due to solubility variation is about ±0.005.

Tables VIII–XI give the thermodynamic elements that were determined graphically or by calculation. The legend for Table VIII applies to all subsequent tables. Inspection of the magnitude of excess free energy

of mixing (11) or ΔF_E for each solute shows that the values decrease to minima (approaching ideality) in the ethanol or propanol and hexanol solvents. This finding, of course, supports the concept of a multiple peak array from a thermodynamic point of view. Furthermore, heats of mixing changes were compensated for by entropy gain such that the free energy was reflective of a twin peak solubility array.

The twin peak array observed in the solubility spectrum shown in Fig. 5 is seen throughout the thermodynamic picture of the investigated compounds.

In Fig. 7, the entropy and corresponding enthalpy for methylparaben are plotted *versus* the carbon number of the alcohol solvent. The parallelism can easily be seen between these elements, leading to the excess free energy minimizing at carbon numbers 2 and 6. Any alteration in ΔH_s is also accompanied by a corresponding change in ΔS_s such that free energy remains consistent for any given system. Therefore, any increase in ΔH_s would be associated with an increase in ΔS_s (tending toward greater disorder or randomness).

Since ΔF_I is a fixed value for any solute regardless of the solvent, any system in which ΔF_A approaches ΔF_I will approach the ideal state. Hence, for any particular solute, there may be many combinations of values for ΔH_s and ΔS_s, depending upon the solvent employed, in which ΔF_A may approximate ΔF_I. In this study, the solutes dissolved in either

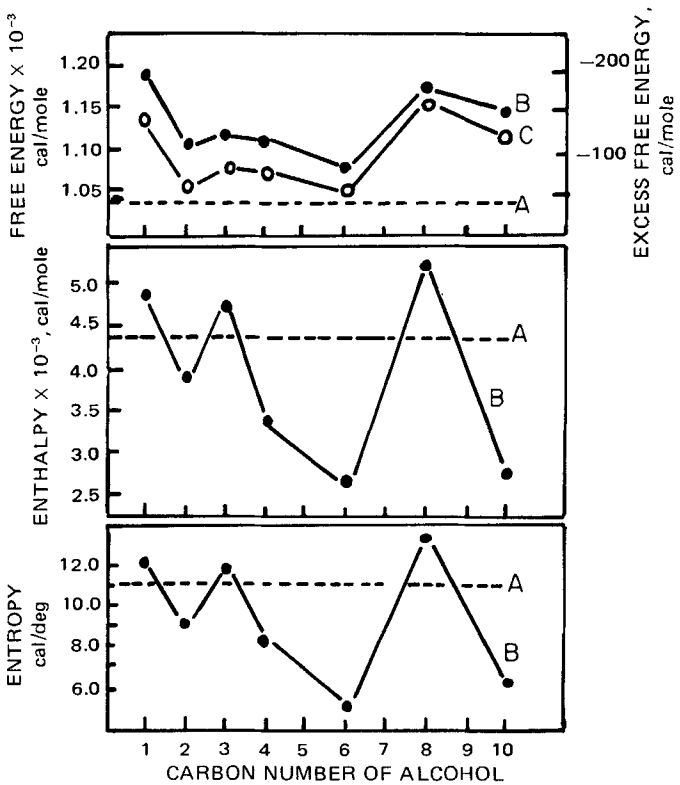

Figure 7—*Plot for methyl p-hydroxybenzoate illustrating the relationship for the entropy (curve A = entropy of fusion and curve B = entropy of solution), enthalpy (curve A = enthalpy of fusion and curve B = enthalpy of solution), and free energy [curve A = ideal free energy, curve B = actual free energy, and curve C = excess free energy (right-hand coordinates)]. Data were taken from Table VIII.*

ethanol or 1-propanol and 1-hexanol have their ΔF_A values approximating ΔF_I. This can be shown by the free energy determinations. However, since the excess free energy terms are based on mole fraction solubility, the emerging trends can be initially perceived by mere inspection of these data.

It has been established that the excess free energy is usually a small value, encompassing a range of 20–200 calories/mole. Since excess free energy is a function of both the mole fraction, which usually ranges from 0.1 to 0.3 for the solute, and the logarithm of the activity coefficient, which usually ranges from −0.75 to −0.9 for the solute and from 0.01 to 0.1 for the solvent, the small numbers obtained are not unexpected.

Thus, total inspection of the thermodynamic functions ΔH_s, ΔS_s, ΔH_m, and ΔF_E truly reveals a trend for a multipeak solubility array. Any solute that exhibits maxima in various solvents may be approaching ideal solubility at the individual maximum in the particular solubility profile.

The dielectric requirement of one peak is now felt to be related to the thermodynamics of the total system; hence, a multipeak system should signify that ideal solubility is being approximated in those particular solvent–solute systems.

Fluorocarbon Aerosol Propellants XI: Pharmacokinetics of Dichlorodifluoromethane in Dogs following Single and Multiple Dosing

SARFARAZ NIAZI and WIN L. CHIOU ˣ

Abstract □ A three-compartment open model was proposed for the disposition of dichlorodifluoromethane in dogs with average half-lives of 1.47, 7.95, and 58.5 min for the three disposition phases. This proposal is contrary to several studies that monitored blood levels for a shorter period. An analysis of the tissue compartment distribution following a single dose showed that about 1.5 hr was required to achieve pseudodistribution equilibration, following which more than 90% of the dose remaining in the body was retained in the tissue compartments. The pulmonary clearance and volumes of distribution were calculated considering the first-pass effect through the lungs. The volume of distribution after reaching pseudodistribution equilibrium was approximately 10 times the body weight in terms of the blood concentration, and about 68% of the propellant was cleared from the blood passing through the lungs in each cycle. Disposition of the propellant followed dose-independent kinetics after multiple dosing. No volatile metabolites were detected in the blood using GC.

Keyphrases □ Fluorocarbon aerosol propellants—dichlorodifluoromethane, single and multiple dosing, pharmacokinetic model proposed, dogs □ Aerosol propellants, fluorocarbon—dichlorodifluoromethane, single and multiple dosing, pharmacokinetic model proposed, dogs □ Dichlorodifluoromethane—single and multiple dosing, pharmacokinetic model proposed, dogs □ Pharmacokinetics—dichlorodifluoromethane, single and multiple dosing, three-compartment open model proposed, dogs □ Distribution—dichlorodifluoromethane, single and multiple dosing, pharmacokinetic model proposed, dogs

The toxicity aspects of fluorocarbon aerosol propellants reflected in their pharmacokinetics were reported recently (1–5). A similar approach is made here for the most commonly used fluorocarbon aerosol propellant, dichlorodifluoromethane, to show that this compound has a longer biological half-life than speculated and undergoes extensive distribution in body tissues. These findings may have bearing on the toxicity profile of this compound.

EXPERIMENTAL

Dichlorodifluoromethane[1] was administered intravenously in polyethylene glycol 400 solution to four male mongrel, unanesthetized, conditioned dogs, 16.8–20 kg. The doses of dichlorodifluoromethane administered ranged from 71 to 135 mg. Procedural details for the preparation of the dosage forms, animal preparation, single- and multiple-dose administrations, blood samples, and analysis of fluorocarbon in the blood samples were reported earlier (3, 4). The blood samples were analyzed as soon as possible to avoid any loss during storage (6). A duplicate study was performed on Dog 2976.

RESULTS AND DISCUSSION

Dosage Form and Route of Administration—The intravenous dosage form was selected to avoid the problems of biological availability in inhalation and oral administration (7–10). This mode of administration would be equivalent to inhalation (3, 4) if one considers that the intravenously administered fluorocarbon first passes through the lungs before being monitored in the blood. The fluorocarbon concentration profile in blood would, therefore, appear as if the fluorocarbon had been administered *via* inhalation, the customary route of its uptake.

Pharmacokinetic Model—In all instances, the blood concentration–time curves were characterized by three exponential equations, which can be represented as a three-compartment open model for the disposition of dichlorodifluoromethane (Fig. 1). The two compartments besides the central compartment can be described as the group of tissues with distinct affinity and capacity for dichlorodifluoromethane. The difference in the affinity may be due to solubility characteristics or to specific interactions such as protein binding or other complexations (11–15). A compartment can also be distinguished based on the blood supply to the tissues such as the vessel-rich group and the vessel-poor group (14, 16).

For further analysis of this model (Scheme I) to calculate various rate constants, a digital computer program was generated based on reported differential equation solutions (17).

The fraction of dose remaining in various pharmacokinetic compartments can be described in terms of hybrid constants (17):

$$X_1/X_0 = C_1e^{-b_1t} + C_2e^{-b_2t} + C_3e^{-b_3t} \quad \text{(Eq. 1)}$$

$$X_2/X_0 = C_{12}e^{-b_1t} + C_{22}e^{-b_2t} + C_{32}e^{-b_3t} \quad \text{(Eq. 2)}$$

$$X_3/X_0 = C_{13}e^{-b_1t} + C_{23}e^{-b_2t} + C_{33}e^{-b_3t} \quad \text{(Eq. 3)}$$

where X_1, X_2, and X_3 are the amounts of fluorocarbon present in different compartments; and X_0 is the dose that, in the model proposed, remains in the body after the first pass through the lungs, as described later.

The values of these pharmacokinetic parameters calculated for dichlorodifluoromethane are summarized in Table I.

Recently, Adir *et al.* (10) also proposed a pharmacokinetic model for this propellant, suggesting a two-compartment body distribution in dogs.

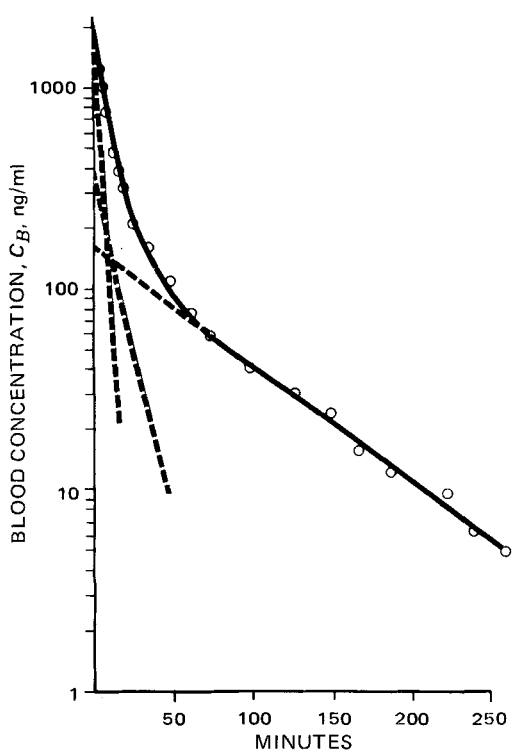

Figure 1—*Triexponential blood concentration decay following intravenous administration of 105.0 mg of dichlorodifluoromethane in 6.6 ml of polyethylene glycol 400 to a 19-kg dog:* $C_B = 1200e^{-0.227t} + 375e^{-0.079t} + 164e^{-0.016t}$

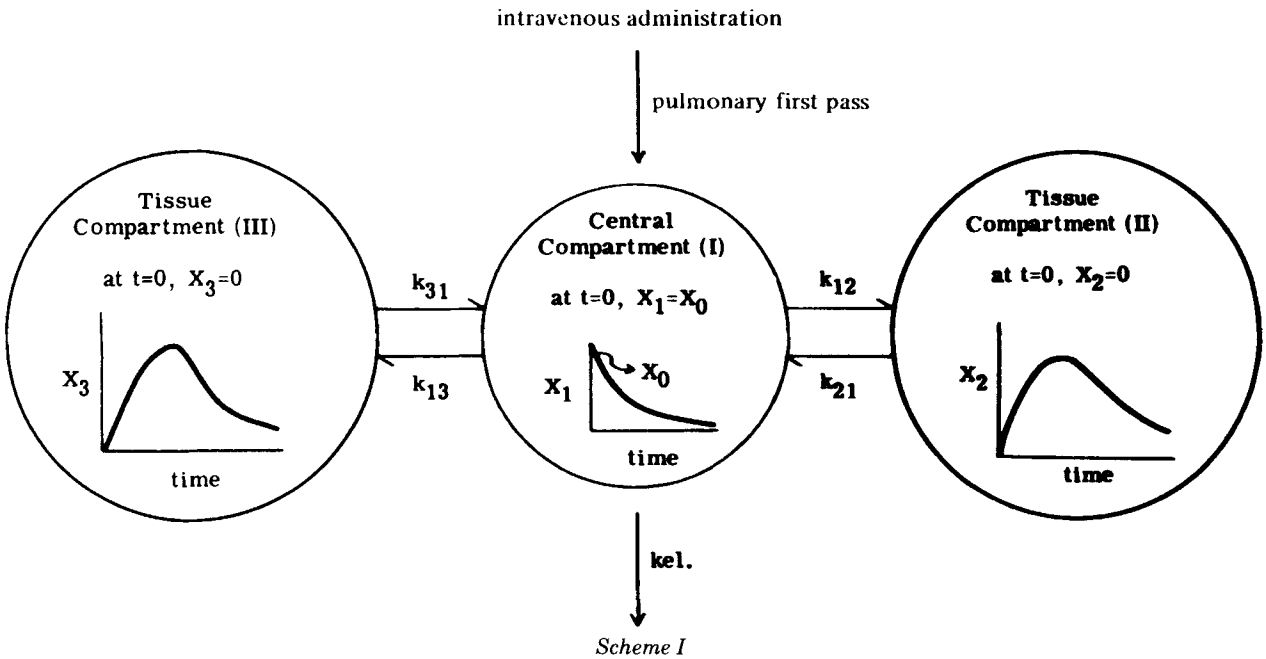
[1] E. I. du Pont De Nemours & Co., Wilmington, Del.



Scheme I

However, their study (10) monitored the blood levels following inhalation for only about 20–30 min, which does not allow for the elucidation of equilibration with the deeper tissue compartment. A comparison of initial and intermediate rate constants (b_1 and b_2 in Table I) shows good agreement with the values reported recently (10). For example, our average value of 0.60 min^{-1} for b_1 compared with 0.64 min^{-1} (10) and the value of 0.09 min^{-1} for b_2 compared with 0.07 min^{-1} (10). However, the actual values of these rate constants in the study of Adir *et al.* (10) will be higher if the deeper tissue compartment is "peeled off" from the observed blood concentrations.

Volume of Distribution and Pulmonary Clearance—In the present study, the dose administered is not the same as the dose made available to the body, since the total dose passes through the lungs where a significant fraction can be eliminated before it is distributed to the body. Therefore, an equation correcting for this first-pass effect was used to calculate the apparent volume of distribution following pseudodistribution equilibrium (3, 4, 18):

$$(V_d)_{b_3} = \frac{PFR \times D^0}{b_3(AUC \times PFR + D^0)} \qquad \text{(Eq. 4)}$$

where *PFR* is the pulmonary flow rate (~cardiac output), *AUC* is the total area under the blood concentration–time curve (extrapolated to time infinity), and D^0 is the dose administered. Equation 4, however, assumes that the pulmonary clearance is the only route of elimination for the compound. In the present study, no volatile metabolites could be detected from the blood sample by the GC analysis. Since the fluorocarbon studied in this investigation has been shown to be primarily eliminated intact from the lungs (19), Eq. 4 can be used as an approximation for the determination of the volume of distribution and pulmonary clearance (*PC*):

$$PC = (V_d)_{b_3}(b_3) \qquad \text{(Eq. 5)}$$

The fraction eliminated in each pass through the lungs, $(1 - f)$, can be calculated as:

$$(1 - f) = \frac{PC}{PFR} \qquad \text{(Eq. 6)}$$

Table II shows the values of the volume of distribution following pseudodistribution equilibrium to be almost 10 times the body weight. This finding indicates an extensive distribution of dichlorodifluoromethane to the body tissues. Recent findings on the binding of the propellant to human and bovine albumin (11) suggest that the propellant may be bound also to other tissue components. The possible high solubility in the fat tissue due to its lipophilic physical property also may contribute to the high apparent volume of distribution, as was found for trichloromonofluoromethane in dogs (3, 15) and chloroform in humans (20).

AUC^∞, μg/ml × min	15.6	16.5	16.0	20.4	18.10

[a] The units for all *b* and *k* values are minutes^{-1}. [b] $X_0 = (f)D^0$, where (f) is the fraction retained after the first pass through the lungs.

Table II—Volumes of Distribution and Clearance of Dichlorodifluoromethane

Dog	$(V_d)_{b_3}$, liters	V_c, liters	PC, liters/min	$(1-f)$, %
3287	135.5	2.73	1.81	60.21
3288	228.5	7.14	2.35	78.20
3457	153.4	9.37	2.04	68.17
2976a	120.3	22.25	1.89	63.14
2976b	237.7	7.45	2.14	71.31
Mean ± *SEM*	175.1 ± 24.3	9.79 ± 3.30	2.05 ± 0.09	68.21 ± 3.15

The average pulmonary clearance values show a clearance of 2.05 liters/min, corresponding to 68% clearance in each passage through the lungs. An error of this magnitude would have been made in the calculation of the volume of distribution had the correction due to the first-pass pulmonary effect not been made, as explained earlier.

The volume of the central compartment, from which the actual elimination takes place, can be calculated easily, since the clearance from the central compartment should be equal to the clearance from the body:

$$(V_d)_{b_3}(b_3) = (V_c)(K_{el}) \qquad \text{(Eq. 7)}$$

where K_{el} is the elimination rate constant from the central compartment. Table II also shows the values for the volumes of the central compartment. Smaller volumes as compared to the total volumes of distribution indicate the retention of a smaller fraction in the central compartment as compared to tissue compartments after the pseudodistribution phase.

Disposition Half-Lives—Table III shows the half-lives for three disposition phases of dichlorodifluoromethane. The terminal disposition half-lives reported here are much longer than those previously reported or speculated (7, 8, 10, 21–23).

The finding that dichlorodifluoromethane shows a multiexponential decay in the blood concentration can be utilized to study the elimination rate constant from the body and to evaluate the accumulation in the body following single or multiple exposures.

Retention following Single Intravenous Administration—Following administration of dichlorodifluoromethane through intravenous infusion, the concentration in the blood dropped sharply. Such an observation also was reported for fluorocarbons following their inhalation (10, 21–23). However, such sharp declines in blood concentrations do not necessarily follow a parallel loss of drug from the body (24). The amount of drug remaining in the body as a function of time can also be calculated using (24):

$$\text{fraction remaining in body} = \frac{(C_1/b_1)e^{-b_1t} + (C_2/b_2)e^{-b_2t} + (C_3/b_3)e^{-b_3t}}{(C_1/b_1) + (C_2/b_2) + (C_3/b_3)} \qquad \text{(Eq. 8)}$$

Figure 2 shows a plot of the amount of dichlorodifluoromethane remaining in the body and in various tissue compartments, as described previously. For example, the amount of dichlorodifluoromethane in the central compartment dropped to about 12% of the absorbed dose (dose after the pulmonary first pass) in 25 min, but about 45% of the absorbed dose was still present in the body.

Although the steady state was reached rather quickly, as indicated by arrows in Fig. 3, the ratio of the amount in tissue compartments over that in the central compartment continues increasing until attainment of the pseudodistribution equilibrium, which would take about 90 min. This finding is of importance because it was quite contrary to previous claims of fast elimination of fluorocarbons from the body (8, 21–23).

The total amount of the absorbed dose retained following pseudodistribution equilibrium is an important parameter, especially for extrapolating the single-dose study to multiple-dose studies. Table IV shows the retention of dichlorodifluoromethane in the tissue and central compartments after pseudodistribution equilibrium has been reached. The fraction of the fluorocarbon retained in the tissue compartments compared to that in the central compartment shows that more than 90% of the total amount present in the body is retained in tissue compartments.

Multiple-Dose Kinetics—The pharmacokinetic parameters calculated following single-dose administration (Table I) can be used to simulate multiple-dose kinetics. A typical study, such as the one with Dog 2976a, was used to generate[2] multiple-dose disposition curves. These curves were then superimposed on the experimental data obtained from two separate studies (Fig. 4). A good agreement between theoretical and experimental values provides the basis for the validity of the premise involved in the generation of multiple-dose curves that each dose decayed independently of the amount present in the body. In other words, dose-independent kinetics were operative for the disposition of this compound in the dose range studied.

Table III—Disposition Half-Lives of Dichlorodifluoromethane

Disposition Phase	Half-Life (Mean ± *SEM*), min (n = 5)
Initial	1.47 ± 0.42[a]
Intermediate	7.95 ± 0.79
Final	58.50 ± 5.99

[a] This value may be slightly different from the true value, because the experimental value would be influenced by the duration of the intravenous infusion.

Table IV—Average Retention ± *SEM* of Dichlorodifluoromethane at 200 min following Pseudodistribution Equilibrium in Various Compartments

Retention	$X_2 + X_3$ Compartments	X_1 Compartment
Percent of absorbed dose	1.88 ± 0.22	0.14 ± 0.07
Relative percent of total amount in body	93.0 ± 10.9	7.0 ± 3.5

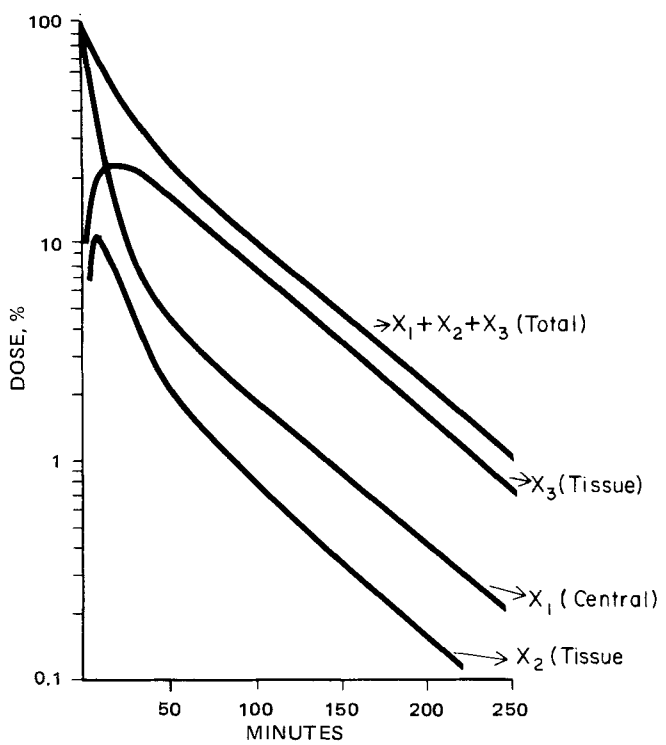

Figure 2—*Percent of absorbed dichlorodifluoromethane remaining in various body compartments based on a typical study (Dog 2976a).*

[2] IBM 370 computer at the University of Illinois Medical Center.

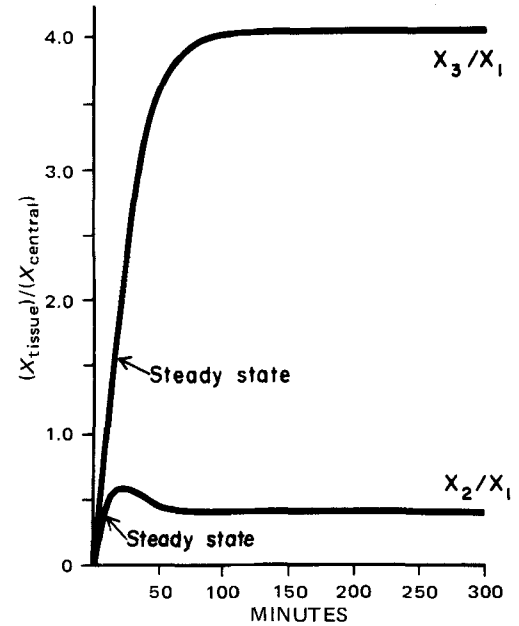

Figure 3—*Comparison of the relative amount of dichlorodifluoromethane remaining in tissue and central compartments based on a typical study (Dog 2976a).*

This approach allows the assessment of the accumulation of dichlorodifluoromethane in the tissue compartments during multiple exposures in the frequent use of commercial products containing fluorocarbon propellants. Figure 5 shows the calculated amount of dichlorodifluoromethane distributed to various tissue compartments following six doses. The magnitude of the problem of accumulation during multiple exposures to dichlorodifluoromethane is well emphasized in this study. For example, the total amount eventually accumulated in the tissues may well exceed the amount administered in one dose (Fig. 5).

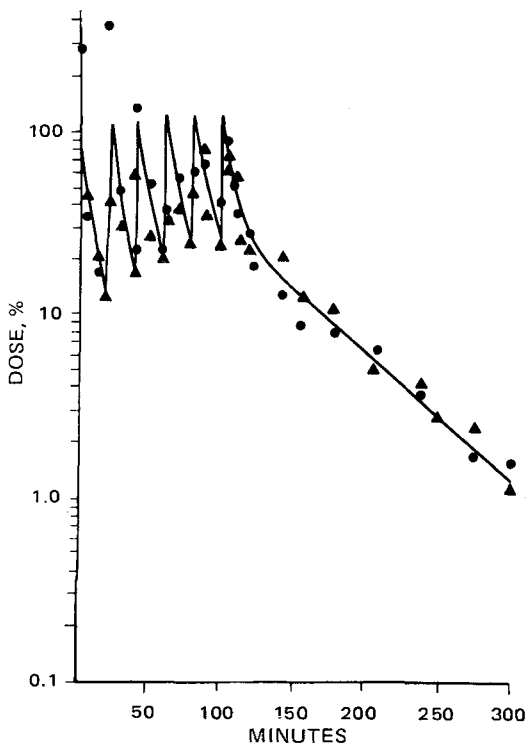

Figure 4—*Percent of absorbed dose remaining in the central compartment following six intravenous administrations of 74 (●) or 89 (▲) mg of dichlorodifluoromethane every 20 min. The solid curve represents the theoretical values based on a typical set of pharmacokinetic parameters obtained from a single-dose study (Dog 2976a).*

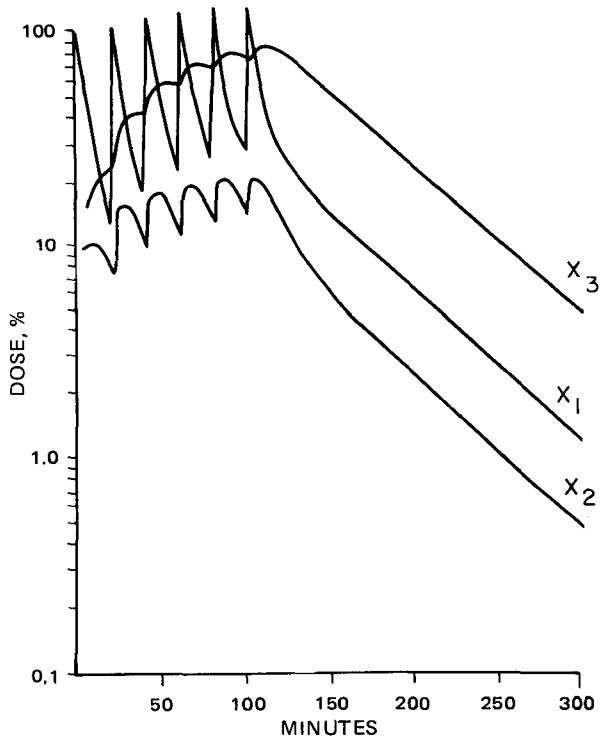

Figure 5—*Computer-generated curves for the distribution of dichlorodifluoromethane in various pharmacokinetic compartments following instantaneous absorption of six doses of 100 units each every 20 min. The pharmacokinetic parameters were obtained from a typical single-dose study (Dog 2976a).*

The toxicological aspects of the observations made here can be twofold. First, during excessive inhalation, it is possible that high tissue levels may be reached in spite of the high volatility of dichlorodifluoromethane. Sudden deaths reported following inhalation of aerosol packages can be attributed, at least in part, to the reaching of threshold toxic limits, although no such direct and reliable data have ever been reported. Second, the accumulation following multiple exposures can result in much higher deep tissue compartment levels than would be apparent from blood levels. Hence, the possibility of chronic toxicity cannot be ruled out entirely.

The toxicological implications of the use of aerosol packages containing fluorocarbon propellants and the environmental pollution hazard from these compounds are matters of controversy, but the data presented here warn against misleading toxicological interpretations that result from the application of erroneous pharmacokinetic principles.

Distribution and Pharmacokinetics of Triamterene in Rats

SEN T. KAU and B. V. RAMA SASTRY [x]

Abstract □ The tissue distribution of ^{14}C-triamterene was examined in the rat. After intravenous administration of ^{14}C-triamterene, high concentration ratios between tissues and blood were found in most tissues except the brain, fat, and testes. The maximal concentration of the drug was in the kidneys, liver, heart, lungs, and skeletal muscle within the first 20 min, when the maximal natriuresis was observed. No metabolite of triamterene was detected in these tissues. The pharmacokinetics of ^{14}C-triamterene also were investigated. The volume of distribution of the drug was greater in the central compartment (60% of the dose) than in the peripheral compartment (40%). The binding of the drug to skeletal muscle is responsible for the fraction of the dose in the peripheral compartment. Rate constants indicate that slow elimination of triamterene is related to its binding to tissue in the central compartment.

Keyphrases □ Triamterene—distribution and pharmacokinetics, radiochemical analysis, rats □ Drug distribution—triamterene, radiochemical analysis, rats □ Pharmacokinetics—triamterene, radiochemical analysis, rats □ Radiochemistry—analysis, triamterene distribution, rats □ Diuretic agents—triamterene, distribution and pharmacokinetics, radiochemical analysis, rats

Triamterene, in addition to its renal effects, significantly decreases the sodium content of cardiac and skeletal muscle without impairing the potassium content in the rat (1). Although an unusual tissue distribution of triamterene was reported in guinea pigs and baboons (2), its distribution in the rat has not been studied. Previous studies (3, 4) indicated that unchanged triamterene itself, rather than its metabolites, accounts for the observed changes of renal clearance of electrolytes.

It is not known whether the metabolism of triamterene in cardiac and skeletal muscle is similar to that in the kidneys in the rat. The contribution of the drug distributed in the tissue and of its metabolites to the total elimination of triamterene by humans and animals also is not known. The purpose of this study was to determine the tissue distribution and pharmacokinetics of triamterene in the rat to obtain a better understanding of the rate of distribution and elimination of triamterene and its extrarenal action.

EXPERIMENTAL

Animals and Materials—Male Sprague–Dawley rats[1], 200–250 g, were used. ^{14}C-Triamterene[2] (0.92 mCi/mmole) was used as supplied. It was found to be chemically pure by descending paper chromatography in two solvent systems, 1-butanol–acetic acid–water (4:1:1) and 2-propanol–water–ammonia (140:50:10), according to literature methods (4–6). A 4 × 4 countercurrent distribution of ^{14}C-triamterene between ethyl acetate (14 ml) and 0.1 *M* borate buffer at pH 10.00 (7 ml) showed that it behaved like a single compound (6–8).

Other commercially available chemical reagents were used.

Tissue Distribution—Rats were prepared for infusion as described previously (9), and ^{14}C-triamterene[3] (1, 2, or 4 mg/kg; 3.8 μCi/mg) was administered by intravenous infusion for 8 min at 0.5 ml/min/kg. Samples of blood and urine were collected 40 min after the beginning of the infusion, and the rat was then immediately decapitated. Submaxillary and thyroid glands, thymus, aorta, heart, lungs, liver, pancreas, spleen, adrenals, kidneys, ileum, biceps femoris, epididymal fat pads, testes, and brain were dissected, blotted, and weighed. The distribution of ^{14}C-triamterene and its metabolites was determined at 40 min, when the maximal potassium-sparing effect of triamterene was observed (3).

In a second series of experiments, a constant dose of ^{14}C-triamterene (2 mg/kg, 3.8 μCi/mg) was administered by infusion; the rats were sacrificed at intervals of 10, 20, 40, or 60 min thereafter. Plasma, liver, lung, heart, kidney, skeletal muscle (biceps femoris), and urine samples were collected.

The total carbon-14 in the tissues samples was measured[4]. About 200 mg of tissue was placed into a 20-ml glass counting vial. A 2-ml aliquot of liquid scintillation solute[5] was added, and the sample was shaken[6] at 50° until solubilized. To increase the counting efficiency of some heavily colored tissues (blood, liver, lungs, and spleen), 0.6 ml of benzoyl peroxide solution was added to the solubilized sample, and the mixture was shaken for an additional 0.5 hr to obtain a colorless solution.

To the solubilized tissues, 18 ml of counting solution[7] was added. The samples were cooled to 4° for 24 hr prior to counting. All samples were counted twice for 10 min. All data were converted to disintegrations per

[a] No metabolites of triamterene were detected in the liver, heart, lungs, kidneys, skeletal muscle, blood, or urine during these short-term studies (40 min after administration of triamterene). Each value is the mean ± *SE* from three rats. When the standard error is smaller than 0.01, it is not shown. [b] Nanocuries per gram of wet tissue. [c] Ratio of the mean value of the concentration in tissues (T) to that in the blood (B). About 50% of the ^{14}C-triamterene present in the blood was in the plasma. [d] Percentage dose was calculated on the basis of total ^{14}C-radioactivity in the whole tissue divided by the administered dose of ^{14}C-triamterene. Organ weights (except for total blood, total fat, and total muscle) were determined in each animal. It was not possible to determine total blood volume, total fat, and total muscle tissue within the same animal in which ^{14}C-triamterene distribution was determined. Therefore, estimated values (12–14) were used in the calculations: total blood, 6%; total fat, 16.5%; and total muscle, 45% of the body weight.

minute, using an automatic external standard and channels ratio technique. The remainder of each tissue was homogenized with 25 ml of aqueous acetone, the homogenate was centrifuged, and the aqueous acetone extract was separated and saved. The pellet was rehomogenized in 25 ml of aqueous acetone and centrifuged, and the supernate was combined with the original extract. After removal of the organic solvent by evaporation, the residue was dissolved in acetone and analyzed by paper chromatography and 4 × 4 countercurrent distribution as described previously (6–8). The procedure was repeated with each tissue.

Pharmacokinetics—Male rats were anesthetized with ketamine[8] (160 mg/kg ip). The femoral vein was cannulated with polyethylene tubing (PE 10) for the injection of ^{14}C-triamterene[9] (2 mg/kg, 3.8 μCi/mg). The femoral artery was cannulated with polyethylene tubing (PE 50) for collection of blood samples (0.3 ml for each) at timed intervals. In a second series of experiments, animals were maintained under light anesthesia with ether during cannulation of the femoral artery and vein. The rats received ^{14}C-triamterene after they recovered from the anesthesia in both series of experiments. Thereafter, blood samples were collected at timed intervals. The second series of experiments was used as a control to examine whether any postanesthetic effect of ketamine would influence the rate of distribution and elimination of triamterene in the first series.

Plasma samples were obtained after centrifuging whole blood samples, which were collected with heparinized syringes. The radioactivity in the samples of plasma was assayed according to the methods described in *Tissue Distribution*. The pharmacokinetic profile of ^{14}C-triamterene was determined in the plasma concentration–time curve, constructed according to the method described by Mayersohn and Gibaldi (10).

RESULTS

Tissue Distribution—In these short-term studies (60 min), no metabolite of triamterene was detected in the plasma, urine, or other tissues (liver, heart, lungs, kidneys, and skeletal muscle) analyzed by paper chromatography and countercurrent distribution. By comparison with the reference material, the single band at R_f 0.47 in 1-butanol–acetic acid–water or at R_f 0.42 in 2-propanol–water–ammonia was identified as unchanged triamterene in all tissues studied.

The distribution of the drug in various tissues after administration of different doses of ^{14}C-triamterene is shown in Table I. For most tissues, the concentration ratio between the tissue and the blood was greater than 1 (range of 1.80–8.53). The descending order of tissue and blood concentration ratios was: kidneys (7.36–8.53) > submaxillary glands > adrenal glands > liver > thyroid gland = pancreas > thymus > aorta = spleen > heart = lungs > diaphragm = biceps femoris > ileum. The ratio for brain was less than 1 (0.29–0.31). It was shown previously that there is a passive diffusion of triamterene into the brain across the blood–brain barrier, but it is actively transported out of the brain. This fact may explain partially the low tissue to blood ratio in the brain (11).

The same fraction of the drug was excreted in the urine irrespective of the size of the dose. The total amount of the drug in the organs was about 78–87% of the dose.

The tissue distribution of ^{14}C-triamterene as a function of time is shown in Fig. 1. The concentration of the drug reached a peak at 20 min in all tissues. The maximum concentration was in the renal tissue within the first 20 min, when the maximal natriuresis was also observed (3). The storehouse of the drug was the skeletal muscle, which contained about 39% of the dose at 20 min.

Pharmacokinetics—The pharmacokinetic profile of ^{14}C-triamterene in the rat was determined utilizing the data obtained following intravenous drug administration. The plasma concentration–time curve[10] of triamterene constructed from these data was biexponential (Fig. 2). The values of the parameters for the biexponential equation ($C_p = Ae^{-\alpha t} + Be^{-\beta t}$) are shown in Table II. The half-lives of the fast and slow components also were obtained. The two-compartment pharmacokinetic model was applied to this study, and its rate constants are shown in Table III.

DISCUSSION

Tissue Distribution—There are several interesting aspects to the distribution of ^{14}C-triamterene in the rat. After intravenous drug administration, the highest concentration was present in the kidneys at all timed intervals and dosage levels, whereas the largest fraction of the administered dose was deposited in the skeletal muscle. No metabolite was detected in these tissues. Therefore, the extensive accumulation of unchanged triamterene probably is responsible for its inhibitory action on sodium transport in skeletal muscle (1) as well as in kidneys (3).

A high concentration of the drug in all tissues analyzed, except the testes, brain, and fat, was maintained against a low concentration in the

[8] Bristol Laboratories.

[9] ^{14}C-Triamterene was suspended in 0.9% sodium chloride with a few drops of 8.5% lactic acid and warming until a clear solution was obtained.

[10] A nonlinear program was used for fitting the plasma concentration–time curve. The program was kindly provided by Dr. James Kao, Department of Chemistry, University of Georgia, Athens, Ga.

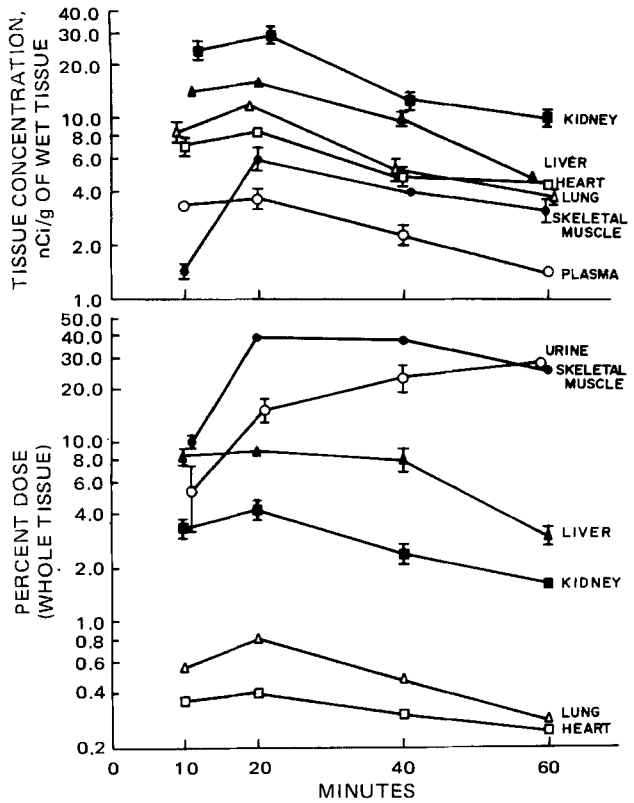

Figure 1—*Tissue distribution of ^{14}C-triamterene as a function of time. The upper panel indicates tissue concentration* versus *time; the lower panel shows percent dose* versus *time. The dose of ^{14}C-triamterene was 2 mg/kg iv. No metabolites of triamterene were detected in these tissues during the timed intervals. Each value is the mean ± SE from three rats. When the standard error is smaller than the dimension of the symbol, it is not shown.*

blood. Higher concentrations of triamterene were found inside dialysis bags in association with tissue homogenates (2). Therefore, the extensive accumulation of the drug in those tissues probably is a consequence of its binding by them.

Although the relationship of the tissue concentration of ^{14}C-triamterene to its effect on tissue electrolytes is not known, the data indicate that secretory (adrenal, submaxillary, and thyroid glands; liver; and kidneys) and lymphoid organs (thymus, spleen, and pancreas) accumulate the drug in higher concentrations than other tissues.

The highest concentration of the drug was found in the kidneys, liver, heart, lungs, and skeletal muscle within the first 20 min, when maximal

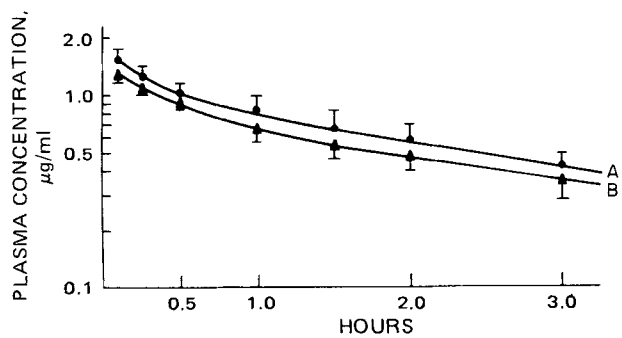

Figure 2—*Semilogarithmic plot of the plasma concentration of ^{14}C-radioactivity as a function of time after administration of ^{14}C-triamterene (2 mg/kg iv). Key: A (●), control group of animals that received light ether anesthesia during cannulation; and B (▲), group of animals that received ketamine instead of ether. Each point represents the mean ± SE for four animals in A and three animals in B. The plasma half-life of the fast component was 0.28 hr in A and 0.27 hr in B; the plasma half-life of the slow component was 2.77 hr in A and 2.78 hr in B. There was no significant difference between A and B in the plasma half-life of either the fast or slow component* ($p > 0.05$).

Table II—Values in the Equation[a] $C_p = Ae^{-\alpha t} + Be^{-\beta t}$ for Triamterene[b]

Parameter	Ketamine Anesthesia	Control[c]
A, μg/ml	0.68 ± 0.27	0.72 ± 0.17
α, hr^{-1}	2.61 ± 0.11	2.49 ± 0.22
B, μg/ml	0.79 ± 0.10	0.95 ± 0.14
β, hr^{-1}	0.25 ± 0.02	0.28 ± 0.03

[a] C_p is the drug concentration in the plasma at any time t, A and B are the ordinate axis intercepts, α is the fast disposition rate, and β is the slow disposition rate. [b] Each value is the mean ± SE for three rats in ketamine anesthesia and four rats in control experiments. [c] Control refers to the group of rats under light ether anesthesia during cannulation of the femoral artery and vein.

natriuresis was also observed (3). Since no metabolite of triamterene was detected in these tissues, there was a good correlation between the tissue concentration of the unchanged drug and its inhibitory effect on sodium transport. These data suggest that the extrarenal effect of triamterene on the tissue content of sodium deserves further investigation.

Pharmacokinetics—The rats were anesthetized with either ketamine or ether during surgery, and they received ^{14}C-triamterene only after they recovered from anesthesia. Although the pharmacology of ketamine is different from that of ether (5), the rate of distribution and elimination of triamterene was not significantly affected by any postanesthetic action of ketamine (Table III). Apparently, ketamine is as suitable as ether as an anesthetic agent in the pharmacokinetic study of triamterene.

The pharmacokinetic profile of triamterene was evaluated by the two-compartment open-model system (10). According to the biexponential plasma concentration–time curve of the drug, the first exponent is the fast disposition rate constant (α) and the second exponent is the slow disposition rate constant (β). The magnitudes of α and β indicate that triamterene ought to be distributed at a fairly rapid rate and be eliminated at a relatively slow rate. The ratio of β/k_{el} indicates that approximately two-thirds of the drug in the body would be in the central compartment available for elimination at any time.

The distribution volume of the drug was greater in the central compartment (*e.g.*, highly perfused tissues such as kidney and liver) than in the peripheral compartment (*e.g.*, poorly perfused tissues such as fat and muscle). These values reflect the high affinity of triamterene for binding substances in the central compartment. The result is well correlated with the present finding on the tissue distribution of ^{14}C-triamterene. A high drug concentration ratio between tissue and blood was found in kidney, liver, and other highly perfused tissues. Furthermore, the sum of the fractions of the dose found in skeletal muscle (37%), smooth muscle (2%), and fat (3%) was close to the value (38%) from pharmacokinetic studies in the peripheral compartment. Apparently, the high affinity of the drug

Table III—Distribution and Elimination Parameters of the Two-Compartment Open Model for Triamterene[a]

Parameter	Ketamine Anesthesia[b]	Control[b]
Distribution volume[c], ml		
V_c	311.1 ± 19.2	317.8 ± 64.2
V_p	175.5 ± 62.8	150.9 ± 17.5
V_d	486.7 ± 48.3	468.7 ± 74.4
Clearance[c], ml/min, C_t	2.27 ± 0.51	2.17 ± 0.39
Rate constants[d], hr^{-1}		
k_{12}	0.81 ± 0.18	0.79 ± 0.12
k_{21}	1.59 ± 0.03	1.56 ± 0.09
k_{el}	0.46 ± 0.13	0.46 ± 0.06
Constant ratio[e], β/k_{el}	0.61 ± 0.10	0.63 ± 0.05

[a] Each value is the mean ± SE as described in Table I. The evaluation of kinetic parameters was according to the methods described in Refs. 10 and 15. [b] Mean values for ketamine anesthesia and control were not significantly different in all parameters, $p > 0.05$ (calculated by the Student t test). Average weights of rats in ketamine and control groups were 210 and 230 g, respectively. [c] V_c = volume of central compartment, V_p = volume of peripheral compartment, V_d = total volume of distribution, and C_t = clearance of a drug from the central compartment. Distribution volume and clearance were calculated per rat. [d] The individual rate constants k_{12} and k_{21} reflect the rate of distribution into and out of the peripheral compartment from the central compartment; k_{el} is the sum of all rate constants governing the elimination process, including metabolism and urinary excretion. [e] Fraction of dose in the central compartment.

for skeletal muscle is responsible for its accumulation in the peripheral compartment.

The ratio of k_{21}/k_{12} ranged from 1.4 to 3.0, with a mean of 2.2, indicating that the drug returns rapidly from distribution sites for elimination from the body. However, the low k_{el}, with a mean of 0.46, indicates that the elimination of triamterene would not be as rapid as the ratio predicts. This situation could be related to the binding of the drug to tissue substances in the central compartment and to the ability of the rat to metabolize a limited amount of the drug (6). According to the plasma half-life of the slow component obtained in the present experiments, after intravenous administration of triamterene there will be a negligible concentration of the drug in the plasma within about five half-lives (13.9 hr).

In conclusion, the present observations illustrate the tissue binding property of triamterene in the rat. Although these data provide limited information about the nature of this property, they reveal the possibility of the effect of unchanged triamterene on the tissue content of sodium. A pharmacokinetic interpretation of the present study appears to be well correlated with the experimental results. Apparently, the tissue binding property of triamterene is an important factor in controlling its rate of distribution and elimination in the rat.

Effect of Sodium Salicylate on Renal Elimination of a Quaternary Ammonium Compound

KISHOR A. DANDEKAR [*] and H. B. KOSTENBAUDER [x]

Abstract □ Administration of sodium salicylate inhibited elimination of the tetraethylammonium ion in rats. A two-compartment open model was used to describe plasma decline of tetraethylammonium bromide administered intravenously. The rate constant describing elimination from the central compartment was decreased by 25 and 40% in rats predosed with sodium salicylate at 30 and 50 mg/kg, respectively. Salicylate also enhanced the distribution of the tetraethylammonium ion to the peripheral compartment. Urinary excretion is the principal route of elimination for the tetraethylammonium ion, and studies of the effect of sodium salicylate on the uptake of the tetraethylammonium ion by rat renal cortical tissue indicated noncompetitive inhibition by salicylate.

Keyphrases □ Sodium salicylate—effect on renal elimination of tetraethylammonium bromide, rats □ Tetraethylammonium bromide—pharmacokinetic model, effect of sodium salicylate on renal elimination, rats □ Elimination, renal—tetraethylammonium bromide, effect of sodium salicylate, rats □ Pharmacokinetics—two-compartment open model for tetraethylammonium bromide, rats □ Quaternary ammonium compounds—tetraethylammonium bromide, pharmacokinetic model, effect of sodium salicylate on renal elimination, rats

Quaternary ammonium and other strongly basic compounds are actively secreted by the renal tubule. The secretory pathway for the basic compounds is similar, but not identical, to the anion transport mechanism. Both mechanisms are known to be saturable, specific, and subject to inhibition by structural analogs and antimetabolic compounds and to require energy for their operation. In general, tubular transport of basic compounds is not known to be inhibited by acidic compounds; conversely, the transport of acidic compounds is not known to be inhibited by basic compounds (1).

The recently reported, partly noncompetitive nature of the inhibition of *p*-aminohippurate tubular transport by salicylate (2) prompted investigation of the effect of salicylate on the renal tubular transport of a quaternary ammonium compound. The effect of sodium salicylate on renal elimination kinetics of the tetraethylammonium cation was investigated in *in vitro* and *in vivo* models. Rat renal cortical slice studies were used to determine the nature of the inhibitory effect of salicylate on the active uptake of the tetraethylammonium ion by cortical tissue. The significance of the salicylate effect on renal elimination of the ^{14}C-tetraethylammonium ion was then evaluated in pharmacokinetic studies in anesthetized rats.

Quaternary ammonium and other strongly basic compounds are actively secreted by the renal tubule. The secretory pathway for the basic compounds is similar, but not identical, to the anion transport mechanism. Both mechanisms are known to be saturable, specific, and subject to inhibition by structural analogs and antimetabolic compounds and to require energy for their operation. In general, tubular transport of basic compounds is not known to be inhibited by acidic compounds; conversely, the transport of acidic compounds is not known to be inhibited by basic compounds (1).

The recently reported, partly noncompetitive nature of the inhibition of *p*-aminohippurate tubular transport by salicylate (2) prompted investigation of the effect of salicylate on the renal tubular transport of a quaternary ammonium compound. The effect of sodium salicylate on renal elimination kinetics of the tetraethylammonium cation was investigated in *in vitro* and *in vivo* models. Rat renal cortical slice studies were used to determine the nature of the inhibitory effect of salicylate on the active uptake of the tetraethylammonium ion by cortical tissue. The significance of the salicylate effect on renal elimination of the ^{14}C-tetraethylammonium ion was then evaluated in pharmacokinetic studies in anesthetized rats.

EXPERIMENTAL

Renal Cortical Slice Study—Male Sprague–Dawley rats, 200–300 g, were killed by decapitation. Kidneys were removed quickly by abdominal laparotomy. The kidneys were decapsulated and stored briefly (not more than 10 min) under ice-cold normal saline bubbled with 100% oxygen. After discarding the two surface slices, three cortical slices, approximately 0.3–0.4 mm in thickness, were cut from dorsal and ventral sides using a tissue slicer[1]. In each experiment, two or three animals were killed and the slices were pooled.

About 60–80 mg of tissue (two to three slices) was equilibrated with 3 ml of incubation medium under 100% oxygen for 5 min. ^{14}C-Tetraethylammonium bromide[2] (100 μCi/19.2 mg) was then added in a volume of 100 μl, and the flasks were incubated for 30 min with continuous shaking at 60 cpm. The period between animal decapitation and the beginning of the incubation was never more than 30 min. At the end of the incubation period, the flasks were chilled in an ice bath, the tissue slices were blotted lightly and weighed, and the ^{14}C-tetraethylammonium-ion content of the slices was determined by liquid scintillation counting.

The incubation medium was prepared as suggested by Robinson (3), except for the addition of 11 m*M* glucose. The optimum incubation period was determined by observing the uptake of the tetraethylammonium ion at the end of 5, 10, 20, 30, 50, and 60 min. This uptake was determined for initial tetraethylammonium bromide concentrations of 0.125, 0.250, 0.500, 1.00, and 2.00 m*M* in the presence and absence of 1 m*M* sodium salicylate. Each solution contained 0.075 μCi of the ^{14}C-tetraethylammonium ion.

Passive uptake of the tetraethylammonium ion by the renal tissue was determined in a separate experiment. Sodium cyanide (1 m*M*) was added to the salicylate-free medium, and nitrogen gas was used in place of oxygen. Ten flasks were used in this experiment.

Pharmacokinetic Studies—Male Sprague-Dawley rats, 420–580 g, were acclimatized to laboratory conditions for at least 2 days. The animals had free access to food and water until the experiments began. Rats were anesthetized with pentobarbital sodium[3], 50 mg/kg ip. The bile duct was cannulated after a small incision (about 1 cm) was made 1 cm below the sternum on the abdominal wall. The wound was sutured and kept covered with 4 × 4 gauze soaked in normal saline. The femoral vein was cannulated and provided with a three-way stopcock and a 5-ml disposable syringe filled with heparinized (10 units/ml) normal saline.

The surgical procedure was completed within 10 min after anesthesia, and 30 min was allowed between its completion and the administration of the intravenous dose of tetraethylammonium bromide. The rats were watched for uniform breathing, proper level of anesthesia, and unobstructed bile flow during this period. In the salicylate treatment experiments, 30 or 50 mg/kg iv of sodium salicylate was given immediately after completion of the surgical procedure. A 0.4-ml blood sample and a 10-min bile sample were collected during this period to serve as a blank or background determination in the analytical procedure.

At the end of 30 min, ^{14}C-tetraethylammonium bromide solution, 10 mg/kg iv, was administered over 20 sec. This injection contained 5 mg of total drug/ml and 3.0 μCi of ^{14}C-tetraethylammonium bromide/ml. The timer was started at the midpoint of the injection period. The dose was flushed into the circulation with about 0.4 ml of normal saline. The three-way stopcock and the 5-ml syringe were discarded, and a new 5-ml syringe containing fresh heparinized normal saline was connected directly to the venous cannula. This procedure prevented contamination of the first blood sample with the very high radioactivity of the dose.

Blood samples, 0.4 ml each, were withdrawn every 5 min for the first 40 min and then every 20 min for a total of 2 hr. The blood volume withdrawn was replaced by injecting 0.4 ml of heparinized normal saline after each withdrawal. Blood clotting in the cannula was avoided by maintaining heparinized normal saline in the cannula tubing between blood samples. The plasma was separated by centrifuging, and the plasma and bile samples were analyzed for carbon-14 radioactivity by scintillation counting immediately after the experiment.

Tetraethylammonium-Ion Partition Study—Five solutions, 5 ml each, containing 0.05 m*M* tetraethylammonium bromide and 0.5, 1.0, 1.5, 2.0, or 2.5 m*M* sodium salicylate were prepared in 0.1 *M* phosphate buffer (pH 7.4). Exactly 0.03 μCi of ^{14}C-tetraethylammonium bromide was added to each tube. Then 5 ml of chloroform was added to each tube, and the tubes were closed and gently rocked for 30 min. The tubes were then centrifuged to separate the two phases. Radioactivity in the aqueous phase, prior to and after partitioning, was determined by scintillation counting.

Table I—Results of Renal Cortical Slice Study

Tetraethylammonium Ion in Medium, m*M*	Micromoles of Tetraethylammonium Ion per Gram of Tissue per 30 min × 10[a]		
	Control (n = 4)	With Sodium Salicylate (1 m*M*) (n = 4)	With Sodium Cyanide (1 m*M*) under Nitrogen (n = 2)
0.125	3.8872 ± 0.7147	2.2731 ± 0.6674	0.9587 ± 0.0143
0.250	5.5133 ± 0.2124	3.9493 ± 0.4507	1.9150 ± 0.0640
0.500	9.4887 ± 1.4737	6.3751 ± 0.2024	3.8604 ± 0.0944

2.00	20.3419 ± 3.3068	17.1054 ± 0.7102	14.8463[b]

[a] Mean ± *SD*. [b] n = 1.

Radioactivity in Renal Cortical Slices—After determination of tissue weight, renal cortical slices were dissolved in 15 ml of a toluene base scintillation cocktail with the aid of 1 ml of tissue solubilizer[4].

Each vial was counted for 10 min in a liquid scintillation counter[5] to determine the carbon-14 radioactivity. An appropriate quench curve was made by adding tissue to a constant amount of ^{14}C-tetraethylammonium bromide (5323 dpm/vial).

Radioactivity in Plasma and Bile—Exactly 100 μl of plasma was placed in the glass scintillation vials and mixed with 15 ml of scintillation fluid. Each vial was counted for 10 min in a scintillation counter. The quench curve made by adding various volumes (20–150 μl) of plasma but the same known amount of ^{14}C-tetraethylammonium bromide (2200 dpm/vial) allowed the exact determination of counting efficiency of the plasma samples.

Entire 10-min bile samples were used for determining the ^{14}C-tetraethylammonium ion in the bile. Addition of 2 ml of methanol to bile prior to mixing it with 15 ml of scintillation fluid improved the sample appearance and the counting efficiency.

Tetraethylammonium-Ion Uptake Calculations—The amount of tetraethylammonium ion in the tissue was expressed in terms of micromoles per gram of tissue. The active uptake of the tetraethylammonium ion was determined by subtracting the uptake in the presence of 1 m*M* potassium cyanide and a nitrogen atmosphere from the aerobic uptake. The active uptake was treated according to Michaelis–Menten kinetics.

Pharmacokinetic Calculations—The plasma tetraethylammonium-ion *versus* time profiles in all experiments were biexponential, suggesting that pharmacokinetic analysis would require minimally a two-compartment open model (4). The average plasma level–time profiles of four experiments done in each category, *i.e.*, control, with 30-mg/kg salicylate dose, and with 50-mg/kg salicylate dose, were determined. The mean plasma level–time data of each category of experiments were fitted to the following biexponential equation using the SAAM-23 digital computer program (5):

$$C = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 1)}$$

The constants A, B, α, and β, estimated by the computer fit, were then used to determine the individual rate constants and related volume parameters of the two-compartment open model (Scheme I) (4).

Each data point represents the mean for the number of studies indicated in Table I.*

RESULTS AND DISCUSSION

Renal Cortical Slice Study—Data for the uptake of the tetraethylammonium ion by renal cortical tissue are presented in Table I. Maximum uptake occurred after 30 min of incubation. Tetraethylammonium-ion uptake in three categories of the experiments, *i.e.*, control, with 1 m*M* salicylate under proper physiological conditions, and in anaerobic conditions under nitrogen in the presence of 1 m*M* sodium cyanide, is illustrated in Fig. 1. The active uptake of the tetraethylammonium ion, with and without salicylate, is shown as a Woolf plot in Fig. 2.

Figure 1 clearly shows that the tetraethylammonium-ion active uptake by the cortical slices was a saturable process and obeyed Michaelis–Menten kinetics. The uptake of the tetraethylammonium ion in the presence of cyanide and nitrogen was the measure of passive diffusion of the tetraethylammonium ion into the cortical tissue and was a linear function of the concentration in the medium. The active oxygen and enzyme-dependent uptake, therefore, was determined by subtracting the passive uptake from the uptake determined in the presence of oxygen under proper physiological conditions. The Woolf plot of the active tetraethylammonium-ion uptake data (Fig. 2) indicates noncompetitive inhibition of the active uptake of the tetraethylammonium ion by salicylate. This result is in agreement with a generally accepted theory that an anionic drug does not compete with a cationic drug for tubular

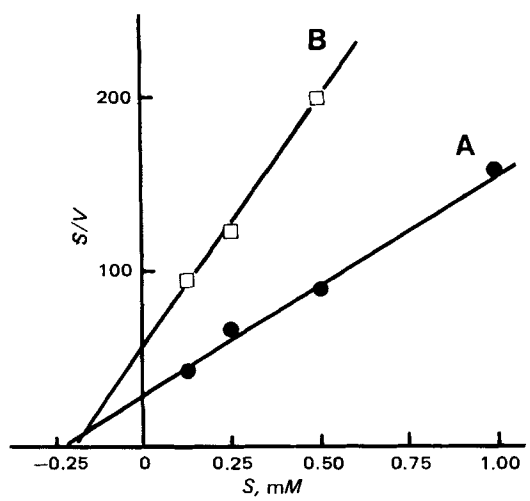

Figure 2—*Woolf plot of the active uptake of the tetraethylammonium ion by renal cortical slices; S is substrate concentration, and V is rate of uptake. Key: A, control, $V_{max} = 7.93 \times 10^{-4}$ mmole/g of tissue/30 min, and $K_m = 0.242$ mM; and B, in presence of 1 mM sodium salicylate, $V_{max} = 3.57 \times 10^{-4}$ mmole/g of tissue/30 min, and $K_m = 0.204$ mM. Data were derived from mean uptake reported in Table I.*

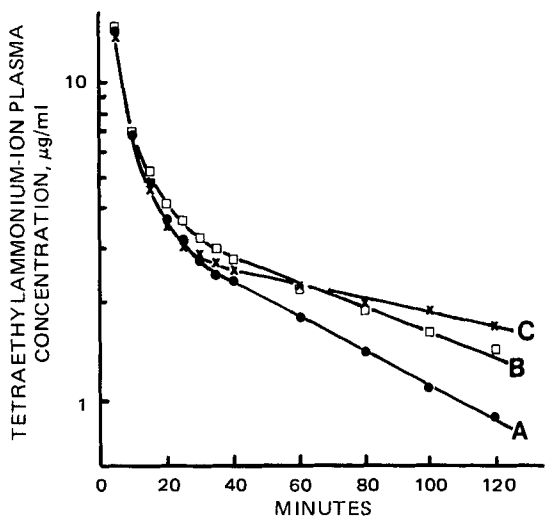

Figure 3—*Influence of salicylate on plasma decline of the ^{14}C-tetraethylammonium ion in rats following rapid intravenous injection of 10 mg of tetraethylammonium bromide/kg. transport. Salicylate apparently did not cause the inhibition by acting as a competitive substrate but must have influenced tetraethylammonium-ion uptake by another mechanism.

Salicylate has been shown to be an uncoupler of oxidative phosphorylation, a subcellular biochemical process responsible for the synthesis of adenosine triphosphate (6). The exact mechanism of the salicylate effect on oxidative phosphorylation is not yet clearly defined (6). Salicylate also affects protein and amino acid metabolism in the body (7), which results in altered permeability of the cellular structure. Alteration of permeability of the cellular structure that constitutes a selective barrier could be the reason for the reduced uptake of the tetraethylammonium ion in the presence of salicylate.

Pharmacokinetic Study in Rats—After the inhibition of active tetraethylammonium-ion uptake by rat renal cortical slices was observed, the significance of the salicylate inhibition of tubular transport was assessed in single-injection pharmacokinetic studies in rats.

Biliary excretion of radioactive drug was examined as a possible route of extrarenal elimination of the tetraethylammonium ion. Biliary excretion of the tetraethylammonium ion was quantitated, but kinetic analysis suggested that less than 1% of the total elimination was taking place in bile.

control (four rats) and salicylate treatment at 30 (four rats) and 50 (three rats) mg/kg, are presented in Table II. The digital computer fit to mean plasma levels is illustrated in Fig. 3, and the pharmacokinetic parameters are given in Table III.

Salicylate treatments resulted in a significant decrease in the elimination rate constant, k_{13} (25 and 40% decrease compared to k_{13} in control experiments). This observation supports the results of the cortical slice study. Although it cannot be concluded whether tubular secretion, glomerular filtration, or tubular reabsorption was altered by salicylate, it appears that salicylate probably inhibited the active tubular secretion.

Besides the decrease in k_{13}, both k_{12} and k_{21} changed in the presence of salicylate. Increases in the volume of distribution and the ratio of k_{12}/k_{21} suggest enhanced distribution of the tetraethylammonium ion in the peripheral compartment. The apparent volume of the central compartment was unchanged by the salicylate treatment (Fig. 4).

Thus, in the present study, both elimination and distribution of the drug were altered by the salicylate treatment.

The actual amounts of the tetraethylammonium ion present in the peripheral compartment at various times in the three categories of experiments can be calculated by (8):

$$X_p = \frac{k_{12}(\text{dose})}{(\alpha - \beta)}(e^{-\beta t} - e^{-\alpha t}) \qquad \text{(Eq. 2)}$$

or they can be simulated using the CSMP (9) digital computer program. The amount of the tetraethylammonium ion in the peripheral compartment *versus* time data calculated by CSMP are shown graphically in Fig. 5.

Table III—Pharmacokinetic Parameters of Tetraethylammonium Ion

Parameter	Control	30 mg of Salicylate/kg	50 mg of Salicylate/kg

Tetraethylammonium ions are known to distribute only in extracellular space (10); penetration of the blood–brain barrier is limited. Pretreatment with salicylate resulted in enhanced distribution to peripheral tissues. An increased distribution could be taken as an opening of some barrier to tetraethylammonium-ion distribution somewhere outside the central compartment. Salicylate has various biochemical effects such as interference with protein and amino acid metabolism (7) and uncoupling of oxidative phosphorylation (11). Uncoupling agents are known to alter the selective barrier of the cellular membrane. Whether this alteration results primarily from the uncoupling action or its effects on protein metabolism is not clearly understood (12).

The results of a partition study suggest that there is no ion-pair formation between salicylate and the tetraethylammonium ion that would account for a change in *in vivo* distribution. The apparent partition coefficient of the tetraethylammonium ion between chloroform and pH 7.4 phosphate buffer in the presence of a 10–50 M excess of salicylate remained unchanged at 1.02×10^{-2}.

The most significant influence of the coadministration of salicylate on tetraethylammonium-ion pharmacokinetics was the increase in the amount of the tetraethylammonium ion in the peripheral compartment. This increase was a result of a decrease in k_{13} and an increase in the distribution of drug into the peripheral compartment. The amount of drug in the central compartment was essentially unchanged by salicylate administration. Therefore, the clinical significance of coadministration of salicylate with a quaternary ammonium drug such as tetraethylammonium bromide depends on whether pharmacological response to the drug most closely parallels the amount of drug in the central compartment or that in the peripheral compartment.

Simultaneous Determination of 4-Nitroanisole, 4-Nitrophenol, and 4-Nitrocatechol by Phase-Sensitive ac Polarography

H. BURGSCHAT and K. J. NETTER x

Abstract □ Phase-sensitive ac polarography was applied to the simultaneous quantitative determination of 4-nitroanisole, 4-nitrophenol, and 4-nitrocatechol in alkaline solutions. Certain experimental precautions are necessary to determine each compound in the presence of the other two. Thus, 4-nitrocatechol is determined indirectly by forming a yellow ratio chelate with cupric ions, whereas 4-nitroanisole is determined directly by the reduction waves of the nitro group. For the determination of 4-nitrophenol, the interference by the simultaneously present 4-nitrocatechol must be eliminated by masking it by the addition of magnesium ions. The method described permits a qualitative and quantitative analysis of all three compounds in one solution since linear calibration curves are obtained.

Keyphrases ■ 4-Nitroanisole—polarographic analysis in presence of 4-nitrophenol and 4-nitrocatechol, alkaline solutions ■ 4-Nitrophenol—polarographic analysis in presence of 4-nitroanisole and 4-nitrocatechol, alkaline solutions ■ 4-Nitrocatechol—polarographic analysis in presence of 4-nitroanisole and 4-nitrocatechol, alkaline solutions □ Polarography—simultaneous analyses, 4-nitrophenol, 4-nitroanisole, and 4-nitrocatechol, alkaline solutions

Polarography is a common procedure in the analysis of aromatic nitro compounds of different character (1–3), because these compounds are easily reduced at the dropping mercury electrode. The mechanism of the electrode reaction was studied in aqueous solutions (4), and the mechanism of nitro derivative reduction was investigated in aprotic solvents (5, 6). More detailed studies with nitrophenol derivatives also were reported (7, 8).

From these studies, it follows that the nitro compounds can be quantitatively determined when analyzed independently. However, conditions become more complex when several nitro compounds are present. As expected (9), the peak potentials of such compounds are so close to each other that their peaks often overlap, and it is difficult to obtain qualitative and quantitative results without prior separation. Because of the inaccuracy of the results obtained by dc polarography (9), use of phase-sensitive ac polarography was suggested (10). This method allows a better interpretation of neighboring peaks. The logarithmic analysis for overlapping waves (11) is not feasible routinely.

In drug metabolism studies, 4-nitroanisole (I) was used as a model drug for demonstrating oxidative *O*-demethylation activity (12). More recently, the production of 4-nitrocatechol (III) was observed in microsomal suspensions after incubations of I or its main metabolic product, 4-nitrophenol (II) (13, 14). Compound III has an absorption maximum slightly different from that of II, the formation of which is usually recorded spectrophotometrically for 5–10 min at pH 7.85 as a routine kinetic method (15) to measure the initial velocity of the oxidative *O*-demethylation of I to II. Thus, III might interfere with the spectral recording of II formation during prolonged incubations[1].

Pharmacologically, it is desirable to determine these three compounds with the greatest possible simplicity and rapidity. The described experiments resulted in the development of a rapid ac polarographic method, allowing the simultaneous determination of these compounds[2]. In this connection, special emphasis is placed on the effects of pH variation in the polarographic base solution.

EXPERIMENTAL

Measurements were carried out using a phase-sensitive ac polarograph, as described previously (16), with an additional phase-sensitive rectifier.

An internal low frequency oscillator creates a frequency of 12 Hz, which is superimposed on the polarographic cell potential. The variable phase of the phase-sensitive rectifier was adjusted so that the capacitance current was largely eliminated. To avoid beat phenomena, a synchronization of the increase in drop size with the alternating current was necessary. Therefore, the internal low frequency was applied to the drop controller in the electrode stand[3]. The amplitude of the alternating current was 30 mv for all experiments.

The polarograms were recorded with an *xy*-recorder[4] after bubbling purified nitrogen through the solution for 2.5 min. The flow rate of mercury dropping into 0.1 *N* NaOH at a potential of −1.0 v was 3.24 mg/sec, and the drop time was 2.72 sec. With automatic drop control, it amounted to 0.69 sec at a reservoir height of 67 cm. All measurements were recorded *versus* a normal calomel electrode at 21 ± 1°. A commercially available pH meter[5] with a glass electrode was used after calibration

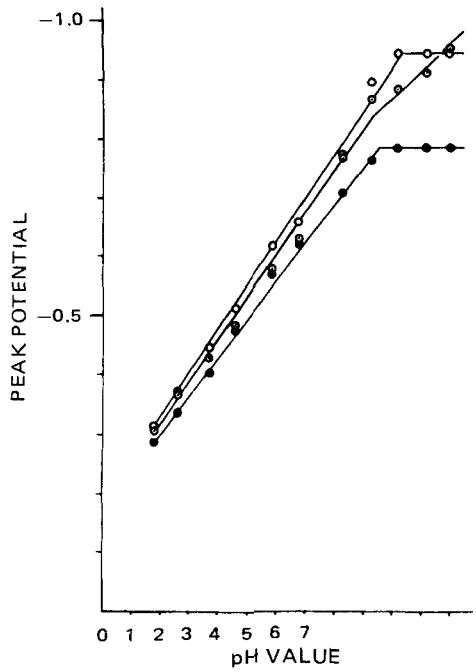

Figure 1—*The pH dependency of the peak potentials of I (●), II (○), and III (⊙). Concentration = 20 μM in Britton–Robinson buffer.*

with standard buffers[6]. All solvents and substances were of analytical grade and were not further purified.

RESULTS AND DISCUSSION

pH Dependency—Figure 1 shows the dependence of the peak potentials of I–III in Britton–Robinson buffer (17). The peak potentials exhibited a linear shift to more negative values with increasing pH; but at pH 9, the peak potentials for I and II became independent of pH. Similar results were obtained previously for nitroaniline (4). For III, however, the pH dependency persisted above pH 9 but showed a smaller increase. The shifts for the peak potentials per pH unit for I and II were 62 and 72 mv, respectively; for III, values of 68 mv below pH 9 and of 46 mv above pH 9 were found.

Further alkalinization above pH 12 by using 0.1 *N* NaOH instead of the buffer led to a further increase of the peak potential of III while the other two compounds showed a plateau. The values at pH 13 were −780 mv for I, −940 mv for II, and −1000 mv for III, showing that the second part of the curve for III in Fig. 1 was continued by 45 mv/pH unit. Therefore, 0.1 *N* NaOH (pH 13) was selected as a suitable medium for the quantitative and qualitative analyses of all three compounds.

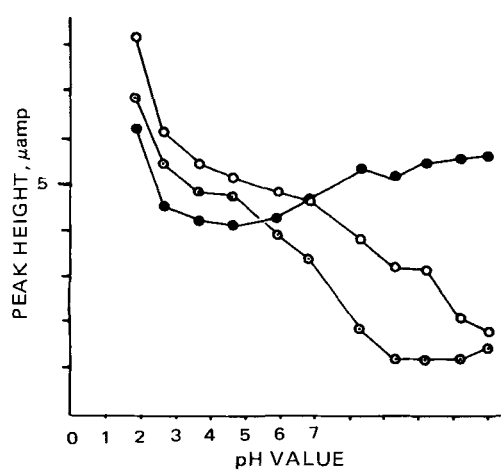

Figure 2—*The pH dependency of the peak heights of I (●), II (○), and III (⊙). Conditions were as in Fig. 1.*

[6] Merck, Darmstadt, Germany.

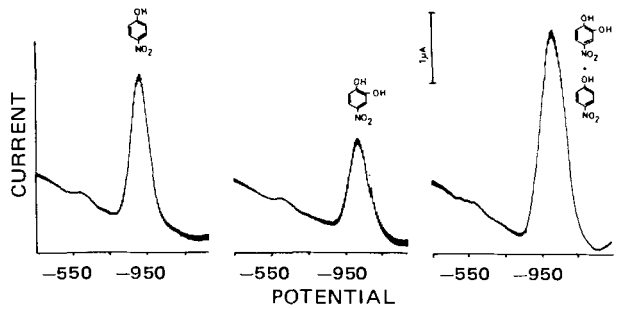

Figure 3—*Polarograms of II and III in 0.1 N NaOH. Key: left, polarogram of II (20 μM); middle, polarogram of III (20 μM); and right, polarogram of both phenols (each 20 μM).*

Not only the position of the peak potentials but also peak heights were influenced by an increase in pH. As shown in Fig. 2, the peak heights of II and III decreased with increasing pH. After an initial decrease, the peak height of I showed a slight increase above pH 4.5, which continued roughly until pH 12. In this region, it again reached the starting peak height of about pH 2.

The data in Fig. 1 show that, in the alkaline solution, I had a peak potential sufficiently different (about 160 mv) to allow a separate determination. The two phenols, however, did not possess peak potentials sufficiently apart from each other (Fig. 3), a fact that necessitated other means of determination. The left and middle polarograms of Fig. 3 represent the peaks of II and III in the base solution; the right one shows the effect of mixing both II and III. The result was a clear superposition of both peaks. The peak potentials and peak heights shown in the figures represent only the first observed reduction step of the nitro groups on the electrode surface. For II and III, this step was followed in alkaline solutions by a second reduction step in a more negative potential region located closely to the reduction of the sodium ion.

The second peaks (about −1.5 v) could not be quantitatively evaluated because of a lack of proportionality with concentration. This separation into two peaks, however, points to a different electrode mechanism for II and III in contrast to I, which did not show a reduction in peak height in alkaline solutions. This behavior is interpreted as representing two or four consecutive electron-transferring steps in II and III reduction (8, 18); in I, the transfer of all six electrons occurs in one step. Consequently, there is no second peak for I. For pH values below 7, however, all three substances seemed to be reduced by the same or a very similar mechanism.

Determination of II and III—*Indirect Determination of III in Presence of II*—In addition to the direct reduction of the nitro group, III can also indirectly be determined by utilizing the neighboring hydroxyl groups by the formation of a metal chelate (19–21).

Studies with a number of cations, *e.g.*, iron, copper, zinc, tin, cadmium, germanium, boron, aluminum, and magnesium, showed that only cupric and magnesium ions provided usable results in alkaline solution. On addition of cupric ions to the base solution containing III, the red color of III changed to yellow and a new peak at −540 mv appeared in the polarogram (Fig. 4, right). It was not obtained with cupric ions alone in the

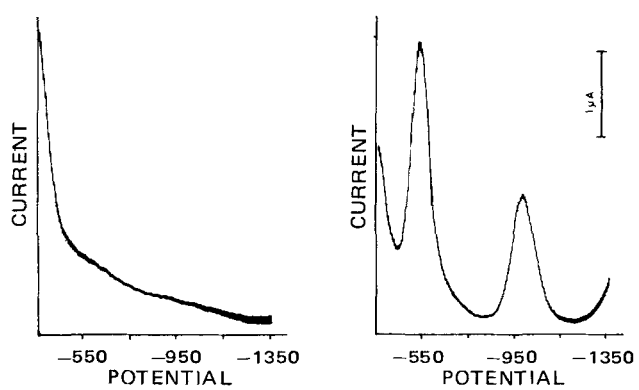

Figure 4—*Polarograms of III. Key: left, base current in 0.1 N NaOH in the presence of 5 μl of 1% $CuSO_4$ (final concentration of 40 μM); and right, polarogram of III (20 μM) under the same conditions. The peak at −540 mv represents chelate reduction, and the peak at −940 mv represents the first reduction step of the nitro group.*

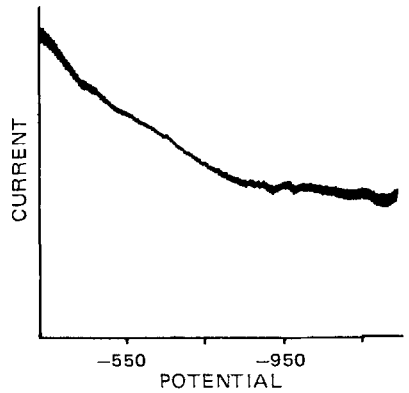

Figure 5—*Masking of III; polarogram after injection of 200 μl of 0.1 M $MgCl_2$ into the base solution containing III (20 μM).*

absence of III (Fig. 4, left). The reduction peaks of the nitro group appeared at the same potentials as mentioned previously.

Further experimentation revealed that only 0.5 mmole of cupric ions was necessary for the determination of 1 mmole of III, indicating that a 2:1 chelate had been formed. An increase in the cupric-ion concentration above this ratio had no effect on the peak height of III. Since it seemed desirable to have an excess of cupric ions, 5 μl of 1% $CuSO_4$ was added to 5 ml of the base solution (final concentration of 40 μ*M*). The relationship between the concentration of III and the respective peak heights of the "chelate peak" at −540 mv under these conditions was linear. The calibration curve was not influenced by the addition of I and II. A similar chelate with catechol and cupric ions was used for an indirect determination of catechol by atomic absorption spectrophotometry (21).

Determination of II in Presence of III—Magnesium ions showed an effect with III opposite to that of cupric ions. The addition of magnesium ions to the solution containing only III (Fig. 4, right) abolished the peaks of the chelate and of the nitro group reduction (Fig. 5). At the same time, the red color of III reappeared. In this case, the magnesium ion displaced the cupric ion in the chelate to form a more stable complex, which gave no polarographic signal in 0.1 *N* NaOH. The behavior of II in the presence of III is shown in Fig. 6. In the left polarogram, both phenols were present in a concentration of 20 μ*M*, each in 5 ml of base solution with 5 μl of 1% $CuSO_4$. The second peak at about −960 mv constitutes an overlapping mixture of the currents of two peaks as in Fig. 3 (right).

After adding 200 μl of 0.1 *M* $MgCl_2$ (Fig. 6, right), only the peak of II at −940 mv remained; the contribution by III disappeared. Experiments made with II alone under the same conditions in a volume of 5.2 ml (5.0 ml of 0.1 *N* NaOH and 0.2 ml of 0.1 *M* $MgCl_2$) gave a linear relationship between concentration and peak height. It is possible to determine II after "masking" III by the addition of magnesium ions.

Determination of I—As can be seen from Fig. 1, the peak potential of I in alkali was sufficiently different from those of the two phenols when measured in the absence of cupric ions. In their presence, there was no

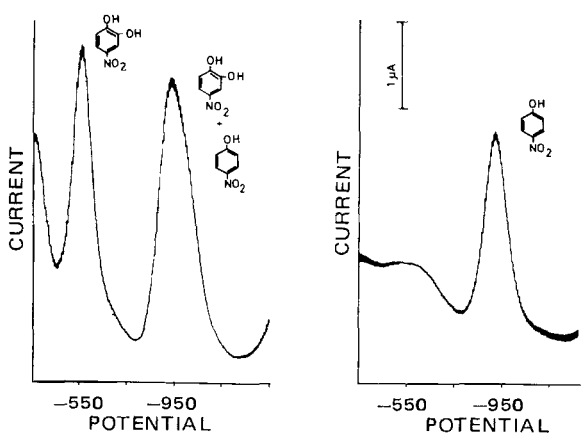

Figure 6—*Masking of III in the presence of II. Key: left, polarogram of both phenols (20 μM) in 0.1 N NaOH in the presence of 40 μM $CuSO_4$; and right, repeat polarogram of the same solution after addition of 200 μl of 0.1 M $MgCl_2$ (final volume of 5.2 ml). Only the peak of II remains in the right polarogram.*

Table I—Simultaneous Determination of I–III

Compound	Concentration Calculated, *M*	Concentration Found, *M*	Recovery, %
Concentration of I Was Varied and Concentrations of II and III Remained Constant			
I	2×10^{-6}	2.1×10^{-6}	105.0

interference from the newly formed chelate peak at −540 mv. The potential differences at pH 13 were 240 and 160 mv, as illustrated (in the presence of cupric ions) in Fig. 7 (left). The addition of magnesium ions did not affect the peak of I (Fig. 7, right), thereby allowing the quantitative evaluation of I in the presence of both II and III. Cupric ions, which are necessary for the routine estimation of III, had no influence on the peak height of I. Also, the subsequent addition of magnesium ions had only a negligible effect on the peak height of I.

Simultaneous Determination of I–III—In summary, the procedure for the polarographic estimation of the three nitro compounds is as follows. The compounds (0–250 nmoles) must be dissolved in 5 ml of 0.1 *N* NaOH in the polarographic vessel. Then 5 μl of 1% $CuSO_4$ in water is added by micropipet, and the vessel is gassed with purified nitrogen for 2.5 min. Recording of the polarogram yields curves of the type shown in Fig. 7 (left). The peak heights of these curves over the base current in

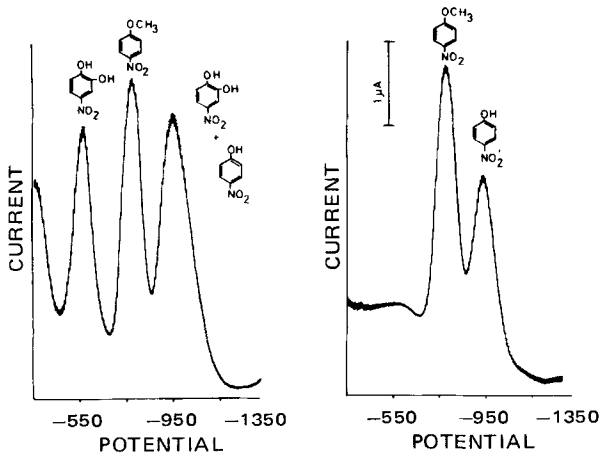

Figure 7—*Polarogram of I (10 μM), II (20 μM), and III (20 μM) in the presence of 40 μM $CuSO_4$. Key: left, before addition of magnesium ions; and right, after addition of magnesium ions.*

conjunction with calibration curves give direct measurements of III and I.

To determine II also, 200 μl of 0.1 *M* $MgCl_2$ is added to the same solution. Then this solution is bubbled again with nitrogen to achieve proper mixing and removal of the oxygen carried in during the manipulation. The newly taken polarogram (Fig. 7, right) shows peaks only for I and II, from which the concentration of II can be obtained by subtracting the base current. Theoretically, a second determination of I is possible from this second polarogram.

The accuracy of this method of determination for each substance in the presence of varying concentrations of the others is shown by the homogeneous and practically complete recovery rates given in Table I.

Sustained-Release Applications of Montmorillonite Interaction with Amphetamine Sulfate

JAMES W. McGINITY [x] and JOHN L. LACH

Abstract □ Urinary recovery studies showed that montmorillonite significantly affects the initial therapeutic levels of amphetamine sulfate. The combination of a 1:20 drug–montmorillonite complex with pure drug in a 1:1 ratio, based on amphetamine content, resulted in recovery profiles resembling those obtained from prolonged-release dosage forms. The 1:20 complex, pure drug, and combination formulations showed comparable bioavailability after 48 hr.

Keyphrases □ Montmorillonite—effect on bioavailability of amphetamine sulfate, urinary recovery studies, applied to sustained-release dosage form □ Amphetamine sulfate—bioavailability, effect of montmorillonite, urinary recovery studies, applied to sustained-release dosage forms □ Urinary recovery studies—effect of montmorillonite on bioavailability of amphetamine sulfate, applied to sustained-release dosage form □ Dosage forms—sustained-release drug–clay complex, effect of montmorillonite on bioavailability of amphetamine sulfate □ Clays—montmorillonite, complex with amphetamine sulfate, effect on bioavailability □ Stimulants—amphetamine sulfate, effect of complexing with montmorillonite on bioavailability

The availability of a drug from a dosage form is dependent on both the rate and the completeness with which the drug is delivered to the absorption site in an absorbable form. In a recent review (1), excipients in solid dosage forms were shown to interact with various medicinals. Such drug–excipient interactions generally influence both the rate of drug absorption and the amount delivered unchanged to the general circulation.

An earlier publication (2) reported that cationic salts

of organic medicinals bind tenaciously to montmorillonite clay. Data *in vitro* demonstrated that the amount of drug released from the drug–clay complex was dependent on the amount of montmorillonite in the formulation.

The influence of montmorillonite in dosage forms containing diazepam (3) and tolbutamide (4) was evaluated clinically. The diazepam study showed that the clay hindered drug absorption; the opposite was true for tolbutamide. Montmorillonite reduced blood levels of dicumarol in dogs by 25% compared to blood levels following the administration of pure drug (5). However, warfarin sodium tablets containing montmorillonite released the drug much faster *in vitro* than did the best commercial tablets (6). These reports demonstrate the complexity of drug–clay interactions and indicate that the presence of montmorillonite in a dosage form may markedly influence drug effects.

The purpose of this investigation was to develop a sustained-release dosage form employing a drug–montmorillonite interaction. Amphetamine sulfate was the model drug chosen, and drug concentrations *in vivo* were followed *via* urinary recovery studies. Pure drug was compared with a 1:20 complex of drug and clay and a 1:1 combination of pure drug and complex. Previous studies *in vitro* (2) demonstrated that little drug was present in the uncomplexed form in the 1:20 formulation.

EXPERIMENTAL

Materials—Amphetamine sulfate[1], montmorillonite[2], anhydrous ether (analytical reagent), sodium hydroxide (analytical reagent), 0.5 *N* hydrochloric acid, pH 7.4 phosphate buffer, *p*-nitroaniline solution (0.69 g in 8.3 ml of concentrated hydrochloric acid, diluted to 100 ml with water and filtered), and 1.4% sodium nitrite aqueous solution were obtained commercially.

Trial Conditions—Six normal healthy subjects, one female and five males ranging in age from 23 to 26 years and weighing from 57 to 84 kg, were utilized. Subjects had no previous history of GI, liver, or kidney disease and did not require any medication on a regular basis. All subjects had undergone a physical examination for an earlier study (7) and were healthy.

The importance of maintaining an acidic urine to prevent reabsorption of amphetamine from the urine back into the blood was reported previously (8, 9). However, chemical acidosis was not induced by ammonium chloride administration for the following reasons: (*a*) huge doses of this substance are required to maintain the pH at 5, (*b*) it has been reported that up to 20% of subjects suffer emetic effects after taking ammonium chloride, (*c*) it was desired to maintain subjects in a normal physiological state, and (*d*) ammonium chloride would upset the release patterns *in vivo*, already established *in vitro*.

Breakfast, 1 hr before the test, consisted of cereal and milk. No food or liquids except water were taken during the first 4 hr following drug administration. Formulations were administered as powders with 100 ml of water and ingested at 8 am during a normal working day; thus, by being active and controlling diet and fluid intake (~200 ml of water/2 hr), a slightly acidic urine (Table I) was attained in the first 10 hr. This period was of major interest, because the maximum for urinary drug elimination would be attained during this interval.

Urine samples were collected every 2 hr for 16 hr and at 24, 36, and 48 hr. All subjects were given 15-mg doses of drug except Subject 3, who ingested 20-mg doses. The order of administration of the amphetamine formulations to the six subjects was randomized, and a washout period of at least 1 month was allowed before administering another formulation. Formulations containing the same amount of amphetamine were in three forms: pure drug, a 1:20 drug–montmorillonite complex (2), and a 1:1 combination of pure drug and complex.

Methods—The spectrophotometric assay developed and employed is similar to that of Alles and Wisegarver (10) but contains several modifications to improve sensitivity and reproducibility. Reproducibility from standard solutions of urine containing amphetamine sulfate was within ±2.5%. The colorimetric reaction used to assay amphetamine in the urine measures both amphetamine and the hydroxylated metabolite. However, in humans, less than 3% of the amphetamine is excreted as the hydroxylated metabolite (11), so interference was assumed to be minimal and fairly constant for a particular patient. In addition, the individual day-to-day variations in the blank for all patients fell within ±3.5%.

Steam Distillation Procedure—Ten milliliters of 5 *N* sodium hydroxide and 50 ml of double-distilled water were added to 50 ml of urine in an all-glass distillation apparatus and steam distilled. The distillate, 50–60 ml, was collected in a flask containing 2 ml of 1 *N* HCl immersed in an ice bath. The distillate was transferred to a separator and made alkaline with 0.5 ml of 5 *N* sodium hydroxide, and 50 ml of ether was added. The flask was shaken for 5 min, and the aqueous layer was separated and extracted with two additional aliquots of ether.

To the final ether extract, 10 ml of 0.5 *N* HCl was added to convert the extracted amphetamine to the acid salt. This flask was shaken for 5 min, and the aqueous acidic layer was transferred to the next flask where the shaking procedure was repeated. The aqueous portion was finally shaken with the first ether extract, which contained most of the drug. This extraction was repeated with another 10 ml of acid followed by 5 ml of distilled water to wash the ether layer. The extracts and washings were combined, and the pH was adjusted to 7.5 with dilute sodium hydroxide solution. The volume was adjusted to 50 ml with distilled water.

Colorimetric Determination—Two milliliters of pH 7.4 phosphate buffer was added to 10 ml of the 50-ml extract. At this point, the pH of the reaction mixture was 7.4 ± 0.1. Then 1 ml of the diazo reagent (10) was added. The solution was mixed and placed in a water bath at 37° for 30 min to allow the reaction to go to completion. The test tube was removed, and 0.5 ml of 5 *N* sodium hydroxide was added. The tube was lightly agitated and allowed to stand for 30 min. Urine collected from the patient during the day, prior to drug administration, was extracted and treated in the same manner and used as the reference sample.

The difference in absorbance between the sample and the blank was determined at 520 nm, and the concentration of amphetamine in the urine was calculated from a standard curve. The standard curve was prepared by adding a known quantity of drug to the urine and plotting absorbance *versus* quantity of drug. The drug solution replaced the distilled water, which was added to the urine prior to the steam distillation procedure. All readings were duplicated, and the average was plotted. An excellent linear correlation between ab-

sorbance and drug concentration was found, and the absorptivity value was 6250.

RESULTS AND DISCUSSION

The effect of montmorillonite in modifying the levels of orally administered cationic drugs was verified *in vivo*. For Subject 1, plots of the time course of drug excretion of pure drug, the 1:20 drug–montmorillonite complex, and the 1:1 combination of pure drug and complex are shown in Fig. 1. The smooth curves were fit by eye and drawn by hand. The peak excretion rates of amphetamine from the pure drug and the 1:20 complex occurred at 2.0 and 7.1 hr, respectivtly. This time difference of 5.1 hr was due primarily to the presence of montmorillonite in the sample, assuming all physiological conditions to be constant in both cases. Since the clay does not hydrate in acidic media, the influence of the montmorillonite on the gastric emptying rate would be minimal.

In vitro studies (2) demonstrated that, under acidic conditions, the uncomplexed moiety rapidly passed into solution, but drug complexed to the clay was bound so strongly that little was released in the medium. This slow release at low pH explains the initial low excretion rates for the 1:20 complex (Fig. 1). However, with the passage of the 1:20 complex down the GI tract, it appeared that drug was released from the complex for absorption. This phenomenon of increased bioavailability in alkaline media could not be illustrated *in vitro* due to problems in methodology; *i.e.*, when the drug–montmorillonite samples were added to alkaline buffer media, hydration of the montmorillonite occurred and the drug was released. If the drug was not removed, then readsorption of the drug onto the clay would occur. However, since the body is a perfect sink, the concentration of drug in the blood is negligible in comparison to the intestinal concentration. Thus, as the formulation passed from the stomach into the small intestine at a higher pH, more drug was released and absorbed before readsorption of the active substance back onto the clay could occur.

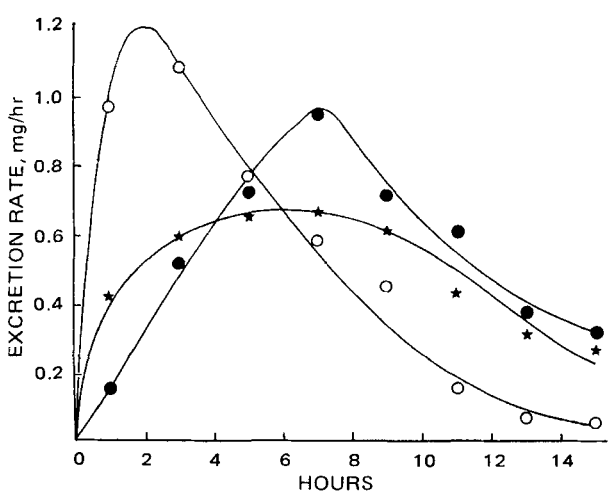

Figure 1—*Urine amphetamine levels following a single oral dose of amphetamine sulfate for Subject 1. Key: ○, 15 mg of drug alone; ★, 7.5 mg of drug–7.5 mg of drug as 1:20 complex; and ●, 15 mg of drug as 1:20 complex.*

Since it was shown *in vitro* that sodium chloride elutes drug from the drug–montmorillonite complex, and because of the high content of Na^+ ions in the intestinal juice, an increase in the concentration of free drug in solution also would be expected. Intestinal juice secreted at the rate of 0.7–3 liters/24 hr is rich in sodium ions (~140 mEq/liter). Because fresh liquid is continually being secreted, the elution rate of drug from the complex due to electrolyte effects would be expected to be greater *in vivo* than that found *in vitro*. The vacant sites on the clay left by the released drug would be occupied by the secreted cations and aid the absorption process. This would make readsorption of the amphetamine back onto the montmorillonite much more difficult and less likely to occur.

At the higher pH of the small intestine, amphetamine sulfate reverts to amphetamine, which is a nonpolar liquid. In such a physical state, this lipid-soluble substance may readily partition into the intestinal wall and be absorbed.

For Subject 1, the recovery curve (Fig. 1) for the combination sample containing 50% amphetamine sulfate and 50% as the 1:20 complex is typical of prolonged-action dosage forms. The peak excretion rate for the pure drug was 1.19 mg/hr, whereas the peak for the combination sample was only 0.66 mg/hr. By eliminating the peak levels seen with the pure drug, the incidence and intensity of possible side effects of the drug are reduced when amphetamine sulfate is administered as a combination of pure and complexed drug.

The peak excretion rates of amphetamine for each subject following the administration of the three test formulations appear in Table II. The time periods for the maxima to occur are also included. In all cases, the times for the peak excretion rates for the combination samples fell between the peak excretion rates for the pure drug and the 1:20 complex. The time period separating the peaks of these latter two samples varied from 2.2 hr for Subject 6 to 5.1 hr for Subject 1.

Montmorillonite affected the pharmacological response of the drug from all formulations. The stimulating effect of amphetamine in the complexed form reached its maximum effect several hours after drug administration. The peak response from the pure drug occurred within the 1st hr after administration. Due to the large doses of amphetamine sulfate administered, it was considered most unlikely that the hyperexcitability experienced by these subjects was psychological. Some subjects who suffered severe headaches from the pure and

Table III—Percent of Dose Recovered in Urine after 48 hr and the Bioavailability[a] of Amphetamine from the Combination Sample and Complex Compared to the Pure Drug for the 48-hr Period

Subject	Pure Drug	Combination	1:20 Complex
1	53	48 (91)	56 (105)
2	54	57 (105)	55 (102)
3	54	51 (94)	58 (107)
4	53	50 (94)	51 (96)
5	37	40 (108)	39 (105)
6	56	55 (98)	54 (96)

[a] In parentheses and expressed as percentage.

complexed drug noticed a decrease in severity or no headache at all with the combination sample. This response can be explained from the recovery curve for the combination samples, since it was unlikely that development of tolerance to the stimulant occurred.

Table III shows the amount of amphetamine recovered in the urine over 48 hr and also the bioavailability of amphetamine from the complex and combination samples. When using the Student paired t test, no significant differences were seen in the bioavailability of amphetamine from all three formulations. However, excretion rates of amphetamine from the 1:20 complex were significantly different from the pure drug during the initial 4 hr.

In conclusion, the drug–excipient interaction between cationic drugs and montmorillonite clay can be employed successfully to prolong the action of such medicinals. The peak urinary excretion rate of amphetamine from the 1:20 drug–clay complex occurred at a much later time than the pure drug, indicating delayed absorption of amphetamine from the complex. In addition, the initial excretion rate of amphetamine from the complex was significantly lower than that of the pure drug. Finally, for all subjects, the bioavailability of the amphetamine from the 1:20 complex and the amphetamine–1:20 complex combination formulations over 48 hr was not significantly different from that of the pure drug.

Mass Screening and Confirmation of Codeine and Morphine in Urine by Radioimmunoassay–GLC

NARESH C. JAIN *‡[x], THOMAS C. SNEATH ‡, WAI J. LEUNG ‡, and ROBERT D. BUDD ‡

Abstract □ A rapid, sensitive, and specific procedure is described for the mass screening and confirmation of codeine and morphine in urine specimens. The method is sensitive to 0.5-μg/ml levels of both opiates in free and/or conjugate forms. The raw urine is screened directly by radioimmunoassay, which is reactive to both free and glucuronide forms of codeine and morphine. Specimens that are screened positive are confirmed by GLC using a flame-ionization detector. The opiates are analyzed as their acetyl derivatives on two different columns, OV-25 and Poly-A 103. This multiple approach eliminates false positives caused by interfering substances or structurally similar compounds present in the urine.

Keyphrases □ Codeine—radioimmunoassay–GLC analysis, human urine □ Morphine—radioimmunoassay–GLC analysis, human urine □ Radioimmunoassay–GLC—analysis, codeine and morphine in human urine □ GLC—analyis, codeine and morphine in human urine □ Opiates—codeine and morphine, radioimmunoassay–GLC analysis in human urine □ Narcotics—codeine and morphine, radioimmunoassay–GLC analysis in human urine

The widespread use and abuse of codeine, morphine, and heroin, which is largely metabolized to morphine (1), necessitate the development of large-scale procedures for the determination of codeine and morphine in urine samples. A large urine drug testing laboratory must have a sensitive and specific method that can rapidly separate "true negative" from "presumptive positive" specimens. It is equally important to have a fundamentally different confirmatory method that can independently and accurately confirm the presence of an opiate and, at the same time, identify the individual drug. The method should also give quantitative results when needed. Since codeine and morphine are primarily excreted in the urine as conjugates in the form of glucuronides (1, 2), the methods of analysis must be able to detect them in both forms.

BACKGROUND

Most laboratories use TLC to screen urine specimens for various drugs including codeine and morphine (3, 4). The technique is relatively inexpensive but, on a large scale, has many disadvantages such as poor sensitivity, inconsistency in R_f values, variations with humidity, subjectivity in data interpretation, and the requirement of hydrolysis to detect the opiate glucuronides. Although the reagents and equipment for radioimmunoassay are expensive, the consistency of results, ability to detect glucuronide forms, increased sensitivity, greater accuracy, and semiautomation of the method make it well worth the cost involved (5–8).

Since free opiates have poor sensitivity by GLC, a number of GLC procedures have been published to separate and identify their derivatives (9–11). Most methods use only one column, which provides no assurance of avoiding false positives from interfering peaks with retention times similar to the opiate derivatives on that particular column.

complexed drug noticed a decrease in severity or no headache at all with the combination sample. This response can be explained from the recovery curve for the combination samples, since it was unlikely that development of tolerance to the stimulant occurred.

Table III shows the amount of amphetamine recovered in the urine over 48 hr and also the bioavailability of amphetamine from the complex and combination samples. When using the Student paired t test, no significant differences were seen in the bioavailability of amphetamine from all three formulations. However, excretion rates of amphetamine from the 1:20 complex were significantly different from the pure drug during the initial 4 hr.

In conclusion, the drug–excipient interaction between cationic drugs and montmorillonite clay can be employed successfully to prolong the action of such medicinals. The peak urinary excretion rate of amphetamine from the 1:20 drug–clay complex occurred at a much later time than the pure drug, indicating delayed absorption of amphetamine from the complex. In addition, the initial excretion rate of amphetamine from the complex was significantly lower than that of the pure drug. Finally, for all subjects, the bioavailability of the amphetamine from the 1:20 complex and the amphetamine–1:20 complex combination formulations over 48 hr was not significantly different from that of the pure drug.

Mass Screening and Confirmation of Codeine and Morphine in Urine by Radioimmunoassay–GLC

NARESH C. JAIN *‡[x], THOMAS C. SNEATH ‡, WAI J. LEUNG ‡, and ROBERT D. BUDD ‡

Abstract □ A rapid, sensitive, and specific procedure is described for the mass screening and confirmation of codeine and morphine in urine specimens. The method is sensitive to 0.5-μg/ml levels of both opiates in free and/or conjugate forms. The raw urine is screened directly by radioimmunoassay, which is reactive to both free and glucuronide forms of codeine and morphine. Specimens that are screened positive are confirmed by GLC using a flame-ionization detector. The opiates are analyzed as their acetyl derivatives on two different columns, OV-25 and Poly-A 103. This multiple approach eliminates false positives caused by interfering substances or structurally similar compounds present in the urine.

Keyphrases □ Codeine—radioimmunoassay–GLC analysis, human urine □ Morphine—radioimmunoassay–GLC analysis, human urine □ Radioimmunoassay–GLC—analysis, codeine and morphine in human urine □ GLC—analyis, codeine and morphine in human urine □ Opiates—codeine and morphine, radioimmunoassay–GLC analysis in human urine □ Narcotics—codeine and morphine, radioimmunoassay–GLC analysis in human urine

The widespread use and abuse of codeine, morphine, and heroin, which is largely metabolized to morphine (1), necessitate the development of large-scale procedures for the determination of codeine and morphine in urine samples. A large urine drug testing laboratory must have a sensitive and specific method that can rapidly separate "true negative" from "presumptive positive" specimens. It is equally important to have a fundamentally different confirmatory method that can independently and accurately confirm the presence of an opiate and, at the same time, identify the individual drug. The method should also give quantitative results when needed. Since codeine and morphine are primarily excreted in the urine as conjugates in the form of glucuronides (1, 2), the methods of analysis must be able to detect them in both forms.

BACKGROUND

Most laboratories use TLC to screen urine specimens for various drugs including codeine and morphine (3, 4). The technique is relatively inexpensive but, on a large scale, has many disadvantages such as poor sensitivity, inconsistency in R_f values, variations with humidity, subjectivity in data interpretation, and the requirement of hydrolysis to detect the opiate glucuronides. Although the reagents and equipment for radioimmunoassay are expensive, the consistency of results, ability to detect glucuronide forms, increased sensitivity, greater accuracy, and semiautomation of the method make it well worth the cost involved (5–8).

Since free opiates have poor sensitivity by GLC, a number of GLC procedures have been published to separate and identify their derivatives (9–11). Most methods use only one column, which provides no assurance of avoiding false positives from interfering peaks with retention times similar to the opiate derivatives on that particular column.

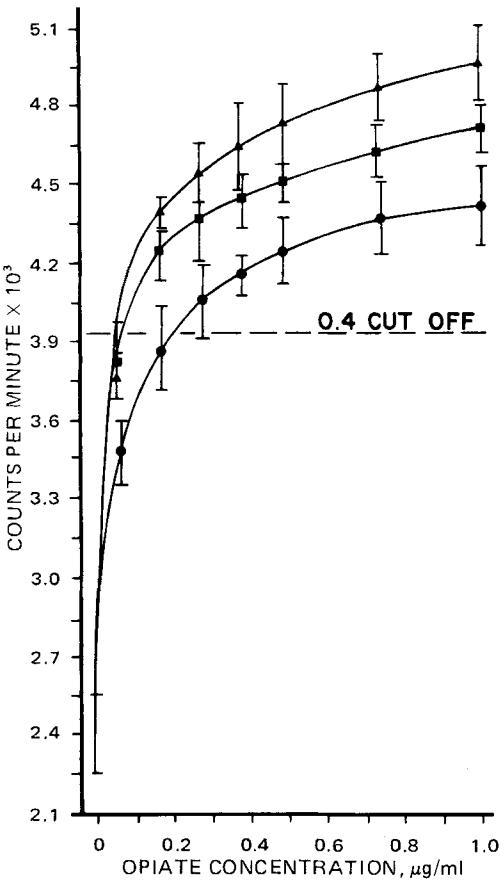

Figure 1—*Radioactive count curves for codeine (▲), morphine (●), and morphine glucuronide (■) with the morphine antibody. Standard deviations are included.*

This confirmation procedure is so designed that interfering substances are not reported as false positives. The opiates are analyzed as their acetyl derivatives on two quite different GLC columns: 3% OV-25 and 3% Poly-A 103. True positives must give the proper response on both columns.

Nalorphine is added to each urine specimen in the first step of extraction and is carried throughout the analytical process as an internal standard to ensure proper extraction and sample preparation. This procedure eliminates false negatives, allows accurate quantitation of positives, and assures correct results.

Several other opiates and drugs such as methadone, the primary metabolite of methadone (2-ethylidine-1,5-dimethyl-3,3-diphenylpyrrolidine), propoxyphene, norpropoxyphene, meperidine, apomorphine, dihydromorphine, hydrocodone, oxycodone, berberine (goldenseal), papaverine, and hydromorphine have been analyzed for possible interference with radioimmunoassay and/or GLC. With the procedure presented here, interference from any of these compounds is eliminated.

Table I—Relative Retention Times (RRT) of Acetylated Opiates and Other Drugs

Drug	Forms Acetyl Derivative[a]	RRT on 3% OV-25[b]	RRT on 3% Poly-A 103[c]
Codeine	Yes	0.50	0.46
Morphine	Yes	0.77	0.68
Nalorphine	Yes	1.00[d]	1.00[e]
Apomorphine	Yes	0.97	1.06
Dihydromorphine	Yes	0.82	0.91
Oxycodone	Yes	0.52	0.53
Hydromorphine	Yes	6.85	1.01[f]
Papaverine	No	1.86	2.35
Methadone	No	6.08	0.08
Methadone metabolite[g]	No	0.07	0.05
Propoxyphene	No	0.12	0.10
Norpropoxyphene	No	0.28	0.30[h]
Meperidine	No	0.03	0.03
Hydrocodone	Yes	0.49	0.60

[a] If "yes," relative retention times are for that derivative; if "no," relative retention times are for the parent drug. [b] Column temperature 250°; injector, 290°; detector, 300°; and carrier gas (nitrogen), 400 ml/min. [c] Column temperature, 230°; injector, 270°; detector, 280°; and carrier gas (nitrogen), 61 ml/min. [d] Retention time = 6.2 min. [e] Retention time = 7.3 min. [f] Second smaller peak with relative retention time of 0.70. [g] 2-Ethylidine-1,5-dimethyl-3,3-diphenylpyrrolidine. [h] Second smaller peak with retention time of 0.54.

EXPERIMENTAL

Materials—The following were obtained from commercial sources: morphine radioimmunoassay kit[1], ammonium sulfate[2], nalorphine hydrochloride[3], *tert*-butanol[2], chloroform[2], spectrograde chloroform[2], butyl acetate[2], dibasic potassium phosphate[2], potassium hydroxide[2], potassium carbonate[2], pyridine[2], anhydrous acetic anhydride[2], sodium hydroxide[2], hydrochloric acid[2], 3% Poly-A 103 on Gas Chrom Q[4] (100–120 mesh), and 3% OV-25 on HP Chrom W[5] (AW + DMCS) (80–100 mesh). All chemicals were reagent grade except as indicated.

Equipment—The following equipment was used: an automatic pipetting station[6], a centrifuge[7], a γ-scintillation counter with printer[8], a high-speed automatic pipet[9], 50-ml round-bottom centrifuge tubes with glass stoppers[10], 40-ml centrifuge tubes with tapered end[10], a dual-pen recorder[11], a gas chromatograph[12] equipped with dual flame-ionization detectors, and dual differential electrometers.

Radioimmunoassay Screening Procedure—The urine samples are screened for opiates using the Roche radioimmunoassay procedure (6) with slight modifications. Automatic pipetting stations are used for all dilutions; 0.40 ml of working reagent (morphine antigen–antibody 1:1) is added rather than 0.20 ml of each component separately.

A specimen is recorded as presumptive positive for opiates if its radioactive count is higher than the established cutoff value. The cutoff value is determined by checking all opiate controls run that day and selecting a level so that all 0.4-μg/ml controls of both opiates are detected. All specimens below the cutoff value are considered "negative." Specimens that give a radioactive count corresponding to 0.4 μg/ml or more of opiate are analyzed by GLC to confirm which particular drug is present.

GLC Confirmation Procedure—The urine samples screened positive by radioimmunoassay are confirmed as their acetylated derivatives by GLC using the procedure of Jain *et al.* (12).

Proper Sample Preparation—A peak for the internal standard (acetylated nalorphine) must appear on both GLC columns even when the specimen is negative for codeine and/or morphine. If the internal standard does not appear on a GLC column, the specimen has not been prepared properly and the procedure must be repeated.

Positive Specimen—A positive specimen for codeine and/or morphine must give the proper internal standard response and must produce acetylated codeine and/or morphine peaks of equal concentrations on both columns.

Negative Specimen—A negative specimen for codeine and/or morphine must give the proper internal standard response and must fail to give the proper acetylated codeine and/or morphine response on one or both GLC columns.

RESULTS AND DISCUSSION

The radioimmunoassay–GLC system is suitable for screening and confirming opiates in urine specimens on a large scale. The procedure can consistently detect 0.5-μg/ml levels of both free and conjugated forms of codeine and morphine.

The radioimmunoassay screening method is considered superior to other screening techniques, including TLC and the enzyme-multiplied

immunoassay technique (13, 14). Both radioimmunoassay and the enzyme-multiplied immunoassay technique have much greater sensitivity, consistency, and accuracy of results than does TLC. They detect both free and glucuronide forms directly from raw urine and can be semiautomated so that one technician can screen many samples, depending upon the availability and type of equipment used. The radioimmunoassay antibody for opiates, however, is more sensitive than the enzyme-multiplied immunoassay technique reagents. For example, radioimmunoassay can detect morphine at a concentration of 0.1 μg/ml with greater than 99% accuracy (Fig. 1), whereas the enzyme-multiplied immunoassay technique requires a morphine concentration of 0.7 μg/ml to detect it 95% of the time (13, 14). The advantages of radioimmunoassay over other screening procedures make it preferable in spite of its increased cost.

As shown in Fig. 1, all of the opiates are not equally reactive to the radioimmunoassay antibody. As a result, the radioactive count cutoff value in radioimmunoassay must be based on the least reactive opiate to ensure that 0.5-μg/ml concentrations of all opiates of interest are detected. Contrary to earlier reports (6), morphine glucuronide is more reactive than free morphine to the opiate antibody.

Each specimen found positive by radioimmunoassay is confirmed by GLC. Since free opiates do not chromatograph well, codeine and morphine are confirmed by analyzing them as acetyl derivatives on two very different columns: OV-25 and Poly-A 103. The relative retention times of the opiates are presented in Table I. Figures 2 and 3 illustrate the clear separation obtained. The GLC confirmation method is designed so that, although the specimen is extracted only once, it is subjected to two parameters of analysis to obtain the most accurate and reliable results. This dual-column approach by GLC virtually eliminates false positive results. If GLC results for a sample require additional confirmation, the residue is spotted on a TLC plate[13], which is developed in ethyl acetate–acetone–concentrated ammonia (100:10:4). The R_f values for acetylated morphine, acetylated codeine, and acetylated nalorphine are 0.50, 0.65, and 0.83, respectively (15).

The use of nalorphine as an internal standard added at the beginning of the analysis not only allows the accurate quantitation of the opiates but also assures that samples are extracted properly. This procedure eliminates the possibility of reporting false negative results.

By using radioimmunoassay and both GLC columns, a series of spiked urine specimens containing varying concentrations of codeine, morphine, and morphine glucuronide, from 0.1 to 10 μg/ml of each, was analyzed. The data obtained showed above 99% accuracy at the 0.5-μg/ml level for each opiate. This error of less than 1% has always been due to borderline cases where a final result has been reported negative when, in fact, the sample

[13] Merck silica gel G, VWR Scientific, Los Angeles, Calif.

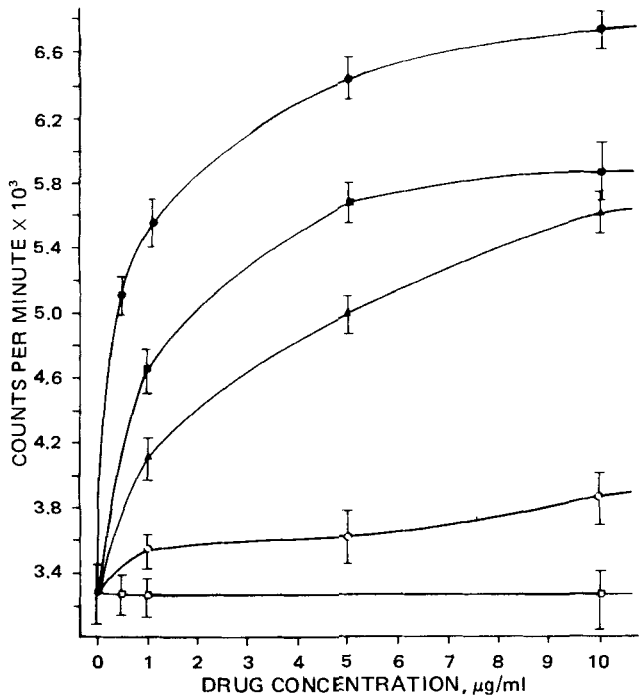

Figure 4—*Radioactive count curves for other drugs with the morphine antibody. Standard deviations are included. Key: ●, morphine; ■, dihydromorphine; ▲, heroin; ○, meperidine; and □, methadone, methadone metabolite, propoxyphene, norpropoxyphene, apomorphine, and papaverine.*

contained a very small amount of an opiate. These cases were detected by radioimmunoassay but, due to occasional variations in the extraction technique and flame-ionization detector response, the opiate gave a GLC response too small to be considered positive.

Urine samples spiked with various concentrations of methadone, methadone primary metabolite, propoxyphene, norpropoxyphene, apomorphine, dihydromorphine, hydrocodone, hydromorphine, heroin, papaverine, oxycodone, and berberine (goldenseal) also were tested. Heroin, dihydromorphine, hydromorphine, hydrocodone, oxycodone, and high concentrations of meperidine reacted with the radioimmunoassay opiate antibody (Fig. 4). All of these drugs could be differentiated from morphine, codeine, or nalorphine by the two GLC columns (Table I).

This radioimmunoassay–GLC method offers a sensitive and reliable confirmation procedure for ascertaining the presence or absence of codeine and morphine in urine on a large scale.

Use of Rabbits for GI Drug Absorption Studies

TADAO MAEDA ˣ, HIROSHI TAKENAKA, YOSHIYA YAMAHIRA, and TAKESHI NOGUCHI

Abstract □ A novel procedure to control the stomach emptying rate in rabbits is presented. Rabbits were given a special solid diet for 1 week, and then the gastric contents were washed out with saline. Then the rabbits were muzzled to prevent coprophagy during the night. Fifty grams of special soft diet given to the "stomach-emptying-controlled" rabbit transferred exponentially from the stomach into the small intestine and almost disappeared from the stomach within 5 hr. Griseofulvin, indomethacin, or nalidixic acid was administered in a hard gelatin capsule or tablet, with subsequent feeding of a special soft diet. Good correlations were observed between the plasma level–time curves of these drugs in the stomach-emptying-controlled rabbits and in human subjects.

Keyphrases □ Absorption, GI—griseofulvin, indomethacin, and nalidixic acid, effect of stomach emptying rate, rabbits □ GI absorption—griseofulvin, indomethacin, and nalidixic acid, effect of stomach emptying rate, rabbits □ Stomach emptying rate—effect on GI absorption of griseofulvin, indomethacin, and nalidixic acid, rabbits □ Griseofulvin—GI absorption, effect of stomach emptying rate, rabbits □ Indomethacin—GI absorption, effect of stomach emptying rate, rabbits □ Nalidixic acid—GI absorption, effect of stomach emptying rate, rabbits

In the study of GI absorption of drugs, various *in vitro* or *in situ* methods have been widely used (1–4). From the physiological point of view, the experimental animal data obtained by these destructive or operative techniques have only limited value in predicting drug absorption characteristics in humans, although such data provide funda-

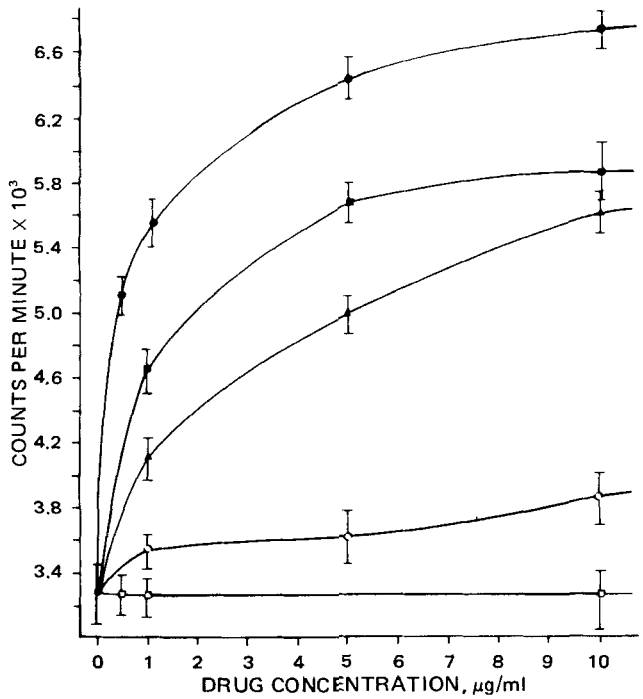

Figure 4—*Radioactive count curves for other drugs with the morphine antibody. Standard deviations are included. Key: ●, morphine; ■, dihydromorphine; ▲, heroin; ○, meperidine; and □, methadone, methadone metabolite, propoxyphene, norpropoxyphene, apomorphine, and papaverine.*

contained a very small amount of an opiate. These cases were detected by radioimmunoassay but, due to occasional variations in the extraction technique and flame-ionization detector response, the opiate gave a GLC response too small to be considered positive.

Urine samples spiked with various concentrations of methadone, methadone primary metabolite, propoxyphene, norpropoxyphene, apomorphine, dihydromorphine, hydrocodone, hydromorphine, heroin, papaverine, oxycodone, and berberine (goldenseal) also were tested. Heroin, dihydromorphine, hydromorphine, hydrocodone, oxycodone, and high concentrations of meperidine reacted with the radioimmunoassay opiate antibody (Fig. 4). All of these drugs could be differentiated from morphine, codeine, or nalorphine by the two GLC columns (Table I).

This radioimmunoassay–GLC method offers a sensitive and reliable confirmation procedure for ascertaining the presence or absence of codeine and morphine in urine on a large scale.

Use of Rabbits for GI Drug Absorption Studies

TADAO MAEDA ˣ, HIROSHI TAKENAKA, YOSHIYA YAMAHIRA, and TAKESHI NOGUCHI

Abstract □ A novel procedure to control the stomach emptying rate in rabbits is presented. Rabbits were given a special solid diet for 1 week, and then the gastric contents were washed out with saline. Then the rabbits were muzzled to prevent coprophagy during the night. Fifty grams of special soft diet given to the "stomach-emptying-controlled" rabbit transferred exponentially from the stomach into the small intestine and almost disappeared from the stomach within 5 hr. Griseofulvin, indomethacin, or nalidixic acid was administered in a hard gelatin capsule or tablet, with subsequent feeding of a special soft diet. Good correlations were observed between the plasma level–time curves of these drugs in the stomach-emptying-controlled rabbits and in human subjects.

Keyphrases □ Absorption, GI—griseofulvin, indomethacin, and nalidixic acid, effect of stomach emptying rate, rabbits □ GI absorption—griseofulvin, indomethacin, and nalidixic acid, effect of stomach emptying rate, rabbits □ Stomach emptying rate—effect on GI absorption of griseofulvin, indomethacin, and nalidixic acid, rabbits □ Griseofulvin—GI absorption, effect of stomach emptying rate, rabbits □ Indomethacin—GI absorption, effect of stomach emptying rate, rabbits □ Nalidixic acid—GI absorption, effect of stomach emptying rate, rabbits

In the study of GI absorption of drugs, various *in vitro* or *in situ* methods have been widely used (1–4). From the physiological point of view, the experimental animal data obtained by these destructive or operative techniques have only limited value in predicting drug absorption characteristics in humans, although such data provide funda-

Table I—Composition of Solid Diet for Rabbits

Composition	Content, %	
	Commercial Solid Diet (Pellets)	Special Solid Diet (Pellets)

mentally useful information on drug absorption.

The principal purpose of this study was to clarify, by use of intact animals, the correlation of GI drug absorption of orally administered drugs between humans and animals so that the need for human trials in developing drugs and dosage forms of increased bioavailability can be minimized. Rabbits are often used for this purpose because of their low cost and ease in handling.

According to a relevant study (5), solid material remains in the rabbit stomach even after fasting for more than 24 hr. Moreover, the stomach emptying time of rabbits differs greatly from that of humans, whose stomachs usually empty within several hours following ingestion of food. Therefore, the rabbit is not a suitable animal for the evaluation of GI absorption characteristics of drugs, especially when stomach emptying is a limiting factor (5).

The present study was designed to examine the stomach emptying characteristics of rabbits and to establish a method for simulating the stomach emptying rate to that of humans so that rabbits could be used for studies of GI drug absorption.

EXPERIMENTAL

Materials—Two kinds of solid diet, commercial[1] and special[2], were used for the rabbits (Table I). The special solid diet was prepared by removing alfalfa from the commercial solid diet. A special soft diet was prepared by adding 60 parts of water to 40 parts of special solid diet. This mixture was left standing overnight in a cool place to swell and was then divided into required amounts and made into balls.

Both griseofulvin USP and indomethacin NF were micronized to less than 5 μm in size using a fluid energy mill[3] and capsulated in a hard gelatin capsule size No. 3. Nalidixic acid NF was milled to about 30 μm utilizing a pulverizer[4] and administered as a tablet. Each tablet contained 250 mg of nalidixic acid, 55 mg of lactose USP, 16 mg of calcium carboxymethylcellulose JP, 3.5 mg of starch USP, and 3.5 mg of magnesium stearate USP. The tablets met the USP disintegration test. The other chemicals were of reagent grade.

Procedure of Stomach-Emptying Control—White male rabbits, 2.4–3.4 kg, were fed the special solid diet in place of the commercial solid diet for 1 week of conditioning before the absorption study.

After being fasted overnight with water given freely, the rabbits were anesthetized by injection of 0.3–0.5 ml/kg of 5% pentobarbital sodium. A rubber stomach tube, 25 cm in length and 5 mm in external diameter with a large hole on the side of the tip, was inserted into the stomach, and 50–100 ml of warm saline (37°) was instilled. The fluid in the stomach was then withdrawn by suction with a syringe. This procedure was repeated until the fluid withdrawn hardly contained any solid material. The rabbits usually recovered from anesthesia within 2–3 hr.

After gastric lavage, the rabbits were allowed water *ad libitum* and were muzzled to prevent coprophagy during the night. On the following morning, the rabbits were given 200 g of the special soft diet and allowed water *ad libitum*. They were muzzled again at night until morning. These pretreated rabbits were called the "stomach-emptying-controlled" rabbits.

Table II—Effect of Diet and Muzzling on Stomach Emptying

Diet	Weight of Gastric Content[a], g	
	Coprophagy Not Restricted	Muzzled during the Night
Commercial pellet diet	97 ± 7.9	33 ± 4.5
Special soft diet	83 ± 6.5	34 ± 3.9

[a] Data represent average and *SE* for rabbits of each group.

Estimation of Coprophagy—Four groups, each consisting of three rabbits, 2.4–2.8 kg, were designated as Groups I-A, I-B, II-A, and II-B. The first two groups were fed 100 g of the commercial diet daily and allowed water *ad libitum* for 3 days. Group I-A was not restricted from coprophagy, while Group I-B was muzzled during the night. Similarly, Groups II-A and II-B were fed 250 g of the special soft diet daily and allowed water *ad libitum* for 3 days. Group II-A was allowed coprophagy, while Group II-B was muzzled during the night. On the morning of the 4th day, the rabbits were sacrificed. The stomach was removed, and the amount of gastric contents was determined by subtracting the weight of the gastric pouch from that of the total stomach.

In another experiment, the effect of muzzling on the amount of feces excreted was examined using stomach-emptying-controlled rabbits. Fifteen stomach-emptying-controlled rabbits, 2.5–3.0 kg, were divided equally into Groups A, B, and C. Each rabbit was housed separately in a cage with a double floor. The upper wire mesh floor was designed to allow feces to drop through so that they could be collected on the lower wire mesh floor. The experiment schedule employed was as follows.

Gastric lavage was performed for all rabbits at 11:00 am. Groups A and B were muzzled for 17 hr during the first period (4:00 pm–9:00 am), while Group C was not muzzled at all. Feces were weighed at the end of this first period. At the beginning of the second period of 7 hr (9:00 am–4:00 pm), every rabbit was fed with 200 g of soft special diet. Only Group A was then muzzled until 4:00 pm (for about 6 hr); Groups B and C were not muzzled. At the end of the second period (4:00 pm), feces excreted were weighed again for all rabbits. During the third period of 17 hr (4:00 pm–9:00 am), Groups A and B were muzzled but Group C was not muzzled. At the end of this period, feces were again weighed for all rabbits. Thus, the total muzzled period was 40 hr for Group A, 34 hr for Group B, and 0 hr for Group C.

Stomach Emptying of Special Soft Diet—Each of the 15 stomach-emptying-controlled rabbits, 2.5–2.7 kg, was fed 50 g of the special soft diet and was allowed water *ad libitum* until sacrifice. At 0.5, 1, 2, 3, and 5 hr after feeding, three rabbits were sacrificed.

The stomach was immediately removed, the contents of the stomach were centrifuged, and the precipitates were dried to constant weight *in vacuo* at 60°. The weight of the gastric residue was calculated on the basis of the weight of the special soft diet dried under the same condition.

Administration of Drugs—To each rabbit, an oral dose of 10 mg/kg of griseofulvin or indomethacin was administered in a capsule. An oral dose of 250 mg of nalidixic acid was administered as an intact tablet. Prior to administration of either the capsule or tablet, rabbits were secured to an animal board and the mouth was pried open with a wooden rod. Then the tongue was pulled out by rolling the wooden rod and pressed down so that the capsule or tablet could be easily placed on the radix linguae and pushed down with a rubber stomach tube to the esophagus. This administration was followed by feeding of 50 g of the special soft diet to the stomach-emptying-controlled rabbits and 20 g of commercial solid diet to the conventionally fasted rabbits. Rabbits not consuming this amount of diet within 5 min were excluded from further studies, being considered not to be in good health. During the blood sampling period, rabbits had free access to water but not to feed, and a blood specimen was drawn at the predetermined time for analysis.

In every drug administration experiment, two groups of five rabbits were used. One group was the stomach-emptying-controlled rabbits; the other group consisted of rabbits fed with commercial solid diet and then fasted but allowed water *ad libitum* for 24 hr prior to the experiment. Rabbits of the latter group are called the conventionally fasted rabbits.

cardiac puncture, using a heparinized syringe, were centrifuged to obtain plasma for analysis. Griseofulvin was extracted with ether from plasma and measured quantitatively by a gas chromatograph[5] equipped with a ^{63}Ni-electron-capture detector. Diazepam was used as an internal standard, and the method of Shah *et al.* (6) was followed.

The chromatographic column was a 1.5-m × 3-mm glass tube packed with 10% SE-30 on Chromosorb W AW DMCS. The column temperature was 270°, the injection port temperature was 300°, the detector block temperature was 310°, and the carrier gas (99.999% nitrogen) flow rate was 60 ml/min. Indomethacin in plasma was determined spectrofluorometrically[6], using a modification of the assay method of Hucker *et al.* (7). In this experiment, 0.01 *N* sodium hydroxide was used in place of 0.1 *N* sodium hydroxide, thus improving the analytical reproducibility in a low concentration of indomethacin. Nalidixic acid in plasma was spectrofluorometrically determined by the method of McChesney *et al.* (8).

RESULTS AND DISCUSSION

In considering stomach emptying of experimental animals, the effect of diet properties and the habit of coprophagy cannot be ignored. For laboratory animals, a solid pellet diet is convenient and popular. The refuse obtained during soybean-curd preparation[7], containing more than 60% water, has been widely used as rabbit feed in Japan. Rabbits do well on this food and require no water.

Preliminary experiments on stomach emptying of diet in the stomach-washed-out rabbits showed that the soybean curd refuse moved into the small intestine faster and more smoothly than the commercially available solid pellet diet. This result may be reasonably explained because the digestive function of the stomach is the formation of chyme and its transfer to the duodenum.

For these reasons, after gastric lavage the rabbits were fed the special soft diet resembling the soybean-curd refuse to satisfy the purpose of this study. Chiou *et al.* (5) reported that the stomachs of rabbits after fasting for 24 hr were almost as full as those of unfasted animals, although the rabbits were maintained on a wire mesh support which allowed feces to drop to the bottom of the cage, thus reducing coprophagy.

Two kinds of feces are excreted by rabbits: round and hard pellets, often seen in the cage, and soft pellets covered by a mucous material. During the night, rabbits take the latter directly from the anus and never take feces dropped on the floor (9, 10). Therefore, it was expected that the effective prevention of coprophagy would result in rather fast and smooth stomach-emptying of the rabbit gastric contents, although the quantitative estimation of coprophagy has not been reported. In this study, a muzzle was adopted for the rabbit to prevent the mouth from making a direct contact with the anus.

The effect of muzzling on the amount of gastric contents was examined (Tables II and III). The amount of the gastric contents of the nonmuzzled rabbits (Groups I-A and II-A) was about twice that of the muzzled rabbits, indicating that a fair amount of the contents was attributable to coprophagy (Table II).

Some soft fecal pellets, which were probably swallowed intact early in the morning, were found in the gastric contents of the nonmuzzled rabbits regardless of diet. The gastric contents of the muzzled rabbits were less solid in consistency but still contained hair, which might have retarded the stomach emptying of food. The amount of residual gastric

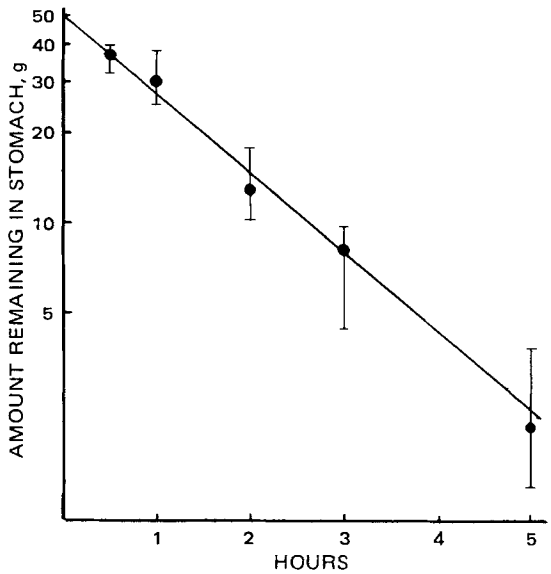

Figure 1—*Stomach emptying pattern of special soft diet (50 g) in the stomach-emptying-controlled rabbits. Each point represents the mean observation and the range on three rabbits.*

contents was not significantly affected by the type of diet. However, the gastric contents of rabbits fed the special solid diet were washed out more easily than those of rabbits fed the commercial solid diet. Therefore, the special solid diet was used during the conditioning period before performing GI absorption studies. In addition, gastric dissection confirmed that no solid material remained in the stomach when the gastric lavage procedure was employed.

The coprophagous amount and the gastric contents were examined using stomach-emptying-controlled rabbits. As shown in Table III, Group C rabbits, who were not restricted from coprophagy, hardly dropped any feces, even after ingesting 200 g of the special soft diet at the beginning of the second period. Group A rabbits, who were muzzled except during feeding time, excreted about 30 g of feces. It was reconfirmed that rabbits took feces directly from the anus as they were being excreted. Group B rabbits, who were not muzzled for several hours after feeding during the second period, ingested about 12 g of feces. This ingestion occurred during the daytime, although it had been believed to occur primarily at night. These findings demonstrate the strong physiological habit of coprophagy in rabbits, the difficulty of completely preventing coprophagy under customary conditions, and also the effectiveness of the muzzle.

After the third period, *i.e.*, after fasting for about 23 hr, all rabbits were sacrificed and the gastric contents of each group were examined. The stomachs of Group C rabbits were full of a wet mass as a result of coprophagy, although gastric lavage had been performed as in Groups A and B. For this reason, Group C was considered not suitable for GI absorption study. The stomachs of Group A rabbits were almost completely empty, and those of Group B contained some solid material, but the contents were so slurred that no difficulty would be expected in the transfer of the contents into the duodenum.

Stomach emptying in the stomach-emptying-controlled rabbits was estimated after feeding of 50 g of the special soft diet. Stomach emptying of diet appeared to be exponential in pattern (Fig. 1), and almost all ingested feed was transferred into the small intestine within 5 hr. This phenomenon is similar to the results of Hunt and Spurrell (11) with humans. The fact that such good semilogarithmic plots of amount were found with rabbits and resembled results with humans suggests that stomach emptying in these rabbits is sufficiently controlled for the GI absorption study of drugs with limited or regional solubility.

Griseofulvin is reported to be absorbed irregularly and incompletely from the GI tract because of its extremely low solubility (12). According to one study (13) on the GI absorption of this drug in rabbits, the blood level peaks occurred 6–11 hr after administration; in humans, the blood level peaks usually occurred approximately 2–3 hr after administration (14). However, Fig. 2 shows that the maximum plasma level was observed 2 hr after administration in the stomach-emptying-controlled rabbits.

Individual data of this experiment showed that the distribution of the plasma peak time observed from 1 to 2 hr after administration was characteristic in the stomach-emptying-controlled rabbits, while indi-

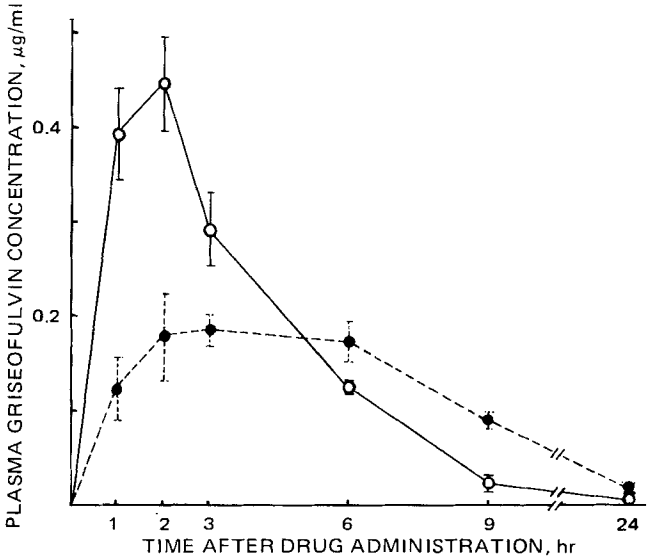

Figure 2—*Plasma levels of griseofulvin following oral administration of 10 mg/kg in the stomach-emptying-controlled rabbits (○) and rabbits fasted for 24 hr by the conventional method (●). Each point represents the mean observation ± SE on five rabbits.*

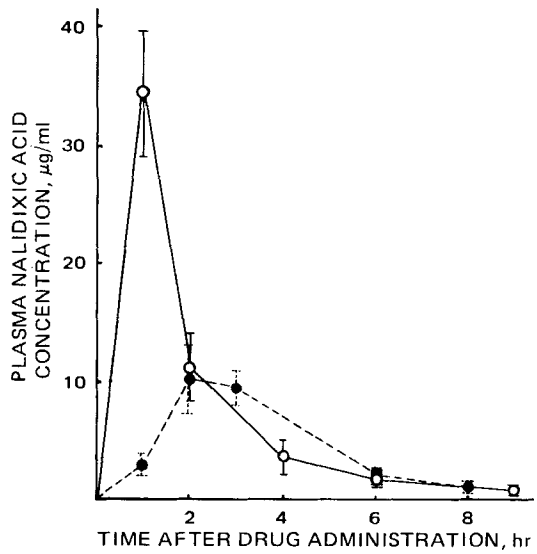

Figure 4—*Plasma levels of nalidixic acid following oral administration of 250 mg as a tablet to the stomach-emptying-controlled rabbits (○) and rabbits fasted for 24 hr by the conventional method (●). Each point represents the mean observation ± SE on five rabbits.*

vidual plasma peak time in the conventionally fasted rabbits ranged from 2 to 6 hr after administration. These results suggest that the slow and prolonged absorption of griseofulvin reported previously (13), after an oral dose of 150 mg/kg was administered as a suspension, was ascribable to an overdose and to the peculiarity of stomach emptying in rabbits, as pointed out in a later report (5).

Indomethacin absorption from the GI tract depends upon its holding time in the stomach and is retarded when stomach emptying is slow (15). The peak plasma level in the stomach-emptying-controlled rabbits prominently appeared in 1 hr, whereas slow absorption of the drug was observed in the conventionally fasted rabbits (Fig. 3). In the latter group, individual peak plasma time ranged from 2 to 5 hr after administration. The difference in the apparent absorption rates of indomethacin between the two groups of rabbits reflected the effect of the gastric emptying control procedure, because the water solubility of indomethacin is quite limited in the acidic pH range of the stomach (16). The fast absorption seen in the stomach-emptying-controlled rabbits is comparable to the

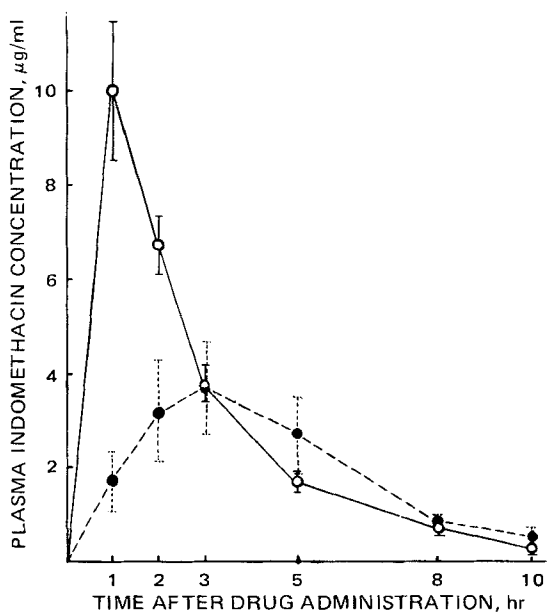

Figure 3—*Plasma levels of indomethacin following oral administration of 10 mg/kg in the stomach-emptying-controlled rabbits (○) and rabbits fasted for 24 hr by the conventional method (●). Each point represents the mean observation ± SE on five rabbits.*

results observed in humans whose peak plasma level occurred 1 hr after drug ingestion (7).

Plasma level curves in Fig. 4 demonstrate that absorption of nalidixic acid in the stomach-emptying-controlled rabbits was rapid. All individual plasma level curves showed a peak 1 hr after administration and the rapid disappearance of the drug from plasma thereafter, comparable to the results observed in humans (8). Individual peak plasma time in the conventionally fasted rabbits ranged from 2 to 6 hr.

Table IV summarizes the comparison of the individual peak plasma level, C_{max}, and its time of occurrence, t_{max}, following oral administration of griseofulvin, indomethacin, and nalidixic acid between two groups of rabbits. Fast and smooth transfer of drugs to the intestine in the stomach-emptying-controlled rabbits resulted in a statistically significant increase in the average C_{max} as compared to that in the conventionally fasted rabbits.

The t_{max} parameter also reflects the drug absorption rate. As mentioned previously, the individual t_{max} of the stomach-emptying-controlled rabbits for the three drugs was within 1–2 hr after drug administration while that of conventionally fasted rabbits ranged from 2 to 6 hr. Since the distribution range of individual t_{max} values differed between the two groups, it is quite obvious, even without statistical analysis, that the average t_{max} of the stomach-emptying-controlled rabbits was significantly less than that of the conventionally fasted rabbits.

The retardation and variation of drug absorption seen in the conventionally fasted rabbits are presumably due to the decrease and difference in the rate in which gastric contents transferred to the intestine, because

Table IV—Comparison of Peak Plasma Levels and Its Time of Occurrence following Oral Administration of Drug in Stomach-Emptying-Controlled and Conventionally Fasted Rabbits

Drug Administered (Dose)	Average of Individual Peak Plasma Level[a], C_{max}, μg/ml: Stomach-Emptying-Controlled Rabbits	Average of Individual Peak Plasma Level[a], C_{max}, μg/ml: Conventionally Fasted Rabbits	p Value[b]
Griseofulvin (10 mg/kg)	0.51 (1.6)	0.24 (3.4)	<0.01
Indomethacin (10 mg/kg)	10.47 (1.2)	5.48 (2.8)	<0.05
Nalidixic acid (250 mg/rabbit)	34.2 (1.0)	12.5 (3.2)	<0.01

[a] Numbers in parentheses are the averages of individual peak time (t_{max}, hr). [b] Determined by Student t test.

their stomachs should have been full of solid material as a result of coprophagy.

The data presented here show that the stomach-emptying-controlled rabbit can be a satisfactory model for evaluation of GI absorption characteristics of these drugs with limited or regional solubility.

CONCLUSION

Chiou *et al.* (5) concluded that the rabbit was not a useful animal for drug absorption studies because it was almost impossible to obtain an empty stomach in the rabbit by using the conventional fasting method and because the fasted state markedly prolonged the stomach emptying time. This conclusion has been very instructive to many investigators. However, in this study it was found possible to simulate the stomach emptying rate of rabbits to that of humans by taking adequate steps to empty the stomach and to feed the animals with a special soft diet. When the stomach emptying rate is controlled, the rabbit can be used as an animal model for predicting bioavailability of oral dosage for human subjects.

Results of bioavailability studies on oral dosage forms will be reported later.

Kinetics of Hydrolysis of Fenclorac

C. M. WON [x], J. J. ZALIPSKY, D. M. PATEL, and N. H. REAVEY-CANTWELL

Abstract □ The kinetics of hydrolysis of fenclorac were studied to determine its stability in aqueous solution at different pH's and temperatures. For this study, a stability-specific liquid chromatographic assay method was developed to separate fenclorac from its hydrolysis product, α-hydroxy-3-chloro-4-cyclohexylbenzeneacetic acid. The *k*–pH profile in the 0–12 pH range in various buffer solutions shows that fenclorac is stable in its undissociated form in strongly acidic media and is unstable in neutral and alkaline media. The instability of fenclorac in aqueous solution is proportional to the degree of ionization of the carboxyl group in the 1–4 pH range and is independent of pH above 4. The rate-determining step in the mechanism of hydrolysis of fenclorac involves ionization of the carbon–chlorine bond. The ionization is catalyzed by an intramolecular nucleophilic attack on the α-carbon by the dissociated carboxyl group, resulting in the formation of an unstable intermediate, a three-membered ring lactone. This unstable intermediate rapidly hydrolyzes to the final hydrolysis product. This mechanism is supported by experimental evidence such as the medium effect, positive salt effect, common ion effect, and substituent effect. Arrhenius parameters for the hydrolysis of fenclorac and its 3-nitro substituted analog were obtained.

Keyphrases □ Fenclorac—kinetics of hydrolysis, stability in aqueous solution, various pH's and temperatures, liquid chromatographic analysis □ Hydrolysis—fenclorac in aqueous solutions, kinetics, various pH's and temperatures, liquid chromatographic analysis □ Stability—fenclorac in aqueous solutions, various pH's and temperatures, liquid chromatographic analysis □ Liquid chromatography—analysis, fenclorac in aqueous solutions □ Anti-inflammatory agents—fenclorac, kinetics of hydrolysis, stability in aqueous solution, various pH's and temperatures, liquid chromatographic analysis

In the search for a new, nonsteroidal, anti-inflammatory compound for clinical utility, a series of substituted benzeneacetic acids was synthesized (1). Fenclorac (I) (α,3-dichloro-4-cyclohexylbenzeneacetic acid) diethylammonium salt exhibited promising anti-inflammatory activities. The anti-inflammatory activity of fenclorac was demonstrated in rats using the carrageenan paw edema assay[1].

A simple, sensitive analytical method was needed to follow the hydrolysis of relatively unstable fenclorac in

Kinetics of Hydrolysis of Fenclorac

C. M. WON [x], J. J. ZALIPSKY, D. M. PATEL, and N. H. REAVEY-CANTWELL

Abstract □ The kinetics of hydrolysis of fenclorac were studied to determine its stability in aqueous solution at different pH's and temperatures. For this study, a stability-specific liquid chromatographic assay method was developed to separate fenclorac from its hydrolysis product, α-hydroxy-3-chloro-4-cyclohexylbenzeneacetic acid. The *k*–pH profile in the 0–12 pH range in various buffer solutions shows that fenclorac is stable in its undissociated form in strongly acidic media and is unstable in neutral and alkaline media. The instability of fenclorac in aqueous solution is proportional to the degree of ionization of the carboxyl group in the 1–4 pH range and is independent of pH above 4. The rate-determining step in the mechanism of hydrolysis of fenclorac involves ionization of the carbon–chlorine bond. The ionization is catalyzed by an intramolecular nucleophilic attack on the α-carbon by the dissociated carboxyl group, resulting in the formation of an unstable intermediate, a three-membered ring lactone. This unstable intermediate rapidly hydrolyzes to the final hydrolysis product. This mechanism is supported by experimental evidence such as the medium effect, positive salt effect, common ion effect, and substituent effect. Arrhenius parameters for the hydrolysis of fenclorac and its 3-nitro substituted analog were obtained.

Keyphrases □ Fenclorac—kinetics of hydrolysis, stability in aqueous solution, various pH's and temperatures, liquid chromatographic analysis □ Hydrolysis—fenclorac in aqueous solutions, kinetics, various pH's and temperatures, liquid chromatographic analysis □ Stability—fenclorac in aqueous solutions, various pH's and temperatures, liquid chromatographic analysis □ Liquid chromatography—analysis, fenclorac in aqueous solutions □ Anti-inflammatory agents—fenclorac, kinetics of hydrolysis, stability in aqueous solution, various pH's and temperatures, liquid chromatographic analysis

In the search for a new, nonsteroidal, anti-inflammatory compound for clinical utility, a series of substituted benzeneacetic acids was synthesized (1). Fenclorac (I) (α,3-dichloro-4-cyclohexylbenzeneacetic acid) diethylammonium salt exhibited promising anti-inflammatory activities. The anti-inflammatory activity of fenclorac was demonstrated in rats using the carrageenan paw edema assay[1].

A simple, sensitive analytical method was needed to follow the hydrolysis of relatively unstable fenclorac in

[1] G. Nuss *et al.*, to be published.

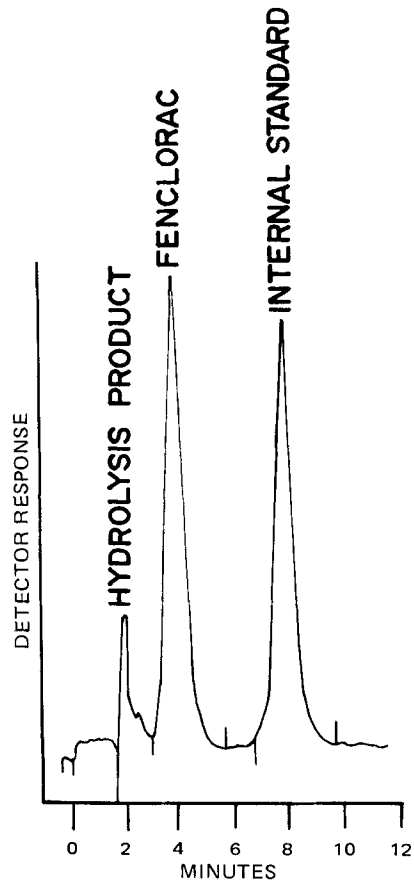

Figure 1—*Typical chromatogram of fenclorac, its hydrolysis product, α-hydroxy-3-chloro-4-cyclohexylbenzeneacetic acid, and the internal standard, triphenylethylene.*

aqueous solution. Previously reported methods for analysis of substituted aryl- and alkylphenoxyalkyl carboxylic acids, based on paper chromatographic separation and ion-pair formation with bromcresol green (2) and GLC assay (3), were not suitable. Therefore, a rapid stability-specific liquid chromatographic assay was developed for kinetic assay.

This report is concerned with the study of the kinetics and the mechanism of the hydrolysis of fenclorac in aqueous solution to utilize the basic information for pharmaceutical formulation design.

EXPERIMENTAL

Analytical Apparatus—A liquid chromatograph[2] equipped with a 254-nm UV detector and an electronic integrator[3] was used. The column was 50-cm × 7.9-mm (i.d.) stainless steel packed with chemically bonded octadecyl hydrocarbon on 30-μm porous silica[4].

Chromatographic Conditions—The solvent system was composed of methanol–water–acetic acid (50:36:14). The flow rate was 4.4 ml/min, and the pressure required to maintain this flow rate was 500 psi. The slightly different solvent systems used for α-chloro-4-cyclohexylbenzeneacetic acid and α-chloro-3-nitro-4-cyclohexylbenzeneacetic acid were methanol–water–acetic acid (54:40:6) and methanol–water–acetic acid (40:46:14), respectively.

Calibration Curve—Separate solutions containing 0.192, 0.384, 0.576, and 0.768 mg/ml of fenclorac standard and 36 μg/ml of internal standard, triphenylethylene[5], in methanol were injected into the column through a six-port injection valve with a loop capacity of 35 μl.

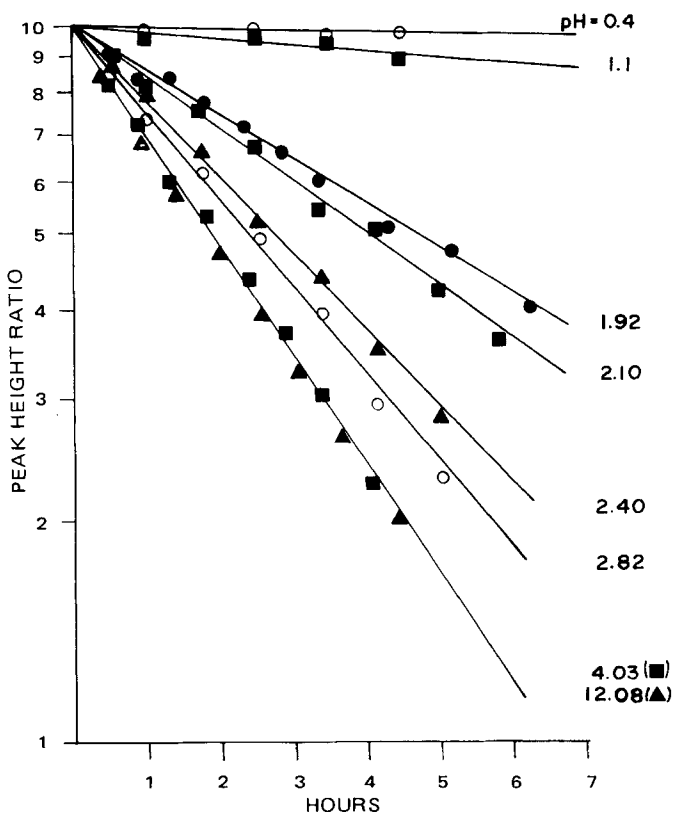

Figure 2—*Typical semilogarithmic plots of the ratio of the peak height of fenclorac to that of the internal standard, triphenylethylene, against time for the hydrolysis of fenclorac at 37.0° and the given pH.*

Kinetic Procedure—All kinetic experiments were performed at an ionic strength of 0.1 with sodium nitrate. Buffers employed were glycine (pH 2.1–2.8), formate (pH 3.3–4.0), acetate (pH 4.4), and carbonate (pH 10.1). An aliquot (0.8 ml) of a methanolic stock solution of fenclorac (50 mg/ml) was transferred into 100 ml of buffer solution equilibrated to the temperature under study. The low solubility of fenclorac in water at pH ≤ 4 necessitated the use of a stock solution of a lower concentration (1 mg/ml). The samples were withdrawn at various time intervals and analyzed as described.

Assay Procedure—Five milliliters of sample solution was cooled in an ice–water bath. An aliquot (4.0 ml) of the cooled sample was introduced into a vial with 4.0 ml of an internal standard solution. The internal standard solution contained 6 mg of triphenylethylene in 6 ml of acetic acid and 94 ml of methanol. The mixed sample was injected into the column through a six-port injection valve with a 35-μl capacity loop. A larger injection loop (1.39 ml) and a lower concentration of internal standard (1.2 μg/ml) were used for the sample solutions studied at pH ≤ 4.0.

RESULTS AND DISCUSSION

Liquid Chromatography—A typical liquid chromatogram of fenclorac (t_R = 4.6 min), its hydrolysis product (t_R = 2.4 min), and the internal standard (t_R = 9.7 min) is shown in Fig. 1. The plot of the ratio of peak height or area of fenclorac to that of internal standard *versus* the concentration of fenclorac showed a linear relationship between 0.192 and 0.768 mg/ml. The calibration curve had a mean slope of 1.945 mg^{-1},

Table I—Apparent First-Order Rate Constant in Hydrolysis of Fenclorac at 37.0° and pH 7.04 as a Function of Phosphate Buffer Anion, $[HPO_4^{2-}]$

$[HPO_4^{2-}]$, $M \times 10^{-2}$	10^4 k, sec^{-1}
1.4	1.15
2.8	1.13
7.0	1.11
11.2	1.11

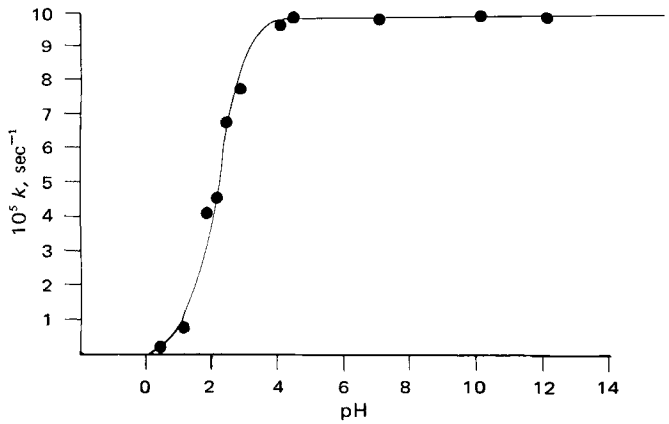

Figure 3—*The k–pH profile for the intramolecular nucleophilic catalysis in the hydrolysis of fenclorac in water (μ = 0.1) at 37.0°*

a mean Y-intercept of 0.014, and a mean correlation coefficient of 0.9998. These data indicate that the liquid chromatographic method can be used with a single-point standard.

Rate Constant—The apparent first-order rate constants were estimated from the slopes of appropriately plotted experimental data using:

$$\log R = \log R_0 - kt/2.303 \qquad \text{(Eq. 1)}$$

where R_0 was the initial ratio of peak height of fenclorac to that of the internal standard, and R was the ratio at any given time t. The reaction was irreversible, and no fenclorac peak was observed when the reaction went to completion. At any given pH, the semilogarithmic plots of the peak height ratio *versus* time showed linearity. Typical first-order plots at various pH values are given in Fig. 2. The hydrolysis of fenclorac was first order with respect to substrate over a 50-fold variation in initial concentration.

General Acid–Base Catalysis—The rate constants were independent of buffer concentration at constant pH and ionic strength when the phosphate buffer concentration was changed eightfold (Table I). This independence indicates that the hydrolysis is not due to the possible catalytic properties of the phosphate ions.

***k*–pH Profile**—The k–pH profile (Fig. 3) was constructed from the first-order rate constants and pH values at 37.0°. The first-order rate constant is independent of pH above 4 and is a sigmoid function of pH below 4. The hydrolysis rate is proportional to the degree of ionization of the carboxyl group, and the first-order rate constant for this system can be formulated as:

$$k = k_{AH}f_{AH} + k_Af_A \qquad \text{(Eq. 2a)}$$

$$k = \frac{k_{AH}[H^+] + k_AK_a}{[H^+] + K_a} \qquad \text{(Eq. 2b)}$$

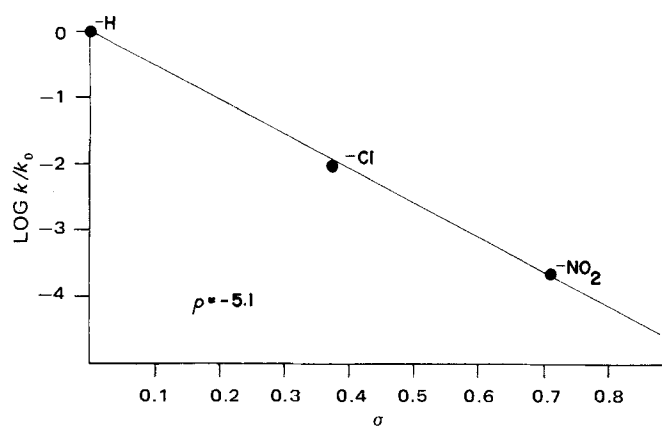

Figure 4—*Linear free energy relationship between the rates of hydrolysis of α-chloro-4-cyclohexylbenzeneacetic acid containing electron-withdrawing substituents and the Hammett substituent constants.*

Table II—Apparent First-Order Rate Constants in Hydrolysis of Fenclorac at 37.0° and pH 7.04 as a Function of Ionic Strength with Sodium Nitrate (k') and with Potassium Chloride (k), and Relative Rates of the Intermediate with Cl^- and Solvent (k_{Cl}/k_s)

μ	$10^5 k'$, sec^{-1}	$[Cl^-]$, M	$10^5 k$, sec^{-1}	k_{Cl}/k_s
0.096	9.86	0	9.86	—
0.446	11.7	0.35	10.2	0.42
0.846	13.6	0.75	10.5	0.39
1.596	14.4	1.50	11.1	0.20

where k_{AH} and k_A are the rate constants for the hydrolysis of undissociated and dissociated fenclorac, respectively; and f_{AH} and f_A are the fractions of undissociated and dissociated species, respectively. Since k_{AH} is negligible compared to k_A, Eq. 2*b* is reduced to:

$$k = \frac{k_AK_a}{[H^+] + K_a} \qquad \text{(Eq. 3)}$$

When $[H^+] \ll K_a$, Eq. 3 is reduced to $k = k_A$.

Thus, the k value becomes k_A when the rate constant is independent of pH above 4. The pKa value (pKa = 2.13) determined from the kinetic data using Eq. 3 agrees with that determined by the solubility method[6].

Salt and Common Ion Effects—The hydrolysis of fenclorac in phosphate buffer at pH 7.04 was tested for a salt effect using sodium nitrate up to an ionic strength of 1.596. An approximately 50% increase in the rate constant resulted by a change in ionic strength from 0.1 to 1.6 (Table II). A positive salt effect indicates generation of charge in the transition state, making the transition state more polar than the reactant. The first-order rate constant was not significantly increased when potassium chloride was used in place of sodium nitrate (Table II). The common ion effect, characteristic of an S_N1 reaction, can be taken into account by a reversible ionization mechanism (4) (Scheme I).

The apparent first-order rate constant, k, when the common ion effect is considered, is:

$$k = \frac{k'}{1 + (k_{Cl})/(k_s)[Cl^-]} \qquad \text{(Eq. 4)}$$

The ratio k_{Cl}/k_s (Table II) was estimated from the rate constants k' and k at a given ionic strength using sodium nitrate and potassium chloride, respectively.

Medium Effect—By changing the solvent from water to 50% aqueous methanol, the first-order rate constant for the hydrolysis of fenclorac at 50.0° and pH 5–12 decreased 6.5-fold ($k = 9.9 \times 10^{-5}$ sec^{-1}). The direction of the medium effect corresponds to that of a salt effect. This finding indicates that the solvent with greater polarity (water) stabilizes the transition state to the greater extent by solvation.

