FDA: POLICEMAN OR TEACHER?

A few years ago, the big thing for the college age crowd was to dwell on the question, "who am I?"

Not only do persons undergo such identity crises but at times organizations and agencies also experience this type of traumatic soul-searching.

In a number of respects, the behavior of the Food and Drug Administration has appeared to this writer as suggesting that it is similarly uncertain as to its proper role or function. In particular, the Agency has often acted ambivalent and wavering as it has moved back and forth between at least two distinctly different roles: namely, that of a police officer and that of a teacher.

By law, the FDA has responsibility to oversee the purity, quality, identity, safety, usefulness, and related characteristics of the nation's food, drug, and cosmetic supply. With this legal mandate, the Agency is clearly a regulatory body and must operate in a manner to assure compliance.

But compliance itself can be achieved by at least two different routes. There is, of course, that of close supervision and monitoring combined with various enforcement measures. However, to rely solely on this approach would virtually necessitate one FDA agent for each person being monitored—clearly an unrealistic system.

This same problem is encountered in other aspects of day-to-day living; for example, adherence to traffic regulations and payment of income taxes. Both of these systems basically rely on voluntary compliance by the general public, coupled with spot checks of driving speed and sampling of tax returns for auditing. Similarly, the FDA must primarily rely on the voluntary compliance of those who operate within the professions and industries that are responsible for the products over which the FDA has jurisdiction. This voluntary compliance is encouraged by a parallel program of regulatory enforcement *via* product sampling, batch testing, marketplace surveys, plant inspections, and so on.

The relative emphasis which the Agency places on the voluntary route *versus* the enforcement route varies greatly from time-to-time depending upon a number of factors.

Among these is the "philosophic bent" of those persons who happen to be in the upper echelons of FDA at any given time. In particular, if the persons at the top are **enforcement oriented,** it can be expected that the general tenor of the Agency will reflect that leaning. Conversely, if they are **education oriented,** it is more likely that they will generally opt for policies that are persuasive toward voluntary compliance.

In Dr. Jere E. Goyan, the new Commissioner, we have someone with a long and distinguished background in health education. This is not to suggest that Dr. Goyan will be reluctant to use the regulatory enforcement approach if he feels it necessary; his past record shows that he can be forceful, decisive, and "hard-nosed" when he feels that such a manner is needed. However, we suspect that he will initially approach each problem with the perspective that education will frequently resolve such difficulties and make regulatory action unnecessary. Moreover, we are hopeful that this philosophy will permeate the entire Agency.

Again, there is an interesting corollary to be drawn from daily life. Society has learned that people's attitude regarding their police force is largely shaped when they are small children. It is far better if children can be taught that the policeman is there to help them and protect them than it is to make them fearful by scaring them with warnings that "the policeman is going to catch you!" By the same token, we expect that the police force will behave in a manner that warrants the trust and respect of both children and adults.

Similarly, if the FDA is to have both the trust and respect of those with whom it interfaces, then it too will need to conduct itself in a manner that encourages such an attitude.

Role of Binders in Moisture-Induced Hardness Increase in Compressed Tablets and Its Effect on *In Vitro* Disintegration and Dissolution

Z. T. CHOWHAN

Received March 2, 1979, from the *Institute of Pharmaceutical Sciences, Syntex Research, Palo Alto, CA 94304.* Accepted for publication July 20, 1979.

Abstract □ The role of commonly used binders in the moisture-induced hardness increase in compressed tablets containing lactose as a major excipient was studied. Tablets compressed from granulations containing different binders at different moisture levels increased in hardness after overnight exposure to ambient room conditions. The results suggest that this hardness increase is related linearly to the amount of moisture loss from the tablets after compression. The magnitude of the hardness increase is related to the type and concentration of the binder used in wet granulation. The moisture-induced hardness increase in tablets prepared from granulations containing different binders had no effect on the tablet disintegration time and *in vitro* drug dissolution.

Keyphrases □ Binders—role in moisture-induced hardness increase in compressed tablets, disintegration, dissolution, *in vitro* □ Disintegration—of compressed tablets following moisture-induced hardness increase, role of binders, *in vitro* □ Dissolution—of compressed tablets following moisture-induced hardness increase, role of binders, *in vitro*

Recent studies (1, 2) discussed the hardness increase induced by partial moisture loss in compressed tablets prepared by wet granulation. Tablets compressed from granulations containing moisture levels above 2% increased in hardness during storage at ambient room conditions. When the granulation moisture levels during compression were below 2%, tablet hardness did not increase during storage at ambient room conditions. However, when these tablets were equilibrated under accelerated humidity and then exposed to ambient room conditions, tablet hardness increased due to partial moisture loss. Moisture-related hardness increases did not decrease *in vitro* drug dissolution.

The exact mechanism by which moisture affects tablet hardness is not understood fully. Previous results (1) suggested that a possible mechanism was the recrystallization of the soluble drug and/or soluble excipient in the void spaces caused by the moisture loss. Obviously, the physical properties of the drug–excipient combinations play a major role.

Since binders impart cohesiveness to the tablet and ensure tablet strength after compression, investigation of their role in the moisture-induced hardness increase is important. In this study, the tablets compressed from granulations containing the most commonly used binders at different moisture levels increased in hardness due to partial moisture loss during overnight exposure to ambient room conditions. The data suggest that the hardness increase is related linearly to the amount of moisture loss after compression. The magnitude of the hardness increase is related to the type and concentration of binder used in wet granulation. The moisture-related hardness increase in tablets prepared from granulations containing different binders did not affect the tablet disintegration time and *in vitro* drug dissolution.

EXPERIMENTAL

Materials—Acacia[1], povidone[2], starch[3], lactose[4], gelatin[5], and magnesium stearate[6] were USP grade, and salicylic acid[6] was analytical reagent grade. Methylcellulose[7], hydroxypropyl methylcellulose[8], hydroxypropylcellulose[9], and ethylcellulose[10] were used as received.

Granulation—The material was prepared by wet granulation. Lactose and salicylic acid were mixed in geometric proportions on a piece of glassine paper and then in a small planetary mixer[11] for 3 min. The granulating solution was added with mixing and was mixed for ~5 min. The wet granulation was passed through a No. 12 mesh screen and dried in trays in a forced-air drying oven at 50°. One-half of the granulation was dried to ~3% moisture, and the other half was dried until the moisture reached below 1%.

Starch	—	—	—	—	—	—	—	—	—	—	10	—	—	—

These granulations then were screened separately through a No. 16 mesh screen, and appropriate proportions were mixed to obtain the desired moisture levels. Starch and magnesium stearate then were blended with the granulation. The granulation was stored in tightly closed jars; the moisture content was determined prior to compression.

The granulating solutions were prepared in the usual fashion. The solvent was water except for the ethylcellulose solution, in which 95% ethanol was used. Starch paste was prepared by boiling the water and mixing with starch.

Compression—Tablets were compressed with a single-punch machine[12] to a targeted hardness of 6 Strong–Cobb units. The punches and die were 0.95 cm in diameter and flat faced. The tablet weight was 380 mg.

Moisture Determination—The granulation moisture was determined with a moisture balance[13] by exposure to a 125-w IR lamp for 1 hr at the 70-v setting. The percent weight loss on drying was read directly from this instrument. The tablets were ground with a mortar and pestle, and the same procedure for moisture determination was followed.

Hardness Determination—Initial hardness was determined immediately after compression. The tablets were placed on open trays, exposed to ambient room conditions (23°, 25–50% relative humidity), and allowed to equilibrate and reach maximum hardness. For each hardness determination[14], 10 tablets were tested and the mean was calculated.

Disintegration Time—The disintegration apparatus consisted of a basket–rack assembly and a 1-liter beaker as described in the USP. The beaker containing 900 ml of distilled water was maintained at 37° in a constant-temperature water bath. The disintegration times of the individual tablets were noted, and the mean of six tablets was calculated.

***In Vitro* Dissolution**—The dissolution apparatus was the same as described previously (1). It consisted of a 1-liter beaker and a stirrer driven by a synchronous motor at 120 rpm. The beaker containing 600 ml of distilled water was maintained at 37° in a constant-temperature water bath. A stainless steel paddle, 2.5 × 7.6 cm, was centered at the end of a stainless steel shaft and was used as a stirrer. The distance between the bottom of the beaker and the bottom of the stirrer was maintained at 1.8 cm.

At zero time, a tablet was dropped into the stirred dissolution medium. Then, 5-ml samples were withdrawn at appropriate time intervals and filtered through a 0.80-μm pore size filter paper. The absorbance[15] of the salicylic acid in the solution was measured at 303 nm. Three tablets were run for each determination.

RESULTS AND DISCUSSION

To study the role of binders in the moisture-induced hardness increase

in compressed tablets, lactose was chosen as a major excipient since it is commonly used in tablets. The salicylic acid, starch, and magnesium stearate percentages were kept constant in the formulations studied (Table I).

The granulations containing 2–3.2% moisture and different binders at the 10-mg tablet level were compressed into tablets at a targeted initial hardness of 6 Strong-Cobb units. Above a 3.1% initial moisture level, it was not possible to compress the povidone, methylcellulose, hydroxypropyl methylcellulose, acacia, hydroxypropylcellulose, and starch granulations into tablets because of picking and sticking to the punches.

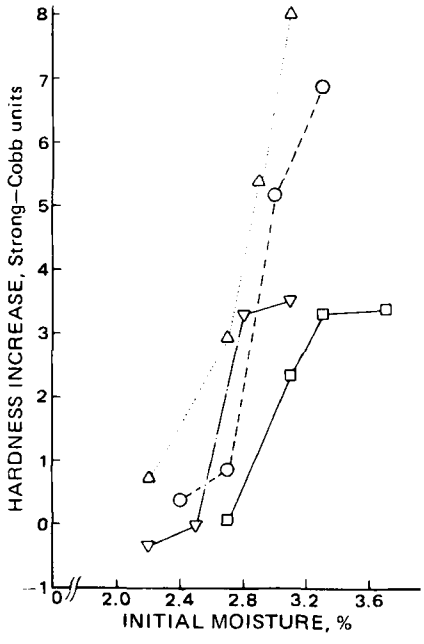

Figure 4—*Effect of the povidone concentration on the hardness increase induced by partial moisture loss in compressed tablets prepared by wet granulation. Key: ○, 5 mg/tablet; △, 10 mg/tablet; ▽, 20 mg/tablet; and □, 30 mg/tablet.*

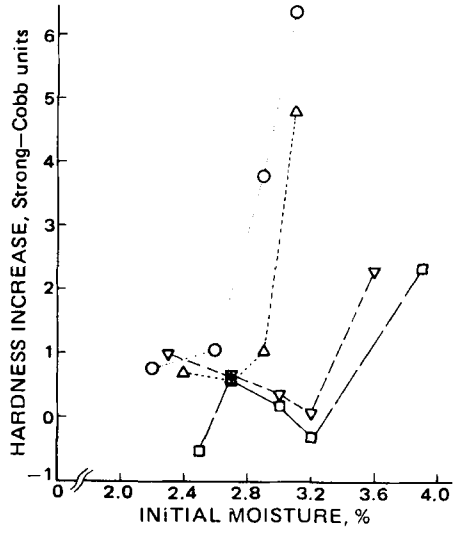

Figure 5—*Effect of the acacia concentration on the hardness increase induced by partial moisture loss in compressed tablets prepared by wet granulation. Key: ○, 5 mg/tablet; △, 10 mg/tablet; ▽, 20 mg/tablet; and □, 30 mg/tablet.*

Tablet hardness was determined again after overnight exposure to ambient room conditions.

The results of the hardness increase *versus* the percent initial moisture are given in Fig. 1. The tablets prepared with different binders that contained a higher moisture content showed large hardness increases, with the exception of starch, which showed a small hardness increase. The magnitude of the hardness increase at a given moisture content depended on the binder.

Plots of the percent moisture loss *versus* the initial moisture are shown in Fig. 2. The tablets prepared with different binders showed an increased moisture loss after overnight exposure to ambient room conditions as the moisture content during compression was increased. The differences in the moisture loss with the binders used in this study were due to the modification of the equilibrium moisture level in the tablets by the binder.

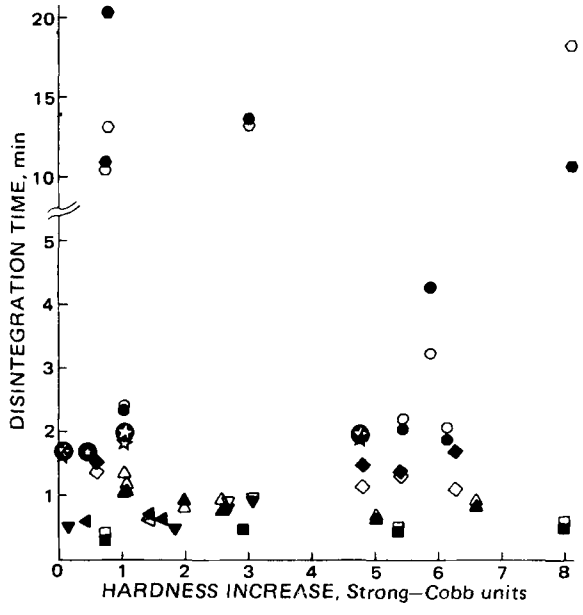

Figure 6—*Role of binders in tablet disintegration time as a function of hardness increase induced by partial moisture loss in compressed tablets prepared by wet granulation. Open symbols give the disintegration time before the hardness increase, and closed symbols give the disintegration time after the hardness increase. Figure 3 gives the relationship between the hardness increase and the percent moisture loss that occurred after the tablets were exposed to ambient room conditions. The tablets containing different binders had a reasonably linear relationship between the hardness increase and the percent moisture loss. These results indicate that the hardness increase in tablets mainly occurred due to the partial moisture loss after compression. Some of the solution of the soluble excipients and/or drug is forced into the void spaces between the compressed granules when the moisture in the granulation exceeds a certain level. Recrystallization of the excipients and/or drug from the saturated solution results in the formation of bridges at the point of contact, leading to a hardness increase.

The strength of the crystalline bridges depends not only on the amount of water-soluble excipient and/or drug deposited in the void spaces but also on the crystallization rate. Any change in the formulation such as the replacement of one binder with another would change the crystallization rate of the drug–excipient solution. This crystallization rate change would modify the size and number of crystalline bridges formed in the void spaces, resulting in different hardness increases.

Any change in the formulation would change the moisture sorption properties of the tablets and the magnitude of the hardness increase. For example, a formulation containing 66% water-insoluble drug, 18% lactose, 10% starch, 5% povidone, and 0.2% magnesium stearate (1) caused greater hardness increases compared to Formula G in this study, which contained about 82% lactose.

Changes in the binder concentrations in the tablet formulations also would change the moisture sorption properties. Two binders, povidone and acacia, were selected to investigate the influence of the binder concentration on the moisture-induced hardness increase. The amount of binder per tablet varied from 5 to 30 mg. The lactose amount was adjusted to keep the total weight per tablet constant. Figure 4 gives the effect of povidone concentration on the hardness increase induced by partial moisture loss. The maximum moisture-induced hardness increase was seen with 10 mg of povidone/tablet. With 20 and 30 mg of povidone/tablet, the hardness increase occurred at higher moisture levels and was less pronounced. With 5 mg of povidone/tablet, the hardness increase was slightly less pronounced compared to the 10-mg of povidone/tablet level at the same initial moisture content.

The effects of the acacia concentration on the hardness increase are shown in Fig. 5. As the amount of acacia in the formulation was increased, a higher initial moisture in the granulation was needed to increase hardness. In agreement with the povidone data (Fig. 4), the effect was less pronounced at higher acacia concentrations.

Physical properties of the drug–excipient combination were changed by changing the binder concentration. The granulations containing 10 mg of povidone/tablet could not be compressed at 3.5% moisture, while the formulation containing 30 mg of povidone/tablet were compressed easily at 3.7% moisture without picking or sticking. However, on equilibration at ambient room conditions, the moisture content of all povidone tablets essentially was the same. Similarly, the granulations containing lower acacia concentrations could not be compressed above 3.2% moisture; at 30 mg of acacia/tablet, the granulation containing 3.9% moisture easily was compressible.

The small hardness increases at higher binder concentrations due to the moisture-related effect could be explained by the crystallization rate decrease of the excipient–drug solution in the voids, which, in turn, results in the formation of fewer crystalline bonds, imparting lower additional strength to the tablet.

The role of binders in tablet disintegration time as a function of hardness increase induced by partial moisture loss is illustrated in Fig. 6. Tablets prepared from most binders did not show an increase in the disintegration time resulting from a moisture-induced hardness increase. However, tablets prepared by wet granulation with gelatin solution had an increased disintegration time in one case, when hardness increased only slightly, but the disintegration time decreased when the hardness increased by about 8 Strong–Cobb units. These results indicate that the hardness increase resulting from partial moisture loss in lactose-based tablets does not affect the tablet disintegration time.

Percent dissolved *versus* time profiles were generated for tablets prepared with different binders at 10 mg of binder/tablet and containing initial moisture levels of 2–3.2% before and after the hardness increase. The data from these tests were plotted on logarithmic probability graph paper (3), and the median ($T_{50\%}$) was obtained from the line. Figure 7 shows linear percent dissolved *versus* time plots. The dissolution median change was obtained by subtracting the dissolution median after the hardness increase from the dissolution median before the hardness increase (Fig. 8). The percent dissolved *versus* time profiles for tablets containing gelatin as a binder at 10 mg of gelatin/tablet and containing different initial moisture levels were not generated. It is obvious from the data given in Fig. 8 that the hardness increase induced by partial moisture loss from lactose-based tablets containing different binders had no effect on drug dissolution.

Photodecomposition of Sulfonamides and Tetracyclines at Oil–Water Interfaces

W. H. K. SANNIEZ and N. PILPEL ˣ

Received December 12, 1978, from the *Department of Pharmacy, Chelsea College of Science, University of London, London SW3 6LX, England.* Accepted for publication July 13, 1979.

Abstract □ Changes that occur in the interfacial tension of hydrocarbon oils floated on dilute aqueous solutions of some sulfonamides and tetracyclines and irradiated with UV light were measured. Photodecomposition products in the oil and aqueous lyers were identified, and reaction mechanisms are proposed.

Keyphrases □ Sulfonamides—photodecomposition at oil-water interface □ Tetracyclines—photodecomposition at oil-water interface □ Photodecomposition—of sulfonamides and tetracyclines at oil-water interface

Many patients undergoing treatment with sulfonamides (1–3) or tetracyclines (4–6) become photosensitive; when subsequently exposed to strong sunlight, they develop skin rashes, fluid in the tissues (edema), and other symptoms.

Storck (7) suggested that sulfonamides in the body are converted into activated species, which combine with protein to form allergens. Alternative mechanisms were proposed to explain the photosensitizing action of the tetracyclines (5, 8). Because of the difficulty in identifying and measuring the reaction products *in vivo*, the processes involved in photosensitization are not well understood.

In vitro techniques recently were developed for studying the reactions of these drugs at air–water and oil–water interfaces under UV light (9–11). One convenient method involves floating a layer of a suitable oil on an aqueous drug solution, irradiating the system with UV light for various times, and analyzing the changes in the interfacial tension of the oil and in the chemical composition of the oil and aqueous layers.

This method was used to study the photochemical decomposition of three sulfonamides and four tetracyclines.

EXPERIMENTAL

Materials—Isopropylbenzene[1] (Puriss) and commercial dodecylbenzene[2] were purified further by passing them three times under slight pressure through a tightly packed bed of fuller's earth (2.5 cm thick), which was renewed after each passage. Sulfanilamide[3] (mp 165°), sulfathiazole[3] (mp 201°), and sulfapyridine[4] (mp 191°) were recrystallized three times from boiling water.

The best available grades of tetracycline[5], chlortetracycline[5], demeclocycline[5], oxytetracycline[6], and deoxytetracycline[7] were used without further purification. Reference standards of epitetracycline (quatrimycin), epichlortetracycline, epidemeclocycline, anhydrotetracycline, anhydrochlortetracycline, and anhydrodemeclocycline were obtained[8].

Triple-distilled water (surface tension 72.1 mN/m at 21°; specific conductivity $1.2 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$ at 21°; pH 5.7) was used.

Apparatus and Technique—The irradiation chamber is shown in Fig. 1. The UV-light source was a 125-w MB/U medium-pressure arc[9] equipped with a silica filter transmitting from 290 to 325 nm (9–11).

Twelve milliliters of isopropylbenzene or dodecylbenzene was floated on 20 ml of a dilute aqueous drug solution in a 6-cm diameter glass pot forming a 0.6-cm deep layer. Each system was placed in turn in the chamber and was irradiated for a predetermined time with its temperature maintained at 25 ± 2°.

After irradiation, the interfacial tension, γ, of the sample was measured *in situ* with a tensiometer[10] using a platinum ring. This technique required the floating hydrocarbon layer to be at least 0.5 cm deep. Wetting of the ring was achieved either by pulling it upward or pushing it downward through the interface, whichever gave the higher reading. The ring had a circumference of 3.86 cm and was made from 0.015-cm radius wire. The tensiometer readings, P, were converted to interfacial tension values, γ, by (12):

$$\gamma = P\left[0.725 + \left(\frac{0.0145P}{C^2(D-d)}\right)^{1/2}\right] \qquad \text{(Eq. 1)}$$

where D and d are the densities of water and the hydrocarbon oil at 20°, respectively. This equation incorporates correction terms for buoyancy and the weight of the liquid raised by the ring (13). The accuracy of the

measurements was estimated at ±1%. Although higher accuracies can be achieved by drop weight or drop volume methods, these methods are unsuited to continuous *in situ* monitoring of samples. Since comparative rather than absolute values were required for this study, the accuracy was considered sufficient. It was confirmed by calibrating the instrument against pure benzene and isopropylbenzene[1] samples. If necessary, results were corrected to 20° by the factor of −0.04 mN/m/deg.

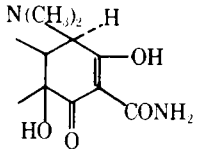
partial tetracycline structure



partial epimer structure

The reaction products that formed in the oil and aqueous layers after irradiation for 4 hr were analyzed by GLC and TLC combined with UV spectroscopy. Peroxides were determined in the oil phase by iodometric titration (14); the quantum efficiency of each additive was calculated from the amount of product and the light intensity, which was determined by an actinometric method using potassium ferrioxolate reagent (15).

RESULTS

The sulfonamides and tetracyclines were more soluble in water than in hydrocarbon oils and thus partitioned mainly in the aqueous phase. They also were adsorbed at the oil–water interface, causing the interfacial tension decreases with concentration that can be observed from the positions at which the various curves intersect the ordinates in Figs. 2 and 3 before irradiation was started.

Irradiation effects on the interfacial tensions of representative samples are shown in Figs. 2 and 3; all samples exhibited interfacial tension decreases with increasing irradiation time. The decrease, expressed as $-\delta\gamma/\delta t$ after 120 min of irradiation, depended on the nature and concentration of the additive but was nearly independent of the oil phase. For example, for a 1.6×10^{-4} mole/dm³ aqueous solution of sulfapyridine in contact with isopropylbenzene, $\delta\gamma/\delta t$ was −0.022; for the same solution in contact with dodecylbenzene, $\delta\gamma/\delta t$ was −0.023.

When the values of the moduli $|\delta\gamma/\delta t|$ were plotted against the square root of the additive concentration, $\sqrt{c}$ in $(\text{moles/dm}^3)^{1/2}$, straight lines were obtained (Figs. 4 and 5) (16). The slopes of these lines are given in Table I and are designated as the photosensitive indexes, X (*cf.*, Ref. 17).

Chemical analysis of the oil layers from systems containing tetracycline, chlortetracycline, and demeclocycline showed that irradiation caused peroxides–hydroperoxides to form fairly rapidly after induction for ~60 min. The peroxide buildup is shown in Figs. 6*a* and 6*b*, and it coincided with a gradual migration of the yellow color from the aqueous phase into the oil phase. Less peroxide was produced by oxytetracycline and by the sulfonamide additives (the latter produced a blue color), and the graphs for these systems approximately coincided with those for the isopropylbenzene and the dodecylbenzene alone, *i.e.*, with the bottom curves in Figs. 6*a* and 6*b*, respectively.

The other reaction products detected in the oil phases of the three tetracyclines (Fig. 6) were anhydrotetracycline, anhydrochlortetracycline, and anhydrodemeclocycline. They were identified by TLC combined with UV spectroscopy. Their R_f values were 0.88, 0.82, and 0.87, respectively. No other reaction products in the oil phases of the systems containing oxytetracycline or the three sulfonamides could be identified, except for the small peroxide amounts already mentioned.

Examination of the aqueous phases from all samples after irradiation for 240 min showed that the pH decreased from 5.4, 5.8, and 5.8 to 3.8, 4.1, and 4.4 in the systems containing sulfanilamide, sulfathiazole, and sulfapyridine, respectively. In the same period, between ~40 and 20% of each additive was converted into the corresponding 2,4-hydroxylaminebenzenesulfonamido derivative. These products were identified by comparing their UV spectra with those of authentic standards (7). Furthermore, the systems containing oxytetracycline produced β-deoxytetracycline, R_f 0.13, and the systems containing tetracycline, chlortetracycline, and demeclocycline produced the corresponding epimers (18) with R_f 0.21, 0.22, and 0.19, respectively.

The quantum efficiencies (moles of product per Einstein) of the additives were: sulfanilamide, 3.70; sulfathiazole, 2.90; sulfapyridine, 1.20; demeclocycline, 2.80; tetracycline, 2.00; and chlortetracycline, 1.60. The fact that the values were greater than unity indicates that the photochemical reactions proceeded by chain mechanisms (19).

DISCUSSION

The main decomposition products from the sulfonamides, *i.e.*, the 2,4-hydroxylaminobenzenesulfonamido derivatives, were soluble in water

This reaction scheme would account satisfactorily for the observed pH decreases in these systems.

The sulfonamides did not produce appreciable amounts of oil-soluble products. If they had, these products might have been expected to catalyze or sensitize the photodecomposition of the supernatant isopropylbenzene or dodecylbenzene (9, 10). In fact, the two oils yielded about the same amount of peroxide whether irradiated on their own or in the presence of the sulfonamides.

In contrast, when the same oils were irradiated in the presence of at least three of the tetracyclines, much larger amounts of peroxide were formed (Fig. 6). This increase presumably was due to the formation of the oil-soluble anhydrotetracycline (AT) derivatives (detected by analysis) as shown in Schemes II and III (8, 21):

$$AT \xrightarrow{h\nu} AT^*$$

Scheme II

$$AT^* + {}^3O_2 \rightarrow AT + {}^1O_2^*$$

Scheme III

The excited singlet molecular oxygen then could react with the hydrocarbon oil, *e.g.*, isopropylbenzene (Scheme IV):

$$C_6H_5CH(CH_3)_2 + {}^1O_2^* \xrightarrow{h\nu} \underset{\text{peroxide}}{C_6H_5C(CH_3)_2OO\cdot}$$

Scheme IV

thus producing the hydroperoxides. (A similar reaction would be expected to occur with dodecylbenzene, and this hypothesis is confirmed by the similarly shaped curves in Figs. 6*a* and 6*b*.)

The present work shows that the breakdown products from both drug classes considerably reduce the tension at an oil–water interface, and a measure of the effect is provided by the drug's photosensitive index, X (Table I) (*cf.*, Ref. 17). As defined, a small X implies a large reduction in interfacial tension during irradiation; on this basis, the sulfonamides (and sulfanilamide in particular) produce substantially larger effects than the tetracyclines.

Some connection eventually may be found between the photochemical decomposition of sulfonamides and tetracyclines at the oil–water interface *in vitro* and at the lipid–water interface of the cell wall (22). Such a connection might assist in elucidating the photosensitization mechanisms that occur *in vivo* and explain, for example, the observation that the ranking order of photosensitivity in Table I for the sulfonamides and oxytetracycline is the same as was obtained from *in vivo* experiments on patients (1, 3).

Comparative Pharmacokinetics of Coumarin Anticoagulants XLIV: Dose-Dependent Pharmacokinetics of Warfarin in Rats

KANJI TAKADA and GERHARD LEVY ˣ

Received June 4, 1979, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication July 13, 1979.

Abstract □ The purpose of this investigation was to determine the effect of dose on warfarin pharmacokinetics in rats. First, in a crossover experiment, rats received ^{14}C-warfarin, 0.2 mg/kg iv, 12 hr after an injection of either nonradioactive warfarin (0.5 mg/kg) or saline solution. Warfarin concentrations in plasma declined triexponentially as a function of time. Pharmacokinetic analysis revealed that pretreatment with warfarin significantly decreased the apparent volume of distribution, total plasma clearance, and intrinsic plasma clearance of the drug. In the second part of the investigation, rats received single intravenous warfarin injections in the order of 0.1–1.0–0.1 or 1.0–0.1–1.0 mg/kg at 2-week intervals. The apparent volume of distribution, total plasma clearance, and intrinsic plasma clearance of the 1.0-mg/kg warfarin dose were appreciably lower than those of the 0.1-mg/kg dose. The decrease in the apparent volume of distribution of warfarin with increasing dose is consistent with the previously observed concentration dependence in hepatic uptake of the drug.

Keyphrases □ Coumarin anticoagulants—warfarin, dose-dependent pharmacokinetics, rats □ Warfarin—dose-dependent pharmacokinetics, rats □ Pharmacokinetics—warfarin, dose dependence, rats

Hepatic uptake of warfarin in rats, as reflected by the ratio of total warfarin concentration in the liver to the free warfarin concentration in serum during the postdistributive (β) phase, is highly dose or concentration dependent. A determination of warfarin concentrations in serum and liver of rats 6 hr after injection of either 0.1 or 1.0 mg/kg showed that concentrations in serum increased much more than proportionally and that concentrations in the liver increased much less than proportionally with dose (1). Therefore, the liver–serum concentration ratio decreased as the dose was increased from 0.1 to 1.0 mg/kg.

Since warfarin in the liver can account for a large fraction of the total drug in the body of rats (2), dose-dependent hepatic uptake may result in a dose-dependent change in the apparent volume of distribution of the drug. This possibility, as well as the possibility of other dose-dependent changes in warfarin pharmacokinetics in rats, was explored in this investigation. The nonlinear uptake or binding of warfarin by the liver in a concentration range in which serum protein binding of the drug is almost independent of concentration provides an opportunity to study a system that has been the subject of considerable theoretical interest and exploration (3, 4).

EXPERIMENTAL

The investigation was carried out in two parts. First, the pharmacokinetics of a small ^{14}C-warfarin dose were determined in a crossover study on rats that had been given either saline solution or a larger dose of nonradioactive warfarin 12 hr earlier. Second, in a triple crossover study, rats received either a high, then a low, and then again a high dose of warfarin or a low, then a high, and then again a low dose of the drug.

In the first part of the study, 10 male Sprague–Dawley rats, 360–505 g, were used. Rats 1a–4a were obtained from a supplier[1] who was unable to provide additional animals at that time; therefore, Rats 6a–10a were obtained from a different source[2]. A two-piece cannula of silicone rubber–polyethylene was implanted in the right jugular vein, under light ether anesthesia (5, 6), 2 days before the start of the experiment. The rats were placed in individual plastic metabolism cages with food[3] and water freely available.

Five rats received an intravenous injection of 0.9% sodium chloride solution while the other five animals received an intravenous injection of nonradioactive racemic warfarin, 0.5 mg/kg, through the cannula at 8 pm. The injection volume was ~2 ml/rat. Twelve hours later, all animals received an intravenous injection of racemic ^{14}C-warfarin[4] (158 μCi/mg), ~3.5 μCi/rat, together with enough nonradioactive racemic warfarin to constitute a total dose of 0.2 mg/kg. Mainstream blood samples (0.15–0.20 ml) were obtained at 5, 15, 30, 45, 60, 80, 100, 120, 150, and 200 min and then at less frequent intervals for ~50 hr by a technique described previously (6), except that saline solution rather than heparinized saline solution was used to displace blood from the external portion of the cannula.

The blood was transferred to heparinized capillary tubes[5], which were

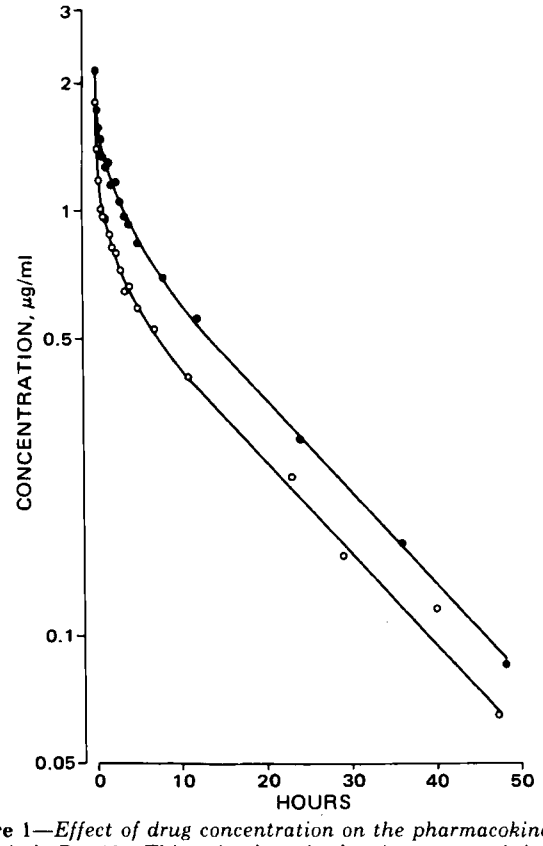

Figure 1—*Effect of drug concentration on the pharmacokinetics of warfarin in Rat 10a. This animal received an intravenous injection of ^{14}C-warfarin 12 hr after injection of saline solution (control experiment, open circles) and, 1 week later, the same dose of ^{14}C-warfarin 12 hr after intravenous injection of nonradioactive warfarin, 0.5 mg/kg (solid circles). The data points show the time course of ^{14}C-warfarin concentrations in serum. The lines were fitted to the data by computer.*

[a] The rats received an intravenous injection of ^{14}C-warfarin, 0.2 mg/kg 12 hr after an intravenous injection of either saline solution or nonradioactive warfarin, 0.5 mg/kg, in crossover fashion 1 week apart. [b] The − equals saline injection, and the + equals nonradioactive warfarin. Even-numbered rats received saline injection in the first experiment. [c] The P, A, and B values are in micrograms per milliliter based on a 0.2-mg/kg dose; π, α, and β values are in hours^{-1}. These constants describe the time course of warfarin concentrations: $C_t = Pe^{-\pi t} + Ae^{-\alpha t} + Be^{-\beta t}$, where C_t is the total drug concentration at time t. [d] Serum was collected 5 days after the end of the second experiment, and portions were spiked with ^{14}C-warfarin to yield total concentrations of about 0.5 and 5 μg/ml. [e] Rat 6 died 2 days after the second experiment, before serum for protein binding studies could be collected. [f] Significantly different from free fraction value at a total concentration of 0.5 μg/ml ($p < 0.001$ by paired t test).

centrifuged and cut at the erythrocyte–plasma interface after determination of the hematocrit. The plasma was removed, and warfarin was extracted, separated from its metabolites by TLC, and assayed by scintillation spectrometry as described previously (7). An aliquot of the injection solution was assayed in the same manner, and the plasma warfarin concentrations were normalized for small (9.5 ± 5.9%) interindividual variations from the designated dose. Crossover experiments were carried out 7 days later; animals that previously received saline pretreatment were pretreated with nonradioactive warfarin and *vice versa*. Cannula patency was maintained by replacing the saline solution in the cannula every day.

Five days after the end of the second experiment, blood was removed from the aorta of all animals under light ether anesthesia, and serum was separated. Portions of the serum were used to determine the free fraction of warfarin by equilibrium dialysis (2, 8) after addition of racemic ^{14}C-warfarin, ~0.5 and 5 μg/ml, respectively. The dialyses were done in duplicate. Total protein concentrations in serum were determined by the method of Gornall *et al.* (9) with rat albumin as the standard.

The second part of the study was carried out on adult male Sprague–Dawley rats[1] weighing 350–485 g at the beginning of the first experiment. They were cannulated and placed in metabolism cages as described in an earlier paragraph. The animals received intravenous injections of ^{14}C-warfarin, ~3.5 μCi, together with sufficient nonradioactive racemic warfarin to constitute a total dose of either 0.1 or 1.0 mg/kg. Two rats received the low, high, and low doses in that order, with a 14-day interval between each dose. Two other animals received the doses in the order high, low, and high dose.

Two additional rats received the high dose and then the low dose but expired due to apparent infection before the third (high) dose could be administered. These were the first two animals studied, and the infection problem was not encountered in the subsequently studied animals, apparently because the nonsterile saline solution previously used to fill the cannulas was replaced by sterile saline solution.

Blood sampling and analyses were carried out as in the first part of the investigation. Serum for protein binding determinations was obtained 14 days after the end of the third experiment.

The plasma warfarin concentration data obtained in the first and second parts of the investigation were fitted to a triexponential equation ($C_t = Pe^{-\pi t} + Ae^{-\alpha t} + Be^{-\beta t}$, where C_t is the drug concentration at time t) by a nonlinear least-squares regression procedure (10). Convergence was defined as a relative change in the residual sum of squares less than 10^{-4}. Data in all functions were weighted numerically equal. The apparent volume of the hypothetical central compartment was determined by dividing the injected dose by $P + A + B$. The area under the concentration–time curve (AUC) was calculated by the trapezoidal method to the last experimentally determined concentration, to which the area Ci/β was added, where Ci is the computer-estimated value of the last experimentally determined concentration. This AUC value was used to calculate total clearance (dose/AUC) and V_{area} (dose/$AUC \cdot \beta$). The AUC also was determined from the constants of the triexponential equation as the sum of P/π, A/α, and B/β. Intrinsic clearance was calculated by dividing the total clearance by the serum free fraction (f), using the average of the f values obtained at the 0.5- and 5-μg of warfarin/ml concentrations.

Statistical analyses were done by Student's t test (paired, two tailed).

RESULTS

Results of the first part of the investigation, in which 10 rats received an intravenous injection of ^{14}C-warfarin 12 hr after an injection of saline solution or of nonradioactive warfarin in a crossover experiment, are summarized in Tables I and II. Figure 1 shows the time course of ^{14}C-warfarin plasma concentrations in a typical animal; Fig. 2 shows the re-

sults obtained in Rat 5a, which exhibited very much lower total and intrinsic clearances of warfarin than the rest of the group. The unusual animal is also noteworthy for its very long (≃ 60 hr) warfarin half-life (which showed excellent reproducibility in the crossover study) and its low serum protein concentration, suggestive of impaired liver function.

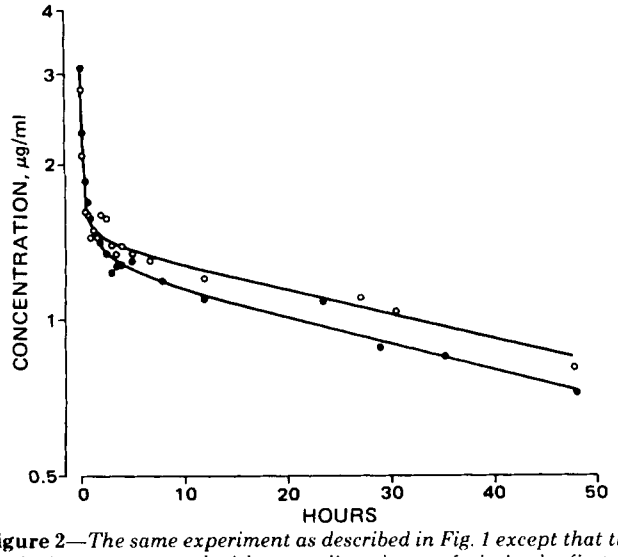

Figure 2—*The same experiment as described in Fig. 1 except that this rat (5a) was pretreated with nonradioactive warfarin in the first experiment and with saline solution in the second experiment. This rat had a much lower total clearance of warfarin and a lower serum protein concentration than the other nine animals, suggesting impaired liver function. The very long and reproducible half-life (60 hr compared to an average of 16 hr in the other rats) should be noted.*

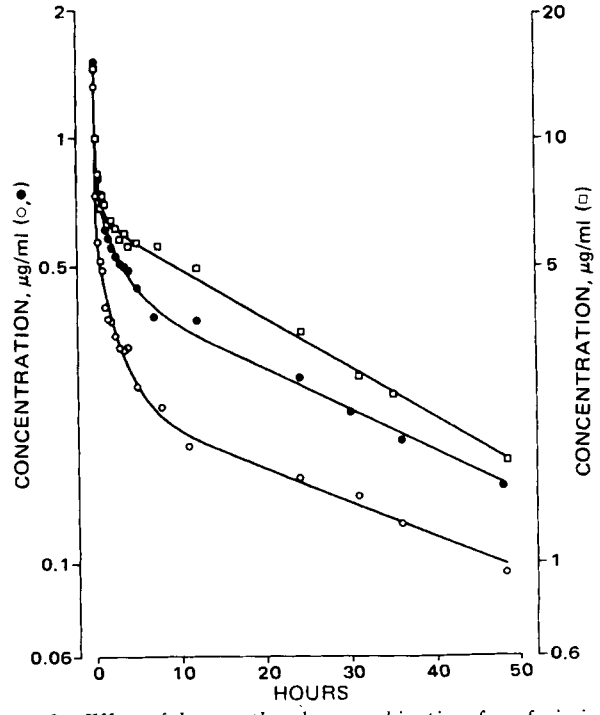

Figure 3—*Effect of dose on the pharmacokinetics of warfarin in Rat 1. This animal received intravenous injections of 0.1, 1.0, and 0.1 mg of ^{14}C-warfarin/kg at 2-week intervals. Key: ○, first dose (0.1 mg/kg); □, second dose (1.0 mg/kg); and ●, third dose (0.1 mg/kg). The data points show the time course of drug concentrations in plasma. The lines were fitted to the data by computer.*

[a] The P, A, and B values are in micrograms per milliliter; the π, α, and β values are in hours^{-1}. These constants describe the time course of warfarin concentrations in serum; $C_t = Pe^{-\pi t} + Ae^{-\alpha t} + Be^{-\beta t}$, where C_t is the total drug concentration at time t. [b] Serum was collected 2 weeks after the end of the third experiment, and portions were spiked with ^{14}C-warfarin to yield total concentrations of about 0.5 and 5 μg/ml. [c] These animals died before the third experiment and before serum for free fraction determination could be obtained.

Therefore, the average results for the group and the statistical analyses in Tables I and II are presented not only for all 10 rats but also for the group without Rat 5a.

The time course of warfarin concentrations in plasma of all animals was best described by a triexponential equation, consistent with previous observations (11). The constants of that equation for each animal are listed in Table I. Pretreatment with 0.5 mg of warfarin/kg 12 hr earlier (a period somewhat shorter than the average biological half-life of the drug in this group of rats) had no apparent effect on the constants that characterize the so-called distribution phase of drug concentrations in plasma, *i.e.*, P, A, π, and α. There was also no apparent effect on β or, therefore, on the biological half-life of the drug. On the other hand, B was significantly increased by pretreatment with warfarin. The free fraction of warfarin in serum was almost constant over a 10-fold concentration range encompassing the maximum concentration of radioactive and nonradioactive drug in warfarin-pretreated animals and concentrations representing ≤20% of the initial warfarin concentration in these animals when they were pretreated with saline solution (Table I).

The apparent volume of the hypothetical central compartment (V_c) and the partial areas of the distribution phase, P/π and A/α, were not affected by warfarin pretreatment. However, V_{area} and total clearance were decreased significantly by that pretreatment (Table II). The intrinsic clearance of the drug decreased also. The excellent agreement of the AUC values determined by the trapezoidal method with those determined by summing the P/π, A/α, and B/β values reflects the good fit of the experimental data to the triexponential equation.

Consistent with theoretical considerations and previous observations (12), there was an essentially linear relationship between total clearance and serum free fraction of warfarin for the nine rats (*i.e.*, excluding Rat 5a), with a correlation coefficient of 0.87 ($p < 0.01$) for clearance values obtained in the control (saline pretreatment) experiments.

The second part of the study was a difficult three-way crossover experiment designed to confirm the effect of dose on V_{area} and total clearance and to examine the possible effect of dose on the distribution phase over a wider (10-fold) dose range. This experiment required measurements on each animal over 6 weeks and could be completed in only four rats during the time available. Figure 3 shows results obtained in one of two rats that received a 0.1-mg/kg dose first, a 1-mg/kg dose 2 weeks later, and another 0.1-mg/kg dose after 2 more weeks and that were sacrificed 2 weeks after the third dose to obtain serum for protein binding determinations. Figure 4 shows results obtained in one of two animals that received first the high dose, then the low dose, and then again the high dose of warfarin.

The results of the balanced three-way crossover experiment on four rats as well as results obtained from two rats that expired before the third dose are summarized in Tables III and IV. No averaging or statistical analyses were done because only two rats completed any one dosing sequence. It should be noted that P, A, and B will increase proportionally with dose if the pharmacokinetics are linear. In fact, P and A increased less than proportionally with only one exception (Rat 3, 5th week). On the other hand, B increased more than proportionally in all experiments (Table III). There were no apparently dose-dependent trends in π, α, and β. Serum free fraction values at warfarin concentrations of 0.5 and 5 μg/ml did not differ appreciably in any one animal (Table III).

The partial areas P/π and A/α did not increase proportionally with dose while B/β increased more than proportionally with dose (Table IV). There was no remarkable effect of dose on V_c, there occurred a consistent decrease of V_{area} at the higher dose, and there were consistent decreases of the total and intrinsic clearances at the higher dose. In all four rats receiving the three-dose sequence, V_c and V_{area} of the third dose were lower than those of the first (and equal) dose (Table IV).

DISCUSSION

The results of this investigation demonstrate a dose dependence in the pharmacokinetics of warfarin: V_{area}, intrinsic clearance, and, therefore, total clearance decreased with increasing dose in the dose range studied. The decrease in V_{area} is probably due, at least in part, to the previously demonstrated decreased uptake of warfarin by the liver with increasing dose (1) since the liver accounts for a major fraction of the total warfarin in the body following administration of a relatively small dose (2). Such a decrease in V_{area} is quite unusual; much more common is an increase in V_{area} with increasing dose due to decreased plasma protein binding of a drug at higher concentrations. However, O'Reilly *et al.* (13) reported a decrease in the apparent volume of distribution of dicumarol with increasing dose over the 150–600-mg dose range in adult humans. On the other hand, they did not observe such dose dependence with warfarin over the 50–200-mg dose range in the two humans studied (13). A limited study in this laboratory, carried out more than 10 years earlier when ^{14}C-warfarin was not available, revealed no apparent difference in the volume of distribution of warfarin in rats given injections of 4 and 12.5 mg/kg (14). Interestingly, the apparent volume of distribution of these very large doses (110–130 ml/kg) was slightly less than that of the 1-mg/kg dose in the present study.

Theoretical considerations suggest that, all else being equal, a reduction in liver uptake should cause an increase in β and, therefore, a decrease in the biological half-life of warfarin (15). However, the same considerations indicate that β will decrease if the intrinsic clearance is decreased. Thus, the lack of appreciable dose dependence of β in the present study may be rationalized by the opposing effects of decreased warfarin binding or uptake by the liver and decreased intrinsic clearance at the higher dose. It is possible that hepatic warfarin uptake may be due largely to specific binding of the drug to warfarin-metabolizing enzymes and that the decreased hepatic uptake and intrinsic clearance of warfarin at higher doses may be reflections of the same dose-dependent phenomenon.