Substituent Effect—It was of interest to determine the electronic effect of different substituents (hydrogen and nitro) at the 3-position of the benzene ring on the hydrolysis rate of these analogs and to compare the effect with that of the 3-chloro substituent in fenclorac. The first-order rate constants were determined for fenclorac and the unsubstituted analog at pH 7.04 and 25.0°. The rate constant for the nitro substituent was extrapolated from its Arrhenius plot. The hydrolysis rate constants of the unsubstituted analog ($k = 1.67 \times 10^{-3}$ sec^{-1}) increased 100-fold from that of fenclorac, and that of the nitro-substituted analog ($k = 3.56 \times 10^{-7}$ sec^{-1}) decreased 50-fold. When the logarithm of k/k_0, where k_0 is the rate constant for the unsubstituted analog, was plotted against Hammett's σ-constants of the substituents, a linear relationship with $\rho = -5.1$ was obtained (Fig. 4). The reaction constant obtained was comparable to that of typical S_N1 reactions, *e.g.*, the solvolysis of 2-chloro-2-phenylpropane in 90% aqueous acetone with $\rho = -4.54$ (5).

From these data, it is seen that the different 3-substituents on the aromatic ring significantly affect the rate of hydrolysis. The large substit-

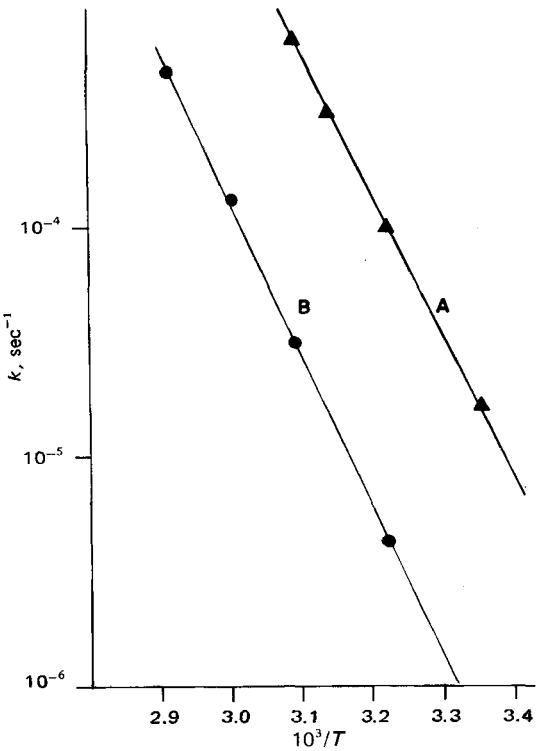

Figure 5—*Arrhenius plots for hydrolysis of fenclorac (A) and the 3-nitro-substituted analog (B).*

uent effect on the hydrolysis rate apparently is due to a change of the activation energy rather than the entropy of activation (Table III). This statement, however, is inconclusive, since the temperature dependence of the substituent effect was studied only for two compounds.

Rate Dependency on Temperature—The first-order rate constants were determined in phosphate buffer (pH 7.04) at four temperatures for fenclorac and the 3-nitro analog (Table III). The Arrhenius equation gives the quantitative relation of the rate constant and temperature. The logarithmic form of the equation is:

$$\log k = \frac{E_a}{2.303RT} + \log A \qquad \text{(Eq. 5)}$$

where E_a is the activation energy, and A is the frequency factor. The Arrhenius plots of the logarithms of the first-order rate constants *versus* $1/T$ are shown in Fig. 5. The Arrhenius parameters were calculated from the plots in accordance with Eq. 5. The values of E_a, log A, and $S^{\ddagger}$ (entropy of activation) are included in Table III.

Mechanism for Hydrolysis of Fenclorac—It has been well demonstrated (6–9) that α-bromopropionate hydrolyzes by the intramolecular displacement of bromine by the carboxyl anion and that the lactone formation follows the ionization of the carbon–bromine bond.

Table III—Apparent First-Order Rate Constants at Different Temperatures, Arrhenius Parameters, and Entropies of Activation for Hydrolysis of Fenclorac and the 3-Nitro-Substituted Analog at pH 7.04

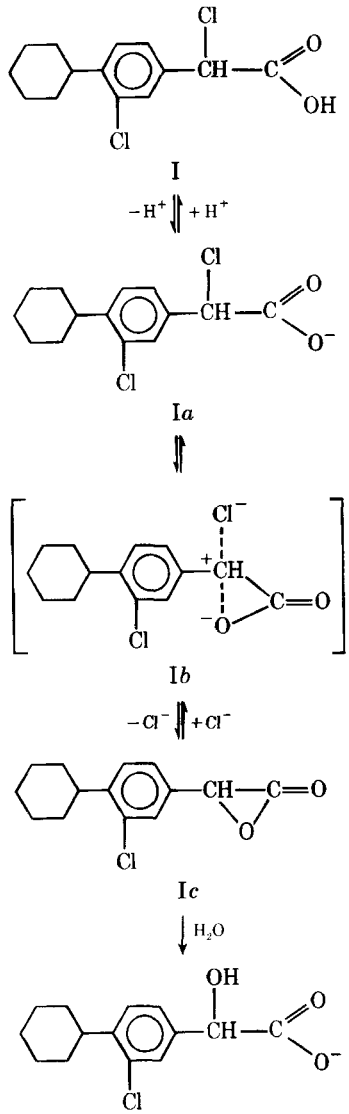
[a] Extrapolated value.



Scheme II

Scheme II is consistent with the proposed mechanism for the hydrolysis of fenclorac. The sequence explains the intramolecular catalysis of carboxyl anion in the ionization of the carbon–chlorine bond and the formation of an unstable intermediate, lactone.

Only the dissociated carboxyl anion participates in the intramolecular catalysis by nucleophilic attack on the α-carbon. The general base mechanism would be ruled out in the intramolecular catalysis, because no general acid–base catalysis was observed (Table I).

Since the increase in the rate constant was observed with an increasing salt concentration and polarity of the medium, it can be deduced that the transition state (Ib) has high ionic character (9). As the carbon–chlorine bond ionizes, a positive charge develops on the α-carbon, and the electron-withdrawing substituents destabilize the transition state by pulling electrons from already electron-deficient α-carbon and thus decrease the hydrolysis rate as shown by the substituent effect. The intermediate Ic, a three-membered ring lactone, would be trapped either by solvent water in the fast step to produce hydrolysis product Id or by added Cl^- to reverse the reaction as observed through the common ion effect.

Quantitative Determination of Amitriptyline and Its Principal Metabolite, Nortriptyline, by GLC–Chemical Ionization Mass Spectrometry

W. A. GARLAND

Abstract □ A quantitative GLC–mass spectrometry assay was developed for the determination of the tricyclic antidepressant amitriptyline and its desmethyl metabolite (nortriptyline) in human plasma. The assay utilizes selective ion detection to monitor in a GLC effluent the MH^+ molecular ions of amitriptyline and nortriptyline generated by isobutane chemical ionization. The procedure, which utilizes deuterated analogs of amitriptyline and nortriptyline as internal standards, requires 1 ml of plasma and can measure 1 ng/ml of amitriptyline and 0.5 ng/ml of nortriptyline. The curves relating the amounts of amitriptyline and nortriptyline added *versus* the amounts found over a 100-fold range of amitriptyline and nortriptyline concentrations are straight lines with intercepts of approximately zero and slopes of unity. Analyses of plasma samples from three subjects receiving 50 mg of amitriptyline orally, three times a day, gave an average plasma concentration of 115 ± 42 ng/ml for amitriptyline and 109 ± 20 ng/ml for nortriptyline. Similar analyses of the plasma of three subjects who had received a single 50-mg oral dose of amitriptyline showed an average maximum plasma concentration of 25 ± 10 ng/ml for amitriptyline and 10 ± 4 ng/ml for nortriptyline. Seventy-two hours after administration, the average plasma amitriptyline and nortriptyline levels were 3 ± 1 and 3 ± 2 ng/ml, respectively.

Keyphrases □ Amitriptyline—GLC–mass spectrometric analysis, human plasma □ Nortriptyline—GLC–mass spectrometric analysis, human plasma □ GLC–mass spectrometry—analyses, amitriptyline and nortriptyline in human plasma □ Antidepressants—amitriptyline and nortriptyline, GLC–mass spectrometric analyses, human plasma

Amitriptyline and nortriptyline are used extensively for treating psychic depression (1). Nortriptyline is also generated metabolically in humans from amitriptyline (2, 3). Indeed, it has been suggested that the action of amitriptyline is mediated through its nortriptyline metabolite (4). Therapeutically, these compounds are reported to be effective over a relatively narrow range of plasma concentrations (5), although large interindividual variations in plasma concentrations are observed with similar dosing schedules (6–8). In addition, there are conflicting reports concerning the relative amelioration of depression as a function of plasma amitriptyline and/or nortriptyline levels (5, 8, 9).

Research on problems associated with amitriptyline therapy has been hindered somewhat by the lack of a sufficiently sensitive and specific assay for determining low levels of amitriptyline in plasma, *e.g.*, no single-dose amitriptyline pharmacokinetic data are available. Two flame-ionization GC assays suitable only for determining "steady-state" plasma concentrations of amitriptyline and nortriptyline were described (10, 11). Both assays require 3–5 ml of plasma and have a sensitivity limit of 25 ng/ml.

Recently, a GC procedure using a nitrogen detector was reported (12). It has a quoted sensitivity of 5 ng/ml for amitriptyline and 10–15 ng/ml for nortriptyline (2 ml of plasma extracted), but it cannot determine nortriptyline in humans following a therapeutic single dose of amitriptyline. Furthermore, it is only marginally suitable for amitriptyline, since the typical maximum concentration of amitriptyline after a 50-mg dose is only 15–25 ng/ml.

An electron-capture GC method for the determination of the heptafluorobutyrate derivatives of nortriptyline and some of its metabolites was reported (13). This procedure requires 4 ml of plasma and has a reported sensitivity of 10 ng/ml.

This report describes a GLC–mass spectrometric assay requiring 1 ml of plasma that is capable of determining 1 ng/ml of amitriptyline and 0.5 ng/ml of nortriptyline. The method, which utilizes chemical ionization GLC–mass spectrometry (14) with isobutane functioning both as a reagent gas and GLC carrier gas, is suitable for measuring amitriptyline and nortriptyline in humans following single-dose amitriptyline administration. To obtain sufficient sensitivity, selective ion detection is used to monitor the MH^+ ion of both amitriptyline and either nortriptyline or the trifluoroacetyl derivative of nortriptyline. Known quantities of deuterated analogs of both amitriptyline and nortriptyline are added to the plasma as internal standards.

EXPERIMENTAL

Apparatus—A quadrupole mass filter system[1] and data system[2] were used in conjunction with the gas chromatograph[3]. The GLC column, 1.21 m (4 ft) × 2 mm i.d., was silanized and packed with 3% OV-17 on 100–

This report describes a GLC–mass spectrometric assay requiring 1 ml of plasma that is capable of determining 1 ng/ml of amitriptyline and 0.5 ng/ml of nortriptyline. The method, which utilizes chemical ionization GLC–mass spectrometry (14) with isobutane functioning both as a reagent gas and GLC carrier gas, is suitable for measuring amitriptyline and nortriptyline in humans following single-dose amitriptyline administration. To obtain sufficient sensitivity, selective ion detection is used to monitor the MH^+ ion of both amitriptyline and either nortriptyline or the trifluoroacetyl derivative of nortriptyline. Known quantities of deuterated analogs of both amitriptyline and nortriptyline are added to the plasma as internal standards.

EXPERIMENTAL

Apparatus—A quadrupole mass filter system[1] and data system[2] were used in conjunction with the gas chromatograph[3]. The GLC column, 1.21 m (4 ft) × 2 mm i.d., was silanized and packed with 3% OV-17 on 100–

IId: R = $N(CD_3)$—$C(=O)CF_3$

120-mesh Gas Chrom Q[4]. The column was conditioned at 325° with no flow for 3 hr and then at 275° overnight with a 20-ml/min helium flow.

Chromatographic conditions were: column oven, 230–240°; injection port, 275°; isobutane[5] gauge pressure, 1–3 lb/in.^{2}; and interface oven and glass-lined source reentrant tube, 250°. The column temperature and isobutane pressure were adjusted to provide an ion source pressure of 0.3–0.4 torr. Typical ion source settings were: ion volume + 8 v, ion repeller + 2 v, ion lens − 30 v, and filament − 150 v. The electron beam total emission was regulated at 800 μamp, while the source was operated without external heating (temperature 50°).

Materials—Nanograde quality *n*-hexane[6] and chloroform[6] and GLC quality trifluoroacetic anhydride[7] were used without further purification. Before each assay, hydrogen chloride gas was gently bubbled through 20 ml of chloroform in a 25-ml flask for 5 min. The flask was then capped, and this solution was used later to wash down the wall of the tubes used for evaporation of the plasma extraction solvent.

Stock solutions of amitriptyline (Ia), amitriptyline-d_3 (Ib), amitriptyline-d_6[8] (Ic), nortriptyline (IIa), and nortriptyline-d_3 (IIb) were made in distilled water using their respective hydrochloride salts, with all concentrations expressed in terms of the free base. Clinical control plasma[9] was used in the preparation of the amitriptyline and nortriptyline plasma standards.

Amitriptyline-d_3 and nortriptyline-d_3 were synthesized from nortriptyline and desmethylnortriptyline, respectively, using a published procedure (15). The relevant amine was treated with ethyl chlorocarbonate, and the resulting carbamate was reduced with lithium aluminum deuteride[10] at room temperature for no more than 8 hr. Both compounds showed satisfactory UV, IR, PMR, and mass spectral (electron and chemical ionization) properties. A selective ion detection analysis of amitriptyline-d_3 showed the presence of an ion equivalent to 3.03 ± 0.16% (n = 6) amitriptyline-d_0. A similar analysis of nortriptyline-d_3 showed the presence of an ion equivalent to 3.84 ± 0.17% (n = 6) nortriptyline-d_0. A selective ion detection analysis of amitriptyline-d_6 failed to detect any amitriptyline-d_0.

Tubes (15 ml)[11] with screw caps[12] were used for the plasma extractions; 5-ml glass-stoppered centrifuge tubes[13] were used for the final solvent evaporation. Pasteur pipets with hand-drawn constricted tips were utilized for all solution transfers. All glassware was soaked for 2 hr in a 0.1% solution of trimethylamine in methanol prior to use.

Assay Procedure—*Steady-State Plasma Concentrations*—One milliliter of plasma, 1.0 ml of internal standard solution (typically ~ 100 ng/ml of amitriptyline-d_3 and nortriptyline-d_3), 0.2 ml of 1 *M* H_2SO_4, and 5.0 ml of hexane were combined in a 15.0-ml test tube, and the mixture was shaken on a metabolic shaker–incubator[14] at 40 oscillations/min for 15 min. After centrifugation at 1000×*g*[15], the organic phase was removed and discarded. To the aqueous phase was then added 1.0 ml of 1.0 *M* NaOH and 5.0 ml of hexane. The mixture was then shaken and centrifuged, and the organic phase was transferred to a 5-ml centrifuge tube.

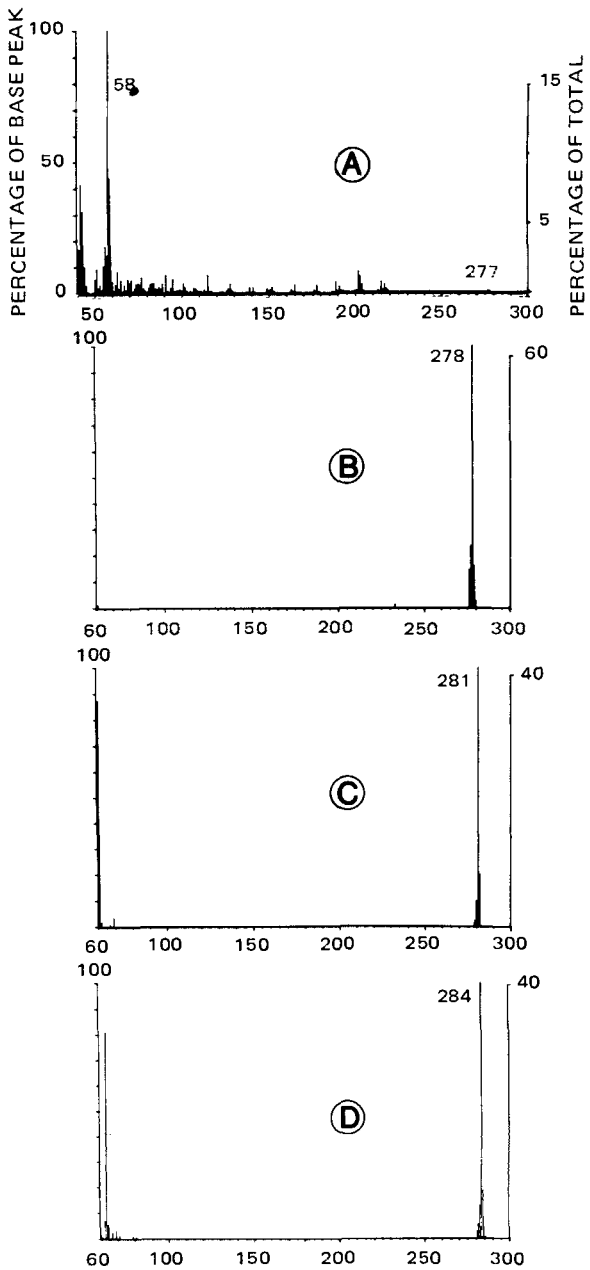

Figure 1—*Key: A, electron ionization (70 ev) mass spectrum of amitriptyline; B, isobutane (0.4 torr) chemical ionization mass spectrum of amitriptyline; C, isobutane (0.3 torr) mass spectrum of amitriptyline-*d_3*; and D, isobutane (0.6 torr) mass spectrum of amitriptyline-*d_6.

While the organic phase was being removed under a gentle stream of nitrogen at room temperature[16], another 5.0 ml of hexane was added to the aqueous phase, which was then shaken and centrifuged as before. This 5.0 ml was then transferred to the centrifuge tube, and the solvent was removed under nitrogen. The centrifuge tube wall was washed down first with 500 μl and then with 100 μl of hydrogen chloride (gas) treated chloroform. Following removal of this second chloroform wash, the residue was reconstituted in 30 μl of chloroform, and 10 μl was injected into the GLC–mass spectrometer.

Forty-five seconds after injection, the electron multiplier was turned on and the GLC flow divert valve was turned off, allowing the GLC effluent to enter the ion source. Fifty-five seconds after injection, the ion

source supplies were turned on. Computer-controlled scanning and data collection were initiated another 5 sec later. Approximate retention times were 1.5 and 1.8 min for amitriptyline and nortriptyline, respectively. Three minutes after injection, the GLC flow divert valve was again turned on, the ion source supplies were turned off, and the computer data collection was halted.

Peak areas and preliminary concentrations were obtained using the software provided with the data system. Final concentrations were obtained by subtraction of the amount of either amitriptyline-d_0 or nortriptyline-d_0 present in the deuterated internal standards from the computer-calculated preliminary concentrations. The amounts of amitriptyline-d_0 and nortriptyline-d_0 in the d_3-labeled standards were periodically checked by selective ion analysis.

Single Amitriptyline Dose—The procedure followed was similar to

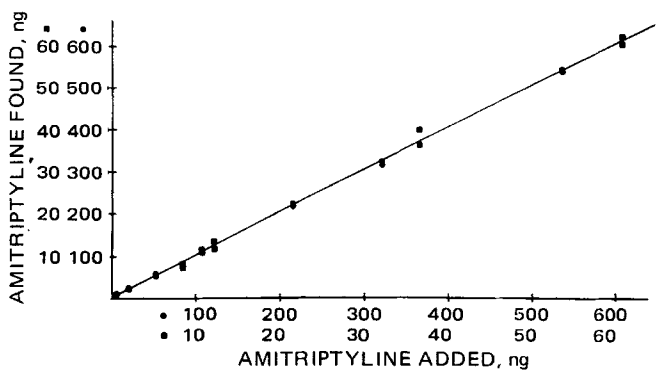

Figure 3—*Curve relating amount of amitriptyline added to clinical control plasma* versus *amount of amitriptyline found. Circles denote determinations using procedure described under* Experimental *for steady-state plasma amitriptyline* (m/e 278) *levels. For these samples, 122 ng/ml of amitriptyline-*d_3 (m/e 281) *was used as an internal standard. For these samples, 7.52 ng/ml of amitriptyline-*d_6 (m/e 284) *was used as an internal standard.*

that used with the steady-state plasma samples with the following three exceptions:

1. A lower internal standard concentration of approximately 20 ng/ml for both amitriptyline-d_6 and nortriptyline-d_3 was used. Amitriptyline-d_6 was usually used in preference to amitriptyline-d_3 in the single-dose assay, since the *m/e* 284 (amitriptyline-d_6) trace showed a significantly lower background signal at this concentration level as compared to that at *m/e* 281 (amitriptyline-d_3).
2. Fifty microliters of trifluoroacetic anhydride was added following the addition of the second hexane extract to the 5-ml centrifuge tube, and the solution was allowed to stand for 30 min before solvent evaporation.
3. The GLC flow divert valve was turned on again 4 min after sample injection. The retention time of *N*-trifluoroacetyl nortriptyline (IIc) and *N*-trifluoroacetyl nortriptyline-d_3 (II*d*) was 3.0 min.

Amitriptyline Single-Dose and Steady-State Human Plasma Samples—Plasma samples from normal adult volunteers were available from previous studies.

RESULTS AND DISCUSSION

A GLC–mass spectrometric assay for the heptafluorobutyrate derivative of nortriptyline was reported using conventional electron ionization and selective ion monitoring of the $M^+ - CH_3NHC(=O)C_3F_7$ fragment ion generated in the electron ionization mass spectrum (16). The quoted sensitivity for this assay is 1 ng/ml using 3 ml of plasma. Since amitriptyline cannot be easily derivatized, a similar electron ionization assay for this compound would require the monitoring of the relatively nonspecific *m/e* 58 ion found in the electron ionization mass spectrum of amitriptyline (Fig. 1A).

Isobutane chemical ionization, however, permits the monitoring of an ion (*m/e* 278) expressing information concerning amitriptyline's molecular weight (Fig. 1B). Similarly, this ionization technique also makes nortriptyline suitable for mass spectral analysis without prior derivatization (Figs. 2A and 2B). The maximum sensitivity obtainable, however, for the assay using underivatized nortriptyline was quite variable. Although this is of little consequence when determining steady-state plasma nortriptyline levels, it is significant when measuring the low nortriptyline levels found after single-dose amitriptyline administration. For low level determinations of nortriptyline, the *N*-trifluoroacetyl derivative had suitable chromatographic and mass spectral (Fig. 2D) properties.

Clinical control plasma subjected to the described procedure for steady-state plasma amitriptyline and nortriptyline levels showed no significant background ions at *m/e* 264, 267, 278, 281, or 284. If this same plasma is subjected to the procedure adopted for a single dose of amitriptyline, a noninterfering *m/e* 278 peak corresponding to a compound with a retention time longer than that of amitriptyline is sometimes observed.

Results obtained from the addition of known amounts of amitriptyline and nortriptyline to clinical control plasma followed by processing according to the described procedure can be seen in Figs. 3 and 4. A least-

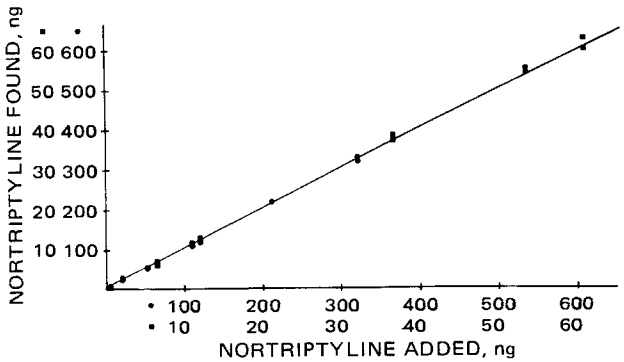

Figure 4—*Curve relating amount of nortriptyline added to clinical control plasma* versus *amount of nortriptyline found. Circles denote determinations using the procedure described under* Experimental *for steady-state plasma nortriptyline* (m/e *264*) *levels. For these samples, 108 ng/ml of nortriptyline-*d_3 (m/e *267*) *was used as an internal standard. Squares denote determinations using the procedure described under* Experimental *for single-dose plasma nortriptyline levels. For these samples, 4.61 ng/ml of nortriptyline-*d_3 *was used as an internal standard* [N-*trifluoroacetylnortriptyline-*d_3, m/e *363*].

squares analysis of the amitriptyline data (Fig. 3) gave a slope of 0.98 ± 0.01 and an intercept of 0.20 ± 0.23 ng. The corresponding curve (Fig. 4) for nortriptyline had a slope of 1.01 ± 0.01 and an intercept of 0.36 ± 0.20 ng. Thus, these data suggest that the extraction, mass spectrometry, and

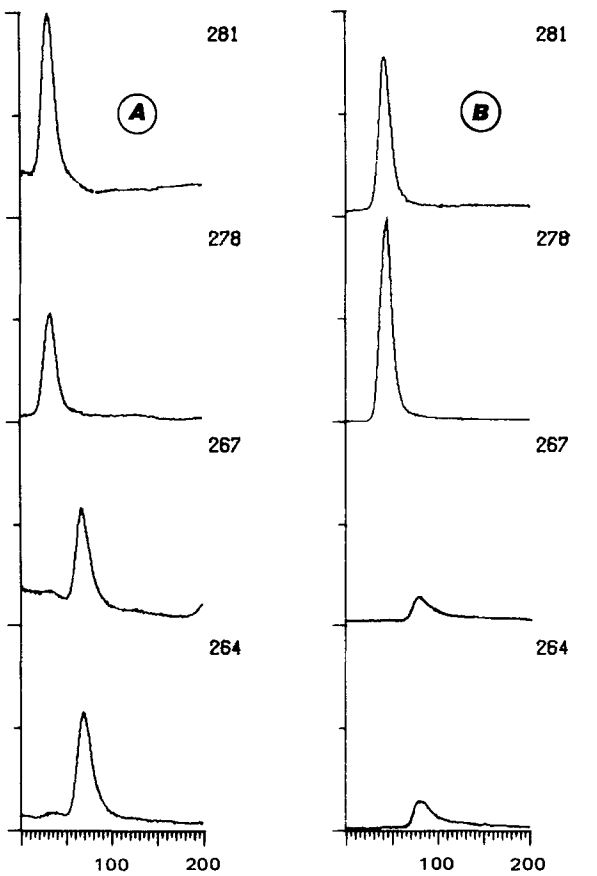

Figure 5—*Selective ion chromatograms for amitriptyline* (m/e *278*) *and nortriptyline* (m/e *264*). *Part A is for plasma obtained from Subject 1, 8 days after beginning oral 50-mg amitriptyline therapy three times a day. Internal standards amitriptyline-*d_3 (m/e *281*) *and nortriptyline-*d_3 (m/e *267*) *were present in concentrations of 122 and 104 ng/ml, respectively. The amitriptyline concentration was 64.2 ng/ml; the nortriptyline concentration was 100 ng/ml. Part B is the same as Part A except that the plasma is from Subject 3, 8 days after beginning amitriptyline therapy. The amitriptyline concentration was 124 ng/ml; the nortriptyline concentration was 87.1 ng/ml.*

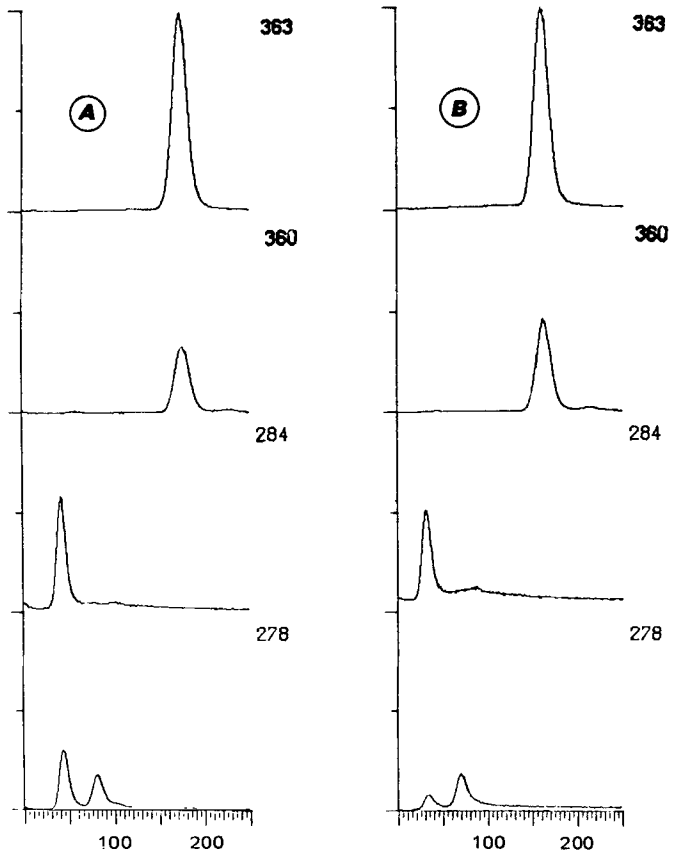

Figure 6—*Selective ion chromatograms for amitriptyline* (m/e *278*) *and* N-*trifluoroacetylnortriptyline* (m/e *360*). *Part A is for plasma obtained from Subject 6, 3 hr after oral administration of 50 mg of amitriptyline. Internal standards amitriptyline-*d_6 (m/e *284*) *and* N-*trifluoroacetylnortriptyline-*d_3 (m/e *360*) *were present in concentrations of 33.3 and 20.3 ng/ml, respectively. The amitriptyline concentration was 11.2 ng/ml; the nortriptyline concentration was 6.1 ng/ml. Part B is the same as Part A except 48 hr after amitriptyline administration. The amitriptyline concentration was 5.1 ng/ml; the nortriptyline concentration was 8.3 ng/ml.*

GLC characteristics of the labeled and unlabeled compounds are essentially identical.

Six samples containing 8.62 ng of amitriptyline plus 6.43 ng of nortriptyline were analyzed by the procedure for single-dose amitriptyline plasma levels using 7.52 ng/ml of amitriptyline-d_6 and 4.61 ng/ml of nortriptyline-d_3 as internal standards. The results ± *SD* for these samples were 8.03 ± 0.29 ng/ml for amitriptyline and 6.51 ± 0.23 ng/ml for nortriptyline. The recoveries ± *SD* for these samples, based on a comparison of the peak areas obtained by injecting known amounts of nortriptyline-d_3 and amitriptyline-d_6 into the GLC–mass spectrometer with those obtained from the internal standards carried through each assay, were 50 ± 26% for amitriptyline and 31 ± 10% for nortriptyline.

Six samples containing 53.9 ng of amitriptyline plus 53.6 ng of nortriptyline and six samples containing 539 ng of amitriptyline plus 536 ng of nortriptyline were analyzed by the procedure for steady-state levels, using 122 ng/ml of amitriptyline-d_3 and 104 ng/ml of nortriptyline-d_3 as internal standards. The results ± *SD* were 54.0 ± 0.5 ng/ml for amitriptyline and 52.8 ± 0.4 ng/ml for nortriptyline for the first set of samples and 547 ± 11 ng/ml for amitriptyline and 546 ± 10 ng/ml for nortriptyline for the second set. The recoveries ± *SD* for these 12 samples, based on a comparison of the peak areas obtained by injecting known amounts of amitriptyline-d_3 and nortriptyline-d_3 into the GLC–mass spectrometer with those obtained from the internal standards carried through each assay, were 80 ± 20% for amitriptyline and 65 ± 19% for nortriptyline.

The fairly wide range of recoveries observed for these 18 samples presumably is the result of considerable intersample variation in both extraction efficiencies and GLC column and glassware adsorption. These results further emphasize the importance of the stable isotope internal standards in ensuring accuracy.

Analyses for amitriptyline and nortriptyline in the plasma of three

Table I—Plasma Amitriptyline and Nortriptyline Levels (Nanograms per Milliliter) in Three Subjects Receiving Amitriptyline Therapy

Days after Beginning of Amitriptyline Therapy[a] (50 mg po Three Times a Day)	Subject 1		Subject 2		Subject 3	
	Amitriptyline	Nortriptyline	Amitriptyline	Nortriptyline	Amitriptyline	Nortriptyline
8	64.2 (63.0)[b]	100 (104)[b]	137	70.2	124	87.1
8.5	59.7 (56.1)	102 (99.4)	106	153	131	88.2
11	91.6 (86.2)	117 (116)	130	154	135	111
11.5	77.6 (74.3)	101 (102)	160	147	103	106
13	61.2 (59.8)	101 (102)	153	125	136	103
13.5	44.4 (40.4)	66.8 (67.3)	201	142	146	88.8
Average ± *SD*	66.5 ± 16.3 (63.3 ± 15.7)	98.1 ± 16.9 (98.3 ± 15.7)	148 ± 32	132 ± 32	129 ± 15	97.2 ± 12.7

[a] First blood sample on Days 8, 11, and 13 was taken immediately before the first dose of the day; the second blood sample was taken 1 hr after receiving the second dose. [b] Amitriptyline and nortriptyline levels obtained from a separate analysis of a 1-ml aliquot from the same plasma sample.

subjects receiving 50 mg of amitriptyline three times a day are presented in Table I. Excellent reproducibility of the duplicate analyses of the plasma samples from Subject 1 is seen, except for the amitriptyline levels calculated for the 13.5-day sample. The actual levels found are similar, if the difference in administered dose is considered, to those previously published (11, 17). Typical ion chromatograms from analyses of steady-state plasma samples can be seen in Fig. 5. In this figure, the substantial variation in nortriptyline and nortriptyline-d_3 recoveries from the two different samples (A and B) should be noted.

The results of single-dose administrations of 50 mg of amitriptyline can be seen in Table II. The maximum plasma amitriptyline levels ranged from 16 to 35 ng/ml in the three subjects. After 72 hr, the amitriptyline levels ranged from 2.3 to 4.4 ng/ml; nortriptyline levels ranged from 0.5 to 5.4 ng/ml. The drug half-lives for the three subjects, obtained using a least-squares analysis of the log amitriptyline concentration *versus* time data for the 8–72-hr plasma samples, were 35, 26, and 51 hr. These half-lives fall within the range (18–93 hr) previously found in 22 human subjects who had received a similar dose of nortriptyline (18). Typical ion chromatograms from an analysis of single-dose plasma samples can be seen in Fig. 6.

The sensitivity obtainable using this assay cannot be quoted in absolute terms but was found to be a function of both the condition of the ion source and quadrupole rod system and the amitriptyline and nortriptyline recoveries. With clean poles and ion source, an assay sensitivity of 1 ng/ml of amitriptyline and 0.5 ng/ml of nortriptyline is possible, provided the amitriptyline and nortriptyline recoveries for the particular samples are greater than 50%.

Table II—Plasma Amitriptyline and Nortriptyline Levels (Nanograms per Milliliter) in Three Subjects after Oral Administration of 50 mg of Amitriptyline

Hours after Administration	Subject 4		Subject 5		Subject 6	
	Amitriptyline	Nortriptyline	Amitriptyline	Nortriptyline	Amitriptyline	Nortriptyline

Vehicle Effects on Activity of an Anticonvulsant Compound

DILIP R. SANVORDEKER ˣ and JAMES BLOSS

Abstract □ The effect of several lipid and nonlipid pharmaceutical solvents on the *in vivo* activity of 1-diphenylmethyl-4-[(6-methyl-2-pyridyl)methyleneamino]piperazine (I) was evaluated in the mouse. The intensity of onset and the duration of anticonvulsant activity of the compound were affected depending on the type and form of liquid dosage preparation used. The rate of decline in anticonvulsant activity in the 80–20% response range followed apparent zero-order kinetics. A linear relationship between the observed ED_{50} and the concentration of sorbitol in the dosage form of I was observed. A reduction in the sorbitol content of the dosage form resulted in a proportional increase in the rapidity of onset and the duration of anticonvulsant activity of I. Emulsification restored both the onset and duration of pharmacological activity, which was virtually arrested when the compound was given orally as a solution in oil.

Keyphrases □ Piperazine, substituted—anticonvulsant activity after oral administration, effect of various solvents and dosage forms, mice □ Solvents, various—effect on anticonvulsant activity of a substituted piperazine after oral administration, mice □ Dosage forms, various—effect on anticonvulsant activity of a substituted piperazine after oral administration, mice □ Anticonvulsant activity—1-diphenylmethyl-4-[(6-methyl-2-pyridyl)methyleneamino]piperazine, effect of various solvents and dosage forms, oral administration, mice

To evaluate the pharmacological activity of a new compound, it is commonly dissolved in a suitable vehicle prior to administration to an animal. This approach is particularly useful for poorly water-soluble drugs, since the rate-limiting drug dissolution process is bypassed and penetration of the drug in solution across biological membranes is facilitated. Drugs with aqueous solubility at and below 0.15 mg/ml can pose potential absorption problems (1). To overcome such difficulties, the pharmaceutical scientist often uses water-miscible nonaqueous solvents that can be suitably blended with water and provide the desired solvency for the drug (2).

1-Diphenylmethyl -4- [(6-methyl -2- pyridyl)methyleneamino]piperazine[1] (I) is a potent anticonvulsant compound in animals (3). The saturation solubility of this compound at 37° is estimated to be less than 0.1 mg/ml. This study was designed to evaluate the effect of several lipid and nonlipid pharmaceutical solvents on the *in vivo* activity of I administered *via* the oral route.

EXPERIMENTAL

Materials—Corn oil[2], dimethylacetamide[3], 2,2-dimethyl-1,3-dioxolane-4-methanol[3], polyethylene glycol 400[3], poloxamer 237[4], sorbitol (70% solution[5]), polysorbate 80[3], propylene glycol[3], and normal saline[6] were used as supplied. Compound I[7] was supplied as the pure compound. The crystals of the compound were ground in a mortar and pestle to a fine powder prior to its use.

Preparation of Suspensions of I—Except for drug suspensions in sorbitol solution, an accurately weighed quantity of I was transferred to a 25-ml test tube. Normal saline[6], with and without 1.5 ml of a propylene glycol–polysorbate 80 (50:50 v/v) mixture as a wetting agent, was added to make suspensions of the compound in the 0.2–0.8-mg/ml range. The suspensions were thoroughly mixed with the aid of a portable homogenizer[8] for 5 min. Suspensions of I at the 0.8-mg/ml concentration in sorbitol solutions (7–70%) were prepared by adding a weighed amount of I to 200 ml of the vehicle followed by mixing and homogenizing[9] the suspensions. Prior to oral administration of the dose, all suspensions were shaken vigorously.

Preparation of Solutions of I—Compound I, 100 mg, was dissolved in a nonaqueous solvent. The final volume of this solution was made with distilled water to obtain 1 mg/ml of I in a cosolvent vehicle of a defined solvent composition. These stock solutions and blank vehicles of the same composition were used to prepare diluted solutions of I at 0.1–0.8-mg/ml concentrations.

Stock solutions of I in corn oil and in soya bean oil[2] were prepared by dissolving 100 mg of I in 100 ml of the oil. This solution was then used to prepare additional solutions at lower concentrations. All solutions were prepared fresh each day prior to testing pharmacological activity.

Preparation of Oil-in-Water Emulsions of I—Accurately weighed amounts of 50–500 mg of I were transferred to 100-ml volumetric flasks. The oil was added to make up the volume, and the flasks were placed on a steam bath for approximately 5 min. After cooling, 40 ml of the oil solution of I was transferred to a 250-ml glass container; the volume was increased to 200 ml with a 0.8% solution of a nonionic surfactant[4] in distilled water. The oil and water layers were then mixed and homogenized for 0.5 hr with a lab size homogenizer[9]. Emulsions without the compound were also prepared by this procedure.

For ED_{50} determinations, the emulsions were prepared 1 day prior to the experiment and stored in a refrigerator. All other studies were performed with emulsions prepared on the same day.

***In Vivo* Studies**—Male HAM/ICR mice[10], 20–30 g, were housed in 20.3 × 35.6-cm (8 × 14-in.) stainless steel cages (12 animals/cage) and maintained on a standard pellet diet and tap water prior to each experiment. All formulations of I were given at 0.1 ml/10 g of body weight by the intragastric (oral) route of administration. The electrical current for induction of seizures was generated by a commercially available apparatus[11].

Determination of ED_{50}—Liquid dosage forms of I and their blanks (without the compound) were tested for anticonvulsant activity according to the method of Swinyard *et al.* (4). Thirty minutes after administration of a dose to a group of 20 mice, each animal was challenged with a current of 50 mamp delivered *via* corneal electrodes. Except for 2,2-dimethyl-1,3-dioxolane-4-methanol solutions, this current was sufficient to induce hindlimb tonic extensor seizure in 100% of the control mice. All data were recorded as the number of mice protected per group of 20 animals dosed with a given dosage form. The ED_{50} values were calculated by the method of Litchfield and Wilcoxon (5).

Determination of Duration of Response to I—The method was essentially the same as described previously. Groups of 20 animals were dosed with 8.0 mg/kg of I in the dosage form. The animals were then challenged with electric shock every 0.5 hr up to 5 hr and then every hour up to 8 hr after dosing. The data were recorded as the ratio of animals protected to animals dosed.

RESULTS AND DISCUSSION

Figure 1 illustrates a log dose–response relationship for I administered intragastrically to mice in three different vehicles. The response to this compound followed a previously established semilogarithmic relationship

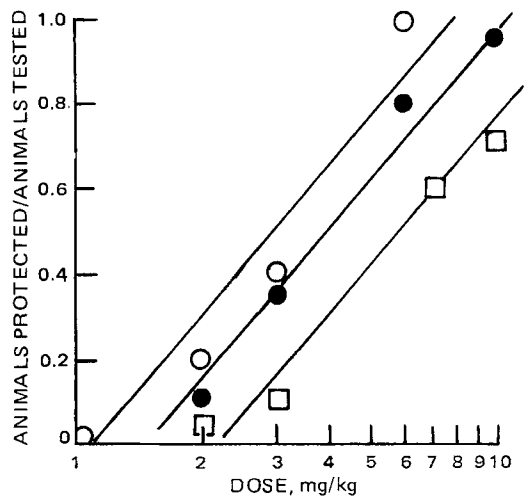

Figure 1—*Linear relationship between log dose and response to I in mice. Key: ○, suspension in saline; ●, solution in polyethylene glycol 400; and □, solution in dimethylacetamide–water (50:50 v/v).*

(6) describable by the following equation:

$$R = m \log D + e \qquad \text{(Eq. 1)}$$

where R is the intensity of the pharmacological response, D is the administered dose, m is the slope of the line illustrating the linear relationship, and e is the intercept on the x (dose) axis. From this plot, it is evident that administration of a solution of I in a water-miscible cosolvent such as dimethylacetamide results in a parallel shift of pharmacological response from lower doses to relatively higher doses.

A least-squares linear regression analysis of the log dose–response data in the 80–20% response range yielded 0.933–1.23 values for the slope. These values provide a good estimate for the free drug occupancy of the receptor sites in the biophase (7). This theoretical consideration implied that practically all of the free concentration of I available in the biophase occupied the receptor sites to provide the desired anticonvulsant response in mice. This observation agrees with the potency of this compound compared to that of its analogs at relatively low doses (1).

Table I lists the effect of several vehicles on the ED_{50} values of I estimated 0.5 hr after intragastric administration of the dosage form. Within 95% confidence limits, no difference was observed for the ED_{50} values estimated after administration of I as a suspension in normal saline and as a solution in polyethylene glycol 400. The apparent twofold increase in ED_{50} values observed for the dimethylacetamide solution is intriguing. Among the possibilities are interference with the bioavailability of I and competition at the receptor site, thus reducing the apparent efficacy by a twofold margin. The log dose–response plot demonstrates that, in the 6–10-mg/kg range, a maximal response was observed at 30 min after oral administration of the drug. With this information, subsequent studies on the duration of drug activity were conducted at the 8-mg/kg dose level to assess the effect of vehicles on this parameter.

Table I—Effect of Vehicles on the ED_{50} of I Estimated 30 min after Intragastric Dosing of Mice

Dosage Form	Vehicle Composition	ED_{50}, mg/kg (95% Confidence Limits)
Suspension	Normal saline	3.0 (2.7–3.7)
Solution	Polyethylene glycol 400–water (60:40 v/v)	3.7 (2.9–4.8)
Solution	Dimethylacetamide–water (50:50 v/v)	6.2 (4.7–8.2)
Solution	2,2-Dimethyl-1,3-dioxolane-4-methanol–water (50:50 v/v)	No effect; vehicle posesses convulsion-blocking activity
Solution	Corn oil	No effect
Emulsion	20% (v/v) corn oil in water emulsified with 0.8% surfactant solution	8.3 (7.9–9.4)

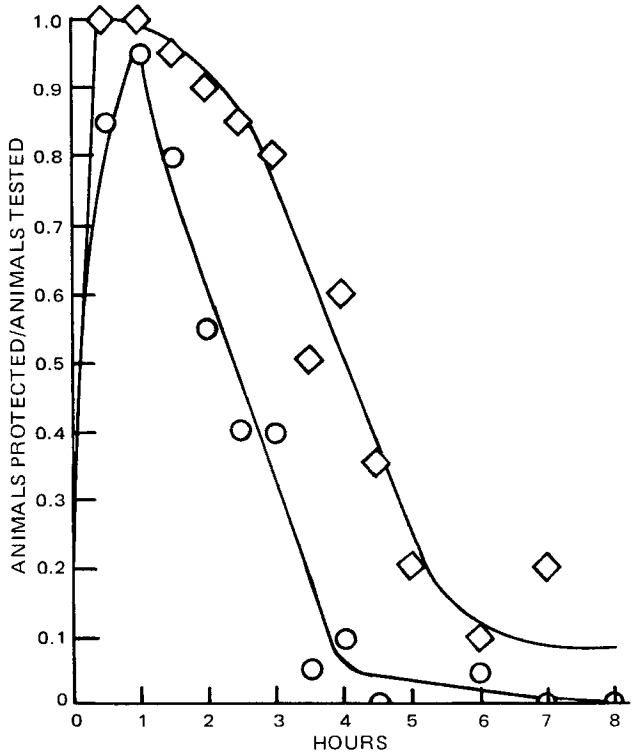

Figure 2—*Time course of pharmacological activity of I after oral administration of a suspension of I without (◇) and with (○) 0.8% surfactant solution in saline.*

Figure 2 illustrates a plot of the intensity, R, of the pharmacological activity of I monitored as a function of time following intragastric administration of an 8-mg/kg dose to mice. The decline in intensity of the anticonvulsant activity in the 80–20% range followed an apparent zero-order process. Since response to a drug is a function of the free drug concentration at the receptor site(s), this observation agrees with previously reported relationships (8–11). It is evident that inclusion of a surfactant (emulsifier) at the 0.8% concentration in the dosage form affects the duration of the anticonvulsant activity of I. However, the rate of decline in intensity of this response remains unaffected as evidenced from the slope of the plot.

The overall inference obtained from these observations is that the availability of the free concentration of I at the anticonvulsant receptor sites may be at a reduced level following its oral administration in the presence of a surfactant. Several investigators have shown that surfactants can affect the rate and extent of drug absorption across the GI tract (12–15). The surfactant solution used in the present study may have modified the extent of absorption of I; consequently, a reduction in the duration of its pharmacological activity can be expected.

Previous investigations (16) showed that absorption of drugs from oily solutions was significantly inhibited. The same authors (16) noted that with an oil-in-water emulsion system where a drug is in solution in the oil phase, the overall absorption rate is significantly large despite a high water-to-oil partitioning property of a drug. In recent years, it has been shown that administration of poorly water-soluble drugs as oil-in-water emulsion dosage forms allows extensive drug absorption as compared with other conventional dosage forms (17–20).

To assess this possibility, the relative pharmacological activity of I was evaluated after oral dosing of an oil-in-water emulsion and an oil solution. As illustrated in Fig. 3, the onset and duration of pharmacological activity of I achieved from an emulsion dosage form were comparable to that of the suspension without the surfactant (Fig. 2). Administration of the compound in a corn oil solution resulted in virtually total arrest of anticonvulsant activity in the mouse. Since the drug has been shown to be very lipophilic[12], it is likely that its transfer rate from large oil globules to intestinal fluid can be insignificant. Consequently, the rate and extent

[12] Lipophilicity of this compound was approximated on the basis of its high partition coefficient (P.C. heptane/pH 7.0 = 34.2). Partitioning data were generated by the Analytical Research Department.

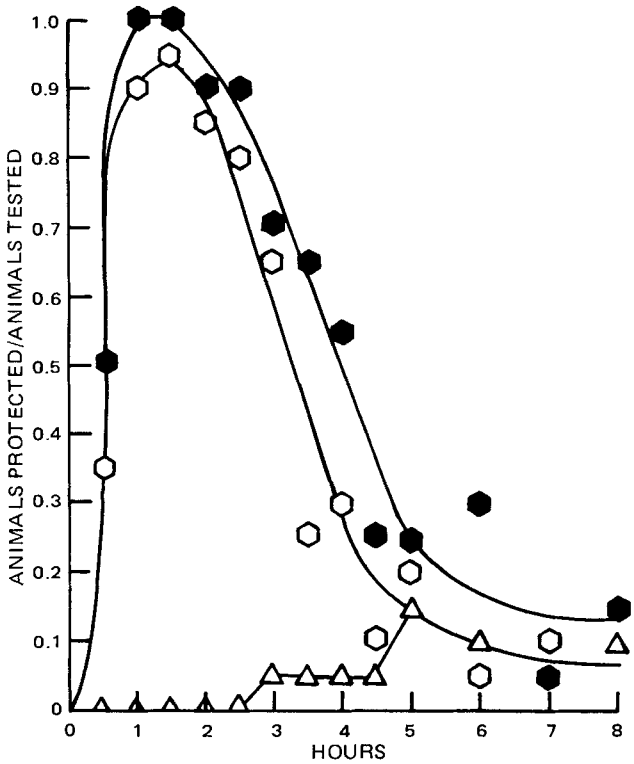

Figure 3—*Time course of pharmacological activity after oral administration of I as an emulsion with corn oil (●), an emulsion with soya bean oil (○), and a solution in corn oil (△).*

of absorption of I can be hindered by this rate-limiting factor. Hence, little or no anticonvulsant effect was observed.

Emulsification of oil in water results in an abundant increase in the surface area of oil, allowing a facile interfacial transport of the anticonvulsant compound from oil to the water phase of the luminal fluid. Under pseudo-sink conditions, rapid absorption of the compound across the intestinal membrane allowed a sufficient concentration to reach the receptor sites, and an optimal duration of anticonvulsant activity was observed.

The foregoing discussion is compatible with the theoretical (16, 21) and observed (17–20, 22) findings on drug delivery from emulsion dosage forms. The medium ED_{50} for a corn oil emulsion was estimated to be 8.3 mg/kg (Table I). It is evident from Fig. 3 that, at 30 min (the time for ED_{50} determination) after oral dosing of the emulsion dosage form, the intensity of the pharmacological response of I was only 50% as compared to the 100% intensity achieved with the drug suspension in normal saline. Thus, to achieve 100% activity at 30 min after dosing, a 16-mg/kg dose of I in the emulsion dosage form is needed. This dose was about 2.6 times higher than that of the suspension dosage form of I. The observed twofold difference between the ED_{50} values for the suspension and the emulsion dosage forms of I may be attributed to the rate-limiting transport of the compound from the oil phase to the aqueous (luminal fluid) phase from which its absorption across the GI tract occurs.

Figure 4 illustrates the effect of sorbitol content (percent w/v) on the apparent ED_{50} of I in mice. A multivariate regression analysis of these data showed that there was an apparent linear relationship (correlation coefficient $r = 0.96$ and residual variance $s^2 = 3.42$) between the observed ED_{50} and the sorbitol content of the dosage form. To test whether or not inclusion of sorbitol in the dosage form modifies the rapidity of onset as well as the duration of anticonvulsant activity of I in mice, experiments were conducted with a suspension dosage form of the compound with varying concentrations of sorbitol (Fig. 5).

The presence of 70% of sorbitol reduced the apparent pharmacological response by as much as 80%. As the concentration of sorbitol in the suspension dosage form was reduced, there was a proportional increase in the rapidity of onset and the duration of pharmacological activity. These results suggest that sorbitol modifies the availability of I for absorption. Animals dosed with distilled water and 70% sorbitol solution and then challenged 0.5 hr later with varying current levels showed no difference in seizure susceptibility. Thus, the possibility of sorbitol interference at the drug receptor sites was ruled out.

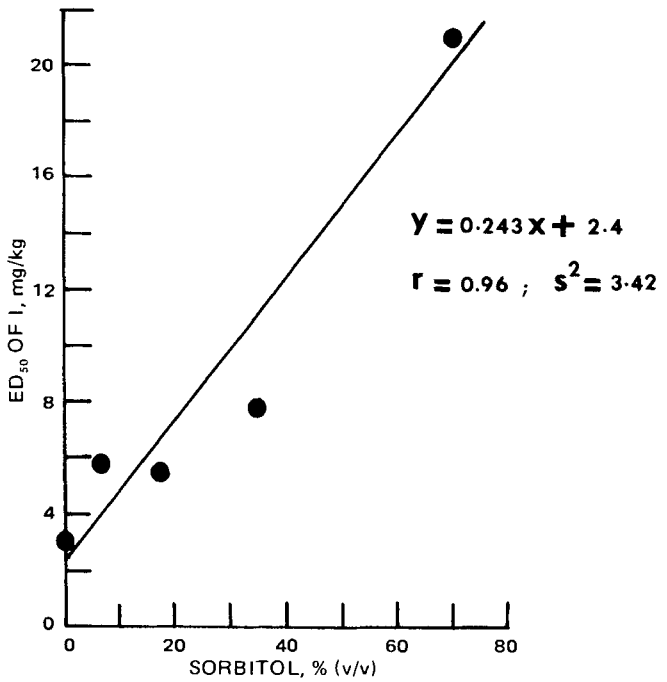

Figure 4—*Effect of sorbitol on the apparent ED_{50} of I in mice.*

Vogel *et al.* (23) reported on the effect of the osmolarity of the instillation fluid on the efficacy and toxicity of drugs given by the intraduodenal route. Administration of drug solutions made hypertonic with mannitol (10–15%) diminished both the efficacy and toxicity of atropine sulfate, pentobarbital sodium, and nicotine. It was concluded that transmucosal movement of fluid from the blood into the intestinal lumen interfered with drug absorption. This finding might explain our observations on the modification of anticonvulsant activity of I in mice in the presence of sorbitol.

Table II illustrates some pharmacokinetic parameters for the anticonvulsant activity of I measured after oral administration of several liquid dosage forms. The time required for peak response of I (T_{max}) showed a range of 0.5–1.5 hr. Emulsification of the drug solution in oil resulted in an increase in this parameter. Whereas the time required for 50% reduction in animal protection ($T_{0.5}$) ranged from 2.45 to 4.0 hr, the presence of a surfactant (emulsifier) at the 0.8% concentration resulted in an appreciable (1.6-fold) decrease in this parameter.

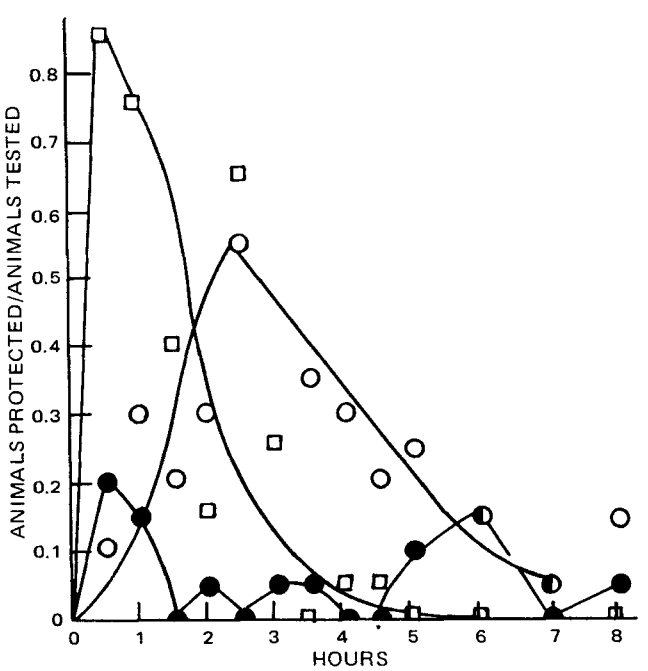

Figure 5—*Time course of pharmacological activity after oral administration of I with 7% (□), 35% (○), and 70% (●) sorbitol in water.*

Table II—Vehicle Effects on the Duration of Anticonvulsant Activity of I

Dosage Form	T_{max}, hr	$T_{0.5}$, hr	$\beta_{apparent}$, $(0.8-0.2)R$
Suspension in normal saline	0.5	4.0	0.265
Suspension in normal saline with 0.8% surfactant	1.0	2.45	0.27
Corn oil emulsion	1.0	3.8	0.26
Soya bean oil emulsion	1.5	3.25	0.24
Corn oil solution	0.5	Not observed	—
Polyethylene glycol (60% v/v) solution	0.5	2.8	0.12
Suspension in 70% sorbitol solution	0.5	Not observed	—

The negative slope, β, of the line (least-squares) drawn between the 80 and 20% response range of the time–response curve was virtually the same except for the polyethylene glycol 400 solutions. The observed constancy of the β-values supports the concept that the rate of decline of the pharmacological effect of a compound is independent of its total amount in the body. The apparent deviation of the β-value estimated for the polyethylene glycol 400 solution is intriguing and may be an artifact of the statistical analysis of the observed data. Binding of I to the polymer (polyethylene glycol 400) may have resulted in erratic absorption of this compound. This could contribute to fluctuations in drug availability at the receptor sites and, consequently, to a decrease in the β-value.

In conclusion, this study has shown that oral administration of I in different liquid dosage forms modified its anticonvulsant activity in mice. The intensity of onset and the duration of the pharmacological activity were affected depending on the liquid vehicle used.

Use of Anemic Piglet to Assess Bioavailability of Iron from Oral Iron Preparations

A. P. INTOCCIA [x], S. S. WALKENSTEIN, R. W. WITTENDORF, R. C. HOPPE, and S. M. FREE

Abstract □ Except for methods using long-lived iron isotopes, there are no reliable means for assessing the bioavailability of iron from oral preparations in human subjects. Use of the anemic piglet as an alternative means was studied. When piglets were made anemic on a commercial milk diet and then dosed with solutions of 1, 2, and 5 mg/kg of ferrous sulfate/day, a dose-related recovery of hematocrit and hemoglobin levels resulted. The most sensitive dose range for use in a bioavailability study of iron was between 1 and 2 mg of iron/kg/day when using these parameters. A study carried out using this method indicated that the iron from a delayed-release capsule and from a ferrous sulfate solution was equally bioavailable. Hemoglobin and hematocrit recovery rates of the anemic piglet were shown to be reliable and sensitive indicators of the bioavailability of iron from various iron dosage forms.

Keyphrases □ Iron—bioavailability, ferrous sulfate delayed-release capsule compared to solution, piglets □ Ferrous sulfate—bioavailability, delayed-release capsule compared to solution, piglets □ Bioavailability—ferrous sulfate delayed-release capsule compared to solution, piglets □ Hematinics—ferrous sulfate, bioavailability, delayed-release capsule compared to solution, piglets

Absorption of iron from the GI tract is regulated by multiple factors, including the amount of iron stored in the body, the degree of hematopoietic activity present, and the amount of iron ingested. For example, an increase in iron absorption takes place if iron is fed orally (1). A study designed to measure the bioavailability of iron from different pharmaceutical iron preparations in human subjects would present many problems, since all of these regulatory factors

Absorption of iron from the GI tract is regulated by multiple factors, including the amount of iron stored in the body, the degree of hematopoietic activity present, and the amount of iron ingested. For example, an increase in iron absorption takes place if iron is fed orally (1). A study designed to measure the bioavailability of iron from different pharmaceutical iron preparations in human subjects would present many problems, since all of these regulatory factors

would have to be controlled to the same extent in all subjects. With a double isotope technique, these problems were circumvented by using each subject as his own control (2, 3). With this technique, differences in iron absorption of various iron salts could be measured. The disadvantages of this method were that radioisotopes had to be used in human subjects and one of the isotopes, iron-55, has a half-life of 2.7 years.

Hemoglobin and/or red cell regeneration studies can be used as an indirect measure of iron bioavailability, but both require the rigid control of iron intake as well as the use of individuals depleted of body iron stores. These conditions are difficult to control in human subjects but can be readily achieved in animals. Several studies (4–6) indicated that suckling pigs rapidly become anemic if they are kept from ingesting soil and maintained solely on a milk diet. Furthermore, this anemia can be satisfactorily controlled by iron supplementation. Kolb (7), in a review of iron metabolism of various domesticated animals, showed that serum iron, iron binding capacity, and serum iron response to iron dosing in the pig is comparable to these parameters in humans. The data in this paper indicate that the anemic pig provides a reasonably alternative means of assessing iron bioavailability that is both reliable and sensitive.

EXPERIMENTAL

Littermate piglets, both male and female, from a crossbred dam (Chester White, Hampshire, Duroc) and a purebred Chester sire[1] were used. Animals were individually housed in galvanized steel monkey cages equipped with nursing bottle holders and rubber mesh floor padding. Room temperature was maintained between 27 and 30°.

A commercial modified milk product[2] at room temperature was placed in disposable-bag, plastic nursing bottles[3]. Piglets were encouraged to suckle by patient hand feeding during the first few days. During this time, the deciduous "needle" teeth were clipped from all animals. In the initial days of the study, it was sometimes necessary to feed this formula to reluctant feeders by stomach tube. The formula was eventually available to the piglets on an *ad libitum* basis.

Blood samples were taken from superficial abdominal skin veins (superficial epigastric) and occasionally, as animals grew older, from ear veins. Enough blood was taken to fill a No. 23, 25-mm disposable needle.

Hematocrit was determined in duplicate using a microhematocrit system[4]. Tubes were spun 4 min and read immediately.

Hemoglobin was measured using a disposable pipet kit[5]. After color development, samples were read on a spectrophotometer at 540 nm, and unknown samples were compared to a standard curve made from a certified cyanomethemoglobin standard[6].

The ferrous sulfate used was the reagent grade heptahydrate[7]. Solutions were made up fresh daily in distilled water. The delayed-release iron formulation used was a commercially available product[8]. The method used was as follows. Piglets, 5 days old, without prior iron supplementation, were fed a commercial modified milk product. When at least two piglets reached the desired level of anemia (approximately 6.5 g/100 ml of hemoglobin and 21% hematocrit) and remained at this level for 2 consecutive days, the animals were placed into the ferrous sulfate or the delayed-release capsule group. If three piglets became simultaneously available, the third animal was placed into a control (no iron) group. Where possible, paired animals of the same sex were used. The selection continued until all animals had been assigned to groups.

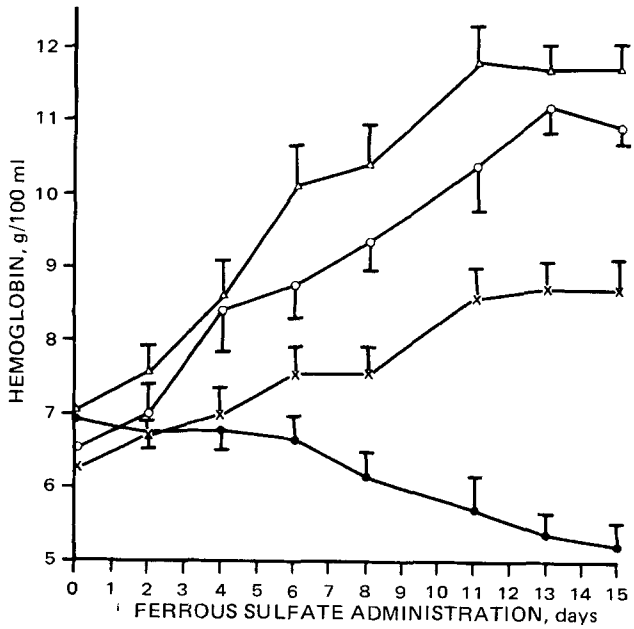

Figure 1—*Mean hemoglobin levels of anemic piglets following oral administration of various doses of iron administered as a ferrous sulfate solution. Each point represents the mean of six piglets* ± SEM. *Key:* △, *5 mg of iron/kg/day;* ○, *2 mg of iron/kg/day;* ×, *1 mg of iron/kg/day; and* ●, *controls (no iron).*

The animals were fed the iron doses daily and, based upon daily body weight, received doses of 1.5 mg of iron/kg as either ferrous sulfate solution or as the delayed-release capsule formulation. The capsule formulation was scaled individually to the weight of each piglet. Blood samples were taken on the 7th and 9th days of iron administration for measurement of both hemoglobin and hematocrit.

RESULTS

Preliminary Studies—To arrive at the final experimental design, preliminary studies had to be carried out to establish the optimum amount of iron for dosing, the iron dosing schedule, and the blood sampling periods necessary to provide a sensitive, comparative assessment of iron bioavailability.

To the uninitiated who desire to use the piglet as an experimental animal, an initial purchase of only two or three animals is suggested to enable laboratory personnel to become familiar with methods of handling, feeding, dosing, and bleeding these animals. With such a starter group, piglets under laboratory conditions were able to survive, grow, and, in the process, rapidly become anemic when fed a diet consisting solely of a commercial modified milk product. Oral administration of sufficient quantities of ferrous sulfate reversed the anemia, as measured by hematocrit and hemoglobin changes.

A second group of piglets was studied when only 24–48 hr old. Animals this age were obtained to avoid the possibility of their having been inadvertently dosed with iron by the supplier. However, an unbelievable amount of constant care was necessary to maintain this age piglet when away from the sow. During this study, one-third of the animals were lost, mostly from severe diarrhea and/or lack of appetite. A few preliminary dosing studies were carried out with the survivors.

When values of both hemoglobin and hematocrit indicated that the animals were anemic, single doses of iron as solutions of ferrous sulfate heptahydrate were administered. A single dose of 2, 10, or 20 mg/kg produced only small, inadequate responses in hematocrit and hemoglobin levels. However, chronic daily dosing of 1, 2, and 5 mg/kg showed promise of a dose–response in both hematocrit and hemoglobin levels. Chronic doses of 10 and 40 mg/kg caused hematocrit and hemoglobin values to rise no higher than did the 5-mg/kg doses. These data indicated that iron between 5 and 10 mg/kg exceeded the iron absorptive rate or the hemoglobin regeneration rate of the piglet and that the desirable dose range for a comparative bioavailability study was 1–5 mg/kg/day.

A third preliminary study was carried out to test this chronic dosing range for a dose–response and sensitivity as well as to determine if slightly older piglets would show an increased survival rate. Twenty-eight piglets were allowed to stay with the sow until 5 days old. These "older" piglets

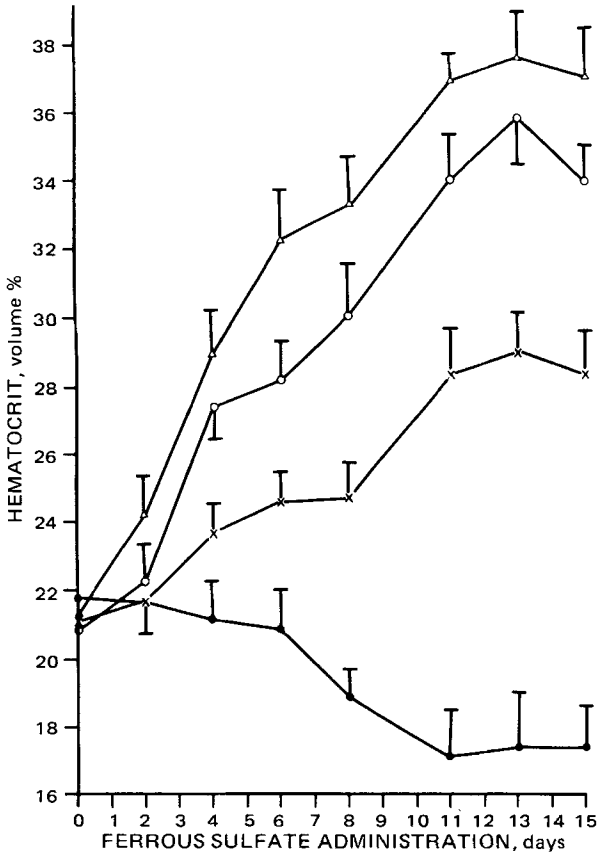

Figure 2—*Mean hematocrit values of anemic piglets following oral administration of various doses of iron administered daily as a ferrous sulfate solution. Each point represents the mean of six piglets* ± SEM. *Key:* Δ, *5 mg of iron/kg/day;* O, *2 mg of iron/kg/day;* ×, *1 mg of iron/kg/day; and* ●, *controls (no iron).*

were healthier and much easier to keep alive; only one of the 28 died. As groups of these piglets became anemic, they were placed into dose groups of 1, 2, and 5 mg of iron/kg. Animals were then dosed daily, and hematocrit and hemoglobin values were determined at frequent intervals.

Figures 1 and 2 show the results obtained. The control values indicated that piglets maintained on the low iron diet remained anemic during the entire experimental period. The data were analyzed statistically, and results are presented in Table I.

The dose of 1.5 mg of iron/kg was chosen for use in a subsequent iron bioavailability comparison study since it fell within the most sensitive detection range. Days 7 and 9 of a daily iron dosing regimen were chosen as hematocrit and hemoglobin measurement periods. Two measurement periods were chosen to assure that hemoglobin and hematocrit levels were monitored during a rising portion of the response curve and not during a plateau period. This criterion is important to establish because a plateau would indicate a maximized hemoglobin and hematocrit response to iron intake, rendering these parameters incapable of rapidly responding to varied levels of iron intake. Once this criterion was established, Day 7 and 9 values could be used individually or averaged for comparative iron bioavailability studies.

Comparison of Iron Bioavailability from Two Different Iron Dosage Forms—Based upon the preliminary studies, a comparative bioavailability study was carried out as outlined under *Experimental.* This study compared the bioavailability of iron from a delayed-release capsule form to similar doses of iron fed as a ferrous sulfate solution.

Thirteen pairs of pigs were assigned to the iron formulations along with six (no iron) controls for each group. Within a pair, both pigs were from the same litter and started on the iron formulation at the same time. Where possible, the same sex was studied as a pair. Table II reports the values obtained.

The results for Days 7 and 9 are reported individually to show that both hematocrit and hemoglobin values were changing in this interval. The differences obtained between Days 7 and 9 were statistically significant for both parameters, confirming that the study did not compare formulations when values were on or near a plateau. The average hemoglobin

[a] Data adjusted by analysis with a multiple regression model that accounted for differences due to litter and starting baseline. Data prior to statistical adjustment are shown in Figs. 1 and 2. [b] Each value represents average of six piglets. [c] *, $p < 0.05$; **, $p < 0.01$; and ---, not significant.

values of 9.12 g/100 ml following the delayed-release capsule and 8.83 g/100 ml following ferrous sulfate solution were not significantly different. Therefore, one can conclude that the bioavailability of iron from the delayed-release capsule was equivalent to that of the ferrous sulfate solution.

Table II—Hemoglobin and Hematocrit Levels in Anemic Piglets following Daily Administration of 1.5 mg of Iron/kg as Either a Delayed-Release Capsule[a] or a Ferrous Sulfate Solution

	Delayed-Release Pelletized Iron Capsule[a]		Ferrous Sulfate Heptahydrate in Solution

[a] Feosol Spansule Capsule, Smith Kline & French Laboratories. [b] To account for design variables and to adjust all results to a common baseline, all data were analyzed with a multiple regression model that accounted for differences due to litter and starting baselines. This produced the "adjusted means." Differences between Day 7 and 9 levels were significant in all cases. [c] All control values represent the mean of six piglets. All other values represent the mean of 13 piglets. [d] This value was significantly higher than hematocrit produced by ferrous sulfate administration, $p < 0.05$. Hemoglobin levels following either dose form were not significantly different. A difference of only 0.44 g of hemoglobin/100 ml would have been significant.

Comparison of hematocrits showed that average values obtained following the delayed-release capsule (32.4%) and following ferrous sulfate (31.1%) were statistically significant ($p < 0.05$). This finding indicated that the bioavailability of iron from the delayed-release capsule was equivalent to, and perhaps somewhat better than, ferrous sulfate solution when using hematocrit regeneration as an index of bioavailability. A difference of 1.2 hematocrit units (only 3.6% of the average hematocrit) would have been statistically significant. The careful selection of a dose of iron that was below the maximum capable of being absorbed by the gut and the regenerating capacity of the bone marrow was probably an important reason for the success of this approach to iron bioavailability methodology. The method demonstrated that delaying the release of iron in the pelletized iron preparations tested in no way impaired its bioavailability.

Antibacterial Structure–Activity Relationships Obtained with Resistant Microorganisms I: Inhibition of R-Factor Resistant *Escherichia coli* by Tetracyclines

G. H. MILLER [x], H. L. SMITH, W. L. ROCK, and S. HEDBERG

Abstract □ Apparent partition coefficients and inhibitory activities against sensitive and resistant *Escherichia coli* were determined for 14 tetracyclines. The difference in the kinetics of inhibition of the two organisms is discussed in terms of their permeabilities. The partition coefficients were determined in an octanol–buffer system. Values for eight compounds were in general agreement with the literature; values for the remaining six compounds had not been reported previously. Growth of the organisms was determined by a single-point turbidimetric method in the presence and absence of tetracyclines. Inhibitory activities were obtained by a kinetic treatment. Derived rate constants for the sensitive organism were linearly related to antibiotic concentration. For the resistant organism and 12 compounds, the derived rate constants and antibiotic concentration were related in a manner typical of saturation kinetics. These inhibitory activities were related to the partition coefficients, while activities against the sensitive strain were not. These findings suggest that activity against the resistant strain is permeability controlled but that activity against the sensitive strain has a different rate-determining step.

Keyphrases □ Antibacterial activity—various tetracyclines, related to partition coefficients, resistant and sensitive microorganisms, structure–activity relationships □ Tetracyclines, various—antibacterial activity, related to partition coefficients, resistant and sensitive microorganisms, structure–activity relationships □ Partition coefficients—various tetracyclines, related to antibacterial activity, resistant and sensitive microorganisms □ *Escherichia coli*—resistant and sensitive, inhibition by various tetracyclines, related to partition coefficients, structure–activity relationships □ Structure–activity relationships—various tetracyclines, antibacterial activity, resistant and sensitive microorganisms

The development of safe, effective antimicrobial drugs has revolutionized medicine in the last 30 years. Unfortunately, microorganisms are highly versatile, and the brilliance of the chemotherapeutic achievement has been dimmed by the emergence of microbial strains resistant to these drugs. This emergence of resistant pathogens is becoming an increasingly important problem. In addition to limiting the use of antibiotics, two possible approaches to the problem would be to seek entirely new antibacterial agents and to modify existing chemotherapeutic agents. The latter approach has the advantage that derivatives of present chemotherapeutic agents are likely to retain the high benefit to risk ratios of the parent drugs.

The general mechanisms by which microorganisms may become resistant to antibiotics were summarized (1), and the one where drug modification might effectively overcome drug resistance is the loss of cell permeability to the drug. Changes in the physicochemical nature of a drug resulting in decreased or increased cell permeabilities were described for many systems (2).

Davies (3) stated that, as far as can be ascertained, all tetracycline-resistant strains obtained from clinical situations are resistant because they carry an R-factor. The nature of R-factor resistance to tetracyclines was investigated extensively and reviewed (4, 5). These studies indicate that tetracycline resistance is related to a decreased uptake of tetracyclines by resistant cells. Several investigators showed that cell-free protein-synthesizing systems from sensitive and resistant strains were equally inhibited by tetracyclines (6–8).

Escherichia coli accumulated oxytetracycline at high concentrations (9), and this accumulation was inhibited by azide and 2,4-dinitrophenol and was dependent upon the energy source in the medium. Similar observations

Comparison of hematocrits showed that average values obtained following the delayed-release capsule (32.4%) and following ferrous sulfate (31.1%) were statistically significant ($p < 0.05$). This finding indicated that the bioavailability of iron from the delayed-release capsule was equivalent to, and perhaps somewhat better than, ferrous sulfate solution when using hematocrit regeneration as an index of bioavailability. [a] These compounds had a linear relationship between tetracycline concentration and derived rate constants for growth of the resistant strain. [b] Samples of these compounds varied in the observed partition coefficients obtained at different wavelengths, so values for these compounds have not been used.

were reported with tetracycline and chlortetracycline at low concentrations (7). The resistance was associated with a marked decrease in the ability of *E. coli* to accumulate tetracyclines (7, 10–12). Similarly, Sompolinsky *et al.* (13) found a decreased uptake in resistant staphylococci, and Tseng and Bryan (14) noted decreased uptake of tetracycline in resistant *Pseudomonas* strains. The uptake of tetracycline by sensitive and resistant *E. coli* was correlated to the minimum inhibitory concentrations of the strains studied (15).

The exact mechanism of the uptake of tetracyclines by sensitive cells is not yet established. It was suggested that accumulation in *Staphylococcus aureus* follows saturation kinetics initially but that a multiplicity of sites becomes available at high antibiotic concentrations and antibiotic concentration becomes limiting (16). The uptake of tetracyclines by *E. coli* as a function of tetracycline concentration was reported to be biphasic (17). Resistance was suggested to be associated with a requirement for higher antibiotic concentrations before the second mode of accumulation became operative. However, Reynard and Nellis (18) were unable to find the initial phase of saturation kinetics in *E. coli*.

Regardless of the exact mechanism, tetracycline resistance probably is associated with a reduced ability to accumulate the antibiotic within the resistant cells. If this assumption is true, then alteration of the balance of water–lipid solubility of the antibiotics might lead to improved permeation by passive diffusion. As lipophilicity increased in a series of tetracycline derivatives, their activity against a tetracycline-resistant *S. aureus* increased (19). Furthermore, recent activity determinations (20) using various resistant *Staphylococcus* strains were also in general agreement with this principle. The present work extends these findings to R-factor resistant *E. coli* in a quantitative fashion.

EXPERIMENTAL

Materials—A tetracycline-sensitive *Escherichia coli* W (ATCC 9637) and a tetracycline-resistant *Escherichia coli* (ATCC 19215, recipient of an R-factor conferring multiple resistance to tetracycline, chloramphenicol, streptomycin, and sulfonamides) were used as test organisms. A high level of tetracycline resistance was induced in the R-factor strain by subculturing it in the presence of tetracycline (12). The culture broth was a high peptone medium buffered at pH 6.65 with potassium salts of phosphoric acid as previously described (21).

Samples of tetracycline, oxytetracycline, and chlortetracycline were purchased[1]; the remaining derivatives were supplied by the manufacturers[2]. Apparent partition coefficients were determined between a pH 6.6 phosphate buffer and 1-octanol[3]. Buffer solutions were prepared with the potassium salts of phosphoric acid and adjusted to an ionic strength of 0.1 *M* with sodium chloride. The water used in these solutions had been redistilled from an all-glass still[4].

Determination of Apparent Partition Coefficients of Tetracycline Analogs—A solution of the tetracycline under study was prepared in buffer saturated with octanol (buffer phase). Sufficient quantities of this solution were placed in 50-ml glass-stoppered centrifuge tubes so that the final concentration was 0.5 m*M* when the volume of solution was brought to 10 ml by the addition of buffer phase. Exactly 10 ml of octanol saturated with buffer (octanol phase) was added to each tube. Duplicate tubes were prepared for each tetracycline analog studied as well as blank tubes containing only buffer phase and octanol phase.

The capped tubes were mounted horizontally in a shaker[5] and vigorously shaken for 10 min. After centrifuging at 1500 rpm for 20 min, a sample of the buffer phase was carefully removed from each tube with a syringe equipped with a 15.2-cm (6-in.) 20-gauge needle. Aliquots of these samples as well as aliquots of the original tetracycline analog solutions were diluted with buffer phase and assayed spectrophotometrically[6]. Absorption measurements were made at wavelengths corresponding to the tetracycline peaks in the regions of 275 and 350 nm and at maxima and/or minima at about 250 and/or 450 nm, if they existed for the derivative. After correcting for blank readings, the absorbance values obtained at each wavelength for each sample and the absorbance values for its corresponding original solution were used to calculate the concentrations of tetracycline analog in both the buffer and octanol phases.

The apparent partition coefficients reported are average values obtained at all wavelengths studied (Table I). The agreement of partition coefficients obtained at several wavelengths for the tetracycline analogs is taken as an indication of their high degree of purity. Accordingly, the values obtained for two of the analogs studied are not reported since the apparent partition coefficients varied as a function of wavelength.

Inhibitory Activity Determinations with Tetracycline-Sensitive *E. coli* W—The inhibitory activities with the sensitive *E. coli* W were determined for tetracycline and its 15 analogs according to the following

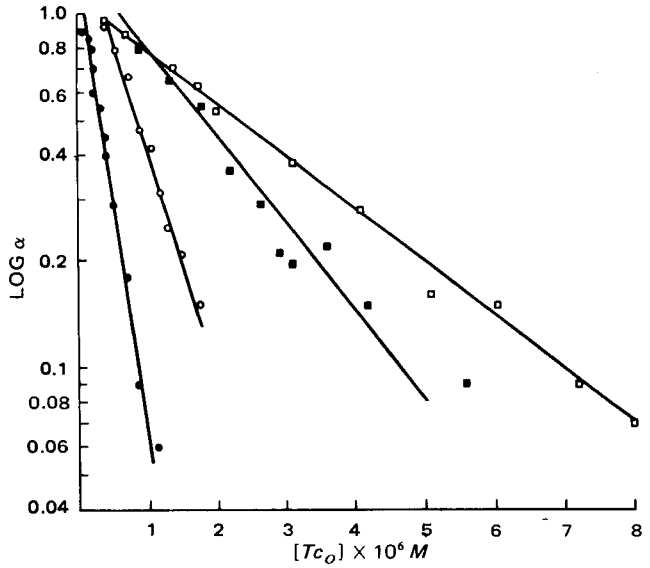

Figure 1—*Fractional activity against tetracycline sensitive* E. coli *W as a function of the concentration of tetracycline analogs. Key:* ●, *7-nitro-6-demethyl-6-deoxytetracycline;* ○, *oxytetracycline;* ■, *6-demethyl-6-deoxytetracycline; and* □, *9-nitro-6-demethyl-6-deoxytetracycline.*

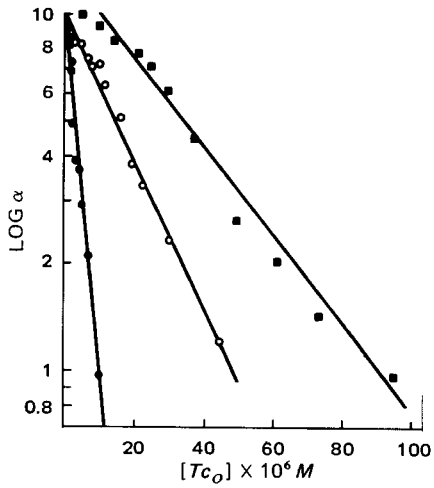

Figure 2—*Fractional activity against tetracycline-resistant* E. coli R^+ *as a function of the concentration of tetracycline analogs. Key:* ●, *5a(6)-anhydrotetracycline;* ○, *4-dedimethylaminotetracycline; and* ■, *12a-deoxytetracycline.*

procedure. Aliquots of a tetracycline analog solution were added to 3 ml of broth in sterile 6-ml capped tubes[7] so that a range of 12 tetracycline concentrations was obtained. Duplicate tubes were prepared and run for all analog concentrations. An overnight peptone broth culture of *E. coli* W was diluted with fresh broth so that a concentration of 1×10^7 *E. coli* W/ml was obtained when an aliquot (5, 10, or 20 μl) was added to each of the 24 tubes containing tetracycline and to two tubes without tetracycline.

The tubes were incubated for 3.5 hr at 37.5° in a constant-temperature water bath. Growth was stopped by the addition of 20 μl of formaldehyde solution. The turbidity of the cultures was determined[6] at 500 nm. The fractional activity, α, was calculated from the ratio of the turbidity of a culture grown in the presence of the tetracycline analog to that obtained for cultures without antibiotic. If one assumes that the turbidity of the cultures is proportional to the number of organisms per milliliter of culture and that growth of the cultures in the presence and absence of tetracyclines is first order in organisms per milliliter (21), then the logarithm of α is proportional to the difference in the growth rate constants in the presence (k_{app}) and absence (k_0) of antibiotic.

Inhibitory Activity Determinations with Tetracycline-Resistant *E. coli*—Inhibitory activities with the resistant *E. coli* were determined for tetracycline and its 14 analogs by the same procedure as that outlined for the sensitive organism except: (*a*) the overnight culture was 320 μ*M* in tetracycline, (*b*) the volume of the overnight culture added to the experimental cultures was between 100 and 300 μl, and (*c*) the time of incubation was 5 hr instead of 3.5 hr.

RESULTS AND DISCUSSION

Apparent Partition Coefficients of Tetracycline Analogs—Colaizzi and Klink (22) reported the apparent partition coefficients of a number of tetracycline analogs at several pH values, including 6.6. Their work was extended by determining the apparent partition coefficients of six compounds not available to those authors. In addition, the values reported by Colaizzi and Klink were verified for eight tetracycline analogs (Table I). The most lipophilic tetracycline analog studied was 5a(6)-anhydrotetracycline, with an apparent partition coefficient (K_p) of 6.0; the most hydrophilic studied was 5a(11)-dehydro-7-chlorotetracycline (K_p = 0.057). Agreement with reported values (22) was excellent except for the most hydrophilic derivatives (tetracycline and oxytetracycline), where the experimental error involved might be expected to be highest for procedures in which only the aqueous phase of the biphasic system is assayed.

As already mentioned, the agreement of apparent partition coefficients calculated at different wavelengths was excellent for the tetracyclines reported, indicating a high degree of purity. Two samples of 7-bromo-6-demethyl-6-deoxytetracycline were examined and showed considerable variation in the apparent partition coefficients calculated at the different wavelengths. Values for this compound as well as a similarly behaving sample of 12a-deoxytetracycline are not reported. The biological activity of these samples (Table I) is, however, similar to that reported (19).

Inhibitory Activities of Tetracycline Analogs against Sensitive *E. coli*—Initial estimates of the activities of the derivatives were made by plotting fractional activities, α, *versus* antibiotic concentration and estimating the concentration of antibiotic that would cause a 50% inhibition of growth. However, it became apparent that plots of log α *versus* antibiotic concentration were linear for all of the compounds studied with the tetracycline-sensitive organism, *E. coli* W (Fig. 1). This finding can be explained if it is assumed that the turbidity of the cultures is proportional to the number of cells per milliliter of culture (N) and that growth is first order for the period of incubation in N, both in the presence ($N = N_0 e^{k_{app} t}$) and absence ($N = N_0 e^{k_0 t}$) of antibiotic. Since N_0 is the same for both cultures, log α becomes equal to $2.3t(k_{app} - k_0)$. It was shown previously that for tetracycline inhibiting *E. coli* B/r (23) and for tetracycline analogs inhibiting *E. coli* W (21):

$$k_{app} = k_0 - K(Tc) \qquad \text{(Eq. 1)}$$

where (Tc) is the concentration of tetracycline analog, and K is a constant typical of the tetracycline analog. Rearrangement of Eq. 1 shows that a plot of log α *versus* (Tc) should be linear. The data suggest that these assumptions are true for all tetracycline derivatives studied with *E. coli* W. The negative slopes of such plots (Fig. 1) were evaluated, and the values obtained for each analog are listed as K_{sens} values in Table I. These activities were in substantial agreement with those previously published for these compounds and this organism but obtained by the more rigorous methods of bacterial growth kinetics (21). This agreement is shown by:

$$K_{sens} = -9.347 + 482.1\, K^I_{avg} \qquad r = 0.98\ n = 15 \qquad \text{(Eq. 2)}$$

where K^I_{avg} is the K of Eq. 1 obtained from kinetic measurements of cell division (total and viable), nucleic acid synthesis, and protein synthesis.

Inhibitory Activities of Tetracycline Analogs against Resistant *E. coli*—The *E. coli* employed was resistant to tetracycline to the extent that the concentration of tetracycline causing a 50% inhibition in growth in the test system was about 175 times greater than that necessary to inhibit *E. coli* W. In contrast to the results already described for *E. coli* W, plots of log α *versus* (Tc) were only linear for four tetracycline analogs (Fig. 2). In addition to the three compounds shown on this figure, 5a(11)-dehydro-7-chlorotetracycline also exhibited a linear relationship between log α and tetracycline concentration. Because of their extremely weak activity, it was not possible to determine the relationship between log α and tetracycline concentration for isochlortetracycline and tetracycline methiodide over a wide range of inhibition, but preliminary experiments indicated that they might also have a linear relationship. All

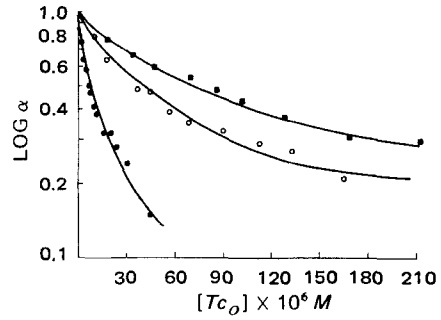

Figure 3—*Fractional activity against tetracycline-resistant* E. coli R^+ *as a function of the concentration of tetracycline analogs. Key:* ●, *6-demethyl-6-deoxytetracycline;* ○, *chlortetracycline; and* ■, *demeclocycline.*

of these compounds are unusual tetracyclines in that either their phenyl diketone moiety or their 4-dimethylamino moiety is modified. These moieties are usually considered to be essential for tetracycline-like activity. However, the activities of these compounds against sensitive *E. coli* W are correlatable with their physicochemical properties (24).

Plots of log α *versus* tetracycline concentration for the remaining 12 compounds studied were not linear, as shown for three of the compounds in Fig. 3. The curvature of these plots suggested that a data treatment typical of saturation kinetics would be useful. Plots of $-(1/\log \alpha)$ *versus* $1/(Tc)$ and of $-[(Tc)/\log \alpha]$ *versus* (Tc) were linear for these compounds. These plots would be expected to be linear if the assumptions given that allow log α to be related to $k_{app} - k_0$ are true and if the more complicated expression:

$$k_{app} = k_0 - K_a(Tc)/1 + K_b(Tc) \qquad \text{(Eq. 3)}$$

is applicable instead of Eq. 1. Such an expression has not been reported as being applicable to tetracycline activities, but similar expressions are known to apply to other antibacterial agents such as sulfonamides (25, 26), trimethoprim (26), and erythromycin (27) and to certain phases of lincomycin inhibition (27). Examples of the fit of the data to Eq. 3 are shown in Figs. 4 and 5. In general, the linearity of these lines is excellent considering the assumptions in the data treatment. Inhibitory activities, K_{R^+}, derived from the slopes and intercepts of the plots are given in Table I.

As might be expected, the activities against the sensitive strain were not related to the activities obtained with the resistant strain, as shown by:

$$K_{R^+} = 0.96 - 0.057\,K_{sens} \qquad r = -0.15 \quad n = 15 \qquad \text{(Eq. 4)}$$

Structure–activity relationships using activities obtained with sensitive strains (28, 29) would not be expected to be valid for resistant strains. Blackwood and English (19) suggested a qualitative relationship between activities obtained against a resistant *Staph. aureus* and lipophilicity. Our data show a quantitative relationship between tetracycline activity against the resistant *E. coli* and lipophilicity, as given in Eq. 5 and shown graphically in Fig. 6:

$$\log K_{R^+} = 1.98 + 1.74 \log K_p \qquad r = 0.918 \quad n = 11 \quad F_9^1 = 48.5 \qquad \text{(Eq. 5)}$$

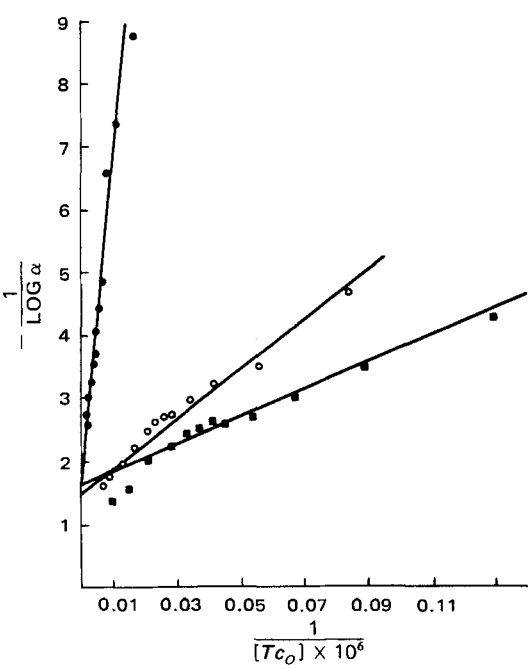

Figure 4—*Relationship between fractional activity against tetracycline-resistant* E. coli R^+ *and the concentration of tetracycline analogs. Key:* ●, *7-amino-6-demethyl-6-deoxytetracycline;* ○, *9-amino-6-demethyl-6-deoxytetracycline; and* ■, *7-nitro-6-demethyl-6-deoxytetracycline.*

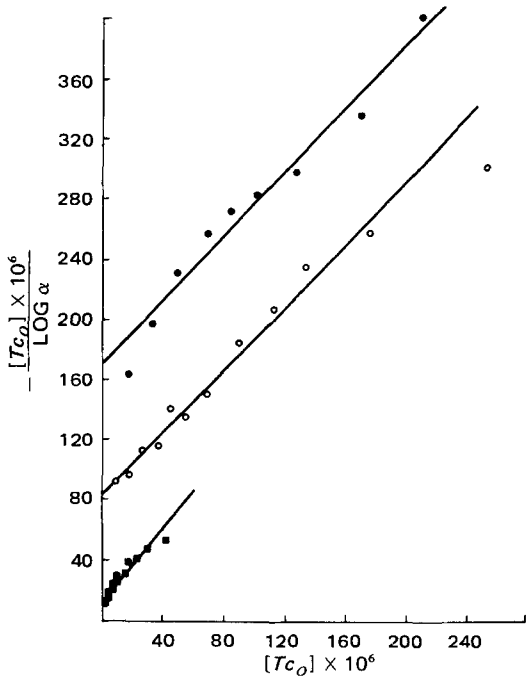

Figure 5—*Relationship between fractional activity against tetracycline-resistant* E. coli R^+ *and the concentration of tetracycline analogs. Key:* ●, *6-demethyl-6-deoxytetracycline;* ○, *chlortetracycline; and* ■, *demeclocycline.*

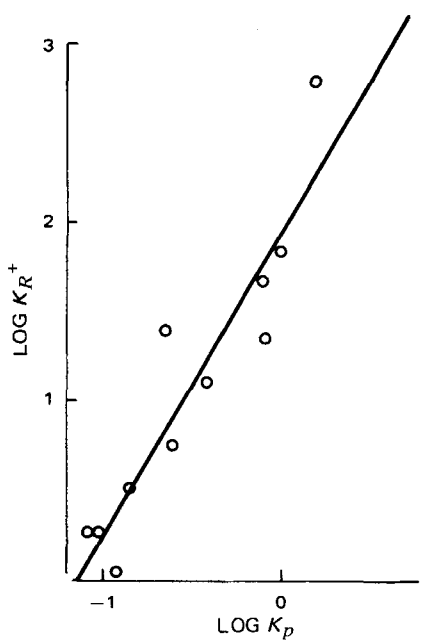

Figure 6—*Relationship of inhibitory activities against tetracycline-resistant* E. coli R^+ *and partition coefficients of tetracycline analogs.*

Inclusion of higher order terms in log K_p did not improve the fit of the data, nor did such expressions allow the fit of the compounds that were typified by a linear relationship between log α and tetracycline concentration. In addition, inclusion of several reported quantum mechanical parameters (24) for tetracyclines did not improve the fit of the data. The activities of the tetracycline antibiotics with intact phenyl diketone and 4-dimethylamino moieties against resistant *E. coli* probably are directly related to their lipophilicity. The compound that had the highest partition coefficient and the highest activity of those studied was 7-dimethylamino-6-demethyl-6-deoxytetracycline (minocycline).

Model of Tetracycline Inhibitory Activity—A reasonable explanation of the discussed structure–activity relationships may be derived from the model given by Garrett (30) or Peradejordi *et al.* (24). In this model, tetracycline outside the cell (Tc_o) is considered to permeate the cell wall (Tc_i) and then to react with a receptor reversibly in such a manner that growth is inhibited according to Schemes I and II:

$$Tc_o \underset{}{\overset{K_1}{\rightleftharpoons}} Tc_i$$

Scheme I

$$Tc_i + \text{receptor} \overset{K_2}{\rightleftharpoons} Tc_i\text{–receptor}$$

Scheme II

If one assumes that the generation of *E. coli* is related to the fraction of free receptors as given by:

$$dN/dt = k_o(1 - \theta)N \qquad \text{(Eq. 6)}$$

where θ is the fraction of receptors occupied by tetracyline, then Schemes I and II and Eq. 6 may be rearranged and related to the experimentally observed growth rate constant, k_{app}, as follows:

$$k_{app} - k_o = -\frac{k_o K_1 K_2 Tc_o}{1 + K_1 K_2 Tc_o} \qquad \text{(Eq. 7)}$$

Equation 7 is similar to Eq. 3, but K_a is now considered to be $k_o K_1 K_2$ and K_b is $K_1 K_2$.

The linear relationship between log α and tetracycline concentration found for *E. coli* W and for four tetracyclines with the resistant *E. coli* results when $K_1 K_2 Tc$ is less than 1. Under these conditions, the K_{sens} values reported are equal to $k_o K_1 K_2$.

In contrast, the complete expression is necessary to fit the data obtained for the 12 tetracyclines with normal phenyl diketone and 4-dimethylamino moieties against the resistant *E. coli*. The reported inhibitory activity, K_{R+}, would be equal to $K_1 K_2$ if this simple model is correct. Since the two activities are not related (Eq. 4) and since K_{R+} is related to the partition coefficients (Eq. 5), it seems logical that K_{sens} is controlled by K_2 and that K_{R+} is controlled by K_1. Thus, the resistance to tetracyclines is associated with a change in the rate-determining step from one involving the receptor to one involving permeation into the cell, consistent with previously published theories of tetracycline resistance (3).

The four compounds with abnormal phenyl diketone or 4-dimethylamino moieties are compounds with intrinsically low activities and, in two cases, very high apparent partition coefficients. Thus, for these compounds, K_2 continues to be the rate-controlling step in the inhibition of resistant *E. coli*.

Role of Neuronal and Extraneuronal Uptake in Responses of Rabbit Iris Dilator Muscle to Levarterenol and Phenylephrine

JAMES L. MATHENY, GERALD O. CARRIER, and RAYMOND P. AHLQUIST ˣ

Abstract □ The roles of neuronal and extraneuronal uptake mechanisms in the response of iris dilator muscles of rabbit to levarterenol (norepinephrine) and phenylephrine were investigated. Chemical denervation with 6-hydroxydopamine was used to eliminate neuronal uptake. Exposure to corticosterone prior to and during exposure to levarterenol or phenylephrine was used to assess the importance of extraneuronal uptake. Dose–response curves and ED_{50} values for levarterenol or phenylephrine in control and 6-hydroxydopamine-denervated tissues, both in the presence and absence of corticosterone, are shown. Curves illustrating the decay of tension on washout of levarterenol or phenylephrine from treated tissues were analyzed. 6-Hydroxydopamine denervation affected the response to levarterenol more than that to phenylephrine. Washout of both agonists was slower after 6-hydroxydopamine pretreatment, and washout of phenylephrine was more rapid when corticosterone was present. These data indicate that extraneuronal uptake in iris dilator muscles was more important in determining the response to phenylephrine than to levarterenol and that neuronal uptake was more important in determining tissue responsiveness to levarterenol than to phenylephrine.

Keyphrases □ Levarterenol—effect on iris dilator muscle response, roles of neuronal and extraneuronal uptake mechanisms, rabbits □ Phenylephrine—effect on iris dilator muscle response, roles of neuronal and extraneuronal uptake mechanisms, rabbits □ Neuronal and extraneuronal uptake mechanisms—roles in iris dilator muscle response, effect of levarterenol and phenylephrine, rabbits □ Iris dilator muscle response—effect of levarterenol and phenylephrine, roles of neuronal and extraneuronal uptake mechanisms, rabbits □ Adrenergic agents—levarterenol and phenylephrine, effect on iris dilator muscle response, roles of neuronal and extraneuronal uptake mechanisms, rabbits

Recent studies (1, 2) demonstrated the importance of extraneuronal uptake in the alteration of the action of adrenergic agonists in vascular smooth muscle. Earlier, the decline of muscle tension during washout of a stimulant drug was found to be a valid index of the decreasing concentration of the drug at its receptor sites (3, 4). Corticosterone blocked the uptake of adrenergic agonists into extraneuronal stores (5, 6), thus altering the time required to wash out the agonists.

6-Hydroxydopamine selectively destroys the adrenergic nerve terminals in many tissues. Since a recent study (7) demonstrated a virtually complete absence of adrenergic innervation of iris muscles of rabbits after treatment with 6-hydroxydopamine, the iris dilator muscle of the rabbit was selected for study. Chemical denervations by 6-hydroxydopamine and blockade of extraneuronal uptake with corticosterone were used to assess the role of various mechanisms in determining muscle responsiveness to α-adrenergic agonists.

EXPERIMENTAL

Materials—Albino rabbits of both sexes, approximately 1.5 kg, were stunned by a blow to the head and exsanguinated and the eyes were enucleated. Two strips of the iris dilator muscle of about 2 mm width were isolated from each eye by the method of Kern (8). The strips were then mounted in 25-ml baths containing a balanced salt solution of the following composition (micromolar): NaCl, 141.58; KCl, 5.40; $NaHCO_3$, 15.00; glucose, 11.00; NaH_2PO_4, 0.40; and $CaCl_2$, 2.10. The solution was aerated with a mixture of 97% oxygen and 3% carbon dioxide. The pH remained constant at 7.4 throughout the experiment after aeration with this gas mixture.

Strain-gauge transducers with microscale accessories were used to measure isometric contractions. Recordings were made of tension changes on an oscillographic recorder. Resting tension was adjusted to approximately 40 mg. Temperature was maintained at 37° using a heater-circulator.

Drugs—Solutions of drugs were prepared fresh in the balanced salt solution throughout the experiments. Levarterenol (norepinephrine), phenylephrine, corticosterone, and 6-hydroxydopamine were employed.

Procedure—Dose–response relationships were determined for levarterenol and phenylephrine using dose levels from 2.4×10^{-7} to 3.5×10^{-5} M and from 2×10^{-7} to 1×10^{-4} M, respectively, added in a cumulative fashion.

One eye of each animal was chemically denervated by administration of 200 μl of 2% (0.12 M) 6-hydroxydopamine subconjunctivally 24 hr prior to sacrifice. 6-Hydroxydopamine was prepared fresh in normal saline containing sodium bisulfite in equimolar concentration. The control eye was injected in the same manner with 200 μl of the sodium bisulfite solvent solution.

Some tissues, both control and denervated, were treated with 8.7×10^{-5} M corticosterone 10 min prior to exposure to the adrenergic agonists. Corticosterone was allowed to remain in the bath only as long as the agonist was present and was removed concurrently with the agonist. Corticosterone was first solubilized in absolute ethanol and then diluted to the final concentration with the balanced salt solution.

Washout curves were determined by exposing control, 6-hydroxydopamine-, and corticosterone-pretreated tissues to the agonists for 10 min. Tissues were initially washed twice and were then washed once every 5 min until they returned to the precontracted baseline level.

Data Analysis—The data were normalized by calculating tension responses as a percent of the maximum value obtained. Semilogarithmic plots represent the mean values of responses obtained for no less than eight tissues for each group. Means ± SE for various groups were calculated; data were compared using the Student t test for paired variables and considered significantly different when $p < 0.05$. The degree of supersensitivity was assessed by the ED_{50} values calculated from tension responses. A programmable calculator was used for all calculations in this study.

RESULTS

Preliminary results revealed no differences in dose–response curves or washout curves for nontreated iris dilator muscles as compared to those injected with the solvent solution for 6-hydroxydopamine. Therefore, muscles treated in this manner are referred to as controls.

Figure 1 illustrates dose–response relationships of iris dilator strips to levarterenol of both control and denervated tissues, obtained in the presence and absence of corticosterone. The dose–response curves for denervated tissues exhibited supersensitivity, as shown by the shift to the left. Also, a slight increase in sensitivity was seen in both control and denervated tissues when corticosterone was present during exposure to the agonist.

Dose–response relationships for phenylephrine in control and denervated tissues both in the presence and absence of corticosterone are illustrated in Fig. 2. The responses to phenylephrine suggested a slight supersensitivity of denervated tissues, but statistical analysis did not support this finding. Both control and denervated tissues appeared slightly more sensitive to phenylephrine when corticosterone was present

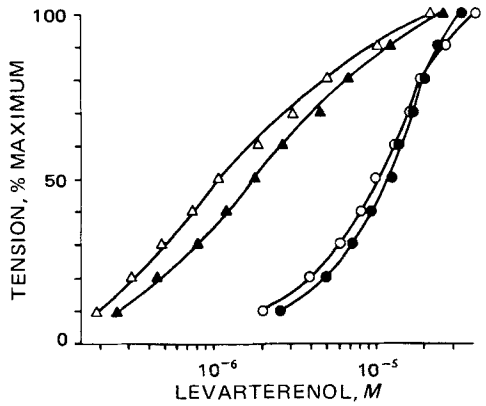

Figure 1—*Effect of 6-hydroxydopamine denervation and corticosterone blockade of extraneuronal uptake on the response of the rabbit iris dilator muscle to levarterenol. Key: ●, control; ○, control + corticosterone; ▲, denervated; and △, denervated + corticosterone. See text for* n *values and procedures of drug administration.*

before and during exposure to this agonist. Again, this finding was not supported by statistical analysis.

The ED_{50} values for levarterenol and phenylephrine on control and denervated iris dilator muscles, both in the presence and absence of corticosterone, are shown in Table I. Supersensitivity of denervated strips to levarterenol, but not to phenylephrine, was demonstrated by a significant decrease in the ED_{50} value for levarterenol as compared to the control value. Conversely, exposure of tissues to corticosterone prior to and during exposure to the agonists significantly decreased ED_{50} values for phenylephrine but not those for levarterenol.

Figure 3 shows tracings of typical response to, and washout of, levarterenol in control and denervated tissues. The marked prolongation of drug washout after chemical denervation is illustrated.

Figure 4 illustrates the washout of levarterenol (3.5×10^{-5} *M*) from control and denervated tissues in the presence and absence of corticosterone. Tension returned to the resting level significantly faster in control tissues ($t_{50\%}$ = 33 sec; time to 50% tension decay) than in denervated tissue ($t_{50\%}$ = 225 sec). The presence of corticosterone before and during exposure to levarterenol slightly increased the time required for washout in control ($t_{50\%}$ with corticosterone = 60 sec) and denervated ($t_{50\%}$ with corticosterone = 255 sec) strips.

The washout of phenylephrine (1×10^{-4} *M*) from control and denervated iris dilator muscle strips in the presence and absence of corticosterone is illustrated in Fig. 5. The washout of phenylephrine from denervated tissues ($t_{50\%}$ = 432 sec) was slower than from control tissues ($t_{50\%}$ = 177 sec), but this alteration was not as dramatic as the effect seen on levarterenol washout. Corticosterone had an effect on phenylephrine washout opposite to its effect on levarterenol washout. The washout times for phenylephrine decreased in both control ($t_{50\%}$ corticosterone = 139 sec) and denervated ($t_{50\%}$ corticosterone = 246 sec) tissues.

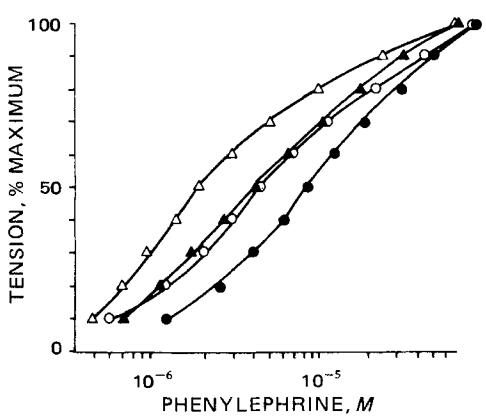

Figure 2—*Effect of 6-hydroxydopamine denervation and corticosterone blockade of extraneuronal uptake on the response of the rabbit iris dilator muscle to phenylephrine. DISCUSSION

Previous studies demonstrated that several factors are involved in the response of smooth muscle to adrenergic agents and that these factors also play a role in the decay of the response during washout of the agonists. The major factors involved are uptake by adrenergic neurons, enzymatic destruction by monoamine oxidase or catechol *O*-methyltransferase, and extraneuronal uptake.

The dose–response curves and ED_{50} values reported here for levarterenol for control and denervated tissues demonstrate the eminent importance of neuronal uptake and enzymatic (monoamine oxidase) mechanisms governing the response to this compound. The dose–response curves and ED_{50} values for phenylephrine were not altered to the same extent. This finding indicates that the neuronal uptake system of iris dilator muscle shows greater affinity for levarterenol than for phenylephrine. Support can be found for this conclusion in studies of the neuronal uptake process in other tissues (9, 10).

Corticosterone at the concentration used has been shown to block extraneuronal uptake of α-receptor agonists in other tissues (5, 6, 11). In this study, the dose–response curves and ED_{50} values for muscles treated with corticosterone suggest that extraneuronal uptake plays a more important role in determining the response to phenylephrine than to levarterenol.

The curves representing washout of agonists are sigmoid in nature and are believed to represent a valid measure of the amount of agonist present at the receptor site at any given time during washout (2). The agonist that is active at the receptor site may represent the agonist that originally interacted with the receptor or a fraction of agonist leaving some storage site such as an extraneuronal store. It is reasonable to suggest that the decline of tension upon washout of an adrenergic agonist is related to the sensitivity of that tissue to the agonist (*i.e.*, denervation-supersensitive tissues *versus* control tissues). Destruction of the adrenergic nerve terminals by 6-hydroxydopamine can potentially alter responses to agonists by two mechanisms. First, the neuronal uptake mechanism is totally absent, and second, the level of monoamine oxidase is decreased. Since corticosterone blocks extraneuronal uptake, the washout of compounds taken up into this store should be more rapid if it is blocked.

The washout of levarterenol is significantly prolonged in denervated tissues. This finding indicates that neuronal uptake and/or monoamine oxidase activity are important in the termination of its action. Levar-

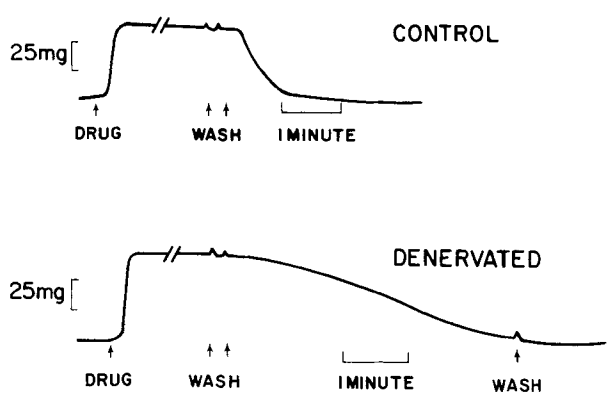

Figure 3—*Typical recording showing the effect of 6-hydroxydopamine denervation on the washout of levarterenol from the rabbit iris dilator muscle. Tissues were washed twice initially and then once every 5 min until baseline levels were reached.*

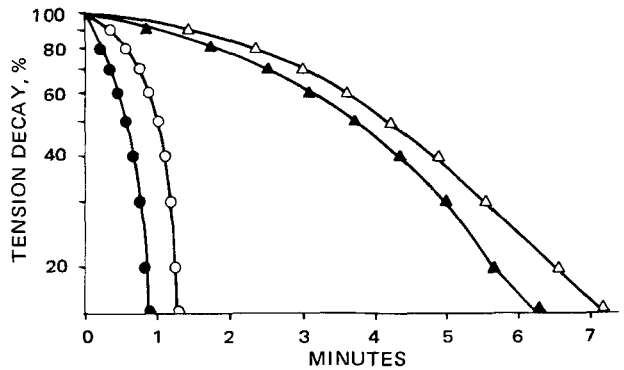

Figure 4—*Effect of 6-hydroxydopamine denervation and corticosterone blockade of extraneuronal uptake on washout of levarterenol from the rabbit iris dilator muscle. Key: ●, control; ○, control + corticosterone; ▲, denervated; and △, denervated + corticosterone. See text for* n *values and drug administration and removal protocol.*

terenol washout in tissues treated with corticosterone is slightly delayed. Thus, if extraneuronal stores are important in the termination of action of this compound, they are corticosterone insensitive in this tissue. Corticosterone-insensitive extraneuronal stores have been demonstrated (10). However, the slight but consistent delay in washout of levarterenol may be due merely to the slight shift in the ED_{50} of levarterenol under these conditions. Another possibility is that the destruction of levarterenol by catechol *O*-methyltransferase obscures the role played by extraneuronal uptake. Some support can be seen for this explanation in the data shown for washout of phenylephrine, which is not destroyed by

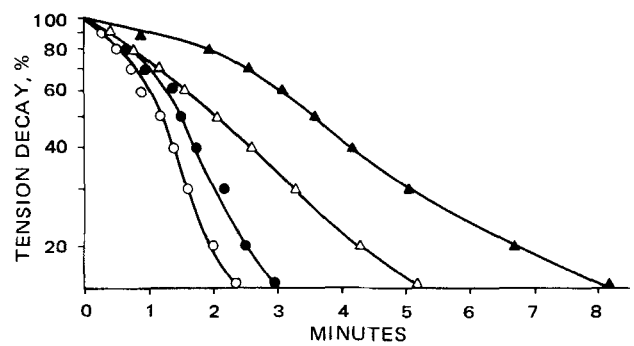

Figure 5—*Effect of 6-hydroxydopamine denervation and corticosterone blockade of extraneuronal uptake on washout of phenylephrine from the rabbit iris dilator muscle. Key: ●, control; ○, control + corticosterone; ▲, denervated; and △, denervated + corticosterone. See text for* n *values and drug administration and removal protocol.*

catechol *O*-methyltransferase.

The washout of phenylephrine from iris dilator muscle strips previously denervated with 6-hydroxydopamine was delayed as compared to control values, but not nearly so dramatically as was that of levarterenol. This finding again indicates that the affinity of the neuronal uptake mechanism is lower for phenylephrine than for levarterenol. The rate of washout of phenylephrine from corticosterone-treated tissues (both control and denervated) was more rapid than that of tissues not subjected to this treatment, indicating that extraneuronal uptake does play a role in the termination of the action of phenylephrine.

The data presented here support the view that extraneuronal uptake in iris dilator muscles from rabbits was more important in the determination of the response to phenylephrine than to levarterenol. Also, neuronal uptake was more important in determining the responsiveness to levarterenol than to phenylephrine. To clarify further the role of catechol *O*-methyltransferase and extraneuronal uptake in the termination of action of adrenergic agents in this tissue, experiments involving catechol *O*-methyltransferase inhibition and uptake of radioactively labeled compounds will be undertaken.

Absorption, Distribution, and Excretion of ^{14}C-Meglumine in Rats and Dogs after Administration of ^{14}C-Meglumine Salicylate

JOEL F. HEEG *, GORDON S. BORN ˣ, WAYNE V. KESSLER, STANLEY M. SHAW, and WINTHROP E. LANGE ‡

Abstract □ Meglumine labeled with carbon-14 was administered orally as ^{14}C-meglumine salicylate to rats and dogs to study its distribution and excretion. The compound was incompletely absorbed; that which was absorbed was rapidly excreted in the urine. Peak blood levels were about 5–10 μg/ml in rats and 2–8 μg/ml in dogs. Tissue levels were negligible at the end of the experimental periods. No evidence for *N*-demethylation or oxidation to carbon dioxide was obtained.

Keyphrases □ ^{14}C-Meglumine—absorption, distribution, and excretion, rats and dogs □ Absorption—^{14}C-meglumine, rats and dogs □ Distribution—^{14}C-meglumine, rats and dogs □ Excretion—^{14}C-meglumine, rats and dogs □ Radiochemistry—analysis, ^{14}C-meglumine, tissues and biological fluids, rats and dogs

Several studies have been reported on the use of meglumine[1] (I) derivatives to increase the water solubility of certain pharmaceuticals, industrial chemicals, and X-ray contrast preparations (1–11). Meglumine salicylate is a promising new water-soluble salicylate compound. The absorption, distribution, and excretion of I have not been reported.

The synthesis of ^{14}C-labeled I was reported previously (12). Compound I was labeled with uniformly labeled ^{14}C-glucose to produce 1-deoxy-1-(methylamino)-D-[U-^{14}C]glucitol (I-G) and with ^{14}C-labeled methylamine to produce 1-deoxy-1-[^{14}C]methylamino-D-glucitol (I-M). These compounds were combined with equal molar amounts of salicylic acid and administered orally to I salicylate-primed and nonprimed rats and dogs to study distribution and excretion. The use of I with the ^{14}C-label in the two positions provided a means for determining whether I was metabolized by *N*-demethylation or glucose catabolism to carbon dioxide.

EXPERIMENTAL

Liquid Scintillation Counting—The liquid scintillation spectrometer was a three-channel, low temperature counter equipped with bialkali phototubes. Optimum counter settings were utilized. The scintillator consisted of 2,5-diphenyloxazole (0.4%) in an equal volume of toluene and 2-ethoxyethanol. The counting efficiency was determined by internal standardization with ring ^{14}C-labeled toluene.

Labeled Compounds—Compounds I-G and I-M were available from the syntheses reported previously (12). The specific activities measured for these compounds were used to determine the percentages of administered dose.

Animals—The rats were male Sprague–Dawley descendants[2], weighing 180–200 g except where noted. Registered male beagle dogs[3] were given a complete physical examination before the studies were initiated and were in good physical condition.

Sample Digestion Procedure—Tissue, blood, urine, bile, and fecal samples were prepared for liquid scintillation counting by a technique that was a slight modification of the acid digestion method of Mahin and Lofberg (13). This technique was similar to the method described by Bishara *et al.* (14) who used perchloric acid and hydrogen peroxide. Approximately 25–250 mg of the sample was placed in a counting vial. The amount of quenching after digestion of a sample dictated the amount of sample used for analysis. Perchloric acid (0.2 ml of 70%) was added, and the contents were mixed well to ensure thorough wetting of the sample. Hydrogen peroxide (0.2 ml of 30%) was added, and the contents were mixed.

The vials were capped, put in an oven at 70° for 30 min, and then cooled to room temperature. Another 0.5 ml of hydrogen peroxide was added, and the samples were bleached for another 30 min at 70°. The vials were again allowed to cool to room temperature, 15 ml of the scintillator was added, and the samples were mixed and counted. With the short periods of heating, there was no evidence of carbon-14 loss.

Triplicate samples (50 mg/organ and 25 mg for fecal material) for all animal studies were digested and analyzed for ^{14}C-activity. To ensure a homogeneous sample, the feces were prepared for counting by adding two to three times the sample weight of water and mixing with a stainless steel spatula in individual glass containers.

Duplicate 100–200-mg urine, bile, and blood samples were analyzed. The carcass of each rat was frozen in liquid nitrogen and then transferred to a blender. Five hundred milliliters of water was added, and the carcass was blended for about 10 min. Five aliquots, each weighing 200–250 mg, were digested. The GI tract was prepared in the same manner as the carcass, using 100 ml of water.

Dosage Preparation—*Rat Studies*—Aqueous solutions of I salicylate prepared from I-G and I-M with an equal molar amount of salicylic acid were employed for the rat studies. These solutions are referred to here as I-G salicylate and I-M salicylate. A solution containing unlabeled I salicylate was prepared for rats that were primed.

The volume of each solution administered was varied slightly for each rat to provide a 400-mg/kg dose of I salicylate. This volume was about 2 ml and contained about 5–6 μCi for the two solutions containing labeled compounds. All solutions were administered by oral intubation.

Dog Studies—The dry materials were placed in hard gelatin capsules for oral administration. Paralleling the rat studies, I-G salicylate, I-M salicylate, and unlabeled I salicylate capsules were prepared to provide each dog with a dose of 50 mg/kg of I salicylate. The amount of radioactivity in the labeled capsules was about 25 μCi.

Preliminary Experiments—Both labeled compounds, without and with salicylic acid, were used in preliminary studies in nonprimed rats. Although detectable amounts of activity were found in certain organs and tissues, no statistically significant ($p < 0.05$) amount of activity was found in any organ or tissue analyzed 24 hr after administration of either ^{14}C-labeled compound without salicylic acid. The addition of salicylic acid did not alter these findings.

Fecal excretion accounted for the largest portion of the administered dose, with renal excretion being second. Excretion of radioactivity *via* the lungs as respired ^{14}C-labeled carbon dioxide was measured by the method described by Meeks *et al.* (15). Respired ^{14}C-labeled carbon dioxide was minimal for both labeled compounds, representing 0.06–0.6% of the administered dose. This range was within the previously determined purity limits of the compounds.

Separation of the red blood cells from the plasma of heparinized whole blood, with subsequent washing of the cells five times with saline, revealed that the cells still contained greater than 33% of the total blood radioactivity 3 hr after administration. For this reason, whole blood was analyzed in the animal studies.

Distribution and Excretion Studies in Rats—A 5-day primed and nonprimed distribution and excretion study was conducted using 12 rats. These rats were divided equally into drug-primed and nonprimed groups. The drug-primed animals received unlabeled I salicylate daily for 7

consecutive days and were then divided into two groups of three animals each. One group was administered I-G salicylate; the other group received I-M salicylate. The nonprimed animals were similarly divided and treated.

The animals were housed in stainless steel metabolism cages with food and water provided *ad libitum*. Blood samples were taken by tail clip at 1, 2, 4, 8, 16, 24, 32, 40, 48, 72, and 120 hr after dosing. Feces and urine samples were collected 8, 16, 24, 32, 40, 48, 72, 96, and 120 hr after dosing.

After the 5-day period, the animals were sacrificed. The liver, kidneys, GI tract, GI tract contents, and remaining carcass were analyzed for ^{14}C-activity. Liver and kidneys were analyzed even though the preliminary studies showed nonsignificant activities. The cages housing the animals were washed and any residual activity was recovered. A materials balance was then conducted in an attempt to recover all of the radioactivity administered to each animal.

Rat Bile Duct Cannulation Study—Each of the two labeled compounds was used to determine biliary excretion. Four nonprimed rats, 325–350 g, were used. Two were dosed with I-G salicylate, and the remaining two received I-M salicylate. Immediately after dosing, the animals were anesthetized with pentobarbital sodium (45 mg/kg ip). An inhalation anesthetic[4] was also administered to control the level of anesthesia during surgery more effectively.

After cannulation of the bile duct, the polyethylene tubing[5] was brought out through the abdominal incision. The tubing was channeled under the skin to the right hindquarter and out an incision in the skin into a collection vial. After the incision was closed, the animal was placed on his stomach in a wire-mesh restraining cage.

Bile was collected beginning 1 hr after administration of the labeled compound, and samples were taken at 2, 3, 4, 6, 8, 12, and 24 hr after dosing. Duplicate 0.1–0.2-ml samples of bile were placed in scintillation vials, digested, and counted.

Five-Day Dog Distribution and Excretion Study—Four nonprimed dogs were used. Two received I-G salicylate, and the other two received I-M salicylate. After administration of the labeled compounds, the dogs were housed in steel cages and the urine and feces were collected. The animals were fed daily with a standard dry dog food[6]. Water was given *ad libitum* throughout the experimental period.

Blood samples were taken from each animal at 1, 2, 4, 8, 16, 24, 48, 72, 96, and 120 hr after dosing. At the end of the 5-day experimental period, the dog cages were washed and the amount of residual activity in the wash solutions was determined.

After termination of this nonprimed study, the dogs were rested for 10 days and then given complete physical examinations again. During the last 7 days of the recovery period, the animals were primed with daily doses of unlabeled I salicylate. After this priming period, the animals were again administered the labeled compounds as described previously; the urine, feces, and blood were collected at the same time intervals and analyzed.

Dog Gallbladder Cannulation Study—The bile ducts of two dogs were ligated as near the gallbladder as possible, and the bile was carefully removed from the gallbladder with a needle and syringe. An incision was made in the gallbladder just large enough to admit the end of a No. 16 French Foley indwelling catheter[7] (approximately 43.2 cm long), with a Luer inflation valve and a 5-ml balloon. The incision in the gallbladder was then closed, and the cannula was secured.

Eight milliliters of a solution of plaster of Paris was then injected into the Luer inflation valve, and the balloon portion of the catheter (within the gallbadder) was inflated. Approximately 15 cm of the catheter was brought out through the abdominal musculature, and the incision was sutured closed. The catheter was secured to the outside of the animal's body with surgical tape. An inflatable rubber collar[8] was placed around the dog's neck to prevent the animal from disturbing the catheter or the sutured area of his stomach. A plastic collection bag[9] was then positioned and secured between the front legs of the dog, the catheter was attached, and the bile was collected.

The rectal temperature of each animal was taken twice daily throughout the recovery and experimental periods. The temperature of each animal remained within normal limits at all times. Eight days after surgery, one dog was administered I-G salicylate and the other received I-M salicylate. Food and water were provided *ad libitum* throughout the experimental period. Bile was collected at 12, 24, 48, 72, 96, and 120 hr after administration of the labeled compounds.

At the end of the 5-day experimental period, the animals were sacrificed by intravenous administration of pentobarbital sodium. The following organs and tissues then were removed and frozen until analyzed: spleen, thymus, heart, kidneys, lungs, liver, adrenal, thyroid, pancreas, testes, muscle (hindleg), salivary gland, and epididymal and perirenal fat.

RESULTS

Table I shows the average percentage of the administered dose of each labeled compound and/or radioactive metabolite excreted at various time

[a] Hours after administration. [b] Percentage of administered dose. Mean ± *SD* for two dogs. [c] One dog did not urinate or did not defecate.

intervals in the urine and feces after oral administration in primed and nonprimed rats. The totals are also shown. The results indicate that excretion was nearly complete after 48 hr, and little difference was noted between urinary and fecal excretion of the glucose-labeled and methylamine-labeled compounds. Priming of the animals for 7 days prior to administration of the labeled compounds made little difference in the route or rate of excretion.

As in the preliminary study, the majority of the radioactivity was excreted in the feces and represented approximately 82–91% of the administered dose. Urinary excretion ranged from 7 to 14% of the administered dose. The total activity recovered, including that in the GI contents, the carcass, and the cage wash, ranged from about 94 to 99% of the administered activity.

The activities found in the GI contents and tract, liver, and kidneys were low and within the purity limits of the radiochemicals. This finding was also true with the carcass, which contained all of the remaining tissues and organs.

The radioactivity eliminated in the bile of rats was less than 0.1% of the administered dose for the 24-hr collection for both labeled compounds.

The urinary and fecal excretion of carbon-14 by primed and nonprimed dogs after oral administration of either I-G salicylate or I-M salicylate is shown in Table II. As was reported for the rat studies, the majority of the labeled compounds was excreted in the feces. This excretion was within the first 24-hr collection period except when the animal did not defecate.

The amount of feces excreted from nonprimed dogs was noticeably greater than from primed animals. Constipation is a possible side effect of salicylate therapy; thus, priming the animals for 7 consecutive days may have caused the decrease in fecal output by the primed animals. Concomitantly, more radioactivity was excreted in the feces of the nonprimed dogs as compared to the primed animals.

The tissue levels of I and/or radioactive metabolites in dogs were low. The muscle, which constitutes approximately 46% of live body weight (16), retained 0.1–0.2% of the administered dose after the 5-day period. Less than 0.1% of the administered dose was found in the fat of the animal. The remaining tissues analyzed showed negligible amounts of activity. All of these amounts were within the purity limits of the two labeled compounds.

Analysis of the biliary excretion data for the two dogs over the 5-day period revealed that no statistically significant ($p < 0.05$) amount of activity was detectable in any sample for either of the labeled compounds.

The peak blood levels for both rats and dogs occurred at 1–2 hr after administration. The level then slowly decreased throughout the experimental periods, with no apparent differences between the primed and nonprimed animals and between the two labeled compounds. Peak blood levels were about 5–10 μg/ml in the rats and 2–8 μg/ml in the dogs.

DISCUSSION

Blood levels of I in rats and dogs remained low, reaching a peak at about 1–2 hr after administration. Levels in other tissues were negligible in the rat and dog 5 days after administration. Thus, I was not retained in the body over a long period.

The feces were the major route of excretion for both animal species. Excretion in the feces was less in the dog than in the rat. Urinary excretion accounted for the remainder, with urinary levels being about three times higher in the dog than in the rat. Excretion by both routes in both species was nearly complete within 48 hr. Essentially no radioactivity was excreted in the bile of either the rat or dog.

Lack of biliary excretion and high fecal excretion indicated that I was poorly absorbed in both species. However, the higher urinary excretion in the dog indicated a greater absorption.

Priming of rats did not affect fecal or urinary excretion. The primed dogs did show a decrease in fecal excretion and a decrease in the total activity excreted in the feces. These decreases were probably due to the constipating effect of salicylates.

The lack of ^{14}C-labeled carbon dioxide excretion in the preliminary studies indicated that glucose catabolism to carbon dioxide did not occur. The similar behavior of both labeled compounds in all aspects studied suggested that *N*-demethylation did not occur.

Bioavailability and Activity of Topical Corticosteroids from a Novel Drug Delivery System, the Aerosol Quick-Break Foam

R. WOODFORD ˣ and B. W. BARRY

Abstract □ Experiments were conducted to: (*a*) compare the bioavailability of betamethasone benzoate in a quick-break aerosol foam and semisolid dosage forms, (*b*) compare the activity of betamethasone benzoate, betamethasone valerate, clobetasol propionate, triamcinolone acetonide, desonide, flumethasone pivalate, and hydrocortisone butyrate in foam concentrates, (*c*) assess steroid reservoir formation in skin, and (*d*) assess the effect of a natural moisturizer. Efficacy was determined by a graded response 6-hr occluded vasoconstriction test with subsequent reocclusion for reservoir demonstration. Moisturizer effect was assessed by a nonoccluded vasoconstriction test using "plain" and sodium 2-pyrrolidone-5-carboxylate-containing concentrates on arms pretreated with water or moisturizer. The activities of betamethasone benzoate concentrate, collapsed foam, ointment, and gel were similar and significantly better than the activity of the cream. Clobetasol propionate was significantly better than the other medicated concentrates, which were equivalent. Steroid-induced blanching decreased in the presence of a moisturizer.

Keyphrases □ Betamethasone benzoate—bioavailability and activity, quick-break aerosol foam and semisolid dosage forms, various corticosteroids in foam concentrates compared, effect of moisturizer □ Bioavailability—betamethasone benzoate, quick-break aerosol foam and semisolid dosage forms, effect of moisturizer □ Drug delivery systems—quick-break aerosol foam, betamethasone benzoate bioavailability and activity compared to semisolid dosage form, effect of moisturizer □ Aerosol foam, quick break—betamethasone benzoate bioavailability and activity compared to semisolid dosage form, effect of moisturizer □ Dosage forms—quick-break aerosol foam and semisolid, betamethasone benzoate bioavailability and activity compared, effect of moisturizer □ Moisturizers—effect on bioavailability and activity of betamethasone benzoate in quick-break aerosol foam and semisolid dosage forms □ Corticosteroids, topical—betamethasone benzoate, bioavailability and activity of quick-break aerosol foam and semisolid dosage forms, effect of moisturizer

Topical corticosteroid preparations are used widely to treat various dermatoses, and new formulations continue to be developed. While topical steroid aerosols have been advocated by dermatologists (1) and are commercially available, most new preparations are ointments, creams, or gels. Aerosols for clinical use are sprays or stable foams; although pharmaceutical quick-break foams offer possibilities (2), their medicinal application has apparently not been developed.

As a topical steroid dosage form, the quick-break aerosol foam offers the advantages of high activity (the steroid is in solution), ease of application, controlled dosage from a metering valve, economy in use, suitability for smooth or hairy skin, and reduced possibility of inhaling corticosteroid compared with aerosol sprays. Logical development involves devising suitable formulations and comparing them with current corticosteroid dosage forms.

This paper reports work performed to: (*a*) compare the activity and bioavailability of 0.025% (w/w) betamethasone benzoate formulated as an ointment, cream, gel, and quick-break aerosol foam, (*b*) compare the activity of 0.025% (w/w) betamethasone benzoate with that of other corticosteroids at the same concentration in quick-break foams, (*c*) assess steroid reservoir formation in the skin, and (*d*) assess the effect of sodium 2-pyrrolidone-5-carboxylate (a natural moisturizing factor) on the blanching response to steroid-containing quick-break foams.

The "activity" of a preparation is its ability to produce skin pallor (assumed to parallel anti-inflammatory activity), while the "bioavailability" of a formulation refers to the activity of a given corticosteroid in a particular base monitored as a function of time compared with this activity in different bases. Bioavailability is assessed from a pharmacological response rather than by measuring drug concentrations in tissues.

EXPERIMENTAL

Preparation of Quick-Break Foam—A nonionic emulsifying wax[1] is a suitable foaming agent for quick-break foams, especially in the presence of dichlorodifluoromethane and dichlorotetrafluoroethane. An aqueous–alcoholic system incorporating these ingredients produces excellent quick-break foams provided that the ethanol–water ratio lies between approximately 50:50 and 70:30 (3). Quick-break foams may also be prepared using propylene glycol–water mixtures. Twelve preliminary formulations were investigated consisting of various combinations of ethanol, propylene glycol, and water: ethanol, 56.5–13.0% (w/w); propylene glycol, 75.0–3.9% (w/w); and water, 27.0–0% (w/w).

Four basic formulations were developed, and from these the following preparation was selected as the most satisfactory: 0.025 g of betamethasone benzoate, 5.50 g of propylene glycol BP, 55.475 ml of dehydrated alcohol BP, 26.50 ml of purified water BP, 2.0 g of nonionic

Bioavailability and Activity of Topical Corticosteroids from a Novel Drug Delivery System, the Aerosol Quick-Break Foam

R. WOODFORD ˣ and B. W. BARRY

Abstract □ Experiments were conducted to: (*a*) compare the bioavailability of betamethasone benzoate in a quick-break aerosol foam and semisolid dosage forms, (*b*) compare the activity of betamethasone benzoate, betamethasone valerate, clobetasol propionate, triamcinolone acetonide, desonide, flumethasone pivalate, and hydrocortisone butyrate in foam concentrates, (*c*) assess steroid reservoir formation in skin, and (*d*) assess the effect of a natural moisturizer. Efficacy was determined by a graded response 6-hr occluded vasoconstriction test with subsequent reocclusion for reservoir demonstration. Moisturizer effect was assessed by a nonoccluded vasoconstriction test using "plain" and sodium 2-pyrrolidone-5-carboxylate-containing concentrates on arms pretreated with water or moisturizer. The activities of betamethasone benzoate concentrate, collapsed foam, ointment, and gel were similar and significantly better than the activity of the cream. Clobetasol propionate was significantly better than the other medicated concentrates, which were equivalent. Steroid-induced blanching decreased in the presence of a moisturizer.

Keyphrases □ Betamethasone benzoate—bioavailability and activity, quick-break aerosol foam and semisolid dosage forms, various corticosteroids in foam concentrates compared, effect of moisturizer □ Bioavailability—betamethasone benzoate, quick-break aerosol foam and semisolid dosage forms, effect of moisturizer □ Drug delivery systems—quick-break aerosol foam, betamethasone benzoate bioavailability and activity compared to semisolid dosage form, effect of moisturizer □ Aerosol foam, quick break—betamethasone benzoate bioavailability and activity compared to semisolid dosage form, effect of moisturizer □ Dosage forms—quick-break aerosol foam and semisolid, betamethasone benzoate bioavailability and activity compared, effect of moisturizer □ Moisturizers—effect on bioavailability and activity of betamethasone benzoate in quick-break aerosol foam and semisolid dosage forms □ Corticosteroids, topical—betamethasone benzoate, bioavailability and activity of quick-break aerosol foam and semisolid dosage forms, effect of moisturizer

Topical corticosteroid preparations are used widely to treat various dermatoses, and new formulations continue to be developed. While topical steroid aerosols have been advocated by dermatologists (1) and are commercially available, most new preparations are ointments, creams, or gels. Aerosols for clinical use are sprays or stable foams; although pharmaceutical quick-break foams offer possibilities (2), their medicinal application has apparently not been developed.

As a topical steroid dosage form, the quick-break aerosol foam offers the advantages of high activity (the steroid is in solution), ease of application, controlled dosage from a metering valve, economy in use, suitability for smooth or hairy skin, and reduced possibility of inhaling corticosteroid compared with aerosol sprays. Logical development involves devising suitable formulations and comparing them with current corticosteroid dosage forms.

This paper reports work performed to: (*a*) compare the activity and bioavailability of 0.025% (w/w) betamethasone benzoate formulated as an ointment, cream, gel, and quick-break aerosol foam, (*b*) compare the activity of 0.025% (w/w) betamethasone benzoate with that of other corticosteroids at the same concentration in quick-break foams, (*c*) assess steroid reservoir formation in the skin, and (*d*) assess the effect of sodium 2-pyrrolidone-5-carboxylate (a natural moisturizing factor) on the blanching response to steroid-containing quick-break foams.

The "activity" of a preparation is its ability to produce skin pallor (assumed to parallel anti-inflammatory activity), while the "bioavailability" of a formulation refers to the activity of a given corticosteroid in a particular base monitored as a function of time compared with this activity in different bases. Bioavailability is assessed from a pharmacological response rather than by measuring drug concentrations in tissues.

EXPERIMENTAL

Preparation of Quick-Break Foam—A nonionic emulsifying wax[1] is a suitable foaming agent for quick-break foams, especially in the presence of dichlorodifluoromethane and dichlorotetrafluoroethane. An aqueous–alcoholic system incorporating these ingredients produces excellent quick-break foams provided that the ethanol–water ratio lies between approximately 50:50 and 70:30 (3). Quick-break foams may also be prepared using propylene glycol–water mixtures. Twelve preliminary formulations were investigated consisting of various combinations of ethanol, propylene glycol, and water: ethanol, 56.5–13.0% (w/w); propylene glycol, 75.0–3.9% (w/w); and water, 27.0–0% (w/w).

Four basic formulations were developed, and from these the following preparation was selected as the most satisfactory: 0.025 g of betamethasone benzoate, 5.50 g of propylene glycol BP, 55.475 ml of dehydrated alcohol BP, 26.50 ml of purified water BP, 2.0 g of nonionic

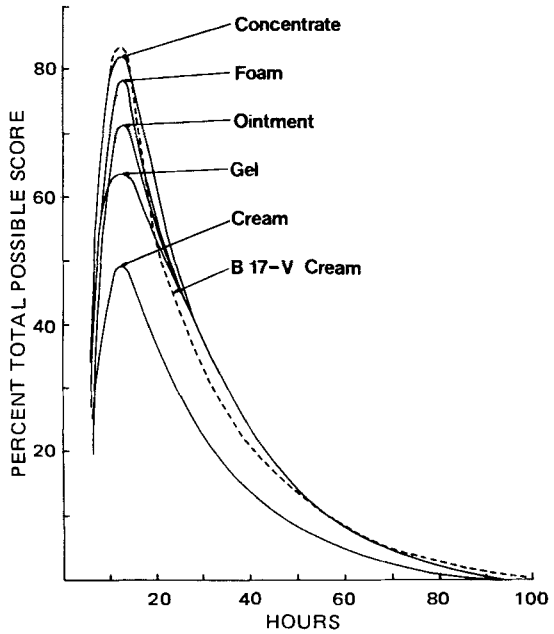

Figure 1—*Blanching response to betamethasone benzoate formulations containing 0.025% steroid and to 0.1% betamethasone valerate cream.*

emulsifying wax[1], 0.50 g of hydroxyethylcellulose[2], 4.0 g of dichlorodifluoromethane[3], and 6.0 g of dichlorotetrafluoroethane[4].

Water was added to the hydroxyethylcellulose with swirling. The mixture was gently heated to 60° until gelling commenced, and it was left to hydrate at room temperature for 1 hr with occasional swirling. Then propylene glycol was added with mixing. The corticosteroid was dissolved at room temperature in the alcohol, and this solution was added gradually with mixing. The nonionic emulsifying wax was added, and the system was warmed to approximately 60° with swirling until the wax dissolved. The homogeneous warm mixture was poured into a tin-plate aerosol container and cooled to below room temperature, and dichlorotetrafluoroethane was added. The valve system was crimped into place, and dichlorodifluoromethane was added *via* a transfer button.

Placebo formulations were prepared by replacing the steroid with dehydrated alcohol. Placebo foams were also produced using 5.0–6.0 g of a suitable mixture of hydrocarbons (propane, *n*-butane, and isobutane)[5] instead of the chlorofluorohydrocarbon propellent blend.

Assessment of Betamethasone Benzoate Formulations—Four formulations containing 0.025% (w/w) betamethasone benzoate were employed (quick-break foam, gel, cream, and ointment) together with the foam concentrate. A placebo foam and concentrate were also included. The carboxypolymethylene-based gel, oil-in-water cream, and white petrolatum-based ointment were used as received from the manufacturer[6].

Efficacy and bioavailability were assessed by a modified skin-blanching test (4, 5). Ten volunteers were selected without reference to their sex or steroid sensitivity. None had received topical corticosteroid therapy for at least 3 months prior to the study. Five milligrams of the semisolid preparations and 5 μl of the concentrates and expelled, collapsed foams were applied with reference to randomization charts to the washed flexor surface of each forearm. Application sites (7 × 7-mm areas punched out from double-sided polyethylene tape[7]) were occluded with polyester film[8] for 6 hr, the sites were washed with soap and water at skin temperature and dried, and readings were taken in a double-blind manner to provide data points for skin blanching at 6, 7, 8, 9, 12, 24, 32, 48, 72, 80, and 96 hr after application.

The degree of pallor was estimated on a 0–4 scale with half-point ratings (4). To assess steroid retention in the skin, the sites on selected volunteers were reoccluded with polyester film for 12 hr, 8 days after commencement of the experiment, and pallor was estimated 5 hr later when blanching was maximal.

Assessment of Steroid-Containing Concentrates—Seven corticosteroids (betamethasone benzoate, betamethasone valerate, clobetasol propionate, flumethasone pivalate, desonide, hydrocortisone 17-butyrate, and triamcinolone acetonide) were separately formulated as quick-break foam concentrates, and their activities were investigated as already described.

Assessment of Effect of Natural Moisturizing Factor—Five corticosteroids (betamethasone benzoate, betamethasone valerate, clobetasol propionate, flumethasone pivalate, and fluocinolone acetonide) were separately formulated in quick-break foam concentrates with and without 5% (w/w) of a 50% aqueous solution of sodium 2-pyrrolidone-5-carboxylate[9]. The "plain" concentrate contained 0.025 g of the corticosteroid, 5.0 g of propylene glycol BP, 55.475 ml of dehydrated alcohol BP, 25.0 ml of purified water BP, 2.0 g of nonionic emulsifying wax, and 0.50 g of hydroxyethylcellulose. The "moisturizing" concentrate was the same except that it contained 22.50 ml of purified water BP and 4.5 g of sodium 2-pyrrolidone-5-carboxylate (50% aqueous solution). The method of preparation was as previously described, the moisturizer being mixed with the hydrated hydroxyethylcellulose before the propylene glycol was added.

To accentuate any effect of the moisturizer, 0.7 ml of a 5% (w/w) aqueous solution of sodium 2-pyrrolidone-5-carboxylate was rubbed (3 min) into one arm of each of 10 volunteers twice a day for 7 days; the other arm was similarly treated with water as a control. A medical rubber finger-cot[10] was used, since experiments had shown that it was impermeable to water and sodium 2-pyrrolidone-5-carboxylate solutions. Five microliters of the plain and moisturizing concentrates were applied to each arm as described, and the polyethylene tape removed. The sites were left nonoccluded but protected by a perforated plastic guard for 6 hr (4) to avoid the hydrating effect of occlusion. Then the sites were washed and dried, and pallor was assessed as before.

In each blanching test, betamethasone valerate cream[11] was employed as a control "standard preparation" so that the results could be correlated with other investigations.

RESULTS AND DISCUSSION

Formulation of Quick-Break Foam—The quick-break foam easily rubbed into glabrous or hairy skin, leaving the site soft and not sticky. The hydroxyethylcellulose increased the viscosity of the liquid remaining after foam collapse, facilitating application to a limited area. During application, some ethanol evaporated, tending to increase the concentration and thermodynamic activity of the steroid in the solvent mixture and thus promoting percutaneous absorption; the propylene glycol minimized precipitation of medicament as the amount of alcohol decreased. Experiments on a placebo formulation, packed in a glass bottle fitted with a metering valve[12] and foam actuator, showed that an undisturbed 180 mg of foam (mean of 10 determinations, range of 178–183 mg) collapsed on the ventral surface of the forearm in 6.5 sec (mean of 10 determinations, range of 6.1–7.0 sec).

A can aged for 1 week at room temperature (17–20°) had a vapor pressure of 24 psig, as did a sample consisting of 90 g of concentrate and 5.8 g of a hydrocarbon propellent blend. Foams produced using chlorofluorocarbon propellents and hydrocarbon propellents usually appeared equally satisfactory, although the hydrocarbon-containing foams were more flammable. Because of their possible adverse effect on the ozone layer, the continued use of halogen-containing propellents has been criticized (6). A suitable mixture of hydrocarbons is a possible alternative propellent for a corticosteroid quick-break foam.

Betamethasone Benzoate Formulations—With each formulation, the results for all volunteers were expressed as a percentage of the total possible score at each time period. The method of calculation was as follows: maximum score per site = 4; for two arms, 4 × 2 = 8; for 10 volunteers, 8 × 10 = 80 (*e.g.*, 6-hr reading for quick-break foam, score of 25 out of a possible 80 = 31.3%). To relate the results obtained with the betamethasone benzoate formulations to those obtained with proprietary

Table I—Blanching Response to Betamethasone Benzoate Formulations Containing 0.025% (w/w) Steroid

Formulation	Area under Curve[a], % *TPS* × hr	Bioavailability[b]	Summed Percent Total Possible Score[c]	*Tm*/10 Mean Value[d]	$t_{1/2}$[e], hr	Percent Total Possible Score on Reocclusion[f]
Betamethasone benzoate concentrate	2350	1.0	392	5.58	13.1	45
Betamethasone benzoate foam	2180	0.93	381	5.50	12.4	45
Betamethasone benzoate ointment	2010	0.85	297	4.84	12.5	28
Betamethasone benzoate gel	2000	0.85	357	5.32	13.2	37
Betamethasone benzoate cream	1290	0.55	240	4.30	14.0	14
Betamethasone valerate cream, 0.1%	2140	—	393	5.58	14.0	24

[a] Obtained by planimetry of the blanching profile to three significant figures; *%TPS* = percent total possible score. [b] The bioavailability of a betamethasone benzoate preparation is the area under its blanching curve divided by the area under the curve of the concentrate (the most active formulation). [c] The percent total possible scores summed for all volunteers over all reading times. [d] The *Tm*/10 mean value is the square root transformation of sum of scores (*Tm*) divided by the number of volunteers (10). The minimum significance range value $k = 0.75$ ($p = 0.05$); *i.e.*, if the *Tm*/10 values of two formulations differ by more than 0.75, there is a significant difference between those formulations. [e] Apparent vasoconstriction half-life = $0.693/K_{vc}$. [f] Reoccluded for 12 hr, 8 days after commencement of the experiment.

preparations (4, 5), the percentages of total possible score values were multiplied by the value: summed percent total possible score value for betamethasone valerate cream in Ref. 4/summed percent total possible score value for betamethasone valerate cream in the betamethasone benzoate study. By this means, the results obtained in the present work were comparable with those reported previously.

Blanching profiles for the betamethasone preparations are shown in Fig. 1; experimental points were omitted for clarity but all lay on or near the curves as drawn. All preparations gave curves with a peak in the 12-hr region and a marked fall-off thereafter. The blanching profile for each formulation was a measure of its activity as a function of time, involving: (*a*) release of corticosteroid from the base, (*b*) penetration of the medicament through the epidermis into the dermis, (*c*) onset and duration of corticosteroid-induced pallor at the vascular region, and (*d*) decline of pharmacological response and elimination of drug from the site of action.

A single numerical parameter that takes account of these four factors is the area under the blanching curve; therefore, it is the parameter most suitable for comparing the bioavailability of steroids in various bases. When arranged in an area under the curve rank order, the aerosol concentrate and foam were superior to the other preparations (Table I). The comparative bioavailability of a formulation was obtained by dividing its area under the curve by that of the most active preparation (*i.e.*, the concentrate). The order was not identical to that based on a summed percentage of the total possible score relationship (*i.e.*, the percentage of the total possible scores summed for all time periods).

The scores for each volunteer were summed over all reading times and analyzed statistically as the nontransformed data and as each of five transformations (x^{-1}, $x^{-1/2}$, $\log x$, $x^{1/2}$, and x^2) (4). Tests for nonadditivity (7) indicated a preference for the square root transformation, and the analysis of variance was calculated using those values. The differences between the preparations were highly significant ($F = 8.36$, $p < 0.01$), while those between the volunteers were significant ($F = 2.21$, $p < 0.05$).

Calculation of the minimum significance range value k using the Student range test (8) permitted comparison of the betamethasone formulations. Significant differences between preparations occurred when their *Tm*/10 mean values (Table I) differed by a figure greater than the value of k. For example, the nonsignificance range for betamethasone benzoate concentration was $5.58 - 0.75 = 4.83$. Hence, the aerosol foam and concentrate were as active in the blanching test as the semisolid formulations with the exception of the betamethasone benzoate cream, which was significantly less active.

Linear plots of log percent total possible score against time over 24–72 hr permitted least-squares evaluation of the apparent vasoconstriction dissipation rate constant (K_{vc}) and the apparent vasoconstriction half-life ($t_{1/2}$) (9). The value of K_{vc} quantifies the disappearance of blanching arising from steroid biotransformation, homeostasis, vascular removal, diffusion from the site of action, and tachyphylaxis. The overall elimination process was described by apparent first-order kinetics, and the values of K_{vc}, $t_{1/2}$ (Table I), and the slope of the regression line equation were similar for all betamethasone formulations. Thus, the equation for the linear plots may be written as:

$$\ln (\%\ TPS) = \ln (\%\ TPS)_0 - K_{vc}t \qquad \text{(Eq. 1)}$$

where $\ln (\%\ TPS)_0$ represents the extrapolated value of the response at time $t = 0$. Regression line equations (for four points) to three significant figures were:

foam	$\ln (\%\ TPS) = 5.32 - 0.0560t$, $r = -0.999$
foam concentrate	$\ln (\%\ TPS) = 5.27 - 0.0529t$, $r = -1.00$
cream	$\ln (\%\ TPS) = 4.57 - 0.0494t$, $r = -0.997$
gel	$\ln (\%\ TPS) = 5.22 - 0.0524t$, $r = -0.997$
ointment	$\ln (\%\ TPS) = 5.31 - 0.0554t$, $r = -0.996$
betamethasone valerate cream	$\ln (\%\ TPS) = 5.01 - 0.0495t$, $r = -0.997$

These results indicated that the disappearance of betamethasone benzoate-induced pallor proceeded at a rate essentially independent of the nature of the vehicle. Furthermore, the replacement of the benzoate group by valerate at the 17-position had little apparent effect on the dissipation of blanching due to the betamethasone derivative.

Reocclusion of the application sites in two volunteers (for which, therefore, statistical analysis was inapplicable) permitted estimation of steroid retention in the stratum corneum. Obvious reservoirs were established with the foam and concentrate, while the least pallor on reocclusion was produced by betamethasone benzoate cream (Table I). Subsequent reocclusion showed that the presence of steroids in the skin could not be demonstrated after 12 days. The placebo concentrate and foam failed to blanch following 6 hr application or after reocclusion.

Steroid-Containing Concentrates—The blanching scores for the steroid-containing concentrates were expressed as percent total possible scores as already described, and blanching curves are shown in Figs. 2 and 3. In all cases, the shapes of the graphs were similar; Table II ranks the concentrates on an area under the blanching curve basis. As with the previous experiment, this listing was not identical to that based on summed percent total possible scores. Least-squares evaluation of linear plots of log percent total possible score against time over 24–72 hr (Figs. 2 and 3) showed that similar steroids (triamcinolone acetonide and desonide and betamethasone benzoate and betamethasone valerate) gave similar values of $t_{1/2}$ and K_{vc}. Regression line equations (for four points) to three significant figures for the medicated concentrates were:

clobetasol propionate	$\ln (\%\ TPS) = 5.02 - 0.0390t$, $r = -1.00$
flumethasone pivalate	$\ln (\%\ TPS) = 5.34 - 0.0596t$, $r = -1.00$
triamcinolone acetonide	$\ln (\%\ TPS) = 5.13 - 0.0463t$, $r = -0.999$
desonide	$\ln (\%\ TPS) = 5.12 - 0.0472t$, $r = -0.999$
hydrocortisone 17-butyrate	$\ln (\%\ TPS) = 5.61 - 0.0731t$, $r = -1.00$
betamethasone benzoate	$\ln (\%\ TPS) = 5.27 - 0.0529t$, $r = -0.999$
betamethasone valerate	$\ln (\%\ TPS) = 5.06 - 0.0530t$, $r = -1.00$
betamethasone valerate cream	$\ln (\%\ TPS) = 5.01 - 0.0497t$, $r = -1.00$

A ranking of steroid concentrates using $t_{1/2}$ values was similar to that based on area under the curve data (Table II).

Statistical analysis showed that the medicated concentrates were as effective in inducing pallor as the standard (betamethasone valerate cream) with the exception of that containing clobetasol propionate, which was significantly more active ($p < 0.05$). Similar steroid reservoirs were produced in the skin with all concentrates (Table II); subsequent reoc-

Table II—Blanching Response to Quick-Break Foam Concentrates Containing 0.025% (w/w) Steroid

Steroid or Formulation	Area under Curve[a], % *TPS* × hr	Summed Percent Total Possible Score[b]	*Tm*/10 Mean Value[c]	$t_{1/2}$[d], hr	Percent Total Possible Score on Reocclusion[e]
Clobetasol propionate	3070	568	6.74	17.8	28
Desonide	2610	441	5.89	14.7	24
Triamcinolone acetonide	2580	453	6.00	15.0	24
Betamethasone benzoate	2350	392	5.58	13.1	45

Betamethasone valerate	2020	409	5.70	13.1	34
Hydrocortisone 17-butyrate	1970	394	5.56	9.5	28
Betamethasone valerate cream, 0.1%	2140	393	5.58	13.9	24

[a] Obtained by planimetry of the blanching profile to three significant figures; *%TPS* = percent total possible score. [b] The percent total possible scores summed for all volunteers over all reading times. [c] The *Tm*/10 mean value is the square root transformation of sum of scores (*Tm*) divided by the number of volunteers (10). The minimum significance range value $k = 0.53$ ($p = 0.05$); *i.e.*, if the *Tm*/10 values of two formulations differ by more than 0.53, there is a significant difference between those formulations. [d] Apparent vasoconstriction half-life = $0.693/K_{VC}$. [e] Reoccluded for 12 hr, 8 days after commencement of the experiment.

clusion showed that the presence of medicament could not be demonstrated after 12 days with the exception of clobetasol propionate, which disappeared after 14 days.

The area under the blanching curve, summed percent total possible score, and percent total possible score on reocclusion values obtained with the foam concentrates were often higher than the values obtained previously with the corresponding commercial creams and ointments (4, 5), although the concentration of steroid in the semisolid formulations was usually two to four times greater than that of the concentrates. For flumethasone pivalate, the concentration of steroid in the ointment and cream was 0.02% (*i.e.*, approximately the same as that in the concentrate). However, the foam concentrate gave blanching values three to four times those of the commercial preparations, depending on the parameter employed (area under the curve or summed percent total possible score). No attempt was made to optimize fully the release and subsequent blanching activity of corticosteroid from each concentrate. It is thus possible that, by careful selection of the ethanol–propylene glycol–water ratio for each steroid (within the limits for quick-break foam production), a further enhanced vasoconstrictor efficacy for the concentrate could be achieved.

Assessment of Effect of Moisturizer—Hydration of the stratum corneum usually facilitates penetration of corticosteroid. To increase skin hydration, a moisturizer was employed both in the formulations and in pretreatment of the arms.

Steroid-induced blanching in the presence and absence of sodium 2-pyrrolidone-5-carboxylate is shown in Table III. Statistical examination by a three-way analysis of variance (10) followed by the Student range test showed significant differences ($p < 0.05$) between moisturizer- and water-treated arms for clobetasol propionate, fluocinolone acetonide, and betamethasone valerate, whereas only clobetasol propionate (the most potent steroid examined) showed a significant difference between concentrates with and without moisturizer on either arm.

The corticosteroids gave values that decreased in the order: control (moisturizer-free) concentrate on control (water-treated) arm > moisturizer-containing concentrate on control arm > control concentrate on moisturizer-treated arm > moisturizer-containing concentrate on moisturizer-treated arm. This sequence was surprising, and the reason

Table III—Blanching Response to Quick-Break Foam Concentrates Containing 0.025% (w/w) Steroid in the Presence and Absence of Moisturizer[a]

	Tm/10 Mean Value[b]	
	Moisturizer-Treated Arm	Water-Treated Arm
Clobetasol propionate plus moisturizer	5.15	11.70
Fluocinolone acetonide plus moisturizer	1.70	6.90
Betamethasone valerate plus moisturizer	0.90	5.50
Betamethasone benzoate plus moisturizer	1.10	3.70
Flumethasone pivalate plus moisturizer	1.15	3.10
Clobetasol propionate	9.85	15.60
Fluocinolone acetonide	4.05	10.75
Betamethasone valerate	4.40	8.60
Betamethasone benzoate	3.25	6.90
Flumethasone pivalate	3.00	5.65

[a] Moisturizer was sodium 2-pyrrolidone-5-carboxylate, 5% (w/w) of concentrate. [b] Sum of scores (*Tm*) divided by number of volunteers (10). The minimum significance range value $k = 3.86$ ($p = 0.05$); *i.e.*, if two formulations differ by more than 3.86, there is a significant difference between those formulations. Betamethasone valerate cream, 0.1%, gave total scores of 38 (moisturizer-treated arm) and 78.5 (water-treated arm).

for the diminution of steroid-induced blanching in the presence of sodium 2-pyrrolidone-5-carboxylate remains unresolved. This result could have been due to the effects of moisturizer within the vehicle and/or within the skin.

For example, sodium 2-pyrrolidone-5-carboxylate may have increased the solubilities of the steroids in the vehicle and/or reduced their thermodynamic activities by complexation, thus lowering the skin–vehicle partition coefficients, with consequent reduction in flux through the skin. (Preliminary work[13] indicated that the water solubility of the parent steroid, hydrocortisone, increased approximately twofold in the presence of 2-pyrrolidone-5-carboxylic acid.) The moisturizer may have altered the diffusional properties of corticosteroid molecules in the skin (*e.g.*, by an effect on skin structure, by binding of water, or by complex formation with the steroid).

In addition, sodium 2-pyrrolidone-5-carboxylate may have had an effect on shunt diffusion; it was suggested[14] that if the corticosteroids penetrated significantly *via* the hair follicles and/or down the ducts of the sweat glands, lower blanching responses in the presence of moisturizer might have been caused by partial constriction of the shunt routes by sodium 2-pyrrolidone-5-carboxylate. To investigate this possibility for sweat glands, a 5% (w/w) aqueous solution of the moisturizer was rubbed into one side of the forehead of one volunteer twice a day for 7 days, the other side being similarly treated with water. After 1 week, the volunteer exercised vigorously to perspire. There was no apparent difference in sweating between the moisturizer-treated and control halves of the forehead. However, when the procedure was repeated using undiluted moisturizer (*i.e.*, 50% aqueous solution of sodium 2-pyrrolidone-5-carboxylate), there seemed to be some reduction in the sweat flow. These results indicate that large amounts of moisturizer may have some vehicle effect on shunt pathways. However, more sophisticated techniques are required to elucidate the reduction of corticosteroid-induced blanching in the presence of sodium 2-pyrrolidone-5-carboxylate.

The present work investigated the possible pharmaceutical use of an aerosol quick-break foam. The foam concentrate together with the propellent gave a homogeneous system at room temperature. When the product was discharged from the container, the propellent vaporized; the foaming agent (nonionic emulsifying wax) crystallized due to a loss of solubilizer (*i.e.*, propellent) and a reduction in temperature to below that at which the foaming agent deposited. The precipitation of the wax from solution produced a foam that collapsed on the skin as the wax redissolved at skin temperature, foam destruction being accelerated by shearing.

In use, the product is expelled onto a limited skin area; the resultant foam breakage brings the homogeneous liquid into intimate contact with the skin surface. The liquid may be rubbed into the skin to leave a site that is dry, soft, and not sticky. The present work indicates that quick-break foams containing corticosteroids are highly active preparations as assessed by the blanching test. Drug bioavailability is good, so the steroid is readily available to the skin from a controlled-dosage, esthetically attractive, economic preparation. It should be possible to modify the basic formulation to optimize release of drug or moisturizer or to control the breaking characteristics of the foam. The quick-break foam should be a suitable vehicle for a wide range of topical corticosteroids and may be a useful delivery system for other medicaments, offering the prospect of a sterile preparation that will remain so during use.

Polydisperse Particulate Solids Mixing and Segregation: Nonstationary Markov Chains

C. H. CHOU, J. R. JOHNSON *, and E. G. RIPPIE ˣ

Abstract □ The feasibility of analyzing interparticulate translocations within agitated beds of polydisperse particulate solids in terms of Markov chains was investigated. A binary mixture of spherical particles subjected to vertical sine wave vibration is shown to behave in accordance with a nonstationary Markov chain having singly stochastic transition matrixes. The transition probability elements of such matrixes, calculated from a knowledge of the initial and final occupancy vectors, agree with those estimated using tracer particles. With appropriate restrictions, the former method, based on the solution of simultaneous equations, permits a quantitative evaluation of particle mobilities throughout the bed.

Keyphrases □ Solids, polydisperse particulate—agitated beds, interparticulate translocations in terms of Markov chains □ Interparticulate translocations—polydisperse particulate solids, agitated beds, in terms of Markov chains □ Markov chains—polydisperse particulate solids, agitated beds, interparticulate translocations

The mixing of solid particles is a key step in many industrial and technical processes. Its pharmaceutical importance related to the manufacture of solid dosage forms is obvious, and the field of solids mixing has developed an extensive literature. Most of this literature deals with the statistical nature of the mixing process in its various forms, with the result that numerous degrees of mixedness (1) have been defined. These quantities are scalar and do not uniquely represent the composition tensors that would otherwise rigorously characterize the total state of mix. Such approaches, while of significant value in characterizing overall kinetic behavior (2), are necessarily incomplete.

A more comprehensive description of the translocations of particles within dynamic particulate beds can be achieved by the analysis of such systems in terms of stochastic theory. Some advantages of this approach are that both particle distributions and particle mobilities can be studied simultaneously and the processes of mixing and segregation can be examined in detail throughout the systems.

Oyama and Ayaki (3) considered the theoretical aspects of a Markov chain, having stationary transition matrixes, applied so as to describe the mixing of monodisperse particles, but they did not verify their results experimentally. The motion of monodisperse solids in a two-dimensional twin-shell mixer was studied, and the applicable stationary transition matrix of a Markov process was established by using single tracer particles (4). Good agreement was found between predicted and measured results using this technique.

The axial mixing of solid particles in a motionless mixer was studied in terms of a Markov chain (5). The transition probabilities were determined by measuring the distribution of tracer particles before and after passage of the bed through the mixer. Good agreement between experiment and theory was found for up to seven mixing passes, assuming the chain to be homogeneous.

The purpose of the present paper is to extend the application of Markov chains to polydisperse solids systems in which the transition matrixes are both nonstationary and singly stochastic. While such systems proceed to equilibrium states, these states represent nonuniform distributions of particles in general; the applicable Markov chains provide insight into the mixing–segregation process. The experimental system was selected to demonstrate the practical applicability of the theory and the experimental approach to polydisperse systems in general.

THEORY

Transition matrixes arising from Markov chains describing the mixing of monodisperse solids are, of necessity, stationary, since the magnitude of the elements representing the probabilities of particle movements from location to location are independent of local bed compositions. This condition is a result of the physical similarity of all particles in the system except for some superficial identifying feature of the tracer particles.

A further simplification results for such systems if, for purposes of analysis, the particulate mass is divided into cells containing equal numbers of particles. The transition matrix then becomes doubly stochastic, since both row and column sums are unity. For such finite, irreducible, aperiodic chains having doubly stochastic transition matrixes, it follows that all states become equally probable in the limit, and the system ultimately assumes a state of random mix. Since such systems are not subject to segregation, they can be mixed satisfactorily by any method, and their study is of somewhat limited practical utility.

Polydisperse particulate solids, in contrast, are subject to segregation; both mixing and segregation occur simultaneously when such systems are agitated. This result is a direct consequence of the fact that the motion of a given particle is affected significantly by the composition gradient it experiences in its immediate neighborhood. As mentioned previously, the transition matrixes of Markov chains applied to these systems are both nonstationary and singly stochastic. In the present paper, binary mixtures of spherical particles are subjected to vertical sine wave oscillation and the resultant particle translocations are analyzed.

A finite, discrete, first-order Markov chain is appropriate for processes where particles move among a finite number of imaginary cells within the bed over arbitrary time intervals and where the transition probabilities for movement depend solely on the state of the system and on the length of the time interval corresponding to a unit step. Mathematically, such a Markov chain can be expressed as the matrix product of a cell occupancy or distribution probability vector with a transition probability matrix. The resultant row vector represents the new occupancy or distribution probability following one or more steps in the chain. Thus:

$$a_i P_{ij} = a_j \qquad \text{(Eq. 1)}$$

where a_i denotes the ith occupancy or distribution probability vector for a system divided into n cells:

$$a_i = [a_1 a_2 \cdots a_n]_i \qquad \text{(Eq. 2)}$$

$$P_{ij} = \begin{bmatrix} p_{11}p_{12}\cdots p_{1n} \\ p_{21}p_{22}\cdots \\ \cdots \\ \cdots p_{kl}\cdots \\ \cdots \\ p_{n1}\cdots p_{nn} \end{bmatrix}_{ij} \qquad \text{(Eq. 3)}$$

P_{ij} is the transition matrix corresponding to the step(s) between the states that exist after steps i and j, respectively; p_{kl} is the probability of movement of a particle from cell k to cell l. Since the matrixes P_{ij} are nonstationary:

$$P_{a,a+2} = P_{a,a+1} P_{a+1,a+2} \neq P^2_{a,a+1} \qquad \text{(Eq. 4)}$$

From the definition of p_{kl}, it is apparent that $\Sigma_{l=1}^{n} p_{kl} = 1$ for all k whereas $\Sigma_{k=1}^{n} \neq 1$ in general. These relationships correspond to the singly stochastic condition.

With successive steps in the chain, $P_{i,i+1}$ approaches a limit having as an eigenvector the equilibrium occupancy or distribution vector and also having a corresponding eigenvalue of unity.

In the event the system is divided into cells of unequal volume, Eq. 1 must be written in the more general form:

$$a_i \Pi P_{ij} \Pi^{-1} = a_j \qquad \text{(Eq. 5)}$$

where:

$$\Pi = \begin{bmatrix} x_1 & 0 & . & . & . & 0 \\ 0 & x_2 & 0 & . & . & . \\ . & . & . & . & . & . \\ . & . & 0 & x_k & 0 & . \\ . & . & . & . & . & 0 \\ 0 & . & . & . & 0 & x_n \end{bmatrix} \qquad \text{(Eq. 6)}$$

and where x_k represents the relative volume of cell k. However, in the present paper, all cells are of the same volume so that Π and Π^{-1} cancel and Eq. 5 can be simplified to Eq. 1.

If it is assumed that the values of p_{kl} are unknown for a given step but that the corresponding initial and final occupancy vectors are known, then from the definition of p_{kl} it is apparent that n linear independent equations exist. Also, because the sum of the elements in any occupancy vector is a constant, an additional $n - 1$ linear independent equations can be written. That is, for a given step in the Markov chain under discussion, $2n - 1$ elements in the corresponding transition matrix can be determined from a knowledge of the states of the system before and after a given step. The remainder of the n^2 elements of the nth-order transition matrix either must be zero or must otherwise be known by some independent means. Unless this latter requirement is met, no unique solution can be found for Eq. 1.

It has been shown, by the experimental means discussed later, that all but $2n - 1$ of the n^2 elements p_{kl} of the transition matrix have negligible values and may be assumed to be zero for suitably short transition time intervals. The transition matrixes corresponding to these observations have the general form:

$$P_{ij} = \begin{bmatrix} p_{11} & 0 & . & . & . & 0 \\ p_{21} & p_{22} & 0 & . & . & . \\ 0 & p_{32} & p_{33} & 0 & . & . \\ . & 0 & p_{43} & p_{44} & 0 & . \\ . & . & . & . & . & . \\ 0 & . & . & 0 & p_{nn-1} & p_{nn} \end{bmatrix}_{ij} \qquad \text{(Eq. 7)}$$

The $2n - 1$ unknowns in P_{ij} can be determined from the solutions of the $2n - 1$ linear independent simultaneous equations, which have been shown to result from the stochastic condition of the transition matrix and from Eq. 1.

EXPERIMENTAL

A segmented brass cylinder, 2.54 cm i.d. and 30 cm in height, containing the particulate system under study was mounted vertically on a specially designed shaking device (2). This shaker imparted a vertical sinusoidal motion to the cylinder and was capable of precise adjustment of both the frequency and amplitude of the shaking motion.

The binary mixture used in this study was comprised of 112.5 g each of 2.38- and 5.56-mm chrome steel balls and was loaded into the cylinder in a randomly mixed state prior to each shaking sequence. A random mixture was achieved by the successive addition of mixtures of equal weights of both components in small increments of less than 8% of the total bed. The adequacy of this mixing method was verified by sampling.

The particulate bed was approximately 14 cm in depth and was permitted to expand freely during shaking. Shaking was conducted at a frequency of 17.08 Hz, with a peak to peak amplitude of 5.08 mm. Maximum expansion was estimated at 1–2 cm within each oscillation of the shaker.

Following agitation for various periods, the occupancy vectors of the bed were determined by sequentially removing the six 2.3-cm segments of the cylinder, one at a time, and noting the weight of the bed contained in each and the corresponding weight of the larger component. The fractional composition of each cell thus corresponded to the components a_j of the occupancy vector following agitation. The components a_i of the initial occupancy vector were taken as 0.5 where the bed was randomly mixed initially. Where the bed was partially segregated at the beginning of the transition time segment of interest, the components a_i were those found by measurement after independent runs of the proper duration. This procedure was necessary since the system was disrupted by the sampling method employed.

[a] Elements estimated from the movements of tracer particles. [b] Elements computed from simultaneous equations.

Transition Matrixes Determined by Tracer Particles—One-sixth of both the large and small components were marked by being blued with a commercial cold process gun bluing solution. The randomly mixed bed was loaded into the segmented cylinder so that the marked particles were located within a given segment. After being vibrated for a predetermined period, the system was analyzed as previously described. The relative movement of the large and small marked components into cylinder segments other than those in which they were located originally corresponds to the transition probabilities p_{kl}. By repeated experiments in which the marked particles are placed in the various cylinder segments, it is possible to construct the transition matrix.

Transition Matrixes Determined by Solution of $2n - 1$ Simultaneous Equations—As discussed previously, Eq. 1 and the singly stochastic transition matrixes define $2n - 1$ linear independent equations whose coefficients correspond to the transition probability elements, p_{kl}, as indicated in Eq. 7. Sets of equations corresponding to various initial and final occupancy vectors were solved on a digital computer[1] using a double precision program based on the Gauss–Jordan method of condensed elimination with partial pivoting. This approach provides a convenient method of obtaining the transition matrixes for any component of a polydisperse mixture without the need for tedious multiple measurements of tagged particles.

RESULTS AND DISCUSSION

Transition matrixes for the large component were determined using tracer particles for transition time periods of 5, 10, 15, and 20 sec, beginning in each case with randomly mixed particulate beds. In no case were marked large particles found in bed segments below their initial location; however, after 20 sec of shaking some particles were found to have moved into the second segment above their original position. This latter movement corresponds to a transition giving rise to a positive value of $p_{k,k-2}$, where the six cylinder segments are serially numbered starting at the top. These results indicate that, for sufficiently short time intervals, transitions can be represented by matrixes of the type given in Eq. 7. However, as the system approaches its equilibrium state, other transitions become significant even for short time intervals. Results of the tracer particle studies are presented in Table I.

An indication of the accuracy of tracer-estimated transition matrixes can be obtained by comparing occupancy vectors computed from Eq. 1 with those obtained by direct bed analysis. Figure 1 displays bed compositions determined by direct measurement together with those predicted by Eq. 1. Errors are within probable statistical limits, and the accuracy permits prediction of the distribution of a component within approximately 3% based on total content. Correspondingly lower percent errors will result where samples contain larger numbers of particles due either to larger sample size or smaller average particle size.

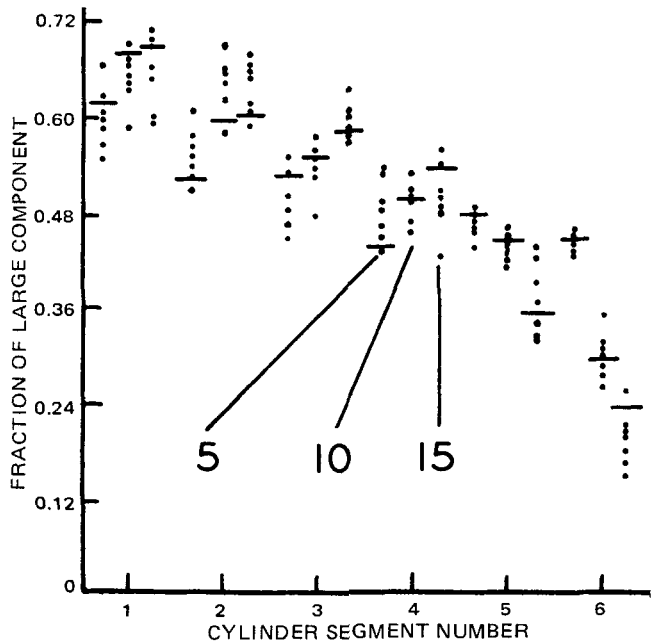

Figure 1—*Fraction of the large component as a function of bed location and time of agitation. Data are shown for 5-, 10-, and 15-sec periods of agitation for each of the six bed positions, numbered from the top. Points represent compositions by analysis, and lines represent calculated values based on the transition matrixes.*

Occupancy vectors, representing the averages of seven identical runs in each case, were used to compute transition matrixes corresponding to those determined by tracer methods. These are presented in Table I as a list of their component transition probability elements. Good agreement can be seen between transition probabilities determined by the two alternative methods used.

The average occupancy vectors were also used to compute P_{ij} for four successive 5-sec time intervals. The inequality expressed by Eq. 4 holds, and the chain is nonstationary (Table II).

Table II—Transition Probability Elements Computed for Successive 5-sec Time Intervals

p_{kl}	0–5 sec	5–10 sec	10–15 sec	15–20 sec
p_{11}	1.000	1.000	1.000	1.000
p_{21}	0.198	0.068	0.040	0.088
p_{22}	0.802	0.932	0.960	0.912
p_{32}	0.296	0.270	0.064	0.131
p_{33}	0.704	0.730	0.936	0.869
p_{43}	0.288	0.350	0.236	0.181
p_{44}	0.712	0.650	0.764	0.819
p_{54}	0.238	0.379	0.323	0.363
p_{55}	0.762	0.621	0.677	0.637
p_{65}	0.136	0.331	0.308	0.428
p_{66}	0.864	0.669	0.692	0.572

Mention should be made concerning the transition matrixes related to the movement of the second component. While it is true that the occupancy vectors of the first component uniquely define those of the second component, the same cannot be said of the respective transition matrixes. Experimentally, the blue 2.38-mm tracer balls had significantly greater mobility than the 5.56-mm balls. The smaller balls moved in both directions from their original locations, and their tracers could be found in as many as five segments after a single 5-sec period of agitation. Since more than $2n - 1$ transition probability elements were nonzero in this case, the transition matrixes could not be calculated from the occupancy vectors but could only be estimated *via* tracer particles.

CONCLUSIONS

The mixing and segregation that occur within vibrated polydisperse particulate beds can be studied as a nonstationary Markov chain. Transition matrixes corresponding to relatively short agitation time intervals can be satisfactorily computed from a knowledge of the initial and final occupancy vectors.

In a binary mixture, a single large particle moving into or out of a given cell does not uniquely imply a corresponding movement of either another single large particle or of several small particles. Hence, the transition matrix established for one component limits, but does not define, the transition matrix of the second component. This limitation is not serious, however, since the occupancy vectors of the two components are complementary. The general methods used in the present study can be applied to the analysis of movement of a given component in a complex polydisperse mixture regardless of the number of components.

The transition probability elements provide a quantitative indication of a given component's mobility as a function of time and location. It is particularly significant that the mechanisms responsible for the observed mobilities are not explicitly implied by the transition matrixes but are accurately manifested by them. Thus, the approach permits the *a posteriori* investigation of a variety of possible mechanistic models. The likelihood of wall effects in the system presented in this paper does not invalidate the analysis but can be investigated in depth using these methods.

Influence of Sunscreening Agents on Color Stability of Tablets Coated with Certified Dyes III: FD&C Yellow No. 6

B. R. HAJRATWALA [x] and A. J. HENNIG

Abstract □ The influence of a protective coating of six sunscreening agents (glyceryl *p*-aminobenzoate, benzocaine, cinoxate, homosalate, *n*-octyl salicylate, and amyl salicylate) upon the photostability of FD&C Yellow No. 6 used to color coat tablets was studied. The alcohol film-, modified sugar-, and film-coating methods were used to apply the sunscreening agents. Tablets were exposed to 1000 foot-candles of light for various times, after which reflectance measurements and visual observations were recorded. FD&C Yellow No. 6 did not follow the Kubelka–Munk equation. The order of relative stability was FD&C Yellow No. 6 > erythrosine sodium (FD&C Red No. 3) > FD&C Blue No. 1. The greatest protection against fading was afforded by benzocaine.

Keyphrases □ Sunscreening agents—effect on color stability of tablets coated with FD&C Yellow No. 6, various coating methods □ Color stability—tablets coated with FD&C Yellow No. 6, effect of sunscreening agents and various coating methods □ Stability, color—tablets coated with FD&C Yellow No. 6, effect of sunscreening agents and various coating methods □ Tablets—coated with FD&C Yellow No. 6, effect of sunscreening agents and various coating methods on color stability □ Dyes—FD&C Yellow No. 6 tablet coating, effect of sunscreening agents and various coating methods on color stability □ FD&C Yellow No. 6—tablet coating, effect of sunscreening agents and various coating methods on color stability

The influence of six sunscreening agents (salicylate, benzoate, and cinnamate types) on the color stability of tablets coated with erythrosine sodium (FD&C Red No. 3) and FD&C Blue No. 1 was reported previously (1, 2). Three different methods were developed for their application. For FD&C Red No. 3, the degree of protection was dependent not only upon the type of sunscreening agent but also upon the application method. For FD&C Blue No. 1, no sunscreening agent exhibited significant protective action.

The purposes of this study were to evaluate the influence of selected sunscreening agents on tablets coated with FD&C Yellow No. 6 and to predict the color shelflife of such coated tablets.

EXPERIMENTAL

Materials—The six sunscreening agents used were glyceryl *p*-aminobenzoate[1], benzocaine, cinoxate[2], homosalate, *n*-octyl salicylate, and amyl salicylate[3]. The dye was FD&C Yellow No. 6. All compounds were used as received without further purification.

Procedure—The preparation of tablets, the equipment, the method of regulating exposure to light, and the determination of the quantity of sunscreening agent per tablet were described previously (1).

Coating Procedure—Ten subcoats and 25 smoothing coats were applied to core tablets, in lots of 6 kg, using medium strength gelatin syrup and white subcoating dusting powder. After the tablets were completely dry, the color coating was applied. Plain coating syrup (170 g of sucrose and 100 ml of deionized water) and color syrup (0.300 g of dye in 100 ml of plain coating syrup) in the stated ratio were applied in the following order: nine coats of 25 ml each in 1:90 parts, nine coats of 30 ml each in 1:75 parts, nine coats of 32 ml each in 1:60 parts, six coats of 32 ml each in 1:20 parts, nine coats of 32 ml each in 1:10 parts, eight coats of 32 ml each in 1:4 parts, and 12 coats of 32 ml each in 1:1 parts of plain syrup and color syrup, respectively.

Application of Sunscreening Agents—Three coating techniques, alcohol film, modified sugar, and film, were used to apply the sunscreening agents to the color-coated tablets. Observations regarding the "wet" feel of tablets coated with glyceryl *p*-aminobenzoate, turbid solutions for the modified sugar-coating method, and mottled appearances of tablets coated with salicylates by the film-coating method were similar to those reported (1). The quantitative assessment of surface mottling of colored tablets as reported by Armstrong and March (3) was not performed, because it was beyond the scope of this study.

No change in hue occurred upon application of various sunscreening agents such as was reported with FD&C Red No. 3 upon the application of glyceryl *p*-aminobenzoate (1) and with FD&C Blue No. 1 upon the application of glyceryl *p*-aminobenzoate or benzocaine (2). However, a brilliant shine was obtained (even before polishing) with FD&C Yellow No. 6 upon the application of cinoxate or glyceryl *p*-aminobenzoate.

Measurement of Color Change—Adequate samples of each set of color-coated tablets were exposed to 1000 foot-candles of light and 26 ± 2° in a light cabinet. Samples were withdrawn at designated time intervals, and the reflectance of the tablets was measured using the transmittance scale. A spectrophotometer[4] and reflectance attachment unit (2) were used to measure the reflectance of individual tablets.

Measurements were made between 400 and 525 nm for each sample at appropriate wavelength intervals and at the maximum for the dye

(475 nm) (Fig 1). Color evaluation by visual observation was carried out as previously reported.

RESULTS AND DISCUSSION

The Kubelka–Munk equation:

$$\ln \theta_t = \ln \theta_t' - ktI \qquad \text{(Eq. 1)}$$

where $\theta_t = (1 - R)^2/2R$, R = reflectance at the absorbance maximum at time t, I = intensity in foot-candles, k = apparent first-order rate constant, and $\theta_t = \theta_t'$ at $t = 0$, conveniently describes the first-order degradation of various dyes, *e.g.*, FD&C Red No. 3 (1, 4) and FD&C Blue No. 1 (2). The data obtained for FD&C Yellow No. 6 plotted as log θ_t *versus* the product of time and intensity did not yield a straight line, indicating that the fading did not occur *via* a simple first-order process. The data were also plotted as $1/\theta_t$ *versus* the product of time and intensity; but this plot also failed to yield a straight line,

Amyl salicylate	1	1	3A

[a] 1 = fading less than alcohol film control, 2 = fading similar to alcohol film control, 3 = fading greater than alcohol film control, 3A = fading greater than alcohol film control but with mottled appearance due to cracked film, and S = brilliant shine. All tablets were polished except as noted.

suggesting that the rate of fading did not follow a second-order equation either.

This failure to comply with the Kubelka–Munk equation prevents prediction of shelflife for color-coated tablets. However, it is possible, on the basis of reflectance measurements and visual observations, to assign an order of protection afforded by the sunscreening agents to FD&C Yellow No. 6. Reflectance measurements are reported for 0, 8, 20, and 40 days. Tables I–III show log (1/reflectance) measurements of various sets of color-coated tablets. These values are an average of two or three determinations. The range of these determinations generally varied between 0.005 and 0.010 unit [log (1/reflectance) was read off the absorbance scale]. Table IV summarizes visual observations.

Control—FD&C Yellow No. 6 exhibited sensitivity to the type of coating applied. The relative order of stability was modified sugar coating < alcohol film coating < film coating. In the absence of any

Table V—Visual Observations of Tablets Coated with Certified Dyes and Exposed to Varying Intensities of Light for up to 70 Days[a]

Days	750 Foot-Candles, Film Coating			1000 Foot-Candles, Sugar Coating		
	FD&C Yellow No. 6	FD&C Red No. 3	FD&C Blue No. 1	FD&C Yellow No. 6	FD&C Red No. 3	FD&C Blue No. 1
0—1	5	5	5	5	5	5
2—5	4	4	4	5	4	3
6—10	4	3	3	4	4	2
11—20	4	3	3	4	3	1
21—30	3	3	2	3	2	1
31—40	3	2	1	2	2	1
41—50	2	2	1	1	1	0
50—70	2	2	0	—	—	—

[a] 5 = no change, 4 = moderate change, 3 = noticeable change, 2 = poor stability, 1 = very poor stability, and 0=colorless. Material was condensed and retabulated from Ref. 5.

numerical values for rate constants or any other linear function, it is difficult to assign the relative order of stability of FD&C Yellow No. 6 with respect to FD&C Red No. 3 and FD&C Blue No. 1. Vaidya (5) assigned the following order: FD&C Yellow No. 6 > FD&C Red No. 3 > FD&C Blue No. 1 (Table V). The present findings are in general agreement with that order.

Glyceryl *p*-Aminobenzoate—FD&C Red No. 3 (1) and FD&C Blue No. 1 (2) both showed a distinct change of hue when tablets were coated by either the alcohol film-coating or the film-coating method. Although no change in hue was observed with any coating procedure in the present study, a different shade of yellow might have been produced that was not readily distinguishable by the eye. Tablets exhibited a brilliant shine (alcohol film- and film-coating method), which was retained even after 10 days of exposure to 1000 foot-candles of light. A chemical reaction between the dye and the glyceryl *p*-aminobenzoate apparently occurred, resulting in a slight shift in the maximum and a new peak at 420 nm (Fig. 2). No attempt was made to isolate the compound or to determine the reaction involved.

Benzocaine—The protective effect of the UV absorber, benzocaine, appeared most effective for FD&C Yellow No. 6 when applied as the modified sugar coat or the film coat.

Cinoxate—This compound appeared to have a distinct protective action on FD&C Yellow No. 6 when applied by the film-coating method. Only moderate fading occurred even after 40 days of exposure. A brilliant shine also was retained for up to 5 days of exposure at 1000 foot-candles of light.

Salicylates—Tablets coated with the salicylates by the film-coating method appeared mottled after 24 hr of drying due to cracking of the film. Compared to control tablets for each coating method, coating by the alcohol film method appeared to afford the best protection.

Quantitative Determination of Benzoic Acid and Salicylic Acid in Ointments by High-Pressure Liquid Chromatography

V. DAS GUPTA

Abstract □ Benzoic acid and salicylic acid in ointments were analyzed quantitatively by reversed-phase high-pressure liquid chromatography. Both benzoic and salicylic acids can be assayed in combinations directly without interference from each other or the ointment bases. The method is accurate, simple, and rapid. Excellent results were obtained with three commercial bases.

Keyphrases □ Benzoic acid—reversed-phase high-pressure liquid chromatographic analysis, pharmaceutical formulations containing salicylic acid □ Salicylic acid—reversed-phase high-pressure liquid chromatographic analysis, pharmaceutical formulations containing benzoic acid □ High-pressure liquid chromatography, reversed phase—analysis, benzoic and salicylic acids, pharmaceutical formulations □ Antifungal agents—benzoic acid, reversed-phase high-pressure liquid chromatographic analysis, pharmaceutical formulations □ Keratolytic agents—salicylic acid, reversed-phase high-pressure liquid chromatographic analysis, pharmaceutical formulations

The quantitative determination of benzoic acid (I) and salicylic acid (II) in ointments was reported (1). That method involved the determination of II by its reaction with ferric nitrate. Benzoic acid was determined by difference from the total acidity reading. Any error in the determination of II is carried over to results on I. The purpose of these investigations was to develop a direct, simple, and accurate method for the quantitative determinations of I and II in combinations.

EXPERIMENTAL

Chemicals and Reagents—All chemicals and reagents were ACS, USP, or NF grade and were used without further purification.

Apparatus—A high-pressure liquid chromatograph[1] equipped with a UV detector (254 nm) and recorder[2] was used.

Column—A very nonpolar packing material[3] consisting of a monomolecular layer of octadecyltrichlorosilane, permanently bonded by silicon–carbon bonds, and a 30-cm long × 4-mm i.d. column were used.

Chromatographic Conditions—The chromatographic solvent was 0.02 *M* KH_2PO_4 in 10% (v/v) methanol in water (pH adjusted[4] to 6.2 with ~0.1 *N* NaOH). The temperature was ambient, and the solvent flow rate was 2.0 ml/min (at an inlet pressure of approximately 1100 psig). The detector was set at a sensitivity of 0.16 absorbance unit full-scale, and the chart speed was 30.5 cm (12 in.)/hr.

Solutions—A standard solution of I (100.0 mg/250 ml) or II (50.0 mg/250 ml) or a combination of I and II was prepared by heating the acid(s) in 15 ml of approximately 0.1 *N* NaOH and 60 ml of water to almost boiling. The mixture was then cooled and brought to volume (250.0 ml).

Preparation of Ointments—Three lots of ointments were prepared by the trituration process. Lot A contained 3.0% of II by weight in white petrolatum; Lot B contained 6.0% of I and 3.0% of II in a cold cream[5]; Lot C contained the same ingredients as Lot B in a different base[6] (2).

Assay Procedure for Ointments—Weigh accurately about 1.667 g of the ointment, transfer it to a 150-ml beaker, and add 15 ml of the

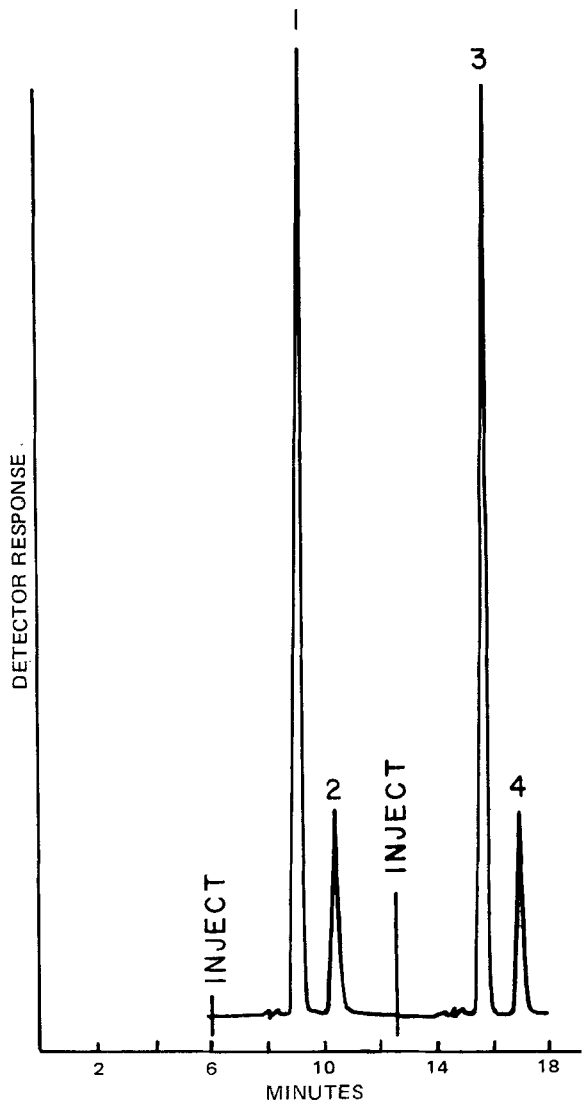

Figure 1—*Liquid chromatogram of I and II in combination (for conditions, see text). Peaks 1 and 2 are I and II from a standard solution, respectively; peaks 3 and 4 are I and II from an ointment sample, respectively.*

Table I—Assay Results[a] on Ointments

Ointment	Assay Results, % I	II
Lot A	0.0	99.6
Lot B	99.4	99.8
Lot C	97.9	99.2
Average deviation (based on six readings)	±2.1	±2.8

[a] Average of three.

0.1 *N* NaOH solution and 60 ml of water. Heat almost to boiling and cool until the base congeals at the top of the aqueous layer. Then decant and transfer the aqueous layer to a 250-ml volumetric flask, wash the beaker with small portions of water, and transfer the rinsings to a volumetric flask to bring the mixture to volume. Filter if necessary and inject 10–20 μl.

For comparison purposes, inject an identical volume of the appropriate standard solution after the assay sample is eluted.

Calculations—Since preliminary investigations indicated that the peak area of each ingredient was directly related to the concentration (range of 4–8 μg for I and of 2–4 μg for II), the results on I and II were calculated by direct comparison of the peak areas:

$$\frac{\text{corrected } A_a}{A_s} \times 100 = \text{percent of label claim} \qquad \text{(Eq. 1)}$$

where corrected A_a = peak area of the assay × (1.667/weight of sample in grams), and A_s = peak area of the standard solution.

A typical liquid chromatogram is shown in Fig. 1, and the assay results are presented in Table I.

DISCUSSION

The results (Table I) indicate that I and II in combinations can be assayed directly by high-pressure liquid chromatography. The separation of I from II is excellent (Fig. 1). The method is accurate, rapid, and simple. The three ointment bases used did not interfere with the assay; other bases may interfere. Any other base should be checked for interference by using the assay procedure on the plain base. It is necessary to run both the assay and the standard with the same lot of the chromatographic solvent, since slight differences in pH may change the area of the peak.

Effects of Aspirin and Acetaminophen on Fetal and Placental Growth in Rats

W. C. LUBAWY ˣ and R. J. BURRISS GARRETT

Abstract □ Aqueous suspensions of aspirin or acetaminophen (125 and 250 mg/kg/day) were administered orally to pregnant Sprague–Dawley rats on Days 8–19 of gestation. On gestation Day 20, each rat was sacrificed and the uterus was examined *in situ*. Each fetal–placental unit was resected and examined. Fetuses from rats given 125 or 250 mg/kg/day of aspirin were shorter and weighed less than those obtained from control rats. In animals receiving the higher dose of aspirin, the placentas were smaller and the number of fetal resorptions was increased. Acetaminophen (250 mg/kg/day) did not affect fetal length or weight or the incidence of resorptions. Acetaminophen interfered less with the normal growth of the rat fetus and placenta than did aspirin.

Keyphrases □ Aspirin—effects on fetal and placental growth, rats □ Acetaminophen—effects on fetal and placental growth, rats □ Fetal growth—effects of aspirin and acetaminophen, rats □ Placental growth—effects of aspirin and acetaminophen, rats

The antigonadal and antireproductive activities of the two most commonly used nonprescription analgesic drugs were reported previously. Chronic administration of acetaminophen to rats produced a decrease in testicular weight and impaired spermatogenesis (1). Also, chronic administration of acetaminophen significantly decreased fecundity in mice, but similar doses of aspirin were ineffective (2). Aspirin administration interfered with the rapid increase in ovarian size following hemicastration (3) and also caused embryotoxicity and teratogenecity in rats (4).

Many studies document the effects of salicylates on fetal growth and development (4–10); however, no studies are known that directly compare the effects of aspirin to those of acetaminophen. Since aspirin and acetaminophen may influence gonadal function, normal reproduction, and the growth of rapidly developing tissue, the effects of these widely used analgesics on fetal and placental growth were compared.

EXPERIMENTAL

Female Sprague–Dawley rats[1] were used. For gravid rats, the sperm-positive date indicated by the supplier was designated Day 0 of pregnancy. If allowed to progress to term, parturition occurred on Day 21. Animals were randomized, housed three or four to a wire mesh bottom cage, and fed rat chow[2] and water *ad libitum*.

From the 8th through the 19th day of gestation, groups of 21 sperm-positive rats were weighed and received aspirin[3] or acetaminophen[4] at 0, 125, or 250 mg/kg by gavage. Groups of nonmated female rats, comparable in age, were treated according to the same regimen. Each drug was suspended fresh daily in 0.5% methylcellulose with a homogenizer[5] at a concentration such that 1 ml was administered for every 200 g of body weight. Drugs were administered without anesthesia, since Kimmel *et al.* (5) observed abnormalities in offspring from rats anesthetized with ether.

Table I—Effect of Aspirin and Acetaminophen on Weight Gain in Pregnant and Nonpregnant Rats[a]

Body Weight	Vehicle (0.5% Methylcellulose)	Aspirin (125 mg/kg/day)	Aspirin (250 mg/kg/day)	Acetaminophen (125 mg/kg/day)	Acetaminophen (250 mg/kg/day)
Nonpregnant rats:					
Initial weight[b], g	214.8 ± 5.4	212.3 ± 2.7	220.7 ± 6.4	219.9 ± 2.1	219.3 ± 3.3
Weight[b] after 12 days, g	242.2 ± 3.5	241.0 ± 2.5	238.0 ± 4.5	243.1 ± 3.5	236.4 ± 2.9
n	10	7	9	7	8
Pregnant rats:					
Initial weight[b], g	240.6 ± 4.6	238.7 ± 2.6	239.9 ± 4.7	240.5 ± 4.7	237.5 ± 4.4
Weight[b] after 12 days, g	332.6 ± 8.4	336.3 ± 4.9	298.9 ± 9.6[c]	320.4 ± 7.6	347.3 ± 4.8
n	18	21	15	17	16

[a] Drugs were administered by gavage once daily for 12 days. [b] Mean ± *SE*. [c] Differs from control at $p < 0.05$.

On Day 20 of gestation, the sperm-positive animals were sacrificed with ether overdosage. The uterus was examined *in situ* for implantation sites, and fetal viability was determined. Each fetal–placental unit was resected. The chorioallantoic placenta was dissected free of the fetus, and both were blotted and weighed. The length of each fetus was measured from crown to rump.

Continuous variables from fetuses and placentas grouped according to treatment were analyzed using an analysis of variance or a *t* statistic. Discrete variables were subjected to the Fisher Exact Probability Test or the χ-square test according to the criteria outlined by Siegel (11).

RESULTS

Among the nonpregnant rats, no significant differences occurred in average body weights between the various treatment groups and comparable controls at the end of the 12-day treatment period (Table I). Although the actual amount of weight gained during the experimental period by the high dose (250 mg/kg/day) aspirin-treated nonpregnant rats was approximately 10 g less than the average weight gain of the control animals, this difference was not statistically significant. Pregnant rats given aspirin at 250 mg/kg/day gained less weight than those receiving the vehicle, and some of this difference was probably due to the effect of the aspirin on the fetuses and placentas.

Data presented in Table II indicate some effects of aspirin and acetaminophen on fetal and placental development. Four of 17 pregnant rats given 125 mg/kg/day of acetaminophen and 12 of 15 pregnant rats given 250 mg/kg/day of aspirin had at least one resorption site. This incidence was statistically different from that seen in rats given the vehicle only in the aspirin-pretreated group. In this group, 44% of the fetuses were resorbed and the weight and length of the remaining fetuses were reduced. Furthermore, placental growth was depressed in these animals. Acetaminophen at a comparable dose level (250 mg/kg/day) did not affect fetal length, fetal weight, or placental weight.

In rats receiving 125 mg/kg/day of aspirin, fetal growth was depressed but placental weight was not influenced. The incidence of resorptions was not increased over control values. In contrast, 125 mg/kg/day of acetaminophen produced more resorptions than occurred in the control group, 16 *versus* 0%, respectively, and also shorter fetuses. At this dose, acetaminophen did not affect either fetal or placental weight.

DISCUSSION

After 12 days of drug administration, no difference resulted in the average body weight of vehicle-treated and analgesic-treated nonpregnant animals. Thus, it seems unlikely that the small fetal and placental sizes in the aspirin-treated rats resulted from reduced food consumption by the dam. This interpretation is only speculative, however, since the compounds may affect the appetite of pregnant rats differently than that of nonpregnant rats. Fetal growth inhibition produced by aspirin could be a result of some of the many biochemical actions of the salicylates such as altered protein synthesis (12–14). Other actions of the salicylates such as uncoupling oxidative phosphorylation (15) and interfering with prostaglandin synthesis (16) may also be involved.

In contrast to aspirin, acetaminophen had little effect on fetal and placental growth. Shorter fetuses did occur in pregnant rats receiving the lower dose of acetaminophen than in those receiving the high dose. No rigorous conclusions about these results should be drawn since the data were obtained from a single experiment. However, lack of a classical dose–response relationship has been reported for other actions of acetaminophen. Dikstein *et al.* (17) reported that doses of 2–10 mg/kg/day of acetaminophen produced a greater increase in the width of the female rat tibial epiphysial cartilage than did doses of 20 mg/kg/day.

As with all animal experiments, these results cannot be extrapolated to other species. Mechanisms involved in fetal development and teratogenesis are so complicated that any conclusions concerning the relative safety of each analgesic during human pregnancy must be drawn with caution. Women taking large doses of salicylates during pregnancy may have a more complicated delivery (18), but even daily

Table II—Effect of Aspirin and Acetaminophen on Placental Weight and Fetal Resorption, Viability, Weight, and Length

doses of 6.5 g taken during an entire pregnancy have resulted in the birth of a normal healthy neonate (19). However, in an animal such as the rat in which a wide variety of compounds can affect fetal growth, acetaminophen in the doses used in this study seems to produce less of an adverse effect than does aspirin.

Baeocystin in *Psilocybe semilanceata*

DAVID B. REPKE [*x] and DALE THOMAS LESLIE [‡]

Abstract □ Baeocystin and psilocybin were found in extracts of a variety of *Psilocybe semilanceata*. Psilocybin (but not baeocystin) was also detected in extracts of a related species, *Psilocybe pelliculosa*. Traces of psilocin were present in these two species. The structures of the isolated compounds were corroborated using mass spectrometry and UV spectroscopy.

Keyphrases □ Baeocystin—isolated from extracts of *Psilocybe semilanceata*, identified by mass spectrometry and UV spectroscopy □ Psilocybin—isolated from extracts of *Psilocybe semilanceata* and *P. pelliculosa*, identified by mass spectrometry and UV spectroscopy □ *Psilocybe semilanceata*—extracts of carpophores, baeocystin and psilocybin isolated, identified by mass spectrometry and UV spectroscopy

The genus *Psilocybe* contains many species with hallucinogenic properties (1). Their use for religious purposes in Mexico was first recorded 4 centuries ago (2). However, only in the last 35 years has serious study been devoted to this subject (3). In 1959, two active principles were isolated from several members of this genus (4): the 4-hydroxy-3-(2-dimethylaminoethyl)-indole (psilocin) and its corresponding phosphate ester (psilocybin). Since then psilocin and psilocybin have been detected in other members of *Psilocybe* and related genera (5).

Heim (6) suggested that the hallucinogenic mushroom described in a 16th century English report was *Psilocybe semilanceata* (Fr.) Kummer (Strophariaceae), considered the type species of the genus (7, 8). Investigators have verified the presence of psilocybin (but not psilocin) in several European collections of *P. semilanceata* (9–12).

The presence of the psilocybin analogs 4-phosphoryloxy-3-(2-methylaminoethyl)indole and its demethyl counterpart (baeocystin and norbaeocystin, respectively) have been reported only in *P. baeocystis* Singer and Smith (13). These compounds were not found in *P. attrobrunnea* (Lasch) Gillet, *P. pelliculosa* (Smith) Singer and Smith, *P. caerulipes* (Peck) Sacc., or *P. strictipes* Singer and Smith (14).

During investigations of the indole alkaloids of the genus *Psilocybe*, a compound with a mobility slightly slower than psilocybin was consistently detected on thin-layer chromatograms of extracts of a Pacific Northwest variety of *P. semilanceata*. This compound was observed in all collections of this species examined over several years.

EXPERIMENTAL[1]

Freeze-dried carpophores of *P. semilanceata*[2], 824 mg, were ground to a powder and extracted by shaking with methanol at room tem-

[1] TLC was carried out using 0.25- and 1.0-mm layers of silica gel GF on glass plates. The solvent system used was 1-propanol–5% ammonium hydroxide (5:2) (13). Mass spectra were obtained with an Atlas CH-4 spectrometer *via* direct inlet. The probe temperature was 300°, and the ion source potential was 70 ev. A Cary model 15 spectrophotometer was used to determine UV spectra.

[2] The collections are in the herbarium of the Escuela Nacional de Ciencias Biológicas, I. P. N., Mexico, D. F., Mexico, and some are also on deposit at the herbarium of the University of Michigan, Ann Arbor, Mich. Carpophores of *P. semilanceata* were collected in pastures at the following locations: Grays Harbor County, Wash., 1972–1975 [LESLIE 1351 (also at MICH), 1807 (also at MICH), 2426 (also at MICH), and 2647]; Jefferson County, Wash., 1973–1975 [LESLIE 1843 (also at MICH), 2409 (also at MICH), and 2664]; Randle, Wash., 1975 (LESLIE 2710); and Sixes, Ore., 1975 (LESLIE 2781). Collections of *P. pelliculosa* were found in forests on wood debris and sawdust in Grays Harbor County, Wash., 1973 (LESLIE 1822) and Maytown, Wash., 1975 (LESLIE 2758). The taxon, designated here as *P. semilanceata*, conforms to published descriptions of the European *P. semilanceata*, but some doubt remains concerning this specific placement which further study may clarify.

doses of 6.5 g taken during an entire pregnancy have resulted in the birth of a normal healthy neonate (19). However, in an animal such as the rat in which a wide variety of compounds can affect fetal growth, acetaminophen in the doses used in this study seems to produce less of an adverse effect than does aspirin.

Baeocystin in *Psilocybe semilanceata*

DAVID B. REPKE [*x] and DALE THOMAS LESLIE [‡]

Abstract □ Baeocystin and psilocybin were found in extracts of a variety of *Psilocybe semilanceata*. Psilocybin (but not baeocystin) was also detected in extracts of a related species, *Psilocybe pelliculosa*. Traces of psilocin were present in these two species. The structures of the isolated compounds were corroborated using mass spectrometry and UV spectroscopy.

Keyphrases □ Baeocystin—isolated from extracts of *Psilocybe semilanceata*, identified by mass spectrometry and UV spectroscopy □ Psilocybin—isolated from extracts of *Psilocybe semilanceata* and *P. pelliculosa*, identified by mass spectrometry and UV spectroscopy □ *Psilocybe semilanceata*—extracts of carpophores, baeocystin and psilocybin isolated, identified by mass spectrometry and UV spectroscopy

The genus *Psilocybe* contains many species with hallucinogenic properties (1). Their use for religious purposes in Mexico was first recorded 4 centuries ago (2). However, only in the last 35 years has serious study been devoted to this subject (3). In 1959, two active principles were isolated from several members of this genus (4): the 4-hydroxy-3-(2-dimethylaminoethyl)-indole (psilocin) and its corresponding phosphate ester (psilocybin). Since then psilocin and psilocybin have been detected in other members of *Psilocybe* and related genera (5).

Heim (6) suggested that the hallucinogenic mushroom described in a 16th century English report was *Psilocybe semilanceata* (Fr.) Kummer (Strophariaceae), considered the type species of the genus (7, 8). Investigators have verified the presence of psilocybin (but not psilocin) in several European collections of *P. semilanceata* (9–12).

The presence of the psilocybin analogs 4-phosphoryloxy-3-(2-methylaminoethyl)indole and its demethyl counterpart (baeocystin and norbaeocystin, respectively) have been reported only in *P. baeocystis* Singer and Smith (13). These compounds were not found in *P. attrobrunnea* (Lasch) Gillet, *P. pelliculosa* (Smith) Singer and Smith, *P. caerulipes* (Peck) Sacc., or *P. strictipes* Singer and Smith (14).

During investigations of the indole alkaloids of the genus *Psilocybe*, a compound with a mobility slightly slower than psilocybin was consistently detected on thin-layer chromatograms of extracts of a Pacific Northwest variety of *P. semilanceata*. This compound was observed in all collections of this species examined over several years.

EXPERIMENTAL[1]

Freeze-dried carpophores of *P. semilanceata*[2], 824 mg, were ground to a powder and extracted by shaking with methanol at room tem-

[1] TLC was carried out using 0.25- and 1.0-mm layers of silica gel GF on glass plates. The solvent system used was 1-propanol–5% ammonium hydroxide (5:2) (13). Mass spectra were obtained with an Atlas CH-4 spectrometer *via* direct inlet. The probe temperature was 300°, and the ion source potential was 70 ev. A Cary model 15 spectrophotometer was used to determine UV spectra.

[2] The collections are in the herbarium of the Escuela Nacional de Ciencias Biológicas, I. P. N., Mexico, D. F., Mexico, and some are also on deposit at the herbarium of the University of Michigan, Ann Arbor, Mich. Carpophores of *P. semilanceata* were collected in pastures at the following locations: Grays Harbor County, Wash., 1972–1975 [LESLIE 1351 (also at MICH), 1807 (also at MICH), 2426 (also at MICH), and 2647]; Jefferson County, Wash., 1973–1975 [LESLIE 1843 (also at MICH), 2409 (also at MICH), and 2664]; Randle, Wash., 1975 (LESLIE 2710); and Sixes, Ore., 1975 (LESLIE 2781). Collections of *P. pelliculosa* were found in forests on wood debris and sawdust in Grays Harbor County, Wash., 1973 (LESLIE 1822) and Maytown, Wash., 1975 (LESLIE 2758). The taxon, designated here as *P. semilanceata*, conforms to published descriptions of the European *P. semilanceata*, but some doubt remains concerning this specific placement which further study may clarify.

perature for 20 hr. The mixture was filtered, and the solids were washed with methanol. The combined filtrate and washings were concentrated *in vacuo*. Analytical TLC of the extract (two developments) showed psilocybin (R_f 0.27) and the slower compound (R_f 0.22). Both spots exhibited the same dark-blue coloration when sprayed with 2% 4-dimethylaminobenzaldehyde in ethanol and exposed to hydrogen chloride vapors. Trace amounts of psilocin were also detected.

The concentrated residue was preparatively chromatographed on a 1.0-mm layer of silica gel in the described solvent system. A band containing the two components was removed from the plate, and the compounds were eluted with methanol containing 5% aqueous ammonia. The eluate was concentrated under reduced pressure, and the residue was rechromatographed on a 0.25-mm layer of silica gel to resolve the two components. Two developments in the propanol–ammonia system followed by elution of the bands afforded psilocybin (3 mg, 0.36%), mp 175–180° [lit. (15) mp 185–195°] and its slower-moving counterpart (1 mg, 0.12%), mp 245–248° [lit. (14) mp 254–258°]. Carpophores of *P. pelliculosa* were extracted in a similar manner to give 0.08% psilocybin. Traces of psilocin were also detected.

RESULTS AND DISCUSSION

The UV spectra of the two compounds were superimposable, with λ_{max} (methanol) 290 (ϵ 4000), 280 (sh)(5000), 268 (6300), and 222 (40,000) nm, typical of psilocybin (4). The mass spectra were consistent with published data for psilocybin (11) and baeocystin (13). Psilocybin showed peaks at *m/e* 204 (relative abundance, 19%), 160 (4), 159 (3), 146 (6), 130 (3), 117 (2), and 58 (100). Baeocystin showed peaks at 190 (8), 160 (4), 159 (4), 147 (16), 146 (14), 130 (4), 117 (5), and 44 (100).

Each compound exhibited typical fragmentations of 3-indolylethylamines (16), *e.g.*, a base peak arising from β-bond fission of the ethylamine side chain (psilocybin, *m/e* 58; and baeocystin, *m/e* 44). While neither compound showed a parent peak, both showed signals for the dephosphorylated species (psilocybin, *m/e* 204; and baeocystin, *m/e* 190). The concentration of psilocybin in *P. semilanceata* was consistent with isolated yields reported from European collections (9, 11).

In agreement with Leung and Paul (14), baeocystin was not detected in *P. pelliculosa*. Psilocybin (but not psilocin) has been reported previously in this species (17).

Preliminary investigations suggest the presence of baeocystin in other species and genera. In fact, Leung and Paul (13) and Benedict (18) suggested that baeocystin may have been the unidentified compound observed by Stein *et al.* (19) in a species of *Panaeolus*.

Pharmacological effects of the analogs of psilocybin have not been studied.

Simple Device for GLC Separations of Cannabinoids Using a Surface-Coated Open Tube Column without Stream Splitting

N. K. McCALLUM ˣ and E. R. CAIRNS

Abstract □ A simple device that allows the GLC analysis of greater than 10 μl of sample solution on capillary columns is described. The conditions necessary for application of this device to the quantitative analysis of cannabinoids are elaborated.

Keyphrases □ Cannabinoids—GLC analysis, device using a surface-coated open tube column □ GLC—analysis, cannabinoids, device using a surface-coated open tube column □ Marijuana—GLC analysis of constituents, device using a surface-coated open tube column

GLC is the method of choice for rapid qualitative and quantitative analysis of marijuana constituents. Much literature (1) is devoted to the use of this analytical technique with packed columns. Several investigators, however, reported problems with packed GLC columns for these analyses. Some long chain alkanes have similar re-

perature for 20 hr. The mixture was filtered, and the solids were washed with methanol. The combined filtrate and washings were concentrated *in vacuo*. Analytical TLC of the extract (two developments) showed psilocybin (R_f 0.27) and the slower compound (R_f 0.22). Both spots exhibited the same dark-blue coloration when sprayed with 2% 4-dimethylaminobenzaldehyde in ethanol and exposed to hydrogen chloride vapors. Trace amounts of psilocin were also detected.

The concentrated residue was preparatively chromatographed on a 1.0-mm layer of silica gel in the described solvent system. A band containing the two components was removed from the plate, and the compounds were eluted with methanol containing 5% aqueous ammonia. The eluate was concentrated under reduced pressure, and the residue was rechromatographed on a 0.25-mm layer of silica gel to resolve the two components. Two developments in the propanol–ammonia system followed by elution of the bands afforded psilocybin (3 mg, 0.36%), mp 175–180° [lit. (15) mp 185–195°] and its slower-moving counterpart (1 mg, 0.12%), mp 245–248° [lit. (14) mp 254–258°]. Carpophores of *P. pelliculosa* were extracted in a similar manner to give 0.08% psilocybin. Traces of psilocin were also detected.

RESULTS AND DISCUSSION

The UV spectra of the two compounds were superimposable, with λ_{max} (methanol) 290 (ϵ 4000), 280 (sh)(5000), 268 (6300), and 222 (40,000) nm, typical of psilocybin (4). The mass spectra were consistent with published data for psilocybin (11) and baeocystin (13). Psilocybin showed peaks at *m/e* 204 (relative abundance, 19%), 160 (4), 159 (3), 146 (6), 130 (3), 117 (2), and 58 (100). Baeocystin showed peaks at 190 (8), 160 (4), 159 (4), 147 (16), 146 (14), 130 (4), 117 (5), and 44 (100).

Each compound exhibited typical fragmentations of 3-indolylethylamines (16), *e.g.*, a base peak arising from β-bond fission of the ethylamine side chain (psilocybin, *m/e* 58; and baeocystin, *m/e* 44). While neither compound showed a parent peak, both showed signals for the dephosphorylated species (psilocybin, *m/e* 204; and baeocystin, *m/e* 190). The concentration of psilocybin in *P. semilanceata* was consistent with isolated yields reported from European collections (9, 11).

In agreement with Leung and Paul (14), baeocystin was not detected in *P. pelliculosa*. Psilocybin (but not psilocin) has been reported previously in this species (17).

Preliminary investigations suggest the presence of baeocystin in other species and genera. In fact, Leung and Paul (13) and Benedict (18) suggested that baeocystin may have been the unidentified compound observed by Stein *et al.* (19) in a species of *Panaeolus*.

Pharmacological effects of the analogs of psilocybin have not been studied.

Simple Device for GLC Separations of Cannabinoids Using a Surface-Coated Open Tube Column without Stream Splitting

N. K. McCALLUM ˣ and E. R. CAIRNS

Abstract □ A simple device that allows the GLC analysis of greater than 10 μl of sample solution on capillary columns is described. The conditions necessary for application of this device to the quantitative analysis of cannabinoids are elaborated.

Keyphrases □ Cannabinoids—GLC analysis, device using a surface-coated open tube column □ GLC—analysis, cannabinoids, device using a surface-coated open tube column □ Marijuana—GLC analysis of constituents, device using a surface-coated open tube column

GLC is the method of choice for rapid qualitative and quantitative analysis of marijuana constituents. Much literature (1) is devoted to the use of this analytical technique with packed columns. Several investigators, however, reported problems with packed GLC columns for these analyses. Some long chain alkanes have similar re-

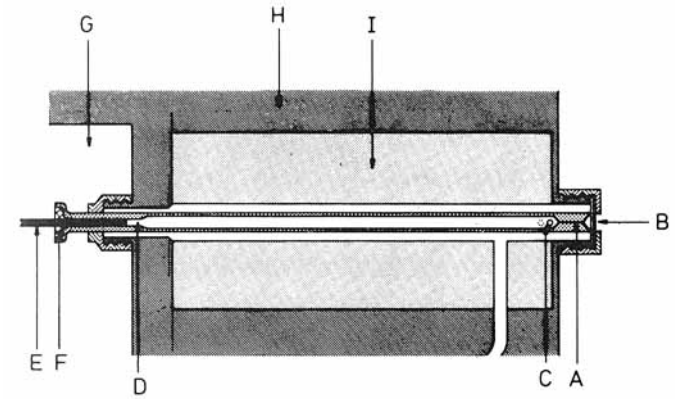

Figure 1—*Inlet port design. (See text.)*

tention times to cannabinoids and can interfere with their analyses (2). Similarly, the retention times of cannabichromene and cannabidiol are the same on most columns, and many reported analytical values for cannabidiol may be suspect for this reason (3).

Such analytical problems generally necessitate an extra analytical step, such as a preliminary chromatographic cleanup or derivatization. However, high-resolution GLC work (4) indicates that interferences by minor constituents are probably more the rule than the exception. Therefore, use of high-resolution capillary columns would be a simpler way of avoiding this problem.

DISCUSSION

Capillary columns have been used for the separation of the naturally occurring volatile terpenes (5) and cannabinoids (4, 6, 7) of *Cannabis*. Unfortunately, the use of capillary columns imposes severe restrictions on the volume of solutions that can be analyzed (0.1–1.0 μl, depending on the column diameter), so a stream splitter is generally used in conjunction with the injection system. Although stream splitters are adequate for qualitative analyses, they can introduce errors into quantitative work (8).

An alternative to the direct injection of very small quantities of solution for quantitative analysis was reported (9). This method allows the direct injection of larger quantities (usually ~0.3 μl) of the solution into an inlet port, designed so that the large amount of solvent vapor initially prevents migration of the sample components, concentrates them to 1% of the original length of the solvent plug, and allows them to be eluted after most solvent has disappeared. The theory of operation was discussed in detail (10).

The design of the inlet port is such that contact of solvent vapors with the septum is reduced to a minimum (solvent bleed from the septum being an important, undesirable factor), and all dead volumes are eliminated (9). A careful choice of solvents is also necessary to utilize the effect; the wrong solvent gives rise to broadened and misshapen peaks (10). Prolonged use of this system has not been found to affect the column life adversely (10).

The advantages of this system are clear: (*a*) utilization of the solvent to produce good resolution rather than complicated procedures to eliminate the solvent, (*b*) greatly improved sensitivity as a natural corollary to improved resolution and the injection of larger samples, and (*c*) strictly quantitative analyses without injection of very small volumes of solution. The disadvantages are designing and building the relatively complicated inlet port system and then finding the optimum solvent and conditions.

This paper presents an alternative, considerably simplified, all-glass system, which can be fabricated by most chemists of average glass-blowing ability. The described system was successfully used for the analysis of hydrocarbons and, in particular, cannabinoids.

EXPERIMENTAL

Inlet Port (Fig. 1)—The capillary (A) was chosen so that its inside diameter was a "snug" fit for the injection syringe needle and its end

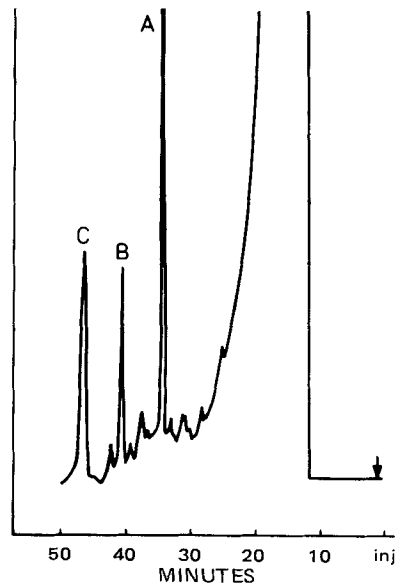

Figure 2—*Gas chromatogram of* Cannabis *sample in methyl laurate. Key: A, cannabidiol; B, Δ^9-tetrahydrocannabinol; and C, cannabinol.*

rested against the septum (B) to eliminate back-diffusion of solvent vapor. The carrier gas entered the system by two holes (C) at the base of the capillary.

The internal diameter of the exit (D) was 1.5 mm, providing an almost exact fit for the glass-lined steel tubing (E) leading to the column. The final seal at the exit was a cut-down, slightly compressed septum (F). Areas G, H, and I are the oven, oven wall, and inlet heater, respectively.

Capillary Column—The glass surface-coated open tube column[1] (70 m × 0.5 mm i.d.) was coated with SE-30, silanized, and deactivated. A "T" piece[1] for makeup gas was fitted at the exit of the capillary column, and connection with the detector port was by means of glass-lined steel tubing[1] to glass tubing (1.5 mm i.d.), using a septum for the final seal as was described for the inlet port.

Operation—A carrier gas flow of about 4 ml/min of helium was used. The makeup gas was nitrogen (~25 ml/min). A light petroleum *Cannabis* extract[2] was evaporated and taken up in the appropriate solvent to a concentration of about 0.1 mg/ml. The sample was then withdrawn completely into the barrel of the syringe, and the GLC[3] septum was penetrated to the full extent of the syringe needle (5–7 cm) and then released. After 2–3 sec, the plunger was withdrawn so that any solvent residues were taken back into the barrel of the syringe; then the syringe was withdrawn from the septum.

Sample sizes of 3 μl were taken when different solvents were being compared; 1–10-μl methyl laurate solutions were selected as the best solvents for these separations. The three major cannabinoids in the extracts (Fig. 2) were identified by comparison with authentic samples. Confirmation of these identities was provided by comparison of the derivatized and underivatized samples with authentic samples on conventional OV-1 and OV-225 columns.

RESULTS

The dimensions of the inlet system appear to have surprisingly little effect on efficiency. Vaporization chambers that were 15 cm × 1.5–3.5 mm i.d. were used and compared to 6-cm × 2.5–4-mm i.d. chambers used previously (9). The system is suitable for large sample sizes (up to 10 μl without sacrificing resolution), and differing dimensions of the oven wall and inlet heater for different models of gas chromatographs apparently present no problem for inlet design.

The suppliers of the capillary column determined its effective theoretical plates (N_{eff}) to be 43,000 for the C_{24} *n*-alkane in methylene chlo-

[1] Supplied by the Scientific Glass Engineering Pty. Ltd., N. Melbourne, Victoria, Australia 3051.

[3] Tracor model 550 with flame-ionization detection.

ride (0.1 μl). When this inlet system was used with the C_{18} *n*-alkane in C_{12} *n*-alkane (5 μl), N_{eff} = 40,000 was obtained. However, GLC of cannabinoids in the higher alkanes produced very poor resolution with considerable peak tailing. Alternative solvents were tested (*e.g.*, *n*-alkanes up to C_{20}, branched chain alkanes up to C_{10}, higher boiling alkenes, alcohols, and ketones), and only fatty acid esters provided acceptable resolution. The best was methyl laurate, which yielded N_{eff} = 25,000 (Fig. 2).

The temperature of the inlet port is critical for good resolution. If the temperature is too low—by as little as 10–15°—no recognizable chromatogram will be achieved. Operating conditions for the cannabinoids in methyl laurate were: oven temperature, 230°; and inlet temperature, 250°.

The N_{eff} for cannabinoids is only 63% that achieved for alkanes. This reduction in efficiency apparently is due, at least in part, to support effects (11); the possibility exists that even more efficient separations of cannabinoids can be achieved with a different stationary phase in combination with another solvent. Different stationary phases may, of course, also provide more convenient elution orders to suit particular problems.

The main point to be noted is that the described device now permits the application of capillary columns (with its attendant 10-fold plus improvement in resolution over conventional columns) to cannabinoid analyses; this system should be of considerable use for biological as well as plant extracts. Other stationary phases and solvents possibly will be applicable to GLC of derivatized cannabinoids. This variety would allow further improvements in the sensitivity of detection of cannabinoids when utilizing electron-capture (12) and flame-ionization (13) detectors.

Dihydralazine Sulfate Analysis Using 2-Methyl-3-nitropyridine-6-carboxaldehyde

A. F. YOUSSEF [x], S. A. IBRAHIM, and S. R. ELSHABOURI

Abstract □ A sensitive, selective colorimetric assay was developed for the quantitative analysis of dihydralazine sulfate. The method is based on the interaction of buffered (pH 4) dihydralazine sulfate with a methanolic solution of 2-methyl-3-nitropyridine-6-carboxaldehyde upon heating to give an orange color. This color can be quantified spectrophotometrically at 450 nm, with a lower limit of detection of 1 μg/ml. The color is stable for at least 24 hr. There is no interference from other drugs likely to be present along with dihydralazine sulfate and common excipients. The method was used successfully for the determination of dihydralazine sulfate in combination with other drugs in different commercial tablets. The developed method was applicable as a stability-indicating assay.

Keyphrases □ Dihydralazine sulfate—colorimetric analysis using 2-methyl-3-nitropyridine-6-carboxaldehyde, prepared samples □ Colorimetry—analysis, dihydralazine sulfate in prepared samples □ 2-Methyl-3-nitropyridine-6-carboxaldehyde—color reagent in analysis of dihydralazine sulfate in prepared samples □ Antihypertensive agents—dihydralazine sulfate, colorimetric analysis in prepared samples

Various methods for the analysis of dihydralazine sulfate (1,4-dihydrazinophthalazine) have been reported (1–11). The bromometric assay for pure dihydralazine sulfate used potassium dichromate (1) or potassium permanganate (2) as the titrant in the presence of potassium bromide. The dihydralazinebenzoic acid–bivalent metal complexes were estimated by titration with edetic acid (3, 4); the dihydralazine–copper thiocyanate complex was estimated by titration with silver nitrate (5).

The reported argentimetric procedures depend on either the estimation of excess silver nitrate added to the buffered solution of dihydralazine at pH 5–6 (6) or stoichiometric determination of metallic silver separated after the addition of ammoniacal silver nitrate (7). Direct potentiometric titration of pure dihydralazine sulfate and other hydrazine derivatives, using chloramine-T in an acidic medium, was reported (8). A coulometric method for dihydralazine, using electrolytically generated bromine, also was reported (9).

Colorimetric methods were developed for the estimation of dihydralazine sulfate in the pure form and in tablets, depending on the formation of a chromogenic product with ammonium molybdate (6) and ferric ion (10); the lower limits of detection were 70 and 150 μg, respectively. Also, a colorimetric method was reported

for the analysis of dihydralazine sulfate using 4,4′-dimethoxydiquinone as the chromogen-developing reagent.

It has been observed in these laboratories that 2-methyl-3-nitropyridine-6-carboxaldehyde interacts with hydrazine derivatives to form chromogenic products. The reaction can be quantified to be used as a simple analytical tool for selective estimation of hydrazine derivatives. This report describes the use of 2-methyl-3-nitropyridine-6-carboxaldehyde as a chromogenic reagent for sensitive and selective estimation of dihydralazine sulfate in the pure form and in combination with other drugs in commercial pharmaceutical formulations. The method also was investigated as a stability-indicating assay.

EXPERIMENTAL

Instrumentation—Spectra and absorbance measurements were made[1] using matched glass cells with 1-cm optical path.

Reagents and Chemicals—The color reagent (2-methyl-3-nitropyridine-6-carboxaldehyde) was prepared according to Banas and Skrowaczewska (12), bp_4 115°. Dihydralazine sulfate[2], hydrochlorothiazide, reserpine, glucose, sucrose, lactose, maize starch, gum acacia, and magnesium stearate were pharmaceutical grade and used as supplied. All solvents and other reagents were reagent grade.

Standard Solution of Dihydralazine Sulfate—Weigh accurately 10 mg of dihydralazine sulfate, transfer to a 10-ml volumetric flask, and dilute to volume with McIlvaine's citric acid–phosphate buffer (pH 4) (13).

Color Reagent—Weigh accurately 25 mg of 2-methyl-3-nitropyridine-6-carboxaldehyde, transfer to a 50-ml volumetric flask, and dissolve in, and dilute to volume with, methanol.

Preparation of Assay Solutions—*For Pure Dihydralazine Sulfate*—Use appropriate volumes of standard dihydralazine sulfate as the assay solution.

For Synthetic Mixture—Transfer an accurately weighed amount of the powdered synthetic mixture, equivalent to 1 mg of dihydralazine sulfate, to a 10-ml volumetric flask. Dissolve as completely as possible in, and dilute to volume with, McIlvaine's citric acid–phosphate buffer (pH 4). Filter and discard the first portion of the filtrate. The clear solution obtained is the assay solution.

For Tablets Containing Dihydralazine Sulfate—Weigh and powder 20 tablets. Transfer an accurately weighed quantity of the powder, equivalent to 10 mg of dihydralazine sulfate, to a 10-ml volumetric flask and proceed as for the synthetic mixture, starting from: "dissolve as completely . . . . "

Recovery Experiment—Add an accurately weighed amount of dihydralazine sulfate to an accurately weighed amount of the powdered tablets, equivalent to a known amount of dihydralazine sulfate, in a 10-ml volumetric flask and proceed as for the synthetic mixture, starting from: "dissolve as completely . . . . "

Development of Color—Into 10-ml volumetric flasks, each containing 1 ml of the color reagent, pipet 1 ml of the assay solution of appropriate dilution. Then heat on a boiling water bath for 5 min and cool. Dilute to volume with methanol and mix well. Determine the absorbance at 450 nm against the blank.

Application of Developed Method as Stability-Indicating Assay—Prepare a 0.1% solution of dihydralazine sulfate in McIlvaine's citric acid–phosphate buffer (pH 8). Titrate an aliquot of this solution with potassium iodate, using the NF XIII method (14). For the colorimetric assay, measure accurately suitable volumes of the prepared solution, make the appropriate dilution with McIlvaine's citric acid–phosphate buffer (pH 4), and carry out the assay as already described. Repeat the analysis by both methods after heating aliquots of the prepared solution on a boiling water bath for 15, 30, and 60 min.

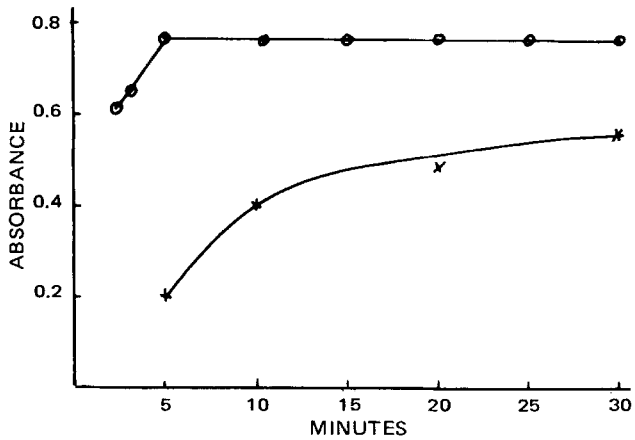

Figure 1—*Effect of the reaction time on the intensity of color. Key:* O, *at the temperature of the boiling water bath; and* ×, *at room temperature.*

RESULTS AND DISCUSSION

The interaction between hydrazino derivatives and aldehydes to yield the respective hydrazones is well known and reported to be acid or base catalyzed (15). Initial trials to react a methanolic solution of 2-methyl-3-nitropyridine-6-carboxaldehyde with dihydralazine sulfate in the presence of trichloroacetic acid failed to yield the chromogenic hydrazone, even upon heating in a boiling water bath for 1 hr.

Accordingly, a rigorous investigation was carried out to develop suitable conditions for color development. Different buffer systems of various constitution and pH were investigated.

When phosphate buffer was used (pH 6–8) (16), an orange-colored product developed with maximum absorption at 440 nm. The extinction of the colored product increased with a decrease in pH (Table I). By using McIlvaine's citric acid–phosphate buffer (pH 2.2–8), the intensity of the color production reached its maximum value at pH 4 (Table I) with an absorption peak at 450 nm and a broad absorption band extending from below 400 to 550 nm. The use of acetic acid–sodium acetate buffer (pH 4.05) (17) instead of McIlvaine's citric acid–phosphate buffer did not significantly affect color intensity or the λ_{max}. However, the McIlvaine's citric acid–phosphate buffer was tentatively chosen as the reaction medium because of the appreciable reduction in color development time compared with the acetate buffer.

Investigations were carried out to determine the solvent and reagent concentration that would give the highest color intensity. Solvents tested include methanol and ethanol. At reagent concentrations greater than 0.4 mg/ml, the intensity of color was only slightly de-

[a] Per milligram of dihydralazine sulfate. [b] Average of four determinations.

pendent upon the reagent concentration. A concentration of 0.5 mg/ml was selected.

The reaction time was determined by following the color development at room temperature and at the temperature of a boiling water bath (Fig. 1). The results indicated that the 30-min interval was not sufficient to bring the color to maximum intensity. Under the same pH, a heating time interval of only 5 min was required to obtain the maximum color intensity, which remained stable for at least 24 hr. This asset is important for a quality control method and for a series of determinations. The color reaction product showed a broad absorption peak with a maximum at about 450 nm and an apparent molar absorptivity of 37.3×10^3.

Beer's law was obeyed ($r = 0.9997$) up to an initial dihydralazine sulfate concentration of 14 μg/ml ($A \approx 1.07$). A typical linear regression line had a slope of 0.078, an intercept of −0.028, and SS of 7.25×10^{-4}.

The specificity of the method for the determination of dihydralazine sulfate in the presence of several frequently encountered excipients, additives, and certain drugs, such as reserpine and hydrochlorothiazide, was investigated. A synthetic mixture was prepared by mixing a known amount of dihydralazine sulfate with an excipient or drug, each approximating sample weights of commercial tablets, and the assay was performed. The average recovery ranged from 97 to 100% (Table II). The relatively low percentage recovery obtained when glucose was the additive may be due to the partial reaction of dihydralazine with nonchromogenic aldose.

Different marketed dihydralazine tablets were satisfactorily analyzed by this method (Table III).

The preliminary stability study showed that solutions of dihydralazine in distilled water and in McIlvaine's citric acid–phosphate buffer below pH 7 were stable at room temperature for at least 48 hr, as shown by the constant readings of samples analyzed by the developed method and by the reference iodate method (14). Upon heating in a boiling water bath for 15 min, the color intensity decrease was not significant. However, a solution of dihydralazine in McIlvaine's citric acid–phosphate buffer (pH 8) acquired rapidly a yellow coloration, which was intensified by heating.

[a] A = reserpine, 0.1 mg; dihydralazine sulfate, 10 mg; hydrochlorothiazide, 10 mg; and excipients. B = reserpine, 0.1 mg; dihydralazine sulfate, 10 mg; and excipients. [b] Average of three determinations.

Table IV—Effect of Time on the Stability of Dihydralazine Sulfate Solution at pH 8

Minutes	Recovery[a], % Iodometric Method	Proposed Method
0	100.0	100.0
15	90.0	85.0
30	89.0	78.7
60	87.1	75.0

[a] Average of two determinations.

The degradation of dihydralazine sulfate at the temperature of the boiling water bath was followed by the colorimetric and iodometric methods at 15, 30, and 60 min. The rather low selectivity of the iodometric method was shown by the pattern of higher results obtained compared to the proposed method (Table IV). Any degradation product susceptible to oxidation by potassium iodate would probably interfere in the iodometric method, but the proposed method allows interaction only with the intact hydrazine moiety. Consequently, the proposed colorimetric method is more selective and can be recommended as a stability-indicating assay.

Biological Effects of Cocaine Derivatives I: Improved Synthesis and Pharmacological Evaluation of Norcocaine

RONALD F. BORNE ˣ, JOHN A. BEDFORD, JUDITH L. BUELKE, CATHY B. CRAIG, THOMAS C. HARDIN, ARTHUR H. KIBBE, and MARVIN C. WILSON

Abstract □ An improved synthesis of norcocaine, a metabolite of cocaine, is reported. Following intravenous administration to a rhesus monkey, respiratory effects were similar to those observed following cocaine treatment. In addition, clonic convulsions, hypothermia, and mydriasis resulted. Norcocaine could be responsible for part of the pharmacological activity of cocaine.

Keyphrases □ Cocaine derivatives—norcocaine synthesized, pharmacological activity evaluated, monkeys □ Norcocaine—synthesized, pharmacological activity evaluated, monkeys □ Structure–activity relationships—norcocaine (cocaine derivative) synthesized, pharmacological activity evaluated, monkeys □ Narcotics, potential—norcocaine synthesized, pharmacological activity evaluated, monkeys

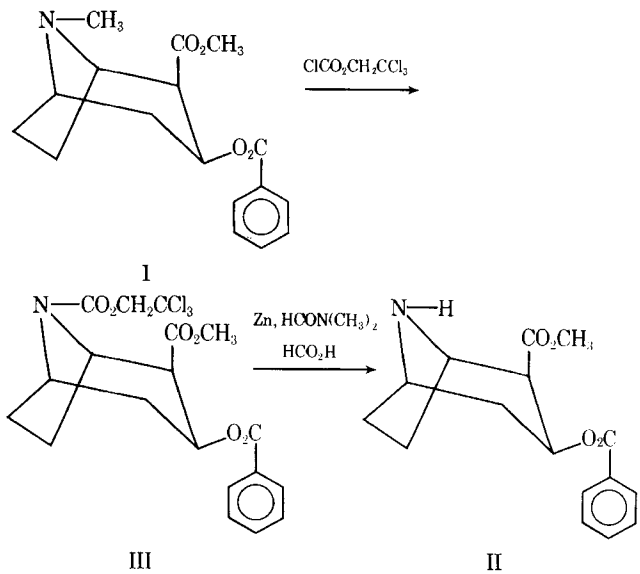
Great attention has been devoted recently to metabolic studies of the potent central nervous system (CNS) agent cocaine (I). Products resulting from ester hydrolysis have been known for some time (1–4), but only recently have *N*-demethylation products been reported (5–8). A recent study (9) regarding the pharmacological activity of norcocaine (II) prompted this examination of its *in vivo* effects. Previous syntheses of norcocaine entailed many steps and involved ester hydrolysis and reesterification procedures (*e.g.*, 10). A facile demethylation procedure was sought which would not result in ester hydrolysis. A report (11) on the synthesis of α-(±)-noracetylmethadol prompted this article.

DISCUSSION

The first attempt to synthesize norcocaine in a one-step synthesis from cocaine involved treating cocaine with potassium permanganate (10). Although some norcocaine was obtained, the product contained considerable amounts of cocaine. Attention was turned to the method of Abdel-Monem and Portoghese (12), which involved treating the *N*-methyl compound with phenyl chloroformate and hydrolysis of the resulting carbamate. Because carbamate hydrolysis requires strong alkaline conditions that would certainly hydrolyze both ester functions of cocaine, this reaction was attempted using benzyl chloroformate instead of phenyl chloroformate. The resulting benzyl carbamate probably could be cleaved under hydrogenolysis conditions that would not cause ester hydrolysis. Although many reaction conditions were employed, no reaction was observed between cocaine and benzyl chloroformate. Treating cocaine with diethyl azodicarboxylate (11) for 4 days in benzene at 50° gave, upon workup, a mixture of cocaine and norcocaine.

The method of Windholz and Johnston (13), as modified (11), was then explored (Scheme I). Norcocaine was obtained as the hydrochloride free of any contaminating cocaine based on data observed from TLC and GLC–mass spectral studies. Since the intermediate carbamate (III) is not purified before treatment with zinc dust, this approach constitutes a one-step synthesis of norcocaine from cocaine in quantities that should permit thorough pharmacological evaluation.

Preliminary evaluation of norcocaine hydrochloride in the rhesus monkey indicated potent CNS effects. Both cocaine and norcocaine produced a rapid increase in the respiratory rate of similar magnitude (Table I). On the basis of these preliminary data, norcocaine may be more potent with regard to this parameter since it produced a greater elevation in rate. However, the duration of this increase was shorter following norcocaine administration.



Scheme I

Within 1 min following the injection of norcocaine, clonic convulsions were observed. They occurred in a cyclical manner for the next 15 min. During this period, the interconvulsion interval increased from 5 sec to 1 min. However, the duration of each convulsive episode remained fairly constant, *i.e.*, 5–10 sec after an initial 45-sec convulsion. During the interconvulsion interval, respiration was shallow but rapid. Respiratory measures were determined during these intervals. The administration of cocaine produced a similar convulsive pattern. This effect began within 1 min following administration and was dissipated within 5 min.

Table I—Respiration and Temperature

	Cocaine Hydrochloride (4.5 mg/kg iv)		Norcocaine Hydrochloride (4.5 mg/kg iv)	
Minutes	Respiration per Minute	Temperature	Respiration per Minute	Temperature
Pre-15	28	38.2°	26	37°
Post-5	36	38°	36	37°
15	32	38°	50	37°
30	30	38°	34	36.8°
45	30	38.2°	36	36.5°
60	30	38.8°	36	36.5°
75	34	38.5°	34	35.5°
90	32	38.4°	30	35.5°
105	34	38.2°	22	35.7°
120	34	38.2°	24	36°
150	32	38.2°	20	36.1°
180	32	38.2°	20	36°
210	34	38°	46	35°
240	34	38.2°	22	35°

Although the convulsive pattern induced by these agents immediately after administration may have contributed to hyperventilation, this result is unlikely. Previous research in this laboratory indicated that respiratory depression is the more common result of convulsions induced with cocaine. Furthermore, with norcocaine, the duration of hyperventilation was much greater than that of the convulsive action. Additional data obtained in this laboratory demonstrate that substantial increases in respiration rate result from the administration of nonconvulsive doses of cocaine.

Cocaine increased body temperature by 0.6° 1 hr following treatment, but the effect was not statistically significant. This hyperthermic effect had dissipated within the next hour. Significant elevations in rectal temperature followed administration of cocaine to other subjects in this laboratory. The time course of this hyperthermic effect was identical to that in the present study.

Following treatment with norcocaine, body temperature significantly decreased within 45 min. This decrement in body temperature was still evident 4 hr posttreatment. Whether this hypothermia was the result of the longer convulsive action of norcocaine or whether it indicates a pharmacological difference between cocaine and norcocaine remains to be determined. It is unlikely that the convulsive pattern and duration that resulted from norcocaine administration would be reflected in temperature changes occurring 3.5 hr later. Hypothermia probably is the result of extensive vasodilation, a common toxic manifestation of local anesthetic agents. Norcocaine appears to resemble cocaine with respect to mydriatic action and enhancement of reactivity to stimuli.

These preliminary data, along with the *in vitro* results of Hawks *et al.* (9), suggest that norcocaine is a pharmacologically active metabolite of cocaine *in vivo*. More detailed pharmacological studies are currently being conducted.

EXPERIMENTAL[1]

Norcocaine (II)—Solutions of cocaine (7.2 g, 0.024 mole) in 50 ml of benzene and 2,2,2-trichloroethyl chloroformate (5.6 g, 0.027 mole) in 25 ml of benzene were combined, and the resulting solution was refluxed for 18 hr. The mixture was cooled to 5°, and 0.4 ml of formic acid was added. After stirring for an additional 30 min, 0.9 ml of triethylamine was added; the resulting mixture was stirred at room temperature for 1 hr. Water (50 ml) was added, and the mixture was extracted with ether (2 × 100 ml).

The organic extracts were combined, extracted with 250 ml of 5 *N* hydrochloric acid to remove any unreacted cocaine, dried over sodium sulfate, and evaporated to yield an oil whose IR and NMR spectra were consistent with Structure III. The oil was dissolved in dimethylformamide (25 ml) and cooled to 5°. Formic acid (2.0 g) was added, followed by the addition of zinc dust (3.6 g) in portions maintaining the temperature at 5°. After the zinc dust addition was complete, the mixture was stirred at room temperature for 18 hr. Then the mixture was filtered, and the filtrate was poured onto 100 g of crushed ice. The mixture was made strongly acidic in the cold with concentrated hydrochloric acid and extracted with ether (2 × 100 ml).

The acidic layer was recooled to 5°, made strongly alkaline with ammonium hydroxide, and extracted with ether (2 × 100 ml). The ether extracts were combined, dried over sodium sulfate, and evaporated to give a viscous oil. This oil gave one spot on TLC and one peak by GLC that differed from the R_f value and retention time, respectively, observed for cocaine. Trituration with petroleum ether gave a solid, mp 82–83°; NMR ($CDCl_3$): δ 3.03 (1H, s, NH, disappeared on addition of D_2O), 3.68 (3H, s, OCH_3), and 7.43–8.17 (5H, m, aromatic); $[\alpha]_D^{26}$ −41.0° (*c* 1, $CHCl_3$).

Anal.—Calc. for $C_{16}H_{19}NO_4$: C, 66.42; H, 6.62; N, 4.84. Found: C, 66.30; H, 6.62; N, 4.78.

The hydrochloride was prepared in the usual manner to give 4.4 g (56%) of II hydrochloride, mp 111–113°; *m/e* 289.

Pharmacological Methods—A male subadult rhesus monkey, surgically prepared with a chronic indwelling jugular catheter, was housed in a primate restraining chair[2] with free access to water. A rectal temperature probe was inserted on the day prior to drug administration, and respirometer bellows were attached on the morning of drug testing. Body temperature and respiratory rate and depth were continuously monitored for 15 min prior to drug administration. These parameters were recorded at 5 and 15 min postinjection, every 15 min thereafter until 2 hr posttreatment, and every 30 min for an additional 2 hr.

Drugs were dissolved in physiological saline and administered at approximately the same time of day *via* an intravenous catheter. Cocaine hydrochloride and norcocaine hydrochloride were administered at 6-week intervals at dose levels of 4.5 mg/kg.

NMR Determination of Trimethoprim and Sulfamethoxazole in Tablets and Powders

MARÍA R. RODRIGUEZ, MARÍA T. PIZZORNO, and SEM M. ALBONICO ˣ

Abstract □ An NMR spectroscopic method for the determination of mixtures of trimethoprim and sulfamethoxazole is described. Spectra are determined in dimethyl sulfoxide-d_6, containing 1,4-dinitrobenzene as an internal standard. Both synthetic mixtures and commercial formulations were assayed, and the results were compared to those obtained using the BP procedure.

Keyphrases □ Trimethoprim—NMR spectroscopic analysis, synthetic mixtures and commercial formulations containing sulfamethoxazole □ Sulfamethoxazole—NMR spectroscopic analysis, synthetic mixtures and commercial formulations containing trimethoprim □ NMR spectroscopy—analysis, trimethoprim and sulfamethoxazole, synthetic mixtures and commercial formulations □ Antibacterial agents—trimethoprim and sulfamethoxazole, NMR spectroscopic analysis, synthetic mixtures and commercial formulations

The chemotherapeutic activity of trimethoprim, 2,4-diamino-5-(3,4,5-trimethoxybenzyl)pyrimidine (I), resulting from its ability to inhibit dihydrofolate reductase is increased as much as 30–60-fold when combined with a sulfonamide (1). Owing to its synergism and pharmacokinetic similarity, the choice association is sulfamethoxazole (II) in a one to five relation (2).

Several methods are available to analyze I and its metabolites in biological fluids. One method requires oxidation and spectrophotofluorometric measuring of the trimethoxybenzoic acid formed (3, 4). The other procedure uses differential pulse polarography (5, 6) or TLC, followed by fluorescence determination (7).

Only a compendial procedure is known for the analysis of the mixture. The BP (8) describes an extraction procedure in an alkaline medium for I, followed by back-extraction with diluted acetic acid and spectrophotometric determination. For II, a simple Bratton–Marshall reaction using the aqueous solution is described.

The procedure for the analysis of mixtures of I and II proposed here uses ^{1}H-NMR spectroscopy. No isolation is required, and good quantitative results were obtained with known mixtures and commercial preparations (tablets and powders).

EXPERIMENTAL[1]

Materials—Standard trimethoprim (I) and sulfamethoxazole (II) were prepared by recrystallization from ethanol–water. 1,4-Dinitrobenzene[2] (III) was used as an internal standard after purification by sublimation, mp 173–174°, and dimethyl sulfoxide-d_6[2] (IV) was used as a solvent. Tetramethylsilane was the internal standard.

Samples—Tablets from two batches of each of the four brands (obtained locally) and two batches of the only pediatric powder available were used.

Procedure—Twenty tablets were weighed and powdered. A sample equivalent to 10 mg of I, 50 mg of II, and 30.0 mg of III was dissolved in 1 ml of IV in a 2-ml centrifuge tube. The tube was placed into a bath (70°)

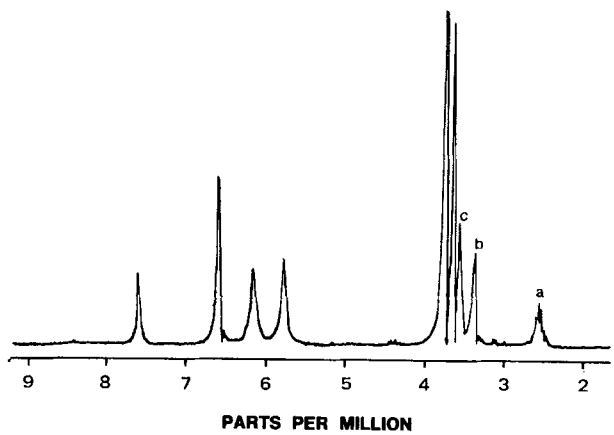

Figure 1—*NMR spectrum of trimethoprim in dimethyl sulfoxide-*d_6. *Key: a, solvent impurity; b, aromatic protons; and c, 4-methoxy group.*

for 2 min and centrifuged. About 0.4 ml of the solution was transferred to an NMR tube, and the spectrum was obtained.

The same procedure was used for the powdered tablets.

The amount of I was calculated as follows:

$$\frac{\text{mg of I}}{\text{tablets}} = \frac{EW_I}{EW_{III}} \times \frac{A_I}{A_{III}} \times \frac{\text{mg of III}}{W_s} \times \text{a.t.w.} \qquad \text{(Eq. 1)}$$

$$\frac{\text{mg of I}}{\text{100 g of powder}} = \frac{EW_I}{EW_{III}} \times \frac{A_I}{A_{III}} \times \frac{\text{mg of III}}{W_s} \times 100 \qquad \text{(Eq. 2)}$$

where EW_I is the molecular weight divided by the number of protons in the signal chosen, EW_{III} is the molecular weight of the internal standard divided by the number of protons in its signal, A_I is the integral value of the signal representing I, A_{III} is the integral value of the signal representing III, W_s is the weight of the sample in milligrams, and a.t.w. is the average tablet weight.

The amount of II was calculated by a similar procedure.

RESULTS AND DISCUSSION

The selection of a solvent and an internal standard is important in any NMR procedure. In this case, since the drugs, I and II, and the internal standard, III, are freely soluble in dimethyl sulfoxide, it is the solvent of

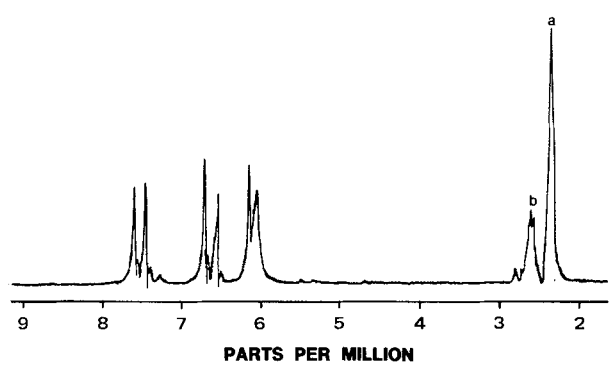

Figure 2—*NMR spectrum of sulfamethoxazole in dimethyl sulfoxide-*d_6. *Key: a, C-CH_3 group; and b, solvent impurity.*

[1] A Perkin-Elmer R-12 NMR spectrometer, 60 MHz, was used. All spectra were scanned at a probe temperature of 35°.

D, Tablet	400.0	396.0	99.0	404.8	101.2	80.0	79.8	99.8	80.0	100.0
E, Tablet	400.0	394.8	98.7	396.0	99.0	80.0	79.2	99.0	78.4	98.0
F, Tablet	400.0	396.8	99.2	393.2	98.3	80.0	80.2	100.2	77.2	96.5
G, Tablet	800.0	796.0	99.5	776.0	97.0	160.0	158.5	99.1	157.1	98.2
H, Tablet	800.0	808.0	101.0	813.6	101.7	160.0	157.6	98.5	155.2	97.0
I, Powder (mg/100 g)	4000.0	4020.0	100.5	3920.0	98.0	800.0	800.0	100.0	792.0	99.0
J, Powder (mg/100 g)	4000.0	3968.0	99.2	4016.0	100.4	800.0	792.0	99.0	808.0	101.0

choice. The use of IV offers the obvious advantage of adding no proton signals to the spectrum; its impurity appears at 2.5 ppm and it does not interfere with the signals chosen. Compound III provides a single signal at 8 ppm; it was used previously as an internal standard (9).

The signals chosen for the analysis were the singlet at 3.40 ppm due to the aromatic protons of I together with the singlet at 3.55 ppm due to the 4-methoxy group of I (Fig. 1), the singlet at 2.3 ppm due to the only C-CH_3 of II (Fig. 2), and the single signal given by III at 8 ppm.

The analysis of a group of known standard I and II mixtures by NMR is summarized in Table I. The method is both accurate and precise, with a mean (standard deviation) of 100.0 ± 0.87% for I and 100.2 ± 0.84% for II. The relative proportions of I and II to III (Table I) have no significant bearing on the accuracy of the determination for the ranges of proportions shown.

By applying this procedure to actual samples, eight commercial lots of tablets from four companies were studied (Fig. 3) together with two lots of the only pediatric powder available (Table II). One product (Samples E and F) also contained 50 mg of benzydamine hydrochloride/tablet. Benzydamine does not interfere in the method; with IV as a solvent, its peaks do not appear in the chosen region of the spectra.

The results are in good agreement with the declared dosages and with results obtained using the official BP (8) procedure (Table II). The NMR procedure has several distinct advantages over the official method.

NMR spectra of such binders as starch, lactose, methylcellulose, and povidone in dimethyl sulfoxide were obtained and examined. They did not interfere with the NMR analysis of I or II.

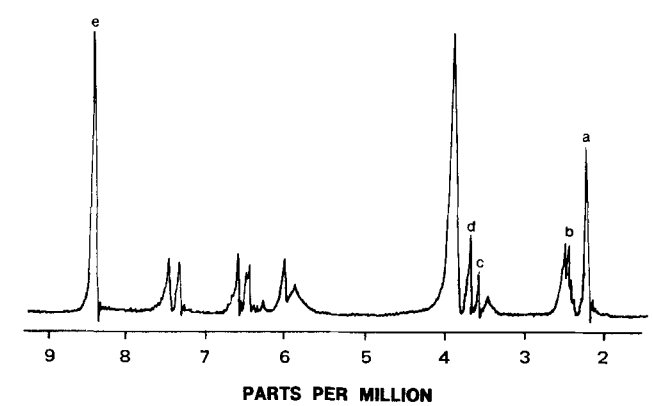

Figure 3—*NMR spectrum of a typical tablet analysis in dimethyl sulfoxide-d_6. Key: a, C-CH_3 group of II; b, solvent impurity; c, aromatic protons of I; d, 4-methoxy group of I; and e, single signal of III.*

Analysis of Homatropine Methylbromide Dosage Forms

S. HANNA [x], M. ROSEN, L. RASERO, and L. LACHMAN

Abstract □ A stability-indicating method of analysis for homatropine methylbromide in pharmaceutical formulations was developed. This method is based on the formation of a picric acid–quaternary ammonium complex, which is adsorbed on acid-washed diatomaceous earth in alkaline media followed by on-column chloroform extraction. The picrate complex is measured spectrophotometrically at 365 nm. The method was selective for homatropine methylbromide in that there was no interference from its major hydrolytic decomposition products, tropinium methylbromide and mandelic acid.

Keyphrases □ Homatropine methylbromide—spectrophotometric analysis, pharmaceutical formulations □ Spectrophotometry—analysis, homatropine methylbromide in pharmaceutical formulations □ Anticholinergic agents—homatropine methylbromide, spectrophotometric analysis in pharmaceutical formulations

Previously reported assay methods employed in the analysis of homatropine methylbromide dosage forms involved the precipitation of an insoluble salt of the methylhomatropine cation by anions such as the reineckate, silicotungstate, and tetraiodomercurate, followed by colorimetry (1) or turbidimetry (2, 3). Other colorimetric procedures involved chromogenesis with Dragendorff's reagent (4, 5) or measurement of the ferric hydroxamate complex (6). Analytical methods utilizing spectrophotometry (7, 8), TLC (9), and GLC (10, 11) also were reported. As previously discussed (12), these methods and official procedures (13) lack sensitivity, selectivity, or specificity or require additional washing or separation steps.

The stability-indicating assay procedure for homatropine methylbromide in syrups (12) is time consuming. This report presents a simple stability-indicating method, a modification of the method of Chin and Lach (14), for the assay of homatropine methylbromide dosage forms. The procedure was applied, with satisfactory results, to several commercial tablets, drops, and elixirs.

EXPERIMENTAL

Instruments—The recording spectrophotometer[1] had 1-cm cells and glass tubing columns[2], 200 × 25-mm o.d. with a tip 50 × 8-mm o.d. The columns were fitted with a small wad of glass wool at the bottom and top of the packing.

Materials and Reagents—The following were used: acid-washed diatomaceous earth[3]; homatropine methylbromide (NF reference standard); ammonium picrate reagent prepared by dissolving 11.2 g of picric acid[4] in 900 ml of distilled water, adding 6 ml of concentrated ammonia[4], and diluting to 1000.0 ml with distilled water; mandelic acid[4]; tropinium methylbromide[5]; and chloroform[4].

Standard Curve—A stock solution of homatropine methylbromide was prepared by dissolving 50.0 mg in 100 ml of distilled water. Further dilutions were made to obtain homatropine methylbromide standard solutions containing 0.125, 0.25, and 0.375 mg/ml. Two milliliters of stock and diluted standard solutions were each transferred into a 100-ml beaker containing 3.0 g of acid-washed diatomaceous earth, and 1.0 ml of ammonium picrate reagent was added. The mixture was mixed thoroughly and quantitatively transferred and packed into the glass column.

Elution was accomplished by immediately passing 17 × 5-ml portions of water-saturated chloroform at a flow rate of 7–9 ml/min, allowing each portion of eluant to run completely into the column before adding the next. The combined eluates were collected separately in 100-ml volumetric flasks and diluted to volume with chloroform. The absorbance of the standard solutions was measured in 1-cm absorption cells at 365 nm against chloroform as a blank.

Sample Procedure—*Tablets*—A number of tablets, equivalent to about 50 mg of homatropine methylbromide, were transferred to a 100-ml volumetric flask, and 75 ml of distilled water was added. The flask was shaken well for 30 min, and distilled water was added to the mark. The mixture was filtered through fluted filter paper, and the first 10 ml of filtrate was rejected. Two milliliters of the filtrate was pipetted into a 100-ml beaker, and the test was conducted as described under *Standard Curve*, beginning with "containing 3.0 g of acid-washed diatomaceous earth, ..."

Drops or Elixir—A volume of drops or elixir, equivalent to about 50 mg of homatropine methylbromide, was accurately measured and transferred to a 100-ml volumetric flask. Distilled water was added to the mark, and the contents were mixed well. Two milliliters was pipetted into a 100-ml beaker, and the test was conducted as described under *Standard Curve*, beginning with "containing 3.0 g of acid-washed diatomaceous earth, ..."

RESULTS AND DISCUSSION

This method, a modification of the one of Chin and Lach (14), is based on the reaction of picric acid with quaternary ammonium compounds in an alkaline medium to form a colored complex. The complex is adsorbed on acid-washed diatomaceous earth and measured spectrophotometrically after on-column extraction with water-saturated chloroform.

Under the experimental conditions, a linear relationship existed between the absorbance and concentration of homatropine methylbromide over the 0.25–1.0-mg/ml concentration range, with a correlation coefficient of 0.9996. Regression analysis showed that the regression equation was $y = 0.421x - 0.003$, with a standard error of the estimate of y on x

Analysis of Homatropine Methylbromide Dosage Forms

S. HANNA [x], M. ROSEN, L. RASERO, and L. LACHMAN

Abstract □ A stability-indicating method of analysis for homatropine methylbromide in pharmaceutical formulations was developed. This method is based on the formation of a picric acid–quaternary ammonium complex, which is adsorbed on acid-washed diatomaceous earth in alkaline media followed by on-column chloroform extraction. The picrate complex is measured spectrophotometrically at 365 nm. The method was selective for homatropine methylbromide in that there was no interference from its major hydrolytic decomposition products, tropinium methylbromide and mandelic acid.

Keyphrases □ Homatropine methylbromide—spectrophotometric analysis, pharmaceutical formulations □ Spectrophotometry—analysis, homatropine methylbromide in pharmaceutical formulations □ Anticholinergic agents—homatropine methylbromide, spectrophotometric analysis in pharmaceutical formulations

Previously reported assay methods employed in the analysis of homatropine methylbromide dosage forms involved the precipitation of an insoluble salt of the methylhomatropine cation by anions such as the reineckate, silicotungstate, and tetraiodomercurate, followed by colorimetry (1) or turbidimetry (2, 3). Other colorimetric procedures involved chromogenesis with Dragendorff's reagent (4, 5) or measurement of the ferric hydroxamate complex (6). Analytical methods utilizing spectrophotometry (7, 8), TLC (9), and GLC (10, 11) also were reported. of 0.005 and standard errors of the estimate of the intercept and slope of 0.05 and 0.84, respectively. The colored complex in chloroform was stable for at least 5 hr.

The precision of the assay procedure was determined by running replicate studies on nine 2.0-ml aliquots of a standard homatropine methylbromide solution containing 0.5 mg/ml. Each solution was assayed by the proposed procedure. The coefficient of variation for the nine replicate samples was 0.52% (Table I). A blank sample, containing tropinium methylbromide and mandelic acid equivalent to 100% hydrolytic degradation of homatropine methylbromide, assayed by the proposed procedure yielded no absorbance at 365 nm, demonstrating that the method is stability indicating.

Results obtained by applying the procedure to commercially available homatropine methylbromide dosage forms are presented in Table II. Comparison of the experimental data with those obtained using an ion-exchange method (12) shows a good correlation.

Physical Form as a Determinant of Effect of Buffered Acetylsalicylate Formulations on GI Microbleeding

BARRIE M. PHILLIPS[x] and BLAZE T. PALERMO

Abstract □ During a 48-day period, 12 male dogs received four buffered sodium acetylsalicylate formulations, quantitatively virtually identical (a homogeneous disintegrating swallow tablet, a swallow tablet in which the sodium acetylsalicylate was contained in a dissolving core, an encapsulated powder, and an aqueous suspension), at 650-mg aspirin equivalent doses twice daily during four 7-day treatment periods (each preceded by a 5-day period of no treatment) in a complete changeover fashion. Mean daily fecal blood losses of 0.75, 1.37, 1.43, and 2.89 ml were observed in the 12 dogs during treatment with the aqueous suspension, the homogeneous tablet, the encapsulated powder, and the core tablet, respectively. These findings indicate that the physical form of buffered acetylsalicylate formulations is a critical factor in the effect of such formulations on GI microbleeding.

Keyphrases □ Sodium acetylsalicylate—buffered formulations, various dosage forms, effect on GI microbleeding, dogs □ Aspirin, sodium salt—buffered formulations, various dosage forms, effect on GI microbleeding, dogs □ GI microbleeding—buffered sodium acetylsalicylate, effect of various dosage forms, dogs □ Dosage forms—buffered sodium acetylsalicylate, effect on GI microbleeding, dogs □ Analgesics—sodium acetylsalicylate buffered formulations, various dosage forms, effect on GI microbleeding, dogs

Gastric mucosal irritation, reflected in increased fecal occult blood loss, is a common side effect of orally administered aspirin. Levy (1) suggested that the degree of gastric mucosal erosion following the oral administration of aspirin is related to two factors: the concentration of aspirin in solution and the duration of contact of the so-

Gastric mucosal irritation, reflected in increased fecal occult blood loss, is a common side effect of orally administered aspirin. Levy (1) suggested that the degree of gastric mucosal erosion following the oral administration of aspirin is related to two factors: the concentration of aspirin in solution and the duration of contact of the so-

Table I—Description of the Buffered Sodium Acetylsalicylate[a] Formulations Employed

Formulation Code	Physical Form	Buffer Component, mg/Unit Dose			Calculated Excess Buffer Capacity, mEq
		Calcium Carbonate	Magnesium Carbonate	Tricalcium Phosphate	
A2	Aqueous suspension of powder[b]	215	182	48	8.98
B2	Encapsulated powder	215	182	48	8.98
C2	Homogeneous, disintegrating swallow tablet	246	211	—	6.77
D2	Dissolving core swallow tablet	215	182	48	8.98

[a] Unit doses of the four formulations contained 365 mg of sodium acetylsalicylate, equivalent to 325 mg of aspirin. [b] Aqueous suspensions were prepared just prior to administration. Powder equivalent to two unit doses was placed in a 150-ml beaker, 75 ml of distilled water was added, and the mixture was stirred manually for a time adequate to give a uniform suspension. The resulting suspension, followed by a 25-ml distilled water rinse, was administered by gavage.

lution with the mucosa. He noted that particles of solid aspirin adherent to the moist mucosal surface are surrounded by a saturated solution of aspirin; as dissolved unionized drug is absorbed into the mucosa, the solid particle acts as a reservoir and provides additional aspirin to the solution. Anderson (2) agreed with this view and noted that, with insoluble aspirin preparations, there was good correlation between the number of aspirin particles in the stomach and the number of focal erosions.

In recent years, Leonards and Levy (3–5) demonstrated conclusively that the effect of aspirin on the gastric mucosa can be minimized by administration of the analgesic either in dilute aqueous solution or as rapidly dissolving tablets buffered to maintain the acetylsalicylate in its ionized form. Phillips *et al.* (6) described a homogeneous swallow tablet formulation[1] containing sodium acetylsalicylate and 6.77 mEq excess base in the form of a nonabsorbable buffer system, which did not elicit GI microbleeding in humans; unfortunately, the formulation ultimately proved to be unstable. A second similar formulation[1] (containing more buffer), except that the sodium acetylsalicylate was contained in a dissolving core surrounded by the buffer ingredients, was prepared in an attempt to achieve adequate stability. While the second formulation proved to be stable, it also increased GI microbleeding significantly in humans[2].

It was hypothesized that the differential effect of the two formulations (C2 and D2, Table I) on GI microbleeding was attributable to the fact that the sodium acetylsalicylate component of the second formulation was contained in a surface-eroding, dissolving core. During the period following disintegration of the buffer shell, when the core is dissolving, the solid core may become adherent to the gastric mucosa. In that case, significant reconversion to the acid could take place.

The present study was undertaken to test this hypothesis; it illustrates the importance of physical form as a determinant of aspirin-induced GI microbleeding and supports the concepts of Leonards and Levy (3–5).

EXPERIMENTAL

Animals—Twelve male beagle dogs[3], 6.7–10.5 kg, were employed. The dogs were immunized previously against distemper and hepatitis and received a vermifuge on at least two occasions. The animals were caged individually and had free access to drinking water; approximately 300 g of dry food[4] was offered to each dog for 2 hr at about 10:00 am daily. Two weeks prior to the start of the experiment (Day −15), each dog received 50 μCi of ^{59}Fe-labeled ferrous sulfate[5] intravenously.

Sample Handling—GI blood loss was determined by measurement of the iron-59 content of 24-hr stool collections. Details regarding the collection, preparation, and counting of 24-hr stool and weekly whole blood samples and calculation of the whole blood content of 24-hr stool collections were described previously (7).

Acetylsalicylate Formulations—Four formulations (two swallow tablets, an encapsulated powder, and a powder suspended in water) were employed in the present study. They were coded at random for convenience and are described in Table I. Unit doses of the four formulations contained the equivalent of 325 mg of aspirin and had similar total buffer capacities.

Experimental Design—The dogs were assigned to three 4 × 4 Latin squares in such a manner as to place the lightest four in one square and the heaviest four in a second square. The four treatments were then assigned to rows within the squares in such a fashion as to balance the design to permit detection of residual effects of the treatments; the dogs were assigned at random to columns within the squares.

Study Days 0 through 5, 13 through 17, 25 through 29, and 37 through 41 were designated as control periods. Days 6 through 12, 18 through 24, 30 through 36, and 42 through 48 were designated as treatment periods. During these treatment times, two tablets (or the equivalent of two tablets as suspended or encapsulated powder) of the appropriate formulations were administered orally twice daily, at 8:00 am and 4:00 pm, in complete changeover fashion.

Statistics—The experimental observations were defined as the average daily fecal blood volume observed in each animal during each treatment period. Average daily fecal blood volumes observed in the 12 dogs during the four treatment periods were subjected to analysis of variance. When this analysis revealed that there were significant differences among the direct effects of the four treatments, the significance of differences between treatments was determined using the Student–Newman–Keuls test (8). Details regarding statistical evaluation of the data were described previously (6).

RESULTS

The average daily fecal blood losses observed in the 12 dogs during the four control and four treatment periods are summarized in Table II. The analysis of variance of the average daily fecal blood loss observed during the four treatment periods indicated that there were significant differences between the direct effects of the four treatments. The significance of differences between the means of average daily fecal blood loss observed during treatment with the four formulations is also summarized in Table II. The results indicate that the homogeneous tablet formulation C2 and the encapsulated powder B2 caused less GI microbleeding than the dissolving core tablet formulation D2 but more than the suspended powder A2.

The analysis of variance also revealed that there were: (*a*) significant differences between squares to which dogs had been assigned on the basis

[a] Significantly ($p < 0.05$) different from B2, C2, and D2. [b] Significantly ($p < 0.05$) different from A2 and D2. [c] Significantly ($p < 0.05$) different from A2, B2, and C2.

of body weight, (*b*) no significant differences among periods, and (*c*) no significant residual effects of the treatments. The finding that there were significant differences between squares is consistent with the dose-dependent nature of aspirin-induced GI microbleeding in dogs (7), since all dogs received a fixed aspirin-equivalent dose regardless of body weight. Similarly, the finding of significant differences between dogs within squares is consistent with numerous reports indicating that the response of individuals to aspirin varies significantly.

DISCUSSION

These findings support the hypothesis that the differential effect of C2 and D2 tablets on the gastric mucosa is attributable to the sodium acetylsalicylate component of D2 being contained in a dissolving core. Of the four quantitatively similar, but physically different, formulations, only with D2, the dissolving core tablet, would significant reconversion of sodium acetylsalicylate to the unionized acid be expected to occur (if the dissolving sodium acetylsalicylate core became adherent to the gastric mucosa during tablet disintegration); D2 caused significantly more GI microbleeding than the other formulations. Therefore, the physical form of a buffered acetylsalicylate formulation is critical in the effect of such formulations on GI microbleeding.

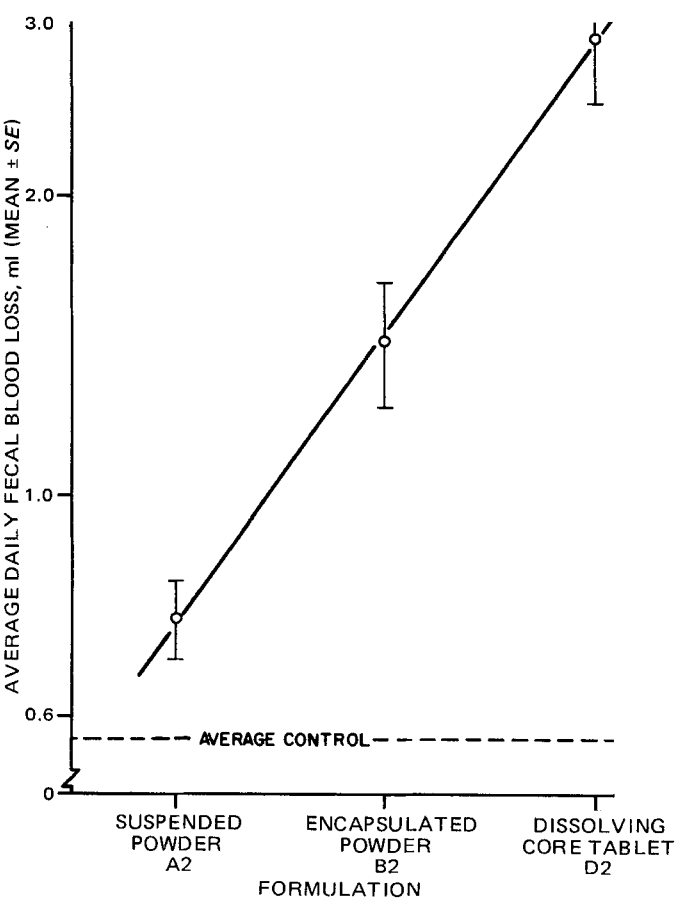

Figure 1—*Relationship of physical form to GI microbleeding.*

Aspirin, in the unionized form, must enter into the gastric mucosal cell to initiate gastric mucosal erosion. Therefore, the relationship of the physical form of a buffered sodium acetylsalicylate formulation to the GI microbleeding produced by the formulation is most likely attributable to the dissolution rate. In the case of a formulation with a rapid dissolution rate, there is little chance for reconversion of sodium acetylsalicylate to the acid; the converse is true for a formulation with a slow dissolution rate.

If it is assumed that the suspended (A2) and encapsulated (B2) powder formulations represent D2 tablet formulations with infinitely short dissolution and disintegration times, respectively (the fact that the encapsulated powder is not presented to the gastric mucosa until the capsule dissolves should be considered a form of delayed drug administration rather than delayed disintegration, since the material is completely disintegrated once presented to the mucosa), these results indicate clearly that a correlation exists between the rate of tablet dissolution and the effect on the gastric mucosa that is independent of total buffer capacity. Thus, a product with finite disintegration and solution times (D2) elicits significant GI microbleeding, while a product with an infinitely short disintegration time but a finite solution time (B2) causes significantly less microbleeding; a product with an infinitely short dissolution time (A2) causes even less microbleeding, despite the fact that all three formulations have similar total buffer capacities (Fig. 1). Almost certainly the fecal blood loss observed during treatment with A2 is not significantly greater than the control, although this possibility could not be tested statistically since no placebo was employed.

Quick Estimation of Kinetic Parameters for a Compartment with Exponential Absorption Rate and First-Order Elimination Rate

C. D. THRON

Abstract □ Two methods are presented for the quick estimation of kinetic parameters for a compartment with an exponential absorption rate and a first-order elimination rate. The first method is by direct computation from the observed levels of substance in the compartment at times t, $2t$, and $3t$, where t is arbitrary. The second method uses a numerical table to estimate the parameters from the observed peak level, the time of the peak level (or the time when the level rises to half of the peak level), and the time when the level has declined to half of its peak value. Some approximation equations also are given.

Keyphrases □ Kinetic parameters—compartment with exponential absorption rate and first-order elimination rate, two methods for quick estimation □ Pharmacokinetics—compartment with exponential absorption rate and first-order elimination rate, two methods for quick estimation of kinetic parameters

If the rate of absorption of a substance into an initially empty, well-stirred compartment declines exponentially with time and the rate of elimination is first order, then the quantity or concentration, y, of the substance in the compartment is a function of time, t, of the general form:

$$y = \frac{C(e^{-k_1 t} - e^{-k_2 t})}{k_2 - k_1} \qquad \text{(Eq. 1)}$$

where C, k_1, and k_2 are constants. The method usually recommended for estimating these constants from experimental data is a graphical procedure known as "peeling," "feathering," or the "method of residuals" (1, pp. 281–292), complemented by least-squares adjustment by computer (1, 2). The graphical procedure can be computerized, and these methods are entirely satisfactory if suitable computer programs and services are available. Without a computer, however, these methods are time consuming and are quite unwieldy for preliminary evaluation of data, rough comparison of published reports, and double-checking calculations.

This report describes methods of rapid, direct computation of C, k_1, and k_2 from experimental data; these methods may be useful for applications not requiring high accuracy or careful statistical weighting.

THEORY AND DISCUSSION

Estimation from y Values at t, $2t$, and $3t$—In principle, any three data points will determine the three parameters. In practice, however, the resulting three simultaneous equations cannot always be solved for the parameters. Therefore, direct computation of the parameters requires a suitable selection of data points.

Let t be any convenient time and let y_1, y_2, and y_3 be the observed levels at t, $2t$, and $3t$, respectively. Equation 1 gives:

$$y_j = \frac{C(e^{-k_1 jt} - e^{-k_2 jt})}{k_2 - k_1} \qquad \text{(Eq. 2)}$$

where $j = 1$, 2, or 3. For the solution of these three simultaneous equations, let:

$$r = +\sqrt{\frac{y_1 y_3}{y_2^2} - \frac{3}{4}} \qquad \text{(Eq. 3)}$$

Then:

$$k_1 = -\frac{1}{t}\log_e\left[\frac{y_2}{y_1}\left(\frac{1}{2} + r\right)\right] \qquad \text{(Eq. 4)}$$

$$k_2 = -\frac{1}{t}\log_e\left[\frac{y_2}{y_1}\left(\frac{1}{2} - r\right)\right] \qquad \text{(Eq. 5)}$$

and:

$$C = \frac{y_1^2(k_2 - k_1)}{2y_2 r} \qquad \text{(Eq. 6)}$$

The labeling of the constants k_1 and k_2 is entirely arbitrary. The conventions adopted here regarding the algebraic sign of r (Eqs. 3–5) assign the label k_2 to the larger of the two. If $r = 0$, then $k_1 = k_2 = k$ and Eq. 1 takes the limiting form:

$$y = Cte^{-kt} \qquad \text{(Eq. 7)}$$

If the quantity under the radical in Eq. 3 is negative, the data are inconsistent with the model underlying Eq. 1.

Equations 3–6 become simpler if t is selected on the rising limb of the y curve (Fig. 1) in such a way that $2t$ intercepts the falling limb at just the same level; *i.e.*, $y_2 = y_1$. Then the limiting case ($k_1 = k_2 = k$, Eq. 7) will have $y_3 = (\frac{3}{4})y_1$ (*cf.*, Eq. 3).

The use of Eqs. 3–6 may be illustrated by the example of Fig. 1. The steps for estimating the parameters are:

1. From the curve of Fig. 1, read the values of y at $t = 2$, 4, and 6: $y_1 = 1.85$, $y_2 = 1.43$, and $y_3 = 1.02$, respectively.
2. Compute $r = \sqrt{(1.85)(1.02)/(1.43)^2 - 0.75} = 0.416$ and $y_2/y_1 = 1.43/1.85 = 0.773$.
3. Compute $k_1 = -(\frac{1}{2})\log_e[0.773(0.5 + 0.416)] = 0.17$, $k_2 = -(\frac{1}{2})\log_e[0.773(0.5 - 0.416)] = 1.4$, and $C = fDk_a/V = (1.85)(1.4 - 0.17)/[2(0.773)(0.416)] = 3.5$.

Like any method of fitting the curve of Fig. 1, this analysis does not tell which of the two constants, k_1 (the smaller) or k_2 (the larger), is identified with k_a or k_e, nor does it evaluate the several factors of the coefficient C.

Estimation from Peak Level, y_m, Time of Peak Level, t_m, and Time of Decline to Half of Peak Level, t_{h_2}—Let y_m be the peak level, t_m be the time of the peak level, t_{h_1} be the time when the rising level first reaches $y_m/2$, and t_{h_2} be the time (after t_m) when the declining level reaches $y_m/2$ (Fig. 1). The theoretical equations (Eq. 1) for these ob-

THEORY AND DISCUSSION

Estimation from y Values at t, $2t$, and $3t$—In principle, any three data points will determine the three parameters. In practice, however, the resulting three simultaneous equations cannot always be solved for the parameters. Therefore, direct computation of the parameters requires a suitable selection of data points.

Let t be any convenient time and let y_1, y_2, and y_3 be the observed levels at t, $2t$, and $3t$, respectively. Equation 1 gives:

$$y_j = \frac{C(e^{-k_1 jt} - e^{-k_2 jt})}{k_2 - k_1} \qquad \text{(Eq. 2)}$$

where $j = 1$, 2, or 3. For the solution of these three simultaneous equations, let:

$$r = +\sqrt{\frac{y_1 y_3}{y_2^2} - \frac{3}{4}} \qquad \text{(Eq. 3)}$$

Then:

$$k_1 = -\frac{1}{t}\log_e\left[\frac{y_2}{y_1}\left(\frac{1}{2} + r\right)\right] \qquad \text{(Eq. 4)}$$

$$k_2 = -\frac{1}{t}\log_e\left[\frac{y_2}{y_1}\left(\frac{1}{2} - r\right)\right] \qquad \text{(Eq. 5)}$$

and:

$$C = \frac{y_1^2(k_2 - k_1)}{2y_2 r} \qquad \text{(Eq. 6)}$$

The labeling of the constants k_1 and k_2 is entirely arbitrary. The conventions adopted here regarding the algebraic sign of r (Eqs. 3–5) assign the label k_2 to the larger of the two. If $r = 0$, then $k_1 = k_2 = k$ and Eq. 1 takes the limiting form:

$$y = Cte^{-kt} \qquad \text{(Eq. 7)}$$

If the quantity under the radical in Eq. 3 is negative, the data are inconsistent with the model underlying Eq. 1.

Equations 3–6 become simpler if t is selected on the rising limb of the y curve (Fig. 1) in such a way that $2t$ intercepts the falling limb at just the same level; *i.e.*, $y_2 = y_1$. Then the limiting case ($k_1 = k_2 = k$, Eq. 7) will have $y_3 = (\frac{3}{4})y_1$ (*cf.*, Eq. 3).

The use of Eqs. 3–6 may be illustrated by the example of Fig. 1. The steps for estimating the parameters are:

1. From the curve of Fig. 1, read the values of y at $t = 2$, 4, and 6: $y_1 = 1.85$, $y_2 = 1.43$, and $y_3 = 1.02$, respectively.
2. Compute $r = \sqrt{(1.85)(1.02)/(1.43)^2 - 0.75} = 0.416$ and $y_2/y_1 = 1.43/1.85 = 0.773$.
3. Compute $k_1 = -(\frac{1}{2})\log_e[0.773(0.5 + 0.416)] = 0.17$, $k_2 = -(\frac{1}{2})\log_e[0.773(0.5 - 0.416)] = 1.4$, and $C = fDk_a/V = (1.85)(1.4 - 0.17)/[2(0.773)(0.416)] = 3.5$.

Like any method of fitting the curve of Fig. 1, this analysis does not tell which of the two constants, k_1 (the smaller) or k_2 (the larger), is identified with k_a or k_e, nor does it evaluate the several factors of the coefficient C.

Estimation from Peak Level, y_m, Time of Peak Level, t_m, and Time of Decline to Half of Peak Level, t_{h_2}—Let y_m be the peak level, t_m be the time of the peak level, t_{h_1} be the time when the rising level first reaches $y_m/2$, and t_{h_2} be the time (after t_m) when the declining level reaches $y_m/2$ (Fig. 1). The theoretical equations (Eq. 1) for these ob-

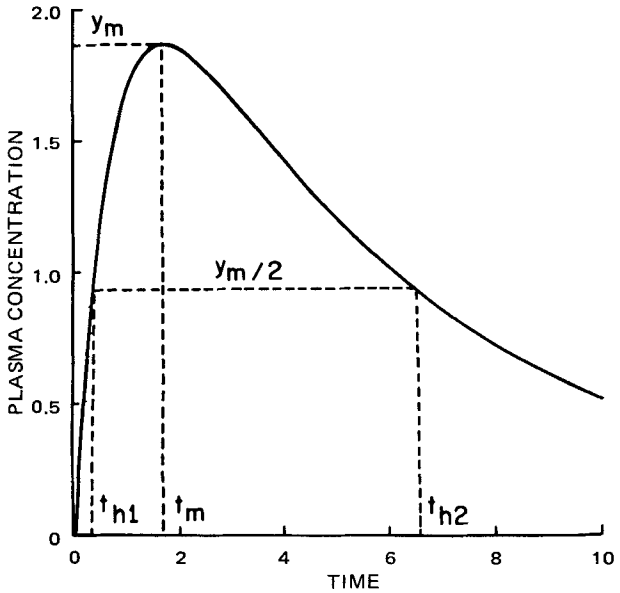

Figure 1—*Plasma concentration–time profile for a one-compartment system with absorption rate constant* $k_a = 1.4$, *elimination rate constant* $k_e = 0.17$, *volume of distribution* $V = 40$, *dose* $D = 100$, *and fraction absorbed* $f = 1$. *The plasma concentration* y *obeys the equation* $y = (fDk_a/V)[exp(-k_e t) - exp(-k_a t)]/(k_a - k_e)$, *where* t *is time* (cf., *Ref. 2, p. 292). The dashed lines indicate the peak level* y_m, *the time of the peak level* t_m, *the time* t_{h_1} *when the rising level first reaches* $y_m/2$, *and the time* t_{h_2} *when the declining level reaches* $y_m/2$.

servable values cannot be solved for the constants C, k_1, and k_2, so a numerical table is used (Table I). This table is based on the fact that if the value of the ratio t_{h_2}/t_m is known, the normalized parameters k_1/t_m, k_2/t_m, and Ct_m/y_m are entirely determined; from these values and the observed y_m and t_m, the constants k_1, k_2, and C are easily computed. The table also includes the ratio t_{h_2}/t_{h_1} in case the available value of t_m is more uncertain than that of t_{h_1}.

Computations for Table I were done as follows. Let $\kappa = k_2/k_1$. As before, the convention is adopted that $k_2 \geq k_1$ and, therefore, $\kappa \geq 1$. When $t = t_m$, $dy/dt = 0$ and Eqs. 1 and 7 give:

$$k_1 t_m = \frac{\log_e \kappa}{\kappa - 1} \qquad (k_1 \neq k_2) \qquad \text{(Eq. 8a)}$$

$$k_1 t_m = 1 \qquad (k_1 = k_2) \qquad \text{(Eq. 8b)}$$

and:

$$k_2 t_m = \kappa k_1 t_m \qquad \text{(Eq. 9)}$$

Equations 8a, 8b, and 9 are used to substitute for k_1 and k_2 in Eqs. 1 and 7 to obtain:

$$\frac{y}{y_m} = \frac{\kappa^{-(t/t_m)/(\kappa-1)} - \kappa^{-[\kappa(t/t_m)]/(\kappa-1)}}{\kappa^{-1/(\kappa-1)} - \kappa^{-\kappa/(\kappa-1)}} \qquad \text{(Eq. 10a)}$$

[a] For values of t_{h_2}/t_m larger than those shown here, the following equations give estimates accurate to within 5%:

$$k_1 \simeq \frac{(\log_e 2)}{t_{h_2} - t_m} \qquad k_2 \simeq \frac{(\log_e 2)}{t_{h_1}} \qquad C \simeq k_2 y_m$$

If t_{h_1} is not available, $k_2 t_m$ can be estimated from the recursion equation $k_{2(i+1)}t_m = k_1 t_m - \log_e(k_1 t_m) + \log_e(k_{2i} t_m)$, where $k_{2i}t_m$ and $k_{2(i+1)}t_m$ are the ith and $(i+1)$th successive approximations to $k_2 t_m$, and a suitable starting estimate, $k_{21}t_m$, is $k_1 t_m - \log_e(k_1 t_m)$ or just $-\log_e(k_1 t_m)$. [b] The value is 2.67835. A value of t_{h_2}/t_m smaller than this is inconsistent with the model on which Eq. 1 is based. [c] 2.71828 = e. [d] The value is 11.54466.

$$\frac{y}{y_m} = \frac{\kappa^{-[(t/t_m)-1]/(\kappa-1)}\,(\kappa^{(t/t_m)} - 1)}{\kappa - 1} \qquad (\kappa \neq 1) \qquad \text{(Eq. 10}b\text{)}$$

$$\frac{y}{y_m} = (t/t_m)e^{-[(t/t_m)-1]} \qquad (\kappa = 1) \qquad \text{(Eq. 10}c\text{)}$$

Let $\theta_1 = t_{h_1}/t_m$ and $\theta_2 = t_{h_2}/t_m$; then, from Eqs. 10*b* and 10*c*:

$$\frac{1}{2} = \frac{\kappa^{-[\kappa(\theta-1)]/(\kappa-1)}(\kappa^{\theta} - 1)}{\kappa - 1} \qquad (\kappa \neq 1) \qquad \text{(Eq. 11}a\text{)}$$

$$\frac{1}{2} = \theta e^{-(\theta-1)} \qquad (\kappa = 1) \qquad \text{(Eq. 11}b\text{)}$$

for $\theta = \theta_1$ or θ_2. An iterative method [a one-dimensional modified version of the flexible simplex method described by Himmelblau (3)] was used to compute θ for a given κ or κ for a given θ from Eqs. 11*a* and 11*b*. (For a given κ, the algorithm employed converged either to θ_1 or θ_2, depending on the initial estimate.) For large κ and θ values, the computation of the right-hand side of Eqs. 11*a* and 11*b* produced intermediate values too large for the computer. To avoid these overflows, an alternative equation was used when κ was greater than 50 and θ was greater than 9:

$$\frac{1}{2} = \frac{\kappa^{(\kappa-\theta)/(\kappa-1)}}{\kappa - 1} \qquad \text{(Eq. 12)}$$

This equation is derived from Eqs. 11*a* and 11*b* by replacing the term $\kappa^{\theta} - 1$ by κ^{θ} and multiplying out the numerator.

Finally, Eqs. 8*a*, 8*b*, and 9 are used to substitute for k_1 and k_2 in Eqs. 1 and 7 to obtain:

$$\frac{Ct_m}{y_m} = \frac{\kappa^{\kappa/(\kappa-1)}\log_e \kappa}{\kappa - 1} \qquad (\kappa \neq 1) \qquad \text{(Eq. 13}a\text{)}$$

$$\frac{Ct_m}{y_m} = e \qquad (\kappa = 1) \qquad \text{(Eq. 13}b\text{)}$$

The use of Table I may be illustrated by the example of Fig. 1. The steps in estimating the parameters are:

1. From the curve of Fig. 1, read $t_m = 1.7$ and $y_m = 1.88$.
2. Compute $y_m/2 = 0.94$.
3. From the curve of Fig. 1, read $t_{h_2} = 6.5$ (where $y = 0.94$).
4. Compute $t_{h_2}/t_m = 3.8$.
5. From Table I, read $k_1 t_m = 0.294$, $k_2 t_m = 2.39$, and $Ct_m/y_m = 3.20$.
6. Compute $k_1 = 0.294/1.7 = 0.17$, $k_2 = 2.39/1.7 = 1.4$, and $C = fDk_a/V = (3.20)(1.88)/1.7 = 3.5$.

If t_{h_1} can be determined more accurately than t_m, the first four steps can be modified as follows:

1. From the curve of Fig. 1, read $y_m = 1.88$.
2. Compute $y_m/2 = 0.94$.
3. From the curve of Fig. 1, read $t_{h_1} = 0.35$ and $t_{h_2} = 6.5$.
4. Compute $t_{h_2}/t_{h_1} = 18.6$.

Since this value of t_{h_2}/t_{h_1} lies between the tabulated values, interpolation might be done. For most purposes, however, it is sufficiently accurate to take the normalized parameter values corresponding to the closest tabulated value of t_{h_2}/t_{h_1}, *i.e.*, 18.7.

The accuracy of this method is obviously limited by the accuracy of determination of t_m and t_{h_2} or t_{h_1}. These parameters, especially t_m and t_{h_1}, are likely to be quite inaccurately known when only a small number of data points are available, as is commonly the case. The values of k_1 and k_2 are especially uncertain when the ratio t_{h_2}/t_m is less than 3 or 3.5, because in this region the dependence of $k_1 t_m$ and $k_2 t_m$ on t_{h_2}/t_m is quite steep (Table I). These limitations on accuracy must be kept in mind when this method is used.

Approximation Equations—Attempts to find simple approximation equations for k_1, k_2, and C in terms of t_m, t_{h_1}, t_{h_2}, and y_m yielded only two that were both simple and reasonably accurate:

$$C = (\log_e 2)y_m/t_{h_1} = 0.693y_m/t_{h_1} \qquad \text{(Eq. 14)}$$

and:

$$k_1 = (\log_e 2)/(t_{h_2} - 1.5t_m) = 0.693/(t_{h_2} - 1.5t_m) \qquad \text{(Eq. 15)}$$

Equation 14 gives slightly high values, accurate to within 5% if $t_{h_2}/t_m > 4.7$ and to within 10% otherwise. Equation 15 gives values within ±5% if $t_{h_2}/t_m > 3.15$ and within 10% if $t_{h_2}/t_m > 2.95$; but for lower values of t_{h_2}/t_m, it gives values of k_1 that are as much as 41% too low.

Equation 15 may be convenient for estimating the elimination rate constant from plasma level–time curves following oral administration, assuming the elimination rate constant is smaller than the absorption rate constant. It is essentially the familiar equation for intravenous administration, $k_1 = (\log_e 2)/t_{h_2}$, corrected for gradual absorption by the term $-1.5t_m$.

The parameter k_2 can be estimated from k_1 and t_m by the recursion equation given in footnote *a* to Table I. Several iterations may be necessary if $k_1 t_m > 0.1$, and a programmable calculator is convenient for doing these calculations.

CONCLUSIONS

The described methods appear to be the best solutions to the problem of getting rough estimates of the parameters of Eq. 1 with minimum computation. These methods do not verify that the data in question do in fact obey Eq. 1; therefore, these methods could be misleading if applied to data that do not obey Eq. 1. If such misapplications are avoided, however, these methods may prove useful, especially for preliminary evaluation of data, rough comparison of published reports, and double-checking calculations.

In Vitro Inhibition of Viral DNA Polymerase Activity by Litmomycin

MANOHAR L. SETHI

Abstract □ Litmomycin, an antibiotic isolated from *Streptomyces litmogenes*, is highly active against Gram-positive bacteria and possesses antitumor activity. It inhibited viral DNA polymerase activity *in vitro*. The amount of litmomycin required to cause 50% inhibition of enzyme activity was 80–100 μg (180–225 nmoles)/ml of reaction mixture. The enzyme inhibition was observed when polyriboadenylate–oligodeoxythymidylate, polydeoxyadenylate–oligodeoxythymidylate, polyribocytidylate–oligodeoxyguanylate, activated DNA, and 70S RNA were used as templates. Reaction kinetics and the mechanism of enzyme inhibition are discussed. The results suggest that litmomycin interacts with the template primer and not with the enzyme protein to stop the polymerization process.

RNA-directed DNA polymerase (reverse transcriptase) is the unique enzyme found (1–4) in nucleocapsids of RNA tumor viruses. This enzyme is required for productive infection and transformation of normal cells by RNA tumor viruses (5–7). Recent publications (8–10) indicate that RNA tumor viruses are involved in at least some forms of human cancer (leukemia). Current evidence indicates that reverse transcriptase is required only to initiate, but not to maintain, the transformed state and the continuous production of new virus particles by these transformed cells (10, 11).

The relationship between the biochemical characteristics of reverse transcriptase from human acute leukemia cells and several RNA tumor viruses is well documented (12). In the event that RNA tumor viruses are involved in human cancer, reverse transcriptase is the important enzyme in the onset of oncogenesis (13). Therefore, specific inhibitors of reverse transcriptase might find use in the development of drugs for leukemia and cancer chemotherapy. In an effort to develop *in vitro* test systems for antiviral activity, an inhibition of reverse transcriptase activity by fagaronine was previously studied (14). This paper reports the effect of litmomycin on the purified protein fraction of reverse transcriptase from RNA tumor viruses.

Litmomycin (granaticin A[1]), an antibiotic isolated from a new *Streptomyces* species, *S. litmogenes* (15), is highly active against Gram-positive bacteria but has little or no activity against Gram-negative bacteria, mycobacterium, molds, and yeast (16). It has significant antitumor activity against P-388 lymphocytic leukemia in mice and cytotoxicity against KB cells (17).

[1] Granaticin B showed a distinct inhibition of various transplanted tumors in rodents after repeated intraperitoneal application (H. Bickel and K. Scheibli, Ciba-Geigy Ltd., Basel, Switzerland, personal communication).

EXPERIMENTAL

Materials—Purified DNA polymerase from avian myeloblastosis virus[2] had a specific activity of 10,108 units/mg and a protein content of 0.35 mg/ml. The enzyme was purified according to the published method (18). DNA polymerase from simian sarcoma virus type 1[3] was derived from tissue culture fluids of the SSV-1-NC-37 cell line and purified by the method described previously (14). It possessed an activity of 6.00 nmoles of thymidine monophosphate incorporation/30 min/ml. Purified DNA polymerase from Rauscher murine leukemia virus[4] propagated in the JLS-V9 cell line had an activity of 4.00 nmoles of thymidine monophosphate incorporation/30 min/ml. Viral 70S RNA[5] was obtained from Rauscher murine leukemia virus, which was purified by the published method (19).

The templates[6], polyriboadenylate–oligodeoxythymidylate (I), polydeoxyadenylate–oligodeoxythymidylate (II), and polyribocytidylate–oligodeoxyguanylate (III), were dissolved in a buffer containing 0.01 *M* tromethamine (IV) (pH 7.0), 0.10 m*M* ethylenediaminetetraacetic acid tetrasodium salt (V), and 0.10 *M* NaCl. ^{3}H-Thymidine triphosphate and ^{3}H-guanosine triphosphate (specific activity of 14 Ci/mmole[7]), unlabeled thymidine triphosphate[6], and guanosine triphosphate[6] were obtained commercially. Activated calf thymus DNA was prepared by incubating 4.50 mg of bovine serum albumin in 10 ml of buffer containing IV (0.05 *M*, pH 7.0) and 5.00 m*M* $MgCl_2$ with 0.01 mg of crystalline pancreatic deoxyribonuclease[8] for 15 min at 37°. It was chilled at 4°, further incubated at 70° for 5 min, and stored at 4°.

All other chemical reagents[9] were of analytical grade. Appropriate concentrations of litmomycin (mol. wt. 444) were made in dimethyl sulfoxide.

Viral DNA Polymerase Assay and Enzyme Inhibition—One hundred microliters of enzyme assay mixture contained 5.00 μmoles of IV (pH 7.30), 8.00 μmoles of potassium chloride, 0.10 μmole of manganese chloride, 0.50 μmole of dithiothreitol, 2.00 μmoles of ^{3}H-thymidine triphosphate (170 cpm/pmole), 20.00 μg of bovine serum albumin, 2.00 μg of I, 10% glycerol, and purified enzyme preparation. The reaction mixture was incubated at 37° for 30 min. The enzyme reaction was stopped by chilling at 4° and by the addition of V (25 μl, 0.10 *M*).

Each reaction mixture (100 μl) was uniformly spotted onto 2.50-cm filter paper[10] disks and kept at room temperature for 15 min. The filter paper disks were washed batchwise six times with 5% $Na_2HPO_4 \cdot 7H_2O$ (10 ml/filter paper disk), followed by two washings each of water and ethanol (10 ml/filter paper disk). Then these disks were dried, and the radioactivity incorporated into an acid-insoluble material was determined[11] in a toluene base scintillation fluid.

For testing the enzyme inhibition, two reaction mixtures (A and B) were prepared. Mixture A contained enzyme, buffer, and bovine serum albumin. Mixture B contained template, substrate, dithiothreitol, and glycerol. The final concentration of ingredients in Mixtures A and B (100 μl) was the same as mentioned previously. Appropriate concentrations of litmomycin were mixed with Mixture A and allowed to react for 10 min at 4° before Mixture B was added. Control assays contained an equivalent volume of dimethyl sulfoxide. The results were expressed as percent of control.

[2] Life Science Research Labs., St. Petersburg, Fla., through the courtesy of Dr. J. Beard. The enzyme preparation contained 3538 units of reverse transcriptase/ml (1 unit of enzyme activity is expressed as the incorporation of 1 nmole of deoxythymidine monophosphate into an acid-insoluble product in 10 min at 37°).

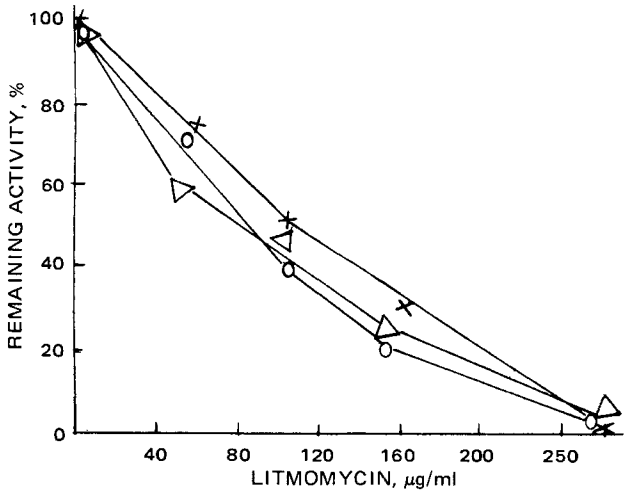

Figure 1—*Effect of litmomycin on the viral DNA polymerase activity. In a standard assay mixture (0.10 ml) containing 5 μl of avian myeloblastosis virus (○), 10 μl of simian sarcoma virus type 1 (△), or 10 μl of murine leukemia virus (×) DNA polymerase, different concentrations of litmomycin were added for enzyme inhibition.*

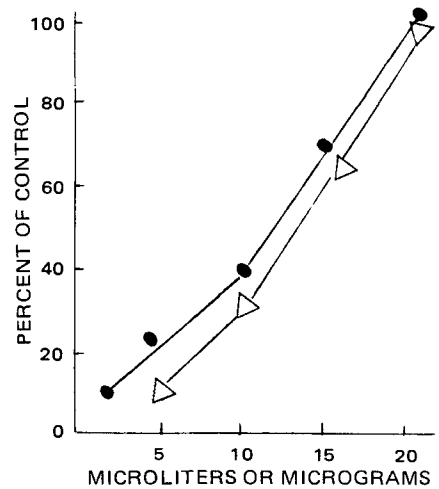

Figure 2—*Effect of increasing concentrations of avian myeloblastosis virus DNA polymerase and template primer on litmomycin-inhibited reaction mixture. The standard reaction mixture (0.10 ml) contained 5 μl of avian myeloblastosis virus DNA polymerase (△) or 2 μg of I (●). Twenty micrograms of litmomycin was used for each assay.*

RESULTS AND DISCUSSION

The inhibition of DNA polymerase activity from murine leukemia virus, simian sarcoma virus type 1, and avian myeloblastosis virus at increasing concentrations of litmomycin (0–240 μg/ml) was undertaken. The enzyme activity gradually declined when the litmomycin concentration in the reaction mixture was increased. The inhibition curves were very close and similar to each other (Fig. 1). Fifty percent inhibition of enzyme activity (ID_{50}) was obtained in the range of 80–100 μg (180–225 nmoles)/ml of the reaction mixture.

To explain the mode of enzyme inhibition, different template primers such as I, II, III, activated DNA, and 70S RNA were employed (Table I); different degrees of enzyme inhibition were obtained with different template primers. A high degree of enzyme inhibition in the presence of I or II, as compared to III, could be due to a strong binding affinity of litmomycin with adenine–thymine template primers. These results suggest that litmomycin did not interact with the enzyme protein. If litmomycin interacted with the enzyme, then the same degree of enzyme inhibition would have been observed regardless of the template primer used.

The interaction or competition of litmomycin with potassium chloride and ^{3}H-thymidine triphosphate or ^{3}H-guanosine triphosphate was not considered since they were present in the reaction mixture in eight- or 25-fold, respectively, in excess of the ID_{50} of the litmomycin concentration. The enzyme activity remained unchanged when the amount of manganese chloride in the assay mixture was increased (data not shown), indicating that the metal ions did not interact with the litmomycin. Therefore, litmomycin interacted with the template primers and not with the enzyme.

Effects of increasing concentrations of avian myeloblastosis virus DNA polymerase and template primer were observed on the litmomycin-inhibited reaction mixture to explain further the mechanism of enzyme inhibition. The enzyme activity of the litmomycin-inhibited reaction mixture was linearly restored when concentrations of I in the assay mixture were increased from 2 to 20 μg and the enzyme concentration was increased from 5 to 20 μl (Fig. 2). These results suggest that the enzyme–template–antibiotic complex in the reaction mixture was completely dissociated in the presence of excess template primers or the enzyme.

In the assay mentioned, litmomycin was added to the reaction mixture containing enzyme, template primer, metal ions, and substrate before incubation. The inhibitory effects of litmomycin were thus primarily directed to the free template primer and its complexes with the enzyme, substrate, and metal ions. In other assays where the enzyme molecule had already initiated the DNA synthesis, with subsequent elongation of polynucleotide chains, the effect of lit-

Table I—Effect of Different Template Primers on Avian Myeloblastosis Virus DNA Polymerase Inhibition by Litmomycin

Template Primer	Radioactive Substrate	Inhibition[a], %
I[b]	Thymidine triphosphate	80
II[b]	Thymidine triphosphate	86
III[c]	Deoxyguanosine triphosphate	15
Activated DNA[d]	Thymidine triphosphate	75
70S RNA[e]	Thymidine triphosphate	70

[a] Litmomycin, 20 μg/assay, was employed for each inhibition. [b] See standard assay conditions as specified in *Experimental* section. [c] Standard assay mixture contained 2 μg of this template primer and 2.0 nmoles of ^{3}H-deoxyguanosine triphosphate (370 cpm/mole). [d] Standard assay mixture contained 2.20 μg of activated DNA, 10 nmoles each of deoxyadenosine, deoxycytidine, and deoxyguanosine triphosphates, and 2.0 nmoles of ^{3}H-thymidine triphosphate. [e] In the standard assay conditions, 70S RNA (murine leukemia virus) with an optical density of 0.06 (260 nm) was used as the template.

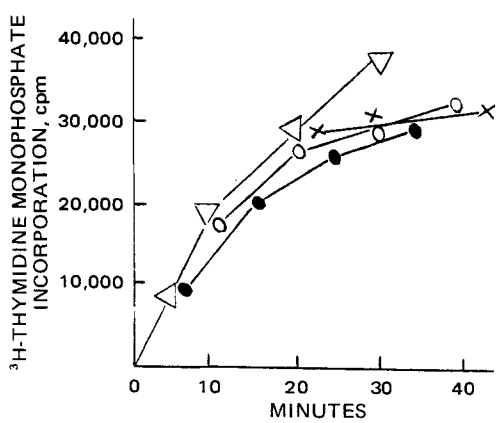

Figure 3—*Effect of addition of litmomycin at different time intervals during avian myeloblastosis virus DNA polymerase reaction. Two milliliters of standard assay mixture contained 100 μl of enzyme. The mixture was divided into four aliquots: A (0.60 ml), B (0.50 ml), C (0.50 ml), and D (0.40 ml). From A, a 0.10-ml sample was withdrawn at 0 min; A–D were incubated at 37°. One-tenth-milliliter samples from A (control, △) were withdrawn after 5, 10, 20, and 30 min of incubation. Litmomycin (250 μg/ml) was added after 5 (●), 10 (○), and 20 (×) min of incubation to B, C, and D, respectively. The enzyme activity was determined 1 min after the addition of litmomycin from the withdrawn samples (0.10 ml) at 10-min intervals.*

momycin was observed. Litmomycin was added to such a mixture at different time intervals during the reaction.

When litmomycin was added at 5 and 10 min after initiation of the polymerization reaction, the enzyme activity continued for about 20 min, comparable to the control. But when the litmomycin was added after 20 min, the enzyme activity stopped instantly, as indicated by the ^{3}H-thymidine monophosphate incorporation (Fig. 3). The results suggest that litmomycin did not inhibit the initial formation of an RNA–DNA hybrid but blocked the subsequent phase of the polymerization processes.

In conclusion, litmomycin inhibits DNA polymerase activity of RNA tumor viruses by interaction with (riboadenylate)$_n$–(deoxythymidylate)$_n$ or adenine–thymine bases and (ribocytidylate)$_n$–(deoxyguanylate)$_n$ or cytosine–guanine bases with a different degree of binding. It may be of interest to investigate the antiviral activity of litmomycin in cell culture.

The author thanks Dr. H. G. Floss, Purdue University, for a gift sample of litmomycin. The arrangements made by Dr. Jack Gruber and Dr. M. A. Chirigos, National Institutes of Health, for the supply of reverse transcriptase are gratefully acknowledged. The technical help of Mr. Warren W. Schadt in the liquid scintillation counting is appreciated.

GLC Determination of Indoprofen in Plasma

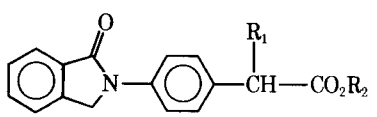
ROBERT V. SMITH ˣ, DAVID W. HUMPHREY, and HENRY ESCALONA-CASTILLO

Abstract □ Implementation of human bioavailability studies with the analgesic indoprofen required a rapid, sensitive, and convenient assay in blood plasma. A procedure based on ether extraction of acidified plasma, derivatization with diazomethane, and GLC analysis using a 3% OV-1 column was sufficiently sensitive for measurement of plasma indoprofen concentrations in the 0.4–16-μg/ml range. An average recovery of 99.0 ± 7.6% (*SD*) was achieved when the pentanoic acid homolog was employed as an internal standard.

Keyphrases □ Indoprofen—GLC analysis, human plasma □ GLC—analysis, indoprofen in human plasma □ Analgesics—indoprofen, GLC analysis in human plasma

Indoprofen, *dl*-2-[4-(1-oxo-2-isoindolinyl)phenyl]propanoic acid (I), possesses promising analgesic and anti-inflammatory properties (1, 2). In humans, I reportedly appears unchanged in plasma (3). Furthermore, enantiomeric enrichment does not seem to be significant in humans (4). Implementation of human bioavailability studies in this laboratory required a rapid, sensitive, and convenient assay of I in blood plasma.

Two GLC methods were reported for the determination of I in plasma (4, 5). Both procedures employ a lengthy series of partition steps. In one (4), a trifluoroethyl ester



I: $R_1 = CH_3$, $R_2 = H$

II: $R_1 = CH_2CH_2CH_3$, $R_2 = H$

III: $R_1 = CH_3$, $R_2 = CH_3$

IV: $R_1 = CH_2CH_2CH_3$, $R_2 = CH_3$

is utilized after preparation with boron trifluoride–trifluoroethanol. The latter reagent is corrosive and difficult to eliminate prior to GLC development. The other method (5) involves preparation and resolution of a diastereomeric pair of amides obtained through reaction of I (as its acid chloride) with *l*-α-methylbenzylamine. While useful in evaluating *in vivo* enantiomeric interconversions, this procedure is not amenable to analyses of large numbers of samples because of its length.

A simplified assay based on a single ether extraction and GLC of I and the internal standard, *dl*-2-[4-(1-oxo-2-isoindolinyl)phenyl]pentanoic acid (II), as their methyl esters (III and IV) was developed and is the subject of this report.

momycin was observed. Litmomycin was added to such a mixture at different time intervals during the reaction.

When litmomycin was added at 5 and 10 min after initiation of the polymerization reaction, the enzyme activity continued for about 20 min, comparable to the control. But when the litmomycin was added after 20 min, the enzyme activity stopped instantly, as indicated by the ^{3}H-thymidine monophosphate incorporation (Fig. 3). The results suggest that litmomycin did not inhibit the initial formation of an RNA–DNA hybrid but blocked the subsequent phase of the polymerization processes.

In conclusion, litmomycin inhibits DNA polymerase activity of RNA tumor viruses by interaction with (riboadenylate)$_n$–(deoxythymidylate)$_n$ or adenine–thymine bases and (ribocytidylate)$_n$–(deoxyguanylate)$_n$ or cytosine–guanine bases with a different degree of binding. It may be of interest to investigate the antiviral activity of litmomycin in cell culture.

The author thanks Dr. H. G. Floss, Purdue University, for a gift sample of litmomycin. The arrangements made by Dr. Jack Gruber and Dr. M. A. Chirigos, National Institutes of Health, for the supply of reverse transcriptase are gratefully acknowledged. The technical help of Mr. Warren W. Schadt in the liquid scintillation counting is appreciated.

GLC Determination of Indoprofen in Plasma

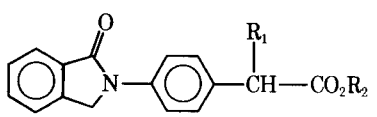
ROBERT V. SMITH ˣ, DAVID W. HUMPHREY, and HENRY ESCALONA-CASTILLO

Abstract □ Implementation of human bioavailability studies with the analgesic indoprofen required a rapid, sensitive, and convenient assay in blood plasma. A procedure based on ether extraction of acidified plasma, derivatization with diazomethane, and GLC analysis using a 3% OV-1 column was sufficiently sensitive for measurement of plasma indoprofen concentrations in the 0.4–16-μg/ml range. An average recovery of 99.0 ± 7.6% (*SD*) was achieved when the pentanoic acid homolog was employed as an internal standard.

Keyphrases □ Indoprofen—GLC analysis, human plasma □ GLC—analysis, indoprofen in human plasma □ Analgesics—indoprofen, GLC analysis in human plasma

Indoprofen, *dl*-2-[4-(1-oxo-2-isoindolinyl)phenyl]propanoic acid (I), possesses promising analgesic and anti-inflammatory properties (1, 2). In humans, I reportedly appears unchanged in plasma (3). Furthermore, enantiomeric enrichment does not seem to be significant in humans (4). Implementation of human bioavailability studies in this laboratory required a rapid, sensitive, and convenient assay of I in blood plasma.

Two GLC methods were reported for the determination of I in plasma (4, 5). Both procedures employ a lengthy series of partition steps. In one (4), a trifluoroethyl ester



I: $R_1 = CH_3$, $R_2 = H$

II: $R_1 = CH_2CH_2CH_3$, $R_2 = H$

III: $R_1 = CH_3$, $R_2 = CH_3$

IV: $R_1 = CH_2CH_2CH_3$, $R_2 = CH_3$

is utilized after preparation with boron trifluoride–trifluoroethanol. The latter reagent is corrosive and difficult to eliminate prior to GLC development. The other method (5) involves preparation and resolution of a diastereomeric pair of amides obtained through reaction of I (as its acid chloride) with *l*-α-methylbenzylamine. While useful in evaluating *in vivo* enantiomeric interconversions, this procedure is not amenable to analyses of large numbers of samples because of its length.

A simplified assay based on a single ether extraction and GLC of I and the internal standard, *dl*-2-[4-(1-oxo-2-isoindolinyl)phenyl]pentanoic acid (II), as their methyl esters (III and IV) was developed and is the subject of this report.

EXPERIMENTAL

Reagents and Materials—Compounds I, II[1], and *N*-methyl-*N*-nitroso-*N'*-nitroguanidine[2] were used as obtained. All other solvents and reagents were analytical reagent grade. GLC columns were prepared with 3% OV-1 on acid-washed silanized Chromosorb W, 100–120 mesh[3].

Reference Methyl Esters—Compound I (1.01 g) was dissolved in 5 ml of methanol; 3 ml of 30% (w/w) boron trifluoride in methanol was added, and the resulting mixture was refluxed for 15 min. The reaction mixture was cooled, reduced to near dryness *in vacuo*, and shaken with 20 ml of water for 5 min. A white precipitate was collected by filtration, and the filtrate was extracted three times with 10 ml of ethyl acetate. The ethyl acetate extracts were combined with the previously collected precipitate, and the total product was crystallized from methanol–acetone (10:1) with a few drops of water to give 1.06 g (100%) of III as white plates, mp 120–122° [lit. (1) mp 124–126°]; mass spectrum, M^+ = 295; GLC, single peak, t_R (solvent front) = 2.87 min.

Compound II (1.00 g) was reacted in the same fashion. Crystallization from methanol–acetone (10:1) with a few drops of water gave 0.99 g (95%) of IV as white plates, mp 125–126°; mass spectrum, M^+ = 323; GLC, single peak, t_R (solvent front) = 4.22 min.

GLC System and Conditions—All chromatography was performed with U-shaped glass columns [0.61 m (2 ft) × 4 mm i.d.] packed with 3% OV-1 on acid-washed silanized Chromosorb W, 100–120 mesh[3]. All newly prepared columns were conditioned at 260° with carrier gas flowing (30 ml/min) for 12 hr. The columns were fitted into a gas chromatograph[4] equipped with dual flame-ionization detectors.

The chromatograph was operated under the following conditions: column and injection port temperature, 255°; detector temperature, 300°; carrier gas (nitrogen) flow, 30 ml/min; hydrogen and air flows, 40 and 300 ml/min, respectively; sensitivity (input attenuation), 10^2 (Mohm); and range, 8 (× 0.01 v). Injections were performed with a 10-μl syringe[5].

Diazomethane Reagent—*N*-Methyl-*N*-nitroso-*N'*-nitroguanidine (296 mg) was reacted with 4 ml of 2 *N* sodium hydroxide in a separator containing 40 ml of ether. The ether solution resulting was sufficient for derivatizing 10 samples and was prepared fresh daily.

Assay Procedure—All glassware was washed in detergent, soaked for 12 hr in alcoholic potassium hydroxide (1000 ml of ethanol added to 120 ml of water and 120 g of potassium hydroxide), thoroughly rinsed with water, silanized by rinsing with 2% trimethylchlorosilane in benzene, and dried at 100° for 15 min.

Preparation of Standards—To six blank plasma samples contained in 60-ml separators, add 2, 4, 6, 10, 12, and 20 μg of I along with 10 μg of II (contained in a total of 2 ml of methanol) and 4 ml of 0.1 *N* hydrochloric acid. Extract and analyze standards in the same manner as described for plasma samples.

Preparation of Samples—Place 2 ml of plasma in a glass-stoppered 60-ml separator and add 10 μg of II (in 2 ml of methanol), 4 ml of 0.1 *N* hydrochloric acid, and 40 ml of ether. Extract by shaking for 5 min and transfer the ether layer to a 50-ml conical flask; evaporate to dryness *in vacuo* at 40° with a rotary evaporator. Add 0.5 ml of methanol and 4 ml of ethereal diazomethane reagent and allow to react at room temperature for 15 min; quench the reaction (loss of yellow color and cessation of effervescence) by dropwise addition of ethyl acetate–acetic acid (10:1).

Reduce the final reaction mixture (~5 ml) in volume (to ~1 ml) *in vacuo* at 40° with a rotary evaporator; reduce the final volume to dryness under a stream of nitrogen at 25° to assure concentration of the residual solids in the tip of the conical flask. Redissolve the residue in 50 μl of ethyl acetate and inject 5 μl into the chromatograph.

Dilute samples that appear to contain greater than 8 μg of I/ml (from the initial GLC development) with an equal volume of ethyl acetate and chromatograph a 5-μl aliquot.

Calculations—The peak heights for III and IV are measured. Peak height ratios are obtained by dividing the peak height of III by the peak height of IV. Calibration curves are prepared by plotting peak height ratios from the standards *versus* the concentration of I in plasma, expressed as micrograms per milliliter. Values for unknown concentrations of I in sample plasma specimens are obtained by interpolation or calculated from the slope of the calibration curve. Once established, the standard curve need only be revalidated on a day-to-day basis with two or three standard samples.

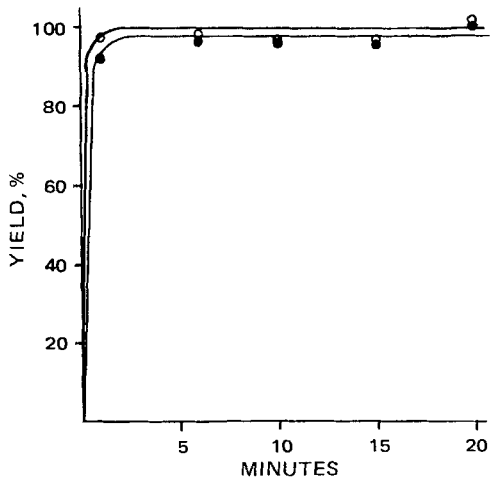


Figure 1—*Diazomethylation of I (●) and II (○).*

RESULTS AND DISCUSSION

Derivatization of I and II—GLC determination of I was initially attempted through use of its trifluoroethyl ester. The latter was reproducibly prepared in good yield through use of the boron trifluoride–trifluoroethanol reagent described previously (4). However, for biological samples containing low microgram amounts of I, it is necessary to eliminate the excess derivatization reagent completely prior to the GLC step, because the broad solvent peak produced by the latter obliterates the drug derivative. Unfortunately, reagent evaporation was not readily accomplished, apparently due to the poor volatility of alcohol–boron trifluoride mixtures[6].

Diazomethylation was studied as an alternative derivatization method[7]. When I and II were reacted with ethereal diazomethane at room temperature in the presence of approximately 10% methanol, essentially quantitative yields of methyl esters were rapidly formed (Fig. 1). Side reactions (6) and reagent polymerization (7) are potential problems with diazomethane. However, if methylation is catalyzed with methanol, these problems are reportedly minimized (7), as was evident in studies with I and II. An impurity appearing at the same retention time as III was observed when *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide[8] was employed as a diazomethane-generating reagent. This apparent impurity was probably reagent derived since it did not appear when *N*-methyl-*N*-nitroso-*N'*-nitroguanidine was employed as indicated under *Experimental.*

Assay Selectivity—After confirming the reported high recovery of I and II from acidified aqueous solutions by extraction with ether (4, 5), the potential selectivity afforded by a single liquid–liquid extraction derivatization procedure was studied. Gas chromatograms resulting from this investigation are depicted in Fig. 2 and reveal no interfering peaks at the retention times for III and IV. Essentially identical chromatograms to those in Fig. 2 were produced when derivatized extracts from plasma samples of 10 different individuals were similarly treated.

Accuracy, Precision, and Convenience—Compounds I and II were added at levels of 1–10 μg/ml to 2-ml volumes of blank plasma samples. The spiked specimens were extracted with ether, and the latter extracts were derivatized and chromatographed according to the described procedure.