Adequate blood volumes for serum protein binding studies were obtained only at the end of the crossover experiments to prevent premature exsanguination of the animals. It has been demonstrated previously in

[a] Based on P, A, B, π, α, and β values in Table III. [b] See footnotes *c*, *d*, and *e* in Table II for additional information. [c] Cannot be calculated due to lack of free fraction values.

this laboratory that serum free fraction values of warfarin in rats remain constant for at least 9 days (16). In another study, in which rats received a large single dose of warfarin, then daily smaller doses for 13 days, and then again a large dose, serum free fraction values were determined before and after this sequence (the time interval being ~35 days) and decreased by 18% on the average (17). We have no direct evidence that the free fraction values remained constant over 6 weeks of the present study. Therefore, there is some uncertainty concerning the *absolute* intrinsic clearance values in this study but not concerning the fact that intrinsic clearance did decrease with increasing dose (since the experiments were carried out in crossover fashion).

The three-way crossover experiments confirmed the results of the first part of the investigation in that they also demonstrated a decrease of V_{area} and intrinsic clearance with increasing dose. In addition, the three-way crossover experiments revealed a *relative* decrease in P and A and, therefore, in P/π and A/α with increasing dose. This result is probably due to an increased serum free fraction at the initial concentrations produced by the 1-mg/kg dose. It has been calculated that the free fraction of warfarin remains essentially constant at plasma warfarin concentrations up to 6 μg/ml and that it increases by 25 and >200% at concentrations of 96 and 282 μg/ml, respectively (18). Initial plasma warfarin concentrations following the 0.1- and 1-mg/kg doses in the present study were ~2 and 17 μg/ml, a difference large enough to expect some change in the free fraction. On the other hand, the first part of this study, in which V and A were not affected by pretreatment with warfarin, involved less than a twofold difference in initial concentration (considering the sum of the concentrations of ^{14}C-warfarin and nonradioactive drug) and these initial concentrations were well below 6 μg/ml.

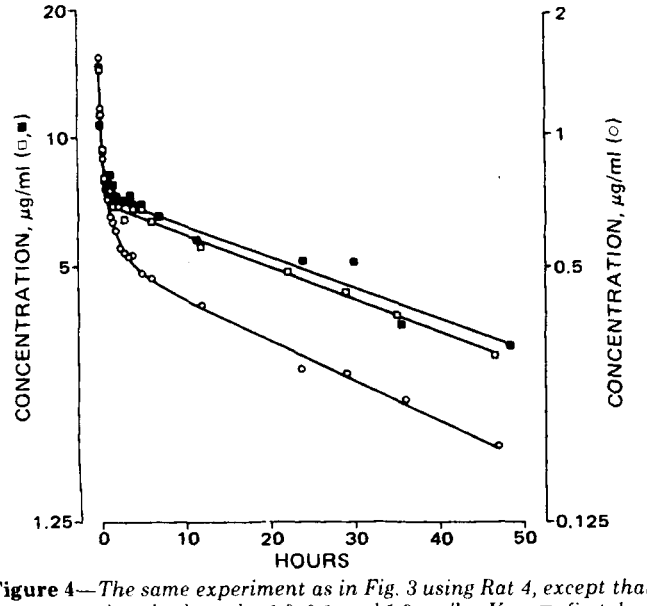

Figure 4—*The same experiment as in Fig. 3 using Rat 4, except that doses were given in the order 1.0, 0.1, and 1.0 mg/kg. Key:* □, *first dose (1.0 mg/kg);* ○, *second dose (0.1 mg/kg); and* ■, *third dose (1.0 mg/kg).*

The suggestion that the decrease in the P and A values after the 1-mg/kg dose (as compared to the corresponding values after the 0.1-mg/kg dose) is due to decreased plasma protein binding of warfarin finds support from results of a previous investigation (11). Studies of warfarin pharmacokinetics were carried out on 14 rats with widely different serum free fraction values (from 0.3×10^{-2} to 2.9×10^{-2}); all animals received a single 0.51-mg/kg injection. There was a statistically significant negative correlation between serum free fraction and P ($r = -0.873$, $p < 0.001$; the negative sign of the correlation coefficient was inadvertently omitted in the cited report).

In summary, warfarin pharmacokinetics in rats are dose dependent; the apparent volume of distribution of the drug, the intrinsic clearance, and the total clearance decrease with increasing dose in the 0.1–1-mg/kg dose range. At least one of these phenomena, *i.e.*, the decrease in the apparent volume of distribution, is probably due largely to decreased hepatic uptake of the drug. In addition, the apparent distribution phase of warfarin concentrations in plasma following intravenous injection of 1 mg/kg is less pronounced than that following a 0.1-mg/kg dose, probably due to decreased protein binding of the drug at the high initial plasma concentrations produced by the larger dose.

Comparative Pharmacokinetics of Coumarin Anticoagulants XLV: Pharmacokinetic and Pharmacodynamic Studies of Acute Interaction between Warfarin and Phenylbutazone in Rats

AVRAHAM YACOBI, CHII-MING LAI, and GERHARD LEVY ˣ

Received June 7, 1979, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication July 6, 1979.

Abstract □ A comprehensive investigation of the effect of phenylbutazone on warfarin pharmacokinetics and anticoagulant activity was carried out in rats to identify and quantify various aspects of the interaction between these drugs. Adult male rats received intravenous racemic warfarin alone and together with phenylbutazone in a crossover experiment. Prothrombin complex activity and the plasma concentrations of phenylbutazone and of free and total (free plus protein-bound) warfarin were determined repeatedly for up to 60 hr. The total plasma clearance, the apparent volume of distribution, and the disposition rate constant (β) of warfarin were significantly increased and the intrinsic plasma warfarin clearance was significantly decreased during phenylbutazone administration. Phenylbutazone decreased the serum protein binding of warfarin both *in vitro* and *in vivo*, but the *in vivo* effect was much more pronounced, apparently due to the displacing effect of phenylbutazone metabolite(s). Phenylbutazone alone had no apparent effect on prothrombin complex activity *in vitro* but caused a modest, yet statistically significant, anticoagulant effect *in vivo*. The anticoagulant effect–plasma warfarin concentration curves for total and free warfarin were shifted to a considerably lower concentration range during phenylbutazone treatment. Thus, the interaction between phenylbutazone and warfarin involves at least three processes: an inhibition of warfarin biotransformation (decreased intrinsic clearance); displacement of warfarin from plasma protein binding sites (increased free fraction); and apparent potentiation of the anticoagulant action produced by a given plasma warfarin concentration. The latter may have been caused, at least in part, by a direct anticoagulant effect of phenylbutazone and/or its metabolite(s). The net effect of decreased protein binding and decreased intrinsic clearance was an increase in the total plasma warfarin clearance. The results of this investigation demonstrate that drug interactions can be complex and multifactorial.

Keyphrases □ Warfarin—interaction with phenylbutazone, pharmacokinetics, *in vitro* and *in vivo*, rats, prothrombin complex activity □ Phenylbutazone—interaction with warfarin, pharmacokinetics, *in vitro* and *in vivo*, rats, prothrombin complex activity □ Anticoagulants—warfarin, interaction with phenylbutazone, pharmacokinetics, *in vitro* and *in vivo*, rats, prothrombin complex activity

There is a tendency to attribute most drug interactions to only one of several theoretically possible mechanisms. This approach is probably unrealistic and reflects the limited scope and the relative lack of pharmacokinetic quantitation characteristic of most drug interaction studies. For example, one drug may displace another from plasma protein binding sites and cause the displaced drug to be eliminated more rapidly. Unless the increased clearance of the displaced drug is *quantitatively* consistent with the increase of its free fraction in plasma, additional interaction mechanisms must be sought. These additional mechanisms may operate in the same direction (*i.e.*, increased clearance) or in the opposite direction from that attributable to reduced plasma protein binding. Moreover, pharmacokinetic as well as pharmacodynamic interactions may occur so that an assessment of the therapeutic implications of the interacting system requires consideration of the net effect resulting from both types of interactions. These potential complexities suggest that comprehensive model drug interaction studies are needed for the development of more effective strategies for exploring potential or suspected interactions involving new drugs.

The interaction between the anticoagulant warfarin and the anti-inflammatory agent phenylbutazone is phenomenologically well established, and its potentially disastrous clinical consequences are generally appreciated (1–3). The interaction between these two drugs has been studied in humans (4–8) and in dogs (9). However, the recent development of clearance concepts (10, 11) and the availability of an animal model exhibiting wide interindividual differences in the plasma protein binding of warfarin under normal physiological conditions (12) have provided a more rational basis and a promising means for better exploration of the interaction.

The investigation described here consisted of a rigorous quantitative determination of the phenylbutazone effect on the elimination kinetics and anticoagulant action of warfarin in a crossover study on rats specially selected for wide interindividual differences in serum protein binding of warfarin and, therefore, in warfarin clearance. The phenylbutazone effect on serum protein binding of warfarin was determined *in vitro* and *in vivo*. The relationship between anticoagulant effect and warfarin concentration in plasma was determined for free and total (free plus bound) drug. The phenylbutazone effect *per se* on the coagulation process was examined *in vitro* and *in vivo*.

It is believed that the results of these studies will demonstrate the potential complexity and multifaceted characteristics of drug interactions, will illustrate the practical limitations of many drug interaction studies in humans,

Comparative Pharmacokinetics of Coumarin Anticoagulants XLV: Pharmacokinetic and Pharmacodynamic Studies of Acute Interaction between Warfarin and Phenylbutazone in Rats

AVRAHAM YACOBI, CHII-MING LAI, and GERHARD LEVY ˣ

Received June 7, 1979, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication July 6, 1979.

Abstract □ A comprehensive investigation of the effect of phenylbutazone on warfarin pharmacokinetics and anticoagulant activity was carried out in rats to identify and quantify various aspects of the interaction between these drugs. Adult male rats received intravenous racemic warfarin alone and together with phenylbutazone in a crossover experiment. Prothrombin complex activity and the plasma concentrations of phenylbutazone and of free and total (free plus protein-bound) warfarin were determined repeatedly for up to 60 hr. The total plasma clearance, the apparent volume of distribution, and the disposition rate constant (β) of warfarin were significantly increased and the intrinsic plasma warfarin clearance was significantly decreased during phenylbutazone administration. Phenylbutazone decreased the serum protein binding of warfarin both *in vitro* and *in vivo*, but the *in vivo* effect was much more pronounced, apparently due to the displacing effect of phenylbutazone metabolite(s). Phenylbutazone alone had no apparent effect on prothrombin complex activity *in vitro* but caused a modest, yet statistically significant, anticoagulant effect *in vivo*. The anticoagulant effect–plasma warfarin concentration curves for total and free warfarin were shifted to a considerably lower concentration range during phenylbutazone treatment. Thus, the interaction between phenylbutazone and warfarin involves at least three processes: an inhibition of warfarin biotransformation (decreased intrinsic clearance); displacement of warfarin from plasma protein binding sites (increased free fraction); and apparent potentiation of the anticoagulant action produced by a given plasma warfarin concentration. The latter may have been caused, at least in part, by a direct anticoagulant effect of phenylbutazone and/or its metabolite(s). The net effect of decreased protein binding and decreased intrinsic clearance was an increase in the total plasma warfarin clearance. The results of this investigation demonstrate that drug interactions can be complex and multifactorial.

Keyphrases □ Warfarin—interaction with phenylbutazone, pharmacokinetics, *in vitro* and *in vivo*, rats, prothrombin complex activity □ Phenylbutazone—interaction with warfarin, pharmacokinetics, *in vitro* and *in vivo*, rats, prothrombin complex activity □ Anticoagulants—warfarin, interaction with phenylbutazone, pharmacokinetics, *in vitro* and *in vivo*, rats, prothrombin complex activity

There is a tendency to attribute most drug interactions to only one of several theoretically possible mechanisms. This approach is probably unrealistic and reflects the limited scope and the relative lack of pharmacokinetic quantitation characteristic of most drug interaction studies. For example, one drug may displace another from plasma protein binding sites and cause the displaced drug to be eliminated more rapidly. Unless the increased clearance of the displaced drug is *quantitatively* consistent with the increase of its free fraction in plasma, additional interaction mechanisms must be sought. These additional mechanisms may operate in the same direction (*i.e.*, increased clearance) or in the opposite direction from that attributable to reduced plasma protein binding. Moreover, pharmacokinetic as well as pharmacodynamic interactions may occur so that an assessment of the therapeutic implications of the interacting system requires consideration of the net effect resulting from both types of interactions. These potential complexities suggest that comprehensive model drug interaction studies are needed for the development of more effective strategies for exploring potential or suspected interactions involving new drugs.

The interaction between the anticoagulant warfarin and the anti-inflammatory agent phenylbutazone is phenomenologically well established, and its potentially disastrous clinical consequences are generally appreciated (1–3). The interaction between these two drugs has been studied in humans (4–8) and in dogs (9). However, the recent development of clearance concepts (10, 11) and the availability of an animal model exhibiting wide interindividual differences in the plasma protein binding of warfarin under normal physiological conditions (12) have provided a more rational basis and a promising means for better exploration of the interaction.

The investigation described here consisted of a rigorous quantitative determination of the phenylbutazone effect on the elimination kinetics and anticoagulant action of warfarin in a crossover study on rats specially selected for wide interindividual differences in serum protein binding of warfarin and, therefore, in warfarin clearance. The phenylbutazone effect on serum protein binding of warfarin was determined *in vitro* and *in vivo*. The relationship between anticoagulant effect and warfarin concentration in plasma was determined for free and total (free plus bound) drug. The phenylbutazone effect *per se* on the coagulation process was examined *in vitro* and *in vivo*.

It is believed that the results of these studies will demonstrate the potential complexity and multifaceted characteristics of drug interactions, will illustrate the practical limitations of many drug interaction studies in humans,

and will suggest the effort required for a comprehensive and quantitative exploration of drug interactions in general.

EXPERIMENTAL

***In Vitro* Phenylbutazone Effect on Serum Protein Binding of Warfarin**—Eight randomly selected adult male Sprague–Dawley rats[1] were sacrificed under ether anesthesia by withdrawal of all blood from the abdominal aorta. The blood was converted into serum, and the latter was pooled. Two-milliliter portions of serum were spiked with racemic ^{14}C-warfarin[2] and with phenylbutazone[3] to produce concentrations of 0.4–3 μg of warfarin/ml and 0–200 μg of phenylbutazone/ml. ^{14}C-Warfarin was dissolved in ethylene dichloride. A portion of this solution was transferred to a glass vial and evaporated under nitrogen flow. Ten microliters of phenylbutazone in 0.1 *N* NaOH was added to the warfarin, and the mixture was shaken thoroughly and mixed with the serum. The serum binding was determined by equilibrium dialysis at 37° (12).

***In Vivo* Phenylbutazone Effect on Serum Protein Binding of Warfarin**—Ten randomly selected rats, 340–415 g, received phenylbutazone, 40 mg/kg ip, initially followed by 20 mg/kg ip every 4 hr for 10 doses. Immediately before the first injection and 2 hr after the last one, 2.5–3.0 ml of blood was withdrawn from the tail artery. Serum was separated and spiked with ^{14}C-warfarin for protein binding determinations.

Assay of Warfarin and Phenylbutazone—The concentrations of warfarin in serum, plasma, and buffer solution were determined by extraction, TLC, and scintillation counting (13). Phenylbutazone in plasma and serum was assayed by the method of Jähnchen and Levy (14). That assay was modified slightly to increase the sensitivity. To 0.1 ml of plasma, 0.1 ml of 3 *N* HCl and 2 ml of *n*-heptane were added. After shaking for 30 min, the phases were separated by centrifugation at 1000×*g* for 3 min. To 1.8 ml of the *n*-heptane phase, 2 ml of 1 *N* NaOH was added. After shaking for 5 min and centrifuging for the same time, the heptane phase was discarded. To 1.8 ml of the sodium hydroxide phase, 3 ml of buffered

Table II—Phenylbutazone Effect on Warfarin Pharmacokinetics in Rats [a]

Pharmacokinetic Constant	Control	With Phenylbutazone
Total plasma clearance, ml/hr/kg	8.88 (2.92–24.0)	17.8[b] (6.74–41.2)
Half-life, hr	16.3 (6.31–31.6)	8.66[b] (4.55–14.6)
Volume of distribution, ml/kg	152 (117–219)	175[b] (128–271)
Serum free fraction × 100	0.908 (0.296–1.90)	2.92[b,c] (0.957–7.03)
Intrinsic plasma clearance, ml/hr/kg	985 ± 163 (764–1304)	651 ± 83[b] (497–796)

[a] Results are reported as mean values for 11 animals, with the range in parentheses. Standard deviations are omitted, with one exception, for reasons discussed in the text. [b] Statistically significantly different from the control value ($p < 0.01$) by paired *t* test. [c] The concentration of phenylbutazone in these serum samples was 67.1 ± 24.6 μg/ml.

permanganate solution (14) was added, and the mixture was incubated at 65° for 5 min. After cooling, 1 ml of *n*-heptane was added, and the procedure was continued as described previously (14). The assay was not affected by warfarin nor was the warfarin assay or recovery affected by phenylbutazone.

Warfarin–Phenylbutazone Interaction—Twelve dicumarol-screened (15, 16) male adult Sprague–Dawley rats, weighing 350–450 g and differing widely in dicumarol half-life, were selected from a group of 30 animals. They had unrestricted access to food[4] and water before and during the experiment. The rats were given intraperitoneal injections of phenylbutazone, 40 mg/kg, or saline solution at −2 hr and then 20 mg of phenylbutazone/kg or saline solution every 4 hr for 50–60 hr. The animals received warfarin, 0.6 mg/kg iv consisting of about 22 μCi of ^{14}C-warfarin[5]/kg and nonradioactive warfarin[6], except for three rats that received only 0.3 mg/kg in the experiment with phenylbutazone. Three weeks later, the rats that had received phenylbutazone received saline solution and *vice versa*. Blood samples were collected repeatedly from the tail artery for 40–60 hr after warfarin injection.

The warfarin injection solutions were prepared by separately dissolving the labeled and unlabeled drug in small volumes of 0.1 *N* NaOH. The

[a] ^{14}C-Warfarin was added to the serum *in vitro*. [b] Measured after equilibrium dialysis. [c] Ratio of free fraction values, with phenylbutazone:control. [d] n = 10. [e] Statistically significantly different from the control value (paired t test, $p < 0.001$).

unlabeled drug solution was added to the labeled drug solution, and this mixture was diluted immediately with pH 7.4, 0.15 *M* phosphate buffer such that 1 ml of the final solution contained 0.29–0.34 mg of warfarin. Phenylbutazone was dissolved in 0.1 *N* NaOH, and the solution was diluted with saline; the pH was adjusted to ~8 with pH 7.4, 0.15 *M* phosphate buffer. The solutions were prepared just before injection.

Collection of multiple blood samples (0.45 ml) from rats, measurement of prothrombin time in 10-fold diluted plasma, conversion of prothrombin time to prothrombin complex activity (PCA), and calculation of prothrombin complex activity synthesis rates (R_{syn}) were carried out as described previously (16). Two 0.1-ml plasma samples were used for warfarin and phenylbutazone determinations, respectively. Two hours after the last phenylbutazone or saline injection, ~1.2 ml of blood was withdrawn, and the serum was separated. The latter was spiked with ~0.3 μg of ^{14}C-warfarin, and ~0.5 ml was used for serum protein binding determinations.

The apparent first-order elimination rate constant (β) and the warfarin biological half-life were determined from the least-squares slope of a plot of log plasma warfarin concentrations *versus* time. The apparent volume of distribution (V_d) was calculated by dividing the injected dose by the extrapolated zero-time plasma warfarin concentration. Total plasma clearance was calculated as the product of β and V_d, and intrinsic plasma clearance was calculated by dividing the total clearance by the serum free fraction of warfarin. The plasma warfarin concentrations at which the prothrombin complex activity R_{syn} was 0 and 50% of normal/day were determined from the linear portion of a plot of R_{syn} *versus* log plasma warfarin concentration.

RESULTS

Table I shows the *in vitro* effect of phenylbutazone (0–200 μg/ml) on the protein binding of warfarin (0.43–2.90 μg/ml) in rat serum. The warfarin concentrations were in the range of experimental interest. The free fraction of warfarin increased with increasing phenylbutazone concentration but was practically independent of warfarin concentration. A plot of mean free fraction value *versus* phenylbutazone concentration shows a shoulder in the 25–100-μg/ml range (Fig. 1). Therefore, the phenylbutazone dosage regimen was designed to maintain concentrations in this range to minimize fluctuations in the free fraction of warfarin in plasma during the *in vivo* experiments.

Figure 2 shows the effect of phenylbutazone administration on the warfarin concentrations in the plasma of a representative rat (Rat 3). Also shown are the plasma phenylbutazone concentrations. Blood samples were obtained at different times relative to the time of phenylbutazone injections (because blood sampling times were dictated primarily by the rate of the prothrombin complex activity change); this accounts for much of the fluctuation of the reported phenylbutazone concentrations in any one animal. The mean plasma phenylbutazone concentration of the 11 rats used in this study ranged from 45 to 90 μg/ml, with an average coefficient of variation of 29% in individual animals.

The phenylbutazone effects on warfarin pharmacokinetics in 11 rats are summarized in Table II. Phenylbutazone administration caused a significant increase in the total plasma clearance, apparent volume of distribution, and serum free fraction of warfarin and a significant decrease in the biological half-life and intrinsic plasma clearance of the drug. The animals used were selected by a screening test from a larger group of rats to obtain animals with widely different and relatively evenly distributed total clearance values. Consequently, all pharmacokinetic data in Table II, except those representing intrinsic clearance (which shows relatively small interindividual variation), are reported in terms of the mean and range of individual values rather than as the mean ± *SD*.

It is more informative to consider the ratio, phenylbutazone:control, than the absolute values of the pharmacokinetic constants. These ratios were determined individually for each animal and are reported as the mean ± *SD*, n = 11: total plasma clearance, 2.10 ± 0.40; intrinsic plasma clearance, 0.674 ± 0.120; and free fraction in serum, 3.16 ± 0.59. The relatively small coefficient of variation of these constants reflects a strong correlation between values obtained from individual rats in control experiments and during phenylbutazone administration. This correlation is shown in Fig. 3 for the biological half-life, in Fig. 4 for the apparent volume of distribution, and in Fig. 5 for the serum free fraction of warfarin.

There is no apparent relationship between the average plasma phenylbutazone concentration (indicative of the total clearance of that drug) in individual rats and the total or intrinsic warfarin clearance (alone or during phenylbutazone administration). On the other hand, there is some indication of a concentration–response relationship with respect to phenylbutazone inhibition of warfarin biotransformation. Specifically, there appears to be a negative correlation between average phenylbuta-

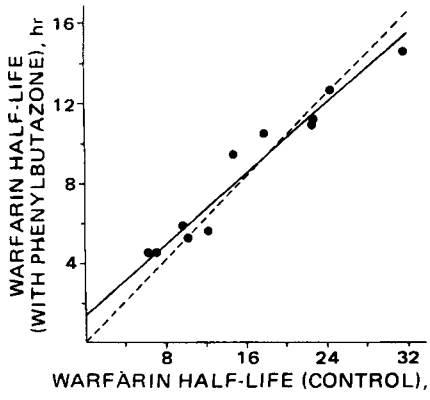

Figure 3—*Relationship between the warfarin biological half-life in control experiments and in the same rats during concomitant phenylbutazone administration. zone concentration in plasma and the phenylbutazone:control ratio of the intrinsic warfarin clearances in individual animals (Fig. 6).

In view of the pronounced difference between the *in vitro* and *in vivo* effects of comparable phenylbutazone concentrations on serum protein binding of warfarin (free fraction values in Tables I and II), a group of rats was given a series of phenylbutazone injections (*i.e.*, no warfarin), and serum free fraction values were determined before and during phenylbutazone treatment. The results (Table III) show a magnitude of displacing effect similar to that observed in the *in vivo* warfarin–phenylbutazone interaction study and much greater than that observed in the *in vitro* experiments.

Theoretical considerations and previous experimental evidence (10) indicate that an essentially linear relationship between the total plasma clearance and the serum or plasma free fraction of warfarin should exist. Such correlations were obtained in the present study for warfarin in control experiments and during phenylbutazone administration (Fig. 7). The differences in the regression line slopes reflect the phenylbutazone effect on the intrinsic warfarin clearance. The shift of the free fraction values during phenylbutazone administration to a higher range than that observed without phenylbutazone is indicative of the displacing effect.

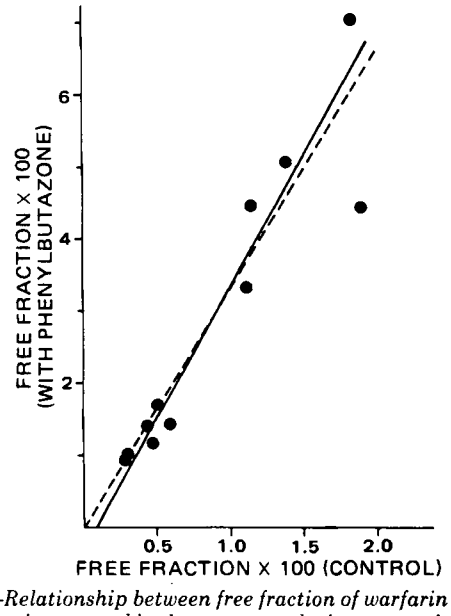

Figure 5—*Relationship between free fraction of warfarin in serum in control experiments and in the same rats during concomitant phenylbutazone administration. The correlation coefficient is 0.927,* $p < 0.001$.

[a] Slope of a plot of R_{syn}/R^0_{syn} *versus* log plasma warfarin concentration. [b] Intercept of the plot described in footnote *a* upon extrapolation to the concentration axis where $R_{syn}/R^0_{syn} = 0$. [c] The experiment with this rat was discontinued because of severe bleeding. [d] Without Rat 10. [e] No statistically significant difference between the two treatments. [f] Statistically significantly different from the control value (paired *t* test, $p < 0.001$).

Phenylbutazone, 100 μg/ml added *in vitro* to individual serum samples from 12 rats, had no effect on prothrombin complex activity. The prothrombin complex activity in serum (mean ± *SD*) was 98.2 ± 8.6% of normal without phenylbutazone and 98.4 ± 7.3% with added phenylbutazone. The ratio of prothrombin complex activity values, phenylbutazone:control, was 1.00 ± 0.03 (mean ± *SD*). On the other hand, phenylbutazone administered to rats caused a small but statistically significant prothrombin complex activity decrease (Table IV). This apparent anticoagulant effect was evident 2 hr after the first phenylbutazone dose, *i.e.*, at zero time relative to the time of warfarin injection when the first (before warfarin) blood sample was obtained (Fig. 2).

The maximum warfarin anticoagulant effect was significantly more pronounced during phenylbutazone administration than in the control experiments (Table IV). One animal (Rat 12), a slow eliminator given warfarin with phenylbutazone, was lost in the first part of the study due to hemorrhage. Therefore, the warfarin dosage in the second (crossover) part of the study was reduced to one-half in the three rats with the lowest total warfarin clearance. Even these three rats exhibited a more pronounced maximum anticoagulant effect during phenylbutazone administration, despite the reduced warfarin dose.

Repeated measurements of warfarin concentrations and prothrombin complex activity in the rats after warfarin administration permitted

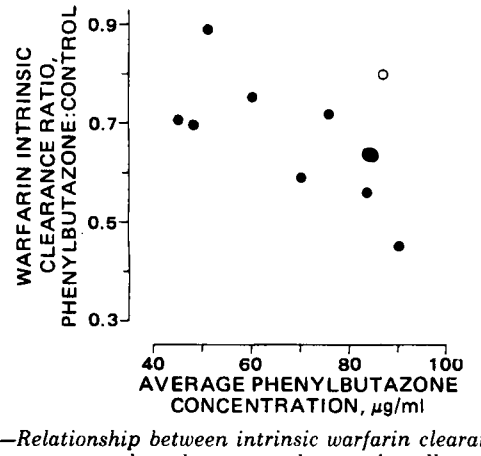

Figure 6—*Relationship between intrinsic warfarin clearance ratio, phenylbutazone:control, and average plasma phenylbutazone concentration. The correlation coefficient is −0.55* ($p < 0.1$) *for all 11 rats and −0.73* ($p < 0.02$) *for 10 rats (with O excluded).*

determinations of the relationship between anticoagulant effect and drug concentration. Results obtained from a representative animal are shown in Fig. 8. The regression line of a plot of the relative prothrombin complex activity synthesis rate *versus* log plasma warfarin concentration can be characterized by its slope (m) and by the extrapolated intercept on the concentration axis at a synthesis rate of zero (C_{max}). The results obtained from all animals are summarized in Table V. The phenylbutazone effect is more readily apparent in Fig. 9, which is a schematic representation of the average results from all animals. There was a pronounced shift of the effect–log concentration regression line to a lower concentration range during phenylbutazone treatment, with no significant change in the slope.

A convenient index of anticoagulant effect is the warfarin concentration required to produce 50% inhibition of the prothrombin complex activity synthesis rate (referred to as the effective concentration). The effective concentrations of total as well as free warfarin were markedly reduced during phenylbutazone administration (Table VI). The average ratio of effective concentrations, control:phenylbutazone, was 5.2 for total drug and 1.8 for free drug. The difference in these ratios reflects the increased serum free fraction values of warfarin during phenylbutazone administration. There is no apparent correlation between the effective concentration ratios and the average phenylbutazone concentration in individual animals.

DISCUSSION

The results of this investigation demonstrate that the acute interaction between phenylbutazone and racemic warfarin in rats involves at least three mechanisms: displacement of warfarin from serum protein binding sites by phenylbutazone and its metabolites, inhibition of intrinsic warfarin clearance, and apparent potentiation of the anticoagulant action produced by a given plasma warfarin concentration. These effects were produced at average phenylbutazone concentrations in plasma (45–90 μg/ml) similar to those observed clinically. For example, 100 mg of the drug given three times a day to normal adult subjects resulted in plasma concentrations (mean ± *SD*) of 76 ± 7 μg/ml (7).

The phenylbutazone displacing effect on warfarin in serum was of similar magnitude in animals who received both drugs and in those who received only phenylbutazone (with warfarin added *in vitro*). On the other hand, *in vitro* phenylbutazone addition to serum from nonmedicated animals had a much less pronounced displacing effect at concentrations comparable to those obtained *in vivo*. These results indicate that the displacing effect is due not only to phenylbutazone but also to one or more of its metabolites. In fact, oxyphenbutazone, a major phenylbutazone metabolite, is strongly bound to albumin (17) and, therefore, may be a very effective displacer of warfarin from binding sites on the albumin molecule.

In theory, the more pronounced phenylbutazone displacing effect *in vivo* can be due also to accumulation of warfarin metabolites capable of competing with warfarin for albumin binding sites. There is indirect evidence that phenylbutazone inhibits the elimination of at least one warfarin metabolite in humans (7). However, the reduction of warfarin binding in serum from phenylbutazone-treated rats and from phenylbutazone- and warfarin-treated rats was comparable, indicating that warfarin metabolites contributed negligibly to the decreased protein binding of warfarin.

A recent report of a long-term multiple-dose study of the warfarin–phenylbutazone interaction in a single normal human subject stated that "changes in the degree of plasma binding of warfarin were the same as those found from *in vitro* experiments in which warfarin and phenylbutazone were added to control plasma samples" (8). Yet, the warfarin free fraction in that subject remained elevated after phenylbutazone

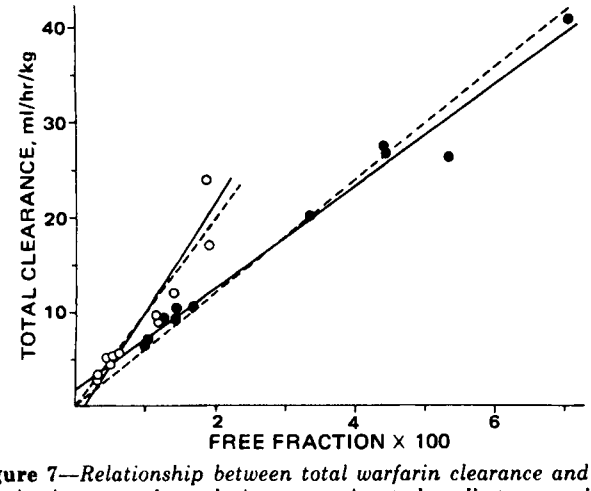

Figure 7—*Relationship between total warfarin clearance and free fraction in serum of rats during concomitant phenylbutazone administration (●) and in the same animals in control experiments (○). The correlation coefficient for the data with phenylbutazone is 0.997, p < 0.001, and that for the control data is 0.940, p < 0.001. There is a statistically significant difference (p < 0.001) in the slopes of the two regression lines.*

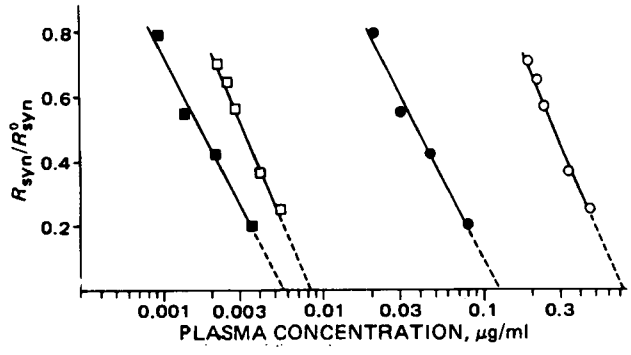

Figure 8—*Relationship between relative synthesis rate of prothrombin complex activity (R_{syn}/R^0_{syn}) and the total (free plus bound) concentration (circles) or the free concentration (squares) of warfarin in plasma of a representative rat. The closed symbols represent the relationship during phenylbutazone treatment, and the open symbols represent the relationship in the control experiment.*

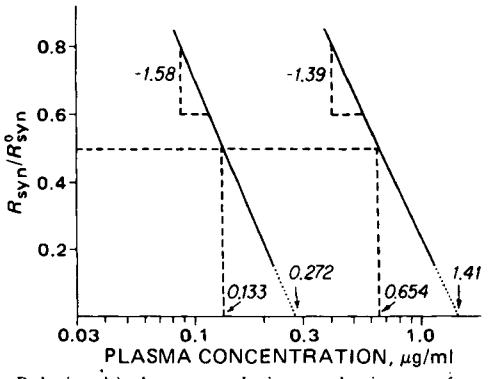

Figure 9—*Relationship between relative synthesis rate of prothrombin complex activity* (R_{syn}/R^0_{syn}) *and the total warfarin concentration in plasma of rats during treatment with phenylbutazone (left) and in control experiments (right) (based on the average data in Tables V and VI).*

administration was discontinued and plasma concentrations of this drug had decreased substantially, suggesting (as the authors acknowledged) that one or more phenylbutazone metabolites contributed to the displacing effect.

Phenylbutazone administration decreased the intrinsic warfarin clearance. This effect was less pronounced than the displacing effect, causing the total warfarin clearance to increase during phenylbutazone administration. Similar effects were observed in a chronic interaction study on one human subject (8). Whether chronic phenylbutazone administration would induce warfarin-metabolizing enzyme systems in rats remains to be determined. Since the total warfarin clearance is proportional to the drug's free fraction in plasma or serum, and since intrinsic drug clearance (*i.e.*, the proportionality constant in the relationship between total clearance and free fraction) differs relatively little between animals, a plot of total clearance *versus* free fraction in serum is essentially linear (10). If phenylbutazone treatment has a quantitatively similar effect on the intrinsic warfarin clearance in all animals, then the linear relationship between total clearance and the serum free fraction should remain. A decrease in intrinsic clearance and an increase in the serum free fraction should then cause the slope of the plot to decrease and the free fraction values to shift to a higher range. This is demonstrated strikingly by the present study (Fig. 7). The free fraction values were determined in serum rather than in plasma because we have found that addition of anticoagulants to blood affects the protein binding of warfarin.

The warfarin anticoagulant effect is a function of its free rather than of its total concentration in plasma (18). Consequently, decreased protein binding of warfarin due to phenylbutazone administration should shift the anticoagulant effect–plasma total warfarin concentration curve to the left, *i.e.*, to a lower concentration range. Such a shift is well demonstrated in this investigation (Fig. 9). However, a similar shift occurred in the anticoagulant effect–*free* warfarin concentration curve, albeit of considerably smaller magnitude. Such a shift may occur for at least two reasons. One is related to the fact that the phenylbutazone effect on warfarin pharmacokinetics is stereoselective. In humans, phenylbutazone decreases the total clearance of the more potent (*S*)-enantiomer and increases the total clearance of the (*R*)-enantiomer (7). The metabolic fate of the warfarin enantiomers in rats differs appreciably from that in humans (19), and there is no information about the possible stereoselectivity of the phenylbutazone interaction with warfarin in rats. A selective inhibition of the intrinsic clearance of (*S*)-warfarin would cause an increase in the (*S*)- to (*R*)-enantiomer concentration ratio in rat plasma after administration of racemic warfarin and a shift of the anticoagulant effect–free warfarin concentration curve to the left due to the higher potency of the (*S*)-enantiomer.

Another possible reason for such a shift is a direct effect of phenylbutazone (or its metabolites) on the blood-clotting process. Our studies have shown that phenylbutazone has no such effect when added *in vitro* to plasma but that even a single 40-mg/kg dose caused a small but statistically significant decrease of prothrombin complex activity 2 hr later (Table IV). It is possible that the effect was more pronounced during the interaction study, *i.e.*, following administration of several phenylbutazone doses.

The literature concerning the phenylbutazone effect on the blood-clotting process is conflicting. Some investigations in humans (6, 20) and a previous but very limited study on rats in our own laboratory (21) revealed no apparent effect. One investigator (22), however, reported observations concerning 44 patients on phenylbutazone of whom about one-third showed prolongation of the one-stage prothrombin time that was sometimes alarming. As explained by Koch-Weser and Sellers (2), a slight hypoprothrombinemic effect of a drug may escape detection in nonanticoagulated subjects but will be obvious in subjects whose prothrombin complex activity has already been depressed by coumarin anticoagulant therapy. Thus, technical difficulties of detection may account for the conflicting data concerning the effect of phenylbutazone administration on blood clotting.

This investigation, despite its relative comprehensiveness and the consequent technical difficulties and cost in time and effort, still falls far short of providing a complete picture of the phenylbutazone–warfarin interaction. The effect of warfarin on the disposition of phenylbutazone and its pharmacologically and physicochemically (with respect to displacing effect on warfarin) active metabolites has not been established; the dose or concentration dependence of the interaction is unknown (warfarin displacement from protein binding sites and warfarin metabolism inhibition may exhibit different effect–phenylbutazone concentration relationships, causing the net effect to be potentiation or reduction of anticoagulant response, depending on the doses used); time-dependent phenomena have not been explored; the mechanism of the increased anticoagulant effect of a given *free* warfarin concentration in plasma during phenylbutazone treatment has not been established. The latter effect could have been explored better if one warfarin enantiomer labeled with carbon 14 and the other labeled with tritium had been available. The alternative, separate interaction studies of phenylbutazone with (*R*)- and (*S*)-warfarin, could be helpful, but this would not reveal a possibly multifaceted interaction with results different from the sum of the interactions between phenylbutazone and each warfarin enantiomer separately.

The effort required to elucidate fully the mechanisms of a drug interaction can be enormous. If the drugs involved can produce potentially hazardous pharmacological effects (as is the case with phenylbutazone and warfarin), comprehensive studies in humans may be difficult or impossible. Cost–benefit and risk–benefit considerations rather than scientific curiosity will ultimately dictate how much we learn about many important drug interactions.

Simultaneous Solubilization of Steroid Hormones III: Thermodynamic Evaluation

B. LUNDBERG

Received December 5, 1978, from the *Department of Biochemistry and Pharmacy, Åbo Akademi, Porthansgatan 3, 20500 Åbo 50, Finland.* Accepted for publication July 11, 1979.

Abstract □ The temperature effect on the solubilization of some androgens, estrogens, and C_{21}-steroids in aqueous polysorbate 40 and in tetradecyltrimethylammonium bromide was studied. Dialysis studies showed a linear relationship between micellar and nonmicellar steroids, which indicates that solubilization is governed by a distribution coefficient. With known water solubilities and solubilization capacities for the steroids at different temperatures, the changes of free energy (ΔG_s°), enthalpy (ΔH_s°), and entropy (ΔS_s°) for solubilization were calculated. All steroids studied had negative ΔH_s° values in polysorbate 40, except progesterone and ethisterone. The ΔS_s° values were positive for all of the actual steroids except for estradiol in both association colloids and for 17α-hydroxyprogesterone in polysorbate 40. The highest values were obtained for progesterone and testosterone. The steroids showed lower ΔS_s° values when they were solubilized simultaneously than when they were solubilized separately. No clearcut correlation between the entropy change of solubilization and the simultaneous solubilization behavior could be derived. Obviously, the solubilization mechanism also must be considered. The thermodynamic solubilization parameters are discussed, and the need for temperature-solubilization studies is stressed.

Keyphrases □ Steroid hormones—solubilization, thermodynamics, temperature effect, micellar structure, androgens, estrogens, C_{21}-steroids, in polysorbate 40 and in tetradecyltrimethylammonium bromide □ Solubilization—steroid hormones in polysorbate 40 and in tetradecyltrimethylammonium bromide, thermodynamics □ Thermodynamics—steroid hormone solubilization in polysorbate 40 and in tetradecyltrimethylammonium bromide

Two previous reports from this laboratory dealt with the simultaneous solubilization of estrogens, C_{21}-steroids, and androgens in aqueous solutions of association colloids (1, 2). Estradiol is solubilized independently of the C_{21}-steroids and testosterone, while the solubilization of ethinyl estradiol with progesterone and with testosterone is dependent. A plausible mechanism for simultaneous solubilization was discussed (2). However, mere solubilization capacities at one temperature are not a good basis for thermodynamic discussion of the solubilization mechanism. In this study, the temperature effect on solubilization was investigated to elucidate the contributions of enthalpy and entropy to the free energy of solubilization.

The thermodynamic parameters controlling micellization have been studied and discussed (3–5), but the corresponding parameters for solubilization have been comparatively neglected. One difficult question is the choice of a model for thermodynamic parameter calculations. Humphreys and Rhodes (6) found that the micellar pseudophase model seemed applicable because solubilization was governed by a form of the distribution law. Plots for the determination of enthalpic and entropic values were complex.

More straightforward results were obtained by Simons and Rhodes (7) with a linear relationship between the free energy of solubilization and temperature, despite much scatter due to experimental difficulties. Their results favor the pseudophase model.

EXPERIMENTAL

Materials—The purification methods and purity tests for the association colloids and steroid hormones[1] were described previously (1), except that the steroid purity was checked by silica gel TLC. The labeled steroids[2], ^{3}H-estradiol, ^{3}H-progesterone, and ^{3}H-testosterone, had a radiochemical purity of 98% by TLC, and they were used without further purification. The association colloids were tetradecyltrimethylammonium bromide[3] and polysorbate 40[4].

Solubilization—Solubility studies were carried out as described previously (1), but samples were filtered through a 0.45-μm filter membrane[5] before steroid quantitation. The UV absorbance was used to calculate the amount of unlabeled steroid solubilized; liquid scintillation counting, with a toluene-based scintillation cocktail, was used for the labeled steroids.

The equilibration temperatures were controlled to ±0.2°. The equilibrium dialysis was performed using dialysis tubing[6]. Complete equilibration of the solutions was ensured. All of the experiments were done at least twice.

RESULTS AND DISCUSSION

Dialysis studies were done with the three ^{3}H-labeled steroids: estradiol, progesterone, and testosterone. Figure 1 shows typical results. The linearity of such plots confirms that the relationship between the micellar and nonmicellar steroid concentrations is linear in both saturated and nonsaturated systems. This linearity indicates that solubilization in these systems is governed by a distribution coefficient.

The solubilization capacities at different temperatures between 293 and 323 °K of the two surfactants (tetradecyltrimethylammonium bromide and polysorbate 40) for the sex steroids (estradiol, ethinyl estradiol, progestone, 17α-hydroxyprogesterone, testosterone, and ethisterone) were calculated from saturation solubilization experiments (Table I).

The temperature effect on simultaneous solubilization was studied with the following combinations: ethinyl estradiol–progesterone, ethinyl estradiol–17α-hydroxyprogesterone, and estradiol–testosterone, all in tetradecyltrimethylammonium bromide; and ethinyl estradiol–proges-

terone, ethinyl estradiol–testosterone, and estradiol–progesterone, all in polysorbate 40 (Table II).

The linear relationship between the surfactant concentration and the amount of solubilized steroid (1, 2) as well as the linearity of the dialysis plots (Fig. 1) indicates that the solubilization is governed by a form of the distribution law. The equilibrium constant, K_s, between the micellar (mole fraction of the solute in the micelle, C_s^m) and the nonmicellar (aqueous solubility of the steroid in moles per liter, C_s^{aq}) steroid can be defined by (2, 6):

$$K_s = C_s^m/C_s^{aq} \qquad \text{(Eq. 1)}$$

Starting with the thermodynamic equilibrium constant for the solubilization, one can calculate the free energy change of solubilization, ΔG_s°:

$$\Delta G_s^\circ = -RT \ln K_s \qquad \text{(Eq. 2)}$$

Figures 2*a* and 2*b* show the variation of the free energy change of solubilization with temperature for steroid hormones in the two association colloids. The ΔG_s° values are calculated starting with the water solubility of the steroids at different temperatures (8) and the solubilization capacities at the corresponding temperatures. Most curves show a fairly linear relationship between ΔG_s° and temperature, which also was found for testosterone solubilization by *n*-alkyl polyoxyethylenes (7). The curves for estradiol and ethinyl estradiol in both surfactants show the greatest deviations from linearity. The most likely explanation for such curvature would be the variation of micellar structure with temperature (6). Estradiol and ethinyl estradiol also had the most negative ΔG_s° values, especially at lower temperatures. These facts may indicate a different solubilization mechanism for these steroids compared to the others.

The ΔG_s° values of testosterone and ethisterone differed only slightly. This finding is remarkable if one considers the much higher solubilization capacity for testosterone compared to ethisterone (2). Progesterone had more negative ΔG_s° values than 17α-hydroxyprogesterone, especially in polysorbate 40.

Estradiol and ethinyl estradiol also gave deviations from linearity in ΔG_s° *versus* T plots (Figs. 3*a* and 3*b*) when solubilized simultaneously with other steroids. Ethinyl estradiol gave more positive ΔG_s° values in combinations with progesterone, testosterone, and 17α-hydroxyprogesterone than when solubilized alone. 17α-Hydroxyprogesterone gave more positive values when solubilized with ethinyl estradiol. There was, however, no clearcut correlation between the ΔG_s° values of the steroids and their behaviors at simultaneous solubilization.

With the assumption that the standard molar enthalpy change is not temperature dependent in the range studied, Eq. 3 can be used:

$$\frac{d \ln K_s}{dT} = \frac{\Delta H_s^\circ}{RT^2} \qquad \text{(Eq. 3)}$$

The standard solubilization enthalpy change, ΔH_s°, may be obtained from the plot of $\ln K_s$ *versus* $1/T$. Such plots are found in Figs. 4 and 5 for steroids solubilized separately and simultaneously. The ΔH_s° values are summarized in Tables III and IV.

Testosterone had low negative ΔH_s° values when solubilized separately in both polysorbate 40 and tetradecyltrimethylammonium bromide. Testosterone had somewhat higher negative values when solubilized simultaneously with ethinyl estradiol in polysorbate 40 and with estradiol in tetradecyltrimethylammonium bromide. Ethinyl estradiol had moderately negative values when solubilized either separately or simultaneously and in both association colloids. Estradiol showed the largest negative values.

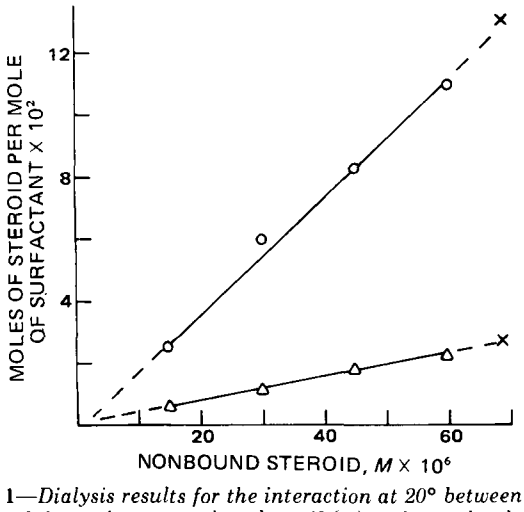

Figure 1—*Dialysis results for the interaction at 20° between testosterone and the surfactants polysorbate 40* (△) *and tetradecyltrimethylammonium bromide* (○) (× = *solubility points*).