The peak heights of the resulting esters (III and IV) were compared to calibration curves prepared with authentic samples of III and IV. The absolute recoveries of I and II from plasma were 69.8% (n = 5) and 71.2% (n = 5), respectively. These results indicate that II could serve as a suitable internal standard for the determination of I.

Accordingly, blank plasma samples were spiked with 0.4–8-μg/ml concentrations of I and 5 μg/ml of II and analyzed using a standard curve prepared with triplicate standards equivalent to 0.4, 1.0, 3.0, 5.0, and 8.0 μg/ml of I in plasma (slope = 0.262; y-intercept essentially zero; r = 0.997). The accuracy and precision of these determinations are presented in Table I. The excellent recovery and acceptable reproducibility observed

[5] Hamilton 701 N.

[6] This was also found to be true when boron trifluoride–methanol was evaluated as a possible derivatization reagent.
[7] *N,O*-Bis(trimethylsilyl)acetamide was tried as a derivatization reagent. However, the trimethylsilyl esters of I and II did not chromatograph well.
[8] Diazald, Aldrich Chemical Co., Milwaukee, Wis.

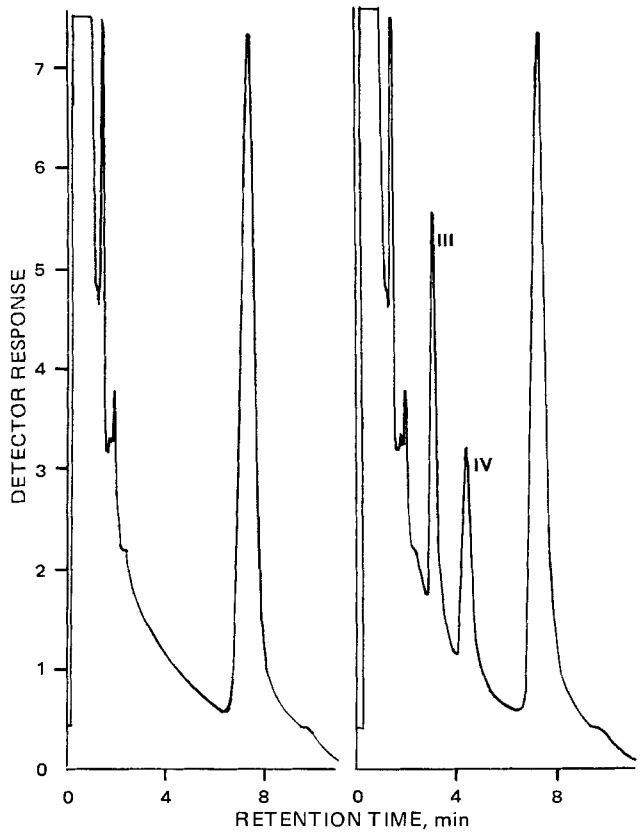

Figure 2—*Gas chromatograms of derivatized human plasma extracts. Key: left, normal plasma specimen; right, plasma specimen containing 6.6 μg of I/ml and 5.0 μg of II/ml; III, indoprofen methyl ester; and IV, internal standard methyl ester.*

provide good evidence for the utility of the developed method for plasma levels of I down to 0.4 μg/ml.

During routine analyses, it was found that a standard curve prepared on Day 1 (as described in *Experimental*) is validated day after day by simple comparison of results from two or three standard samples. In a recent series of determinations, for example, two to five (total = 13) standard samples were analyzed on 4 separate days over a 3-week period. After plotting the data from these determinations, a curve was produced with a slope of 0.269, an r of 0.999, and a y-intercept essentially equal to zero. These data are in excellent agreement with the parameters of the standard curve utilized in evaluating the accuracy and precision of the method and support the utility of the proposed method for routine determinations.

Table I—Accuracy and Precision of GLC Method for I

Concentration of I, μg/ml		
Added	Found	Recovery, %
0.4	0.40	100
0.4	0.41	103
1.0	0.82	82.0
1.0	1.00	100
1.0	1.12	112
3.0	2.65	88.3
3.0	2.99	99.7
3.0	3.08	103
5.0	4.55	91.0
5.0	5.06	101
5.0	5.36	107
8.0	7.55	94.4
8.0	7.73	96.6
8.0	8.16	102
8.0	8.39	105
Mean = 99.0% (n = 15)		
SD = ±7.6%		

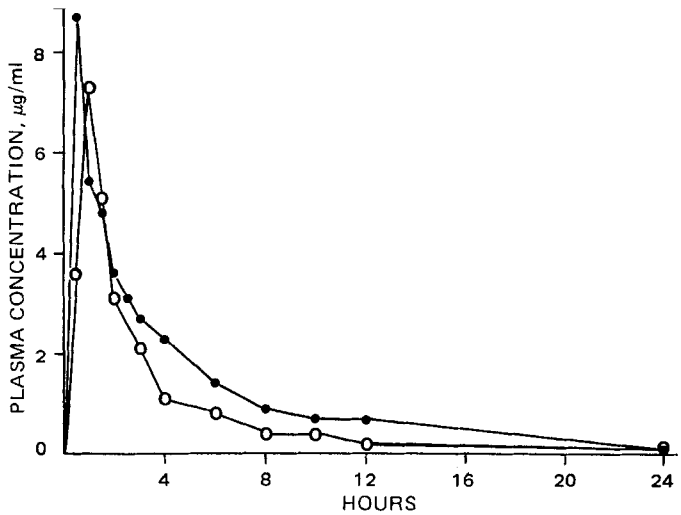

Figure 3—*Individual plasma levels of indoprofen following oral administration of single 100-mg capsules to two subjects as determined by the GLC method. Values less than 0.4 μg/ml are approximations only, since the method was not validated at concentrations below this level.*

The described method was devised as a convenient and more rapid procedure than those reported previously (4, 5). During ordinary usage, the described method permits analysis of 15 samples/one-worker day. This is a marked improvement over the 3–4 hr/sample required to assay I by the previously reported boron trifluoride–trifluoroethanol procedure (4), which is estimated to be the shorter of the two methods described in the literature (4, 5).

Plasma levels obtained in two patients administered single oral doses of 100 mg (capsules) of I were followed with the method described. Results of these analyses are presented in Fig. 3 and nicely parallel the findings published by Tosolini *et al.* (4).

Application of Salivary Concentration Data to Pharmacokinetic Studies with Antipyrine

PETER J. MEFFIN *x, ROGER L. WILLIAMS ‡, TERRENCE F. BLASCHKE ‡§, and MALCOLM ROWLAND *¶

Abstract □ The concentrations of antipyrine in plasma and saliva were equivalent in normal volunteers and in patients with acute viral hepatitis following oral doses of antipyrine. Estimates of clearance, volume of distribution, and half-life made from either plasma or saliva samples were not statistically different in these subjects. Differences in the disposition kinetics of antipyrine during the acute phase of viral hepatitis and on recovery were detected using either plasma or saliva samples.

Keyphrases □ Antipyrine—pharmacokinetics, normal subjects and hepatitis patients, plasma and saliva concentration data □ Pharmacokinetics—antipyrine, normal subjects and hepatitis patients, plasma and saliva concentration data □ Analgesics—antipyrine, pharmacokinetics, normal subjects and hepatitis patients, plasma and saliva concentration data

Antipyrine, used as an investigational marker of drug metabolism in humans, is thought to be metabolized in the liver; when given orally, less than 0.1% of the dose is excreted unchanged in the stool and less than 5% is excreted unchanged in the urine (1). The plasma half-life of antipyrine has small intrasubject variability (2–5) and has been correlated with genetic (2, 5, 6) and environmental (2, 3) factors, sex, and age (7). The antipyrine half-life or clearance also correlates with the half-life or clearance of phenylbutazone (4), phenytoin (8), and warfarin (9). However, no significant correlation was found between the antipyrine half-life and the half-life of amobarbital, glutethimide, or sulfinpyrazone (10). Because the many studies with antipyrine may eventuate in its use as a marker of drug metabolism, we decided to investigate the possibility that the disposition kinetics of antipyrine could be determined by studying the concentrations of antipyrine in saliva.

The concentrations of drugs in saliva have been used to determine the disposition kinetics of many drugs [*e.g.*, salicylate (11), theophylline (12), acetaminophen (13), digoxin (14), sulfonamides (15, 16), and tolbutamide (17)]. In humans, the concentration of antipyrine in saliva correlates with that in plasma (18).

Recently, two papers reported the equivalence of antipyrine concentrations in plasma and saliva and demonstrated the utility of salivary antipyrine measurements in estimating pharmacokinetic parameters in normal subjects and epileptic patients (19, 20). The present study confirmed these findings and extends the use of antipyrine salivary concentrations by demonstrating their validity in patients with acute viral hepatitis.

EXPERIMENTAL

Subjects and Treatment—Subjects 1 and 2 were normal, healthy, male volunteers who weighed 70.1 and 75 kg, respectively. Subjects 3 and 4 were studied during the acute phase of viral hepatitis (Studies 3A and 4A) and after recovery (Studies 3B and 4B); these latter studies took place 2–6 weeks after the initial study and after biochemical indexes of hepatic function had returned to normal. Subjects 3 and 4 weighed 51.0 and 60.5 kg, respectively.

Each subject fasted for approximately 12 hr before and 1 hr after ingesting 250 ml of an aqueous solution containing 1.0 g of antipyrine. During the first 8 hr, blood was drawn from a peripheral vein *via* an indwelling catheter; venipuncture was used thereafter. Heparin was used to prevent coagulation; plasma was obtained by centrifugation. Plasma samples were obtained prior to each dose for use as an analytical blank.

Saliva was collected at the same time that blood was drawn. If saliva flow was insufficient, the subjects chewed on a piece of plastic film[1] for 3 min; they then expectorated into a sampling container. Each saliva sample collected from Subjects 1 and 2 was weighed to determine the effect of saliva flow on antipyrine concentration. After each dose, the patients rinsed their mouths thoroughly before providing the first saliva sample. All plasma and saliva samples were frozen until they were analyzed.

Procedure—The following were added to a 15-ml tube fitted with a lined screw cap[1]: 0.5–2 ml of plasma or 0.5–2 g of saliva, both containing an estimated 1.0–30 μg of antipyrine; internal standard solution (10 μg of 4-bromoantipyrine[2] in 0.1 ml of water); and 7 ml of dichloromethane. The tube was then gently shaken by hand for 10 min and centrifuged. The organic phase was transferred carefully to a second 15-ml tube, which had a conical tip at its base, and the solvent was evaporated to dryness on a water bath at 45°. Immediately before injection into the gas chromatograph, 15 μl of distilled water was added to the tube and mixed gently.

Approximately 5 μl of water was injected into the gas chromatograph with a flame-ionization detector[3]. A glass column (1.8 m long and 0.32 cm o.d.), packed with a 3% OV-17 on 100–120-mesh Gas Chrom Q[4], was used. The injector port, fitted with a glass liner, was maintained at 150°; the oven was kept at 220°, and the detector was kept at 250°. The injector port liner was changed and the column was treated with a silylating agent[5] prior to each day's analyses.

Under these conditions, antipyrine and the internal standard had retention times of 1.6 and 3.5 min, respectively. Calibration curves, obtained by adding known amounts of antipyrine to samples of plasma and saliva and taking them through the analytical procedure, had an average coefficient of variation of 5.6% in the 1–30-μg range.

Data Analysis—A log-linear least-squares method was used to fit the data obtained in the postabsorptive period (usually those data obtained at times greater than 1 hr after dosing) to a straight line and thus to estimate the plasma and saliva half-life ($t_{1/2}$) values. Clearance was determined by dividing the dose by the area under the saliva and plasma concentration–time data sets (AUC) from zero to infinite time. The oral dose was assumed to be completely absorbed (21). The trapezoidal rule was used to determine the AUC. The area beyond the last data point was estimated by dividing the least-squares estimate of the concentration at that time by the elimination rate constant. The volume of distribution of antipyrine was determined using (22):

$$\text{volume of distribution} = \frac{\text{clearance} \times t_{1/2}}{0.693} \qquad \text{(Eq. 1)}$$

The correlation between plasma and saliva antipyrine concentrations was determined by standard regression analysis techniques. A paired t-test was used to compare the pharmacokinetic parameters in plasma to those in saliva for each individual.

RESULTS AND DISCUSSION

Comparison of Salivary and Plasma Concentrations—The results

Table I—Regression Analysis of Antipyrine Concentrations Measured in Saliva against Those Found in Plasma

Study	r	p
All data	0.958	<0.01
Study A data	0.967	<0.01
Nonstudy A data[a]	0.926	<0.01
Subject 1	0.909	<0.01
Subject 2	0.984	<0.01
Subject 3 (Studies A and B)	0.966	<0.01
Subject 4 (Studies A and B)	0.992	<0.01

[a] All data minus Study A data.

of the regression analysis of the plasma and saliva antipyrine concentrations are shown in Table I. As indicated, the correlation coefficients were all statistically significant.

Although the overall ratio between saliva and plasma concentrations was very close to 1, the correlation coefficients in Table I show that there was considerable scatter in the data. The major contribution to this scatter was probably analytical error. Because of the scatter, the ability to estimate plasma concentration from a single saliva antipyrine determination may err in the order of 20% at low antipyrine concentrations where analytical error is greatest. However, this limitation may not affect the use of saliva antipyrine concentrations in pharmacokinetic investigations involving multiple determinations.

These studies are in agreement with two recent reports which found no significant differences between saliva and plasma antipyrine concentrations in normal subjects (19, 20) and epileptic patients (19). When data from individuals with acute viral hepatitis were analyzed separately (Study A data, Table I), no apparent change in the correlations was observed, either for data obtained during disease or for the remaining analyses. This particular disease state apparently did not alter the ratio of saliva to plasma concentrations of antipyrine.

The influence of saliva flow on the ratio of antipyrine concentrations found in saliva to those found in plasma was examined by plotting this ratio *versus* the weight of saliva collected during 3 min (Fig. 1). The lack of correlation (r = 0.034) suggests that partitioning of antipyrine between saliva and plasma is independent of saliva flow.

Estimation of Pharmacokinetic Parameters—Table II shows the estimates of clearance, half-life, and volume of distribution for each study as calculated from saliva and plasma concentration–time data sets. No significant differences were noted between these estimates. Similar findings were reported recently (19, 20). The agreement in Table II is better than might have been anticipated, primarily because the multiple concentration data tend to average out analytical error. Salivary data could have been used to detect the difference in the pharmacokinetic parameters of Subject 4 during the acute phase of hepatitis (Study 4A, Fig. 2) and after the subject recovered (Study 4B, Fig. 2). It is in comparison studies of this sort that the use of salivary concentration will be most applicable. Saliva antipyrine concentration measurements have also been used to detect differences in antipyrine pharmacokinetic parameters in epileptic patients treated with anticonvulsants compared to those found in normal volunteers (19).

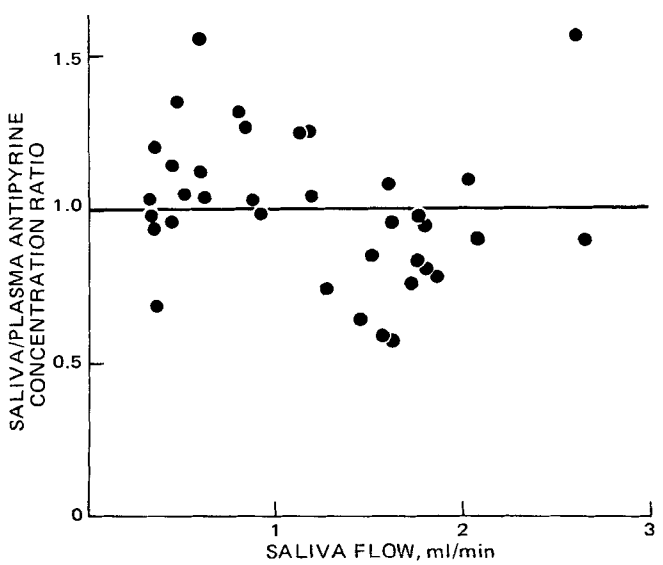

Figure 1—*Ratios of the concentrations of antipyrine in saliva to those in plasma* versus *the saliva flow during the 3-min collection period. The line would be obtained if the ratio were independent of plasma flow.*

Table II—Pharmacokinetic Parameters for Antipyrine Calculated from Saliva and Plasma Concentration–Time Data

	Clearance, ml/hr/kg		Volume of Distribution, liter/kg		Half-Life, hr	
Subject	Plasma	Saliva	Plasma	Saliva	Plasma	Saliva
1	38.8	38.2	0.71	0.64	12.7	11.6
2	34.1	40.2	0.60	0.60	12.1	10.3
3A	8.9	10.9	0.58	0.66	45.0	42.3
3B	58.0	50.8	0.80	0.63	9.4	8.6
4A	30.0	29.5	0.53	0.50	12.2	11.8
4B	45.9	48.5	0.49	0.54	7.5	7.8
Mean	36.0	36.6[a]	0.62	0.60[a]	16.5	15.4[a]

[a] These pairs of values were not significantly different.

Estimates of antipyrine clearance may effectively serve as a standard for evaluating the clearance of other drugs metabolized in the liver, although caution must be used in interpreting the results (23). The potential widespread clinical use of antipyrine clearance as an index of the capacity of the liver to metabolize drugs is enhanced because concentrations of antipyrine are equal in plasma and in saliva, because multiple saliva samples are easily obtained, and because determinations can be made by a simple GLC assay. If useful correlations between antipyrine clearance and the clearance of other drugs could be established, then the complete oral availability of antipyrine (21) and its low toxicity would make antipyrine a suitable test drug for individualizing doses of drugs that exhibit large intersubject variability in clearance. Data presented in this paper and elsewhere (19) indicate that it may prove possible to use saliva antipyrine concentration measurements to detect changes in pharmacokinetic parameters resulting from disease and coadministration of other drugs.

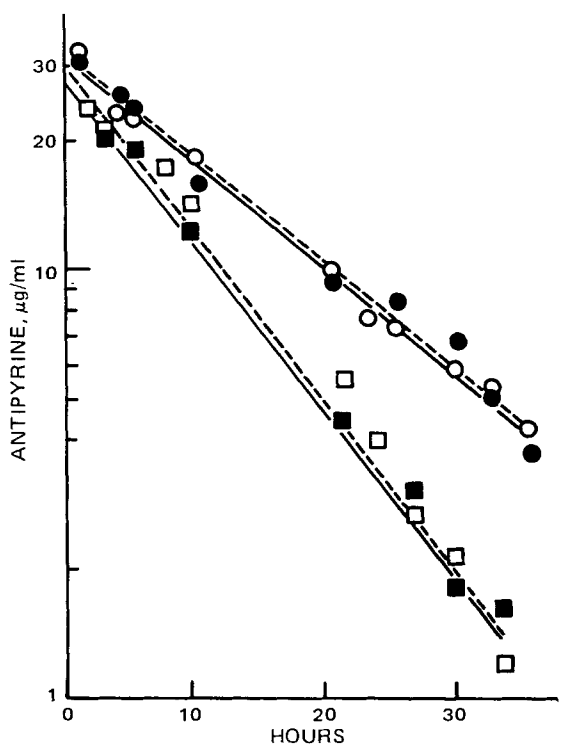

Figure 2—*Antipyrine concentrations in plasma (solid symbols, micrograms per milliliter) and in saliva (open symbols, micrograms per milliliter) at various times after a 1-g oral dose of antipyrine in Subject 4 during the acute phase of viral hepatitis (Study 4A, ○, ●) and after recovery (Study 4B, □, ■).*

Application of a Convective Diffusion Model to Membrane Transport

K. G. NELSON * and A. C. SHAH ‡ˣ

Abstract □ Studies were carried out on the permeation rate of butamben through a dimethicone membrane. Under conditions of "aqueous diffusion layer control," the permeation rate was accurately described by a mathematical model based on convective diffusion theory. In accordance with the model, the rate of permeation from a saturated donor phase was shown to be equal to the rate of dissolution from a pure solid.

Keyphrases □ Diffusion, convective—model applied to permeation rate of butamben through dimethicone membrane □ Membrane transport—convective diffusion model applied to permeation rate of butamben through dimethicone membrane □ Permeation rate—butamben through dimethicone membrane, convective diffusion model □ Butamben—permeation rate through dimethicone membrane, convective diffusion model

One fundamental process that occurs during drug absorption is the transport of the active ingredient across various biological membranes. The study of membrane transport is thus of considerable interest, and the theoretical aspects of permeation models were recently reviewed (1).

In the model most frequently used to describe membrane transport, the membrane is considered to be in series with a stagnant or unstirred liquid diffusion layer on each side (2–5). For a liquid flowing past a surface, however, fluid flow occurs even at very small distances from the solid. Therefore, convective diffusion theory that accounts for fluid flow as well as diffusion should be applied (6). The differential equation of convective diffusion theory requires a mathematical description of the liquid flow past the dissolving surface. Although flow profiles are generally nonlinear, a constant velocity gradient can be assumed if the dissolving surface is relatively short (7, 8). Such a model recently was applied to describe drug dissolution into a moving liquid (9, 10). The purpose of this study was to evaluate the application of convective diffusion theory to membrane transport under conditions where transport across the dynamic liquid layer adjacent to the membrane is the rate-limiting step.

EXPERIMENTAL

The laminar flowcell was a modification of the dissolution cell described previously (10). The dissolution cell was adapted for membrane transport studies by constructing a donor compartment in the die such that the membrane would be positioned coplanar with the die surface. As shown in Fig. 1, the donor compartment consists of a cylindrical metal cup over which the membrane is positioned. When placed in the die as shown, the membrane made a watertight seal over the donor compartment. The donor compartment was stirred with a magnetic stirring bar.

The permeation rates were determined as follows using butamben as the permeating species. The donor cup was filled with an aqueous suspension of butamben and was mounted in the die with the membrane (thickness 0.025 cm) positioned as described. The membrane was prepared as described by Roseman (11). The die was placed in the flowcell, which was leveled and mounted on a vibration-free platform. Distilled

Application of a Convective Diffusion Model to Membrane Transport

K. G. NELSON * and A. C. SHAH ‡ˣ

Abstract □ Studies were carried out on the permeation rate of butamben through a dimethicone membrane. Under conditions of "aqueous diffusion layer control," the permeation rate was accurately described by a mathematical model based on convective diffusion theory. In accordance with the model, the rate of permeation from a saturated donor phase was shown to be equal to the rate of dissolution from a pure solid.

Keyphrases □ Diffusion, convective—model applied to permeation rate of butamben through dimethicone membrane □ Membrane transport—convective diffusion model applied to permeation rate of butamben through dimethicone membrane □ Permeation rate—butamben through dimethicone membrane, convective diffusion model □ Butamben—permeation rate through dimethicone membrane, convective diffusion model

One fundamental process that occurs during drug absorption is the transport of the active ingredient across various biological membranes. The study of membrane transport is thus of considerable interest, and the theoretical aspects of permeation models were recently reviewed (1).

In the model most frequently used to describe membrane transport, the membrane is considered to be in series with a stagnant or unstirred liquid diffusion layer on each side (2–5). For a liquid flowing past a surface, however, fluid flow occurs even at very small distances from the solid. Therefore, convective diffusion theory that accounts for fluid flow as well as diffusion should be applied (6). The differential equation of convective diffusion theory requires a mathematical description of the liquid flow past the dissolving surface. Although flow profiles are generally nonlinear, a constant velocity gradient can be assumed if the dissolving surface is relatively short (7, 8). Such a model recently was applied to describe drug dissolution into a moving liquid (9, 10). The purpose of this study was to evaluate the application of convective diffusion theory to membrane transport under conditions where transport across the dynamic liquid layer adjacent to the membrane is the rate-limiting step.

EXPERIMENTAL

The laminar flowcell was a modification of the dissolution cell described previously (10). The dissolution cell was adapted for membrane transport studies by constructing a donor compartment in the die such that the membrane would be positioned coplanar with the die surface. As shown in Fig. 1, the donor compartment consists of a cylindrical metal cup over which the membrane is positioned. When placed in the die as shown, the membrane made a watertight seal over the donor compartment. The donor compartment was stirred with a magnetic stirring bar.

The permeation rates were determined as follows using butamben as the permeating species. The donor cup was filled with an aqueous suspension of butamben and was mounted in the die with the membrane (thickness 0.025 cm) positioned as described. The membrane was prepared as described by Roseman (11). The die was placed in the flowcell, which was leveled and mounted on a vibration-free platform. Distilled

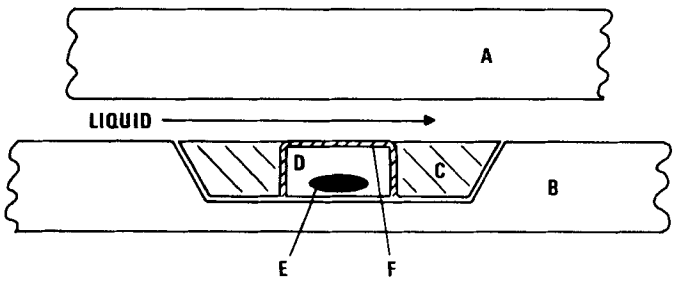

Figure 1—*Cross-sectional view of diffusion cell. Key: A, top plate; B, bottom plate; C, die; D, donor compartment; E, stirring bar; and F, membrane.*

water (25°) was pumped through the flowcell at a set flow rate with an infusion syringe pump[1], and the effluent was assayed spectrophotometrically[2] at 285 nm for the ester concentration. The ester concentration together with the flow rate permitted calculation of the permeation rate.

The permeation rate was studied as a function of the liquid flow rate and membrane area. The former was varied by changing the pump speed, while the latter was changed by using three donor cup–die assemblies with different radii (0.65, 1.0, and 1.25 cm).

RESULTS AND DISCUSSION

Figure 2 is a log–log plot of permeation rate *versus* flow rate. The initial rise followed by a plateau indicates that at low rates the permeation rate is influenced significantly by the transport in the liquid; at the higher flow rates, the major resistance to transport is offered by the membrane. The conditions corresponding to the former case are commonly called "diffusion layer control." Because the membrane offers only negligible resistance to permeation under these conditions, the aqueous concentration of solute at the interface between the membrane and the flowing liquid is equal to the concentration in the donor phase, which in this case is the solubility of the solute. Therefore, at low flow rates, the mathematical model describing the permeation rate should be the same as that used to describe the drug dissolution rate into a moving liquid (9, 10). The model, based on convective diffusion theory, gives the permeation rate, R, as:

$$R = 2.157 D^{2/3} C_0 \alpha^{1/3} r^{5/3} \qquad \text{(Eq. 1)}$$

where D is the diffusivity of the solute in water, C_0 is the solubility (or more generally the concentration of solute in the donor phase), α is the rate of shear over the membrane, and r is the radius of the membrane. The rate of shear immediately over the membrane is given by (10):

$$\alpha = \frac{6Q}{H^2 W} \qquad \text{(Eq. 2)}$$

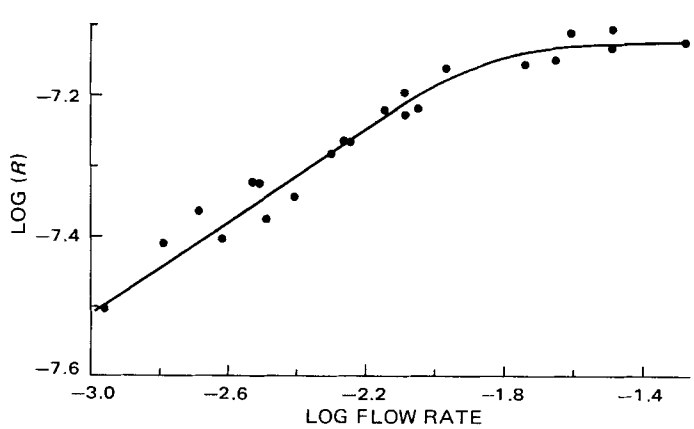

Figure 2—*Log–log plot of the permeation rate,* R, *as a function of the fluid flow rate.*

Table I—Permeation Rate as a Function of Fluid Flow Rate

Flow Rate (Q) × 10^3, liters/min	Permeation Rate × 10^8, moles/min
1.00	3.126
1.60	3.880
2.05	4.328
2.38	3.934
2.92	4.740
3.03	4.692
3.24	4.180
3.92	4.497
5.00	5.176
5.50	5.455
5.68	5.400
7.17	5.985
8.12	6.405
8.25	5.886
8.83	6.033
10.70	6.827
18.20	6.967
22.00	7.044
24.30	7.752
32.25	7.295
32.50	7.840
52.50	7.490

where Q is the volumetric flow rate, and H and W are the height and width of the diffusion cell, respectively. Thus, Eqs. 1 and 2 would predict a straight line with a slope of one-third on a plot of log R *versus* log Q. In Fig. 2, a line with a slope of one-third is drawn through the data up to log $Q = -2.0$ to permit visual correlation between theory and experiment. The data are given in Table I, and a statistical analysis of the data up to log $Q = -2.0$ gives a least-squares slope of 0.297 (SD = 0.0215) with a correlation coefficient of 0.9626.

The permeation rate also was determined using the area of the membrane as a variable. Figure 3 shows a log–log plot of permeation rate *versus* membrane radius at a constant flow rate of 2.24 ml/min. The slope of this line is 1.66, which is in excellent agreement with the exponent of 5/3 on the radius in Eq. 1. These results indicate that, under conditions of diffusion layer control, the permeation rate is not directly proportional to area but to a somewhat reduced function of area ($r^{5/3}$) because of the interaction of diffusion and convection. Solute leaving the membrane near the upstream edge of the membrane enters liquid largely devoid of solute, whereas there is a buildup of solute further downstream. The model based on convective diffusion can quantitatively account for such phenomena.

A calculation of the permeation rate using Eqs. 1 and 2 further supports the applicability of the convective diffusion model. Independently determined values used for the calculation are: $D = 6 \times 10^{-6}$ cm^2 sec (12), $C = 9.4 \times 10^{-4} M$ (10), $r = 1.25$ cm, $H = 0.31$ cm, $W = 3.65$ cm, and $Q = 2.05$ ml/min. The permeation rate is calculated to be 4.88×10^{-8} mole/min, which corresponds quite well to the experimentally determined rate of 4.33×10^{-8} mole/min.

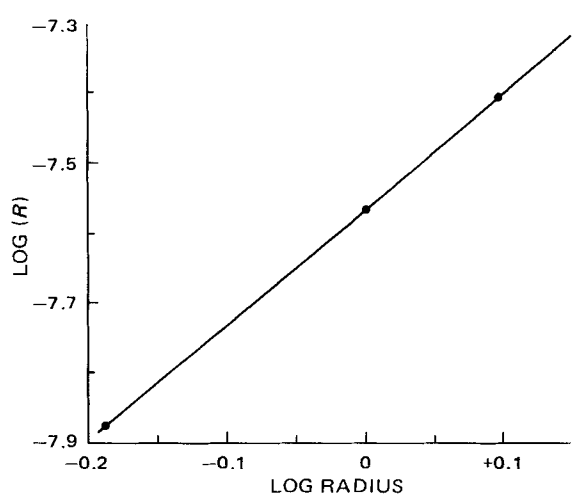

Figure 3—*Log–log plot of the permeation rate,* R, *as a function of the membrane radius.*

As in the studies on dissolution rates of drugs (9, 10), the model based on convective diffusion theory is able to describe quite accurately the membrane transport rate as a function of the physical–chemical parameters of the system. The convective diffusion model should apply to membrane transport for conditions intermediate between extremely low and high liquid flow rates. For the former conditions, as the flow approaches zero, it would be more appropriate to base a model on a nonsteady-state differential equation; for the latter, the transport is "membrane controlled" and has been thoroughly discussed (1).

Quick Specific Assay for Aspirin

EDGAR E. THEIMER [x] and EMIL W. CIURCZAK

Abstract □ Use of the Schoenemann reaction for the assay of aspirin in pharmaceutical combinations is described.

Keyphrases □ Aspirin—colorimetric analysis using Schoenemann reaction, pharmaceutical combinations □ Colorimetry—analysis using Schoenemann reaction, aspirin in pharmaceutical combinations □ Analgesics—aspirin, colorimetric analysis using Schoenemann reaction, pharmaceutical combinations

Aspirin is often the most labile component in a combination-type analgesic compound. Therefore, its stability is often the initial concern in any formulation screening program. Preliminary screening of a large number of potential formulations can be arduous, since most current methods of analysis generally consist of several steps: extractions or column separations followed by UV, colorimetric, or GLC assay (1–4). The method proposed here is quite suited to large numbers of assays. It is straightforward and is not subject to interference from substances such as salicylic acid, caffeine, phenacetin, acetaminophen, and codeine. It is essentially a Schoenemann reaction with slight modifications (5, 6).

EXPERIMENTAL

Preparation of Sample—An amount of tablet granulation equivalent to 100 mg of aspirin is weighed into a 250-ml volumetric flask, and 200 ml of distilled water is added. The slurry is shaken for about 10 min; then the flask is diluted to volume with distilled water.

Standard—Aspirin, 0.4 mg/ml of water, is prepared freshly.

Equipment—A recording dual-beam spectrophotometer[1] was used at 455 nm with the recorder speed at 5 mm/min.

Reagents—*o*-Dianisidine hydrochloride[2] (3,3′-dimethoxybenzidine dihydrochloride) was obtained commercially[3]. Tribasic sodium phosphate, 3% hydrogen peroxide, and the various pharmaceuticals tested were all reagent or USP grade or good commercial grade. Acetone[4] was reagent spectrophotometric grade and was used without purification. Previous investigators warned that impure acetone leads to false results (5).

Assay—The reagents were mixed in the following order: 0.5 ml of *o*-dianisidine hydrochloride (0.5% aqueous solution), 3.0 ml of acetone, 1.0 ml of 3% hydrogen peroxide, 1.0 ml of standard, and 2.0 ml of 0.05 *M* tribasic sodium phosphate.

The maximum color developed was measured in a 1-cm cell against water in the reference beam of the spectrophotometer at 455 nm by recording absorbance as a function of time. The maximum always occurred within 5 min.

The entire procedure was repeated, substituting the sample solution for the standard.

The ratio of the maximum absorbances of sample and standard was used to calculate the amount of aspirin in the sample taken.

RESULTS AND DISCUSSION

Linearity—The maximum absorbance was determined for the standard over a concentration range from 0.1 to 1.6 mg/ml and found to be linear and directly proportional to concentration throughout this range.

Interferences—The specificity of the Schoenemann reaction for certain esters and anhydrides is well documented (8) and was confirmed by testing a wide range of pharmaceuticals likely to be present in aspirin formulations. Only salicylsalicylic acid interfered; it gave absorbance proportionate to its molar concentration when compared to aspirin. That is, the method should also be applicable to salicylsalicylic acid. Minor interference was noted with propylene glycol diacetate and acetylated mannitol.

Color of Blank—Initially, a reagent blank was routinely used in the reference beam during absorption scanning. However, it was unnecessary for aspirin samples, since the color change was negligible in the few minutes required to reach the maximum color of the sample.

Method Validation—The proposed method and a chromatographic method analogous to the NF procedure for aspirin, phenacetin, and caffeine tablets were used for the analysis of aspirin in stability samples of an experimental preparation containing aspirin, acetaminophen, and caffeine. The aspirin found (percent of label) with the chromatographic

EXPERIMENTAL

Preparation of Sample—An amount of tablet granulation equivalent to 100 mg of aspirin is weighed into a 250-ml volumetric flask, and 200 ml of distilled water is added. The slurry is shaken for about 10 min; then the flask is diluted to volume with distilled water.

Standard—Aspirin, 0.4 mg/ml of water, is prepared freshly.

Equipment—A recording dual-beam spectrophotometer[1] was used at 455 nm with the recorder speed at 5 mm/min.

Reagents—*o*-Dianisidine hydrochloride[2] (3,3′-dimethoxybenzidine dihydrochloride) was obtained commercially[3]. Tribasic sodium phosphate, 3% hydrogen peroxide, and the various pharmaceuticals tested were all reagent or USP grade or good commercial grade. Acetone[4] was reagent spectrophotometric grade and was used without purification. Previous investigators warned that impure acetone leads to false results (5).

Assay—The reagents were mixed in the following order: 0.5 ml of *o*-dianisidine hydrochloride (0.5% aqueous solution), 3.0 ml of acetone, 1.0 ml of 3% hydrogen peroxide, 1.0 ml of standard, and 2.0 ml of 0.05 *M* tribasic sodium phosphate.

The maximum color developed was measured in a 1-cm cell against water in the reference beam of the spectrophotometer at 455 nm by recording absorbance as a function of time. The maximum always occurred within 5 min.

The entire procedure was repeated, substituting the sample solution for the standard.

The ratio of the maximum absorbances of sample and standard was used to calculate the amount of aspirin in the sample taken.

RESULTS AND DISCUSSION

Linearity—The maximum absorbance was determined for the standard over a concentration range from 0.1 to 1.6 mg/ml and found to be linear and directly proportional to concentration throughout this range.

Interferences—The specificity of the Schoenemann reaction for certain esters and anhydrides is well documented (8) and was confirmed by testing a wide range of pharmaceuticals likely to be present in aspirin formulations. Only salicylsalicylic acid interfered; it gave absorbance proportionate to its molar concentration when compared to aspirin. That is, the method should also be applicable to salicylsalicylic acid. Minor interference was noted with propylene glycol diacetate and acetylated mannitol.

Color of Blank—Initially, a reagent blank was routinely used in the reference beam during absorption scanning. However, it was unnecessary for aspirin samples, since the color change was negligible in the few minutes required to reach the maximum color of the sample.

Method Validation—The proposed method and a chromatographic method analogous to the NF procedure for aspirin, phenacetin, and caffeine tablets were used for the analysis of aspirin in stability samples of an experimental preparation containing aspirin, acetaminophen, and caffeine. The aspirin found (percent of label) with the chromatographic

Single-Dose Assay of Ferrous Ion in Pharmaceuticals

RICHARD JUNEAU

Abstract □ A method for the assay of the ferrous ion in hematinics or multivitamin tablets is described. The method is based on the spectrophotometric measurement of the chromophore produced by reacting the ferrous ion with the highly specific chelating agent ferrozine. The method is proposed as an alternative to the redox methods in the USP and NF.

Keyphrases □ Ferrous ion—spectrophotometric analysis, pharmaceutical formulations □ Iron—ferrous ion, spectrophotometric analysis, pharmaceutical formulations □ Spectrophotometry—analysis, ferrous ion in pharmaceutical formulations □ Hematinics—ferrous ion, spectrophotometric analysis in pharmaceutical formulations

The presence of the ferrous ion in many pharmaceutical preparations necessitates a rapid, economical, and sensitive method for its determination in pharmaceuticals. The official USP and NF methods primarily rely on the classical redox conversion of the ferrous to the ferric ion (1, 2). These redox methods are tedious and inaccurate due to difficult end-point visualization.

Other methods are available for the assay of iron-containing products, *e.g.*, atomic absorption spectrophotometry and X-ray emission spectrometry. However, these methods require involved sample preparation as well as sophisticated instrumentation (3, 4). This report describes a simple colorimetric procedure applicable to ferrous-containing pharmaceuticals such as hematinics and multiple-vitamin preparations with iron. The sensitivity is such that the method is ideal for single-dose assays.

The present method utilizes the reagent ferrozine, 3-(2-pyridyl)-5,6-bis(4-phenylsulfonic acid)-1,2,4-triazine disodium salt, a chelating agent highly specific for the ferrous ion. Although this compound is similar to the well-known chelating agent 2,4,6-tripyridyltriazine, previously used for iron assays of pharmaceuticals, it has the advantages of being significantly more water soluble, more sensitive, and possibly more economically feasible for repeated analyses (4, 5).

Ferrozine has been shown to react with the ferrous ion to yield a magenta-colored tris complex, *i.e.*, Fe-(ferrozine)$_3^{2+}$. This species forms completely in aqueous solution between pH 4 and 9 and exhibits a sharp peak with maximum absorbance at 562 nm (5). Interference studies showed that only monovalent copper and divalent cobalt formed colored species with ferrozine (5). Ferrozine was used in the determination of iron in municipal waters (5) and serum iron levels (6).

Replication	Amount Found, mg	Percent Label
1	62.4	96.0
2	62.9	96.7
3	62.5	96.2
4	62.4	96.0

[a] Feosol tablets.

solution, 2.0 ml of the stock solution was placed in a 100-ml volumetric flask and brought to volume with deionized water.

Calibration Curve—Into separate 50-ml volumetric flasks were added 5.0, 4.0, 3.0, 2.0, or 1.0 ml of ferrous ammonium sulfate working solution, 2.0 ml of buffer solution, and 25 ml of deionized water. To these mixtures was added 1.0 ml of color reagent, and the mixtures were then brought to volume with deionized water. The solutions were allowed to stand with intermittent shaking for a minimum of 10 min, after which the solutions were read spectrophotometrically at 562 nm against a blank containing 2.0 ml of buffer solution and 1.0 ml of color reagent. (*Note:* Blanks did not give any visible color change upon addition of color reagent.)

Sample Preparation—*Solid Samples*—The tablet or contents of one capsule was placed in 100 ml of boiling deionized water containing 5 mg of ascorbic acid, and the mixture was boiled until complete dissolution occurred. The boiling mixture was then quantitatively filtered through a filter paper previously rinsed with several portions of boiling deionized water. After filtration, the residue on the filter paper was washed once with 50 ml of boiling deionized water followed by 100 ml of deionized water at room temperature. (If the sample contains ferrous fumarate, 100 ml of 0.1 *N* HCl should be used as the dissolution solvent.)

The mixture was then brought to volume. The final volume is variable and dependent on the labeled amount of iron. For example, if it is labeled 65 mg of elemental iron, the final volume may be 1 liter; if 33 mg of iron, then 500 ml; *etc.* One milliliter of this solution was then placed in a 50-ml volumetric flask, and the sample was prepared as were the solutions for the calibration curve and read against a blank prepared as described.

Liquid Samples—The liquid preparation (1.0 ml) was placed in a suitable volumetric flask (1 liter, 500 ml, *etc.*) and brought to volume with deionized water. Then 1.0 ml of this solution was placed in a 50-ml volumetric flask, and the sample was prepared as already described.

RESULTS AND DISCUSSION

A plot of absorbance *versus* concentration demonstrated that the Beer–Lambert law was obeyed over a wide concentration range as previously observed (5). Previous work indicated that an incubation step was needed for full color development (5, 6), but this step was shown to be unnecessary in these laboratories. Each calibration point of the Beer–Lambert plot was composed of three determinations. Two of these determinations utilized a 10-min incubation period at 40°; the third determination was allowed to stand at room temperature for this same period. Reading all three samples at room temperature gave readings that did not differ significantly, *i.e.*, a typical average deviation of 0.006 absorbance unit. Thus, it was only necessary to wait 10 min after mixing to obtain absorbance readings.

Once the color formed, it was stable almost indefinitely if kept at room temperature. Table I demonstrates the permanency of the chromophore produced. The data suggest that the permanency of color was not affected by product formulation, since iron from two different commercial formulations yielded colors as permanent as that obtained from analytical grade ferrous ammonium sulfate. The excellent stability of the chromophore offers distinct advantages when large numbers of assays must be performed since the chromophore can be produced and assayed at some later time without concern for stability. The instant and permanent color development was probably due to the fact that the concentration of ferrozine in the color reagent was well in excess of the required stoichiometric quantity.

[a] Prepared from ferrous ammonium sulfate and Clusivol tablets (Ayerst).

Tables II and III give typical results of replicated assays on a single tablet and demonstrate that the method gives values of relatively high precision. Initially, values were low for solid preparations containing ferrous fumarate. However, use of 0.1 *N* HCl for dissolution promoted the quantitative dissolution of the poorly soluble ferrous fumarate. The quantitativeness of the reaction with iron in pharmaceutical dosage forms was assured by adding ferrous ammonium sulfate to several iron-free multivitamin preparations of the solid or liquid type. In all cases, the iron content of these prepared samples was no less than 98.5% nor more than 101% of the amount added.

For example, the data in Table IV were obtained from a synthetic multiple-tablet composite. The composite was prepared by adding an accurately known amount of ferrous ammonium sulfate to 20 iron-free multivitamin tablets whose weight also was accurately known. The mixture was then thoroughly triturated, and approximately one-twentieth of the combined weight was used as a tablet sample. The data indicate that recovery and precision were excellent. It is assumed that the formulation characteristics of the spiked samples were comparable to the iron preparations assayed. This assumption appears to be valid, since assay of the iron-containing commercial products led to values very close to label claims.

Thus, the proposed method seems to offer several advantages over the present USP–NF method in terms of time, sensitivity, and convenience, especially when it is realized that one reagent suffices for all ferrous-containing products and that there are no interferences with tablet fillers, excipients, or colorants. The procedure should also have utility in automated assay methods.

High-Pressure Liquid Chromatographic Analysis of Drugs in Biological Fluids I: Warfarin

THORIR D. BJORNSSON *, TERRENCE F. BLASCHKE *, and PETER J. MEFFIN ‡x

Abstract □ A rapid, sensitive, and specific high-pressure liquid chromatographic (HPLC) method for the quantitative analysis of warfarin in plasma is described. The method involves a single solvent extraction of warfarin and the internal standard from acidified plasma, followed by evaporation and HPLC analysis. The method is sufficiently sensitive and accurate for most pharmacokinetic studies; concentrations between 0.1 and 4.0 μg/ml can be measured with a coefficient of variation of 2–5%. Known metabolites of warfarin do not interfere with the analysis.

Keyphrases □ Warfarin—high-pressure liquid chromatographic analysis, human plasma □ High-pressure liquid chromatography—analysis, warfarin in human plasma □ Anticoagulants—warfarin, high-pressure liquid chromatographic analysis, human plasma

Several methods have been reported for the analysis of warfarin in biological fluids, but each has some disadvantage in specificity, sensitivity, reproducibility, or convenience. One reported method (1) involves solvent extraction of warfarin from plasma with dichloroethane, followed by a buffer wash and back-extraction of warfarin into dilute sodium hydroxide solution. Concentration is calculated by UV absorbance at two wavelengths. A modification of this method (2) is still time consuming, since it requires several quantitative transfers. A fluorometric method (3) is rapid but gives consistently higher values than the more commonly used spectrophotometric methods. Thus, its specificity is in doubt. A TLC method for the analysis of warfarin and its metabolites also was described (4), but it is time consuming, making the analysis of a large number of samples difficult.

More recently, two GLC methods were described for the analysis of warfarin. One method (5) involves a complex solvent extraction, evaporation, and derivatization before GLC analysis, but it offers no apparent benefits over other methods. The other GLC method (6) is sensitive and can detect as little as 0.02 μg of warfarin/ml of plasma. The procedure, however, is complex and includes solvent extraction, evaporation, TLC, derivatization, and GLC analysis. In view of the commonly encountered therapeutic levels of warfarin of 1.5 ± 0.5 μg/ml, the added sensitivity of this method will be required in only a few types of investigations.

A high-pressure liquid chromatographic (HPLC) analysis of warfarin was described previously (7), but this report gave few details. Moreover, an internal standard was not used, thus necessitating quantitative transfer and sampling techniques, with their inherent inconveniences.

The method described in this paper is specific, accurate, and convenient, and it has sufficient sensitivity to measure accurately concentrations of warfarin as low as one-tenth of the normally encountered therapeutic levels in humans.

Table I—Statistics of Calibration Curves and Reproducibility

[a] PHR = peak height ratio of warfarin to internal standard.

EXPERIMENTAL

Reagents and Materials—Warfarin[1] and *p*-chlorowarfarin[2] [3-(α-acetonyl-*p*-chlorobenzyl)-4-hydroxycoumarin] were used as supplied. Stock solutions of warfarin (2.0 mg/ml) and the internal standard (1.2 mg/ml) were prepared in methanol[3] and stored in the dark at 4°. Appropriate dilutions of these stock solutions with water were made weekly to produce working standards of 1.2 μg/100 μl for the internal standard and 0.1–4.0 μg/100 μl for warfarin.

Sample Preparation—Plasma, 0.2–1 ml, was placed in a screw-capped[4] centrifuge tube, and 100 μl of internal standard solution (containing 1.2 μg of *p*-chlorowarfarin), 0.5 ml of 0.5 *N* aqueous sulfuric acid[5], and 5 ml of ether[5] were added. The samples were extracted by mixing, using gentle hand tilting of the tubes for 10 min or using any method of gentle mechanical agitation, followed by centrifugation at 2500 rpm for 10 min to separate the organic and aqueous phases.

The lower aqueous phase was frozen by immersing the tube in a dry ice–acetone bath, and the organic phase was poured off into another tube having an elongated cone at its base of approximately 50-μl capacity. The organic solvent was evaporated to dryness in a water bath at 40–45°. The residue was dissolved in 25 μl of methanol[3] by washing the sides of the lowest part of the tube and its elongated cone several times with the aid of a 25-μl syringe. Then 15–20 μl of the methanol solution was injected into the chromatograph.

Chromatography—A high-pressure liquid chromatograph[6] fitted with a 25-cm long, 6.3-mm o.d., 2.2-mm i.d. reversed-phase column[7] was used. The detector was a variable wavelength spectrophotometer[8] with a 10-μl flowcell. Absorbance was measured at 308 nm, with 0.1 absorbance unit full scale and 2-nm slit width. One pump of the dual-pump gradient elution chromatograph contained methanol[3], and the other contained 0.5% acetic acid in distilled water. An isocratic 1:1 mixture of the two solvents was used. Although it was convenient to use two pumps operating under isocratic conditions, a 1:1 mixture of the two solvents in a single pump can be used.

[8] Variscan, Varian, Palo Alto, Calif.

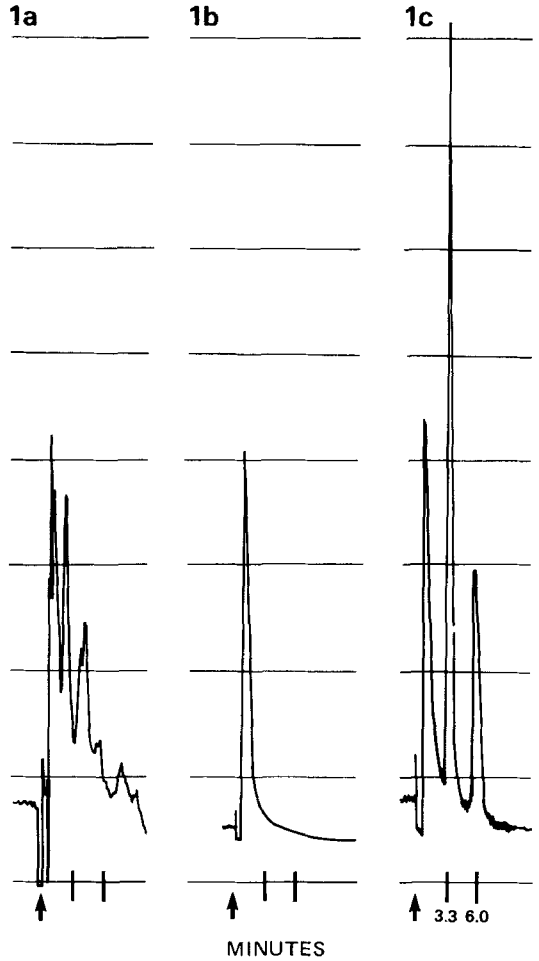

Figure 1—(a) *Chromatogram obtained when 1 ml of control plasma is extracted and absorbance is measured at 280 nm.* (b) *Chromatogram of the same control plasma with absorbance measured at 308 nm.* (c) *Typical chromatogram of plasma containing warfarin (2.0 μg/ml) and the internal standard. The marks on the chromatograms of control plasma correspond to the retention times of warfarin (3.3 min) and the internal standard (6.0 min). To improve visual clarity, only one tracing of the dual-pen recorder is shown.*

The flow rate of the solvent mixture was 60 ml/hr, with a column input pressure of 390–420 kg/cm^2 (374–408 atm). Chromatograms were recorded on a dual-pen recorder[9] with 0–50- and 0–100-mv spans.

Calibration and Accuracy—Calibration curves were constructed by adding known amounts of warfarin and internal standard to control plasma. The peak height ratio of warfarin to the internal standard was plotted against the amount of warfarin added. To calibrate the method and to determine its accuracy for each batch of unknown samples, standards of 0.1, 0.5, 1.0, 2.0, and 4.0 μg of warfarin were added to 1-ml samples of control plasma, which were assayed concurrently with the unknown samples. The peak height ratio of each standard was divided by the amount of warfarin added to give normalized peak height ratios. The mean normalized peak height ratio was used to calculate the amount of warfarin in unknown samples, and the standard deviation of the normalized peak height ratios was used to determine the accuracy of the method over the range of warfarin standards employed.

Reproducibility of the method was also studied by carrying replicate plasma samples containing 0.5, 1.0, and 2.0 μg of warfarin through the procedure. The effect of sample size on the method was investigated by adding 1 μg of warfarin to tubes containing different volumes of plasma, 0.2–2 ml, which were then assayed for warfarin. The volumes of internal standard solution, sulfuric acid, and ether were constant.

Plasma Level Study—A normal human male volunteer (weight 63.0 kg) was given 15 mg of warfarin sodium in aqueous solution after fasting for approximately 12 hr. Samples of venous blood (3 ml) were withdrawn

[9] Varian A-25, Varian, Palo Alto, Calif.

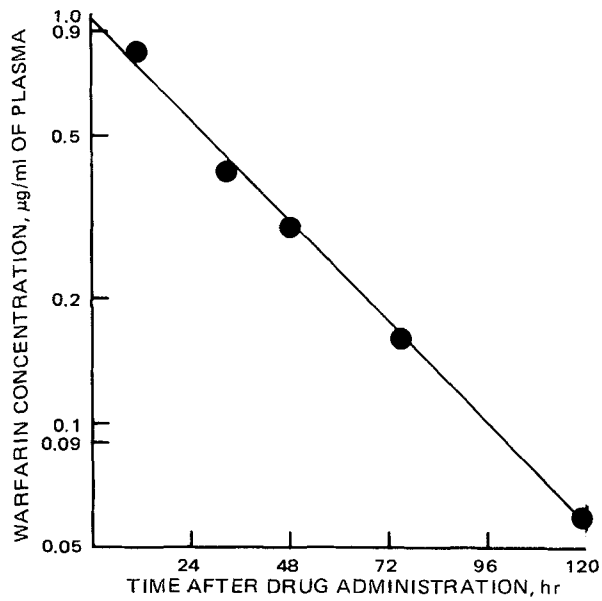

Figure 2—*Semilog plot of plasma warfarin levels in a male volunteer who received 15 mg of warfarin orally.*

by means of heparinized containers[10] prior to, and at intervals over 120 hr after, drug administration. The blood samples were centrifuged, and the plasma was transferred to glass containers; these containers were stored at −15° until analyzed.

RESULTS AND DISCUSSION

In preliminary work, ^{14}C-warfarin[11] was satisfactorily extracted from plasma acidified with dilute sulfuric acid by toluene, ether, isopentyl acetate, dichloroethane, and ethyl acetate. These solvents extracted 90–95% of warfarin from the plasma using a solvent to plasma ratio of 3:1. Although dichloroethane is used frequently, ether was selected for the extraction of warfarin from plasma for the following reasons. Ether has a lower specific gravity than water and has a low freezing point; thus it can be separated easily from the aqueous phase by freezing. It is readily evaporated and, because of its lower polarity, it is less likely to extract interfering compounds than dichloroethane.

Initially, absorbance was measured at 280 nm with a sensitive fixed-wavelength detector. At that wavelength, however, peaks interfering with both warfarin and the internal standard were present on chromatograms from control plasma (Fig. 1*a*). Extractions with various solvents and back-extraction of warfarin into 2.5 *N* sodium hydroxide solution failed to eliminate these peaks. The use of a UV absorbance detector at 308 nm eliminated these interfering peaks from the chromatograms and enabled the use of the simple extraction procedure described earlier. A chromatogram of control plasma sample (1 ml) obtained under these conditions is shown in Fig. 1*b*.

Although the use of a variable wavelength detector resulted in a loss in sensitivity compared to that possible with the fixed-wavelength detector due to differences in the energy output of the lamps, good reproducibility and accuracy were still attainable with 0.1 μg of warfarin. This lower limit is sufficient for most clinical and pharmacokinetic purposes. When using the chromatographic conditions previously described, the peaks corresponding to warfarin and the internal standard had retention times of 3.3 and 6.0 min, respectively. A typical chromatogram of a plasma sample containing 2.0 μg of warfarin/ml is shown in Fig. 1*c*.

There has been some controversy about the specificity of the nonchromatographic methods for the quantitative determination of warfarin in plasma (2, 4, 7–9). Lack of specificity in such analyses arises from variable blank values and the measurement of drug metabolites. Although not specifically investigated by some authors, it is probable that the chromatographic methods measure only unchanged warfarin.

The effect of known metabolites of warfarin on the assay was investigated by adding 6-hydroxy- and 7-hydroxywarfarin[11] and the ste-

Table II—Comparison of Published Methods for the Analysis of Warfarin in Plasma

Reference	Method	Sensitivity, μg/ml	Specificity[a]	Reproducibility (Coefficient of Variation), %
1	Spectrophotometric	Not given	Questionable	9.9[b] (duplicates of mean 7.1 μg/ml)[c]
2	Spectrophotometric	0.1	Questionable	2.2[b] (replicates at 5 and 10 μg/ml)
3	Fluorometric	Not given	Nonspecific	1.0[b] (replicates at 5 μg/ml)
4	TLC–fluorometric	0.25	Specific	1.6 (replicates between 2 and 7 μg/ml)
5	GC	0.25	Specific	3.15 (replicates between 0.25 and 8.0 μg/ml)
6	TLC–GC	0.02	Specific	Not given
7	HPLC	Not given	Specific	2.0 (Not specified)
This method	HPLC	0.1	Specific	3.0 (replicates at 0.5, 1.0, and 2.0 μg/ml)

[a] See *Discussion*. [b] Value not reported but calculated by present authors from published data. [c] Comments in parentheses indicate the range of concentrations over which estimates of reproducibility were made.

reoisomeric alcohol metabolites[12] (10) to plasma samples, which were then taken through the procedure. These four metabolites all had retention times of 2 min or less under the conditions described and did not interfere with measurement of the peaks corresponding to warfarin or the internal standard. Since no peaks interfere with warfarin or the internal standard in blank plasma and the known metabolites of warfarin are well separated from the two peaks of analytical interest, it may be concluded that the method is specific for warfarin. Furthermore, plasma samples obtained in 18 patients receiving 50 different drugs were handled in a manner identical to that for samples known to contain warfarin, except that an internal standard was not added. Chromatograms of these samples showed no peaks that would interfere with the peaks of warfarin or the internal standard[13].

The average normalized peak height ratios obtained from seven calibration curves containing five or more data points had a mean coefficient of variation of 4.8% over approximately 3 months (Table I). This estimate of accuracy covers the entire range of the assay procedure, from 0.1 to 4.0 μg of warfarin/sample. Reproducibility studies using replicates of five samples of 0.5 μg of warfarin, 10 samples of 1.0 μg of warfarin, and five samples of 2.0 μg of warfarin/ml of plasma gave coefficients of variation of 4.0, 1.7, and 3.4%, respectively (Table I). Although these estimates of reproducibility for this method are larger than some estimates shown in Table II for other methods, most estimates for other methods were made at plasma warfarin concentrations in the upper range of therapeutic values or above. In contrast, the coefficients of variation presented in this paper were calculated at concentrations more commonly encountered in patients. Since it may be necessary to take variable volumes of plasma for warfarin measurement, the effect of plasma volume on the peak height ratio of warfarin to the internal standard was examined. Between the range of 0.2 and 2 ml, the peak height ratios were independent of the volume of plasma.

Application of the method to plasma level determinations in a normal human male volunteer is demonstrated in Fig. 2. The data are well described by a one-compartment open model, with $r = 0.998$ for a plot of log warfarin concentration *versus* time. The half-life of 29.5 hr and the volume of distribution of 0.25 liter/kg [assuming complete absorption (11)] are within the range of previously reported values (11). After this relatively small dose, it was possible to monitor plasma concentrations for four half-lives.

The HPLC method described here for the quantitative determination of warfarin in plasma is simpler and more rapid than other published methods with similar sensitivity or specificity (Table II). By using the techniques described, 30–40 samples can easily be assayed in a day. The method is not only convenient, but it is specific; and its accuracy and sensitivity are satisfactory for most pharmacokinetic studies.

Comparative Pharmacokinetics of Coumarin Anticoagulants XXVIII: Predictive Identification of Rats with Relatively Steep Serum Warfarin Concentration–Anticoagulant Response Characteristics

Keyphrases □ Warfarin—serum concentration related to anticoagulant response characteristics, rats □ Anticoagulants—serum warfarin concentration related to response characteristics, rats □ Prothrombin complex synthesis—related to serum warfarin concentration, rats

To the Editor:

The coumarin anticoagulants produce their effect by inhibiting the synthesis of the vitamin K-dependent clotting factors. There is an essentially linear relationship between the degree of inhibition of the prothrombin complex synthesis rate, R_{syn}, and the logarithm of the plasma or serum concentration of warfarin and dicumarol in humans (1, 2) and rats (3, 4). The slope of a plot of R_{syn} *versus* log drug concentration is negative and was designated by the letter m in previous publications. Studies in humans showed pronounced and quite reproducible interindividual differences in m (1, 2).

One may assume that individuals with high m values are particularly likely to be subject to excessive or inadequate anticoagulation, with the attendant risks, since a small change in the drug concentration in these subjects causes a large change in the anticoagulant effect. It is impractical and probably unwise to determine m values directly in patients at the start of anticoagulant therapy since this approach requires administration of a very large dose (about 10 times larger than the usual therapeutic dose). Since the rat also exhibits pronounced interindividual differences in m, we used this animal as a model to explore the possibility of prospectively identifying "steep" responders to warfarin (*i.e.*, those with a high m value).

Ten male Sprague–Dawley rats received a single 0.6-mg/kg iv injection of ^{3}H-(*S*)-(−)-warfarin. Blood samples were collected periodically, and the concentration of warfarin and the prothrombin complex activity were determined in serum. A larger blood sample was obtained at the end of the experiment for determination of the serum free fraction of (*S*)-warfarin by equilibrium dialysis against pH 7.4 buffer containing 1.5 μg of (*S*)-warfarin/ml.

Another 10 rats received daily 0.083–0.098-mg/kg injections of (*S*)-warfarin for 13 days, the dose being adjusted to maintain a prothrombin complex activity of 30–40% of normal. On the 15th day, these rats received a single 0.6-mg/kg dose of (*S*)-warfarin, and studies were carried out as described in the previous paragraph.

The analytical procedures, the method for the determination of the serum free fraction of warfarin, and the calculations required to determine R_{syn} and m were described previously (1, 3). Separate experiments with a large dose of unlabeled (*S*)-(−)-warfarin and ^{3}H-(*S*)-(−)-warfarin, in which serum warfarin concentrations were determined both spectrophotometrically and by scintillation counting after extraction and TLC, demonstrated that the specific activity of the drug in serum remained constant with time after injection.

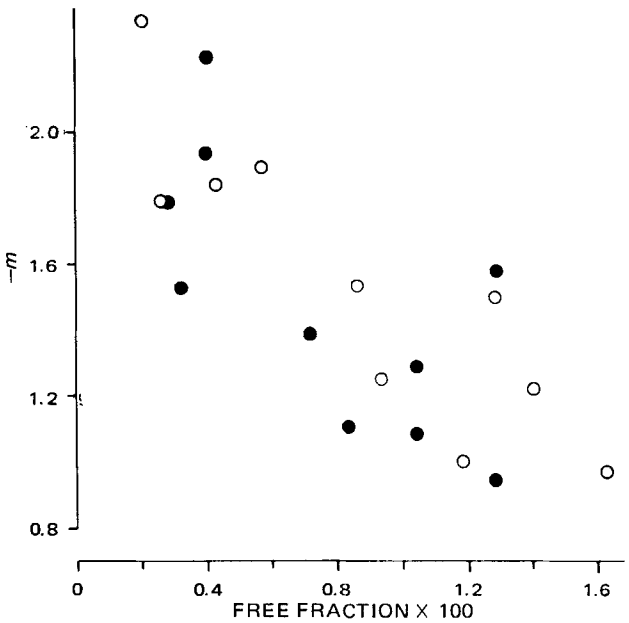

Figure 1—*Relationship between the slope of the relative anticoagulant effect–log warfarin concentration in the serum curve and the serum free fraction of* (S)-(−)-*warfarin in rats. Key:* ●, *acute dose; and* ○, *chronic dose.*

As shown in Fig. 1, m ranged from −0.939 to −2.33 and showed a statistically significant negative correlation with the serum free fraction value for warfarin ($r = -0.785$, $p < 0.001$). There was no apparent difference between acutely and chronically dosed animals. Thus, animals that showed the most extensive serum protein binding of warfarin also exhibited the steepest anticoagulant effect–log warfarin concentration curve. It is feasible, therefore, to identify predictively the steep responders to warfarin.

If the observations in rats can be confirmed in humans, it will be possible to identify, before institution of warfarin treatment, patients who have relatively steep anticoagulant effect–log serum warfarin concentration characteristics by taking a blood sample and determining the free fraction of warfarin in serum following *in vitro* addition of the drug. Previous studies showed more than fourfold differences in the serum free fraction of warfarin among 31 patients with cardiovascular disease who were being treated with warfarin (5).

Estimation of Free Energy Change Associated with Conformational Transition of Proteins Showing Cooperative Binding Properties

Keyphrases □ Protein binding—log Q plot used to estimate free energy change associated with conformational transition □ Conformational transition—unbound to complexed proteins, log Q plot used to estimate free energy change □ Cooperative protein binding—log Q plot used to estimate free energy change associated with conformational transition □ Binding, cooperative protein—log Q plot used to estimate free energy change associated with conformational transition

To the Editor:

Sokoloski and Hoener (1) recently pointed out some corrections necessary in the use, as suggested by Ma *et al.* (2), of a log Q plot to determine protein–ligand affinity constants in systems where interaction between binding sites is indicated. These plots are usually used to calculate the relevant binding parameters following assumption of a model. However, in this article, we shall show that such plots can be used to evaluate a parameter that plays a key role in cooperative binding processes.

A protein–ligand system exhibiting positive interactions is used to illustrate the calculations. It is generally accepted, and supported by experimental evidence, that the protein must be able to assume at least two different conformations, depending upon the state of ligation (3, 4), for such cooperativity to occur. Let the conformation in the absence of ligand be the T conformation and that of the fully saturated protein be the R conformation. During ligation, the molecule changes its conformation from the T to the R form. Whether this process occurs stepwise or not is irrelevant to the current problem; Scheme I (where L is the ligand, n is the number of binding sites, and b is the experimentally observable ligation reaction) can be assumed to hold.

$$\begin{array}{ccc} T + nL & \overset{b}{\rightleftharpoons} & RL_n \\ {\scriptstyle a}\searrow & & \nearrow{\scriptstyle c} \\ & R + nL & \end{array}$$

Scheme I

The standard free energy change of this step can be considered to be composed of at least two other steps, namely the T to R conformational change as indicated by a and the binding of ligands to the R conformation as indicated by c in Scheme I. The standard free energy change, ΔF_a, of step a can be viewed as the driving force for cooperativity, its magnitude and variation with experimental conditions being important for understanding the molecular mechanism of cooperative effects. It is possible to estimate ΔF_a from a log Q plot as shown below.

The observed mean number of sites occupied is ν, so the fractional saturation, Y, is equal to ν/n, where n is the total number of binding sites. The free ligand concentration is x, allowing Q to be defined by (5):

$$\log Q = \log(Y/1 - Y) - \log x \qquad \text{(Eq. 1)}$$

where Q can be considered to be the apparent affinity constant at a given value of Y. In the case of a single site or of independent and equivalent sites, Q is a constant. Figure 1, constructed from the data of Tyuma *et al.* (6), illustrates the variation of log Q with Y when cooperativity occurs. If a model is assumed, then such a plot can be used to estimate successive binding constants. The method described in this article permits the evaluation of ΔF_a when suitable values for Y and x are available.

Wyman (7) showed that ΔF_b, the total standard free energy of ligand binding, is equal to $nRT \int_0^1 \ln x \, dY$. This true thermodynamic expression can be related to log Q as follows:

$$\int_0^1 \ln x \, dY = -\int_0^1 [\ln(Y/1 - Y) - \ln x] dY \qquad \text{(Eq. 2a)}$$

$$\int_0^1 \ln(Y/1 - Y) dY = 0 \qquad \text{(Eq. 2b)}$$

Therefore:

$$\Delta F_b = -nRT \int_0^1 \ln Q_b \, dY \qquad \text{(Eq. 3)}$$

where b indicates that Q is concerned with step b. A similar argument can be used to obtain:

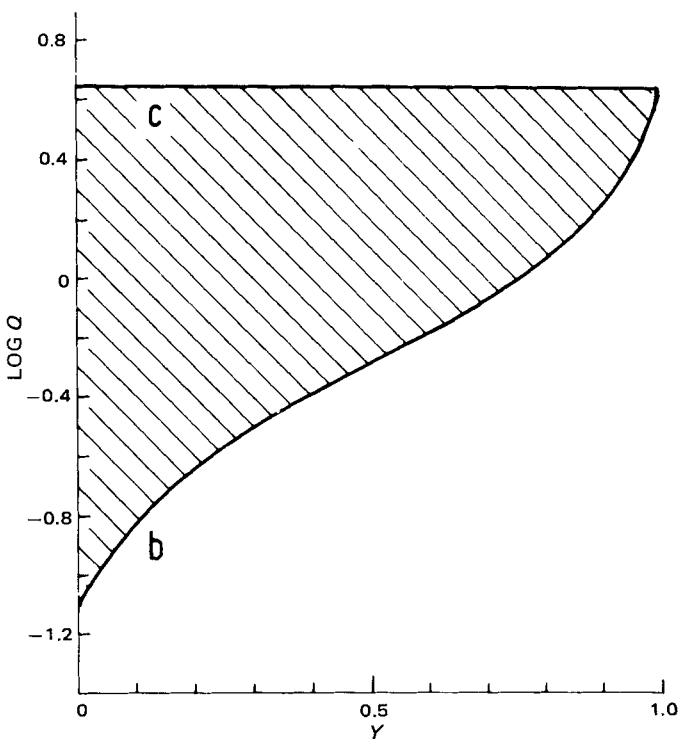

Figure 1—*Log Q plot of binding of oxygen to hemoglobin, calculated from the data in Ref. 6. In the calculation, partial oxygen pressure (in mm Hg) was used instead of molar oxygen concentration. Therefore, a conversion factor is involved in the calculation of* ΔF_b *or* ΔF_c *following the procedure outlined in the text. However, in the calculation of* ΔF_a, *this factor cancels out.*

Estimation of Free Energy Change Associated with Conformational Transition of Proteins Showing Cooperative Binding Properties

Keyphrases □ Protein binding—log Q plot used to estimate free energy change associated with conformational transition □ Conformational transition—unbound to complexed proteins, log Q plot used to estimate free energy change □ Cooperative protein binding—log Q plot used to estimate free energy change associated with conformational transition □ Binding, cooperative protein—log Q plot used to estimate free energy change associated with conformational transition

To the Editor:

Sokoloski and Hoener (1) recently pointed out some corrections necessary in the use, as suggested by Ma *et al.* (2), of a log Q plot to determine protein–ligand affinity constants in systems where interaction between binding sites is indicated. These plots are usually used to calculate the relevant binding parameters following assumption of a model. However, in this article, we shall show that such plots can be used to evaluate a parameter that plays a key role in cooperative binding processes.

A protein–ligand system exhibiting positive interactions is used to illustrate the calculations. It is generally accepted, and supported by experimental evidence, that the protein must be able to assume at least two different conformations, depending upon the state of ligation (3, 4), for such cooperativity to occur. Let the conformation in the absence of ligand be the T conformation and that of the fully saturated protein be the R conformation. During ligation, the molecule changes its conformation from the T to the R form. Whether this process occurs stepwise or not is irrelevant to the current problem; Scheme I (where L is the ligand, n is the number of binding sites, and b is the experimentally observable ligation reaction) can be assumed to hold.

$$\begin{array}{ccc} T + nL & \overset{b}{\rightleftharpoons} & RL_n \\ {\scriptstyle a}\searrow & & \nearrow{\scriptstyle c} \\ & R + nL & \end{array}$$

Scheme I

The standard free energy change of this step can be considered to be composed of at least two other steps, namely the T to R conformational change as indicated by a and the binding of ligands to the R conformation as indicated by c in Scheme I. The standard free energy change, ΔF_a, of step a can be viewed as the driving force for cooperativity, its magnitude and variation with experimental conditions being important for understanding the molecular mechanism of cooperative effects. It is possible to estimate ΔF_a from a log Q plot as shown below.

The observed mean number of sites occupied is ν, so the fractional saturation, Y, is equal to ν/n, where n is the total number of binding sites. The free ligand concentration is x, allowing Q to be defined by (5):

$$\log Q = \log(Y/1 - Y) - \log x \qquad \text{(Eq. 1)}$$

where Q can be considered to be the apparent affinity constant at a given value of Y. In the case of a single site or of independent and equivalent sites, Q is a constant. Figure 1, constructed from the data of Tyuma *et al.* (6), illustrates the variation of log Q with Y when cooperativity occurs. If a model is assumed, then such a plot can be used to estimate successive binding constants. The method described in this article permits the evaluation of ΔF_a when suitable values for Y and x are available.

Wyman (7) showed that ΔF_b, the total standard free energy of ligand binding, is equal to $nRT \int_0^1 \ln x \, dY$. This true thermodynamic expression can be related to log Q as follows:

$$\int_0^1 \ln x \, dY = -\int_0^1 [\ln(Y/1 - Y) - \ln x] dY \qquad \text{(Eq. 2a)}$$

$$\int_0^1 \ln(Y/1 - Y) dY = 0 \qquad \text{(Eq. 2b)}$$

Therefore:

$$\Delta F_b = -nRT \int_0^1 \ln Q_b \, dY \qquad \text{(Eq. 3)}$$

where b indicates that Q is concerned with step b. A similar argument can be used to obtain:

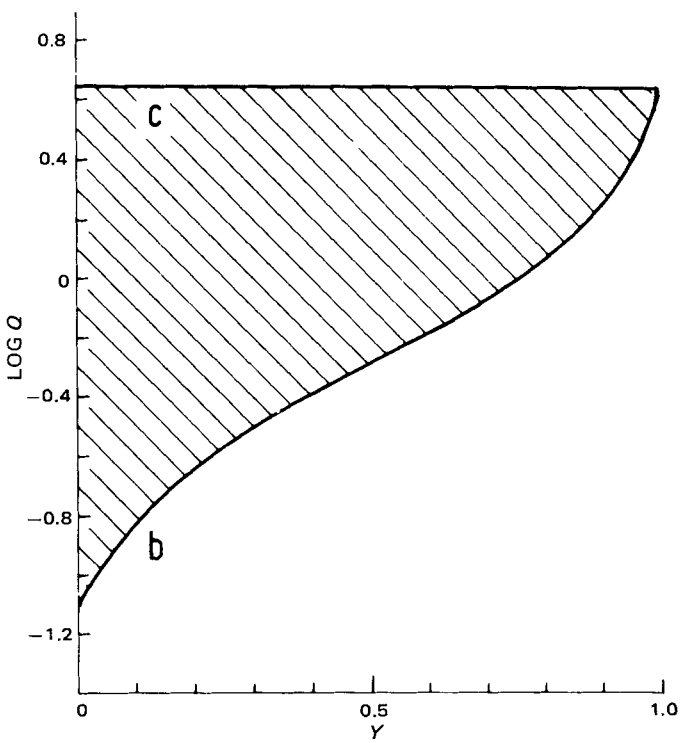

Figure 1—*Log Q plot of binding of oxygen to hemoglobin, calculated from the data in Ref. 6. In the calculation, partial oxygen pressure (in mm Hg) was used instead of molar oxygen concentration. Therefore, a conversion factor is involved in the calculation of* ΔF_b *or* ΔF_c *following the procedure outlined in the text. However, in the calculation of* ΔF_a, *this factor cancels out.*

$$\Delta F_c = -nRT \int_0^1 \ln Q_c \, dY \qquad \text{(Eq. 4)}$$

Therefore, as $\Delta F_a = \Delta F_b - \Delta F_c$:

$$\Delta F_a = 2.3nRT \int_0^1 (\log Q_c - \log Q_b) dY \qquad \text{(Eq. 5)}$$

In Fig. 1, curve b represents log Q_b, so the area under the curve multiplied by $-2.3nRT$ is equal to ΔF_b. However, Q_c cannot be obtained in a similar manner, because, in general, reaction c cannot be followed experimentally. A good approximation for log Q_c can be obtained, because all protein molecules are in the R state when Y approaches 1 so the limiting value of log Q_b and log Q_c must be the same. Therefore, an estimate of log Q_c can be obtained from Fig. 1, because line c should equal log Q_c when it is assumed that all sites are equal in the R state. This assumption immediately implies that, from Eq. 5, ΔF_a is equal to the shaded area of Fig. 1 multiplied by $2.3nRT$. In the figure, this area is equal to 5.0 kcal. From the figure, it can be seen that ΔF_a is always a positive quantity in a cooperative process, so the associated equilibrium constant is less than 1 or, in other words, the T conformation is highly favored in the absence of ligand.

This important result is obtained following the assumption that all sites in the R state are equal. A qualitative picture of the situation, when this assumption does not hold, can be obtained in the following way. All protein molecules are in the R state when Y approaches 1, so the limiting value of log Q_b when Y approaches 1 should form one point of the line representing log Q_c. However, when the binding sites are unequal, log Q_c is no longer equal to line c in Fig. 1. Log Q_c cannot lie below line c in Fig. 1, because this would indicate cooperativity in a molecule totally in the R state. Under these circumstances, log Q_c must lie somewhere above line c. This means that the true value of ΔF_a for nonidentical sites is higher than that obtained by applying the method for identical sites. Only when some specific model is assumed can the exact value of ΔF_a be calculated (8). It is obvious that dissimilarity of binding sites in the T state has no influence on the determination of ΔF_a.

BOOKS

REVIEWS

Topics in Infectious Diseases. Vol. 1. Drug Receptor Interactions in Antimicrobial Chemotherapy. Edited by J. DREWS and F. E. HAHN. Springer-Verlag, 175 Fifth Ave., New York, NY 10010, 1975. 314 pp. 17 × 24.5 cm. Price $19.40.

This book contains the papers presented at the Sandoz Symposium held in Vienna on September 4–6, 1974. It is divided into five general areas, *i.e.*, receptor hypothesis, DNA as a drug receptor, ribosomes as drug receptors, mode of action of chloramphenicol, and microbial enzymes as drug receptors, and includes papers that were contributed by 20 participants. The text of the book has 300 pages, 130 figures and illustrations, and 60 tables.

Drug–receptor interaction is the key to the effect and fate of a drug in the biological system. The authors exemplified the underlying mechanism of antibiotic–receptor interactions by systematically quantifying the relationship between physicochemical parameters and biological responses elicited by interactions of the drug with bioreceptors. Recent advances in research on binding sites of drug molecules to DNA and ribosomal subunits are presented.

The book offers a further insight into the mechanism of development of resistance in microorganisms and the role of plasmids in transmitting resistant genetic elements into the new cell line. Evidence has been produced demonstrating that there can be a surge of R factors in nonpathogenic enterobacteria which may be transferred to the pathogens such as *Shigellae* and *Salmonellae* due to the worldwide indiscriminate use of antibiotics. This is part of the endless race between medical science and microorganisms. The authors discussed the elimination of the genetic determinant elements from plasmids by binding DNA with a number of antibiotic as well as nonantibiotic agents. Enzyme inhibitory actions demonstrated by antibiotics and nonantibiotics suggest potential development of a bacterial enzyme inhibitor as an antimicrobial agent.

The authors suggest that when theory and knowledge of drug–receptor interactions are put into practice, a more ideal drug molecule with precise effect and anticipated mode of action may be designed with less time and expense.

Medication Law and Behavior. By J. TYRONE GIBSON. Wiley, 605 Third Ave., New York, NY 10016, 1976. 407 pp. 16 × 23.5 cm. Price $15.95.

"The book is designed to help the reader learn more about the influence of medication law on the behavior of health care personnel who assist in providing medication and medication services." The author establishes this objective in the preface and in a highly readable style achieves it in the text.

Nonlawyers and those not in the health professions, as well as health professionals, can learn from reading this book. The book

$$\Delta F_c = -nRT \int_0^1 \ln Q_c \, dY \qquad \text{(Eq. 4)}$$

Therefore, as $\Delta F_a = \Delta F_b - \Delta F_c$:

$$\Delta F_a = 2.3nRT \int_0^1 (\log Q_c - \log Q_b) dY \qquad \text{(Eq. 5)}$$

In Fig. 1, curve b represents log Q_b, so the area under the curve multiplied by $-2.3nRT$ is equal to ΔF_b. However, Q_c cannot be obtained in a similar manner, because, in general, reaction c cannot be followed experimentally. A good approximation for log Q_c can be obtained, because all protein molecules are in the R state when Y approaches 1 so the limiting value of log Q_b and log Q_c must be the same. Therefore, an estimate of log Q_c can be obtained from Fig. 1, because line c should equal log Q_c when it is assumed that all sites are equal in the R state. This assumption immediately implies that, from Eq. 5, ΔF_a is equal to the shaded area of Fig. 1 multiplied by $2.3nRT$. In the figure, this area is equal to 5.0 kcal. From the figure, it can be seen that ΔF_a is always a positive quantity in a cooperative process, so the associated equilibrium constant is less than 1 or, in other words, the T conformation is highly favored in the absence of ligand.

This important result is obtained following the assumption that all sites in the R state are equal. A qualitative picture of the situation, when this assumption does not hold, can be obtained in the following way. All protein molecules are in the R state when Y approaches 1, so the limiting value of log Q_b when Y approaches 1 should form one point of the line representing log Q_c. However, when the binding sites are unequal, log Q_c is no longer equal to line c in Fig. 1. Log Q_c cannot lie below line c in Fig. 1, because this would indicate cooperativity in a molecule totally in the R state. Under these circumstances, log Q_c must lie somewhere above line c. This means that the true value of ΔF_a for nonidentical sites is higher than that obtained by applying the method for identical sites. Only when some specific model is assumed can the exact value of ΔF_a be calculated (8). It is obvious that dissimilarity of binding sites in the T state has no influence on the determination of ΔF_a.

REVIEWS

Topics in Infectious Diseases. Vol. 1. Drug Receptor Interactions in Antimicrobial Chemotherapy. Edited by J. DREWS and F. E. HAHN. Springer-Verlag, 175 Fifth Ave., New York, NY 10010, 1975. 314 pp. 17 × 24.5 cm. Price $19.40.

This book contains the papers presented at the Sandoz Symposium held in Vienna on September 4–6, 1974. It is divided into five general areas, *i.e.*, receptor hypothesis, DNA as a drug receptor, ribosomes as drug receptors, mode of action of chloramphenicol, and microbial enzymes as drug receptors, and includes papers that were contributed by 20 participants. The text of the book has 300 pages, 130 figures and illustrations, and 60 tables.

Drug–receptor interaction is the key to the effect and fate of a drug in the biological system. The authors exemplified the underlying mechanism of antibiotic–receptor interactions by systematically quantifying the relationship between physicochemical parameters and biological responses elicited by interactions of the drug with bioreceptors. Recent advances in research on binding sites of drug molecules to DNA and ribosomal subunits are presented.

The book offers a further insight into the mechanism of development of resistance in microorganisms and the role of plasmids in transmitting resistant genetic elements into the new cell line. Evidence has been produced demonstrating that there can be a surge of R factors in nonpathogenic enterobacteria which may be transferred to the pathogens such as *Shigellae* and *Salmonellae* due to the worldwide indiscriminate use of antibiotics. This is part of the endless race between medical science and microorganisms. The authors discussed the elimination of the genetic determinant elements from plasmids by binding DNA with a number of antibiotic as well as nonantibiotic agents. Enzyme inhibitory actions demonstrated by antibiotics and nonantibiotics suggest potential development of a bacterial enzyme inhibitor as an antimicrobial agent.

The authors suggest that when theory and knowledge of drug–receptor interactions are put into practice, a more ideal drug molecule with precise effect and anticipated mode of action may be designed with less time and expense.

Medication Law and Behavior. By J. TYRONE GIBSON. Wiley, 605 Third Ave., New York, NY 10016, 1976. 407 pp. 16 × 23.5 cm. Price $15.95.

"The book is designed to help the reader learn more about the influence of medication law on the behavior of health care personnel who assist in providing medication and medication services." The author establishes this objective in the preface and in a highly readable style achieves it in the text.

Nonlawyers and those not in the health professions, as well as health professionals, can learn from reading this book. The book

$$\Delta F_c = -nRT \int_0^1 \ln Q_c \, dY \qquad \text{(Eq. 4)}$$

Therefore, as $\Delta F_a = \Delta F_b - \Delta F_c$:

$$\Delta F_a = 2.3nRT \int_0^1 (\log Q_c - \log Q_b) dY \qquad \text{(Eq. 5)}$$

In Fig. 1, curve b represents log Q_b, so the area under the curve multiplied by $-2.3nRT$ is equal to ΔF_b. However, Q_c cannot be obtained in a similar manner, because, in general, reaction c cannot be followed experimentally. A good approximation for log Q_c can be obtained, because all protein molecules are in the R state when Y approaches 1 so the limiting value of log Q_b and log Q_c must be the same. Therefore, an estimate of log Q_c can be obtained from Fig. 1, because line c should equal log Q_c when it is assumed that all sites are equal in the R state. This assumption immediately implies that, from Eq. 5, ΔF_a is equal to the shaded area of Fig. 1 multiplied by $2.3nRT$. In the figure, this area is equal to 5.0 kcal. From the figure, it can be seen that ΔF_a is always a positive quantity in a cooperative process, so the associated equilibrium constant is less than 1 or, in other words, the T conformation is highly favored in the absence of ligand.

This important result is obtained following the assumption that all sites in the R state are equal. A qualitative picture of the situation, when this assumption does not hold, can be obtained in the following way. All protein molecules are in the R state when Y approaches 1, so the limiting value of log Q_b when Y approaches 1 should form one point of the line representing log Q_c. However, when the binding sites are unequal, log Q_c is no longer equal to line c in Fig. 1. Log Q_c cannot lie below line c in Fig. 1, because this would indicate cooperativity in a molecule totally in the R state. Under these circumstances, log Q_c must lie somewhere above line c. This means that the true value of ΔF_a for nonidentical sites is higher than that obtained by applying the method for identical sites. Only when some specific model is assumed can the exact value of ΔF_a be calculated (8). It is obvious that dissimilarity of binding sites in the T state has no influence on the determination of ΔF_a.

"The book is designed to help the reader learn more about the influence of medication law on the behavior of health care personnel who assist in providing medication and medication services." The author establishes this objective in the preface and in a highly readable style achieves it in the text.

Nonlawyers and those not in the health professions, as well as health professionals, can learn from reading this book. The book

provides a thorough review of medication law, particularly the Federal Food, Drug, and Cosmetic Act. However, it also considers such areas as professional practice acts and negligence.

The book, however, is not a text on pharmacy law. Rather, it relates the law to the behavior of people, primarily patients and providers of health care. For example, two chapters on the requirements of drug labeling are followed by a chapter on "How Drug Information is Used." The book deals not only with the legal controls on drug distribution but also with the behavioral aspects of why people take drugs (medication).

The book is well referenced and draws on legal citations, behavioral studies, and the clinical literature. The liberal use of figures and tables enhances the value of the book as a learning device. The book is unique in combining the legal aspects of medication with the behavioral aspects. It would be a valuable addition to the library of anyone involved in the drug use process.

Microencapsulation. Edited by J. R. NIXON. Dekker, 270 Madison Ave., New York, NY 10016, 1976. 215 pp. 16 × 23.5 cm. Price $19.50.

This book constitutes a collection of 17 papers delivered in London at the second international symposium on microencapsulation. The contributors to this hard-covered book are recognized international authorities in the field of microencapsulation.

In Chapter 1, the processes of coacervation, spray encapsulation, and nanoencapsulation are reviewed by P. Speiser. The intricacies of each method are well defined by the author, and applications are also given.

In Chapter 2, A. Watanabe and T. Hayashi describe gelatin–gum arabic coacervation, interfacial polymerization, and the preparation of multiwalled microcapsules. The authors describe the applications of microcapsules in the manufacture of carbonless copy paper, encapsulated perfume ink, and the image display panel, the latter employing the electrophoretic behavior of microcapsules. The chapter is well illustrated with several photographs and diagrams.

In Chapter 3, A. T. Florence and A. W. Jenkins deal with the assessment *in vitro* of microencapsulated drug systems utilized in sustained-release parenteral dosage forms. Drug dissolution, stability, and biodegradability are discussed. The paper is clearly written, well referenced, and illustrated with photographs.

T. M. S. Chang, in Chapter 4, reviews the vast amount of research and clinical applications of semipermeable microcapsules used as artificial cells. Professor Chang, being a leading world authority in this area, is amply qualified to handle this topic, and his paper is documented with 42 references. The applications of microcapsules to augment artificial kidney function are further discussed by R. E. Sparks *et al.* in Chapter 9.

A major problem in the microencapsulation of enzymes has been the loss of enzyme activity during the microencapsulation process. T. Kondo and N. Muramatsu suggest solutions to this problem in Chapter 5.

The use of microcapsules as food particles for marine particulate feeders is discussed by D. A. Jones and P. A. Gabbott in Chapter 6. A nylon coat for the microcapsules provided an indigestable wall to reduce bacterial contact with the enclosed diet. The authors also suggest another important use for microcapsules in the cultivation of marine organisms and that is to supply medicinal compounds, *e.g.*, antibiotics, to prevent or cure disease.

In Chapter 7, M. Calanchi describes several new dosage forms containing microcapsules prepared *via* coacervation. The author discusses the microencapsulation of antibiotics, aspirin, vitamin C, and steroids and suggests applications of the technique to improve drug stability, overcome incompatibilities, prolong the action of drugs, and conceal the bitter taste of medicinals. Further applications for microcapsules as drug delivery systems, particularly in topical dosage forms, are described in Chapter 10 by R. H. Sudekum.

In Chapter 8, G. C. Maggi and F. DiRoberto outline a method used to diagnose and monitor peripheral vascular disorders by employing encapsulated liquid crystal thermography. R. G. Arnold, in Chapter 11, reviews the many varied applications of microencapsulation and describes the sequence of events and procedures the FDA requires to approve a new microencapsulated animal drug product for marketing. This chapter should be of great interest to those interested in marketing such products. Further veterinary applications of microencapsulation are outlined in Chapter 12 by G. Rognoni.

V. de Sabata, in Chapter 13, reviews several published articles concerned with drug bioavailability from microencapsulated dosage forms. Chapter 14 should be of particular interest to the biologist. T. Kondo *et al.* describe the preparation and properties of artificial red blood cells containing hemoglobin solution.

Chapter 15, an excellent chapter by J. R. Nixon and B. R. Matthews, deals with the surface characteristics of gelatin coacervate microcapsules using scanning electron microscopy. Photographs of microcapsules prepared *via* alcohol coacervation and sodium sulfate coacervation procedures display definite surface properties, and these differences are discussed in the paper. Further physicochemical studies of microcapsules appear in Chapter 16. L. Nang and P. F. Carlier mathematically derive the wall diffusion coefficient and discuss its importance in evaluating microencapsulating methods and the optimization of a coacervation process.

In Chapter 17, the final chapter in the book, L. A. Luzzi reviews the applications, methods of preparation, and physicochemical properties of microcapsules. The chapter is well written and well referenced.

Discussions of some applications and methodologies, such as coacervation and interfacial polymerization, are redundant in the book; however, due to the multiple authorship, this repetition could be expected. The book contains an even balance of reviews and original research. It provides an insight to the science of microencapsulation and should stimulate new research ideas. The book is not only of interest to the pharmaceutical scientist but is also intended for pharmacologists, biologists, chemists, and veterinary scientists.

Practical Pharmaceutical Chemistry. Third Edition—Part One. By A. H. BECKETT and J. B. STENLAKE. Humanities Press, Atlantic Highlands, NJ 07716, 1975. 370 pp. 16 × 24.5 cm. Price $25.00.

Two major additions and several minor revisions have been made in the third edition of this textbook. A new chapter on the registration and assessment of medicines in the United Kingdom has been added. The implications of the Medicines Act of 1968 and Good Manufacturing Practices published by HMSO in 1971 to the analysts and compilers of product applications is presented in a general manner. The treatment of general analytical procedures has been extended. This new chapter covers all important product types including tablets, capsules, suspensions, ointments, creams, pressurized aerosols, lozenges, suppositories, solutions, and mixtures as well as dissolution testing, sustained-release preparations, and particle-size control.

The subject matter is presented in 14 chapters. A limited theoretical treatment is presented, where pertinent, followed by practical examples which have been drawn from the British Pharmacopoeia and other sources. These examples are intended to serve as laboratory exercises.

The book is practical in every sense of the word. It covers primarily the classical methods of analysis, with discussion of the more sophisticated methods being reserved for Part 2. Although the style of presentation of determination of equivalent weights is somewhat different than this reviewer is accustomed to, it is very easy to follow. An insight into the chemistry of many of the limit tests as well as many of the monographs in the British Pharmacopoeia is provided. Of particular interest to this reviewer were the chapters on chemical purity and control, registration and assessment of medicines, and techniques of quantitative analysis. These chapters very basically cover the what, why, and how of quantitative analysis, something that is not infrequently overlooked in the education of analysts.

The book contains an even balance of reviews and original research. It provides an insight to the science of microencapsulation and should stimulate new research ideas. The book is not only of interest to the pharmaceutical scientist but is also intended for pharmacologists, biologists, chemists, and veterinary scientists.

Practical Pharmaceutical Chemistry. Third Edition—Part One. By A. H. BECKETT and J. B. STENLAKE. Humanities Press, Atlantic Highlands, NJ 07716, 1975. 370 pp. 16 × 24.5 cm. Price $25.00.

Two major additions and several minor revisions have been made in the third edition of this textbook. A new chapter on the registration and assessment of medicines in the United Kingdom has been added. The implications of the Medicines Act of 1968 and Good Manufacturing Practices published by HMSO in 1971 to the analysts and compilers of product applications is presented in a general manner. The treatment of general analytical procedures has been extended. This new chapter covers all important product types including tablets, capsules, suspensions, ointments, creams, pressurized aerosols, lozenges, suppositories, solutions, and mixtures as well as dissolution testing, sustained-release preparations, and particle-size control.

The subject matter is presented in 14 chapters. A limited theoretical treatment is presented, where pertinent, followed by practical examples which have been drawn from the British Pharmacopoeia and other sources. These examples are intended to serve as laboratory exercises.

The book is practical in every sense of the word. It covers primarily the classical methods of analysis, with discussion of the more sophisticated methods being reserved for Part 2. Although the style of presentation of determination of equivalent weights is somewhat different than this reviewer is accustomed to, it is very easy to follow. An insight into the chemistry of many of the limit tests as well as many of the monographs in the British Pharmacopoeia is provided. Of particular interest to this reviewer were the chapters on chemical purity and control, registration and assessment of medicines, and techniques of quantitative analysis. These chapters very basically cover the what, why, and how of quantitative analysis, something that is not infrequently overlooked in the education of analysts.

RELIABILITY OF SCIENTIFIC DATA

It is late Friday afternoon as this editorial is being written. In doing so, this writer has been reflecting on the numerous and varied occasions during this past week that he had occasion to make a judgment, or to base some decision, or otherwise to draw upon the research reports and laboratory findings of fellow scientists.

Just a few such examples might be mentioned by way of illustration: (*a*) we reviewed a draft monograph in APhA's Bioavailability series, (*b*) we examined in proof form a chapter for the new edition of the *OTC Drug Handbook*, (*c*) we assessed drafts of several abbreviated drug interaction monographs for the supplement that is now underway for *Evaluations of Drug Interactions*, (*d*) we provided advice and recommendations to a state government agency regarding inclusion of certain drugs in its state drug formulary, (*e*) we supplied information for inclusion in a background paper for one of the APhA policy committees, (*f*) we participated in the decision on whether a certain research report was sufficiently novel to warrant journal publication, and (*g*) we were involved in staff meetings, telephone inquiries, correspondence, and outside meetings too numerous to mention—all of which, in some way, involved a scientific component based upon somebody's research findings.

No matter how one views it, that is a lot of reliance on the findings and reports of others. And, we suspect, if our readers were to perform a similar exercise, many if not most of them would probably find that they have also depended very substantially on reports in the literature, personal communications, or other sources of information which have been drawn upon and utilized in carrying out their own activities.

Having said all this, what is our point? Simply put, it is that the workings of our whole scientific system rest on the fundamental assumption that scientists have integrity and that their reports can be accepted as being honest, factual, and reliable. Anything less will destroy the entire process and turn it into veritable shambles.

Fortunately, it has been exceedingly rare that scientists have violated this self-imposed code. In fact, in recent memory the only intellectually dishonest acts—in contrast to morally questionable research which is an entirely different matter—that come to mind were charges that certain people plagiarized the results of others to their own advantage, such as to complete requirements for a graduate degree. But as reprehensible as this practice may be, at least it did not introduce false and erroneous information into the body of scientific information.

People have observed that nothing is sacred any more. So perhaps it should not come as a surprise or disappointment that recent revelations have disclosed falsified, dishonest research reports. We refer to the recent disclosures by Food and Drug Administration spokesmen that data submitted to the agency to demonstrate the safety or efficacy of a number of drugs have been altered, "fudged," or otherwise falsified.

Although these deficient data have been submitted to FDA by pharmaceutical companies, in fairness to them it should be pointed out that for the most part the invalid data came from outside sources such as consulting laboratories. In accord with traditional scientific practice, the pertinent drug company innocently accepted the reports at face value and submitted them to the FDA as supporting documentation.

FDA Bureau of Drugs Director J. Richard Crout initially revealed the problem last fall in connection with agency action to review the approval of a new antiarthritic drug: *"We have learned that we cannot accept the test results submitted by drug sponsors on faith alone. Recent history has convinced us that we must look more closely at the validity and quality of the research done by industry."*

Subsequently, the FDA Commissioner has issued proposed new stringent regulations described in the press as an *"impressively detailed and sweeping Good Laboratory Practice code that would cover all labs carrying out preclinical studies intended to be submitted to the agency."* The new rules set forth standards for organization and personnel, buildings and facilities, equipment, testing facility operations, quality assurance, protocols, study implementation and conduct, recording and handling of data, and records and reports. Penalties for not following good laboratory practices range all the way to criminal prosecution.

In his preamble, the Commissioner cites several examples of problems which FDA staff have recently uncovered in the supporting data submitted by drug sponsors. Hence, corrective action clearly is needed.

However, we are grieved that this last bastion of honesty and reliability has fallen into question and disrepute. Until now, scientific research was virtually unregulated simply because it had never been felt necessary to impose regulations and controls. That has now all changed and, in the process, every scientist has lost an intangible little something. Perhaps this denouement is simply part of technical progress and the development of a more complex society. But still it leaves us just a little sad.

Disintegration Test for Enteric-Coated Tablets

Enteric-coated dosage forms are intended to resist the release of their active ingredients in the acidic gastric fluid but to disintegrate and release their contents in the less acidic environment of the intestine. The official compendia recognize the use of enteric-coated dosage forms in situations where the drug may be destroyed or inactivated by the gastric juice or where it may irritate the gastric mucosa[1,2]. The compendia also recognize that such coatings are intended to delay the release of the medication until the dosage form passes through the stomach[1,2]. Therefore, the enteric coating must resist the release of its ingredient(s) in the stomach until gastric emptying can occur.

The official compendia specify disintegration test requirements for the enteric-coated tablet only, apparently because it is the only popular enteric-coated dosage form. The requirements of this disintegration test are met if the tablets show no evidence of disintegration, cracking, or softening in 1 hr in simulated gastric fluid TS maintained at 37 ± 2° but disintegrate completely in simulated intestinal fluid TS maintained at 37 ± 2° in a period equal to 2 hr plus the time limit specified in the individual monograph or, where only an enteric-coated tablet is recognized, for only the time specified in the monograph[3,4].

Thus, the test in its present form appears to fulfill the following two objectives: (*a*) prevent the disintegration, cracking, or softening of the tablets in 1 hr in the acidic environment, and (*b*) assure the disintegration of the tablets in the intestinal environment within a given period of time.

However, the test in its present form does not take into account the fact that the stomach residence time of enteric-coated tablets may not necessarily be 1 hr or less but may, in fact, vary greatly. For example, studies with various nondisintegrating solid dosage forms indicated an average residence time in the stomach ranging from 1.5 to 5.75 hr, with standard deviations of 50% from the mean[5,6]. Moreover, although the tablets may show no evidence of cracking (with the naked eye) or softening in the acidic gastric environment, they may be releasing their content(s) due to diffusion or leaching through the intact coating and/or small pores or minute cracks.

In a recent study dealing with commercially available enteric-coated sodium salicylate tablets[7], all products tested met the official test requirement but the coating on many of the products failed to prevent the release of sodium salicylate in the acidic environment. Recent evidence indicating that the local concentration of mucosal irritants at sites in contact with the tablets may be important and the fact that the enteric-coated tablet does not ensure safety from gastric toxicity[8] suggest that the present test requirement for the enteric-coated tablets may not be adequate.

Thus, to improve the performance of the disintegration test and enhance its validity, a more realistic test requirement should include "prevention of release" in the acidic environment as the primary objective.

Nucleophilic Addition of Bisulfite Ion to Prostaglandins E_2 and A_2: Implication in Aqueous Stability

M. J. CHO ˣ, W. C. KRUEGER, and T. O. OESTERLING

Abstract □ Evidence is presented to indicate that the bisulfite ion (HSO_3^-) adds across the C-9 carbonyl group of dinoprostone (prostaglandin E_2) and across the $\Delta^{10,11}$-bond of prostaglandin A_2. At room temperature, the apparent equilibrium constant, determined by phase solubility analysis, circular dichroism, UV spectroscopy, and partitioning, for the formation of the bisulfite adduct of dinoprostone is about 7.5 M^{-1} at neutral pH. From this result and a free energy relationship reported in the literature for the thermodynamics of nucleophilic addition to carbonyl groups, it is concluded that the chemical reactivity of the C-9 carbonyl group of dinoprostone is not high enough to improve aqueous stability through reversible one-step nucleophilic reactions. However, from a series of kinetic experiments, it is concluded that the equilibrium is extremely favorable for the formation of the bisulfite adduct of prostaglandin A_2 over pH 4–8 at room temperature. The second-order rate constant for the attack of sulfite ion (SO_3^{2-}) to prostaglandin A_2 is 1.75 $sec^{-1}\ M^{-1}$.

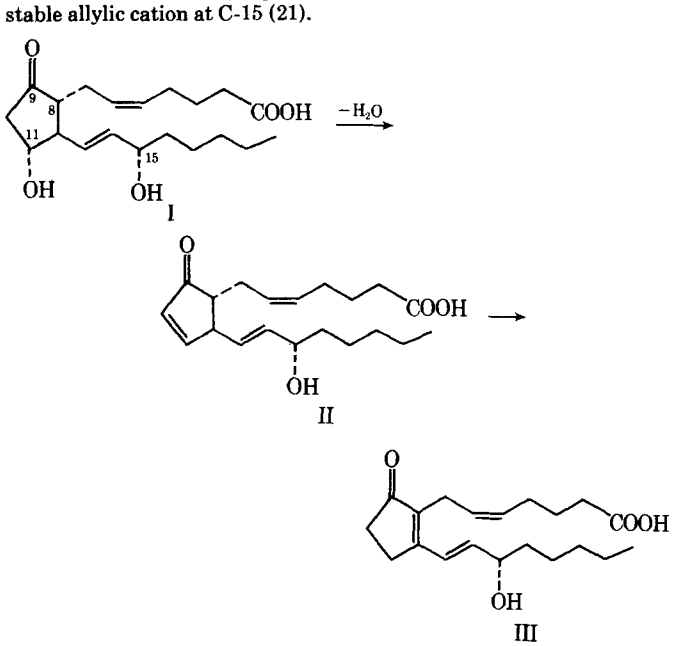
Keyphrases □ Prostaglandins—dinoprostone and prostaglandin A_2, nucleophilic addition of bisulfite ion, effect on aqueous stability □ Dinoprostone—nucleophilic addition of bisulfite ion, effect on aqueous stability □ Nucleophilic addition—bisulfite to dinoprostone and prostaglandin A_2, effect on aqueous stability □ Bisulfite ion—nucleophilic addition to dinoprostone and prostaglandin A_2, effect on aqueous stability □ Stability, aqueous—bisulfite adducts of dinoprostone and prostaglandin A_2

Prostaglandins are analogs of the parent 20-carbon prostanoic acid found in virtually all mammalian cells. After Bergström's pioneering work on the structural characterization and biosynthsis of prostaglandins (1), numerous articles have appeared defining the physiological role and total synthesis of prostaglandins (2). Recently, their general biology (3–5) and chemistry (6–8) were extensively reviewed.

BACKGROUND

Some of the naturally occurring E and F prostaglandins have found wide clinical application in human reproduction (9). In particular, dinoprostone (prostaglandin E_2) (I) has been successfully used for labor induction (10–12). However, the chemical instability of dinoprostone has limited the development of dosage forms, particularly those in aqueous solutions. The instability problem has resulted in a substantial challenge to the pharmaceutical scientist, and this work is part of a fundamental study aimed at exploring the utility of reversible chemical reactions in improving the stability of the E series prostaglandins.

As shown in Scheme I, dinoprostone, being a β-ketol, readily undergoes dehydration to produce prostaglandin A_2 (II) (13–18), which has a different spectrum of biological activity. In aqueous solutions, dinoprostone shows maximum stability at pH 3.5, but the half-life is only about 40 days at 25° (18); prostaglandin A_2, in turn, isomerizes to prostaglandin B_2 (III) in alkaline conditions. In addition to this major degradation reaction, the compound epimerizes at C-8 in the presence of general base (19), presumably because of the high acidity of the proton at C-8 (20). It also epimerizes at C-15 in acid, apparently because of the easy formation of a stable allylic cation at C-15 (21).



Scheme I

Kinetically, dinoprostone appears to undergo dehydration through the E1cB mechanism, with either the formation of enolate at C-9 or the expulsion of OH^- from C-11 as the rate-determining step. Although a thorough kinetic study has to be carried out to identify this proposed mechanism, it is strongly supported by a series of studies (22, 23) on the β-elimination reactions of β-oxy cyclic ketones with various leaving groups of pKa ranging from 5 to 16, including OH^-.

Thermodynamically, the fundamental driving force for the dehydration, which is practically irreversible, appears to be the reduction in free energy content derived from an extended conjugation present in prostaglandin A_2. Therefore, any reversible chemical reactions saturating the carbonyl group at C-9 of dinoprostone should enhance the overall stability through the relationships:

$$\frac{-d(\text{total dinoprostone})}{dt} = k(\text{free dinoprostone}) \qquad \text{(Eq. 1}a\text{)}$$

$$\frac{-d(\text{total dinoprostone})}{dt} = \frac{k}{1+K_{eq}}(\text{total dinoprostone}) \qquad \text{(Eq. 1}b\text{)}$$

where k is the apparent dehydration rate constant of dinoprostone, so long as the attainment of the reaction equilibrium is fast enough that it can be considered as an equilibrium reaction (with an equilibrium constant K_{eq}) prior to the dehydration of dinoprostone and the product of the reversible reaction is chemically stable.

The nucleophilic addition reaction of the bisulfite ion (HSO_3^-) to the carbonyl group at C-9 of dinoprostone was investigated to see if the reaction could be utilized to improve the aqueous stability of dinoprostone. Bisulfite was chosen, among many nucleophilic reagents, because it is relatively nontoxic and hence can be used in pharmaceutical formulations (24) and also because it is an extremely good nucleophile in a thermodynamic as well as a kinetic sense (25, 26). Thus, reactivity of bisulfite with dinoprostone can serve as a measure of the chemical reactivity (*i.e.*, electrophilicity) of the carbonyl group of C-9 of the E prostaglandins in general. The enone system present in prostaglandin A_2 was expected to be very susceptible to nucleophilic addition reactions, as frequently found in many Michael-type 1,4-additions (27). Therefore, it was necessary to study the extent of bisulfite addition to prostaglandin A_2 to draw a complete picture of an aqueous system of dinoprostone containing the nucleophilic reagent.

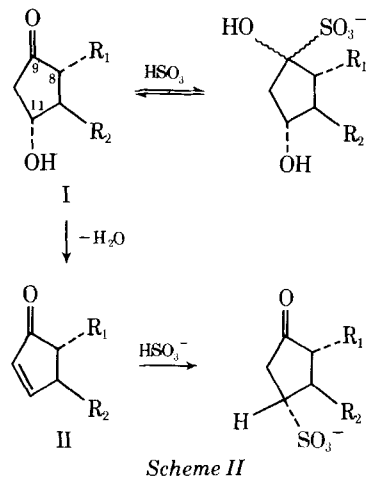
RESULTS AND DISCUSSION

Characterization of Reaction System—It is often difficult to identify chemically a facile equilibrium reaction, especially when the reaction product cannot be easily isolated. Consequently, various physical methods such as UV, IR, and NMR spectroscopic techniques are frequently employed, since in most cases the equilibrium condition is not to be disturbed.

In aqueous solutions, dinoprostone exhibits a negative circular dichroism band near 292 nm with $[\theta] = -1.35 \times 10^4$ due to the $n \rightarrow \pi^*$ transition of the C-9 carbonyl chromophore (5, 28). As shown in Fig. 1, the negative molar rotation was reduced in the presence of the bisulfite ion. At equilibrium, the reduction was a function of the total bisulfite concentration, indicating that the reaction was reversible in nature. If the reaction went to completion, the final spectrum would be independent of the total bisulfite concentration, unless its stoichiometric ratio to dinoprostone concentration was below 1:1.

The ketone carbonyl chromophore of dinoprostone absorbs UV energy very weakly ($\epsilon_{288} \sim 50$), so its absorption band is easily swamped by the bisulfite absorption at the bisulfite concentration level where the reaction can occur to a significant extent. Nevertheless, the absorption peak was significantly reduced upon addition of sodium bisulfite. As in the case of the circular dichroism spectrum, at equilibrium the decrease in absorbance at 288 nm was a function of the total bisulfite concentration. In identifying the reaction, attempts were also made to utilize the carbonyl stretching vibration at 1725 cm^{-1} (5.80 μm) in the IR spectrum of dinoprostone, the C-9 signal at 215.4 ppm (tetramethylsilane) in the ^{13}C-NMR spectrum of dinoprostone, and the quartet at 2.70 ppm due to the equatorial proton at C-10 in the PMR spectrum of dinoprostone. In all cases, supportive but inconclusive data were obtained, mainly because of the small magnitude of the equilibrium constant for the bisulfite adduct formation. From the results obtained from the spectroscopic studies together with the fact that cyclopentanone adds bisulfite (29), it was concluded that the bisulfite ion adds across the C-9 carbonyl group of prostaglandin E_2 in a reversible fashion (Scheme II). At present, the stereochemistry of the addition is not established.

A brief attempt was made to follow the kinetics of bisulfite addition to dinoprostone by monitoring the change in molar rotation at 292 nm,



Scheme II

but no reliable data were obtained because the reaction occurred too rapidly. For example, the rotation at 292 nm of a 1.00-mg/ml solution of dinoprostone containing 0.692 mole of total bisulfite (spectrum C in Fig. 1) was identical after 4 and 20 min of the sample preparation. From this observation and the equilibrium constants measured, it was concluded that the bisulfite addition to dinoprostone is kinetically favorable, even though it is not so favorable thermodynamically.

The high reactivity of the enone system in prostaglandin A_2 is well exemplified by the easy formation of 11-substituted E prostaglandins from the reactions of nucleophiles with the A prostaglandins (28, 30). For instance, hydrogen peroxide adds to C-11 of prostaglandin A_2 to form eventually prostaglandin A_2 10,11-epoxide, an important intermediate in the process of converting prostaglandin A_2 to dinoprostone (31). According to the Sander and Jencks (32) γ-parameter, a measure of thermodynamic nucleophilicity originally derived from a series of reversible nucleophilic addition reactions across a carbonyl group, any nucleophiles of γ-value greater than that of hydrogen peroxide (−0.65) are expected to add to C-11 of prostaglandin A_2, as long as a proper reaction condition is provided. This hypothesis is based on the fact that the thermodynamics governing the nucleophilic addition across a carbonyl group were proved to predict the nucleophilic addition of the reactions across >C=N- (25) and >C=C< (26) bonds. However, no evidence can be found to support that water ($\gamma = -3.58$) adds to prostaglandin A_2 to form dinoprostone. In practice, dehydration of dinoprostone can be considered as an irreversible reaction. On the other hand, the addition of bisulfite ($\gamma = 4.02$)

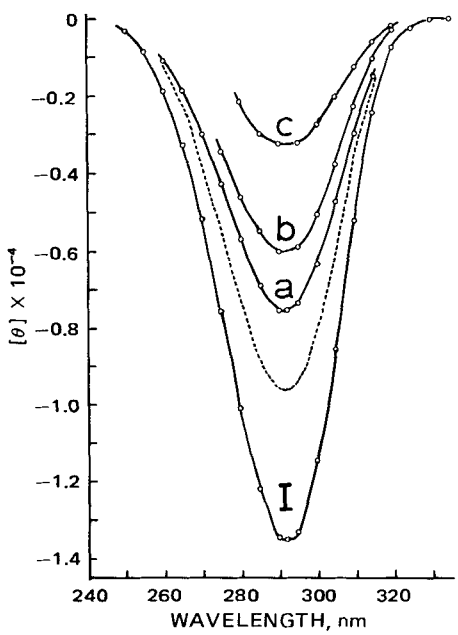


Figure 1—*Circular dichroism spectrum of dinoprostone (I) and its change in the presence of the bisulfite ion at 25°: dinoprostone = 1.00 mg/ml = 2.84 × 10⁻³ M in a phosphate buffer of pH 6.5. Total bisulfite concentrations were 1.042, 0.277, and 0.69 M for a, b, and c, respectively. For comparison, spectrum a in Fig. 2 is shown as a dotted line.*

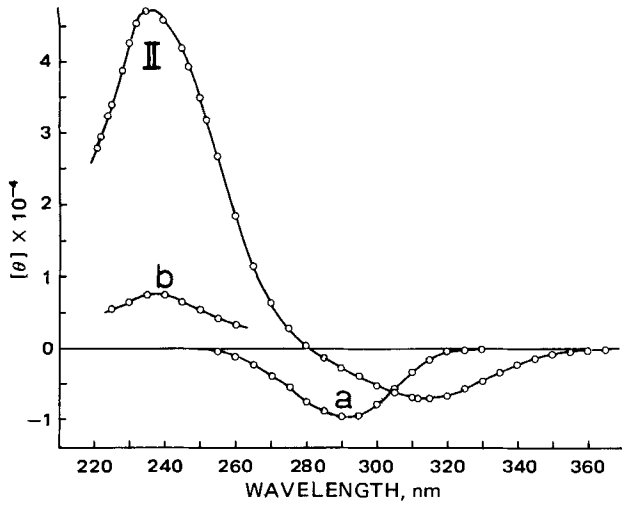

Figure 2—*Circular dichroism spectrum of prostaglandin A_2 (II) and its change in the presence of the bisulfite ion at 25°: prostaglandin A_2 = 0.02 mg/ml = 5.98 × 10^{-5} M in a phosphate buffer of pH 6.5 and I = 0.1 M. Total bisulfite concentrations were 5.38 × 10^{-3} and 2.99 × 10^{-3} M for a and b, respectively.*

to C-11 of prostaglandin A_2 was expected to be very favorable, and even the formation of the 9,11-bis derivative was considered to be possible.

The PMR spectrum of prostaglandin A_2 in deuterated bisulfite buffer of pD = 7.0 (pD = pH read on a meter + 0.4) (33) showed neither the two doublets at 7.6 ppm due to the proton at C-11 nor the two doublets at 6.2 ppm due to the proton at C-10, indicating that bisulfite either adds across the $\Delta^{10,11}$-bond or attacks at C-9 or both. However, the overall spectrum looked similar to that of dinoprostone. Especially at 2.9 ppm, where the equatorial proton at C-11 of dinoprostone was expected to show up as a quartet, poorly resolved but distinctive peaks were still observed, implying the presence of the proton at the carbon alpha to a carbonyl group.

That the C-9 carbonyl group of prostaglandin A_2 is intact in the presence of bisulfite, *i.e.*, that the 9,11-bis derivative is not formed, was also supported by the change in the circular dichroism spectrum of prostaglandin A_2 in the presence of bisulfite. As shown in Fig. 2, prostaglandin A_2 exhibits a strong positive band at 235 nm ($[\theta] = 4.72 \times 10^4$) and a negative band at 312 nm ($[\theta] = -0.69 \times 10^4$) due to the $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions of the enone chromophore, respectively. When bisulfite was introduced to a prostaglandin A_2 solution, the spectrum underwent a hypsochromic shift of about 20 nm, and the final spectrum became similar to that of dinoprostone (Fig. 1). This type of spectral change arising from breaking a conjugated system is well known in circular dichroism spectroscopy (34).

The similarity of the final PMR and circular dichroism spectra of prostaglandin A_2 in the presence of bisulfite to those of dinoprostone unambiguously indicates that bisulfite adds across the $\Delta^{10,11}$-bond of prostaglandin A_2 (Scheme II). Because dinoprostone and the bisulfite adduct at C-11 of prostaglandin A_2 are similar to each other in chemical structure, a nearly identical spectroscopic behavior is expected. The possibility of forming the 9,11-bis derivative was ruled out not only by the presence of the C-9 carbonyl group at equilibrium, which was indicated by the PMR study, but also by the fact that only one molecule of bisulfite adds to the enone system in cortisone (35) and to the 1,4-dien-3-one system in dexamethasone (36). Formation of the bis derivative is probably hindered by the electrostatic repulsion between the negative charge on the sulfonate group at C-11 of the monoadduct and the oncoming second molecule of bisulfite.

According to Crabbé (28), various 11α-substituted derivatives of dinoprostone display a more negative Cotton effect with $[\theta] \sim -10{,}000$ at $\lambda_{max} \sim 298$ nm than their corresponding 11β-substituted derivatives. As shown by curve a in Fig. 2, the circular dichroism spectrum of the bisulfite adduct of prostaglandin A_2 is in accord with that of 11α-sulfonate. If this is the case, the stereochemistry involved in the nucleophilic attack at C-11 of prostaglandin A_2 appears to be sterically controlled by the β-side chain at C-12. The PMR study could have given additional information on the stereochemistry of the reaction if an accurate value of ^3J for the coupling of the protons at C-10 and C-11 of the adduct had been available. Such data would give an estimate of the dihedral angle between the deuterium

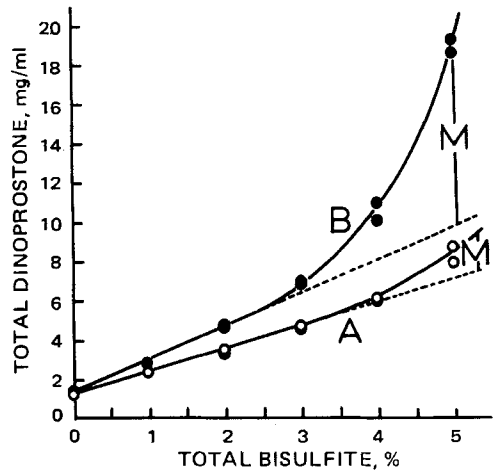

Figure 3—*Aqueous solubility of dinoprostone at 25° as a function of the total bisulfite concentration at pH 3 (A) and 4 (B). The portion showing deviation from linearity (M) indicates the contribution from the micelle formation.*

at C-10 and the sulfonate at C-11. However, as pointed out earlier, the resolution was unfortunately poor at about 3 ppm.

Measurement of Equilibrium Constant for Formation of Bisulfite Adduct of Dinoprostone—Of the many methods commonly employed in determining the equilibrium constant for a reversible reaction or complex formation, phase solubility analysis (37–40), UV and circular dichroism spectroscopic techniques (38, 39, 41), and the partition technique (39, 42) were chosen for the present study. The apparent equilibrium constant is defined as:

$$K = \frac{[ES]}{[E][S]} \qquad \text{(Eq. 2)}$$

where $[ES]$, $[E]$, and $[S]$ are the concentrations of all possible species of the adduct, dinoprostone, and bisulfite, respectively, at equilibrium.

In solubility analysis, if $K[E] \ll 1$, as in the present case ($\sim 10\ M^{-1} \times 2.8 \times 10^{-3}$), then the slope and the intercept of plots of $[E_T]$ *versus* $[S_T]$ become $K[E][S_T]$ and $[E]$, respectively (37, 38), where $[E]$ is the solubility of dinoprostone in the absence of bisulfite, and the subscript T refers to the total concentration of a given species. Therefore, the quantity obtained by dividing the slope by the intercept should be equal to K. However, as shown in Fig. 3, at both pH 3.0 and 4.0, positive deviations from the expected linearity were observed in the plot of $[E_T]$ *versus* $[S_T]$, starting at $[E_T]$ of about 6 mg/ml ($1.7 \times 10^{-3}\ M$). The equilibrium constants estimated from the initial straight lines in Fig. 3 are listed in Table I, together with those obtained by other methods.

The solubility behavior of dinoprostone shown in Fig. 3 can be best explained in terms of mixed micelle formation. The surface tension of a dinoprostone solution (20 mg/ml) at pH 4.0 in 5% bisulfite, measured by the drop-volume technique (43), was about 35 dynes/cm, which is very close to that of a typical surfactant solution (44); the surface tension of a blank solution without dinoprostone was 63 dynes/cm. This result is not surprising, because aqueous prostaglandin solutions are known to be surface active. For example, the dinoprostone-9-dihydro analog, *i.e.*, dinoprost (prostaglandin $F_{2\alpha}$), was reported to form micelles with a

Table I—Equilibrium Constant for the Formation of the Bisulfite Adduct of Dinoprostone at 25°

pH	K, M^{-1}	Method

6.4	10.1	Partition

[a] The most accurate value; see the text for the accuracy level.

critical micelle concentration (CMC) close to 0.02 M (7 mg/ml) (45). In this context, it is interesting that the deviations shown in Fig. 3 start at about 6 mg/ml. At present, the exact chemical composition of the micelle phase is not known.

Equilibrium constants also were calculated from differences in absorbance at 288 nm in the UV spectrum and in molar rotation at 292 nm in the circular dichroism spectrum (Fig. 1) between the buffered solutions of dinoprostone and the same solutions containing various amounts of bisulfite. The values of K calculated by an iterative procedure similar to the one described by Higuchi *et al.* (39) are listed in Table I.

One major assumption made in the partitioning experiment was that the bisulfite adduct of dinoprostone, being an ionic species under the experimental pH range, does not dissolve in the organic layer. Since dinoprostone is highly soluble in ethyl acetate and insoluble in hexane, the 1:1 (volume ratio) mixture of these two solvents was chosen as the organic layer to have an apparent partition coefficient of unity around pH 6. The values of K computed in a conventional manner (42) are collected in Table I. During the partitioning experiment, the apparent pKa of dinoprostone was obtained from a series of blank samples without bisulfite through the relationship:

$$PC' = \frac{(PC)[H^+]}{[H^+] + K_a} \qquad \text{(Eq. 3)}$$

where PC' and PC are the pH-dependent apparent partition coefficient and the intrinsic partition coefficient of neutral species of dinoprostone, respectively. From the data at pH around 5, a pKa value of 4.73 was obtained, which is somewhat lower than the values reported in the literature [5.32 in 85% aqueous ethanol (17), 5.00 (18), and 4.90 for dinoprost (45)].

Data given in Table I are approximately in ±20% error, except the K value obtained from the circular dichroism work, which is in ±5% error. Because of this large experimental error, the pH profile of the K value is not clearly revealed in the present study. As the pH approaches the pKa of the sulfonic acid in the adduct (pKa ~ 1.0), K is expected to decrease since HSO_3^-, a better leaving group than SO_3^{2-}, is formed on the adduct. On the other hand, in alkaline solutions, desulfonation is expected to occur, which is initiated by proton abstraction from the hydroxyl group at C-9 of the adduct. In fact, desulfonation occurring in acidic or alkaline conditions is widely used in purifying cyclic ketones (46).

Because of the low equilibrium constant (~7.5 M^{-1}) for the reaction of the bisulfite ion with dinoprostone, at least a 12.5% (1.2 M) sodium bisulfite solution is required to achieve a mere 10-fold increase in the aqueous stability of dinoprostone when the total concentration of dinoprostone is about 1 mg/ml (2.84×10^{-3} M). Under this condition, not only the toxicity but also the side reaction of the bisulfite ion with other functional groups in dinoprostone becomes troublesome. The side reaction observed is believed to be the substitution of the allylic hydroxyl group at C-15 by the bisulfite ion, since dinoprost, a dinoprostone 9-dihydro analog, also slowly reacts with the bisulfite ion when the latter is in a 100-fold excess of the former. Also, the related allylic system such as the benzylic hydroxyl group in epinephrine is known to undergo substitution with the bisulfite ion (47).

A patent was issued to a claim that the E prostaglandins can be stabilized by incorporation of bisulfite salts (48). Since the systems described in the patent were very rich in alcohol content (50% or sometimes up to 90%), the claimed stability might be the result of the change in the solvent composition rather than the reversible addition of the bisulfite ion to the prostaglandins.

Since the equilibrium constant is only about 7.5 M^{-1}, other nucleophiles known to be *thermodynamically* inferior to bisulfite (25, 32, 49) are not expected to add significantly to dinoprostone in aqueous solutions. Such a consideration of the linear free energy relationship governing the thermodynamics of nucleophilic addition to carbonyl groups appears to indicate that the chemical reactivity of the C-9 carbonyl group of dinoprostone is not high enough to be utilized in improving aqueous stability through reversible one-step nucleophilic reactions.

Kinetics of Bisulfite Addition of Prostaglandin A_2—Even though mathematical manipulation of the rate expression for a reversible reaction is generally more complicated than for an irreversible reaction, it is necessary to treat its kinetics by assuming that the reaction is reversible when it is not known whether the reaction can be considered practically irreversible or not. The reaction:

$$A + S \underset{k_{-1}}{\overset{k_2}{\rightleftharpoons}} AS$$

Scheme III

where A, S, and AS are all possible species of prostaglandin A_2, bisulfite, and the bisulfite adduct of prostaglandin A_2, respectively, can be schematically represented as:

$$A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} AS$$

Scheme IV

under pseudo-first-order kinetic conditions that can be established in the presence of a large excess of S over A, where $k_1 = k_2(S)$. The rate expression for Schemes III and IV becomes:

$$-\frac{d[A]}{dt} = k_2[A][S] - k_{-1}[AS] = k_1[A] - k_{-1}[AS] \qquad \text{(Eq. 4)}$$

One easy way to determine k_1, k_{-1}, and eventually the second-order rate constant k_2 is to follow the change in absorbance at a given wavelength accompanied by the reaction. Plots of log $(D - D_\infty)$ *versus* time t should result in a straight line where the slope is equal to $-(k_1 + k_{-1})/2.303$, where D and D_∞ are the absorbance at any t and at equilibrium, respectively. If k_{obs} is defined as the sum of k_1 and k_{-1}, then:

$$k_{obs} = k_1 + k_{-1} = k_2[S] + k_{-1} \qquad \text{(Eq. 5)}$$

Under a given reaction condition, k_{obs} is determined at various $[S]$ values, which must be at least 25 times excess over $[A]$ to ensure a pseudo-first-order kinetic condition. From the slope and the intercept of the plot of Eq. 5, k_2 and k_{-1} are obtained. Finally, the equilibrium constant can be obtained from:

$$K = \frac{k_2}{k_{-1}} \qquad \text{(Eq. 6)}$$

The absorption band at λ_{max} 220 nm with $\epsilon_{220} = 1.02 \times 10^4$ of prostaglandin A_2 gradually disappeared in the presence of bisulfite. Figure 4 shows typical plots of log $(D - D_\infty)$ *versus* t with varying concentrations of total bisulfite at pH 6.04. Linearity was observed at least over three $t_{1/2}$ periods. The lowest $[S_T]$ was still about 25 times in excess of the concentration of prostaglandin A_2. From the slopes, k_{obs} values were determined. Isolation of k_2 and k_{-1} from k_{obs} thus obtained is shown in Fig. 5 for all experimental pH values. Values of k_{obs} and k_2 estimated from k_{obs} are listed in Table II.

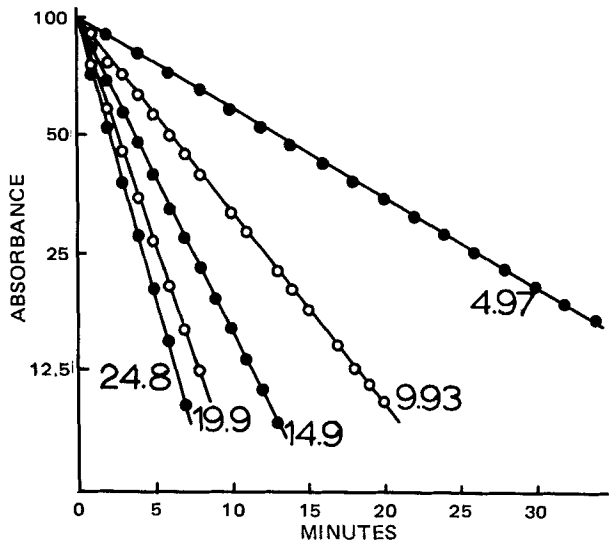

Figure 4—*Semilogarithmic plots against time of absorbance changes that occurred during bisulfite addition to prostaglandin A_2 in a phosphate buffer of pH 6.0 and I = 0.1 M at 25°. Experimental points were normalized to facilitate visual comparisons. Total absorbance changes were at least 0.5 absorbance unit. Prostaglandin A_2 = 2.12 × 10^{-4} M, and total bisulfite concentrations in 10^{-3} M are given on the figure.*

One interesting result indicated by Fig. 5 is the fact that the intercepts k_{-1} are all zero regardless of the pH; *i.e.*, the rate constant for the reverse adduct dissociation is extremely small. This would make the equilibrium constant K for the adduct formation very large over the experimental pH range. From this kinetic study, it is concluded that bisulfite adds across the $\Delta^{10,11}$-bond of prostaglandin A_2 practically in an irreversible fashion over a pH range of 4–8.

The pH dependence of k_2 (*i.e.*, the slope of Fig. 5) is better illustrated in Fig. 6. As pH increases, k_2 also increases, clearly indicating that the kinetically reactive species is SO_3^{2-} and that, under the experimental

[a] Data not shown in Fig. 5.

conditions, the rate-determining step involves the attack of SO_3^{2-} at C-11. From a mechanistic point of view, protonation of C-10 can occur simultaneously (*i.e.*, 1,2-addition in a true sense) or the sulfite attack can lead to the formation of C-9 enolate (*i.e.*, 1,4-addition). But this point is not the concern of the present study. The reactivity of the $\Delta^{10,11}$-bond of prostaglandin A_2 should not be affected by the ionization of C-1 carboxylic acid (unless there is an unusual proximity field effect between C-1 and C-11). Therefore, when analyzing the pH profile of k_2, it is not necessary to assign a different reactivity to the free acid and to the carboxylate ion. Under this condition, the observed rate expression becomes:

$$\text{rate} = k_2[A][S] = k_2[A][SO_3^{2-}]\left(1 + \frac{[H^+]}{K_a}\right) \qquad \text{(Eq. 7)}$$

where K_a is the ionization constant of HSO_3^- (1.15×10^{-7} at $I = 0.1 M$). Since SO_3^{2-} is the kinetically reactive species, another rate expression is obtained:

$$\text{rate} = k_2^0[A][SO_3^{2-}] \qquad \text{(Eq. 8)}$$

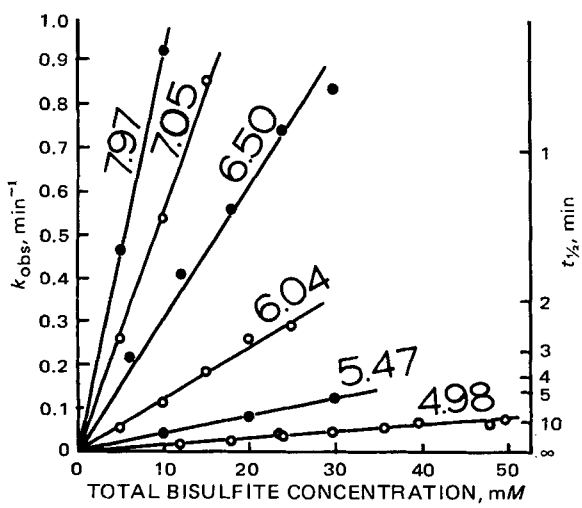

Figure 5—*Relationship of* $k_{obs} = k_2[S] + k_{-1}$ *for bisulfite addition to prostaglandin A_2 at 25° under pseudo-first-order kinetic conditions. The pH values are given on the figure.*

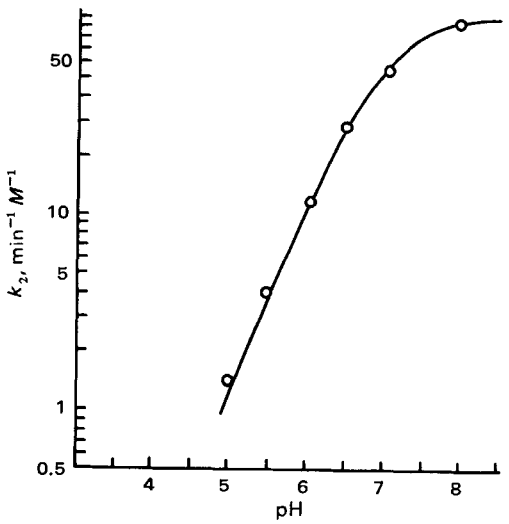

Figure 6—*Dependence on pH of the second-order rate constant,* k_2, *for the formation of the prostaglandin A_2 bisulfite adduct at 25°. The solid curve was theoretically generated using 105 min^{-1} M^{-1} as the value of the pH-independent second-order rate constant,* k_2^0, *for SO_3^{2-} attack on prostaglandin A_2.*

where k_2^0 is the pH-independent second-order rate constant specifically for SO_3^{2-} attack at C-11 of prostaglandin A_2. From Eqs. 7 and 8:

$$k_2 = k_2^0\left(1 + \frac{K_a}{K_a + [H^+]}\right) \qquad \text{(Eq. 9)}$$

By using four values of k_2 at pH > 6, the average k_2^0 of 1.75 $sec^{-1} M^{-1}$ (105 $min^{-1} M^{-1}$) was obtained. The solid curve on Fig. 6 was generated from this value of k_2^0 and Eq. 9. The small but significant (within the experimental accuracy) positive deviation of the experimental data from the theoretical pH profile observed at pH values below 5.5 is attributed to an extra kinetic contribution of HSO_3^- to k_2. The contribution of HSO_3^- is seldom reported as an additional kinetically reactive species; but at a sufficiently low pH range where the fractional concentration of HSO_3^- far exceeds that of SO_3^{2-}, its contribution to the observed rate constant can be clearly detected (25).

EXPERIMENTAL

Reagents and Apparatus—The following chemicals were used without further purification: dinoprostone[1], mol. wt. 352.46, mp 62–64°; prostaglandin A_2[1], mol. wt. 334.46, oily liquid at room temperature; dinoprost[1], mol. wt. 354.46, oily liquid at room temperature; and sodium bisulfite[2] (granular), analytical reagent. All other chemicals were of analytical reagent grade. Buffer systems used were the same as described previously (25). The spectroscopic data were obtained using commercially available instruments[3].

Procedure—The circular dichroism curves of Figs. 1 and 2 are expressed in terms of the molar ellipticity, $[\theta]$, in degrees centimeters[2] decimole^{-1}; $[\theta] = RM/100\,Cl$, where R = rotation (or ellipticity) in degrees, M = molecular weight, C = concentration in grams per milliliter, and l = path length in decimeters. The observed rotation was measured using 0.5-cm cells, except spectrum c. In each case, approximately 30 min passed after a sample solution was prepared when the rotation at 292 nm was measured. Because of the high concentration of bisulfite in Sample c, the noise–signal ratio was very high (dynode voltage was over 0.5 kv). Therefore, spectrum c was obtained using a 0.1-cm cell, and a fivefold increase in sensitivity was employed.

The circular dichroism spectra shown in Fig. 2 were constructed from the observed rotation measured using 1-cm cells for the λ range from 220 to 260 nm and 5-cm cells for the λ range from 250 to 400 nm. About 30 min elapsed after the sample solutions were prepared when the rotation at 285 and 235 was measured for both Samples a and b.

Throughout the phase solubility analysis and the partition experiment, the concentration of dinoprostone was determined by measuring absorbance at 283 nm after dinoprostone had been converted to prosta-

[1] The Upjohn Co.

glandin B_2 in 1 *N* KOH: $\epsilon_{283} = 1.62 \times 10^4$. A quantitative conversion of dinoprostone to prostaglandin B_2 was obtained within 10 min at room temperature.

In phase solubility analysis, excess dinoprostone was added to each of 5-ml buffer solutions containing varying amounts of sodium bisulfite. Seven-milliliter capped[4] vials were used for both solubility and partition experiments. At equilibrium, attained by shaking the samples in a water bath of 25° for 20 hr, the vials were subjected to centrifugation. Undissolved dinoprostone formed an oily droplet at the bottom of the vials, and an aliquot of the supernate was taken out and diluted in 1 *N* KOH. At 25°, less than 2% of total dinoprostone is expected to degrade in 10 hr, since $k_{obs} \sim 10^{-3}$ hr^{-1} under the same conditions (18).

In partition experiments, 3.0 ml of a stock solution of dinoprostone in ethyl acetate–hexane (1:1), which had been saturated with water, and 3.0 ml of a buffer solution in a 7-ml vial were vigorously shaken for 5 hr in a water bath at 25°. At equilibrium, an aliquot of the organic solvent layer was withdrawn; dinoprostone was converted to prostaglandin B_2 after the solvent was evaporated under a nitrogen stream at room temperature. The aliquot from the aqueous layer was directly diluted with 1 *N* KOH.

The equilibrium constant determined by the UV spectrophotometric technique was not as accurate as that determined by circular dichroism spectroscopy, mainly because a wide range of bisulfite concentrations could not be employed. The absorbance of bisulfite solutions is a square (not linear) function of the bisulfite concentration (50).

Because of the UV absorption due to buffer components and bisulfite and other ionic species derived from it (50), the absorbance of λ_{max} of prostaglandin A_2 (220 nm) could not be used in the kinetic study of bisulfite addition to prostaglandin A_2. The results shown in Fig. 4 were, therefore, obtained by following the absorbance change at various wavelengths ranging from 230 to 254 nm (see Table II), using prostaglandin $A_2 = 2.12 \times 10^{-4}$ *M*. The lowest concentration of total bisulfite was about 5×10^{-3} *M*, which satisfies the pseudo-first-order kinetic condition. To protect the bisulfite solution from oxidation, usually a stock solution of about 0.1 *M* was prepared accurately in a deoxygenated buffer solution containing less than 0.5% of methanol as a free radical scavenger. This stock solution was diluted just prior to a kinetic run. To a spectrophotometer cell, 10 μl of stock solution of prostaglandin A_2 in methanol (10 mg/ml) was introduced, and 2.8 ml of a buffer solution containing bisulfite was rapidly added. The absorbance change at a given wavelength was then immediately followed using an identical solution without prostaglandin A_2 as a blank. The ionic strength of the reaction medium varied from 0.1 to about 0.2 *M*, and the temperature of the cell chamber was 24 ± 2°.

Plastic Flow during Compression of Directly Compressible Fillers and Its Effect on Tablet Strength

S. T. DAVID * and L. L. AUGSBURGER ˣ

Abstract □ The effects of the duration of the overall compression cycle and of the duration of the maximum compressive force on tablet strength were studied using an instrumented rotary tablet press. Various direct compression fillers were evaluated. Increasing the overall compression cycle duration to 10 sec resulted in significantly greater tablet tensile strengths with microcrystalline cellulose and compressible starch fillers but not with lactose or compressible sugar. Increasing the duration of the maximum compressive force to 20 sec significantly increased the tensile strength in all cases, but microcrystalline cellulose and compressible starch tablets were affected more than lactose or sugar tablets. The maximum compressive force decayed with time for all fillers but at a greater rate with microcrystalline cellulose and compressible starch. This behavior was attributed to differences in the extent of plastic flow. The decay curves were analyzed using the Maxwell model.

Keyphrases □ Tablets—plastic flow during formation, effect of duration of compression cycle and maximum compressive force on tensile strength □ Plastic flow—during tablet formation, effect of duration of compression cycle and maximum compressive force on tensile strength □ Compression cycle—tablet formation, effect of duration and maximum force on tablet tensile strength □ Dosage forms—tablets, effect of duration of compression cycle and maximum compressive force on tensile strength □ Tensile strength—tablets, effect of duration of compression cycle and maximum compressive force

In the mid-1950's, Train (1) formulated a hypothesis on the mechanics involved in tablet formation. The consolidation process was divided into stages. Stage I takes into account interparticulate slippage of the powder particles, which leads to a decrease in the relative volume of the compact. The formation of temporary struts, columns, and vaults due to the increased resistance of the powder to compression is manifested in Stage II. Failure of these structures, brought about by increasing the compression forces on the powder material, is obtained in Stage III. Here the structure failure is a result of the crushing of particles or plastic flow. In Stage IV, rebonding is taking place more quickly than particle fracture, and the decrease in the relative volume of the compact becomes quite small as compared to the former stages.

As stated by Train, one event reported to occur during the formation of tablets is plastic deformation, which results from the crushing or fracturing of particles or by plastic flow. Plastic flow in various materials has been evaluated by comparing their stress relaxation behavior under constant load (2, 3).

The purpose of this study was to investigate plastic flow, with particular reference to its effect on tablet tensile strength. Therefore, the effects of the duration of the total compression cycle and of the duration of the maximum compressive force on tablet strength were investigated. Directly compressible fillers were chosen, because there is much interest today in materials and formulas that permit the manufacture of tablets without the traditional and costly granulating step.

EXPERIMENTAL

Tablet Preparation—Tablets were prepared on a rotary tablet press[1], which had been instrumented with resistance strain gauges after the manner of Wray *et al.* (4) to monitor compression and ejection forces. The instrumentation of this machine was described in detail previously (5). Only a single station was used to help minimize tooling errors. The same circular, flat-faced punches and die, 1.588 cm in diameter, were used throughout the study.

Tablet weights were held constant at 750 mg, unless otherwise stated. When a lubricant was necessary, it was first prescreened through an 80-mesh screen to facilitate blending. Lubricated blends (500-g batches) were prepared by mixing in a 1.92-liter (2-qt) twin-shell blender[2] for 12 min, with the intensifier bar running for only the final 2 min. All tableting was conducted in a room where temperature and relative humidity were maintained at 26 ± 1° and 35 ± 5%, respectively.

Tablet Tensile Strength—Tablet tensile strength was determined from the force required to fracture tablets by diametral compression on a motorized tablet hardness tester[3]. Rather than report tablet strength as hardness (*i.e.*, fracture force), force readings were converted to tensile strength in the manner of Fell and Newton (6), because tensile strength is independent of tablet dimensions and is a measure of the strength of the "as compacted" material (7, 8). The equation used to compute tensile strength was:

$$\sigma_0 = \frac{2F}{\pi dt} \qquad \text{(Eq. 1)}$$

where σ_0 is the tensile strength, F is the force needed to cleave the tablet, d is the diameter of the tablet, and t is the tablet thickness. Care was taken to use only the fracture forces generated when tablets failed in tension, as evidenced by their uniform splitting into halves. Tablet dimensions were determined using an inch measure[4]. All tensile strengths reported are based on 10 determinations.

Effect of Duration of Compression Cycle—Compression cycle durations were varied from 0.09 to 10 sec for the following directly compressible materials: lactose[5] USP, direct compressible sugar[6] USP, microcrystalline cellulose[7] NF, and compressible starch[8] (pregelatinized starch USP). The first two materials each contained 0.50% magnesium stearate[9] USP as a lubricant to facilitate ejection of the compacts from the die cavity. In most cases, machine speed could be altered by making a mechanical adjustment to vary the time of the compression cycle; however, the 10-sec time was achieved by rotating the flywheel of the press manually at a relatively constant rate.

Ten tablets, representing each cycle duration, were evaluated for tensile strength (Table I). Increasing the duration of the compression cycle did not result in significantly different tensile strengths for the lactose or sugar tablets; however, the microcrystalline cellulose and compressible starch tablets were significantly stronger when the compression cycle was increased to 10 sec (5% level).

starch	643	0.12	8.0	0.41	—
	643	10	8.7	0.50	3.72[c]

[a] Standard deviation, based on 10 determinations. [b] Student t statistic for difference comparing shortest cycle with each longer cycle. [c] Significant difference (5% level).

fect of the duration of the maximum compressive force on tablet tensile strength was examined using compressive forces required to make tablets of acceptable hardness. The same compressible materials used in the preceding study were again examined. The lactose and sugar contained 0.50% magnesium stearate.

Initially, samples were compressed utilizing a rotary tablet machine speed of 25 rpm where the duration of the compression force was less than 0.1 sec. Additional samples of the fillers were compressed on the same machine with the same maximum force but the duration of the force was prolonged. This change was accomplished by manually rotating the flywheel at approximately 0.5 rpm until the maximum compressive force was observed on a strip-chart recorder tracing. The position of the flywheel was held constant for 20 sec, and then the compressional force was released.

Tensile strengths were determined on 10 tablets produced on each run (Table II). Tablet strengths for these compacts increased significantly (5% level) in all cases when the duration of the maximum compressive force was increased to 20 sec.

Plastic Flow—In the previous experiment, increasing the duration of the maximum compressive force resulted in increased tablet tensile strength. However, of the four fillers tested, microcrystalline cellulose and compressible starch were affected to a markedly greater extent than compressible lactose and sugar. The compaction forces used in making these tablets were presumably in the range of Train's Stage III of compression, in which plastic flow and fracture take place. The differences could have been due to differences in the extent of plastic flow. To test this possibility, an experiment was designed to evaluate the role of plastic flow in the compaction of these materials.

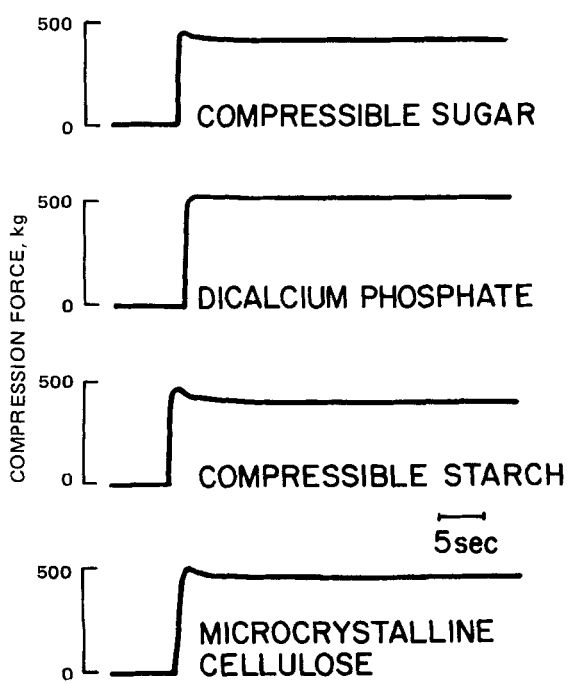

Figure 1—*Typical compression force decay curves.*

In the previous experiment, it was observed from the recorder tracings that during the extended times in which the compression cycle was halted at the point of maximum compressive force, this force tended to decay with time. This observation both supported the proposed role of plastic flow and suggested the instrumented rotary press as an experimental tool to evaluate this phenomenon. Thus, tablets were compressed manually on the instrumented rotary press by turning the flywheel by hand at an approximate rate of 0.5 rps until the maximum compressive force was observed on the recorder tracing. The flywheel was halted at this point, but the recorder was permitted to run, thus producing a continuous tracing of the compressive force.

Compressible starch, microcrystalline cellulose, dicalcium phosphate dihydrate[10] USP, and compressible sugar were evaluated. In all cases, maximum decay appeared to be reached within about 10 sec. The lactose used in the previous study was not used since a change had taken place in the material. Although microcrystalline cellulose and starch do not require a lubricant when tableted alone (9, 10), 0.30% magnesium stearate was added to each of the four fillers to keep the experimental conditions the same in all cases. Tablet weights for each blend were adjusted carefully to produce tablets with the same thickness of 0.300 ± 0.001 cm. Typical tracings appear in Fig. 1.

The data were treated in a manner similar to that of Shlanta and Milosovich (2). These substances were treated as materials showing both an elastic and a plastic nature during deformation. A linear, Hookean stress-strain relationship is combined in series with a linear, Newtonian viscous relationship to describe the material's behavior

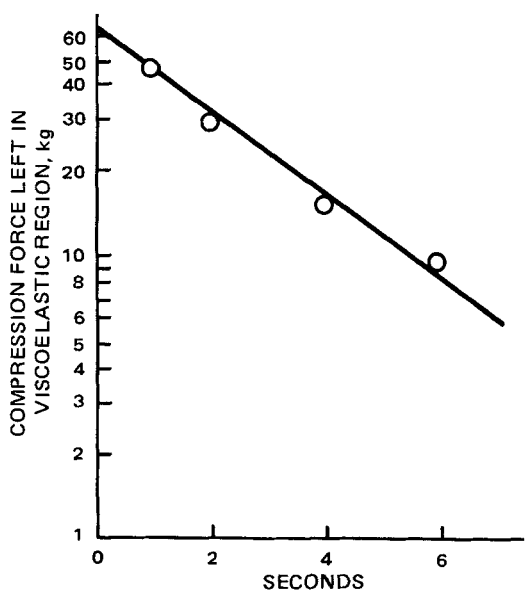

Figure 2—*Effect of time on the compression force observed for a compressible starch containing 0.30% magnesium stearate. Slope = 0.336 sec^{-1}. Intercept = 63 kg.*

Table II—Effect of Duration of the Maximum Compressive Force on Tablet Strength for a Few Directly Compressible Fillers

Filler	Compression Force, kg	Duration of Maximum Compressive Force, sec	Tablet Strength		
			kg/cm²	S^a	t^b
Compressible lactose with 0.50% magnesium stearate	826	<0.1	16.3	0.48	—
	826	20	18.8	0.77	8.71
Compressible sugar with 0.50% magnesium stearate	826	<0.1	10.0	0.42	—
	826	20	12.3	0.29	14.4
Microcrystalline cellulose	203	<0.1	13.6	0.62	—
	203	20	18.7	0.60	18.2
Compressible starch	643	<0.1	8.0	0.30	—
	643	20	18.8	0.44	63.5

[a] Standard deviation, based on 10 determinations. [b] Student t statistic comparing each pair. All differences are significant at the 5% level.

under real conditions. Thus, the plastic flow concept is treated mathematically as the Maxwell model under constant strain (11, 12), which involves combining one viscous parameter and one elastic parameter. The Hookean element is given by:

$$\sigma_1 = Ee_1 \qquad \text{(Eq. 2)}$$

From Newton's law of flow, the plastic or viscous relationship is:

$$\sigma_2 = n\frac{de_2}{dt} \qquad \text{(Eq. 3)}$$

where σ is the stress, e is the amount of powder constriction, de/dt is the rate of constriction with time, E is Young's modulus, and n is a viscosity coefficient. Since:

$$\sigma = \sigma_1 = \sigma_2 \qquad \text{(Eq. 4a)}$$

and:

$$e = e_1 + e_2 \qquad \text{(Eq. 4b)}$$

then:

$$\frac{de}{dt} = \frac{de_1}{dt} + \frac{de_2}{dt} = \frac{1}{E}\frac{d\sigma}{dt} + \frac{\sigma}{n} \qquad \text{(Eq. 4c)}$$

When a fixed constriction is applied to the powder mass at time t = 0 and held constant, one can express stress as a function of time. Therefore, de/dt is equal to zero so:

$$E^{-1}\frac{d\sigma}{dt} + \frac{\sigma}{n} = 0 \qquad \text{(Eq. 5a)}$$

and after integration:

$$\ln\frac{\sigma}{\sigma_0} = -Et/n \qquad \text{(Eq. 5b)}$$

or:

$$\Delta\sigma = \Delta\sigma_0 e^{-Et/n} \qquad \text{(Eq. 5c)}$$

The symbol Δ in front of the σ symbol represents the total range of compressive stresses located in the viscoelastic region in question. Since the area of contact between powder and punches was constant throughout, Eq. 5c becomes:

$$\Delta F = \Delta F_0 e^{-Et/n} \qquad \text{(Eq. 6)}$$

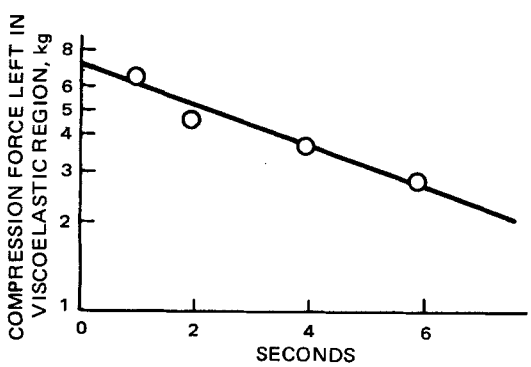

Figure 3—*Effect of time on the compression force observed for dibasic calcium phosphate containing 0.30% magnesium stearate. Slope = 0.182 sec^{-1}. Intercept = 7 kg.*

where ΔF is the amount of the compressional force left in the viscoelastic region at time t, and ΔF_0 is the total magnitude of this force at t = 0. Thus, according to Eq. 6, the decay of compression force with time from the continuous trace recordings can be treated as a first-order rate process. The logarithmic form of Eq. 6 is:

$$\ln \Delta F = \ln \Delta F_0 - kt \qquad \text{(Eq. 7)}$$

where the first-order rate constant, k, equals E/n and is the viscoelastic slope. Accordingly, compressive force data were obtained from tracings of the force decay curves of each filler. Data points were obtained and plotted in accordance with Eq. 7 on semilogarithmic paper. The first-order plots appear in Figs. 2–5. The data, including the first-order rate constants and the total magnitude of compression force decay, ΔF_0, appear in Table III. Results are based on three separate determinations for each filler.

RESULTS AND DISCUSSION

Although increasing the duration of the compression cycle did not result in statistically significant changes in the strength of the sugar or lactose tablets, the microcrystalline cellulose and starch tablets were significantly stronger (5% level) when a compression cycle of 10 sec was utilized (Table I). Plastic deformation results from fracture of particles and/or plastic flow. If plastic flow is an important factor affecting the compressibility of a substance, a prolongation of the compression cycle would be expected to increase the strength of tablets produced from such a substance, since more surface contact for interparticulate bonding would be produced through plastic flow.

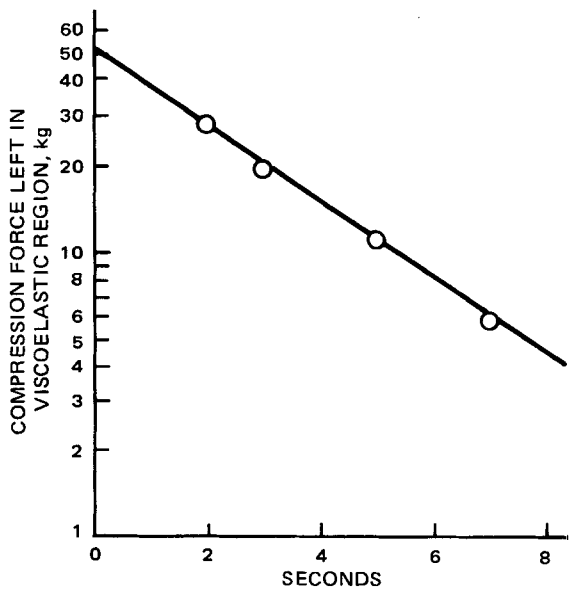

Figure 4—*Effect of time on the compression force observed for microcrystalline cellulose containing 0.30% magnesium stearate. Slope = 0.332 sec^{-1}. Intercept = 53 kg.*

Table III—Effect of Time on the Compression Force Observed for a Few Directly Compressible Fillers, All Containing 0.30% Magnesium Stearate

	4	525	502	529		
	6	522	502	529		
	12	518	500	527		

To investigate further the role of the basic deformation properties of materials on compressibility, the effect of the duration of the maximum compressive force on tablet strength was examined. Increasing the duration of the maximum compressive force resulted in significantly greater tablet strengths in all cases (Table II). However, the differences appeared relatively greater with microcrystalline cellulose and compressible starch. These results, together with the findings of the experiment in which the overall compression cycle times were varied, give evidence that plastic flow may play a more important role in particle–particle bonding in the microcrystalline cellulose and starch tablets than in the lactose and compressible sugar tablets.

In the experiment in which the effect of the duration of the maximum compressive force on tablet tensile strength was studied, this compressive force decayed with time. As this result was no doubt due to plastic flow (3), this observation suggested that plastic flow data could be obtained by treating these compressive force decay curves viscoelastically using the Maxwell element. Accordingly, viscoelastic slopes, based on compressive force decay curves, were determined for compressible starch, microcrystalline cellulose, compressible sugar, and dicalcium phosphate. Dicalcium phosphate was included as an example of an inorganic compound.

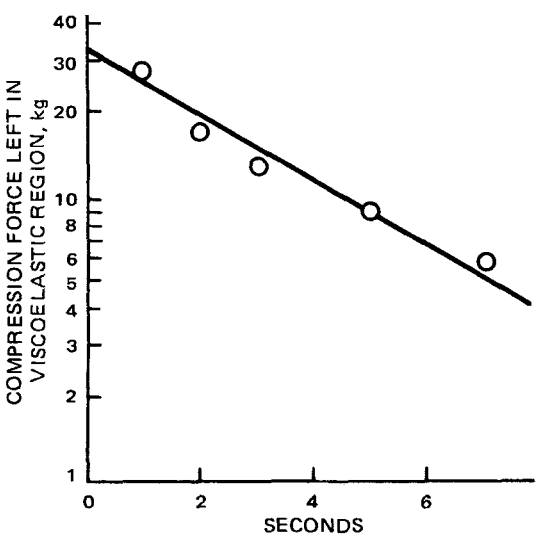

Figure 5—*Effect of time on the compression force observed for compressible sucrose containing 0.30% magnesium stearate. Slope = 0.281 sec^{-1}. Intercept = 37 kg.*

If the previous finding that plastic flow is more predominant in the compaction of compressible starch and microcrystalline cellulose and not as dominant in the compaction of sugar is correct, the viscoelastic slope, k, may be expected to be greater for the former two materials than for sugar. Furthermore, the total amount of compressive force decay, ΔF_0, should be less with sugar than with microcrystalline cellulose or compressible starch, as was found to be the case. The order of decreasing slopes and decreasing ΔF_0's (Figs. 2–5) is as follows: compressible starch > microcrystalline cellulose > compressible sugar > dicalcium phosphate. The viscoelastic plot for compressible sugar (Fig. 5) seems to deviate from linearity. One possible explanation is that, instead of a linear Newtonian element being applied, a nonlinear viscous relationship or a combination of the two may be involved.

The Maxwell element was used to determine the qualitative nature of polymers under stress, since it is generally unable to describe truly polymer properties quantitatively (11, 12). Vincent (12) pointed out that more complex models would be more suitable, but the behavior of the more complex models becomes "less easy to picture, as well as more difficult to analyze." However, since the Maxwell element is used to determine the qualitative behavior of polymers, the same treatment may be expected to help understand the important compressibility characteristics of various pharmaceutical materials during tablet compression. For example, Rees and Shotton (13) found that the tablet strength of sodium chloride tablets increased up to 100% or more 1 hr after tablet compression. This result was attributed to "stress relief of the crystals and interparticulate bonds" due to plastic flow. Therefore, a similar type of mathematical treatment, as described utilizing the Maxwell element, may become a useful tool in explaining unusual shifts in tablet hardness with time.

These results suggest that direct compression fillers can be classified according to their degree of plastic flow under compaction. Furthermore, these results help explain the phenomenon in which the compressibility of either microcrystalline cellulose or compressible starch is reduced to a much greater extent by the presence of lubricants than is observed with spray-dried lactose or sugar. It was suggested (5) that crystal fracture and the creation of new surfaces under compression may be more predominant factors in the bonding of tablets formed from lactose and sugar fillers than from microcrystalline cellulose or compressible starch. Thus, in the former cases, more new surfaces uncontaminated with lubricant would be formed which could participate essentially unhindered in bonding. Although plastic flow would be expected to increase the true area of contact

between particles, a lubricant initially present at particle surfaces would still exist at the interfaces formed by plastic flow where it could interfere with particle–particle bonding. The results of the present study help support this thesis, since microcrystalline cellulose and compressible starch appeared to exhibit a greater degree of plastic flow under compression than did sugar.

Zero-Order Drug Delivery System: Theory and Preliminary Testing

D. BROOKE [x] and R. J. WASHKUHN *

Abstract □ A new approach to zero-order drug delivery that includes geometric factors is described. An experimental device based on the theory was tested by following the release of stearic acid into ethanol. Three separate trials indicated that the solid was released *via* a zero-order process in a reproducible manner.

Keyphrases □ Drug delivery—zero-order system, geometric factors considered, experimental device tested □ Delivery, drug—zero-order system, geometric factors considered, experimental device tested □ Stearic acid—release into ethanol, zero-order drug delivery system, experimental device tested

Roseman and Higuchi (1) and, more recently, Roseman (2) treated the subject of drug release from silicone polymer matrixes containing suspended particulate drug. They developed equations for drug release from both planar and cylindrical surfaces (1). Roseman (2) showed that the fraction of drug release from a matrix with a planar surface was linear—not with time but with the square root of time. This finding confirmed an expectation published earlier (3). Roseman (2) also showed that the initial portion of a similar plot for a matrix of cylindrical shape was similar to that for the planar case. However, as more drug was released, the slope for the fraction *versus* square root of time plot decreased.

A study of these results indicates that polymer devices might be useful in dispensing drug to tissues or body cavities at fairly constant rates over reasonable periods of time. However, the ideal of a zero-order drug delivery system cannot be realized from planar or cylindrical devices of silicone polymer containing suspended particulate drug.

BACKGROUND

The planar case of a drug suspended in a polymer matrix fails as a zero-order drug delivery system because, as the drug is released, the boundary in the matrix at which drug dissolution occurs recedes from the surface from which the drug is released. The problem is one of a decreasing release rate due to an increasing drug diffusion path length within the matrix. For the cylindrical case, the situation is more complicated. Here, the diffusion path increases and the drug core within the matrix decreases in area.

The reduction of an effective dissolution surface, given a constant diffusion barrier, and its effect on drug dissolution, *e.g.*, from implants, are fairly well understood. In their derivation of the well-known "cube root law," Hixson and Crowell (4) showed an appreciation for the decreasing area of a single particle that maintained its shape during the dissolution process. Ballard and Nelson (5) related the rate of absorption from spherical implants to size. The same investigators (6) developed a graphical method of estimating the area of subcutaneously implanted cylindrical drug pellets.

More recently, Rippie and Johnson (7) attempted to regulate the dissolution behavior of drug pellets by controlling their geometry. However, their work involved dissolution in a turbulent flow, so that transport of the drug from the surface could not be considered limited to diffusion across a constant diffusion barrier.

between particles, a lubricant initially present at particle surfaces would still exist at the interfaces formed by plastic flow where it could interfere with particle–particle bonding. The results of the present study help support this thesis, since microcrystalline cellulose and compressible starch appeared to exhibit a greater degree of plastic flow under compression than did sugar.

Zero-Order Drug Delivery System: Theory and Preliminary Testing

D. BROOKE [x] and R. J. WASHKUHN *

Abstract □ A new approach to zero-order drug delivery that includes geometric factors is described. An experimental device based on the theory was tested by following the release of stearic acid into ethanol. Three separate trials indicated that the solid was released *via* a zero-order process in a reproducible manner.

Keyphrases □ Drug delivery—zero-order system, geometric factors considered, experimental device tested □ Delivery, drug—zero-order system, geometric factors considered, experimental device tested □ Stearic acid—release into ethanol, zero-order drug delivery system, experimental device tested

Roseman and Higuchi (1) and, more recently, Roseman (2) treated the subject of drug release from silicone polymer matrixes containing suspended particulate drug. They developed equations for drug release from both planar and cylindrical surfaces (1). Roseman (2) showed that the fraction of drug release from a matrix with a planar surface was linear—not with time but with the square root of time. This finding confirmed an expectation published earlier (3). Roseman (2) also showed that the initial portion of a similar plot for a matrix of cylindrical shape was similar to that for the planar case. However, as more drug was released, the slope for the fraction *versus* square root of time plot decreased.

A study of these results indicates that polymer devices might be useful in dispensing drug to tissues or body cavities at fairly constant rates over reasonable periods of time. However, the ideal of a zero-order drug delivery system cannot be realized from planar or cylindrical devices of silicone polymer containing suspended particulate drug.

BACKGROUND

The planar case of a drug suspended in a polymer matrix fails as a zero-order drug delivery system because, as the drug is released, the boundary in the matrix at which drug dissolution occurs recedes from the surface from which the drug is released. The problem is one of a decreasing release rate due to an increasing drug diffusion path length within the matrix. For the cylindrical case, the situation is more complicated. Here, the diffusion path increases and the drug core within the matrix decreases in area.

The reduction of an effective dissolution surface, given a constant diffusion barrier, and its effect on drug dissolution, *e.g.*, from implants, are fairly well understood. In their derivation of the well-known "cube root law," Hixson and Crowell (4) showed an appreciation for the decreasing area of a single particle that maintained its shape during the dissolution process. Ballard and Nelson (5) related the rate of absorption from spherical implants to size. The same investigators (6) developed a graphical method of estimating the area of subcutaneously implanted cylindrical drug pellets.

More recently, Rippie and Johnson (7) attempted to regulate the dissolution behavior of drug pellets by controlling their geometry. However, their work involved dissolution in a turbulent flow, so that transport of the drug from the surface could not be considered limited to diffusion across a constant diffusion barrier.

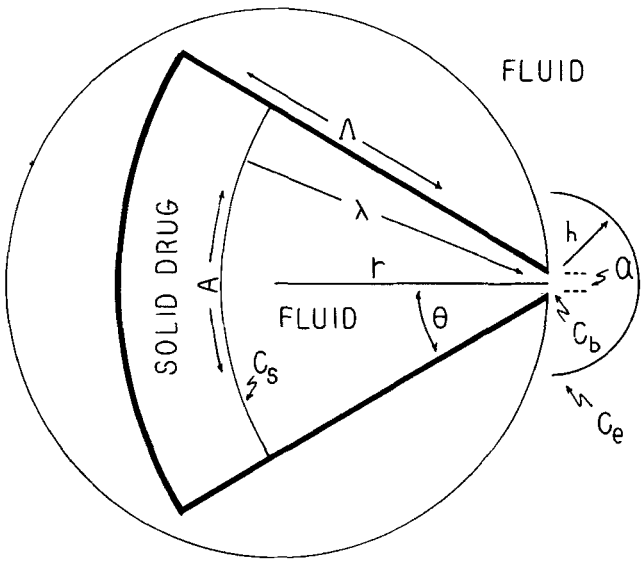

Figure 1—*Cross section of a zero-order drug delivery system containing solid drug. (See text.)*

This report details the theory for a drug delivery system that might be incorporated into implants or devices to be placed into body cavities or tissues. Under ideal conditions, this system should release drug *via* zero-order kinetics for virtually as long as it contains drug. The principle involves a particular geometry which, in turn, keeps a constant relationship between the drug diffusion path and the effective area of the dissolution boundary. The rigid device can be charged with a drug pellet or a suspension of drug in an aqueous gel, a waxy matrix, or a polymeric matrix. It is postulated that the principle described would be useful, not only in drug delivery systems, but as a means of experimentally defining physical parameters such as diffusion coefficients.

THEORETICAL

The essence of the drug delivery system described is a cavity of length L having a uniform cross section with geometric properties like those depicted in Fig. 1. Here, the bold lines describe the cross section of a cavity that might be found within a rigid cylinder having a base of radius r. The cavity communicates with the fluid in which the device is placed only through a narrow opening of width a, which runs the length of the device. In Fig. 1, this width is indicated by a pair of dashed lines. Although the opening must have a finite width, for theoretical purposes the width should be considered negligibly small. The cavity may be considered as a portion of a right circular cylinder of radius Λ and altitude L. Thus, in the ideal construction, the wall opposite the opening will be arcuate.

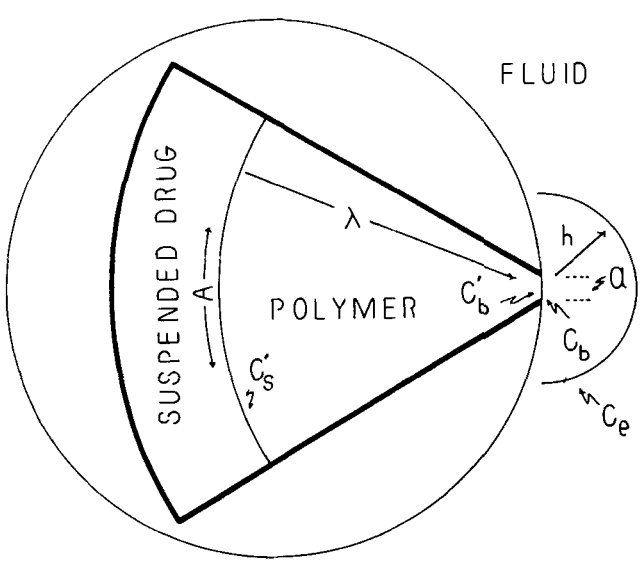

Figure 2—*Cross section of a zero-order device charged with a polymeric matrix containing suspended drug. (See text.)*

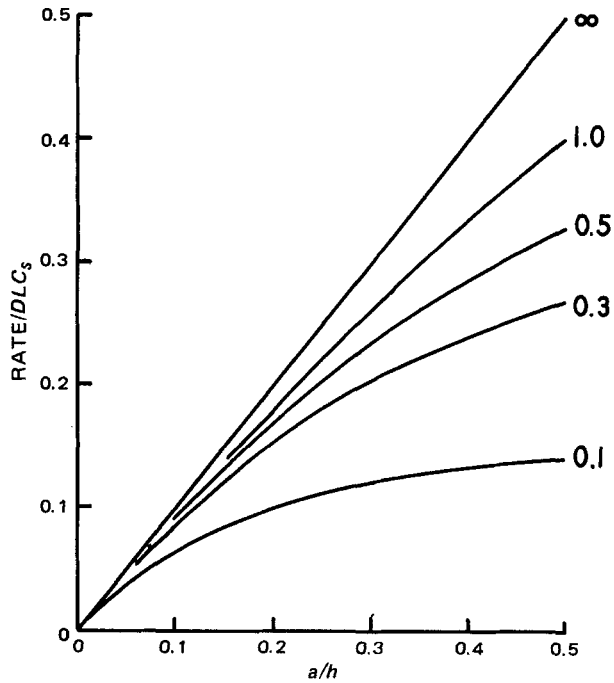

Figure 3—*Plot showing the interrelationships of a and θ in regard to release rate. The value for θ is indicated for each profile. (See text.)*

The device in Fig. 1 had been charged with a solid pellet of drug which dissolves isotropically. It is assumed that diffusion of drug out of the device and into the surrounding fluid is the rate-controlling process. In this case, about 60% of the initial charge has been released and fluid has diffused into the cavity. As drug continues to dissolve and diffuse from the curved surface through a distance, λ, to the opening, length A of the curve grows. It is clear from inspection that $A = 2\theta\lambda$ (for θ in radians). The fact that the relationship between the area of dissolving drug, AL, and the diffusion path length, λ, is a constant is the key to the zero-order performance of the device.

The rate equation describing the release of drug into the surrounding fluid can be derived by assuming that the rate of transport of drug to the opening of the device is equal to the rate of transport into the surrounding fluids. The concentration of drug at the dissolving surface is the solubility of drug, C_s, in the fluid. The concentration of drug at the opening is taken as C_b, and the concentration of drug at some distance, h, into the fluid is taken as C_e. The rate of transport of drug to the opening, R', is given in Eq. 1; the rate of transport away from the opening, R, is given in Eq. 2:

$$R' = \frac{DAL}{\lambda}(C_s - C_b) = 2D\theta L(C_s - C_b) \qquad \text{(Eq. 1)}$$

$$R = \frac{DaL}{h}(C_b - C_e) \qquad \text{(Eq. 2)}$$

Here, the diffusion coefficient for drug in fluid is indicated by D. By assuming that sink conditions prevail, *i.e.*, $C_e = 0$, and setting Eqs. 1 and 2 equal, it can be shown that the rate of drug release during steady state is described by:

$$R = \frac{2DaL\theta C_s}{a + 2\theta h} = \frac{DLC_s}{\frac{h}{a} + \frac{1}{2\theta}} \qquad \text{(Eq. 3)}$$

It is clear from Eq. 3 that, in a constant environment, *i.e.*, h constant, the release of drug occurs at a constant rate.

A different situation is shown in Fig. 2, where the cavity of a device has been filled with a suspension of drug in a polymeric matrix. The assumptions applied to this situation are those of Roseman and Higuchi (1). It is assumed that the total concentration of drug initially is large compared to the solubility of drug in the matrix, C_s'. It is assumed that steady-state conditions exist, that diffusion is the rate-controlling process, and that diffusion occurs through the matrix, not through pores.

The case depicted in Fig. 2 is one in which about 60% of the drug has been released, giving rise to a region depleted of solid drug particles. As drug dissolves at the boundary of the "zone of depletion," it must diffuse a distance, λ, to the opening where the concentration is C_b'. The rela-

Table I—Effect of a/h and θ on Rate × $100/DLC_s$

	θ

0.02	1.82	1.94	1.96	1.97	1.98	1.99	2.00
0.05	4.00	4.62	4.76	4.83	4.87	4.96	5.00
0.10	6.67	8.57	9.09	9.33	9.52	9.84	10.0
0.20	10.0	15.0	16.7	17.5	18.2	19.4	20.0
0.30	12.0	20.0	23.1	24.7	26.1	28.6	30.0
0.40	13.3	24.0	28.6	31.1	33.3	37.5	40.0
0.50	14.3	27.3	33.3	36.8	40.0	46.2	50.0

tionship between the area of the boundary where dissolution occurs, AL, and the diffusion path length, λ, is a constant since $A = 2\theta\lambda$. If the diffusion coefficient for drug in the matrix is D', the rate of transport of drug to the opening is given by:

$$R'' = \frac{D'AL}{\lambda}(C_s' - C_b') = 2D'\theta L(C_s' - C_b') \qquad \text{(Eq. 4)}$$

The rate of transport away from the opening is given by Eq. 2. By assuming that the partitioning of drug at the matrix–fluid interface can be described by a constant, K, such that:

$$K = C_b'/C_b = C_s'/C_s \qquad \text{(Eq. 5)}$$

it can be shown that the rate of drug release is given by:

$$R = \frac{DLC_s}{(h/a) + (D/D'K)(1/2\theta)} \qquad \text{(Eq. 6)}$$

The similarity between Eqs. 3 and 6 is obvious.

Equations 3 and 6 are derived for an ideal case wherein the opening is infinitely small (*i.e.*, $a \to 0$) but presents no barrier to diffusion of drug. In the real case, the zero-order phase develops only after the diffusion path length, λ, becomes significantly larger than the slit width, a. That is, a constant release rate occurs only after all points within the slit opening are approximately equidistant from any one point on the dissolution boundary, A. It should be obvious that in the initial portion of the drug release profile, where a has a small but real value and $\lambda \simeq 0$, the situation approximates the planar model of Roseman and Higuchi (1). Thus, in the real case, the rate of drug release is initially higher than that of the subsequent "zero-order" phase.

Equation 6 should also describe the release of drug from a device charged with a thixotropic aqueous suspension of drug. In that instance, D' would be the diffusion coefficient of drug in the suspension and K would, in a steady-state circumstance, have a value of unity.

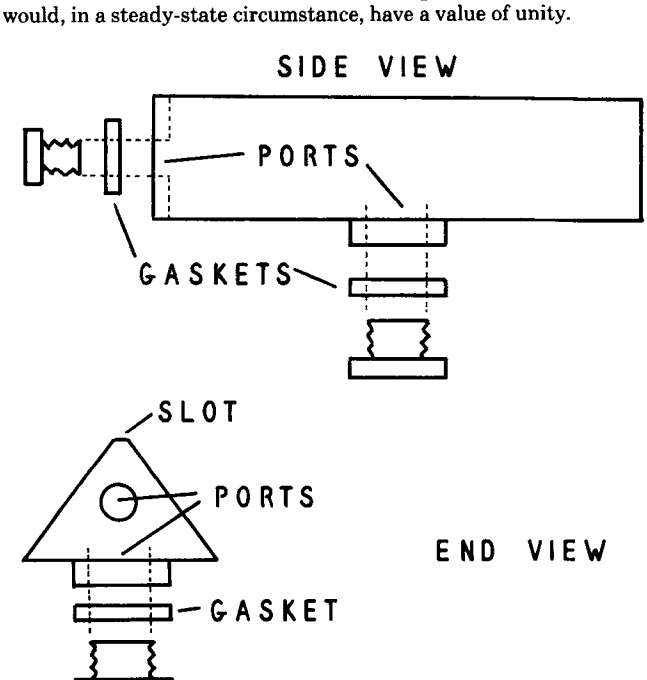

Figure 4—*Side and end views of an experimental stainless steel device used to test the zero-order theory.*

It is clear from Eqs. 3 and 6 that some latitudes prevail in the adjusting of the release rate through changes in a, θ, and L. The interrelationships of a and θ as concern the rate of release of drug from a cavity filled with solid material are depicted in Fig. 3 and Table I. Obviously, without specific knowledge of C_s, D, and h, exact values cannot be assigned. In general, however, the larger the values of a and θ, the larger is the rate. It is also clear from the equations that changes in the length, L, of the device result in proportionate changes in rate. Similar arguments hold for a cavity filled with a suspension of drug in a polymer.

Adjustments in the design parameters of a device might also prove useful in determining h and D. If one varies only the slit width, a, for a number of solid-filled cavities and plots the reciprocals of rates of release against $1/a$, a line with a slope of h/DLC_s and an intercept of $1/2\theta DLC_s$ is obtained. By dividing the slope by the intercept and multiplying by 2θ, one obtains a value for h. With a knowledge of C_s, θ, and L, one can calculate the diffusion coefficient, D, from the intercept value.

EXPERIMENTAL

The theory of the zero-order drug delivery system was tested experimentally by following the amount of stearic acid released from a device fabricated from stainless steel. The prism-shaped device used is illustrated in Fig. 4. Overall, it was 6.4 cm (2.5 in.) long, 2.54 cm (1.0 in.) wide at the base, and 1.6 cm (0.63 in.) high from the base to the slot. The sides, base, and one end were 18-gauge stainless steel. The other end was cut from 0.5-cm (3/16-in.) stainless steel and was drilled to provide a filling port which could be closed with a stainless steel bolt. All joints were silver soldered. A larger filling port was made in the base of the prism-like device by cutting a hole of appropriate size and soldering into place a stainless steel nut to be closed with a stainless steel bolt. Gaskets[1] were used at both filling ports. The slot width, a, was 0.08 cm (0.030 in.); the effective slot length, L, was 5.75 cm (2.263 in.). The angle, 2θ, was 80°.

For filling, the slot was covered with polyethylene and the device was inverted. Molten stearic acid[2] was added through the large port in increments. The device was rocked back and forth, and the portions were allowed to solidify after each addition. The device held approximately 9.5 g of stearic acid. After the port was closed, the polyethylene was removed carefully from the slit.

The release of stearic acid from the device into alcohol USP was followed by placing the device in the bottom of a double-walled beaker, 11.0 cm i.d., containing 1000 ml of alcohol. The port in the base and the bolt used to close it served as a pedestal for the device. The beaker was kept at 30°, and its contents were stirred with a three-blade propeller (radius of 2 cm and blade pitch of 30°) rotated at 50 rpm 2.5 cm below the surface. The distance between the top of the device and the propeller was 4.9 cm. A cover[1] with a hole for the stirrer and one for the sampling port was kept on the beaker.

Samples were withdrawn periodically. Alcohol at 30° was added to the beaker to maintain volume. The stearic acid concentration in the samples was estimated *via* an ion-pair extraction with methylene blue. A 5- or 10-ml aliquot of the ethanolic sample containing stearic acid was placed into a separator. A 50-ml volume of a 0.01 M pH 7.0 phosphate buffer containing 0.1% methylene blue (USP grade) and a 20-ml volume of redistilled reagent grade chloroform were added. If a 5-ml aliquot from the ethanolic sample was used, an additional 5 ml of alcohol was added. The separator was shaken, and the layers were allowed to separate. A 5-ml portion of the chloroform layer was diluted to 100 ml with methanol, and the density of the blue color was estimated at 640 nm against an appro-

[1] Teflon (du Pont).

priate blank. The blue color was stable after approximately 30 min. The absorbance was linearly dependent on the stearic acid in the sample.

RESULTS AND DISCUSSION

The cumulative release of stearic acid from the device tested for three different trials is shown in Fig. 5. The linear regression analysis for each trial is summarized in Table II. A survey of Table II shows that the coefficient of determination (r^2) was 0.99 in each case, indicating that the data were zero order. The variations in the slopes and intercepts do not appear to be great when it is understood that it was difficult to fill the device uniformly. Problems included the trapping of air bubbles in the melted stearic acid and a slight shrinkage of the melt on cooling. In the ideal case, there must be no penetration of fluid between the cavity wall and the fill. Shrinkage might have allowed spaces to form between the fill and the cavity wall.

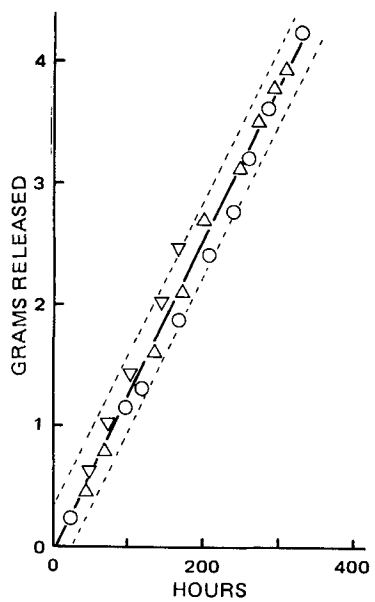

Figure 6—*Profile showing the amount of stearic acid released from the zero-order device. The regression line is based on a composite of all data from three trials, and the 95% confidence bounds are given as dashed lines. Selected points from Fig. 5 are shown. (See text.)*

Table II—Summary of Regression Analysis on Each Trial and on Composite of All Data

Parameter	Trial I	Trial II	Trial III	Composite Data
Release rate, mg/hr	12.73	14.24	12.89	12.72
SD (slope), mg/hr	0.23	0.41	0.24	0.18
r^2	0.990	0.990	0.991	0.985
Intercept, mg	−12.7	−48.3	+74.2	−21.9
SD (intercept), mg	44.5	41.3	47.2	33.1
n	32	14	30	76

Additionally, the theory requires that transport of solid within the cavity be diffusion controlled. If any currents arose in the fluid within the device during the experiment, then deviations from theory could occur. (Obviously this could not be a source of error in the case of a cavity filled with a polymeric matrix.)

It is calculated that the fabricated device, under ideal conditions, could release approximately 8.0 g of stearic acid at a zero-order rate. However, the trials were terminated after the release of 2.5–4.2 g when irregularities in the surface of the fill became obvious. The arcuate nature of the surface was always in evidence after a trial was terminated, but the surface did not show the perfect arc depicted in Fig. 1. Variations in the distance of the surface of the fill to the slot were also noted. Such variations, however, apparently "averaged out."

All data were collected under approximate "sink conditions" because the highest concentration of stearic acid achieved was about 0.4% compared to a solubility in ethanol of nearly 5% (8).

A summary of the regression analysis of a composite of all data for the three trials is given in Table II. The regression line and the 95% confidence bounds for single predicted values are shown in Fig. 6. Selected points from each individual trial are also given in Fig. 6 to illustrate the distribution of the data points.

Although the testing of the zero-order principle with stearic acid has been encouraging, a more critical approach will be necessary to validate the theory thoroughly. The filling of the device with a solid may prove to be more of an engineering problem than it is a pharmaceutical problem. A solid that is fused under high temperature and pressure in the process of filling the cavity should allow the most critical kind of test of the interrelationships of slit width, a, angle, 2θ, and length, L, of the device.

Analysis of Theoretical Behavior of a Proposed Zero-Order Drug Delivery System

R. A. LIPPER and W. I. HIGUCHI ˣ

Abstract □ An analysis of the theoretical behavior of a proposed zero-order drug delivery system is presented. Equations describing drug release with time are developed using a physically realistic model. The theory agrees well with experimental data and indicates that drug release from the device is nearly, although not rigorously, zero order.

Keyphrases □ Drug delivery—zero-order system, theoretical behavior, equations developed □ Delivery, drug—zero-order system, theoretical behavior, equations developed

Brooke and Washkuhn (1) presented the design of a drug delivery device, the unique geometry of which would, ideally, lead to zero-order release of its contents *via* dissolution from a solid pellet or diffusion from a suitable matrix. This ideal behavior depends in theory, however, on both the drug molecules and the opening through which they must pass having infinitely small dimensions. In this paper, the theoretical behavior of such a device modeled entirely with finite dimensions will be examined.

Discussion of prior work dealing with geometrical considerations in the determination of drug dissolution and release rates may be found in the previous paper (1).

THEORETICAL

The case to be treated here is that of a device charged with pure solid drug. It is assumed that dissolution takes place isotropically and that diffusion of drug out of the device is the rate-determining process. Similar equations could be derived for the case of drug being released from a polymer or other matrix.

The drug-containing cavity of the device in question (1) is essentially a sector of a right circular cylinder. Its cross section is shown in Fig. 1.

Let the center that defines the arc be outside the device and let the opening of the device be at radius n. The area of arcuate surface at diffusion path length s is then $2\theta L(s + n)$, where L is the length of the drug-filled cavity. The flux, J, at s is, therefore:

$$J = 2\theta LD(s + n)\frac{dC}{ds} \qquad \text{(Eq. 1)}$$

where D is the drug's diffusivity in the dissolution medium. The drug concentration at the dissolving surface is the solubility, C_s. The concentration at the opening is C_b; if sink conditions are assumed, the concentration at distance h into the bulk is zero. At steady state, integration of Eq. 1 from C_b to C_s and from zero to $\lambda - n$ yields:

$$J = \frac{2\theta LD(C_s - C_b)}{\ln\frac{\lambda}{n}} \qquad \text{(Eq. 2)}$$

Diffusion from the opening into the bulk is described by:

$$J = \frac{2\theta LDnC_b}{h} \qquad \text{(Eq. 3)}$$

Equation 3 treats the effective diffusion layer as the typical planar case rather than as radial diffusion from a point source. This treatment is justified if h is much less than the arc length at the opening. In any event, hydrodynamic conditions are important in determining release rate only at very early times when λ is of the order of magnitude of the opening arc length.

By solving for C_b in Eq. 3 in order to eliminate it from Eq. 2, the rate of drug release can be shown to be:

$$J = \frac{2\theta LDC_s}{\frac{h}{n} + \ln\frac{\lambda}{n}} \qquad \text{(Eq. 4)}$$

Given drug of density ρ, the mass dissolved at any time is:

$$M = (\lambda^2 - n^2)L\theta\rho \qquad \text{(Eq. 5)}$$

Integration of Eq. 4 after substituting for λ from Eq. 5 yields a relationship between mass dissolved and time:

$$\frac{\left(\frac{h}{n} - \frac{1}{2}\right)M + \left(\frac{M + L\theta\rho n^2}{2}\right)\ln\left(\frac{M}{L\theta\rho n^2} + 1\right)}{2\theta LDC_s} = t \qquad \text{(Eq. 6)}$$

If it is assumed that the mass in solution in the diffusion layer is negligible compared to the total drug mass, then:

$$M_r = M - M_d \qquad \text{(Eq. 7)}$$

where M_r is the mass released, and M_d is the mass dissolved within the device. At any given time:

$$M_d = \int_0^{\lambda - n} 2\theta L(s + n)C\,ds \qquad \text{(Eq. 8)}$$

where:

$$C = \frac{J}{2D\theta L}\ln\left(\frac{s + n}{\lambda}\right) + C_s \qquad \text{(Eq. 9)}$$

Following integration and the appropriate substitutions, Eq. 7 becomes:

$$M_r = (\lambda^2 - n^2)\left[L\theta\rho - L\theta C_s + \frac{L\theta C_s}{2\left(\frac{h}{n} + \ln\frac{\lambda}{n}\right)}\right] - \frac{L\theta C_s n^2}{\frac{h}{n} + \ln\frac{\lambda}{n}}\ln\frac{\lambda}{n} \qquad \text{(Eq. 10)}$$

and if Eq. 5 is substituted into Eq. 6, the following is obtained:

$$t = \frac{\left(\frac{h}{n} - \frac{1}{2}\right)(\lambda^2 - n^2)\rho + \lambda^2\rho\ln\frac{\lambda}{n}}{2DC_s} \qquad \text{(Eq. 11)}$$

Equations 10 and 11 relate λ to M_r and t, respectively. Thus, values for λ may be selected to generate M_r *versus* t data.

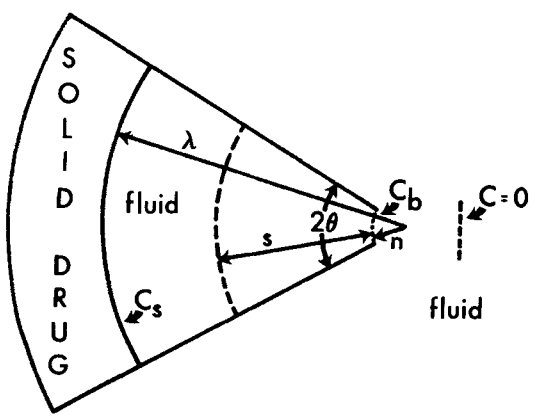

Figure 1—*Cross-sectional view of the device's drug-containing cavity, illustrating the case where the original charge of solid drug is partially dissolved. (See text.)*

RESULTS AND DISCUSSION

Equation 4 differs from the previously derived equation describing the idealized case (1) in that Eq. 4 contains a $\ln \lambda/n$ term. Since λ, the distance from the solid drug surface to the arc center, is time dependent, the flux expression derived here has a time dependence that was previously absent.

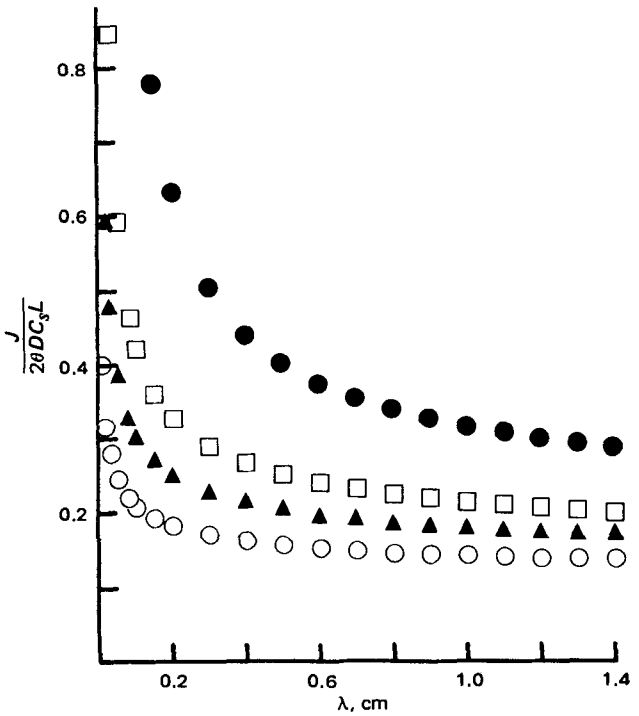

Figure 2—*Flux as a function of* λ *predicted by Eq. 4. The parameters used (in centimeters) are:* n = *0.050 and* h = *0.010* (●), n = *0.025 and* h = *0.025* (□), n = *0.010 and* h = *0.010* (▲), *and* n = *0.010 and* h = *0.025* (○).

Figure 2 shows the behavior of flux as a function of λ as predicted by Eq. 4, using four sets of reasonable parameters. In all cases, flux is initially high but quickly drops to a lower and nearly constant value. Thus, a small portion of the mass within the device would be released quickly, but by far the major portion would be released at a rate *approximating* zero order.

This point is further illustrated in Fig. 3 where the rate of change of flux with respect to λ is shown. The resulting family of curves clearly demonstrates the effect of diffusion layer thickness. For simplicity, λ and h are expressed as multiples of n, and $dJ/d\lambda$ is normalized by dividing by the initial $dJ/d\lambda$, i.e., when $\lambda/n = 1$. The rate of change of flux decreases markedly for $n \leq \lambda \lesssim 2n$; for $\lambda \gtrsim 2n$, the asymptotic approach to zero, *i.e.*, flux constant with λ, is obvious.

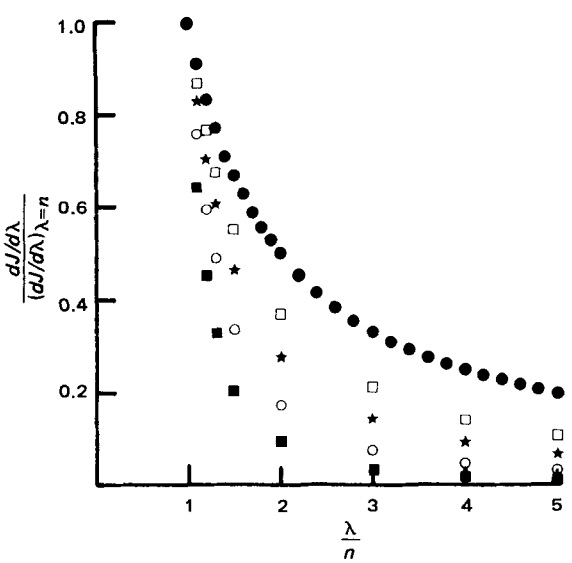

Figure 3—*Relative rate of change of flux with respect to* λ. *For simplicity,* λ *and* h *are expressed as multiples of* n, *such that* h = in *and* λ = jn. *The data shown are for* i = *0.5* (■), *1* (○), *2* (★), *and 4* (□) *and for the limiting right rectangular hyperbola as* i → ∞, i.e., *infinitely thick diffusion layer* (●).

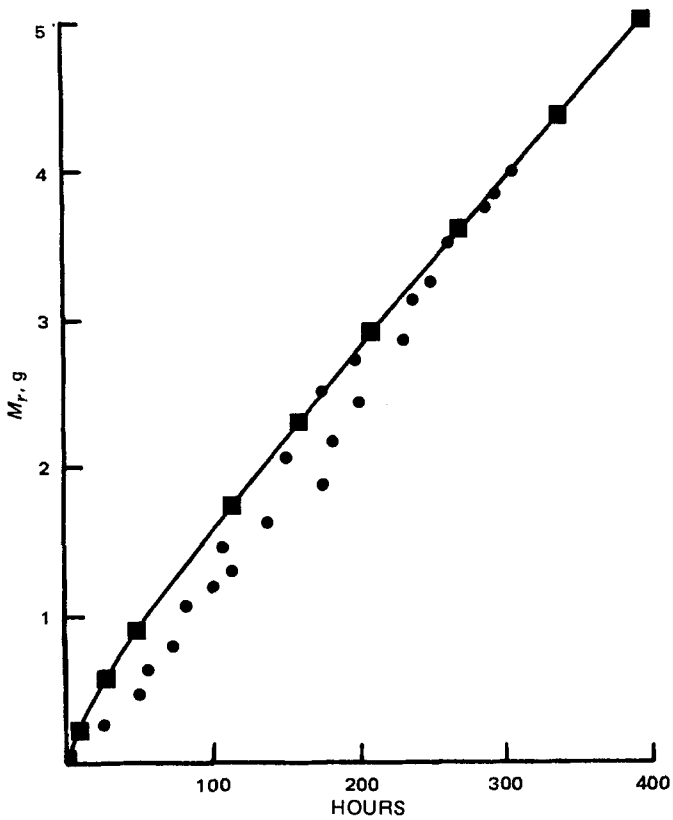

Figure 4—*Mass of stearic acid released with time as predicted by Eqs. 10 and 11* (■). *Experimental data* (●) *are from Ref. 1.*

Mass released *versus* time data were generated from Eqs. 10 and 11 to simulate the case experimentally tested by Brooke and Washkuhn (1), that of stearic acid being released into alcohol USP. The following parameters were used: $h = 100\ \mu m$, $n = 540\ \mu m$, $2\theta = 1.4$ radians, $L = 5.75$ cm, $C_s = 0.048$ g/cm^3 (2), and $\rho = 0.94$ g/cm^3 (3). A value for the only remaining parameter, diffusivity, was generated by forcing Eqs. 10 and 11 to yield the point $M_r = 5.07$ g at $t = 400$ hr from the previous paper's composite regression data (1). This leads to $D = 2.65 \times 10^{-5}$ cm^2/sec, which does not appear to be an unreasonable value (4, 5).

Figure 4 shows the resultant data. Good agreement is seen between the theoretically predicted release profile and the experimental data. Although systematic deviation from true zero order is apparent, the rapid approach to linearity is also evident. Indeed, a linear regression on the data for $t = 100$, 200, 300, and 400 hr gives $r^2 = 0.999$.

Although further experimental testing is certainly in order, it is thus concluded that the device examined here might exhibit release behavior that is nearly zero order and that, as such, it might be useful as a constant-rate drug delivery system.

Effect of Symmetrical Tetraalkylammonium Salts on Cloud Point of Nonionic Surfactants

HANS SCHOTT *x and SUK KYU HAN ‡

Abstract □ The salting in and salting out of the nonionic surfactant octoxynol NF by halides of ammonium and the four lowest symmetrical tetraalkylammonium cations were investigated by measuring their effect on the cloud point at various salt concentrations. The chloride anion tended to salt the surfactant out, lowering its cloud point. The iodide anion tended to salt it in, raising the cloud point, while the bromide ion had no pronounced effect. The ammonium and tetramethylammonium cations tended to lower the cloud point, the latter more extensively than the former. The tetraethylammonium cation had no pronounced effect, while the tetra-*n*-propylammonium and tetra-*n*-butylammonium cations tended to raise the cloud point, the latter more extensively than the former. The salt effect on the cloud point generally increased with increasing salt concentration. Tetramethylammonium chloride was the most efficient salt in lowering the cloud point (by 4° at the 0.10-molal level and by 20° at the 1.00-molal level), while tetrabutylammonium halides were the most efficient salts in raising the cloud point (by 18–19° at the 0.10-molal level for chloride and bromide). Cloud point increases were attributed to the formation of mixed micelles or to hydrotropy. The salting-out efficiency of tetramethylammonium chloride and bromide was ascribed to their ability to increase the structure of water.

Keyphrases □ Surfactants, nonionic—octoxynol, effect of tetraalkylammonium salts and ammonium halides on cloud point, various salt concentrations □ Octoxynol—effect of tetraalkylammonium salts and ammonium halides on cloud point, various salt concentrations □ Tetraalkylammonium salts—effect on cloud point of octoxynol, various salt concentrations □ Ammonium halides—effect on cloud point of octoxynol, various salt concentrations □ Cloud point—octoxynol, effect of tetraalkylammonium salts and ammonium halides, various salt concentrations

Two major trends were observed during a systematic investigation of the effect of inorganic cations on the cloud points of polyoxyethylated nonionic surfactants (1, 2). All polyvalent cations plus lithium form complexes with the ether oxygens of simple, model ethers like dioxane as well as with those of the polyoxyethylene moiety of nonionic surfactants. In this complex formation, which competes with the hydration of the cations, the flexible polyoxyethylene chains probably act as polydentate ligands (1, 2). The result is salting in of the surfactants, which manifests itself as an increase in cloud point. The reason that increases in this upper consolute temperature represent salting in is that they correspond to an increase in solubility, namely, an extension of the temperature range in which the nonionic surfactants exist in single-phase, undersaturated solutions (3).

The only inorganic cations incapable of forming complexes with the oxygen of ether groups or of water are sodium, potassium, ammonium, cesium, and, probably, rubidium. Their effect on nonionic surfactants is to lower the cloud points, salting them out (1, 2).

BACKGROUND

The cations of symmetrical tetraalkylammonium halides are of considerable physicochemical and biological interest. Their effect on the structure of water results in unusual behavior of their aqueous solutions such as peculiar activity and osmotic coefficients (4, 5) and conductance (6), high viscosity with large temperature coefficients (7), and unusual partial molal volumes (8–11).

Examples of tetraalkylammonium derivatives of biological importance are choline, found in lecithins and sphingomyelins; acetylcholine, crucial in the transmission of nerve impulses; and naturally occurring betaines including trimethylglycine. Examples of quaternary ammonium compounds with pharmacological activity include many alkaloidal salts and synthetic neuromuscular blocking drugs. An interesting type of interaction, pertinent to the present research, is supplied by the work of Belleau. The binding of tetraalkylammonium halides to the surfaces of acetylcholinesterase and of muscarinic and nicotinic receptors was shown to involve the structure of water in the vicinity of the receptor sites (12, 13).

The purpose of the present investigation was to examine the effect of tetraalkylammonium halides on the cloud point of a polyoxyethylated nonionic surfactant. It represents a logical sequence in our studies of the effect of the various categories of cations on cloud points and solubility of nonionic surfactants. Ether groups cannot act as ligands for tetraalkylammonium cations as they do for inorganic polyvalent cations. However, ion–dipole attraction (14) and hydrophobic interaction between the alkyl groups of the salts and the ethylene groups of the polyoxyethylene moiety of nonionic surfactants may take place.

Since the properties of symmetrical tetraalkylammonium halides strongly depend on the length of the alkyl groups (4–13), the number of carbon atoms per alkyl group was varied from zero (unsubstituted ammonium) to four.

The anion of the tetraalkylammonium halides was varied for two reasons. First, anions can enhance or reduce the structure of water. Structure-forming anions such as fluoride and chloride lower cloud points, salting the nonionic surfactants out, while structure-breaking anions such as iodide and thiocyanate have the opposite effect (2, 15). Second, large and poorly hydrated anions such as iodide are prone to ion-pairing, either of the usual electrostatic kind or "water structure enforced" (4–6).

Finally, there is the possibility of using the surfactant through its cloud point as a probe to obtain information on the structure and behavior of aqueous solutions of tetraalkylammonium salts.

EXPERIMENTAL

The nonionic surfactant employed was octoxynol NF[1], a branched octylphenol with an average of nine to 10 ethylene oxide units. It was selected because it is a monograph in the National Formulary and because it has been employed extensively in cloud point measurements (16), particularly when these were used as a criterion for salting in or out (1, 2). Its properties were given in Ref. 2 under Surfactant I.

The viscous liquid was dried over anhydrous calcium sulfate[2] to constant weight, losing less than 1% of moisture. The tetra-*n*-alkylammonium halides[3] were also dried to constant weight over anhydrous calcium sulfate. Sodium *m*-xylenesulfonate[4] was used as received. All other reagents were ACS reagent grade. Water was double distilled.

The procedures for preparing the ternary electrolyte–surfactant–water mixtures and for measuring cloud points were described previously (1). The surfactant concentration was 1.00% (w/w) based on the amount of water present, except for the hydrotrope experiments described in the *Appendix* where it was 2.00%. Such relatively small differences in surfactant concentration have no effect on the cloud point (17). Electrolyte concentrations are expressed as molality or as percent (w/w) based on the amount of water present in the mixtures.

RESULTS

The cloud point of octoxynol as a function of the concentration of the various electrolytes is listed in Table I.

	0.20		72.8°	78.5°	
	0.50		87.5°	—	
Tetra-*n*-butyl-ammonium	0.05	73.5°	74.0°		
	0.10	83.0°	84.1°		

[a] Concentration of octoxynol was 1.00% (w/w) based on the weight of water. Its cloud point in the absence of electrolytes was 64.3°.

Effect of Anion—The anions are ranked in the following order of decreasing effectiveness for salting out (lowering the cloud point) or increasing effectiveness for salting in (raising the cloud point): chloride > nitrate ≅ bromide > iodide. This order is the same as the Hofmeister or lyotropic series (18), which was also followed by the anions of inorganic salts (1, 2, 15). The large, polarizable iodide ion is particularly effective in breaking the structure of water.

The destructuring of water increases the concentration of nonassociated water molecules. These molecules become available to hydrate the ether groups of the nonionic surfactant, increasing its solubility and raising its cloud point (1, 2). The effect of the anions on the cloud point is minor compared to the large effect of the cations.

Effect of Cation Size—The behavior of the electrolytes underwent profound changes as the number of carbon atoms per alkyl group was increased from zero to four. As is seen from Figs. 1–3, tetramethylammonium salts had the strongest salting-out efficiency. The chloride lowered the cloud point by more than 30° at the 2-molal level. Only the iodide raised the cloud point, because of the strong salting-in tendency of the anion.

The salts of ammonium and tetraethylammonium at low and intermediate concentrations produced moderate decreases or increases in cloud point, depending on the anion. Except for ammonium bromide and tetraethylammonium bromide, the tendency to lower or to raise the cloud point of octoxynol became stronger with an increasing concentration of the electrolyte. As the alkyl groups were increased to *n*-propyl and *n*-butyl, the salting-in effect became very pronounced. The 20° increase in cloud point produced by 0.10 molal tetrabutylammonium chloride and bromide was considerably greater than the increases produced by inorganic salts at comparable concentrations. A 20° increase in the cloud point of octoxynol required over 2 molal sulfuric or hydrochloric acid, over 3 molal cadmium or magnesium nitrate, 4 molal nickel nitrate, and nearly 6 molal calcium nitrate (1).

The salt effect of the tetraalkylammonium halides as a function of the number, p, of carbon atoms per alkyl group is illustrated in Fig. 4. The ammonium and tetramethylammonium salts lowered the cloud point, salting the surfactant out. The curves have a minimum for $p = 1$. As p increased beyond 2, the cloud point underwent steep increases. The tetrapropyl- and tetrabutylammonium cations were very effective at salting the surfactant in.

DISCUSSION

The influence of the chain length of the alkyl groups on the nature and magnitude of the salt effect must be attributed to more than one factor, because the effect changes from salting out for $p = 0$ and 1 to salting in for $p = 3$ and 4. Attempts to explain these observations in terms of existing theories of salt effects and water structure are made here.

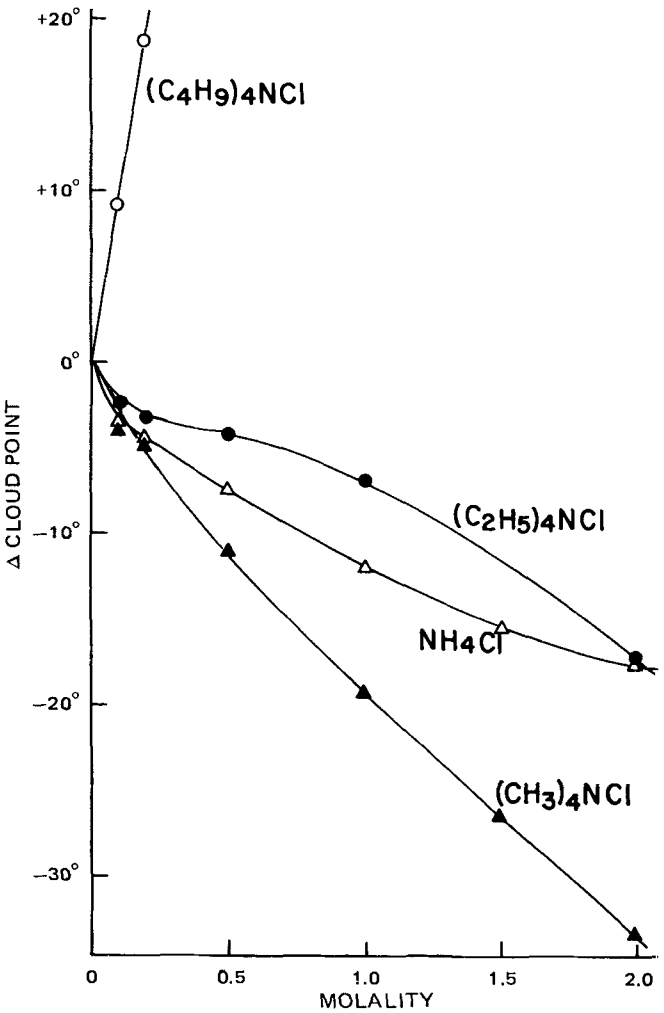

Figure 1—*Change in the cloud point of octoxynol as a function of the molal concentrations of added chlorides.*

Internal Pressure Theory—Long and McDevit (19) derived the following equation, which explains the effect of electrolytes on the solubility of nonelectrolytes in terms of internal pressure:

$$\ln \frac{S_n^o}{S_n} = \left[\frac{\bar{V}_n^o (V_e - \bar{V}_e^o)}{\beta RT} \right] C_e \qquad \text{(Eq. 1)}$$

The subscripts n and e designate the nonelectrolyte (*i.e.*, the nonionic surfactant) and electrolyte, respectively. The superscript o designates the property of the solute in water. Thus, S_n^o and S_n are the molar solubilities of the surfactant in water and in a solution containing C_e moles/liter of electrolyte, respectively; $\bar{V}^o$ represents partial molal volumes at infinite dilution; and V_e is the partial molal volume of the pure "liquid" electrolyte. The difference $(V_e - \bar{V}_e^o)$ represents the extent of electrostriction of water by the electrolyte. If $V_e > \bar{V}_e^o$, this difference is positive as is the logarithm of the ratio S_n^o/S_n. Hence, $S_n^o/S_n > 1$ and $S_n^o > S_n$. Physically, a positive $(V_e - \bar{V}_e^o)$ means that dissolution of the electrolyte produces a contraction in the volume of water. The solvent medium is compressed by the electrolyte, and the nonelectrolyte is squeezed out of solution or salted out.

The difference $(V_e - \bar{V}_e^o)$ was found to be negative for the three tetraalkylammonium bromides tested, namely, −10, −23, and −32 ml/mole for the tetramethyl-, tetraethyl-, and tetrapropylammonium bromides, respectively (20). These three salts loosen the solvent medium and should thereby increase the solubility of the nonelectrolyte, salting it in. This effect was observed with the nonpolar compound benzene (20). However, when the nonelectrolyte was the amphiphilic surfactant octoxynol, of the three salts only tetrapropylammonium bromide raised its cloud point, salting it in as predicted by the theory. Tetramethylammonium bromide salted it out, while tetraethylammonium bromide had no pronounced effect on the cloud point.

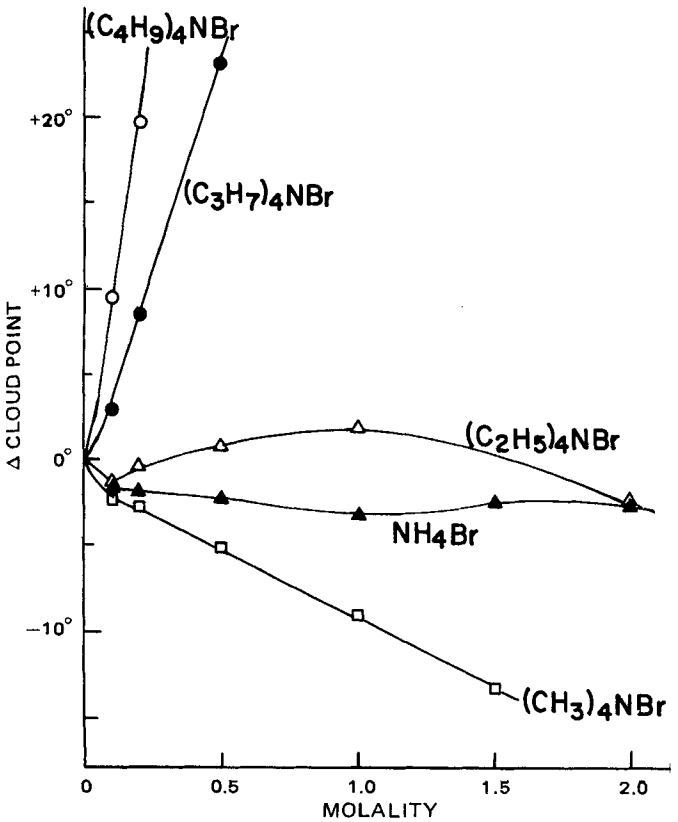

Figure 2—*Change in the cloud point of octoxynol as a function of the molal concentrations of added bromides.*

Thus, the internal pressure theory does not apply to the present situation, either because the nonelectrolyte is a large molecule or because it is a polar molecule (19). This finding represents a further limitation of the theory. Previously (2), it was found to fail because it did not take into account association between electrolytes and the nonelectrolyte by complex formation.

Effect of Alteration of Water Structure —Tetraalkylammonium salts are known to enhance the structure of water; the larger the alkyl groups, the greater is this effect (4). These hydrophobic groups do not attract or orient the water molecules in their immediate vicinity as strongly as does the next shell of water molecules, which surrounds the water molecules nearest to the hydrocarbon groups. Thus, the nearest water molecules are oriented and hydrogen bonded more strongly to the water molecules beyond them than would be the case if there were a strong counterattraction from the side of the hydrocarbon groups. This produces a tightening of the structure of the water surrounding these groups. Such an increase in water structure results in a large decrease in

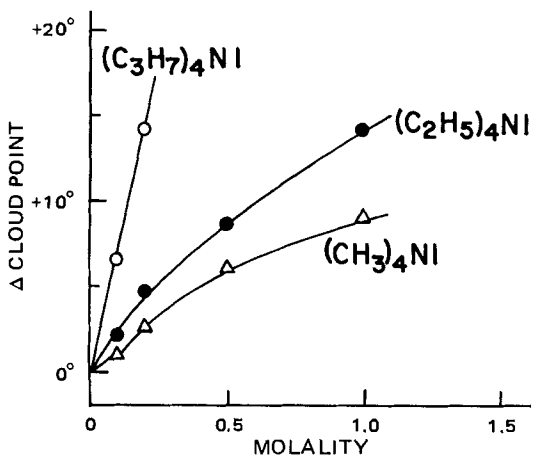

Figure 3—*Change in the cloud point of octoxynol as a function of the molal concentrations of added iodides.*

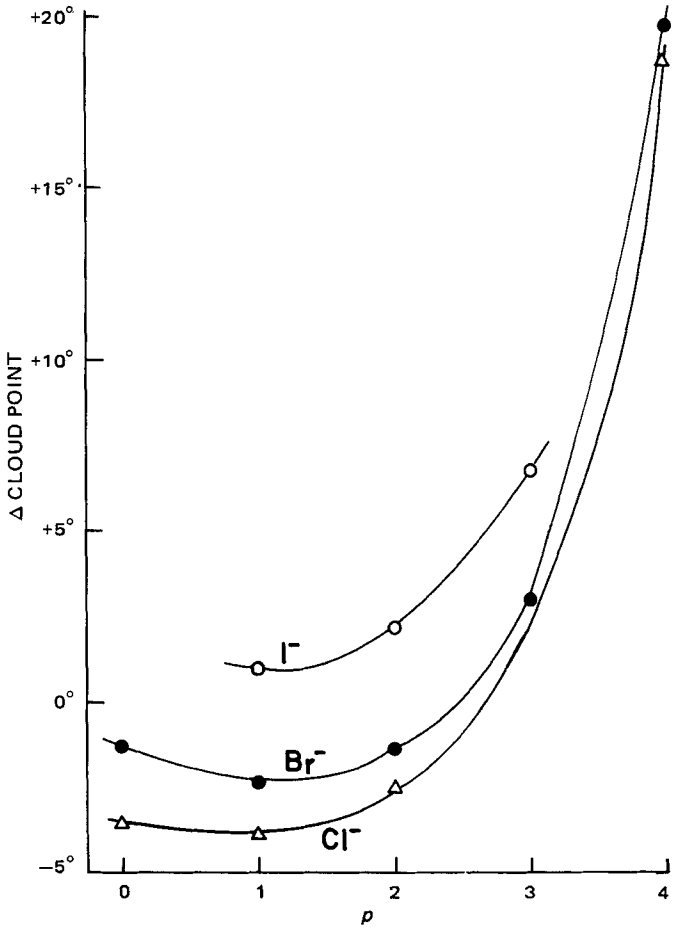

Figure 4—*Effect of chain length of the tetraalkylammonium ion on the cloud point of octoxynol at 0.10-molal electrolyte concentration;* p = *number of carbon atoms per alkyl group.*

entropy on dissolving a tetraalkylammonium salt in water compared with its dissolution in an unstructured organic solvent (4). Evidence of the enhanced water structure is the high viscosity and molal heat capacity of aqueous solutions of tetraalkylammonium halides (7).

As structure makers, tetraalkylammonium halides enhance the association among water molecules to the detriment of the hydration of the surfactant molecules. Thus, these electrolytes should salt the surfactant out. The observed increases in cloud point produced by the tetrapropyl- and tetrabutylammonium salts are in direct opposition to their structure-making activity. This finding indicates that a mechanism other than their effect on water structure is responsible for their salting-in or cloud point-raising ability. The new mechanism must be strong enough to overcome the effect of enhanced water structure formation by the tetrapropyl- and tetrabutylammonium ions, because this effect consists in reducing the solubility of nonelectrolytes or salting out. It is likely that at the cloud point temperature of 64° in the absence of electrolytes, the "icebergs" or "flickering clusters" (21) are largely melted or broken up. The tetrapropyl- and tetrabutylammonium salts boosted the cloud point to even higher temperatures, the latter above 80°, where these water structures cannot persist even in the presence of structure-making salts.

Electrolyte Association—Tetraalkylammonium halides reportedly associate in aqueous solution, either by cation–cation pairing (22) or by micelle formation (5, 23–25). The evidence for micellization is not supported by surface tension measurements (26) and could also be construed as indicating hydrotropy (27). The latter possibility is discussed in the *Appendix*. However, there is a strong likelihood that octoxynol and the tetraalkylammonium halides form mixed micelles, since the critical micelle concentration (CMC) of octoxynol is far below the 1.00% use level even at room temperature. Nonionic surfactants have a pronounced tendency to form mixed micelles with anionic (28) and cationic (29) surfactants at temperatures above the Krafft point of the ionic surfactants. The cloud points of the nonionic surfactants are considerably raised by comicellization (16, 30).

Of the four cations, ammonium salts do not form micelles. Tetramethylammonium bromide slightly increased the surface tension of water (26) in the manner of inorganic salts and is, therefore, also unlikely to associate into micelles. For the remaining tetraalkylammonium bromides, the decrease in surface tension with increasing salt concentration was steeper the larger their alkyl groups (26). This fact indicates that the tetrabutylammonium salts have the greatest tendency and the tetraethylammonium salts the least tendency toward forming micelles by themselves or mixed micelles with octoxynol. It corroborates the proposed concept of salting in of octoxynol through comicellization.

Ammonium and tetramethylammonium chloride and bromide salt octoxynol out because they are incapable of forming mixed micelles with it. The greater salting-out efficiency of tetramethylammonium salts compared to the corresponding ammonium salts may be due to their greater ability to increase the "ice-like" structure of water and/or to the smaller structure breaking caused by increasing temperatures in their presence. This assumption is corroborated by the observation that, in a group of salts including 15 different cations and eight anions, the tetramethylammonium ion had the largest negative activation energy for viscous flow of all the ions examined. These ions included barium and magnesium, the alkali metal cations and the halide anions, iodate, chlorate, hydroxyl, and sulfate. The ammonium ion had a small negative value. The activation energies of the higher tetraalkylammonium ions were positive and increased in the order tetraethyl-, tetrapropyl-, and tetrabutylammonium (7).

APPENDIX: EFFECT OF A HYDROTROPE ON CLOUD POINT

Hydrotropy is an increase in the water solubility of compounds of low intrinsic solubility by the addition of relatively large amounts of a second solute of high solubility. Such hydrotropic solubilizing agents, while amphiphilic in nature, are not surface active. They do not associate into micelles because their hydrophobic moiety is not large enough (27). Typical hydrotropes are alkali salts of benzene-, toluene-, xylene-, or cymenesulfonic acids and of benzoic, salicylic, or phthalic acids (27, 31, 32).

Even though hydrotropes are widely used as solubilizing or salting-in agents, their effect on the cloud point of polyoxyethylated nonionic surfactants has not been investigated. To examine the possibility that the salting-in action of the tetrapropyl- and tetrabutylammonium salts discussed may be one of hydrotropy, it became necessary to measure the effect of a typical hydrotrope on the cloud point of octoxynol to compare its direction and magnitude with those of the higher tetraalkylammonium salts.

The hydrotrope selected was sodium *m*-xylenesulfonate. The cloud points of solutions containing 2.00% (w/w) octoxynol at different hydrotrope concentrations were as follows: 64.7° in the absence of hydrotrope, 82.5° in the presence of 0.061 molal (1.25%) hydrotrope, 92.5° in the presence of 0.123 molal (2.50%) hydrotrope, and above 99° in the presence of 0.253 molal (5.00%) hydrotrope.

Interpolation places the cloud point of octoxynol in 0.10 molal sodium xylenesulfonate at 90°, compared to 83 and 84° in 0.10 molal tetrabutylammonium chloride and bromide, respectively (Table I). Sodium xylenesulfonate is more effective in raising the cloud point of the surfactant than the two tetrabutylammonium salts. If the trend of larger cloud point increases with increasing p values (Fig. 4) can be extrapolated, the tetrabutylammonium iodide or the tetrapentylammonium bromide would be more effective in salting the surfactant in than the anionic hydrotrope. The cloud point increases produced by the higher tetraalkylammonium salts and by a typical hydrotrope are thus of the same order of magnitude. Therefore, hydrotropy is another possible mechanism for the salting in of octoxynol by tetraalkylammonium salts instead of the formation of mixed micelles proposed.

The phenomenon of hydrotropy is poorly understood at the molecular level (27, 33). In our opinion, solutions of hydrotropes at the customary concentrated use levels contain patches that are largely oleophilic because of high local concentrations of aromatic groups. These hydrocarbon patches are not unlike the hydrocarbon cores of micelles but lack the precise boundaries of the latter. The formation of such patches with an increasing hydrotrope concentration is much more gradual than the sudden formation of micelles by surfactants once the CMC is exceeded. Nevertheless, the two phenomena may be so similar that the differences in the salting in of octoxynol by tetrapropyl- and tetrabutylammonium salts *via* mixed micelle formation and *via* hydrotropy are more semantic than based on physical reality. The higher tetraalkylammonium salts resemble some conventional hydrotropes in general composition (33). That the latter are usually anionic whereas the former are cationic is immaterial as far as their interaction with a nonionic surfactant is concerned.

Stereochemistry of Metabolism of Amphetamines: Use of (−)-α-Methoxy-α-(trifluoromethyl)phenylacetyl Chloride for GLC Resolution of Chiral Amines

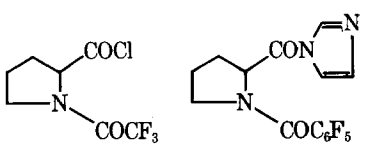
JOSEPH GAL

Abstract □ Amphetamine and eight related compounds were reacted with the chiral acylating reagent (−)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride to obtain, in each case, two diastereomeric amide derivatives. GLC conditions were found for the separation of the diastereomers in seven of the nine cases studied. This procedure may be suitable for the resolution of amino acid enantiomers *via* the amide derivatives of the methyl esters. Secondary amines were not derivatized under the reaction conditions used. A correlation between absolute configuration and elution order of the diastereomeric amides was observed for five compounds. The chiral acylating reagent was used in the determination of the enantiomeric composition of 2,5-dimethoxy-4-methylamphetamine excreted in rat urine after intraperitoneal drug administration. The chiral acylating reagent is suitable for the determination of the optical composition of compounds extracted from biological fluids.

Keyphrases □ Amphetamine and related compounds—reacted with chiral acylating reagent, GLC separation of diastereomeric amide derivatives □ Chiral acylating reagents—(−)-α-methoxy-α-(trifluoromethyl)phenylacetyl chloride, reacted with amphetamine and related compounds, GLC separation of diastereomeric amide derivatives □ GLC—separation of diastereomeric amide derivatives of amphetamine and related compounds after reaction with chiral acylating reagent □ Stereochemistry—amphetamine and related compounds, reacted with chiral acylating reagent, GLC separation of diastereomeric amide derivatives □ Stimulants—amphetamine and related compounds, reacted with chiral acylating reagent, GLC separation of diastereomeric amide derivatives

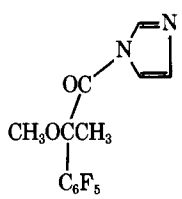
While studying the stereochemistry of the metabolism of amphetamine (1-phenyl-2-aminopropane) derivatives, it was necessary to determine the enantiomeric compositions of several members of this class of compounds extracted in small amounts from biological fluids. A literature survey revealed that derivatization of an amphetamine with chiral acylating reagent I (1), II (2), or III (3), followed by GLC separation of the resulting diastereomeric amides, provides a sensitive analytical method for the determination of the enantiomeric composition of the parent amine extracted from a biological medium.

However, none of these compounds was deemed entirely satisfactory for this study. Compound I, an *l*-proline derivative, is easily racemized (1, 4), and commercial samples are contaminated with about 6–10% of the *d*-form. Attempts to achieve the resolution of *p*-methoxyamphetamine by derivatization with I failed, since five GLC bands were obtained when the reaction product was injected into the gas chromatograph. Others also reported (4) difficulties with I, although the reagent has been successfully used (5, 6).

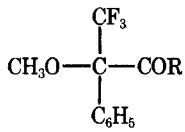


I

II



III



IV: R = OH
V: R = Cl

Compound II is highly suitable for electron-capture GLC due to the pentafluorophenyl group and has been employed with good results in the determination of the optical composition of a ring-substituted amphetamine derivative in metabolic studies (7). However, II provides poor GLC separation of the diastereomeric amides derived from amphetamine (2). Finally, III also appeared impractical since it must be synthesized *via* an elaborate route and its precursor carboxylic acid must be resolved (3). For these reasons, an alternative chiral reagent was sought.

Dale *et al.* (8) first reported the synthesis of α-methoxy-α-(trifluoromethyl)phenylacetic acid (IV) and its application to the determination of the enantiomeric purity of amines and alcohols by fluorine and proton NMR. Nichols *et al.* (4) extended the use of IV to the GLC determination of the enantiomeric purity of amphetamine derivatives prepared *via* a new asymmetric synthesis. Acid IV, lacking α-hydrogens, is highly resistant to racemization (8) and is commercially available in its resolved form[1]. In this paper, the applicability of IV to the GLC resolution of several amines of pharmacological interest is examined, and the suitability of this reagent for the determination of the enantiomeric composition of an amphetamine derivative excreted in rat urine is demonstrated.

EXPERIMENTAL

Materials—(*R,S*)- and (*S*)-Amphetamines[2] (VI), (*R,S*)- and (*R*)-*p*-hydroxyamphetamine[2] hydrobromides, (*R,S*)- and (*R*)-phenylalanine methyl ester[3] (VII) hydrochlorides, (*R,S*)- and (*S*)-α-methylbenzylamines[1] (VIII), (*R,S*)-*p*-chloroamphetamine[4] (IX) hydrochloride, (*R,S*)-β-phenylisopropylhydrazine[4] (X) hydrochloride, (*R,S*)-tranylcypromine[4] (XI) hydrochloride, and (*R,S*)-*p*-chlorophenylalanine[4] were obtained from commercial sources. (*R,S*)-*p*-Chlorophenylalanine methyl ester (XII) was prepared from the amino acid by the method of Brenner and Huber (9), using methanolic thionyl chloride. The treatment of (*R,S*)- and (*R*)-*p*-hydroxyamphetamines with diazomethane gave the corresponding *p*-methoxy compounds, (*R,S*)- and (*R*)-XIII. Samples of (*R,S*)- and (*R*)-2,5-dimethoxy-4-methylamphetamines (XIV) were donated[5].

The preparation (8) of V was carried out by refluxing for 50 hr a mixture of IV (1.0 g) and freshly distilled thionyl chloride (3 ml). The excess thionyl chloride was removed under reduced pressure (~30 mm), and the crude V was dissolved in 10 ml of 1,2-dichloroethane (XV). The solution

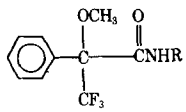
Table I—GLC Data on Amides Derived from (—)-IV and Various Amines



Amine Precursor	Retention Times of Diastereomers, min	Column Temperature	Resolution Factor[b]
VI	12.4[c], 14.0[d]	185°	1.4
XIII	12.5[c], 14.1[d]	210°	1.6
XIV	11.4[c], 13.6[d]	220°	2.3
IX	5.3, 6.0	210°	1.5
VII	11.6[d], 12.8[c]	206°	1.4
XII	8.4, 9.5	215°	1.5
VIII	13.4[c], 14.9[d]	175°	1.4

[a] See *Experimental* for GLC conditions. [b] See Ref. 11. Note that when the resolution factor = 1.0, the peak resolution is about 98% complete; when the resolution factor = 1.5, baseline separation (99.7%) is achieved. [c] From (*R*)-amine. [d] From (*S*)-amine.

was stored in a rubber-septum-capped bottle in a refrigerator. This reagent solution was used in the derivatizations.

Organic solvents used in the analytical procedures were of spectral quality grade.

GLC Analysis—GLC was carried out on two gas chromatographs[6,7], both equipped with flame-ionization detectors. System I[6], used to obtain the data in Table I and Fig. 1, consisted of a U-shaped glass column, 1.8 m × 0.2 cm i.d., packed with 3.0% phenyl methyl silicone[8] coated on acid-washed, dimethylchlorosilane-treated diatomite support[9]. The column temperatures used are given in Table I; the injector temperature was 250°, the detector temperature was 280°, and the nitrogen flow rate was 30 ml/min.

GLC System II[7], used for the analysis of XIV extracted from urine and derivatized with V, was performed using a coiled glass column of the same dimensions and containing the same packing as the column of System I. The nitrogen carrier gas rate was 20 ml/min. The ratios of diastereomeric amide derivatives of XIV were calculated from the area percent data of each peak provided by the instrument.

Mass Spectrometry—A quadrupole GLC–mass spectrometry system[10] was used with the GLC conditions given for GLC System II, except helium carrier gas was used at a flow rate of 50 ml/min.

Animal Procedures—Male Sprague–Dawley rats, 250–300 g, were given XIV hydrochloride (5 mg/kg ip) in saline or saline only. The animals were housed in individual metabolic cages with free access to food and water. Urine was collected for 24 hr.

Extraction, Purification, and Derivatization of XIV—To 4 ml of urine in a 20-ml screw-capped test tube were added 0.4 ml of 5 *N* NaOH and 6 ml of heptane. The mixture was shaken mechanically[11] for 15 min. After centrifugation for 10 min, 5 ml of heptane was transferred to a 12-ml conical screw-capped centrifuge tube containing 0.6 ml of 1 *N* HCl. The tubes were shaken for 10 min and centrifuged for 5 min. The heptane was aspirated and discarded.

One 500-μl aliquot of the acidic lower phase was removed with a micropipet and transferred to another conical centrifuge tube containing 1.2 ml of benzene and 0.2 ml of 5 *N* NaOH. After shaking for 15 min and centrifuging for 5 min, 1.0 ml of benzene was transferred to a 3-ml microcentrifuge tube[12], and the benzene was evaporated in a stream of nitrogen. To the residue were added 50 μl of the reagent solution of V and 10 μl of pyridine, and the mixture was swirled on a mixer[13] for 10 sec. The tube was then capped and heated at 70° for 30 min, followed by cooling in ice for 5 min.

The reaction mixture was treated with 1 ml of 1 *N* HCl, and the tube was shaken for 5 min and centrifuged for 5 min. The acidic upper layer was aspirated off and discarded, and 0.4 ml of 15% Na_2CO_3 was added to the tube. The tube was then shaken for 10 min and centrifuged for 10 min, followed by GLC analysis of the lower organic layer as described.

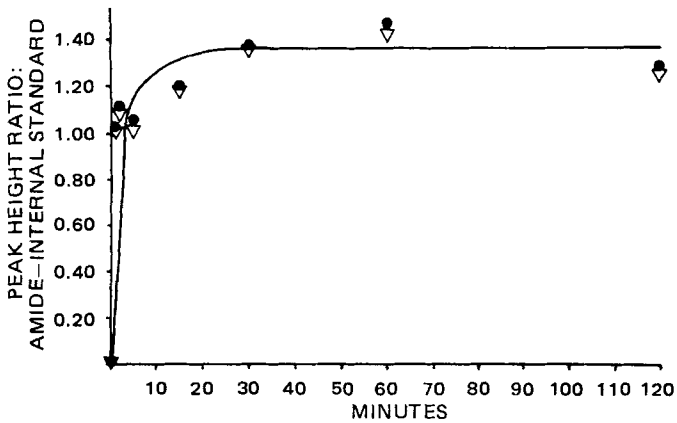

Figure 1—*Rates of formation of amides from V and (R)-VI (●) and (S)-VI (▽). See* Experimental *for reaction conditions and analytical procedure.*

Derivatization of Pure Compounds—The amine or amine salt (0.1–0.2 mg) in a conical screw-capped tube was treated with XV (50 μl), V reagent solution (50 μl), and pyridine (20 μl). The tube was heated in an oil bath at 70° for 30 min and then cooled in an ice bath. Hydrochloric acid (1 *N*, 1 ml) was added, and the tube was shaken mechanically for 5 min and centrifuged at 3000 rpm for 10 min. The aqueous acid layer was aspirated off, and 15% sodium carbonate solution (0.5 ml) and XV (100 μl) were added. The tube was shaken for 5 min and centrifuged for 10 min. The organic phase was then analyzed by GLC.

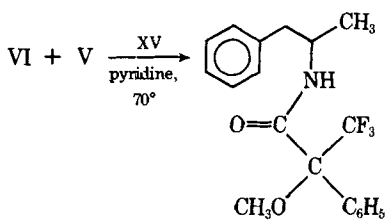
Rate of Formation of Derivatives—To a solution of (*R,S*)-amphetamine (2.0 mg) in 100 μl of XV was added 40 μl of dry pyridine. The solution was heated to 70°, 100 μl of the V reagent solution was added, and the stopwatch was started. At the appropriate times, a 25-μl aliquot was withdrawn and added to an ice-cold mixture containing 100 μl of XV, 1.0 ml of 1 *N* HCl, and 100 μl of a 10 m*M* solution of the internal standard, 1-methoxymethyl-3-methylphenobarbital (10).

The mixture was swirled for 15 sec and then frozen in dry ice–acetone until all of the time-point samples had been collected. The tubes were then shaken for 5 min and centrifuged for 10 min. The aqueous layer was aspirated off, 100 μl of 15% Na_2CO_3 solution was added, and the mixture was shaken for 5 min and centrifuged for 10 min. The organic layer was then analyzed by GLC.

RESULTS AND DISCUSSION

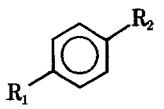
Acid IV was converted to V, its acid chloride (8), which could be used to acylate amines. The reaction (Scheme I) of V with racemic amphetamine at 70°, catalyzed by pyridine, was studied as a function of time (Fig. 1). The reaction was essentially complete in 30 min, and the product amides appeared to be stable under the reaction conditions. This short reaction time allows the use of the reagent in routine procedures where overnight reaction times (4) would be cumbersome.

Several amines (VI, VIII, IX, XI, XIII, and XIV), a hydrazine derivative (X), and two amino acid esters (VII and XII) were derivatized with V. The free base or a salt (*e.g.*, hydrochloride or sulfate) could be used in the acylation reaction with identical results. With two exceptions, the resulting diastereomeric amides[14] were well resolved by GLC (Table I). The identity of the product amides in Table I was confirmed by GLC–mass spectrometry. All amides gave a molecular ion[15].

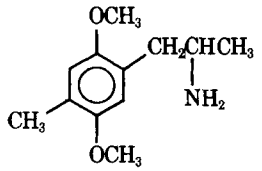


Scheme I

[14] All of the amides prepared were derived from (−)-IV.
[15] A detailed study of the mass spectral fragmentation of the amides prepared will be published.



VI: R_1 = H, R_2 = $CH_2CH(NH_2)CH_3$
VII: R_1 = H, R_2 = $CH_2CH(NH_2)COOCH_3$
VIII: R_1 = H, R_2 = $CH(CH_3)NH_2$
IX: R_1 = Cl, R_2 = $CH_2CH(NH_2)CH_3$
X: R_1 = H, R_2 = $CH_2CH(NHNH_2)CH_3$
XI: R_1 = H, R_2 = *trans*-cyclo-$(C_3H_4)NH_2$
XII: R_1 = Cl, R_2 = $CH_2CH(NH_2)COOCH_3$
XIII: R_1 = OCH_3, R_2 = $CH_2CH(NH_2)CH_3$



XIV

The successful resolution of the enantiomers of VII and XII indicates that V may be suitable for the resolution of amino acids (as their methyl esters), an area of considerable current interest (12). Two compounds, X and XI, gave diastereomeric amides that were not sufficiently resolved under the GLC conditions used, since only a slight "fork" at the top of the peak was observed in each case.

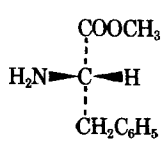
Attempts to derivatize secondary amines, *e.g.*, *N*-methylamphetamine, showed that the reaction of these amines with V was considerably slower than the reaction of primary amines. Under the reaction conditions used, secondary amines remained essentially underivatized.

Compounds VI–VIII, XIII, and XIV were available in their resolved form and, since their absolute configurations are known, the relationship between the elution order of their diastereomeric amide derivatives and absolute configuration could be examined. As seen from Table I, with one exception, the amides derived from the (*R*)-amines had shorter retention times than those from the corresponding (*S*)-amines, in agreement with the findings of Nichols *et al.* (4). The exception was VII, where the amide from (*S*)-VII eluted before the amide from (*R*)-VII. This finding is stereochemically logical, since (*S*)-VII and (*R*)-amphetamines have corresponding configurations, even though the configurational notations are opposite.

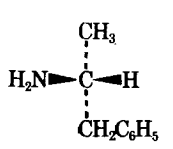
Among the desirable characteristics of a chiral reagent suitable for routine use in biological studies are: (*a*) ready availability in resolved form, (*b*) chemical stability and resistance to racemization, (*c*) simple derivatization procedure and workup, (*d*) good GLC resolution of the diastereomeric derivatives without unduly long retention times, and (*e*) high response of the derivatives to the GLC detector. While no chiral reagent has yet been developed that is superior in all of these considerations, the results described indicate that V offers distinct advantages over reagents I–III. In addition to the earlier mentioned ready availability and stability of V, this reagent was superior to I–III in providing better GLC resolution in cases where comparison could be made. For example, VI (5, 6), VII (13), and XIII (14) were derivatized with reagent I; VI, VIII, and XIV were resolved with II (2) and III (3). In these cases, V tended to give better resolution and/or shorter retention times. However, II and III gave derivatives with excellent electron-capture properties, most likely not equaled by those of V, which lacks the pentafluorophenyl group. This disadvantage of the derivatives of V may be partially overcome by using GLC–mass spectrometry in the selected-ion-monitoring mode, which provides extremely high sensitivity (15). Experiments in this direction are in progress.

By using a flame-ionization detector, the minimum detectable amount of V-derivatized (*R*)- or (*S*)-amphetamine was of the order of 1×10^{-13} mole/sec or 5 ng of sample injected.

The applicability of V to metabolic studies was tested by examining an aspect of the stereochemistry of the *in vivo* metabolism of XIV. The



(*S*)-VII



(*R*)-amphetamine

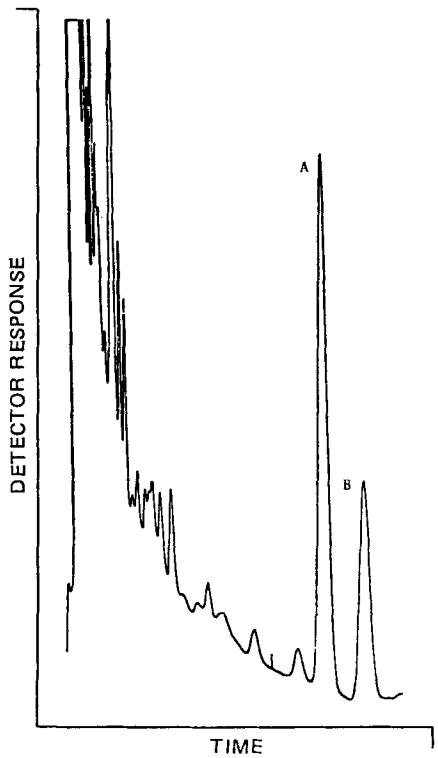


Figure 2—*Gas chromatogram of V-derivatized XIV extracted from rat urine. Key: A, derivative from* (R)*-XIV; and B, derivative from* (S)*-XIV. See* Experimental *for GLC conditions.*

metabolic fate of this compound, a potent psychotomimetic agent (16, 17), was studied in the rabbit (7, 18) and rat (19). Since the psychotomimetic activity of XIV resides in the (*R*)-enantiomer but not in the (*S*)-enantiomer (20), some investigators have paid special attention to the stereochemical aspects of its metabolism (7, 18). Thus, it was found (7) that the (*R*)/(*S*) ratio of unchanged XIV excreted in the 24-hr urine of rabbits administered racemic XIV was dose dependent and varied between 1.0 and 1.7.

Since the metabolism of XIV in the rabbit differs from that in the rat (7, 19), it seemed of interest to examine the stereochemistry of unchanged XIV excreted in the urine of rats. Racemic XIV hydrochloride (5 mg/kg ip) in saline was given to rats, and the urine was collected for 24 hr. Unchanged XIV was extracted from urine using a multistep procedure (21), which purifies and concentrates the amine before derivatization. Reaction with V was followed by GLC analysis. No peaks attributable to the amide derivatives of XIV were observed when the urine of the two animals given saline only was analyzed. The (*R*)/(*S*) ratio of XIV in the urine of three animals given the drug was 2.0, 2.1, and 1.3, respectively. Figure 2 shows a typical gas chromatogram of V-derivatized XIV extracted from rat urine.

The amount of unchanged XIV excreted was not determined, although it was reported (19) that 5% of a 5-mg/kg ip dose of racemic hydrochloride appeared as unchanged XIV in the 24-hr urine of rats. The magnitude of the (*R*)/(*S*) ratio of XIV found in rat urine is in the same direction as that observed in rabbits (7). However, at the 5-mg/kg dose level, the (*R*)/(*S*) ratio in rabbits was 1.0 and reached 1.7 only at 21 mg/kg (7).

Differences in pharmacological activity and in disposition between enantiomers of amphetamines and of related compounds are receiving considerable attention (7, 17, 22–24). Resolution of the optical isomers by GLC of diastereomeric derivatives may be useful in studying such differences. Compound V is an important addition to the list of chiral acylating agents (3, 25, 26) used for this purpose.

Use of Microcapsules as Timed-Release Parenteral Dosage Form: Application as Radiopharmaceutical Imaging Agent

JOHN D. SCHEU *, GLEN J. SPERANDIO, STANLEY M. SHAW, ROBERT R. LANDOLT, and GARNET E. PECK ˣ

Abstract □ The development of a new type of parenteral dosage form is described. A system of microencapsulation was formulated which produced microcapsules containing a water-soluble core material. The basic microencapsulation system could be altered to produce microcapsules with varied timed-release characteristics. Tracer methodology was employed as a sensitive and versatile analytical tool for the development and evaluation of the microencapsulation system. The core material was labeled by neutron activation after microcapsule formulation, which eliminated the radiation hazard and contamination problems that could occur during formulation with a labeled core material. Both *in vitro* and *in vivo* testing showed that the release patterns of labeled core material could be altered and detected. The microcapsules developed have potential as a timed-release parenteral dosage form and as an organ-imaging radiopharmaceutical.

Keyphrases □ Microcapsules—formulated, potential as timed-release parenteral dosage form and organ-imaging radiopharmaceutical evaluated *in vitro* and *in vivo*, mice □ Dosage forms, parenteral—timed-release microcapsules formulated, evaluated *in vitro* and *in vivo*, mice □ Radiopharmaceuticals—timed-release microcapsules formulated, potential use in organ imaging evaluated, mice

A dependable parenteral timed-release dosage form would eliminate many problems associated with oral administration. The process of microencapsulation may hold the key to the ideal timed-release dosage form because of the smallness of the produced microcapsules and the various properties instilled into the microcapsules. However, such a dosage form must contain microcapsules with very precise properties.

The main objective of this investigation was to develop a microencapsulating system that utilized a water-soluble polymer as the chief capsule wall component and allowed for the encapsulation of a water-soluble material. Other desired characteristics included microcapsules from 1 to 20 μm in diameter and formulation flexibility allowing alterations in core release rates. Tracer methodology was selected as the analytical tool for evaluation of the microcapsules. A second objective was to produce radioactivity in the core material by neutron activation after formulation. *In vitro* and *in vivo* test procedures were derived to evaluate the microcapsules as a timed-release parenteral dosage form and as a radiopharmaceutical imaging agent.

EXPERIMENTAL

Basic Procedure—Coacervation was selected as the microencapsulation method after a review of other methods (1–16). The following general procedure (Table I) was used in preparing all microcapsules.

Forty milliliters of dioxane[1], analytical grade, was added to a 50-ml beaker. A 1.25-cm magnetic stirrer bar was placed in the beaker, which

[a] Variable.

was then positioned on a stirrer hot plate and warmed to 35° (the time can vary). Glycerin USP was added and allowed to go into solution. Heating was terminated, and the magnetic stirrer was removed.

The beaker was then placed in an ultrasonic bath[2]. Micronized core material was added and dispersed by holding the beaker in the bath for 30 sec. When the core material was well dispersed, polyethyleneimine-18[3] solution was added, and the beaker was held in the ultrasonic bath for 15 more sec. The beaker was then removed from the ultrasonic bath, and a pH-controlling agent was added with light stirring.

After the mixture was allowed to stand for a desired length of time, ethylcellulose[4] solution was added with stirring. The ultrasonic bath was again used to disperse the microspheres. Glutaraldehyde[5] solution was added, and the beaker was left standing for 5 min. Then it was placed in a water bath at the desired temperature with moderate agitation for a desired time period. After the beaker was removed from the water bath, the contents were poured into a test tube and centrifuged. The top liquid was decanted off and replaced with fresh dioxane.

The microcapsules were redispersed in dioxane and left standing for 5 min. They were then centrifuged and washed with dioxane. After washing, the microcapsules were poured on a watch glass over a steam bath and allowed to dry. Microcapsules were recovered as a dry fine powder.

Core Material and Neutron Activation—Amaranth was used as the core material in the preliminary development of the microencapsulation system because it is a water-soluble colored material of a complex organic nature. These qualities simplified the microscopic examination of the effects of water on microcapsules. In the later stages of experimentation, gold sodium thiosulfate and sodium chloride were used as core materials. These three materials are water soluble, relatively nontoxic, and compatible with the microencapsulation system, and they can be micronized[6] to a particle size of 1–15 μm and labeled by exposure to a thermal neutron flux. The elemental gold-197 and sodium-23 contained in gold sodium thiosulfate and the sodium-23 in sodium chloride and amaranth were easily activated upon exposure to the thermal neutron flux of a reactor[7].

All samples to be activated in both the encapsulated and unencapsulated form were placed in polyethylene irradiation vials. The samples were then placed in a styrofoam container and lowered down a 10-cm diameter tube located at the face of the reactor core. The reactor was operated at a power level of 900 w, and the sample was irradiated for 60 min. The estimated fluence rate was 10^9 neutrons/cm^2/sec. After neutron exposure, the specific activity of samples was calculated.

Sample Counting—A sodium iodide scintillation crystal (25 × 27.5 cm) with a well[8] (10 × 20 cm) attached to a single-channel analyzer[9] was used in the detection of the γ-rays emitted by gold-198 and sodium-24, which were the respective radionuclides obtained from the activation of gold-197 and sodium-23. Differential counting was used for both nuclides to allow counting of one radionuclide in the presence of the other. Counting correction factors, applied as necessary, included coincidence loss, background, geometry, instrumentation efficiency, and radioactive decay.

Microcapsule Timed-Release Dosage Form *In Vitro* Testing Procedure—An *in vitro* test was designed to evaluate quantitatively the release rate of core material from microcapsules. The procedure allowed test fluid to contact the microcapsules and to leach out the core material contained inside. The core material, being radioactive and in solution, could be sampled and counted and the rate of release could be determined.

The *in vitro* test apparatus (Fig. 1) consisted of a constant-temperature water bath fabricated from a 10-cm deep plastic rectangular container supported by a wood platform. The platform was of sufficient height to allow a magnetic stirrer to be placed underneath. The plastic container was filled with water, which was circulated and kept at 3°. A 12.5-cm, 100-ml graduated cylinder containing a 1.88-cm magnetic stirring rod was placed in the center of the bath directly above the magnetic stirrer. The cylinder was filled with 100 ml of test fluid, which was isotonic sodium chloride solution at pH 7.4.

The *in vitro* test chamber consisted of a glass tube with a syringe on top and a filtering system on the lower portion. Microcapsules were placed within the chamber; the test fluid was drawn in and expelled through the filter, which retained all of the microcapsules. The chamber was supported by a ring stand with the lower portion of the chamber immersed in the test fluid in the graduated cylinder.

The test fluid was drawn into the chamber and expelled at set time intervals. One-milliliter samples of the test fluid in the cylinder were drawn for counting at the end of each expulsion from the test chamber. Then 1 ml of fresh test solution was added to the cylinder to maintain the volume. The procedure was repeated until the desired number of samples was obtained.

The samples were counted, and all necessary counting corrections were made. Based on the count rate of the samples, standards, and microcapsules prior to placement in the test chamber, the amount of core material removed from the microcapsules was determined.

Effect of Hardening Process on Microsphere Droplets—The basic formulation procedure was used to microencapsulate amaranth. During the hardening process, the microsphere droplets were exposed to 0.18 ml of glutaraldehyde at 60°. Samples of the microcapsules were removed after 1.5, 5, and 15 min of exposure and placed on separate glass slides, and a drop of isotonic sodium chloride solution at pH 7.4 was added.

Influence of pH on Dissolution Patterns—To investigate the effect

of pH on the microcapsule properties, gold sodium thiosulfate was encapsulated using the basic formulation procedure except that the pH of the microencapsulating system was varied during the process. The pH was varied by the careful addition of 0.14 ml of hydrochloric acid stock solution[10] to one batch, 0.06 ml of sodium hydroxide stock solution[11] to a second batch, and no pH-controlling agent to the third batch. After the microcapsules were dried and collected, they were exposed to thermal neutrons, counted, and tested *in vitro* as described previously.

Influence of Test Fluid pH—To investigate the influence of test fluid pH on the release of gold-198, procedures similar to those in NF XIV (17) were followed. Two batches of microcapsules were prepared using the basic procedure, and neutron exposure and counting procedures were used as before. One batch was studied *in vitro* with a pH 5 test fluid while the other was placed in a test fluid of pH 7. When a dissolution plateau was reached, sodium hydroxide solution was added to change the pH of the test fluid to 8.

Screening of Microencapsulation Formulations—By using the basic formulation procedure and different combinations of materials, microcapsules were produced containing gold sodium thiosulfate. These microcapsules were exposed to thermal neutrons, counted, and subjected to *in vitro* testing as described previously. In evaluating the formulations, certain values were considered. The ratio between core material weight and encapsulation weight of the microcapsules and the percent of core material placed in the microencapsulated system were used to indicate microencapsulating system efficiency. The amount of core material released during *in vitro* testing within the first 15 min and the amount released at 120 min were important. Also, the difference between the two values was used as a basis for projecting *in vivo* release patterns from *in vitro* data.

[10] Hydrochloric acid stock solution was prepared by adding 0.8 ml of hydrochloric acid, reagent grade, to 29.2 ml of dioxane.

[11] Sodium hydroxide stock solution was prepared by adding 1 ml of 1 *M* NaOH solution, reagent grade, to 29 ml of dioxane.

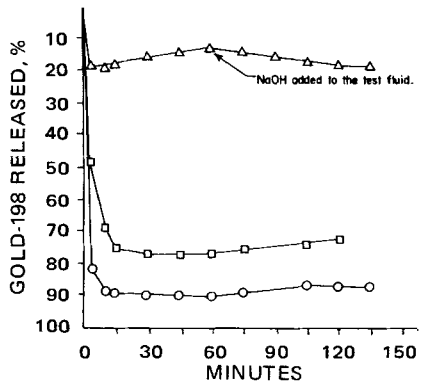

Figure 2—*Effect of the microencapsulation system pH on the release of gold-198. Key:* △, *hydrochloric acid added during microcapsule formation;* □, *no acid or base added during microcapsule formation; and* ○, *sodium hydroxide added during microcapsule formation.*

Five formulations (Table I) produced dissolution curves showing promise for use for either *in vivo* timed-release or radiopharmaceutical imaging studies.

Timed-Release Dosage Form *In Vivo* Testing Procedure—The *in vivo* testing was conducted to determine the levels of gold-198 in the blood and organs of a mouse after the injection of either unencapsulated or microencapsulated labeled gold sodium thiosulfate. The investigation consisted of injecting three groups of 21 mice[12] as follows. The first group was subcutaneously injected with unencapsulated labeled gold sodium thiosulfate. The second group was injected with microcapsules containing labeled gold sodium thiosulfate that had shown a relatively small release of gold-198 *in vitro* (Formulation 1, Table I). The third group was injected with microcapsules containing labeled gold sodium thiosulfate that had shown a timed-release pattern *in vitro* (Formulation 2, Table I).

The microcapsules and unencapsulated gold sodium thiosulfate were exposed to thermal neutrons, and the specific activity of each sample was calculated. The radioactive samples were suspended in a 50% glycerin–water for injection vehicle just prior to administration. To aid in microcapsule dispersion, 0.05 ml of polysorbate 80[13] was added to the injection vehicle. The mixtures were placed in an ultrasonic bath until good dispersion was observed.

Volumes of 0.25 ml of each material containing the same amount of either encapsulated or unencapsulated ^{198}Au-labeled gold sodium thiosulfate were injected subcutaneously behind the heads of 25–30-g mice, using a 1-ml tuberculin syringe fitted with a 26-gauge needle. At 2, 5, 8, 11, 16, 20, and 23 hr, three mice from each group were removed, and blood samples were obtained by means of ocular puncture. Blood was weighed according to the method of tares. The mice were sacrificed; their kidneys, lungs, livers, and spleens were removed, washed with saline, weighed, and stored individually. The remainder of the mouse, which was referred to as the carcass, was weighed and stored.

Each complete mouse was counted in the well detector after dissection by pooling the dissected parts of the mouse and the carcass. The count

rate of the pooled tissues was considered to represent 100% of the gold-198 activity. Organs were counted individually, and the percent of radioactivity in each organ was determined relative to the total mouse. The percent of activity per organ was divided by the milligram weight of the organ, with the resultant data referred to as the percent of total activity per milligram (% *Ta*/mg).

Radiopharmaceutical Imaging Agent *In Vivo* Testing Procedure—This test procedure was conducted to determine if Formulation 1 microcapsules (Table I), which exhibited low release of gold-198, had potential as imaging agents. The influence of microcapsule size on organ distribution was investigated.

Formulation 1 microcapsules were separated by scalping with nylon screens[14] into four size ranges: ≤5, 6–10, 11–15, and ≥16 μm. With a standard light microscope, the sizes were compared to reference pollen samples for verification of the scalping technique. No microcapsules exceeded 20 μm in diameter. Once the microcapsules were separated and dried, they were placed in separate 1-ml polyethylene vials and exposed to thermal neutrons. Unencapsulated gold sodium thiosulfate was also exposed. After exposure, the specific activity of each material was determined. The injection vehicle consisted of water for injection USP with 0.05 ml of polysorbate 80 added.

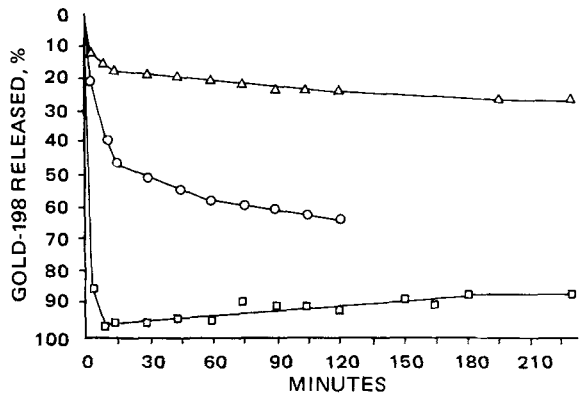

Figure 6—In vitro *release patterns in isotonic test fluid for timed-release dosage form samples later studied* in vivo. *Key:* △, *Formulation 1;* ○, *Formulation 2; and* □, *unencapsulated labeled gold sodium thiosulfate.*

With a 1-ml tuberculin syringe and a 27-gauge needle, 0.2 ml of suspension was injected intravenously into the tail vein of each mouse. Each group of animals consisted of seven mice. One group was injected with unencapsulated labeled gold sodium thiosulfate. A separate group was used for each size range of microcapsules. Two hours after injection, all mice were sacrificed. The liver, spleen, heart, lungs, and kidneys of each mouse were removed. The procedures of counting and calculation were identical to those utilized for testing the microcapsule timed-release dosage form.

RESULTS AND DISCUSSION

Changes in the basic formulation procedure influenced the microcapsules and their properties. Variables noted were: order of mixing of ingredients, temperature of the system during microcapsule formation, strength and type of acid used, the plasticizer, the hardening agent, the concentration, and the length of time microcapsules were hardened. These findings are consistent with those of earlier investigators (10).

The influence of pH during the encapsulation process is illustrated in Fig. 2. The dissolution curves show an alteration in the release of gold-198 activity resulting from variation in pH during this process. The labeled core material discussed throughout this section is based upon the gold-198 activity except where otherwise noted.

During the *in vitro* testing of the microcapsules prepared with hydrochloric acid, sodium hydroxide solution was added after a plateau in gold-198 release occurred (Fig. 2). An immediate increase in activity was noticed in the test fluid, indicating that the test fluid pH influenced the

release of gold-198. The observation was confirmed with additional experimentation. More gold-198 was released from microcapsules in a test fluid of pH 7 than of pH 5 (Fig. 3). The addition of sodium hydroxide solution increased the release of gold-198 after a plateau was reached.

Microscopic examination of microcapsules containing amaranth was used to study the influence of the hardening process on core release. As the time of exposure to the hardening agent was increased, diffusion of the amaranth through the microcapsules decreased. Amaranth was used to aid in defining the hardening process. Figure 4 is representative of microcapsules produced throughout the investigation.

After extensive investigation, five formulations produced dissolution curves showing promise for use as either *in vivo* timed-release agents or radiopharmaceutical imaging agents. The formulations are listed in Table I, and dissolution curves are illustrated in Figs. 5 and 6. The apparent loss in activity by the unencapsulated sample with time (Fig. 6) could be eliminated by the addition of unlabeled gold sodium thiosulfate. This phenomenon was probably due to the adsorption of the labeled material of high specific activity by the test chamber.

The dissolution curves showed that the basic microencapsulation formulation could be altered to produce microcapsules with differing timed-release characteristics. A rather extensive release of gold-198 was attained with Formulations 2–5 in contrast to a limited gold-198 release from Formulation 1. The maximum release of gold-198 was variable among Formulations 2–5. Representative aliquots of formulations prepared for *in vivo* experimentation were subjected to *in vitro* testing. Dissolution curves for the samples are presented in Fig. 6. The release patterns showed that Formulation 1 microcapsules inhibited the release of the labeled core material more than Formulation 2 microcapsules. The dissolution rate for unencapsulated labeled core material was much greater than exhibited by the microcapsules.

***In Vivo* Timed-Release Dosage Form Study**—The percent of total activity per milligram (% *Ta*/mg) of organ, carcass, and blood was calculated for samples obtained during the *in vivo* study. The data, presented as mean values for each group of three mice sacrificed at a particular time period (Figs. 7–12), were subjected to statistical examination. A Burr–Foster test was employed to determine homogeneity of variance of the means; a two-way analysis of variance also was applied, followed by a Newman–Keuls test for comparison of the means.

The results of the statistical analysis showed that the three lines in each figure (Figs. 7–12) were statistically different and distinct from each other at the 95% confidence level. The unencapsulated labeled gold sodium thiosulfate produced the highest activity levels in the blood, kidneys, lungs, spleen, and liver; the least amount of activity remained in the carcass, indicating an extensive removal of the unencapsulated labeled compound from the site of injection. Formulation 1 microcapsules provided the lowest tissue activity levels and resulted in the highest amount of labeled gold sodium thiosulfate remaining at the site of injection. Gold-198 release exhibited by Formulation 2 microcapsules fell between the two extremes shown by unencapsulated gold sodium thiosulfate and Formulation 1 microcapsules. The timed-release data from the *in vivo* study correlated with the data generated by the dissolution curves.

Statistically, there was no evidence at the 95% confidence level that the three lines within each figure (Figs. 7–12) were anything but parallel to each other. If present, differences in slopes were not observed statistically because of the variance error in the data resulting from the small number of animals per time interval and the short duration of the *in vivo* study.

***In Vivo* Radiopharmaceutical Imaging Agent Study**—The data for this phase of the investigation were subjected to statistical examination as in the timed-release phase. The data are presented as a mean value per organ per micrometer particle-size range in Fig. 13.

The gold-198 level in the lungs of animals receiving microcapsules of ≤5, 6–10, and 11–15 μm was statistically greater at the 95% confidence level than the activity present in the lungs of mice receiving unencapsulated labeled gold sodium thiosulfate. The largest lung uptake was observed with 11–15-μm microcapsules. The microcapsules exhibited localization properties favorable for a radiopharmaceutical lung-imaging agent.

No consistent statistical differences were found between the microcapsules of differing micrometer ranges and the unencapsulated labeled gold sodium thiosulfate for the carcass, spleen, kidneys, liver, and heart. The data may reflect the high level of free gold-198 produced in the process of separating the microcapsules into size ranges.

The *in vivo* data only illustrate the applicability of the basic microcapsule formulation for the production of a radiopharmaceutical imaging agent. Extensive experimentation must be conducted to ascertain the true potential of the microcapsules.

SUMMARY AND CONCLUSIONS

A new method of preparing parenteral dosage forms was developed. A system of microencapsulation was formulated that produced microcapsules containing a water-soluble core material. The microcapsules ranged in size from 1 to 20 μm and could be collected as a fine powder. The basic microencapsulation system allowed for many variable changes which affected the properties of the microcapsules. Only a few of these variables and their effects on the microcapsules were studied. Although a great deal of research on this microencapsulation system still must be accomplished, a basic workable process was developed which can serve as a model for further study for parenteral application.

Neutron activation of the microencapsulated core material proved to be an efficient and convenient procedure for producing a radioactive core material. Contamination problems that would occur if the core material was labeled during formulation were avoided. The radioactivity was used as a sensitive and versatile analytical tool in evaluating the microencapsulation system and the properties of the microcapsules.

An *in vitro* test for ascertaining the properties of the microcapsules was developed and proved to be sensitive and reproducible. The test was designed to evaluate the applicability of the labeled microcapsules produced in the study as a timed-release dosage form and as a radiopharmaceutical.

In vitro and *in vivo* experimentation showed that release patterns of labeled core material could be altered by the formulation process. A direct correlation in release patterns was found for microcapsules studied *in vitro* and *in vivo*. The data showed that the basic microencapsulation system developed in this investigation has potential as a timed-release parenteral dosage form.

Microcapsules containing labeled gold sodium thiosulfate concentrated in the lungs after intravenous injection. The potential of the basic microencapsulation system as an *in vivo* diagnostic radiopharmaceutical was illustrated. Further testing is needed to demonstrate the total potential of this microcapsule in the parenteral field.

Interpretation of Plasma Concentration–Time Curves after Oral Dosing

ROBERT A. RONFELD *x **and LESLIE Z. BENET** ‡

Abstract □ The pharmacokinetic information obtained after oral administration is examined using the two-compartment model. Data were obtained by simulation and experimentally by administering sulfisoxazole by an exponential infusion to rabbits. When the absorption rate constant is allowed to approach α, a typical two-compartment oral absorption curve is obtained, which is described by a triexponential equation. However, if the absorption rate constant approaches E_2 (the sum of the elimination rate constants out of the peripheral compartment), the data are adequately fit by a one-compartment model, with the calculated absorption rate equal to α. The relative error in using a one-compartment model to calculate absorption rate constants for two-compartment data is also evaluated.

Keyphrases □ Pharmacokinetics—interpretation of plasma concentration–time curves after oral administration of sulfisoxazole, rabbits □ Absorption rate constants—data fitted to one- and two-compartment models, relative error evaluated, oral administration of sulfisoxazole, rabbits □ Oral administration—sulfisoxazole, interpretation of plasma concentration–time curves, rabbits □ Sulfisoxazole—oral administration, interpretation of plasma concentration–time curves, rabbits □ Antibacterial agents—sulfisoxazole, oral administration, interpretation of plasma concentration–time curves, rabbits

One major problem confronting the drug industry is the correlation of *in vitro* dissolution studies with *in vivo* absorption measurements for oral dosage forms. Information can be gained about the pharmacokinetics of a drug and the relative efficacy of its oral dosage forms from oral plasma concentration–time curves where no data exist describing the drug disposition after intravenous administration. Although it would always be better to have intravenous data in humans, regulations and therapeutic considerations often dictate situations where this kind of data is not available even for drugs in current clinical use. The present work describes a situation where completely invalid measurements of absorption rates would be obtained if previous intravenous measurements had not been made.

The determination of absorption rate constants that depend on the model used to describe the disposition kinetics of the drug after an intravenous dose has been the subject of several publications. Most absorption calculations have been made using a one- or two-compartment body model. The Wagner–Nelson method (1) has been used for drugs seemingly described by the one-compartment model, and the Loo–Riegelman method (2) has been used for those following kinetics consistent with the two-compartment model. The representative equations for the one- (Eq. 1) and two-compartment (Eq. 2) models are:

$$C_p = \frac{k_{a1}FD}{V_d(k_{a1} - k_d)}(e^{-k_d t} - e^{-k_{a1}t}) \qquad \text{(Eq. 1)}$$

and:

$$C_p = \frac{k_{a2}FD}{V_1}\left[\frac{(E_2 - k_{a2})}{(\alpha - k_{a2})(\beta - k_{a2})}e^{-k_{a2}t} + \frac{(E_2 - \alpha)}{(\beta - \alpha)(k_{a2} - \alpha)}e^{-\alpha t} + \frac{(E_2 - \beta)}{(\alpha - \beta)(k_{a2} - \beta)}e^{-\beta t}\right] \qquad \text{(Eq. 2)}$$

where:

C_p = plasma concentration
FD = available dose
k_{a1} = absorption rate constant, one-compartment body model
k_{a2} = absorption rate constant, two-compartment body model
k_d = elimination rate constant, one-compartment body model
E_2 = sum of the exit (or micro) rate constants out of Compartment 2 in a two-compartment model
α, β = disposition (or macro) constants describing distribution and elimination in a two-compartment model
V_d, V_c = volumes of distribution for a one-compartment model and central compartment of a two-compartment model, respectively.

The term "flip-flop model" has been used recently to illustrate the nonuniqueness of any concentration–time curve believed to describe first-order input and disposition from a one-compartment pharmacokinetic model, since the slow rate constant may be attributed to *either* absorption or elimination and the fast rate constant may be attributed to the alternate. Therefore, it is impossible to tell from a single curve (following an oral dose) whether the terminal half-life is due to absorption or elimination. The two-compartment model is somewhat more unique in that it does take on characteristic shapes depending on the relative size of the absorption rate constant with respect to α, β, or E_2.

In this study, generated curves are used to illustrate characteristic shapes and to compare one- and two-compartment analyses. In addition, representative curves were obtained experimentally in the rabbit, using sulfisoxazole [N^1-(3,4-dimethyl-5-isoxazolyl)sulfanilamide]. Oral absorption was simulated experimentally with a logarithmic infusion.

EXPERIMENTAL

The left and right marginal ear veins of 4-kg rabbits were cannulated[1], one ear being used for chronic sampling and the other ear for drug administration. One-milliliter blood samples were taken at frequent intervals and analyzed according to the Bratton–Marshall method (3). Initially, the drug was administered as a bolus injection, and the disposition parameters were calculated from the plasma concentration–time curve.

Subsequent experiments were run in which oral absorption was simulated by administering the drug by a first-order intravenous infusion, accomplished by exponential dilution of a drug solution with the apparatus represented in Fig. 1. A 5–10-ml disposable syringe (pictured) on the left was fixed at a constant volume, while a 50-100-ml syringe in a Harvard syringe pump determined the flow and constantly diluted the

[1] Intracath catheter sets.

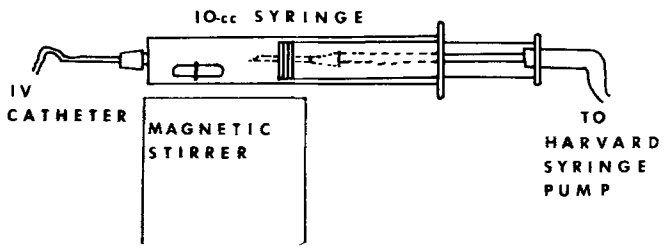

Figure 1—*Apparatus used to administer first-order infusions intravenously.*

contents in the small syringe with dextrose (5%). A magnetic stirring bar was activated in the small syringe to ensure proper mixing. Any first-order infusion rate can be obtained by proper selection of the infusion rate in milliliters per minute on the Harvard infusion pump and the appropriate fixed volume of the small syringe.

The value of the simulated first-order absorption rate constant is equal to the zero-order infusion rate (maintained with the infusion pump) divided by the fixed volume in the small syringe. Each infusion was continued until at least 97% of the dose was administered. Both the experimental sulfisoxazole data and the generated data were fit on a digital computer[2] using the nonlinear least-squares fitting program NONLIN (4).

RESULTS AND DISCUSSION

Analysis of oral data can be very inexact, since oral absorption often adds more than one variable to the intravenous data even though the data appear to be fit adequately by addition of a single exponential term and an availability constant. However, this "smoothed" interpretation of the absorption process may include variations due to nonlinearities in dosage form release and dissolution of the drug, first-pass effects and decreased physiological availability, stomach emptying, biliary recycling, blood flow to the GI tract, and other problems of non-first-order absorption related to distribution into and diffusion through the GI membrane. However, despite the complexity of the absorption process, there are numerous examples of oral absorption being adequately described by a single first-order process. This may be due to the lack of sufficient blood level data to model the absorption process precisely or to the fact that one of these processes becomes rate limiting, thereby simplifying the absorption mechanism into a process that may be described by a single exponential term.

A single first-order absorption process, commonly used in pharmacokinetic modeling, is assumed for the remainder of this discussion. If absorption can be represented by a first-order process, then, in the case of the two-compartment model, the shape of the blood level curve can

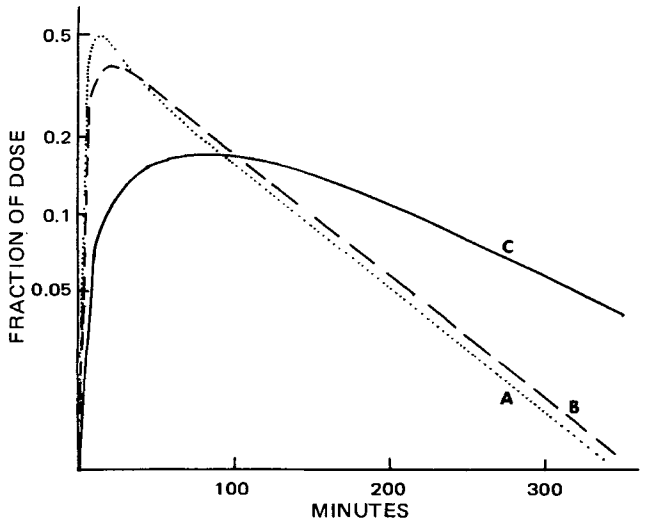

Figure 2—*Blood level curves for two-compartment model following first-order absorption. Key: A,* $k_{a2} \simeq \alpha$; *B,* $k_{a2} \simeq E_2$; *and C,* $k_{a2} \simeq \beta$.

Table I—Comparison of One-Compartment Analysis of Two-Compartment-Generated Data

Case	Two Compartment[a], k_{a2}, hr^{-1}	One Compartment	
		k_{a1}, hr^{-1}	k_d, hr^{-1}
A	7.2	25.9	0.83
D	5.4	14.1	0.76
B	3.6	7.54	0.67
E	1.8	2.58	0.61
C	0.6	1.10	0.40

[a] The two-compartment rate constants were $\alpha = 7.46\ hr^{-1}$, $\beta = 0.67\ hr^{-1}$, and $E_2 = 3.57\ hr^{-1}$.

be indicative of the relative size of the absorption rate constant. Figure 2 illustrates three blood level curves, generated using the same two-compartment rate constants (given in the left-hand side of Table I) and differing only in the absorption rate constants following oral dosing. Curve A is characterized by a "nose," which can be visualized by extrapolating back the log-linear line and having a convex curve lie above it. Curve A is generally thought to be characteristic of a two-compartment model, whereas curve B is often representative of a one-compartment model.

Curve A in Fig. 2 is an example of a case where the absorption rate constant approached α ($k_{a2} = 7.2$, $\alpha = 7.46$). When referring to Eq. 2, it is important to realize that although two of the exponentials are almost equal to each other, this triexponential equation does not simplify to a biexponential equation. This predominant nose is characteristic of a two-compartment model when k_{a2} is larger than E_2 and approaching or larger than α. However, based on oral data alone, it is not possible to predict whether the larger rate constant in the triexponential equation describing this curve should be assigned to k_{a2} or α.

Curve B of Fig. 2 illustrates a curve apparently following a one-compartment model. Actually, this curve was generated with the two-compartment equation and the rate constants given in the left-hand side of Table I, but with k_{a2} very nearly equal to E_2 ($k_{a2} = 3.6$, $E_2 = 3.57$). This curve could be perfectly fit to a one-compartment model. The slow rate constant could be correctly assigned to β. However, the fast rate constant, regardless of whether it was obtained by the method of residuals or by a computer fit, would not be equal to the absorption rate constant k_{a2} but rather equal to α. This result can be explained quite easily by referring to Eq. 2. As k_{a2} approaches E_2, the coefficient of the exponential term describing absorption approaches zero.

Curves A and B in Fig. 2 could present a perplexing problem if they resulted from the administration of two different dosage forms of the same drug. That is, both dosage forms seem to be equally available (from a comparison of areas under the curves) and to have the same slow rate of disposition from the body (both curves are parallel and log linear after 1 hr). However, dosage form B appears to follow a one-compartment body model and dosage form A follows a two-compartment body model. And, if each set of data is treated by the seemingly appropriate model, the absorption rates calculated would almost be equal.

Curve C in Fig. 2 is an example of a case where k_{a2} is allowed to approach β ($k_{a2} = 0.6$, $\beta = 0.67$). Here, it appears that the data could be fit by either a one- or two-compartment model, depending upon the number and preciseness of the data points. Even though this curve is described by a triexponential equation, it will not have the characteristic nose of curve A. If the oral blood curve is of this form, it is not possible to make a unique assignment of the slow rate constant to either β or k_{a2} when only a single oral data curve is available.

Even though the investigator may fit oral data to the seemingly appropriate model, significant errors may occur when interpreting and comparing the absorption rate constants. In cases such as these, inconsistencies between the relative absorption rate constants and relative times of peak concentration may arise. Time of peak concentration should be a reliable relative measurement since it is model independent. That is, from the peak times in Fig. 2, the investigator should know that the absorption rate constant for curve A is greater than that for curve B, which is greater than that for curve C. However, due to experimental error, it is often difficult to define the peak time precisely. In addition, any lag time greatly influences the peak time and may invalidate comparisons between different dosage forms based upon peak time measurements.

Similar data obtained experimentally for sulfisoxazole are pictured in Fig. 3. The parameters obtained after an intravenous dose (curve A)

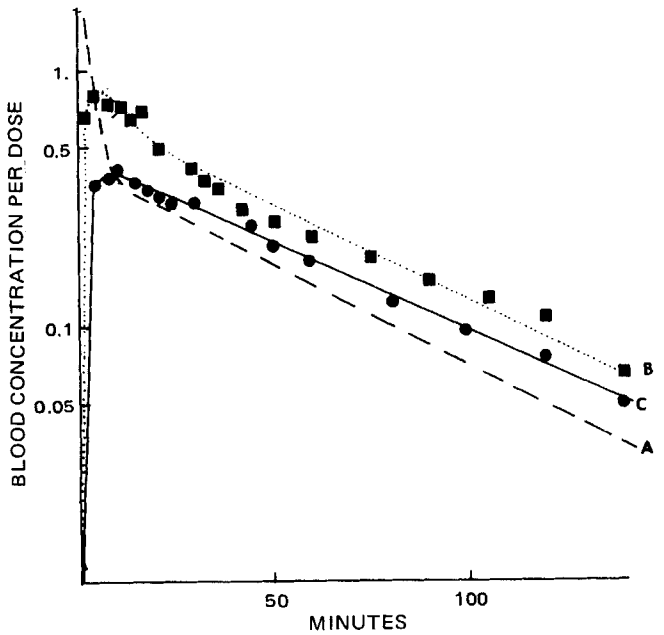

Figure 3—*Blood sulfisoxazole levels in the rabbit following intravenous administration as a bolus and as two different first-order infusions. Key: A, intravenous bolus; B,* $k_{a2} = 0.16$*; and C,* $k_{a2} = 0.08$.

were $\alpha = 0.45$, $\beta = 0.018$, and $E_2 = 0.11$. Curve B, the result of a first-order infusion (with a rate constant of 0.16), is obviously two-compartment data and was fit to Eq. 2. The computer-fitted parameters for curve B were equal to the intravenous disposition parameters and the actual absorption rate constant (0.16). Curve C appears to be one-compartment data and was fit to Eq. 1, resulting in fitted values of $k_{a1} = 0.47$ and $k_d = 0.016$. These values are approximately equal to the α and β obtained with the intravenous data. The actual k_a in this case was 0.08, a value less than E_2. Without the intravenous curve, there would be an apparent inconsistency to these data. Curve B has a characteristic nose, yielding an absorption rate constant of either 0.45 or 0.16 since the investigator cannot distinguish between k_{a2} and α. The apparent one-compartment data (curve C), in which absorption appears to be slightly slower on the basis of the peak time comparisons, yields an absorption rate constant of 0.47.

Wagner and Metzler (5) showed that simulated two-compartment blood level data can often be fit with minimal error to a one-compartment model. Table I gives the results from computer fitting the two-compartment data illustrated in Fig. 2 (A, B, and C) and two intermediate absorption rate constants (D and E) to a biexponential equation (Eq. 1). The best-fit absorption and elimination rate constants for the one-compartment model are listed. Although the computer-fitted absorption rate constants yield marked overestimates of the real absorption rate constants, the relative order of these fitted constants agrees with the relative order of the real absorption constants. In the case where k_{a2} approaches E_2, the computed absorption rate constant, k_{a1}, approaches α.

Wagner (6) suggested that even in cases where the one-compartment fit is poor, the ratio of the absorption rate constants calculated for two dosage forms using one-compartment analyses would be a good approximation of the actual ratio of the absorption rate constants. Such a comparison was made using the values in Table I. Table II gives the ratios of the fitted or determined absorption constants using a one-compartment model (k_{a1x}/k_{a1y}) in comparison to the ratio of the actual absorption constants (k_{a2x}/k_{a2y}), followed by a column giving the percent error found in the computer-fitted ratio with respect to the actual ratio. Although the percent error is quite large in some cases, an evaluation of the relative rank merits of different dosage forms can be accurately determined with one-compartment fits, as pointed out by Wagner (6).

SUMMARY

The present work analyzes the information that may be obtained concerning the pharmacokinetics of drug absorption from oral plasma concentration–time curves when no data exist describing drug disposition after intravenous administration. All examples used here describe the absorption process by a single rate constant, although this constant may represent the best fit to limited data for a very complex multistep process.

Sulfisoxazole, a drug following two-compartment kinetics after an intravenous bolus, is infused logarithmically into male rabbits at absorption rates approximately equal to values found for α, β, and E_2 (data determined from intravenous bolus data) in addition to rates between and above these values. When the absorption rate approaches α, the data points yield a curve consistent with the usual two-compartment oral absorption picture where a relatively fast absorption rate constant gives a large hump or nose in the early part of the curve. However, when the absorption rate is close to E_2, the data are best fit by a one-compartment model. Yet, the "absorption rate" calculated from these data will, in fact, be α and will often overestimate the absorption rate constant by more than a factor of 2.

This error in assigning the α-value as the absorption rate constant will occur no matter what calculation method is utilized if no data from other experiments are available (*e.g.*, intravenous studies or studies with drug delivery systems having a markedly different absorption rate). Data points measured after low absorption rates (close to β) will appear to follow a one-compartment model. Although the percent error in calculation of the absorption rate constant may be relatively large, evaluation of the relative rank order of absorption rates will be correct even when the one-compartment model is chosen instead of the correct two-compartment model.

Table II—Comparison of Actual Absorption Rate Constant Ratios for Two-Compartment Data with Ratios Obtained when Data Are Analyzed According to a One-Compartment Model, Utilizing Input and Output Values Given in Table I

k_{a2x}	k_{a2y}	Input Ratio, k_{a2x}/k_{a2y}	Output Ratio, k_{a1x}/k_{a1y}	Error, %

Quantitative Estimation of Particulate Matter in Pharmaceutical Preparations Intended for Intravenous Administration

ANWAR B. BIKHAZI ˣ, JOANNIS A. SHIATIS, and AMIN F. HADDAD

Abstract □ A fast, reproducible, economical, and dependable automated counter method is recommended for the quality control of pharmaceutical preparations intended for intravenous administration. The USP gives no specifications on the limitations of particulate matter in intravenous products, while the BP specifies limitations on intravenous solutions of more than 500-ml volume. Out of 15 different marketed products, few passed the BP specifications. The microscopically identifiable particles included starch, cellulose fibers, glass, rubber, lacquer flakes, carbon black, and metal shavings. The proposed quality control method introduces a modification to the BP specifications. The method includes a standard log–log plot obtainable from a least-squares line fit to the data of the marketed products showing minimal particle contamination. The standard plot is compared to the experimental data obtained from any other product and, accordingly, it is decided whether the product is acceptable or not.

Keyphrases □ Particles—automated counter analysis, intravenous pharmaceutical preparations, proposed as quality control method □ Intravenous dosage forms—automated counter particle analysis proposed as quality control method □ Dosage forms—intravenous pharmaceutical preparations, automated counter particle analysis, proposed as quality control method □ Automated counter—particle analysis, intravenous pharmaceutical preparations, proposed as quality control method

The presence of particulate matter in parenteral preparations for intravenous administration gave rise to three important questions: the nature and origin of particulate matter (1–4), the hazards produced by these particles (5–12), and quality control of such products. Recent investigations (13–23) in this area have not covered quality control. The present work resulted in a quality control method for the analysis of particulate matter in any intravenous preparation.

EXPERIMENTAL

Sample Analysis—An automated counter[1] was employed. The test solutions were placed in carefully washed beakers to eliminate the possibility of contamination. The particulate matter concentrations in the tested products were small enough to allow the particles to pass through the aperture one at a time.

Calibration of Counter—According to a rough estimate of the particle-size distribution of the tested solution, a 30-, 50-, 70-, or 100-μm aperture tube opening was installed into the machine. Standard monosized calibration materials with a size range between 5 and 20% of the aperture diameter were used to estimate the calibration factor, K, calculated by:

$$K = \frac{D}{\sqrt[3]{t}} \qquad \text{(Eq. 1)}$$

where D is the particle diameter, and t is the threshold value setting on the machine.

Materials such as polyvinyl toluene latex (D = 1.87 μm), polystyrene divinyl benzene latex (D = 5.02 μm), and puff ball spores[1] (D = 3.36 μm) were used for calibration of the machine. The particles were dispersed in a particle-free normal saline solution (see *Preparation of Particle-Free Control Stocks*) in a beaker and placed on the counter stand for counting. The desired dilution of the calibration material was used such that at low threshold (t) settings, the machine was counting at a low coincidence factor.

Standard calibration curves were obtained from a plot of the number of particles oversize *versus* threshold. The threshold corresponding to 50% of the number of particles oversize was taken to be proportional to the volume of a sphere whose average diameter was that of the calibration material. The calibration factor, K, was then calculated from Eq. 1. During experimentation, the machine was occasionally recalibrated.

Preparation of Particle-Free Control Stocks—A particle-free stock solution for control experiments was prepared as follows. Nine grams of sodium chloride[2] was dissolved in 1000 ml of distilled water. A stainless filter holder[3] adapted with a 47-mm, 0.45-μm membrane filter[3] and attached to a vacuum flask was used for the filtration. This procedure resulted in the filtration of particulate matter whose diameter exceeded 0.45 μm. The filtrate was refiltered through a newly installed filter until it was almost particle free, as checked microscopically and by the automated counter.

Part of the freshly prepared particle-free stock was used to fill the reservoir of the machine to avoid leakage of particulate matter from the reservoir during flushing of the inner part of the aperture tube. Another part of the particle-free stock solution served to run the baseline control experiments for a particle-free solution. The control study was run in exactly the same manner as the study of the marketed products. The solution was poured into a clean beaker and then placed on the automated counter stand. Aluminum foil was placed around the stand to eliminate electrical noise pickup from the environment. The aperture tube and the outer electrode were then dipped into the solution, and the counts were taken at different thresholds. The counts obtained at specified thresholds from the control stock were considered as background counts and, therefore, were subtracted from the corresponding threshold counts when the marketed products were being counted for adulterated particles. During the experiments, the solution in the beaker was constantly stirred by a stirrer attached to the counter. The rest of the particle-free stock solution was used as a suspending fluid for the calibration material.

Testing Marketed Products for Particulate Matter—Three types of marketed products intended for intravenous administration were studied. First, intravenous infusion fluids packed in plastic bags and in glass containers with lacquered and nonlacquered rubber stoppers were chosen. Products containing an electrically conductive liquid were directly used in the counting process; those containing a nonconductive liquid, such as 5% dextrose solution, were diluted in a 1:1 ratio with 4% particle-free sodium chloride solution.

Second, plastic bags employed for blood collection in blood banks were selected. They contained anticoagulant citrate dextrose solution. Since the label stated that they should be made up to 500 ml with blood, they were diluted in a 1:4 ratio with 0.9% particle-free sodium chloride solution.

Third, powdered unexpired antibiotic products (some of them lyophilized), packed in glass containers with rubber-like stoppers, were randomly selected from the market. These products were dissolved in 250 ml of particle-free normal saline solution, exactly as recommended by the manufacturers.

All of the products were tested for particulate matter utilizing the automated counter and microscopy for possible particle identification. Each container was lightly shaken before opening to assure uniform distribution of particles. A sample of 200 ml was then placed into a very clean beaker for counting. The procedure followed was exactly the same as that described in the previous sections.

Flocculation Experiments—Flocculation experiments were done to study the particle-size distribution of flocculated and deflocculated systems and to correlate the results with those obtained using the mar-

[1] Coulter counter model A, Coulter Electronics, Hialeah, Fla.; puff ball spores were also obtained from Coulter Electronics.

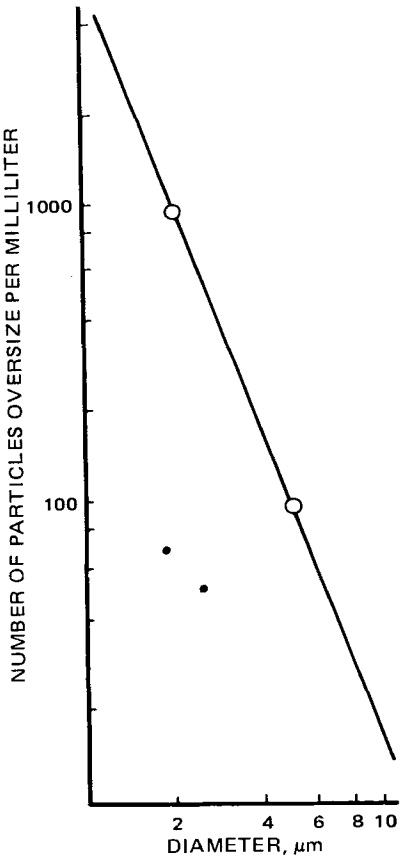

Figure 1—*Logarithmic plot of log (number of particles oversize per milliliter) versus log (diameter) for the extrapolated BP specification.*

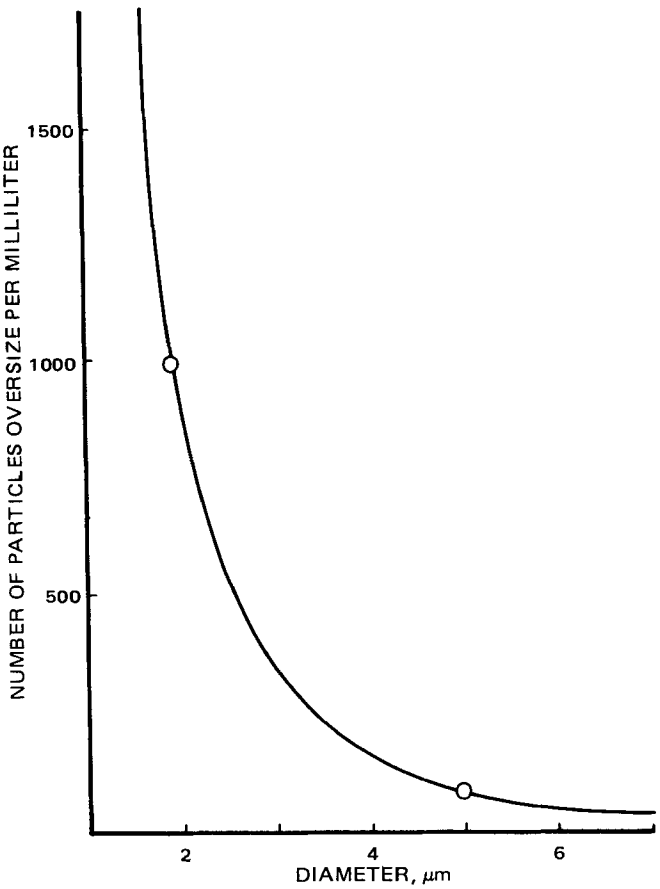

Figure 2—*Rectangular coordinate plot of log (number of particles oversize per milliliter) versus log (diameter) for the extrapolated BP specification.*

keted products. A 0.9% particle-free sodium chloride solution was prepared as described under *Preparation of Particle-Free Stock Solutions.* A small quantity of puff ball spores (D = 3.36 μm) was suspended in 100 ml of this solution with the aid of 2 ml of 1% aqueous dioctyl sodium sulfosuccinate[4] solution. This served as a nonflocculated suspension stock. Then 35 ml of this nonflocculated suspension stock was diluted to 250 ml with particle-free normal saline solution, resulting in a nonflocculated suspension sample for counting. To another 35-ml sample, 10 drops of saturated magnesium chloride[5] solution were added, providing the counterion effect for flocculation. The suspension was then made up to 250 ml with particle-free normal saline solution.

These solutions were gently shaken and left to sediment for a few days. At the time of counting, the suspension was shaken and counted by the automated counter.

Microscopic Identification of Particulate Matter—A 13-mm membrane filter[3] (0.45-μm pore size) adapted to a filter holder[3] was used for the collection of particulate matter. A 10-ml syringe was fitted to the filter holder, and the sample containing particulate matter was poured into the syringe. A vacuum flask attached with a rubber tube to the end of the filter holder was used for the filtration of the solution. The particulate matter was collected on the filter. A filter through which particle-free normal saline solution was filtered was used as a control. The filter was carefully removed from the filter holder, placed in a petri dish, dried in an oven, and then mounted on a slide.

To use transmitted polarized light, it is necessary to make the filter transparent by immersing it in a liquid of the same refractive index as that of the filter. Immersion oil[6] with a refractive index of 1.515 was used. Several drops were placed on a clean glass slide, and the filter was lowered onto the oil drops and allowed to soak up the oil. A scrupulously clean cover glass was placed over the filter. Subsequently, the mounted filters were systematically scanned with a polarizing microscope so that the entire 13-mm diameter filtration area was observed. Finally, a photomicrograph was taken for each sample, using a camera attached to a polarizing microscope[7].

Calculations and Treatment of Data—Groves (14) reported the following log–log relationship between the number of particles oversize *versus* diameter:

$$\log_{10}N = a + k \log_{10}D \qquad \text{(Eq. 2)}$$

Furthermore, the BP reported the following on the limit test of intravenous solutions of more than 500-ml volume: "The mean counts of particles per 1.0 ml do not exceed 1000 equal to or greater than 2 μm and 100 equal to or greater than 5 μm" (24). Application of Eq. 2 to the BP specification would result in a two-point plot on log–log graph paper, namely the points (2, 1000) and (5, 100). The equation of the straight line joining these two points was then deduced to be:

$$\log_{10}N = \log_{10} 5630 - 2.5 \log_{10}D \qquad \text{(Eq. 3)}$$

where N is the number of particles oversize, and D is the diameter. Figure 1 shows the log–log plot of the BP recommendation using Eq. 3. Also, Eq. 3 can be simplified into the following relationship:

$$N = \frac{5630}{D^{2.5}} = \frac{a}{D^b} \qquad \text{(Eq. 4)}$$

Equation 4 is an exponential (to the base D) type of relationship that would fit with any automated counter data when the value of a is 5630 and that of b is 2.5. A rectangular coordinate plot of Eq. 4 is shown in Fig. 2.

RESULTS

The results are presented as graphs. Particulate matter identification and measurement are presented in Table I, which was formulated from the photomicrographs taken of these samples. Because of lack of space, photomicrographs were not included.

Table I—Compilation of Some Identifiable Particles in the Marketed Products with Their Approximate Sizes[a]

Product[b]	Particles Identified and Size
1H	Rubber (2–100 μm), carbon black (1–5 μm), pigments (1–5 μm), calcium carbonate crystals (2 μm), cellulose fibers (up to 100 μm), glass (5–10 μm), starch grains (10 μm), *etc.*
1G	Carbon black (1–5 μm), starch grains (15 μm), unidentified particles (1–3 μm), *etc.*
1P	Rubber (5–40 μm), carbon black (1–5 μm), lacquer coating (5–100 μm), pigments (3 μm), calcium carbonate crystals (2 μm), *etc.*
1AL	Carbon black (1–5 μm), pigments (1–5 μm), calcium carbonate crystals (2 μm), lacquer flakes (5–50 μm), rubber (5–50 μm), starch grains (8 μm), metal shavings (5 μm), *etc.*
1S	Unidentified particles (1–2 μm), few particle contaminants
2AL	Carbon black (1–10 μm), starch grains (8–15 μm), lacquer flakes (20 μm), rubber (5–100 μm), unidentified particles (1–5 μm), *etc.*
2G	Carbon black (1–3 μm), unidentified particles (1–5 μm), *etc.*
3AL	Carbon black (1–5 μm), pigments (1–3 μm), rubber (5–50 μm), starch grains (15 μm), fibers (100 μm), *etc.*
3G	Unidentified particles (1–3 μm), few particle contaminants
4G	Unidentified particles (1–5 μm)
1E	Unidentified particles (1–5 μm)
1B	Carbon black (1–5 μm), starch grains (10–50 μm), fibers (100 μm), unidentified particles (1–5 μm), *etc.*
4AL	Starch grains (25 μm), carbon black (1–10 μm), fibers (up to 100 μm), unidentified particles (1–4 μm), *etc.*
1A	Unidentified particles (1–5 μm)
2A	Fibers (up to 120 μm), carbon black (1–10 μm), unidentified particles (1–5 μm), *etc.*

[a] Particles identified with help of Ref. 25. [b] For type of formulation, check Figs. 3–14. The letter H after a number signifies a product manufactured by a local hospital in Lebanon. The letter P designates a local Lebanese product, G designates a German product, S designates a Swiss product, B designates a Belgian product, and E designates an Egyptian product. The letter A signifies a United States product, and AL indicates a product manufactured by a United States company under license in a European or Middle Eastern country.

Cumulative Size Distribution in Solutions Intended for Intravenous Administration—Figures 3 and 4 are representative plots on rectangular and logarithmic coordinates for particulate matter in Products 1AL, 1P, and 1S. Similarly, Figs. 5 and 6 are representative rectangular and logarithmic plots for data obtained for Products 1H and 1G. In both plots, a profile was drawn of data obtained on particulate matter existing in the filtrate of Product 1H after filtration through a 0.45-μm membrane filter.

Figures 7 and 8 represent data for Products 2AL and 2G, while Figs. 9 and 10 represent data for anticoagulant citrate dextrose solutions of Products 4G and 1E. Figures 3–10 include a comparison between the results of the marketed products and the smooth curves obtained from the extrapolated BP specifications as already described.

Cumulative Size Distribution in Powdered Antibiotic Products Intended for Intravenous Administration—The dilutions of these products were already discussed. Figures 11 and 12 represent rectangular and logarithmic plots for particulate matter in Products 1B and 4AL containing ampicillin sodium. Figures 13 and 14 are similar plots for Products 1A and 2A for cephapirin sodium and cephalothin sodium, respectively. The smooth curves appearing in Figs. 11–14 are the extrapolated BP limit test plots. The BP does not mention any limit test for the quality control of adulterated particles in antibiotic products.

Cumulative Size Distribution in Deflocculated and Flocculated Puff Ball Spores—Figures 15 and 16 represent typical rectangular and logarithmic plots on deflocculated and flocculated systems. The plots show the monosized distribution in the deflocculated systems and the deviation from monosized distribution in flocculated systems. Similar deviations resulted in the data obtained for some marketed products as shown in Figs. 5–12 and 14.

Microscopic Identification of Particulate Matter in Marketed Products—Table I represents a compilation of most of the identifiable particles, with their approximate sizes, in the tested products.

DISCUSSION

A thorough literature survey revealed that previous findings concerning quantifying and identifying particulate matter in intravenous solutions did not result in substantial recommendations for quality control. There appeared to be agreement that particulate matter in intravenous products was hazardous to patients and that the pharmacopeias should include specific and strict recommendations for its limitations.

Proposed Analysis of Results on Basis of BP Specifications—The advantages of this method of analysis based on the extrapolated BP specifications, as described under *Experimental*, are that it is fast, reproducible, economical, and dependable for the quality control of pharmaceutical preparations intended for intravenous administration. As previously reported, the particle-size distribution of the particulate matter in an intravenous infusion under storage may change with time due to particle aggregation or deaggregation. The BP has given only two specific particle numbers with their corresponding sizes, with no mention of possible aggregation or deaggregation.

The proposed analysis, based on the extrapolated BP limitations, gives a whole range of size distributions, permitting quality control personnel to check possible particle flocculation or deflocculation instantaneously. This check is in addition to a general analysis of the particle-size distribution in the products. A simple comparison analysis was needed. To support this method, Figs. 15 and 16 showed the general trend of the curve for flocculated and deflocculated systems. Any deviation from this curve due to flocculation would result from a change in the particle-size distribution. Therefore, in an intravenous product, any behavior similar to that of these plots could be explained on the basis of particle aggregation or deaggregation.

Recommendations—Some drug companies have been able to produce products for intravenous administration in which the particulate matter is far below BP limitations. Some marketed products, especially the powdered antibiotic products, far exceed the proposed limitations. The comparison of the results obtained in this work with the BP specifications for powdered antibiotic and blood bank bag products was done to show the importance of limitations for the quality control of these pharmaceutical preparations.

Recommendation I—The following model is proposed for all products manufactured for intravenous administration. This model is very arbitrary and flexible and is not mentioned as a replacement for any limitations proposed by a pharmacopeia. The emphasis is directed toward a similar applicability in any quality control laboratory.

Since the particle-size analysis of some marketed products showed low particle contamination and since any limit test is arbitrary, the best products (1G, 1S, and 3G) were used to set out the proposed limit test. The number of particles oversize per 1.0 ml *versus* diameter was plotted on log–log paper (Fig. 17). The best straight line through all points was drawn utilizing the method of least squares (26). The following is the equation of the straight line obtained as a result of the least-squares line method:

$$\ln N = \ln 225 - 1.80 \ln D \qquad \text{(Eq. 5)}$$

where N is the number of particles oversize per 1.0 ml, -1.8 is the slope of the line, D is the particle diameter, and 225 is the intercept when $D = 1$ μm. Equation 5 can be reduced to:

$$N = \frac{225}{D^{1.80}} \qquad \text{(Eq. 6)}$$

A plot of N *versus* D of Eq. 5 on rectangular coordinates is shown in Fig. 18.

The best least-squares line fit shown in Fig. 17 was used in this work as the basis for the proposed limitations. However, some products had particle contaminants (as seen in Fig. 17) that did not pass the specifications. To take this into account, it was suggested that a line be drawn parallel to the least-squares line and that products (1S, 1G, and 3G) fitting this line be considered acceptable. This procedure also took into account flocculated systems where the size distribution caused a change in the linearity of the plot (Fig. 16). The straight line passed through the points (1, 700), (2, 200), (3, 100), and (5, 40). The following is the equation of the straight line passing through these points:

$$\ln N = \ln 700 - 1.80 \ln D \qquad \text{(Eq. 7)}$$

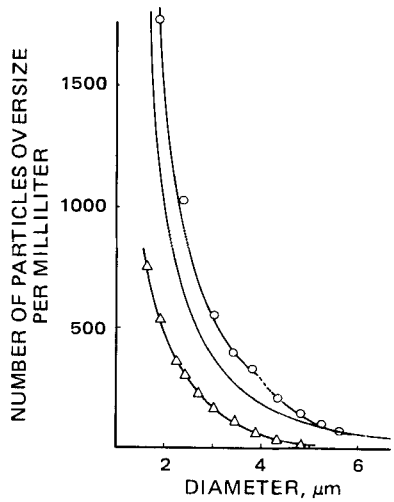

Figure 9—*Cumulative particle-size distribution in anticoagulant citrate dextrose solutions intended for blood collection. Key: ○, Product 4G packed in 500-ml plastic bags; △, Product 1E packed in 500-ml plastic bags; and smooth curve, BP specification.*

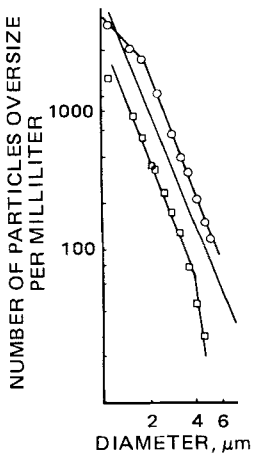

Figure 10—*Logarithmic plot of cumulative particle-size distribution in anticoagulant citrate dextrose solutions intended for blood collection. Key: ○, Product 4G; □, Product 1E; and smooth curve, BP specification.*

Therefore, the proposed limitations should be: "For any product intended for intravenous administration, regardless of its volume, the average counts per 1.0 ml of five to 10 samples should not be more than 700 equal to or greater than 1 μm, 200 equal to or greater than 2 μm, 100 equal to or greater than 3 μm, and 40 equal to or greater than 5 μm."

The plots in Figs. 17 and 18 can be used as standard curves for the quality control of any product intended for intravenous administration, utilizing for counting an electronic counting device that can count the cumulative number of particles in a solution. Five to 10 products from the production line could be randomly picked up and sent to the quality control laboratory. By using a precalibrated counting device with an aperture tube of 30, 50, or 70 μm and counting the number of particles oversize *versus* particle diameter, a similar plot could be drawn. Comparison of the standard plots (Figs. 17 and 18) to the experimentally obtained plot will indicate whether the product is acceptable or not. Such a quality control method will take only a few minutes, provided the machine is kept clean, precalibrated, and ready for use. The handling and maintenance of the machine should not be more difficult than for any equipment utilized in a quality control laboratory.

Recommendation I has the disadvantage that large particles may not be counted by the counter. Microscopic analysis could concurrently be done on the product. This does not mean that microscopic analysis, which is very tedious and time consuming, is a better tool.

Recommendation II—Figures 5 and 6 present the cumulative size distribution of particulate matter when Product 1H was filtered through a 0.45-μm membrane filter. It appeared obvious that the number of particle contaminants was far below the BP specification. Therefore, filtration prior to administration of the product was recommended as an efficient method of removing particulate matter. This could be accomplished by using an in-line final filtration device.

Oxidation Photosensitized by Tetracyclines

JOY ANNE WIEBE and DOUGLAS E. MOORE [x]

Abstract □ Irradiation with 365-nm UV light of aerated aqueous solutions of tetracycline gives rise to oxygen uptake when the pH of the solution is above 7.5. The kinetics of the reaction were followed using a polarographic oxygen electrode at a range of pH values for seven currently prescribed tetracyclines. Variation of tetracycline concentration, UV light intensity, and temperature showed the characteristics normally associated with a sensitized photo-oxygenation mechanism rather than a free-radical process. Copper(II) ions inhibited the photo-oxidation of tetracycline, apparently by complex formation. The tetracyclines were tested for photosensitizing capability with oxidizable acceptors. In aqueous solution, no photosensitizing effect could be seen, but methanol solutions of 2,5-dimethylfuran and *dl*-limonene were oxidized at considerably increased rates when small amounts of tetracyclines were present. This observation has implications for the mechanism of *in vivo* photosensitivity reactions that occur when tetracyclines are taken internally.

Keyphrases □ Tetracyclines, various—photosensitized oxidation, reaction kinetics followed using polarographic oxygen electrode, effect of pH and copper(II) ions □ Photosensitized oxidation—various tetracyclines, reaction kinetics followed using polarographic oxygen electrode, effect of pH and copper(II) ions □ Oxidation, photosensitized—various tetracyclines, reaction kinetics followed using polarographic oxygen electrode, effect of pH and copper(II) ions □ Polarography—determination, rate of oxygen uptake by solutions of various tetracyclines irradiated with UV light, effect of pH and copper(II) ions □ Antibacterial agents—various tetracyclines, photosensitized oxidation, reaction kinetics followed using polarographic oxygen electrode, effect of pH and copper(II) ions

Photosensitivity reactions have been reported for the tetracyclines after exposure of the patient to strong sunlight (1). The phenomenon of "photodynamic action" has been recognized since 1900, when it was discovered that microorganisms can be killed when exposed to light in the presence of oxygen and sensitizing dyes (2). The basic mechanism is the photosensitized oxidation of the adsorbate or substrate by molecular oxygen (3, 4). All tetracycline antibiotics have a strong absorption in the near UV region at about 365 nm, the first requirement for a sensitizer of photodynamic action.

Little information is available, however, concerning the reactions of tetracyclines following absorption of UV light. Chlortetracycline, tetracycline, and oxytetracycline lost significant antibiotic potency when irradiated with visible light in solution with riboflavin, which probably acted as a photosensitizer (5). Leeson and Weidenheimer (6) reinvestigated this system at pH 4.5 and concluded that the loss of tetracycline activity could be suppressed by the addition of ascorbic acid. Thus, an oxidative pathway was implied for degradation of tetracycline after irradiation.

This paper reports a more detailed study of the photooxidation of seven currently prescribed tetracyclines, together with some experiments that indicate that the tetracyclines can act as photosensitizers for the oxidation of suitable acceptor molecules.

[Tetracycline], $M \times 10^4$	Initial Rate[a], moles/liter/min $\times 10^6$	Transmittance[b] at 373 nm, %
0.5	1.7 ± 0.2	17.8
1.0	3.5 ± 0.1	3.2
1.5	5.3 ± 0.3	<0.01
3.0	5.8 ± 0.2	<0.01
5.0	5.8 ± 0.2	<0.01
6.0	5.7 ± 0.3	<0.01
10.0	5.4 ± 0.2	<0.01

[a] Mean of at least three determinations from initial slope of P_{O_2} recorder trace. [b] Calculated for 1-cm path length and molar absorptivity of $1.5 \times 10^4 M^{-1}$ cm^{-1} at pH 9.0.

cycline[1], chlortetracycline[2], demeclocycline[2], and minocycline[2] of the purest grade available commercially were used without further purification. The absorbance ratio method of McCormick *et al.* (7) showed that the purity of tetracycline, oxytetracycline, and chlortetracycline was at least 99%.

Rates of oxygen uptake by solutions irradiated by UV light were determined using the polarographic oxygen electrode apparatus described previously (8). In the procedure used, 2 ml of freshly prepared solution of I in buffer was mixed with 200 ml of air-saturated buffer solution before filling the reaction vessel. Buffers (0.05 *M*) were prepared in double-distilled water using analytical grade materials as follows: pH 4.0–4.9, acetate; pH 6.0–8.4, phosphate; pH 9.0, tromethamine; and pH 10.0–10.8, carbonate.

For experiments in which the tetracyclines were tested as photosensitizers, benzyl alcohol[3], benzaldehyde[3], *dl*-limonene[4], and 2,5-dimethylfuran[5] were purified by distilling twice under high vacuum in an all-glass apparatus at room temperature. Sodium xanthine[6], α-tocopherol[6], *dl*-tyrosine[6], and *l*-phenylalanine[6] were used as received. Limonene, dimethylfuran, and α-tocopherol are almost insoluble in aqueous systems, so experiments with these compounds were performed in methanol solution.

The rate data were recorded with the oxygen electrode operating successfully in methanol, although it was designed for operation in aqueous phases only (9). The validity of oxygen uptake data measured in methanol solution was verified by experiments with benzaldehyde for which the mechanism is known (8). Moreover, the stability of the oxygen electrode and the reproducibility of readings were greatly improved in methanol solutions; this finding may be attributed to the greater concentration of oxygen in air-saturated methanol ($2.06 \times 10^{-3} M$) compared to air-saturated water ($2.35 \times 10^{-4} M$) at 30° (10).

RESULTS

Preliminary Measurements with Tetracycline—The rate of oxygen uptake by UV-irradiated I in solution was examined over pH 4.0–10.8. No significant oxygen uptake occurred below pH 8, although there were changes in absorbance[7] at pH 4 and 5 in the 240–280-nm range, corresponding to epimerization (11). The loss of antibiotic activity of irradiated I reported (6) at pH 4.5 is thus largely due to epimerization, which occurs only between pH 2 and 6 (11).

During irradiation at pH 9.0, oxygen consumption was accompanied by color change of the solution from yellow to pink, red, or brown (depending on the extent of oxidation), with the appearance of a broad absorption centered at 530 nm. The absorbance decreased at 373 nm, which is the λ_{max} for I at pH 9.0, and disappeared completely if irradiation was continued. There was no absorption in the 400–450-nm region, indicating that neither acid degradation product (12) (anhydrotetracycline or epianhydrotetracycline) was formed during photo-oxidation. The oxygen uptake from irradiated I solutions continued (at a much reduced rate) after the lamp had been switched off, indicating that the product(s) of I photo-oxidation are labile. Analysis of these solutions with iodine immediately after irradiation produced no evidence of peroxides.

Table II—Effect of Edetate Disodium and Copper(II) Ions on Tetracycline Photo-Oxidation at pH 9.0 and 30°[a]

[Edetate Disodium], $M \times 10^5$	[Cu^{2+}], $M \times 10^5$	Initial Rate, moles of Oxygen/liter/min $\times 10^6$
0	0	3.5 ± 0.1
10	0	3.5 ± 0.2
0	1.0	2.2 ± 0.1
0	2.5	1.46 ± 0.10
0	5.0	1.17 ± 0.10
0	40	0.1 ± 0.1

[a] [Tetracycline] = $10^{-4} M$ in all experiments.

Correlation of the amount of oxygen consumed with the depletion of I, as indicated by the spectral change at 373 nm, established that 1.06 ± 0.08 moles of oxygen reacted per mole of I. These experiments were performed at two concentrations of I; to keep secondary reactions to a minimum, irradiation was continued until no more than 15% of the dissolved oxygen was consumed.

To test for general acid or base catalysis by the buffer components, a characteristic of the epimerization reaction (7), the irradiation of I was performed at pH 9.0 in: (*a*) 0.05 *M* tromethamine buffer, (*b*) 0.05 *M* carbonate buffer, and (*c*) unbuffered solution adjusted to pH 9.0 with 1 *M* NaOH solution. After 20 min of irradiation, the pH of the unbuffered solution had fallen to 8.6 but the initial rate of oxygen uptake was the same for all three solutions, indicating that there is no participation by the buffers in the reaction nor any effect of ionic strength.

Temperature variation over 25–40° showed that the reaction rate was independent of temperature. The incident light intensity was varied as previously described (8), and the reaction rate was directly dependent. Both these observations are characteristic of a primary photochemical process rather than a free radical chain mechanism (13).

Variation of Tetracycline Concentration—Table I shows the measured initial rate of oxygen uptake as the I concentration was varied from 5×10^{-5} to $10^{-3} M$. Straight-line (*i.e.*, zero-order) recorder traces of oxygen pressure (P_{o_2}) *versus* time were obtained for $[I] \geq 10^{-4} M$. Below $10^{-4} M$, the traces were curved, but straight lines were obtained for plots of log P_{o_2} *versus* time. The solubility of oxygen in dilute buffer is $2.35 \times 10^{-4} M$ (10), so I concentration was rate limiting here and the rate can be said to be first order in I concentration. At the lower I concentrations, the rate was proportional to [I]; above $3 \times 10^{-4} M$, the light intensity was the limiting factor, as indicated by the percent transmittance values given in Table I. This effect also was observed previously (5, 6).

Effect of Edetate Disodium and Copper on Tetracycline Photo-Oxidation—It is well known that traces of metal ions catalyze radical chain oxidation (14) and that I complexes with many metal ions (15). The experiments summarized in Table II showed that the addition of edetate disodium to the buffer had no effect on the photo-oxidation rate, indicating that there are no accelerating effects of trace metal ions. The addition of copper(II) ions, however, led to a decrease in rate, indicating that complexed I is not susceptible to photo-oxidation. The fact that a complex was formed was indicated by a shift in the absorption maximum of I from 373 to 405 nm. The absorbance of the complex at 365 nm (the wavelength of maximum output of the UV lamp) remained sufficient to initiate photo-oxidation, provided that the complex was susceptible.

Comparative Study of Seven Tetracyclines—The initial rates of photo-oxidation for seven tetracyclines at a range of pH values are recorded in Table III. Minocycline showed little reactivity under the present conditions; methacycline also reacted more slowly than the other five tetracyclines. In general, the reaction rate was at a minimum at neutral pH and increased as the alkalinity of the solution was raised. Doxycycline showed a maximum oxidation rate at pH 9.0, while tetracycline exhibited a similar maximum at pH 10.0.

The UV spectral changes described earlier for tetracycline were observed for the other members of the group, the extent of the change in the 360–380-nm peak being directly proportional to the oxygen uptake. Chlortetracycline alone had a significant dark reaction, not involving oxygen uptake but involving a 10% reduction in absorbance of the 380-nm peak at pH 9.0 in 1 hr, the time course of the photo-oxidation reaction. Hughes and Wilson (16) showed that isochlortetracycline forms upon heating alkaline solutions of chlortetracycline while other tetracyclines are less labile in this respect.

Tetracyclines as Photosensitizers—The fact that I is the primary UV-absorbing species for its own photo-oxidation suggests that it may

Table III—Initial Rates of Photo-Oxidation of Tetracyclines at 30° and Various pH Values

be capable of sensitizing the photo-oxidation of other molecules. Various concentrations (10^{-5}–10^{-4} M) of I were tested for sensitizing capability with the following systems:

System 1—Benzyl alcohol or benzaldehyde (2×10^{-2} M) in aqueous solution at pH 4.0 and 9.0, as representative of compounds susceptible to free radical oxidation (8).

System 2—Xanthine, phenylalanine, or tyrosine (10^{-2} M) in aqueous solutions at pH 6.0 and 8.0. Both purines (17) and aromatic amino acids (18) undergo sensitized photo-oxidation in alkaline solution.

System 3—α-Tocopherol (2×10^{-2} M), a natural antioxidant that undergoes both free radical autoxidation (19) and dye-sensitized photo-oxidation (20) in methanol solution.

System 4—2,5-Dimethylfuran or *dl*-limonene in methanol solution. These agents were used (21, 22) previously as model compounds in dye-sensitized photo-oxygenations and chemical oxygenations to test for the participation of singlet molecular oxygen.

For Systems 1–3, the oxygen uptake upon irradiation was very slight and corresponded to that recorded in control experiments with I or substrate alone. Dimethylfuran and limonene, however, were oxidized significantly in the presence of all tetracyclines except minocycline (Table IV). A 10-fold change in [I] produced less than double the rate of limonene oxidation, while the doubling of doxycycline increased the rate of dimethylfuran oxidation by only 6%. Also, the absorbance of the reaction mixtures at 370 nm decreased by only about 2%, and the tetracyclines by themselves in methanol did not absorb measurable amounts of oxygen in the time course of the irradiation (1 hr). These observations establish the role of the tetracyclines as photosensitizers.

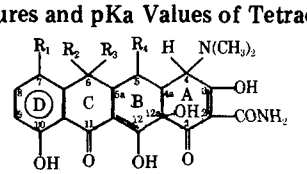
DISCUSSION

The major kinetic characteristics observed for the photo-oxidation of I in aqueous alkaline solution may be summarized as follows: (*a*) dependence on [I] only at low concentrations, (*b*) direct dependence on incident light intensity, (*c*) independence of temperature, and (*d*) use of oxygen in a 1:1 stoichiometry with I. These are the characteristics of a photosensitized oxygen addition or photo-oxygenation process (2) rather than of a free radical chain mechanism such as occurs with benzaldehyde (8).

The structures of the tetracyclines in this study are given in Table V together with the known pKa values. While it is difficult to correlate differences in structure with the differences in photo-oxidative reactivity, the rate variation with pH is clearly related to the state of ionization of the tetracyclines in mildly alkaline solution and is similar to the pH profile observed for the photo-oxidation of several aromatic amino acids (18). The pKa values are attributed (23) respectively to the tricarbonyl system of ring A (pK_1), the dimethylammonium function of ring A (pK_2), and the phenolic β-diketone system in the C-10–11–12 region (pK_3). From the pKa values, I is said to exist as a zwitterion at neutral pH and increasingly as the monoanion as the pH is raised above 8. On this basis, the monoanion would appear to be the reactive species.

The photo-oxidation reaction is accompanied by a loss of the absorption peak at about 370 nm, which is due to the chromophore grouping in the BCD ring (7, 24) containing the ionizable system corresponding to pK_3. The dissociation of this group is essentially unaffected by the 7-chloro substitution, but it is not known whether the different substituents

Table V—Structures and pKa Values of Tetracyclines



Name	R_1	R_2	R_3	R_4	pK_1	pK_2	pK_3	Reference
Tetracycline	H	CH_3	OH	H	3.30	7.68	9.69	23
Chlortetracycline	Cl	CH_3	OH	H	3.30	7.44	9.27	23
Oxytetracycline	H	CH_3	OH	OH	3.27	7.32	9.11	23
Doxycycline	H	CH_3	H	OH	3.4	7.7	9.7	30
Demeclocycline	Cl	H	OH	H	3.30	7.16	9.25	31
Methacycline	H	—CH_2—		OH	—	—	—	—
Minocycline	$N(CH_3)_2$	H	H	H	—	—	—	—

in methacycline and minocycline cause a significant alteration in the pK value and, therefore, the concentration of the monoanion. There is no marked difference in the absorption peak at 370 nm for all tetracyclines studied here.

The addition of copper(II) ions shifts the 370-nm absorption to longer wavelength and renders the complex stable to photo-oxidation at pH 9.0. This tends to implicate the C-10–11–12 grouping as the binding site for metal ions. Mitscher *et al.* (24) concluded, from optical rotatory dispersion studies, that chelation occurred first in the BCD ring and then in the A ring as the pH was raised above 10. Williamson and Everett (25) recently suggested, on the basis of NMR studies in dimethyl sulfoxide, that the tricarbonylmethane function of ring A is the chelating group, but the solvent difference may give rise to a different binding behavior.

The decreased rate of photo-oxidation above pH 10.0 for I and pH 9.0 for doxycycline are not easily attributable to the decrease in the concentration of the monoanion in solution; if the monoanion is the only oxidizable species of I, the maximum rate should occur at pH 8–9, where its concentration would be at a maximum on the basis of the pK values.

The demonstration that the tetracyclines are capable of acting as photosensitizers for the oxygenation of suitable acceptor molecules has relevance to the photosensitivity reactions observed following the ingestion of I and its analogs. Dimethylfuran and limonene are acceptors (A) of energy transferred from $^1O_2$, the excited singlet molecular oxygen (21). This implies that excited I is capable of interacting with $^3O_2$ (ground-state triplet oxygen) to give singlet oxygen according to Scheme I.

$$(I) \xrightarrow{h\nu} (I)^*$$

$$(I)^* + {}^3O_2({}^3\textstyle\sum_g^-) \rightarrow (I) + {}^1O_2({}^1\Delta_g)$$

$$^1O_2 + A \rightarrow AO_2$$

Scheme I

This phenomenon has been principally studied using dyes that absorb in the visible region, such as methylene blue or rose bengal, since the energy difference between the triplet oxygen ground state and the singlet excited state is only 92 kJ (22 kcal), which corresponds to a wavelength of 1270 nm (21). It also usually requires that the dye pass to the excited triplet state, which has a longer lifetime in which to effect the energy transfer.

Foote (26) stated that if the oxidation proceeds purely through singlet oxygen as an intermediate, it should produce the same rate for all acceptors at constant sensitizer and oxygen concentrations. Thus, the similarity in rates observed with limonene and dimethylfuran is in agreement with this concept. No photosensitizing capability of I could be demonstrated in aqueous solution, so it is clear that the acceptor or substrate molecule and solvent medium have to be specifically matched to the sensitizer for greatest efficiency. Young *et al.* (27) suggested that the lifetime of singlet oxygen in photosensitized oxidations increases as the polarity decreases. This aspect could not be tested, since the amino acids and purines are insufficiently soluble in methanol and limonene and dimethylfuran are insoluble in water.