Table III—Thermodynamic Changes [a] in Solubilization of Hormonal Steroids in Surfactants at 293°K

Surfactant	Steroid	$-\Delta G_s^\circ$, joules/mole	$-\Delta H_s^\circ$, joules/mole	ΔS_s°, joules/deg/mole
Polysorbate 40	Estradiol	18,631	28,018	−32
	Ethinyl estradiol	21,578	8,314	45
	Testosterone	14,552	1,081	46
	Ethisterone	14,816	−699	53
	Progesterone	17,174	−11,889	99
	17α-Hydroxyprogesterone	14,993	27,686	−43
Tetradecyltrimethylammonium bromide	Estradiol	22,661	32,674	−34
	Ethinyl estradiol	22,566	8,563	48
	Testosterone	20,740	2,744	61
	Ethisterone	19,344	5,570	47
	Progesterone	18,381	11,640	23
	17α-Hydroxyprogesterone	19,400	9,727	33

[a] ΔG_s°, ΔH_s°, and ΔS_s° refer to the unitary free energy, enthalpy, and entropy of solubilization, respectively.

17α-Hydroxyprogesterone had a large negative value in polysorbate 40 but had considerably lower values when alone and when together with ethinyl estradiol in tetradecyltrimethylammonium bromide. Progesterone showed the most ambivalent behavior. Solubilized separately and together with ethinyl estradiol in polysorbate 40, it gave positive ΔH_s° values. Alone in tetradecyltrimethylammonium bromide and together with estradiol and ethinyl estradiol in polysorbate 40, progesterone gave negative values.

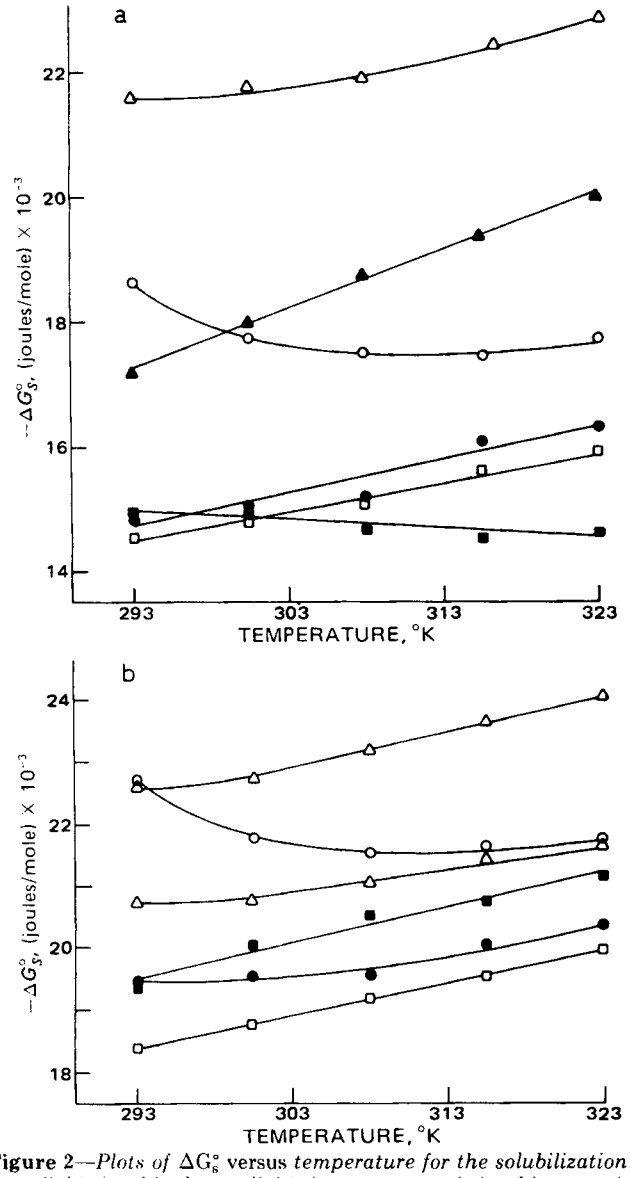

Figure 2—*Plots of* ΔG_s° versus *temperature for the solubilization of estradiol* (○), *ethinyl estradiol* (△), *testosterone* (□), *ethisterone* (●), *progesterone* (▲), *and 17α-hydroxyprogesterone* (■) *in polysorbate 40* (a) *and in tetradecyltrimethylammonium bromide* (b).

Starting with the ΔG_s° and ΔH_s° values, one can calculate the standard entropy change of solubilization, ΔS_s°:

$$\Delta G_s^\circ = \Delta H_s^\circ - T\Delta S_s^\circ \qquad \text{(Eq. 4)}$$

The ΔS_s° values for separate and simultaneous solubilization appear in Tables III and IV. The steroids showed large differences in entropy values. All of the steroids except estradiol and 17α-hydroxyprogesterone in polysorbate 40 had positive values. Progesterone in polysorbate 40 and testosterone in tetradecyltrimethylammonium bromide showed the highest values. At simultaneous solubilization, all steroids had lower entropy values than when solubilized individually, except progesterone in tetradecyltrimethylammonium bromide.

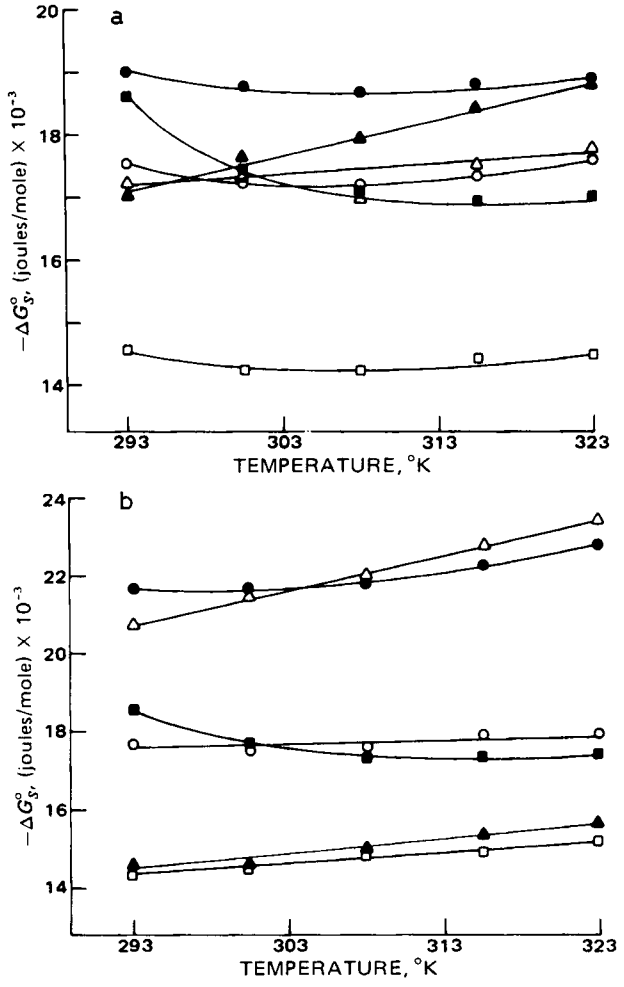

Figure 3—*Plots of* ΔG_s° versus *temperature for the simultaneous solubilization of* (a) *ethinyl estradiol* (○) *plus progesterone* (△), *ethinyl estradiol* (●) *plus testosterone* (□), *and estradiol* (■) *plus progesterone* (▲) *in polysorbate 40 and of* (b) *ethinyl estradiol* (○) *plus progesterone* (△), *ethinyl estradiol* (●) *plus 17α-hydroxyprogesterone* (□), *and estradiol* (■) *plus testosterone* (▲) *in tetradecyltrimethylammonium bromide.*

Table IV—Thermodynamic Changes[a] in Simultaneous Solubilization of Hormonal Steroids in Surfactants at 293°K

Surfactant	Steroid Pair	$-\Delta G_s^\circ$, joules/mole	$-\Delta H_s^\circ$, joules/mole	ΔS_s°, joules/deg/mole
Polysorbate 40	Ethinyl estradiol +	17,518	18,041	−2
	progesterone	17,174	11,058	21
	Ethinyl estradiol +	19,021	19,954	−3
	testosterone	14,552	15,797	−4
	Estradiol +	18,631	36,582	−61
	progesterone	17,174	−690	61
Tetradecyltrimethylammonium bromide	Ethinyl estradiol +	17,724	15,963	6
	progesterone	20,740	−5,570	90
	Ethinyl estradiol +	21,710	11,640	34
	17α-hydroxyprogesterone	14,291	6,901	25
	Estradiol +	18,631	32,591	−48
	testosterone	14,552	4,988	33

[a] ΔG_s°, ΔH_s°, and ΔS_s° refer to the unitary free energy, enthalpy, and entropy of solubilization, respectively.

A comparison of the contribution of the enthalpy and entropy changes to the free energy change of solubilization displayed large differences among the steroids. For estradiol in both surfactants, 17α-hydroxyprogesterone in polysorbate 40, and progesterone in tetradecyltrimethylammonium bromide, the enthalpy factor made the largest contribution to the negative free energy change. For the other steroids, the entropy was larger, and solubilization was thus essentially an entropy-driven process. The same situation generally applies to micelle formation from detergent molecules, which is accompanied by very small heat changes and is assumed to be controlled by a large ΔS.

The most popular explanation of the large unitary entropy change involved in the partitioning of hydrophobic molecules between aqueous and nonaqueous phases is the flickering cluster hypothesis (9). When organic compounds are placed in water, the water molecules arrange themselves around the apolar parts in flickering clusters. Stripping the water molecules from the apolar part of the solute results in large entropy and in the randomization of the water molecules. This treatment assumes that solubilization can be described as the transfer of a molecule from an aqueous to a nonaqueous phase. Application of this assumption to

steroid hormone solubilization is supported by the similarity between the thermodynamic parameters found in this study and those from octanol–water partitioning (8).

Although the flickering cluster hypothesis seems plausible, and the water ordering–disordering is important for the entropy change of solubilization, other factors may be significant. It was proposed (10) that the apolar solute molecule is held rigidly in a favored rotational configuration in the aqueous phase by the layer of water molecules surrounding it. In the micelle hydrocarbon core, its rotational oscillations are relatively unrestricted. This proposal is supported by the fact that there is no clearcut correlation between water solubility and ΔS_s°. Ethisterone has a much lower water solubility than testosterone [1.6 against 68.7 μmoles/liter at 20° (8)] and can be regarded as more hydrophobic. According to the flickering cluster hypothesis, ethisterone should have more structured water around it and should give a more positive ΔS_s° at the randomization of the water molecules. Thus, both the water and solute effects probably contribute to the effective ΔS_s°, but which is quantitatively the most important cannot be determined.

The contribution of the enthalpy change to the free energy change of solubilization is quantitatively minor for most steroids. Hence, there are interesting differences in their ΔH_s° values (Table III). The most notable difference is the rather large positive value of progesterone in polysorbate 40. Because similar ΔH_s° values can be expected for steroids solubilized by the same mechanism, the differences obtained indicate variations in that respect.

The simultaneous solubilization of steroids cannot be predicted by their free energies of solubilization (2). Testosterone and progesterone have less negative ΔH_s° values than ethinyl estradiol but are solubilized maximally in polysorbate 40, while the latter steroid has a lower solubility at simultaneous solubilization. These discrepancies may be explained by differences in the solubilization mechanism. If the solubilization loci of the steroids partly overlap, a steric hindrance to simultaneous solubilization will exist. When solubilized on its own in tetradecyltrimethylammonium bromide, ethinyl estradiol has a considerably larger ΔS_s° than progesterone, but the opposite is true at simultaneous solubilization (Tables III and IV).

On the contrary, progesterone and estradiol are solubilized independently of each other in polysorbate 40, and the ΔS_s° values of both decrease to about the same extent when the steroids are solubilized together. Also, the solubilizations of both testosterone and estradiol are changed at simultaneous solubilization in tetradecyltrimethylammonium bromide, and their ΔS_s° values are both lowered when the steroids are solubilized together. However, at this stage it is hard to rationalize these results in terms of the precise structure and ordering of the micelle and the solute in it.

Of course, the thermodynamic treatment in this study has limitations. Although the amount of solubilizate bound in a micellar system can be measured with accuracy, the calculation of C_s^m presents problems because it is a concentration term, and precise delineation of the micellar pseudophase boundary is difficult. Two other difficult aspects of the thermodynamic calculations regarding micellar binding are the selection of the standard state for the micellar cosolute and the incorporation of the appropriate activity corrections (11). For cosolutes with low water solubility such as steroid hormones, the C_s^{aq} term probably will approximate the activity value. However, the micellar solubilizate activity coefficients may differ significantly from unity. This deviation will introduce errors into the calculations of thermodynamic parameters derived from micellar binding equilibrium constants.

Although these limitations exist, data from studies of the temperature effect on solubilization processes can prove useful in expanding knowledge of this important branch of surface chemistry. Clearly, further studies of the effect of solutes on micelle structure are required before a theory rationalizing micellar solubilization can be formulated.

Tetrazolium Salts in Pharmaceutical Analysis II: Direct Assay of Diethylstilbestrol and Diethylstilbestrol Dipropionate

NABIL M. OMAR ˣ and NAWAL A. EL-RABBAT

Received November 24, 1978, from the *Department of Pharmaceutical Chemistry, Faculty of Pharmacy, University of Assiut, Assiut, Egypt.* Accepted for publication July 10, 1979.

Abstract □ A convenient spectrophotometric determination of diethylstilbestrol and diethylstilbestrol dipropionate was developed involving their interaction with triphenyltetrazolium chloride at 50° for 45 min and subsequent measurement of the formazan formed. The significance of extended conjugation within the 4,4′-stilbenediol molecule to induce the color reaction is documented. Ideal adherence of color absorption to Beer's law permitted accurate and precise determination of diethylstilbestrol and diethylstilbestrol dipropionate pure forms over the range of 2–22 μg of diethylstilbestrol/ml. Application of the tetrazolium color reaction to the analysis of diethylstilbestrol dipropionate dosage forms was achieved without prior hydrolysis or extraction.

Keyphrases □ Diethylstilbestrol and diethylstilbestrol dipropionate—analysis, triphenyltetrazolium chloride colorimetry □ Colorimetry—analysis of diethylstilbestrol and diethylstilbestrol dipropionate with triphenyltetrazolium chloride □ Tetrazolium salts—colorimetric analysis of diethylstilbestrol and diethylstilbestrol dipropionate

The usual relatively small doses of diethylstilbestrol [(*E*)-α,α′-diethyl-4,4′-stilbenediol] require especially sensitive and precise pharmaceutical analysis. The phenolic hydroxyl group reactivity of this stilbene derivative has been used to develop diverse estimation procedures based on acetylation (1, 2), nitrosation (3), polarography of the nitrosation product (4), bromination (5), and UV irradiation (6).

Of the chromogenic reagents reported for interaction with phenols, interest has focused on the utility of phosphomolybdotungstate (7), iron (8), antimony (9), and vanadium (10) salts for diethylstilbestrol colorimetry. Some

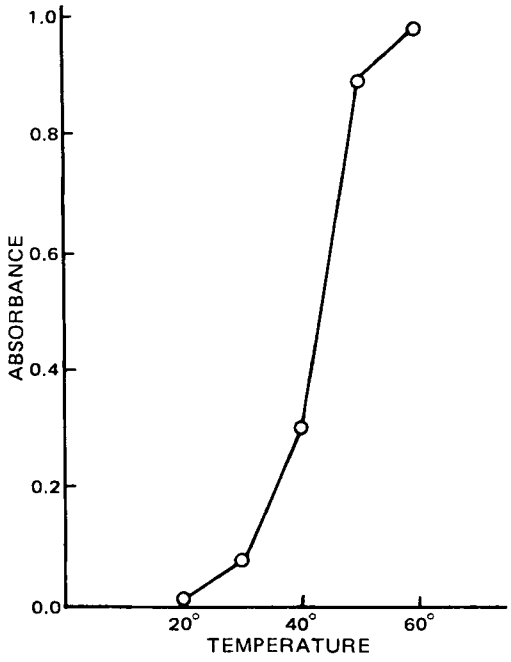

Figure 1—*Temperature effect on color development using 20 μg of diethylstilbestrol/ml, 45 min.*

of these methods lack specificity or sensitivity, and they often are subject to limitations. The compendial UV-irradiation procedures (11, 12), although apparently specific for diethylstilbestrol, may be tedious and time consuming, especially when oily formulations of diethylstilbestrol dipropionate are analyzed. Essential preliminary hydrolysis to diethylstilbestrol and its subsequent extraction might interfere with the accurate estimation of this ester.

Triphenyltetrazolium chloride (I) can be reduced to the corresponding highly colored formazan derivative by various dihydroxybenzene derivatives (13–15). This reduction offered a basis for investigating possible interactions of I with a different aromatic diol system such as 4,4′-stilbenediol, with the hope of introducing a new formazan-based colorimetric analysis of diethylstilbestrol and its dipropionate ester.

EXPERIMENTAL

Instrumentation—A double-beam spectrophotometer[1], a pH meter[2] fitted with calomel and glass electrodes, and a suitable thermostated[3] water bath were used.

Materials—Pharmaceutical grade diethylstilbestrol and diethylstilbestrol dipropionate were the working standards. Ethyl oleate, peanut oil, and sesame oil were chemically pure; other chemicals were analytically pure. As dosage forms, commercially marketed tablets[4,5] and parenteral solutions[6–9] of diethylstilbestrol and diethylstilbestrol dipropionate were analyzed.

[4] Stilbestrol (Misr Co. for Pharmaceuticals, Cairo, Egypt) contains 5.0 mg of diethylstilbestrol/tablet.
[5] Stilbestrol Dipropionate (G. Richter, Budapest, Hungary) contains 1.0 mg of diethylstilbestrol dipropionate/tablet.
[6] Stilbestrol (Misr Co. for Pharmaceuticals, Cairo, Egypt) contains 1.0 mg of diethylstilbestrol/1-ml ampul.
[7] Stilbestrol Dipropionate (G. Richter, Budapest, Hungary) contains 5.0 mg of diethylstilbestrol dipropionate/1-ml ampul.
[8] Stilbestrol Dipropionate (Evans, Bristol, England) contains 10.0 mg of diethylstilbestrol dipropionate/1-ml solution in ethyl oleate.
[9] Stilbestrol Dipropionate (Bayer, Liverkühsen, Germany) contains 5.0 mg of diethylstilbestrol dipropionate/1-ml solution in sesame oil.

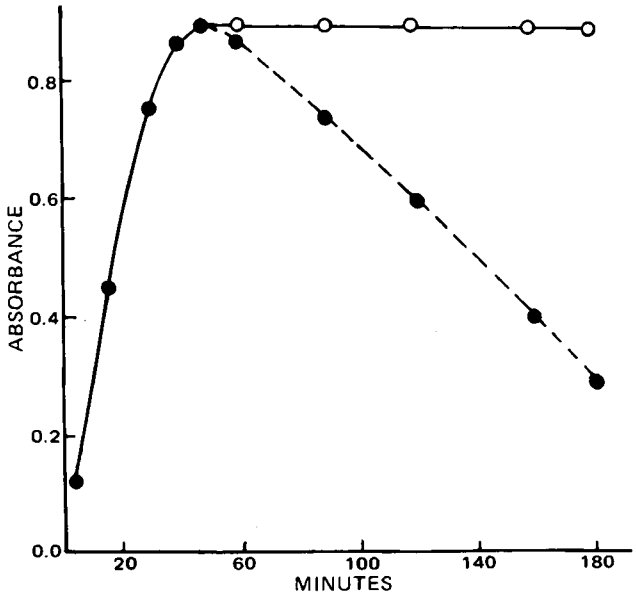

Figure 2—*Diethylstilbestrol–tetrazolium color–time curve using 20 μg of diethylstilbestrol/ml at 50° (●) and after cooling to room temperature (○).*

Reagents—*Tetrazolium Solution*—Compound I was diluted to 0.5% (w/v) in aldehyde-free ethanol[10]. This solution was kept in the dark.

Potassium Hydroxide Solution—Carbonate-free potassium hydroxide, 0.1 g, was dissolved in ~2 ml of distilled water and diluted to 100 ml with anhydrous ethanol. A fresh solution was prepared every 48 hr.

Standards—An accurately weighed amount of diethylstilbestrol or diethylstilbestrol dipropionate, previously dried at 80° *in vacuo* for 2 hr, was dissolved in anhydrous ethanol to a final concentration of 200 μg of diethylstilbestrol/ml.

Assay Samples—*Tablets*—Not less than 20 tablets were ground to a fine powder. An accurately weighed powder sample, equivalent to ~5 mg of diethylstilbestrol, was transferred to a 50-ml volumetric flask. Then 25 ml of anhydrous ethanol was added, and the solution was allowed to stand for 30 min with frequent shaking. The solution was diluted to volume with anhydrous ethanol, mixed well, and filtered through a dry filter into a dry flask. The first portions of the filtrate were discarded.

Injections and Solutions—A 1-ml precision syringe was used to transfer 1.0 ml of the injection solution into a suitable volumetric flask. The syringe was rinsed with 20% (v/v) *n*-heptane in ethanol; the rinses were collected in the flask and diluted quantitatively and stepwise with heptane–alcohol to obtain ~100–140 μg of the claimed diethylstilbestrol/ml.

Procedure—A 1.0-ml sample of the standard or of the sample was pipetted into a 10-ml volumetric flask containing 3.0 ml of the tetrazolium solution and 1.0 ml of the potassium hydroxide assay solution. The sample was mixed well, stoppered, and allowed to stand in the dark in a thermostated water bath at 50 ± 0.1° for 45 min. The red-orange reaction mixture was cooled and brought to volume with ethanol. The absorbance of this solution was measured in a 1-cm glass cell at 485 nm *versus* a blank prepared from 1.0 ml of ethanol (for tablets) or from *n*-heptane–ethanol (for injections) and treated as for the assay solution (heated at 50° for 45 min).

RESULTS AND DISCUSSION

Tetrazolium–Stilbenediol Interaction—Tetrazolium salts were considered for use in pharmaceutical colorimetric analysis because they yield highly colored formazans upon reduction (14–21). The tetrazolium cation may oxidize the enediol function with appreciable selectivity since only the 1,2- and 1,4-dihydroxybenzene derivatives induce blue tetrazolium reduction (13).

Reaction of the following phenols with I in 0.1% KOH at 20° for 30 min also gave no color with resorcinol and phloroglucinol, while a moderate to intense color was observed with pyrocatechol, pyrogallol, and hydroquinone. The 4,4′-stilbenediol reaction mixture became faint orange-red, but the color was augmented by the application of heat. Neither dihy-

drostilbestrol[11] nor *trans*-stilbene induced formazan development under these conditions. These findings, although mostly qualitative, underline the possible reduction of tetrazolium salts by aromatic diols with widely separated enediol functions when the latter are conjugated properly with the carrier aromatic nuclei. This possibility encouraged further investigation of I for use in the photometric analysis of pharmaceutical 4,4′-stilbenediol derivatives.

Assay—Interaction of diethylstilbestrol with I proceeded analogously to 4,4′-stilbenediol; heating of the reaction mixture gradually intensified the color. The formazan absorbed with minimum and maximum extinctions at 408 and 485 nm, respectively, consistent with the absorption of triphenylformazan (17, 19, 22).

For the diethylstilbestrol concentration range studied, appropriate absorptivity readings were attained at 50–60° (Fig. 1). However, at >50°, blank solutions acquired a red tinge that could lower the sensitivity of the diethylstilbestrol–tetrazolium interaction. Accordingly, 50° was a convenient temperature because it combined a reasonable heating time with the production of only a faintly colored blank.

The color–time curve (Fig. 2) revealed maximum formazan formation when the reaction mixture was at 50° for 45–50 min; heating for longer periods seriously lowered color absorptivity. Interruption of the reaction after 45 min by efficient cooling to ambient temperature was sufficient to achieve good sensitivity. The formazan remained stable for >2 hr when kept in the dark. Under these conditions, maximum formazan development was effected by the addition of 1.0 ml of the working diethylstilbestrol solution to 3–4 ml of I in the presence of 1.0 ml of 0.1% KOH (Table I).

Quantitative Analysis—At fixed experimental conditions, the formazan absorption intensity was a function of the diethylstilbestrol concentration. Linear regression analysis of a Beer's plot at 485 nm revealed excellent adherence ($r = 0.9994$), with a slope (α) of 0.0465 ($\pm 1.08 \times 10^{-3}$) and an upper sensitivity limit of ~22 μg ($A = 1.02$) of diethylstilbestrol/ml. Replicate analyses of diethylstilbestrol working solutions (Table II) were fairly precise ($RSD = 2.811 \times 10^{-3}$). Recovery studies at different diethylstilbestrol concentrations (Table III) afforded a mean recovery of 99.45 ± 0.93%.

Since I could be used successfully for the photometric estimation of beclomethasone dipropionate[12] without prior hydrolysis (12, p. 44), a similar interaction for diethylstilbestrol dipropionate was considered.

Table IV—Analysis of Diethylstilbestrol and Diethylstilbestrol Dipropionate Dosage Forms

Preparation[a]	Content, mg/unit Label Claim	Found[b]	Added	Recovered
Diethylstilbestrol				
Tablets	5.0	4.96	10.0	14.94
Injection	1.0	0.98	25.0	26.00
Diethylstilbestrol dipropionate				
Tablets	1.0	1.10	5.0	6.11
Injection[c]	5.0	4.98	5.0	9.95
	10.0	10.05	10.0	20.00
	10.0	9.75	10.0	19.80

[a] See *Experimental* for composition. [b] Average of three determinations. [c] Found 4.75, 9.89, and 9.64, respectively, as analyzed by the NF XIV procedure.

A direct estimation of this ester has not been reported. When reacted under the standard diethylstilbestrol assay, diethylstilbestrol dipropionate produced formazan with Beer's plot r and α values of 0.9992 and 0.0328 ($\pm 1.05 \times 10^{-3}$), respectively. Comparison of the diethylstilbestrol–diethylstilbestrol dipropionate molecular weight ratio to the respective Beer's plot slopes at 485 nm confirmed quantitative *in situ* diethylstilbestrol generation during the base-catalyzed interaction of I with diethylstilbestrol dipropionate.

The color reaction was applied successfully to the analysis of diethylstilbestrol and diethylstilbestrol dipropionate tablets (Table IV). Potential interference by reducing sugars in the tablets was eliminated by alcohol extraction prior to analysis. Interference studies of some common ingredients in diethylstilbestrol dipropionate formulations revealed no reduction of I. The compounds studied included phenobarbital, tetracaine, benzocaine, sulfathiazole, sulfathiourea, and nitroglycerin. Pharmaceutical catecholamines oxidized by I are not likely to be in diethylstilbestrol dosage forms.

Direct spectrophotometric determination of oily diethylstilbestrol dipropionate dosage forms is unreliable because of the high absorptivity of the oily vehicles (1, p. 475). However, neither sesame and olive oils nor ethyl oleate showed measurable absorptivity at 485 nm when tested as 0.8% (w/v) in heptane–alcohol. In addition, no formazan was observed when such solutions were reacted with I under the standard assay conditions. These results encouraged direct estimation of diethylstilbestrol dipropionate dosage forms by the proposed tetrazolium reaction (Table IV). Concordant results were obtained when the oily dipropionate formulations were analyzed directly by I or were preliminarily freed from their vehicles by the NF XIV procedure (10). However, relatively higher values than the claimed diethylstilbestrol dipropionate contents were shown by some intense yellow batches. Correction for intrinsic absorption of such samples was made by determining their initial absorptivity at 485 nm.

Tissue Distribution and Metabolism of Drugs V: Effect of Secretin and Pancreozymin on Drug Transport in Rabbit Pancreas

MASATO ARAKAWA *§, KATSUHIKO OKUMURA *, and RYOHEI HORI‡x

Received April 10, 1979, from the **Institute of Pharmaceutical Sciences, Hiroshima University School of Medicine, Hiroshima 734, Japan,* and the ‡*Department of Pharmacy, Kyoto University Hospital, Sakyo-ku, Kyoto 606, Japan.* Accepted for publication July 16, 1979. §Present address: General Research Center, Wakunaga Pharmaceutical Co. Ltd., Kotachi, Hiroshima, Japan.

Abstract □ The effect of secretin and pancreozymin on the tissue distribution and penetration of drugs in the rabbit pancreas was studied to clarify hormonally regulated drug distribution. Drugs with high liquid solubility were distributed easily within the pancreas even during secretin or pancreozymin treatment, and these hormones had little effect on drug distribution from the blood to the pancreas. However, secretin increased the concentration ratio of dimethadione in the pancreatic juice (J) to plasma unbound dimethadione (Pf), probably because the pancreatic juice during secretin infusion is alkaline relative to the control. Secretin had no effect on the J/Pf of isonicotinamide and sulfanilamide. Secretin decreased the J/Pf of drugs with low lipophilicity or large molecular weight because the penetration rates of these drugs from cell water to pancreatic juice were not rapid enough to reach equilibrium. Pancreozymin was unable to change the J/Pf of any drug tested. These results suggest that the barrier between the blood and the pancreas or the barrier between the pancreas and the pancreatic juice is unchanged by secretin or pancreozymin.

Keyphrases □ Pancreas—drug transport, various drugs, effect of secretin, pancreozymin, pancreatic juice flow □ Pancreatic juice—effect of flow rate on pancreatic drug transport, various drugs □ Drug transport—pancreas, effect of secretin, pancreozymin, pancreatic juice flow, various drugs

Drug distribution has received increasing attention during recent years because such knowledge concerning the blood, organs, and tissues is needed to provide optimal treatment or protection from adverse reactions. Previous papers reported tissue distribution and penetration of drugs in the pancreas (1), lungs, (2, 3), and testes (4).

It was suggested that the lipid barrier in the pancreas plays a dominant role in drug distribution from the blood to the pancreas and that the lipid barrier and the molecular sieve barrier have independent roles in transport from the pancreas to the pancreatic juice. In these experiments, pancreatic juice secretion was stimulated by secretin infusion to maintain a constant juice flow. However, the pancreatic barriers could be changed by endogenous hormones that regulate pancreatic secretion during food digestion.

The purpose of this study was to determine experimentally whether secretin and pancreozymin, typical peptide hormones that stimulate pancreatic juice flow and bicarbonate or enzyme secretion, affect drug distribution and penetration in the pancreas. Some model drugs that exhibit remarkable lipophilicity, molecular size, and pKa were selected as discussed previously (1).

EXPERIMENTAL

Materials—Secretin[1], 3110 CHR U[2]/mg, was used. Pancreozymin[3], dimethadione, isonicotinamide, isonicotinic acid, sulfanilamide, sulfanilic acid, sulfisoxazole, and procainamide hydrochloride were obtained commercially. All other chemicals were analytical grade.

Animals—Male white rabbits, 2.0–3.0 kg, were housed in constant environment rooms and allowed free access to water and food.

Drug Permeation from Blood to Pancreatic Juice—The experimental procedures were almost identical to those described previously (1). Rabbits were anesthetized with pentobarbital sodium (27 mg/kg iv). Pancreatic juice was collected by cannulation into the pancreatic duct as described in the literature (5). Plasma drug concentrations were established and maintained by a suitable combination of priming injections and continuous intravenous infusion.

As the control, pancreatic juice was collected over 75 min prior to the administration of secretin or pancreozymin. The secretin effect was studied by a priming injection (1 CHR U/kg) and continuous intravenous infusion (2 CHR U/kg/hr), after which the pancreatic juice flow was stimulated from 14 (7–24 μl/min) to 39 (15–66 μl/min) μl/min. Pancreozymin also was studied using a priming injection (1 CHR U/kg) and continuous infusion (4 CHR U/kg/hr)[4]. In this experiment, secretin also was infused simultaneously to minimize the effect of secretin contamination in the pancreozymin preparation.

Drug Distribution—The pancreas was removed and homogenized at the end of each permeation experiment, and drug concentrations in the pancreas and blood were measured to determine the distribution ratio.

Analytical Methods—Drug concentrations in the plasma, plasma ultrafiltrate, pancreatic juice, and pancreas homogenate were determined

Sulfanilic acid	0.21 ± 0.01 (3)	0.25 ± 0.02 (4)	—

[a] Panc/Pf indicates the concentration ratio of drug in the pancreas to unbound drug in the plasma. These data were obtained 2 hr after the constant drug infusion and represent the mean ± *SEM*, with the number of animals in parentheses.

according to the procedure described previously (1). The protein content of the pancreatic juice was measured by the Lowry method (6), and the calcium level in the biological fluids was analyzed by the *o*-cresolphthalein-edetate sodium method with a minor modification (7).

RESULTS AND DISCUSSION

Effect of Secretin and Pancreozymin on Drug Distribution in Pancreas—To ascertain the effect of secretin or pancreozymin on drug distribution in the pancreas, drug uptake was studied after constant infusion for 2 hr. Table I illustrates the concentration ratios of drugs in the pancreas to the plasma of unbound drugs, expressed as the distribution ratio (Panc/Pf) under various conditions. Acidic drugs did not distribute into the pancreas as easily as did the cationic or neutral drugs studied previously (1). However, there was no significant difference in distribution ratio between controls and secretin-infused animals or between secretin-infused animals and secretin–pancreozymin-coinfused animals.

Intracellular pH decreases following secretin infusion and ^{14}C-dimethadione (an acidic compound) in male rats and the decrease in the dimethadione distribution have been explained by the pH-partition theory (8). In the present study, no significant difference was detected in dimethadione distribution when the pancreas was stimulated by secretin. The pH change of the pancreatic juice during secretin infusion has been reported as 0.09, from pH 6.86 to 6.77 (8). When the values of 0.53 ml/g for the intracellular water space and 0.22 ml/g for the extracellular water space were adopted[5], the ratio of the secretin-stimulated pancreatic drug level to the control drug level was ≥0.93. This value is so low that it was difficult to detect by the methods used.

Secretin increased the pancreatic juice flow by 2.8 times, and pancreozymin increased the protein and calcium secretion by 6 times. Furthermore, significant decreases were detected in the physiological calcium

content of the rat pancreas during pancreozymin infusion (Panc/Pf of calcium content decreased from 1.41 ± 0.05 to 1.14 ± 0.08). This result probably was due to accelerated calcium secretion into the pancreatic juice during pancreozymin administration; the decreased pancreatic calcium could not be compensated fully by calcium from the blood. Thus, calcium apparently does not play a role in the distribution of these drugs in the pancreas. These results suggest that there is no correlation between drug distribution in the pancreas and pancreatic juice secretion or between the enzyme and calcium secretion.

Effect of Secretin and Pancreozymin on Drug Permeation from Blood to Pancreatic Juice—The effect of secretin on drug transport from the blood to the pancreatic juice was examined to clarify the transport barrier located in the luminal side of the pancreas. Drug levels in plasma and in the pancreatic juice following constant intravenous infusion of isonicotinamide, dimethadione, and isonicotinic acid with or without secretin are presented in Figs. 1–3 as a function of time. The ratios of pancreatic juice drug concentration to unbound plasma drug concentration (J/Pf) during the control period and during secretin infusion are listed in Table II, in which the percent change of J/Pf following secretin infusion also is indicated.

The values were calculated from the data obtained during the control period (45–75 min) and during secretin infusion (90–120 min). With isonicotinamide and sulfanilamide, whose molecular sizes are comparatively small, the J/Pf concentration ratios were almost unity and hardly were affected by secretin infusion (Fig. 1 and Table II). Dimethadione, whose molecular size and lipophilicity resemble those of isonicotinamide, exhibited significant concentration ratio increases (J/Pf) with secretin treatment (Fig. 2 and Table II).

Isonicotinic acid, which possesses structural units similar to isonicotinamide and has lower lipophilicity, showed smaller J/Pf ratios during secretin infusion than those of the controls (Fig. 3 and Table II). Almost the same results were obtained with sulfanilic acid, which has lower lipophilicity than sulfanilamide. Sulfisoxazole and procainamide, compounds with large molecular size compared with sulfanilamide and dimethadione, showed smaller J/Pf ratios during secretin infusion.

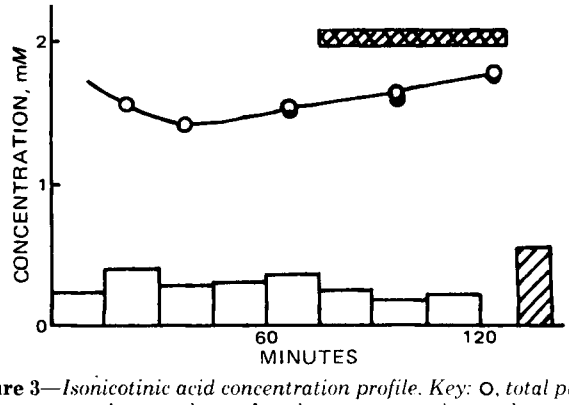

Figure 3—*Isonicotinic acid concentration profile. Key: ○, total plasma drug concentration; ●, plasma free drug concentration; and ⊠, secretin infusion period. Open and hatched columns denote drug concentration in the pancreatic juice and in the pancreas, respectively.*

Table II—Effect of Secretin on Drug Permeation into Pancreatic Juice

Drug	$(J/Pf)_{secretin}$[a]	$(J/Pf)_{control}$	Percent Change[b]	Statistics[c]
Dimethadione	1.83	1.41	+31 ± 6 (3)	$p < 0.05$
Isonicotinamide	0.91	0.92	−2 ± 2 (3)	NS
Sulfanilamide	1.08	1.23	−12 ± 2 (4)	$p < 0.05$
Isonicotinic acid	0.17	0.29	−40 ± 8 (3)	$p < 0.05$
Sulfanilic acid	0.03	0.08	−58 ± 6 (3)	$p < 0.01$
Sulfisoxazole	0.14	0.35	−57 ± 7 (3)	$p < 0.01$
Procainamide	0.09	0.19	−51 ± 6 (3)	$p < 0.01$

[a] J/Pf indicates the concentration ratio of drug in the pancreatic juice to unbound drug in the plasma. [b] Percent change was calculated from the individual data obtained during the control period and during the secretin infusion period. Data are presented with the standard error of the mean (*SEM*), and with the number of animals in parentheses. [c] The statistical test was the *t*-test of percent change.

These results suggest that drugs whose J/Pf ratios are almost unity easily penetrate the blood–pancreas barrier even during secretin treatment, unless there is a change in charge. Eventually, the pancreatic transport of drugs with high permeability would be independent of secretin treatment and of the pancreatic juice flow rate. However, with dimethadione, a weak acid with pKa 6.1, the high J/Pf ratios during secretin infusion could not be explained by its high permeability alone. One possible reason for this finding was the difference between the pancreatic juice pH during secretin treatment and that in the controls. According to the generally accepted view, increased pancreatic juice flow induced by secretin is linked with bicarbonate concentration increments (9).

If complete equilibrium were attained in the concentration ratio between the blood and the pancreatic juice, the transport ratio of acidic drugs would increase with the increase in juice alkalization by secretin infusion. Therefore, the increased transport ratio (J/Pf) of dimethadione caused by secretin infusion could be due to pancreatic juice alkalization and to the rapid partition. With acidic drugs such as isonicotinic acid, sulfanilic acid, and sulfisoxazole, the transport ratios decreased following secretin infusion. Since the transport ratio of acidic drugs theoretically would be greater than unity, as mentioned previously, the difference between the transport ratios of dimethadione and other acidic drugs might arise from differences in lipophilicity and molecular size. Procainamide was the model for basic drugs; the small J/Pf ratio and its decrease by secretin may be due to the alkaline state of pancreatic juice or to the bulky nature of the molecule.

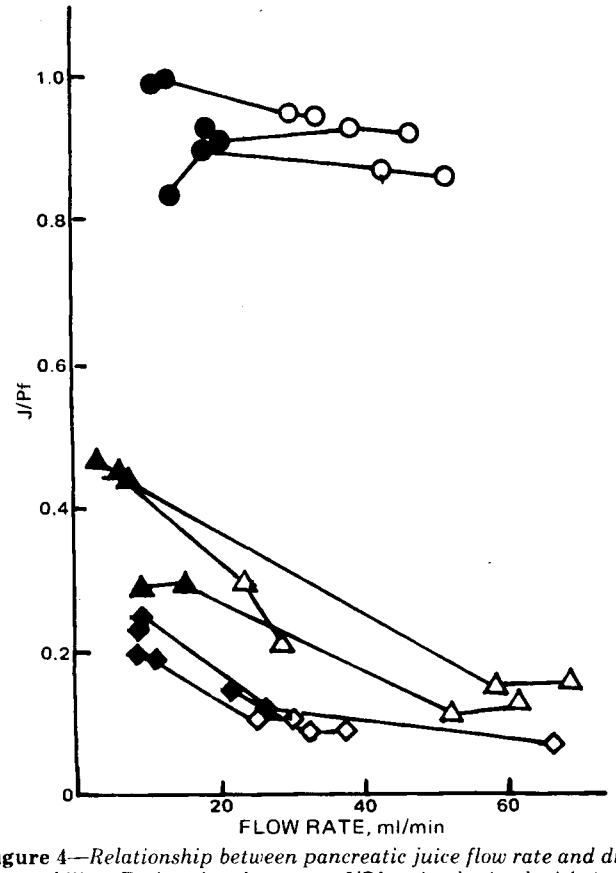

Figure 4—*Relationship between pancreatic juice flow rate and drug permeability. Each point denotes a J/Pf ratio obtained with (open symbol) or without (closed symbol) secretin. Key: ●—○, isonicotinamide; ▲—△, sulfisoxazole; and ♦—◇, procainamide.*

Table III—Effect[a] of Pancreozymin on Drug Permeation into Pancreatic Juice

Drug	$(J/Pf)_{secretin\ pancreozymin}$[b]	$(J/Pf)_{secretin}$	Percent Change[c]
Dimethadione	1.72	1.49	15 ± 4 (3)
Sulfanilamide	1.04	1.04	0 ± 4 (3)
Sulfisoxazole	0.09	0.10	−10 ± 9 (3)

[a] Data were not significant. The statistical test on the *t*-test of percent change. [b] See footnote *a* of Table II. [c] Percent change was calculated from the individual data obtained during secretin infusion period and during the secretin–pancreozymin coinfusion period. Data are presented with the standard error of the mean (*SEM*) and with the number of animals in parentheses.

To demonstrate the role of juice flow on drug movement from the blood to the pancreatic juice, the relationship between the transport ratio (J/Pf) and the pancreatic juice flow rate was examined (Fig. 4). The transport ratios (J/Pf) of procainamide and sulfisoxazole decreased as the juice flow increased, while the isonicotinamide J/Pf was unchanged. It was inferred that the transport ratios of drugs that cannot penetrate easily from the blood to the pancreatic juice due to their low lipophilicity and bulky molecular size decrease as pancreatic juice flow increases, probably because the penetration rates of these drugs are too slow to reach equilibrium before secretion.

A model of salicylic acid transfer from salivary gland cells into saliva by slower diffusion *via* lipid solvation was proposed (10, 11). Salicylic acid diffusion from cell water to saliva was not rapid enough to reach equilibrium, thus decreasing the salivary flow rate, which increased the saliva-to-plasma unbound salicylic acid concentration ratio by about one-third; dimethadione movement was rapid enough to reach equilibrium prior to excretion. In a study of the penetration of six water-soluble chemicals in bile, the permeation rate of small molecules was unchanged during bile flow stimulation while the penetration rate of large molecules decreased as bile flow increased (12). Based on these findings, it is speculated that the molecular sieve barrier and the lipid barrier exist independently even in secretin treatment. The effects of pancreozymin infusion on the permeation of dimethadione, sulfanilamide, and sulfisoxazole from the blood to the pancreatic juice are shown in Table III by the transport ratio (J/Pf) during pancreozymin treatment and during the control experiment.

The percent change of these transport ratios also is presented in Table III. During pancreozymin infusion, the protein and calcium contents of pancreatic juice increased 3.1- and 1.3-fold, respectively, while juice flow increased slightly. No significant difference was observed in the transport rate of these three drugs by pancreozymin infusion. Since no drug binding to enzyme protein in the pancreatic juice was detected by ultracentrifugation, these drugs must exist in the pancreatic juice as unbound molecules. Thus, the data given in Table III indicate that drug transport from the blood to the pancreatic juice is not changed by pancreozymin infusion. The data obtained using a limited number of model drugs support the suggested transport model of drug transfer from the blood to the pancreatic juice through a two-step barrier system: (*a*) a lipoidal barrier from the blood to the pancreas, and (*b*) a molecular sieve barrier and a lipoidal barrier from the cell to the pancreatic juice that coexist independently near the pancreatic duct surface. These barriers probably are rigid even during secretin or pancreozymin treatment.

Distribution Coefficients and *In Vitro* Human Serum Protein Binding of Spironolactone and Its 7α-Carboxymethyl Analog

ANTHONY S. NG *, RONALD B. KLUZA, and DAVID W. NEWTON ˣ

Received February 22, 1979, from the *Department of Pharmaceutics, Massachusetts College of Pharmacy, Boston, MA 02115.* Accepted for publication July 19, 1979. *Present address: Pharmacy Department, Children's Hospital of San Francisco, San Francisco, CA 94199.

Abstract □ The distribution coefficients of spironolactone (I) and its 7α-carboxymethyl analog (II) were determined at 22–25° in systems of *n*-octanol or chloroform and 0.1 *M* phosphate buffer at pH 7.4. The respective values for I in the two systems were 153.9 and 15.1, and those for II were 15.9 and 3.1. Protein binding studies of I and II were conducted with human serum albumin and human γ-globulin *via* equilibrium dialysis at 37°. The I fractions bound to 4% (w/v) albumin and to 1.16% (w/v) γ-globulin were 66 and 18%, respectively. The corresponding II fractions bound to the two proteins were 46 and 12%. The greater protein binding of I agrees with its superior lipophilicity to that of II. The binding of both I and II to albumin increased with increasing albumin concentration, whereas the binding of I and II to albumin did not change significantly as the concentrations of I or II were varied from 50 to 1300 ng/ml. Cooperativity and/or multiple classes of binding sites appear to be associated with the binding of I and II to albumin.

Keyphrases □ Spironolactone—distribution coefficients, *in vitro* human serum protein binding, 7α-carboxymethyl analog □ Protein binding—spironolactone, 7α-carboxymethyl analog, *in vitro* human serum □ Distribution coefficients—spironolactone, 7α-carboxymethyl analog, phosphate buffer with *n*-octanol or chloroform

The spirolactones are steroidal aldosterone antagonists clinically used to produce potassium-sparing diuresis. The spirolactones have been studied extensively because of their considerable biotransformation (1), potential carcinogenicity (2), and ability to induce hepatic detoxification of chemicals (3–5). The pharmacodynamic properties of spirolactones vary because of their differing structure–activity relationships and physicochemical properties (6). At least 19 spirolactones have been investigated (6, 7).

The purpose of this study was to determine the lipid–aqueous distribution coefficients and the extent of plasma protein binding of spironolactone and its 7α-carboxymethyl derivative.

EXPERIMENTAL

Materials—Spironolactone[1] (I) was tritiated[2] randomly and used without further purification. Tritiated 7α-carboxymethyl spirolactone[3] (II), human serum albumin[4], and human γ-globulin[5] were used as received. Other solvents and reagents were of analytical grade of purity.

Procedures—Ten solutions of I and II in the 50–500-ng/ml range were prepared in 0.1 *M* phosphate buffer at pH 7.4 and saturated previously with *n*-octanol or chloroform.