Reports of *in vivo* photosensitivity have implicated demeclocycline more frequently than the other members of the group (28, 29). The results in Table IV indicate some differences in photosensitizing efficiency, with demeclocycline, chlortetracycline, and tetracycline being the most efficient. The relative inactivity of minocycline is due to a shift of the λ_{max} in methanol solution to 345 nm, so that its molar absorptivity at 365 nm is approximately half that of the other tetracyclines. The investigation is continuing with systems that can be related more closely to the skin.

Identification of Nonpolar Methotrimeprazine Metabolites in Plasma and Urine by GLC–Mass Spectrometry

SVEIN G. DAHL *x and MATS GARLE ‡

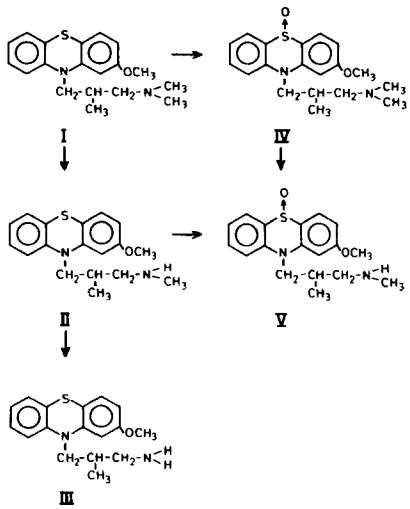
Abstract □ Two metabolites of methotrimeprazine, the sulfoxide and the demethylated analog, were identified in extracts from patient plasma by combined GLC–mass spectrometry. Methotrimeprazine and its sulfoxide had similar mass spectra but different GLC retention times. In addition to the metabolites found in plasma, two other metabolites, the didesmethyl analog and the monodesmethyl sulfoxide, were identified in a urine extract.

Keyphrases □ Methotrimeprazine and metabolites—GLC–mass spectral analysis, human plasma and urine □ GLC–mass spectrometry—analysis, methotrimeprazine and four metabolites, human plasma and urine □ Phenothiazines—methotrimeprazine and four metabolites, GLC–mass spectral analysis, human plasma and urine □ Analgesics—methotrimeprazine and four metabolites, GLC–mass spectral analysis, human plasma and urine

Information about plasma levels of the phenothiazine drug methotrimeprazine[1] (I) and a metabolite (IV) recently was published (1). The biological half-life of I appeared similar to that of its congener chlorpromazine (2), and the apparent volume of distribution (V_β or $V_{d,area}$) appeared somewhat larger. A striking observation was that the plasma levels of the sulfoxide (IV) were about twice as high as the levels of I after oral drug administration. *In vitro* studies later demonstrated that IV must be considered pharmacologically active with regard to cardiac effects, differing in this respect from the corresponding metabolite of chlorpromazine (3).

The plasma levels of I and IV were measured by a GLC method based on flame-ionization detection (4), and the probable identity of the extracted compounds with I and IV was shown by their GLC retention times. The present study was carried out to ascertain the identity of the compounds extracted from plasma by combined GLC–mass spectrometry. A urine extract was analyzed by the same procedure to verify that the metabolites excreted were identical to the corresponding reference compounds.

The molecular formulas of I and its monodesmethyl (II), didesmethyl (III), sulfoxide (IV), and monodesmethyl sulfoxide (V) metabolites are shown in Scheme I.



Scheme I

EXPERIMENTAL

Standard Solutions—Reference samples were supplied by various companies[2,3]. Compounds I, III, and IV were dissolved in heptane containing 1.5% isopentyl alcohol; the bases of II and V were extracted from 0.5 ml of 5% NaOH into 10 ml of the same heptane–isopentyl alcohol mixture.

Blood and Urine Sampling—Blood and urine were collected from four somatically healthy psychiatric patients treated with I tablets for at least 4 weeks, without any additional medication. Subjects 1 and 2 were females, 49 and 43 years old, respectively; Subjects 3 and 4 were males, 46 and 38 years old, respectively. Blood samples were collected 3 and 5 hr after the morning dose and immediately centrifuged, and the plasma was frozen and kept at −24°. Urine was collected before and 5 hr after the morning dose and kept at −24° until analyzed.

Extraction and GLC—The plasma concentrations of I and IV were determined by a GLC method (4) prior to the GLC–mass spectral analysis. The urine concentrations of I, II, and IV were determined by the same procedure but without the internal standard, using peak heights for quantitation.

The plasma and urine extracts analyzed by GLC–mass spectrometry were obtained by the same extraction procedure. For each patient, two 4.5–6-ml aliquots of the plasma sample containing the highest sulfoxide concentrations (Table I) were extracted simultaneously, and the organic phases from the two aliquots of plasma were combined before evaporation to dryness. A 6-ml aliquot of urine from Subject 1, collected 5 hr after the morning dose, was extracted by the same procedure.

GLC–Mass Spectrometry—The evaporated extracts from plasma or urine were dissolved in 10 μl of heptane containing 20% isopentyl alcohol, and 4 μl of this solution was analyzed on a computerized GLC–mass spectrometer[4] (5). The gas chromatograph was equipped with a 120-cm silanized glass column, 2 mm i.d., packed with 3% OV-17 on 80–100-mesh Gas Chrom Q. The injector and column temperatures were 255 and 242°, respectively; the flow rate of helium carrier gas was 30 ml/min. The ionizing potential, trap current, and accelerating voltage were 20 ev, 60 μamp, and 3.5 kv, respectively; the temperatures of the separator and ion source were 270 and 290°, respectively.

Mass spectra were obtained by repetitive scanning over the mass range of *m/e* 10–500 every 2.9 sec and stored in the external memory of the computer. The scan speed was 0.8 sec/spectrum. Gas chromatograms showing total ion current as a function of scan number and mass chromatograms showing the intensity of particular ions as a function of scan number were later generated by the computer.

RESULTS

Reference Samples—The relative retention times of I, II, III, IV, and V were 1, 1.25, 1.40, 3.95, and 4.70, respectively, in the GLC system connected to the mass spectrometer.

Mass spectra of reference samples of I, II, and IV are shown in Fig. 1. The mass spectrum of IV, which was similar to that of I, contained only traces (relative intensity 0.2%) of the molecular ion (*m/e* 344). The base

Table I—Dosages and Concentrations of Methotrimeprazine and Metabolites in Plasma 3 and 5 hr after, and in Urine before (0 hr) and 5 hr after, Administration of the Morning Dose

Subject	I Dose, mg		Plasma Concentration, ng/ml				Urine Concentration, ng/ml					
			I		IV		I		II		IV	
	Morning	Evening	3 hr	5 hr	3 hr	5 hr	0 hr	5 hr	0 hr	5 hr	0 hr	5 hr
1	100	200	59	36	257	163	135	432	220	850	4,510	4081
2	200	200	141	135	231	336	500	—	555	—	10,594	—
3	175	175	76	66	389	237	175	371	345	857	5,359	7714
4	100	200	51	61	208	353	84	125	128	150	4,414	2120

peak in both mass spectra had mass number 58, corresponding to the dimethylaminomethylene group at the end of the side chain. The most abundant ion in both mass spectra was the molecular ion of I (*m/e* 328).

The molecular ion of II (*m/e* 314) was the most abundant peak in its mass spectrum. The mass spectra of II and its sulfoxide (V) were similar, like the mass spectra of I and IV. The predominant peaks in the mass spectrum of V had the following mass numbers (and relative intensities): 44 (14%), 58 (20%), 229 (96%), 242 (61%), 269 (36%), 312 (27%), and 314 (100%).

The predominant peaks in the mass spectrum of the reference sample of III were at 228 (41%), 242 (70%), 269 (18%), 300 (100%), and 314 (13%). The ion of mass 314 probably arises from contamination with II in the reference sample, since the molecular weight of III is only 300.

Plasma and Urine Extracts—The concentrations of I and IV in plasma and of I, II, and IV in urine are given in Table I.

Figure 2 shows computer-generated mass chromatograms of ions with mass numbers 314 and 328, obtained after injection of a plasma extract. The chromatogram of mass number 328 contained two peaks with retention times similar to those of I and IV, while the chromatogram of mass number 314 contained one peak with a retention time similar to that of II. The mass spectra corresponding to the peak intensities in the mass chromatograms shown in Fig. 2 are shown in Fig. 3.

The total ion current gas chromatograms of plasma extracts from all subjects showed three peaks with retention times similar to I, II, and IV. The mass numbers and relative intensities of the predominant peaks in the corresponding mass spectra are summarized in Table II.

Figure 4 shows mass chromatograms of ions with mass 314, 300, and 328, obtained from a urine extract. The *m/e* 314 mass chromatogram contained two peaks with maximum intensities obtained in scan numbers 230 and 300, corresponding to the retention times of II and V. The mass spectrum recorded in scan number 230 was similar to the mass spectrum of II (Fig. 1). The predominant peaks in the mass spectrum recorded in scan number 300 had the following mass numbers (and relative intensities): 58 (100%), 229 (72%), 242 (52%), 269 (28%), and 314 (77%).

The *m/e* 300 mass chromatogram showed one small peak with peak intensity obtained in scan number 232, corresponding to the retention time of III. The predominant peaks in the mass spectrum recorded in scan number 232 had the following mass numbers (and relative intensities): 44 (25%), 86 (12%), 229 (74%), 242 (45%), 269 (17%), 300 (10%), and 314 (100%).

The *m/e* 328 mass chromatogram (Fig. 4) contained two peaks with retention times similar to I and IV. The mass spectra recorded in scan numbers 225 and 300 were similar to the mass spectra of I and IV shown in Fig. 1.

It was previously reported that peaks from two unidentified substances appeared in the flame-ionization gas chromatograms of samples extracted

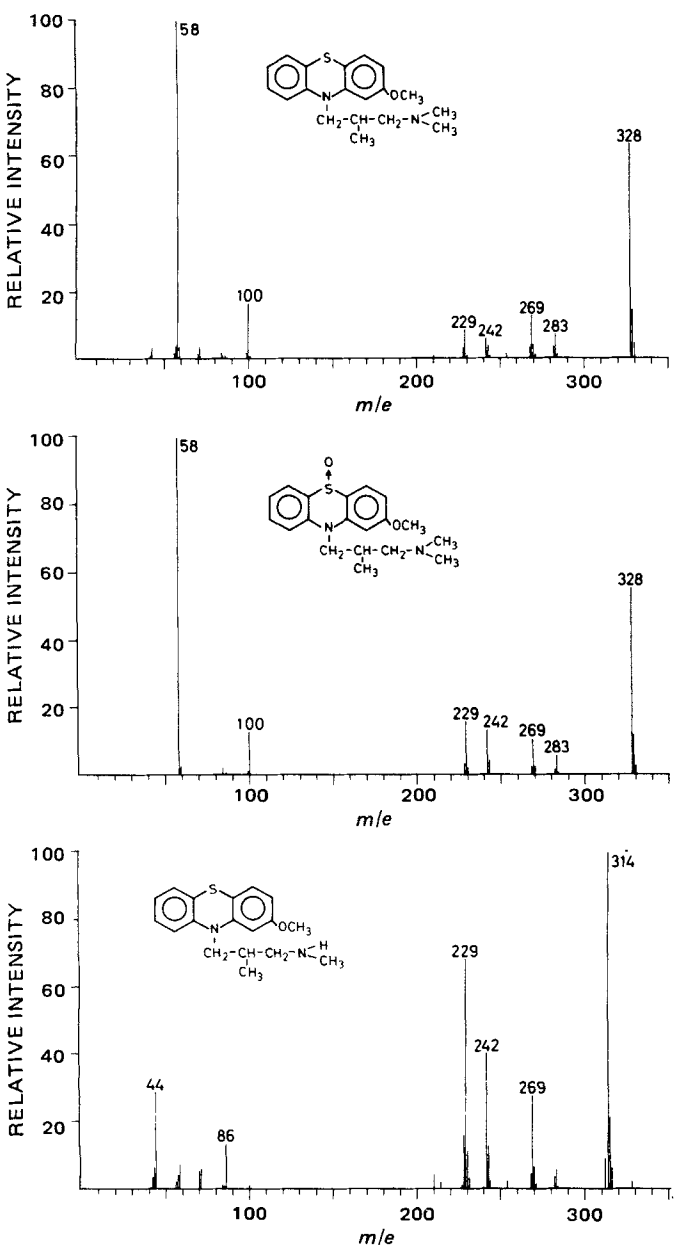

Figure 1—*Mass spectra of I, IV, and II obtained after injection of 1 μg of each compound from organic standard solutions.*

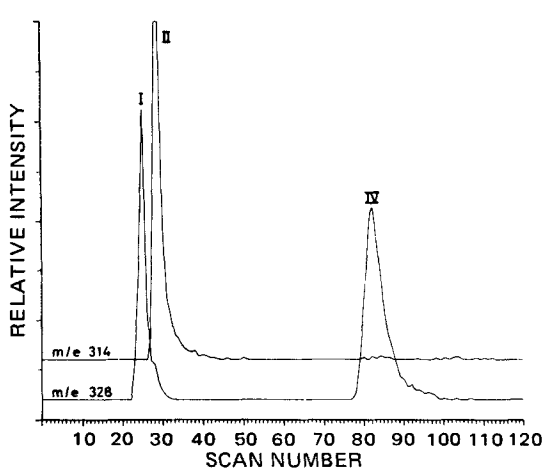

Figure 2—*Mass chromatograms obtained from an extract of 11.3 ml of plasma from Subject 1, collected 3 hr after administration of the morning dose.*

from plasma by this procedure (4). The mass spectrum of the one with the shortest retention time on the OV-17 column showed relatively high intensities of ions with mass numbers 149, 167, and 279, indicating that this compound was the commonly used plasticizer bis(2-ethylhexyl) phthalate (6).

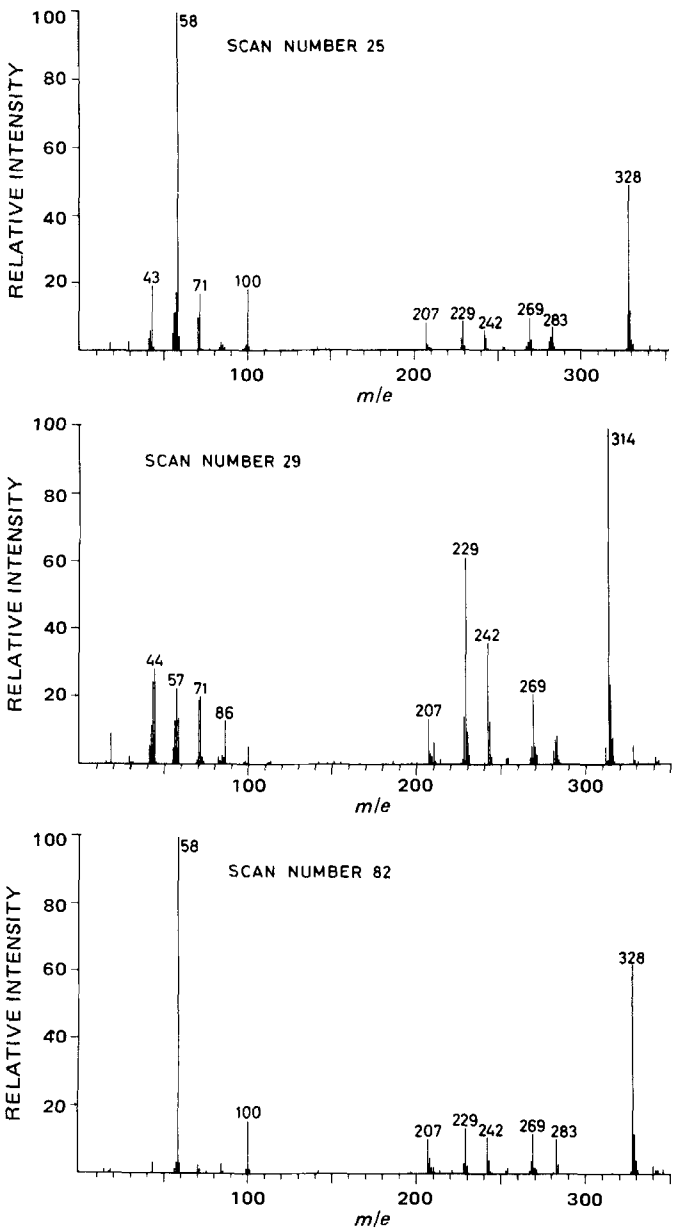

Figure 3—*Mass spectra obtained from the same sample as the mass chromatograms shown in Fig. 2.*

DISCUSSION

The 70-ev mass spectra of chlorpromazine sulfoxide and promazine sulfoxide were reported to contain an ion of mass corresponding to the dimethylamino side chain less two hydrogen atoms, which was absent from the mass spectra of the parent drugs (7). It was later reported that the two hydrogen atoms were eliminated from the methylene group in the middle of the side chain (8). In methotrimeprazine, one of these hydrogen atoms is substituted by a methyl group; no ion of mass corresponding to the side chain less one or two hydrogen atoms was seen in the mass spectra of I and IV, which were similar (Fig. 1).

It was reported previously that the 70-ev mass spectrum of IV, obtained by using a direct inlet system at 150°, showed a relatively high intensity of the molecular ion (*m/e* 344) and was distinguishable from the mass spectrum of I by the absence of ions with mass numbers 100 and 149 (9). The absence of the molecular ion of IV in the mass spectrum shown in Fig. 1 might have been due to reduction of the sulfoxide in the molecule separator, which was kept at 270°. A 70-ev mass spectrum of IV, recorded under otherwise the same conditions, was similar to the 20-ev mass spectrum and showed a relative intensity of the molecular ion of 0.9%.

The blood and urine samples were collected from patients receiving relatively large doses of I (Table I) and at the times of the day when the highest concentrations of I, II, and IV were expected. The method used for assay of I, II, and IV in urine was less accurate than the original procedure for I and IV in plasma, since no internal standard was used. Nevertheless, the results were sufficiently accurate for the scaling of the mass spectrometric analysis.

Several different components supposed to be conjugated metabolites of I were found previously in urine from psychiatric patients (10). Relatively polar components like glucuronides or hydroxylated metabolites of I are not, however, likely to be extracted by the present procedure. Compounds I, II, and IV previously were identified and quantitated in human urine (9), and the results given in Table I are in good agreement with the previously reported concentrations.

The peak in the *m/e* 300 mass chromatogram shown in Fig. 4 was not resolved from the peak of II (*m/e* 314), which had a much higher intensity;

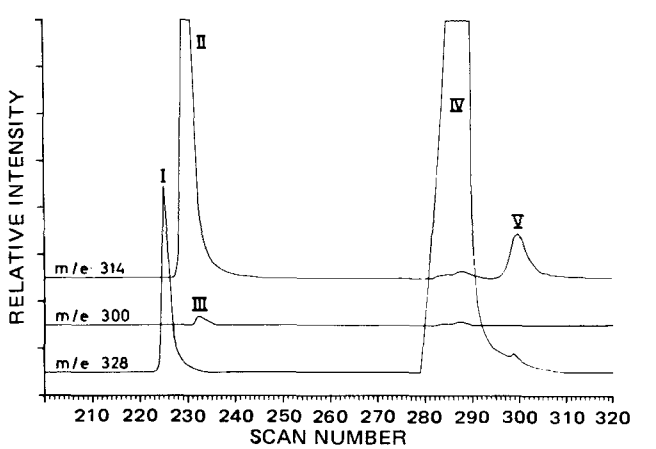

Figure 4—*Mass chromatograms obtained from an extract of 6 ml of urine from Subject 1, collected 5 hr after administration of the morning dose.*

therefore, the mass spectrum recorded in scan number 232 was similar mainly to that of II. Since the mass spectra of reference samples of I and II contained no ion with mass number 300, which was the base peak in the mass spectrum of III, the peak in the *m/e* 300 mass chromatogram still indicates that the urine contained III, although in apparently low concentration compared to I, II, and IV. The total recoveries of III and V by the extraction procedure were, however, not determined and may have been lower than the recoveries of I, II, and IV.

The mass spectrum recorded in scan number 300 was similar to the mass spectrum of V, confirming that the urine also contained this metabolite.

It may be concluded from the data given in Table II that all plasma extracts analyzed by combined GLC–mass spectrometry contained I, II, and IV. Some additional peaks of relatively high intensities, originating from the background, appeared in the mass spectra of plasma extracts from Subject 4.

In vitro studies indicated that IV must be considered pharmacologically active with regard to cardiac effects, while chlorpromazine sulfoxide possesses much less activity (3). The chlorpromazine (11–13) and promazine (14) metabolites analogous to II have proved pharmacologically active in different biological systems, and it seems reasonable that II should also possess significant pharmacological activity. Therefore, it would be desirable to have a sufficiently sensitive and specific method for quantitation of I and both of its nonpolar metabolites, II and IV, in plasma.

Potential Long Acting Opiate Antagonists: Preparation, Pharmacological Activity, and Opiate–Receptor Binding of *N*-Substituted 2′-Hydroxy-5-methyl-9α-propyl-6,7-benzomorphans

KENNER C. RICE *, WERNER A. KLEE ‡, MARIO D. ACETO §, HENRY H. SWAIN ¶, and ARTHUR E. JACOBSON *ˣ

Abstract □ A homologous series of *N*-substituted 2′-hydroxy-5-methyl-9α-propyl-6,7-benzomorphans (hydrogen to octyl inclusive, allyl, and cyclopropylmethyl) was prepared. In contradistinction to the normetazocine, normorphine, and (−)-3-hydroxymorphinan series, the *N*-pentyl and *N*-hexyl derivatives do not have the analgesic potency of the parent *N*-methyl compound; instead, they are narcotic antagonists with a long duration of action. All of the *N*-substituted 9α-propylbenzomorphans, except for methyl, heptyl, and octyl, have antagonist activity. The receptor binding constants of the *N*-alkyl compounds are uniformly two- to threefold lower than those of the *N*-substituted normetazocines.

Keyphrases □ Opiate antagonists, potential—various *N*-substituted benzomorphans synthesized, pharmacological activity and opiate–receptor binding evaluated □ Benzomorphans, *N*-substituted—synthesized, pharmacological activity and opiate–receptor binding evaluated □ Structure–activity relationships—various *N*-substituted benzomorphans synthesized, pharmacological activity and opiate–receptor binding evaluated □ Binding, opiate–receptor—various *N*-substituted benzomorphans evaluated

Narcotic analgesics based on fused ring systems, such as the 6,7-benzomorphans and the more complex morphinans and morphines, have commonly been converted to antagonists by modification of the *N*-substituent (1, 2) [classically by replacing the *N*-methyl with allyl (3), cyclopropylmethyl (1), or propyl (1)]. Many antagonists prepared in this manner are highly potent and some are used clinically (2). Most antagonists studied have only a short duration of action, for reasons that are not exactly clear. Long duration of action is a useful property in treating opiate overdosage and in some addiction treatment programs.

therefore, the mass spectrum recorded in scan number 232 was similar mainly to that of II. Since the mass spectra of reference samples of I and II contained no ion with mass number 300, which was the base peak in the mass spectrum of III, the peak in the *m/e* 300 mass chromatogram still indicates that the urine contained III, although in apparently low concentration compared to I, II, and IV. The total recoveries of III and V by the extraction procedure were, however, not determined and may have been lower than the recoveries of I, II, and IV.

The mass spectrum recorded in scan number 300 was similar to the mass spectrum of V, confirming that the urine also contained this metabolite.

It may be concluded from the data given in Table II that all plasma extracts analyzed by combined GLC–mass spectrometry contained I, II, and IV. Some additional peaks of relatively high intensities, originating from the background, appeared in the mass spectra of plasma extracts from Subject 4.

In vitro studies indicated that IV must be considered pharmacologically active with regard to cardiac effects, while chlorpromazine sulfoxide possesses much less activity (3). The chlorpromazine (11–13) and promazine (14) metabolites analogous to II have proved pharmacologically active in different biological systems, and it seems reasonable that II should also possess significant pharmacological activity. Therefore, it would be desirable to have a sufficiently sensitive and specific method for quantitation of I and both of its nonpolar metabolites, II and IV, in plasma.

BACKGROUND

This paper explores the effects of replacing a methyl group with a propyl group at the 9α-position of a benzomorphan. This simple substitution has led to a series of compounds with dramatic changes in biological activity. Of particular interest is the fact that some of these compounds are relatively pure antagonists with a long duration of action. Also interesting is the fact that the *N*-pentyl derivative, which in the normetazocine, normorphine, and 3-hydroxymorphinan series is approximately equipotent with the methyl derivative as an agonist, is devoid of analgesic activity in 2′-hydroxy-5-methyl-9α-propyl-6,7-norbenzomorphan.

In the metazocine series (I), replacement of the *N*-methyl (I*b*) by saturated alkyl moieties (4, 5) from ethyl to butyl (I*c*–I*e*) caused a diminution or loss of analgesic activity and a concurrent gain in narcotic antagonist activity (6), which was maximal with the *N*-propyl (I*d*) derivative (7). The *N*-ethyl compound (I*c*) (8, 9) was a weak agonist and a longer lasting but less potent antagonist than nalorphine with a steeper dose–response curve (9). The *N*-butyl derivative (I*e*) (7) had 0.2 times the antagonist potency and the same duration of action as nalorphine, and it had little analgesic activity, as measured by the Eddy hot-plate (10, 11) and Nilsen (12) assays.

When a five- or six-carbon side chain was introduced to form the *N*-pentyl (I*f*) or *N*-hexyl (I*g*) compounds, the potent analgesia associated with the parent *N*-methyl compound, metazocine (I*b*), was restored. A slight lessening of agonist potency was noted in I*g* (13). Although I*f* and, presumably, I*g* did not have the high physical dependence capacity associated with morphine, the *N*-pentyl did show a low physical dependence capacity, similar to metazocine, in single-dose suppression tests and in nonwithdrawn monkeys (14). These physical dependence capacity data are presently being reinvestigated.

A similar fluctuation of analgesic potency was noted in the comparable homologous normorphine (15) and (−)-3-hydroxymorphinan (16) series. Maximal analgesic potency was noted with the *N*-methyl and *N*-pentyl compounds in these series; the analgesic potency of the *N*-hexyl compound decreased a little. A considerable loss of analgesic potency was

IIk: R = CH_2—▽

noted with the *N*-ethyl and *N*-butyl derivatives. Thus, a binodal curve for analgesic activity could be used to describe the variation in potency in each of the three homologous series of compounds.

From the morphine data, a hypothesis was generated (17) which could be reformulated to say that compounds with narcotic antagonist activity have a saturated, aliphatic, three-carbon side chain on the nitrogen atom or the structural components of an allyl group. Potent analgesics with the physical dependence capacity of the opiate type are usually obtainable from methyl, pentyl, or hexyl substituents.

Since only these three groups of structurally rigid analgesics had been examined in this way, and the hypothesis certainly appeared to be valid for them, it was of interest to see whether it could be verified using a fourth homologous series prepared from a different benzomorphan, 2′-hydroxy-5-methyl-9α-propyl-6,7-norbenzomorphan (IIa). Thus, the methyl to octyl, allyl, and cyclopropylmethyl derivatives (IIb–IIj) of this benzomorphan were prepared by known methods (1, 13, 18).

EXPERIMENTAL[1]

Method A: 2-Alkyl-2′-hydroxy-5-methyl-9α-propyl-6,7-benzomorphans—A mixture of IIa (737 mg, 3.0 mmoles) (18), the appropriate alkyl iodide (allyl bromide for IIj) (3.1 mmoles), anhydrous potassium carbonate (1.0 g, 7.25 mmoles), and dry dimethylformamide (10 ml) was heated at 100–110° for 2.5 hr with stirring. After cooling, the inorganic material was filtered and washed with chloroform, and the filtrate and washings were evaporated *in vacuo*. The residue was dissolved in chloroform, washed with water, and dried (sodium sulfate).

Evaporation of the solvent left a residue, which was dissolved in acetone (15 ml) and treated with oxalic acid (288 mg, 3.2 mmoles) in acetone (5 ml). The crystalline acid oxalate salt that separated was collected, washed with acetone, and dried. Treatment of a methanol–water solution of the oxalate with 12 *M* ammonium hydroxide and extraction of the resulting oil into chloroform, drying (sodium sulfate), and evaporation of the solvent gave the purified base, which was recrystallized from the appropriate solvent for analysis (Table I).

Method B: 2-Cyclopropylmethyl-2′-hydroxy-5-methyl-9α-propyl-6,7-benzomorphan (IIk) Oxalate—A solution of cyclopropylcarbonyl chloride (1.0 g, 9.6 mmoles) in chloroform (5 ml) was added dropwise to a slurry of IIa (18) (737 mg, 3.0 mmoles) in dry pyridine (15 ml) maintained at 5–10°. When the addition was completed, stirring was continued at 5–10° until the solid dissolved and then at 25° for an additional 1 hr. The solution was evaporated to a semisolid, chloroform (70 ml) was added, and the solution was washed successively with water (50 ml), 1 *N* hydrochloric acid (50 ml), and brine (30 ml).

The chloroform solution was dried (sodium sulfate) and evaporated to give a syrupy, crude *O,N*-dicyclopropylcarbonyl derivative (1.265 g). This material was added to a slurry of lithium aluminum hydride (900 mg, 23.8 mmoles) in dry tetrahydrofuran (100 ml), and the mixture was refluxed overnight (stirring). After cooling, 12 *M* ammonium hydroxide (8 ml) was slowly added. The mixture was stirred for 1.0 hr, the tetrahydrofuran was decanted from the semisolid inorganic material and evaporated, the residue was dissolved in chloroform (100 ml), washed with water (50 ml), and dried (sodium sulfate), and the solvent was removed *in vacuo*. The residual base was dissolved in acetone (15 ml) and treated with oxalic acid (300 mg, 3.33 mmoles) in acetone (5 ml). The resulting crystalline salt was filtered, washed with acetone, and dried to give 991 mg of IIk. Recrystallization from 95% ethanol gave pure material (Table I).

[1] Melting points were determined in open capillary tubes using a Thomas-Hoover apparatus and are corrected. Microanalyses were performed by the Laboratory of Chemistry's Section of Microanalytical Services and Instrumentation. IR (Perkin-Elmer 257) and NMR (Varian A-60) spectra were consistent with the assigned structures. Mass spectra of the free bases were obtained using a Hitachi Perkin-Elmer RMU6E spectrometer (70 ev); each spectrum was consistent with the assigned structure and showed the expected molecular ion.

[k] Five out of 10 mice were affected at 20 mg/kg; toxic at 50 mg/kg (convulsions). [l] Toxic at 10 mg/kg (convulsions). [m] Inactive at 100 mg/kg. [n] Inactive at 50 mg/kg.

RESULTS AND DISCUSSION

The homologous series prepared from 2′-hydroxy-5-methyl-9α-propyl-6,7-norbenzomorphan did not follow the described biological patterns established by the normetazocines, morphines, and (−)-3-hydroxymorphinans. Analgesic potency dropped considerably in the *N*-ethyl (IIc) and *N*-butyl (IIe) compounds, as compared with the *N*-methyl (IIb), and did not return with the introduction of *N*-pentyl (IIf) into the molecule (Table II). The *N*-ethyl to *N*-hexyl (IIc–IIg) derivatives all appeared to have narcotic antagonist activity (Table III). Both agonist and antagonist activities disappeared in the *N*-heptyl (IIh) and *N*-octyl (IIi) compounds.

The unsubstituted benzomorphan, a secondary amine (IIa), had no antagonist activity (Table III). Benzomorphans unsubstituted on the nitrogen atom generally do not display antagonist behavior in monkeys. Normetazocine (Ia), normorphine, norketobemidone, and norbemidone have been shown to have a weak antagonist component in their pharmacological profile by their actions on the narcotic receptor in the guinea pig ileum (19). A strong agonist component in the pharmacological activity of IIa has been shown by an adenylate cyclase assay[2].

As the number of carbon atoms on the nitrogen increased, the duration of action of the compound as an antagonist also increased (Table III). The *N*-ethyl compound had a moderate duration of antagonist action (Table III). The *N*-propyl compound had a very long duration. Compound IIe was less potent than nalorphine but longer lasting. Compound IIf had a rapid onset and long duration of action as an antagonist. Compound

Table III—Summary of Data Obtained from Monkey Studies

N-Substituent	Test[a] / Dose Range[b]	Duration of Antagonist Action[c]	Comments
H (II*a*)	SDS / 5.0–10.0	—	Did not substitute for morphine and exacerbated withdrawal reaction only slightly
	NW / 10.0–20.0	—	Did not precipitate withdrawal; only a slight increase in respiration
Methyl (II*b*)	SDS / 1.5–6.0	—	Nondose-related reduction in withdrawal signs; did not substitute for morphine
Ethyl (II*c*)	SDS / 2.0–8.0	—	Nondose-related reduction in withdrawal signs; did not exacerbate withdrawal reaction
	NW / 4.0–32.0	1.5	Precipitated withdrawal; quick onset (0–30 min) and moderate duration of action
Propyl (II*d*)	SDS / 0.5–2.0	>3*c*	Did not substitute for morphine and appeared to exacerbate withdrawal; long duration of action
Butyl (II*e*)	SDS / 5.0	—	Increase in severity of abstinence signs
	NW / 1.25–5.0	10	Precipitation of moderate to severe abstinence; very long duration of action
Pentyl (II*f*)	SDS / 3.0–12.0	—	Did not substitute for morphine; severe withdrawal in one-third animals at highest dose
	NW / 4.0–32.0	2.5	Precipitated withdrawal; rapid onset (0–30 min) and long duration of action
Hexyl (II*g*)	SDS / 3.0–12.0	>3*c*	Did not substitute for morphine in the dose range tested and appeared to exacerbate withdrawal reaction; very long duration of action
Heptyl (II*h*)	SDS / 10.0	—	Neither suppresses nor precipitates abstinence syndrome
Octyl (II*i*)	SDS / 10.0	—	No alteration of signs of morphine abstinence
Allyl (II*j*)	SDS / 0.5–1.0	—	Increase in severity of abstinence signs
	NW / 0.125–2.0	10	Possible precipitation of abstinence signs at low doses; precipitation of severe, very long lasting abstinence at high doses
Cyclopropylmethyl (II*k*)	SDS / 0.5	—	Prompt intensification of signs of morphine abstinence
	NW / 0.03–1.25	0.5–1.5	Precipitation of mild abstinence signs at the low doses; severe abstinence signs at highest dose
Naloxone or nalorphine	NW / 0.5	0.5–1.5	Precipitated intense withdrawal reactions; rapid onset (0–30 min) and short to moderate duration of action

[a] SDS is single-dose suppression; NW is nonwithdrawn (see Ref. 6). [b] Milligrams per kilogram, subcutaneous injection, oxalate salts. [c] In hours. The duration of action ascertained by NW studies can be directly compared with nalorphine and naloxone data; SDS test data do not have reference standards (see Ref. 6) and can only be compared with other SDS results.

II*g* was a little different in that it had a slow onset and a very long duration of antagonist action. The *N*-allyl (II*j*) and *N*-cyclopropylmethyl (II*k*) compounds were potent, long acting antagonists.

The binding constants of these homologous compounds to rat brain homogenates known to contain receptors to the narcotic analgesics and their antagonists, as determined by standard techniques (13, 20), are presented in Table II. There appears to be a qualitative agreement between these binding constants and overall *in vivo* activity (analgesic or agonist-antagonist). There can be, of course, no quantitative fit to these data since antagonist activity has not been quantified, and only a few of the compounds show analgesic activity *in vivo* by either the hot-plate or Nilsen assay. However, it is thought that they all have an agonist component. This possible agonist activity will be examined in the future using the guinea pig ileum (21) and adenylate cyclase (22) assays.

There is less variation in the binding constants of the homologous normetazocine series (13) than with II*b*–II*j*. The *N*-unsubstituted normetazocine had a binding constant (EC_{50}) of 50; the *N*-ethyl had an EC_{50} of 20. The *N*-methyl, *N*-propyl, *N*-butyl, *N*-pentyl, and *N*-hexyl normetazocines all had EC_{50} values between 5 and 10. Thus, introduction of the 9α-propyl substituent increases the selectivity with which the opiate receptor recognizes different *N*-alkyl substituents. In all cases, however, binding of the 9α-propyl *N*-alkyl-substituted compounds was two- to threefold weaker than the corresponding 9α-methyl derivatives.

The 9α-alkyl group has been shown to be conformationally oriented toward the aromatic ring (away from the nitrogen atom) (23). The upfield position of those protons in the NMR spectra, as compared with the protons on a 9β-alkyl group, is due to the shielding influence of the aromatic ring (23). The introduction of a larger group in that area, such as a 9α-propyl group, may interfere with the fit of the flat phenolic region to a receptor, a fit that was previously postulated to be of importance to the interaction of the structurally rigid analgesics to the receptor (24).

This sterically generated interference could conceivably alter a conformational fit and, thus, cause a different pharmacological response.

Within the benzomorphans, it is unusual to find a statistically good fit between binding constants and *in vivo* analgesic activity[2]. The only series in which such correlations have been achieved are the structurally less rigid homologous ketobemidones (25), the benzazocines (13), and prodines (26). Evidently, the homologous ketobemidones had predominantly analgesic activity; only a few had an antagonist component in their pharmacological activity, and those were relatively weak antagonists. Thus, pharmacological activity could be closely approximated by analgesic potency with homologous ketobemidones, and analgesic activity was shown to be directly related to their binding constants (26). Unfortunately, homologous benzomorphans do not have pharmacological activity that is predominantly related to an accurately measurable analgesic potency. As has been seen, many *N*-substituted 9α-propylbenzomorphans are long acting antagonists, a pharmacological activity difficult to quantify in monkeys. Even if this activity could be quantified, as it might be using the guinea pig ileum assay procedure, pharmacokinetic factors, such as transport to the active site and metabolism, could complicate a correlation between *in vivo* pharmacological activity and *in vitro* binding constants.

A simple modification of the 9α-position in the benzomorphan molecule converted potent agonists (the *N*-pentyl- and *N*-hexylnormetazocines) to long acting antagonists (the *N*-pentyl- and *N*-hexyl-9α-propylbenzomorphans). The 9α-alkyl moiety has never before been implicated in the change of the pharmacological profile of a benzomorphan. This change, from potent agonist to narcotic antagonist, was thought to be caused only by the *N*-substituent. Further variation of the 9α-alkyl substituent to produce benzomorphans with bulkier and more hydrophobic groups in this position may be worthy of investigation to obtain even longer acting antagonists and to provide more clues to the nature of receptor interactions leading to antagonist activity.

High-Performance Liquid Chromatographic Determination of Diethylpropion Hydrochloride in Tablets: Isolation and Identification of Two Decomposition Products

MILDA J. WALTERS and STEPHEN M. WALTERS ˣ

Abstract □ A rapid assay was developed for diethylpropion hydrochloride tablets using high-performance liquid chromatography (HPLC) with UV detection. This technique provided separation of the drug from other UV-absorbing components present as the result of decomposition. A major decomposition product detected by HPLC in extracts of tablets and of the cotton filler from a tablet bottle was collected from the column effluents. This product was subsequently identified as 1-phenyl-1,2-propanedione, a highly volatile compound. A second decomposition product, isolated from decomposed drug by distillation from alkaline solution, was identified as diethylamine, apparently present as the hydrochloride salt. GLC, UV, IR, NMR, and mass spectrometry were used to confirm the identity of the decomposition products. HPLC assay results compared favorably with results of the NF assay; the latter procedure separates the drug from 1-phenyl-1,2-propanedione *via* liquid–liquid extraction.

Keyphrases □ Diethylpropion hydrochloride—high-performance liquid chromatographic analysis in tablets, identification of two decomposition products □ High-performance liquid chromatography—analysis, diethylpropion hydrochloride in tablets, identification of two decomposition products □ Anorectic agents—diethylpropion hydrochloride, high-performance liquid chromatographic analysis in tablets, identification of two decomposition products □ Decomposition products—of diethylpropion hydrochloride, identification, high-performance liquid chromatographic analysis in tablets

Diethylpropion has been reported to be an effective anorectic agent (1–3). A GLC method for the analysis of diethylpropion and its basic metabolites in urine was described previously (4). The metabolites investigated in that study (4) and in a later study (5) consisted of amino ketones and amino alcohols formed by *N*-dealkylation and keto reduction. Another study (6) detected 23 metabolic products of diethylpropion in human urine, of which 21 were identified. Two major products remained unidentified.

The investigation of possible decomposition of diethylpropion hydrochloride (I) in tablets was prompted by a disparity in analytical results obtained during the assay of several samples. Results obtained by the NF UV spectrophotometric procedure (7) were significantly lower than the monograph requirements. However, assays of extracts of these samples by perchloric acid titration gave results near the labeled amounts. Therefore, it was assumed that molecular dissociation had occurred, leaving the diethylamine group (reactant with perchloric acid) separated at some point from the remaining UV-absorbing portion. This assumption was further evidenced by the discovery of a yellow, highly volatile, UV-absorbing material in the cotton filler of a freshly opened bottle of tablets.

A high-pressure liquid chromatography (HPLC)–UV detection method was developed to provide a relatively rapid assay of I in tablets. It provided an additional advantage of isolating I from other UV-absorbing components present as the result of decomposition. GLC, UV, IR, NMR, and mass spectrometry were subsequently used to identify two decomposition products, 1-phenyl-1,2-propanedione (II) and diethylamine as the hydrochloride (III).

A report of the formation of II as a product of I has not been found, and the mechanism involved remains to be elucidated. The formation of diethylamine, in addition to ethylamine, acetaldehyde, and propiophenone, was reported as a result of photo- (254 nm) and radium-irradiation of aqueous and methanolic solutions of I (8).

EXPERIMENTAL

Instrumentation—*HPLC*—The liquid chromatograph[1] was equipped with a variable wavelength spectrophotometric detector[2] and a 2.6-mm i.d. × 50-cm stainless steel column containing a chemically bonded octadecylsilane on silica (13 ± 5 μm particle size) reversed-phase packing[3]. The detector wavelength was set at 255 nm, and the sensitivity was adjusted to produce a peak height of approximately 100 mm for 1.25 μg of I on a 50-mv recorder[4].

Two mobile solvent systems were used: A, a mixture containing 70% acetonitrile, 10% methanol, and 20% aqueous 0.1% ammonium carbonate; and B, a mixture containing 35% acetonitrile, 5% methanol, and 60% aqueous 0.1% ammonium carbonate. The flow rate was 1.0 ml/min, and elutions were made at ambient temperature. The retention volumes (V_R's) of I and II were 5.2 and 2.7 ml, respectively, using System B. The V_R of the internal standard, procaine hydrochloride, was 10.5 ml using System A for the quantitation of I.

GLC—A gas chromatograph[5] equipped with a flame-ionization detector was used. Compound II was chromatographed on a 2-mm × 1.83-m (6-ft) glass column packed with 16% DC 200 on Chromosorb WHP (80–100 mesh), with injector, column, and detector temperatures at 200, 100, and 250°, respectively. The helium carrier gas flow was 90 ml/min, and the detector sensitivity was 8×10^{-10} amp/mv. The retention time of II was 7.4 min.

Compound III was chromatographed on a 2-mm × 1.83-m (6-ft) glass column packed with 20% Carbowax 20M on Chromosorb WHP (80–100 mesh), with injector, column, and detector temperatures at 150, 60, and 250°, respectively. The helium carrier gas flow rate was 24 ml/min, and the detector sensitivity was 8×10^{-9} amp/mv. The retention time of III was 1 min.

IR—The IR spectrum of neat II was obtained[6] between sodium chloride plates, scanning from 2.5 to 16 μm. The spectrum of III was obtained[7] in the vapor phase in a 10-cm gas cell, scanning from 2 to 14 μm.

UV—The UV spectra of I and II were obtained[8] using 1-cm cells, scanning from 350 to 200 nm.

NMR—The NMR spectrum of II was obtained[9] in deuterated chloroform, scanning from 0 to 9 ppm.

Mass Spectrometry—The mass spectrum of II was obtained on a magnetic deflection mass spectrometer[10]. The sample was introduced *via* the liquid–solid direct insertion probe and ionized at a potential of 70 ev.

Table I—Assays of Drug Substance and Commercial 25-mg Tablets[1]: Comparison of Titrimetric, NF, and HPLC Methods

Sample	Diethylpropion Hydrochloride, % of Labeled Amount Found		
	Titrimetric	NF	HPLC
A (tablets)	101.0	88.6	—
B (tablets)	96.8	86.2	—
C (tablets)	—	82.4	81.7[a]
D (tablets)	—	80.8	83.6[a]
E (tablets)	96.8	97.2	96.3 ± 0.53[b]
F (drug substance)	98.9	98.9	99.9

[a] Average of three determinations. [b] Average ± *SD* of six determinations.

tablet composite equivalent to 25 mg of I was weighed into a 50-ml volumetric flask, and 25 ml of methanol was added. The flask was placed in an ultrasonic bath[11] for 10 min, and then the solution was diluted to volume with methanol. The solution was filtered through fast filter paper, the first 10 ml of filtrate was discarded, and a 2-ml aliquot was mixed with 2.0 ml of procaine hydrochloride internal standard solution (2 mg/ml in methanol). A standard solution of I was prepared by mixing 2.0 ml of a stock solution (0.5 mg/ml in methanol) with 2.0 ml of internal standard solution.

Five-microliter injections of these solutions were made into the liquid chromatograph using mobile Solvent System A. When the peak height ratios (*PHR*) of I to the internal standard were reproducible within ±1% of the average for at least three consecutive injections of the standard

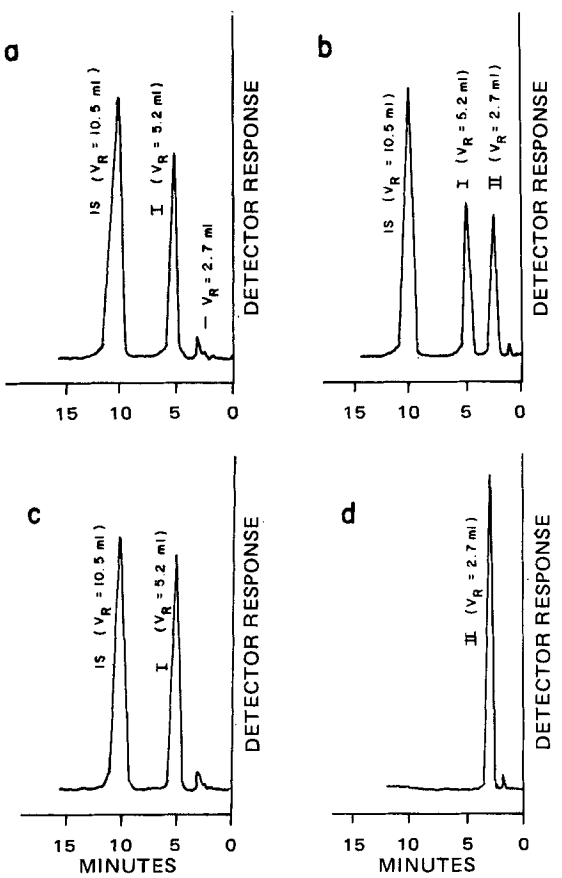

Figure 1—*HPLC separation of diethylpropion hydrochloride (I), decomposition product 1-phenyl-1,2-propanedione (II), and internal standard procaine hydrochloride (IS). Chromatograms are: a, an extract of a freshly prepared composite of undecomposed tablets; b, an extract of an aged, decomposed tablet composite; c, a standard solution of I; and d, an extract of yellow material from a cotton filler removed from a tablet bottle.*

	50°	Humid	528	90.0	NF
				105.0	Titrimetric

[a] All results are corrected for weight increases due to absorption of water.

solution, alternate sample and standard injections were made and the concentration of I in the tablets was calculated as:

$$\frac{PHR_{spl}}{PHR_{std}} \times \text{standard concentration, mg/ml} \times \text{dilution of sample (50 ml)} \times \frac{\text{average tablet weight, g}}{\text{weight of sample, g}} = \frac{\text{mg of I}}{\text{tablet}} \quad \text{(Eq. 1)}$$

Titrimetric Determination of I in Tablets—A portion of tablet composite equivalent to 200 mg of I was weighed and transferred into a separator containing 25 ml of water. The solution was made alkaline with 0.1 *N* NaOH and extracted with three 50-ml portions of chloroform. The extracts were filtered through a funnel containing a cotton plug covered with 5 g of anhydrous sodium sulfate. To the filtrate was added 25 ml of acetic acid, and the solution was titrated with 0.1 *N* perchloric acid in acetic acid, using 2 drops of gentian violet solution (10 mg/ml in acetic acid) as indicator.

Isolation of II from Tablets and Cotton Fillers—The yellow substance found in the cotton fillers in the tablet bottles and a portion of an aged tablet composite were both extracted with methanol, concentrated, and injected into the liquid chromatograph. Retention volumes were measured and compared using both Solvent Systems A and B. Fractions of the eluant corresponding to the equal retention volumes of the major peak in the cotton extract chromatogram and of the extraneous peak in the tablet extract chromatogram were collected from System B. UV spectrophotometric measurements were made directly on the collected eluants. The eluants were then extracted into pentane and concentrated by evaporation for GLC, IR, and mass spectrometric analyses. The volatility of the collected material proved to be a problem in isolating sufficient amounts for IR and mass spectrometric analyses. A satisfactory mass spectrum of the cotton extract only was obtained.

Accelerated Production of II—In an attempt to collect larger amounts of this unknown component for further analysis, accelerated degradation of I (drug substance) was performed. The most efficient method found was to place 1–2 g of the drug substance in an erlenmeyer flask with 1–2 ml of water, connecting the flask to a distilling adapter with the tip immersed in distilled water contained in a second erlenmeyer flask, and placing the first flask on a steam bath while maintaining the second flask near room temperature. After collecting the volatile product in this manner over 3–4 days, the unknown component was isolated from the water solution by extraction into pentane; very careful evaporation of the solvent yielded a yellow liquid residue.

Stability Study on Tablets and Drug Substance—A limited study of the effects of elevated temperature and humidity on the stability of I in both tablet and drug substance form was performed. Portions of previously assayed samples were weighed into small beakers. Some portions were subjected to an elevated temperature condition by placing them in an oven at 50°. The remaining portions were subjected to humid, elevated temperature conditions by placing them in a large beaker containing a smaller beaker of water, covering the large beaker with aluminum foil, and placing it in an oven at 50°.

The samples were assayed at various times by the NF or HPLC method, and some were assayed by the titrimetric method as well. All results were corrected for weight increases due to water absorption.

Isolation of III from Decomposed Drug Substance—To a portion

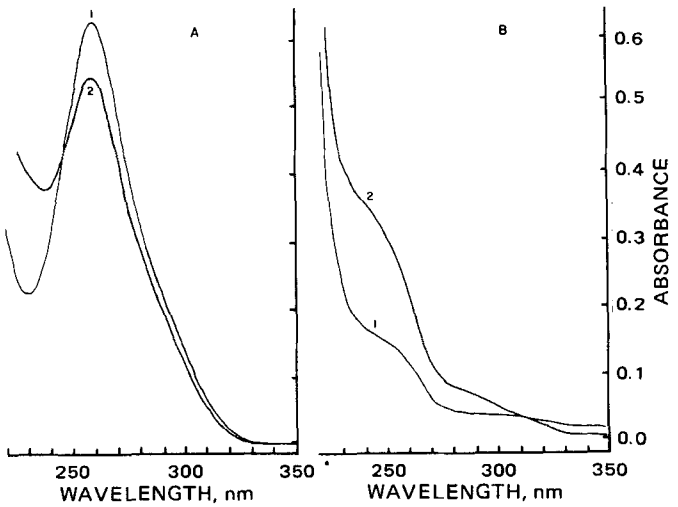

Figure 2—*UV spectra of (1) 1-phenyl-1,2-propanedione reference material and (2) isolated decomposition product II. A shows spectra obtained in water, and B shows spectra obtained after addition of sodium hydroxide.*

(~0.5 g) of decomposed drug substance remaining from the stability study was added 10 ml of 1 *N* NaOH. This solution was distilled from a microdistillation apparatus[12] by placing the distilling flask on a steam bath until several drops (~0.5 ml) of distillate were collected.

A portion of the aqueous distillate was extracted with chloroform for GLC analysis. Another portion was placed in a gas cell and warmed briefly to induce vaporization just prior to obtaining the IR spectrum.

RESULTS AND DISCUSSION

The assumption that partial decomposition of I in tablets had occurred *via* molecular dissociation of the amine group and the UV chromophore, with a rearrangement of the latter to a volatile compound, is evidenced by the comparative results of the titrimetric and NF or HPLC assays (Table I). This assumption was further evidenced by the finding of a foreign, UV-active, yellow material in a cotton filler, which was examined immediately upon removal from a bottle of tablets.

The volatile decomposition product exhibited UV activity with maximum absorbance near that of I. Thus, the agreement of results between the NF and the specific HPLC assays suggests that the volatile decomposition product (II) had escaped entirely from the tablet samples prior to performing the NF assays or that isolation of I from any remaining residues of II occurred in the liquid–liquid extraction steps of the NF procedure. A subsequent investigation found that the latter would occur.

The results of the limited stability study (Table II) indicate a significantly faster rate of decomposition with increased humidity, suggesting that hydrolysis may be involved in the process.

The relative values obtained by the NF and titrimetric assays of the decomposed samples again reflect the loss of UV-absorbing material in the decomposition process.

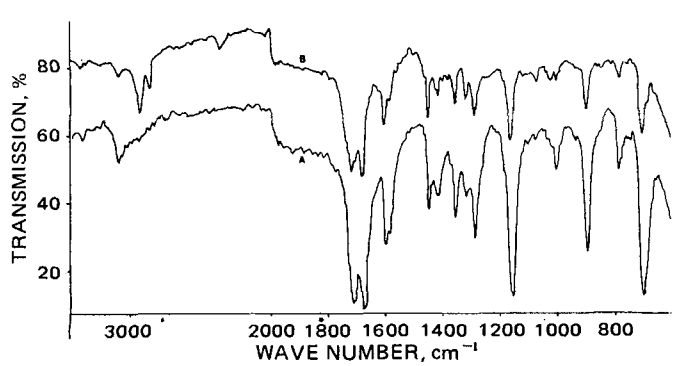

Figure 3—*IR spectra of (A) 1-phenyl-1,2-propanedione reference material and (B) isolated decomposition product II.*

[12] Ace Glass Inc., Vineland, N.J.

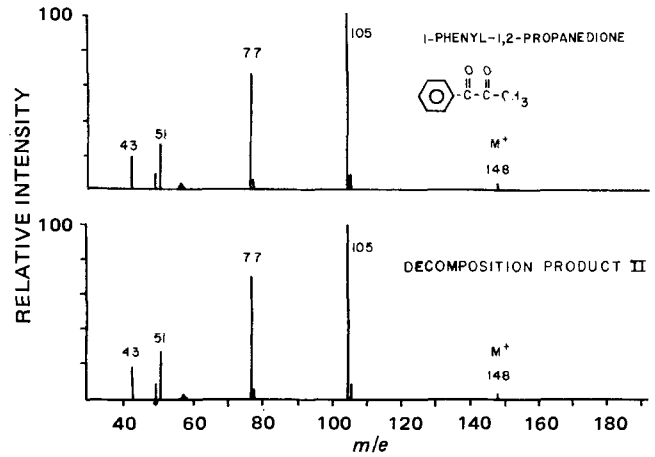

Figure 4—*Mass spectra of 1-phenyl-1,2-propanedione reference material and isolated decomposition product II.*

Typical liquid chromatograms obtained using Solvent System A are shown in Fig. 1. The aged tablet composite chromatogram contains an extraneous peak with the same V_R as the peak seen in the cotton filler chromatogram. This peak is absent in the standard and fresh composite chromatograms.

The liquid chromatograms obtained for the aged tablet composite and the cotton filler using Solvent System B also show an extraneous peak in the former with the same V_R as the peak seen in the latter. The use of this solvent system provided a larger V_R than did System A for the extraneous peak, with greater resolution from minor unknown peaks (probably decomposition by-products), thus permitting greater selectivity in the fraction collection process.

Subsequent HPLC analysis of the laboratory-produced decomposition product resulted in chromatograms similar to those of the cotton filler extract for both solvent systems.

The gas chromatograms and UV spectra showed identical characteristics for the laboratory-produced material and the collected HPLC fractions of the cotton filler and aged tablet composite extracts. The UV spectra consisted of a single maximum at about 255 nm when scanned in methanol or water, but it changed to a shoulder after addition of sodium hydroxide (Fig. 2).

The mass spectra of the laboratory-produced material and the collected fraction of the cotton extract showed identical fragmentation patterns, with a molecular ion peak at *m/e* 148 and major peaks at *m/e* 105, 77, 51, and 43.

The IR spectrum of the laboratory-produced material showed a double carbonyl band in the 1700-cm^{-1} region. A lack of bands in the 3500–

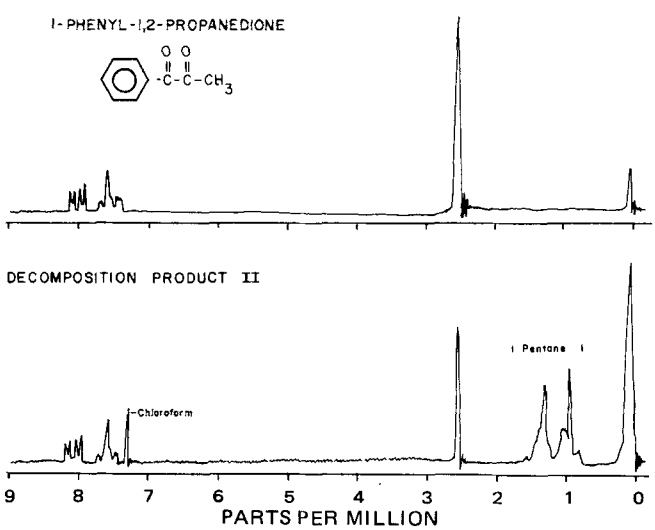

Figure 5—*NMR spectra of 1-phenyl-1,2-propanedione reference material and isolated decomposition product II.*

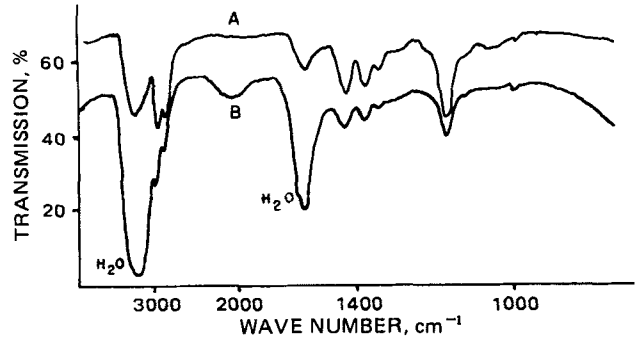

Figure 6—*IR spectra of (A) diethylamine reagent and (B) isolated decomposition product III.*

3000-cm^{-1} region indicated the absence of hydroxyl and primary or secondary amine groups.

The mass and IR spectra provided sufficient evidence for the elucidation of the structure of II. This compound was available commercially[13] and was purchased to serve as a reference material. The UV spectra of this reference material were nearly identical to those of the laboratory-produced decomposition product (Fig. 2). However, some background absorbance was apparent in the latter.

The IR and mass spectra of these two materials appeared identical (Figs. 3 and 4). The NMR spectra (Fig. 5) were also identical, with the exception of pentane peaks in the spectrum of the laboratory-produced material due to a residue remaining from the extraction step. A peak due to a chloroform impurity in the deuterated solvent was also visible in this spectrum because of the higher instrument gain used.

Gas and liquid chromatograms subsequently obtained for the reference material showed peaks identical to those of the previously unknown component. The chromatographic and spectral data combined with the identical physical characteristics of the cotton filler extract, the laboratory-produced material, and the reference material provided convincing evidence that II was formed as a major decomposition product of I.

Prior to the distillation of III from decomposed drug substance, the latter material was tested and found positive for secondary amines by the NF monograph test. The identity of III as a second decomposition product was then established by comparison of the gas chromatogram and the IR spectrum of the distillate with those of the diethylamine reagent[14]. Water was added to the latter prior to vaporization in the IR cell to simulate better its effect on the isolate spectrum (Fig. 6).

The distillate of an alkaline solution of undecomposed drug substance was found to contain no diethylamine, thus eliminating the suspicion that the latter may have been formed during the isolation procedure.

The route of decomposition from I to II and III has not been satisfactorily elucidated at this time and is apparently quite complex. However, it has been demonstrated that this type of decomposition has occurred in commercial tablet products and that it is accelerated by the presence of moisture.

The NF monograph assay procedure is specific for I in the presence of II, since it was found that II is retained in the sodium hydroxide solution while I is extracted into chloroform. However, the content uniformity procedure involves the direct UV determination of filtered hydrochloric acid solutions of the tablets. Since II was found to have considerable absorptivity and a maximum at 257 nm in this solvent, its presence in tablets could be expected to increase significantly the absorbance readings of their solutions, leading to inaccurately high results.

Identification of Diacetylmorphine Metabolites in Humans

S. Y. YEH[x], R. L. McQUINN, and C. W. GORODETZKY

Abstract □ With the techniques of column chromatography, TLC, and GLC, morphine, 6-acetylmorphine, normorphine, morphine 3-glucuronide, 6-acetylmorphine 3-glucuronide, and normorphine glucuronide were identified as metabolites of diacetylmorphine (heroin) in the urine of humans administered 10 mg iv/70 kg body weight.

Keyphrases □ Diacetylmorphine—metabolites identified using TLC, GLC, and column chromatography, human urine □ Metabolites—diacetylmorphine, identified using TLC, GLC, and column chromatography, human urine □ TLC—identification, diacetylmorphine metabolites, human urine □ GLC—identification, diacetylmorphine metabolites, human urine □ Column chromatography—identification, diacetylmorphine metabolites, human urine □ Narcotics—diacetylmorphine, metabolites identified using TLC, GLC, and column chromatography, human urine

Studies in laboratory animals *in vitro* and *in vivo* indicated that diacetylmorphine (heroin) (I) was rapidly metabolized first to 6-acetylmorphine and then to morphine (1–5). In humans, diacetylmorphine was excreted in the urine mainly as morphine (6, 7). Approximately 50–60% of I administered to heroin addicts was excreted in the urine as conjugated morphine and 7% as free morphine (8, 9). In addition to free and conjugated morphine, small

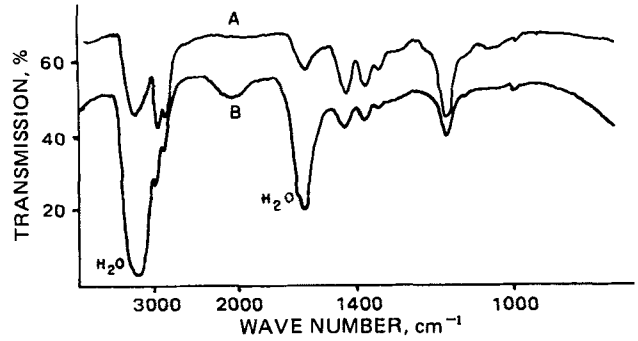

Figure 6—*IR spectra of (A) diethylamine reagent and (B) isolated decomposition product III.*

3000-cm^{-1} region indicated the absence of hydroxyl and primary or secondary amine groups.

The mass and IR spectra provided sufficient evidence for the elucidation of the structure of II. This compound was available commercially[13] and was purchased to serve as a reference material. The UV spectra of this reference material were nearly identical to those of the laboratory-produced decomposition product (Fig. 2). However, some background absorbance was apparent in the latter.

The IR and mass spectra of these two materials appeared identical (Figs. 3 and 4). The NMR spectra (Fig. 5) were also identical, with the exception of pentane peaks in the spectrum of the laboratory-produced material due to a residue remaining from the extraction step. A peak due to a chloroform impurity in the deuterated solvent was also visible in this spectrum because of the higher instrument gain used.

Gas and liquid chromatograms subsequently obtained for the reference material showed peaks identical to those of the previously unknown component. The chromatographic and spectral data combined with the identical physical characteristics of the cotton filler extract, the laboratory-produced material, and the reference material provided convincing evidence that II was formed as a major decomposition product of I.

Prior to the distillation of III from decomposed drug substance, the latter material was tested and found positive for secondary amines by the NF monograph test. The identity of III as a second decomposition product was then established by comparison of the gas chromatogram and the IR spectrum of the distillate with those of the diethylamine reagent[14]. Water was added to the latter prior to vaporization in the IR cell to simulate better its effect on the isolate spectrum (Fig. 6).

The distillate of an alkaline solution of undecomposed drug substance was found to contain no diethylamine, thus eliminating the suspicion that the latter may have been formed during the isolation procedure.

The route of decomposition from I to II and III has not been satisfactorily elucidated at this time and is apparently quite complex. However, it has been demonstrated that this type of decomposition has occurred in commercial tablet products and that it is accelerated by the presence of moisture.

The NF monograph assay procedure is specific for I in the presence of II, since it was found that II is retained in the sodium hydroxide solution while I is extracted into chloroform. However, the content uniformity procedure involves the direct UV determination of filtered hydrochloric acid solutions of the tablets. Since II was found to have considerable absorptivity and a maximum at 257 nm in this solvent, its presence in tablets could be expected to increase significantly the absorbance readings of their solutions, leading to inaccurately high results.

Identification of Diacetylmorphine Metabolites in Humans

S. Y. YEH[x], R. L. McQUINN, and C. W. GORODETZKY

Abstract □ With the techniques of column chromatography, TLC, and GLC, morphine, 6-acetylmorphine, normorphine, morphine 3-glucuronide, 6-acetylmorphine 3-glucuronide, and normorphine glucuronide were identified as metabolites of diacetylmorphine (heroin) in the urine of humans administered 10 mg iv/70 kg body weight.

Keyphrases □ Diacetylmorphine—metabolites identified using TLC, GLC, and column chromatography, human urine □ Metabolites—diacetylmorphine, identified using TLC, GLC, and column chromatography, human urine □ TLC—identification, diacetylmorphine metabolites, human urine □ GLC—identification, diacetylmorphine metabolites, human urine □ Column chromatography—identification, diacetylmorphine metabolites, human urine □ Narcotics—diacetylmorphine, metabolites identified using TLC, GLC, and column chromatography, human urine

Studies in laboratory animals *in vitro* and *in vivo* indicated that diacetylmorphine (heroin) (I) was rapidly metabolized first to 6-acetylmorphine and then to morphine (1–5). In humans, diacetylmorphine was excreted in the urine mainly as morphine (6, 7). Approximately 50–60% of I administered to heroin addicts was excreted in the urine as conjugated morphine and 7% as free morphine (8, 9). In addition to free and conjugated morphine, small

amounts of I and free 6-acetylmorphine were observed in the urine of humans infused with a large dose of I intravenously (10). Morphine ethereal sulfate, free and conjugated normorphine, morphine 6-glucuronide, and dihydromorphinone could also be metabolites of I, since these substances have been identified as morphine metabolites in humans and laboratory animals (11–19). The present article reports the identification of I metabolites in humans following intravenous administration of a single 10-mg dose.

EXPERIMENTAL

Materials—Diacetylmorphine hydrochloride [free of contaminant when determined by TLC (20) but shown to contain about 5% 6-acetylmorphine as determined by GLC], 6-acetylmorphine hydrochloride, and normorphine hydrochloride were obtained[1]. Morphine sulfate and codeine phosphate were commercial products. Morphine 3-glucuronide and morphine 3-ethereal sulfate were isolated, respectively, from the urine of dogs and cats administered morphine (14, 21). Normorphine 3-glucuronide was isolated from the urine of dogs administered normorphine hydrochloride (22).

Methods—Twelve healthy, postaddict, male, federal prisoner volunteers, with an average age of 36 years and an average body weight of 77 kg, were administered 10 mg iv of I/70 kg body weight. Urine collections were made before drug administration and at intervals of 2, 4, 6, 8, 16, and 24 hr and *ad libitum* following drug administration. The urine was frozen after collection.

Extraction of I Metabolites—The method for extraction and determination of I metabolites was described previously (23).

Glucuronic Acid Determination—The content of glucuronic acid in the conjugated metabolites was determined according to the procedure of Dische (24).

Hydrolysis of Conjugated Metabolites: Acid Hydrolysis—Conjugated metabolites were hydrolyzed by autoclaving the sample in 2.2 *N* HCl [20% (v/v) concentrated hydrochloric acid] in a steam-jacketed autoclave at 6.8 kg of pressure and 115° for 30 min. After cooling, the sample was adjusted to about pH 10 and then extracted and silylated for GLC determination according to the procedure described (11, 23). Under these conditions, 6-acetylmorphine and its conjugates were hydrolyzed to morphine. Identical samples without hydrolysis were used as controls.

Hydrolysis of Conjugated Metabolites: Enzymatic Hydrolysis—Samples were adjusted to pH 7, buffered with 1.0 ml of 0.1 *M* phosphate buffer at pH 6.8, and incubated with 5 mg of β-glucuronidase[2] (type II bacterial powder, 170 Fishmen units/mg and no sulfatase activity) and 2 drops of chloroform at 37° for 4 hr (for hydrolysis of 6-acetylmorphine conjugate) or 18 hr (for hydrolysis of morphine and normorphine conjugates). Samples incubated without enzyme were used as the control. After incubation, the sample was adjusted to pH 8.5 (for extraction of 6-acetylmorphine and morphine) or pH ~10 (for extraction of normorphine and morphine) and then extracted and silylated for GLC determination according to the described procedure (11, 23).

TLC—TLC was performed with either instant TLC silica gel sheets[3] or linear preadsorbent TLC silica gel plates[4]. With the instant TLC silica gel sheets, samples were spotted 2.54 cm (1 in.) above the edge. The chromatogram was developed with 1-butanol–acetic acid–water (35:3:10). With the linear TLC silica gel plates, aliquots of unknown samples along with authentic samples were spotted on the preadsorbent section. The chromatogram was developed with ethyl acetate–methanol–ammonium hydroxide (17:2:1), and the R_f values were calculated using the beginning of the silica gel section as the origin. All chromatograms were visualized by spraying with iodoplatinate reagent[5].

GLC—A gas chromatograph[6] equipped with dual flame-ionization detectors and dual columns was used. A 0.9-m (3-ft) × 2-mm glass column (Column 1) was packed with 3% OV-17 coated on Gas Chrom Q (60–80 mesh). A 1.5-m (5-ft) × 2-mm stainless steel column (Column 2) was packed with 3% SE-30 coated on Varaport (100–200 mesh). The temperatures of the injector and detector were set at 255 and 295°, respectively; gas flow rates were 30 ml/min for nitrogen and hydrogen and 300–400 ml/min for compressed dried air.

Derivatization—An aliquot of the sample was placed in an acylation tube and evaporated to dryness under a stream of nitrogen in a water bath at about 60°. The residue was derivated to make silyl, trifluoroacetyl, acetyl, or propionyl derivatives. Silylated derivatives were prepared by heating the residue with 50 μl of 25% trimethylsilylimidazole in pyridine[7] at 90–95° for 1 hr. Trifluoroacetyl derivatives were prepared by heating the residue with 0.2 ml of trifluoroacetic anhydride at 60–70° for 0.5 hr. Acetyl derivatives were made by heating the residue with 0.2 ml of acetic anhydride and 0.1 ml of pyridine at 60–70° for 0.5 hr. Propionyl derivatives were prepared by heating the residue with 0.2 ml of propionic anhydride (glass redistilled) and 0.1 ml of pyridine at 60–70° for 0.5 hr. The excess anhydride and pyridine were removed by evaporation, and the residue was reconstituted with 50 μl of ethyl acetate. One microliter of the solution was injected into the gas chromatograph.

GLC–Mass Spectrometry— The chemical ionization mass spectral data were obtained[8] using a glass column [1.5 m (5 ft) × 2 mm] packed with 3% SE-30 coated on Gas Chrom Q. Methane was used as the carrier gas as well as the chemical ionization reagent gas in the ion source. The column, injector, and ion source temperatures were 240, 250, and 100°, respectively. The electron energy was 80 ev, and ion repeller voltage was 3 v.

Isolation with Column Chromatography—The urine samples collected during the 0–16-hr period from 10 subjects were pooled, centrifuged to remove insoluble substances, and chromatographed with a resin[9] column. Two hundred milliliters of the urine was passed, at a flow rate of about 2–4 ml/min, through the column (2.1 × 40 cm) previously washed with acetone, methanol, and water. The column then was washed with 150 ml of distilled water and eluted with 250 ml of methanol. The first 100 ml of washing was discarded, and the second 50 ml of washing was combined with the eluate. The eluate was evaporated to dryness under vacuum in a rotary evaporator in a water bath between 40 and 50° (all evaporation was done in the same manner). The residue was triturated with methanol and yielded methanol-soluble and insoluble (water-soluble) fractions.

Methanol-Soluble (Free Base Drug) Fraction—The methanol-soluble fraction was evaporated to dryness. The residue was dissolved with 15 ml of 10% acetic acid solution and extracted three times with 15 ml of *n*-butyl chloride to remove such substances as nicotine and caffeine. Morphine, I, and acetylmorphine were not extracted under these circumstances. The aqueous phase, after extraction with *n*-butyl chloride, was adjusted to pH 4.5 with 1 *N* NaOH and extracted with 15 ml of chloroform three times to attempt to extract I. After extraction with chloroform, the aqueous phase was adjusted to pH 8.5 with 1 *N* NaOH and extracted three times with 15 ml of 1,2-dichloroethane containing 30% (v/v) 2-propanol.

After extraction, the aqueous phase was again evaporated to dryness and triturated with methanol. The methanol-soluble portion was combined with the extract of 1,2-dichloroethane containing 30% 2-propanol. The methanol-insoluble portion was discarded. The extracts of *n*-butyl chloride, chloroform, and 1,2-dichloroethane containing 30% 2-propanol were separately pooled and evaporated to dryness, and the residues were dissolved with 1 ml of *n*-butyl chloride, chloroform, and ethyl acetate, respectively.

RESULTS

Aliquots of the extracts of *n*-butyl chloride, chloroform, and 1,2-dichloroethane containing 30% 2-propanol were chromatographed on linear TLC silica gel plates with ethyl acetate–methanol–ammonium hydroxide (17:2:1) as the developing solvent. The chromatogram of the extract of *n*-butyl chloride showed two spots with R_f 0.35 and 0.8. The retention time of the peaks of the extract did not correspond to any hypothesized possible I metabolite. The chromatogram of the chloroform extract showed three spots with R_f 0.43 (morphine), 0.8 (to be identified), and 0.9 (6-acetylmorphine and I). The chromatogram of the 1,2-dichloroethane containing 30% 2-propanol extract showed three spots with R_f 0.23 (normorphine), 0.43, and 0.9.

Preparative TLC of the chloroform extract was performed on two large

Methanol-insoluble fraction	—	0.03, 0.40, 0.76, 0.90

plates (20 × 20 cm), and preparative TLC of the 1,2-dichloroethane–2-propanol extract was performed on one plate. A section of the chromatogram was sprayed with iodoplatinate reagent. The zones corresponding to the iodoplatinate-positive regions and to R_f 0.7 (where codeine would be expected) were horizontally scraped off and eluted with methanol. The eluate was concentrated and aliquots were derivatized and determined by GLC. The identity of metabolites with R_f 0.23, 0.4, and 0.9 was further supported as normorphine, morphine, and 6-acetylmorphine, respectively, by cochromatography with authentic samples and by GLC (Table I).

Compound I was not detected in the eluate obtained from the region with R_f 0.9. The retention time of the peaks of the eluate with R_f 0.8 did not correspond to any hypothesized possible I metabolite. Norcodeine and codeine were not detected in the eluate obtained from the zone with R_f 0.4 and 0.7.

Methanol-Insoluble Fraction—The chromatogram of the methanol-insoluble (water-soluble) fraction on an instant TLC silica gel sheet developed with 1-butanol–acetic acid–water (35:3:10) showed four iodoplatinate-positive spots with R_f 0.03, 0.4, 0.76, and 0.9 (Table II). Preparative TLC was performed on 10 instant TLC silica gel sheets (20 × 20 cm), and a section of the chromatogram was sprayed with iodoplatinate reagent. The zones corresponding to the iodoplatinate-positive spots were horizontally cut off and eluted with warm water. The material located at R_f 0.9 was eluted first with methanol and then with water. In addition, the iodoplatinate-negative regions with R_f 0.5 and 0.6 (corresponding to R_f values of morphine 6-glucuronide and morphine 3-ethereal sulfate) were isolated and eluted with water. It was thought that these metabolites could be present in small amounts, too low to show positive with iodoplatinate.

The metabolite with R_f 0.03 was hydrolyzed to yield morphine. Since this metabolite could have been due to morphine 3-glucuronide, held back by an impurity, it was rechromatographed. The chromatogram again showed one spot with R_f 0.03. The metabolite with R_f 0.03 was negative with the phenolic test and hydrolyzed with β-glucuronidase or with acid to yield morphine. This metabolite appears to be a polar morphine metabolite, but its identity has not yet been determined.

The metabolite with R_f 0.4 was negative with the phenolic test, positive with the glucuronic acid test, and hydrolyzed with β-glucuronidase or with acid to give morphine. Cochromatography of this metabolite with authentic morphine 3-glucuronide showed a single spot. Therefore, this metabolite was identified as morphine 3-glucuronide.

The metabolite with R_f 0.76 was positive with the glucuronic acid test and hydrolyzed with β-glucuronidase to yield 6-acetylmorphine and normorphine. These metabolites were tentatively identified as 6-acetylmorphine 3-glucuronide and normorphine glucuronide, respectively.

The material with R_f 0.9, corresponding to the R_f of free morphine and 6-acetylmorphine, showed peaks of morphine and 6-acetylmorphine on GLC. The concentration of morphine and 6-acetylmorphine did not significantly increase after enzymatic hydrolysis, suggesting that the compound was in the free form. Other peaks were also observed but did not correspond to those of any known I metabolites.

The eluate obtained from the iodoplatinate-negative region with R_f 0.5–0.6 was concentrated and passed through a neutral alumina column (1.0 × 2.5 cm). The column was eluted with 100 ml of water. The eluate was concentrated to about 1.5 ml and rechromatographed on one instant TLC silica gel sheet (20 × 20 cm), using 1-butanol–acetic acid–water (35:3:10) as the developing solvent. After a section of the chromatogram was sprayed with iodoplatinate reagent, a faint spot with R_f 0.5 was clearly distinguished from the spot of morphine 3-glucuronide (0.4) and codeine 6-glucuronide (0.6). The zone corresponding to R_f 0.5 was cut off and eluted with water, and the eluate was concentrated. The eluate was positive with the Folin–Ciocalteu phenolic test and with a glucuronic test. After hydrolysis with β-glucuronidase, the metabolite yielded morphine. The content of glucuronic acid in the eluate was determined according to the described procedure (24), and the content of morphine was determined by GLC. The ratio of morphine to glucuronic acid was about 1:1. These data suggest this metabolite to be morphine 6-glucuronide.

Identification of Normorphine by GLC–Mass Spectrometry—The chemical ionization mass spectral data of a sample (as the acetyl derivative) showed a peak with a retention time and mass fragmentation spectrum [with mass at *m/e* 398 (M − 1) and 338 (M − acetic acid + 1)] identical with those of authentic triacetylnormorphine (Fig. 1).

Search for Dihydromorphinone as Possible Metabolite of I—Aliquots (200 ml) of the first 8-hr urine from two subjects were acid hydrolyzed, buffered at pH ~10, and extracted with chloroform instead of 1,2-dichloroethane containing 30% 2-propanol according to a described triple-extraction procedure (11). The organic phase was concentrated and applied along with authentic samples to an aluminum oxide 1B plate[10]. The chromatogram was developed using the lower phase of the solvent mixture of chloroform–methanol–water–acetic acid (20:10:20:2) (19). A section of the plate was sprayed with iodoplatinate, and a spot corresponding to morphine was observed; no dihydromorphinone spot was seen. The presence of normorphine was inconclusive because of an impurity masking the spot.

The zones corresponding to normorphine (R_f 0.03), morphine (0.23), and dihydromorphinone (0.38) were separately scraped off and eluted with methanol. Aliquots of the eluate were evaporated to dryness, and the residues were made into propionyl derivatives. One microliter of the reconstituted solution was injected into Column 2 with an oven temperature at 240°. Peaks corresponding to normorphine (R_t 22) and morphine (7.2) were observed in the eluate. The dihydromorphinone peak (R_t 4.9) was not observed. A detailed procedure for the determination of dihydromorphinone as a morphine metabolite will be published later.

DISCUSSION

Free morphine, 6-acetylmorphine, free normorphine, morphine 3-glucuronide, morphine 6-glucoronide, 6-acetylmorphine 3-glucuronide,

[10] J. T. Baker, Phillipsburg, N.J.

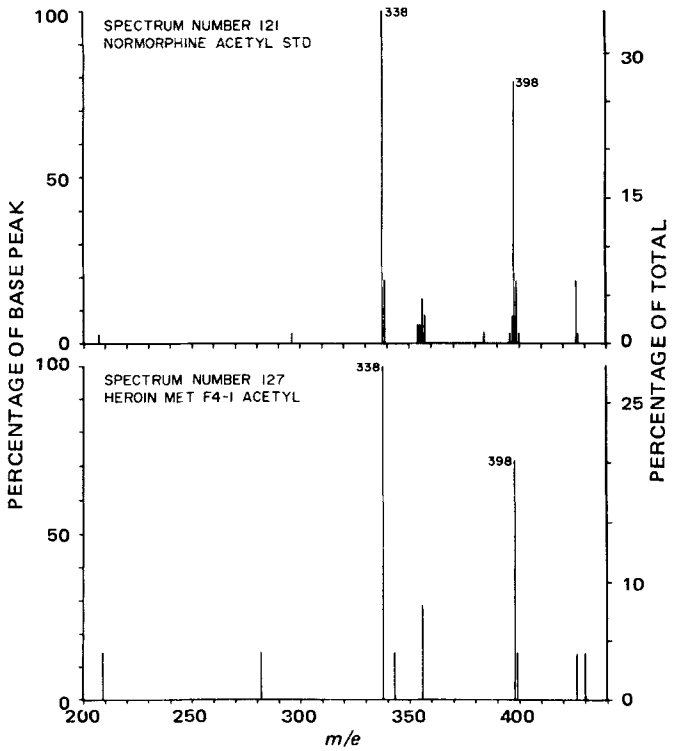

Figure 1—*GLC–mass spectrometric analysis of acetylated normorphine and the peak corresponding to acetylated normorphine of the extract of 5 ml of urine collected 0–8 hr from Subject F administered 10 mg of diacetylmorphine hydrochloride.*

and normorphine glucuronide were found as metabolites of I in human urine. Morphine 3-glucuronide was the major metabolite, accounting for approximately 50% of the administered dose. Free morphine accounted for about 7%, and the remaining metabolites were present in a magnitude of less than 5%. The quantitative studies on metabolism of I in humans will be published elsewhere (25).

Since heroin is deacetylated to 6-acetylmorphine and then to morphine (2, 3, 5), it seems likely that the 6-acetylmorphine present in the administered dose was deacetylated to morphine *in vivo* and the 6-acetylmorphine found in the urine was a minor I metabolite. However, the possibility could not be ruled out that it was an autohydrolysis product of I excreted in the urine or that it occurred during the process of extraction.

An attempt to isolate 6-acetylmorphine 3-glucuronide was unsuccessful because of the small amount of material and the labile acetyl group. The existence of 6-acetylmorphine 3-glucuronide could be further illustrated by incubation of the eluate obtained from the resin[9]. The eluate was evaporated to dryness and reconstituted with water prior to incubation with β-glucuronidase. The amount of 6-acetylmorphine was increased about twofold after incubation, while morphine increased five- to sixfold as compared to that without incubation.

In the present study, normorphine glucuronide together with 6-acetylmorphine 3-glucuronide was located at R_f 0.76. An attempt to isolate normorphine glucuronide was unsuccessful because of the small amount of material.

Codeine and norcodeine were not observed as metabolites of I in the present studies, although they have been reported as metabolites of morphine in humans (26, 27). The existence of codeine and norcodeine as metabolites of morphine in humans has been questioned (28, 29). The sensitivity of the present GLC method could detect 0.5 μg of codeine, 1.0 μg of norcodeine, and 5 μg of dihydromorphinone. Dihydromorphinone has been reported as a morphine metabolite in the rat chronically administered morphine but was not observed in the present study. This result could be due to a species difference.

The chromatograms of the extract of *n*-butyl chloride on a linear TLC silica gel plate, developed with ethyl acetate–methanol–ammonium hydroxide (17:2:1), showed spots with R_f 0.35 and 0.8. These spots were probably due to nicotine and caffeine and their metabolites. A chromatographic study on the urine from cigarette smokers and coffee drinkers was described previously (30).

Kinetic Spectrophotometric Study of Effect of Triazolopyrazines on *p*-Benzoquinone Complexes

G. H. MOXON and M. A. SLIFKIN ˣ

Abstract □ The effect of adding triazolopyrazines to a *p*-benzoquinone–proline system and a *p*-benzoquinone–histamine system was studied by observing the kinetics of the spectral changes and analyzing the results using digital simulation methods. Below 35°, the major effect was that the triazolopyrazine competed with the electron donors for the acceptors to form complexes. Above 35°, there was predominantly a chemical interaction between the triazolopyrazine and the acceptors. A separate experiment showed that the triazolopyrazine interacted with *p*-benzoquinone to form a complex initially but that a chemical interaction took place later.

Keyphrases □ *p*-Benzoquinone complexes—with proline and histamine, effect of various triazolopyrazines, kinetic spectrophotometric study □ Triazolopyrazines, substituted—effect on complexes of *p*-benzoquinone with proline and histamine, kinetic spectrophotometric study □ Complexes—*p*-benzoquinone with proline and histamine, effect of various triazolopyrazines, kinetic spectrophotometric study □ Spectrophotometry—kinetic study, effect of triazolopyrazines on complexes of *p*-benzoquinone with proline and histamine □ Structure–activity relationships—various triazolopyrazines, effect on complexes of *p*-benzoquinone with proline and histamine

The spectral properties of some nitrogen heterocyclic drugs, some triazolopyrazines, and a triazolopyrimidine (1) have been studied, as has the effect of these drugs on the potentiation of the reversal of metachromasia of a toluidine blue–heparin complex in the presence of amino acids (2). It was suggested that the triazolopyrazines might function as electron donors, competing with both the dye and amino acids for acceptor sites on the dye. The electron-donating properties of some of these drugs have now been studied by observing the interaction directly with the electron acceptor *p*-benzoquinone and by observing the effect of the drugs on systems of *p*-benzoquinone with the electron acceptors histamine and proline.

Both systems were studied extensively by the method of time-dependent spectrophotometry under various temperature, solvent, and pH conditions. The curves were analyzed using digital simulation methods (3, 4). Furthermore, since some of these heterocyclic drugs have antiasthmatic activity, their interaction with a histamine system might have medicinal interest. The alteration of a reaction rate by the complexing of one reactant in a two-molecule system with an added third compound has been studied (5, 6) and is a very useful technique where the interaction between the added third compound and either interactant is weak or is not shown clearly by the techniques in use.

EXPERIMENTAL

Histamine, *p*-benzoquinone, and proline were obtained and purified as described previously (3, 4). 3-Amino-6-methyl-8-propyl-*s*-triazolo[4,3-*a*]pyrazine (I), 3-acetamido-5-methyl-8-*n*-propyl-*s*-triazolo[4,3-*a*]pyrazine (II), 3-acetamido-6-methyl-8-*n*-propyl-*s*-triazolo[4,3-*a*]pyrazine (III), and 2-amino-5-*n*-propyl-*s*-triazolo[2,3-*c*]-pyrimidine (IV) were used as supplied[1]. (Their structures are shown in Fig. 1 of Ref. 1.) The experimental methods and techniques were described previously (3, 4).

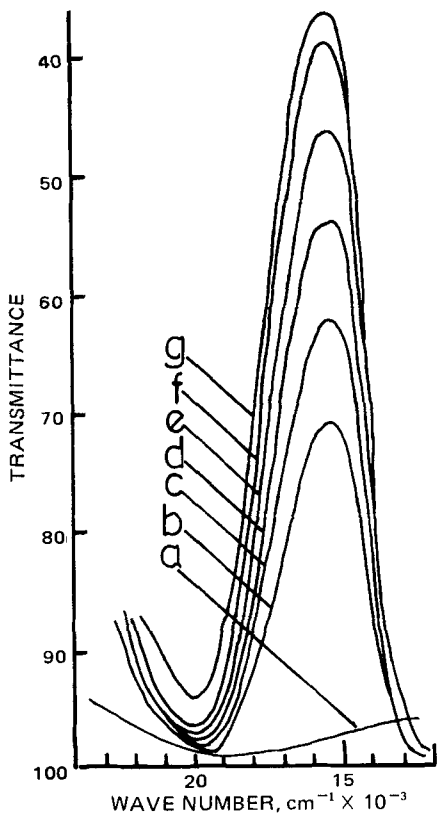

Figure 1—*Development of peak at 15,200 cm^{-1} (658 nm) attributed to the I (2 × 10^{-2} M)-p-benzoquinone (2 × 10^{-4} M) complex at 25° in pH 7 phosphate buffer. Readings were at: (a) zero time, (b) 6 days, (c) 7 days, (d) 8 days, (e) 9 days, (f) 10 days, and (g) 15 days.*

RESULTS AND DISCUSSION

Interaction of I with p-Benzoquinone—The effect of I with *p*-benzoquinone in phosphate buffer was studied first. Figure 1 shows the spectrum obtained in a mixed solution of the drug and quinone in pH 7 phosphate buffer. The effect of drug concentration on the development of the absorption spectrum is illustrated in Fig. 2. The shape of the curve is indicative of the formation of more than one species (7) and indicates that the interaction is of the form:

$$A \underset{k_2}{\overset{k_1}{\rightleftharpoons}} B \xrightarrow{k_3} C$$

The observed peak at 15,200 cm^{-1} (658 nm) corresponds not to the immediate product of the interaction but to some subsequent reaction product (*C*), as evidenced by the initial induction period and the shape of its growth curve.

Figure 3 shows the effect of temperature on the absorption band at 15,200 cm^{-1} (658 nm). Increasing the temperature from 25 to 55° resulted in a marginal increase in the intensity which was not reversible. This behavior indicates a chemical interaction and not a complexing mechanism. The initial reaction between the drug and the quinone, which was not observable spectroscopically, probably is the formation of a reversible complex, since many organic amines and amides are known to form complexes with quinones and then chemical products (3, 8).

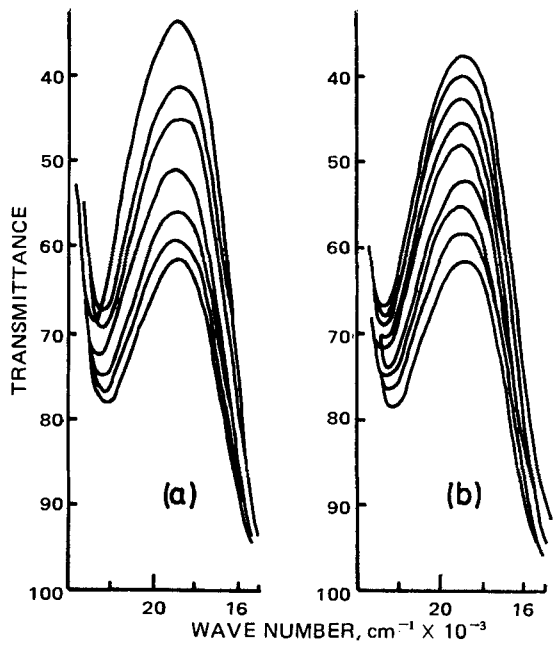

Figure 4—*Effect of I (2 × 10^{-2} M) on the absorption band at 18,800 cm^{-1} (532 nm) ascribed to the* p*-benzoquinone (2 × 10^{-4} M)–proline (7 × 10^{-2} M) complex in pH 7 phosphate buffer at 55°. Key: a, peak decreasing with time (0, 7, 10, 15, 20, 25, and 35 min); and b, peak increasing with time (35, 50, 60, 70, 85, 100, 120, 150, and 180 min).*

Interaction of I and Proline with *p*-Benzoquinone—To clarify the interactions of this termolecular system, three separate sets of experiments were performed. In Experiment A, both proline and I were added more or less simultaneously to the quinone. Experiment B concerned the effect of adding proline to a solution to which I had been added to the quinone several hours previously. Experiment C examined the effect of adding I to a solution in which a proline–quinone complex equilibrium had been established.

Experiment A—The addition of proline and I to the *p*-benzoquinone solution caused changes in absorption that were identical to those caused when proline alone was added to the quinone (4). Compound I can be dissolved in *p*-benzoquinone for up to 4 hr before adding proline without affecting the rate of formation of the proline–quinone complex.

Experiment B—When I was added to *p*-benzoquinone and allowed to stand for many hours, a band at 15,200 cm^{-1} (658 nm) gradually formed. The addition of proline to the solution in which this band was fully formed had no effect whatsoever. Old solutions of proline and quinone also gave rise to a similar band, preceded by the formation of a proline–quinone complex (4).

Experiment C—The addition of proline to *p*-benzoquinone resulted in the formation of a reversible complex with maximum absorption at 18,800 cm^{-1} (532 nm). After many hours, this absorption slowly decreased and was replaced by an absorption at 15,200 cm^{-1} (658 nm), belonging to some later formed reaction product (4). The addition of I to a solution

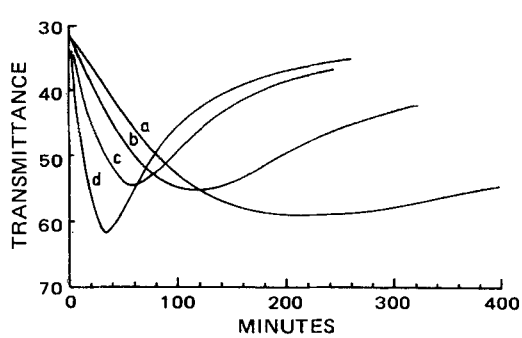

Figure 5—*Effect of varying concentration of I on changes in the proline–*p*-benzoquinone complex as measured by the absorption band at 18,800 cm^{-1} (532 nm) in phosphate buffer at pH 7 and 55°. Key: a, 10^{-3} M; b, 4 × 10^{-3} M; c, 10^{-2} M; and d, 2 × 10^{-2} M.*

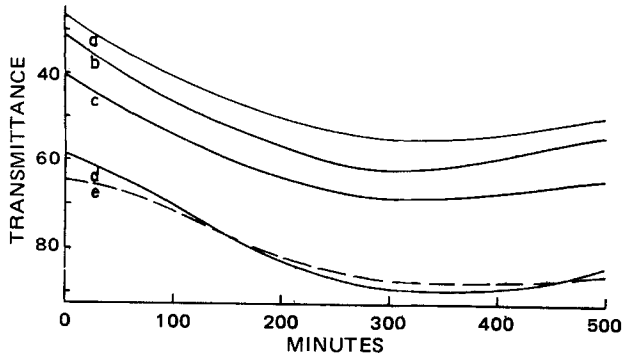

Figure 6—*Effect of I (2×10^{-2} M) on the absorption band at 18,800 cm^{-1} (532 nm) formed by mixing, at pH 7 and 25°, 2×10^{-4} M p-benzoquinone and the following concentrations of proline: (a) 4×10^{-1} M, (b) 7×10^{-2} M, (c) 1.5×10^{-2} M, (d) 2×10^{-4} M, and (e) 10^{-4} M.*

of *p*-benzoquinone and proline in which the complex absorbing at 18,800 cm^{-1} (532 nm) was fully formed but had not begun to decompose to give the absorption at 15,200 cm^{-1} (658 nm) gave some surprising changes. There was an initial slow decrease in the absorption at 18,800 cm^{-1} (532 nm) followed by an increase in the absorbance back toward the initial absorbance (Fig. 4).

Figures 5 and 6 show the effect of varying the drug and proline concentrations. As the drug concentration increased, so did the rate of its interaction with the proline–quinone system. From Fig. 6 it can be deduced that the concentration of proline does not affect the initial interaction rate—only the rate at which the absorption peak regains its equilibrium value.

Figure 7 shows the effect of temperature on the interaction of the drug on the quinone–proline system. As expected, raising the temperature caused an increase in the rate of interaction for both the decrease and later increase of the complex. The higher the temperature above 35°, the greater was the effect of temperature on the decrease of the complex as compared with the later increase. This trend was reversed below 35°. A similar effect was noted later with the histamine–quinone system.

From these experiments, it can be concluded that:

1. Compound I does not interfere with the initial complexing reaction between proline and the quinone.

2. There is a very slow chemical interaction between I and quinone with a large induction time, showing that intermediates are produced before the final product absorbing at 15,200 cm^{-1} (658 nm). This final product may be a disubstituted quinone (9).

3. A reaction between I and the proline–quinone complex leads to a decrease in the concentration of the complex.

Presumably there is competition for complexing with the quinone between I and proline. However, at a later time, the concentration of the complex returns to its original value with proline alone due to either an increase in the proline available for complexing or a decrease in drug. The proline exists mainly in its zwitterionic form at pH 7, but interaction is *via* the neutral amino form. At these pH's, this form is present only in about 1 part in 1000 (4). Similarly, the drug exists mainly in its ionized form at pH 7 (1), although some unionized form is present. This system

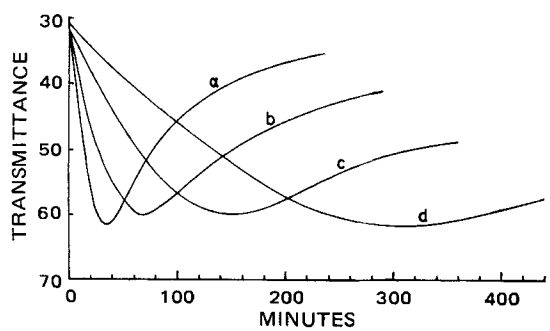

Figure 7—*Effect of I (2×10^{-2} M) on the absorption band at 18,800 cm^{-1} (532 nm) formed by mixing proline (7×10^{-2} M) with p-benzoquinone (2×10^{-4} M) at 25° in pH 7 phosphate buffer. Key: a, 55°; b, 45°; c, 35°; and d, 25°.*

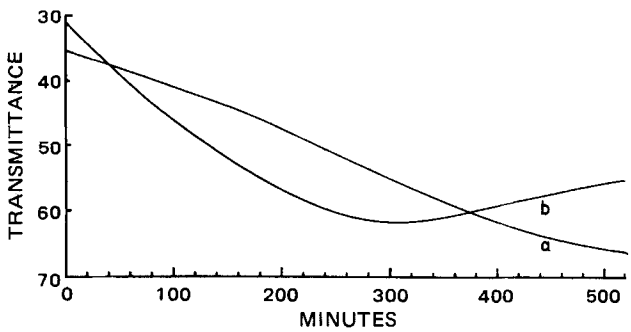

Figure 8—*Effect of I (2×10^{-2} M) on the absorption at 18,800 cm^{-1} (532 nm) of the proline (7×10^{-2} M)–p-benzoquinone (2×10^{-4} M) complex in phosphate buffer at 25°. Key: a, pH 8.0; and b, pH 7.0.*

is obviously very complicated; the various equilibria producing complexing forms of proline and drug are interdependent. Thus, either the shift of the equilibrium to produce more unionized proline or to produce less unionized drug would explain the results, the latter seeming more suitable.

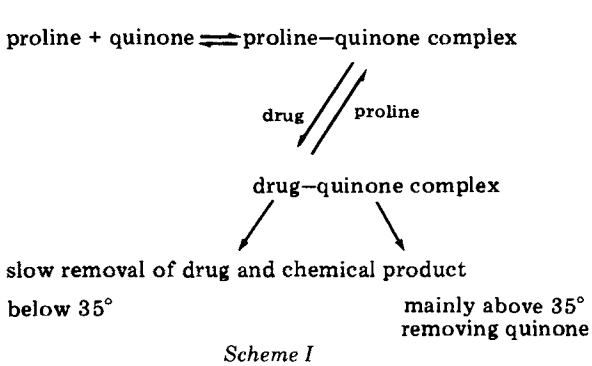
Another explanation for the slow recovery of the proline–quinone complex concentration is the removal of drug by dimerization, although there is not any evidence for this, or by some other chemical reaction. However, at this stage of the interaction, the quinone is not removed from solution, as seen by the return of the complex absorption to its initial value at temperatures less than 35°. Only at higher temperatures is quinone removed from the solution and the complex does not regain its initial value with time. These various reactions are summarized in Scheme I.

It was previously observed that an increase in pH leads to a considerable apparent increase in the reaction rate between proline and *p*-benzoquinone (4). Therefore, the interaction of the drug with the proline–quinone system at pH 8 also was investigated (Fig. 8). There was the decrease of the band associated with the complex but no subsequent increase as at pH 7. The binding between the drug and *p*-benzoquinone at pH 8 apparently is stronger than that between proline and *p*-benzoquinone. Thus, pH is a strong determining factor in the interaction of this termolecular system. The effect of the drug on the hydroxyproline–quinone system is similar to that described for proline, but the reaction rates are slightly different.

Figure 9 shows the effect of some related drugs (II–IV) on the proline–quinone complex. Compound IV, a triazolopyrimidine, had only a marginal effect; the other drugs, all triazolopyrazines, had a marked effect, albeit in different ways. Among the triazolopyrazines, only I exhibited the reversal in the downward trend of the complex concentration at pH 7. None of these drugs other than I showed any spectroscopic evidence of an interaction with *p*-benzoquinone alone, although II and III obviously interacted with the proline–*p*-benzoquinone system (Fig. 9).

There is now a body of evidence showing that amines and amides, especially biological amines and amides in the unionized form, complex with quinones and other charge acceptors (3, 4, 8). If the drugs interact in a similar manner, then this interaction explains the rather slow forward reaction times; at the pH values used, the amines or amides are mainly in the ionized XNH_3^+ or XNH_2^+ form, so the effective concentration of XNH_2 or XNH is quite low.

Interaction of I with Histamine–*p*-Benzoquinone Complex—In the presence of I, there was a change in both the apparent rate constants



Scheme I

Table I—Apparent and Corrected Rate Constants for the Interactions of Histamine with *p*-Benzoquinone in the Presence of I in pH 7 Phosphate Buffer[a]

k_1, M^{-1} min^{-1}	k_2, min^{-1}	k_3, min^{-1}	$\frac{k_1}{k_2}$, M^{-1}	Temperature
1.51×10^{-2} (8.4)	4.53×10^{-4}	2.72×10^{-6}	33.3 (18,700)	25°
4.37×10^{-2} (1.26×10)	3.52×10^{-3}	6.77×10^{-5}	12.4 (3570)	35°
1.19×10^{-1} (2.07×10)	2.63×10^{-2}	1.21×10^{-3}	4.5 (784)	45°
2.87×10^{-1} (2.92×10)	1.02×10^{-1}	7.57×10^{-3}	2.8 (286)	55°

[a] Data in parentheses are corrected for histamine concentration only and not for I.

and the thermodynamic parameters of the histamine–quinone complex (Tables I and II). The effect of the drug was greater the longer it was dissolved in quinone solution prior to the addition of histamine, confirming that the drug interacts slowly with the quinone, forming a chemical compound. After 24 hr, almost all quinone had interacted with the drug, as evidenced by the negligible reaction with histamine if added after this time. On the other hand, there was no evidence of the 15,200 cm^{-1} (658 nm) peak at this time.

The data in Table I can be compared with the data for the interaction of histamine with *p*-benzoquinone alone given in Tables 1 and 2 of Ref. 3[2]. The data in Table I are compatible with a competitive reaction between the drug and the histamine for complexing with *p*-benzoquinone. There was a decrease in the apparent interaction rate between histamine and the *p*-benzoquinone in the presence of the drug at lower temperatures. However, at higher temperatures, there was an apparent increase in the interaction rate of histamine, showing that a more complicated set of interactions occurred in the presence of the drug at these elevated temperatures. A similar effect of temperature was already noticed for the interaction of the drug with the proline–*p*-benzoquinone system (4). Presumably, at the higher temperatures, the chemical interactions become significantly large compared to the complexing mechanism that predominates at the lower temperatures.

Obviously, any rate constants derived for the interaction of the drug with the *p*-benzoquinone from these termolecular systems will contain a contribution from the irreversible chemical interactions. The apparent rate constants for the drug–quinone complex derived from these data, assuming a simple competition between the drug and histamine, are:

$$k_1 = 1.04 \times 10^{-2} \text{ liter mole}^{-1} \text{ min}^{-1} \quad \text{(Eq. 1)}$$

$$k_2 = 7.28 \times 10^{-4} \text{ min}^{-1} \quad \text{(Eq. 2)}$$

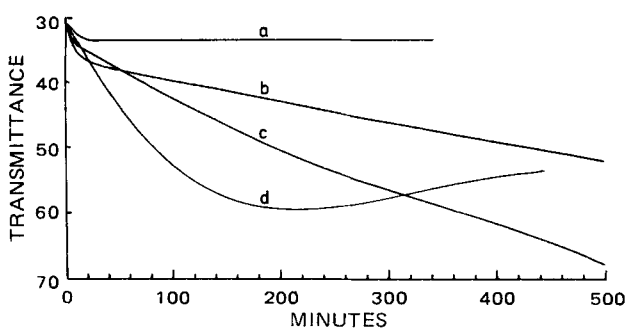


Figure 9—*Effect of different drugs (10^{-3} M) on the absorption at 18,800 cm^{-1} (532 nm) of the proline (7×10^{-2} M)-p-benzoquinone (2×10^{-4} M) complex in pH 7 phosphate buffer at 25°. Key: a, IV; b, III; c, II; and d, I.*

[2] Due to a mistake in the computer printout, all values of k_1, k_2, and k_3 in Ref. 3 should be multiplied by 10^5. Other parameters are not affected.

Table II—Apparent and Corrected Thermodynamic Data for the Interaction of Histamine with *p*-Benzoquinone in the Presence of I in pH 7 Phosphate Buffer[a]

	ΔH	ΔS	ΔG	E_A
k_1	18.3 (6.6)	−36.6 (−31.2)	29.2 (15.9)	18.9 (7.2)
k_2	34.6	11.4	31.2	35.2
k_3	50.9	56	34.2	51.5
$\frac{k_1}{k_2}$	−16.3 (−28)	−48.0 (42.6)	−2.0 (15.3)	

[a] Data in parentheses are corrected for histamine concentration only and not for I. H = enthalpy, S = entropy, G = free energy, and E_A = activation energy; all parameters are in kilocalories mole^{-1} except entropy which is in entropy units.

with $k_1/k_2 = 14.3\ M^{-1}$, and:

$$k_3 = 2.05 \times 10^{-5} \text{ min}^{-1} \quad \text{(Eq. 3)}$$

all at 25°. Since the ionization constant of the drug is unknown, it is not possible to give corrected data. The thermodynamic data in Table II are averaged out over the temperature range and again must contain substantial contributions from the irreversible chemical interactions.

CONCLUSIONS

The addition of certain heterocyclic nitrogen compounds to solutions of the electron-acceptor *p*-benzoquinone causes no change in the absorption spectrum in the near UV and visible regions. The only exception is I, which shows very slow changes after a long induction period. However, the addition of these compounds to solutions containing electron donors and acceptors has marked spectral effects which demonstrate that these compounds do initially complex with electron acceptors and later form chemical compounds with them. At temperatures below 35°, the interaction is due to some form of complexing; at higher temperatures, irreversible chemical reactions between the drugs and acceptors occur quite rapidly. This study illustrates the utility of using termolecular systems to characterize reactions that cannot be characterized by observing directly the interactions between the compounds and the acceptors. The pH effects suggest that these amines and amides interact in their neutral form—not the ionic form that predominates at the pH's studied.

Protein Binding of Benz[a]anthracene and Benzo[a]pyrene

JOSEPH K. H. MA ˣ, PETER P. FU, and LOUIS A. LUZZI

Abstract □ Fluorometric studies on the binding of benz[a]anthracene and benzo[a]pyrene to human serum albumin are described. The protein molecule appears to have one binding site for the hydrocarbons, but all of the sites on the protein are not fully occupied even in relatively large hydrocarbon concentrations. Equilibrium studies showed that both hydrocarbons bind to the protein to the same extent. Evidence for the energy transfer from the tryptophan residue of the protein to bound hydrocarbons is examined. By using Förster's theory, the mean distance between the tryptophan residue and bound ligand was found to be 15.2 Å for benz[a]anthracene and 19.6 Å for benzo[a]pyrene. It is concluded that the two hydrocarbons may bind to the same general area on the protein molecule near the tryptophan residue but at different sites. The structural differences of the hydrocarbons, which may greatly affect their orientations on the protein molecule, affect mainly the selection of the binding site rather than the binding equilibrium.

Keyphrases □ Benz[a]anthracene—binding to human serum albumin, fluorometric analysis □ Benzo[a]pyrene—binding to human serum albumin, fluorometric analysis □ Binding, protein—benz[a]anthracene and benzo[a]pyrene to human serum albumin, fluorometric analysis □ Fluorometry—binding of benz[a]anthracene and benzo[a]pyrene to human serum albumin □ Hydrocarbons—benz[a]anthracene and benzo[a]pyrene, binding to human serum albumin, fluorometric analysis □ Carcinogens—benz[a]anthracene and benzo[a]pyrene, binding to human serum albumin, fluorometric analysis

Carcinogenic hydrocarbons are biologically active but chemically inert. Because of the aromatic system, these hydrocarbons are capable of forming complexes with macromolecules *via* hydrophobic stacking forces. The hydrophobic interaction is not uncommon in biological systems. For example, a nucleic acid possesses profound hydrophobic stacking interaction between its bases (1, 2), and the binding of protein to nucleic acid involves the stacking interaction between the tryptophan residues of the protein and the nucleic acid bases (3, 4).

The hydrophobic binding of the carcinogenic hydrocarbons with proteins or other macromolecules is important for several reasons. Carcinogenesis may be initiated by the covalent binding of the carcinogens with cell constituents (5–7). Therefore, the hydrophobic binding represents the initial step toward carcinogenesis. Transport of the carcinogens to active receptor sites and the activation of parent carcinogens are also necessary for chemical reaction.

Furthermore, because of the extensive, delocalized π-electron system, these hydrocarbons can be easily activated into long-lived free radicals (8), which may efficiently form covalent bonds with macromolecules if a strong hydrophobic stacking interaction occurs. Therefore, binding information such as the nature of the binding sites on the macromolecule should help in understanding the mechanism of carcinogenic action. Besides the plausible involvement of carcinogenesis, the interaction of these hydrocarbons with macromolecules may result in other serious biological effects yet to be known, since such binding may effectively change the conformations of the macromolecules and, consequently, alter the precision of their physiological functions.

The carcinogenicity of the polycyclic aromatic hydrocarbons is sensitive to trivial structural changes. For example, 7,12-dimethylbenz[a]anthracene is the most potent of the known chemical carcinogens, whereas 7,12-diethylbenz[a]anthracene does not evoke cancer; benz[a]anthracene is only a weak carcinogen, whereas benzo[a]pyrene is strongly carcinogenic. The structural differences may have a profound effect on the orientation of these compounds on a macromolecule, resulting in binding at different sites. Thus, the measurement of binding affinity alone is insufficient for the correlation of binding with biological effects.

Fluorescence spectroscopy is one of the most useful tools for energy transfer studies. In a protein interaction, the tryptophan residue of the protein may transfer its electronic energy to a bound ligand if, among other conditions, the two units are closely located on the macromolecule. The energy transfer data permit calculation of the mean distance between the energy donor and the acceptor, which can be used to differentiate the binding sites for compounds with similar structures.

This study was an attempt to provide additional insight into the interaction of carcinogenic hydrocarbons with proteins. By using the fluorescence technique, studies were made on the binding of benz[a]anthracene and benzo[a]pyrene to human serum albumin. Emphasis was placed on the nature and quantitative aspects of the binding and the difference in binding between benz[a]anthracene and benzo[a]pyrene.

EXPERIMENTAL

Materials—Benz[a]anthracene[1], benzo[a]pyrene[1], L-tryptophan[2], crystalline human serum albumin[3], and soluble ribonucleic acid from liver[4] were purchased from commercial sources. Further purification of benz[a]anthracene and benzo[a]pyrene was made by recrystallization from methanol. The solvents were spectroscopic grade, and all other chemicals were reagent grade.

Instruments and Methods—Fluorescence measurements were made with a spectrophotofluorometer[5] equipped with a 150-w xenon lamp and a 1P21 photomultiplier tube. Fluorescence spectra were recorded with an *x–y* recorder[6]. The entrance slit of the excitation light and the exit slit of the fluorescence emission were 4 and 5 mm, respectively. Absorption spectra and measurements were made with a UV–visible spectrophotometer[7]. Except in the solvent and pH studies, all measurements were carried out in pH 7 phosphate buffer (0.5 *M*). The temperature was controlled at 25 ± 0.5°.

Human serum albumin was freeze dried to constant weight before use. The concentration of the protein was calculated with a molecular weight of 69,000. The concentrations of benz[a]anthracene and benzo[a]pyrene used were 10^{-7}–10^{-5} *M*; microliter amounts of stock solution (10^{-3} or 10^{-4} *M* in acetone) were transferred, using microsyringes, into a fluorescence cell containing 2 or 3 ml of a protein or other solution.

Binding Studies—The binding of benz[a]anthracene and benzo-

[*a*]pyrene to human serum albumin was determined by the Scatchard equation:

$$\overline{V}/D_f = nK - \overline{V}K \qquad \text{(Eq. 1)}$$

where D represents the hydrocarbons, D_f is the concentration of unbound D, $\overline{V}$ is the ratio of bound D per protein concentration, n is the number of binding sites on the protein, and K is the binding constant. The values of $\overline{V}$ and D_f were measured by fluorescence quenching titration (9). In this method, a protein solution is titrated with successive additions of D, and the quenching of the native fluorescence of the protein is recorded after each addition. The quenched fluorescence, expressed as a percentage of the initial fluorescence of the protein, is then plotted as a function of the concentration ratio of D and the protein.

The method requires titration curves at several protein concentrations. Above a certain protein concentration, the titration curves are superimposable since D is all bound. This superimposed curve represents the degree of quenching as a function of $\overline{V}$. In a solution of lower protein concentration, D is only partially bound, and $\overline{V}$ is equal to the concentration ratio on the superimposed curve at the same degree of quenching.

The quenching of the fluorescence of human serum albumin by benz[*a*]anthracene and benzo[*a*]pyrene was measured at the emission wavelength of 348 nm with the excitation at 280 nm. The binding constants were calculated for solutions containing 2.5×10^{-6} *M* human serum albumin and varying concentrations of the hydrocarbons in the 5×10^{-7}–6×10^{-6} *M* range. The high protein concentration, in which the hydrocarbons were all bound, was 2.5×10^{-5} *M*.

Energy Transfer Theory—The quenching of the fluorescence of human serum albumin by benz[*a*]anthracene and benzo[*a*]pyrene, like that observed in other protein interactions (10, 11), is due to energy transfer from the excited-state tryptophan residue (energy donor) to the bound ligand (energy acceptor). The energy transfer information allows calculation of the mean distance, R, between the donor and acceptor by the equation (12):

$$X/(1 - X) = (R_0/R)^6 \qquad \text{(Eq. 2)}$$

where X is the fraction of the absorbed photons transferred, and R_0 is the characteristic distance at which the probability of energy transfer is equal to the probability of fluorescence. The degree of energy transfer may be measured by the degree of quenching of the protein fluorescence.

According to Förster's theory (13):

$$R_0 = (1.69 \times 10^{-33}\, \tau J_v / r^2 \bar{v}_0^2)^{1/6} \text{ cm} \qquad \text{(Eq. 3)}$$

where τ is the fluorescence lifetime of the donor in the absence of transfer, r is the refractive index of the solvent, $\bar{v}_0$ is the mean of the wave numbers of maximum absorption of the acceptor and the emission of the donor, and J_v is the overlap integral. To determine $\bar{v}_0$ and J_v, Eq. 4 may be used:

$$J_v = \int_0^\infty E(v)F(v)dv \qquad \text{(Eq. 4)}$$

where $E(v)$ is the molar absorptivity of the acceptor, and $F(v)$ is the molar emission coefficient of the donor. The molar emission function, $F(v)$, represents the photospectral distribution of the fluorescence in units dependent on $F(v)$ at maximum emission being equal to the molar absorptivity of the donor. By redrawing the absorption and emission data of the acceptor and donor in terms of the wave number scale, J_v and $\bar{v}_0$ can be determined by graphical integration.

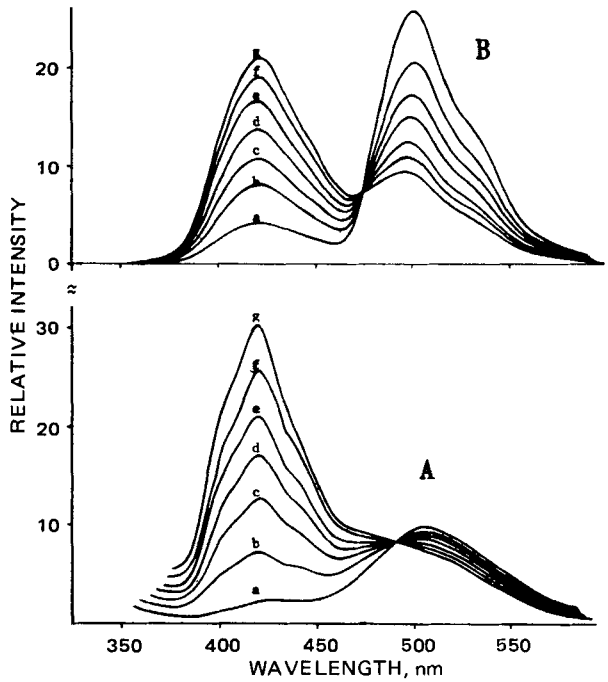

Figure 1—*Effect of human serum albumin on the fluorescence spectrum of (A) 10^{-6} M benzo[a]pyrene (excited at 310 nm) and (B) 10^{-6} M benz[a]anthracene (excited at 300 nm) in pH 7 buffer. The concentration of the protein (a to g) was 0–3 × 10^{-6} M with an increment of 0.5 × 10^{-6} M. In B, a polarizing film was used in the emission slit slide to diminish the protein fluorescence.*

RESULTS

The fluorescence data of 10^{-6} *M* benz[*a*]anthracene (I) and of benzo[*a*]pyrene (II) measured in various solvents are shown in Table I. In pH 7 phosphate buffer, the emission maxima of the hydrocarbons were found to be in two regions: the A region bands at 500 and 505 nm for I and II, respectively, and the relatively weak fluorescence bands in the B region at 395–420 nm. In organic solvents, the A region bands were diminished and strong fluorescence bands were found in the B region. Despite the spectral difference as observed in aqueous and organic solvents, the emission maxima of the hydrocarbons did not shift according to the solvent polarity. The spectra obtained in cyclohexane and in methanol were almost identical. Thus, the spectral change cannot be explained by the dipole–dipole interaction theory (14). Except in acetone, two excitation maxima were observed for the hydrocarbons. Acetone was able to eliminate the short wavelength excitation bands (320 nm or shorter) of many fluorescent compounds. For example, salicylic acid was fluorescent in water when excited at 300 nm but nonfluorescent in acetone when excited at any wavelength.

Figure 1A shows the effect of human serum albumin on the fluorescence spectrum of benzo[*a*]pyrene in pH 7 buffer. The excitation wavelength was set at 310 nm. The binding of the hydrocarbon to the protein was clearly indicated by the spectral change and the appearance of an isosbestic point, indicating the existence of two species in the solution, *i.e.*, the bound and unbound benzo[*a*]pyrenes. The spectra of the enhanced B region fluorescence were similar to those observed in organic solvents.

The effect of human serum albumin on the fluorescence spectrum of benz[*a*]anthracene, excited at 300 nm, at neutral pH is shown in Fig. 1B. Since the excitation wavelength was quite close to that of the protein fluorescence, interference of the B region fluorescence of the hydrocarbon by the fluorescence of the protein was expected. To eliminate the interference, the spectra of Fig. 1B were recorded using a polarizing film in the emission slit slide. Although the B region fluorescence spectrum was slightly changed and shifted toward longer wavelength, the effect of the protein on the spectrum of the hydrocarbon clearly indicated the binding.

The enhancement of the B region fluorescence of the hydrocarbons by the protein was stronger in high pH than in low pH solutions. Below pH 4, where most serum albumins undergo molecular unfolding (9), no significant enhancement was observed. These results suggest a strong interaction between the protein and the hydrocarbons in basic solution,

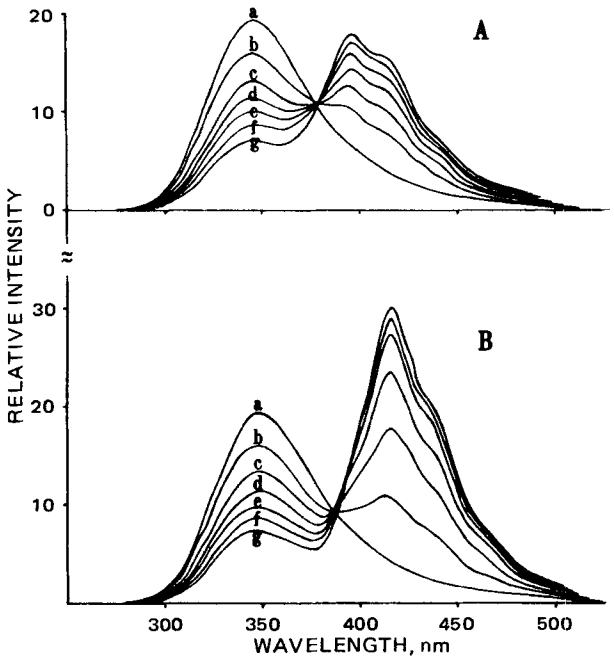

Figure 2—*Effect of benz[a]anthracene (A) and benzo[a]pyrene (B) on the fluorescence spectrum of 2.5 × 10^{-5} M human serum albumin (excited at 310 nm) at neutral pH. The concentration of the hydrocarbons (a to g) was 0–3 × 10^{-6} M with an increment of 0.5 × 10^{-6} M.*

presumably due to a conformational change of the protein upon changing pH. The fluorescence of the hydrocarbons was not affected by solution pH.

Figure 2 shows the effect of I and II on the fluorescence spectrum of human serum albumin at neutral pH. The excitation wavelength was set at 280 nm. The quenching of the protein fluorescence was again accompanied by the enhancement of the B region fluorescence.

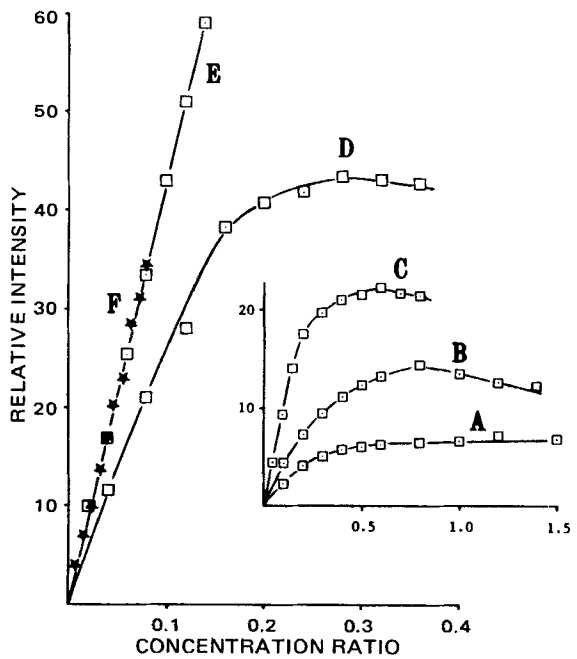

Figure 3—*Plots of the fluorescence enhancement at 420 nm (excited at 310 nm) for benzo[a]pyrene as a function of the concentration ratio of benzo[a]pyrene and human serum albumin at several protein concentration levels. The protein concentrations were: A, 1.25 × 10^{-6} M; B, 2.5 × 10^{-6} M; C, 5 × 10^{-6} M; D, 1.25 × 10^{-5} M; E, 2.5 × 10^{-5} M; and F, 5 × 10^{-5} M. The data were obtained by titrating the protein solutions in pH 7 buffer with successive additions of benzo[a]pyrene. Corrections of the residue fluorescence of the protein and the hydrocarbon were made before the plot.*

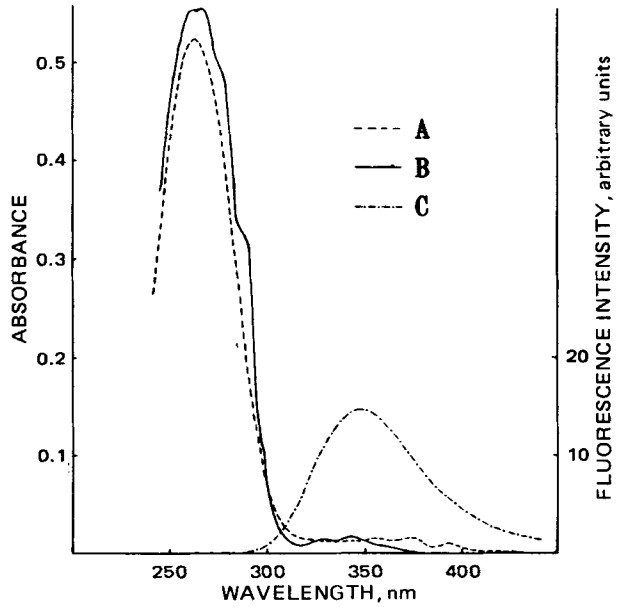

Figure 4—*(A) Absorption spectrum of 2 × 10^{-6} M benz[a]anthracene. (B) Absorption spectrum of 2 × 10^{-6} M benz[a]anthracene in the presence of 2.5 × 10^{-5} M human serum albumin. The same amount of protein was also present in the reference cell. In this spectrum, the hydrocarbon is all bound. (C) Fluorescence spectrum of 2.5 × 10^{-5} M human serum albumin (excited at 280 nm). All solutions were prepared in pH 7 phosphate buffer.*

Figure 3 shows the plots of the fluorescence enhancement at 420 nm *versus* the concentration ratio of benzo[a]pyrene and the protein at several protein concentration levels. Corrections of the residue fluorescence of the protein and benzo[a]pyrene were made prior to the plots. In curve A, where the protein concentration was 1.25 × 10^{-6} *M*, the titration curve plateaued when the concentration ratio was one or larger. This finding suggests that the protein molecule has one binding site for benzo[a]pyrene. The same is true for benz[a]anthracene. At higher protein concentrations, the fluorescence enhancement reached a maximum with the concentration ratio well less than one. Further addition of benzo[a]pyrene led to fluorescence quenching.

Although the reason for the quenching is not clear, the results suggest that the binding sites of the protein are not fully occupied by the hydrocarbon at high protein concentrations. This result is possible since, at high concentrations, the protein molecules tend to self-associate and the binding of hydrocarbon may even aid in the association by forming complexes with more than one protein molecule. When the protein concentration was 2.5 × 10^{-5} *M* or larger, the hydrocarbon in the concentration range shown in Fig. 5 was all bound. This result is indicated by the superimposed straight-line plot and by the absence of the A region fluorescence. Similar results were obtained for benz[a]anthracene.

To elucidate the enhancement of B region fluorescence by the protein, similar studies were made with tryptophan and soluble ribonucleic acid. Tryptophan also can induce the B region fluorescence of the hydrocarbons, but the concentration of tryptophan has to be much larger than that of the protein containing one tryptophan residue per molecule. On the other hand, the addition of soluble ribonucleic acid did not enhance the B region fluorescence; instead, the fluorescence of the hydrocarbons was strongly quenched by an interaction with nucleic acid. These results suggest that the B region fluorescence in protein interaction is due to energy transfer from the tryptophan residue to bound hydrocarbons. The absence of the B region fluorescence in the nucleic acid interaction may be attributed to the lack of an energy donor in the nucleic acid molecule.

A prerequisite for energy transfer is that the absorption spectrum of the energy acceptor must overlap the fluorescence spectrum of the donor. Figures 4 and 5 show that this prerequisite is met in the binding of the hydrocarbons to human serum albumin. In binding with the protein, the visible absorption bands of the hydrocarbons shifted toward high energy or shorter wavelength. The difference spectra of bound hydrocarbons (spectrum B of Figs. 4 and 5), in which the protein absorption was canceled using a double-beam technique, exhibited shoulder bands in the 280–300-nm region, indicating the involvement of the tryptophan residue

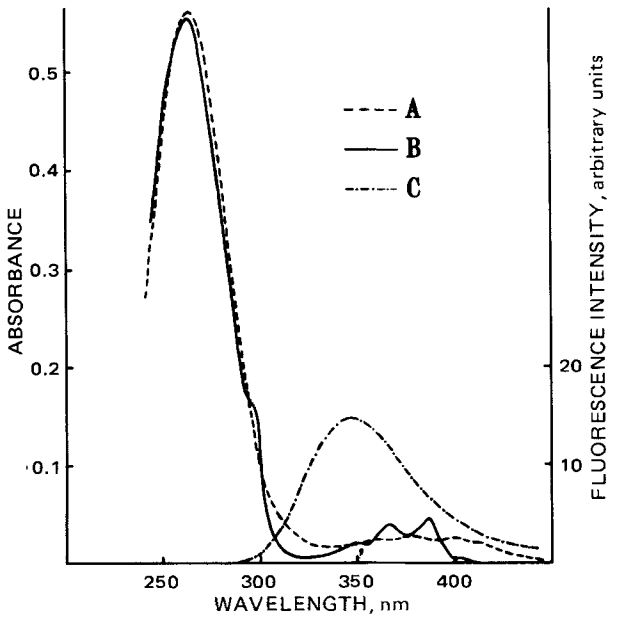

Figure 5—*(A) Absorption spectrum of 2 × 10^{-6} M benzo[a]pyrene. (B) Absorption spectrum of 2 × 10^{-6} M benzo[a]pyrene in the presence of 2.5 × 10^{-5} M human serum albumin. In this solution, the hydrocarbon is all bound. The protein absorption is canceled using a double-beam method. (C) Fluorescence spectrum of 2.5 × 10^{-5} M human serum albumin. All solutions were prepared in pH 7 phosphate buffer.*

in the binding. This finding is particularly true for benz[a]anthracene, whose binding site may be in the vicinity of the tryptophan residue.

The energy transfer data for the binding of I and II to human serum albumin are shown in Table II. The characteristic distances, R_0, were 25.9 and 32.0 Å for I and II, respectively, and were calculated from the following data: r = 1.36, τ = 2.64 nsec, $\bar{\nu}_0$ = 2.90 × 10^4 cm^{-1} for I and 2.72 × 10^4 cm^{-1} for II, and J_ν = 1.05 × 10^{11} cm^3-$mmole^{-2}$ for I and 3.25 × 10^{11} cm^3-$mmole^{-2}$ for II. The value of τ was calculated from the equation: $\tau = Q\tau_n/P$, where Q is the quantum yield of human serum albumin; τ_n is the natural fluorescence lifetime of tryptophan, which was taken to be 12 nsec (15); and P is the fraction of protein absorption due to the tryptophan residue, which was reported to be 19.5% for human serum albumin (16).

The quantum yield of human serum albumin in pH 7 phosphate buffer was determined by comparison of the emission peak areas of the protein and the tryptophan solutions of equal absorbance at 280 nm. The quantum yield of tryptophan was taken to be 0.13 (17). The values of $\bar{\nu}_0$ and J_ν were graphically determined, according to Eq. 4, by redrawing the data of Figs. 4 and 5 in terms of the wave number scale. The unit of the molar emission function, $F(\nu)$, was set so that $F(\nu)$ at maximum emission was equal to 0.59 × 10^4 cm^2-$mmole^{-1}$, the molar absorptivity of tryptophan at 280 nm in pH 7 phosphate buffer. Although the characteristic distance, R_0, calculated in this manner is an approximation because of the complicated protein system, the results show the difference in binding sites for the two hydrocarbons.

Figure 6 shows the fluorescence quenching titrations of human serum albumin with I and II. The data were obtained by titrating the protein solutions with successive additions of the hydrocarbons, with the excitation and emission wavelengths set at 280 and 348 nm, respectively. In a high protein concentration (2.5 × 10^{-5} M), about 95% of the protein fluorescence was quenched as a result of energy transfer. According to Eq. 2, the mean distances between the tryptophan residue of the protein and bound hydrocarbons were 15.2 and 19.6 Å for I and II, respectively.

Table II—Energy Transfer Data for the Binding of Benz[a]anthracene and Benzo[a]pyrene to Human Serum Albumin

	J_ν, cm^3-$mmole^{-2}$	R_0, Å	R, Å	K^a, M^{-1}
Benz[a]anthracene	1.05 × 10^{11}	25.9	15.2	1.56 × 10^5
Benzo[a]pyrene	3.25 × 10^{11}	32.0	19.6	1.46 × 10^5

[a] Binding constant.

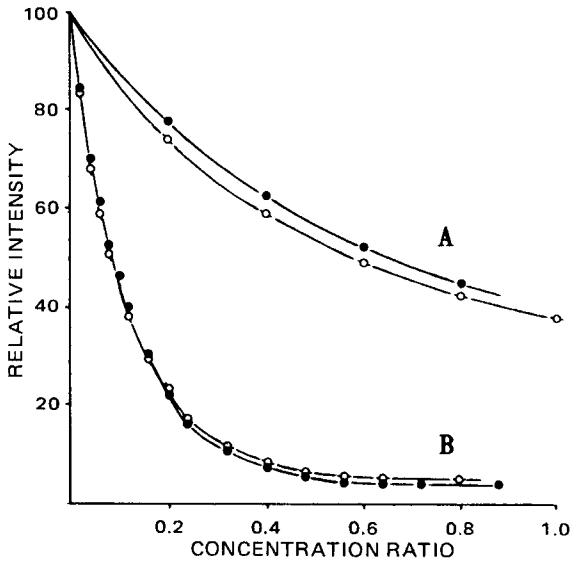

Figure 6—*Quenching of the fluorescence of human serum albumin by benz[a]anthracene and benzo[a]pyrene. The quenched fluorescence is plotted as a function of the concentration ratio of the hydrocarbons and the protein. Key: ●, benz[a]anthracene; ○, benzo[a]pyrene; A, 2.5 × 10^{-6} M protein concentration; and B, 2.5 × 10^{-5} M protein concentration.*

The Scatchard plots for the binding of I and II to human serum albumin are shown in Fig. 7. In a protein solution of 2.5 × 10^{-6} M, the number of binding sites was 0.5 for both compounds. The binding constants for I and II were 1.56 × 10^5 and 1.46 × 10^5 M^{-1}, respectively. Despite the structural difference of the two hydrocarbons, their binding affinities to the protein were approximately equal. In view of the energy transfer and binding data, it is concluded that the two hydrocarbons bind in the same general area on the protein molecule but at different sites. The structural factor, which may greatly affect the orientations of the hydrocarbons on the protein molecule, affects mainly the energy transfer distance rather than the binding equilibrium.

DISCUSSION

The quenching of the fluorescence of human serum albumin by benz[a]anthracene and benzo[a]pyrene, as well as the strong enhancement of the B region fluorescence of the hydrocarbons, indicates the transfer of electronic energy from the tryptophan residue to bound ligands. The conditions necessary for energy transfer are: (*a*) the donor must be a fluorescent group with a sufficiently long lifetime, (*b*) the absorption spectrum of the acceptor must overlap the emission spectrum of the donor, (*c*) the relative orientations of the oscillators must permit a strong interaction, and (*d*) the donor and the acceptor must be within a certain distance for a given efficiency of energy transfer (18). The results of the present study are in excellent agreement with these conditions.

As shown in Figs. 4 and 5, the protein fluorescence band strongly ov-

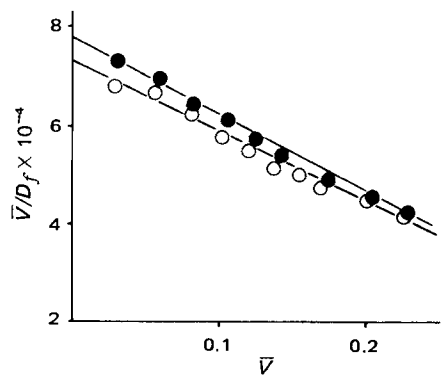

Figure 7—*Scatchard plots for the binding of benz[a]anthracene (●) and benzo[a]pyrene (○) to 2.5 × 10^{-6} M human serum albumin at neutral pH.*

erlapped the absorption bands of the hydrocarbons. The absorption spectra of the protein-bound hydrocarbons exhibited shoulder bands in the 280–300-nm region, indicating the involvement of the tryptophan residue in the interaction. The strong enhancement of the B region fluorescence for the hydrocarbons in binding with the protein represents a transition resulting from an energy transfer process because the binding of these compounds with soluble ribonucleic acid, a macromolecule without an energy donor, does not induce the B region fluorescence.

Excluding the fact of energy transfer, the fluorescence of the hydrocarbons is strongly quenched by interacting with the protein and soluble ribonucleic acid. This result probably indicates a stacking interaction between the hydrocarbon and the aromatic moieties of the macromolecules. The association of fluorescence quenching with stacking interactions was reported previously. For example, the binding of protein to nucleic acid always results in strong quenching of the protein fluorescence, which has been shown to be due to the stacking interaction between the tryptophan residues and the nucleic acid bases (3, 4). In a fluorescence study of compounds in which an indole group is connected to nucleic acid bases by a three- or four-atom bridge, Mutai *et al.* (19) showed that the stacked form, in contrast to the fluorescent unstacked form, is nearly nonfluorescent. Benz[*a*]anthracene and benzo[*a*]pyrene are planar molecules. In binding with nucleic acid, benzo[*a*]pyrene intercalates with the nucleic acid bases (8). In protein interactions, it is possible that the binding allows plane parallelism between the tryptophan residue and the hydrocarbon and, therefore, results in fluorescence quenching of both units.

The fact that only bound benz[*a*]anthracene and benzo[*a*]pyrene can receive energy is indicated by the fluorescence studies of tryptophan with the hydrocarbons. Human serum albumin has one tryptophan residue per molecule. However, the addition of tryptophan, in the same concentration range as that of the protein (Fig. 1), does not induce the B region fluorescence. Only in high tryptophan concentrations do the spectra of the hydrocarbons become similar to those observed in protein solutions, since the two units are then close enough for the efficiency of energy transfer. These results suggest that the binding sites for the hydrocarbons are quite close to the tryptophan residue and that the hydrocarbons are favorably oriented with the tryptophan residue to permit interaction and energy transfer. The small R value for benz[*a*]anthracene indeed suggests that the binding site is in the vicinity of the tryptophan residue.

The energy transfer information is important in understanding the interaction of carcinogenic hydrocarbons with proteins. Benz[*a*]anthracene and benzo[*a*]pyrene interact with human serum albumin to approximately the same extent as indicated by the binding constants. This is expected since these compounds are chemically inert and the binding is of a hydrophobic nature. The difference in structure of the two would probably make little difference in their binding affinities. The difference in ring structure, however, may have a profound effect on their orientations on the protein molecule. Conclusions based on binding strength alone could be misleading. Benzo[*a*]pyrene is strongly carcinogenic, whereas benz[*a*]anthracene is not. While the binding constants of the two suggest similar binding, their protein binding sites are distinguished by energy transfer data.

Rapid Sensitive Fluorometric Analysis of Cephalosporin Antibiotics

A. B. C. YU [*], C. H. NIGHTINGALE [‡], and D. R. FLANAGAN [x]

Abstract □ A rapid and sensitive fluorometric analysis for cephalosporins, which can also be applied to penicillins, is presented. The method involves reaction with 0.1 *N* sodium hydroxide at 100°, producing stable fluorescent products. This method was applied to cephalexin and ampicillin with detection at concentrations as low as 0.01 μg/ml.

Keyphrases □ Cephalosporins, various—fluorometric analysis, commercial samples in aqueous solutions □ Fluorometry—analysis, various cephalosporins, commercial samples in aqueous solutions □ Antibacterials—various cephalosporins, fluorometric analysis, commercial samples in aqueous solutions

Several methods for the quantitative measurement of cephalosporins in aqueous solution have been described. They utilize such techniques as microbiological assay (1), GLC (2), formol titration (3), colorimetry (4–7), liquid chromatography (8, 9), iodometry (4, 10), reaction with hydroxylamine (4), and polarography (11). The nonmi-

erlapped the absorption bands of the hydrocarbons. The absorption spectra of the protein-bound hydrocarbons exhibited shoulder bands in the 280–300-nm region, indicating the involvement of the tryptophan residue in the interaction. The strong enhancement of the B region fluorescence for the hydrocarbons in binding with the protein represents a transition resulting from an energy transfer process because the binding of these compounds with soluble ribonucleic acid, a macromolecule without an energy donor, does not induce the B region fluorescence.

Excluding the fact of energy transfer, the fluorescence of the hydrocarbons is strongly quenched by interacting with the protein and soluble ribonucleic acid. This result probably indicates a stacking interaction between the hydrocarbon and the aromatic moieties of the macromolecules. The association of fluorescence quenching with stacking interactions was reported previously. For example, the binding of protein to nucleic acid always results in strong quenching of the protein fluorescence, which has been shown to be due to the stacking interaction between the tryptophan residues and the nucleic acid bases (3, 4). In a fluorescence study of compounds in which an indole group is connected to nucleic acid bases by a three- or four-atom bridge, Mutai *et al.* (19) showed that the stacked form, in contrast to the fluorescent unstacked form, is nearly nonfluorescent. Benz[*a*]anthracene and benzo[*a*]pyrene are planar molecules. In binding with nucleic acid, benzo[*a*]pyrene intercalates with the nucleic acid bases (8). In protein interactions, it is possible that the binding allows plane parallelism between the tryptophan residue and the hydrocarbon and, therefore, results in fluorescence quenching of both units.

The fact that only bound benz[*a*]anthracene and benzo[*a*]pyrene can receive energy is indicated by the fluorescence studies of tryptophan with the hydrocarbons. Human serum albumin has one tryptophan residue per molecule. However, the addition of tryptophan, in the same concentration range as that of the protein (Fig. 1), does not induce the B region fluorescence. Only in high tryptophan concentrations do the spectra of the hydrocarbons become similar to those observed in protein solutions, since the two units are then close enough for the efficiency of energy transfer. These results suggest that the binding sites for the hydrocarbons are quite close to the tryptophan residue and that the hydrocarbons are favorably oriented with the tryptophan residue to permit interaction and energy transfer. The small R value for benz[*a*]anthracene indeed suggests that the binding site is in the vicinity of the tryptophan residue.

The energy transfer information is important in understanding the interaction of carcinogenic hydrocarbons with proteins. Benz[*a*]anthracene and benzo[*a*]pyrene interact with human serum albumin to approximately the same extent as indicated by the binding constants. This is expected since these compounds are chemically inert and the binding is of a hydrophobic nature. The difference in structure of the two would probably make little difference in their binding affinities. The difference in ring structure, however, may have a profound effect on their orientations on the protein molecule. Conclusions based on binding strength alone could be misleading. Benzo[*a*]pyrene is strongly carcinogenic, whereas benz[*a*]anthracene is not. While the binding constants of the two suggest similar binding, their protein binding sites are distinguished by energy transfer data.

Rapid Sensitive Fluorometric Analysis of Cephalosporin Antibiotics

A. B. C. YU [*], C. H. NIGHTINGALE [‡], and D. R. FLANAGAN [x]

Abstract □ A rapid and sensitive fluorometric analysis for cephalosporins, which can also be applied to penicillins, is presented. The method involves reaction with 0.1 *N* sodium hydroxide at 100°, producing stable fluorescent products. This method was applied to cephalexin and ampicillin with detection at concentrations as low as 0.01 μg/ml.

Keyphrases □ Cephalosporins, various—fluorometric analysis, commercial samples in aqueous solutions □ Fluorometry—analysis, various cephalosporins, commercial samples in aqueous solutions □ Antibacterials—various cephalosporins, fluorometric analysis, commercial samples in aqueous solutions

Several methods for the quantitative measurement of cephalosporins in aqueous solution have been described. They utilize such techniques as microbiological assay (1), GLC (2), formol titration (3), colorimetry (4–7), liquid chromatography (8, 9), iodometry (4, 10), reaction with hydroxylamine (4), and polarography (11). The nonmi-

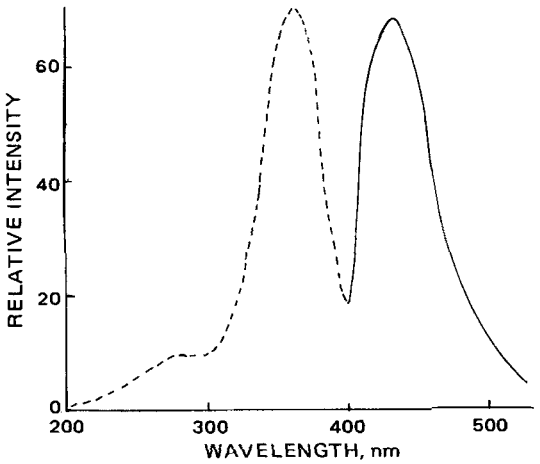

Figure 1—*Fluorescence spectra of caphalothin (1 μg/ml) after reaction at 100° for 75 min in 0.1 N NaOH. Key: - - -, excitation; and —, emission.*

crobiological methods cited are not generally used routinely for analysis of biological samples because of limited sensitivity or, if sensitive enough, because they are less practical than microbiological assays.

This report describes a fluorometric analysis that is simple, rapid, and sensitive enough to be useful for determining cephalosporin levels in biological samples. This same procedure can be applied to ampicillin, amoxicillin, penicillin G, and possibly other penicillins.

EXPERIMENTAL

Samples of cephalothin[1], desacetyl cephalothin[1], cephalexin[1], cephaloglycin[1], cefamandole[1], cefazolin[2], ampicillin[3], amoxicillin[4], and penicillin G[1] were used as received. Stock solutions containing 100 μg/ml of drug in distilled water were freshly prepared prior to use. The stock solution was appropriately diluted with sodium hydroxide solution (various concentrations), and the resulting solutions were sealed in capped[5] culture tubes and heated at various temperatures to produce fluorescent products. After heating in a water bath, the samples were cooled under cold tap water and the fluorescence was measured with a scanning[6] or filter[7] fluorometer.

Separation of the fluorescent products was accomplished with TLC using silica gel precoated plates[8]. The plates were developed for 1.5 hr in chloroform–acetone–acetic acid (50:50:7) and visualized with a UV viewing box.

Standard curves for cephalexin and ampicillin in bovine serum were made using a modification of the extraction procedure described by Jusko (12). This procedure involves adding 0.5 ml of 10% trichloroacetic acid and 0.5 ml of water to 1.0 ml of serum containing drug, mixing for 1 min, and centrifuging at 5000×*g* for 5 min. The supernate (1.3 ml) is mixed with 0.4 ml of 1.0 *N* NaOH and then heated to form fluorescent products as described. After cooling, 0.5 ml of 1 *N* HCl and 8 ml of chloroform–acetone (1:1) are added; the solution is shaken for 15 min and centrifuged at 2000×*g* for 2 min. The organic layer (5 ml) is shaken with 2 ml of 0.1 *N* NaOH for 15 min and centrifuged at 2000×*g* for 2 min. The fluorescence of the aqueous layer is then measured and compared to similarly prepared standards.

RESULTS AND DISCUSSION

Cephalothin—Assay conditions were optimized with cephalothin and then applied with minor variations to other cephalosporins and penicillins. The fluorescence of cephalosporins depends upon their reaction with sodium hydroxide at elevated temperatures. The reaction conditions varied to optimize fluorescence included the sodium hydroxide concentration, the reaction temperature, and the reaction time.

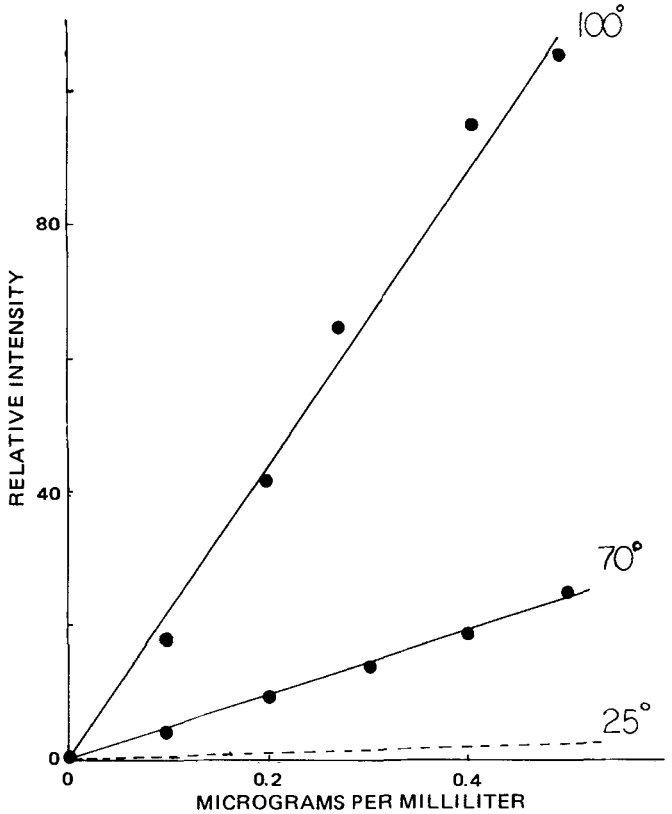

Figure 2—*Effect of temperature on the fluorescence of cephalothin standards reacted in 0.1 N NaOH at 100, 70, and 25° for 75, 240, and 1380 min, respectively. Dashed line is an extrapolation from a linear curve made at concentrations of 1.0–10 μg/ml. Reaction times are optimized for each temperature.*

Figure 1 shows the fluorescence spectrum of a 1-μg/ml solution of cephalothin after reaction at 100° for 75 min in 0.1 *N* NaOH. Figure 2 shows the fluorescence of cephalothin standards reacted in 0.1 *N* NaOH at 100, 70, and 25° for 75, 240, and 1380 min, respectively; 100° was the optimum reaction temperature. At lower reaction temperatures, even at much longer reaction times, the fluorescence intensity did not approach that obtained at 100°. Therefore, all further studies were conducted at 100°.

The effect of sodium hydroxide concentration upon fluorescence is shown in Fig. 3. When 1.0 μg of cephalothin/ml was reacted with 0.1 *N* NaOH, a higher fluorescence was obtained compared to reaction with 0.5 or 1.0 *N* NaOH. At least 75 min was required for maximal fluorescence

Table I—Relative Fluorescent Intensities and Reaction Conditions for Various Cephalosporins

Compound	Reaction Conditions at 100°	Excitation (Ex), Emission (Em)	Relative Intensity
Cephalothin	0.1 *N* NaOH, 75 min	360 Ex 435 Em	1
Desacetyl cephalothin	0.1 *N* NaOH, 75 min	360 Ex 435 Em	0.33
Cephaloridine	0.1 *N* NaOH, 2.5 hr	360 Ex 435 Em	2.5
Cefazolin	0.05 *N* NaOH, 35 min	330 Ex 415 Em	0.14
Cephaloglycin	0.1 *N* NaOH, 30 min	342 Ex 430 Em	0.45
Cephalexin	0.1 *N* NaOH, 30 min	340 Ex 425 Em	0.55
Cefamandole	0.1 *N* NaOH, 12 hr	310 Ex 390 Em	0.03

to develop in 0.1 *N* NaOH, while only half that time was required for 0.5 or 1.0 *N* NaOH. If assay sensitivity is not as important as rapidity of assay, the higher sodium hydroxide concentrations may be more advantageous.

After maximal fluorescence was attained with 0.1 *N* NaOH, longer reaction times up to 2.5 hr did not affect the fluorescence, indicating fairly stable products. Sodium hydroxide concentrations as low as 0.05 *N* did not significantly alter the fluorescence from that observed with 0.1 *N* NaOH. Cephalothin standards exhibited linear fluorescence from 0.05 up to 5 μg/ml. Linearity may extend beyond concentrations of 5 μg/ml, but such experiments were not performed.

Other Cephalosporins—Table I and Fig. 4 summarize the fluorescence results for various cephalosporins. The fluorescence properties of the alkaline reaction products varied from one cephalosporin to another with respect to excitation and emission maxima, the degree of fluorescence, and optimum reaction time. Minor variations in excitation and emission wavelengths can be ignored if a filter fluorometer[7] is used with specific excitation[9] and emission[10] filters. A filter fluorometer does not alter the detection limits of the assay and may be more convenient.

Since reaction conditions were not completely optimized for each cephalosporin (except reaction time), the fluorescence possibly could be increased by altering the sodium hydroxide concentration or reaction temperature for each cephalosporin. In general, detectable fluorescence was obtained at 0.05 μg/ml (except for cefamandole) and linearity extended to 0.5–1.0 μg/ml or above. Certainly, this assay is applicable in nonlinear regions by comparison with actual standard curves.

Penicillins—Fluorescence was observed with penicillin G, ampicillin, and amoxicillin when subjected to the same reaction conditions producing fluorescence with cephalosporins. Penicillin G was only weakly fluorescent compared to cephalothin, requiring concentrations above 10 μg/ml to obtain detectable fluorescence after reaction times over 3 hr. The fluorescence obtained, though, confirms an earlier observation that a fluorescent product is produced from penicillin G when subjected to alkaline degradation conditions (13).

Ampicillin and amoxicillin were much more fluorescent than cephalothin after reaction in 0.1 *N* NaOH. Ampicillin standards exhibited linear fluorescence down to concentrations as low as 0.005 μg/ml. Comparison with the results of Jusko (12) is difficult, but the limits he suggested (0.01–20 μg/ml) for his fluorescent assay indicate that the sodium hydroxide reaction is of approximately the same sensitivity. Jusko obtained maximal fluorescence in pH 2 reaction solutions at 75° and observed much reduced (~10-fold) fluorescence when alkaline conditions up to pH 9 were employed.

This study indicates that the reaction profile for ampicillin may have two pH maxima (pH 2 and 13) or that entirely different products are obtained under extremely alkaline conditions compared to acidic conditions. This latter possibility is quite likely, since penicillin G and cephalothin were nonfluorescent after reaction under acidic conditions but fluorescent after reaction under high temperature and high pH conditions.

Fluorescent Products—The literature on cephalosporins gives no hint to possible fluorescent products under extremely alkaline conditions.

[9] Corning 7-60.

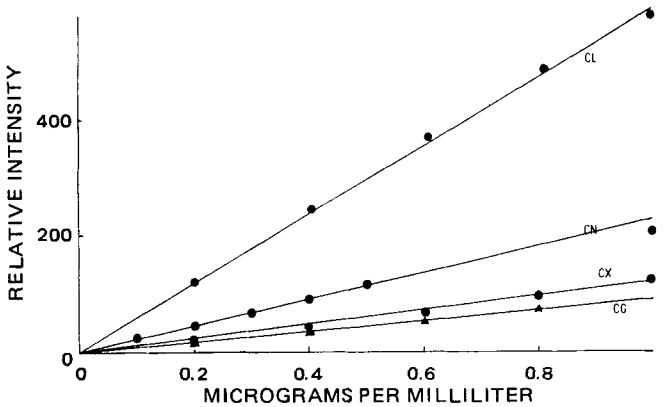

Figure 4—*Fluorescence of cephalosporin standards reacted with sodium hydroxide according to the conditions shown in Table I. Key: CL, cephaloridine; CN, cephalothin; CX, cephalexin; and CG, cephaloglycin.*

Alkaline degradation studies on cephradine, which is structurally similar to cephalexin, indicate the formation of a diketopiperazine product (14) similar to the structure Jusko (12) proposed for the fluorescent product obtained by acidic hydrolysis of ampicillin. Neither of these products would account for the fluorescence of penicillin G or cephalosporins without the α-aminobenzyl side chain.

The thin-layer chromatograms of the final reaction solutions for a number of cephalosporins after heating with 0.1 *N* NaOH for 1 hr are shown in Fig. 5. In each case, except for cefamandole and cefazolin, at least two fluorescent spots were obtained, one with a high R_f value and one with a low R_f value. Cephalexin also gave two fluorescent spots with intermediate R_f values. At this time, the nature of these fluorescent products is speculative. Nevertheless, further investigation of the relationship between cephalosporin and penicillin degradation products is warranted.

It has been observed that penicillenic acid-type compounds and oxazolones, in general, are not obtained from cephalosporins (15). This may be true under the reaction conditions studied to date. However, under the high temperature and extreme alkaline conditions employed in our studies, such degradation pathways possibly may become preferred or at least comparable in rate to other pathways. Oxazolone production could account for the general fluorescence obtained from cephalosporins and penicillins of varying side chains. The various degrees of fluorescence could also be explained on the basis of faster parallel pathways for certain cephalosporins (*i.e.*, cefamandole) leading to a greater proportion of nonfluorescent products than fluorescent products. Studies are in progress to elucidate these fluorescent species.

Fluorescence in Biological Fluids—To assess the utility of this fluorometric method for the analysis of biological samples, cephalexin and ampicillin standards were prepared in serum and treated as described previously, and their fluorescence intensity was measured. Although the fluorescence intensity was reduced compared to aqueous samples, linearity was obtained over the concentration range studied (0.05–10.0 μg/ml).

It is expected that other cephalosporins could be treated similarly or

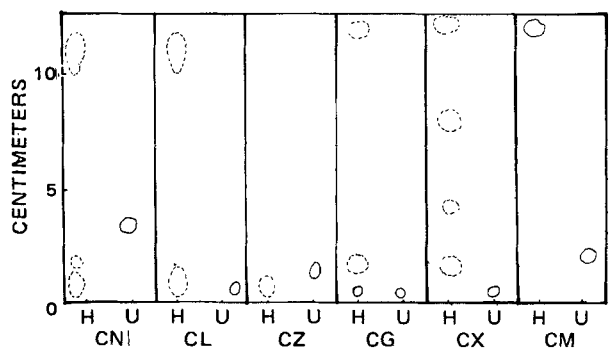

Figure 5—*Chromatogram of hydrolyzed (H) and unhydrolyzed (U) cephalosporins. Dotted lines indicate fluorescence under long UV light. Key: CN, cephalothin; CL, cephalexin; CZ, cefazolin; CG, cephaloglycin; CX, cephalexin; and CM, cefamandole.*

extracted and then reacted with sodium hydroxide to give sufficient fluorescence for detection in serum or tissue samples.

Vaginal Drug Absorption in Rhesus Monkeys I: Development of Methodology

E. OWADA, C. R. BEHL, S. S. HWANG, L. SUHARDJA, G. L. FLYNN, N. F. H. HO, and W. I. HIGUCHI ˣ

Abstract □ Earlier reports from these laboratories described a procedure for determining vaginal drug absorption in the rabbit based upon a perfusion system, and data on the vaginal absorption of the straight-chain aliphatic alcohols and carboxylic acids were given. These studies have been extended to the rhesus monkey. Rib-cage-type cells were designed for intravaginal insertion through the vulval orifice and to fit the specific dimensions of the monkey vagina. The general design of the cell was similar to that used in the rabbit vaginal absorption studies. The perfusion system was checked by using ^{3}H-polyethylene glycol 4000, and no significant leaks from the cell were found. The absorption of the alcohols followed first-order kinetics. The computed apparent permeability coefficients for the alcohols were of comparable magnitude to those previously reported for the rabbit vaginal membrane.

Keyphrases □ Absorption, vaginal—various straight-chain aliphatic alcohols, perfusion system designed, rhesus monkeys □ Vaginal absorption—various straight-chain aliphatic alcohols, perfusion system designed, rhesus monkeys □ Perfusion systems—vaginal drug absorption, various straight-chain aliphatic alcohols, rhesus monkeys □ Alcohols, straight-chain aliphatic, various—vaginal absorption, perfusion system, rhesus monkeys

Research efforts in these laboratories have been based upon the premise that the pivotal event in regional or systemic therapy *via* the vaginal absorption route may be drug transport across the vaginal membrane. A method was described (1) for evaluating drug absorption in the vagina, using the rabbit doe as a prototype animal. A rib-cage-type cell, which provided a closed absorption compartment in the vaginal tract, was designed and surgically implanted. Drug absorption was determined by perfusing the drug solution through this system.

In subsequent reports, the absorption of straight-chain aliphatic alcohols (2) and aliphatic carboxylic acids (3) was described. The data agreed with a physical model involving a diffusion layer in series with a membrane consisting of two parallel pathways: a lipoidal pathway and an aqueous "pore" pathway. The surface pH of the rabbit vaginal membrane under the conditions prevailing during the experiments could be well approximated by the pH of the bulk lumenal solution (4).

The rabbit doe was chosen for these studies because it does not exhibit an estrous cycle and the vaginal tissues exhibit a constancy in their histological, biochemical, and physiological properties not seen with other rodents and most other mammals (5). The lack of a sexual cycle in the rabbit was expected to provide minimum variability in the membrane permeability behavior (1–4).

In the human female, however, the secretion of estrogenic hormones in the ovarian cycle induces cyclic changes in the histology, biochemistry, and physiology of the vaginal tissues; therefore, the vaginal membrane might exhibit a corresponding cyclic barrier behavior. Thus, the rationale for the present investigation was to extend the studies to a sexually cyclical animal, closely approximating the human female with regard to ovarian-induced membrane changes. The Macaques rhesus species of the higher primates was selected. The rhesus has an ovarian cycle of approximately 28 days, as does the human female. It is widely believed by researchers in the fertility area that the rhesus and human reproductive systems are functionally similar in that they have comparable anatomy and phys-

extracted and then reacted with sodium hydroxide to give sufficient fluorescence for detection in serum or tissue samples.