Three milliliters each of the sample solution and of the *n*-octanol or chloroform saturated previously with the phosphate buffer were placed in a glass tube with a polytef-lined screw cap, and the mixture was agitated on a horizontal shaker[6] for 30 min at room temperature (22–25°). The mixtures were allowed to stand for 2 hr, during which time the phases separated. An accurate volume from each phase then was mixed with 10 ml of Bray's solution (8), and the samples were analyzed for I or II by counting on a liquid scintillation spectrometer[7] for 5 min. Each experiment was conducted in triplicate. Distribution coefficient (*P*) values were calculated from (9):

$$P = (\text{counts in } n\text{-octanol phase}/\text{counts in aqueous phase}) \quad \text{(Eq. 1)}$$

$$\log P_{\text{chloroform}} = 1.12 \log P_{n\text{-octanol}} - 1.343 \quad \text{(Eq. 2)}$$

Eight solutions of I and II in the 50–1300-ng/ml range were prepared in 0.1 *M* phosphate buffer at pH 7.4. Human serum albumin solutions (1, 2, 3, 4, and 5% w/v) and a human γ-globulin solution (1.16% w/v) also were prepared in the phosphate buffer. Exactly 1.0 ml of the sample solution was introduced into one side of a dialysis cell[8] separated by a cellulose membrane[9], and 1.0 ml of protein solution was placed into the opposite half. After the cells were incubated for 24 hr at 37°, measured volumes of the sample and protein solutions were mixed with 10 ml of Bray's solution, and the mixtures were counted on a liquid scintillation spectrometer for 5 min. The percent of I or II bound to albumin or γ-globulin was determined from:

$$\text{percent bound} = \left[\frac{(\text{counts in protein}) - (\text{counts in sample solution})}{\text{counts in protein}}\right] \times 100 \quad \text{(Eq. 3)}$$

DISCUSSION

The distribution coefficients of I and II are reported in Table I. There is a considerable discrepancy between the values for I and II in this study and those determined previously (7). The I value determined in chloroform was 17% greater than the theoretical I value in chloroform calculated from Eq. 2 using the experimental value for the distribution coefficient of I in *n*-octanol. However, the reported value (7) for the distribution coefficient of I in *n*-octanol is 289% larger than the corresponding present study value. Similarly, the experimental value for the distribution coefficient of II in chloroform was 210% greater than the corresponding theoretical value, whereas the reported value (7) for the distribution coefficient of II in *n*-octanol is 449% greater than the value determined from this study.

The disagreement between the reported (7) and present study distribution coefficients of I and II in *n*-octanol is not readily discernible. The

Table I—Distribution Coefficients of I and II Determined in 0.1 *M* Aqueous Phosphate Buffer at pH 7.4 *versus* *n*-Octanol and Chloroform

Compound	Experimental Values, mean ± *SEM*, %		Reported Values for	Calculated Values[a] for
	n-Octanol	Chloroform	*n*-Octanol	Chloroform
I	153.9 ± 15.3	15.1 ± 1.7	598.4[b]	12.9[c]
II	15.9 ± 0.7	3.1 ± 0.3	87.3[d]	1.0[e]

[a] From Eq. 2. [b] Antilog of log P = 2.777; Ref. 7. [c] Antilog of log P = 1.11, calculated from Eq. 2. [d] Antilog of log P = 1.941; Ref. 7. [e] Antilog of log P = 0.001, calculated from Eq. 2.

Table II—Binding of I and II to Human Serum Albumin and Human γ-Globulin.

Compound	Protein Binding, mean ± *SEM*, %			Binding Difference, %[a]		
	Albumin, 4%	Globulin, 1.16%	Total	Albumin, 4%	Globulin, 1.16%	Total
I	66.5 ± 0.4	18.3 ± 0.5	84.7 ± 0.4	—	—	—
II	45.7 ± 0.5	11.8 ± 0.5	57.5 ± 0.5	−31.2	−35.4	−32.1

[a] [(percent II − percent I)/percent I] × 100.

Table III—Comparison of Protein Binding Values for I and II

Compound	Present Study[a]	Protein Binding, %	
		Reference 7[b]	Reference 10[c]
I	84.7	94.2	91.1, 98.2
II	57.5	73.5	—

[a] Based on the sum of binding by 4% human serum albumin and 1.16% human γ-globulin. [b] Ultrafiltration method. [c] Lower value was obtained *via* equilibrium dialysis, and higher value was obtained *via* ultrafiltration; both were determined in human plasma at 550 ng of I/ml.

experimental distribution coefficients for I and II reported here are in closer agreement with the values predicted by Eq. 2. All distribution coefficient data determined in *n*-octanol indicate I to be 7–10 times more lipophilic than II. This difference may be attributed to the presence of a sulfur atom in the acetylthio substituent at the 7-position on I. The dominating contribution of the sulfur atom to lipophilicity is emphasized often *via* reference to the exemplary ninefold greater distribution coefficient of thiopental *versus* that of pentobarbital (9).

The values for percent protein binding determined in this study and those reported earlier (7, 10) are listed in Tables II and III. No binding of I or II to the dialysis membrane was demonstrated. The significant disagreement of the present results with those reported earlier may be attributed to at least the following factors:

1. The experimental conditions of Ref. 7 included using 20% (v/v) 1,3-butylene glycol and 4% (v/v) methanol to maintain drug solubility in the phosphate buffer as well as sample ultrafiltration *via* centrifugation at 4°. This low temperature could have influenced binding, resulting in values different from those found at 37°. The concentrations of human serum albumin utilized (7) are typical of clinical hypoalbuminemia (11). The previous investigators (7) did not study the binding of I or II to human γ-globulin.

2. The authors of Ref. 10 used fresh human plasma for I binding studies; however, serum protein concentrations and temperature conditions were not reported.

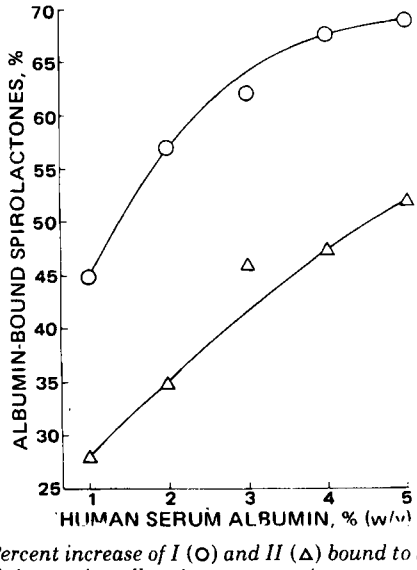

Figure 1—*Percent increase of I (○) and II (△) bound to human serum albumin with increasing albumin concentration.*

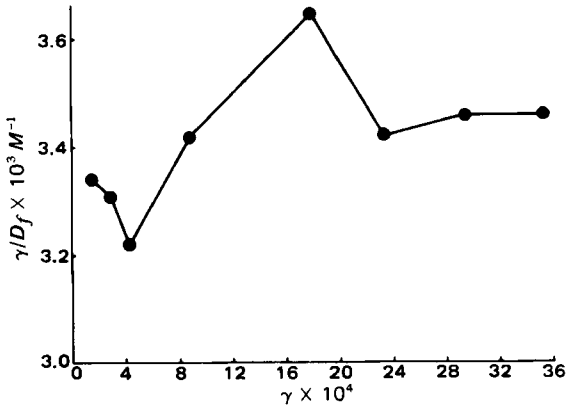

Figure 2—*Scatchard plot of* γ/D_f *versus* γ *for I over the 53.3–1278.0-ng/ml range (1.3–30.1 × 10⁻⁷ M) in 4.0% (w/v) (5.8 × 10⁻⁴ M) human serum albumin at pH 7.4 and 37°.*

Although several steroidal compounds, *e.g.*, corticosteroids, are bound extensively to human γ-globulins, albumin accounts for the greatest proportion of binding of these drugs to serum or plasma proteins (11–13). Furthermore, some steroids also are highly bound to serum lipoproteins (14). The present study results indicate 18% binding of I to human γ-globulin. Therefore, the comparative data in Table III suggest that the percent protein binding of I reported in Ref. 7 may be an overestimate resulting from the use of a mixed aqueous solvent system and albumin-only protein solutions. The low temperature centrifugation conditions used (7) also would increase the fraction of drug bound to albumin (11).

The present 85% value for the total binding of I in 4% (w/v) human serum albumin and 1.16% human γ-globulin (Table II) agrees with the 91% value determined in human plasma reported elsewhere (10). There was no significant variation in the percent binding of I or II to the serum proteins over the drug concentration range investigated. However, Fig. 1 shows that the binding of I and II increased proportionally with increasing albumin concentration.

A causal relationship between hydrophobicity (lipophilicity) and drug–protein binding was demonstrated for steroids (15) and other drugs (16, 17). The fact that the distribution coefficient of I is 7–10 times greater than that of II (Table I) correlates with the 32% superiority in protein binding of I over II (Table II). Scatchard plots (7, 18–20) of I and II in 4% (w/v) human serum albumin (Figs. 2 and 3) were prepared from:

$$\gamma/D_f = K(n - \gamma) \qquad \text{(Eq. 4)}$$

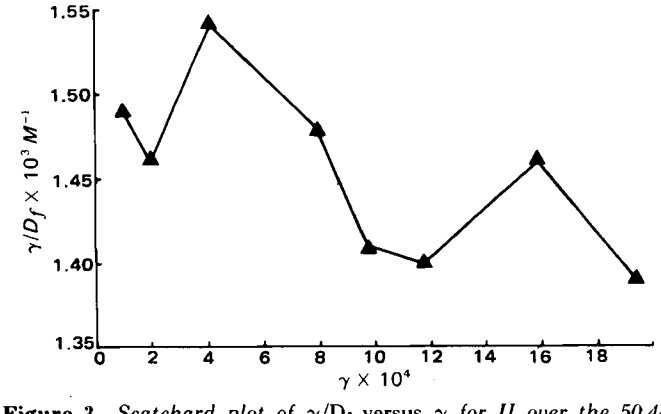

Figure 3—*Scatchard plot of* γ/D_f *versus* γ *for II over the 50.4–1006.0-ng/ml range (1.3–25.1 × 10⁻⁷ M) in 4% (w/v) (5.8 × 10⁻⁴ M) human serum albumin at pH 7.4 and 37°.*

where γ is the ratio of the concentration of albumin-bound spirolactone to that of albumin, D_f is the concentration of unbound spirolactone at dialysis equilibrium, K is the binding constant at equilibrium, and n is the number of a single type of binding sites. The previous investigators (7) apparently obtained linear plots of γ/D_f *versus* γ for several spirolactones. The concentrations of spirolactone used (7) appear to have been ~30–800 times higher than the peak serum concentrations of I and its metabolites detected in human males given a 200-mg oral dose (10).

The observed absence of linearity, together with the complexity of the Scatchard plots for I and II, strongly suggests diverse protein–ligand binding characteristics. Such deviations were reported to be due to cooperative ligand interaction, multiple-contact binding sites, or nonequivalent binding sites (20). Inspection of the Scatchard plots reveals several points of inflection, as well as both concave and convex curvatures at varying concentrations of bound I and II. Such patterns generally are the results of different types of binding sites, each exhibiting cooperative character. Furthermore, individual binding sites for I and II may overlap and also may contribute to the diverse binding pattern observed. Although no absolute conclusion can be drawn regarding which phenomenon dominates the binding pattern of I and II for human serum albumin, a single model of independent, equivalent binding is not applicable for the spirolactones studied.

Lidocaine Pharmacokinetics in Pregnant and Nonpregnant Sheep

DUANE C. BLOEDOW *x, DAVID H. RALSTON, and JOHN C. HARGROVE

Received November 6, 1978, from the *Department of Anesthesiology, University of Washington, Seattle, WA 98195.* Accepted for publication July 24, 1979.

*Present address: School of Pharmacy, University of Colorado, Boulder, CO 80309.

Abstract □ Lidocaine disposition kinetics were studied in the pregnant ewe following 0.5-, 1.0-, and 2.0-mg/kg iv bolus doses and in the nonpregnant ewe following a 1.0-mg/kg iv bolus dose. Arterial blood was assayed for lidocaine by GLC. The blood lidocaine concentration–time curves were computer fitted to a two-compartment open model. In the pregnant ewe, the total body clearance of lidocaine (38 ml/min/kg) remained constant with increasing dose and was correlated linearly with preinjection cardiac output. The apparent volume of distribution of the central compartment apparently increased with increasing dose. The half-life of the postdistributive phase and the volumes of distribution at steady state and during the postdistributive phase increased as the dose was increased from 0.5 to 1.0 mg/kg. These observations suggest dose-related distribution of lidocaine in the pregnant ewe. The total body clearance of lidocaine in the pregnant ewe was not different from that in the nonpregnant ewe after 1.0-mg/kg doses; however, the volumes of distribution of the central compartment at steady state and during the postdistributive phase and the half-life of the postdistributive phase were greater in the pregnant ewe. The greater total body clearance for lidocaine in sheep as compared to humans is consistent with the greater hepatic blood flow in sheep; calculated hepatic extraction ratios for sheep are similar to hepatic extraction ratios for humans.

Keyphrases □ Lidocaine—pharmacokinetics, pregnant and nonpregnant sheep □ Pharmacokinetics—lidocaine, pregnant and nonpregnant sheep □ Anesthetics—lidocaine, pharmacokinetics, pregnant and nonpregnant sheep

Few literature reports describe drug disposition kinetics in the pregnant individual, but drug pharmacokinetics during pregnant and nonpregnant states may differ markedly. Alterations in drug disposition kinetics could be related to maternal changes, including blood and/or tissue binding of the drug, changes in the rates or distribution of blood flow, and drug metabolism changes. More importantly, drug kinetics during pregnancy may be altered by the addition of the fetal–placental unit with its inherent abilities to distribute, bind, metabolize, and clear drugs.

Lidocaine disposition kinetics at three doses in the pregnant ewe are presented in this report, and a comparison is made with lidocaine disposition kinetics in the nonpregnant ewe.

EXPERIMENTAL

Pregnant and nonpregnant pure or crossbred Suffolk ewes, 64.6 ± 11.3 (mean ± *SD* on the day of surgery) and 66.7 ± 11.9 kg, respectively, were obtained locally. Pregnant ewes were studied from Day 137 to Day 143 of gestation (full term 147–150 days). The ewes were catheterized during sterile surgery under general endotracheal anesthesia, using halothane and oxygen with controlled mechanical ventilation.

Polyethylene catheters were placed into the femoral artery and femoral vein and advanced to the abdominal aorta and inferior vena cava, respectively. The femoral artery catheter was used for continuous blood pressure and heart rate monitoring, and the femoral vein catheter was used for lidocaine administration. A central venous catheter was inserted *via* percutaneous puncture into the external jugular vein and positioned in the right atrium. This catheter was used for the injection of indocya-

where γ is the ratio of the concentration of albumin-bound spirolactone to that of albumin, D_f is the concentration of unbound spirolactone at dialysis equilibrium, K is the binding constant at equilibrium, and n is the number of a single type of binding sites. The previous investigators (7) apparently obtained linear plots of γ/D_f *versus* γ for several spirolactones. The concentrations of spirolactone used (7) appear to have been ~30–800 times higher than the peak serum concentrations of I and its metabolites detected in human males given a 200-mg oral dose (10).

The observed absence of linearity, together with the complexity of the Scatchard plots for I and II, strongly suggests diverse protein–ligand binding characteristics. Such deviations were reported to be due to cooperative ligand interaction, multiple-contact binding sites, or nonequivalent binding sites (20). Inspection of the Scatchard plots reveals several points of inflection, as well as both concave and convex curvatures at varying concentrations of bound I and II. Such patterns generally are the results of different types of binding sites, each exhibiting cooperative character. Furthermore, individual binding sites for I and II may overlap and also may contribute to the diverse binding pattern observed. Although no absolute conclusion can be drawn regarding which phenomenon dominates the binding pattern of I and II for human serum albumin, a single model of independent, equivalent binding is not applicable for the spirolactones studied.

Abstract □ Lidocaine disposition kinetics were studied in the pregnant ewe following 0.5-, 1.0-, and 2.0-mg/kg iv bolus doses and in the nonpregnant ewe following a 1.0-mg/kg iv bolus dose. Arterial blood was assayed for lidocaine by GLC. The blood lidocaine concentration–time curves were computer fitted to a two-compartment open model. In the pregnant ewe, the total body clearance of lidocaine (38 ml/min/kg) remained constant with increasing dose and was correlated linearly with preinjection cardiac output. The apparent volume of distribution of the central compartment apparently increased with increasing dose. The half-life of the postdistributive phase and the volumes of distribution at steady state and during the postdistributive phase increased as the dose was increased from 0.5 to 1.0 mg/kg. These observations suggest dose-related distribution of lidocaine in the pregnant ewe. The total body clearance of lidocaine in the pregnant ewe was not different from that in the nonpregnant ewe after 1.0-mg/kg doses; however, the volumes of distribution of the central compartment at steady state and during the postdistributive phase and the half-life of the postdistributive phase were greater in the pregnant ewe. The greater total body clearance for lidocaine in sheep as compared to humans is consistent with the greater hepatic blood flow in sheep; calculated hepatic extraction ratios for sheep are similar to hepatic extraction ratios for humans.

nine green[1] in the cardiac output determination by a dye dilution technique.

An arterial catheter was placed through a branch of the carotid artery and advanced centrally to obtain arterial blood for blood gas, cardiac output, and lidocaine determinations. Arterial rather than venous blood was chosen for lidocaine determination because of expected arterial–venous lidocaine concentration differences resulting from tissue drug uptake (1, 2). The arterial lidocaine concentration better reflects presentation of the drug to well-perfused vital organs, especially during drug distribution. A laparotomy was performed on the pregnant ewe for placement of a fetal arterial catheter for obtaining fetal blood samples for blood gas and lidocaine determinations and for monitoring fetal heart rate and blood pressure.

All catheterizers were filled with heparinized saline and either tunneled subcutaneously to the flank or wrapped securely around the neck or hindlimb. The animal was allowed a minimum of 24 hr to recover from anesthesia and surgery before studies were initiated. For all animals, the heart rate, blood pressure, and blood gases were used as measures of well-being during surgery and subsequent studies. The results of these physiological determinations and the fetal blood lidocaine levels will not be presented in this report.

On experimental days, the animal was placed in a sheep-restraining cage and measurements were taken during a 30-min control period to produce baseline blood gas[2], blood pressure, and heart rate[3] data. Cardiac output was measured three times during the control period. Following the control period, lidocaine hydrochloride[4] was injected intravenously over 10 sec at one of three doses (0.5, 1.0, or 2.0 mg/kg) to the pregnant ewe or at one dose (1.0 mg/kg) to the nonpregnant ewe. All lidocaine doses are expressed as amounts of lidocaine hydrochloride administered. In the pregnant animal, the lidocaine doses were administered randomly on consecutive days following surgery to quantitate possible lidocaine pharmacokinetic variations as a function of postsurgical time.

No systematic variations were apparent in lidocaine pharmacokinetics or in the heart rate, blood pressure, or blood gases measured on consecutive days following surgery. Arterial blood samples were collected at 1, 2, 5, 10, 15, 20, 30, 45, 60, 90, 120, and 150 min following lidocaine injection and were stored frozen in heparinized tubes until subsequent determination of whole blood lidocaine by a GLC method having a coefficient of variation of <5% over the concentration range studied (3). All lidocaine concentrations and pharmacokinetic data were expressed in terms of lidocaine base. Four of the 14 pregnant ewe studies were performed on ewes with twin fetuses. No significant pharmacokinetic differences were found between the pregnant ewes carrying one fetus and those carrying two fetuses.

Blood lidocaine concentration–time curves for each ewe were described adequately by the biexponential equation:

$$C = Ae^{-\alpha t} + Be^{-\beta t} \quad \text{(Eq. 1)}$$

where C is the blood lidocaine base concentration at time t and A, α, B, and β are constants. The blood concentration–time data were fitted[5] to Eq. 1 using the NONLIN nonlinear least-squares program (4). Each blood concentration data point was weighted with its squared reciprocal. This weighting factor was selected based on (5):

$$\ln \sigma^2 = \ln a + n \ln \bar{C} \quad \text{(Eq. 2)}$$

where σ^2 is the variance corresponding to the mean drug concentration, $\bar{C}$, for a group of subjects at a given time following injection and a and n are constants. If $n = 1$, an appropriate weighting factor is the reciprocal of the plasma drug concentration; if $n = 2$, the squared reciprocal of the plasma drug concentration may be used. Linear regression of $\ln \sigma^2$ as a function of $\ln \bar{C}$ for the data in this study resulted in n values of 1.39 ($r = 0.970$), 1.59 ($r = 0.923$), and 1.76 ($r = 0.890$) for the 0.5-, 1.0-, and 2.0-mg/kg doses in the pregnant ewes, respectively, and of 1.68 ($r = 0.986$) for the 1.0-mg/kg dose in the nonpregnant ewes. Because the n values approach two, each plasma concentration data point was weighted with its squared reciprocal.

Tables I and II contain estimates of the pharmacokinetic constants (A, α, B, and β) for each subject and values for the criteria used to assess the data fit from each subject to Eq. 1. The criteria were: the coefficient of variation of the estimated pharmacokinetic constants (standard deviation of the estimate/estimated constant), the coefficient of determination [$r^2 = \Sigma(\text{obs}^2 - \Sigma\text{dev}^2)/\Sigma\text{obs}^2$], and the correlation coefficient relating the equation-predicted and observed lidocaine concentrations. The coefficients of determination and correlation coefficients approached

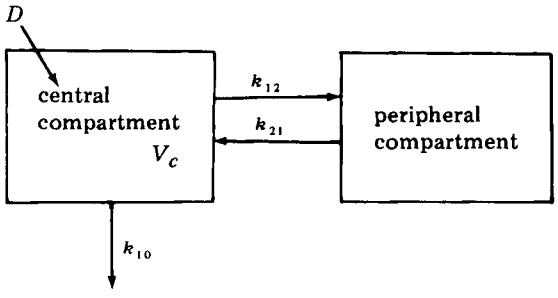
1.0, indicating that Eq. 1 adequately described the time course of the lidocaine concentration following bolus intravenous administration to pregnant and nonpregnant ewes.

The values for A, α, B, and β were used to calculate (6) pharmacokinetic parameters for the two-compartment open model (Scheme I):



Scheme I

where D represents the intravenous bolus lidocaine hydrochloride dose, V_c is the apparent volume of distribution of the central compartment, k_{12} and k_{21} are the apparent first-order intercompartmental lidocaine distribution rate constants, and k_{10} is the apparent first-order lidocaine elimination rate constant.

RESULTS

The computer-determined estimates of A, α, B, and β for all pregnant animals within each dosage group were averaged and used to generate curves indicating the blood lidocaine concentration change with time following intravenous bolus dosing to pregnant ewes (Fig. 1). The equations in Fig. 1 indicate the average values of A, α, B, and β for each dosage group. Table III shows the means and standard deviations for physiological data and the pharmacokinetic parameters calculated from A, α, B, and β for the three doses in the pregnant ewes.

As the lidocaine dose increased, the slope of the α-phase (distributive phase) of the blood concentration–time curve increased (Fig. 1), as indicated by the increase in the α-phase half-life [$t/2$ (α), Table III]. Although the mean α-phase half-lives for the three doses did not all differ significantly from each other, the α-phase half-life following the 0.5-mg/kg dose differed significantly ($p < 0.05$) from that following the 2.0-mg/kg dose. The curves in Fig. 1 also indicate different slopes for the β-phases (postdistributive phase) of the blood concentration–time curves. These differences are reflected in the β-phase half-lives [$t/2$ (β)] in Table III. The β-phase half-life following the 0.5-mg/kg lidocaine dose differed significantly ($p < 0.01$) from that following the 1.0-mg/kg dose.

The correlation between the total body clearance (calculated by dividing the intravenous bolus dose by the area under the curve for each animal) and the body weight was positive ($r = 0.576$, $p < 0.05$). Therefore, the total body clearance values were normalized for weight prior to averaging within each group (Table III). Cardiac output (mean of the three control period determinations for each study) showed no significant statistical correlation with body weights. However, the correlation between total body clearance and cardiac output was positive ($r = 0.673$, $p < 0.02$, Fig. 2) for all studies performed with the pregnant ewes.

Each of the three volumes of distribution for lidocaine showed statistically significant ($p < 0.05$) positive correlations with body weight and, therefore, were weight normalized for inclusion in Table III. The mean apparent volume of distribution for the central compartment, V_c, following the 0.5-mg/kg dose differed significantly ($p < 0.05$) from that following the 2.0-mg/kg dose. The apparent volume of distribution of

lidocaine at steady state, V_{ss}, relates the amount of lidocaine in the body to the blood lidocaine concentration at steady state; the apparent volume of distribution of lidocaine during the postdistributive phase, V_B, relates the amount of lidocaine in the body to the blood lidocaine concentration at any time during the postdistributive, β, phase (6). Mean values for these apparent volumes of distribution also are found in Table III. Both the apparent volume of distribution at steady state and the apparent volume of distribution during the postdistributive phase following the 0.5-mg/kg dose differed significantly ($p < 0.05$) from the corresponding volumes following the 1.0-mg/kg dose.

Table III shows that the lidocaine elimination rate constant, k_{10}, decreased as the dose increased; however, the mean elimination rate constants for each dose did not differ significantly from one another. The rate constants for lidocaine transfer between the central and peripheral compartments also are found in Table III. As the lidocaine dose was increased, both intercompartmental rate constants, k_{12} and k_{21}, decreased.

Figure 3 shows curves generated from averaged computer-determined estimates of A, α, B, and β from pregnant and nonpregnant ewes following 1.0 mg of lidocaine/kg. The Fig. 3 equations indicate the average values of A, α, B, and β. Table IV shows the means and standard deviations of physiological data and pharmacokinetic parameters for 1.0-mg of lidocaine/kg doses in nonpregnant ewes. Comparison of parameters

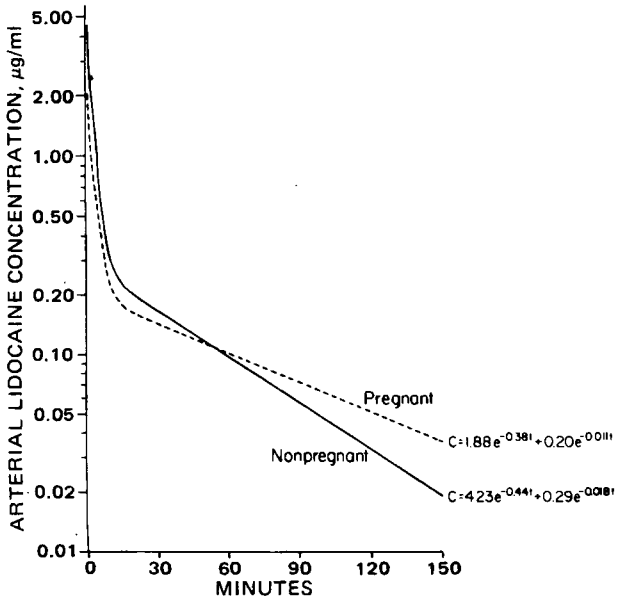

Figure 3—*Arterial blood lidocaine concentration–time curves following intravenous bolus administration of 1.0 mg of lidocaine hydrochloride/kg to pregnant and nonpregnant ewes. The equations indicate the averaged computer estimates for* A, α, B, *and* β *used to generate each curve.*

in the nonpregnant ewe with those in the pregnant ewe (Table IV) shows that the β-phase half-lives differed significantly ($p < 0.05$) between the two groups. Although the volumes of distribution and clearances in this limited sample of nonpregnant ewes did not correlate with weight, the values for these parameters were weight normalized for comparison with the pregnant animal group. The volume of distribution at steady state in the nonpregnant animal differed significantly ($p < 0.01$) from that in the pregnant animal. In addition, the apparent volume of distribution of the central compartment and during the postdistributive phase differed significantly between the two groups but at a lower level of significance ($p < 0.10$).

DISCUSSION

The use of the two-compartment open model (Scheme I) to describe lidocaine disposition in the pregnant ewe implies linearity of lidocaine disposition kinetics as a function of dose. The total body clearance for lidocaine (Table III) remained relatively constant as the intravenous bolus dose was increased from 0.5 to 2.0 mg/kg. Also, the area under the blood lidocaine concentration–time curve, AUC, showed a statistically significant ($r = 0.921$, $p < 0.001$, Fig. 4) linear correlation with the weight-normalized dose, D, according to:

$$AUC = \frac{1}{Cl_T}(D) \qquad \text{(Eq. 3)}$$

where Cl_T represents total body clearance. The regression line passed through the vertical axis near zero (−2.0 min × mg/liter), and the reciprocal of the slope (total body clearance) was 38 ml/min/kg.

Another linearity test in pharmacokinetics involves computer fitting of the blood drug concentration–time data for each animal to an appropriate linear pharmacokinetic model, computing and averaging the pharmacokinetic parameters for each dose, and comparing these averaged parameters among doses. The dose-related trends in the magnitudes of the pharmacokinetic parameters provide strong evidence of nonlinear kinetics (7). Comparisons of averaged pharmacokinetic parameters among different doses in pregnant ewes in this study can be made from the data in Table III. These data showed dose-related increases in the apparent volume of distribution of the central compartment and in the half-life of the α-phase and dose-related decreases in k_{10}, k_{12}, and k_{21} as the dose was increased from 0.5 to 2.0 mg/kg.

The dose-related increase in the apparent volume of distribution of the central compartment could be a result of the hemodynamic effects of lidocaine. Lidocaine is known to increase cardiac output in humans (at arterial lidocaine concentrations of 4–7 μg/ml) and in dogs (8–10), presumably by a central nervous system (CNS) effect evoked through the sympathetic nervous system. Following a bolus lidocaine injection, transient high lidocaine levels in the CNS could produce a brief, dose-related increase in cardiac output. Resulting tissue perfusion increases would promote more rapid tissue uptake of lidocaine and, therefore, an apparent dose-related increase in the volume of distribution of the central compartment. The effect of lidocaine on cardiac output and, hence, on tissue uptake would be brief and would not significantly alter lidocaine elimination; therefore, total body clearance of lidocaine remained un-

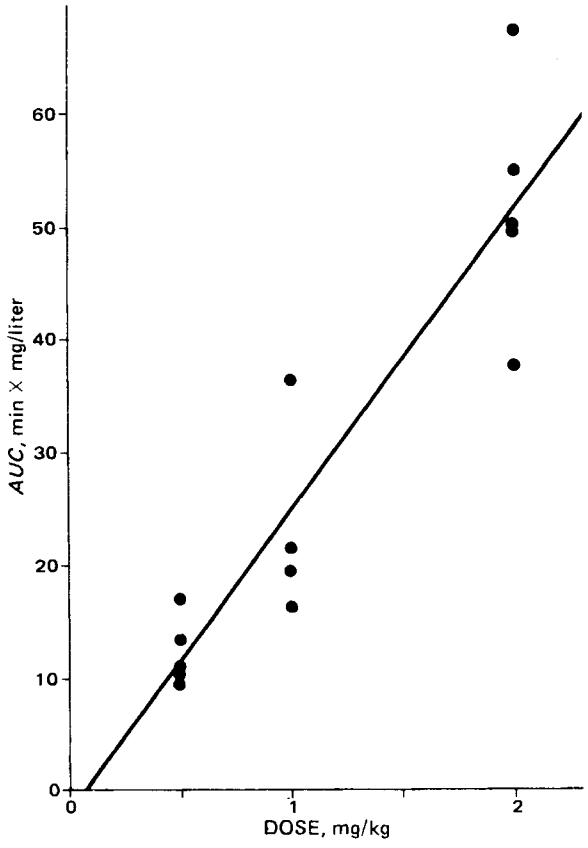

Figure 4—*Correlation between dose and area under the blood lidocaine concentration–time curve following administration of 0.5, 1.0, and 2.0 mg of lidocaine hydrochloride/kg to pregnant sheep.*

changed with dose (Table III). The brevity of the effect of lidocaine on cardiac output is supported by cardiac output measurements at 5 min following bolus lidocaine[6] injection; these cardiac output measurements were not different from the control values shown in Table III.

The dose-related increase in the apparent volume of distribution of the central compartment also is consistent with a probable decrease in the lidocaine fraction bound in plasma as blood lidocaine levels increase. A transient decrease in the lidocaine fraction bound at high blood lidocaine levels following a bolus dose may allow lidocaine to distribute more widely in the body, thus increasing the distribution volume.

The observation of a dose-related increase in the apparent volume of distribution of the central compartment (and a concomitant decrease in k_{10} and k_{12}) in pregnant sheep is consistent with trends reported describing lidocaine disposition kinetics in normal human volunteers (10). In that study, the apparent volume of distribution of the central compartment increased (0.44–0.48 liter/kg), the elimination rate constant k_{10} decreased (0.24–0.22 min^{-1}), and the intercompartmental rate constant k_{12} decreased (0.066–0.041 min^{-1}) as the intravenous bolus dose was increased (50–100 mg). An increase in the apparent volume of distribution of the central compartment in normal humans is consistent with a probable transient increase in cardiac output following a bolus lidocaine dose. In addition, this volume increase is consistent with a decrease in the percent of lidocaine bound in plasma as blood lidocaine levels increase. In humans, plasma lidocaine binding decreases from 75% at 0.4 μg/ml to 58% at 5 μg/ml (11). The mean extrapolated zero-time lidocaine concentrations in normal humans, 1.80 and 2.79 μg/ml following bolus doses of 50 and 100 mg, respectively (10), are in the concentration range where significant plasma binding changes occur. Thus, although pharmacokinetic parameters may not show statistically significant differences as the dose is increased, dose-related trends in pharmacokinetic parameters may offer increased insight into the drug disposition kinetics.

In addition to possible dose-related nonlinearities in the α-phase of lidocaine disposition, Table III shows evidence for dose-related kinetics during the β- or postdistributive phase in pregnant ewes. Following the 0.5-mg/kg dose, the β-phase half-life (42.2 min) differed significantly from that (61.8 min) following the 1.0-mg/kg dose. The β-phase half-life [$t/2(\beta)$] is related to the total body clearance, Cl_T, and to the apparent volume of distribution during the postdistributive phase, V_B, according to:

$$t/2(\beta) = \frac{0.693 V_B}{Cl_T} \qquad \text{(Eq. 4)}$$

Since the total body clearance of lidocaine in the pregnant ewe does not appear to change with dose, Eq. 4 indicates that an increase in the β-phase half-life of lidocaine may be a function of an increase in the apparent volume of distribution. This concept is consistent with the significant change in the volume of distribution during the postdistributive phase (2.24–3.63 liters/kg, Table III) as the lidocaine dose was increased from 0.5 to 1.0 mg/kg. A better indication of dose-related distribution changes is a comparison of the apparent volumes of distribution at steady state following different doses. This parameter is not dependent on elimination processes as is the apparent volume of distribution during the postdistributive phase. The change in the volume of distribution of lidocaine at steady state from 1.69 to 2.73 liters/kg as the dose was increased from 0.5 to 1.0 mg/kg was significant. Thus, the data indicate that dose-related changes in the apparent volume of distribution of lidocaine in the pregnant ewe may influence the biological half-life.

Lidocaine disposition kinetics in the nonpregnant ewe differed from the lidocaine disposition kinetics in the pregnant ewe (Table IV) at a 1.0-mg/kg dose. Figure 3 indicates that the initial lidocaine levels following a 1.0-mg/kg bolus dose were higher in the nonpregnant ewe, but that during the β-phase the blood levels in the nonpregnant ewe decreased more rapidly than in the pregnant ewe. These blood level changes are reflected in the pharmacokinetic parameters in Table IV. The lower apparent volume of distribution of the central compartment in the nonpregnant ewe resulted in higher initial blood lidocaine levels in the nonpregnant animal following a bolus dose based on body weight. In addition, the lower β-phase half-life in the nonpregnant ewe, 41.4 *versus* 61.8 min in the pregnant ewe, reflected the more rapid decline in blood lidocaine levels during the β-phase in the nonpregnant animal following a bolus dose.

Because total body clearances of lidocaine in the nonpregnant and pregnant animals were similar, the greater apparent volumes of distribution (V_c, V_{ss}, and V_B) in the pregnant animals indicated that differences between disposition kinetics in the nonpregnant and pregnant ewes probably were due to drug distribution changes. These changes may be due to differences between lidocaine binding in the plasma, blood, and/or peripheral tissues of the nonpregnant ewe as compared to binding in the corresponding maternal tissues of the pregnant ewe. In addition, fetal lidocaine uptake in the pregnant ewe undoubtedly influences distribution parameters as determined from maternal blood lidocaine levels.

The values for total body clearance of lidocaine in the pregnant sheep (38 ml/min/kg as determined by the method illustrated in Fig. 4) and in the nonpregnant sheep (38 ml/min/kg, Table IV) were considerably greater than the total body clearance reported for lidocaine in humans (9–14 ml/min/kg) (2, 10). In humans, the total body clearance of lidocaine increases as the cardiac output and, therefore, the hepatic blood flow increase (12, 13). In the pregnant sheep, the total body clearance also increased as the cardiac output (Fig. 2) and, presumably, the hepatic blood flow increased. Hepatic blood flow in normal humans is about 21 ml/min/kg (1.5 liters/min in a 70-kg human), and hepatic blood flow in pregnant and nonpregnant ewes is about 65 and 55 ml/min/kg, respectively (14). Thus, the hepatic blood flow in the ewe is sufficient to account for the comparatively higher total body clearance of lidocaine in sheep.

The proportion of the total drug entering the liver to that metabolized by the liver is the extraction ratio. The extraction ratio, E, may be calculated by (15):

$$E = \frac{Cl_T(1-f)}{Q} \qquad \text{(Eq. 5)}$$

where Cl_T is the total body clearance of drug, f is the drug fraction excreted unchanged from the body, and Q is the hepatic blood flow. Use of Eq. 5 for hepatic lidocaine extraction in the pregnant ewe is based on the assumptions that: (*a*) renal excretion is the only nonmetabolic excretory pathway for lidocaine, (*b*) the dose fraction excreted unchanged in the urine [0.014 (16)] in normal adult sheep is the same as that for pregnant ewes, (*c*) lidocaine metabolism occurs only in the liver, and (*d*) hepatic blood flow [65 ml/min/kg (14)] does not change significantly following the lidocaine injection. Cardiac output in the pregnant sheep measured 5 min following injection of 0.5, 1.0, or 2.0 mg of lidocaine/kg[6]

[6] D. C. Bloedow, D. H. Ralston, and J. C. Hargrove, unpublished results.

did not change significantly from control values; presumably, hepatic blood flow behaves similarly. The extraction ratio for lidocaine in the pregnant sheep was 0.57 using Eq. 5. Similar assumptions and calculations for the nonpregnant sheep [Q = 55 ml/min/kg (14)] yielded an extraction ratio of 0.69. These values are similar to the extraction ratio (~0.68) reported for lidocaine in humans (17).

The results of these studies provide evidence for subtle dose-related lidocaine kinetics in pregnant sheep. Further studies on lidocaine binding in ovine plasma and on cardiac output and blood flow distribution during the initial lidocaine distributive phase in sheep are necessary to substantiate the reasons for the apparent nonlinearity of lidocaine disposition.

False-Positive Alkaloid Reactions

ABDEL-AZIM M. HABIB

Received February 15, 1979, from the *Faculty of Pharmacy, Alexandria University, Alexandria, Egypt.* Accepted for publication July 20, 1979.

Abstract □ A variety of nonnitrogenous oxygenated compounds gave false-positive alkaloid reactions with Dragendorff's spray reagent. These compounds reacted positively if the oxygen function and the β-carbon bonded to the oxygen had high electron density. Thus, aldehydes, ketones, lactones, ethers, esters, epoxides, and peroxides with an ethylene bond or free alkyl groups at the β-carbon gave a positive reaction, provided that the availability of electrons at the oxygen and the β-carbon was not altered by electron withdrawal or hydrogen bonding. Carbonyl, ether, and ethylene functions were shown by IR evidence to be involved in coupling. Nitrogen-free, alkaloid-like acetone artifacts were obtained by interaction with fixed alkali and with acids. These compounds were postulated to be α,β-unsaturated aldol condensation products of acetone. Interaction with ammonia in addition yielded nitrogenous alkaloid-like artifacts.

Keyphrases □ Alkaloids—interference by nonnitrogenous alkaloid-like compounds, structural requirements for false-positive reaction □ Acetone artifacts—nonnitrogenous, alkaloid-like compounds, interference with alkaloid detection, structural requirements for false-positive reaction □ Dragendorff's reagent—false-positive alkaloid reaction with nonnitrogenous oxygenated compounds

Of the numerous reagents described for the detection of alkaloids (1), only a few have reliable sensitivity (2). All of these reagents suffer from nonspecificity. Many nitrogenous and nonnitrogenous plant constituents react with several of these reagents similarly to alkaloids (3–8). Some nonnitrogenous compounds react similarly to alkaloids in giving crystalline salts with acids (8).

BACKGROUND

TLC is the most versatile technique for alkaloid detection, separation, monitoring, identification, and quantitation. Dragendorff's spray, in its different modifications, is usually used for visualization of alkaloidal spots on paper and thin-layer chromatograms and in field tests with alkaloid test paper (9–11). Many reports have discussed its sensitivity and specificity (2), false reactions (3, 12), and modifications (13–20). However, many nonnitrogenous plant constituents react with this reagent in a manner typical of alkaloids (3, 12, 21). Such compounds may create difficulty, especially during alkaloid screening without sufficient partition purification steps (4). Complete elimination of these constituents cannot be accomplished through the one partition purification step required in many reported screening procedures (22–26). Moreover, significant amounts of such nonalkaloidal constituents may be detected even after further partition purification (12).

Farnsworth *et al.* (3) determined that any nonnitrogenous compound having conjugated carbonyl or lactone functions would react in a manner typical of alkaloids. The range of compounds that produce a false-positive reaction is greater than is generally realized (27), and compounds such as the common plant sterols and triterpenes are readily detected by Dragendorff's spray.

Table I—Compounds Tested in the Present Study that Reacted Positively with Dragendorff's Spray Reagent

Column A: Compounds with Conjugated Carbonyl or Lactone Functions		Column B: Compounds Lacking any Conjugated Carbonyl or Lactone Function	
Compound	Reaction[a]	Compound	Reaction[a]
With carbonyl or lactone as only reactive function		Nonconjugated aldehydes and ketones	
Conjugated aldehydes and ketones		Isobutyraldehyde	+++
Acrolein	+++	Menthone	++
Crotonaldehyde	+++	Camphor	++
Furfural	+++	Acetonylacetone	+
Cinnamic aldehyde	+++	Nonconjugated lactones	
Citral	++	Picrotoxin (picrotoxinin)	++
Carvone	+++	Arctiin	+++
3-Hydroxybenzaldehyde	+(±)	Isolipidiol	+
Acetophenone	+++	*Judeicin*	+
Benzophenone	++	α-β-Unsaturated alcohols (their ethers and esters)	
Chalcone	+++	Geraniol	+(±)
Benzil	++	Geranyl acetate	+
Progesterone	+	Linalyl acetate	+
Testosterone	+	Phenols, phenolic ethers, and esters	
Cortisone	++	Eugenol	+++
Conjugated lactones		Acetyleugenol	+++
Coumarin	+++	Anethole	+
Umbelliferone	+	Guaiacol	+(±)
Digitoxin	+++	Thymol	+(±)
Digoxin	+++	Acetylated thymol	+
Strophanthin	++	α,β-Unsaturated (or aromatic) acids and their esters	
Ouabain	+	Cinnamic acid	+(±)
Acovenosides[b]	+++	Ethyl cinnamate	+
Lactone *S.a.*[c]	+	Phenyl salicylate	+
With additional reactive ether or ester functions		Methyl salicylate	+
Piperonal	+++	Veratric acid	+++
Veratraldehyde	+++	Alcohols (their ethers and esters) with branching at β-carbon	
Anisaldehyde	++	Primary isobutanol	+
Vanillin	+(±)	Primary isobutyl acetate	+++
Acetylated vanillin	++	Isobutyl epoxide	+++
3-Butoxybenzaldehyde	++	Isoamyl alcohol	+
Khellin	+++	Isoamyl acetate	+++
Visnagin	+++	Isoamyl ether	++
Methoxsalen (xanthotoxin)	+++	Menthyl acetate	++
Bergapten	+++	Bornyl acetate	+
Imperatorin	+++	Isobornyl acetate	+
Santonin	+++	Acetylated β-amyrin	++
Xanthumin	++	Miscellaneous compounds	
Rotenone	(+++)[d]	Cineole	++
Total withanolides[e]	+++	*Ascaridole*	+++
Withaferin A	+++	Digitonin	++
A C_{28} steroid lactone from *Withania somnifera*[f]	(+)[f]	Diosgenin	+++
Acetylated rutin	+++	2,3-Dihydro-4-pyrone	+
Acetylated quercitin	++	Ethyl-2-cyclohexanone carboxylate	+++
Acetylated kaempferol glucoside	++	Cannabinoids[g]	+
Acetylated hyperoside	+		
Acetylated quercitin glucuronide	+(±)		
Acetylated quercitin pentoside	+		
Acetylated chrysophanic acid	+		
Acetylated sennidins A + B	+		
β-Glycyrrhetinic acid	+(±)		

[a] Key: +, faint reaction; ++, typical reaction; and +++, immediate typical reaction. [b] The total -olide fraction of *Acokanthera spectabilis*, isolated by a reported method (29), showed at least four Dragendorff-positive components on TLC. [c] A conjugated ketolactone isolated from *Senecio aegyptius* (38). [d] Some compounds that gave a typical orange-red color with the fresh reagent gave a typical bluish color with old reagent (*e.g.*, cortisone and rotenone). [e] The lactonic fraction of *Withania somnifera*, freed from any contaminating alkaloids, showed at least six Dragendorff-positive spots. [f] Isolated from the roots and reported to give a positive reaction with Dragendorff's reagent. [g] Extracted from *Cannabis* and chromatographed by reported methods (33, 34).

Farnsworth *et al.* (3) gave convincing explanations for certain confusing cases (7, 8) as well as certain claims about the detection and isolation of alkaloids (28) that were denied in a subsequent report (29). Nevertheless, the conclusion of these investigators did not apply to 19 of the 29 compounds listed as positively reacting miscellaneous compounds (Ref. 3, Table II, column B). Moreover, it gave no persuasive answer to observations by the present author; phytochemical screening of *Mentha microphylla* and *Lavandula dentata* of Saudi Arabia revealed two constituents in the former and one in the latter species that gave a positive reaction with Dragendorff's spray, and these compounds were identified as menthone, carvone, and camphor (30, 31). Arctiin, a nonconjugated lactonic lignan glycoside, also gave[1] a positive reaction with Dragendorff's reagent as well as with other alkaloid precipitants. The spray reagent was used for visualization of cineole and ascaridole on TLC. Menthone, camphor, cineole, ascaridole, and arctiin lack the minimal structural features determined by Farnsworth *et al.* (3).

This ambiguity prompted the present study to determine the minimal structural features for a false-positive alkaloid reaction with emphasis on the reaction with Dragendorff's spray.

EXPERIMENTAL

Test Compounds—The compounds were obtained from commercial sources. Some natural products were provided by investigators or separated by TLC from plant materials, crude drugs, or preparations. Localization of these compounds was achieved through reliance on reported R_f values in specified TLC systems and the use of specific chromogenic reagents (32–35), and no quantitation was attempted.

Acetylated Compounds—Acetylation of the test compounds was effected by pyridine–acetyl chloride or acetic anhydride–sulfuric acid. Chloroform extracts of the acetylated compounds were washed thoroughly with 2% HCl and water or with 2% $NaHCO_3$ and water, respectively.

[a] Key: Drag. sp., Dragendorff's spray reagent (Munier–Macheboeuf modification) (13); Drag. pt., Dragendorff's precipitation reagent (16); STA, silicotungstic acid; and R. salt, Reinecke salt. [b] Key: NACP, ammonia-catalyzed acetone condensation products; HACP, acid-catalyzed acetone condensation products; FACP, fixed alkali-catalyzed acetone condensation products; RuAc, acetylated rutin; QuAc, acetylated quercitin; KmAc, acetylated kaempferol; ChAc, acetylated chrysophanic acid; RhAc, acetylated rhein; Meth, methoxsalen; Imp, imperatorin; Sant, santonin; F1, fraction 1 (initial chloroform extract from acid medium); and F2, fraction 2 (purified chloroform extract from alkaline medium), as described under *Experimental*.