Keyphrases □ Absorption, vaginal—various straight-chain aliphatic alcohols, perfusion system designed, rhesus monkeys □ Vaginal absorption—various straight-chain aliphatic alcohols, perfusion system designed, rhesus monkeys □ Perfusion systems—vaginal drug absorption, various straight-chain aliphatic alcohols, rhesus monkeys □ Alcohols, straight-chain aliphatic, various—vaginal absorption, perfusion system, rhesus monkeys

Research efforts in these laboratories have been based upon the premise that the pivotal event in regional or systemic therapy *via* the vaginal absorption route may be drug transport across the vaginal membrane. A method was described (1) for evaluating drug absorption in the vagina, using the rabbit doe as a prototype animal. A rib-cage-type cell, which provided a closed absorption compartment in the vaginal tract, was designed and surgically implanted. Drug absorption was determined by perfusing the drug solution through this system.

In subsequent reports, the absorption of straight-chain aliphatic alcohols (2) and aliphatic carboxylic acids (3) was described. The data agreed with a physical model involving a diffusion layer in series with a membrane consisting of two parallel pathways: a lipoidal pathway and an aqueous "pore" pathway. The surface pH of the rabbit vaginal membrane under the conditions prevailing during the experiments could be well approximated by the pH of the bulk lumenal solution (4).

The rabbit doe was chosen for these studies because it does not exhibit an estrous cycle and the vaginal tissues exhibit a constancy in their histological, biochemical, and physiological properties not seen with other rodents and most other mammals (5). The lack of a sexual cycle in the rabbit was expected to provide minimum variability in the membrane permeability behavior (1–4).

In the human female, however, the secretion of estrogenic hormones in the ovarian cycle induces cyclic changes in the histology, biochemistry, and physiology of the vaginal tissues; therefore, the vaginal membrane might exhibit a corresponding cyclic barrier behavior. Thus, the rationale for the present investigation was to extend the studies to a sexually cyclical animal, closely approximating the human female with regard to ovarian-induced membrane changes. The Macaques rhesus species of the higher primates was selected. The rhesus has an ovarian cycle of approximately 28 days, as does the human female. It is widely believed by researchers in the fertility area that the rhesus and human reproductive systems are functionally similar in that they have comparable anatomy and phys-

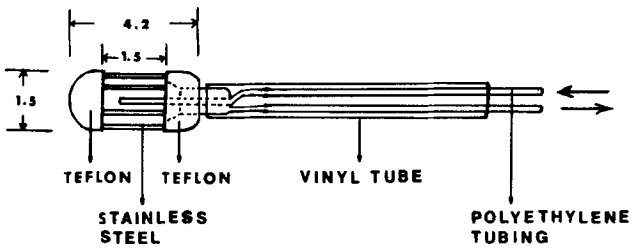

Figure 1—*Drawing of a typical rib-cage cell, which is inserted into the vagina of the monkey through the vulval orifice (all dimensions are given in centimeters for the medium size cell).*

iology (6). Therefore, the female rhesus is believed to provide an excellent model for the human female.

The purpose of the present report is to describe a method for the determination of the vaginal membrane permeability using the female rhesus monkey and straight-chain aliphatic alcohols as model compounds.

EXPERIMENTAL

Animals—Mature female Macaques rhesus monkeys (4–9 years old and 4–6 kg) known to have menstrual cycles were employed. Their vaginal tracts ranged from 1.3 to 1.7 cm in diameter and were approximately 4 cm in length. The animals were maintained under regular animal health care in an air conditioned building (25°) with free access to water and a normal diet.

The condition of the monkeys was monitored by visual examination throughout the studies. The overall procedure did not appear to affect the appetite or temperament of the animals, nor was there any significant change in body weight. Vaginal examinations revealed no vaginal infections due to the inserted rib-cage cell in any monkey.

Materials—All materials were used without further purification. A liquid scintillator was prepared by dissolving 18 g of 2,5-diphenyloxazole[1] and 300 g of naphthalene[2] in 3 liters of dioxane[2]. The buffer solution of

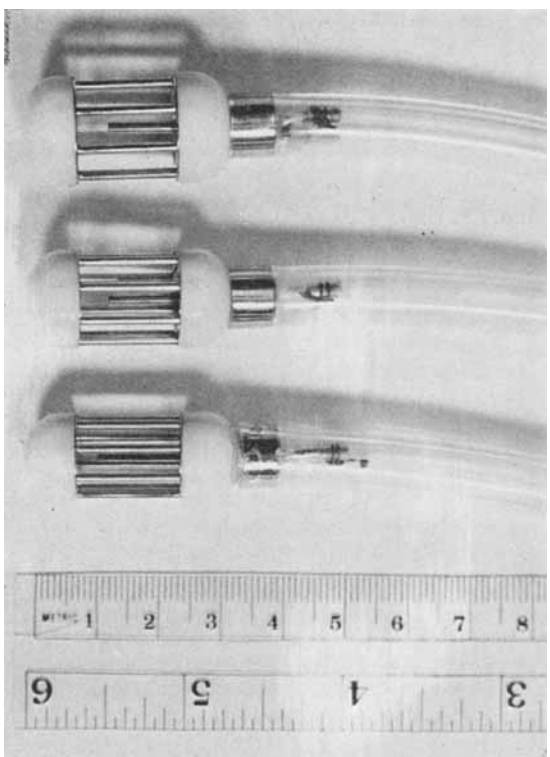

Figure 2—*Photograph of three rib-cage cells.*

[1] Isolab Inc., Akron, Ohio.
[2] Matheson, Coleman and Bell, Norwood, Ohio.

Table I—Dimensions of the Three Rib-Cage Cells Designed for Intravaginal Insertion

Cell	Length of Stainless Steel Rods, cm	Diameter of Ends, cm	Volume within Cage, ml	Surface Area, cm^2
Small	1.53	1.30	1.83	6.10
Medium	1.53	1.50	2.43	7.03
Large	1.53	1.70	3.13	7.98

pH 6.0 was prepared by dissolving 13.8 g of monobasic sodium phosphate[2] in 16.0 ml of 1.0 *N* sodium hydroxide[3] and adding distilled water to give a final volume of 1 liter. The buffer solution was then made isotonic by adding sodium chloride[3].

Design of Rib-Cage Cell—The rib-cage cell was designed to fit the vaginal dimensions of the monkey in such a way as to provide a constant volume and surface area in the absorption compartment (Fig. 1). The general design was similar to that used in the rabbit vaginal absorption studies (1). The cell was constructed with two smooth endings[4] connected by eight stainless steel rods. The stainless steel inlet and outlet for the perfusate were installed through one ending from which polyethylene tubes were led through vinyl tubing, for protection and convenient handling, to the rest of the perfusion system.

The dimensions of the cells were adjusted to fit each specific monkey, and the cell was constructed so it could be inserted through the vulval orifice without difficulty. The dimensions of three such cells (Fig. 2) are presented in Table I.

Perfusion System and General Procedure—The perfusion system consisted of two sections (Fig. 3). The first included the rib-cage cell, which was intravaginally inserted. The second section, external to the animal, consisted of a rotating and reciprocating pump[5] and a constant-temperature solution reservoir. The entire perfusion path in the system was glass tubing and stainless steel, except for the connections, which were polyethylene tubing[6]. A washing device and drain flasks were connected through two three-way stopcocks to the reservoir. During the experiments, the two sections were securely attached to provide a closed system for perfusion.

The monkeys were anesthetized by administering approximately 20 mg/kg im of ketamine hydrochloride[7]. The level of anesthetization was maintained by administering additional doses of ketamine every 0.5 hr.

The monkey was positioned on an operating table with the dorsal side up. The rib-cage cell was inserted into the monkey's vagina with care and connected by tubing to the rest of the perfusion system (Fig. 4). A sodium chloride irrigation solution was passed through the vagina for approximately 15 min at a flow rate of 20 ml/min to remove any exfoliated cells and other debris and secretions. Then the saline was replaced by the

buffer solution used in the experiments, warmed to 37°, and the washing was continued for an additional 5 min. The washings were not circulated but were collected and discarded.

Independently, 5 ml of a perfusate concentrate solution was placed in the reservoir at the perfusion system, which could be isolated from the rib-cage cell and lines leading to it by a set of stopcocks. Upon completion of the rinsing procedure, the contents of the reservoir were introduced into the perfusion circuit, which contained about 10 ml of additional buffer in the cell and lines, *via* the stopcocks. This manipulation also formed a closed perfusion loop consisting of a total volume of approximately 15 ml in the reservoir, tubing, and rib-cage cell. This procedure was employed in studies checking the tightness of fit of the cell using radiolabeled polyethylene glycol 4000 (I) and in the permeation studies using the alcohols.

In all experiments, the flow rate through the pump was 20 ml/min. In order that the solution in the system would be mixed well, a 10-min period was allowed before the first sample was withdrawn. Further samples were withdrawn at 10-min intervals up to 80 min. At the end of a perfusion run, the solution was washed out with isotonic saline introduced into the system *via* the three-way stopcocks (polyethylene glycol 4000) or quantitatively collected (alcohols). In the polyethylene glycol 4000 experiments, the wash was collected and a mass balance on the radiolabeled compound was obtained after bringing the wash volume up to 250 ml. The residual I concentration was determined radioisotopically by using a liquid scintillation counter[8].

In the experiment with I, its perfusate concentration was 2.5×10^{-4} *M*. Initial concentrations were 5×10^{-6}, 4.8×10^{-5}, and 4.1×10^{-5} *M* for ^{3}H-methanol, ^{14}C-1-butanol, and ^{14}C-1-octanol, respectively. ^{3}H-Methanol was used as a reference permeant, and its absorption was followed simultaneously with that of the ^{14}C-labeled alcohols using a dual-label analytical procedure (2).

RESULTS AND DISCUSSION

Tightness of Rib-Cage Cell—The experiments with ^{3}H-I were aimed at assessing whether the cell was leakproof as used and whether there was

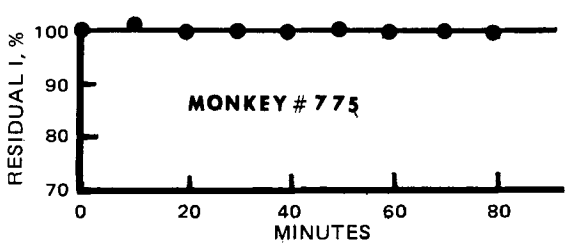

Figure 5—*Typical plot of change in concentration of I as a function of perfusion time.*

774	Medium	90.3
788	Large	91.1

a significant or measurable amount of water gained or lost during the experiment. Compound I, being a large and very polar molecule, is essentially unabsorbed. Its constancy in concentration over the lifetime of a typical run coupled with total recovery is adequate evidence of the absence of *in situ* leakage. Gradual increases in the concentration of I coupled with its total recovery would suggest water absorption. Constancy of concentration without total recovery would suggest leakage.

The percent residual I values were plotted as a function of the perfusion time. A typical plot is shown in Fig. 5. The data generally indicated no significant water flux across the vaginal membrane. The computed values of I recovery (Table II) indicated no significant leakage from the cell.

Absorption of Alcohols—The primary purpose of these experiments was to assess the utility of the perfusion procedure and system for measuring vaginal permeability. Consequently, in these experiments, the periodicity of the vaginal cycle, which is presumed to affect vaginal permeability, was neglected. Rather, each run constituted an absolute test of the procedure; first-order absorption patterns previously seen in the rabbit work were expected and sought.

The logarithm of the percent residual alcohol concentrations was plotted as a function of the perfusion time (Figs. 6 and 7). The linear relationship obtained on a semilogarithmic scale indicates that the drug disappearance followed a first-order pattern. The rate of disappearance can thus be expressed by:

$$\frac{dC_b}{dt} = -K_u C_b \qquad \text{(Eq. 1)}$$

$$K_u = \frac{A}{V} P_{app} \qquad \text{(Eq. 2)}$$

where C_b is the concentration of the drug in the bulk solution, K_u is the first-order rate constant, A is the effective surface area of the vaginal membrane exposed to the drug solution and is dependent on the geo-

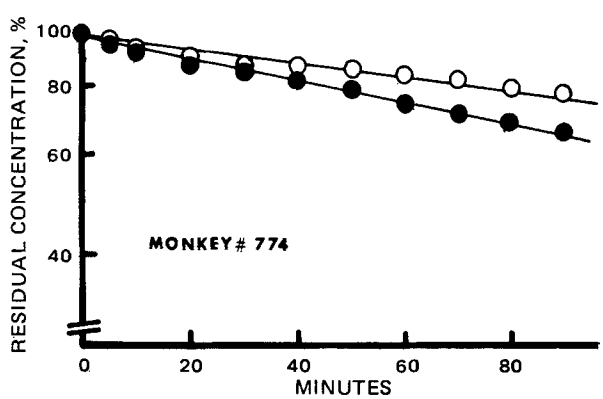

Figure 6—*Typical plots of the change in the concentrations of methanol and 1-butanol in the sampling reservoir as a function of perfusion time.*

Table III—Apparent Permeability Coefficient, P_{app}, Determined for the Vaginal Absorption of the Alcohols

Monkey	$P_{app} \times 10^4$, cm/sec		
	Methanol	1-Butanol	1-Octanol
774	0.80	1.44	2.18
775	1.16	1.77	3.52
778	0.75	0.96	2.85

metrical surface area of the cell used, V is the total volume of the drug solution, and P_{app} is the apparent permeability coefficient. The ratio of the surface area to the volume depended upon the cell employed.

The results of some typical P_{app} determinations are summarized in Table III. As can be seen, the values increased from methanol through octanol for all monkeys used. This finding is in qualitative accord with the results obtained in the rabbit vaginal absorption studies. Furthermore, the P_{app} values for the monkey were approximately of the same order of magnitude as those obtained with the rabbit system (2). However, since these experiments were carried out with little regard for the menstrual cycle effects, the results in Table III mainly represent a demonstration of the feasibility of the experiments. A rather systematic study of the menstrual cycle effects, that is, the influence of the phase of the cycle and the influence of the alkyl chain length as a function of the menstrual cycle, will be reported[9] (7).

In separate experiments, as was found in the rabbit studies, there were no significant losses of the alcohols in the perfusion system through, for example, adsorption when the rib-cage cell was bypassed.

[9] Presented at the APhA Academy of Pharmaceutical Sciences, New Orleans meeting, Apr. 1976 (abstract 54).

In conclusion, this study has shown that a relatively simple procedure involving perfusion and a special cell inserted into the vagina may be used to carry out vaginal membrane permeability experiments in the rhesus monkey. The procedure should be well suited for determining vaginal membrane permeability coefficients over a wide range of conditions, especially as a function of the menstrual cycle employing, wherever possible, the particular monkey as its own control.

Aqueous Chamber Drug Distribution Volume Measurement in Rabbits

JOSEPH M. CONRAD and JOSEPH R. ROBINSON [x]

Abstract □ A method was developed for aqueous chamber drug distribution volume measurement in the albino rabbit, and the apparent volume of distribution was determined for inulin, pilocarpine alkaloid, and 1-hexanoic acid. The method consists of injecting a suitable concentration of drug, in an appropriate volume of fluid, into the anterior chamber of the eye and monitoring the decline in drug concentration as a function of time by periodic sampling of the aqueous humor. Graphical analysis of the resulting data yields both the apparent volume of distribution and the turnover rate constant of the aqueous humor. The technique does traumatize the eye, causing formation of plasmoid aqueous, which does not interfere with the apparent drug distribution volume measurement or the determination of aqueous humor turnover. Inulin was used to determine the physiological aqueous volume, 287 μl, in good agreement with literature values. The turnover rate constant was 0.016 min^{-1}, also in good agreement with literature values. The apparent volume of distribution for pilocarpine alkaloid was 575 μl in albino eyes and 760 μl in pigmented irides; for 1-hexanoic acid in albino eyes, it was 760 μl. For pilocarpine alkaloid, literature citations on the fraction of dose absorbed have been based on an assumed apparent volume of distribution of 250–300 μl. Therefore, a factor of two error has been introduced when using albino eyes and a factor of almost three has been introduced when using pigmented eyes. The implication of the apparent volume of distribution for pilocarpine in its ocular disposition is discussed, as is the unexpected observation that pilocarpine alkaloid apparently inhibits formation of plasmoid aqueous and follows one-compartment kinetics during these studies. It is shown that the one-compartment kinetics for pilocarpine are due to its biological activity in the aqueous chamber.

The implication of the apparent volume of distribution for pilocarpine in its ocular disposition is discussed, as is the unexpected observation that pilocarpine alkaloid apparently inhibits formation of plasmoid aqueous and follows one-compartment kinetics during these studies. It is shown that the one-compartment kinetics for pilocarpine are due to its biological activity in the aqueous chamber.

Keyphrases □ Drug distribution—aqueous chamber drug volume, inulin, pilocarpine, and 1-hexanoic acid, rabbit eyes □ Inulin—aqueous chamber volume of distribution, rabbit eyes □ Pilocarpine—aqueous chamber volume of distribution, rabbit eyes □ 1-Hexanoic acid—aqueous chamber volume of distribution, rabbit eyes □ Ocular volumes of distribution—aqueous chamber, pilocarpine, inulin, and 1-hexanoic acid, rabbit eyes

To make meaningful quantitative statements about the bioavailability of an ophthalmic preparation, it is necessary to know the apparent volume of distribution for that drug in the eye. At present, the ophthalmic literature contains statements on the bioavailability of topically applied ocular drugs that are based, at best, only on an approximation to the actual aqueous humor volume, ignoring all other factors, and, at worst, on poorly controlled clinical studies

(1–4). The present study was designed to establish procedures for obtaining ocular volumes of distribution in the anterior and posterior chambers of the eye, to provide an accurate value for aqueous humor volume, and to determine the apparent volume of distribution of some typical ophthalmic drugs.

BACKGROUND

The apparent volume of distribution for ocular drugs can be used to provide insight on drug disposition if a physiological basis for the actual volume is provided, *i.e.*, if the ocular tissue volume is known. Significant deviations from the physiological volume for a determined apparent volume of distribution would be helpful in a mechanistic understanding of a drug's disposition.

Reported values for the physiological volume of the aqueous humor in rabbits have been derived primarily from paracentesis studies where the anterior chamber was aspirated and the volume was determined. Such values, however, may be in error since they may not measure the aqueous humor in the posterior chamber or fluid adhering to the walls of the anterior chamber. The aqueous humor contained in and on these structures is not measurable *via* normal aspiration techniques. Moreover, the iris and ciliary body are relatively porous structures containing aqueous humor that probably will not be removed *via* paracentesis.

Apparently, there are no reports on the apparent volumes of distribution for ocular drugs. For situations requiring an apparent volume of distribution, *e.g.*, determination of the fraction of dose absorbed, it is common practice to assume a 250–300-μl volume, irrespective of the drug under study.

Without an accurate value for the apparent volume of distribution of a drug in the eye, it is still possible to make statements regarding the percent of an applied dose that crosses the cornea to the aqueous humor. However, these values are only estimates and do not consider many parameters that can affect the bioavailability of a particular drug, *e.g.*, protein binding, partitioning into tissues, and poor mixing. By determining a precise value for the apparent distribution volume, it is possible to calculate accurately the fraction of dose absorbed. Armed with this information, it is possible to modify the size of the dose, the frequency of dosing, the vehicle for the dose, *etc.*, and to gauge the improvement in drug bioavailability due to these manipulations. In addition, the apparent volume of distribution for a drug can be used as an initial probe in the design of mechanistic studies of drug disposition.

An additional parameter, important to the disposition of a drug in the aqueous chamber, is aqueous humor turnover, since drug can be rapidly eliminated by the inflow and outflow of the aqueous humor. Removal of drug *via* this route is influenced by distribution equilibria of the drug in the aqueous chambers. Hence, the terminal elimination portion of the aqueous humor drug concentration–time profile can be used to estimate the importance of aqueous humor turnover, as well as distribution, on drug elimination.

Physiological turnover rates have been determined by various invasive and noninvasive techniques in several animal species (5–9). The results derived from the present method compare well with previously reported values. The salient feature of the described method is that it allows calculation of both the rate of aqueous humor turnover and the apparent volume of distribution for the drug from a single experimental technique. Other methods, both invasive and noninvasive, do not have the capability of determining the apparent volume of distribution, since they are mainly either continuous perfusions of the anterior chamber or intravenous injections of tracer material that appears in the eye after penetration of the blood–aqueous barrier *via* the animal's circulatory system (5–14). Thus, these methods do not provide for extrapolating drug concentration–time data to zero time, which is a necessary feature in developing a procedure to obtain the apparent volume of distribution for a drug.

EXPERIMENTAL

Materials—Male, albino, and mixed breed dark iride rabbits[1], 1.8–2.4 kg, were maintained on a regular diet with no restrictions on food or water intake.

^{14}C-Inulin[2] dry powder, specific activity 2.47 μCi/mg, was used as received. ^{3}H-Pilocarpine alkaloid[2] alcoholic solution, specific activity 2.4 mCi/mg, was purified by vacuum distillation (15) prior to use. The purification of pilocarpine was carried out immediately before each experimental run to minimize tritium exchange with the solvent. ^{14}C-1-Hexanoic acid[3], sodium salt aqueous solution, specific activity 10 mCi/mmole, was used as received. ^{14}C-Inulin and ^{14}C-1-hexanoic acid were 99% chromatographically pure. All other chemicals were either reagent or analytical grade.

Methods—*Preparation of ^{14}C-Inulin Solution*—^{14}C-Inulin was dissolved in water so that a concentration of 2×10^{-5} *M* was obtained. Since this concentration represents the limit of aqueous solubility for inulin, no "cold" (nonlabeled) inulin was added to the solution. This concentration corresponds to 0.1 μg of inulin/μl of solution. In the study employing an inulin–pilocarpine solution, radioactive inulin, 2×10^{-5} *M*, was added to a 1×10^{-4} *M* cold pilocarpine solution.

Preparation of ^{3}H-Pilocarpine Solution—Earlier work established a peak aqueous humor drug level of approximately 1×10^{-4} *M* from topical application of a 1×10^{-2} *M* solution of pilocarpine (16). Since the present study involved direct injection of drug into the anterior chamber, 1×10^{-4} *M* pilocarpine was used. The alcoholic solution of ^{3}H-pilocarpine alkaloid was evaporated to dryness. To the evaporated ^{3}H-pilocarpine was added 5 ml of 1×10^{-4} *M* cold pilocarpine alkaloid in aqueous solution. The addition of ^{3}H-pilocarpine alkaloid was small enough to have no appreciable effect on the molarity of the final solution. The solution concentration corresponded to 2.08 μg of pilocarpine alkaloid/μl.

Preparation of ^{14}C-1-Hexanoic Acid Solution—From the aqueous solution of the sodium salt, 50-μl samples were diluted to 3 ml with water to produce a solution that was 1.67×10^{-4} *M* in ^{14}C-1-hexanoic acid. Therefore, the solution for injection corresponded to 1.94×10^{-2} μg of hexanoic acid/μl.

Aqueous Humor Drug Concentration–Time Profile—Rabbits were anesthetized by intraperitoneal injection of pentobarbital sodium solution followed by phenobarbital sodium solution (17). Due to variations in response to the anesthetic doses, some animals had to be titrated with additional anesthetic until no head movements and/or blink responses were present. Also, for time points beyond 30 min, an intravenous infusion of a phenobarbital sodium solution was administered periodically to maintain anesthesia.

Anesthetized animals were then placed in wooden restraining boxes which maintained the normal upright posture for the animal. About 10 min prior to dosing, each eye received 1 drop of 0.5% tetracaine hydrochloride solution[4]. Due to the manipulations required, each rabbit was used for two different time points. For example, the left eye was dosed 10 min after the right eye so that at the end of 20 min the right eye yielded a 20-min point while the left eye yielded a 10-min point. To eliminate any right to left or left to right bias, the next rabbit was dosed so that the left eye yielded the 20-min point while the right eye yielded the 10-min point. For the later time points of 60 min and beyond, the same time point could be obtained from both eyes since the entire procedure of refilling the syringes, injecting the drug solution, and positioning the delivery apparatus on the wooden blocks took approximately 1 min, and this period introduced a potential error of only 1.67% in a 60-min time point. Moreover, this error was averaged out by reversing the order of dosing in the next rabbit.

Once the anesthetized animal was positioned in the restraining box and the topical anesthetic was applied, measured volumes of drug solution (5, 10, or 20 μl) were accurately administered to each rabbit eye *via* a microliter syringe[5]. The syringe was fitted with a modified vein infusion set[6] prefilled with the drug solution. The modification consisted of shortening the tubing length from the normal 30 cm to approximately 3 cm. This change was made to minimize drug solution loss and to make the delivery apparatus more manageable. Once the needle of the infusion set had punctured the cornea and was in position in the anterior chamber, the appropriate dose was delivered from the syringe. To prevent leakage of the aqueous humor fluid, the 3-cm tubing was then clamped off with Kelly forceps and the tubing was cut just behind the clamp. The clamp was then supported on a wooden block so that its weight would not pull on the punctured cornea and produce leakage at the entrance point of the needle into the cornea.

The clamp assured no loss of aqueous humor due to positive pressure outflow caused by the intraocular pressure. The small amount of tubing

remaining, 1.5 cm, and the supported clamp allowed the rabbit some head movement without danger of dislodging the needle.

At the end of the designated time periods, 5, 10, 15, 20, 30, and 60 min, the rabbit was sacrificed by rapid marginal ear vein injection of an overdose of phenobarbital sodium. The 90- and 120-min time points were obtained only with the ^{14}C-inulin at the 20-μl volume. The aqueous humor was aspirated from each eye using a 1-ml tuberculin syringe fitted with a 27-gauge, 1.27-cm needle. Aqueous humor samples, 100 μl, were quantitatively transferred to scintillation counting vials[7] containing 5 ml of a scintillation cocktail[8]. Samples were then stored in the dark at room temperature for a minimum of 48 hr prior to counting to eliminate error due to chemiluminescence. Ten-minute counts of each sample were made using a liquid scintillation spectrometer[9]. The final count for each sample, corrected for background, was then converted to a microgram of drug per milliliter of aqueous humor basis by standardization techniques to facilitate analysis and interpretation of results.

A minimum of 10 eyes was used for each data point, with the exception of the 60-min point for pilocarpine in albino rabbits where four eyes were used; no animal was used more than once. Mean values and standard errors of the mean were determined from the pooled data at each time point. The concentration–time profiles were least-squares fit to the one- or two-compartment model.

RESULTS

Inulin has been employed in the past to measure renal clearance values. Since it does not readily penetrate tissues and is not bound to protein to any measurable extent, it was considered ideal for such clearance measurements because it is eliminated solely by glomerular filtration. These same properties make inulin an attractive probe for measuring the physiological aqueous humor volume. In addition, tissues surrounding the aqueous chamber, *i.e.*, iris and ciliary body, are porous and should allow free movement of the relatively small inulin molecule so that all resident aqueous humor is detected. These assumptions are borne out by experimentation. Assay of ocular tissues surrounding the anterior chamber, *i.e.*, cornea, ciliary body, iris, vitreous humor, and lens, shows that inulin is not absorbed and/or adsorbed onto these tissues. Thus, the only means of exit for inulin from the anterior chamber is by normal aqueous humor drainage.

Figure 1 shows the aqueous humor inulin concentration–time profile for three different injected volumes (5, 10, and 20 μl). Different volumes were employed to determine the influence of instilled volumes on the apparent volume of distribution and apparent aqueous humor turnover as well as to check on the proposed mechanism for inulin removal, *i.e.*, to explain the shape of the drug concentration–time profile. The drug concentration–time profiles were analyzed as an apparent two-compartment open model[10], with the initial portion of the curve attributed to an effect due to injection of a volume above that of the normal resident volume and the terminal portion due to normal aqueous humor turnover.

An analogy can be made between this system and instilling a volume of drug into the precorneal portion of the eye (18). In the precorneal portion, an instilled solution is diluted by resident tears, the tear–drug solution then rapidly drains from the eye until the volume is back to the normal resident volume, and, finally, tear turnover accounts for most of the remaining drug removal. In the aqueous chamber, the injected inulin mixes with resident aqueous humor and drains from this area until a normal volume is achieved, at which point aqueous humor turnover is responsible for additional removal. Thus, the initial portion of the inulin profile is attributed to rapid removal of drug simply because a volume has been injected. The increasing slopes of these lines with an increasing volume support this proposal. The terminal portion of the profile corresponds to aqueous humor turnover. Since no distribution of inulin into aqueous chamber tissues occurs, the terminal slope can be directly related to aqueous humor turnover.

After graphical analysis and extrapolation to time zero, the volume of distribution of the aqueous humor can be calculated in the usual manner. These values for the three volumes are presented in Table I along with the turnover rate constants obtained from the terminal portion of the curves. The physiological volume of distribution, *i.e.*, true aqueous humor volume, and the turnover rate constant derived from these measurements agree very well with those reported for rabbits using other techniques (5, 19).

The problem of plasmoid aqueous formation due to trauma has been well documented for the rabbit (20–22). Any trauma such as inflammation or puncture of the globe of the eye leads to a breakdown on the blood–

[10] The term compartment is used in a very loose sense throughout this article. With inulin, only the aqueous chamber is involved, *i.e.*, one compartment, and the biphasic concentration–time profile is simply a fast volume-dependent removal of drug followed by a slower removal.

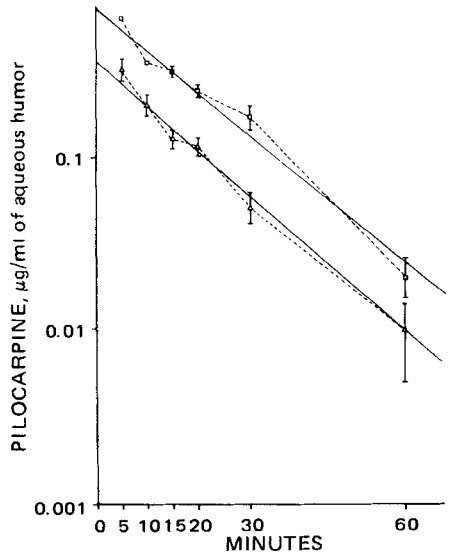

Figure 2—*Aqueous humor drug concentrations following intracameral injection of 1 × 10^{-4} M pilocarpine solutions in albino rabbits. Error bars represent the standard error of the mean. aqueous barrier with a concomitant rise in the protein content of the aqueous humor. In the inulin study, plasmoid formation was visually observed at the 30-min time point and beyond. Plasmoid formation results in an extremely viscous aqueous humor, which is difficult to aspirate into the tuberculin syringe. It appears as a transparent semisolid, gel-like substance which undergoes shear thinning with repeated uptake and discharge through the syringe needle.

Formation of plasmoid aqueous in the rabbit occurs with very mild trauma, whereas the human eye seems much more resistant to its formation (23). Since plasmoid aqueous does not appear to affect vision, at least in the human eye, and the calculated turnover rate constant of the aqueous humor from the present study agrees well with that of normal aqueous humor in rabbits, its formation does not appear to be a cause for concern in the present study. Apparently, the rabbit eye makes all necessary accommodative changes to compensate for the more viscous plasmoid aqueous. Plasmoid aqueous formation is, of course, a reversible process; in a relatively short period, *i.e.*, a few hours, a normal aqueous humor is again formed.

Figure 2 shows the aqueous humor drug concentration–time profile for pilocarpine, and Table I shows the apparent volume of distribution and turnover rate constant for pilocarpine derived from graphical analysis of the data. From the data in Table I, it is clear that the apparent volume of distribution for pilocarpine is twice that of the physiological volume and the turnover rate constant is significantly greater than the normal value. The larger volume of distribution can be attributed to the fact that pilocarpine is somewhat protein bound, can and does penetrate ocular tissues, and may be bound to tissue surfaces (4, 24–27)[11].

Because protein contained in the aqueous humor leaves the eye during the normal removal of the aqueous humor, the present method is unable to discern whether or not a drug is highly bound to protein, as can be done with the traditional drug volume of distribution in the blood. However, the method can discern tissue penetration and binding of drugs to ocular tissue surfaces, as was shown clearly in the study of pilocarpine in dark iride rabbits (Fig. 3). The apparent volume of distribution for pilocarpine was 760 μl, considerably larger than the 575 μl determined in albino rabbits. For comparative purposes, Fig. 3 includes the albino rabbit data for pilocarpine. The decline in drug concentration between pigmented and nonpigmented animals was parallel. However, the 60-min point was considerably different between the pigmented and nonpigmented animals. No explanation for this difference is offered, but it is important to recognize that the data from albino rabbits are based on only four eyes with a large standard error and that the radioactive counts at this level are uncomfortably low. Thus, we have less confidence in this point as compared to others.

The shape of the drug concentration–time profile for pilocarpine was considerably different than that of inulin. A biphasic curve was not observed over the time course of the study, and the slope of the line yielded a rate constant considerably greater than physiological turnover of the aqueous humor. A suggested explanation for this behavior is related to the pharmacological effect of pilocarpine. It is well known that pilocarpine exerts various pharmacological effects in the eye, such as decreased anterior chamber depth (28) and an influence on aqueous humor turnover (9, 29–30). These effects were absent with inulin as well as with 1-hexanoic acid, and both of these compounds showed the expected biphasic appearance. In support of the idea that this finding is not an artifact of the present technique, it was observed that the 1st hr or so beyond the peak of the aqueous humor pilocarpine–time profile, from topically applied drug, also showed an increased rate of removal over and above physiological turnover[11].

As an alternative explanation for the data, it is possible that the apparent one-compartment profile for pilocarpine represents a nonsteady-state distribution into other tissues, which would invalidate this approach for pilocarpine apparent volume of distribution measurement. However, other data[11] do not support this thesis; therefore, a pharmacological effect is offered as a reasonable explanation. As added support for a pharmacological effect explanation, a study was undertaken where inulin and pilocarpine were injected together and the decline in inulin concentration was monitored as a function of time. If a pharmacological effect from pilocarpine occurs, it would be expected that the decline in inulin concentration, when an inulin–pilocarpine solution is injected, would be more rapid and perhaps follow different kinetics than when inulin is administered by itself.

Figure 4 shows the results of this study as well as the data for inulin and pilocarpine. Inulin did indeed leave the aqueous chamber at a more rapid rate when pilocarpine was present. Although there are insufficient data to draw a firm conclusion, it appears that the inulin–pilocarpine data closely parallel the pilocarpine elimination line, and it is considerably different than the inulin line by itself.

When pilocarpine was injected into the anterior chamber, no plasmoid aqueous humor was observed up to 60 min postinjection while with inulin and 1-hexanoic acid, a plasmoid aqueous formed readily.

Figure 5 presents the aqueous humor drug concentration–time profile for 1-hexanoic acid. This compound, of course, is not used in ophthalmic therapy. However, because it is a medium chain-length fatty acid, it can be expected to penetrate tissues readily and to have a relatively large apparent volume of distribution. As indicated in Table I, its apparent volume of distribution was approximately 2.5 times larger than the true physiological volume of distribution obtained in the inulin study.

Graphical analysis of the 1-hexanoic acid data yielded an apparent two-compartment open model with the same volume effect initially as that shown for inulin. The break points in the curves for the two volumes followed the same pattern established for inulin, and this finding lends credibility to the volume effect argument.

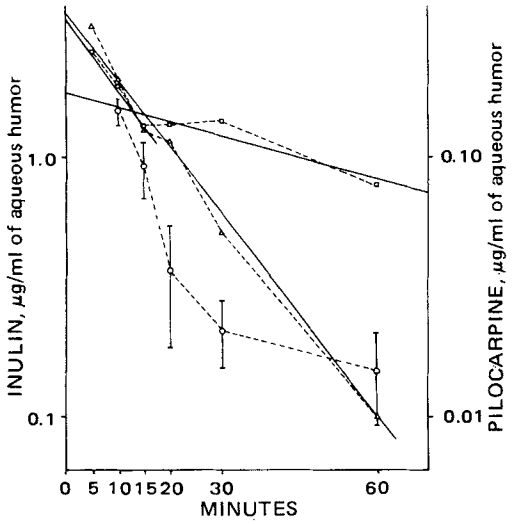

Figure 4—*Comparison of aqueous humor drug concentrations following intracameral injection of 10 μl of 2 × 10^{-5} M inulin solutions (□), 1 × 10^{-4} M pilocarpine solutions (△), or 2 × 10^{-5} M inulin in 1 × 10^{-4} M cold pilocarpine solutions (○) in albino rabbits. Error bars represent the standard error of the mean. Error bars were deleted from the 2 × 10^{-5} M inulin and from the 1 × 10^{-4} M pilocarpine data to facilitate comparisons. Solid lines are best-fit lines. Dotted lines connect the mean value at each time point.*

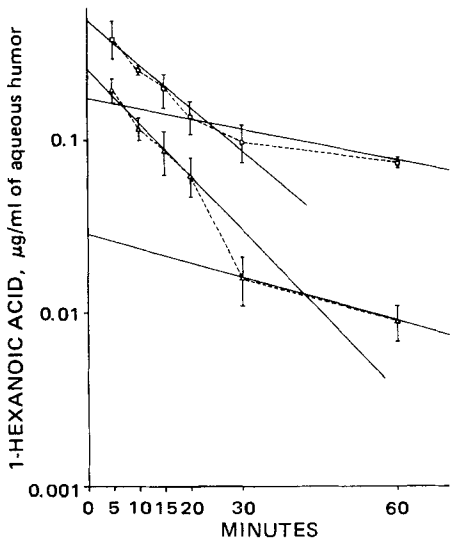

Figure 5—*Aqueous humor drug concentrations following intracameral injection of 1.67 × 10^{-4} M 1-hexanoic acid solutions in albino rabbits. Error bars represent the standard error of the mean. Where no error bars are drawn, the standard error was smaller than the symbol used. Solid lines are best-fit lines. Dotted lines connect the mean value at each time point. Key: △, 10 μl injected; and □, 20 μl injected.*

Another feature of the apparent two-compartment open model used to describe the inulin and 1-hexanoic acid data is that the turnover rate constant obtained after curve stripping of the initial phase of the curves, *i.e.*, that portion attributed to the volume effect, agrees reasonably well with the turnover rate constant found for pilocarpine in that study. This result indicates that the volume effect is qualitatively similar to the pharmacological effect produced by pilocarpine.

DISCUSSION

A primary consideration of this study was the development of a technique for systematically measuring the apparent volume of distribution of ophthalmic drugs. The method itself is obviously unrealistic for human use, since it involves puncturing the cornea and direct injection of drug solution into the anterior chamber. However, the insights gained from animal studies are useful in providing initial estimates of ocular behavior in humans. For example, since the rabbit eye is similar in size and gross morphology to the human eye, a drug's apparent volume of distribution measured in rabbits is expected to approximate that of human eyes.

The described method has limitations. As mentioned previously, protein binding will not be detected *per se*, because the movement of drug bound to protein will be indistinguishable from free drug movement. Both bound and free drug leave the chamber *via* normal aqueous humor drainage, and the present technique cannot distinguish free and bound drug.

A second limitation is that the drug must be in an aqueous vehicle. Since it is injected into a small confined aqueous milieu, an oil-soluble drug in an oily vehicle could precipitate in the anterior chamber and block the aqueous humor drainage pathways or the oil vehicle could cause a physical blockade to drainage.

Based on the previous discussion, relative to the effect of injected volume on the pharmacokinetic profile, it is clear that there should be constraints on the volume employed. Too large a volume may result in possible tissue damage so that an upper limit is placed on the accommodative mechanism of the rabbit eye. A small volume is limited by the reproducibility of repetitive injections. It is suggested that the 10-μl volume be used on a routine basis, because the 5-μl volume requires considerable skill for reproducibility and the 20-μl volume might generate damage to the eye, particularly if small rabbits are employed. However, if solubility problems or assay limitations are encountered, the 20-μl volume can be employed; in fact, a 30-μl volume can be used. Studies using 30 μl were also conducted for inulin, and the results (not reported here) from these studies are consistent with the reported volumes.

One concern with the proposed experimental technique was that having the test animal under general anesthesia throughout the experiment might decrease the rate of aqueous humor formation and removal (6, 31). Results, namely that physiological turnover rates of the aqueous humor were determined from the inulin and 1-hexanoic acid data, indicate that this reduction or stoppage does not occur in the rabbit under anesthesia.

Several additional observations made during this study require further comment. As noted earlier, the trauma of intracameral injection and increased volumes in the chamber due to injection caused the formation of plasmoid aqueous within 30 min postinjection of inulin and 1-hexanoic acid. At first glance, it would seem likely that this more viscous, proteinaceous aqueous humor should not leave the anterior chamber very easily, thus leading to a slow turnover rate. This is obviously not the case. Two possible mechanisms can explain this finding. Either the rabbit's trabecular meshwork expands to accommodate the plasmoid aqueous or a microdiffusion effect removes the more fluid portions of the plasmoid, leaving behind a "matrix" of highly viscous protein plasmoid aqueous which is subsequently removed at a slower rate.

If increased accommodation is the method of plasmoid aqueous removal, this process is easily reversible since, upon removal of the cause of plasmoid aqueous, the rabbit aqueous humor returns to normal within a matter of a few hours (32). The accommodation must be throughout the anterior and posterior chambers because, not only does the viscous plasmoid leave at a normal rate, it must form and enter the posterior chamber at a normal rate to maintain a constant turnover rate (20, 32).

The second possibility, a microdiffusion effect, would involve formation and destruction of a protein matrix with relatively free flow of the aqueous humor in and through this matrix. If this microdiffusion mechanism is operative, it presents an interesting form of sustained release for any highly protein-bound drug. The drug would be bound to the protein matrix, which should prolong its residence time in the aqueous chamber. These possible mechanisms for plasmoid aqueous removal are interesting and require additional work. However, the most important factor relative to the proposed technique is that plasmoid aqueous formation does not interfere with the apparent volume of distribution determination.

The pilocarpine and 1-hexanoic acid data were intriguing from several points of view. As noted in Table I, the apparent volume of distribution for pilocarpine in the aqueous humor was 575 μl, and the concentration–time data fit a monoexponential curve with an apparent first-order rate constant of 0.059 min^{-1}. The apparent volume of distribution was twice the physiological volume, which was attributed to sorption of the drug into and onto tissues lining the aqueous chamber (4, 24–27)[11]. Since published studies on the fraction of dose absorbed for pilocarpine have relied on an assumed volume of distribution of 250–300 μl, these values probably are off by a factor of two for albino rabbits and by a factor of almost three for pigmented rabbits. The more important point is that other drugs, as illustrated by 1-hexanoic acid, could have much larger

apparent volumes of distribution and be off by factors of three, four, or greater.

In defense of the proposed mechanism for the increased turnover rate constant due to pilocarpine, *i.e.*, a pharmacological effect, a comparison of these results in rabbits with those obtained in humans (33) for topically applied pilocarpine is in order. Yoshida and Mishima (33) found that the rate constant for normal aqueous turnover in humans was 0.7 hr^{-1} while that following topical dosing with pilocarpine was 0.27 hr^{-1}. In the present study, the normal aqueous turnover in rabbits was 0.72 hr^{-1} while the turnover following pilocarpine injection was 4.2 hr^{-1}. It would appear that these data are in conflict. However, it should be kept in mind that topical dosing leads to a reservoir effect in the corneal epithelium (34) so that, at later times, the turnover of pilocarpine appears slower than it actually is. As pilocarpine leaves the aqueous chamber, more drug is being fed in to maintain a level of drug in the aqueous chamber that falls less rapidly than would occur if the reservoir was absent. Application of drug through direct injection bypasses the reservoir effect of the corneal epithelium and generates a more rapid removal of the aqueous humor, in keeping with what one would intuitively expect for a glaucoma drug. Over the time course of these studies, pilocarpine apparently is unable to penetrate the corneal epithelium from direct injection so there is no reservoir effect. Recent evidence (4, 24)[11] demonstrates that pilocarpine disposition from the aqueous humor is quite complex and does not follow a simple one- or two-compartment model.

From the results of this pilocarpine study in albino and pigmented animals, it is clear that the method can discern binding. Thus, the earlier noted differences in pilocarpine uptake in heavily pigmented animal eyes (4, 25) as well as humans (26) have been borne out in an *in vivo* experiment and support the need for more drug to treat glaucoma in heavily pigmented eyes.

1-Hexanoic acid data were biphasic, with the terminal portion of the curve having an apparent rate constant of 0.017 min^{-1}, in agreement with normal aqueous humor turnover. One would intuitively expect that the elimination of a drug that distributes extensively into aqueous chamber tissues would be influenced by this distribution and that, therefore, the terminal portion of the 1-hexanoic acid curve should probably not correspond to normal turnover. One can speculate that drug taken up by tissue is removed from the aqueous chamber by absorption into the general circulation or perhaps that the drug is irreversibly bound to tissue or in some manner degraded.

Biological Distribution of Chemical Analogs of Fatty Acids and Long Chain Hydrocarbons Containing a Strong Chelating Agent

STEPHEN M. KARESH *, WILLIAM C. ECKELMAN *‡x, and RICHARD C. REBA *‡

Abstract □ The pharmaceutical preparation, chromatography, and biological distribution of a series of new chemical analogs of palmitic acid and diethylenetriaminepentaacetic acid, ethylenediaminetetraacetic acid, or diethylenetriamine are described. The biological distribution in rabbits 30 min after intravenous administration of these ^{99m}Tc-labeled and ^{57}Co-labeled derivatives was compared to the biological distribution of the parent compound, ^{3}H-palmitic acid. The average myocardial uptake for these compounds was 0.04%/g, compared to 0.15%/g for palmitic acid. The heart to blood ratio at 30 min reached a maximum of 3:1 for the best physiological analog of palmitic acid, compared to an average of 30:1 for palmitic acid. Although none of these analogs appears to be clinically useful, their production methods might be applicable to the synthesis of new compounds that might increase the specificity of radiopharmaceuticals.

Keyphrases □ Fatty acid analogs, ^{99m}Tc- and ^{57}Co-labeled—containing chelating agents, biological distribution, compared to ^{3}H-palmitic acid, rabbits □ Distribution, biological—^{99m}Tc- and ^{57}Co-labeled fatty acid analogs containing chelating agents, compared to ^{3}H-palmitic acid, rabbits □ Radiochemistry—technetium Tc 99m as label for fatty acid analogs containing chelating agents, biological distribution, compared to ^{3}H-palmitic acid, rabbits □ Technetium Tc 99m—label for fatty acids containing chelating agents, biological distribution, compared to ^{3}H-palmitic acid, rabbits

Of the conveniently available radionuclides, technetium Tc 99m has the best physical characteristics for external imaging; however, poor chemical properties have limited its use as a label for biological molecules. The weak chelate ion characteristics of technetium Tc 99m in aqueous solution are such that many organic compounds have been only nominally labeled with it. For example, for such molecules as tetracycline (1) and the carbohydrates (2), the chelating strength of the functional groups on the molecule itself is apparently too weak to assure the integrity of the chelate *in vivo*.

The preparation of derivatives may be a means of producing radiopharmaceuticals with better metal binding properties but similar biological properties. Specifically, a biologic molecule covalently bound to a strong chelating group should then bind technetium Tc 99m more strongly than the biologic molecule itself. Simple polyaminopolycarboxylic acids like diethylenetriaminepentaacetic acid (I) have been shown to bind technetium Tc 99m so that it is distributed and excreted in vertebrates in a manner similar to that of ^{14}C-labeled I (3). Compound I, therefore, seems to be a useful chelating agent to bind to interesting biologic molecules.

The fatty acids are a class of compounds known to localize in the myocardium. By combining long chain fatty acids with I-like compounds (strong chelating agents to carry the ^{99m}Tc-label for other cations), new compounds were obtained (4). This paper describes the pharmaceutical preparation, chromatography, and relative distribution at 30 min of this series of compounds designed as myocardial imaging agents.

EXPERIMENTAL

Synthesis, Purification, and Characterization of New Compounds—The synthesis, purification, and physical characterization of II–X and XII–XIV were published previously (4).

Preparation of Radioactive Compound—The tin chelates of VII, IX, X, and XIV were prepared in a nitrogen atmosphere. Twenty-five milligrams of stannous chloride dihydrate was placed in a 100-ml serum vial, and the vial was nitrogen purged and sealed. Three milliliters of nitrogen-purged absolute ethanol was then added by syringe, and the vial was shaken. To the vial was added 1.25 ml of a hot nitrogen-purged ethanol solution of the chelating agent (150 mg/ml, pH 4), and the mixture was shaken vigorosly. Then a nitrogen-purged ethanol–water solution was added so that the final volume was 100 ml and the resulting ethanol concentration was 20% by volume.

After the solution cooled to room temperature, it was filtered through a 0.22-μm filter. Then 2 ml of ^{99m}Tc-labeled sodium pertechnetate was added to 2 ml of the tin chelate solution. In every case, the reduced technetium bound to the chelating agent. Chromatography data showed no evidence of either $^{99m}TcO_4^-$ or ^{99m}Tc-labeled technetium stannous oxide for all of the compounds (Table I). Potentiometric titration of an aliquot of the tin chelate solution was performed for each preparation using a glass electrode[1] and standard iodine solution prior to addition of the $^{99m}TcO_4^-$ to the tin chelate solution.

The cobalt-57 chelates of IV, VII, IX, X, and XIV were prepared by heating alcoholic solutions of ^{57}Co-labeled cobalt chloride and the chelating agent in sealed serum vials for 1 hr at 100°. Labeling of each compound with cobalt-57 was verified by paper chromatography or TLC, using ^{57}Co-labeled cobalt chloride as a reference standard (Table I). Cobalt chelates were preferred for preliminary studies because of the stable oxidation state of cobalt(III).

[a] Female New Zealand White rabbits, 2.5–3.5 kg, were used. Each value in Table III represents the average for three rabbits. Blanks in table indicate that particular organ was not assayed. [b] With 250 ml of 10% dextrose in place of drinking water the night before and 1 ml iv of 50% dextrose 10 min prior to injection. [c] Fraction V human serum albumin, fatty acid free (Miles Laboratories). [d] Phosphate-buffered saline, pH 7.4.

Compounds V and IX were labeled with tritium by catalytic reduction, using tritium gas[2] and palladium-on-charcoal catalyst[2]. Compounds VII and XIV were labeled with tritium by Wilzbach bombardment with tritium gas over 2 weeks. All tritiated compounds were purified by suitable preparative thin-layer methods and were redissolved in absolute ethanol. 9,10-^{3}H-Palmitic acid[2] was used as a reference standard for biodistribution studies, since this simple long chain fatty acid is known (5, 6) to localize in, and be metabolized by, normal myocardium in humans.

Chromatography of Radiolabeled Chelates and Chelating Agents—Paper chromatography[3], TLC on silica gel glass plates[4] or cellulose plates[5], and column chromatography on 1 × 30-cm cross-linked polysaccharide columns[6] were performed (Table I). Tritium counting of scraped sections from radiochromatograms was performed using a liquid scintillation counter; the channels-ratio method was used for quench correction. All strips containing γ-emitting isotopes were cut and counted in a sodium iodide crystal scintillation counter. In most cases, two systems are presented for verification of the degree of labeling.

Thirty-Minute Biodistribution Studies—Male New Zealand White rabbits, 2–4 kg, were used for each distribution study. After purification by preparative chromatography, 0.10 ml (~10 μCi) was injected into the marginal ear vein of the rabbit. The animal was sacrificed 30 min postinjection, unless otherwise specified. A midline incision was made, and the heart, lungs, liver, spleen, and kidneys were removed, as well as samples of skeletal muscle, perirenal fat, urine, and blood.

For each whole organ or tissue sample containing a tritium-labeled compound, one 25–50-mg sample of each type of tissue from each animal was removed, weighed (±0.01 mg), digested in 0.5 ml of 5 *N* NaOH overnight, bleached with 2 drops of hydrogen peroxide, and finally suspended in 10 ml of scintillation fluid[2]. After 4-day dark-adaption and cooling, each sample was counted for 40 min (at ≥5000 counts/sample) in a liquid scintillation counter. All data are reported in terms of percent administered dose per organ and percent administered dose per gram of organ.

Table II summarizes the tissue concentrations for the various labeled compounds and specifies the experimental conditions of the biodistribution study. Ethanol, saline, and dilute human serum albumin were used as solvents to determine if the insolubility of the fatty acid derivatives is a factor in the distribution. The dose of the chelating agent was varied to study the possibility of the saturation of the transport mechanism. Fasted animals received water *ad libitum*. The dextrose diet consisted of the normal pellet diet plus 10% dextrose solution instead of water and 1 ml of 50% dextrose injected intravenously 10 min before injection of the compound. The distribution with time was studied for ^{3}H-palmitic acid.

In a preliminary experiment, the cobalt-57 chelate of IX was studied in two 18–20-kg mongrel dogs with experimentally induced infarcts. The infarcts were induced by ligation of the anterior descending branch of the left coronary artery just distal to the origin of the circumflex branch. This procedure produced an area of ischemia in the apical region of the left ventricle, which was evident by ECG. The radiopharmaceutical was injected intravenously 30 min after sudden and complete ligation. The animal was killed 30 min after injection, and the heart was immediately excised and divided into the left and right ventricles and the interventricular septum. Each part was then further subdivided, and the radioactivity was counted.

RESULTS AND CONCLUSIONS

Chromatographic studies of the radiolabeled derivatives in the appropriate system (Table I) indicate that the technetium Tc 99m or cobalt-57 was quantitatively bound to the new derivative. However, the results presented in Tables II and III show a significantly lower ($p \leq 0.05$) concentration in the myocardium for all chelates tested than for palmitic acid, the reference standard. Approximately 0.04%/g of the administered dose localized in the entire heart, compared to 0.15%/g for ^{3}H-labeled palmitic acid. The generally high degree of localization of these compounds in the liver (~20–30%) was approximately the same as that for palmitic acid. There was no evidence of particle formation in the chromatographic studies of the original chelate.

A significant percentage of the injected dose of most of these synthetic compounds remained in the intravascular space (15–25% of the admin-

istered dose) at the 30-min observation point. This finding compares with an average of about 3% remaining in the blood at 30 min for palmitic acid. Heart–blood ratios for palmitic acid on a per gram basis were in the range of from a 30:1 to 40:1; for the metal chelates the concentration was always less than 3:1, thus making it impossible to differentiate myocardium from blood.

The high blood concentration may be due to the fact that these compounds are more tightly bound to serum albumin so that the transport of fatty acid derivatives across the cell membrane into the intracellular fluids is reduced. The greater difference in polarity between a simple fatty acid, *e.g.*, palmitic acid, and fatty acid derivatives (*i.e.*, IX) could affect the localization of the labeled compound. Compounds containing a diethylenetriamine chelating group also showed slow blood clearance.

The 30-min distribution was chosen to screen this series of compounds rapidly. Because the palmitic acid does not concentrate in an infarct but does concentrate in the normal myocardia, the 30-min myocardia to blood ratio is the important factor and should indicate if the compound may be useful.

The results of the distribution of the labeled IX in dogs with experimentally induced infarcts revealed that an average accumulation of 0.94% of the injected dose was localized in the heart, 16.6% was in the liver, and 2.7% was in the lungs and that 3.8% remained in the intravascular compartment at 30 min. The infarct contained less than half of the radioactivity found in adjacent normal myocardium.

The chemical analogs described here are not sufficient biological analogs to act as tracers for fatty acid metabolism in the myocardium. However, this approach of preparing drug derivatives should lead to more specific radiopharmaceuticals and will be pursued using other biologic molecules.

Chemical Ionization Mass Spectra of Phenothiazine Derivatives and Their Oxygenated Analogs

ARMEN P. MELIKIAN *ˣ, NORMAN W. FLYNN ‡, FREDERICK PETTY ‡, and JOSEPH D. WANDER ‡§

Abstract □ Twenty-nine derivatives of phenothiazine formed relatively stable ions by proton capture under conditions of chemical ionization, using methane or isobutane as reagent gas. Fragments of generally low abundance formed by simple bond cleavage in the trimethylene portion of the side chain and by loss of water or hydrogen halide. Mass spectra obtained from pyrolyzates of amine salts and from the corresponding free bases were essentially identical.

Keyphrases □ Chemical ionization mass spectrometry—various phenothiazines and oxygenated analogs □ Phenothiazines, various—and oxygenated analogs, chemical ionization mass spectra □ Mass spectrometry, chemical ionization—various phenothiazines and oxygenated analogs

Phenothiazines have dominated the interest of researchers in many diverse areas since the discovery that they exert profound effects upon the central nervous system, and a wealth of information pertaining to pharmacological action, therapeutic applications, and biotransformation pathways has been accumulated (1, 2). Some of the vicissitudes encountered in assaying phenothiazine compounds and their metabolites in biological fluids were summarized by Usdin (3).

Elucidation of the mechanisms of action and metabolic conversion and evaluation of the relationship of plasma concentrations of these drugs to their clinical efficacy became possible only after analytical procedures possessing adequate sensitivity and specificity had been developed. A recent monograph outlining many aspects of current research efforts in the area of phenothiazine derivatives describes three approaches to mass spectrometric identification of promazine, chlorpromazine, and several oxygenated homologs (4–6). Whereas electron-impact mass spectrometry has made significant contributions to the biomedical and pharmaceutical sciences over the years, application of chemical ionization mass spectrometry to these areas represents a fairly recent development (7). Finkle *et al.* (8) reported chemical ionization (methane) mass spectra of pharmaceutical agents, including some phenothiazines, and their metabolites as part of a broad program for rapid identification of the contents of body fluids in patients suspected to be intoxicated by a drug overdose.

As part of a continuing program of developing applications of chemical ionization GC–mass spectrometry in neurochemistry (9, 10), the chemical ionization mass spectra for 29 derivatives of phenothiazine were investigated including the tranquilizing agents chlorpromazine (VII), promazine (XV), promethazine (XVI), prochlorperazine (XVIII), trifluoperazine (XXII), perphenazine

EXPERIMENTAL

Chemical ionization mass spectra were obtained using a quadrupole mass spectrometer[1] interfaced to an interactive data system[2]. Source pressures were maintained at 1 (methane) or 0.8 (isobutane) Torr. These pressures were found, by observing the spectrum of the reagent gas, to afford optimal conditions for chemical ionization in the instrument. The source temperature was 110–130°. Samples (1 ± 0.5 μg) were placed in glass capillary tubes (5 mm long × 1 mm i.d.) and introduced through a vacuum lock into the source by a direct-insertion probe, which was then gradually heated above 300° to effect volatilization.

Tabulated intensities are expressed as the percent of the intensity of the base peak; satellite peaks due to isotopes present in natural abundance are not included, although characteristic satellite clusters facilitated the identification of some ions at unit resolution. Compounds XIII, XVIII, and XXIX were introduced into the mass spectrometer as bimaleate salts; the remainder of the compounds were examined as hydrochlorides.

RESULTS AND DISCUSSION

Relative intensities of prominent peaks larger than *m/e* 100 in the chemical ionization mass spectra of I–XXIX are given in Table II; separate determinations are presented using methane or isobutane as the reactant gas. Although these values were obtained for the hydrochloride or bimaleate salts of amines subjected to pyrolysis in the region proximate to the source of the mass spectrometer, essentially identical results were found using the free bases of VII, VIII, XVIII, XXII, XXIII, XXVII, and XXIX; an intense peak at *m/e* 117 (MH^+ of maleic acid) was observed for derivatives (XIII, XVIII, and XXIX) introduced as bimaleate salts.

In all chemical ionization (isobutane) spectra and in all but a few of the chemical ionization (methane) spectra, the base peak was the intact, protonated molecular ion (MH^+); intensity of the MH^+ ion exceeded 50% of the base peak in the spectra of XX and XXI. The failure of VI to afford a prominent MH^+ ion is a consequence of spontaneous degradation of VI (prior to ionization) by the Cope-elimination process (11) illustrated in Scheme I. The MH^+ ion of the resulting *N*-allyl derivative (VIa) was the base peak in the spectrum under both chemical ionization conditions. In general, the usual satellite pattern of hydrocarbon-capture ions [M + $C_2H_5^+$ and M + $C_3H_5^+$ for chemical ionization (methane) and M + $C_4H_9^+$ for chemical ionization (isobutane)] was present to confirm the molecular weight indicated by the MH^+ ion.

Apparent molecular ions (M^+) were found one mass number below the MH^+ ion in these spectra. Although the precise abundance of the M^+ ion varied somewhat between determinations for a given compound, the value was generally >30% of the base peak for all derivatives except the sul-

[a] CH_4 = chemical ionization (methane), and C_4H_{10} = chemical ionization (isobutane). [b] The *m/e* ratio of the ion (intensity of the ion expressed as the percent of the intensity of the MH^+ ion). [c] Possibly due to unchlorinated contaminants. [d] The tertiary *N*-oxide VI undergoes virtually complete degradation by a Cope reaction (Scheme I) preceding or concurrent with vaporization, affording the *N*-allyl derivative VI*a*. [e] Probably arising by loss of C_3H_4 from the allyl substituent. [f] Compound VII is present as a contaminant. [g] Compound IX is present as a contaminant. [h] Compound XII and its monoacetate appear to be present as contaminants. [i] Compound XVI is present as a contaminant. [j] Compound XXII is present as a contaminant.

foxides VIII, X, XVII, and XXIII, the latter affording M^+ ions having <15% relative abundance. The variations in the abundance of this ion are not surprising because plausible processes leading to its formation (including charge transfer to M, loss of H· from MH^+, and direct ionization by electron impact) are sensitive to slight variations in temperature, pressure, and chemical entities in and near the source.

Fragmentation processes involving the trimethylene bridge appeared to be common to the spectra of II–V, VII–XV, and XVIII–XXIX (phenothiazine–$CH_2CH_2CH_2$–base) and to XVI and XVII, producing weak ions that corresponded in mass to the (substituted) phenothiazin-10-yl nucleus (Ion A) and to its methylene homolog (Ion B). Generally more abundant ions, corresponding in mass to the terminal methylene unit plus the attached aliphatic nitrogen atom and its substituents (Ion C, CH_2–base or CH_3CH–base) and to the ethylene homolog (Ion D, C_3H_6–base), were observed at *m/e* 113 and 141 (XVIII–XXIII) or 143 and 171 (XXIV–XXIX), respectively. Although the corresponding ions in the spectra of III–XVIII had *m/e* values <100 and were, therefore, not measured in this study, the chemical ionization (methane) mass spectra of XII and two other hydroxylated homologs of XII were found (6) to exhibit prominent ions at *m/e* 58 and 86, corresponding to $[CH_2N(CH_3)_2]^+$ and $[C_3H_6N(CH_3)_2]^+$, respectively, in accord with the idea that these form by processes general for compounds of this type.

Molecules in this study having polar substituents (halogen or hydroxyl groups) also generally appeared to undergo loss of a hydrogen atom plus the substituent from the MH^+ species. Fragments resulting from such processes were relatively abundant in the chemical ionization (methane) spectra but minor or not observed in the corresponding chemical ionization (isobutane) spectra. The derivatives of 2-chlorophenothiazine (I–XII, XVIII–XXI, and XXIV–XXVI) also exhibited an $MH^+ - 34$ ion that did not have a satellite ion heavier by two mass numbers; this resulted from contamination by the respective halogen-free homologs.

In summary, derivatives of phenothiazine generally form very stable MH^+ and M^+ ions under conditions of chemical ionization. Although no simple correlation is obvious to account for the variations in relative intensity of fragment ions formed by different compounds in this study, decomposition appears to be limited mainly to cleavage of exocyclic carbon–carbon single bonds, plus loss of water or hydrogen halide in appropriately substituted derivatives. The prominence of these stable proton-capture ions in the chemical ionization spectra affords a measurable property that is not only characteristic of a given drug or metabolite but also exquisitely sensitive for its detection. These two conditions suggest that selective ion monitoring techniques (12) in conjunction with chemical ionization are potentially useful for bioanalytical studies of phenothiazines.

ACKNOWLEDGMENTS AND ADDRESSES

Received January 9, 1976, from the **Department of Medicinal Chemistry, the ‡Charles B. Stout Neuroscience Laboratory, and the §Department of Biochemistry, University of Tennessee Center for the Health Sciences, Memphis, TN 38163.*

Accepted for publication March 29, 1976.

Supported in part by U.S. Public Health Service Grant RR 05423 and by the Charles B. Stout Memorial Fund. Upgrading of the mass spectrometer was accomplished with funds from the Memphis Regional Medical Program.

Sincere gratitude for generous gifts of the compounds used in the study is extended to Dr. A. A. Manian of the National Institute of Mental Health, Psychopharmacology Research Branch, Rockville, MD 20852 (I–VI, IX–XIV, XIX–XXI, XXIII, XXV, XXVI, and XXVIII); to Wyeth Laboratories, Philadelphia, Pa. (XV–XVII); to E. R. Squibb and Sons, Princeton, N.J. (XXVII); to Smith Kline and French Laboratories, Philadelphia, Pa. (VII, VIII, XVIII, and XXII); and to Schering Corp., Kenilworth, N.J. (XXIV, XXVII, and XXIX).

ˣ To whom inquiries should be directed. Present address: Drug Metabolism Department, Warner-Lambert Research Institute, Morris Plains, NJ 07950.

Possible Antineoplastic Agents II

A. U. DE ˣ and D. PAL

Abstract □ Various glutarimide derivatives were synthesized, and some showed significant activity against Ehrlich ascites carcinoma in Swiss albino mice.

Keyphrases □ Glutarimides, substituted—various derivatives synthesized, antineoplastic activity evaluated, mice □ Antineoplastic activity, potential—substituted glutarimides synthesized and screened, mice □ Structure–activity relationships—various substituted glutarimides synthesized and screened for antineoplastic activity in mice

Synthesis of a few glutarimide analogs of the types 2-phthalimidoglutarimide (thalidomide) (I) and 3-phenylglutarimide (II) and their biological evaluation in Ehrlich ascites carcinoma were reported previously (1). Meanwhile, more derivatives of I and II were synthesized and evaluated biologically according to the same procedures (1) (Table I).

In the previous article (1), the rationale behind the projected synthesis of these glutarimides (I and II) and others with some structural variations (II*a*–II*l*, III, and IV) was discussed. These structural changes were designed to determine the effects of electron-repelling or electron-

Possible Antineoplastic Agents II

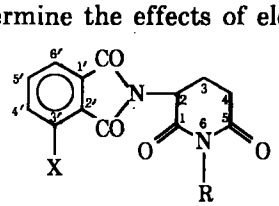
A. U. DE ˣ and D. PAL

Abstract □ Various glutarimide derivatives were synthesized, and some showed significant activity against Ehrlich ascites carcinoma in Swiss albino mice.

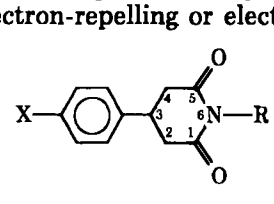
Keyphrases □ Glutarimides, substituted—various derivatives synthesized, antineoplastic activity evaluated, mice □ Antineoplastic activity, potential—substituted glutarimides synthesized and screened, mice □ Structure–activity relationships—various substituted glutarimides synthesized and screened for antineoplastic activity in mice

Synthesis of a few glutarimide analogs of the types 2-phthalimidoglutarimide (thalidomide) (I) and 3-phenylglutarimide (II) and their biological evaluation in Ehrlich ascites carcinoma were reported previously (1). Meanwhile, more derivatives of I and II were synthesized and evaluated biologically according to the same procedures (1) (Table I).

In the previous article (1), the rationale behind the projected synthesis of these glutarimides (I and II) and others with some structural variations (II*a*–II*l*, III, and IV) was discussed. These structural changes were designed to determine the effects of electron-repelling or electron-



I



II

attracting groups on carcinolytic activity. The inclusion of a sulfonamide moiety in either the cyclic or noncyclic parts of the glutarimide analogs was utilized to evaluate antineoplastic effects. Synthesis and biological evaluation of 6-substituted 3-*p*-methoxyphenylglutarimides (IIc–II*l*), 2-benzenesulfinocarboximidoglutarimide (III) and 2-*p*-substituted benzenesulfonamidoglutarimides (IV) have been accomplished. The *p*-acetamido derivative (IV*c*) was selected with the hope that it might be hydrolyzed *in vivo* to the therapeutically active sulfanilamido derivative.

DISCUSSION

Chemistry—Treatment of 3-*p*-methoxyphenylglutaric anhydride (2) with appropriate amines furnished the described imides (IIc–II*l*) (3). Possible formation of the diamides was ruled out by elemental analyses and IR spectra.

Reaction between saccharin sodium and 2-bromoglutarimide (4) in the presence of dimethylformamide resulted in the desired imide (III), as confirmed by elemental analysis and IR spectra.

Interaction of potassium benzenesulfonamides and 2-bromoglutarimide in dimethylformamide or water did not give the desired imides (IV*a*–IV*c*) because the anionic parts of the benzenesulfonamides, acting as strong bases, brought about the β-elimination-type reaction. Hence, 2-benzenesulfonamidoglutaric acids (5) were either converted to the corresponding dichlorides with thionyl chloride or to the diethyl esters to avoid any acid hydrolysis of the *p*-acetamido group by thionyl chloride. Interaction of these dichlorides and diesters with ammonia led to the diamides. These compounds were heated in the presence of refluxing nitrobenzene, with liberation of ammonia, to provide the desired imides (IV*a*–IV*c*).

Biological Activity (6)—Antineoplastic potency was evaluated against Ehrlich ascites carcinoma in Swiss albino mice according to the procedure described previously (1, 7) (Table I). In the present case also, both test and control groups contained five animals. The compounds were administered at a dose level of 50 mg/kg ip in buffered saline (pH 7.2); both the cell count and weight of ascitic fluid were regarded as activity parameters. Mitomycin at 1 mg/kg ip in buffered saline was used as a standard. Compounds I*a*, II*f*, and IV*a* showed significant activity.

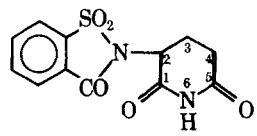
Structure–Activity Relationships—Although a systematic interpretation has not been attempted, some logical deductions can be made after examination of the observed antineoplastic potency of the compounds listed in this article as well as in a previous one (1). In the 2-phthalimidoglutarimide series (I*a*–I*d*), an alkyl or aryl substituent at the 6-position and an electronegative substituent like a nitro group in the benzene ring separately increased the activity. But an aralkyl or cycloalkyl group at the 6-position or the simultaneous combination of a nitro group at the 3-position and an alkyl group such as hexyl at the 6-position had the reverse effect.

In the 3-phenylglutarimides (II*a*–II*l*), introduction of an alkyl substituent at the 6-position and an electron-donating group such as methoxyl at the *para*-position of the benzene ring increased the activity. Aliphatic substituents such as ethyl, *n*-propyl, *n*-butyl, *n*-pentyl, and *n*-hexyl at the 6-position increased the activity, which reached a maximum when the substituent was *n*-propyl. Cycloalkyl, aralkyl, and aryl groups had the opposite effect.

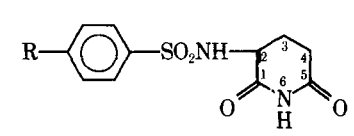
In the sulfonamidoglutarimides (III and IV*a*–IV*c*), incorporation of the sulfonamide group in a ring structure tended to decrease the activity more than when it was in a straight chain; significant activity was observed in the latter case. Introduction of an electron-donating group such as methyl at the *para*-position of the benzene ring did not improve the activity, while an acetamido group decreased the activity considerably. However, the most significant feature is that all the glutarimide derivatives had higher activity than the glutarimide itself.

EXPERIMENTAL[1]

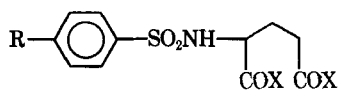
6-Substituted 3-*p*-Methoxyphenylglutarimides (IIc–II*l*)—A mixture of 3-*p*-methoxyphenylglutaric anhydride (1 mole) and the appropriate amine (1 mole) was heated in a sealed tube on an oil bath at 180° for 8 hr. The reaction mass was washed with sodium bicarbonate solution and crystallized from dilute ethanol after charcoal treatment (Table I).



III



IV



V*a*: R = H, X = Cl
V*b*: R = CH_3, X = Cl
V*c*: R = $NHCOCH_3$, X = OC_2H_5
V*d*: R = H, X = NH_2
V*e*: R = CH_3, X = NH_2
V*f*: R = $NHCOCH_3$, X = NH_2

6-Methyl-3-*p*-methoxyphenylglutarimide (II*d*) showed the characteristic carbonyl stretching frequency at 1675 cm^{-1} and no amino stretching frequency, the absence of which ruled out the possibility of diamide structure formation.

2-Benzenesulfinocarboximidoglutarimide (III)—A mixture of 2-bromoglutarimide (2 g), saccharin sodium (2.2 g), and dimethylformamide (20 ml) was stirred at room temperature for 10 hr until a negative Beilstein test was observed. Dimethylformamide was removed as completely as possible by distillation under reduced pressure in an oil bath, and the residual colored mass was washed with a little water to remove the excess saccharin sodium. The desired imide (III) was obtained by crystallization from dilute ethanol with charcoal treatment. Its physical characteristics are recorded in Table I.

Compound III showed characteristic sulfonyl stretching frequencies at 1165 and 1330 cm^{-1}, a carbonyl stretching frequency at 1705 cm^{-1}, and an amino stretching frequency at 3120 cm^{-1}.

2-*p*-Substituted Benzenesulfonamidoglutaryl Dichlorides (V*a* and V*b*)—A mixture of the diacids (10 mmoles) and thionyl chloride (15 ml) was refluxed on a steam bath until hydrogen chloride evolution ceased. Excess thionyl chloride was exhaustively removed, first by distillation under reduced pressure and then by adding 3 × 10 ml of benzene to the mass with subsequent removal by distillation. The acid chlorides solidified on cooling and were sufficiently pure for the next step. Compound V*a* had a melting point of 95–97°; the melting point of V*b* was 58–60°.

Diethyl 2-*p*-Acetamidobenzenesulfonamidoglutarate (V*c*)—A mixture of 2-*p*-acetamidobenzenesulfonamidoglutaric acid (6 g), absolute ethanol (25 ml), and sulfuric acid (specific gravity 1.84; 0.36 ml) was refluxed for 8 hr and worked up in the usual way. Compound V*c* had a melting point of 104–106°.

2-*p*-Substituted Benzenesulfonamidoglutaricdiamides (V*d*–V*f*)—The acid dichlorides (V*a* and V*b*, 5 g) were slowly basified with liquor ammonia (20 ml) under cooling in an ice bath to give the crude diamides (V*d* and V*e*). Compounds V*d* and V*e* were then crystallized from dilute ethanol after charcoal treatment to yield the pure product. The diethyl ester (V*c*, 2 g) and liquor ammonia (10 ml) were heated in a sealed tube in a steam bath for 8 hr to yield the crude diamide (V*f*), which was crystallized from dilute ethanol with charcoal treatment. Compound V*d* had a melting point of 214–216°, V*e* had a melting point of 219–221°, and V*f* had a melting point of 231–233°.

2-*p*-Substituted Benzenesulfonamidoglutarimides (IV*a*–IV*c*)—Mixtures of the diamides (V*d*–V*f*, 2 g) and nitrobenzene (10 ml) were refluxed on an oil bath until ammonia evolution ceased. The reaction mass then was cooled and diluted with benzene or petroleum ether (bp 60–80°) to yield the crude imides. These compounds were purified by crystallization from dilute ethanol after charcoal treatment as glistening needles. Their physical characteristics are recorded in Table I.

2-Benzenesulfonamidoglutarimide (IV*a*) showed sulfonyl stretching frequencies at 1165 and 1340 cm^{-1}, a carbonyl stretching frequency at 1650 cm^{-1}, and an amino stretching frequency at 3500 cm^{-1}. 2-*p*-Toluenesulfonamidoglutarimide (IV*b*) showed sulfonyl stretching frequencies at 1165 and 1346 cm^{-1}, a carbonyl stretching frequency at 1655 cm^{-1}, and an amino stretching frequency at 3505 cm^{-1}. 2-*p*-Acetamidobenzenesulfonamidoglutarimide (IV*c*) showed sulfonyl

[1] Melting points were recorded with a Gallenkamp instrument and are uncorrected. IR spectra were recorded in potassium bromide pellets using a Perkin-Elmer spectrophotometer, Infracord model 137.

Radioimmunoassay of the Anticonvulsant Agent Clonazepam

W. R. DIXON [x], R. L. YOUNG, R. NING, and A. LIEBMAN

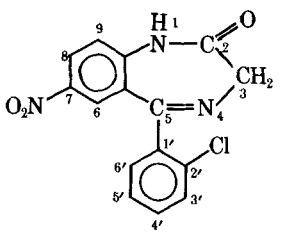
Abstract □ A simple and specific radioimmunoassay was developed for the determination of the anticonvulsant agent clonazepam directly in plasma without extraction. Antibodies to clonazepam were produced in rabbits after immunization with an immunogen prepared by covalently linking the 3-hemisuccinyloxy derivative of clonazepam to bovine serum albumin. When employing ^{3}H-clonazepam as the tracer, the radioimmunoassay has a limit of sensitivity of 5 ng/ml using a 0.1-ml sample of plasma. The antibodies exhibited a high degree of specificity for clonazepam; no cross-reactivity was observed with its 7-amino and 7-acetylamino metabolites nor with a number of other widely prescribed anticonvulsant agents that might be administered in conjunction with clonazepam. Satisfactory agreement was obtained for the plasma levels of clonazepam in humans when samples were assayed by the radioimmunoassay and an established electron-capture GC technique. By virtue of its simplicity, the radioimmunoassay offers a distinct advantage to the clinician for monitoring plasma clonazepam levels and the compliance of patients undergoing anticonvulsant therapy with the drug.

Keyphrases □ Clonazepam—radioimmunoassay, human plasma □ Radioimmunoassay—clonazepam, human plasma □ Anticonvulsants—clonazepam, radioimmunoassay, human plasma

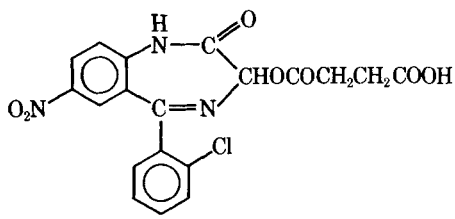
Clonazepam (I) is a member of the 1,4-benzodiazepine class of compounds which has recently been found to be clinically effective in controlling minor motor seizures (petit mal) in humans (1–4). Studies on the pharmacokinetics and metabolism of the drug also have been reported (5–7).

At the present time, only electron-capture GC methods have been reported for the determination of the nanogram levels of clonazepam that exist in the plasma of subjects undergoing anticonvulsant therapy (8–10). These electron-capture–GC methods have a limit of sensitivity in the order of 1 ng of clonazepam/ml of plasma using a 2-ml sample. However, apart from requiring skilled technical operation, these techniques are time consuming and thereby restrictive for the routine analysis of the numerous samples obtained during clinical studies.

The present report concerns the development of a specific and rapid radioimmunoassay for clonazepam in plasma. This assay allows the clinician to relate therapeutic response to plasma levels of the drug in individual patients.



I



II

EXPERIMENTAL

Tritium-Labeled Clonazepam—^{3}H-Clonazepam was prepared by tritium exchange using dimethylformamide–tritiated water (specific activity 100 Ci/g). The product was purified by silica gel column chromatography, yielding material with a specific activity of 4.23 mCi/mg. This method of introducing tritium probably provided exchange mainly at the C-3 position.

Preparation of Immunogen—The 3-hemisuccinyloxy derivative of clonazepam (II) was covalently coupled to bovine serum albumin using the mixed anhydride procedure of Erlanger *et al.* (11). After successive dialysis against dioxane–water (1:1), 0.05 *M* borate buffer (pH 9), and water, the immunogen was isolated by lyophilization.

On the basis of its absorbance at 365 nm in 0.1 *N* NaOH against a standard solution of II mixed with albumin, it was estimated that the immunogen consisted of 35 moles of II covalently coupled to 1 mole of albumin.

Antibody Production—Two New Zealand White female rabbits were immunized intradermally at multiple sites with 1 mg of the immunogen as an emulsion in Freund's complete adjuvant as previously described (12). The animals were then boosted intravenously with 50 μg of immunogen at monthly intervals, and serum was harvested 10–14 days after each administration. Both rabbits produced satisfactory titers of antibodies to clonazepam within 3 months following the initial immunization, and their serum was pooled. At a 1:2000 dilution, 1 ml of diluted serum bound approximately 60% of the ^{3}H-clonazepam used for the assay.

stretching frequencies at 1160 and 1340 cm^{-1}, a carbonyl stretching frequency at 1680 cm^{-1}, and an amino stretching frequency at 3405 cm^{-1}.

Table I—Cross-Reactivity of Substituted 1,4-Benzodiazepines

Compound	R_1	R_2	R_3	R_4	Cross-Reactivity, %[a]
Clonazepam	NO_2	H	H	Cl	100
Clonazepam 3-hydroxy derivative	NO_2	H	OH	Cl	24
Nitrazepam	NO_2	H	H	H	3.2
III	Cl	H	H	Cl	1.4
Oxazepam	Cl	H	OH	H	0.3
Desmethyldiazepam	Cl	H	H	H	0.06
Clonazepam 7-amino derivative	NH_2	H	H	Cl	0.04
Nitrazepam 7-amino derivative	NH_2	H	H	H	0.02
IV	H	H	H	Cl	0.02
Clonazepam 7-acetylamino derivative	CH_3CONH	H	H	Cl	<0.01
V	CH_3CONH	H	OH	Cl	<0.01
Diazepam	Cl	CH_3	H	H	<0.01

[a] Percentage cross-reactivity is defined as $100\ x/y$, where x is the mass of unlabeled clonazepam and y is the mass of competitor required to produce 50% inhibition of binding of ^{3}H-clonazepam by the antiserum.

Radioimmunoassay Procedure—The following stock solutions were prepared for the assay: standard solutions of 5, 10, 20, 50, 100, and 200 ng of clonazepam/ml of assay buffer (sodium phosphate, 0.01 *M*, pH 7.4, containing 0.9% sodium chloride); a solution of ^{3}H-clonazepam in buffer, 25,000 cpm/ml; and antiserum diluted 1:800 with buffer and containing 0.01% sodium azide. All stock solutions were stored at 4°.

To perform the assay, 0.1 ml of control plasma was added to 0.1 ml of each clonazepam standard in a 12 × 75-mm disposable tube to generate a calibration curve. Appropriate controls were included by adding the control plasma to 0.1 ml of buffer alone. Each unknown plasma sample (0.1 ml) was added to tubes containing 0.1 ml of buffer. Then 0.4 ml (10,000 cpm) of the ^{3}H-clonazepam solution followed by 0.4 ml of the diluted antiserum was added, and the contents (1.0 ml) of each tube were mixed and allowed to stand at room temperature for 30 min. Saturated ammonium sulfate (1 ml) was added to precipitate the globulin-bound ^{3}H-clonazepam and, after mixing, the tubes were allowed to stand for 15 min at 0° in a refrigerated centrifuge and were then centrifuged at 3000 rpm for 30 min.

Each supernate, containing the unbound ^{3}H-clonazepam, was decanted into a counting vial, and 10 ml of toluene scintillator[1] was added. The vials were then placed in a covered vial tray and shaken for 5 min on a reciprocating shaker with the tray in the vertical position. In this way, the ^{3}H-clonazepam was quantitatively extracted into the toluene scintillator. The samples were assayed for ^{3}H-activity in a liquid scintillation counter.

All samples including the standards, unknowns, and controls were assayed in duplicate, and the average of the tritium counts was used for calculation of percentage inhibition of binding (12). Quantitation of unknown samples was accomplished by interpolation from a logit–log plot of the percentage inhibition of binding *versus* the concentration of each standard (13).

RESULTS AND DISCUSSION

Sensitivity and Precision of Radioimmunoassay—Linearization of the calibration curve was obtained by plotting the percentage inhibition of binding of the ^{3}H-clonazepam *versus* the concentration of unlabeled clonazepam on logit–log transformation graph paper[2]. An almost perfect straight line was obtained in the range of 0.5–20 ng of unlabeled clonazepam added. The calibration lines obtained using 0.02, 0.05, and 0.1 ml of plasma were virtually superimposable. In repeated assays, the percentage inhibition of binding by 0.5 ng of clonazepam always exceeded 10%. However, since 0.1 ml of plasma was routinely assayed, the working limit of sensitivity was actually 5 ng/ml. This sensitivity is adequate for routine clinical determination of clonazepam (4).

The accuracy and intraassay precision of the radioimmunoassay were determined by the addition of 10, 50, and 100 ng of clonazepam to separate 1.0-ml aliquots of a clonazepam-free plasma pool obtained from 20 patients receiving other anticonvulsants. Six 0.1-ml replicates of each of the three concentrations were assayed. The mean values and coefficients of variation obtained were 9.62 ± 7.1, 49.7 ± 5.2, and 99.7 ng/ml ± 4.9%, respectively. The interassay precision was determined by assaying unknown samples from four different subjects who had received 5–29 mg of clonazepam/day in conjunction with other anticonvulsants. The samples were stored at 4° and assayed on five different occasions over 2 weeks. The mean values for clonazepam and the coefficients of variation were 21.4 ± 4.2, 36 ± 2, 69.6 ± 2.4, and 625 ng/ml ± 4%. The sample with a mean value of 625 ng/ml was diluted 1:10 with control plasma prior to analysis.

The foregoing data, apart from showing adequate intra- and interassay precision for routine clinical analysis, indicate no decomposition of clonazepam in plasma when stored at 4°.

Specificity—In designing the radioimmunoassay for clonazepam, several points were considered regarding a suitable hapten. As in any radioimmunoassay procedure, antibody specificity was of the utmost importance. In the case of clonazepam, this specificity centered on the ability of the antibodies to recognize clonazepam alone in the presence of its known major metabolites in plasma: the 7- amino and 7-acetylamino derivatives (5). Recent studies[3] (7) have shown that the 7-amino metabolite is present in plasma in almost equal concentration to clonazepam on chronic administration. The 7-acetylamino metabolite appears to be present in considerably lower concentrations (9). Another consideration was that other benzodiazepines might be administered concomitantly to subjects receiving clonazepam. For these reasons, II was chosen as a possible hapten to fulfill the specificity requirements of the antibodies. By coupling at the C-3 position to the protein, the 7-nitro and 2′-chloro groups are relatively free to act as antigenic determinants.

To determine which functional groups on the hapten influenced the specificity of the antibodies obtained to clonazepam, various benzodiazepines with different substituents in the 1-, 2′-, 3-, and 7-positions were examined for their extent of cross-reactivity. The greatest cross-reactivity (24%) occurred with the 3-hydroxy derivative of clonazepam (Table I). This is not surprising, since the hapten was coupled to the protein at the C-3 position. Although the 3-hydroxy derivative of clonazepam has been isolated as a conjugated metabolite of clonazepam in urine (5), it has not been detected in plasma.

Nitrazepam, which differs from clonazepam by the absence of the 2′-chloro group, showed only 3.2% cross-reactivity. This result illustrates the effect of the 2′-chloro group on the immunogen as an antigenic determinant. However, when rabbits were immunized with an albumin conjugate of the 3-hemisuccinyloxy derivative of nitrazepam, the resulting antibodies recognized both nitrazepam and clonazepam almost equally well[3]. The most significant lack of cross-reactivity was observed with compounds that did not have a nitro group but had some other substituent at the 7-position. The latter included the 7-amino and 7-acetylamino metabolites of clonazepam, which showed 0.04 and <0.01% cross-reactivity, respectively.

Table II—Specificity of the Radioimmunoassay for Clonazepam in Plasma Containing 20 ng of Clonazepam/ml in the Presence of High Concentrations of Various Potential Competitors

Competitor	Competitor Concentration, ng/ml	Clonazepam Found, ng/ml
Clonazepam 7-amino derivative	10,000	21
Diazepam	10,000	19
Desmethyldiazepam	10,000	23
Acetazolamide	20,000	19
Phenytoin	50,000	20
Phenobarbital	50,000	19
Primidone	50,000	20
Ethosuximide	100,000	21
Trimethadione	100,000	21

To evaluate further the specificity of the radioimmunoassay in the clinical situation, several drugs commonly used for seizure control that might be administered with clonazepam were checked for their possible interference. Control plasma containing 20 ng of clonazepam/ml was used as the reference standard, and aliquots were spiked with each compound listed in Table II. The concentration of each potential competitor added was judged to be greater than the concentration that might be encountered in plasma during routine seizure control therapy.

Each sample was assayed for clonazepam, and Table II shows the percent response for clonazepam in the presence of each compound studied as compared to the control sample containing 20 ng/ml of clonazepam alone (100% response). No competitor, including the 7-amino metabolite of clonazepam, which was in a 500–5000-fold excess, caused any serious error in the clonazepam determination, and it is unlikely that a false positive reaction would be encountered. These studies are further substantiated when one considers the almost quantitative response previously obtained for clonazepam when added to the pool of plasma from patients receiving other anticonvulsants. In the latter instance, the plasma pool contained all anticonvulsants listed in Table II and their respective plasma metabolites.

Comparison of Radioimmunoassay with Electron-Capture GC Determination of Clonazepam—Sixteen plasma samples, obtained from subjects receiving clonazepam either alone or with concomitant anticonvulsants, were assayed for clonazepam using the radioimmunoassay and the electron-capture GC method[4] of de Silva *et al.* (8). The joint determinations were subjected to straight-line analysis by the method of Wald (14) using a 95% confidence ellipse[5]. The fitted intercept and slope (−0.56 and 0.94, respectively) were not significantly different from 0 and 1 over a range of 7–130 ng of clonazepam/ml. This result shows that the radioimmunoassay can measure clonazepam as precisely as the electron-capture GC method.

Plasma Clonazepam Levels during Routine Anticonvulsant Therapy—To obtain data regarding the range of plasma levels of clonazepam *versus* dose that might be encountered during routine anticonvulsant therapy, plasma samples from subjects who had received various doses of clonazepam in conjunction with other anticonvulsants were assayed by the radioimmunoassay. Figure 1 shows the steady-state plasma levels of clonazepam *versus* dose for 15 subjects, each of whom had been treated chronically with at least two different doses of the drug. Each subject was also receiving concomitantly at least one anticonvulsant listed in Table II, and 10 subjects were receiving two or three of the latter anticonvulsants in various combinations. There was as much as a fivefold variation in the plasma levels at steady state with the same chronic dose

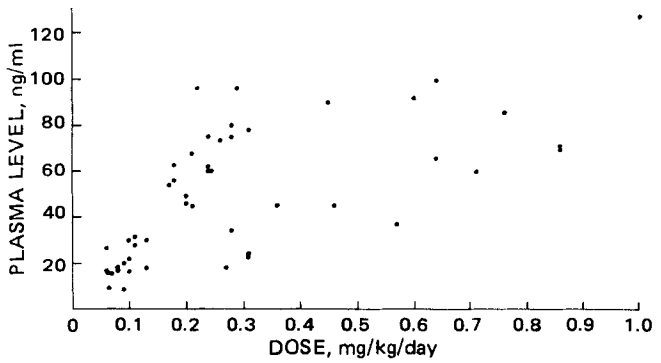

Figure 1—*Steady-state plasma levels of clonazepam in 15 subjects, each of whom had been treated chronically with at least two different doses of the drug.*

of clonazepam. Several factors probably contributed to this result. First, it was not known at what time the blood samples were drawn relative to the time the patient took the last dose of clonazepam. Although the half-life of clonazepam ranges from 19 to 39 hr, somewhat elevated plasma levels would exist for a few hours following each dose (6). Second, every patient was receiving concomitant anticonvulsants, and their effect on the disposition of clonazepam is unknown. Third, the compliance of each patient for the prescribed dosage regimen was unknown.

Although there is undoubtedly some correlation between plasma level and dose, no attempt has been made to define it statistically in this instance since such a definition could be misleading in view of the lack of controlled experimental conditions. The data, however, realistically illustrate the range of plasma clonazepam levels that may be encountered in the clinical situation.

Effects of Long-Term Exposure to Environmental Levels of Polychlorinated Biphenyls on Pharmacokinetics of Pentobarbital in Rats

C. K. CHU, V. J. STELLA ˣ, J. V. BRUCKNER *, and W. D. JIANG *

Abstract □ The pharmacokinetics of pentobarbital, 30 mg/kg iv, were studied in untreated rats and rats pretreated with 1, 5, and 25 ppm of polychlorinated biphenyls in food for up to 140 days. Environmental contaminants may contribute to variations in metabolic rates of drugs by causing enzyme induction. The objective of this work was to quantitate the effects of environmental levels of the contaminant and enzyme inducer, a polychlorinated biphenyl, on the pharmacokinetics of pentobarbital, a drug whose primary elimination route is liver metabolism. The pharmacokinetics of pentobarbital in rats could be fit to a biexponential equation of the type $C_p = Ae^{-\alpha t} + Be^{-\beta t}$. After 35 days of pretreatment, only the 25-ppm-treated rats showed any significant acceleration of pentobarbital elimination. At the 70- and 140-day samplings, both the 5- and 25-ppm pretreatments showed significant acceleration of pentobarbital elimination. There were no significant effects on A, α, B, and V_d for any pretreatment. The β-values for the 25-ppm-pretreated rats reached a constant value from the 35-day pretreatment period onward. A calculation of total body clearance suggested that pentobarbital elimination in those rats had approached portal blood flow rate-limited metabolism.

Keyphrases □ Biphenyls, polychlorinated—effects on pharmacokinetics of pentobarbital, rats □ Pharmacokinetics—pentobarbital, effects of polychlorinated biphenyls, rats □ Pentobarbital—pharmacokinetics, effects of polychlorinated biphenyls, rats □ Contaminants, environmental—polychlorinated biphenyls, effects on pharmacokinetics of pentobarbital, rats □ Sedatives—pentobarbital, pharmacokinetics, effects of polychlorinated biphenyls, rats

Polychlorinated biphenyls have become a major environmental contaminant because of their extreme stability and lipophilicity (1–4). Polychlorinated biphenyls have been found in human tissues (5), and an outbreak of chloracne in Japan (6) has been attributed to their accumulation in tissue. Adverse effects on reproduction in rats (7) and monkeys (8) have also been associated with polychlorinated biphenyl ingestion. Polychlorinated biphenyls induce the activity of the hepatic mixed-function oxidase system (1, 4, 9–14), and several studies showed that polychlorinated biphenyl-treated animals have enlarged livers (10, 15). However, most previous studies were carried out on animals pretreated with high levels of polychlorinated biphenyls over a relatively short time.

Rational drug therapy requires an understanding of the pharmacokinetics of drug substances and the effects that dietary, genetic, and environmental factors, as well as disease states, have on pharmacokinetics. The pharmacokinetics of pentobarbital in rats *per se* have been studied (16, 17). The objective of this study was to quantitate the effects of environmental levels of polychlorinated biphenyls on the pharmacokinetics of pentobarbital, a drug whose primary elimination route is liver metabolism (17).

This report appears to be the first to present a full pharmacokinetic study of the effects of an environmental contaminant on the distribution and elimination kinetics of a drug. The study deals with the effect of exposure to a commercial polychlorinated biphenyl for up to 140 days. The pharmacokinetics were studied in control groups and groups exposed to three different levels of polychlorinated biphenyls[1]. The three levels were 1, 5, and 25 ppm in food, representing submaximum, maximum, and above maximum Food and Drug Administration (FDA) and Environmental Protection Agency (EPA) recommended allowable limits in most food products (18), respectively.

EXPERIMENTAL

Male, Sprague–Dawley rats[2], ~100 g, were housed in stainless steel cages in groups of three or four. Tap water was available *ad libitum*. The rats were fed standard powdered laboratory rat chow diet[3] for 1 week before a special diet was started. The animals were divided into four groups and were fed the lab chow in powdered form containing 0, 1, 5, or 25 ppm of the polychlorinated biphenyl.

The powdered diet was prepared by dissolving appropriate quantities of polychlorinated biphenyl in acetone and mixing this solution thoroughly with a small amount of ground chow. After allowing the acetone to evaporate, this contaminated chow was mixed by geometric dilution with increasing amounts of ground chow until the desired concentrations of polychlorinated biphenyl were achieved.

Four rats from each group were studied at the end of each period (35, 70, and 140 days). Each rat received 30 mg/kg iv of pentobarbital sodium *via* the dorsal vein of the penis. Blood sampling from the tail vein was started immediately after drug administration. About 250 μl of blood was collected in a heparinized microcapillary tube at specified timed intervals (Table I). The time required for the animal to regain its righting reflex was also noted. The blood was immediately centrifuged; the plasma was removed, placed into a test tube, and kept frozen until analyzed. All plasma samples were analyzed within 1 month (19).

The plasma concentration was analyzed using GC. This method was a modification of the procedure of Ehrnebo *et al.* (20). To each 100-μl plasma sample, 25 μl of internal standard (80 μg/ml of secobarbital sodium in methanol) and 0.1 ml of 0.05 *N* sodium hydroxide were added. The mixture was extracted with 1.0 ml of water-saturated ether on a mixer[4] for about 1 min. After centrifugation, the organic phase was discarded. The aqueous phase was then acidified with 1.0 ml of 4 *M* monobasic sodium phosphate and reextracted with 1.0 ml of water-saturated ether. The ether extract was then evaporated to dryness under nitrogen.

Just before injection into the chromatograph, 25 μl of 0.2 *M* trimethylanilinium hydroxide[5] was added and the sample was agitated in a mixer. An aliquot of 1.5–3.5 μl of this mixture was then injected into a gas chromatograph[6] equipped with a flame-ionization detector. The column of choice was a 1.83-m (6-ft) × 0.31-cm (0.125-in.) U-shaped glass column[7] packed with 3% OV-1 on 100–120-mesh Gas Chrom Q[8]. The following conditions were used: injector temperature, 250°; column temperature, 130°; detector temperature, 240°; nitrogen flow, 50 ml/min; hydrogen flow, 40 ml/min; and compressed air (19–23% O_2, 77–81% N_2) flow, 365 ml/min. The sensitivity was 10^{-12} amp/mv. The described procedure was used for plasma samples containing known amounts of

Table I—Plasma Sampling Times in the Study of Pentobarbital Pharmacokinetics in Rats Pretreated over Various Time Intervals with Polychlorinated Biphenyls

Days of Treatment	Sampling Time, min									
35	0	5	10	15	30	60	90	120	—	—
70	5	10	15	20	30	45	60	75	90	—
140	2	3	5	10	15	20	30	45	60	75[a]

[a] The 75-min sample was omitted for 5- and 25-ppm groups.

pentobarbital and secobarbital to produce a standard curve of the area under the peak *versus* the pentobarbital concentration (5–50 μg/ml of plasma).

The pharmacokinetics of pentobarbital in rats were fit to a two-compartment model (21) previously (16, 17). This model predicts that the data for plasma pentobarbital levels *versus* time in rats after rapid intravenous injection should show a biexponential decay. The decay curve should be described by:

$$C_p = Ae^{-\alpha t} + Be^{-\beta t} \quad \text{(Eq. 1)}$$

where C_p is the plasma level at any time t, and A, α, B, and β are parameters which were described adequately by others (21). If only a single exponential decay is noted because of the sampling schedule or because of a rapid distribution phase, then the plasma concentration *versus* time curve will be given by:

$$C_p = Be^{-\beta t} \quad \text{(Eq. 2)}$$

In the present case, for the 35- and 70-day pretreatments, the data were fit to a one-compartment model (Eq. 2) because plasma sampling times were started too late to fit the data to a two-compartment model. Therefore, the postdistribution data for each 35- and 70-day-pretreated animal were fit to Eq. 2 utilizing the simplex method of fitting[9] (22). This approach helped generate appropriate values of β and B from which the volume of distribution extrapolated (23), $V_{d(ext)}$, and total body clearance (24), Cl_{TB}, could be calculated from Eqs. 3 and 4, respectively:

$$V_{d(ext)} = \frac{\text{dose}}{B} \quad \text{(Eq. 3)}$$

$$Cl_{TB} = \beta V_{d(ext)} \quad \text{(Eq. 4)}$$

The mean values for all calculated parameters for each pretreatment were determined and statistically compared to the same parameters for the control group using the standard Student t test. The mean values of β and B were then used to generate lines to describe the plasma pentobarbital level *versus* time curves for each group.

For the 140-day-pretreated rats, plasma samples at 2 and 3 min as well as other plasma samples (Table I) did allow the fit of the data to a two-compartment model using the simplex method of fitting (22). The mean values for A, α, B, and β as well as values for $V_{d(ext)}$, $V_{d(area)}$, and Cl_{TB} were calculated for each animal in each pretreatment. The value of $V_{d(area)}$ was calculated using:

$$V_{d(area)} = \frac{\text{dose}}{\beta\left(\frac{A}{\alpha} + \frac{B}{\beta}\right)} \quad \text{(Eq. 5)}$$

These values were compared, using the Student t test, to the same parameter for the control animals. The mean values of A, α, B, and β were then used to generate lines representing the mean plasma levels *versus* time decay curves for pentobarbital in rats pretreated over 140 days with 0, 1, 5, and 25 ppm of polychlorinated biphenyl. The plasma pentobarbital concentration at the righting reflex time for each animal was determined by substituting the righting reflex time for that animal into the equation describing the plasma level *versus* time curve for that animal.

RESULTS AND DISCUSSION

Based on the study of Lin *et al.* (16), plasma samples for pentobarbital determination for both the 35- and 70-day-pretreated rats were begun at 5 min postdosing with 30 mg of pentobarbital sodium/kg (27.22 mg of pentobarbital acid/kg). Unfortunately, this time proved to be too late

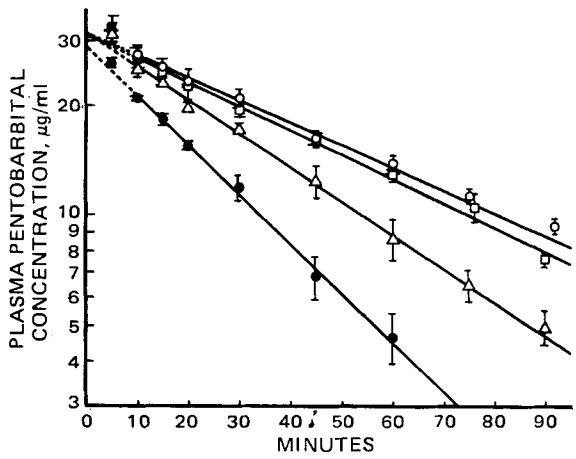

Figure 1—*Time courses of plasma concentration ± SE of pentobarbital in rats pretreated over 70 days at 1 (□), 5 (△), and 25 (●) ppm of polychlorinated biphenyls in food and in a control group of rats (○) after administration of pentobarbital sodium (30 mg/kg iv). Each point is the mean of four animals. Lines are generated utilizing pharmacokinetic parameters in Table III.*

to observe the distribution phase of the pentobarbital decay curve. Figure 1 shows the plasma level *versus* time plots for pentobarbital decay in the 70-day-pretreated rats. The solid lines are drawn by a fit to Eq. 2 utilizing the mean values of B and β for each group.

Tables II and III summarize the pharmacokinetic parameters for pentobarbital determined for the 35- and 70-day polychlorinated biphenyl-pretreated rats compared to the same parameters for the control groups. The only parameters affected by the polychlorinated biphenyl pretreatments to any significant extent were those directly related to β, the total body elimination rate constant.

At the 35-day pretreatment, β for the 1-ppm-pretreated rats was significantly smaller than β for the control and 5-ppm-pretreated rats. The cause of this apparent inhibition is unknown. There was a significant catalysis of pentobarbital elimination at 35 days in the 25-ppm-pretreated animals.

With the 70-day-pretreated animals, both the 5- and 25-ppm-pretreated animals showed a significant catalysis in pentobarbital total body elimination compared to the elimination in the control and 1-ppm-pretreated groups. These results are consistent with the shorter sleeping time in the 5- and 25-ppm-pretreated animals *versus* the controls and 1-ppm-pretreated animals.

Figure 2 shows the plasma level *versus* time plots for pentobarbital decay in the 140-day-pretreated animals. The data had been fit to a two-compartment model. Table IV summarizes the pharmacokinetic parameters for these animals. The only parameters affected by the polychlorinated biphenyl pretreatments to any statistically significant extent were those directly related to β, the total body elimination rate constant. Both the 5- and 25-ppm-pretreated animals showed a significant catalysis of pentobarbital elimination, total body clearance, and sleeping time.

A number of other observations can be made. The righting times were directly related to the plasma concentration of pentobarbital (~15 μg/ml). The β and Cl_{TB} for the 25-ppm-pretreated animals remained constant from the 35-day sampling period onward, and a similar observation can be made for the 5-ppm-pretreated animals when the results for the 70- and 140-day pretreatments are compared.

The clearance of any compound from the body whose primary mode of elimination is liver metabolism can be given by:

$$Cl_{TB} = QE \quad \text{(Eq. 6)}$$

where Q is the portal blood flow rate, and E is the extraction ratio for the liver. Literature values of Q for rats are 60 (25) and 42 (26) ml/min/kg and 1.2 ml/min/g (27) of liver. Since liver to body weights for the rats were determined[10] in the present study, the clearance value of 1.2 ml/min/g

[9] The program was developed by Dr. W. White and various graduate students of the Department of Pharmaceutical Chemistry, University of Kansas. The program was run on a Hewlett-Packard model 2100 computer. For copies of the program and further information, contact Dr. W. White.

[10] Independent *in vitro* metabolism studies were carried out on paired animals receiving the same diet and pretreated over the same time interval as the animals used in the present study. Liver weights as percent of total body weight were determined. An average liver weight of 3.75% of total body weight was used. This value of 3.75% is the percent liver weight of 25-ppm-pretreated animals. The percent liver weight for the 0-, 1-, and 5-ppm-treated animals was 3.41%.

Table II—Pharmacokinetic Parameters[a] of the Disposition of Pentobarbital in Rats Pretreated at Three Different Levels of Polychlorinated Biphenyls over 35 Days

Parameter	Pretreatment Level

[a] Mean value ± *SE* of the mean. [b] Results are significantly different from the control group of animals at the level indicated.

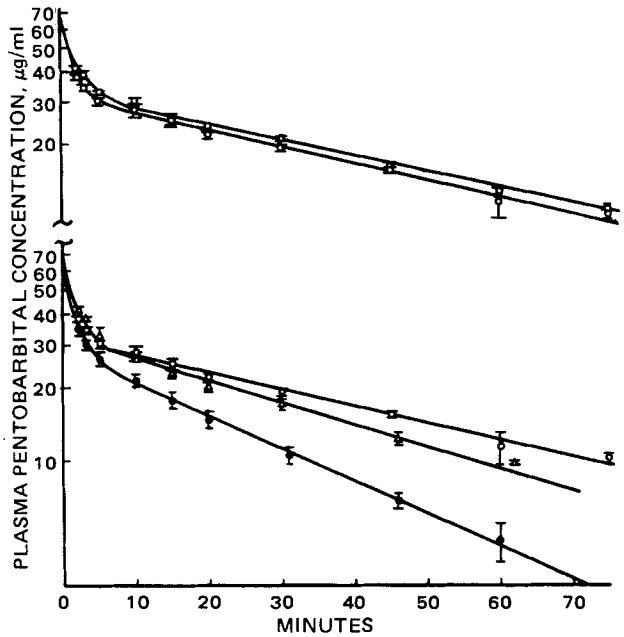

Figure 2—*Time courses of plasma concentration ± SE of pentobarbital in rats pretreated over 140 days at 1 (□), 5 (△), and 25 (●) ppm of polychlorinated biphenyls in food and in a control group of rats (○) after administration of pentobarbital sodium (30 mg/kg iv). Each point is the mean of four animals. Lines are generated utilizing pharmacokinetic parameters in Table IV.*

of liver translates to approximately 45 ml/min/kg. This value was then used for further calculations. Total body clearance in the 25-ppm-pretreated animals was calculated to be approximately 30 ml/min/kg. The extraction constant for the liver is then 0.67. This figure is only approximate in that the potential effect of enzyme induction on liver blood flow was not corrected for.

It is obvious, therefore, that two possible conditions can explain the constant pentobarbital clearance value for the 25-ppm-pretreated rats between 35 and 140 days: (*a*) the extraction constant reached a constant value and this constant value was a function of the amount of liver enzyme inducer, and/or (*b*) the clearance approached portal blood flow rate-limited metabolism. The second explanation is not totally valid in that an extraction constant of >0.8 is usually taken as portal blood flow rate-limited metabolism (28). The fact that a constant clearance was also seen in the 5-ppm-pretreated animals (70- and 140-day pretreatment) is more consistent with the first explanation that a constant E value was reached. Mechanistically, this can be explained by the hypothesis that the liver simply synthesized sufficient microsomal enzyme to prevent accumulation of the contaminant. Residues of polychlorinated biphenyls in body tissues of rats have been demonstrated to remain relatively constant on long-term feeding of similar dietary levels of polychlorinated biphenyls (29). The 1-ppm pretreatment with the polychlorinated biphenyl appeared to have no significant long-term effects on pentobarbital pharmacokinetics, suggesting that a critical mass of contaminant was needed to produce liver microsomal enzyme stimulation; *i.e.*, normal liver enzyme levels were capable of handling the 1 ppm of polychlorinated biphenyl.

Obviously, it is impossible to carry out controlled experiments of the effects of low levels of polychlorinated biphenyls on human liver microsomal enzyme activity. The FDA and EPA currently allow an upper limit of 5 ppm of polychlorinated biphenyls in most food substances (18). The present study demonstrated that 5 ppm of a polychlorinated biphenyl in food can, over a period greater than 35 days, induce liver microsomal metabolism of pentobarbital in rats as measured by the shorter half-lives of pentobarbital. At 5 and 25 ppm, the polychlorinated biphenyl stimulated pentobarbital elimination as measured by increased β and Cl_{TB} values, decreased half-lives, and shorter righting reflex times. The polychlorinated biphenyl did not significantly affect the distribution kinetics or the volume of distribution of pentobarbital, suggesting strongly that its primary effect was to induce liver metabolism *via* enzyme stimulation[10].

Pharmacokinetics of β-Methyldigoxin in Healthy Humans I: Intravenous Studies

PETER H. HINDERLING *, EDWARD R. GARRETT ˣ, and RONALD C. WESTER ‡

Abstract □ The pharmacokinetics of intravenously administered solutions of 0.30- and 0.60-mg bolus doses of ^{3}H-β-methyldigoxin, labeled in the 12α-position, were dose independent. Individual radioactivities assignable to the parent drug and specifically identified metabolites after TLC separation were followed in the plasma, urine, and feces. A sum of four exponentials described the plasma β-methyldigoxin data with apparent half-lives of 0.04, 0.33, 3.5, and 41 hr. β-Methyldigoxin was 10% plasma protein bound and had a red blood cell–plasma water partition coefficient of 0.9. The only significant metabolite observed in plasma was digoxin, although glucuronides and sulfates of β-methyldigoxin, digoxin, and digoxigenin also were observed in urine. As much as 92 ± 3% of the dose was excreted by all processes by 144 hr. Of this amount, renal excretion accounted for fractions that were 0.47 unchanged, 0.35 digoxin, and 0.058 water-soluble metabolites. The fraction in the feces was 0.13. The urine flow independent renal clearances of β-methyldigoxin and derived digoxin were 59 and 206 ml/min, respectively. The metabolism was a relatively fast process. The terminal pseudo-steady-state elimination of β-methyldigoxin with a half-life of 41 hr was reached 27 hr after drug administration and was primarily dependent on the slow release of sequestered or distributed drug from the tissues into the central compartment. The drug and metabolite levels in plasma and urine were consistent with analog computer fitting to the proposed pharmacokinetic multicompartmental model.

Keyphrases □ β-Methyldigoxin—intravenous, pharmacokinetics in humans, radiochemical–TLC study □ Pharmacokinetics—intravenous β-methyldigoxin, humans, radiochemical–TLC study □ Radiochemistry–TLC—study of pharmacokinetics of intravenous β-methyldigoxin in humans □ Cardiac glycosides—β-methyldigoxin, intravenous, pharmacokinetics in humans, radiochemical–TLC study

Frequently used methods for the assay of digoxin glycosides, radioimmunoassay (1) and liquid scintillation spectrophotometry (2–4) of labeled drug, are not specific for the parent compounds *per se* and measure drug plus metabolites. Their only valid use in pharmacokinetics or bioavailability studies is after proper separation of the drug and its metabolites or if the metabolic route of disposition is negligible. An argument could be made for those clinical circumstances where the sum of cardioactive drug and metabolites could be correlated with observed cardial or extracardial pharmacodynamic parameters.

Pharmacokinetic and bioavailability studies of glycosides with specific analyses of the parent drug and metabolites in plasma and urine as functions of the dose, formulation, and route of administration are needed. Apparently, no published studies demonstrate the linearity of the area under blood level–time curves (*AUC*) with the administered dose of digoxin-like drugs, a necessary prerequisite for the use of *AUC* as a criterion of bioavailability. The studies that did attempt to separate such drugs from their metabolites prior to assay by such nonspecific methods were limited. Column chromatographic (2, 3) and extraction (4) procedures were used to separate the labeled parent drug and metabolite. However, none of these papers clearly showed quantifications based on evaluated extraction efficiencies, nor did they demonstrate specific identifications of parent drug and metabolites in plasma or urine.

The present studies were conducted to determine the time course of radiolabeled ^{3}H-β-methyldigoxin (medigoxin) and its identified metabolites, separated and analyzed individually after both oral and intravenous administration at two dosage levels in the same individual, and to establish valid pharmacokinetic models and their parameters. This paper considers the pharmacokinetics of β-methyldigoxin after intravenous administration.

EXPERIMENTAL

Materials—The following were used: ^{3}H-β-methyldigoxin[1], digoxin[1], digoxigenin bisdigitoxoside[1], digoxigenin monodigitoxoside[1], and digoxigenin[1]. ^{3}H-β-Methyldigoxin was synthesized with the label in the 12α-position according to the method of von Wartburg *et al.* (5) and had a specific activity of 431 μCi/mg. β-Glucuronidase[2] and aryl sulfatase[3] were used for the enzymatic hydrolysis of conjugated metabolites. All organic solvents were analytical grade.

Commercially available scintillation fluids[4,5], solubilizer[6], dioxane, and a scintillation fluid prepared as described previously (6) were used for radioactivity counting. Heparin sodium[7] was used to prevent coagulation.

Heparinized blood and plasma with known protein fractions were obtained from healthy volunteers[8] who had no prior drug intake.

Criteria for Volunteer Selection—Seven healthy male Caucasian volunteers[9] between 21 and 25 years of age were selected. An individual was considered healthy when there was no history of problems with the cardiovascular system, kidneys, liver, blood, GI tract, and endocrine organs and no prostatic hypertrophy, drug addiction, and alcoholism. The volunteers had a normal status, ECG, blood pressure, and X-ray (chest).

The following initial laboratory checkup was performed on each volunteer: complete blood count (hematocrit included), sedimentation rate, serum electrophoresis, creatinine clearance, urinalysis, bilirubin, serum glutamic oxaloacetic transaminase, serum glutamic pyruvic transaminase, alkaline phosphatase, and serum electrolytes (sodium, potassium, calcium, and inorganic phosphate). The following tests were repeated prior to the second, third, and fourth studies on each individual to determine toxic drug effects or clinical changes due to the experimental procedures: complete blood count (hematocrit included), sedimentation rate, serum electrophoresis, serum creatinine, and serum electrolytes.

Pharmacokinetic Procedures—Four diffferent studies were performed in each of the seven volunteers; 0.30- and 0.60-mg doses in solution were administered both orally and intravenously. A total of 28 studies was conducted with an incomplete Latin-square design. Intervals of 3 weeks were maintained between studies in a subject to exclude any possible enzyme induction due to repeated drug administration. The volunteers were supine during the first 24 hr after drug administration. Later they were ambulant, although no exercise was allowed.

The individuals were fasted 12 hr before drug administration in both the intravenous and oral experiments. After drug administration, the

[9] Informed consent was obtained from all volunteers, and the experimental protocol was approved by both the Committee for Protection of Human Subjects and the Clinical Research Advisory Committee, Health Center, University of Florida.

volunteers fasted 8 hr. Within the first 24 hr after drug administration, food intake was restricted to fluids, *e.g.*, soups, milk shakes, and other beverages. The caloric intake was balanced in all studies to maintain constant weight. The daily fluid intake was fixed at 2500 ml/24 hr. Neither beverages nor food containing caffeine or other diuretically effective substances were allowed.

Three hours prior to drug administration, the volunteers were given water (10 ml/kg). One hour before the drug was given, a butterfly needle[10] was placed in a cubital vein. A constant drip of 0.45% sodium chloride[11], 1.7 ml/min in the oral experiments and 1.5 ml/min in the intravenous experiments, was started immediately through the butterfly needle. In the intravenous experiments, a catheter[12] was placed in the cubital vein on the other side and a constant drip of 0.9% sodium chloride (2.0 ml/min) was started immediately through the catheter. Both infusion solutions contained heparin[7], 1000 I.U./1000 ml, to prevent coagulation. Both the butterfly needle and the catheter were removed 11 hr after drug administration. Later blood samples were taken by venipuncture.

The freshly prepared solutions in 0.9% sodium chloride were assayed. They were intravenously administered at a constant rate for 1 min through the catheter, which was immediately flushed with 20 ml of 0.9% sodium chloride.

Blood (6 ml) was taken within 10 sec at 0, 1.5, 2, 2.5, 3.5, 7, 10, 15, 30, 45, 60, and 90 min and at 2, 3, 5, 7, 9, 11, 15, 20, 24, 36, 48, 60, 72, 84, 96, 120, and 144 hr after intravenous drug administration through the butterfly needle with syringes using a three-way stopcock[13]. An initial 2 ml of blood was discarded. The samples were immediately transferred to glass tubes[14] containing 12 mg of edetate disodium to prevent coagulation. After centrifugation at 1500 rpm for 20 min within 1 hr after sampling, the plasma was transferred to storage tubes and then frozen until assayed.

Total volumes of urine were obtained for the following collection periods: −3–0, 0–2, 2–4, 4–6, 6–8, 8–10, 10–12, 12–18, 18–24, 24–48, 48–72, 72–96, 96–120, and 120–144 hr. The pH was monitored, and aliquots were transferred to storage containers and frozen until assayed. Total feces were collected for the following collection periods: −12–0, 0–24, 24–48, 48–72, 72–96, 96–120, and 120–144 hr; the samples were frozen until assayed.

Analytical Procedures—The ^{3}H-β-methyldigoxin had a specific activity of 431 μCi/mg. Its purity was investigated in three different TLC systems: A, acetone–chloroform (4:6) on silica gel; B, ethyl acetate–formic acid (98:2) developed three times on basic alumina; and C, chloroform–ethanol–acetic acid–water (91.0:7.5:1.0:0.5) on basic alumina. Quantities and identities of the separable contaminants were determined by thin-layer scraping, elution of the material, and radioactivity counting in a liquid scintillation counter[15]. Corrections were made for background and efficiency using the channels ratio method (7).

When the ^{3}H-β-methyldigoxin used in the pharmacokinetic studies was chromatographed, the developed TLC spot assignable to the ^{3}H-β-methyldigoxin retained 97.6% (System A), 83.7% (System B), and 84.6% (System C) of the total radioactivity spotted in the three thin-layer systems used. It was concluded that 0.837 of the material represented ^{3}H-β-methyldigoxin, and this fraction of the total radioactivity was considered as the dose of β-methyldigoxin. The TLC separable contaminants assignable to digoxigenin monodigitoxoside (3.3%), digoxigenin (2.5%), digoxin (1.6%), and digitoxin and digoxigenin bisdigitoxoside (<1.0%) retained the percentages of the total radioactivity designated.

Since TLC System A was the least sensitive, only Systems B and C (with 250-μm basic alumina[16]-coated glass plates in activated chambers) were used in all other TLC studies on plasma and urine composition. The compounds were visualized by spraying with 50% aqueous sulfuric acid and heating the plates at 110° for 10 min. For the detection of the individual radioactive compounds, 4-mm bands of alumina were scraped from the plates using a zonal scraper[17]; the radioactivity in each zone was determined by liquid scintillation spectrophotometry using a prepared scintillation fluid (6). The radioactivity distribution pattern was then plotted by a computer plotter programmed to give the total radioactivity eluted from the plates, the number of radioactivity peaks, their R_f values, and the percentage of radioactivity in each peak. The efficiency of this process, 46.3 ± 1.3%, was determined by counting the scrapings of known spotted amounts. Corrections were made for the individual extractability of each compound.

For the determination of total radioactivity in plasma and urine, the samples were thawed and shaken, and 100- and 500-μl replicates were pipetted into vials containing 10 ml of scintillation fluid. In three of the seven investigated volunteers, total radioactivity was determined in the feces. Fecal samples were freeze dried and the dry powder was mixed thoroughly. Weighed aliquots were then combusted[18] to tritiated water, which was added to 10 ml of scintillation fluid and counted.

Aliquots of plasma (0.5–3.0 ml) were acidified to pH 4–5 with 10% HCl and extracted twice with three times the volume of ethyl acetate. The extracts were swirled over anhydrous sodium sulfate and decanted, and the solution was concentrated to dryness under nitrogen and then redissolved in 95% methanol (0.1 ml). Aliquots of the resultant solutions were then spotted on thin-layer plates, which were developed with Solvent Systems B and C. Sequential plasma samples with low radioactivity counts were pooled before extraction and TLC, and the weighted average of their sample times was taken as representative.

The extraction efficiencies into ethyl acetate of plasma samples spiked with various compounds were: β-methyldigoxin, 74.6 ± 0.7%; digoxin, 77.0 ± 1.6%; digoxigenin bisdigitoxoside, 74.3 ± 1.0%; digoxigenin monodigitoxoside, 85.5 ± 3.0%; and digoxigenin, 76.0 ± 1.0%.

Aliquots of urine (5 ml) were acidified with 10% HCl to pH 4–5 and extracted three times with equal volumes of chloroform. Each chloroform extract was swirled over anhydrous sodium sulfate, decanted, concentrated to dryness under nitrogen, and then redissolved in 95% methanol (0.1 ml). Aliquots of the resultant solutions were then spotted on thin-layer plates, which were developed with Solvent Systems B and C.

The aqueous phase was further analyzed in all urine samples in the 0.6-mg oral experiments of three volunteers. Aliquots of urine (5 ml) (Scheme I) were acidified with 10% HCl to pH 4–5 and extracted three times with equal volumes of chloroform to give chloroform extracts, C_1, which contained β-methyldigoxin and the less polar metabolites. The aqueous eluate, A_1 (pH 5.0), was incubated for at least 12 hr with 1.0 ml (5000 Fishmann units) of β-glucuronidase/ml of eluate. Extraction of A_1 with chloroform generated the chloroform eluate, C_2, which was chromatographed, and the generated aqueous eluate, A_2 (pH 5.0), was incubated with 0.1 ml of aryl sulfatase (5000 Whitehead units) for at least 12 hr.

After a third chloroform extraction of A_2, the newly generated aqueous eluate, A_3 (pH 5.0), was incubated with 1.0 ml of β-glucuronidase for at least 12 hr to assure complete enzymatic hydrolysis. The generated chloroform eluate, C_3, was subjected to TLC. After a final chloroform extraction of A_3, the generated aqueous eluate, A_4, was also chromatographed. The chloroform eluate, C_4, was not processed further, since it did not contain any radioactivity. Each chloroform extract was swirled over anhydrous sodium sulfate, decanted, concentrated to dryness under nitrogen, and assayed for percent recovery.

Recoveries of the compounds from urine spiked with specific radiolabeled compounds were, in the chloroform and residual water layer, respectively: β-methyldigoxin, 96.6 ± 1.5 + 2.1 ± 0.3 = 98.7%; digoxin, 100.9 ± 1.5 + 1.9 ± 0.3 = 102.8%; digoxigenin bisdigitoxoside, 104.2 ± 0.9 + 3.2 ± 0.8 = 107.4%; digoxigenin monodigitoxoside, 76.8 ± 2.7 + 18.9 ± 1.0 = 95.7%; and digoxigenin, 69.9 ± 1.8 + 31.6 ± 0.5 = 101.5%.

The β-methyldigoxin and metabolites in the extracts of plasma and urine were identified by admixing known standards with the extracts and separating in Systems B and C. The scrapings that corresponded to the R_f values were eluted with 95% methanol and definitely identified by three consecutive recrystallizations to constant specific activity (8) with standard deviations of less than ±4%. The metabolites in plasma and urine whose extraction efficiencies and recoveries were studied were checked by this procedure.

The extent of tritiated water formation was checked in urine by distillation (9). Equal aliquots of five total volumes of urine collected between 0 and 10 hr after 0.3 mg po was administered to one volunteer were combined and distilled. Distillate aliquots were assayed for tritiated water and compared with aliquots of water serving as controls. Triplicates (0.1 ml) of each were added to 10 ml of scintillation fluid and counted. Only 0.035% of the total radioactivity excreted was tritiated water. This amount was considered as a measure of negligible tritium exchange of labeled β-methyldigoxin with body water.

Protein Binding of β-Methyldigoxin—Plasma was equilibrated with chromatographically pure β-methyldigoxin (TLC System B) for 0.5 hr

and filtered at 1200 rpm for 18–20 min in a centrifuge[19] through two to four high flux cone membranes[20]. Half-filtration was preferred, since complete filtration of plasma might trap and inhibit the free passage of other soluble plasma components (10–12). Total drug concentration (bound and unbound) in the plasma prior to filtration and the free drug concentration in the plasma water of the filtrate were determined by liquid scintillation spectrophotometry.

The protein binding of β-methyldigoxin was investigated at five pharmacokinetically observed concentrations between 0.49 and 76.0 ng/ml at 25–29°, pH 7.32–7.34, in the fresh human plasma of two healthy fasted volunteers with no prior drug intake. The total protein content and the protein fractions of the two plasmas were determined (13).

The concentration-dependent membrane binding of β-methyldigoxin was compensated for by presaturating the cones. Several prior half-filtrations of 3–4 min of plasma water spiked with drug of the same concentration as the plasma were half-filtered through the cone. Only those membranes that yielded greater than 85% recovery of plasma water concentration and less than 5% variability in two consecutive filtrations were used.

Red Blood Cell–Plasma Water Partition Coefficient of β-Methyldigoxin—Centrifugally separated red blood cells were washed twice with sterile isotonic sodium chloride solution, recentrifuged, and suspended in plasma water obtained by ultrafiltration. Chromatographically pure β-methyldigoxin (TLC System B) was added to prepare 45.2-, 5.53-, and 2.90-ng/ml concentrations in the presence and absence of unlabeled digoxin at the pharmacokinetically anticipated 31 and 42% of these concentrations. Aliquots were centrifuged, and their plasma water concentrations were assayed at 6, 10, and 16 min. The reproducibility of the hematocrits[21] after each sampling demonstrated thorough mixing of the red blood cell–plasma water suspensions.

The partition coefficient was also determined in whole blood with 8.3–47.8 ng/ml of radiolabeled β-methyldigoxin sampled from three volunteers shortly after intravenous administration when minimum metabolites were present. The plasma water concentrations were assayed after separation by centrifugation at 1500 rpm for 15 min. The concentrated red blood cells after two consecutive centrifugations at 2500 rpm for 20 min had hematocrits of 0.80–0.90 and were hemolyzed at −4°. The ghost cells were removed by centrifugation, and radioactivity was analyzed in the hemolysate.

RESULTS AND DISCUSSION[22]

Protein Binding of β-Methyldigoxin—The percent of drug bound to protein was calculated from:

$$f = \frac{100([A_p] - [A_p{}^u])}{[A_p]} = \frac{100[A_p{}^b]}{[A_p]} \qquad \text{(Eq. 1)}$$

where $[A_p]$, $[A_p{}^u]$, and $[A_p{}^b]$ are the concentrations of total, free, and bound drug in plasma, respectively. The value of $[A_p]$ was measured in plasma after the drug was added and before ultrafiltrations were performed.

The average f values for the parenthetical total plasma concentrations of drug, $[A_p]$, were 10.9% (76.0 ng/ml), 7.6% (30.4 ng/ml), 9.9% (6.00 ng/ml), 10.2% (2.40 ng/ml), and 11.4% (0.49 ng/ml), with an overall mean of 9.8 ± 1.1% for the concentration-independent protein binding of β-methyldigoxin. This amount is close to the 14% value of Dengler *et al.* (14) from equilibrium dialysis of radiolabeled drug in human plasma. Both do not agree with the reported 28.8% of Kramer *et al.* (15), obtained by dual closed-loop dialysis. By using their reported equation (15) to calculate protein binding, a value of 15% was obtained.

Red Cell Partitioning of β-Methyldigoxin—The red cell–plasma partition coefficient, D, of a drug has been defined as the ratio of the total drug concentration in the erythrocytes, $[A_{RBC}]$, to the free or unbound concentration of drug in plasma, $[A_p{}^u]$ (16):

$$D = [A_{RBC}]/[A_p{}^u] \qquad \text{(Eq. 2)}$$

The $[A_p{}^u]$ was calculated from $[A_p{}^u] = (1 - f)[A_p]$, with $f = 0.10$ for blood and $f = 0$ for red blood cell suspensions in plasma water.

The average D values obtained for the parenthetical concentrations in whole blood were: 0.86 ± 0.05 (45.0 ng/ml), 0.93 ± 0.04 (30.0 ng/ml), 0.91 ± 0.04 (20.0 ng/ml), and 0.87 ± 0.05 (10.0 ng/ml). Similar D values resulted with red blood cell–plasma water suspensions: 0.84 ± 0.04 (45.2 ng/ml) and 1.03 ± 0.06 (5.5 ng/ml). Therefore, D is invariant with changing concentrations of β-methyldigoxin. The drug equilibrated rapidly between red blood cells and plasma water, at least in the first sample that was taken 6 min after drug addition. The addition of digoxin to give molar ratios of 2.4 and 3.20 of β-methyldigoxin to digoxin had no effect on the rate or the extent of partitioning in red blood cells: 0.91 ± 0.02 (5.53 ng of β-methyldigoxin/ml–2.27 ng of digoxin/ml) and 1.11 ± 0.03 (5.53 ng of β-methyldigoxin/ml–1.73 ng of digoxin/ml).

Plasma Pharmacokinetics of ^{3}H-β-Methyldigoxin after Intravenous Administration—The concentrations of plasma β-methyldigoxin and digoxin were determined in three subjects at the two different dose levels for intravenous and oral administrations. They were calculated from the fraction of the total radioactivity of the TLC plate that could be assigned to the radioactivities of their respective spots. The fractions bound to plasma proteins were taken as 0.10 and 0.25 (17), respectively.

The concentrations of unbound β-methyldigoxin, $[A_p{}^u]$, in plasma were fitted against time by "feathering," the method of residuals (Figs. 1 and 2):

$$[A_p{}^u] = A_1'e^{-\alpha_1 t} + A_2'e^{-\alpha_2 t} + B'e^{-\beta t} + C'e^{-\gamma t} \qquad \text{(Eq. 3)}$$

The evaluated parameters for the various studies are given in Table I.

Attempts to fit with a linear sum of only three exponentials consistently underestimated plasma data in the 3–30-hr time interval (Fig. 2).

The apparent volumes of distribution of the central compartment, $V_p{}^u$, referenced to the unbound drug in the plasma were estimated (16) from the individual $[A_p{}^u]_0$, 8.4 ± 1.9% of the dose per liter of plasma calculated at $t = 0$ from Eq. 3 and the intravenously administered dose, D = 100%:

$$V_p{}^u = D/[A_p{}^u]_0 \qquad \text{(Eq. 4)}$$

In 65% of the intravenous experiments, the plasma sample value taken at 90 sec after the start of the 1-min drug infusion was less than that taken at 120 sec. In some cases, the plasma maximum was not reached until 180 or 300 sec (Fig. 2). Thus, the injection and sampling sites could not be considered as being in the same kinetic compartment, and simultaneous penetration into and distribution from the central compartment must be postulated. The apparent volumes of distribution, $V_p{}^u$, as estimated by application of Eqs. 3 and 4, would be overestimated in these cases; large variability existed in the estimates of α_1 and A_1'.

The $V_p{}^u$ values were reasonably consistent within an individual for the two dose levels (Table I). If the α_1 phase, with its inherent variability in parameter estimations, were excluded, the apparent volume of distribution, $(V_p{}^u)'$, estimated on the premise that α_1 is infinite and A_1' is zero in Eq. 3 to produce an $[A_p{}^u]_0'$ value for Eq. 4, represented the volume of a central compartment larger than $V_p{}^u$. These volumes, $(V_p{}^u)'$ = 38.5 ± 3.7 liters, were remarkably consistent among individuals for all doses (Table I).

Plasma Pharmacokinetics of Digoxin after ^{3}H-β-Methyldigoxin Administration—Digoxin was the only metabolite of β-methyldigoxin found in significant concentrations in plasma, with a peak of 0.15 ± 0.03% of the dose per liter of plasma at 32.3 ± 7.0 min after intravenous administration of ^{3}H-β-methyldigoxin (Figs. 1–3). The plasma digoxin levels decreased subsequently by processes that could be described by the sum of two exponentials: a β-phase, $\beta = 0.68 \pm 0.21$ hr^{-1}, and a slower terminal γ-phase, $\gamma = 0.012 \pm 0.001$ hr^{-1}, that was reasonably linear in log plasma concentration–time and log digoxin to be excreted in urine–time plots (Figs. 1–3). Obviously, these values do not fully characterize the pure pharmacokinetic parameters since digoxin is being simultaneously formed from β-methyldigoxin.

When the concentration of total radioactivity in the plasma was plotted against time, a small anomalous increase in the plasma level with a subsequent decrease was consistently observed between 18 and 24 hr after both oral and intravenous administrations. This result could indicate enterohepatic circulation consistent with the observations of Doherty *et al.* (18) for digoxin. The time at which this increase occurred was consistent with such absorption being effected in the lower small intestine but was not of sufficient magnitude to perturb greatly the pharmacokinetic analyses.

Excretion Pharmacokinetics—The total radioactivity excreted in a time interval was the product of the concentration, microcuries per liter or gram, and the volume of urine or weight of feces collected. The amounts of ^{3}H-β-methyldigoxin and its individual metabolites excreted in the urine were calculated from the respective fractions of total radioactivity assignable to each on TLC analysis for the same three subjects for which β-methyldigoxin and digoxin had been analyzed in plasma. These amounts of materials in urine, U_t, were plotted cumulatively as the percent of dose against time (Fig. 4) to estimate the total recovery, U_∞, and were reasonably superimposable for all doses.

The semilogarithmic plots of the amounts of drug or metabolite not yet excreted in the urine, ln $(U_\infty - U_t)$, and the rate of excretion, ln $\Delta U/\Delta t$, against time (Figs. 3 and 5) exhibited the apparent terminal phases observed previously in the plasma (Figs. 1 and 2).

The percentages of the ^{3}H-β-methyldigoxin dose renally excreted as β-methyldigoxin, digoxin, and water-soluble metabolites are given in Table I. The percentages of the total administered radioactivity renally and totally (renal plus fecal) excreted also are given.

There were no apparent dose-dependent pharmacokinetics. When the plasma concentrations and cumulative urine content of β-methyldigoxin and digoxin were plotted against time in terms of the percent of the

[a] Parameters of the sum of exponentials to express the unbound β-methyldigoxin concentration in percent of dose per liter of plasma: $10^2[A_p{}^u]/D = A_1e^{-\alpha_1 t} + A_2e^{-\alpha_2 t} + Be^{-\beta t} + Ce^{-\gamma t}$, where $[A_p{}^u]$ is the concentration in micrograms per liter at time *t*. Values were obtained by the method of residuals (35) from urine or plasma. [b] Estimated apparent volume of distribution of the central compartment referenced to unbound β-methyldigoxin in plasma from $D/[A_p{}^u]_0 = 10^2/(A_1 + A_2 + B + C)$ for $t = 0$ in equation of footnote *a*, where $[A_p{}^u]_0$ estimates the concentration of drug in plasma at zero time. [c] Estimated apparent volume of distribution of the equilibrated combined α-compartments from $D/[A_p{}^u]_0' = 10^2/(A_1 + B + C)$ from $t = 0$ in equation of footnote *a*, where $[A_p{}^u]_0'$ estimates the concentration of drug in plasma at zero time on assumption of instantaneous equilibration in the α_1- and α_2-compartments. [d] Determined by graphical integration of the area in micrograms-hour per liter under the unbound β-methyldigoxin plasma concentration–time curve; the area is divided by the administered dose in micrograms. [e] Total clearance from dose, *D*, divided by the area under the unbound plasma concentration–time plots. [f] Renal clearance from slope of plots of renal elimination rates of β-methyldigoxin, $\Delta U/\Delta t$, against plasma concentrations of unbound drug. [g] Metabolic clearance from the difference of total and renal clearances, $(Cl_p{}^u)_{tot} - (Cl_p{}^u)_r$. [h] Estimated equilibrated apparent volume of distribution during the psuedo-steady state or γ-phase, $(Cl_p{}^u)_{tot}/\gamma$. [i] Calculated from the micrograms of β-methyldigoxin renally excreted at infinite time, U^{BMD}_{∞}, which was estimated by adding to the amount excreted at 144 hr that amount that would have been excreted for five more half-lives if the slope of the natural logarithm of the excretory rate, ln $\Delta U/\Delta t$, against time was a constant, $-\gamma$. [j] Calculated from the micrograms of β-methyldigoxin renally excreted at 144 hr, $U^{BMD}_{144\ hr}$. [k] Calculated from the micrograms of β-methyldigoxin equivalent of the digoxin renally excreted at 144 hr, $U^{DIG}_{144\ hr}$. [l] Calculated from the micrograms of β-methyldigoxin equivalent of water-soluble metabolites renally excreted at 144 hr, $U^{H_2O}_{144\ hr}$. [m] Percent of total radioactivity administered excreted by 144 hr by specified route(s). [n] Percent of dose of β-methyldigoxin excreted by 144 hr renally as unchanged drug, digoxin, and water-soluble metabolites plus fecal excretion.

^{3}H-β-methyldigoxin dose per liter of plasma and the percent of dose, respectively, for the two dose levels of ^{3}H-β-methyldigoxin, the curves were superimposable (Fig. 4).

It can be estimated (Table I) that 92 ± 2.7% of the intravenous ^{3}H-β-methyldigoxin dose was eliminated by all processes at 144 hr. Of this percent, renal excretion accounted for fractions that were 0.470 unchanged, 0.345 digoxin, and 0.058 water-soluble metabolites. The fraction in the feces was 0.127. As will be justified later, the biliary excretion of unchanged β-methyldigoxin was negligible. The biliary excretion of digoxin has been estimated as 0.16 of its renal excretion (18). Thus, the fraction of digoxin formed from the dose of ^{3}H-β-methyldigoxin was estimated on the premise of negligible enterohepatic reabsorption as 0.16 (0.345) + 0.345 = 0.40. The fraction of the other metabolites of β-methyldigoxin would then be 0.127 [fecal] − 0.16 (0.345) [biliary digoxin] + 0.058 [urinary water solubles] = 0.130, of which 0.67 (0.058) = 0.039 would be renally excreted sulfates and glucuronide conjugates of β-methyldigoxin.

Clearances of β-Methyldigoxin—Total clearances of plasma-unbound β-methyldigoxin $(Cl_p{}^u)_{tot}$ of 126 ± 4 ml/min were estimated from the areas (Table I) under the plasma unbound concentration–time curves extrapolated to infinite time on the presumption of terminal first-order decay of plasma levels. Total clearance does not necessarily imply pharmacodynamic inactivation, since it includes the metabolic clearance of β-methyldigoxin where pharmacodynamically active digoxin is the major metabolite. There was no dose dependency. Thus:

$$(Cl_p{}^u)_{tot} = fD/\text{area} \qquad \text{(Eq. 5)}$$

where *D* = administered dose, and *f* = 1 for intravenously administered β-methyldigoxin.

The renal clearances of β-methyldigoxin, $(Cl_p{}^u)_r$, were determined from the slopes of plots (Fig. 6) of the rates of urinary excretion, $\Delta U/\Delta t$, against the plasma concentrations of unbound drug, $[A_p{}^u]$, taken at the midtime of the urine collection period. There was no apparent dose dependency (Table I). The average renal clearance was 59 ± 7 ml/min. The renal clearances appeared to be independent of urine flow between 0.9 and 5.5 ml/min and of urinary pH between 5.5 and 7.4. Literature values of renal clearances corrected for protein binding were 73 ml/min based

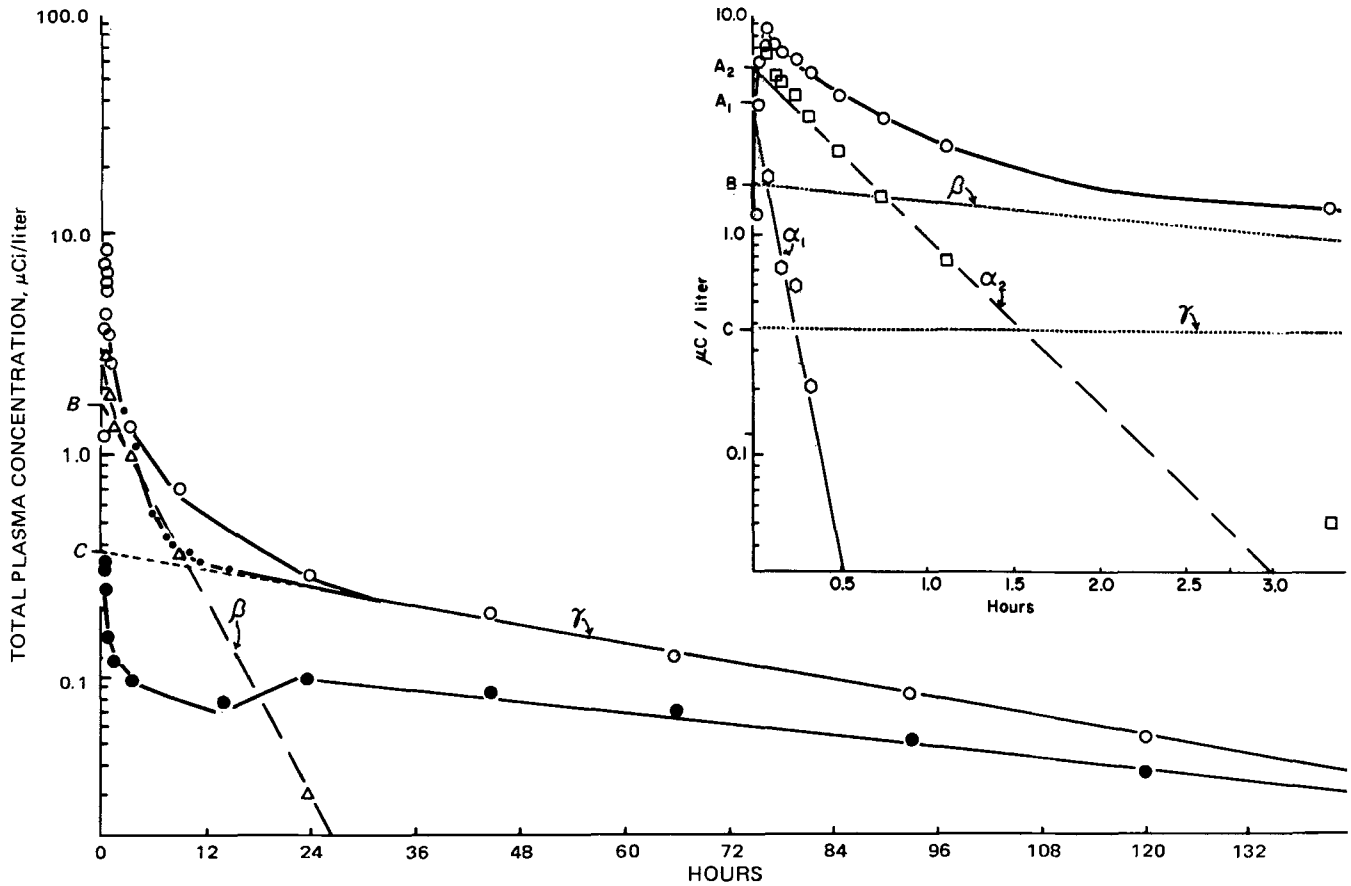

Figure 2—*Typical semilogarithmic plots of plasma β-methyldigoxin (○) and digoxin (●) concentrations, [A_p], against time for intravenous administration: 254.1 μCi = 589 μg of ^{3}H-β-methyldigoxin to Subject A. The various lines and symbols obtained by the method of residuals are as specified in Fig. 1. The dotted segment (·····) between 3 and 24 hr represents the best fit if [A_p] was the sum of only three exponentials. In this subject, there was a time delay in obtaining the maximum plasma concentration of β-methyldigoxin after intravenous administration.*

on total radioactivity (19) and 84 ml/min based on radioimmunoassay (20). These latter values overestimate the true renal clearance of β-methyldigoxin because they are modified by the simultaneous clearance of the major metabolite, digoxin, which is significantly higher than that of the parent drug.

The fraction of the total radioactivity administered intravenously that was fecally excreted in the first 48 hr was 0.083 ± 0.012 (n = 3) and agreed with the data of Abshagen *et al.* (21) for the fraction of total radioactivity excreted biliary. These investigators obtained the value of 0.105 ± 0.027 (n = 3) for the fraction of total radioactivity administered intravenously as tritiated β-methyldigoxin that appeared in the bile within 48 hr from patients with biliary tract disease in whom a biliary cannula was inserted. The average biliary clearance, $(Cl_p{}^u)_G$, of unbound β-methyldigoxin was estimated from the quotient of the average rates, dG/dt, of biliary excretion of β-methyldigoxin for the three patients given in the literature (21), dG/dt = 0.32, 0.032, and 0.0092% of the total dose of radioactivity excreted per hour during 0–4-, 4–24-, and 24–48-hr intervals, respectively, and the average plasma concentrations of unbound drug, $[A_p{}^u]$ = 2.21, 0.187, and 0.066% of the dose of unbound β-methyldigoxin per liter of plasma at the 2-, 14-, and 36-hr midpoints of these intervals in the three subjects of this present study who were given the drug intravenously. The respective individual quotients, $(Cl_p{}^u)_G = dG/dt/[A_p{}^u]$, were 0.145, 0.171, and 0.135 liter/hr and averaged 2.5 ± 0.2 ml/min (n = 3).

Since this biliary clearance would make a negligible contribution to the total clearance, the average metabolic clearance of unbound β-methyldigoxin, $(Cl_p{}^u)_m$ = 66 ± 10 (intravenous), was determined only from the differences between the total and renal clearances (Table I). If β-methyldigoxin metabolism occurs only in the liver and the average hepatic plasma flow is 800 ml/min (22), the metabolic efficiency is 66/800 = 0.083.

The endogenous creatinine clearances were normal (23) and were 129 ± 6 ml/min (n = 7), corrected for a body surface of 1.73 m^2 (n = 7) at urine flows of 1.2 ± 0.2 ml/min. The ratio of the renal clearance of β-methyldigoxin to creatinine was 0.42 ± 0.02 and implies an excess of tubular reabsorption for β-methyldigoxin.

Clearances of Digoxin after Intravenous ^{3}H-β-Methyldigoxin Administration—The average renal clearance, $(Cl_p{}^u)_r$ = 222 ± 32 ml/min (n = 5), of plasma-unbound digoxin was determined by the method described previously for β-methyldigoxin (Fig. 6) and can be compared with the values calculated for unbound digoxin of 163 (24), 133 (25), 120 (26), and 205 (27) in normal subjects. However, these estimates were based on total radioactivity or immunoassay rather than pure di-

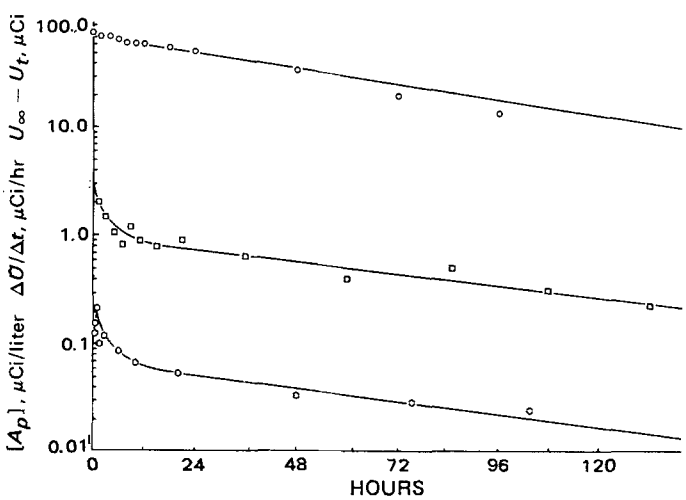

Figure 3—*Typical semilogarithmic plots of plasma concentrations of digoxin, [A_p] (○); amounts of digoxin yet to be excreted, $U_\infty - U_t$ (○); and rates of urinary excretion of digoxin, $\Delta U/\Delta t$ (□), against time for intravenous administration: 272.8 μCi = 633 μg of ^{3}H-β-methyldigoxin to Subject A.*

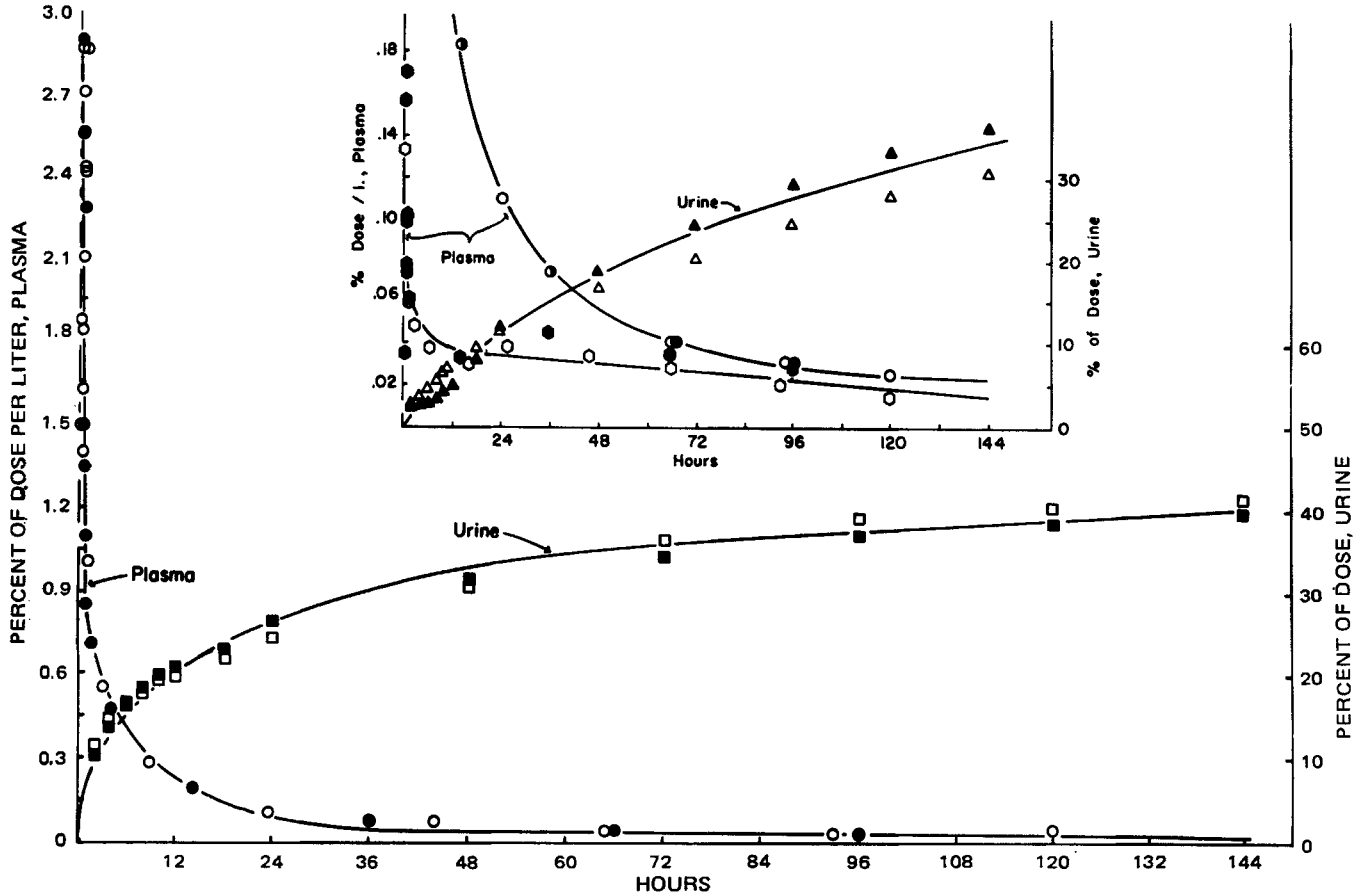

Figure 4—*Typical plasma concentrations and cumulative urine excretions in percent of β-methyldigoxin dose per liter of plasma and percent of dose, respectively, against time for intravenous administration: 126.7 μCi = 294 μg (open symbols) and 254.1 μCi = 590 μg (solid symbols) of ^{3}H-β-methyldigoxin to Subject A. Key: ○, ●, plasma levels of β-methyldigoxin; □, ■, urinary amounts of β-methyldigoxin; ○, ● (inset), plasma levels of digoxin; and △, ▲ (inset), urinary amounts of digoxin.*

goxin in plasma and underestimated the renal clearance when the plasma values were not corrected for metabolites, particularly if the metabolites had a smaller volume of distribution than digoxin. The urine flows in these studies were not specified. Evidence for urine flow dependency of the renal clearance of digoxin was reported (28). In these studies, the renal clearance of the metabolite appeared to be independent of urine flow between 0.9 and 5.5 ml/min and of urinary pH between 5.5 and 7.4.

An alternative rationale for the apparent discrepancy between the renal clearance values is a pharmacokinetic interaction between β-methyldigoxin and digoxin. β-Methyldigoxin could alter the renal clearance of digoxin by increasing its volume of distribution and/or its rate constant

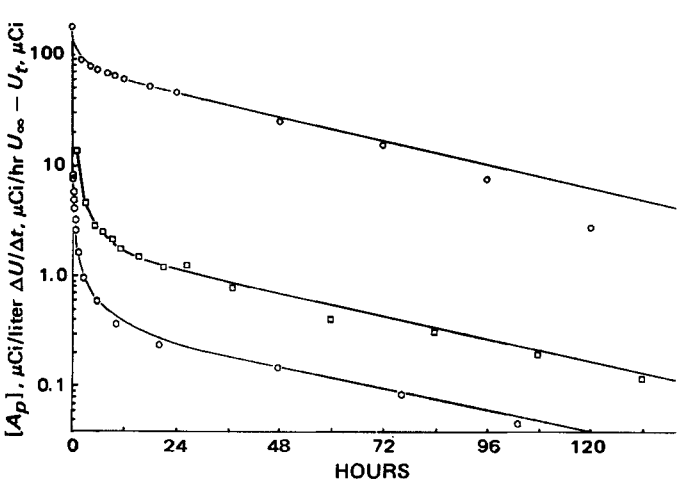

Figure 5—*Typical semilogarithmic plots of plasma concentrations of β-methyldigoxin, [A_p] (○); amounts of β-methyldigoxin yet to be excreted, $U_\infty - U_t$ (○); and rates of urinary excretion of unchanged drug, $\Delta U/\Delta t$ (□), against time after intravenous administration: 272.8 μCi = 633 μg of ^{3}H-β-methyldigoxin to Subject B.*

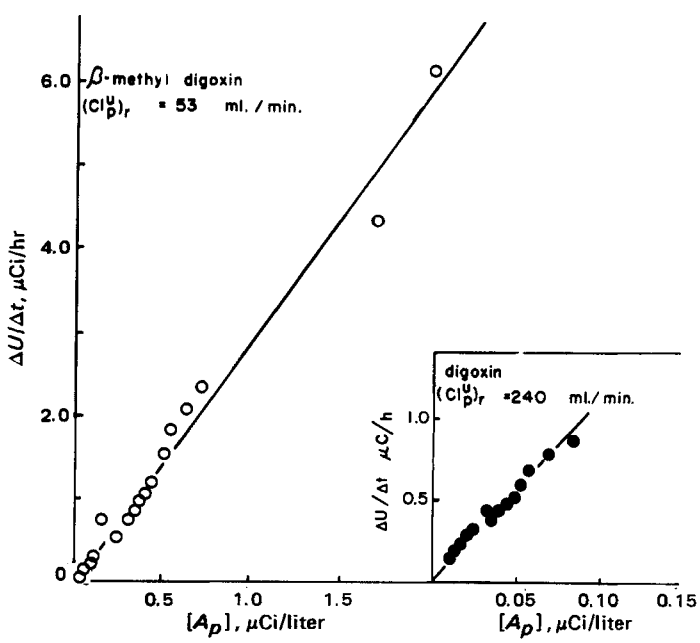

Figure 6—*Typical renal clearance plots for β-methyldigoxin and digoxin (inset) after ^{3}H-β-methyldigoxin intravenous administration of 126.7 μCi = 294 μg and 117.5 μCi = 272.6 μg to Subjects A and B, respectively. The renal clearances, (Cl$_p^u$)$_r$, of unbound drug were obtained by multiplying the slopes by the respective fractions of drug unbound to plasma protein.*

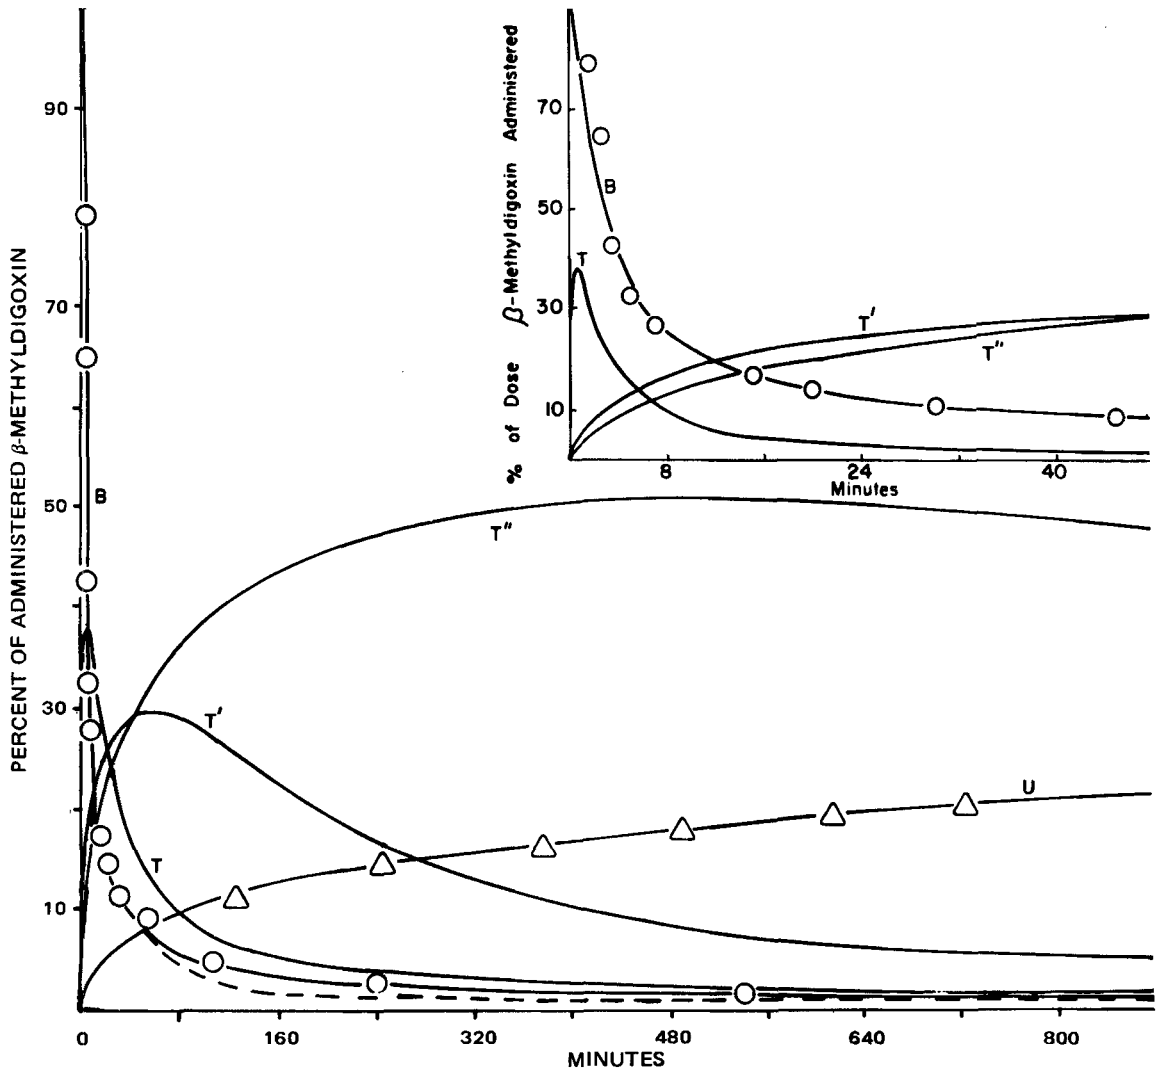

Figure 7—*Typical analog computer fitting of plasma water (unbound drug),* B (○), *and urine,* U (△), *data of β-methyldigoxin to the four-compartment body model for the 0.3-mg iv administration to Subject C over 13 hr with the parameters of Table II. The amounts of drug in various tissues* T, T′, *and* T″ *are generated in terms of percent of administered dose where the concentration of drug at zero time is taken as 100%. The inset is for an expanded time scale and shows the fit for the early plasma data. The dashed line represents the best attempt to fit the plasma data to a three-compartment body model.*

of elimination. The latter would imply saturable renal elimination of digoxin, but the renal clearances for digoxin were constant over wide ranges of plasma concentration ratios of β-methyldigoxin to digoxin (Fig. 6).