Acetone Condensation Products—The products (if any) from the interaction of acetone with concentrated hydrochloric acid, acetone with sodium hydroxide pellets, or acetone with concentrated ammonium hydroxide solution were prepared by keeping each pair in a closed flask for 3 days with frequent agitation. The dark-brown residue obtained with acetone and concentrated hydrochloric acid contained acid-catalyzed acetone condensation products, the viscid brown residue obtained with acetone and sodium hydroxide pellets contained fixed alkali-catalyzed acetone condensation products, and the dark, brittle, glassy solid residue obtained with acetone and concentrated ammonium hydroxide solution contained ammonia-catalyzed acetone condensation products.

Preparation of Nonalkaloidal Coupled Compounds with Dragendorff's Reagent—For IR analysis, complexes of khellin, imperatorin (ammidin), veratric acid, and cineole were prepared by dissolving the test compounds in aqueous acetic acid (20–50%, according to solubility) and adding dropwise Dragendorff's precipitation reagent. Khellin gave a heavy reddish-brown precipitate instantaneously, imperatorin gave a dark-brown crystalline compound after several hours, veratric acid gave an amorphous dark-brown deposit after sitting overnight, and cineole yielded a deep blood-red oil.

Reagents—Munier–Macheboeuf Dragendorff's spray reagent (13), Dragendorff's precipitation reagent (36), Mayer's reagent (36), Wagner's reagent (23), Kraut's reagent (37), 12% aqueous silicotungstic acid solution, and saturated Reinecke salt solution were used.

Test Procedure—The test compounds were dissolved in chloroform, alcohol, acetone, or chlorofrom–alcohol to make 0.2% solutions when solubility permitted or lower concentrations otherwise. Dissolution of very volatile liquids was not attempted to guard against loss of the test compound during solvent evaporation.

Aliquots, 10 μl, of individual test compounds were applied to microchromatoplates prepared by the slurry technique (32). Without attempting development, the spotted areas were sprayed with Dragendorff's reagent. The reaction results were recorded immediately (11). Spots of some very volatile liquids were examined by viewing the chromatoplates from the back (*e.g.*, isobutyraldehyde and isobutyl epoxide).

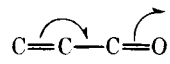
When certain constituents were extracted from preparations, two initial spots of the crude extract were cochromatographed using specified TLC systems (32–35). In one chromatogram, the constituents were located using specific chromogenic reagents (32–35) and then were used to monitor the second chromatogram that was sprayed with Dragendorff's reagent.

Partition of Test Compounds and Preparations—The purified total cardenolide fraction of *Acokanthera spectabilis* (29), the alcoholic extract of *L. dentata*, certain acetylated flavonoids [rutin, quercitin, kaempferol, hyperoside (3-D-galactoside hemipentahydrate), and quercitin glucuronide], the fixed alkali-catalyzed acetone condensation products, the acid-catalyzed acetone condensation products, the ammonia-catalyzed acetone condensation products, santonin, methoxsalen (xanthotoxin), and imperatorin were subjected to partition between acid–base and organic solvents. A concentrated alcoholic solution of the material was taken in dilute hydrochloric acid, the acidic solution was extracted with two portions of chloroform (fraction 1), and the aqueous phase was alkalinized with ammonia solution and reextracted with two portions of chloroform (fraction 2). Both fractions were tested with Dragendorff's spray and precipitation reagents, Mayer's reagent, Wagner's reagent, silicotungstic acid solution, Reinecke salt solution, and Kraut's reagent.

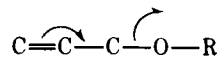
Recording Results—If a very slight or no color was observed with the spray reagent, larger quantities of the test solution (20–50 μl) were retested. Test compounds and results are given in Tables I and II; Table III gives the results of the partition experiments.

RESULTS AND DISCUSSION

Of the many organic compounds tested, only positively reacting compounds are given in Table I. Compounds reported by Farnsworth *et*



I

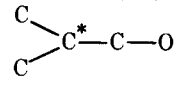


II

al. (3) to give a positive reaction are given in Table II after being categorized according to whether they conform to the structural requirements determined by these investigators.

The structures of 86 positively reacting compounds (Table I) and some of the 55 compounds reported by Farnsworth *et al.* (3) (Table II) were

III



IV

studied. Many of the compounds were conjugated aldehydes, ketones, and lactones, thus fulfilling the minimal structural requirement indicated by Farnsworth *et al.* (3). These compounds are listed in column A of Tables I and II. Many other compounds lack these structural features (column B of Tables I and II).

Compounds of column B (Table I) have no common structural feature that correlate them to compounds of column A. While some have carbonyl or lactone functions (the first eight compounds), they lack conjugation to these functions. All other compounds of column B lack carbonyl or lactone functions. Thus, neither these features nor the conjugation is necessary for the reaction.

All of the positively reacting compounds are oxygenated, and the oxygen represents a site of high electron density—*viz.*, carbonyl, lactone,

ether, ester, epoxide, and peroxide. This observation suggested that: (*a*) it may not be the carbonyl function *per se* but instead the high availability of its electrons that accounts for the reaction, and (*b*) other oxygen functions of comparably high electron density may react similarly. This suggestion has been realized by the strong positive reactions of some conjugated ethers and esters (Table I) and the positive reaction of some α,β-unsaturated alcohols and acids. The existence of the α,β-unsaturation in these compounds would increase substantially the electron density at the oxygen function (I and II), rendering it sufficiently basic to form coordinate complexes with Lewis acids (alkaloidal reagents).

The compounds studied lacking any conjugated carbonyl or lactone function were V, isobutyraldehyde; VI, isobutyl epoxide; VII, isobutyl ether (R = alkyl) or ester (R = acyl); VIII–X esters (R = acyl) or ethers (R = alkyl): VIII, active isopentyl ethers or esters; IX, neopentyl ethers or esters; and X, isopropylmethyl ethers or esters; XI, ascaridole; XII, camphor; XIII, bornyl acetate; XIV, menthone; XV, 1,4- and 1,8-cineoles; XVI, 2,3-dihydro-4-pyran; XVII, 5,6-dihydro-2-pyran; XVIII, ethyl-2-cyclohexanone carboxylate; XIX, geranyl acetate; XX, linalyl acetate; XXI, citronellal; XXII, thymol acetate; XXIII, acetyleugenol; XXIV, acetyl anethole; XXV, guaiacol; XXVI, veratric acid; XXVII, ethyl cinnamate; XXVIII, picrotoxinin; XXIX, arctiin; XXX, acetyl-β-amyrin; XXXI, lipidiol; and XXXII, digitonin (R = sugar moiety).

Many compounds that lack α,β-unsaturation (to the oxygen) react positively (Tables I and II). Nonetheless, in almost all of these compounds, the β-carbon (denoted by an asterisk) bears one or more free alkyl groups. The electron-repelling methyl groups increase the electron density at the β-carbon, resulting in the same effect as does α,β-unsaturation. In V–XV, the effect of the free alkyl groups is demonstrated; the arrowheads in the structural formulas of these compounds qualitatively represent the electron-repelling effect of these groups.

These observations were significant in establishing III or IV as the structural feature necessary for the false alkaloid reaction, provided that the high availability of electrons at the oxygen was not altered by other functions.

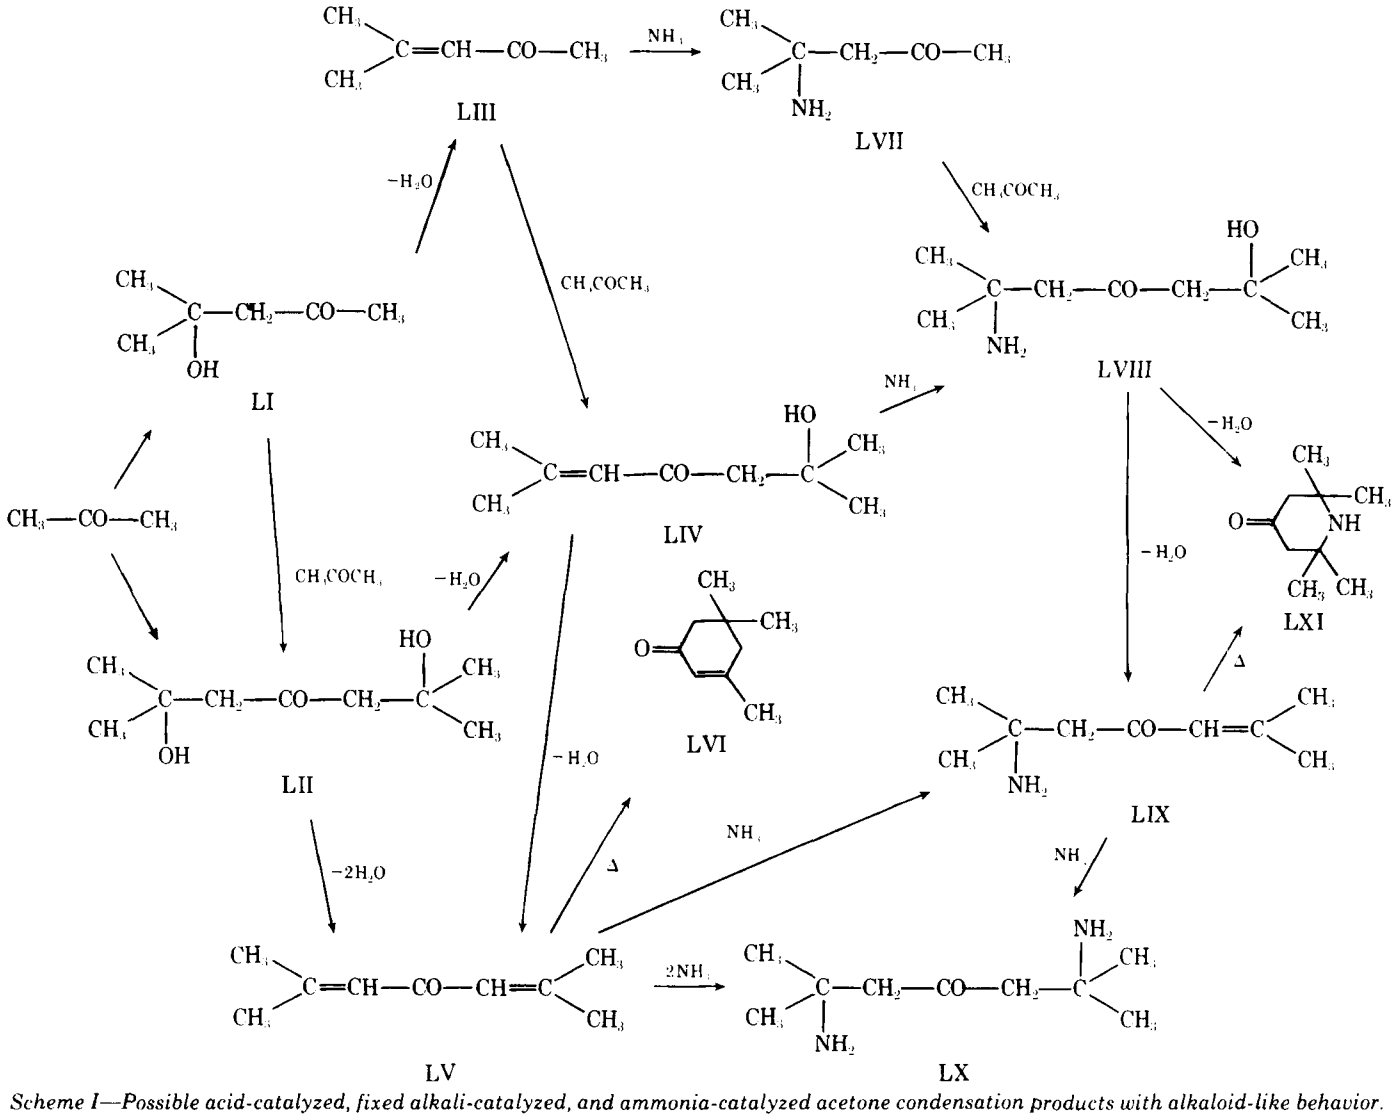
The β-carbon (denoted by an asterisk) of III may constitute a part of an aromatic structure. The oxygen function in III and IV may be an aldehyde, a ketone, a lactone, an alcoholic or phenolic ether, an ester, an oxide, or a peroxide.

Structures III and IV were demonstrated to fulfill the requirements of the test by the typical alkaloid-like reactions given by acrolein, crotonaldehyde, citral, carvone, XI, XIX, piperonal (XXXV), and veratraldehyde (XXXVI) (General Structure III) and by V–XV (General Structure IV).

If the oxygen of the essential structure is an alcohol, a phenol, or a hemiacetal, a negative or slight reaction is given, *e.g.*, geraniol, terpineol, linalool, borneol, isoborneol, primary isobutanol, pyrocatechol, resorcinol, pyrogallol, orcinol, hydroquinone, guaiacol, benzhydrol, thymol, α-amyrin, lanosterol, salicyl alcohol, isopentanol, and cinnamyl alcohol. Esterification of these alcohols and phenols in many instances gave positively reacting esters (Table I).

Carboxylic acids also were expected to react negatively due to their low availability of electrons at the carboxylic group or because acids tend to associate as cyclic dimers (39). Thus, crotonic, anisic, maleic, acrylic, benzoic, cinnamic, *p*-hydroxybenzoic, glycyrrhizic, glycyrrhetinic, and quillaic acids gave negative tests, despite the fulfillment of the structural requriement. Maleic anhydride, phthalic anhydride, and cantharidin also gave a negative reaction.

The reaction of compounds that fulfilled the essential requirement was affected by other functions that altered the electron density at the oxygen or the β-carbon. Thus, when the β-carbon was involved in an aromatic structure or a conjugated double bond system, electron-repelling substituents enhanced the reaction, *e.g.*, pyrocatechol (−) [*cf.*, guaiacol (±)



Scheme I—Possible acid-catalyzed, fixed alkali-catalyzed, and ammonia-catalyzed acetone condensation products with alkaloid-like behavior.

and eugenol (+++)], *m*-cresol (−) [*cf.*, thymol (+)], anisole (−) [*cf.*, anethole (+)], and benzaldehyde (−) and 3-hydroxybenzaldehyde (−) [*cf.*, anisaldehyde (++), veratraldehyde (+++), piperonal (+++), and 3-butoxybenzaldehyde (++)]. On the other hand, an electron-attracting substituent decreased or even eliminated the reaction, *e.g.*, acetophenone (+++) and *p*-aminoacetophenone (+++) [*cf.*, *p*-nitroacetophenone (−) and *p*-hydroxyacetophenone (−)].

The strong reactions given by 3-butoxybenzaldehyde, piperonal, veratraldehyde, eugenol, and acetyleugenol in contrast to the negative reactions given by benzaldehyde, 3-hydroxybenzaldehyde, and vanillin mean that the reaction of the former five compounds should not be attributed wholly to the conjugated carbonyl structure but should partially be attributed to their conjugated ether and/or ester functions. The same also applies to conjugated carbonyl compounds and lactones with additional reactive ether, ester, or carbonyl functions: XXXIII, vanillin; XXXIV, 3-butoxybenzaldehyde; XXXV, piperonal; XXXVI, veratraldehyde; XXXVII, anisaldehyde; XXXVIII, yangonin; XXXIX, methysticin; XL, dihydromethysticin; XLI, psoralen (furocoumarin) ($R_1 = R_2 = H$), bergapten ($R_1 = OCH_3$), methoxsalen ($R_2 = OCH_3$), imperatorin (R_2 = isoamyleneoxy), and isopimpinellin ($R_1 = R_2 = OCH_3$); XLII, furochromones khellin (R = OCH_3) and visnagin (R = H); XLIII, santonin; XLIV, xanthumin; XLV, meliternatin; XLVI, meliternin; XLVII, ternatin; XLVIII, rotenone; XLIX, withaferin A; and L, glycyrrhetinic acid.

The IR spectra of khellin, imperatorin, and veratric acid provided evidence that both the carbonyl and ether functions in these compounds are involved in the reaction. The strong band assigned to the carbonyl function (1655–1620 cm^{-1} in khellin, 1710–1650 cm^{-1} in imperatorin, and 1685–1655 cm^{-1} in veratric acid) were distorted and split in the spectra of the corresponding coupled compounds. More pronounced changes were observed in the region of the ether and aralkyl ether stretching vibration; thus, the strong bands at 1085 cm^{-1} in khellin and 1090 cm^{-1} in imperatorin were split into doublets of medium intensity in the spectra of the coupled compounds. The band at 1095 cm^{-1} with veratric acid appeared only as a shoulder in the spectrum of the coupled compound. The bands between 1000 and 979 cm^{-1} (–C=CH deformation) also were affected, *i.e.*, weakened and shifted toward a higher frequency in the spectra of the coupled compounds.

The reactivity of compounds with the essential structure was eliminated almost completely by hydroxyl groups in their structures. The hydroxyl groups competed for the oxygen function of the essential structure, through inter- and/or intramolecular hydrogen bonding. This competition may explain the contrast in the reaction of acetophenone (+++) *versus* *p*-hydroxyacetophenone (−), coumarin (+++) *versus* umbelliferone (±), anisaldehyde (+++) *versus* vanillin (±), digitoxin (+++) and strophanthin (++) *versus* ouabain (G-strophanthin) (+), menadione (++++) *versus* 3-hydroxymenadione (−), and santonin XLIII (+++) and xanthumin XLIV (+++) *versus* lipidiol XXXI (−) and isolipidiol (±).

Therefore, naturally occurring hydroxylated flavonoids and hydroxyanthracene derivatives were expected to react negatively. Acetylated derivatives of these compounds gave positive tests with Dragendorff's spray reagent (Table I) as well as with some other alkaloidal precipitants (Table III). Acetylation and alkylation not only eliminated the interfering action of the hydroxyls but also introduced additional conjugated ester or ether functions; thus, the alkaloid-like reaction was intensified.

Briggs and Locker (8) reported that XLV–XLVII, three alkylated hydroxyflavones, gave precipitates with the usual alkaloid reagents and gave crystalline salts with acids. This alkaloid-like behavior was attributed to the fact that each molecule was completely alkylated. However,

Farnsworth (4) stated that the reaction was due to the conjugated carbonyl function and that other flavonoids would react similarly. The present work shows both of these reports to be partially correct; despite the conjugated carbonyl nature, flavonoids do not show alkaloid-like behavior unless they are almost completely alkylated.

Being alkylated isoflavonoids, all rotenoids presumably give positive alkaloid reactions; *e.g.*, rotenone (+++).

Housholder and Camp (40) stated that treatment of plant material with acetone and ammonia solution can give rise to alkaloid-like artifacts. These investigators were unable to identify the condensation products of the reaction, but they reported that the reaction rate was enhanced by light and the atmosphere.

Upon wet packing a column of silica gel with benzene–acetone–ammonia and keeping it overnight prior to the application of any material, discoloration of the column was observed[2]. Draining and evaporating the brown solvent mixture yielded a brown residue, which gave typical alkaloid reactions with Dragendorff's spray reagent as well as with other alkaloid precipitants. Neither benzene nor the plant material but instead acetone and/or ammonia apparently were responsible for the production of the alkaloid-like artifacts because both were common factors.

These artifacts may be either nitrogenous condensation products of acetone and ammonia or nonnitrogenous, alkali-catalyzed aldol condensation products of acetone that fulfill the requirements of the false reaction.

Acid-catalyzed, fixed alkali-catalyzed, and ammonia-catalyzed acetone condensation products gave a strong positive reaction with Dragendorff's spray reagent. TLC revealed three main, qualitatively identical Dragendorff-positive spots in acid-catalyzed and fixed-alkali-catalyzed acetone condensation products at R_f 0.78, 0.67, and 0.55 on silica gel in chloroform–methanol (93:7) and at R_f 0.65, 0.53, and 0.42 on silica gel in chloroform–methanol–acetic acid (89:10:1), respectively. The ammonia-catalyzed acetone condensation products revealed at least seven spots, including three identical to those of the acid-catalyzed and fixed alkali-catalyzed condensation products. The additional four spots were at low R_f values: 0.32, 0.21, 0.11, and 0.00 in chloroform–methanol and 0.26, 0.45, 0.05, and 0.00 in chloroform–methanol–acetic acid. An eighth spot, R_f 0.50 in chloroform–methanol and 0.46 in chloroform–methanol–acetic acid, gave a typical pink color.

Obviously, the spots common in the acid-catalyzed, fixed alkali-catalyzed, and ammonia-catalyzed acetone condensation products were of nonnitrogenous compounds. This conclusion indicates the compounds to be aldol condensation products of acetone. Scheme I shows the possible reaction products of acetone with acids, fixed alkalis, and ammonia. Compounds LIII–LVI are α,β-unsaturated ketones that fulfill the structural requirement of the false reaction. The additional low R_f spots in the ammonia-catalyzed acetone condensation products were assumed to be amino compounds (LVII–LXI) that arise from the condensation of ammonia with the reactive α,β-unsaturated ketones LIII–LV. This assumption was favored by the positive nitrogen test given by the ammonia-catalyzed acetone condensation products. Further evidence for the postulated reaction sequence was the development of the additional low R_f spots, absent from the acid-catalyzed and fixed alkali-catalyzed condensation products, when the latter two were kept with concentrated ammonia solution overnight.

From the results of the partition experiments (Table III), nonnitrogenous Dragendorff-positive plant constituents apparently do not interfere with alkaloid detection and isolation if necessary partition purification steps are performed. The nitrogenous acetone–ammonia reaction products react typically as alkaloids and interfere seriously with alkaloid detection and/or isolation.

Prodrugs as Drug Delivery Systems IV: *N*-Mannich Bases as Potential Novel Prodrugs for Amides, Ureides, Amines, and Other NH-Acidic Compounds

HANS BUNDGAARD ˣ **and MARIANNE JOHANSEN**

Received May 21, 1979, from the *Department of Pharmaceutics, Royal Danish School of Pharmacy, 2 Universitetsparken, DK-2100 Copenhagen, Denmark.* Accepted for publication July 31, 1979.

Abstract □ The hydrolysis kinetics of a series of *N*-Mannich bases of carboxamides, thioamides, and other NH-acidic compounds were studied to assess their suitability as prodrugs for various drugs. The pH–rate profiles for the compounds were determined at 37° and were accounted for by assuming the spontaneous decomposition of both free and protonated Mannich bases. The reaction rate for the free base increased sharply with increasing steric effects of the amine component of the *N*-Mannich bases and also with increasing acidity of the amide component. *N*-Mannich bases may be potentially useful prodrugs for NH-acidic compounds such as various amides, imides, and ureides and for amines.

Keyphrases □ Prodrugs—*N*-Mannich bases of amides, ureides, amines, and imides, hydrolysis kinetics □ Hydrolysis kinetics—*N*-Mannich base prodrugs of amides, ureides, amines, and imides □ Amides—*N*-Mannich base derivatives as prodrugs, hydrolysis kinetics □ Amines—*N*-Mannich base derivatives as prodrugs, hydrolysis kinetics □ Imides—*N*-Mannich base derivatives as prodrugs, hydrolysis kinetics □ Ureides—*N*-Mannich base derivatives as prodrugs, hydrolysis kinetics □ *N*-Mannich bases—derivatives of amides, amines, imides, and ureides, potential as prodrugs, hydrolysis kinetics

Bioreversible derivatization of drug substances to produce prodrugs with altered physiochemical properties can improve substantially both drug efficacy and safety (1–3). Chemical transformation of active drug substances into inactive derivatives *per se*, which convert to the parent compounds within the body, may be relatively simple for drug substances possessing groups (*e.g.*, hydroxyl or carboxyl) that are bioreversibly esterifiable. However, for many drug molecules, no apparently readily derivatizable functional groups or entities are present.

BACKGROUND

As a part of studies (4–6) to identify potentially useful bioreversible derivatives of difficult-to-derive chemical entities and drug molecules, it was found that *N*-Mannich bases may be potentially useful prodrugs for NH-acidic compounds such as various amides, imides, and ureides and for amines.

N-Mannich bases of amides, imides, and various other NH-acidic compounds are known (7–10), and several drug substances bearing an NH-acidic group have been modified by *N*-aminomethylation and tested as potential medicinal agents, *e.g.*, hydantoins (11, 12), barbituric acids (13), sulfonamides (14), and succinimides (15, 16). However, almost no information on the stability and reactivity of such derivatives in aqueous solution is available. A recent study (17) of the degradation kinetics of rolitetracycline, a highly water-soluble *N*-Mannich base formed by condensation of the carboxamide group in tetracycline with formaldehyde and pyrrolidine (18), showed that the compound readily decomposed in aqueous solution to yield tetracycline, formaldehyde, and pyrrolidine quantitatively. The degradation half-life at pH 7.4 and 35° was 43 min, indicating the potential of *N*-Mannich bases as prodrugs, at least for carboxamides.

Based on this observation, numerous *N*-Mannich bases of various amides and other NH-acidic compounds were prepared. The decomposition kinetics of the compounds were studied in aqueous solution over a broad pH range to elucidate their stability and to assess their suitability as prodrugs for various drugs.

EXPERIMENTAL

The compounds (Table I) were prepared by heating formaldehyde, the amine (or the amine hydrochloride), and the amide in water–ethanol solutions according to standard literature procedures (7, 9, 10, 19). Several compounds were obtained as the hydrochloride (19).

All kinetic experiments were carried out in aqueous buffer solutions at 37.0 ± 0.1°. Hydrochloric acid, acetate, phosphate, borate, and carbonate buffers were used; the total buffer concentration was 0.1 *M* except in experiments where buffer effects were studied specifically. A constant ionic strength ($\mu = 0.5$) was maintained for each buffer by adding a calculated amount of potassium chloride. The initial concentration of the *N*-Mannich bases in the buffers was in the 10^{-4}–5×10^{-3} *M* range.

In rapid reactions, decomposition was followed spectrophotometrically[1] by recording absorbance changes at a wavelength where the absorptions of substrate and products differed maximally. Slower reactions were followed by measuring the amount of formaldehyde released using a colorimetric procedure described previously (20). The rate constants were determined from plots of log $(A_t - A_\infty)$ or log $(A_\infty - A_t)$ *versus* time, where A_t and A_∞ are the absorbance readings at time t and infinity, respectively.

RESULTS AND DISCUSSION

Decomposition Kinetics—At constant pH and temperature, the decomposition rates of the compounds studied followed strict first-order kinetics; the reactions went to completion in all kinetic runs, as revealed by the formation of formaldehyde and parent amide in stoichiometric amounts. Since the degradation rates were unaffected by variations (0.02–0.5 *M*) in the buffer concentrations used to maintain a constant pH, no general acid–base catalysis was apparent.

The influence of pH on the degradation rate for some compounds is shown in Fig. 1, where the logarithm of the observed apparent first-order rate constants, k_{obs}, was plotted against pH. The pH–rate profiles for the other compounds listed in Table I have a similar shape as those shown in Fig. 1. These pH dependences of k_{obs} can be accounted for by assuming spontaneous decomposition of the Mannich bases, B, and their conjugate acids, BH^+, as shown in Schemes I and II:

$$B \xrightarrow{k_1} \text{products}$$

Scheme I

$$BH^+ \xrightarrow{k_2} \text{products}$$

Scheme II

With $[B]_T$ as the total concentration of *N*-Mannich base (*i.e.*, $[B]_T = [B] + [BH^+]$), the overall rate equation is:

$$k_{obs}[B]_T = k_1[B] + k_2[BH^+] \qquad \text{(Eq. 1)}$$

where k_1 and k_2 are the apparent first-order rate constants for the spontaneous degradation of B and BH^+, respectively.

By introducing into Eq. 1 the identities:

$$[B] = \frac{K_a}{a_H + K_a}[B]_T \qquad \text{(Eq. 2)}$$

and:

$$[BH^+] = \frac{a_H}{a_H + K_a}[B]_T \qquad \text{(Eq. 3)}$$

N-(Morpholinomethyl)-*N'*-acetylthiourea	0.91	ND	4.7	0.8
N-(Piperidinomethyl)methylurea	ND	ND	ND	5

[a] ND = not determined. [b] Kinetically determined values; for some compounds, pKa values also were determined titrimetrically and agreed with the kinetically obtained values. [c] Hydrolysis half-lives at pH 7.4 and 37°. [d] $k_1K_a = 1.9 \times 10^{-2}$ *M*/min.

where K_a is the apparent ionization constant of the protonated *N*-Mannich bases and a_H is the hydrogen-ion activity, the expression for k_{obs} is:

$$k_{obs} = \frac{k_1K_a}{a_H + K_a} + \frac{k_2a_H}{a_H + K_a} \qquad \text{(Eq. 4)}$$

The lines in Fig. 1 were constructed from Eq. 4 and the rate constants and pKa values given in Table I. Although Eq. 4 and, consequently, Schemes I and II adequately describe the observed degradation kinetics, other kinetically equivalent reactions can account for the observed k_{obs}–pH relationship.

Structural Effects on Reaction Rate—The rate data in Table I show that the structure of the amine component in the *N*-Mannich bases dramatically affected the rate constant, k_1 and, accordingly, the decomposition rate of the compounds in weakly acidic to basic aqueous solutions (*cf.*, the half-lives at pH 7.4). This result was predominantly a steric effect of the alkyl groups on the amine nitrogen. For some *N*-Mannich bases of benzamide, an excellent linear correlation existed between log k_1 and Charton's steric parameter, ν (21), for alkylamino groups (Fig. 2). The only deviation observed was for the benzylamine derivative and may have been due to the lower pKa value for the corresponding Mannich base as compared with the other compounds (Table I).

The data also show that for the same amine component, the *N*-Mannich base decomposition rate increased sharply with increasing acidity of the parent amide. The k_1 values of the piperidine derivatives increased in the order benzamide < niacinamide < thiobenzamide < trichloroacetamide, which is also the order of amide acidity. The difference in acidity among these amides was reflected in the pKa values for the Mannich bases with piperidine (Table I), and a linear correlation can be shown to exist between log k_1 and the pKa values for these *N*-Mannich base derivatives. For the most acidic amide of the compounds studied, *p*-toluenesulfonamide (pKa 10.3), k_1 was too high to be determined. A high k_1 value also was observed for morpholine derivatives of other acidic compounds such as succinimide, phenytoin, and barbital.

Structural factors other than steric effects and stability of leaving groups also may influence the reactivity of *N*-Mannich bases. Urea and thiourea Mannich bases were more reactive than expected on the basis of their acidity. Salicylamide derivatives degraded markedly faster in neutral solution than did the corresponding benzamide derivatives. The degradation half-lives of salicylamide *N*-Mannich bases with morpholine and α-alanine at pH 7.4 and 37° were 38 and 17 min, respectively [*cf.*, 1400 min for *N*-(morpholinomethyl)benzamide].

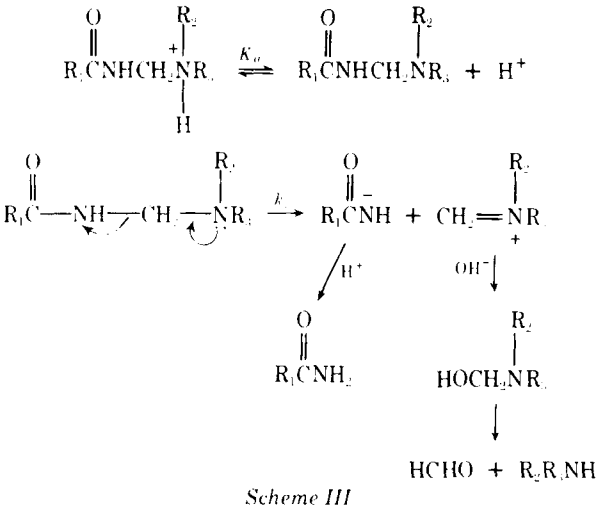

Scheme III

exists for a firm mechanistic scheme for the degradation, a plausible mechanism that agrees with the observed data is given in Scheme III. The rate-determining step involves unimolecular N–C bond cleavage with formation of an amide anion and an immonium cation. In subsequent fast steps, a solvent molecule transfers a proton to the amide anion and a hydroxide ion to the immonium ion, giving carbinolamine, which rapidly dissociates (22, 23) to formaldehyde and amine. In accord with this mechanism, the large steric effects exhibited by the amine alkyl groups may be explained as hindrance of amine solvation (*cf.*, 24), resulting in increasing nucleophilicity with increasing steric hindrance and, hence, increasing the lability of the N–C bond. The possible formation of *N*-(hydroxymethyl)amides in a rate-determining step does not seem likely since these compounds degraded much slower than the corresponding *N*-Mannich bases in separate experiments.

CONCLUSION

The present study shows that *N*-Mannich bases can be considered as potentially useful prodrugs of amides and various other compounds containing acidic NH-groups. By appropriate selection of the amine component, it should be feasible to obtain prodrugs with varying physicochemical properties such as the cleavage rate, aqueous solubility, and lipophilicity. Transformation of an amide into an *N*-Mannich base introduces a readily ionizable moiety, which may allow the preparation of derivatives with greatly increased aqueous solubilities at slightly acidic pH values where the stability is sufficiently high. For example, morpholine derivatives possess good aqueous solubility[2].

Finally, *N*-Mannich bases also can be considered as prodrug candidates for primary and secondary amines. The pKa of amines decreases considerably by *N*-amidomethylation. [With benzamide, the decrease is ~3 pKa units (*cf.*, Table I)]. Therefore, a potentially useful purpose for transforming amino compounds into *N*-Mannich base transport forms would be to increase the lipophilicity of the masked amines at physiological pH by depressing the ionization of the conjugate acid forms.

Abstract □ The metabolism of tocainide, an experimental antiarrhythmic drug, was studied in humans. Urinary excretion of unchanged drug was 28–55% in 24 hr after oral dosing. Urine hydrolysis with hydrochloric acid or β-glucuronidase increased tocainide recovery to 55–79%. Saccharo-1,4-lactone inhibited the β-glucuronidase-mediated tocainide recovery increase. Adjustment of urine to pH 13 produced a compound identified as 3-(2,6-xylyl)-5-methylhydantoin. Evidence suggests that it was derived from the same metabolite that formed the additional tocainide after acid or β-glucuronidase treatment. Tocainide carbamoyl *O*-β-D-glucuronide is the structure proposed for the metabolite. The suggested pathway for its formation involves the addition of carbon dioxide to the amino nitrogen of tocainide followed by uridine diphosphate glucuronic acid conjugation.

Keyphrases □ Tocainide—human metabolism, conjugation □ Antiarrhythmic agents—tocainide, human metabolism, conjugation □ Metabolism—tocainide in humans, conjugation

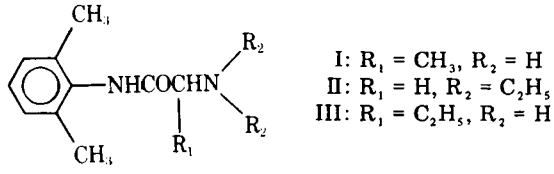
Tocainide, 2-amino-2′,6′-propionoxylidide (I), an analog of lidocaine (II), is an experimental antiarrhythmic drug undergoing clinical evaluation (1–6). Several studies of tocainide pharmacokinetics have been reported (2, 7, 8). In a human pharmacokinetic study, 90–100% bioavailability and 40% excretion of unchanged drug in the urine were reported (7). A novel metabolic pathway for the conjugation of this primary amine is described in this report.

EXPERIMENTAL

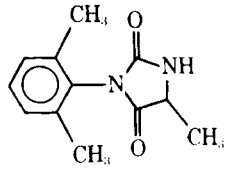
Chemicals—Tocainide (I), 3′,4′,5′-trideuterotocainide, and 2-aminobutyro-2′,6′-xylidide (III) were prepared as the hydrochloride salts by standard methods[1] (9).

Synthesis of 3-(2,6-xylyl)-5-methylhydantoin (IV) was carried out using a modification of a literature method (10). DL-Alanine ethyl ester hydrochloride was treated with phosgene in toluene to produce ethyl α-isocyanatopropionate, which then was treated with 2,6-xylidine. Cyclization was accomplished by treating the intermediate with 5 *N* NaOH. The crude product was purified by high-pressure liquid chromatography (HPLC). Compound IV was obtained as colorless crystals, mp 138.5–140.5°; NMR[2] ($CDCl_3$): δ 1.47 (d, J = 6.5 Hz, CH_3), 2.19, 2.17 (2s, 2 CH_3), 4.16 (q, J = 6.5 Hz, CH), and 7.16 (broad s, 3 aromatic, NH); electron-impact mass spectrometry[3]: 218 (M^+), 203 ($M - CH_3$), 157, 148, 147 (base peak), 132, 119, 113 (hydantoin ring), 105 (2,6-dimethylphenyl), 91, 77, 70, and 44; IR[4] (KBr): λ_{max} 3235 (NH), 1775 (C=O), 1703 (C=O), 1407, 1324, 1178, and 771 (3 adjacent H's) cm^{-1}.

Heptafluorobutyrylimidazole[5], mollusk β-glucuronidase (lyophilized; <0.7% arylsulfatase), and saccharo-1,4-lactone[6] were obtained from commercial sources. All other reagents were spectral or HPLC grade.



I: $R_1 = CH_3$, $R_2 = H$
II: $R_1 = H$, $R_2 = C_2H_5$
III: $R_1 = C_2H_5$, $R_2 = H$



IV

Mass Spectrum[3]—GLC–mass spectrometry conditions were: glass column, 1.8 m × 2 mm i.d., 3% JXR on 100–120-mesh Gas Chrom Q[7]; carrier gas, helium at 30 ml/min; injector temperature, 250°; column temperature, programmed from 150 to 250° at 8°/min; separator temperature, 250°, transfer line temperature, 225°; ion source temperature 125°; vacuum, 5×10^{-6} torr; ionization energy, 70 ev; emission current, 0.3 mamp; and electron multiplier, 2.5 kv.

Determination of Tocainide in Biological Fluids—Samples were extracted using an aliquot of urine or plasma, 1 ml of the internal standard (III, 5 μg/ml), 1 ml of 1 *N* NaOH, distilled water to bring the solution to a total volume of 5 ml, and 5 ml of methylene chloride. The solution was mixed for 10 min and centrifuged at 2000 rpm, and the aqueous layer was discarded. The organic layer was transferred to a clean tube. Heptafluorobutyrylimidazole, 20 μl, was added for derivatization, and the sample was evaporated to dryness in a 45° water bath. The dry residue was washed with 2 ml of methylene chloride and 1 ml of 0.1 *N* NaOH. The aqueous layer was discarded, and the methylene chloride was evaporated. Ethyl acetate, 20 μl, was added, and 1 μl was injected into a gas–liquid chromatograph equipped with a flame-ionization detector[8].

An electron-capture detector[9] also was used, in which case ethyl acetate was substituted for the methylene chloride in the final wash without evaporation. Concentration was determined by measuring the peak height ratio of drug to internal standard and relating this ratio to a calibration curve (0.5–20 μg).

The monoheptafluorobutyryl derivative was stable for 24 hr. The GLC conditions were: glass column, 1.8 m × 2 mm i.d., 3% OV-17 on 80–100-mesh Gas Chrom Q[7] or 3% PC-3210 Ultraphase on 80–100-mesh Chromosorb WHP[5]; and carrier gas, helium at 30 ml/min. The injector, column, and detector temperatures were 250, 205, and 275°, respectively, for the OV-17 column and 220, 165, and 210° for the PC-3210 column.

In addition, tocainide and IV were assayed by HPLC. The liquid chromatograph consisted of a high-pressure pump[10], a valve and a 25-μl loop injector[11], a 30 × 0.39-cm octadecylsilane reversed-phase column[12], and a variable-wavelength detector[13] set at 205 nm. The mobile phase consisted of 25% acetonitrile in 0.05 *M* $NaClO_4$ at pH 4.0 with a 2-ml/min flow rate.

A single extraction was used as described except for the heptafluorobutyryl derivatization prior to evaporation. The dry sample was dis-

WC[a]	2400	42	16	28

[a] Chronic administration, 24-hr urine collection. [b] Single dose, 24-hr urine collection.

solved in 200 μl of the mobile phase, and 25 μl was injected. Urine also was diluted 10-fold with distilled water and injected directly. Tocainide, III, and synthetic IV eluted at 4.3, 5.3, and 7.4 min, respectively.

Isolation of IV from Urine—A urine aliquot was adjusted to pH 9 with sodium hydroxide and extracted five times with equal volumes of methylene chloride to remove the tocainide. The pH was adjusted to 13 by the addition of sodium hydroxide, leading to the formation of IV. Hydrochloric acid was used to return the pH to 9, and the sample was extracted with methylene chloride. Preparative HPLC[14] was used to purify the crude IV. The other chromatographic conditions included a 1.0-ml injection loop[11], a 1.2-m × 0.95-cm porous silica column[15] (37–75-μm particles), and a 1% ethanol in chloroform mobile phase. The column was purged thoroughly with methanol each morning before use.

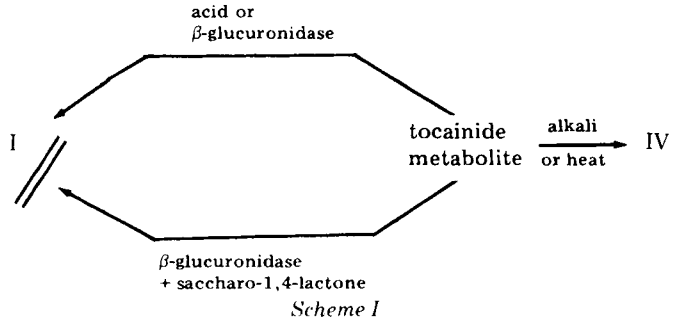
Drug Administration—Twenty-four-hour urine collections were obtained from five patients (two females and three males, ages 40–60) undergoing long-term treatment with tocainide hydrochloride. Individual oral doses ranged from 1.8 to 3.2 g/day in divided doses. A male volunteer received a single 300-mg oral dose of tocainide hydrochloride following an overnight fast. A second volunteer received a 300-mg dose as a 50:50 (w/w) mixture of tocainide and 3′,4′,5′-trideuterotocainide. Twenty-four-hour urine samples were collected from both volunteers.

Urine Hydrolysis—The acid hydrolysis involved mixing of 5.0 ml of urine with 5.0 ml of 4 *N* HCl, followed by incubation for 1 hr at 100°. An aliquot was taken for tocainide analysis by GLC and HPLC after cooling.

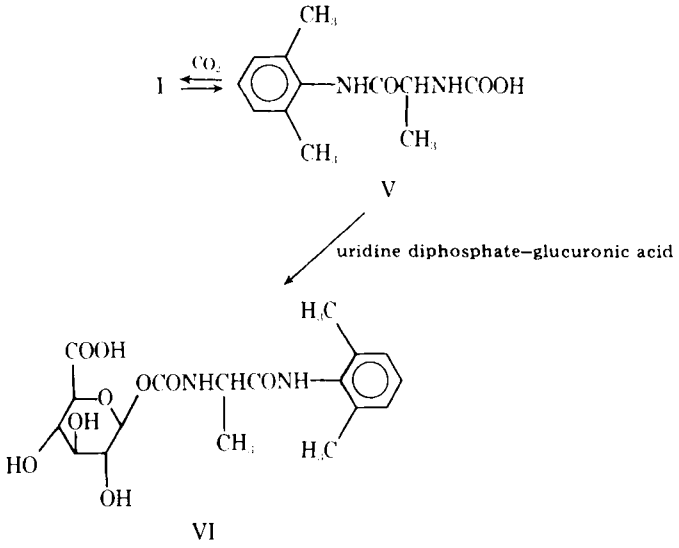
For the enzyme hydrolysis, a 1.0-ml urine aliquot adjusted to pH 4.0 with 0.5 *N* acetic acid was incubated with β-glucuronidase (pH 4, 25,000 Fishman units) in a water bath at 37°. After 12 hr, an additional 25,000 units of β-glucuronidase was added, and the incubation was continued for another 12 hr. Aliquots were assayed for tocainide as described. An identical set of samples was subjected to enzyme hydrolysis with 2 mg of saccharo-1,4-lactone, a specific inhibitor of β-glucuronidase, added with each addition of enzyme.

RESULTS AND DISCUSSION

Either acid hydrolysis or treatment with β-glucuronidase increased the tocainide amount recovered from the urine (Table I). Based on the five patients who received multiple tocainide doses, 44% of the oral dose was excreted as free tocainide. An acid or β-glucuronidase hydrolyzable metabolite accounted for an additional 23% of the dose. The excretion



Scheme I



Scheme II—Metabolic pathway for tocainide uridine diphosphate–glucuronic acid conjugation.

pattern for the volunteer (Subject DL) who received a single dose was similar.

The basis for elucidating the metabolite structure is described in Scheme I. There was essentially complete recovery of the free tocainide with the five methylene chloride extractions at pH 9.0. These methylene chloride extracts did not contain IV. The remaining aqueous phase was adjusted to pH 13 and then readjusted to pH 9 prior to a methylene chloride extraction. This methylene chloride extract contained a significant amount of IV but not tocainide. Typically, the urine tocainide concentrations ranged from 200 to 600 μg/ml, and the IV concentrations were approximately half of that. These concentrations indicated that IV was formed at pH 13, that it could be extracted at pH 9, and that it was not derived directly from tocainide.

Direct injection of urine onto the HPLC column confirmed the absence of IV in the untreated urine. However, direct injection of urine, from which free tocainide had been removed, onto the GLC column resulted in a peak for IV, demonstrating its thermal formation. After acid hydrolysis or β-glucuronidase treatment of the urine, it was not possible to generate IV at pH 13. Furthermore, after extraction of IV from the alkaline urine, acid hydrolysis of the remaining urine did not yield additional tocainide.

The synthetic IV and the IV isolated from urine had identical retention times upon GLC analysis. Further confirmation of identity was obtained by IR, NMR, mass spectral, mixed melting-point, and elemental analyses. The mass spectrum of IV for the subject who had ingested tocainide with 3′,4′,5′-trideuterotocainide exhibited doublets with each ring fragment, confirming that IV arose from ingested tocainide.

The formation of tocainide upon acid- or β-glucuronidase-catalyzed hydrolysis suggested that the metabolite was a glucuronide conjugate of tocainide or of a labile compound that easily formed tocainide. The presence of a glucuronide conjugate was confirmed when simultaneous treatment with saccharo-1,4-lactone prevented enzyme-catalyzed tocainide release. For example, the tocainide concentrations in untreated urine, β-glucuronidase-treated urine, and urine treated with β-glucuronidase and saccharo-1,4-lactone were 199, 395, and 209 μg/ml, respectively. This specific inhibitor of β-glucuronidase was used since commercial β-glucuronidase preparations often contain other hydrolytic enzymes. Also, preliminary electrophoretic studies[16] indicated that the metabolite was negatively charged at pH 4.6 and neutral at pH 2.2. The metabolite on the electrophoretogram was identified by treatment with alkali, resulting in IV, and by acid hydrolysis, resulting in tocainide.

The simplest interpretation of these data was to hypothesize an *N*-glucuronide of tocainide for the metabolite structure. However, the formation of IV from the metabolite under strongly basic conditions or upon thermal decomposition could not be reconciled with the *N*-glucuronide structure.

An extra carbonyl group clearly was present in IV that was not present in tocainide. Compound IV definitely was a product of the metabolite

[14] Model ALC 202/401, Waters Associates, Milford, Mass.
[15] Porasil B, Waters Associates, Milford, Mass.
[16] Electrophoretic studies were conducted as described previously (11) using a HV-5000A power supply and FP-30S flat plate (Savant Instruments, Hicksville, N.Y.).

since tocainide did not produce IV when treated with alkali or heat. The explanation is that a carbonyl group is present in the metabolite between the amino nitrogen and the glucuronide moiety.

A proposed reaction for metabolite formation *in vivo* is presented in Scheme II. Based on the proposed metabolite structure, the data can be explained easily. Acid or enzyme hydrolysis initially would yield the carbamic acid (V), which would then easily generate tocainide. A carbamic acid is in a constant and rapid equilibrium with an amine. A change in the pH or the carbon dioxide–bicarbonate concentration can easily shift the equilibrium. Conjugation of V with glucuronic acid produces the proposed metabolite (VI), tocainide carbamoyl *O*-β-D-glucuronide. This structure also provides a reasonable explanation for the facile conversion to IV by attack of the amide nitrogen on the carbonyl carbon with displacement of the glucuronide moiety as a leaving group. The uncharged species at pH 2.2 found in the electrophoretic studies also can be explained since the inclusion of the carbonyl group would result in a loss of basicity of the nitrogen atom.

The reaction of tocainide with carbon dioxide has ample precedent in the transport mechanism for carbon dioxide by hemoglobin; hemoglobin carbamic acid accounts for ~12% of the carbon dioxide transported by the blood of resting humans (12). Glycine and glycylglycine with pKa values of ~8.0 often have been used as models for the reaction of hemoglobin with carbon dioxide (12); tocainide has a pKa of 7.8. Among other factors, the degree to which any amine combines with carbon dioxide will depend on its pKa, the pH, and the carbon dioxide concentration (12).

In summary, a pathway for the conjugation of an amine has been proposed. It was fortunate that tocainide carbamoyl *O*-β-D-glucuronide yielded a characteristic degradation product (IV). Whether this pathway applies to amines other than tocainide can be resolved only by further research.

Secondary Products of Itanoxone

JEAN-PIERRE RIEU *, GILBERT MOUZIN *, HENRI COUSSE *x, and ANDRÉ BOUCHERLE ‡

Received February 26, 1979, from the **P. Fabre S.A. Research Center, 17 avenue Jean Moulin, 81106 Castres, France*, and the ‡*U.E.R. of Pharmaceutical and Biological Sciences, 38240 Meylan, France.* Accepted for publication August 7, 1979.

Abstract □ Itanoxone synthesis by Friedel–Crafts reaction between itaconic anhydride and 2-chlorobiphenyl was studied. Five isomers corresponding to possible impurities were prepared and studied to perfect a reliable and practical method to detect these impurities in itanoxone.

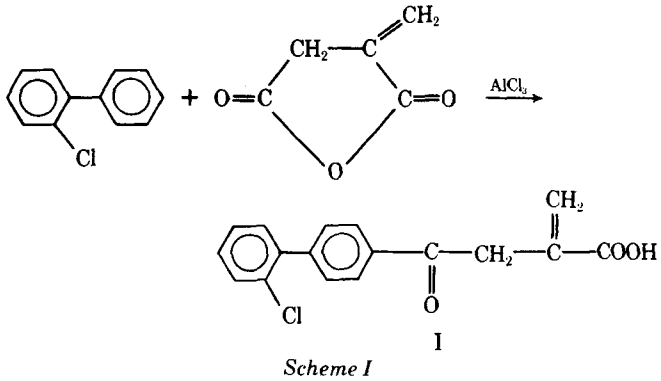
Keyphrases □ Itanoxone—synthesis, synthesis and detection of impurities □ Hypolipidemic agents—itanoxone, synthesis, synthesis and detection of impurities □ Hypouricemic agents—itanoxone, synthesis, synthesis and detection of impurities

The Friedel–Crafts reaction between itaconic anhydride and an aromatic derivative was reported (1–3). This reaction was adapted to many aromatic substrates and led to the synthesis of a chemical series with interesting pharmacological properties (4, 5). Pharmacological and toxicological studies yielded a new compound, 4-[4′-(2-chlorophenyl)phenyl]-4-oxo-2-methylenebutanoic acid (F 1379) (I), whose International General Designation is itanoxone. Compound I is a powerful hypolipidemic and hypouricemic agent (6–8).

The impurities that might be found in I were defined, isolated, or synthesized. With both chemical and physicochemical data of secondary products and samples, a detection method for these impurities in the end-product was investigated.

BACKGROUND

The Friedel–Crafts reaction between itaconic anhydride and 2-chlorobiphenyl gave I as the main product as reported previously (4, 5) (Scheme I).



I

Scheme I

since tocainide did not produce IV when treated with alkali or heat. The explanation is that a carbonyl group is present in the metabolite between the amino nitrogen and the glucuronide moiety.

A proposed reaction for metabolite formation *in vivo* is presented in Scheme II. Based on the proposed metabolite structure, the data can be explained easily. Acid or enzyme hydrolysis initially would yield the carbamic acid (V), which would then easily generate tocainide. A carbamic acid is in a constant and rapid equilibrium with an amine. A change in the pH or the carbon dioxide–bicarbonate concentration can easily shift the equilibrium. Conjugation of V with glucuronic acid produces the proposed metabolite (VI), tocainide carbamoyl *O*-β-D-glucuronide. This structure also provides a reasonable explanation for the facile conversion to IV by attack of the amide nitrogen on the carbonyl carbon with displacement of the glucuronide moiety as a leaving group. The uncharged species at pH 2.2 found in the electrophoretic studies also can be explained since the inclusion of the carbonyl group would result in a loss of basicity of the nitrogen atom.

The reaction of tocainide with carbon dioxide has ample precedent in the transport mechanism for carbon dioxide by hemoglobin; hemoglobin carbamic acid accounts for ~12% of the carbon dioxide transported by the blood of resting humans (12). Glycine and glycylglycine with pKa values of ~8.0 often have been used as models for the reaction of hemoglobin with carbon dioxide (12); tocainide has a pKa of 7.8. Among other factors, the degree to which any amine combines with carbon dioxide will depend on its pKa, the pH, and the carbon dioxide concentration (12).

In summary, a pathway for the conjugation of an amine has been proposed. It was fortunate that tocainide carbamoyl *O*-β-D-glucuronide yielded a characteristic degradation product (IV). Whether this pathway applies to amines other than tocainide can be resolved only by further research.

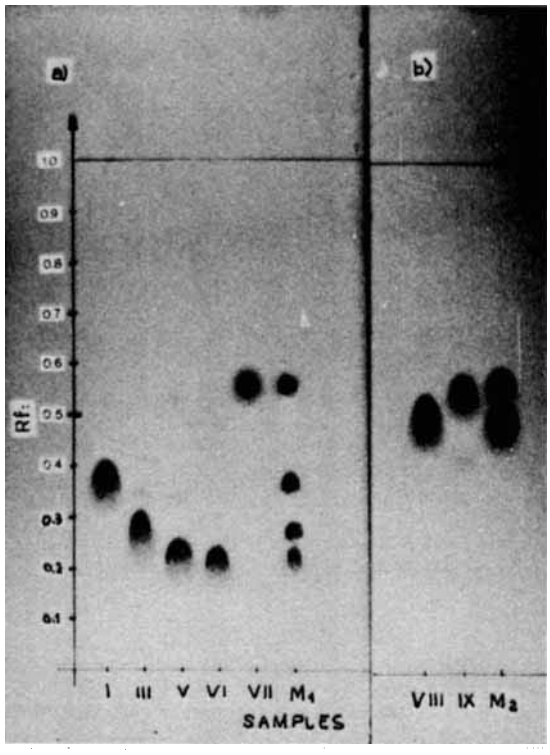

Figure 1—*Comparative thin-layer chromatograms of I, its isomers (III, V, VI, and VII), and M_1 (a mixture of I and its isomers) (a), and VIII and IX (hydrogenation products from III and I, respectively), and M_2 (a mixture of VIII and IX) (b).*

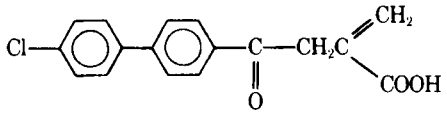


II

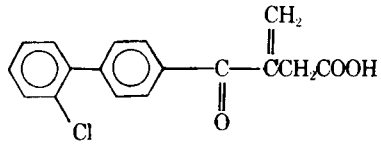
Impurities may be due to the raw material, unspecific reaction, or I degradation. The raw material, 2-chlorobiphenyl, may contain 4-chlorobiphenyl as an impurity. 2-Chlorobiphenyl, synthesized from 2-chloroaniline by a Gomberg–Bachmann–Hey reaction, must be analyzed for the 4-chlorobiphenyl impurity before itanoxone synthesis. After the Friedel–Crafts reaction with itaconic anhydride, 4-chlorobiphenyl gave another itanoxone isomer [4-[4′-(4-chlorophenyl)phenyl]-4-oxo-2-methylenebutanoic acid, II].

Secondary products are formed in the reaction since itaconic anhydride is asymmetric. Although the acylation is selective (1–3), it could give equally another derivative [4-[4′-(2-chlorophenyl)phenyl]-4-oxo-3-methylenebutanoic acid, III].

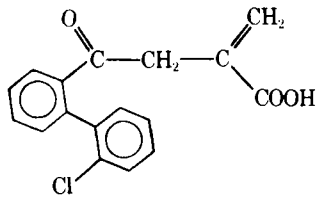
Furthermore, chlorobiphenyl acylation takes place preferentially in the *para*-position of the nonchlorinated ring, but the formation of IV is conceivable. This derivative has not been observed and was not prepared as a reference sample.

Degradation products also may be present as impurities. In I and III, the double bond can shift, as was found (1–3) with similar compounds. Shifting the double bond of I to an adjacent carbon gave a more highly conjugated isomer [4-[4′-(2-chlorophenyl)phenyl]-4-oxo-2-methyl-2-butenoic acid, V].

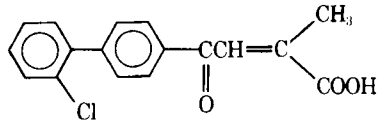
Compound V exists as two geometrical isomers, *Z* and *E*. Theoretically, the *Z* form is more stable in the cyclized form [5-[4′-(2-chlorophenyl)-phenyl]-5-hydroxy-3-methyl-2,5-dihydrofuran-2-one, VI] (1–3, 9, 10). Since VI is a lactone, V can be regarded as the *E*-isomer. Compound VI



III



IV



V

was prepared by sunlight isomerization of V (1–3, 10). Analogous reasoning applied to III led to the postulation of a derivative 5-[4′-(2-chlorophenyl)phenyl]-5-hydroxy-4-methyl-2,5-dihydrofuran-2-one (VII).

Compounds V and VII also may be obtained by Friedel–Crafts reaction of 2-chlorobiphenyl with citraconic anhydride, as reported for similar products (1–3, 10–12). This anhydride may be an impurity of itaconic anhydride, but not when the latter compound is crystallized. The isomerization of III or VII to the open *E* form is more difficult, as was shown (1, 11, 13) with similar compounds, and was not investigated. These derivatives are isomers with the formula $C_{17}H_{13}ClO_3$; their presence in I was not revealed by elemental analysis. These compounds, except IV, were synthesized.

EXPERIMENTAL

General Methods—NMR spectra were recorded on a 60-MHz apparatus[1] with tetramethylsilane as an internal reference; the chemical shifts were expressed in δ relative to tetramethylsilane. IR[2] and UV[3] spectra were obtained in a double-beam spectrometer. Melting points were taken on a hot stage[4] and were not corrected. TLC utilized precoated silica gel plates[5] with chloroform–methanol (85:15); after development to 12–15 cm, the plate was exposed to 254-nm UV radiation or iodine vapor for visualization (Figs. 1*a* and 1*b*).

Synthesis of I—A solution of 47.3 g (0.25 mole) of 2-chlorobiphenyl and 28 g (0.25 mole) of itaconic anhydride (rhombic bipyramidal prisms, mp 68–69°) in 120 ml of methylene chloride was preheated to 30° and placed in a 500-ml round-bottom flask. The flask was fitted with a mechanical stirrer, a thermometer, a dropping funnel, and a reflux condenser connected to a hydrochloric acid absorber. Freshly ground anhydrous aluminum chloride (74 g, 0.55 mole) was added in portions. After boiling

under reflux for 3 hr, 350 ml of concentrated hydrochloric acid mixed with 200 g of crushed ice was added to the mixture.

The organic phase was separated and washed with water until the wash water was neutral. It then was poured into a mixture of 200 ml of acetone and 100 ml of 95% ethanol, which gave a first crop of crystals. These crystals were filtered off and rinsed with acetone (yield of 43.7 g). The mother liquor was evaporated to dryness, giving an oil (27 g) containing some crystals. This oil was taken up in 100 ml of 95% ethanol, and a second crop of crystals precipitated. These crystals were filtered off and washed with acetone (yield of 4.7 g). The solution (A) was retained.

The crystals were combined and purified by recrystallization from dioxane to give 46.5 g (62% yield) of I as small colorless needles, mp 212–214°; IR (potassium bromide): 1690 (COOH), 1675 (C=O), and 1610 (C=C aromatic) cm^{-1}; UV (95% ethanol): λ_{max} 267 (log ϵ 4.24) nm; NMR (dimethyl sulfoxide-d_6): δ 4.1 (s, 2H, $COCH_2$), 5.85 (d, 1H, J = 1.2 Hz, *trans*-HC=CCOOH), 6.3 (d, 1H, J = 1.2 Hz, *cis*-HC=CCOOH), 7.3–7.9 (m, 7H, COOH and aromatic protons), and 8.1 (d, 2H, J = 8 Hz, aromatic protons *ortho* to C=O) ppm; TLC: R_f 0.41.

Anal.—Calc. for $C_{17}H_{13}ClO_3$: C, 67.89; H, 4.35; Cl, 11.78. Found: C, 67.52; H, 4.30; Cl, 11.76.

Isolation of III—Solution A was evaporated to dryness under reduced pressure, and the residue was taken up in 250 ml of ether. The ethereal solution was washed with water and then dried over anhydrous sodium sulfate. On evaporation, it gave a yellow-orange oil (22 g) containing some crystals. This oil was extracted continuously for 8 hr with petroleum ether in a soxhlet apparatus. The resulting solution contained only unreacted 2-chlorobiphenyl and a small quantity of I.

The insoluble matter was purified by recrystallization from boiling isopropyl ether and gave 1.58 g (2.1% yield) of III as colorless crystals, mp 120°; IR (potassium bromide): 1705 (COOH), 1650 (C=O), and 1630 and 1605 (C=C) cm^{-1}; UV (95% ethanol): λ_{max} 269 (log ϵ 4.15) nm; NMR (chloroform-d and dimethyl sulfoxide-d_6): δ 3.5 (s, 2H, CH_2COOH), 5.75 (d, 1H, J = 0.6 Hz, *trans*-HC=CC=O), 6 (d, 1H, J = 0.6 Hz, *cis*-HC=CC=O), 7.2–7.7 (m, 6H, aromatic protons), 7.9 (d, 2H, J = 10 Hz, aromatic protons *ortho* to carbonyl), and 9.6 (s, 1H, COOH) ppm; TLC: R_f 0.32.

Anal.—Calc. for $C_{17}H_{13}ClO_3$: C, 67.89; H, 4.35; Cl, 11.78. Found: C, 68.02; H, 4.18; Cl, 11.74.

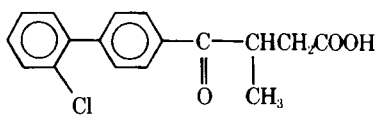
Determination of Structure of III—Compound III was hydrogenated to give a derivative [4-[4′-(2-chlorophenyl)phenyl]-4-oxo-3-methylbutanoic acid, VIII], which also could be obtained unequivocally by the action of citraconic anhydride on 2-chlorobiphenyl followed by reduction by a literature method (12).

Hydrogenation of III—A solution of 300.7 mg (10 mmoles) of III in 5 ml of ethanol was hydrogenated under normal pressure in the presence of 30 mg of 10% palladium-on-charcoal. After the catalyst was removed, the solvent was evaporated under reduced pressure, and the residue was recrystallized from boiling benzene–cyclohexane (2:1) to give 172 mg (58% yield) of colorless crystals, mp 139°; IR (potassium bromide): 1705 (COOH), 1680 (C=O), and 1605 (C=C aromatic) cm^{-1}; UV (95% ethanol): λ_{max} 266 (log ϵ 4.23) nm; NMR (dimethyl sulfoxide-d_6): δ 1.25 (d, 3H, J_{ad} = 7 Hz, $CHCH_{a3}$), 2.4 (q, 1H, J_{bd} = 6 Hz, J_{bc} = 16.5 Hz, CH_bCOOH), 2.9 (q, 1H, J_{cd} = 8 Hz, J_{cb} = 16.5 Hz, CH_cCOOH), 3.95 (m, 1H, CH_dCH_3), 7.2–7.7 (m, 6H, aromatic), 8 (d, 2H, J = 10 Hz, aromatic protons *ortho* to C=O), and 8.6 (s, 1H, COOH) ppm; TLC: R_f 0.46.

Anal.—Calc. for $C_{17}H_{15}ClO_3$: C, 67.44; H, 4.99; Cl, 11.71. Found: C, 67.64; H, 5.27; Cl, 11.61.

Preparation of VII—A suspension of 30 g (0.23 mole) of freshly ground anhydrous aluminum chloride in 80 ml of anhydrous carbon disulfide was treated dropwise with 11.2 g (0.1 mole) of citraconic anhydride. The solution was stirred for 30 min, and a solution of 18.8 g (0.1 mole) of 2-chlorobiphenyl in 30 ml of anhydrous carbon disulfide was added over 40 min. When the addition was complete, the mixture was refluxed for 2 hr.

The usual workup with hydrochloric acid and crushed ice gave 28 g of yellow-green crystals. When these crystals were recrystallized in boiling isopropyl ether, 15.5 g (52% yield) of VII was obtained as colorless crystals, mp 146°; IR (potassium bromide): 3280 (OH), 1740 (C=O lactone), and 1640 (C=C) cm^{-1}; UV (95% ethanol): λ_{max} 248 (log ϵ 4.16) nm: NMR (chloroform-d, dimethyl sulfoxide-d_6): δ 1.9 (s, 3H, CH_3), 5.7 (s, 1H, CH=CCH_3), and 7.8 (m, 9H, aromatic protons and OH) ppm; TLC: R_f 0.55.



VIII

Anal.—Calc. for $C_{17}H_{13}ClO_3$: C, 67.89; H, 4.35; Cl, 11.78. Found: C, 67.41; H, 4.17; Cl, 11.81.

Hydrogenation of VII to VIII—An intimate mixture of 4.5 g (0.015 mole) of VII in 10 ml of acetic acid and 25 ml of water was refluxed in the presence of 3 g of zinc powder in a 100-ml round-bottom flask. After 1 hr, the mixture was filtered while still boiling. The insoluble matter was extracted several times with ethyl acetate, which also was used to extract the filtrate.

The combined organic extracts were washed with 50 ml of 5 N HCl and with water and then were dried over anhydrous sodium sulfate and evaporated. The residue was purified with boiling benzene–cyclohexane (2:1) and gave 2 g (45% yield) of VIII as colorless flakes, mp 139° (not depressed by mixing with the sample prepared by hydrogenation of III); IR (potassium bromide): 1705, 1680, and 1605 cm^{-1}; UV (95% ethanol): λ_{max} 266 (log ϵ 4.24) nm; NMR (dimethyl sulfoxide-d_6): δ 1.25, 2.4, 2.9, 3.95, 7.2–7.7, and 8 ppm; TLC: R_f 0.46.

Anal.—Calc. for $C_{17}H_{15}ClO_3$: C, 67.44; H, 4.99; Cl, 11.71. Found: C, 67.69; H, 5.09; Cl, 11.69.

Isomerization of I to V—Compound I was isomerized to V by the procedure of Lutz *et al.* (1) as adapted by Bailey and Dien (13) and Fateen *et al.* (3). Pure triethylamine (12.5 ml) was added to 5 g (16.6 mmoles) of I, suspended in 25 ml of water. The yellow solution that formed was stirred for 12 hr at room temperature. After a small quantity of insoluble matter was removed, the filtrate was diluted with 50 g of crushed ice and was acidified with 6 N HCl to pH 2–3. The yellow crystals were collected on a fritted filter, dried, and rinsed with distilled water until the wash water was neutral.

After drying, the crystals were recrystallized from 15 volumes of boiling isopropyl alcohol to give 3.5 g (70% yield) of V as yellow needles, mp 196°; IR (potassium bromide): 1690 (COOH), 1665 (C=O), 1630 and 1610 (C=C), and 975 (*trans*-CH_3C=C–H) cm^{-1}; UV (95% ethanol): λ_{max} 287 (log ϵ 4.25) nm; NMR (dimethyl sulfoxide-d_6): δ 2.15 (d, 3H, J = 1.4 Hz, CH_3) and 7.2–8.2 (m, 10H, other protons) ppm; TLC: R_f 0.28.

Anal.—Calc. for $C_{17}H_{13}ClO_3$: C, 67.89; H, 4.35; Cl, 11.78. Found: C, 68.06; H, 4.52; Cl, 11.59.

Isomerization of V to VI—Compound VI was obtained by sunlight isomerization of V according to the procedure of Lutz *et al.* (1) as adapted by Bowden and Henry (10). Compound V (15 g, 50 mmoles) was dissolved in methanol–dioxane, and the solution was exposed to sunlight for 12 hr. After the solvents were evaporated, the residue was purified by extraction with anhydrous ether. Petroleum ether was added, and 12 g (80% yield) of VI as colorless crystals precipitated, mp 130°; IR (potassium bromide): 3400 (OH), 1730 (C=O lactone), and 1610 (C=C) cm^{-1}; UV (95% ethanol): λ_{max} 249 (log ϵ 4.12) nm; NMR (dimethyl sulfoxide-d_6): δ 2.0 (d, 3H, J = 1 Hz, CH_3), 7 (d, 1H, J = 1 Hz, =C–H), and 7.15–7.8 (m, 9H, aromatic protons and COOH) ppm; TLC: Rf 0.26.

Anal.—Calc. for $C_{17}H_{13}ClO_3$: C, 67.89; H, 4.35; Cl, 11.78. Found: C, 67.64; H, 4.92; Cl, 11.62.

Synthesis of II—A solution of 20.6 g (0.1093 mole) of 4-chlorobiphenyl and 12.26 g (0.1093 mole) of itaconic anhydride in 70 ml of anhydrous methylene chloride was added with vigorous stirring to a suspension of 32.4 g (0.24 mole) of ground anhydrous aluminum chloride in 70 ml of anhydrous methylene chloride. After 2 hr at room temperature, the reaction mixture was refluxed for 3 hr and then left overnight at room temperature. The mixture was hydrolyzed in the usual manner. The organic phase was separated and rinsed several times by shaking with water. The solvent was removed under vacuum without heating.

The crystals obtained were rinsed with water until the wash water was neutral and were allowed to dry in the air. They finally were recrystallized from 11 volumes of boiling ethyl acetate to give 17 g (52% yield) of II as pale-beige powdery crystals, mp 192°; IR (potassium bromide): 1700 (COOH), 1675 (C=O), and 1630 and 1610 (C=C) cm^{-1}; UV (95% ethanol): λ_{max} 285 (log ϵ 4.47) nm; NMR (dimethyl sulfoxide-d_6): δ 4.05 (s, 2H, $COCH_2$), 5.75 (s, 1H, *trans*-HC=CCOOH), 6.3 (s, 1H, *cis*-HC=CCOOH), and 7.3–8.3 (m, 9H, other protons) ppm; TLC: R_f 0.38.

Anal.—Calc. for $C_{17}H_{13}ClO_3$: C, 67.89; H, 4.35; Cl, 11.78. Found: C, 67.12; H, 4.55; Cl, 11.49.

Hydrogenation of I to 4-[4′-(2-Chlorophenyl)phenyl]-4-oxo-2-methylbutanoic Acid (IX)—A semisolution of 54 g (0.179 mole) of I in 1080 ml of dioxane containing 36 ml of acetic acid was treated with 2.7 g of 10% palladium-on-charcoal in a 3-liter erlenmeyer flask connected to a hydrogen gas holder. After the apparatus was purged with nitrogen and hydrogen, the stirrer was started and hydrogenation began after induction for 40 min. The theoretical quantity of hydrogen was absorbed in 6 hr. The gas holder was disconnected, the catalyst was removed by

filtration through kieselguhr, and the filtrate was evaporated to dryness and gave beige crystals.

The solid was recrystallized from boiling alcohol, and 34.2 g (63% yield) of IX was produced as brilliant-beige needles on cooling, mp 172°. When IX was mixed with VIII, the melting point was depressed to 128–131°, and TLC gave a spot with two parts (Fig. 1*b*); IR (potassium bromide): 1700 (COOH), 1680 (C=O), and 1610 (aromatic C=C) cm^{-1}; UV (95% ethanol): λ_{max} 262.5 (log ϵ 4.21) nm; NMR (dimethyl sulfoxide-d_6): δ 1.25 (d, 3H, J = 7 Hz, $-CH_3$), 2.7–3.8 (m, 3H, $-COCH_2CHCOOH$), 7.2–7.8 (m, 7H, aromatic protons and COOH), and 8 (d, 2H, J = 8 Hz, aromatic protons *ortho* to the carbonyl) ppm; TLC: R_f 0.50.

Anal.—Calc. for $C_{17}H_{15}ClO_3$: C, 67.44; H, 4.99; Cl, 11.71. Found: C, 67.41; H, 5.10; Cl, 11.49.

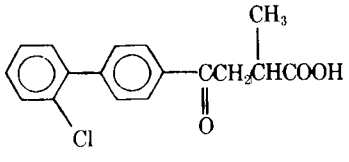
DISCUSSION

Structure of III—The results of the experimental analysis confirmed the structure of III. The IR spectrum of III compared to that of I showed a shift of the acidic carboxyl band toward the shortwave region, which indicates that the carboxyl group was attached to an sp^3 carbon. Moreover, the shift of the ketonic carbonyl band toward the longwave region suggested that this function was adjacent to a double bond. Furthermore, the UV spectrum showed the presence of an absorption maximum at 269 nm (which excluded the existence of conjugation between the carbonyl and the carboxyl groups as in V).

In comparison with I, there also was a slight bathochromic effect (λ_{max} 269 *versus* 267 nm), which indicated that IV was not present since in that case there would have been a conjugation breakdown leading to a hypsochromic effect. This observation was in agreement with the slight bathochromic effect observed previously (14) in passing from α-methylpropiophenone or α-methylbutyrophenone to α-methylenepropiophenone. Finally, the NMR spectrum gave an identical picture for the block representing the aromatic protons of I and of III, which proved that the two isomers had the *para* structure. Shielding was also noticeable for the two signals of the ethylenic protons, but this shielding was especially remarkable for the methylenic protons since the chemical shift passed from δ 4.1 for I to δ 3.5 for III. Such a shift could be explained only by chain isomerism. Its intensity made it possible to note the presence of I in III and to calculate the percentage of it by integration ($\simeq$4% in the sample obtained).

These results were confirmed by the conversion into the saturated derivative. The saturated derivative was identical to an authentic sample prepared unequivocally by chemical reduction of the hydroxylactone (VII) formed by the reaction between citraconic anhydride and 2-chlorobiphenyl. The hydrogenated derivative (VIII) differs from its isomer (IX) obtained by hydrogenating I (different IR and NMR spectra). The melting point of a mixture of VIII and IX showed a distinct depression. Upon TLC, the mixture of VIII and IX gave a stain consisting of two parts (Fig. 1*b*). Therefore, the formation of this isomer showed that, contrary to the opinion of several investigators (1–3, 13), opening of the itaconic anhydride ring by an aryl group does not give a single product but instead leads to the formation of the two isomers in unequal proportions. NMR carried out on a crude reaction mixture after hydrolysis, washing with water, and solvent evaporation showed that the ratio by weight of I to III was ~80:20.

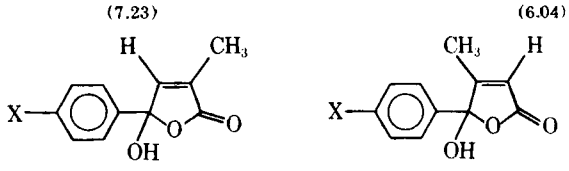
Structure of V—The method of formation of V showed that it is not easy to purify I by converting it into the water-soluble alkali metal salt followed by acidification after separating insoluble matter, unless the conditions are chosen carefully. The isomer structure was deduced from spectral analysis. The NMR spectrum agreed with a 4-aryl-4-oxo-2-methyl-2-butenoic acid. The presence of the doublet with δ 2.15, J = 1.4 Hz, was concordant with the values [δ 2.2, 2.14, and 2.18 (average)] reported (11, 12, 15) for similar aryl-substituted acids. With IR spectroscopy, two absorption bands were found at 1690 (COOH) and 1665 (C=O) cm^{-1}, which showed that the compound had an open structure. The stretching frequency observed at 975 cm^{-1} is characteristic of $=C-CH_3$ in the *trans*-$CH_3-C=C-H$ group (15, 16). As reported by various investigators (1, 3, 9–11), the *trans*-geometrical isomers of these acids are linked to the open form, the *cis*-isomer being stable only as the cyclized hydroxylactone.



IX

Structure of VII—The IR spectrum of VII showed the absence of a ketonic carbonyl group and the very strong absorption of the lactone group at 1740 cm^{-1}. In addition, the presence of a hydroxyl group was indicated by an absorption band at 3280 cm^{-1}. The UV spectrum confirmed this result by the absence of conjugation between the aromatic ring and the carboxyl group through the intermediary of the carbonyl group excited by the double bond (λ_{max} 248 nm). Finally, the NMR spectrum agreed with the values of the signals given (10, 12) by analogous compounds.

The NMR spectrum was close to that of the isomeric hydroxylactone, VI. However, the signal relating to the ethylenic proton was more depressed with VI (7.0 *versus* 5.8), which confirmed the position assigned to the methyl group in these two compounds. The values of the chemical shifts observed for the ethylenic protons in VI and VII were in good agreement with those given by Bowden and Henry (10) in a review of ring–chain tautomerism for the derivatives:



CONCLUSIONS

With the samples prepared as described and after comparative studies of R_f values, specific absorptions in the UV range, and specific NMR signals, a method was developed for detecting these impurities. The most suitable method for routine analysis is TLC on silica gel using methanol–chloroform (15:85) and developing to 15 cm. With these conditions, four isomers exhibited sufficient R_f differences to permit their detection in I (Fig. 1*a*). The respective R_f values for I, II, III, V, VI, and VII were 0.41, 0.38, 0.32, 0.28, 0.26, and 0.55. Nevertheless, considering the close R_f values for I and II, this method is not sufficiently accurate for the determination of II; in this case, GLC of 2-chlorobiphenyl provides a better control for the absence of II in I.

The most frequent impurity is V, which can be formed even when starting with pure I. Compound VI, formed with greater difficulty in the solid state, is present to a lesser extent in industrial samples. Compounds V and VI correspond to the evolution products of the I molecule, and their absence in the starting material does not exclude their detection in the finished pharmaceutical form. The other secondary products are manufacturing impurities, which must be tested for in the starting material. Their absence in the starting material is adequate to guarantee the quality of the pharmaceutical form since they cannot be formed spontaneously from I.

Systematic tests have shown that this method makes possible the detection of these main impurities in I concentrations as low as 0.2%. Levels as low as 1% of V can be detected in I by NMR using a routine 60-MHz apparatus. A standard range has been carried out in dimethyl sulfoxide-d_6 with I containing increasing quantities of V (0.5, 1, 2, 3, 5, and 7.5%); at 1%, the signal at δ 2.1 ppm clearly was distinct from the background noise. These UV or NMR physicochemical methods do not provide any advantage for detecting the impurities studied in comparison with TLC.

Chemical Constituents of Gentianaceae XXVIII: Flavonoids of *Enicostemma hyssopifolium* (Willd.) Verd.

S. GHOSAL ˣ **and D. K. JAISWAL**

Received January 16, 1978, from the *Pharmaceutical Chemistry Research Laboratory, Department of Pharmaceutics, Banaras Hindu University, Varanasi-5, India.* Accepted for publication June 20, 1979.

Abstract □ The whole plant of *Enicostemma hyssopifolium* (Willd.) Verd. (Gentianaceae) was collected at different growth stages and was shown to contain seven flavonoids: apigenin (I), genkwanin (II), isovitexin (III), swertisin (IV), saponarin (V), 5-*O*-glucosylswertisin (VI), and 5-*O*-glucosylisoswertisin (VII). Compounds VI and VII previously were unreported in nature. The yields of the flavonoids varied with the growth stage. The biochemical and chemotaxonomic significance of these results is appraised.

Keyphrases □ Flavonoids—isolation from *Enicostemma hyssopifolium*, identification □ Medicinal plants—isolation of flavonoids from *Enicostemma hyssopifolium*, identification □ Gentianaceae—isolation of flavonoids from *Enicostemma hyssopifolium*, identification □ *Enicostemma hyssopifolium*—isolation and identification of flavonoids

The genus *Enicostemma* (Gentianaceae) is monotypic; the only recorded species is *E. hyssopifolium* (Willd.) Verd. (synonymous with *E. littorale* Blume) (1). The plant is found throughout India up to 450 m (1500 ft). Extracts of the plant are used in Indian medicine to treat cardiac dropsy, rheumatism, and certain mental disorders. Significant antipsychotic (3), anti-inflammatory (4), and anthelmintic (5) activities were reported for its major alkaloid, gentianine; the corresponding heteroside, swertiamarin, was reported to produce central nervous system depressant (6) and cardiostimulant (7) activity.

The chemicals previously reported in this species were monoterpene alkaloids (8–12), heterosides (6, 7, 10, 13, 14), and a triterpene (14). This paper describes the isolation and characterization of the flavonoids of this species. The biochemical significance of the chemical constituent changes during vegetation is appraised in light of its separation as a monotypic genus.

EXPERIMENTAL[1]

All solutions were dried with anhydrous sodium sulfate. Silica gel[2] (60–120 mesh) was used for column chromatography. TLC was performed on silica gel[3] with chloroform–acetic acid (98:2, Solvent 1) and *n*-butanol–acetic acid–water (4:1:2, Solvent 2). Iodine vapor and ferric chloride solution were used for staining. Glucose was detected by partition paper chromatography[4] using sodium metaperiodate–benzidine reagent for staining (15).

Dried and milled whole plants of *E. hyssopifolium*[5] at the flowering stage (5.2 kg) were extracted continuously with light petroleum ether (bp 60–80°) in a soxhlet apparatus for 30 hr. The defatted plant material was extracted with ethanol for 30 hr. The petroleum ether extract contained alkanes and alkanols and was not processed further. The alcoholic extract was concentrated under reduced pressure and processed as shown in Scheme I.

The relative percent yields of the individual compounds at various stages of plant development are given in Table I. Determination of the mixed minor entities was accomplished by preparative layer chromatography of mixture extracts and absorptiometry of the layers after the components in these layers were identified by the usual methods.

Treatment of Fraction A—Fraction A was dissolved in 250 ml of hot ethyl acetate, the solution was concentrated, and a yellow solid (14.2 g) was separated. The solid showed two major spots on TLC at R_f 0.68 and 0.74 (Solvent 2). The two components were separated by fractional crystallization from methanol.

Swertisin (IV)—The sparingly methanol-soluble solid crystallized from methanol–dioxane as cream-colored crystals (7.65 g), mp 240–242°; $[\alpha]_D^{24}$ −9° (c 0.33, pyridine); UV: λ_{max} (ethanol) 272 (log ϵ 4.28) and 334 (4.38) nm; IR: ν_{max} 3360, 1668, and 1610 cm^{-1}; NMR (deuterodimethyl sulfoxide): δ 7.88 (2H, d, J = 9 Hz, H-2′,6′), 6.80 (2H, d, J = 9 Hz, H-3′,5′), 6.54 (1H, s, H-8), 6.50 (1H, s, H-3), 4.78 (1H, broad, glucosyl H-1), and 3.98 (3H, methoxyl). The hexaacetate, formed with acetic anhydride and pyridine under reflux, crystallized from alcohol as colorless needles, mp 150–151°; mass spectrum: *m/e* 698 (M$^+$, relative intensity 8%), 656 (22), 639 (12), 597 (20), 537 (12), 463 (80), 421 (98), 313 (100), 297 (60), and 139 (20).

Methylation with ethereal diazomethane gave swertisin-4′,5-di-*O*-methyl ether, mp 298–300°. Acetylation of the di-*O*-methyl ether with acetic anhydride and pyridine under reflux afforded swertisin-di-*O*-methyl ether tetraacetate, mp 128–129°; mass spectrum: *m/e* 642 (M$^+$, 5%), 583 (100), 582 (22), 523 (8), 341 (55), 325 (62), 294 (5), and 139 (5). The physical and spectral properties of the parent compound and its derivatives were indistinguishable from those of swertisin (16, 17).

Isovitexin (III)—After separation of swertisin, the methanol mother liquor was concentrated and diluted with acetone. It was kept at ordinary temperature overnight, and a yellow solid precipitated. Repeated crystallization of the solid from acetone–methanol gave isovitexin (18, 19) as yellow needles (6.4 g), mp 229–230°; $[\alpha]_D^{28}$ +15.4° (c 0.37, ethanol); UV: λ_{max} (ethanol) 272 (log ϵ 4.45) and 338 (4.42) nm; IR: ν_{max} 3300 (broad), 1662, 1628, 1600, and 1588 cm^{-1}; NMR (deuterodimethyl sulfoxide): δ 7.95 (2H, d, J = 9 Hz, H-2′,6′), 6.95 (2H, d, J = 9 Hz, H-3′,5′), 6.72 (1H, s, H-3), 6.54 (1H, s, H-8), and 4.70 (1H, broad, glucosyl H-1); mass spectrum: *m/e* 414 (M − 18, 20%), 396 (8.5), 378 (14), 295 (18), 283 (100), and 165 (20). The 4′,5,7-tri-*O*-methyl ether tetraacetate, prepared as de-

[1] Melting points were taken on a Kofler block in open capillaries and are uncorrected. UV spectra were determined on a Cary model 14 recording spectrophotometer. IR spectra were taken in Nujol using a Perkin-Elmer model 337 spectrophotometer, and only the major bands are quoted. ^{1}H-NMR spectra were recorded on an XL 100 instrument with tetramethylsilane as the internal standard. Mass spectra were determined with an MS-9 or MS-50 spectrometer at 70 ev.

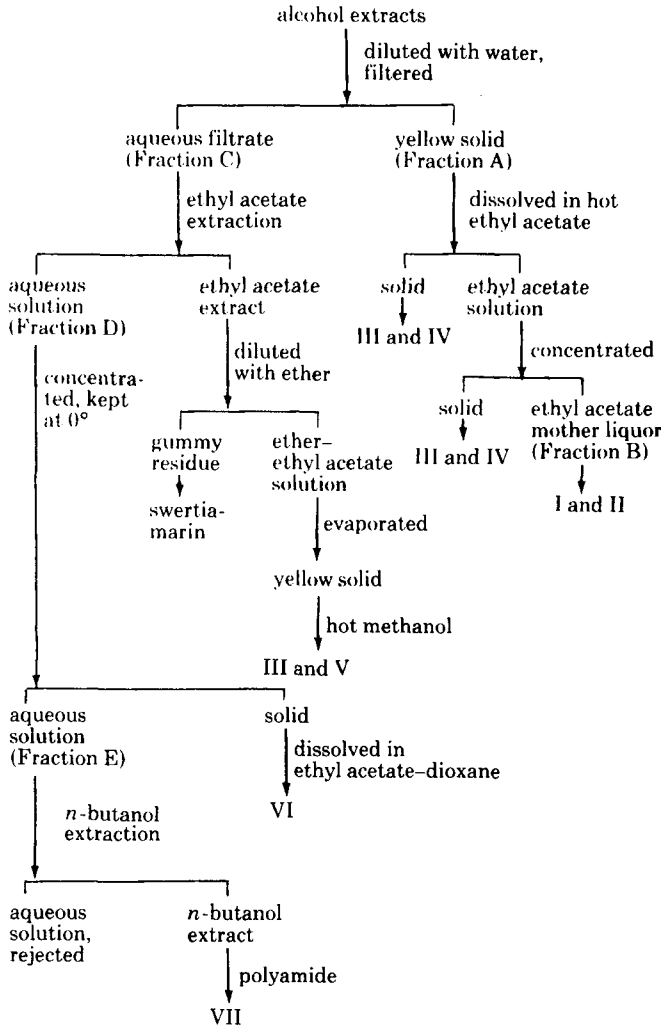


Scheme I—Isolation of flavonoids of E. hyssopifolium

scribed, was identified by melting-point, mixed melting-point, and co-TLC analyses as the di-*O*-methyltetraacetate derivative of IV.

Treatment of Fraction B—The ethyl acetate mother liquor was evaporated. The residue was dissolved in chloroform and chromatographed over silica gel (30 × 3 cm). Elution was carried out with benzene, benzene–chloroform (1:1), and chloroform (1 liter each), and 100-ml fractions were collected.

Genkwanin (II)—On evaporation, the middle benzene–chloroform eluates (fractions 14–17) afforded genkwanin (20) as yellow needles (0.37 g), mp 285–286°; R_f 0.48 (Solvent 1); UV: λ_{max} (ethanol) 268 (log ϵ 4.40) and 337 (4.47) nm; IR: ν_{max} 3250, 1660, 1600, 1592, and 1498 cm^{-1}; mass spectrum: *m/e* 284 (M^+, 100%), 256 (5), 255 (22), 254 (5), 167 (18), 166 (19), 138 (10), 128 (20), 118 (12), and 95 (11). The diacetate, prepared with acetic anhydride and pyridine under reflux, crystallized from ethanol as colorless needles, mp 195–198°. Correspondence of these properties with those reported previously (20–22) established the identity as II.

Apigenin (I)—The chloroform eluates were combined and evaporated. The residue crystallized from aqueous pyridine to give apigenin as yellow needles (0.46 g), mp 340–343° dec.; R_f 0.3 (Solvent 1); UV: λ_{max} (ethanol) 265 (log ϵ 4.44) and 336 (4.48) nm. 4′,5,7-Tri-*O*-methyl ether, prepared with dimethyl sulfate and potassium carbonate in anhydrous acetone under reflux for 40 hr, crystallized from ethanol as light-yellow needles, mp 153°; NMR (deuterochloroform): δ 7.91 (2H, d, J = 9 Hz, H-2′,6′), 6.94 (2H, d, J = 9 Hz, H-3′,5′), 6.70 (1H, s, H-3), 6.48 (1H, d, J = 3 Hz, H-8), 6.22 (1H, d, J = 3 Hz, H-6), and 4.0–3.98 (9H, methoxyl protons); mass spectrum: *m/e* 312 (M^+, 100%), 297 (22), 295 (10), 269 (22), and 254 (11). The melting point and spectral properties of the flavone and its permethyl ether were indistinguishable from those reported for apigenin (20, 21).

Treatment of Fraction C and Isolation of Saponarin (V)—The aqueous filtrate was extracted with ethyl acetate (5 × 1 liter), and the ethyl acetate extract was worked up in the usual fashion to give a brown concentrate (200 ml). It was diluted with 200 ml of ether, and swertiamarin (6) was precipitated as a brown gum. The ethyl acetate–ether mother liquor was evaporated to give a dull-yellow solid (0.28 g), which showed two major spots on TLC at R_f 0.42 and 0.7 (Solvent 2). Trituration of the residue with hot methanol gave 0.1 g of swertisin as the sparingly methanol-soluble solid.

Table I—Flavonoids of *E. hyssopifolium* during Growth [a] (Relative Percent Yield)

Flavone	2–3 Weeks Old	6–8 Weeks Old	Flowering Stage	Fruiting Stage
I	44	20	3	5
II	32	28	2	4
III	–	12	35	–
IV	–	7	42	–
V	–	14	+	8
VI	–	+	5	40
VII	–	–	+	24
Unidentified phenolic constituents	24	17	12	19
Yield, %	0.08	0.22	0.37	0.30

[a] n = 3; + denotes 1–2%; – denotes absence.

After separation of swertisin, the methanol mother liquor was evaporated to give a hygroscopic solid (0.11 g), mp 228–231°; R_f 0.4 (Solvent 2); $[\alpha]_D^{28}$ −8.5° (c 0.45, water) and −73.4° (c 0.55, pyridine); UV: λ_{max} (ethanol) 270 and 335 nm; NMR (deuterodimethyl sulfoxide): δ 7.95 (2H, d, J = 8 Hz, H-2′,6′), 6.98 (2H, d, J = 8 Hz, H-3′,5′), 6.92 (1H, s, H-8), 6.68 (1H, s, H-3), 4.95 (1H, broad, *O*-glucosyl H-1), and 4.8 (1H, d, J = 10 Hz, C-glucosyl H-1). Treatment with acetic anhydride and pyridine afforded a decaacetate, which crystallized from hexane–methylene chloride as a glassy solid, mp 142–144°. The physical and spectral properties of the compound and its acetate derivative were identical to those reported for saponarin (20, 23).

Treatment of Fraction D—The aqueous mother liquor was concentrated at 30° under reduced pressure to about 25 ml and kept at 0° for ~2 weeks, during which time a light-yellow solid precipitated. The solid was collected by filtration and dissolved in ethyl acetate–dioxane.

Swertisin-5-O-β-D-glucoside (VI)—On concentration and cooling, the ethyl acetate–dioxane solution gave an amorphous solid, which crystallized from methanol–dioxane as ivory-colored needles (0.93 g), mp 200–202°; R_f 0.32 (Solvent 2); $[\alpha]_D^{28}$ −77° (c 0.73, pyridine); UV: λ_{max} (ethanol) 271 (log ϵ 4.26) and 335 (4.30) nm; UV: λ_{max} (ethanol–0.2% sodium acetate) 262 sh, 268, and 388 nm; IR: ν_{max} 3300 (broad), 1668, 1662, 1630, 1612, 1295, 1255, 1020, and 838 cm^{-1}; NMR (deuterodimethyl sulfoxide): δ 7.98 (2H, d, J = 8.5 Hz, H-2′,6′), 6.95 (2H, d, J = 8.5 Hz, H-3′,5′), 6.82 (1H, s, H-8), 6.38 (1H, s, H-3), 5.0 (1H, broad, *O*-glucosyl H-1), 4.80 (1H, d, J = 10 Hz, C-glucosyl H-1), 3.94 (3H, methoxyl), and 3.35 (complex multiplet, 12 glucosyl protons plus water); ^{13}C-NMR (deuterodimethyl sulfoxide): δ 161.40 (C-2), 103.07 (C-3), 182.30 (C-4), 156.90 (C-5), 90.88 (C-6), 161.42 (C-7), 104.8 (C-8), 159.86 (C-9), 109.57 (C-10), 121.08 (C-1′), 128.46 (C-2′), 116.08 (C-3′), 164.05 (C-4′), 116.02 (C-5′), 128.46 (C-6′), 56.28 (methoxyl-C), and 56.0–100.5 (12 lines, C,*O*-glucosyl-C) (24).

Anal.—Calc. for $C_{28}H_{32}O_{15}\cdot H_2O$: C, 53.67; H, 5.43. Found: C, 52.99; H, 5.86.

Hydrolysis of VI with Emulsin—Compound VI, 52 mg, was dissolved in 20 ml of pH 5 aqueous buffer (0.5 *M* sodium acetate adjusted to pH 5 with acetic acid) to which 20 mg of powdered emulsin[6] was added. The mixture was kept at ambient temperature overnight. The reaction product was concentrated and subjected to paper chromatography[7] along with glucose, rhamnose, and glucuronic acid. Only glucose was detected as the sugar component in the hydrolyzed product. The aglucone was extracted with ethyl acetate, the solvent was removed, and the residue was crystallized from methanol–dioxane. Direct comparison of the aglucone by melting-point, mixed melting-point, and co-TLC analyses with swertisin established that they were identical.

Methylation of VI—Compound VI, 48 mg, was methylated by repeated addition of ethereal diazomethane daily for 7 days. After the usual workup, the methyl ether was obtained as a light-yellow solid.

[6] Sigma Corp.
[7] Whatman No. 1.