A more plausible rationale is to postulate renal metabolism of β-methyldigoxin to digoxin, which could account for the apparent discrepancy between the apparent renal clearances of digoxin observed when the drug *per se* or β-methyldigoxin was administered.

The biliary clearances of plasma-unbound digoxin were determined by the method described previously for β-methyldigoxin. The average rates, dG/dt, of biliary excretion of digoxin for the three patients given in the literature (21) were dG/dt = 0.188, 0.052, and 0.029% of the total dose of radioactivity excreted per hour during 0–4-, 4–24-, and 24–48-hr intervals, respectively. The average plasma concentrations of unbound digoxin were $[A_p{}^u]$ = 0.070, 0.026, and 0.016% of the dose of ^{3}H-β-methyldigoxin per liter of plasma at the 2-, 14-, and 36-hr midpoints of these intervals in the three subjects of this present study who were given ^{3}H-β-methyldigoxin intravenously. The respective individual quotients for the biliary clearance of digoxin, $(Cl_p{}^u)_G = dG/dt/[A_p{}^u]$, were 2.69, 2.00, and 1.83 liters/hr and averaged 36 ± 4 ml/min (n = 3). The ratio of these estimates of biliary and renal clearances of digoxin is 0.16, which agrees well with the ratio of drug biliary excreted to drug renally excreted of 0.16 obtained by Doherty *et al.* (18).

The total clearances of digoxin were also calculated from Eq. 5 from the areas up to the 144 hr studied, where the average area divided by the dose was 0.025 ± 0.005 hr/liter (n = 5) for the area under the plasma unbound concentration–time curves of digoxin for intravenously administered ^{3}H-β-methyldigoxin. However, the f in Eq. 5 is that fraction of the dose, D, of intravenously administered ^{3}H-β-methyldigoxin that is transformed to digoxin in 144 hr. It can be estimated from the ratio of the metabolic clearance, $(Cl_p{}^u)_m$, of β-methyldigoxin to its renal clearance, $(Cl_p{}^u)_r$, which is equal to the ratio of metabolites formed to renally excreted unchanged β-methyldigoxin. Thus, the average fraction transformed to metabolites is:

$$f = (U_{144}^{BMD}/D)(Cl_p{}^u)_m/(Cl_p{}^u)_r = 0.48 \pm 0.05 \qquad \text{(Eq. 6)}$$

where U_{144}^{BMD}/D is the fraction of ^{3}H-β-methyldigoxin dose renally excreted unchanged at 144 hr. To be completely rigorous, the fraction of β-methyldigoxin that is biliary excreted or changed to other metabolites than digoxin (such as conjugates of β-methyldigoxin) should be subtracted from f. It can be estimated from the experimentally determined composition of the water-soluble metabolite fraction of urine and the biliary excretion (29) that this amount comprises only 0.09 of the total ^{3}H-β-methyldigoxin dose; a better estimate of f is 0.39 ± 0.05, which agrees well with the previous estimates of 0.40 from the excretion pharmacokinetics.

The total clearance of digoxin was estimated as 290 ± 73 ml/min (n = 5). Subtraction of an estimated renal clearance of 222 ± 32 ml/min (n = 5) and a biliary clearance of 36 ml/min implies that the metabolic clearance of digoxin is 34 ± 16 ml/min. If digoxin metabolism occurs only in the liver, the metabolic efficiency is 34/800 = 0.043. Total and extrarenal unbound digoxin clearances of 277 and 72 ml/min, respectively,

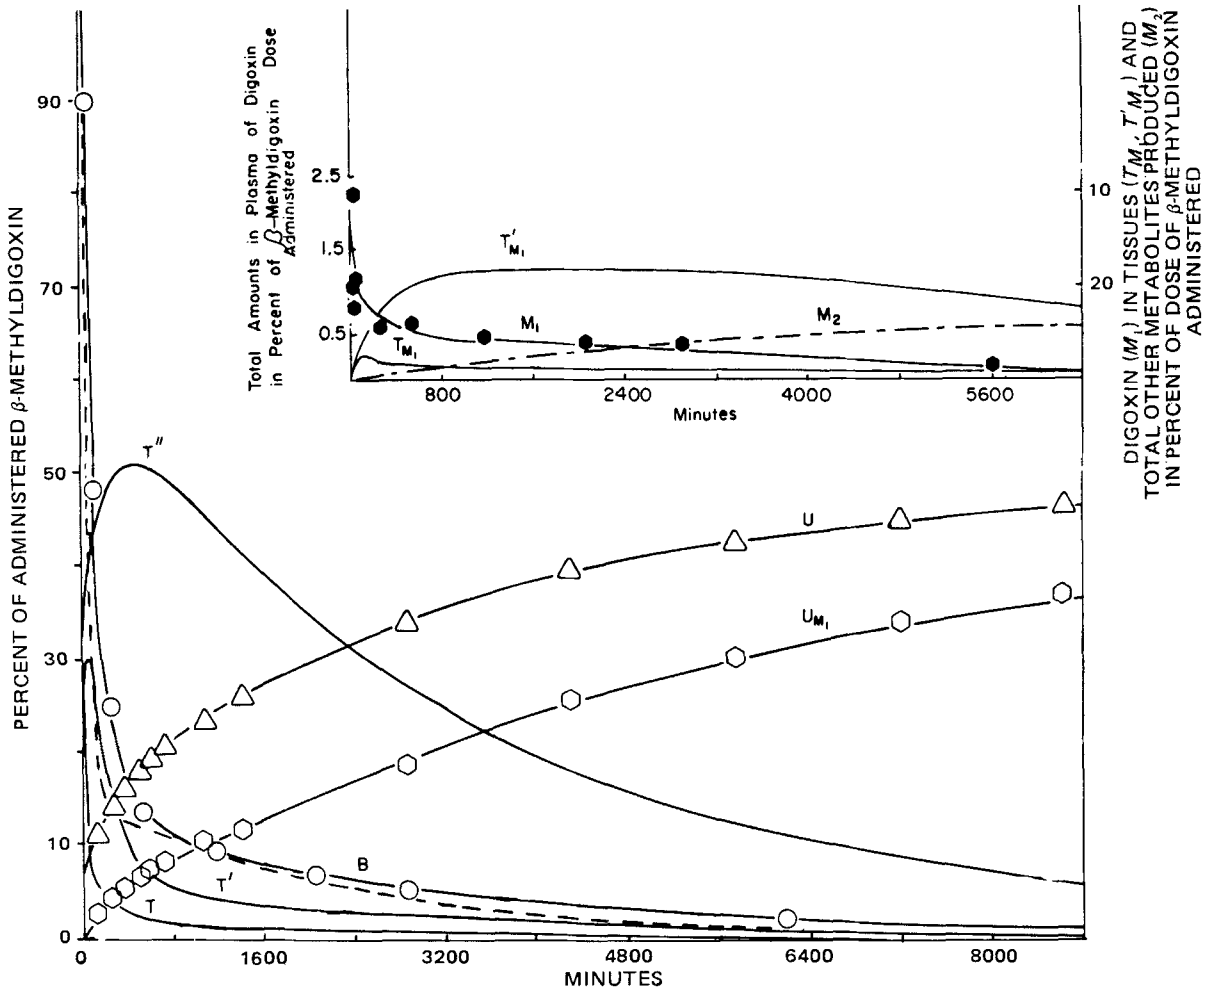

Figure 8—*Typical analog computer fitting of plasma water (unbound drug), B (○), and urine, U (△), data of β-methyldigoxin for the four-compartment body model for the 0.3-mg iv administration to Subject C over the complete time of the study. The digoxin (○) urine values, U_{M_1}, are fitted, and the amounts of drug in various tissues T, T′, and T″ are generated in terms of percent of administered dose where the concentration of drug at zero time is taken as 100%. The plasma β-methyldigoxin values (○) are shown multiplied by a factor of 10. The inset demonstrates the fitting to the total plasma data of formed digoxin, M_1 (●), in accordance with the necessary three-compartment body model (left scale); the amounts of digoxin in the various tissues are generated (T_{M_1} and T'_{M_1}) (right scale). The amounts of other metabolites, M_2, produced are also shown in the inset (right scale). The dashed line represents the best attempt to fit the plasma β-methyldigoxin data to a three-compartment body model.*

were reported for digoxin administration (27), in agreement with the values of this study.

The ratio of the renal clearance of digoxin to creatine was 1.52 ± 0.10 (n = 5) and implies an excess of tubular secretion in addition to glomerular filtration. Evidence for the tubular secretion of digoxin was reported previously (27, 30).

Pharmacokinetic Models for Intravenously Administered ^{3}H-β-Methyldigoxin and Digoxin and Their Fitting by Analog Computer—The model with the minimum number of compartments consistent with the experimental data was sought. The four-compartment body model postulated for plasma β-methyldigoxin levels with time by graphical analysis was challenged by both digital[23] and analog computation. A three-compartment body model (Scheme II) failed consistently to fit the terminal portion of the data (Figs. 1, 2, 4, 7, and 8) by both computer methods. Residual plots (31) showed definite trends about the mean with the three-compartment body model but random distribution with the four-compartment body model (Scheme III) to confirm the latter; typical best fits on this premise are given in Figs. 7 and 8.

Similar procedures were used in analog computer fitting of the digoxin metabolite, M_1, generated from β-methyldigoxin. A two-compartment body model (Scheme IV) failed consistently to fit the initial plasma data of the metabolite, M_1, and a three-compartment body model (Scheme V) was preferred (Fig. 7). This result agrees with the findings of Kramer *et al.* (32), who obtained better overall fits with a three- than with a two-compartment body model for digoxin on digoxin administration.

Typical computer programs and details were given previously (16). The initial conditions were placed on the central compartment, B, to obtain the initial drug concentration, $[A_p{}^u]_0$, from the best analog computer fit to Scheme III of the unbound plasma concentrations of β-methyldigoxin against time (Figs. 7 and 8). This voltage was considered as 100% of the drug in the central compartment that contained the plasma and associated fluids on the assumption of instantaneous mixing.

The cumulative urinary excreted amounts of the parent drug and metabolite, M_1, in microcuric-equivalent metabolite were plotted in terms of percent of dose administered. The simultaneous analog computer fitting of the plasma and urine data generated drug and metabolite amounts in the peripheral tissues and the total body, respectively, with time. Good and consistent fits were obtained with the four-compartment body model for the parent drug in plasma and urine and with the three-compartment body model for M_1 in urine. A typical fitting is shown in Figs. 7 and 8. The experimental plasma data of digoxin metabolite M_1 showed greater variability. Sets of microscopic rate constants that gave the best analog computer fittings to a four-compartment body model and the derived apparent volumes of distribution are given in Table II. The route of M_1 to bile M_1 in Scheme V was omitted in the analog computer fitting; therefore, $k_{M_1M_2}$ in the program and Table II was actually $k_{M_1M_2} + k_{M_1\,\text{bile}}$, which overestimates the former by 12% since the biliary clearance of digoxin is this percent of its total clearance.

Significance of Apparent Volumes of Distribution—The apparent

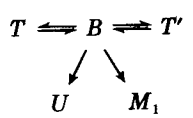
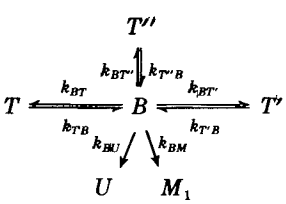
[a] Values for the microscopic rate constants in second^{-1} of distribution and elimination were obtained from the best simultaneous analog computer fits of the plasma and urine data in accordance with Schemes III and V. [b] The value is 112% of $k_{M_1M_2}$, since the biliary clearance of digoxin is 12% of its total clearances. [c] Values for the apparent volumes of distribution of the central compartment referenced to unbound β-methyldigoxin in plasma were calculated from the estimate of $[A_p{}^u]_0$ obtained from the initial conditions placed on B to give the best analog computer fit of the plasma data according to Scheme III, where $V_p{}^u = [A_p{}^u]_0/\text{dose}$. [d] The volumes of distribution for β-methyldigoxin at steady state for the different tissue compartments were calculated from $V_{pT}{}^u = V_p{}^u(k_{BT}/k_{TB})$, $V^u_{pT'} = V_p{}^u(k_{BT'}/k_{TB})$, and $V^u_{pT''} = V_p{}^u(k_{BT''}/k_{T''B})$. [e] The values of the overall steady-state volume of distribution for β-methyldigoxin were calculated (35) from $V_p{}^u[1 + (k_{BT}/k_{TB}) + (k_{BT'}/k_{T'B}) + (k_{BT''}/k_{T''B})]$. [f] The values of the overall pseudo-steady-state volume of distribution (36) for β-methyldigoxin were calculated from $(\text{Cl}_p{}^u)_{\text{tot}}/\gamma$, where $(\text{Cl}_p{}^u)_{\text{tot}} = (k_{BM} + k_{BU})V_p{}^u$ on the presumption that this value is $\gamma V^u_{pD_{ps}}$ in the terminal pseudo-steady state. The value of γ was estimated from the terminal slope of the semilog plot of the terminal analog computer fit of the plasma data. [g] Values for the apparent volume of distribution of the central compartment referenced to total (bound and unbound) digoxin in plasma were obtained from the best analog computer fit of the data for a three-compartment body model. [h] The values of the overall steady-state volumes of distribution of digoxin were calculated (35) from $(V_p)_{\text{DIG}}[1 + (k_{MT}/k_{TM}) + (k_{MT'}/k_{T'M})]$. The mean value is 1182 ± 542 if the anomalous 3596 of Subject B is excluded.

volume of distribution, $V_p{}^u$, of the central compartment referenced to unbound β-methyldigoxin in the plasma is 15 ± 3 liters by graphical methods (Table I) and 12 ± 2 liters by analog computer fitting (Table II). This amount is approximately the 15-liter extracellular body water of a young man (22).

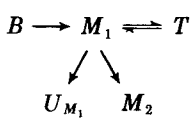
The overall volumes of distribution at steady state (Table II) of β-methyldigoxin, $(V_{pD}{}^u)_{\text{BMD}} = 326 \pm 27$ liters, and digoxin, $(V_D)_{\text{DIG}} = 1182 \pm 245$ liters ($n = 5$) if one anomalous value of 3596 liters is excluded, are larger than the total body water volume of 40 liters (22) and imply significant binding to and/or partitioning into tissues. A similar mean $(V_D)_{\text{DIG}}$ for digoxin of 800 liters can be calculated from the data obtained in healthy volunteers after digoxin administration by Kramer *et al.* (32). The overall volume of distribution at pseudo-steady state of β-methyldigoxin is significantly larger than the overall volume of distribution at steady state for β-methyldigoxin ($V^u_{D_{ps}} = 1.75 \times V^u_{D_{ss}}$). This result is a normal consequence of the kinetic properties of a slowly equilibrating deep compartment, T'', of large capacity (33) and implies that, after administration of a single dose of β-methyldigoxin, a relatively larger fraction of the dose in the body is in the tissue compartment than after chronic dosing with steady-state conditions.



Scheme II

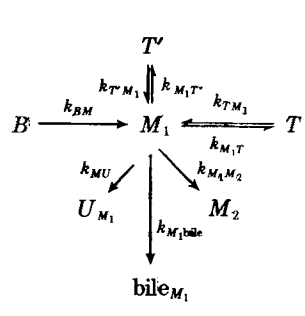


Scheme III



Scheme IV

Criteria for Determination of Terminal Half-Lives of β-Methyldigoxin Disposition—The magnitudes of the microscopic rate constants of equilibration for the shallow compartments T and T' (Scheme III), imply that these are relatively rapidly equilibrating with the central compartment and that the model ultimately degenerates to a two-compartment body model consisting of a new "central compartment," B +



Scheme V

Table III—Data for Estimates of "True" Renal Clearances of 0.6-mg Doses, D, of β-Methyldigoxin on Premise of Renal Metabolism

Subject	$Cl_{app\ BMD}$[a]	$(U_{BMD})144\ hr/D$[b]	$(U_{DIG})144\ hr/D$[b]	AUC_{DIG}/D[c]
A	50	0.416	0.305	1.808×10^{-3}
B	79	0.434	0.288	0.923×10^{-3}
C	40	0.381	0.227	1.178×10^{-3}
Mean ± *SD*	56 ± 20	0.410 ± 0.027	0.273 ± 0.041	$1.30 \pm 0.46 \times 10^{-3}$

[a] Obtained from slopes of plots of the rates of urinary excretion of β-methyldigoxin against unbound plasma concentrations at the midtime of the urine collection interval. [b] Fractions of total dose excreted into urine at 144 hr. The individual doses are given in Table I. [c] Areas under the plasma concentrations of plasma unbound digoxin concentrations with time are expressed as micrograms per milliliter per minute.

$T + T'$, and the peripheral compartment, T''. It is practical and useful to ascertain the time of pseudo-steady-state equilibration between this new central compartment and the tissue, T'', so that the terminal slopes, $-\gamma$, of the natural logarithm of the plasma level against time can be considered as constant and truly representative of the overall half-life of drug elimination from the body, a constant of importance in the prediction of blood level on chronic administration.

Representative analog computation (Subject B, 0.6 mg iv of ^{3}H-β-methyldigoxin) using the appropriate pharmacokinetic parameters (Table II) showed that changes in the ratios, r, of the amounts in the peripheral compartment to the amounts in this new central compartment:

$$r = T''/(B + T + T') = T''/C \qquad \text{(Eq. 7)}$$

were relatively small, <7.5%, 1600 min after drug administration and that the semilogarithmic plot of plasma level, $[A_p{}^u]$, against time of slope $-\gamma$ was reasonably linear after that time.

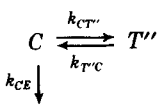
Thus, Eq. 7 for the expression of plasma level of β-methyldigoxin as a sum of exponentials can be reduced to two exponentials:

$$[A_p{}^u] = A'e^{-\alpha' t} + C'e^{-\gamma t} \qquad \text{(Eq. 8)}$$

where after 1600 min the term $A'e^{-\alpha' t}$ should become negligible. It was stated previously (34) that the final pseudo-steady state would be achieved for all practical purposes when, as applied to this case of β-methyldigoxin, the fractional contribution, $f_{\alpha'}$, of the α' term to the total plasma concentration of Eq. 8 is:

$$f_{\alpha'} = A'e^{-\alpha' t}/(A'e^{-\alpha' t} + C'e^{-\gamma t}) < 0.01 \qquad \text{(Eq. 9)}$$

The amounts of drug in the $C = B + T + T'$, T'', and $E = U + M$ compartment were generated on the analog computer for the four-compartment body model of Scheme III using the parameters listed in Table II for Subject B at the 633-μg dose (0.6 mg). The generated data were then fit by analog computation to the degenerated two-compartment body model (Scheme VI).



Scheme VI

The values of $k_{CT''} = 3.72 \times 10^{-5}\ sec^{-1}$, $k_{T''C} = 1.18 \times 10^{-5}\ sec^{-1}$, and $k_{C,E} = 2.85 \times 10^{-5}\ sec^{-1}$ fit the C, T'', and E compartments generated from the four-compartment body model of Scheme III excellently after 1600 min with the same terminal half-life of 42 hr. The ratios, r (Eq. 7), generated by the parameters of the two-compartment body model were definitely coincidental with those generated by the parameters of the four-compartment body model after 4000 min at 5.18; r was 5.17 compared to 5.10 at 2200 min and 5.10 compared to 4.90 at 1600 min for the two- and four-compartment body models, respectively. The $f_{\alpha'}$ was less than 0.01 (Eq. 9) subsequent to this 1600 min.

Valid estimates of the overall half-life of β-methyldigoxin must be based on satisfactory numbers of points adequately placed in time at least 1600 min or 27 hr after drug administration. This fact casts doubts on the validity of estimates of half-lives of all digoxin-type drugs based on plasma levels obtained within the 1st day after acute drug administration.

Effect of Renal Metabolism on Apparent Renal Clearances of a Drug and Its Metabolite—If a drug is metabolized by the liver *and* the kidney, the apparent renal clearances of both the drug and the metabolite are erroneous and the renal clearances of the metabolite derived from the administered drug and the metabolite administered *per se* differ significantly.

A model for both liver and kidney metabolism of β-methyldigoxin to digoxin from β-methyldigoxin content (B) in the central compartment is given in Scheme VII, where M_B is the amount of digoxin metabolite from hepatic metabolism, M_K is the amount of digoxin metabolite in the kidney that results from renal metabolism, and U_{DIG} and U'_{DIG} are the amounts of digoxin in the urine that result from the hepatic and renal processes, respectively. The area under a plasma level–time curve, AUC, can be related to the amount of drug provided to the body, D, and the total clearance, Cl_{tot}, of that drug provided that all elimination processes are first order (33). Thus, the AUC for digoxin on digoxin administration is:

$$AUC_{DIG} = D_{DIG}/(Cl_{tot})_{DIG} \qquad \text{(Eq. 10)}$$

where:

$$(Cl_{tot})_{DIG} = (Cl_{met})_{DIG} + (Cl_G)_{DIG} + (Cl_{ren})_{DIG} \qquad \text{(Eq. 11)}$$

and the amount of digoxin ultimately renally excreted, $(U_{DIG})_\infty$, from the amount in the body can be estimated from the fraction of the total clearance that is due to renal clearance:

$$(U_{DIG})_\infty = \frac{(Cl_{ren})_{DIG}}{(Cl_{tot})_{DIG}} D_{DIG} \qquad \text{(Eq. 12)}$$

Combination of Eqs. 10 and 12 gives:

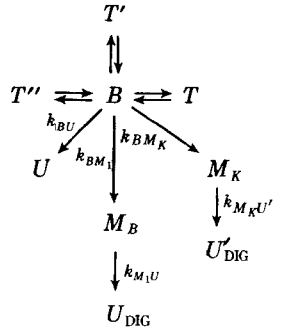
$$(U_{DIG})_\infty = (Cl_{ren})_{DIG}\, AUC_{DIG} \qquad \text{(Eq. 13)}$$

This equation also represents the amount of digoxin at infinite time appearing in the urine as a consequence of the renal clearance of digoxin produced by the hepatic metabolism of β-methyldigoxin.

Thus, the difference between the total digoxin excreted into the urine, $(U_{DIG})_{tot}$, and the value from Eq. 13 represents that amount of digoxin, $(U'_{DIG})_\infty$, that could be a product of renally metabolized β-methyldigoxin:

$$(U'_{DIG})_\infty = (U_{DIG})_{tot} - (U_{DIG})_\infty = (U_{DIG})_{tot} - (Cl_{ren})_{DIG} AUC_{DIG} \qquad \text{(Eq. 14)}$$

The ratio of the true renal clearance of β-methyldigoxin, $Cl_{true\ BMD}$, to its apparent renal clearance, $Cl_{app\ BMD}$, is equal to the ratio of the sum of the ultimate amount of β-methyldigoxin excreted in the urine, $(U_{BMD})_\infty$, and the ultimate amount of digoxin excreted in the urine that was formed from renal metabolism of the β-methyldigoxin filtered and secreted into the kidney, $(U'_{DIG})_\infty$, to the ultimate amount of β-methyl-



Scheme VII

digoxin excreted:

$$\frac{Cl_{true\ BMD}}{Cl_{app\ BMD}} = \frac{(U_{BMD})_\infty + (U_{DIG})_\infty}{(U_{BMD})_\infty} \quad \text{(Eq. 15)}$$

Thus, on consideration of Eqs. 14 and 15 with appropriate rearrangement:

$$Cl_{true\ BMD} = Cl_{app\ BMD}\left[\frac{(U_{BMD})_\infty + (U_{DIG})_{tot} - (Cl_{ren})_{DIG}AUC_{DIG}}{(U_{BMD})_\infty}\right] \quad \text{(Eq. 16)}$$

and if renal metabolism of β-methyldigoxin does exist, its true renal clearance can be calculated from the experimental values (Table III) of its apparent renal clearance, $Cl_{app\ BMD}$, appropriate values of the renal clearance of digoxin obtained on digoxin administration *per se*, $(Cl_{ren})_{DIG}$, and the area under the plasma digoxin level–time curve on intravenous β-methyldigoxin administration, AUC_{DIG}. The amounts of β-methyldigoxin and digoxin excreted into the urine at 144 hr on intravenous β-methyldigoxin administration were considered to be estimates of $(U_{BMD})_\infty$ and $(U_{DIG})_\infty$, respectively (Table III).

When the renal clearance of unbound digoxin, $(Cl_{ren})_{DIG}$, on digoxin administration was taken as 205 ml/min, close to the 222 value obtained in these studies and the average for all values on bolus and infusion digoxin administration given in the literature (27) after correction for protein binding, the calculated "true" renal clearance of β-methyldigoxin (Eq. 16) was equal to its apparent renal clearance, 56 ml/min. When $(Cl_{ren})_{DIG}$ was taken as 120 (26), 133 (25), and 163 (24) ml/min, the true renal clearances of β-methyldigoxin were 72, 70, and 64 ml/min, respectively, to suggest respective renal metabolisms of 16, 14, and 8 ml/min. Only if a true renal clearance for digoxin of 78 ml/min could be postulated would the true renal clearance of β-methyldigoxin be the same as this value.

Prediction of Tableting Problems such as Capping and Sticking: Theoretical Calculations

SHUN-ICHI NAITO *x, KEIJI MASUI *, and TAMOTSU SHIRAKI ‡

Abstract □ Tabletability factors were developed through the use of an automated tabletability tester, and the applicability of these factors to actual manufacturing procedures was tested by the large-scale manufacturing of tablets. Use of this approach does not require knowledge of the tablet's physical properties, *e.g.*, moisture content, porosity, particle size, fluidity, and angle of repose.

Keyphrases □ Tablet formulation—prediction factors developed, applied to manufacturing procedures □ Powdered materials—capacity for tablet formulation, prediction factors developed, applied to manufacturing procedures □ Dosage forms—tablets, formulation prediction factors developed, applied to manufacturing procedures

A tabletability tester, a device used to measure the passive pressure of a lower punch and the degree of binding between the punch face and the surface of a tablet (1), was previously proposed to predict the capacity of a powdered material to form a "good" or "bad" tablet. From the direct compression of common tablet ingredients (2) with a tabletability tester, four factors were found to be critical in the making of a good tablet: (*a*) the pressure of a loaded upper punch, (*b*) the passive pressure of a lower punch, (*c*) the force of the lower punch to extrude a tablet, and (*d*) the slipping force of the tablet surface.

The observed values of these four factors were difficult to reproduce due to the lack of consistency in manual determinations. Therefore, a fully automatic tabletability tester was developed to measure the four tabletability factors. The principles of the compression fixture and the sizes of the upper punches, lower punches, and dies are identical to those described previously (1, 2).

EXPERIMENTAL

Apparatus—The compression fixture used to determine the slipping force (*SF*), the passive pressure of the lower punch (*R*), the pressure of the loaded upper punch (*U*), and the force needed to extrude a tablet by the lower punch (*E*) were essentially the same as described previously (2), but the current fixture was automated by adding an electrical mechanism.

The values of *R*, *U*, and *E* were measured by using strain gauges[1] (type S-104, resistance 119.3Ω, gauge factor 1.92); *SF* was measured by using a U-gauge (type UT, capacity 1 kg, resistance 119.30Ω, gauge factor 1.92). The actual procedure of determining the slipping force was described previously (2), but the principle is as follows. When the upper plunger of the tablet machine strikes the head of the upper punch at a constant pressure and the striking is stopped, a split die is removed and the upper plunger is pulled out. The strain gauge is activated electrically and pushes the knob attached to the upper punch. The upper punch is supported by both a ball-bearing ring and a nonskid ring. Deformation of the strain gauge is recorded on a chart. Thus, the slipping force between the punch face and the tablet surface can be determined. The tablet held in the die does not rotate while the upper punch is rotated on the tablet surface. Presumably, the binding force between the tablet side and the die wall is larger than the slipping force because *E* is in kilograms and *SF* is in grams.

The cross section of the automatic tabletability tester is illustrated in Fig. 1. Since an important feature of the tester is the device used to measure the slipping force (2), a stereogram of this device is depicted in Fig. 2. Figure 2 clarifies the independent position of the upper punch (relative to the position) when the slipping force is measured.

Table I—Formulas of Materials Compressed into Test Tablets

Material	Composition
1	Mixture[a,b]
4	Calcium cellulose gluconate[c,d]
5	Magnesium oxide–aluminum oxide–silicon dioxide[e,f] (1:1:2)
6	Magnesium, oxide–aluminum oxide–silicon dioxide[g,f] (1:1:2)
10	Microcrystalline cellulose[h,i]
12	Dibasic calcium phosphate, anhydrous[j]
13	Dibasic calcium phosphate, anhydrous light[j]
14	Dibasic calcium phosphate, anhydrous, heavy[j]
15	Magnesium silicate, JP
19	Aluminum silicate, synthetic, JP
24	Aluminum hydroxide, anhydrous[j]
29	Aluminum hydroxide gel–magnesium hydroxide[j,l]
31	Dibasic calcium phosphate[j,m]
32	Magnesium oxide–aluminum oxide–silicon dioxide (1:1:2), neutral fine particles[f,n]
33	Magnesium oxide–aluminum oxide–silicon dioxide (1:1:2), fine particles[f,o]
34	Magnesium oxide–aluminum oxide–silicon dioxide (1:1:2), superfine particles[f,p]
39	Magnesium silicate[j]
40	Aluminum silicate, synthetic[j]
42	50% Lactose–19.5% potato starch–15% microcrystalline cellulose–15% synthetic aluminum silicate– 0.5% calcium stearate

Materials—The pharmaceutical materials were simple compounds or mixtures widely used as tablet additives in direct tableting (Table I). The materials and their numbers are identical to those used in previous experiments (2) so that the new data can be easily compared with data from the manual hand process.

A tablet hardness tester[2] was also used.

Calculations—When pressure is loaded on a powder housed in a cylinder (and the stress distribution due to the dead load of a powder itself is neglected), the vertical stress distribution in the powder layer may be shown by Eq. 1 as presented by Train and Lewis (3):

$$P/P_0 = \exp\left(-\frac{4\mu\beta h}{D}\right) \qquad \text{(Eq. 1)}$$

where P is the vertical load, h is the upper limit of the lower punch (the depth of the powder layer when compressed), D is the diameter of the cylinder, μ is the friction coefficient of the cylinder wall, β is the ratio of horizontal pressure to P, and P_0 is the loaded pressure at $h = 0$.

From Fig. 3*b*, the following equation can be derived using Eq. 1:

$$R/U = \exp\left(-\frac{4\mu'\beta'h'}{D}\right) \qquad \text{(Eq. 2)}$$

where:

$$\mu'\beta' = \frac{D(\ln U - \ln R)}{4h'} \qquad \text{(Eq. 3)}$$

and R is the passive pressure of the lower punch, U is the pressure of a loaded upper punch, and μ' and β' correspond to μ and β in Eq. 1 in the powder layer between the surfaces b and c.

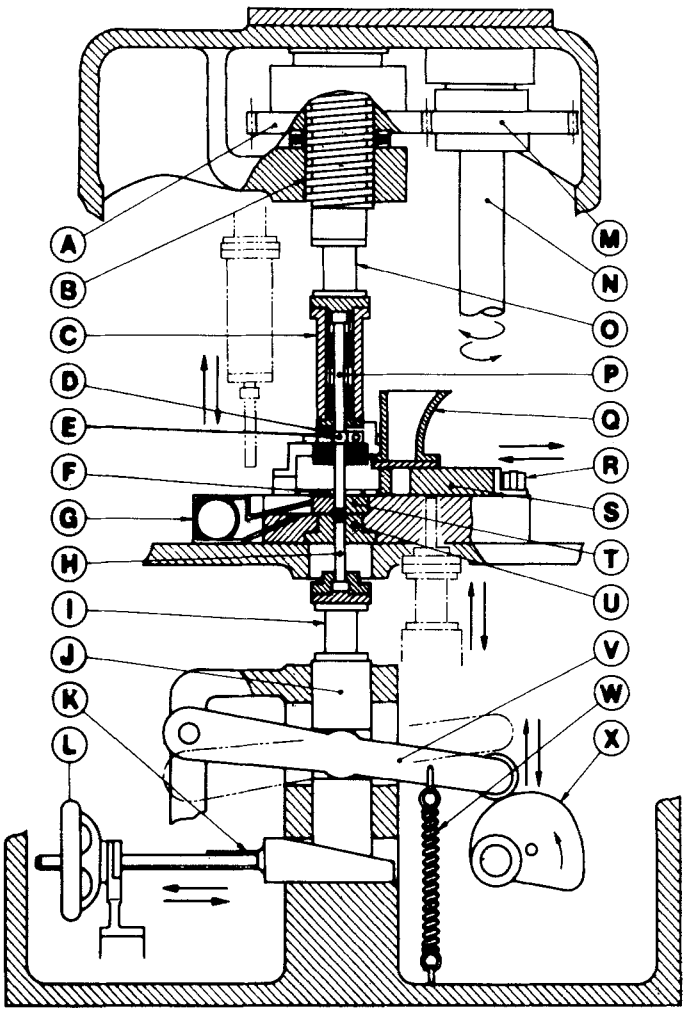

Figure 1—*Cross section of the main parts of the automatic tabletability tester. Key: A, pressure gear; B, piston; C, needle-bearing case; D, strain gauge for recording the slipping force; E, holder for the upper punch when the slipping force is measured; F, adjustment plate for the split die; G, exhaust pipe for the powder, H, lower punch; I, strain gauge for recording the force of the lower punch, J, adjustment liner for adjusting the filling depth of the powder; K, adjustment table for changing the filling depth of the powder; L, adjustment handle for controlling the quantity of the powder; M, vertical shaft gear; N, interlocker for upper punch; O, strain gauge for recording the force of the upper punch; P, upper punch; Q, hopper for powder; R, lever of feed-shoe; S, shuttle feed-shoe; T, split die; U, die base; V, push-up lever; W, spring for push-up lever; and X, push-up cam for the lower punch. The broken line illustrates a hypothetical scheme.*

Train and Lewis (3) stated that β does not show a constant value even in the same powder layer at different positions. However, if $\mu'\beta'$ is constant for the same powder in a range that is not yet known, the $\mu'\beta'$ obtained from Eq. 3 can be used for the calculation of U_1 and U_2 in Fig. 3c:

$$\ln U_1 = \ln U - \frac{4\mu'\beta' h_1}{D} \qquad \text{(Eq. 4)}$$

$$\ln U_2 = \ln R + \frac{4\mu'\beta' h_2}{D} \qquad \text{(Eq. 5)}$$

Adding Eqs. 4 and 5 yields:

$$\ln U_1 + \ln U_2 = \ln U + \ln R - \frac{4\mu'\beta'(h_1 - h_2)}{D} \qquad \text{(Eq. 6a)}$$

$$\ln U_1 U_2 = \ln UR - \frac{4\mu'\beta'(h_1 - h_2)}{D} \qquad \text{(Eq. 6b)}$$

when $h_1 = h_2$, $\ln U_1 U_2 = \ln UR$, and, logically, $U_1 = U_2$. Therefore, if $U_1 = U_2 = U_c$, the following simple relationships can be derived:

$$U_c^2 = UR \qquad \text{(Eq. 7a)}$$

$$U_c = \sqrt{UR} = K_V \qquad \text{(Eq. 7b)}$$

The pressure K_V obtained involves the pressure at the center layer of a formed tablet; K_V can be calculated without knowing the value of $\mu'\beta'$. Since K_V is concerned with vertical stress distribution, K_V should be called a "vertical factor."

In Fig. 3a, P is the pressure set mechanically at surface a. If the upper punch moves from surface a to surface b, P at surface a changes to U at surface b. Accordingly, $\mu\beta$ of a powder confined between surfaces a and b should differ from a powder confined between surfaces b and c. The former product is designated $\mu''\beta''$, and the latter is designated $\mu'\beta'$. Equations 8–12 are derived theoretically:

$$\ln U = \ln P - \frac{4h\mu''\beta''}{D} \qquad \text{(Eq. 8)}$$

$$\mu''\beta'' = \frac{D(\ln P - \ln U)}{4h} \qquad \text{(Eq. 9)}$$

$$\ln R = \ln U - \frac{4h'\mu'\beta'}{D} \qquad \text{(Eq. 10)}$$

$$\mu'\beta' = \frac{D(\ln U - \ln R)}{4h'} \qquad \text{(Eq. 11)}$$

$$\mu''\beta''/\mu'\beta' = \frac{h'(\ln P - \ln U)}{h(\ln U - \ln R)} = K_H \qquad \text{(Eq. 12)}$$

The value of K_H represents the horizontal stress distribution at the surface of a formed tablet. Since K_H is concerned with horizontal stress distribution, this value is termed a horizontal factor to contrast with K_V, the vertical factor.

It is of particular interest to ascertain whether the capacity of a material or a mixture to form a good or bad tablet (especially with respect to capping and/or sticking) could be manifested in either K_H or K_V. The ability of a powder to form a tablet is subject not only to vertical and horizontal pressure transmissions but also to the nature of the tablet surface and tablet hardness. Therefore, it is desirable to use the term "tabletability factors" for the prediction of tableting problems. This general term consists of K_H, K_V, SF (1), and tablet hardness. The significance of the surface factor is to predict the behavior of the surface

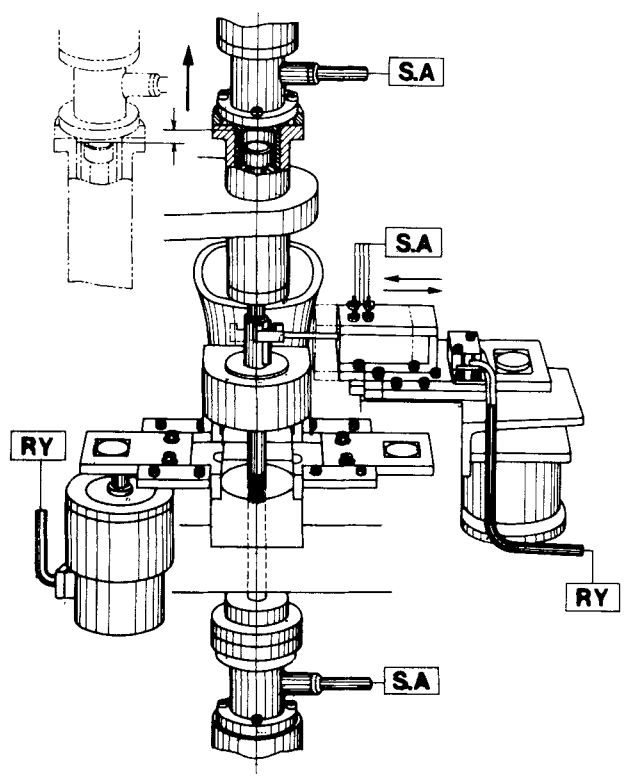

Figure 2—*Stereogram of the main parts for measuring slipping force. Key: S.A, strain amplifier; and RY, relay. The broken lines show a hypothetical scheme.*

[a] All values are the mean of five experiments ±SE. Material numbers are the same as given in a previous paper (2). R = passive pressure of the lower punch in kilograms, E = force to extrude a tablet from the lower punch in kilograms, U = pressure of the loaded upper punch in kilograms, SF = slipping force of the tablet surface in grams [first, second, and third observations (1)], and OS = off scale.

between the upper punch and the surface of a tablet when a powder is compressed. As mentioned earlier (1, 2), if major tableting problems are attributed to sticking, the differences between the first, second, and third observations of the surface factors and their standard errors are relatively large.

RESULTS AND DISCUSSION

The purpose of the present work was to discover what properties of a material contribute to the formation of a good or bad tablet without knowing the physical properties of the material (*e.g.*, moisture content, porosity, particle size, fluidity, and angle of repose), and other independent factors (*e.g.*, tablet thickness and tablet size).

Presumably, these results demonstrate that the capping and/or sticking tendency of a material during tableting could be predicted primarily from data from tabletability factors. The constant values established for the tabletability tester were P = 2000 kg, h = 15.5 mm, and D = 10 mm. The passive pressure data of the loaded upper punch are shown in Tables II and III. Data for tabletability factors are shown in Table IV.

Although the force applied to the lower punch to extrude a tablet is not included in the calculation for tabletability factors *per se*, this force may serve to provide some general guidelines concerning the operation of a tableting machine. An extremely low force may result in a tendency toward capping, and an extremely high force may cause physical damage to the machine from the high binding tendency. Empirically, it was found that when more than 500 kg of pressure was required to extrude tablets (at a die depth of 22 mm), the likelihood of some damage to the machine was high.

Although these studies were only preliminary, the results suggest that tabletability factors may prove to be useful for the prediction of some tableting problems. The following interpretations of the data obtained from this study are proposed.

Table III—Tabletability and Other Factors[a]

Material	K_V	K_H	TT	TH
		Filling Depth 18 mm

42	912	0.43	9.54	11.8

[a] All values are the mean of five experiments ±SE. Material numbers are the same as given in a previous paper (2). K_V = vertical factor; K_H = horizontal factor; TT = tablet thickness in millimeters; and TH = tablet hardness in kilograms, measured by a Monsanto tablet hardness tester.

Data in Tables II and III—Even though the poor fluidity of a material may have caused relatively large standard errors, comparisons of the present results with earlier data (2) show that the standard errors of observed values were diminished by using a fully automated tabletability tester instead of a manually operated one.

To compare the data, a standard material should be chosen and, ideally, its characteristics should take into account good compressibility, good formation, and the appearance of the tablet surface. Material 1 was selected as the standard since it came closest to meeting these criteria and included characteristics such as good lubricity and compressibility without apparent capping or sticking when incorporated as an excipient in a tablet. Material 1 consisted of a combination product whose formulation is a company trade secret. Hereafter, unless otherwise indicated, discussions of the data are based on a comparison between Material 1, the standard, and all other materials.

When the die whose filling depth (the lower limit of the lower punch) was 18 mm was used, only seven out of 19 materials gave complete data, *i.e.*, values for R as well as E and U. Materials for which only incomplete data could be obtained caused mechanical problems with the tabletability tester. For example, when Materials 19 and 39 were introduced, the force needed to extrude tablets by the lower punch registered zero. The reason for this reading was traced by observation to the fugacity of the powdered material outside of the die which flew about in all directions.

Another problem centered around the sticking tendencies of Materials 6, 13–15, 24, 31–34, and 42. An alarm bell was activated and the tester shut down automatically any time the pressure of the loaded upper punch exceeded 2500 kg. All of these materials caused a shut down at one time or another and made it impossible to obtain the mean of five consecutive and continuous tableting operations. The powders adhered heavily to the upper punch face, and the distance between the upper and lower punch faces was constantly lessened. Because of this phenomenon, the pressure of the loaded upper punch was increased during each successive operation, causing the alarm to ring and halting all operations and measurements. Since the reason for this occurrence was unknown, data for the dies with filling depths of 18 and 22 mm could not be used to predict tabletability.

However, the surface factor data obtained when using the die with a filling depth of 22 mm in a large-scale operation were better predictors of problems between the upper punch face and the tablet surface than the data obtained when using the other dies with filling depths of 18 and 26 mm. When slipping force is measured in the field to predict surface-sticking problems, a combination of high pressure and a die depth of 22 mm apparently is preferable to a combination of a more moderate pressure and a die depth of 26 mm. A powder that exhibited a very high surface factor, *i.e.*, an "off scale" powder or a powder that requires a force greater than the upper range of the instrument[3] (1), showed a strong tendency to stick to the face of the upper punch.

The fact that dies of different depths must be selected according to the directions of the forces or factors measured is an indication that when a powder is compressed, its various properties are changed and it no longer maintains the original physical relationships and proportions between those properties.

Table IV—Data obtained with a die depth of 26 mm showed no contradictions such as a negative value for K_H. To interpret the data, four assumptions were made:

1. An adequate value of the vertical factor, K_V, should exist for the formation of a good tablet from a powder. A material having a small K_V cannot be compressed into tablet form due to the poor transmittance of pressure.
2. An adequate value of the horizontal factor, K_H, should exist for the formation of a good tablet from a powder. Generally, the horizontal factor is considered to be the ratio of the compression stress of a powder occupying an upper space in a die (from surface a to b in Fig. 3*a*) to that of a powder occupying a lower space in a die (from surface b to c). Obviously, these two stress distributions must be different from each other. On the one hand, if a material has a relatively small K_H, the pressure of an upper punch can easily reach the surface of a tablet being compressed. However, if a material shows a large K_H, the pressure of an upper punch cannot reach the surface of a tablet effectively. An ideal K_H value is around 1.0.
3. The logical interrelationship between K_V and K_H is when: (*a*) K_V is large and K_H is small (capping would take place between the hard layer on the top and the tablet body below) and (*b*) K_V is small and K_H is large (capping would take place between the soft layer on the top surface of a tablet and its body) (Fig. 4).
4. The balance between the horizontal factor, K_H, and the vertical factor, K_V, can govern the tabletability of a powder. By definition, a good balance is reached when a powder could be compressed into a tablet with uniform compactness throughout its layers, but the numerical values of such a condition are still unknown. However, it should be possible to attain a numerical balance experimentally by repeated trials of many different kinds of materials and by a comparison of results from large-scale tablet manufacturing operations.

If these assumptions are applied, it is easier to understand the reasons for the capping problems encountered in industry. In addition, these assumptions indicate that a favorable balance of vertical and horizontal components in tableting is normally difficult to attain in large-scale production. It makes little difference if the values for K_H or K_V are large or small, as long as a suitable ratio or balance is maintained between the two components. This concept also takes into account the reality that, in a tableting operation, the production of acceptable thin tablets is easier than the production of acceptable thick ones.

34	11.34	9.0	298	1.46	OS	OS	OS
39	11.64	<2	514	0.62	128 ± 3	111 ± 5	107 ± 4
40	11.84	7.0	647	0.47	190 ± 3	178 ± 8	176 ± 9
42	11.74	3.2	305	1.62	68 ± 3	63 ± 3	62 ± 3

[a] All values are the mean of five experiments ±SE. TT = tablet thickness in millimeters (filling depth 26 mm), TH = tablet hardness in kilograms (filling depth 26 mm), K_V^{26} = vertical factor (filling depth 26 mm), K_H^{26} = horizontal factor (filling depth 26 mm), and SF^{22} = surface factor in grams (filling depth 22 mm).

In this discussion, the compressibility of a powder was based on the balance of the two factors during tableting. However, some materials rated high on the tabletability factor but could not be compressed into a tablet because of their poor binding characteristics. In these cases, results can be justified by measuring tablet hardness.

The substances used in the present experiment were primarily tablet additives. Therefore, few of the substances could be compressed to form good tablets in actual production practice[4]. The results of the experiment were categorized and analyzed as follows.

Material Compressed into Good Tablets by Using the Tabletability Tester, Not on a Large-Scale Manufacturing Basis (Table IV)—Material 1 was compressed to form a good tablet (tablet hardness = 8.2 kg). Materials 15 and 19 exhibited a K_V^{26} and K_H^{26} similar to those of Material 1, but the SF^{22} of Material 15 was "off scale" and could not be compressed into an acceptable tablet. Material 19 was compressed into a tablet (hardness ≅ 1.0 kg), but its SF^{22} was somewhat scattered.

Material 5 exhibited a small K_V^{26} and a large K_H^{26}, but it produced a good tablet. This result could be explained on the basis of Assumption 4; *i.e.*, it could have attained a suitable balance between K_V and K_H. Otherwise, Material 5, whose SF^{22} was off scale, showed a strong sticking tendency to the face of the upper punch and could not be compressed regularly into good tablets under regular production procedures.

The results with Material 24 were similar to those of Material 5. Material 24 could be made into good tablets by using the tabletability tester, for possibly the same reasons as with Material 5, but its SF^{22} was also off scale; it could not be compressed into good tablets under regular production conditions because of sticking and cracking. The reason for cracking may be due to the relatively smaller K_H^{26} value when compared to that of Material 5; the K_H of No. 24 was not strong enough to form a thicker, harder layer to prevent cracking.

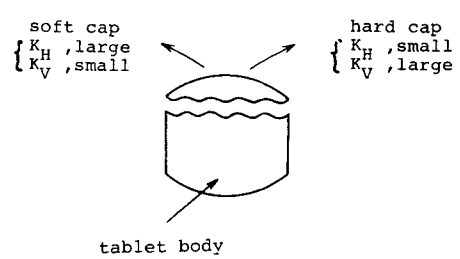

Figure 4—*Diagram of capping.*

[4] Tablet machine RT-S15-H, Kikusui Seisakusho Co., Kyoto, Japan. This machine had an 8-mm (5/16-in.) diameter standard-faced punch and die system, a tableting speed of 15 rpm, and an upper limit of the lower punch of 7.5 mm. When a powder was tabletable, about 30 kg of the powder was tableted continuously.

Material Compressed to Form Good Tablets on a Large-Scale Manufacturing Basis—Material 4 had a small K_H^{26} and a large K_V^{26} with a good balance between them. Although the SF^{22} of Material 4 was not measured, it was possible to make a good tablet, especially when relatively thin tablets were produced. The hardness of the tablets averaged about 7.8 kg (in actual tablet manufacturing).

Material 10 had a large K_H^{26} and a small K_V^{26}, but the balance between these factors allowed it to be compressed into a good tablet. The SF^{22} of Material 10 was somewhat scattered, and the lubricity of the tablet surface was poorer than others. The hardness of a tablet produced in actual tablet manufacturing was about 2.2 kg, but it was possible to make good tablets, especially when thin tablets were required.

Tableting problems arising from large-scale production procedures included the definite capping of tablets from Materials 6, 12–14, 29, 31, 33, 34, 39, 40, and 42. These materials exhibited K_H^{26} values that had both small and large variances from the ideal value of 1.0. Furthermore, there was strong adherence of Materials 5, 6, 12, 13, 15, 29, and 31–34 to the face of the upper punch after capping. All of these materials had an SF^{22} that was off scale. A creaking sound was also heard between the die and the lower punch when introducing Materials 14, 19, 24, 31, and 39. All of these materials required more than 500 kg of pressure to extrude the tablets.

The present investigation demonstrated the possibility of using tabletability factors to predict some tableting problems. It may be surmised that when a given powder sample exhibits a large K_V^{26}, it may be desirable to mix in a powder with a small K_V^{26} or K_H^{26}. Changes in K_V and K_H under these mixed powder conditions will be investigated at a later time.

In conclusion, it should be reiterated that the purposes of this study were to find a practical use for data obtained from a tabletability tester and to predict tableting problems. It was not intended to provide a detailed theoretical discussion of the data obtained. Further treatment of the theoretical considerations of the compression of powder-like materials can be found in Ref. 4. Although the present work was undertaken to obtain practical information from compression data, a major question still remains as to the final definition of the horizontal factor, since $\mu''\beta''$ in Eqs. 8 and 9 has no theoretical basis at all. The use of the horizontal factor seems to be helpful in predicting tableting problems when a powder is compressed into tablets in a large-scale operation instead of a tabletability tester. Therefore, further evaluation of this factor as a practical method for predicting tableting problems in a large-scale manufacturing procedure is still necessary.

Indolizine Derivatives with Biological Activity I: *N'*-Substituted Hydrazides of Indolizine-2-carboxylic Acid

MARIO CARDELLINI ˣ, FRANCESCO CLAUDI, MARIO GRIFANTINI, UGO GULINI, and SANTE MARTELLI

Abstract □ The synthesis and antimonoamine oxidase activity of some *N'*-substituted hydrazides of indolizine-2-carboxylic acid are described. They all inhibit monoamine oxidase and are more active than iproniazid. The structure–activity relationships also are discussed.

Keyphrases □ Indolizine-2-carboxylic acid hydrazides—synthesized, screened for effect on monoamine oxidase activity □ Hydrazides, *N'*-substituted—of indolizine-2-carboxylic acid synthesized, screened for effect on monoamine oxidase activity □ Monoamine oxidase activity—effect of various *N'*-substituted hydrazides of indolizine-2-carboxylic acid □ Structure–activity relationships—*N'*-substituted hydrazides of indolizine-2-carboxylic acid screened for effect on monoamine oxidase activity

Numerous *N'*-substituted hydrazides of indolecarboxylic acids have been synthesized in recent years as potential psychotherapeutic agents, and their inhibiting activity on monoamine oxidase has been tested *in vitro* (1, 2). The fundamental characteristic of such derivatives, some of which have proved to be intensely active, is the association in a single compound of a functional group with known antimonoamine oxidase activity, such as the hydrazide group, and the indole system. The indole system is present in various natural and synthetic compounds distinguished by psychotropic properties. The present paper reports the synthesis and study of the antimonoamine oxidase activity of a series of *N'*-substituted hydrazides of indolizine-2-carboxylic acid, which are analogs of the indole derivatives.

There are few literature reports on analogs of biologically active indole derivatives in which indole is replaced by indolizine. 1-Indolizinylalanine (3) has been prepared as a potential tryptophan antimetabolite; 1-indolizineacetic acid (4), an analog of 3-indoleacetic acid, has shown moderate auxinic activity; and numerous alkylindolizines (5), arylindolizines (6), and alkylaminoalkylindolizines (7, 8) have been synthesized and shown to influence the central nervous system.

Some 1-indolizineacetic acids (9, 10) possess analgesic and anti-inflammatory activity. Several indolizine analogs of indoxole (11, 12), a well-known anti-inflammatory agent, were synthesized recently.

CHEMISTRY

The *N'*-substituted hydrazides of indolizine-2-carboxylic acid (XV–XXVI) were synthesized according to Scheme I. On treatment with hydrazine hydrate, methyl indolizine-2-carboxylate (I), obtained by esterification of the corresponding acid (13) with methanol, gave indolizine-2-carboxylic acid hydrazide (II). The latter, by reaction with aldehydes and ketones, yielded the corresponding hydrazones, which were reduced with sodium borohydride.

It is not possible to perform the reduction of benzylidenehydrazide (IX) by this method. It was performed with lithium aluminum hydride or with hydrogen in the presence of palladium-on-charcoal and traces of acetic acid. At the end of each reduction, the IR spectrum of the product obtained indicated that the characteristic band of the C=N group of the initial hydrazones had disappeared.

EXPERIMENTAL[1]

Methyl Indolizine-2-carboxylate (I)—Indolizine-2-carboxylic acid (0.2 mole) (13) was added to 500 ml of methanol saturated with dry hydrogen chloride gas. The mixture was refluxed for 6 hr, and hydrogen chloride gas was bubbled through the solution. The solvent was then eliminated under vacuum, and the residue was extracted with hot *n*-hexane. Evaporation of the *n*-hexane gave a solid, which was crystallized from ethanol, yielding 80%, mp 96–97° [lit. (13) mp 97–99°].

Hydrazide of Indolizine-2-carboxylic Acid (II)—Hydrazine hydrate (85%) (1.06 moles) was added to a solution of 0.14 mole of I in 260 ml of methanol, and the mixture was refluxed for 6 hr. Cooling led to the precipitation of a solid which was washed with water and crystallized; IR (ν_{max}): 1660, 1620 (C=O), 3290, and 3200 (NH) cm^{-1} (Table I).

***N'*-Alkylidene- and *N'*-Arylalkylidenehydrazides of Indolizine-2-carboxylic Acid (III–XIV)**—The appropriate aldehyde or ketone (0.006 mole) was added to a solution of 0.005 mole of II in 40 ml of methanol. The mixture was stirred at room temperature or was heated for various times. With 3,4-methylenedioxybenzaldehyde and the ketones, the reaction was promoted by the addition of 0.005 mole of acetic acid. The products precipitated directly on cooling or by concentration of the solution and were subsequently crystallized; IR (ν_{max}): 3120–3390 (NH), 1630–1655 (C=O), and 1600–1630 (C=N) cm^{-1} (Table II).

***N'*-Alkyl- and *N'*-Arylalkylhydrazides of Indolizine-2-carboxylic Acid (XV–XXVI)**—With stirring at 0°, 0.020–0.10 mole of sodium borohydride was slowly added to 0.021 mole of one compound, III–XIV, dissolved in the minimum amount of solvent. At the end of the addition, the mixture was stirred for 5 hr and the solvent was evaporated under vacuum. The residue was treated with water and extracted with a suitable solvent. The organic solution was dried over sodium sulfate, and the solvent was eliminated under reduced pressure. The residue was crystallized; IR (ν_{max}): 3200–3290 (NH) and 1620–1660 (C=O) cm^{-1} (Table I).

***N'*-Benzylhydrazide of Indolizine-2-carboxylic Acid (XXI)**—*Method A*—The benzylidenehydrazide IX (0.0046 mole) in 50 ml of anhydrous tetrahydrofuran was added to a suspension of 0.021 mole of lithium aluminum hydride in 20 ml of anhydrous tetrahydrofuran. The mixture was refluxed for 2.5 hr and then stirred overnight at room temperature. Excess lithium aluminum hydride was destroyed with water-saturated ether. The mixture was filtered, the solvent was evaporated under vacuum, and the residue was crystallized.

Method B—A suspension of 0.0038 mole of IX in 200 ml of absolute ethanol and 30 ml of dioxane containing 0.1 g of 10% palladium-on-charcoal and a few drops of acetic acid was hydrogenated at 1.5 atm and 60°. When the theoretical amount of hydrogen had been consumed, the suspension was filtered while hot. The solvent was evaporated under vacuum, and the residue was crystallized, yielding 45%.

Hydrochlorides of *N'*-Alkyl- and *N'*-Arylalkylhydrazides of Indolizine-2-carboxylic Acid—Dry hydrochloric acid was bubbled through a solution of 0.005 mole of one of the hydrazides, XV–XXVI, in the minimum amount of absolute ethanol. The hydrochlorides precipitated directly or on the addition of anhydrous ether and were crystallized from absolute ethanol (Table I).

Antimonoamine Oxidase Activity *In Vitro*—The enzyme was prepared from pig plasma by a reported method (14). For the tests of

[1] Melting points were determined with a Büchi apparatus and are not corrected. IR spectra were taken in mineral oil using a Perkin-Elmer 257 spectrophotometer.

enzyme activity and inhibition, the protein extract derived from stage II (precipitation with 35–55% ammonium sulfate) was used. The monoamine oxidase activity of the enzyme, determined by the method of Zeller *et al.* (15), was followed at 253 nm[2] at 37° and pH 7.2, and the values of ΔE/min during the first 10 min of the reaction were calculated. The reaction mixture consisted of 40 μl of 4.29×10^{-3} *M* 3-iodobenzylamine, 20 μl of protein solution (1.6 mg), 1500 μl of 0.1 *M* sodium phosphate buffer (pH 7.2), and double-distilled water to a final volume of 2000 μl. The same reaction mixture not containing the substrate was used as the reference sample.

The inhibition tests were performed (15) using the described mixture and keeping the concentrations of the components and the final volume constant while varying only the inhibitor concentration, both in the reference solution and the test solution. The I_{50} values (inhibitor molar concentration producing 50% inhibition) were calculated graphically.

Some water-insoluble compounds were added to the reaction mixture in dioxane solution. The dioxane concentration in the reaction mixture was less than 3%. To determine the I_{50} values, the inhibition due to the dioxane was taken into account, since this solvent has a weak inhibiting effect on enzymatic activity. Compounds XV–XVIII were added to the reaction mixture as hydrochlorides, while the others were used in the form of the free bases dissolved in dioxane because of the low solubility of the hydrochlorides in the aqueous solution and in dioxane.

RESULTS AND DISCUSSION

All tested compounds proved to be about three to 58 times more active than iproniazid in the inhibition of monoamine oxidase (Table I). In addition, their activity was distinctly greater than that of the corresponding hydrazides of indole-2-carboxylic and indole-3-carboxylic acids tested on an enzyme from calf liver with iproniazid as the standard. Hence, the displacement of the nitrogen from the 1-position of the indole to the bridge 4-position of indolizine leads, at least in the cases studied, to an enhancement of activity.

The unsubstituted hydrazide was most active. In general, the activity was greater in the series containing arylalkyl groups on the *N'*-nitrogen of the hydrazide chain than in the series with simple alkyl chains.

In the first series, one of the most active compounds was the benzyl derivative (XXI). Compounds XXII and XXIII, with a methyl substituent on the benzyl methylene group or on the benzene ring, were less active than the parent compound; XXVI, with a methylbenzodioxole substituent, was more active. The α-methyl- and α-ethyl-β-phenylethyl homologs (XXIV and XXV) were also more active than the α-methylbenzyl derivative (XXII).

In the second series, the activity decreased with an increase in the length of the chain (XV–XVII). However, with the same number of carbon atoms, branching (XVII *versus* XVIII) and replacement of the alkyl group by the corresponding cycloalkyl group (XIX *versus* XX) appeared to have a positive influence.

Synthesis and Anticancer Screening of 2-Indolyl 5-(1,2,3,6-Tetrahydropyridyl) Ketones

RICHARD J. SUNDBERG ˣ, D. EUGENE REARICK, and HENRY F. RUSSELL

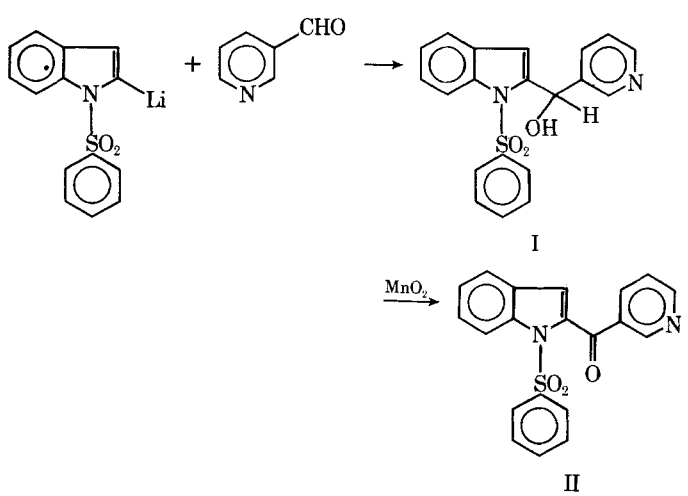
Abstract □ Several derivatives of 2-indolyl 5-(1,2,3,6-tetrahydropyridyl) ketone with various substituents on the pyridine nitrogen and with or without a benzenesulfonyl group on the indole nitrogen were synthesized and characterized by spectroscopic and analytical data. Only one showed erratic but confirmed activity in the P-388 screen. The other derivatives were inactive in the L-1210 leukemia screen.

Keyphrases □ 2-Indolyl 5-pyridyl ketone derivatives—synthesized, screened for cytotoxic activity □ Cytotoxic activity—various 2-indolyl 5-pyridyl ketone derivatives screened □ Structure–activity relationships—various 2-indolyl 5-pyridyl ketone derivatives screened for cytotoxic activity

An intermediate from a program to prepare biologically active indole derivatives submitted for anticancer screening was 1-benzenesulfonyl-2-indolyl 5-[1,2,3,6-tetrahydro-1-(2-oxo-2-ethoxyethyl)pyridyl] ketone (IV*a*). Since this compound showed erratic but confirmed activity in the mouse P-388 leukemia screen, several analogs were prepared.

DISCUSSION

The starting material for each compound was 1-benzenesulfonyl-2-indolyl 5-pyridyl ketone (II), which is obtained efficiently in two steps from 1-benzenesulfonyl-2-lithioindole (1) (Scheme I). Alkylation of II with alkyl bromides followed by catalytic reduction gives analogs of IV with various substituents at the pyridine nitrogen. The partial reduction of 3-acylpyridines is a well-documented procedure that owes its success to the resistance to reduction of the residual vinylogous amide unit (2). Analogs lacking the 1-benzenesulfonyl substituent were prepared by hydrolytic cleavage of the 1-benzenesulfonyl substituent from I prior to alkylation (1). The yields in the alkylation step were good in each case. The yields in the reduction step were lower and are given in Table I.



Scheme I

PMR, UV, and mass spectral data were indicative of the assigned structures. The PMR and UV data are given in Table II. All tetrahydropyridines exhibited a characteristic set of two broadened triplets at δ 2.5 ± 0.2 and 3.2 ± 0.1, attributable to the C-4 and C-2 methylene groups, respectively. The C-3 methylene signal appeared as a broader multiplet at about 2 ppm. There is some uncertainty about the assignment of the vinyl proton at C-6. It probably appears as the signal at 6.2–6.8 ppm observed in each spectrum. An alternative assignment for this peak would be the indole 3-proton, but this proton usually is found in the aromatic multiplet when the indole ring carries a carbonyl substituent as in the present case.

The only chemical complication noted in the preparation of these compounds was in the reduction of III*d*. Concomitant reduction of the ketone group in the *N*-phenacyl substituent occurred, giving the carbinol (IV*e*). The reduction products were usually contaminated with unidentified colored impurities and were best purified by preliminary chromatography on silica gel followed by crystallization. Some products had the troublesome property of forming nonstoichiometric solvates, but satisfactory analyses were obtained by drying at the melting point immediately prior to combustion analysis. The pyridinium salts were also troublesome in this regard and tended to form methanol solvates. Analytical data are given in Table III.

No analog of IV*a* showed significant activity. Compounds I, II, III*h*, IV*c*, and IV*e*–IV*g* were inactive in the L-1210 mouse leukemia screen in the 100–400-mg/kg dose range. Compound IV*b* was inactive in the P-388 leukemia screen, and III*g* and IV*c* showed no cytotoxicity in KB cell culture.

EXPERIMENTAL

Alkylations—The pyridyl ketone and a slight excess (~10%) of the appropriate halide were dissolved in acetonitrile (~2 ml/mmole) and

[a] For absolute ethanol solutions; the wavelengths (in nanometers) of maxima or distinct shoulders (sh) and absorptivities are given. [b] For deuterochloroform solutions~50 mg/ml; chemical shifts are relative to the internal standard, tetramethylsilane, and coupling constants are given in hertz.

heated to reflux overnight under nitrogen. The pyridinium salts precipitated and were isolated by filtration. With III*f*, addition of ether was necessary to effect precipitation. The salts were recrystallized from methanol.

Reductions—The pyridinium salts were suspended or dissolved in ethanol. For the unsubstituted indoles, about 2 mmoles of triethylamine was added per millimole of pyridinium salt. A palladium-on-carbon catalyst was used, and the reductions were carried out at atmospheric pressure, usually overnight. The solutions were filtered and evaporated to dryness. The residue was dissolved in chloroform, and the solution was washed with aqueous sodium bicarbonate solution. The solvent was then evaporated, and the residue was chromatographed on silica gel using chloroform containing 0.5% methanol for elution. Pure fractions were combined and crystallized from chloroform or ethyl acetate.

Rapid Determination of Nitroglycerin Volatility Using Thermogravimetric Analysis

H. GUCLUYILDIZ ˣ, F. W. GOODHART, and F. C. NINGER

Abstract □ The effect of selected tablet components on the volatility of nitroglycerin from compressed sublingual tablets was studied by thermogravimetric analysis. The results, confirmed by chemical analyses, showed that nitroglycerin volatility is significantly reduced by the use of povidone USP and microcrystalline cellulose NF in tablet formulations. In general, the stabilizing effect of these materials was dependent on the presence and the concentration of each other. These studies demonstrated the utility of thermogravimetric analysis as a rapid and reliable means of screening nitroglycerin formulations for stability purposes.

Keyphrases □ Nitroglycerin—volatility, effect of various tablet components, thermogravimetric determination □ Volatility—nitroglycerin, effect of various tablet components, thermogravimetric determination □ Thermogravimetry—determination, effect of various tablet components on nitroglycerin volatility □ Tablets—nitroglycerin, effect of various tablet components on volatility, thermogravimetric determination □ Vasodilators, coronary—nitroglycerin, volatility, effect of various tablet components, thermogravimetric determination

In recent years considerable attention has been focused on nitroglycerin stability. Several investigators have conducted extensive research to improve the volatility and, thus, content uniformity of nitroglycerin tablets (1–9). It is now well established that nitroglycerin stability can best be improved by reformulation of conventional molded tablets rather than by modifications in packaging materials. One approach toward this end has been the inclusion of various macromolecular substances in tablet formulations (3–7, 9).

From the experimental standpoint, the dependency of nitroglycerin stability in tablet formulations has been studied using extreme conditions of storage, *i.e.*, completely exposing the tablets to air or to high vacuum, followed by chemical analysis of individual tablets. While studies of this type are of fundamental value in development work, they are generally time consuming when a large number of formulations is investigated.

Therefore, as an alternative procedure, thermogravimetric analysis was explored for its utility in screening various nitroglycerin formulations. It was found that thermogravimetric analysis affords a rapid and reliable means of evaluating the influence of various tablet components on the volatility of nitroglycerin. This report describes preliminary studies which ultimately led to the development of a stabilized compressed nitroglycerin tablet (9).

EXPERIMENTAL

Tablet Preparation—Nitroglycerin tablets, containing 0.6 mg of drug in each 30-mg tablet, were prepared using nitroglycerin spirit (9.1% w/v), alcohol USP, lactose (anhydrous) USP, starch USP, microcrystalline cellulose[1] NF, and calcium stearate NF. The diluent mixture was granulated with a solution or dispersion of a binder in nitroglycerin spirit and alcohol USP. When necessary, a small amount of water was employed to aid dispersion of the binder.

Ethylcellulose[2], povidone USP[3], hydroxypropyl methylcellulose[4], and gelatin USP were used as binders and were added to each formulation at a ratio of 1:2 with respect to nitroglycerin. The amount of starch was maintained constant (25%) while, in later experiments, microcrystalline cellulose and povidone were included at various levels to determine the stabilizing effects of these materials. The wet granulated product after drying at 30–35° was mixed with the lubricant and compressed into 0.40-cm tablets.

Thermogravimetric Studies—The volatility of nitroglycerin from tablets was studied by following the change in sample weight as a function of time under isothermal conditions. Two tablets representing each formulation were placed into the pan of the thermogravimetric analyzer[5] previously equilibrated at the desired temperature. The instrument was operated at a sensitivity of 0.2 mg/2.54 cm (1 in.). A stream of nitrogen gas was passed through the furnace containing the sample at a constant flow rate of 20 ml/min to remove the gaseous products evolved during the experiment.

Generally, after 1.5 hr of treatment at 80°, sufficient weight loss was observed for comparison of relative stability. However, in later experiments, it was necessary to extend the tests over 4 hr to permit adequate opportunity for volatilization of nitroglycerin.

Nitroglycerin Assay—To compare and confirm the volatility of nitroglycerin by thermogravimetric analysis, samples of each formulation were subjected to individual tablet assay before and after the thermogravimetric analysis treatment using the spectrophotometric method of Bell (10).

RESULTS AND DISCUSSION

The results of nitroglycerin volatility from various tablet formulations are summarized in Fig. 1 and Table I. Figure 1 depicts typical thermograms, which are of two general types. The first type, represented by curves A and B, shows linearity over the entire thermogram. These linear thermograms correspond to formulations prepared from anhydrous materials, so the weight loss observed can be totally attributed to the volatility of nitroglycerin.

The second type (curves C–G and placebo) is characterized by a sudden change in sample weight during the initial stage of the experiment but later exhibits the same general linearity as the first type. These thermograms are associated with tablets prepared from excipients containing water, *e.g.*, starch. It can be seen from Fig. 1 that the placebo tablets containing lactose and starch exhibited a similar pattern of weight loss in the first 10 min of the thermogravimetric analysis.

In duplicate determinations, the initial portions of the thermograms exhibited slight variations in the amount of weight loss, apparently due to minor differences in the water content of different samples, but reproducibility was excellent for the remaining linear portions of the curves. From these results, it can be assumed that the initial weight loss is almost entirely due to the evaporation of water and, for practical purposes, can be omitted from consideration. Therefore, the volatility of nitroglycerin is taken as the loss in sample weight after the first 10 min of the thermogravimetric analysis.

From the data in Table I, it can be seen that nitroglycerin volatility in different formulations as determined by thermogravimetric analysis showed an acceptable level of agreement with chemical assay results. Table I also shows that tablets containing povidone had a significant reduction in the loss of nitroglycerin. Formulations containing gelatin, on the other hand, exhibited similar stability as the tablets containing no binder. The addition of hydroxypropyl methylcellulose or ethylcellulose caused some improvement in tablet stability but not to a significant extent.

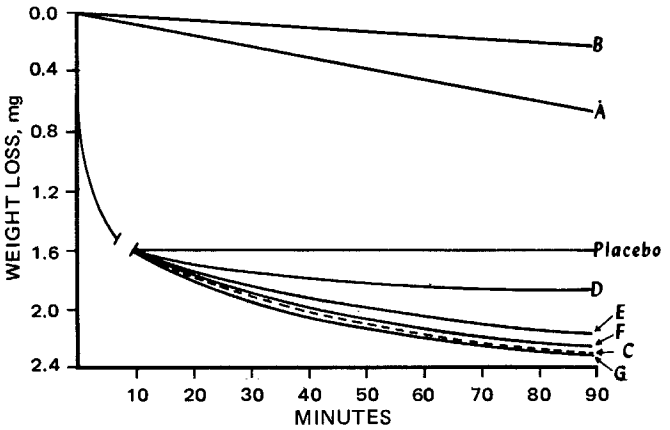

Figure 1—*Typical thermograms of nitroglycerin tablets containing various binders. See Table I for details.*

These preliminary experiments prompted the use of povidone as a stabilizing agent in the formulation of a compressed sublingual nitroglycerin tablet. Additional stability screening experiments were then designed to examine further the effect of various concentration ratios of povidone along with an additional stabilizer, *i.e.*, microcrystalline cellulose (11).

Figure 2 summarizes the volatility of nitroglycerin tablets prepared with three different concentrations of microcrystalline cellulose and povidone at various ratios with respect to nitroglycerin. The samples were subjected to thermogravimetric analysis at 80° for 4 hr. This figure illustrates the stabilizing effect of povidone and shows that better nitroglycerin stability was achieved as the level of povidone was increased in each formulation. This result can best be seen with formulations containing no microcrystalline cellulose, where addition of povidone at a 1:4 ratio resulted in a retention of 86% of the original potency during the test period as compared to 10% for tablets without povidone. The retention of nitroglycerin content in formulations prepared with 50% microcrystalline cellulose was also increased from 81 to 92% by inclusion of povidone at a 1:4 ratio.

Figure 2 also demonstrates the effect of microcrystalline cellulose in reducing the volatility of nitroglycerin. Since this material possesses

Table I—Comparison of Thermogravimetric and Chemical Analyses for the Volatility of Nitroglycerin Tablets

Formulation		Nitroglycerin Remaining, %	
Designation	Composition[a]	Thermogravimetric Method	Chemical Method
A	Lactose	54	51
B	Lactose, povidone	84	83
C	Lactose, starch	25	23
D	Lactose, starch, povidone	84	82
E	Lactose, starch, hydroxypropyl methylcellulose	45	42
F	Lactose, starch, ethylcellulose	34	30
G	Lactose, starch, gelatin	25	22

[a] Each tablet also contained 0.6 mg of nitroglycerin.

excellent compression characteristics, judicious selection of its concentration along with that of povidone allows the formulation of compressed nitroglycerin tablets with optimum stability as well as disintegration and bioavailability properties (9).

The studies reported here clearly show the utility of thermogravimetric analysis as a simple, rapid, and reliable means to investigate the volatility of nitroglycerin formulations. This method also permits the selection of accelerated test conditions which can be controlled precisely. The volatility of nitroglycerin can be studied from one or two tablets, thereby eliminating the migration of the drug from tablet to tablet during accelerated stability studies. By the use of thermogravimetric analysis, potentially stable formulations can be selected in a short period; and, finally, by the use of thermogravimetric analysis at various temperatures, the kinetics of nitroglycerin volatility from tablets may be studied.

Bioavailability of Digoxin in a New Soluble Pharmaceutical Formulation in Capsules

P. GHIRARDI ˣ, G. CATENAZZO *, O. MANTERO *, G. C. MEROTTI, and A. MARZO

Abstract □ The *in vitro* dissolution and the bioavailability of two pharmaceutical formulations of digoxin were compared, one being a common commercial tablet form and the other a solution of the glycoside in soft gelatin capsules. Digoxin capsules dissolved more readily *in vitro* and showed higher bioavailability than digoxin tablets in both dogs and humans. In dogs, the capsules and tablets were compared with an elixir of digoxin, which possesses complete bioavailability. The better bioavailability of digoxin capsules as compared with tablets may be explained by the fact that this formulation contains the cardiac glycoside in a solution.

Keyphrases □ Digoxin—*in vitro* dissolution and bioavailability, commercial tablets and soft gelatin capsules, dogs and humans □ Dissolution, *in vitro*—digoxin, commercial tablets and soft gelatin capsules compared □ Bioavailability—digoxin, commercial tablets and soft gelatin capsules compared, dogs and humans □ Cardiotonic agents—digoxin, *in vitro* dissolution and bioavailability, commercial tablets and soft gelatin capsules compared, dogs and humans □ Dosage forms—digoxin tablets and soft gelatin capsules, *in vitro* dissolution and bioavailability, dogs and humans

Several investigators (1–8) have reported marked differences in the bioavailability of digoxin tablets among different products of the glycoside or different batches of the same product. In addition, a lack of digoxin content uniformity was observed in the same tablet preparations, varying from 28 to 148% (9). To control this problem, the Food and Drug Administration standardized an analytical monitoring program (10) to ensure that individual tablets of digoxin do not differ significantly in glycoside content.

The best bioavailability of digoxin is achieved when the glycoside is administered in a solution or in the form of an elixir (11, 12). This paper reports a comparative study of the composition, *in vitro* dissolution, and bioavailability in dogs and humans of two pharmaceutical formulations of digoxin, a commercial tablet[1] and soft gelatin capsules containing the glycoside in a dissolved form[2].

EXPERIMENTAL

Digoxin Tablets and Capsules—Both capsules and tablets contained 250 μg of the glycoside and were from the same batch. The capsules also contained 1.500 mg of *N,N*-dimethylacetamide and 139.250 mg of polyethylene glycol 400.

Tablets and capsules were assayed for glycoside content according to Italian F.U. 1972 (13). The capsules contained 102% ± 0.35 (*SE*) of glycoside; this value is marginally higher than the 97% ± 0.35 (*SE*) found in the tablets.

Dissolution Rate—The dissolution rate of both tablets and capsules of digoxin was investigated *in vitro* according to the "paddle water" (distilled water) and "paddle acid" [0.6% (v/v) HCl] methods (14). Five hundred milliliters of distilled water or 0.6% HCl and a digoxin tablet or capsule were placed in a 1000-ml flask, thermostated at 37°, and stirred at 50 ± 2 rpm. After 15 or 60 min, a sample was taken from the flask. Digoxin was extracted and determined by the spectrophotofluorometric method. Evaluation of dissolution rates was made using the Student *t* test for independent data (Table I).

Bioavailability in Dogs—Four mongrel dogs, 16–18 kg, received the digoxin tablets during a single trial, followed 10 days later by the capsules and 10 days later by a digoxin elixir.

All dogs received 250 μg of the glycoside in each of the three formulations. The digoxin elixir contained 50 μg/ml of the glycoside in propylene glycol–95% ethanol–water [10:2.5:112.5 (v/v/v)]. Venous blood samples were taken from each dog at 0, 7.5, 15, 30, 45, 60, 90, 120, and 240 min. Plasma digoxin levels were determined by the radioimmunoassay method of Smith *et al.* (15)[3].

The statistical comparison of results was processed using an analysis of variance for all three preparations, followed by a Tukey test for specific pairs (Table II).

Bioavailability in Humans—The investigation was carried out on six healthy volunteers (58–82 kg and 36–70 years of age). Each subject received two digoxin capsules (500 μg) and two digoxin tablets (500 μg). The two administrations were carried out with a crossover design at an interval of 10 days.

The statistical comparison of capsules and tablets was made using the Student *t* test for paired observations.

Venous blood samples were taken from each patient at 0, 15, 30, 45, 60, 120, and 240 min. Plasma digoxin levels were determined as described previously.

Blood samples in both dogs and human subjects were taken over 4 hr, on the basis of reported observations (16–18). These reports concluded that areas under the plasma level–time curves (*AUC*) correlate well for the first 5 hr with areas obtained after longer sampling times, indicating that extended sampling may not be necessary for digoxin studies.

RESULTS

With the paddle water method, both digoxin tablets and capsules dissolved almost entirely in 15 min. Standard errors with digoxin tablets were two to three times higher than with digoxin capsules. With the paddle acid method, the degree of dissolution of digoxin tablets after 15 min was about 70% of the values obtained in the same time with capsules ($p < 0.001$); after 60 min, both the capsules and tablets dissolved almost entirely and to a similar degree (Table I).

In the dog, the digoxin solution showed the best bioavailability in terms of plasma levels of the glycoside, followed by the capsules and tablets (Table II). Average peak times were the earliest (22 min) with the solution, followed by the capsules (45 min) and tablets (52 min). A difference of $p < 0.05$ existed between the solution and capsules, and a difference of $p < 0.01$ existed between the solution and tablets. A comparison between the capsules and tablets gave a statistically insignificant p value. Peak concentrations were highest with the solution, followed by the capsules and tablets. For the solution–tablet comparison, $p < 0.01$; tablet–capsule and solution–capsule comparisons did not give any statistically significant p value.

The area under the plasma level–time curve, evaluated by the trapezoidal rule from 0 to 240 min, showed the highest value with the solution, followed by the capsules and tablets. A statistical comparison gave the following values: solution–capsules and solution–tablets, $p < 0.01$. Tablet–capsule comparisons did not give a statistically significant p. The differences found in bioavailability between the capsules and solution of digoxin might be explained in part by the much higher concentration in the capsules than in the solution.

In human subjects, the best bioavailability was found with the capsules, which is in accord with previous findings with dogs. The peak times were longer with the tablets than with the capsules ($p > 0.05$), the peak con-

centration was higher with the capsules (4.5 ng/ml) than with the tablets (2.2 ng/ml) ($p < 0.02$), and the *AUC* was higher with the capsules than the tablets ($p < 0.05$) (Table III).

DISCUSSION

The area under the plasma level–time curve is a useful parameter and allows the relative bioavailability of the oral formulation of a drug to be evaluated as a percentage related to an intravenous or oral solution of the same drug.

According to this method, several investigators (16, 17, 19) obtained a relative bioavailability of the tablets (of the same commercial type as those investigated here) of around 56–58%, assuming 100% values after intravenous solution, and of around 70%, assuming 100% values after oral solution.

From these data on the dog, it is possible to calculate a relative bioavailability of 56.5% for capsules and 44% for tablets. These values are a little lower than those obtained previously (16, 17, 19). However, dogs may absorb digoxin at a different rate from humans. In effect, the mean peak time with capsules was 45 min in dogs and 72 min in humans; with tablets, it was 52 min in dogs and 95 min in humans. For human subjects, all three parameters (peak plasma concentration, peak time, and *AUC*) agree with the data on the dog concerning the better bioavailability with the capsules than with the tablets.

Table III—Peak Plasma Concentration, Peak Time, and *AUC* in Six Human Volunteers after Administration of Digoxin Capsules (500 μg) and Digoxin Tablets (500 μg)

	Peak Plasma Concentration, ng/ml		Peak Time, min		*AUC*, ng/ml/min

p[a]	<0.02		>0.05		<0.05	

[a] Evaluated with the Student t test for paired observations.

The problem of drug bioavailability as a whole is serious. Digoxin possesses an unfavorable therapeutic index, which requires optimum absorption from an oral pharmaceutical preparation. A digoxin product with poor or incomplete absorption could cause a poor or incomplete effect on myocardial contractility. However, it is undesirable to adjust dosage of an incompletely absorbed digoxin product because it may be associated with individual variability in enteral absorption related principally to the GI transit rate. It is also undesirable to adjust dosage in patients being treated with other drugs (*e.g.*, metoclopramide) (20). None of the digoxin tablet preparations available possesses total bioavailability, as does the solution or elixir (11, 12). The preparation of digoxin in soft gelatin capsules, containing a solution of the drug, dissolved faster *in vitro* and possessed better bioavailability in the dog and human subjects than did the preparation in tablets.

Some clinical trials (21–23) showed an earlier, more intense, and longer lasting effect with digoxin capsules than with tablets in terms of heart rate and polycardiographic measurements in both healthy subjects and in patients suffering from heart failure, thus confirming the greater efficacy of the capsules.

These data, obtained from both human subjects and dogs, agree with the recent results of Mallis *et al.* (24). They found better bioavailability with a digoxin solution in capsules than with tablets in human subjects. The results of this investigation also demonstrate that dogs are a valid model for testing experimental digoxin formulations.

Cardiovascular and Neuromuscular Effects of Dimethyl Sulfoxide in Anesthetized Rabbits

FLOYD R. DOMER [x], DAVID M. CHIHAL, and H. CECIL CHARLES

Abstract □ In rabbits anesthetized with pentobarbital, the carotid arterial blood pressure and bilateral contractions of the gastrocnemius muscles due to electrical stimulation of the sciatic nerves were recorded. Intravenous administration of up to 1 ml of dimethyl sulfoxide/kg caused profound hypotension and eventually failure of neuromuscular transmission. Caution must be used in considering dimethyl sulfoxide as a solvent for drug administration.

Keyphrases □ Dimethyl sulfoxide—intravenous administration, cardiovascular and neuromuscular effects, anesthetized rabbits □ Toxicity—dimethyl sulfoxide, intravenous administration, anesthetized rabbits □ Cardiovascular system—effects of intravenous administration of dimethyl sulfoxide, anesthetized rabbits □ Nerve impulse transmission—effects of intravenous administration of dimethyl sulfoxide, anesthetized rabbits

Previous reports demonstrated that dimethyl sulfoxide (I) has blocking activity at the neuromuscular junction *in vitro*. These studies ranged from depression of the guinea pig phrenic nerve diaphragm (1) to partial reversal of tubocurarine blockade in the frog sartorius nerve-muscle preparation (2) to a shift in the dose–response curve with acetylcholine in the chicken biventer cervicis muscular preparation (3). *In vivo* reports of the effects of I include the slow infusion of a 40% solution intravenously in unanesthetized rabbits; this dose (19.2 g/kg) resulted in a 12-mm Hg rise in arterial blood pressure and then bradycardia, which continued until death at 92 min (4). In unanesthetized cats, the LD_{50} for I was approximately 4 g/kg (5), but it was less than 0.4 g/kg in anesthetized cats (6). These findings imply that central nervous system (CNS) depression would have an appreciable effect on the toxicity caused by I.

EXPERIMENTAL

The present experiments were occasioned by the need to have a solvent for some bisquaternary ammonium water-insoluble compounds. Since the compounds were found to have sufficient solubility in I, its effect in one biological preparation to be used for the evaluation of the activity of the bisquaternary compounds was studied.

Albino rabbits, 2.2–2.5 kg, were anesthetized with pentobarbital sodium, 30 mg/kg, administered into the marginal ear vein. The right carotid artery and jugular vein were cannulated to permit the recording of the blood pressure *via* a pressure transducer and the administration of drugs, respectively. The trachea was cannulated, and the respiratory activity was monitored with a transducer connected to a polygraph. The sciatic nerve of each leg was cut proximally, and the distal stump was placed on an electrode connected to a stimulator. The Achilles tendon was cut at its insertion and attached to a transducer. The right leg was stimulated with supramaximal voltage at 1 Hz, and the left leg was stimulated at 0.1 Hz. Doses of I, 0.1, 0.5, and 1.0 ml/kg iv, were given.

RESULTS AND DISCUSSION

The lowest dose caused the diastolic blood pressure to decrease initially about 25 mm Hg. It returned to the control level within 25 min. There was an associated decrease of 50% in the force of contraction of the leg being stimulated at the faster rate. There was no appreciable change in the response occurring on the side being stimulated at the slower rate or in respiration.

When the 0.5-ml/kg dose of I was administered, there was a rapid decrease of 55 mm Hg in diastolic pressure, which returned to the control level within 1 min. Subsequently, there was a second decrease of 35 mm Hg in pressure, which was maximal at 3 min and returned to the control

Cardiovascular and Neuromuscular Effects of Dimethyl Sulfoxide in Anesthetized Rabbits

FLOYD R. DOMER [x], DAVID M. CHIHAL, and H. CECIL CHARLES

Abstract □ In rabbits anesthetized with pentobarbital, the carotid arterial blood pressure and bilateral contractions of the gastrocnemius muscles due to electrical stimulation of the sciatic nerves were recorded. Intravenous administration of up to 1 ml of dimethyl sulfoxide/kg caused profound hypotension and eventually failure of neuromuscular transmission. Caution must be used in considering dimethyl sulfoxide as a solvent for drug administration.

Keyphrases □ Dimethyl sulfoxide—intravenous administration, cardiovascular and neuromuscular effects, anesthetized rabbits □ Toxicity—dimethyl sulfoxide, intravenous administration, anesthetized rabbits □ Cardiovascular system—effects of intravenous administration of dimethyl sulfoxide, anesthetized rabbits □ Nerve impulse transmission—effects of intravenous administration of dimethyl sulfoxide, anesthetized rabbits

Previous reports demonstrated that dimethyl sulfoxide (I) has blocking activity at the neuromuscular junction *in vitro*. These studies ranged from depression of the guinea pig phrenic nerve diaphragm (1) to partial reversal of tubocurarine blockade in the frog sartorius nerve-muscle preparation (2) to a shift in the dose–response curve with acetylcholine in the chicken biventer cervicis muscular preparation (3). *In vivo* reports of the effects of I include the slow infusion of a 40% solution intravenously in unanesthetized rabbits; this dose (19.2 g/kg) resulted in a 12-mm Hg rise in arterial blood pressure and then bradycardia, which continued until death at 92 min (4). In unanesthetized cats, the LD_{50} for I was approximately 4 g/kg (5), but it was less than 0.4 g/kg in anesthetized cats (6). These findings imply that central nervous system (CNS) depression would have an appreciable effect on the toxicity caused by I.

EXPERIMENTAL

The present experiments were occasioned by the need to have a solvent for some bisquaternary ammonium water-insoluble compounds. Since the compounds were found to have sufficient solubility in I, its effect in one biological preparation to be used for the evaluation of the activity of the bisquaternary compounds was studied.

Albino rabbits, 2.2–2.5 kg, were anesthetized with pentobarbital sodium, 30 mg/kg, administered into the marginal ear vein. The right carotid artery and jugular vein were cannulated to permit the recording of the blood pressure *via* a pressure transducer and the administration of drugs, respectively. The trachea was cannulated, and the respiratory activity was monitored with a transducer connected to a polygraph. The sciatic nerve of each leg was cut proximally, and the distal stump was placed on an electrode connected to a stimulator. The Achilles tendon was cut at its insertion and attached to a transducer. The right leg was stimulated with supramaximal voltage at 1 Hz, and the left leg was stimulated at 0.1 Hz. Doses of I, 0.1, 0.5, and 1.0 ml/kg iv, were given.

RESULTS AND DISCUSSION

The lowest dose caused the diastolic blood pressure to decrease initially about 25 mm Hg. It returned to the control level within 25 min. There was an associated decrease of 50% in the force of contraction of the leg being stimulated at the faster rate. There was no appreciable change in the response occurring on the side being stimulated at the slower rate or in respiration.

When the 0.5-ml/kg dose of I was administered, there was a rapid decrease of 55 mm Hg in diastolic pressure, which returned to the control level within 1 min. Subsequently, there was a second decrease of 35 mm Hg in pressure, which was maximal at 3 min and returned to the control

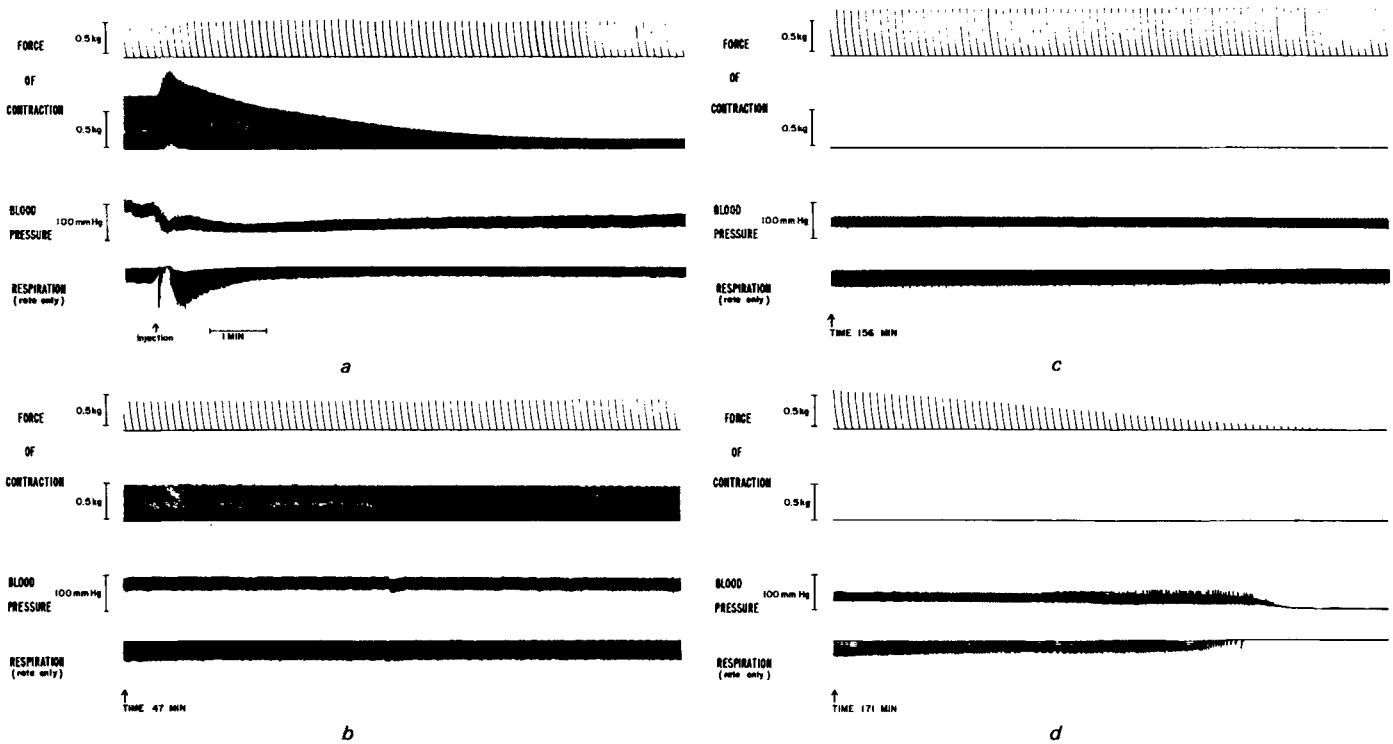

Figure 1—*Effect of dimethyl sulfoxide (1 ml/kg) on force of contraction, blood pressure, and respiration rate in anesthetized rabbits.*

level at 22 min. The leg being stimulated at the faster rate exhibited a 3–7% decrease in the force of contraction during the 1st min. After returning to the control intensity of contraction, there was a secondary decrease to a maximum of 31% at 6 min, which returned to the control level at about the same time as the blood pressure.

When the 1.0-ml/kg dose was administered, there was a rapid decrease of 55 mm Hg in diastolic pressure (Fig. 1*a*) during the 1st min. At 47 min (Fig. 1*b*), the blood pressure was still 20 mm Hg less than it had been prior to the injection. Thereafter, the blood pressure decreased progressively and the animal died at 179 min. The neuromuscular activity was initially decreased 83% at about 10 min. Subsequently, the force of contraction returned to 70% of control at 47 min (Fig. 1*b*). A secondary blockade developed, which became 100% by 156 min (Fig. 1*c*). The animal died 23 min later (Fig. 1*d*).

The profound effects upon the cardiovascular system are in agreement with a recent report (7) indicating that I caused a profound negative chronotropic effect. The effect on the force of myocardial contraction was variable and was thought to be dependent upon the efficiency of filling of the ventricles prior to each beat. The profound, sustained hypotension may have embarrassed the neuromuscular function too.

The fact that such profound effects were found in anesthetized rabbits with a total dose of 1.6 ml/kg of I is rather striking when compared to the infused dose of 19.2 g/kg required to kill unanesthetized rabbits (4). A similar enhancing effect of anesthesia on toxicity of I was found in cats (5, 6). This finding indicates that CNS depression caused by general anesthetics potentiates the toxic effects of I.

These results characterize the profound effects of I on both the cardiovascular and neuromuscular systems of the rabbit. They severely restrict its possible utility as a solvent for *in vivo* studies of poorly water-soluble compounds.

Biological Disposition of Rigid Analogs of Amphetamine

RAY W. FULLER[x], JOHN C. BAKER, and BRYAN B. MOLLOY

Abstract □ Tissue levels of amphetamine and of amphetamine analogs with a rigid conformation (2-aminoindan, 2-aminotetralin, and 2-aminobenzocycloheptene) were measured in rats by a spectrofluorometric method involving the reaction of the primary amine group with fluorescamine. All drugs were concentrated in tissues, the order of distribution being lungs > kidneys > liver = spleen = brain > muscle > fat = heart > blood. In brain, amphetamine and 2-aminoindan were present mostly in the supernatant fraction after high speed centrifugation of brain homogenates; the two higher molecular weight drugs were present at slightly greater concentrations in the particulate fraction. All four drugs disappeared from rat brain with half-lives of 1–2 hr. Iprindole pretreatment increased drug levels in brain and prolonged the half-lives by two- to threefold. The data suggest that the biological disposition of the rigid analogs resembles generally that of amphetamine and that all of the drugs are probably metabolized by ring hydroxylation in the rat.

Keyphrases □ Amphetamine and analogs—with rigid conformation, biological disposition, spectrofluorometric analysis in rat tissues, effect of pretreatment with iprindole □ Distribution, biological—amphetamine and analogs with rigid conformation, spectrofluorometric analysis in rat tissues, effect of pretreatment with iprindole □ Spectrofluorometry—analysis, amphetamine and analogs with rigid conformation, rat tissues □ Iprindole—pretreatment, effect on biological disposition of amphetamine and analogs with rigid conformations, rats □ Stimulants, central—amphetamine and analogs with rigid conformation, biological disposition, rats

Among drugs acting on the central nervous system, amphetamine has been one of the most widely investigated. Numerous structural derivatives of amphetamine have been synthesized and studied, including amphetamine analogs having a rigid conformation due to a bridge between the α-carbon and the ring. For instance, hydroxylated and methoxylated 2-aminotetralins have been of interest because of their relationship to psychotomimetic drugs such as mescaline (1, 2). 2-Aminoindans and 2-aminotetralins have been evaluated as potential antiparkinsonism drugs based on their structural similarity to dopamine (3, 4). Effects of these rigid analogs on monoamine metabolism *in vivo* and on monoamine oxidase *in vitro* have been reported (5, 6).

This paper deals with three rigid analogs of amphetamine (I), in which the α-carbon is connected to the *ortho*-position of the ring directly (2-aminoindan, II) or through one (2-aminotetralin, III) or two (2-aminobenzocycloheptene, IV) methylene units. Much is known about the metabolism and biological disposition of amphetamine in various animal species. This study compares some fundamental pharmacokinetic parameters of these rigid analogs of amphetamine in rats, including their levels in tissues and rates of disappearance from brain.

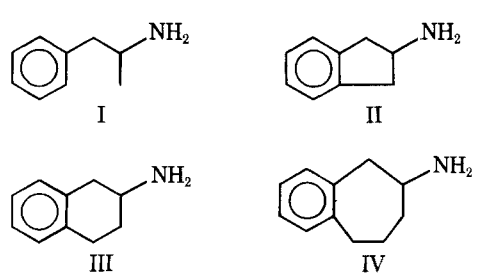

Table I—Subcellular Distribution of Amphetamine and Rigid Analogs in Rat Brain[a]

Drug	Drug Level in Brain, nmoles/g: Particulate (P)	Supernate (S)	Ratio, P/S
I	44 ± 7	75 ± 7	0.6
II	51 ± 1	90 ± 3	0.6
III	67 ± 1	62 ± 5	1.1
IV	61 ± 7	49 ± 2	1.2

[a] Drugs were injected at 0.1 mmole/kg ip 1 hr before the rats were killed. Brain homogenates (in 2.5 m*M* sucrose) were centrifuged for 30 min at 100,000×*g*. Drug levels were measured both in particulate and supernatant fractions.

EXPERIMENTAL

dl-Amphetamine hemisulfate was used as purchased[1]. The derivatives of amphetamine were synthesized[2] as hydrochloride or hemisulfate salts. All were racemic mixtures. The drugs were injected intraperitoneally in aqueous solution into male Wistar rats[3] weighing about 150 g. The rats were maintained in a room with controlled lighting and temperature and with food and water available *ad libitum*. After they were treated with drugs, the rats were killed by decapitation. Tissues were quickly removed and frozen on dry ice and then stored frozen prior to analysis.

Drug levels were measured spectrofluorometrically[4] by a previously described method (7) after extraction and reaction with fluorescamine. All data are expressed as mean values with standard errors for five rats per group. Comparisons between groups were made by the Student *t* test.

RESULTS AND DISCUSSION

The three rigid analogs of amphetamine reacted with fluorescamine to form fluorophores with characteristics similar to those of the fluorophore produced by amphetamine, *i.e.*, with maximum excitation at 390 nm and maximum emission at 490 nm. Standard curves over a 30–90-nmoles/ml concentration range established fluorescent intensity to be linearly proportional to concentration. The standard curves were similar for all four amines, so reaction with fluorescamine provided a sensitive means for assaying tissue levels of these drugs.

Figure 1 shows the distribution of the drugs in various tissues 1 hr after injection of equimolar doses. All compounds were highly concentrated in tissues, with blood levels of the drugs (not shown) being very low (about half of the levels shown for heart). The general pattern of tissue distribution was similar for the four drugs. For instance, drug levels in lung were higher in all cases than in any other tissue. Drug levels in skeletal muscle were low, and drug levels in epididymal fat and heart were even lower for all four drugs.

Some differences in relative drug levels were noticed in the remaining tissues. Compound II was present in most tissues at higher levels than amphetamine or the other derivatives with a rigid conformation. Levels of all rigid analogs tended to be higher in brain than those of amphetamine. Levels of III and IV were at least as high in brain as in liver or spleen. The ratio of drug levels in brain–skeletal muscle progressively increased with size of the drug molecule (1.3 for I, 2.0 for II, 3.2 for III, and 3.9 for IV). These differences suggest that the larger bicyclic compounds have a greater relative affinity for brain than does amphetamine.

The subcellular distribution of the drugs in brain homogenates subjected to centrifugation at 100,000×*g* is shown in Table I. As reported

Table II—Drug Levels and Half-Lives of Rigid Analogs of Amphetamine in Brains of Control Rats and Rats Treated with Iprindole to Inhibit Aromatic Hydroxylation

Drug	Iprindole	Drug Level in Brain, nmoles/g				Half-Life, hr
		1 hr	2 hr	3 hr	4 hr	
I	–	84 ± 6	49 ± 10	39 ± 4	18 ± 3	1.4
	+	109 ± 9[a]	103 ± 9[a]	83 ± 8[a]	65 ± 5[a]	3.9[a]
II	–	148 ± 6	110 ± 7	78 ± 6	44 ± 6	1.7
	+	136 ± 4	111 ± 3	91 ± 6	73 ± 4[a]	3.3[a]
III	–	120 ± 7	69 ± 8	52 ± 8	25 ± 4	1.3
	+	133 ± 9	103 ± 7[a]	87 ± 5[a]	71 ± 3[a]	3.6[a]
IV	–	100 ± 7	55 ± 4	26 ± 4	16 ± 5	1.0
	+	120 ± 7	89 ± 2[a]	78 ± 3[a]	81 ± 3[a]	3.3[a]

[a] Significant difference from corresponding group without iprindole, $p < 0.05$. Drugs were injected at zero time at a dose of 0.1 mmole/kg ip; some rats had been pretreated 1 hr earlier with iprindole (10 mg/kg ip).

previously (8), about two-thirds of the amphetamine (I) in brain was recovered in the supernatant fraction. The same distribution was found for II, but III and IV were present in the particulate fraction at slightly higher concentrations than in the supernatant fraction. This distribution may reflect, at least in part, the lipophilic character of the drug molecule, since halogenated derivatives of amphetamine have high particulate–supernatant ratios (8).

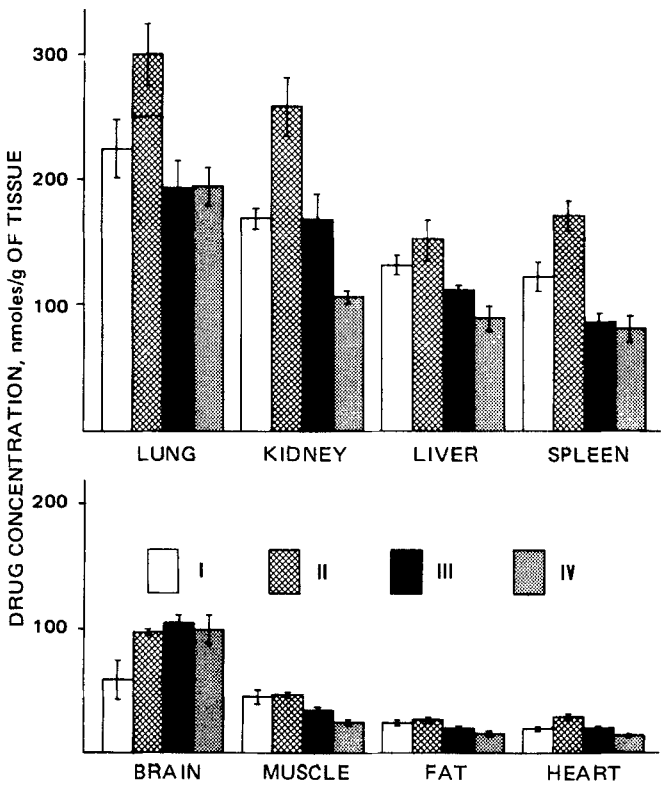

Figure 1—*Tissue distribution of amphetamine and rigid analogs in various organs of the rat. Drugs were injected at 0.1 mmole/kg ip 1 hr before the rats were killed.*

Drug levels in brain at four different times are shown in Table II. From semilogarithmic plots of drug levels *versus* time, half-life values of all four drugs were calculated to be between 1 and 2 hr. In rats pretreated with iprindole, an inhibitor of the aromatic hydroxylation of amphetamine (9), half-lives were increased two- to threefold. This finding constitutes indirect evidence that all of these drugs are metabolized by aromatic hydroxylation in the rat.

Rapid Acetylation of a Dihydroxy Compound by 4-(Dimethylamino)pyridine Catalysis: Application to GLC Determination of Clindamycin Palmitate Hydrochloride

ENGLEBERT L. ROWE ˣ **and SUSAN M. MACHKOVECH** *

Abstract □ The acetylation of clindamycin palmitate hydrochloride, preparatory to GLC assay, was accelerated greatly by the use of 4-(dimethylamino)pyridine as a catalyst. The reaction time was reduced from 2.5 hr at 100° using pyridine and acetic anhydride to 30 min or less at ambient temperature upon addition of excess catalyst.

Keyphrases □ Clindamycin palmitate hydrochloride—GLC analysis after acetylation catalyzed by 4-(dimethylamino)pyridine □ 4-(Dimethylamino)pyridine—catalyst for acetylation of clindamycin palmitate hydrochloride preparatory to GLC assay □ GLC—analysis, clindamycin palmitate hydrochloride, after acetylation catalyzed by 4-(dimethylamino)pyridine □ Dihydroxy compounds—clindamycin palmitate hydrochloride, GLC analysis after acetylation catalyzed by 4-(dimethylamino)pyridine □ Antibacterials—clindamycin palmitate hydrochloride, GLC analysis after acetylation catalyzed by 4-(dimethylamino)pyridine

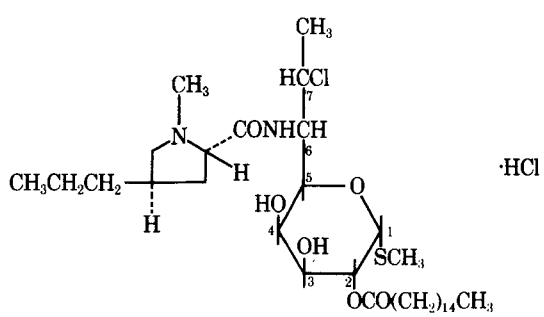
The acetylation of clindamycin palmitate hydrochloride (I) for GLC assay is catalyzed by the use of pyridine, which also acts as a solvent for the reaction (1). Pyridine forms an intermediate with acetic anhydride, acetylpyridinium ion (2), which then reacts with the hydroxyl groups at the 3- and 4-positions of clindamycin palmitate hydrochloride. The reaction requires 2.5 hr at 100° for completion.

4-(Dimethylamino)pyridine (II) recently was reported to be a much better catalyst than pyridine for various acylations (2, 3). The present study compares the rate of acetylation of I in pyridine in both the presence and absence of II.

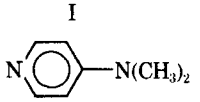
EXPERIMENTAL

Materials—All materials were analytical reagent grade.

GLC Conditions—A gas chromatograph[1] equipped with a flame-ionization detector and an electronic integrator[2] was used. The glass U-shaped column, 3 mm × 60 cm, was packed with 1% SE-54 on Gas Chrom Q (100–120 mesh). The column was conditioned for 1 week at 295° under low helium flow. The operating temperatures were: column, 275°; detector, 290°; and flash heater, off. Helium was used as the carrier gas at about 60 ml/min. One microliter of sample was injected, and the attenuation was adjusted to give peak heights averaging about 50% of the chart heights.



I



II

Internal Standard Solution—A solution of trilaurin in chloroform was used at a concentration of 5 mg/ml.

Procedure—About 75 mg of I was accurately weighed and dissolved in 5 ml of double-distilled water. One milliliter of 30% sodium carbonate solution and 5 ml of internal standard were added, and the solution was shaken vigorously for 10 min and centrifuged to form distinct layers. The aqueous layer was aspirated off, and 1-ml portions of the chloroform layer were transferred to 15-ml centrifuge tubes. One milliliter of acetic anhydride and 1 ml of pyridine were added to the tubes, and the tubes were stoppered and allowed to react at the appropriate temperature.

In the standard method, the reaction was carried out in an oven at 95° and sampled at various intervals. In the modified method, II was dissolved in pyridine at a concentration of 15 mg/ml. One milliliter of this solution (instead of pure pyridine) was used for the acylation medium. The tubes were held at ambient temperature (23–26°) and sampled for GLC injection at various times.

RESULTS AND DISCUSSION

The progress of acetylation of I using II as a catalyst at room temperature is compared to the pyridine-catalyzed reaction at 95° in Fig. 1. The GLC peak for diacetylated I becomes sharper as the reaction progresses. The disappearing peak on the tailing edge of the main peak is the 3-monoacetate ester of I. It was reported (4) that the 3-hydroxy group is the least sterically hindered hydroxyl group in the lincomycin[3] molecule

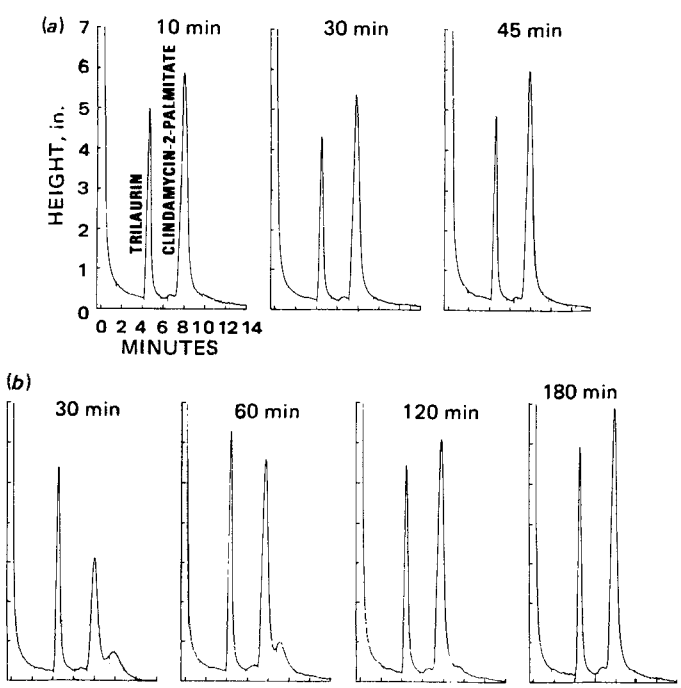


Figure 1—*Gas chromatograms illustrating the acetylation of I. Key: a, 4-(dimethylamino)pyridine added to pyridine, reaction at room temperature; and b, pyridine alone, reaction at 95°.*

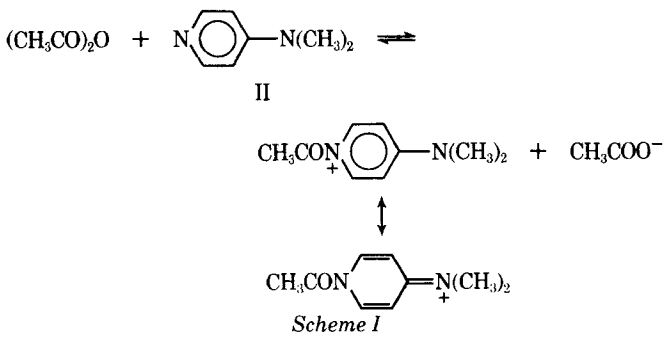
[1] F & M model 402.

[2] Infotronics model CRS-104.

[3] Clindamycin is the 7-deoxy-7-(*S*)-chloro analog of lincomycin.



Scheme I

and, therefore, the most reactive. The 4-hydroxy group reacts more slowly and is the controlling factor in the diacetylation of I. The shoulder on the leading edge, always present even in highly purified lots of I, is the acetate esters of clindamycin B-2-palmitate (the 4′-ethyl analog of I) and clindamycin 3-palmitate, as indicated by Brown (1). In practice, this latter peak is not integrated with the main peak.

The acetylation reaction, using II as a catalyst, was virtually complete within 30 min at ambient temperature (Fig. 1*a*). In the absence of II, the reaction was not complete until well after 2 hr at 95° (Fig. 1*b*).

The quantitative GLC data are given in Table I. Clearly, the two procedures differed considerably in their reaction rates. Even after 26 hr, the peak area ratio for the II-catalyzed reaction was still at the plateau value without significant change.

The complete acetylation of I is a two-step reaction as already described. Acetylation of the more labile 3-hydroxy group is fast, so the reaction is controlled primarily by the second acetylation of the 4-hydroxy group. The rate of reaction is dependent on the concentrations of I, II, pyridine, and acetic anhydride. Since the latter three reagents are present in large excess compared to I, they can be considered constant. Therefore, the reaction can be approximated by the simple first-order expression:

$$-\frac{d[I]}{dt} = k_{obs}[I] \qquad \text{(Eq. 1)}$$

In integrated form, expressing concentration in percent:

$$\log \frac{100[I]}{[I_0]} = \log 100 - k_{obs}t \qquad \text{(Eq. 2)}$$

where $[I_0]$ is the initial concentration of I, and [I] is the concentration at time t.

In Fig. 2, the data are plotted according to Eq. 2. The slopes differ by a factor of about nine. In other words, even with a temperature difference of 70°, the room temperature reaction using II as a catalyst was about nine times faster than the pyridine-catalyzed reaction at 95°. If the temperatures were equal, the differences would be several orders of magnitude. Connors and Albert (2) found that the rate constant using II was 2×10^4 greater than that of the corresponding pyridine-catalyzed acetylation of 2-propanol at 54°.

The intercepts from least-squares regression analysis of the data are considerably less than 100%, as can be seen from Fig. 2. This result is due to the stepwise nature of the acetylation, which is better represented by two consecutive first-order reactions rather than by a single first-order reaction. If sufficient early time points were available, it would be apparent that there is a steep slope initially which would intersect the y-axis at about 100%.

The mechanism of the catalytic action of pyridine involves formation of an intermediate with acetic anhydride. The acetylpyridinium ion then undergoes nucleophilic attack by the hydroxy group. There is spectroscopic evidence that the acetylpyridinium ion has a very small stability constant because its presence is almost undetectable (5). Connors and Albert (2) suggested that the intermediate formed by II has enhanced stability due to the resonance forms made possible by the dimethylamino group (Scheme I).

The modified assay was applied to other 2-acyl esters of clindamycin ranging in chain length from 10 to 18 carbon atoms. The reaction rates were about equal to the palmitate, requiring no more than 30 min at ambient temperature in any case. Compound II should prove to be a versatile catalyst for acylation of other hydroxy compounds being prepared for GLC analysis.

Tissue Distribution of ^{3}H-Canrenoate Potassium in Rabbits

A. MICHAELS FINN, R. BROWN, and W. SADÉE ˣ

Abstract □ Plasma and various organ concentrations of canrenone, canrenoate, and total ^{3}H-activity were measured following single doses of 20 mg of ^{3}H-canrenoate/kg iv to rabbits. Organs studied included heart, lungs, brain, kidneys, liver, adrenal glands, and spleen. Canrenoate was shown to be in rapid equilibrium with canrenone. Both were eliminated from plasma and other tissues with a half-life of about 1 hr. Plasma concentrations of both drugs were equal as early as 10 min after intravenous drug administration. Canrenone was concentrated about 10-fold in organ tissues when compared to plasma, while no such preferential uptake was found with canrenoate. Total ^{3}H-activity declined slowly in all tissues with a half-life of approximately 15 hr, indicating extensive metabolism and metabolite retention in the rabbit.

Keyphrases □ Canrenoate potassium—tissue distribution and metabolism, radiochemical study, rabbits □ Distribution, tissue—canrenoate potassium, radiochemical study, rabbits □ Metabolism—canrenoate potassium, radiochemical study, rabbits □ Radiochemistry—study of tissue distribution and metabolism, canrenoate potassium, rabbits □ Aldosterone antagonists—canrenoate potassium, tissue distribution and metabolism, radiochemical study, rabbits

The antimineralocorticoid compounds spironolactone[1] (I) and canrenoate potassium (III) are useful diuretic agents (1). Spironolactone is rapidly metabolized *via* a 7α-thiol derivative (2) to canrenone (II), a major metabolite, which exists in enzymatic equilibrium with III (Scheme I). The pharmacokinetics of I–III were investigated in rats (3), dogs (4), and humans (5, 6). Data on the kinetic disposition and further metabolism of II and III are scant (2, 7). Large differences between the tissue distribution of the lipophilic II and the water-soluble III can be expected and should be considered in the interpretation of plasma II and III levels. In this study, the tissue distribution of III potassium was investigated in rabbits.

EXPERIMENTAL

Chemicals—Pure crystalline samples of I and III were used[2], and II was prepared from III as previously described (8). ^{3}H-Canrenoate potassium[3], with a specific activity of 860 μCi/mg, was purified by solvent extraction (8) and TLC[4] in dichloromethane–methanol (8:2) prior to use. All reagents and chemicals were spectroquality.

Analytical Procedures—The fluorometric determination of II and III was performed as described previously (9). This method was specific for II and III in the presence of all other metabolites of III (8). Tritium measurements were performed by liquid scintillation counting as described previously (8). Efficiency was measured by the channels ratio method.

Rabbit Protocols—*Serial Blood Sampling*—Female New Zealand White rabbits, 2–2.5 kg, were used. Each rabbit was prepared for blood sampling by insertion of a polyethylene 50 catheter about 4 cm into an ear artery. Doses of 5, 10, and 20 mg of III/kg in aqueous solution were given by venous injections into the opposite ear. Blood samples of 2 ml each were taken with heparinized syringes at appropriate time intervals and centrifuged, and the plasma was frozen for subsequent analysis.

Tissue Analysis—Doses of 20 mg of ^{3}H-III/kg, with a specific activity of 0.2–0.5 μCi/mg, were given intravenously into an ear vein. Rabbits were sacrificed by decapitation at the following times after drug administration: 5, 10, 20, 30, 60, and 90 min and 2, 4, 8, 16, and 32 hr. One animal was used per time interval, with the exception of the 2-hr experiments where three animals were used.

Blood was collected by exsanguination from the abdominal aorta. The heart, lungs, brain, kidneys, liver, adrenal glands, and spleen were re-

Tissue Distribution of ^{3}H-Canrenoate Potassium in Rabbits

A. MICHAELS FINN, R. BROWN, and W. SADÉE ˣ

Abstract □ Plasma and various organ concentrations of canrenone, canrenoate, and total ^{3}H-activity were measured following single doses of 20 mg of ^{3}H-canrenoate/kg iv to rabbits. Organs studied included heart, lungs, brain, kidneys, liver, adrenal glands, and spleen. Canrenoate was shown to be in rapid equilibrium with canrenone. Both were eliminated from plasma and other tissues with a half-life of about 1 hr. Plasma concentrations of both drugs were equal as early as 10 min after intravenous drug administration. Canrenone was concentrated about 10-fold in organ tissues when compared to plasma, while no such preferential uptake was found with canrenoate. Total ^{3}H-activity declined slowly in all tissues with a half-life of approximately 15 hr, indicating extensive metabolism and metabolite retention in the rabbit.

Keyphrases □ Canrenoate potassium—tissue distribution and metabolism, radiochemical study, rabbits □ Distribution, tissue—canrenoate potassium, radiochemical study, rabbits □ Metabolism—canrenoate potassium, radiochemical study, rabbits □ Radiochemistry—study of tissue distribution and metabolism, canrenoate potassium, rabbits □ Aldosterone antagonists—canrenoate potassium, tissue distribution and metabolism, radiochemical study, rabbits

The antimineralocorticoid compounds spironolactone[1] (I) and canrenoate potassium (III) are useful diuretic agents (1). Spironolactone is rapidly metabolized *via* a 7α-thiol derivative (2) to canrenone (II), a major metabolite, which exists in enzymatic equilibrium with III (Scheme I). The pharmacokinetics of I–III were investigated in rats (3), dogs (4), and humans (5, 6). Data on the kinetic disposition and further metabolism of II and III are scant (2, 7). Large differences between the tissue distribution of the lipophilic II and the water-soluble III can be expected and should be considered in the interpretation of plasma II and III levels. In this study, the tissue distribution of III potassium was investigated in rabbits.

EXPERIMENTAL

Chemicals—Pure crystalline samples of I and III were used[2], and II was prepared from III as previously described (8). ^{3}H-Canrenoate potassium[3], with a specific activity of 860 μCi/mg, was purified by solvent extraction (8) and TLC[4] in dichloromethane–methanol (8:2) prior to use. All reagents and chemicals were spectroquality.

Analytical Procedures—The fluorometric determination of II and III was performed as described previously (9). This method was specific for II and III in the presence of all other metabolites of III (8). Tritium measurements were performed by liquid scintillation counting as described previously (8). Efficiency was measured by the channels ratio method.

Rabbit Protocols—*Serial Blood Sampling*—Female New Zealand White rabbits, 2–2.5 kg, were used. Each rabbit was prepared for blood sampling by insertion of a polyethylene 50 catheter about 4 cm into an ear artery. Doses of 5, 10, and 20 mg of III/kg in aqueous solution were given by venous injections into the opposite ear. Blood samples of 2 ml each were taken with heparinized syringes at appropriate time intervals and centrifuged, and the plasma was frozen for subsequent analysis.

Tissue Analysis—Doses of 20 mg of ^{3}H-III/kg, with a specific activity of 0.2–0.5 μCi/mg, were given intravenously into an ear vein. Rabbits were sacrificed by decapitation at the following times after drug administration: 5, 10, 20, 30, 60, and 90 min and 2, 4, 8, 16, and 32 hr. One animal was used per time interval, with the exception of the 2-hr experiments where three animals were used.

Blood was collected by exsanguination from the abdominal aorta. The heart, lungs, brain, kidneys, liver, adrenal glands, and spleen were re-

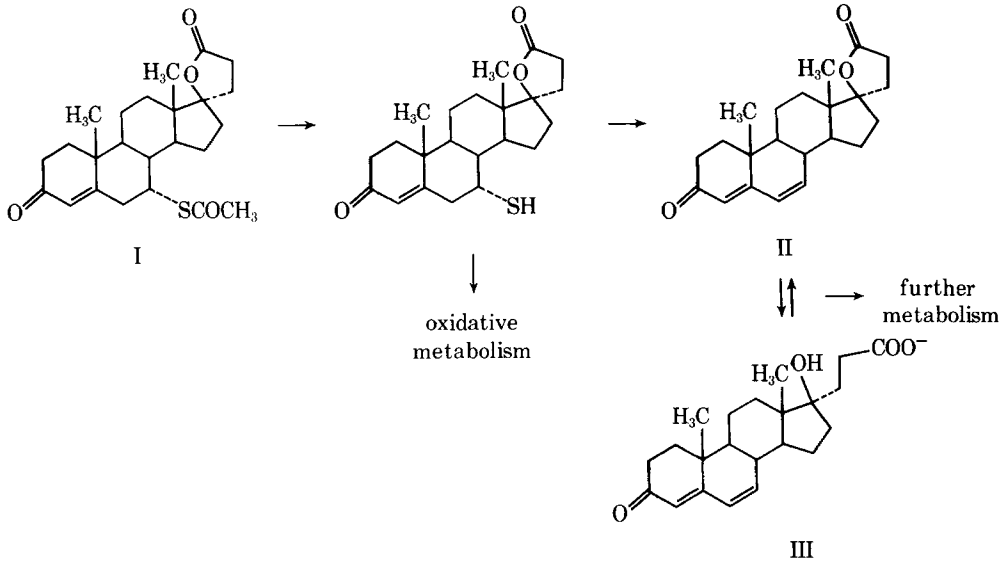

Scheme I—Metabolic pathways of the spirolactones

moved. Tissue samples were homogenized using a tissue homogenizer in a fivefold volume of methanol. After centrifugation at 2000 rpm, the supernate was removed and the tissue pellet was washed with methanol and kept at 20° for further analysis. The supernate (0.3 ml) or 0.1 ml of plasma was placed in a counting vial, and ^{3}H-counts were determined by scintillation counting or measured fluorometrically for II and III.

Tissue pellets were analyzed to measure the extraction yield by methanol homogenization. Liquefaction of the methanol and water-washed pellet was achieved using a tissue solubilizer[5], and an aliquot of the total volume was counted in 10 ml of counting solution[6]. Pellet extractibility was quantitative in all tissues, since all counts were found in the supernate. ^{3}H-Activity was not significantly accounted for by ^{3}H-water following possible ^{3}H-exchange from ^{3}H-III or its metabolites, since the ^{3}H-activity of the supernates was the same when measured directly and following evaporation to dryness.

RESULTS AND DISCUSSION

Plasma concentration *versus* time curves of II and III were obtained by serial blood sampling after 5, 10, and 20 mg of III/kg iv. Equilibrium between II and III was obtained as early as 10 min following administration of III. The plasma elimination half-life was about 1 hr, which is much faster than that observed in other species (2, 4, 5), and was unchanged at all dose levels studied. Following increased doses, proportionally increased plasma levels with the same elimination half-life demonstrated linear first-order disposition kinetics. A dose of 20 mg of III/kg was selected for all subsequent studies.

Figure 1 shows measurements of total radioactivity and of II and III

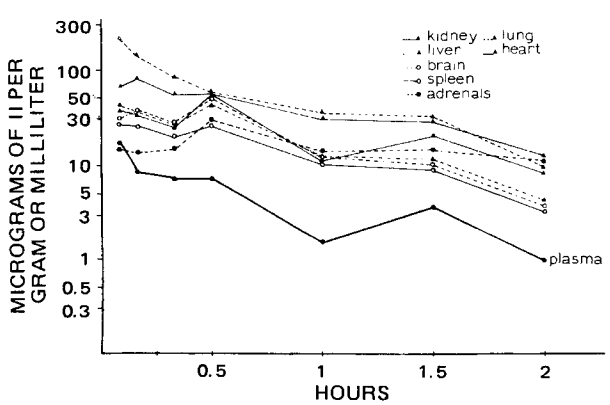

Figure 2—*Plasma and organ concentrations of II.*

[6] Aquasol, New England Nuclear.

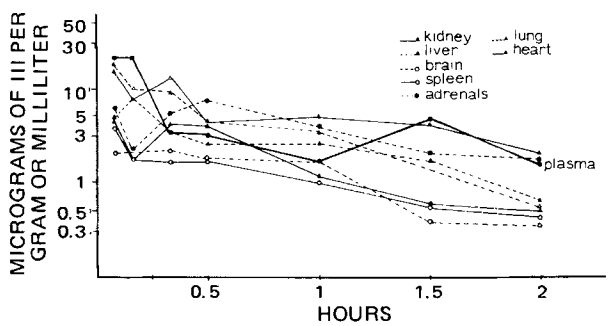

Figure 3—*Plasma and organ concentrations of III.*

measured by a specific fluorescence assay in rabbit liver tissue. Liver appears to show a high uptake of II and not III, even at the earliest time point of 10 min after a dose of III potassium where II accounts for most of the radioactivity. This result indicates a rapid conversion of III to II. The high concentration and slow elimination of ^{3}H-activity suggest extensive metabolism.

Figure 2 shows II levels in plasma and all tissues analyzed. Canrenone is rapidly taken up and concentrated in tissues, by a factor of 10 compared to plasma. The large differences in II concentration after 10 min in various tissues may be attributed in part to perfusion differences of the various organs. Levels of III in plasma and tissues (Fig. 3) are similar in order of magnitude, indicating a lower tissue affinity of III when compared to II.

To examine the variability between animals, three animals were analyzed at the 2-hr time point. All other points are represented by single-animal experiments. Table I shows the averaged values and ranges for the 2-hr experiments in rabbit plasma and liver.

Plasma concentrations of II represent a larger amount of this metabolite in the body when compared to plasma levels of III. Therefore, it seems justified to consider II as a major metabolite upon which pharmacokinetic studies such as bioavailability should be based. This result

Table I—Levels of Canrenone (II) and Canrenoate (III) in Plasma and Liver at 2 hr following Administration of ^{3}H-III to Three Rabbits

	Mean (Range)		
	Total ^{3}H-Activity	II	III
Plasma, μg/ml	18 (12–25)	1.16 (0.6–1.48)	1.3 (0.36–1.76)
Liver, g	68 (35–119)	10 (4–16)	1 (0.6–1.2)

can probably also be applied to species other than the rabbit. However, extensive transformation to metabolites of unknown structures and pharmacological activity appears to occur, which will be discussed in a separate report.

Synthesis and Biological Activity of a Novel Analog of Nitrofurantoin

RALPH L. WHITE [x], STANLEY E. BURROUS, and THOMAS J. SCHWAN

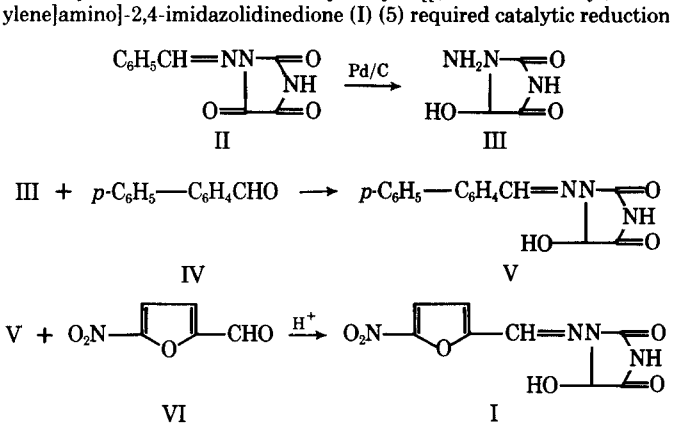
Abstract □ The synthesis of 5-hydroxy-1-[[(5-nitro-2-furanyl)methylene]amino]-2,4-imidazolidinedione is described, and its antibacterial activity is reported.

Keyphrases □ Nitrofurantoin analog—synthesized, screened for antibacterial activity □ 2,4-Imidazolidinedione, substituted—synthesized, screened for antibacterial activity □ Antibacterial activity—substituted 2,4-imidazolidinedione evaluated

Because of the continuing interest (1–3) in the chemotherapeutic properties of 1-[[(5-nitro-2-furanyl)methylene]amino]-2,4-imidazolidinediones, the 5-hydroxy analog of nitrofurantoin[1] was prepared by utilizing the general preparative route to 5-hydroxy-1-(substituted amino)-2,4-imidazolidinediones (4, 5).

DISCUSSION

The synthesis of the desired 5-hydroxy-1-[[(5-nitro-2-furanyl)methylene]amino]-2,4-imidazolidinedione (I) (5) required catalytic reduction of 1-[(phenylmethylene)amino]imidazolidinetrione (II) to yield 1-amino-5-hydroxy-2,4-imidazolidinedione (III). Compound III was not isolated but was trapped with 1,1′-biphenyl-4-carboxaldehyde (IV) to yield 1-[[[(1,1′-biphenyl)-4-yl]methylene]amino]-5-hydroxy-2,4-imidazolidinedione (V). Exchange on the 1-amino-5-hydroxyimidazolidinedione moiety of V was accomplished by stirring V and 5-nitro-2-furancarboxaldehyde (VI) in the presence of an acid catalyst, which yielded the desired product I (Scheme I).



Scheme I

Evidence supporting reduction of II at the 5-oxo group to give a 5-hydroxy-1-substituted 2,4-imidazolidinedione was found by comparing the NMR spectrum of I with spectra of nitrofurantoin (VII) and its isomer 3-[[(5-nitro-2-furanyl)methylene]amino]-2,4-imidazolidinedione (VIII) (6). The NH signal of I is at 11.5 ppm, the N_3H signal of VII occurs at 11.2 ppm, and the N_1H signal of VIII is at 8.57 ppm, indicative of a N_3H proton for I rather than an N_1H proton. These NMR data confirm that I is a 5-hydroxy-1-(substituted amino)-2,4-imidazolidinedione and not a 5-hydroxy-3-(substituted amino)-2,4-imidazolidinedione. The structure of I is thus a 5-hydroxy-substituted nitrofurantoin.

Compound I was tested for antibacterial activity against eight bacterial species in a standard broth dilution assay and had good activity against

Table I—Serial Dilution Method for I and Nitrofurantoin[a]

Table II—Serial Dilution Method for the Urine of Rats Dosed with I[a]

Collection Interval, Hours after Dosing	*Escherichia coli* (Es-90)	*Proteus mirabilis* (Pr-91)	*Aerobacter aerogenes* (Ae-6)	*Pseudomonas aeruginosa* (Ps-44)
0—4	48	48	<6	<6
4—8	<6	<6	<6	<6

[a] Activities are given in RID values (reciprocal of the highest inhibitory dilution).

all organisms tested except *Aerobacter aerogenes, Pseudomonas aeruginosa,* and *Proteus mirabilis* in a standard minimum inhibitory concentration (MIC) serial dilution test (Table I). Antibacterial activity of nitrofurantoin was measured by the serial dilution method to have a direct comparison of MIC values in the same species. Nitrofurantoin exhibited better general antibacterial activity than I for the bacteria tested. MIC values for nitrofurantoin against various bacterial species also may be found in the literature (7, 8).

Urine collected in 0.1 *N* HCl from rats fasted overnight prior to receiving a single oral dose (30 mg/kg) of I was evaluated for antibacterial activity in a broth dilution assay (Table II) (9). Rats dosed with I excreted urine having excellent antibacterial activity against *Escherichia coli* and *P. mirabilis* (Table II). The *in vivo* antibacterial activity was measured in a standardized rat unilateral pyelonephritis model (Table III) (10); efficacy against *E. coli* and *P. mirabilis* was apparent. The estimated oral 72-hr LD_{50} for I in mice was 668 mg/kg. Urine from rats or dogs fed nitrofurantoin (VII) contained no detectable I, and urine from rats fed I contained no detectable VII, as indicated by TLC with three different solvent systems [(*a*) 1-butanol–ethanol–ammonium hydroxide, (*b*) ethyl acetate–hydrochloric acid, and (*c*) 1-butanol–ethanol–acetic acid] on nitromethane extracts (pH 2.0) of appropriate urines and standards, internal standards, control urines, and spent, extracted urines.

EXPERIMENTAL[2]

1-[[[(1,1′-Biphenyl)-4-yl]methylene]amino] -5-hydroxy-2,4-imidazolidinedione (V)—In each of two 2-liter reduction vessels were placed 1-(benzylideneamino)imidazolidinetrione (87 g, 0.40 mole) (1), palladium-on-charcoal (5% with 50% water, 20 g), and methanol (500 ml). The mixtures were reduced on a Parr apparatus until about 95% of the theoretical three equivalents of hydrogen was taken up (24 hr). The combined reduction mixtures were filtered, and the insoluble residue was rinsed with methanol (600 ml). The combined methanolic solution was made acidic with concentrated hydrochloric acid, and then 1,1′-biphenyl-4-carboxaldehyde (73 g, 0.40 mole) was added. The mixture was stirred for 2 hr, and the resulting solid was collected (21 g, 28% yield). A sample was recrystallized from absolute ethanol, mp 224–225°.

Anal.—Calc. for $C_{16}H_{13}N_3O_3$: C, 65.08; H, 4.44; N, 14.23. Found: C, 65.19; H, 4.52; N, 14.10.

5-Hydroxy-1-[[(5-nitro-2-furanyl)methylene]amino]-2,4-imidazolidinedione (I)—In tetrahydrofuran (500 ml) were placed V (20 g, 0.070 mole), VI (11 g, 0.080 mole), and concentrated hydrochloric acid (5 ml). The solution was refluxed for 1 hr and concentrated under reduced pressure to a yellow solid. Benzene (100 ml) was added, and the mixture was again concentrated to a solid. The solid was stirred for 30 min with anhydrous ether (400 ml), and the mixture was filtered to yield the desired product I (15 g, 88% yield). Recrystallization of a sample from acetonitrile gave the white product, mp 213–214°; NMR: δ 5.68 (d, 1H, CH, J = 10 Hz, s after exchange), 7.18 (d, 1H, furan CH, J = 4 Hz), 7.47 (d, 1H, OH, J = 10 Hz, exchange), 7.75 (d, 1H, furan CH, J = 4 Hz), 8.18 (s, 1H, azomethine CH), and 11.5 (broad s, 1H, NH, exchange).

Anal.—Calc. for $C_8H_6N_4O_6$: C, 37.80; H, 2.38; N, 22.05. Found: C, 37.77; H, 2.35; N, 22.00.

NMR Spectrum of Nitrofurantoin (VII)—Signals were observed at δ 4.40 (s, 2H, CH), 7.15 (d, 1H, furan CH, J = 4 Hz), 7.78 (d, 1H, furan CH, J = 4 Hz), 7.82 (s, 1H, azomethine CH), and 11.2 (broad s, 1H, NH, exchange).

NMR Spectrum of 3-[[(5-Nitro-2-furanyl)methylene]amino]-2,4-imidazolidinedione (VIII)—The synthesis of this compound was reported previously (6); NMR: δ 4.10 (s, 2H, CH), 7.33 (d, 1H, furan CH, J = 4 Hz), 7.66 (d, 1H, furan CH, J = 4 Hz), 8.57 (s, 1H, NH, exchange), and 9.51 (s, 1H, azomethine CH).

[2] A Varian Associates A-60A instrument was used for NMR spectra, which were run in dimethyl sulfoxide-d_6 with tetramethylsilane as the internal standard. Melting points were determined in open capillary tubes with a Mel-Temp melting-point apparatus and are uncorrected.

Table III—Standard Rat Bacterial Pyelonephritis Efficacy[a]

Organism	Treated	Untreated
Escherichia coli (Es-90)	2.6	4.9
Proteus mirabilis (Pr-91)	3.8	4.8
Aerobacter aerogenes (Ae-6)	4.5	5.2
Klebsiella pneumoniae (Kl-10)	4.9	5.5

[a] Activities are expressed as the $\log_{10}$ of the geometric mean of the viable bacterial titers of the infected kidneys from 10 rats (per group) dosed 10 mg/kg twice daily for 14 days with I.

Survival of Pleomorphic Sarcoma-37 Transplanted Virgin Female DBA/2J Mice: Effects Produced by High Blood Glucose Levels Alone and in Combination with Drugs

RONALD E. ORTH ˣ, HOWARD J. SWIDLER, and MILO S. ZARAKOV

Abstract □ Procedures for producing, monitoring, and maintaining 3-hr 400–500-mg % whole blood glucose levels in Sarcoma-37 (S-37) transplanted virgin female inbred DBA/2J mice are described. Aqueous infused 40% (w/v) dextrose was evaluated as a potential therapeutic factor. The effects of procedural variations on treatment survival and longevity are discussed. One hundred percent infusion safety and 25% increased longevity over nontreated transplanted mice were achieved. Doxorubicin and/or dacarbazine were also evaluated when administered prior to the dextrose infusion. Doxorubicin followed by intravenous dextrose increased survivor longevity by 37%, but this combination was unsafe at the drug dosages employed. A large dose of dacarbazine was safe and effective alone but unsafe when given prior to the infusion, although the survivors lived 29% longer than the untreated transplanted controls. Both drugs were marginally effective, but safe, when given together. When given together prior to the infusion, only 87% survived the treatment. The survivors lived 6 days longer than the controls.

Keyphrases □ Blood glucose—high levels, alone and with doxorubicin or dacarbazine, effect on survival of tumor-transplanted mice □ Dextrose infusion—alone and with doxorubicin or dacarbazine, effect on survival of tumor-transplanted mice □ Doxorubicin—combined with high blood glucose levels, effect on survival of tumor-transplanted mice □ Dacarbazine—combined with high blood glucose levels, effect on survival of tumor-transplanted mice □ Antineoplastics—doxorubicin and dacarbazine, alone and with high blood glucose levels, mice

The selectively higher aerobic glycolytic rate noted in cancerous tissue as opposed to normal tissue was reported by Warburg in 1930 (1). This finding is controversial (2), although it has been demonstrated (3, 4) that dextrose levels of 400 mg/100 ml of whole blood cause a pH differential of as much as 1 unit to exist only a few millimeters apart in normal *versus* malignant tissues of the same organ. Tumor remissions were reported following the maintenance of hyperacidic tumor tissue (5).

Cancerous mice, stabilized at 400-mg % blood glucose levels, exhibit slower tumor growth, more remissions, and greater longevity than untreated mice (6). Maintenance of 400-mg % dextrose-induced hyperglycemia assures equilibration between tissues and high target tissue acidity. Although the pH of both tumor and normal tissues drops, the acidity of the former is greatest. Lysosomal enzymes, more active at lower pH's, catabolize the malignant tissue preferentially. The less acidic normal tissue provides a poorer substrate for the lysozymes, and the "self-destruction" stops according to this hypothesis.

It was suggested (6) that a "triggering attack" by one or more agents be employed in addition to dextrose infusion, since higher remission rates are desirable. X-Irradiation, massive doses of vitamin A, and cell cycle-specific or nonspecific antineoplastic agents disrupt the DNA and/or protein synthetic sequence, weakening lysosomal and cellular membranes. In theory, the application of several membrane-weakening agents with different mechanisms of action, given together, could produce additive, if not synergistic, beneficial results.

This study was designed to: (*a*) create an easily duplicated procedure for producing, monitoring, and maintaining safe 3-hr 400–500-mg % whole blood glucose levels in Sarcoma-37[1] (S-37) transplanted DBA/2J mice; (*b*) determine whether a causal relationship exists between this treatment and mouse longevity; and (*c*) evaluate whether doxorubicin (I) and/or dacarbazine (II), administered prior to the dextrose infusion, alter safety and longevity results. This investigation utilized known active mouse (7) and human (8) antisarcoma agents I and II. Tumor size, shape, and growth characteristics were observed.

EXPERIMENTAL

The following materials were used: genetically standardized inbred strains of virgin female DBA/2J mice with in-host S-37 transplanted tumors[2]; an infusion pump with variable rate settings and interchangeable holders for different syringe capacities[3], syringes[4]; polyethylene tubing[5]; 26-gauge 12.7-mm hypodermic needles[6]; a reflectance colorimeter[7]; glucose oxidase reagent strips[8]; capillary tubes (1.12–1.17 mm i.d.); I and II[9]; 40 % (w/v) aqueous dextrose; aqueous pentobarbital sodium, 32 mg/10 ml; and normal saline.

Virgin female DBA/2J mice, 15–20 g, were transplanted with 1 mm^3 of vascular S-37 tumor tissue[10]. They were treated 6 days later; chemotherapeutic agents were administered 15 min prior to anesthesia. Compound I was administered subcutaneously, II was given intraperitoneally, and 80 mg of pentobarbital sodium/kg was given with an oral syringe. Anesthetized mice were secured, and the tails were immobilized.

An infusion pump syringe holder was adapted to contain six 1-ml syringes. Each syringe was connected to 1 m of polyethylene tubing by a 26-gauge 12.7-mm needle. Another needle of the same size was broken near the syringe adaptor end, and this end was fitted into the far end of the tubing. The beveled end of the needle was then inserted into the mouse tail vein. The six syringes, prefilled to 0.5 mg with 40 % (w/v) aqueous dextrose, were activated at a slow setting (No. 19-21) on the pump.

Postorbital venous blood samples were periodically taken with a capillary tube. Blood glucose levels were determined by comparing the glucose oxidase strip color with chart standards (Cage 2 in Table I) or by reading the strip in a reflectance colorimeter (Cages 3–9 and 13 in Table I). Levels of 450 mg % were usually obtained in 60 ± 15 min (~0.2 ml of infusate). The infusion was discontinued at this time, and blood sampling was continued for another 2 hr. If the level fell below the desired 400 mg %, the infusion was reinstated. To prevent blinding the mice, no more than three samples were taken from behind either eye. A limit of four samples per mouse prevented too great a reduction in blood volume.

The dextrose original method (Cage 2) involved a 1:2 blood to saline

13	Dextrose second modification plus I, 2.5 mg/kg sc plus II, 100 mg/kg ip	14/16	32.1 ± 2.4

[a] Includes deaths occurring within 24 hr of treatment. [b] The mean and the standard error of the mean in days surviving transplantation with 95% confidence. [c] Obtained from Cages 2–13 following transplantation prior to treatment. [d] Insignificant change in longevity from control values of Cage 1 (Student two-tailed t test with 95% confidence).

dilution and then placement of this mixture on the glucose oxidase reagent strip 1 min before washing and reading. The results were compared with a color chart on the reagent strip container. Data collected by reading the strips in a reflectance colorimeter were obtained by the dextrose first modification procedure (Cage 3). These mice were infused with aqueous dextrose immediately upon immobilization while still unconscious. This method required no dilution of the fresh venous blood samples, since readings up to 1000 mg % were possible using the expanded scale of the colorimeter. The dextrose second modification procedure (Cage 4) introduced a time lapse between immobilization and treatment. Therapy was commenced only when the mice were conscious.

These first three procedures rely on tail vein intravenous aqueous dextrose administration. The dextrose third modification (Cage 5) varied from the second modification procedure only by the route of administration. The intraperitoneal method was adopted in this latter infusion technique. The control mice (Cage 1) were anesthetized, secured, and infused with 0.2 ml of isotonic saline for 1 hr. The dextrose second modification method was utilized in all combination therapy with drugs.

RESULTS AND DISCUSSION

Untreated control mice lived 26.3 days beyond the S-37 tumor transplantation date (Cage 1). Twenty-three percent of the mice subjected to the dextrose original method died during treatment (Cage 2). The longevity for survivors in Cage 2 was about the same as for the Cage 1 controls. This dextrose monitoring procedure, employing a blood–saline dilution technique coupled with naked eye reagent strip color comparison with chart standards, was ineffective. The technique yielded false low values, resulting in extremely high actual blood glucose levels. More accurate assessments of undiluted blood glucose concentrations were obtained with the three following procedural modifications. An expanded scale reflectance colorimeter was utilized in which readings up to 1000 mg % were possible.

The dextrose first modification procedure (Cage 3) differed from the original method only by utilization of the colorimeter. Mice were unconscious at the time the infusion was initiated in both procedures. A safe treatment (100% survival) and a small but insignificant increase in longevity were observed. If, as in the dextrose second modification procedure (Cage 4), the sugar infusion was commenced only after the animal regained consciousness, the treatment yielded a safe and a significant 5-day increase in life expectancy over the control group.

The last variation of the infusion procedure was administration of the 40% (w/v) aqueous dextrose intraperitoneally (Cage 5). This dextrose third modification method resulted in a 100% safe treatment and a significant 6-day increase in longevity over the controls.

Obtaining and maintaining 400–500-mg % blood glucose levels was more difficult intraperitoneally than intravenously. The longevity differences obtained by these two procedures were statistically insignificant. Therefore, the more easily regulated intravenous dextrose second modification method is preferred and was used with drug therapy (Cages 6–9 and 13).

A 5-mg/kg sc dose of I (Cage 10) was safe and effected a significant 4-day increase in transplanted mouse lifespan. When I was given with infused dextrose, the treatment was unsafe, but the survivors of either 2.5 (Cage 6) or 5 (Cage 7) mg/kg lived 10 days longer than the controls. Although hyperglycemic treatment with I yielded significant longevity increases, the great deviations from the mean longevity and poor treatment survival rates did not favor adoption of this therapy.

A 200-mg/kg ip dose of II (Cage 11) was safe and resulted in a significant 5-day increase in longevity over the controls. If this same dose of II was administered with the dextrose treatment (Cage 8), the 75% surviving lived 7 days longer than did the control animals. By reducing the dose of II to 100 mg/kg prior to infusion with dextrose (Cage 9), survival was assured but therapy was minimally effective.

Given together, I and II provided safe but marginally effective therapy for the S-37 transplanted mice (Cage 12). However, when hyperglycemic treatment was added to the regimen (Cage 13), the mice survived an additional 6 days. Unfortunately, 12% of the mice died during treatment.

"Selective survival" may account, in whole or in part, for the increased longevity noted for mice given I and/or II during unsafe treatments (Cages 6–8 and 13). A toxic treatment may selectively kill the weakest mice, allowing the stronger animals to survive and live longer lives. The 26-day longevity values noted for both the controls and the unsafe dextrose original method survivors may provide evidence that conflicts with the selective survival concept.

SUMMARY

Safe procedures for producing, monitoring, and maintaining 3-hr 400–500-mg % whole blood glucose levels in S-37 transplanted virgin female inbred DBA/2J mice were achieved (Cages 3–5). Sarcoma-37 transplanted mouse longevity was significantly increased following a 100% safe treatment with a single incident of: 40% dextrose infusion (Cages 4 and 5), 5 mg/kg sc of I (Cage 10), 200 mg/kg ip of II (Cage 11), or 2.5 mg/kg sc of I with 100 mg/kg ip of II (Cage 12). Combinations of I and/or II with the dextrose may be less than 100% safe, but survivor longevity is increased (Cages 6–8 and 13).

New and Simple Method for Determination of 2-(3-Benzoylphenyl)propionic Acid in Body Fluid

R. BALLERINI, A. CAMBI, and P. DEL SOLDATO ˣ

Abstract □ A simple, fast, sensitive, and reliable method for the determination of 2-(3-benzoylphenyl)propionic acid in biological fluid is described. The method is based on a quantitative ether extraction of plasma samples followed by TLC separation, spot visualization and elution, and determination at 255 nm. The acid is detectable in amounts as low as 1 μg.

Keyphrases □ 2-(3-Benzoylphenyl)propionic acid—TLC analysis, plasma, rats □ TLC—analysis, 2-(3-benzoylphenyl)propionic acid, plasma, rats □ Analgesic agents—2-(3-benzoylphenyl)propionic acid, TLC analysis, plasma, rats

GC, polarographic, and colorimetric methods (1) have been used to determine the concentration of 2-(3-benzoylphenyl)propionic acid (I), a recently synthesized compound with analgesic and anti-inflammatory properties (2), in body fluids. Unfortunately, these methods are complicated, unreliable, time consuming, nonspecific, and not sufficiently sensitive. Furthermore, they are limited to the determination of I in the urine and require rather expensive instrumentation.

The thin-layer method described in this paper overcomes most of these limitations.

EXPERIMENTAL

Reagents and Materials—Compound I was synthesized and characterized by means of IR, NMR, UV, and TLC techniques[1]. All solvents were analytical reagent grade[2], and the developing solvent, ether–benzene–1-butanol–methanol (85:8:6:1), was prepared fresh daily. Silica gel plates[3], 250 μm thick, were activated at 105° for 1 hr.

Instrumentation—A UV lamp[4] (250 nm), a prism spectrophotometer[5], and 1-cm quartz microcells[6] were used.

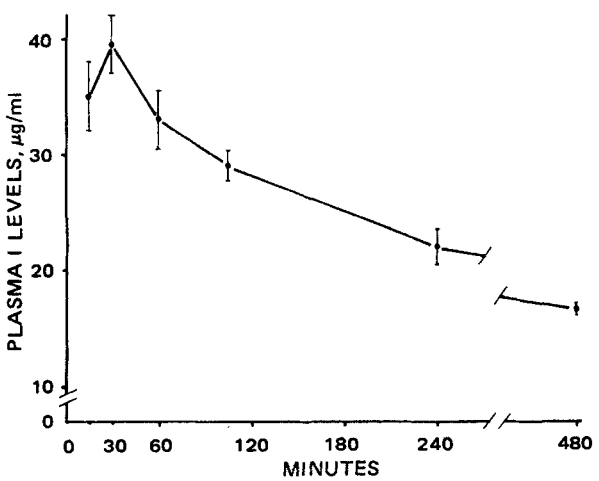

Figure 1—*Concentration of I in plasma of male rats at different time intervals after oral administration of 25 mg/kg.*

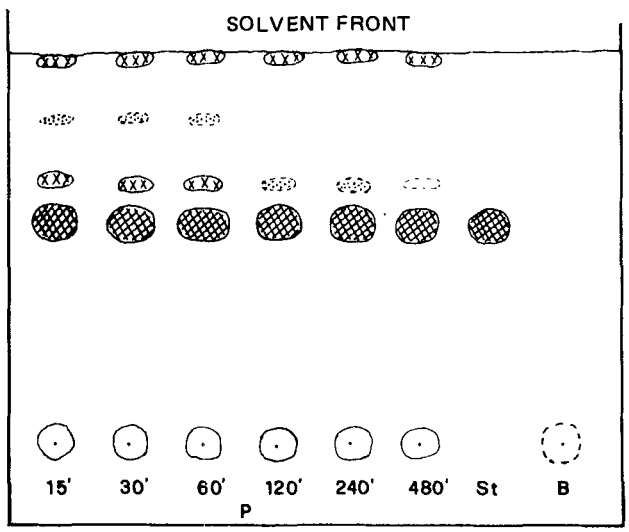

Figure 2—*Thin-layer chromatogram of I. Key: B, 0.1 ml of plasma from untreated rats; St, 0.1 ml of I (250 μg/ml in 96% ethanol); and P, plasma sample obtained at different time intervals from I-treated rats (25 mg/kg po).*

Preparation of Standards—Compound I was dissolved in 96% ethanol. Aliquots equivalent to 2.5, 7.5, 10, and 12.5 μg were placed in glass-stoppered centrifuge tubes and evaporated to dryness under a gentle stream of nitrogen. Then 0.25 ml of plasma from untreated rats was added to each tube and mixed well. These standards and the appropriate blanks were handled in the same manner as the plasma specimens.

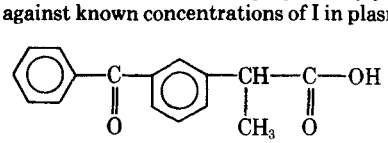
Preparation of Samples—Plasma (0.25 ml) from treated animals, 10 ml of water, and 1 ml of 1 *N* HCl were introduced into a 100-ml separator.

Compound I was extracted with three 40-ml portions of ether. The standards and the appropriate blanks were handled in a similar manner. The pooled extracts were washed with 20 ml of 0.1 *N* HCl and 20 ml of water, dried on sodium sulfate, and flash evaporated to a volume of about 5 ml. This final amount as well as the successive ether washes was transferred to a glass-stoppered centrifuge tube and evaporated to dryness under a gentle stream of nitrogen.

TLC—Each sample was taken up in 0.2 ml of ethanol, and 100-μl aliquots were spotted 2 cm from the edge of the chromatographic plate. Aliquots equivalent to 1.25, 2.5, 5, and 6.25 μg of I standard ethanolic solution were likewise spotted on the plate.

The chromatograms were developed in an ascending system of ether–benzene–1-butanol–methanol (85:8:6:1) in a saturated atmosphere. After 30 min the solvent front was marked, plates were dried, and I spots were visualized by exposure to the UV lamp. These areas were scraped into glass-stoppered centrifuge tubes, eluted with 1.5 ml of ethanol, and shaken every 5 min for 30 min. A similar spotless area (blank) was also scraped off and subjected to the identical procedure. The test tubes were then centrifuged at 4000 rpm for 10 min, and the relative absorbance of the supernates was measured at 255 nm against a blank.

Calculation—Calibration curves were prepared by plotting absorbance at 255 nm against known concentrations of I in plasma or 96% ethanol. Values for unknown concentrations of I in plasma specimens were calculated from the slope of the standard curve.



I

Table I—Recovery of I Added to Rat Plasma or 96% Ethanol

Amount of I Added to Plasma or 96% Ethanol, μg/ml	Amount Recovered from Plasma, μg/ml	Recovery, %	Amount Recovered from 96% Ethanol, μg/ml	Recovery, %
2.50	2.24	89.6	2.30	92.0

10	9.10	91.0	9.00	90.0
	9.15	91.5	8.80	88.0
	9.15	91.5	9.15	91.5
	9.12	91.2	9.10	91.0
	8.90	89.0	8.80	88.0
	9.10	91.0	8.90	89.0
		Mean ± *SD* = 90.95 ± 1.22		Mean ± *SD* = 90.35 ± 1.41

Drug Administration to Rats—Male Wistar albino rats, 300–330 g, were divided into six groups of six or seven animals each. Compound I was suspended in an aqueous vehicle consisting of 0.9% sodium chloride, 0.4% polysorbate 80, 0.5% carboxymethylcellulose sodium, and 0.9% benzyl alcohol and administered by gavage at a dose of 25 mg/kg in a constant volume of 5 ml/kg.

Blood samples were obtained by cardiac puncture by means of a heparinized syringe at time intervals ranging from 15 min up to 8 hr after drug administration. Plasma samples were obtained by centrifugation at 2000 rpm for approximately 10 min.

Table II—Precision Data from Determinations in Plasma[a]

Sample	Concentration of I at 15 min, μg/ml	Concentration of I at 480 min, μg/ml
Mean	16.5	38.4
SD	0.45	1.21
RSD	2.75	3.15

[a] Reproducibility limits are $RL = \bar{X} \pm RSD.t_{38;0.05} = \bar{X} \pm 6.01\%$ of $\bar{X}$.

RESULTS AND DISCUSSION

Known amounts of I were added either to plasma or 96% ethanol. The percentage recovery of I from plasma was identical to that from the alcoholic solution spotted directly on the plate (Table I), with an accuracy index of 100%. This method is adequately specific, since it was unaffected by endogenous substances. The values relative to plasma concentration at different time intervals after oral administration of 25 mg/kg of I to male rats are shown in Fig. 1.

Preliminary chromatograms of I added to plasma indicated that recoveries of 90 ± 1.2% were obtained following an elution time of 30 min. Prolongation of the elution time (up to 5 hr) did not improve recovery. Compound I has an R_f value of 0.75 (Fig. 2). No attempt was made to identify the chemical nature of the substances (metabolites) with an R_f greater than that of I. Due to a sufficiently high molar absorptivity ($E^{1\%}_{1cm}$ in 96% ethanol or plasma at 255 nm is 640), I can be determined in an amount as low as 1 μg.

To assess the precision of the procedure, 20 determinations were carried out on two plasma samples obtained at 15 and 480 min following I administration (Table II). The relative mean standard deviation was 2.95% and the reproducibility limits were ±6.01%.

The time required to determine the concentration of I in plasma varies according to number of samples, *i.e*, about 3 hr for one sample and 1 day for six samples.

The described method is fast and reliable and does not require expensive instrumentation. Furthermore, it is sensitive enough for the determination of unaltered I in the biological fluids of both experimental animals and humans.

Water as a Nonpolar Partition Medium

H. TAKRURI *§, B. ECANOW *‡x, and R. BALAGOT *‡

Abstract □ Coacervates have been suggested as models for cytoplasm since cytoplasm is also essentially an aqueous phase of water–protein–colloid complexes. This study on partition coefficient properties made use of coacervate phases as the nonpolar phases in equilibrium with polar water phases. The partition coefficients of four barbiturates were obtained, and their values correlated with those reported in the literature for systems using organic solvents as the nonpolar medium. These values also correlated with reported values for the absorption ranking of the barbiturates in the rat colon. The partition coefficients of theobromine and theophylline in gelatin–benzalkonium chloride coacervate systems were also found to correlate with the partition values reported in the literature for heptane–water and chloroform–water systems. It is suggested that coacervate systems form a more realistic model for studying and predicting the absorption characteristics of drugs than do conventional organic solvent–water systems.