Isovitexin-4′,7-di-O-methyl Ether—The methyl ether of VI was dissolved in 20 ml of 10% aqueous acetic acid and kept at ambient temperature overnight. The solvent was removed under high vacuum, and a straw-colored residue was obtained. It was triturated with hot methanol. The methanol solution was concentrated and afforded 38 mg of a microcrystalline solid, mp 268–270°; R_f 0.42 (Solvent 2); UV: λ_{max} (ethanol) 268 (log ϵ 4.28) and 324 (4.36) nm; UV: λ_{max} (ethanol–aluminum chloride) 278, 300, and 345 nm (indicating the presence of a C_5-OH group); mass spectrum: *m/e* 460 (M^+, 3%), 445 (7), 442 (100), 431 (7), 430 (8), 422 (3), 417 (5), 311 (34), 296 (17), 281 (24), and 179 (7). The physical and spectral properties of the compound suggested its identity as isovitexin-4′,7-di-*O*-methyl ether.

Isovitexin-4′,5,7-tri-O-methyl Ether Tetraacetate—Further methylation of isovitexin-4′,7-di-*O*-methyl ether with excess ethereal diazomethane followed by acetylation with acetic anhydride and pyridine on a steam bath for 4 hr afforded isovitexin-tri-*O*-methyl ether tetraacetate, mp 127–129° (25); mass spectrum: *m/e* 642 (M^+, 3%), 583 (100), 541 (2), 523 (10), 481 (8), 463 (18), 421 (12), 408 (2), 341 (68), 339 (44), 31 (22), 294 (2), 179 (2), and 139 (25).

Permethylation of VI—The diglucoside, 24 mg, in 5 ml of *N,N*-dimethylformamide was treated with 1 ml of methyl iodide and 60 mg of sodium hydride under nitrogen. After 1 hr at ambient temperature, the reaction mixture was diluted with 50 ml of water and extracted with chloroform. The chloroform layer was worked up in the usual fashion, and the chloroform concentrate was subjected to preparative layer chromatography with Solvent 1 as the developer. The blue fluorescent zone at R_f 0.5 under a shortwave UV lamp was cut out and eluted with chloroform. Evaporation of the solvent from the chloroform solution gave a pale-yellow gum, which crystallized from benzene as yellow needles, mp 168–171°; mass spectrum (no M^+ was observed, only fragment ions were recorded): *m/e* 516 (relative intensity 12%), 501 (22), 485 (20), 469 (8), 341 (100), 311 (5), 101 (55), and 88 (47).

Treatment of Fraction E—Fraction E was extracted with *n*-butanol (4 × 250 ml). The residue from the butanol extract was dissolved in ethyl acetate and subjected to preparative layer chromatography on polyamide[8] plates (20 × 20 cm) with methanol–acetic acid–water (90:5:5) as the developer.

Isoswertisin-5-O-β-D-glucoside (VII)—The zone at R_f 0.4 was eluted with methanol, and the solvent was evaporated. The residue crystallized from methanol–dioxane as light-yellow microcrystals (0.1 g), mp 212–215°; R_f 0.37 (Solvent 2); $[\alpha]_D^{28}$ −91° (c 0.51, pyridine); UV: λ_{max} (ethanol) 270 (log ϵ 4.23) and 336 (4.26) nm; UV: λ_{max} (ethanol–0.2% sodium acetate) 262 sh, 268, and 390–395 nm; IR: ν_{max} 3300 (broad), 1665, 1610, 1502, 1362, 1295, 1258, 1212, 1196, 1035, and 842 cm^{-1}; NMR (deuterodimethyl sulfoxide): δ 7.92 (2H, d, J = 8.5 Hz, H-2′,6′), 6.95 (2H, d, J = 8.5 Hz, H-3′,5′), 6.34 (1H, s, H-6/H-3), 6.32 (1H, s, H-3/H-6), 5.0 (1H, broad, *O*-glucosyl H-1), 4.78 (1H, d, J = 10 Hz, C-glucosyl H-1), 3.92 (3H, methoxyl), and 3.50 (complex multiplet, 12 glucosyl protons plus water).

Anal.—Calc. for $C_{28}H_{32}O_{15}\cdot H_2O$: C, 53.67; H, 5.43. Found: C, 53.18; H, 5.82.

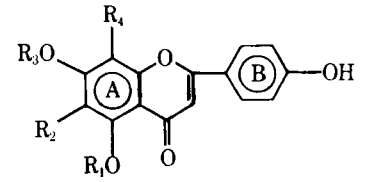
Hydrolysis of VII—Compound VII, 23 mg, was hydrolyzed with 10 mg of emulsin as described when glucose was detected as the only glucone moiety present. The aglucone, mp 295–298°, showed UV: λ_{max} (ethanol) 272 (log ϵ 4.17) and 335 (4.30) nm, identical to that reported for isoswertisin (17). It afforded a hexaacetate, mp 128–131°.

Methylation of VII—Compound VII, 22 mg, was methylated with excess ethereal diazomethane. After the usual workup, the methyl ether was obtained as an amorphous solid (21 mg).

Vitexin-4′,7-di-O-methyl Ether—The methyl ether of VII was hydrolyzed with acetic acid as described, and vitexin-4′,7-di-*O*-methyl ether was obtained as yellow microcrystals (9 mg), mp 260–262°; UV: λ_{max} (ethanol) 270 (log ϵ 4.27) and 324 (4.22) nm; UV: λ_{max} (ethanol–aluminum chloride) 277, 300, 345, and 383 nm.

Vitexin-4′,5,7-tri-O-methyl Ether Tetraacetate—Further methylation of vitexin-4′,7-di-*O*-methyl ether with ethereal diazomethane and subsequent acetylation afforded vitexin-4′,5,7-tri-*O*-methyl ether tetraacetate (26), mp 220–221°; mass spectrum: *m/e* 642 (M^+, 100%), 583 (8), 541 (12), 523 (18), 481 (5), 463 (4), 341 (35), 339 (11), 311 (28), 294 (6), 179 (5), and 139 (10). The mass fragmentation data of this compound are consistent with those reported for vitexin-4′,5,7-tri-*O*-methyl ether tetraacetate (16).

Permethylation of VII—Compound VII was permethylated as described for VI. The derivative crystallized from acetone–benzene as a light-brown solid, mp 122–125°; mass spectrum (no M^+ was observed, only fragment ions were recorded): *m/e* 516 (relative intensity 80%), 486 (5), 341 (100), 327 (22), 311 (8), 101 (70), and 88 (68). The mass spectral data were consistent with those reported (27) for the permethyl ether of vitexin-5-*O*-glucoside.



I: $R_1 = R_2 = R_3 = R_4 = H$
II: $R_1 = R_2 = R_4 = H$, $R_3 = CH_3$
III: $R_1 = R_3 = R_4 = H$, R_2 = glucosyl
IV: $R_1 = R_4 = H$, R_2 = glucosyl, $R_3 = CH_3$
V: $R_1 = R_4 = H$, $R_2 = R_3$ = glucosyl
VI: $R_1 = R_2$ = glucosyl, $R_3 = CH_3$, $R_4 = H$
VII: $R_1 = R_4$ = glucosyl, $R_3 = CH_3$, $R_2 = H$

RESULTS AND DISCUSSION

Seven flavonoids (22) were isolated from the whole plants of *E. hyssopifolium* at different vegetation periods by solvent extraction and column and preparative layer chromatography. These compounds, apigenin (I), gerkwanin (II), isovitexin (III), swertisin (IV), saponarin (V), swertisin-5-*O*-β-D-glucoside (VI), and isoswertisin-5-*O*-β-D-glucoside (VII), were characterized by chemical transformation and the UV, IR, NMR, and mass spectra of the compounds and their methyl ether and acetate derivatives. The structural elucidation of the two new compounds (VI and VII) that were not encountered before in nature or prepared synthetically is described.

Flavonoid VI—Compound VI ($C_{28}H_{32}O_{15}\cdot H_2O$), mp 200–202°, showed UV absorption maxima in neutral ethanol and in the presence of the usual shift reagents (21), characteristic of 4′,5,7-trioxygenated flavones with a free 4′-hydroxyl group (21). The 100-MHz PMR spectrum of the compound in deuterodimethyl sulfoxide exhibited signals due to 12 glucosyl protons, one aromatic methoxyl proton, two glucose anomeric protons, and six aromatic protons ascribable to C-3, C-8, and C-2′,3′,5′,6′-H (21). Its ^{13}C-NMR spectrum, interpreted on the basis of two recent reports of the ^{13}C-spectra of hydroxy–methoxy flavones (27, 28), also was consistent with this assignment.

On hydrolysis with emulsin, the compound gave IV and glucose. Methylation with ethereal diazomethane and subsequent acid hydrolysis afforded isovitexin-4′,7-di-*O*-methyl ether, which showed a mass spectrum consistent with this structure (16, 18). Likewise, the mass spectrum of the permethyl ether of the parent compound produced fragment ion peaks characteristic of 6-C,*O*-diglucosyl flavones (29). Based on these observations, the flavonoid was identified as 5-*O*-β-D-glucopyranosyl-6-C-β-D-glucopyranosyl genkwanin (VI).

Flavonoid VII—Compound VII ($C_{28}H_{32}O_{15}\cdot H_2O$), mp 212–215°, showed a close similarity in its UV absorption spectra in neutral ethanol and in the presence of the usual shift reagents (21) with those of VI. In the 100-MHz PMR spectrum, a significant difference from that of VI was discernible in the A-ring proton singlet, which appeared near the signal due to C_3-H. Therefore, the A-ring proton was assigned to C_6-H. The downfield shift was due to the glucosyloxy function at C-5. On hydrolysis with emulsin, it afforded isoswertisin and glucose. Methylation with ethereal diazomethane followed by acid hydrolysis under mild conditions yielded vitexin-4′,7-di-*O*-methyl ether. The permethyl ether of the parent compound produced fragment ion peaks in its mass spectrum that are characteristic of 8-C,*O*-diglucoside flavones (29). Based on these observations, the compound was identified as 5-*O*-β-D-glucopyranosyl-8-C-β-D-glucopyranosyl genkwanin (VII).

The glycoflavones (III–VII) were absent in the seedling stage (2–3 weeks) of the plant. At this stage, only the free flavones (I and II) were detected in the roots, stalks, and leaves of *E. hyssopifolium*. From the onset of maturity (6–8 weeks), biosynthesis of the C-glycoflavones (III and IV) started. At the flowering stage, the free flavones were largely replaced by these entities. At the fruiting stage, III and IV were represented by the C,*O*-diglycoflavones (V–VII). However, at this stage, I and II reappeared as minor entities.

Since previous results of biosynthetic experiments suggested that C-glycosylation of flavones takes place at the chalcone stage (30), it seemed plausible that elaboration of the free flavones (I and II) in *E.*

[8] Powder D, Riedel, Haen AG.

hyssopifolium was interrupted during the early growth of its stalk and leaves and substituted by the synthesis of the C-glycoflavones (III and IV). Toward the end of vegetation, synthesis of the free flavones revived, while the C-glycoflavones were further *O*-glycosylated to afford V–VII. This time lag in the *O*-glycosylation is surprising because *O*-glycosides are less toxic to plants than the free phenols (31); the reaction, therefore, was expected at an early stage of plant growth but was not observed in *E. hyssopifolium*. However, a similar ontogenic variation in the content of free xanthones and of xanthone-*O*-glycosides was reported recently in *Swertia angustifolia* (32).

Another noteworthy feature of *E. hyssopifolium*, whose certain chemical characters, *e.g.*, monoterpene alkaloids, heterosides, and flavonoids, are similar to those of *Gentiana* species (12), is the apparent complete absence of xanthones. Xanthones occur almost ubiquitously in *Gentiana* species (33, 34). From the chemotaxonomic point of view, this observation is significant since *E. hyssopifolium* was known previously as *Gentiana verticillata* Linn. but later was separated from the *Gentiana* genus on other taxonomic grounds (1). The chemical results reported in this paper support this separation of *E. hyssopifolium* as a monotypic species.

New Compartment- and Model-Independent Method for Rapid Calculation of Drug Absorption Rates

WIN L. CHIOU

Received April 16, 1979, from the *Department of Pharmacy, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612.* Accepted for publication August 22, 1979.

Abstract □ A simple and rapid method for the absorption rate calculation for drugs exhibiting linear pharmacokinetics is proposed. The method employs the novel instantaneous midpoint-input principle, which assumes that all drug absorbed during a given interval, regardless of the complexity of the absorption kinetics, is absorbed instantaneously at the midpoint of the interval. The drug amount absorbed is calculated by comparing the net plasma level resulting from the absorption during that interval with the plasma drug level obtained after intravenous dosing at the midpoint of the absorption interval. The method does not assume any compartments or models commonly used in pharmacokinetic studies. In examples with markedly different pharmacokinetic properties, the new method yielded accurate results almost identical to those obtained with the standard Wagner–Nelson and Loo–Riegelman methods. The method often is accurate to two to four significant figures in absorption rate calculations. For first-order absorption, the new method appears to be less subject to the influence of timing of the first blood sample. Theoretically, information on only a small portion of the intravenous plasma level–time profile is sufficient for the analysis. Data on plasma levels shortly after intravenous dosing and the terminal biological half-life are not always needed. Thus, the method might be particularly useful for drugs with long or uncertain biological half-lives. Theoretically, the method also can be applied to urine or saliva data. The method assumes the same drug disposition kinetics between the intravenous and absorption studies.

Keyphrases □ Drug absorption—compartment- and model-independent calculation for drugs with linear pharmacokinetics □ Pharmacokinetics, linear—compartment- and model-independent drug absorption calculation □ Absorption—compartment- and model-independent calculation for drugs with linear pharmacokinetics □ Instantaneous midpoint–input principle—drug absorption, linear pharmacokinetics

Calculation of the drug absorption rate from various dosage forms or administration routes is important in biopharmaceutical and pharmacokinetic studies. Many methods for calculating the absorption rate have been reported or reviewed (1–17). The original Wagner–Nelson (1) and Loo–Riegelman (2) methods have been the most widely and successfully used numerical methods in the past decade.

BACKGROUND

The original Wagner–Nelson method (1) is based on the linear one-compartment open model for drug disposition. Since the disposition kinetics of almost all drugs can be described more accurately by multicompartment models (2, 18), its use in many cases can be viewed only as an approximation. Precautions for using this method were discussed previously (2–4).

The Loo–Riegelman method (2) can be used for drugs exhibiting linear multicompartment properties. The method was derived based on multicompartment models in which drug elimination was assumed to take place exclusively from the central compartment (2). Although such an assumption probably is correct for most drugs, for some drugs various degrees of elimination probably also can take place in the tissue or peripheral compartments. However, it was shown subsequently that such an assumption is not necessary for the correct calculation of absorption rates (10, 15). In addition, the pharmacokinetic parameters of the drug in the body are assumed to remain the same during intravenous and absorption studies (2). For intrasubject variation in the terminal biological half-life during intravenous and oral studies, a new elimination rate constant from the central compartment must be used. This new rate constant is calculated based on the assumption that the central compartment volume and the intercompartmental first-order transfer rate constants remain the same (19).

Three approximations are made in the derivation of the final equations used in the original Loo–Riegelman method:

1. The linear trapezoidal rule method is used to estimate the area under the plasma level–time curve for the calculation of the drug amount eliminated from the body during a time interval. Such an approximation method also is employed in the Wagner–Nelson method. The accuracy of the linear trapezoidal rule method for calculating the area under the curve was discussed (15, 20, 21). An improper blood sampling schedule during absorption might result in significant errors in the estimate of the plasma area and, hence, the absorption rate calculation.
2. The plasma level is assumed to change linearly with time in the calculation of the drug distribution rate from the central compartment to the tissue or peripheral compartment. Again, various degrees of under- or overestimation probably occur if an improper blood sampling schedule is employed.
3. The two-term Taylor expansion series is used as a substitution for the exponential term in the equation. Such an approximation occasionally may result in serious errors. As a result, a three-term Taylor expansion series (4) or one without the Taylor series (16) was recommended.

Despite the assumptions and approximations for solving the absorption differential equation, the method has yielded excellent results (16).

This article reports a new, simple, compartment- and model-independent method for the rapid calculation of the absorption rate of drugs exhibiting linear pharmacokinetics. No assumptions regarding specific pharmacokinetic models or the drug elimination site from the body are necessary. Although the development of this method is empirical, it generally is highly accurate when properly used and might be satisfactory for many pharmacokinetic studies. Such use is analogous to the empirical use of the linear trapezoidal rule method for estimation of the area under the curve (20, 21).

THEORETICAL

It was shown (22, 23) that the plasma drug concentration after the constant intravenous infusion period for the one-compartment open model system can be approximated by assuming that the entire infused dose is injected instantaneously into the body as a bolus dose at the midpoint of the infusion period. Errors in such an approximation are negligible or insignificant when the infusion period to biological half-life ratios are low (22). For example, the error is ~0.1% when the ratio is 0.25.

In absorption studies, the plasma drug concentration of the first blood sample shortly after dosing, $C^{o}_{pt_1}$, also might be approximated satisfactorily by assuming that all drug absorbed up to the first sampling time, t_1, is absorbed instantaneously at the midpoint of the absorption period (*i.e.*, $0.5t_1$). The drug amount absorbed into the general circulation up to t_1 then can be calculated by comparing the $C^{o}_{pt_1}$ value with the theoretical plasma drug concentration, $C^{iv}_{p0.5t_1}$, at the midpoint of the absorption period (*i.e.*, $0.5t_1$) after an intravenous bolus dose. The drug amount absorbed between the first (t_1) and second (t_2) blood sampling periods can be estimated by the same principle after correction for the plasma level contribution, $C^{o}_{pp_1}$, at t_2 from the drug absorbed prior to t_1. Again, to calculate $C^{o}_{pp_1}$, all drug absorbed prior to t_1 is assumed to be absorbed instantaneously at $0.5t_1$. This can be done as follows: $C^{o}_{pp_1}$ = fraction of dose absorbed during the first absorption period × $C^{iv}_{p(t_2-0.5t_1)}$, where $C^{iv}_{p(t_2-0.5t_1)}$ is the theoretical plasma concentration at $(t_2 - 0.5t_1)$ when the same extravascular dose is given intravenously as a bolus. The same principle then can be used to calculate the drug amounts absorbed during other sampling intervals. The known or estimated absorption lag time should be corrected for the calculation of absorption periods.

[a] Based on data reported in Ref. 2. [b] Based on data generated by the first-order input equation using Eq. A8 in the *Appendix* where $K = 0.41\ hr^{-1}$. [c] Based on data reported in Refs. 2 and 4. [d] Based on the new method. [e] Based on $(1 - e^{-K_a t})$, where $K_a = 0.41\ hr^{-1}$. [f] Based on the newly generated C_p data shown in Column 3 of this table and the new method for absorption rate calculations.

The proposed method also can be described mathematically:

$$f_1 = \frac{C^o_{pt_1}}{C^{iv}_{p0.5t_1}} \qquad \text{(Eq. 1)}$$

where f_1 is the dose fraction absorbed up to t_1, expressed in terms of the fraction of the intravenous bolus dose. If the same dose is used in both intravenous and oral absorption studies, then the f_1 value will equal exactly the fraction of the oral dose absorbed into the general circulation up to t_1. The dose fraction absorbed during each subsequent period can be calculated by:

$$f_2 = \frac{C^o_{pt_2} - C^o_{pp_1}}{C^{iv}_{p0.5(t_2-t_1)}} \qquad \text{(Eq. 2)}$$

$$f_3 = \frac{C^o_{pt_3} - (C^o_{pp_1} + C^o_{pp_2})}{C^{iv}_{p0.5(t_3-t_2)}} \qquad \text{(Eq. 3)}$$

$$f_n = \frac{C^o_{pt_n} - \sum_{i=1}^{n-1} C^o_{pp_i}}{C^{iv}_{p0.5(t_n-t_{n-1})}} \qquad \text{(Eq. 4)}$$

The $C^o_{pp_i}$ value for the calculation of absorption in each period (Eq. 1, 2, or 4) is different, although the same symbol is used in these equations. For example, for the calculation of f_n in Eq. 4, the values are: $C^o_{pp_1} = f_1 C^{iv}_{p(t_n-0.5t_1)}$, $C^o_{pp_2} = f_2 C^{iv}_{p(t_n-0.5t_1-0.5t_2)}$, $C^o_{pp_3} = f_3 C^{iv}_{p(t_n-0.5t_2-0.5t_3)}$, and $C^o_{pp_{n-1}} = f_{n-1} C^{iv}_{p(t_n-0.5t_{n-2}-0.5t_{n-1})}$.

EXPERIMENTAL

Since this method was developed empirically, its validity must be examined using many examples with different disposition kinetic characteristics under various conditions such as first-order and zero-order absorptions.

Example 1—Loo and Riegelman (2) discussed a detailed theoretical example to illustrate the application of their method for a two-compartment open model system. Their absorption profile was reanalyzed using the proposed method. Close agreement between the two methods would support the applicability of the new method. Based on their microscopic rate constants (2) and other relevant data, the following biexponential plasma level equation may be obtained if the entire dose is injected instantaneously into the general circulation:

$$C_p = 12.37e^{-0.684t} + 7.857e^{-0.0725t} \qquad \text{(Eq. 5)}$$

where t is in hours.

Table II—Comparisons of Absorption Rates of Sulfisoxazole Calculated by the Proposed Method with the Theoretical Values following First-Order Absorption Kinetics

Hours	C_p[a], mg/liter	Cumulative Dose Fraction Absorbed	
		Calculated	Theoretical[b]
0.5	65.58	0.2925	0.2928
1.0	98.20	0.4994[c]	0.5000
1.5	113.29	0.6457	0.6464
2.0	118.95	0.7491[d]	0.7499
2.5	119.45	0.8222	0.8232

[a] Plasma levels after absorption study. [b] Based on $(1 - e^{-K_a t})$, where $K_a = 0.693\ hr^{-1}$. [c] With the assumption that the first blood sample was obtained at 1.0 hr, the calculated dose fraction absorbed would be 0.4977. [d] With the assumption that the first blood sample was obtained at 2 hr, the calculated dose fraction would be 0.7349.

The first-order absorption rate constant used in their simulation was $0.41\ hr^{-1}$. Some detailed absorption rate calculations based on this new method are illustrated in the *Appendix*, and the analysis results are summarized in Table I.

Example 2—The following mean biexponential equation was obtained after a bolus intravenous injection of 2000 mg of sulfisoxazole to seven normal subjects (24):

$$C_p = 108.43e^{-1.393t} + 152.13e^{-0.12t} \qquad \text{(Eq. 6)}$$

where C_p is in micrograms per liter and t is in hours.

Theoretical plasma drug concentrations at various times using a first-order absorption rate constant of $0.693\ hr^{-1}$ were generated in part with a programmable calculator. The dose used for absorption simulation also was 2000 mg. The plasma level data up to 2.5 hr after dosing are summarized in Table II.

The absorption simulation data generated throughout this discussion are based on a compartment- and model-independent approach. This approach is in contrast with the more commonly used compartmental approach. The general equation of the plasma level profile after a first-order input with an initial one-unit dose into a system where drug disposition kinetics following the intravenous bolus injection of the same unit of dose can be described by a polyexponential equation ($C_p = \Sigma_{i=1}^{n} A_i e^{-K_i t}$) is shown in the *Appendix*.

Example 3—The following mean biexponential equation was obtained after a bolus intravenous injection of 615 mg of ampicillin to nine subjects (25):

$$C_p = 120.4e^{-2.40t} + 12.12e^{-0.39t} \qquad \text{(Eq. 7)}$$

where C_p is in milligrams per liter and t is in hours.

The plasma level profile (Table III) during the early absorption phase was generated based on an initial dose of 615 mg and a first-order absorption rate constant of $2.0\ hr^{-1}$.

Example 4—The mean plasma level profile following the intravenous rapid injection of 10 mg of diazepam to four subjects (26) can be expressed by the following triexponential equation:

$$C_p = 0.23e^{-4.62t} + 0.15e^{-0.41t} + 0.062e^{-0.0225t} \qquad \text{(Eq. 8)}$$

where C_p is in milligrams per liter and t is in hours.

Based on the same intravenous dose absorbed with a first-order rate constant of $0.693\ hr^{-1}$, the plasma level data during the first 2.5 hr after dosing are summarized in Table IV.

Example 5—The drugs described in Examples 1–4 were infused at a unit intravenous bolus dose (the same intravenous dose used individually in each example) per hour to the same subjects. Theoretical plasma

level data at various times after the beginning of infusion were generated by the programmable calculator based on a compartment- and model-independent equation (see *Appendix*).

RESULTS AND DISCUSSION

The results of the absorption rate calculation using the standard Loo–Riegelman method (2, 4) and the proposed method for Example 1 are summarized in Table I. The values for cumulative dose fractions absorbed from 0.5 to 9.0 hr after dosing obtained from the two methods were essentially identical (up to three significant figures for some data). Since absorption was assumed to follow first-order kinetics with a rate constant, K_a, of 0.41 hr^{-1}, the cumulative dose fraction, F_t, absorbed at various times can be determined theoretically by:

$$F_t = 1 - e^{-K_a t} \qquad \text{(Eq. 9)}$$

These theoretical values are summarized in Table I; compared to them, the absorption rates calculated by the two methods were underestimated. Recalculation of theoretical plasma level data based on Eq. A2 in the *Appendix* revealed slight discrepancies between the reported values (2, 4) and the newly generated values (Table I). Using these new plasma level data and the proposed absorption rate calculation, the calculated cumulative dose fractions (Table I) absorbed at various times were essentially identical (identical values up to four significant figures for data at 3, 3.5, and 4 hr) to the theoretical values. These results were encouraging during early evaluation of the new method.

The total area under the plasma level–time curve from Eq. 5 calculated by the integration method was essentially identical to the total area from the absorption study reported (4) (126.46 *versus* 126.44), indicating the correctness of Eq. 5. In the absorption rate analyses, 97.5% of the dose theoretically was absorbed at 9 hr after dosing.

The results of the absorption study on sulfisoxazole (Example 2), which exhibited two-compartment properties, are summarized in Table II. The excellent accuracy of the new method also was demonstrated in this example. The first blood sample, obtained 1 or 2 hr after dosing, gave calculated fractions of the dose absorbed of 0.4977 and 0.7349, respectively. These values compared well with the corresponding theoretical values: 0.5000 and 0.7491.

The results for ampicillin (Example 3) are shown in Table III. This drug was selected due to its relatively large contribution of the distribution phase (21.5% of the total area, AUC_∞). A high degree of accuracy also was observed with the new method.

The results of the absorption rate analysis of diazepam in Example 4 are summarized in Table IV. Despite its three-compartment characteristics, errors of the absorption rate estimate for each sampling period and the cumulative absorption calculated by the new method were insignificant, except for the first 0.5-hr point where absorption was overestimated by 4.17%. The overestimation for the 0.5–1.0-hr period was only 0.63%, and the underestimations for the next three sampling periods were <2% (Table IV). The accuracy of the new method was improved considerably if the first blood sample was obtained at an earlier time. For example, the overestimation was reduced to only 1.48% when the 0.25-hr plasma level (0.05382 mg/liter) was used for calculation.

The Loo–Riegelman method without the Taylor expansion series also was employed to calculate the diazepam absorption rate discussed in Example 4. The results are summarized in Table IV. The Loo–Riegelman method underestimated absorption up to 0.5 hr by 5.55%, which was slightly greater (based on absolute percent) than the 4.17% underestimation based on the new method. In this example, the new method always overestimated the cumulative absorption values (up to 2.5 hr) while the Loo–Riegelman method always underestimated them. However, the absolute percentages of over- or underestimation by these two methods were practically the same (Table IV). The accuracy of both methods for calculating the diazepam absorption rates was demonstrated by the fact that, at 2.5 hr after dosing when 82.32% of the dose had been absorbed, the new method overestimated the absorption by 1.1% while the Loo–Riegelman method underestimated it by 1.22% (Table IV).

The new method also had essentially the same accuracy as the Wagner–Nelson method on theoretical compounds with one-compartment characteristics.

These results clearly demonstrate the accuracy and applicability of the new simple method for the calculation of absorption rates of compounds with markedly different pharmacokinetic properties under first-order absorption. In Examples 1 and 4, both the new method and

[a] Percent difference from the theoretical value.

the standard Loo–Riegelman method yielded essentially the same results, indicating the similar accuracy of both methods.

In absorption rate studies, the first blood sample occasionally is not collected soon after dosing. Evaluation of the effect of the time of the first blood sample on the accuracy of the new method was important. This effect was evaluated thoroughly using the data in Example 1. Results of comparisons using the first plasma level at 1, 2, 3, 4, 5, or 6 hr are summarized in Table V. This example shows that the new method is much less subject to the influence of the timing of the first sample. For example, with samples at 4, 5, and 6 hr, the new method gave underestimations in absorption of 4.18, 6.13, and 8.24%, respectively, while the Loo–Riegelman method gave underestimations of 19.0, 24.1, and 28.6%, respectively. For diazepam (Example 4), the new method resulted in a 7.22% overestimation, and the Loo–Riegelman method (without the Taylor expansion series) yielded a 10.1% underestimation if the first sample at 1 hr was used. The results for the new method are encouraging since the majority of drug absorption kinetics reported in the literature appear to follow the first-order process. Frequent blood sampling and the use of interpolated plasma level data between adjacent observed points were recommended for obtaining greater accuracy when applying the Loo–Riegelman method to oral data (15).

The accuracy of the new method under zero-order absorption was evaluated also. Extremely accurate (identical up to three or four significant figures in many cases) results were obtained for the hypothetical drug discussed in Example 1, ampicillin, and sulfisoxazole (Tables VI and VII). For sulfisoxazole and ampicillin, the results from the Loo–Riegelman method without the Taylor approximation were equally accurate (Table VII). For diazepam, which exhibited triexponential decay after intravenous dosing, the new method overestimated the absorption (Table VIII) in the first 2.5 hr of simulation. The overestimation was the greatest (6.5%) in the first 0.5 hr of study and decreased gradually (only 1.2% between 2.0 and 2.5 hr). The overestimation was reduced to only 2.2% when the first blood sample was taken at 0.25 hr after the beginning of the zero-order absorption. Considering the variability in the biological system and the accuracy of the dose administered and the plasma levels analyzed, these overestimations can be regarded as insignificant. However, the Loo–Riegelman method yielded more accurate results in this example (Table VIII). For example, it resulted in only a 3.43% underestimation when the first sample at 0.5 hr was used for calculation.

The oral absorption kinetics of sulfadimethoxine in a steer were reported previously (16). The steer, 190.68 kg, was given an initial oral dose of 12.5 g; blood samples were collected at 4, 8, 12, and 24 hr after dosing. Approximately 5 months later, the same animal, weighing 266.8 kg, received a rapid intravenous injection of 17.502 g. The plasma level profile after intravenous injection was described by a triexponential equation, which corresponded to a three-compartment open model (16). The absorption rates were calculated by the Loo–Riegelman method with and without the Taylor approximation.

Since the body weights of the steer during the oral and intravenous studies were different, an approximation assuming that the intercompartmental distribution rate constants remained constant during the two studies was made (16). In other words, intercompartmental clearances were assumed to increase with increasing body weight, as reflected by changes in the volume of distribution. In applying the proposed method for the absorption rate calculation to this example, only the coefficients of the triexponential plasma level decay equation were inversely corrected for the body weight change (*i.e.*, the volume of the central or initial compartment was proportional to the body weight). Thus, the C_p profile after a 1.0-g intravenous bolus dose at the time of the oral study can be expressed by:

$$C_p = 16.00e^{-9.11t} + 5.281e^{-0.55t} + 15.36e^{-0.0580t} \quad \text{(Eq. 10)}$$

when C_p is in milligrams per liter and t is in hours.

The results of the absorption rate analysis using the new method and the Loo–Riegelman method without the Taylor approximation were similar and encouraging (Table IX); the difference in the cumulative absorption at 24 hr was only 1.56%. The facts that the absorption rate appeared to follow approximately the first-order process (16) and that the first sample was collected only 4 hr after dosing may partially explain why the cumulative absorption at 4 hr calculated by the new method was 8.17% higher than that obtained with the Loo–Riegelman method (in view of the data in Table V). The validity of the new method in the flip-flop absorption condition also was confirmed.

The results of the extensive example analyses clearly demonstrate that the new method might be potentially useful for absorption rate calculations. Its simplicity is shown clearly in the *Appendix*. In contrast to the standard Loo–Riegelman method, the present method does not require the assumption of any pharmacokinetic compartmental model and the calculation of microscopic compartmental constants. Such calculations would be complicated in the classical three-, four-, or five-compartment mammillary model systems (27, 28). The volume of the central compartment (the initial volume of distribution) also is not needed.

Furthermore, the plasma level profile shortly after intravenous dosing theoretically does not need to be known in the new method. For example, the intravenous plasma data before 0.25, 0.75, and 0.125 hr were not necessary in the absorption rate calculations in Examples 1, 2, and 4, respectively. This feature of the new method may be important since drug disposition kinetics immediately or shortly after intravenous dosing often are much more complicated than commonly assumed or understood in conventional pharmacokinetic studies (29). In addition, the apparent value of the volume of the central compartment and the apparent number of compartments in the multicompartment analysis often may be subject to the influence of the frequency and timing of the blood sampling schedule in intravenous studies (30).

Moreover, the new method requires an accurate plasma level profile in the intravenous study for only a short period. For example, the intravenous data up to only 8.75 hr were required for the absorption rate calculation in Example 1. The terminal biological half-life of this hypothetical compound is 9.56 hr. For sulfisoxazole in Example 2, the intravenous data up to 2.25 hr were sufficient for the absorption rate calculation. The terminal half-life of the drug in this example is 5.78 hr. Therefore, if the individual or mean pharmacokinetic parameters (*i.e.*, the disposition function discussed in the *Appendix*) between the intra-

Table VIII—Comparisons of the Zero-Order Absorption Rate Analysis of Diazepam in Examples 4 and 5 Calculated by the Loo–Riegelman Method and the New Method

Hours	C_p, mg/liter	Cumulative Fraction of Unit Intravenous Dose Absorbed: Theoretical	Calculated by New Method	Calculated by Loo–Riegelman Method
0.5	0.1435	0.5000	0.5325 (6.50)[a]	0.4829 (−3.43)[a]
1.0	0.2337	1.0000	1.0472 (4.72)	0.9875 (−1.25)

2.5	0.4351	2.5000	2.5690 (2.76)	2.4912 (−0.352)
0.25[b]	0.08520	0.25000	0.2555 (2.2)	0.2459 (−1.64)

[a] Percent deviation from the theoretical value. [b] Data are based on the first blood sample collected at 0.25 hr.

venous and oral studies in the same subject or same panel of subjects may be assumed to be the same, the present method may be applied without knowledge of the terminal biological half-life of the drug as long as the intravenous data during a certain period can be obtained or generated accurately. This feature could be valuable for drugs with long biological half-lives (*e.g.*, greater than several days or weeks). As an approximation for the absorption rate calculation, the needed plasma level data can be obtained directly from a semilogarithmic intravenous data plot.

Despite these advantages, experimental protocols for studying complete plasma level profiles are recommended. For more accurate determination of absorption kinetics, a sufficient number of blood samples should be collected in absorption studies. The present method also might be used (perhaps as a good approximation) for drugs showing unusual plasma level profiles due to extensive enterohepatic circulation. Similarly, the method probably can be used with some salivary or urinary data obeying linear pharmacokinetic principles. Precautions in using saliva level data for pharmacokinetic studies were discussed previously (31–34).

The most unique assumption made in the proposed method is that all of the drug absorbed during a given interval, regardless of the complexity of the true absorption kinetics, is absorbed instantaneously at the midpoint of the interval. This assumption now has been shown to result in useful and practical applications for the determination of the apparent volume of distribution and total body clearance after a constant-rate intravenous drug infusion (22, 23) and for the absorption rate calculation. The method using such an assumption will be referred to as the instantaneous midpoint-input method.

The absolute accuracy of this new method for absorption rate calculations is a function of many factors such as the absorption rate, the drug disposition function, and the blood sampling schedule. This dependence is similar to the problems of the accuracy of the trapezoidal rule method for the estimation of the area under the curve (21) and the instantaneous midpoint-input method for the estimation of the volume of distribution and total body clearance (22, 23). Many digital computer programs also are available for the calculation of drug absorption rates (3, 4, 35).

APPENDIX

Sample Calculations Using New Method for Example 1—Absorption rate calculations based on the oral data reported in the literature (2, 4) in the first 1.5 hr after dosing are used for illustration. The oral data were taken from Table I. The intravenous data were generated from Eq. 5. They are 18.14, 14.85, and 12.437 at 0.25, 0.75, and 1.25 hr, respectively.

The dose fraction absorbed up to 0.5 hr, $f_{0.5\text{ hr}}$, is:

$$f_{0.5\text{ hr}} = \frac{C^o_{p0.5\text{ hr}}}{C^{iv}_{p0.25\text{ hr}}} = \frac{3.0}{18.14} = 0.1654 \qquad \text{(Eq. A1)}$$

The dose fraction absorbed between 0.5 and 1 hr, $f_{1\text{ hr}}$, is calculated from:

$$\text{contribution from 0 to 0.5 hr } (C^o_{pp0.5\text{ hr}}) = C^{iv}_{p0.75\text{ hr}} \times f_{0.5\text{ hr}} \qquad \text{(Eq. A2}a\text{)}$$

$$= 14.85 \times 0.1654 \qquad \text{(Eq. A2}b\text{)}$$

$$= 2.456 \qquad \text{(Eq. A2}c\text{)}$$

Table IX—Comparisons of Absorption Rate Calculations of Sulfisoxazole in a Steer by the Loo–Riegelman Method and the New Method

Hours	Cumulative Amount Absorbed, mg: Based on Loo–Riegelman Method[a]	Based on New Method
4	3294	3563 (8.17)[b]
8	5445	5679 (4.30)
12	6525	6710 (2.83)
24	7610	7729 (1.56)

[a] Calculated from Ref. 16. [b] Percent overestimation as compared to the value obtained from the Loo–Riegelman method.

and:

$$f_{1\text{ hr}} = \frac{C^o_{p1\text{ hr}} - C^o_{pp0.5\text{ hr}}}{C^{iv}_{p0.25\text{ hr}}} = \frac{5.20 - 2.456}{18.14} = 0.1513 \qquad \text{(Eq. A3)}$$

Therefore, the cumulative dose fraction absorbed up to 1 hr = 0.1654 + 0.1513 = 0.3167.

The dose fraction absorbed between 1.0 and 1.5 hr, $f_{1.5\text{ hr}}$, is calculated from:

$$C^o_{pp0.5\text{ hr}} = C^{iv}_{p1.25\text{ hr}} \times f_{0.5\text{ hr}} = 12.437 \times 0.1654 = 2.057 \qquad \text{(Eq. A4)}$$

$$C^o_{pp1\text{ hr}} = C^{iv}_{p0.75\text{ hr}} \times f_{1\text{ hr}} = 14.85 \times 0.1513 = 2.247 \qquad \text{(Eq. A5)}$$

and:

$$f_{1.5\text{ hr}} = \frac{C^o_{p1.5\text{ hr}} - C^o_{pp0.5\text{ hr}} - C^o_{pp1\text{ hr}}}{C^{iv}_{p0.25\text{ hr}}} \qquad \text{(Eq. A6}a\text{)}$$

$$= \frac{6.5 - 2.057 - 2.247}{18.14} = 0.1211 \qquad \text{(Eq. A6}b\text{)}$$

Therefore, the cumulative dose fraction absorbed up to 1.5 hr = 0.3167 + 0.1211 = 0.4378. For the calculation of absorption between 7 and 9 hr, $C^{iv}_{p1.0\text{ hr}}$ rather than $C^{iv}_{p0.25\text{ hr}}$ should be used.

General Equation for Plasma Level Profile after First-Order Input—If it is assumed that after an instantaneous intravenous injection of a unit drug dose, the plasma level–time profile, $C_{p_{inst}}$, can be described adequately by the following polyexponential equation (disposition function):

$$C_{p_{inst}} = \sum_{i=1}^{n} A_i e^{-K_i t} \qquad \text{(Eq. A7)}$$

the general equation to describe its plasma level profile, C_p, after the same unit drug dose with a first-order absorption rate constant, K_a, can be derived by using the input–output convolution method with the assistance of the Laplace transform technique (36). The general equation derived is:

$$C_p = K_a \sum_{i=1}^{n} \frac{A_i}{K_i - K_a} (e^{-K_a t} - e^{-K_i t}) \qquad \text{(Eq. A8)}$$

In absolute terms, Eq. A7 is incorrect because the plasma drug level at the sampling site immediately after dosing (*i.e.*, time = zero) is zero due to a definite lag time of the drug to be transported from the injection site to the sampling site and the complicated disposition kinetics shortly after dosing (29).

General Equation for Plasma Level Profile after Zero-Order Input—When the zero-order absorption rate is K_0 unit of dose per unit of time, the general equation to show the plasma level profile, C_p, during the zero-order absorption can be derived similarly as:

$$C_p = K_0 \left(\sum_{i=1}^{n} \frac{A_i}{K_i} - \sum_{i=1}^{n} \frac{A_i}{K_i} e^{-K_i t} \right) \qquad \text{(Eq. A9)}$$

Oxygen Solubilization in Egg Lecithin Dispersed in Distilled Water and Physiological Electrolyte Fluids

R. SAUL LEVINSON *[x], SERAP BUYUKYAYLACI [‡], and LOYD V. ALLEN, Jr. [§]

Received April 10, 1979, from the **Arnold & Marie Schwartz College of Pharmacy and Health Sciences, Long Island University, Brooklyn, NY 11201*, the [‡]*School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907*, and the [§]*College of Pharmacy, University of Oklahoma, Oklahoma City, OK 73190.* Accepted for publication July 31, 1979.

Abstract □ Gaseous oxygen solubilization in egg lecithin dispersed in distilled water, saline, and a multi-ion physiological electrolyte solution was determined and compared to controls deficient in egg lecithin. Significant oxygen solubilization occurred in the presence of egg lecithin. Oxygen solubilization was significantly greater in saline and in the multi-ion physiological electrolyte solution than in distilled water.

Keyphrases □ Solubilization—of oxygen in egg lecithin dispersed in distilled water and physiological electrolyte fluids □ Lecithin, egg—dispersions in distilled water and physiological electrolyte fluids, oxygen solubilization □ Pulmonary surfactant model systems—egg lecithin dispersions in distilled water and physiological electrolyte fluids, oxygen solubilization □ Model systems, pulmonary surfactant—egg lecithin dispersions in distilled water and physiological electrolyte fluids, oxygen solubilization □ Oxygen—solubilization in egg lecithin dispersions in distilled water and physiological electrolyte fluids

Several studies (1–5) demonstrated that respiratory disease syndrome[1] is a direct result of a pulmonary surfactant deficiency. Mammalian lung surfactant was shown to be primarily dipalmitoyl phosphatidylcholine (I) (6–8). Since I also is the major constituent of egg (*Gallus domesticus*) lecithin (9), egg lecithin dispersions serve as convenient and relatively inexpensive pulmonary surfactant model systems.

[1] Hyaline membrane disease.

Micellar oxygen solubilization in lung surfactant was proposed (10) as a mechanism for oxygen transposition at the alveolar membrane. Other studies (11–14) demonstrated the ability of lung surfactant to solubilize oxygen and other nonpolar gases.

The effect of the presence of electrolytes at physiological concentrations on oxygen solubilization in aqueous egg lecithin dispersions is reported here.

EXPERIMENTAL

Glass reaction vials were cleaned ultrasonically[2] in 2% aqueous detergent[3], rinsed three times with tap water, and rinsed three times with deionized, glass-distilled water[4]. The vials were air dried in a ventilated oven at 200°.

Egg lecithin[5] was weighed accurately to yield 50-ml samples of 0.25, 0.50, 0.75, and 1.00% (w/v) phospholipid in normal saline[6], physiological electrolyte solution[7], and deionized, glass-distilled water. A magnetic

stirring bar was included in each sample vial before addition of the dispersion medium. Each vial was sealed with a rubber septum and an aluminum crimp seal and then was flushed with ultrapure (99.99%) humidified nitrogen[8]. Accurately measured volumes of the dispersion media were added after an equivalent volume of nitrogen gas was withdrawn from the vial. Each vial then was stirred gently on a magnetic stirring plate until homogeneous dispersion was effected.

Ten milliliters of nitrogen gas was withdrawn accurately from each vial, and an equivalent volume of ultrapure oxygen[9] was added with gas-tight gas transfer syringes[10]. While the dispersions were stirred gently on the magnetic stirring plate, 10-μl samples of the gaseous phase were withdrawn at 0, 24, 48, 96, and 120 hr.

Vials of normal saline, physiological electrolyte solution, and distilled water were prepared deficient in egg lecithin to serve as controls.

Each egg lecithin sample and its corresponding control sample were prepared and analyzed in triplicate, and each experiment was done in duplicate.

Analysis of the residual oxygen at the indicated times was accomplished by GLC[11]. The nitrogen–oxygen mixture was resolved on a molecular sieve[12] with thermal conductivity detection[13]. The peak area as the percent of detector response for oxygen was calculated and recorded with an electronic integrator[14].

Helium[8] was the carrier gas at 21 ml/min. The inlet, detector, and column temperatures were 100, 100, and 50°, respectively.

Since the sealed experimental and control vials were flushed with nitrogen to an open atmosphere and an equivalent volume of nitrogen gas was withdrawn when oxygen was added, the pressure in the closed system was equal to atmospheric pressure during sample preparation. Minor pressure effects due to the withdrawal of 10-μl gas samples at the indicated times were regarded as insignificant. Furthermore, any manipulative error introduced was offset in the statistical analysis because the control samples were treated the same as the experimental samples.

RESULTS AND DISCUSSION

Figures 1–3 indicate that, in comparison to the controls, considerable oxygen solubilization occurred in aqueous egg lecithin dispersions. Furthermore, differences in the amount of gaseous oxygen solubilized can be demonstrated for all three aqueous media used, with the multi-ion physiological electrolyte fluid and saline exhibiting the greatest solubilization. Statistical analysis of the data (Tables I and II) utilizing a three-factor analysis of variance indicated statistically valid differences in gaseous oxygen solubilization among the media employed, the egg lecithin concentration, and time.

Table II presents the statistical data including the control samples, while Table I excludes the controls. This contrast was done to identify the greatest variance ratio components. The incubation time had the greatest influence on oxygen solubilization, followed by the medium employed and then the egg lecithin concentration. This egg lecithin concentration effect, as determined statistically, is not surprising because solubilization requires only that micelles be present. Apparently, the egg lecithin concentration range used (0.25, 0.50, 0.75, and 1.00%) was above the critical micelle concentration for the surfactant in the media.

The presence of electrolytes can affect the size of surfactant micelles by forcing surfactant molecules into micellar units similar to the way in which electrolytes can be used to dehydrate or salt out sparingly soluble organic molecules from water.

The diffusional aspect of oxygen transposition was the rate limiter because the effect of time on oxygen transposition can be demonstrated statistically to be the predominant factor controlling oxygen solubilization.

This study indicated that, in the development of synthetic, natural, or semisynthetic lung surfactant for treatment of respiratory disease syndrome and other pulmonary surfactant diseases, the medium employed may overshadow the particular surfactant used. Further study with the egg lecithin pulmonary surfactant model system is warranted.

Kinetics and Mechanisms of Monolayer Interactions V: Surface Activities of Alkylamides, Alkylmonocarboxylic Acids, and Alkylketones and Their Interaction Energies with Phospholipid Monolayers

FEDERICO A. VILALLONGA ˣ **and EDWARD W. PHILLIPS**

Received May 2, 1979, from the *College of Pharmacy, University of Florida, Gainesville, FL 32610.* Accepted for publication July 24, 1979.

Abstract □ The adsorption free energies of the C_1–C_6 alkylamides, C_3–C_8 alkylketones, and C_1–C_{10} alkylmonocarboxylic acids at the air–water interface, estimated from plots of the surface pressure (≤5 dynes/cm) *versus* the bulk concentration, were linear functions of the total surface area per molecule (square angstroms per molecule), with a slope 46% higher for the alkylamides and 25% lower for the alkylketones than that for the monocarboxylic acids. The interaction energies of alkylamides with dipalmitoyl lecithin and dipalmitoyl phosphatidylethanolamine spread at the air–water interface, estimated from the surface pressure increase with increasing concentrations of the injected C_1–C_5 compounds, were linear functions of the total surface area per molecule. The diffusion free energies, ΔG_{dif}, of the alkylamides within a phospholipid bilayer, predicted from the permeability equation and their interaction energies with dipalmitoyl lecithin monolayers by assuming the additivity of their free energies of adsorption and dehydration at the solution–bilayer interface, agreed with the literature data.

Keyphrases □ Surface activity—alkylamides, alkylmonocarboxylic acids, and alkylketones, interaction energies with phospholipid monolayers □ Phospholipid monolayers—interaction energies with alkylamides, alkylmonocarboxylic acids, and alkylketones □ Interaction energies—alkylamides, alkylmonocarboxylic acids, and alkylketones with phopholipid monolayers

The adsorption free energies of alkanols at the air–aqueous interface estimated from plots of the surface pressure *versus* the bulk concentration were compared (1) with their interaction energies with dipalmitoyl lecithin (I) and dipalmitoyl phosphatidylethanolamine (II) monolayers, estimated from the variation of the equilibrium surface pressure with varying concentrations of subphase-injected alkanols based on a collision model and a constant entropy factor (2, 3).

The present work compares the adsorption free energies at the air–aqueous interface of alkylamides, their *N*-methyl derivatives, alkylmonocarboxylic acids, and alkylketones with those of the alkanols and with their interaction energies with I and II monolayers. Correlations between the surface activities and the molecular surface areas of the compounds are considered, and the implications with partition coefficients and permeabilities of these substances through biomembranes and liposomes are discussed.

EXPERIMENTAL

Reagents—Dipalmitoyl lecithin[1] and dipalmitoyl phosphatidylethanolamine[1] were homogeneous by TLC (4). Reagent grade formamide[2], acetamide[3], propionamide[4], butyramide[5], valeramide[2], hexanamide[2], *N*-methyl-[2] and *N,N*-dimethylformamide[2], *N*-methyl-[2] and *N,N*-dimethylacetamide[5], *N*-methyl-[2] and *N,N*-dimethylpropionamide[2], *N*-methyl-[6] and *N,N*-dimethylbutyramide[6], *N,N*-dimethylvaleramide[2], *N,N*-dimethylhexanamide[2], formic acid[4], propionic acid[3], butyric acid[5], valeric acid[5], hexanoic acid[5], octanoic acid[5], decanoic acid[5], propanone[5], 2-butanone[5], 2-pentanone[5], 2-hexanone[5], and 2-octanone[5] were used without further purification. The hexane[7] used to prepare the spreading solution and the distilled water used to prepare the aqueous solution and as a subphase for the phospholipid monolayers fulfilled the requirements described previously (2, 3).

Instruments—A 9-cm diameter polytef dish with two identical microburets[8] and a polytef-coated stirring bar (1.25 × 0.8 cm) was used as a trough in the closed system described previously (2, 3). Surface tension was measured with a Wilhelmy platinum plate (2.5 × 1.25 × 0.01 cm) attached to an electrobalance[9] whose output was fed into a recorder[10].

Surface Tensions of Aqueous Solutions—The surface tension of the aqueous solutions was measured as described previously (1). The reproducibility was within ±0.2 dyne/cm. All experiments were performed at 21 ± 1°. The surface pressure, π, obtained by the difference between the previously determined surface tension of the pure water and the surface tension of the aqueous solution, was fitted to an exponential function of the concentration, C (moles per liter), by digital computerized nonlinear regression (1). The Gibbs adsorption equation was used in the form described previously (1):

$$\Gamma_2 = \frac{d\pi}{d \ln C_2}\left(\frac{1}{kT}\right) \qquad \text{(Eq. 1)}$$

where Γ_2 is the solute surface concentration (molecules per square centimeter), π is the surface pressure (dynes per centimeter), C_2 is the solute concentration in the bulk solution (moles per liter), k is the Boltzmann constant (ergs per molecule per degree), and T is the absolute temperature (°K). The derivative ($d\pi/d \ln C_2$) of the exponential function that approximates the surface pressure dependence on concentration was computed with respect to the logarithm of the concentration. Substitution of these values into Eq. 1 permitted calculation of Γ_2 at any C_2.

Injection under Phospholipid Monolayers—Spreading of the phospholipid monolayers and injection of the test substance were performed as described previously (1–3). The initial phospholipid monolayer surface pressure was 5 ± 0.1 dynes/cm in all experiments. The criterion of equilibrium after the injection of the studied substance was the constancy (±0.1 dyne/cm) of the surface pressure increment, $\Delta\pi$, during 30 min.

RESULTS

Adsorption at Clean Air–Aqueous Interface—Typical plots of the surface pressure *versus* the logarithm of the concentration for some compounds are given in Figs. 1–4. Plots of surface pressure *versus* log concentration obtained with 0.1 *M* HCl solutions of the alkylmonocarboxylic acids coincided with those of their pure water solutions within reproducibility limits.

The standard free energy change, ΔG°_{ad} (ergs per molecule), associated with solute adsorption at the clean air–aqueous interface was estimated from (1, 5):

$$\Delta G^\circ_{ad} = -kT \ln \frac{\pi}{x_2^*} \qquad \text{(Eq. 2)}$$

where x_2^* is the solute activity. The ΔG°_{ad} values were calculated from the slope (π/x_2^*) of the plot of π (≤5 dynes/cm) *versus* the solute mole fraction

in the bulk solution, x_2, when $x_2 \rightarrow 0$ and $x_2^* \rightarrow x_2$ at low mole fractions. For all compounds, plots of the surface pressure ($\pi \leq 5$ dynes/cm) *versus* the solute mole fraction in the bulk solution were reasonably linear. The correlation coefficients (r), the slopes, and the estimated ΔG°_{ad} values obtained from such plots are given in Table I.

It was shown previously (1) that the simultaneous effect of the chain length and the position of the hydroxyl group on the alkanol surface activity is described best by the total molecular surface area, TSA (square angstroms per molecule), of the alkanol molecule. Molecular surface areas of the compounds were calculated by a modified version (6) of the original computer program MOLAREA (7). The molecule was considered as a collection of spherical groups and individual atoms. The methyl, methylene, and hydroxyl groups were approximated as single spheres, and standard geometry and interatomic bond lengths and angles (8, 9) were used in the construction of the molecules. These molecular surface areas are listed in Table I.

Plots of ΔG°_{ad} *versus* the total molecular surface area of alkylamides, their *N*-methyl derivatives, alkylmonocarboxylic acids, and alkylketones are compared in Fig. 5 with those for the alkanols. The experimental points yielded reasonably straight lines within the estimated experimental error (0.14 erg/molecule or 0.2 kcal/mole). The correlation coefficients and the slopes are listed in Table II.

[a] From Ref. 31. [b] From Ref. 12. [c] From Ref. 33. [d] Number of carbon atoms in the hydrocarbon chain.

The slopes of the plots of the alkylmonocarboxylic acids and the *N*-methyl- and *N*-dimethylalkylamides were 13 and 10% smaller than those of the alkanols, respectively. The slopes of the plots of the alkylamides and alkylketones were 27% greater and 35% smaller than those of the alkanols, respectively.

Interaction with Phospholipid Monolayers—The interaction energies, ψ, were estimated from the slopes of the plots of the reciprocals of the equilibrium surface pressure, $\Delta\pi_{eq}$, after injection *versus* the reciprocals of the final concentration, n (molecules per cubic centimeter), of the subphase-injected substance (1–3). They are listed in Table I and are plotted in Figs. 6 and 7 *versus* the total surface area per molecule.

The plots for I monolayers were reasonably linear for alkylmonocarboxylic acids (C_1–C_8) and alkylamides (C_1–C_6) and their *N*-dimethyl derivatives. The interaction energies per methylene group, ψ_{CH_2}, estimated from the slopes of the plots of alkylmonocarboxylic acids and alkylamides (Table II), were similar to those of the alkanols (7), but the interaction energy of the *N*-dimethylalkylamides was 50% smaller.

For II monolayers, the interaction energies of formic acid, hexanamide, and *N*,*N*-dimethylhexanamide presented gross departures from linearity. The interaction energies per methylene group were higher for alkylamides and alkylmonocarboxylic acids and smaller for *N*-dimethylalkylamides than those of the alkanols.

The interaction energies of the first three compounds of the alkylketone series with I monolayers showed the same value within the estimated experimental error. In the interaction with II monolayers, the correlation coefficient was 0.93.

DISCUSSION

Adsorption at Clean Air–Aqueous Interface—From one compound of each of the studied homologous series to the next compound, there was a constant surface area increase of the hydrophobic moiety that progressively changed the hydrophilic–hydrophobic balance of the molecules. The slopes of the linear plots of the adsorption free energy *versus* the total

molecular surface area thus represent the contribution of each square angstrom increment of the hydrophobic surface area of the molecules to their total adsorption free energy.

The contribution to the molecular surface area due to an incremental methylene group in a straight chain extended conformation was estimated recently to be 18.1 Å² (6). The adsorption free energies per methylene group, ΔG_{CH_2}, of the studied homologous series calculated using this surface area contribution are listed in kilocalories per mole in Table II.

Since early findings obtained mainly with aliphatic alcohols, acids, and their esters (10, 11) were confirmed by several subsequent studies (1, 12–15), it generally has been accepted that the adsorption free energy increase produced by an incremental methylene group addition to a saturated straight hydrocarbon chain that adsorbs at the air–water interface is between 0.600 and 0.625 kcal/mole. The average value (0.603 ± 0.07 kcal/mole) obtained in the present study (Table II) for alkanols, alkylmonocarboxylic acids, and *N*-dimethylalkylamides reasonably agreed.

It is difficult to understand why the slope corresponding to the plot of the adsorption free energy *versus* the total molecular surface area for the alkylamides is 39% higher and that of the alkylketones is 29% lower than the average value (0.603 ± 0.07 kcal/mole) obtained for the rest of the homologous series.

The possibility existed that a different polar group attached to the same hydrocarbon chain might cause a different charge to be transferred along the methylene groups of the hydrocarbon chain, thus altering their interaction with the solvent molecules. Molecular orbital calculations performed on isolated molecules of 23 selected alkylamides, alkylmonocarboxylic acids, and alkanols failed to show evidence of a charge perturbation of the methylene groups beyond the first that could account for the observed effects of the amide group.

The fact that the adsorption free energy per methylene group of the *N*-methyl- and *N,N*-dimethylalkylamides is practically the same as that of the alkanols and alkylmonocarboxylic acids seems to indicate that the unsubstituted amino (NH_2) group is responsible for the higher adsorption free energy per methylene group in amides. Of the studied series, the amide group presents the higher hydrogen bonding capability. On the basis of *ab initio* self-consistent field method (SCF) computations of various polyhydrates, evidence was presented (16) for the structure of formamide in aqueous solutions consistent with a model of four water molecules in the primary hydration sphere, two of them hydrogen bonded to the amino group acting as a proton donor.

The standard adsorption free energy, ΔG°_{ad} (Eq. 2), is the free energy change associated with the transfer of one molecule from infinite dilution in bulk solution to infinite dilution at the interfacial region (5) and thus is a measure of the work of transfer. Kinetic data obtained for the time-dependent effect of cetrimonium ions injected beneath an air–aqueous interface on the water surface tension showed (17) excellent fit and consistency with a model that postulates an intermediate compartment (subinterface) between the plane of the interface and the bulk aqueous solution. This compartment is assumed to be a thin region with a thickness of 10–10^3 water molecule diameters (18) where the water molecules are oriented in a given array (19–21). Consequently, adsorption might be assumed to be energetically equivalent to the transfer of a solute molecule from a normal water environment in the bulk solution to the subinterface region where the water molecules are abnormally oriented.

Solute molecules such as those studied in the present work may interact with water molecules through hydrogen bonding of the polar hydrophilic group and through London dispersion forces generated mainly from its hydrophobic moiety. The negative standard adsorption free energies of formamide (−2.2 kcal/mole), formic acid (−3.3 kcal/mole), and methanol (−3.6 kcal/mole) indicate that the spontaneous tendency to perform the transfer from the bulk solution to the subinterface increases in the order: methanol > formic acid > formamide. Methanol and formamide present the minimum and maximum capabilities, respectively, to hydrogen bond with water; therefore, these results seem to indicate that, for these short-chain molecules, a correlation exists between their adsorption free energies at the air–aqueous interface and the hydrogen bonding capability of their hydrophilic moieties. The facts that aqueous urea solutions showed (22) a negative excess surface concentration (*i.e.*, $\Delta G^{\circ}_{ad} > 0$) and that thiourea in aqueous solution showed a negative adsorption free energy in preliminary experiments performed in this laboratory seem to corroborate this hypothesis.

The increase of the hydrocarbon chain length increases the surface area of the hydrophobic moiety only, enhancing its interaction through London dispersion forces with the water molecules. It seems reasonable that, at a given chain length, the adsorption free energy difference provoked by the different hydrophilic groups should be minimized due to the preponderant effect of the hydrophobic moiety. The adsorption free energies of hexanol, hexanoic acid, and hexamide are −6.8, −6.9, and −6.3 kcal/mole, respectively, in accord with this expectation; however, even for this chain length, hexanamide shows a significantly smaller value.

Experiments performed in this laboratory showed that, at constant temperature, the surface tension of heptanol–heptane mixtures adheres to the additivity rule represented by:

$$\gamma_{12} = \gamma_1 X_1 + \gamma_2 X_2 \qquad \text{(Eq. 3)}$$

where γ_{12} is the surface tension of the mixture and γ_1, γ_2, X_1, and X_2 are the surface tensions in the pure state (26.4 and 20.6 dynes/cm) and the mole fractions of heptanol and heptane in the mixture, respectively.

The surface tension of an aqueous solution containing 5.8×10^{-5} mole fraction of heptanol is 55 dynes/cm at 20°; *i.e.*, the surface tension of pure water (72.6 dynes/cm) is decreased 23% by the initial presence in the bulk solution of approximately six heptanol molecules/10^5 water molecules. A heptanol–heptane mixture containing this same heptanol mole fraction has the same surface tension as pure heptane within experimental error. In this last case, Eq. 1 predicts that the heptanol concentration at the interface is identical to that of the bulk solution. This fact suggests that

Table III—Diffusion Free Energies, ΔG_{dif}, of Alkylamides within a Phospholipid Bilayer

Compound	K, water–ether	$P^a \times 10^5$, cm/sec	$\Delta G_{dif}^{\ddagger a}$, kcal/mole	$\frac{\lambda^2}{l}\left(\frac{kT}{h}\right) \times 10^{-4}$, cm/sec	$-\psi_I$, kcal/mole	$\Delta G_{tr}^{\circ} - \Delta G_{ad}^{\circ}$ (o/w), kcal/mole	$\Delta G_{dif}^{calc\ b}$, kcal/mole
Formamide	0.0014	7.8 ± 0.5	6.15	1.61	0.43	5.61	6.10
Acetamide	0.0025	2.4 ± 0.4	7.55	2.11	0.86	5.61	7.46
Propionamide	0.013	6.1 ± 0.6	7.90	2.36	1.87	5.61	7.98
Valeramide	0.23	18.3 ± 1.1	8.00	2.98	3.60	5.61	9.18

[a] From Ref. 26. [b] Calculated from the equation: $\Delta G_{dif} = kT \ln [(\lambda^2/l)(kT/h)] + \psi_I - [\Delta G_{tr}^{\circ} - \Delta G_{ad}^{\circ}(o/w)] - kT \ln P$.

the different surface tension effects of the solvent produced by the presence of the same number of solute molecules in the two solutions may be related to some differential property between the water and heptane solvents.

The surface tension of a pure liquid is essentially a manifestation of the unbalanced molecular interactions on the surface molecules. The main intermolecular forces in liquid hydrocarbons are London dispersion forces. The hydrogen bond and London dispersion forces are the main intermolecular forces in water. The hydrogen bond component has been estimated to be responsible for two-thirds of the total surface energy of water (23).

The difference between the effect of heptanol on the surface tension of water and heptane could be related to the effect on the hydrogen bond component of the surface energy of water. The total molecular surface area of heptanol and the accepted water molecule radius (1.5 Å) lead to an estimated 25 water molecules packed closely around a heptanol molecule; *i.e.*, only 25 × 6 molecules out of 10^5 water molecules in this solution can be affected directly by the presence of heptanol molecules at that concentration.

If the assumption that the subinterface compartment with water molecules oriented in a given array (and, consequently, in a comparatively low entropic state) is valid, a plausible explanation of the magnitude of the observed effect on water could be that direct solute molecule interaction with a relatively small number of water molecules generates and propagates significant disruption of the water structure in the bulk solution. The entropic contribution thus created could be the driving force of the spontaneous heptanol molecule adsorption at the air–aqueous solution interface.

Interaction with Phospholipid Monolayers—Plots of the interaction energies, ψ, of alkylamides, *N*-dimethylalkylamides, and alkylmonocarboxylic acids with I monolayers *versus* the total molecular surface area are compared in Fig. 6 with those of their adsorption free energy at the clean air–water interface. The regression coefficients, the slopes, and the adsorption free energy per methylene group are listed in Table II.

The linearity of the plots of the compounds from C_1 to C_6 in the main hydrocarbon chain of the alkylamide and *N*-dimethylalkylamide series and from C_1 to C_8 in the alkylmonocarboxylic acids contrasts with the reported departure from linearity observed for the C_6 and C_8 compounds of the alkanol series in their interaction with I monolayers (1).

The interaction energies per methylene group of the alkylamides and alkylmonocarboxylic acids were practically identical to the adsorption free energies per methylene group at the hydrocarbon–water interface. This finding seems to indicate that I monolayers behave as ultrathin oil phases for these compounds, as was observed previously with alkanols (1). The observed 50% reduction of the interaction energy per methylene group of the hydrocarbon chain of the *N*-dimethylalkylamides compared with that of the adsorption free energies at the clean air–water interface. No literature data were found on the adsorption free energy of these compounds at the hydrocarbon–water interface.

The plots corresponding to II monolayers (Fig. 7) indicate a marked departure from linearity for hexanamide and *N*-dimethylhexamide and compare with that reported recently (7) for hexanol and octanol in their interaction with I and II monolayers. The interaction free energies per methylene group compare with those of the interaction with I monolayers. The small differences observed within the experimental error could be reasonably attributed to the different molecular surface density of I and II monolayers.

Correlations with Permeability—Three important variables govern nonelectrolyte permeation across biomembranes: (*a*) the partition coefficient of the membrane–bathing solution, (*b*) the rate constant for entrance into the membrane from the aqueous environment, and (*c*) the diffusion coefficient within the membrane (24). Solute permeation across the lipid regions of biomembranes can be separated into three successive events that contribute to the total permeation rate: (*a*) adsorption of the hydrated solute at the lipid–bathing solution interface, (*b*) dehydration, and (*c*) solute diffusion through the lipid region (25).

Kinetic analysis of membrane permeability (26, 27) based on the absolute rate theory treatment of diffusion (28) shows the permeation rate to be proportional to the product of the probability of occurrence of the three successive events (25):

$$P = \left(\frac{\lambda^2}{l}\right)\left(\frac{kT}{h}\right) \exp(-\Delta G_{ad}/RT) \exp(-\Delta G_{deh}/RT) \exp(-\Delta G_{dif}/RT) \quad \text{(Eq. 4)}$$

where P is the permeability (centimeters per second), λ is the average distance between equilibrium positions (angstroms), l is the membrane thickness (angstroms), h is the Planck constant (ergs × seconds), and ΔG_{ad}, ΔG_{deh}, and ΔG_{dif} are the contributions to the total activation energy of the adsorption, dehydration, and diffusion steps, respectively.

The ΔG_{ad} and ΔG_{deh} terms of Eq. 4 correspond to the first energetic barrier found by the solute molecule during its permeation, *i.e.*, the crossing of the bathing solution–lipid interface. Adsorption of the amides at the water–air or decane–water interface is spontaneous so that ΔG_{ad} is intrinsically negative. On the contrary, the nonspontaneity of dehydration indicates that ΔG_{deh} is intrinsically positive. Consequently, the total energetic cost of crossing the interfacial region is $-\Delta G_{ad} + \Delta G_{deh}$.

The free energy change, ΔG_{tr}, associated with the transfer of a solute from an aqueous solution to dimyristoyl lecithin liposomes was estimated by (29):

$$\Delta G_{tr}^{\circ} = -kT \ln P \quad \text{(Eq. 5)}$$

where P is the molal partition coefficient, which can be related to the thermodynamic partition coefficient through an expression containing

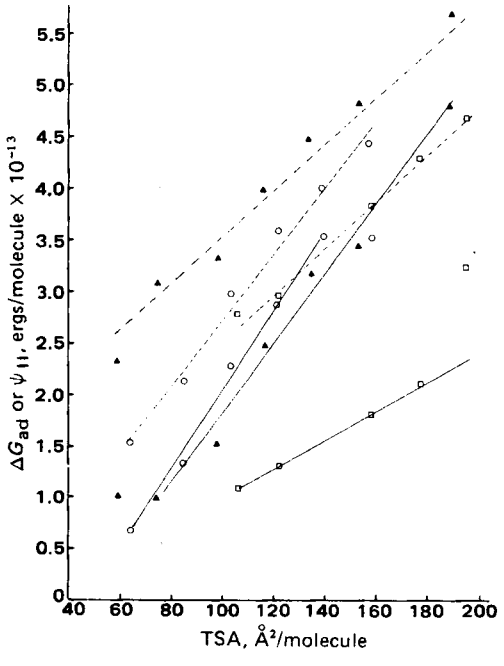

Figure 7—*Plots of the adsorption free energies at the air–aqueous solution interface (- - -) and the interaction energies with II monolayers (—)* versus *the total molecular surface area. Key:* ▲, *alkylmonocarboxylic acids;* ○, *alkylamides; and* □, N,N-*dimethylalkylamides.*

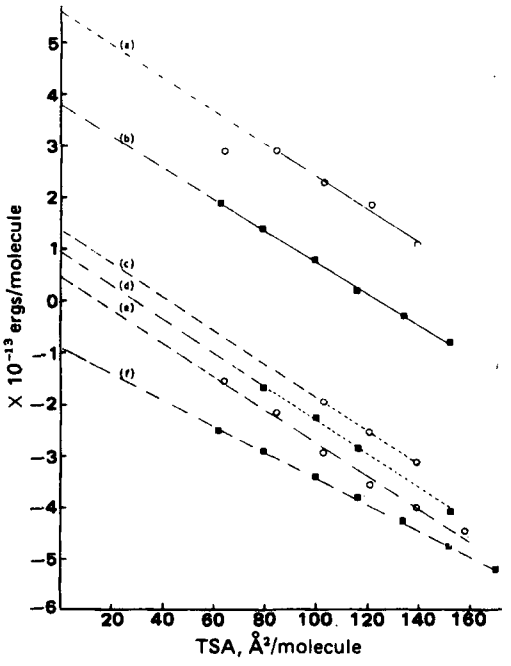

Figure 8—*Plots of the transfer free energies of the oil–water solution, ΔG°_{tr} (a, b); the adsorption free energies at the hydrocarbon–water interface, ΔG°_{ad} (o/w) (c, d); and the adsorption free energies at the air–water interface, ΔG°_{ad} (e, f), against the total molecular surface area. Key:* ○, *alkylamides; and* ■, *alkanols.*

the natural logarithm of the ratio of the molecular weights of the nonpolar and polar phases (29). However, for comparative purposes, the P values can be used to estimate a relative free energy change.

The plots of ΔG°_{tr} obtained from literature data (30) on partition coefficients of oil–aqueous solutions of alkylamides and alkanols *versus* the total surface area per molecule are compared in Fig. 8 with those of the adsorption free energy, $\Delta G^{o/w}_{ad}$, at the hydrocarbon–aqueous (obtained from Refs. 31 and 12, respectively) and at the air–aqueous interfaces. With the exception of formamide in the ΔG°_{tr} plot, the points determined reasonably straight lines. The slopes, intercepts, and correlation coefficient are given in Table II.

Parallelism of the plots of ΔG°_{tr} and ΔG°_{ad} at the hydrocarbon–water interface permitted estimation of the constant difference $(\Delta G^{\circ}_{tr} - \Delta G^{o/w}_{ad})_{TSA=0}$ for the alkylamides and the alkanols, 3.91×10^{-13} and 2.84×10^{-13} erg/molecule, respectively.

The partition of a surface-active solute between aqueous and nonaqueous phases can be separated into two successive events: the spontaneous adsorption of the hydrated solute at the interface ($\Delta G_{ad} < 0$) and its subsequent dehydration ($\Delta G_{deh} > 0$) that permits penetration into the nonaqueous phase (31). It can be reasonably assumed that the total free energy change of the partition, ΔG_{tr}, should reflect both events so that $\Delta G_{tr} = \Delta G^{o/w}_{ad} + \Delta G_{deh}$ and $\Delta G_{deh} = \Delta G_{tr} - \Delta G^{o/w}_{ad}$.

It is generally accepted (27, 32) that the amide group and the hydroxyl group form three and two hydrogen bonds with water, respectively. However, from *ab initio* SCF computations of various polyhydrates, evidence was presented recently (16) for the structure of formamide in aqueous solution consistent with a model of four water molecules in the primary hydration sphere, two of them hydrogen bonded to the amino group acting as a proton donor.

By assuming that the constant difference $(\Delta G^{\circ}_{tr} - \Delta G^{o/w}_{ad})_{TSA=0}$ is related to the free energy change that corresponds to dehydration, the contribution of each hydrogen bond to the total dehydration free energy can be estimated by dividing $(\Delta G_{tr} - \Delta G^{o/w}_{ad})_{TSA=0}$ by three for alkylamides and by two for alkanols. The values obtained, 1.31×10^{-13} and 1.42×10^{-13} erg/molecule, respectively, seem to indicate the validity of this assumption for the two series.

The equation used to estimate the interaction energies of subphase-injected solutes with phospholipid monolayers was derived originally (2) based on the statistical thermodynamic treatment of the Langmuir adsorption equation (33, 34). The Boltzmann–Maxwell exponential factor consequently contained an activation energy term about which, under the experimental conditions, no valid assumption could be made on the thermodynamic function (ΔE, ΔH, or ΔG) that it really represents. The ambiguous interaction energy term was coined, and the symbol ψ was used to represent it.

The order of magnitude of the experimentally measured interaction energies, ψ, of alkylamides and alkanols with phospholipid monolayers and their dependence on the total surface area per molecule strongly suggest that they could be related to the adsorption free energy of the solute at the phospholipid monolayer–aqueous solution interface. The validity of this suggested relationship and the former assumption of the dependence of ΔG_{deh} on $(\Delta G_{tr} - \Delta G^{o/w}_{ad})$ can be tested with Eq. 4.

The activation free energies for the diffusion, ΔG_{dif}, of formamide, acetamide, propionamide, and valeramide within egg lecithin bilayers estimated recently (26) from their measured permeability coefficients by assuming that the unknown bathing solution–lipid bilayer partition coefficients are proportional to the known water–ether partition coefficients are compared in Table III with those obtained by substituting ΔG_{ad} for the interaction energies with dipalmitoyl lecithin monolayers, ψ_I (Table I), and ΔG_{deh} for the corresponding values of $(\Delta G_{tr} - \Delta G^{o/w}_{ad})_{TSA=0}$ in Eq. 4. The coincidence of the calculated values of the activation free energy of the diffusion within the lipid bilayer for formamide, acetamide, and propionamide favors the validity of the former assumptions. The discrepancy between the calculated values of ΔG^{calc}_{dif} and $\Delta G^{\ddagger}_{dif}$ in the case of valeramide could be explained on the basis that as the solute size increases, the crossing of the interface becomes the rate-determining step; for valeramide, it constitutes 90% of the total resistance to permeation (24). The fact that in this case ΔG^{calc}_{dif} compares with ΔG°_{dif}, which contains the contribution corresponding to the partition coefficient $[\Delta G^{\circ}_{dif} = \Delta G^{\ddagger}_{dif} - \ln A/A'$ (24)], favors this explanation.

The results presented here seem to indicate that the interaction energy of alkylamides with dipalmitoyl lecithin monolayers spread at the air–water interface can be reasonably identified with the adsorption free energy at the aqueous solution–monolayer interface, which constitutes the first energetic step involved in alkylamide permeation across a phospholipid bilayer, and that the dehydration free energy constituting the second energetic step can be identified with the difference between the transfer free energy from an aqueous phase to an oil phase and the adsorption free energy at the water–hydrocarbon interface.

Protein Concentration Effects on Binding of ^{14}C-Codeine, ^{14}C-Morphine, and ^{3}H-Methadone to Human Serum Albumin

JOSEPH JUDIS

Received February 26, 1979, from the *College of Pharmacy, University of Toledo, Toledo, OH 43606.* Accepted for publication August 8, 1979.

Abstract □ The binding of ^{14}C-codeine, ^{14}C-morphine, and ^{3}H-methadone to human serum albumin was studied at a constant ligand concentration and varying albumin concentrations. Scatchard plots of the data were linear and had positive slopes. The curves for the three ligands had similar data values and slopes. With increasing albumin concentrations, β (fraction bound) values increased. The β change per albumin concentration change $[d(\beta)/d(\text{albumin})]$ dropped most markedly at lower albumin concentrations and changed less as the albumin concentrations approached those normally observed in human blood. Values of nK, the number of binding sites or systems on the protein times the association constant, calculated from β and the albumin concentrations decreased with an increase in albumin concentration increase. The curves were similar for codeine and morphine, while the methadone curve indicated less of a decrease in nK with an increasing albumin concentration. For data published previously on the binding of various ligands at different albumin concentrations, plots of β values or calculated nK values *versus* albumin concentration revealed that β generally increased and nK decreased with an increasing albumin concentration. Desipramine, propoxyphene, prednisone, and phenylbutazone were exceptions to these relationships.

Keyphrases □ Codeine—binding to human serum albumin, varying albumin concentration □ Morphine—binding to human serum albumin, varying albumin concentration □ Methadone—binding to human serum albumin, varying albumin concentration □ Binding, protein—codeine, morphine, and methadone to human serum albumin, varying albumin concentration

In most studies of drug binding to serum proteins, a single protein concentration was used and the ligand concentration was varied (1–3). Scatchard plots of the data gave either a straight line or curve and almost invariably had a negative slope. However, studies of cortisol binding to serum albumin were conducted in which the cortisol concentration was constant and the albumin concentration was varied (4). The resulting Scatchard plot was a straight line with a positive slope. The results could not be explained on the basis of microheterogeneity or by variations of the albumin activity coefficient. This observation was not investigated further.

Several subsequent studies involved the binding of various ligands to serum proteins using a constant ligand concentration and varying protein concentrations. Scatchard plots with a positive slope were observed with thiopental (5), phenytoin (6, 7), and L-tryptophan (6, 7). Bowmer and Lindup (8) recently commented on the several published studies involving data yielding Scatchard plots with positive slopes and the significance of obtaining binding data when the protein concentration is varied and the ligand concentration is constant.

Previous studies involving the binding of ^{14}C-codeine, ^{14}C-morphine, and ^{3}H-methadone to human serum albumin yielded Scatchard plots with positive slopes when the albumin concentration was constant and the ligand concentration was varied (9). No explanation for the positive slopes (rather than the usually observed negative slopes) could be offered. This report is an extension of the earlier studies and involves variation of the albumin concentration and constant ligand concentrations.

EXPERIMENTAL

Methods—All protein binding determinations were performed by the equilibrium dialysis method (9) using multiple-cell blocks. Each cell had 1 ml on each side of the cellulose membrane. Radioactivity was determined in a liquid scintillation system as described previously (9).

Materials—^{14}C-Codeine[1], ^{14}C-morphine[1], ^{3}H-methadone[2], and crystalline human serum albumin[3] were obtained commercially. All chemicals were reagent grade.

RESULTS AND DISCUSSION

The human serum albumin concentration was varied between 0.217×10^{-4} and 0.87×10^{-3} *M*. The ligand concentration was kept constant (^{14}C-morphine, 0.00356; ^{14}C-codeine, 0.00339; and ^{3}H-methadone, 0.00332 *M*). Scatchard plots of the data for the three ligands are shown in Fig. 1. The albumin concentrations for each ligand fell in the same sequence on the curve as found in studies (4, 5, 7) involving a constant ligand concentration and varying albumin concentrations. The slopes

[a] The r value is the correlation coefficient for the best fit of the data points to a straight line. The slope given is that calculated for the best fit straight line.

for the curves for all three ligands were on the same order of magnitude.

When the extent of binding *versus* albumin concentration was examined, β (fraction of ligand bound) increased with albumin concentration (Fig. 2). The slopes of the curves were relatively close for codeine and morphine and slightly higher for methadone. Since it generally is recognized that drug binding to serum proteins may affect pharmacological activity because the active drug form is the free or unbound drug, serum albumin concentration changes could be important. Serum albumin concentrations vary among normal individuals to a limited extent and may be reduced in certain pathological circumstances.

To understand the relative effects of differences in the serum albumin concentration and the fraction of ligand bound, $d(\beta)/d$(albumin) was calculated for each albumin concentration and its corresponding β value. This parameter is the rate of change in β with respect to a change in albumin concentration. The value was calculated by fitting albumin concentrations and corresponding β values to a curve for which a statistically significant fit could be obtained by a computer. The first derivative of the curve then was taken at each albumin concentration.

The $d(\beta)/d$(albumin) values dropped rapidly as the albumin concentration increased from the low values and then dropped less as the higher albumin concentrations were reached (Table I). These values are represented in Fig. 3. At the higher albumin concentrations, β changed less per albumin concentration change. Since the higher albumin concentrations are those generally encountered, even in individuals with albumin concentrations considered somewhat below normal, β would not be reduced drastically, and only moderate modifications (if any) of the dose level would be indicated with slightly decreased albumin concentrations. The large β change per change in albumin concentration would exist at the much lower albumin concentrations, which generally are not encountered clinically.

Numerous studies were identified (8) in the literature in which binding was affected by albumin concentration changes. A protein concentration increase corresponding to an nK decrease was common to these studies[4]. The data obtained in this study were analyzed similarly, and nK was calculated using an equation (2) that permitted calculation of nK from β and the protein concentration. Figure 4 shows the curves obtained when the calculated nK values were plotted *versus* albumin concentration. For all three ligands, an albumin concentration increase was accompanied by an nK decrease.

Numerous investigators (10–16) have published data for drug binding

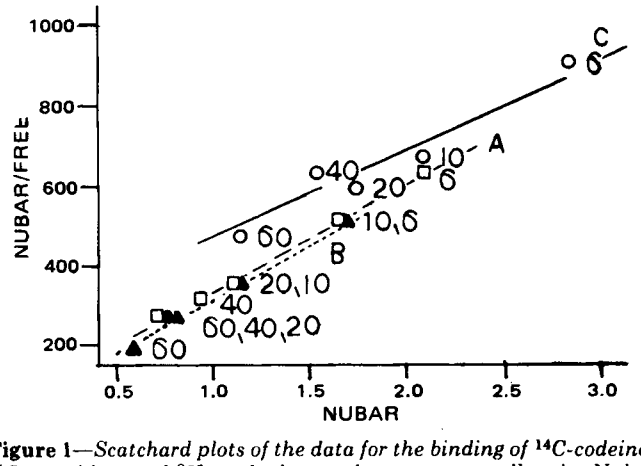

Figure 1—*Scatchard plots of the data for the binding of ^{14}C-codeine, ^{14}C-morphine, and ^{3}H-methadone to human serum albumin. Nubar refers to the moles of ligand bound per mole of albumin in the system. Numbers near the data points represent the milligrams of albumin per dialysis cell (1-ml cell). Key: A, □, ^{14}C-morphine; B, ▲, ^{14}C-codeine; and C, ○, ^{3}H-methadone.*

Key: A,* □, ^{14}*C-codeine; B,* △, ^{14}*C-morphine; and C,* ○, ^{3}*H-methadone.*

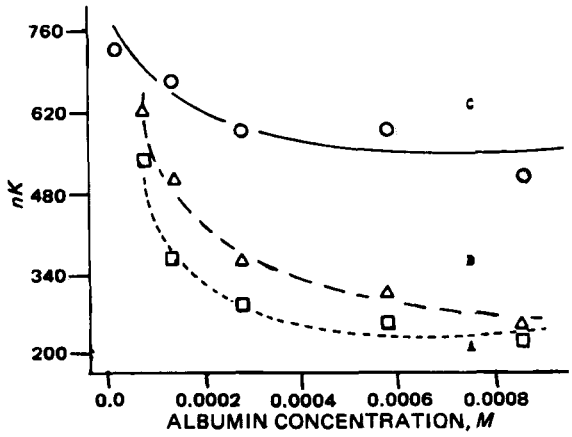

Figure 4—*Relationship between* nK *and human serum albumin concentration for the binding of* ^{14}*C-codeine,* ^{14}*C-morphine, and* ^{3}*H-methadone to human serum albumin. Key: A,* □, ^{14}*C-codeine; B,* △, ^{14}*C-morphine; and C,* ○, ^{3}*H-methadone.*

(β) at varying human serum albumin concentrations. The data in these reports were plotted as β *versus* albumin concentration (molar) and calculated *nK* values (calculated as described) *versus* albumin concentration.

The results are summarized in Table II. In many cases, the plots did not follow closely a straight line, as evidenced by statistically insignificant correlation coefficients (*i.e.*, <0.9); the slopes calculated thus represent a trend of the scattered points rather than a precise slope. In general, β increased with an albumin concentration increase except for desipramine and propoxyphene. The *nK* values decreased with an albumin concentration increase, as found by Bowmer and Lindup (8) in their study of literature for binding data. Table II reveals two other exceptions, prednisone and phenylbutazone. Thus, *nK* values apparently do decrease with an albumin concentration increase but with some exceptions. These exceptions merit further study for other possible unique albumin binding characteristics.

Bowmer and Lindup (8) suggested that positive-slope Scatchard curves might be explained by cooperativity if the positive-slope curves are obtained from data where the protein concentration was constant and the ligand concentration was varied, as well as from data for the same system where the ligand concentration was constant and the protein concentration was varied. This cooperativity seems to apply to the binding of codeine, morphine, and methadone to human serum albumin. Positive-slope Scatchard plots were obtained in a previous study (9) where the albumin concentration was constant and the ligand concentration was varied. In the present study in which the ligand concentration was constant and the albumin concentration was varied, Scatchard plots with positive slopes also were obtained.

More ligand–protein systems should be reinvestigated by keeping the ligand concentration constant and varying the protein concentration, not only for more complete characterization of these systems but also for the determination of the relative effects on the fraction bound with protein concentration changes, especially where blood proteins are involved. For drugs that are highly bound and very potent, the dosage may have to be adjusted for a reduction in serum protein concentration when the latter deviates significantly from normal.

Abstract □ The prolactin response in the rat is proposed as a convenient and inexpensive test system for the assessment of the clinical potency of neuroleptic agents. Times of maximum elevation ($p < 0.01$) of serum prolactin levels were determined by a one-way analysis of variance and the Newman–Keuls test for a period of 180 min following intraperitoneal administration of chlorpromazine hydrochloride, fluphenazine hydrochloride, perphenazine, prochlorperazine edisylate, and trifluoperazine hydrochloride (phenothiazines); haloperidol (a butyrophenone); chlorprothixene (a thioxanthene); loxapine succinate (a dibenzoxazepine); and molindone hydrochloride (a dihydroindolene). Maximum serum prolactin elevations occurred as follows: chlorpromazine hydrochloride, 30–90 min; chlorprothixene and trifluoperazine hydrochloride, 30–150 min; fluphenazine hydrochloride, 90–150 min; haloperidol, 90 min; loxapine succinate, 30 min; molindone hydrochloride, 30 and 60 min; and perphenazine and prochlorperazine edisylate, 30–180 min. For drugs that exhibited statistically indistinguishable maximum serum prolactin elevations at more than one sampling time, one of these times was selected arbitrarily for construction of a log dose–prolactin response curve. Log dose–serum prolactin curves were constructed at a time of maximum serum prolactin elevation for each drug. Thirty minutes was utilized for loxapine succinate and molindone hydrochloride, and 90 min was used otherwise. These curves were nearly parallel, and each had an excellent linear fit. Based on these curves, the ratio of the weights of the neuroleptic and chlorpromazine hydrochloride required to produce the same prolactin-stimulating potency was determined for each drug. This ratio was compared to the clinically accepted ratio of the weights of the neuroleptic and chlorpromazine hydrochloride required to produce the same antipsychotic potency. This technique demonstrated a close correlation between the prolactin-stimulating potencies of neuroleptics in rats and accepted antipsychotic potency relationships in humans.

Keyphrases □ Neuroleptic agents—model for evaluation of potency, prolactin response in rats □ Phenothiazines—model for evaluation of potency, prolactin response in rats □ Models—evaluation of neuroleptic potency, prolactin response in rats □ Prolactin response, rats—model for evaluation of neuroleptic potency

Prolactin, an anterior pituitary hormone in animals, is structurally similar to growth hormone (1). The dominant hypothalamic regulation of prolactin secretion in mammals appears to be inhibitory and under the control of prolactin-inhibitory factor (2). Prolactin-inhibitory factor is liberated by the hypothalamus into the portal vessels as a result of afferent dopaminergic impulses (3). It is unclear whether dopamine is a constituent of prolactin-inhibitory factor or is the factor itself (4).

Evidence of a prolactin-releasing factor exists, but its activity in controlling prolactin secretion clearly is less important than prolactin-inhibitory factor (5). Thyrotropin-releasing hormone also stimulates the secretion of prolactin- and thyroid-stimulating hormone, but thyrotropin-releasing hormone presumably does not play an important role in physiological prolactin regulation (5).

BACKGROUND

Enhanced prolactin secretion was reported following neuroleptic administration to humans (6, 7) and is associated with galactorrhea and other endocrine disturbances which may accompany the use of such drugs (8). A fairly good correlation between the antipsychotic potency of various neuroleptics and their human prolactin-stimulating response was found (6, 9, 10). A notable exception is clozapine, which does not seem to be a potent or consistent prolactin stimulator in humans; however, it does stimulate prolactin in rats (11, 12). Despite this exception, the prolactin response to a test dose of a new neuroleptic in normal human volunteers was proposed as a useful means to screen its efficacy and potency prior to clinical studies in humans (6, 10).

In addition to the various neurochemical techniques using animals to assess antipsychotic activity and/or potency (13–16), Clemens *et al.* (17) reported that when chlorpromazine and thioridazine, two phenothiazines of comparable antipsychotic potency, were given to rats, serum prolactin levels were stimulated to a similar extent. This observation was based on serum samples obtained 2 hr after drug administration. Meltzer *et al.* (18) demonstrated that the rank orders of average daily doses of nine neuroleptic agents in rat serum samples obtained 30 min after drug administration correlated with their corresponding doses needed to double serum prolactin levels. These correlation studies as well as other studies (11, 12) did not consider the possibly significant variation in serum prolactin profiles with respect to time for individual antipsychotic drugs and the effects of this parameter on observed magnitudes of prolactin stimulation. Furthermore, it was suggested that pituitary dopamine receptors that influence prolactin secretion in rats may differ significantly from those relevant to the antipsychotic action of neuroleptics (12).

A study was designed in rats to determine the times of maximum elevation of serum prolactin for representative antipsychotic drugs following their intraperitoneal administration and to investigate thoroughly the correlation between prolactin-stimulating potency of neuroleptics in rats and their clinical potency.

EXPERIMENTAL

In Stage 1 of this study, experiments were conducted to determine the times of maximum serum prolactin elevation for representative neuroleptics following their intraperitoneal administration. In Stage 2, experiments were conducted to determine the potency of each neuroleptic in inducing prolactin release at a time of maximum serum prolactin elevation.

Drugs—The following nine pharmacological agents, representing all five classes of antipsychotics approved for clinical use in the United States, were investigated: chlorpromazine hydrochloride[1], fluphenazine hydrochloride[2], perphenazine[3], prochlorperazine edisylate[1], and trifluoperazine hydrochloride[1] (phenothiazines); haloperidol[4] (a butyrophenone); chlorprothixene[5] (a thioxanthene); loxapine succinate[6] (a dibenzoxazepine); and molindone hydrochloride[7] (a dihydroindolone).

Animals—Male Sprague–Dawley rats[8], 225–300 g, were housed for 21 days in a temperature-controlled environment (23 ± 3°) which was illuminated artificially (lights on daily from 7:00 am to 7:00 pm). The animals were given food[9] and water *ad libitum*.

Times of Statistically Significant Maximum Serum Prolactin Elevation—Rats were divided into 11 groups of 48. The following antipsychotics were administered in equipotent dose equivalents for humans (19): chlorpromazine hydrochloride (10 mg/kg), chlorprothixene (10 mg/kg), fluphenazine hydrochloride (0.2 mg/kg), haloperidol (0.2 mg/kg), loxapine succinate (1 mg/kg), molindone hydrochloride (1 mg/kg), perphenazine (1 mg/kg), prochlorperazine edisylate (1.5 mg/kg), and trifluoperazine hydrochloride (0.5 mg/kg).

Solutions of these drugs were prepared to contain the indicated mil-

Table I—Prolactin-Stimulating and Therapeutic Potencies of Neuroleptics Relative to Chlorpromazine Hydrochloride

Neuroleptic	Prolactin-Stimulating Potency[a]	Antipsychotic Potency[b]
Chlorpromazine hydrochloride	1.0	1
Chlorprothixene	1.0	1–2.3
Prochlorperazine edisylate	5.7	6.2–7.7
Perphenazine	9.1	10–11.9
Molindone hydrochloride	9.3	5–19.6
Loxapine succinate	10.6	8–12
Trifluoperazine hydrochloride	33.3	20–35
Fluphenazine hydrochloride	62.5	50–90.9
Haloperidol	86.0	50–91

[a] Calculated from log dose–response regression curves (Figs. 4 and 5). [b] From Refs. 19, 24, and 26.

ligram-per-kilogram doses in 1 ml of physiological saline or, with haloperidol, chlorprothixene, and perphenazine, in 1 ml of 0.1 *M* tartaric acid to solubilize these agents. These solutions or equal volumes of vehicles were given intraperitoneally to experimental and control groups, each group consisting of eight subgroups of six animals each. Blood samples were collected by decapitation at 0, 30, 45, 60, 90, 120, 150, and 180 min after drug or vehicle administration.

Potency of Neuroleptics in Inducing Prolactin Secretion—Rats were divided into nine groups of 42. For each drug, six subgroups of seven rats were utilized. One animal in each subgroup served as a control. Every drug was administered in six serial dilutions. The concentrations in 1 ml of vehicle were: chlorpromazine hydrochloride and chlorprothixene, 25–0.781 mg/kg; fluphenazine hydrochloride, 1–0.031 mg/kg; haloperidol, 0.5–0.012 mg/kg; loxapine succinate and molindone hydrochloride, 1.25–0.078 mg/kg; perphenazine and prochlorperazine edisylate, 5–0.156 mg/kg; and trifluoperazine hydrochloride, 2–0.062 mg/kg.

Blood samples were obtained by decapitation at a statistically significant ($p < 0.01$) time of maximum serum prolactin elevation for each drug as determined by a one-way analysis of variance (20) and the Newman–Keuls test (21) from Stage 1 of this study.

Sample Collection and Assay—All decapitations were conducted between 2:00 and 4:00 pm. Blood was collected from the trunk portion and allowed to stand for 10 min at 4°; the serum was separated and frozen at −40° until hormone analysis could be performed. Serum samples were measured for prolactin using a radioimmunoassay kit[10]. The assays, using a double antibody radioimmunoassay, were performed according to the instructions.

The rat prolactin was iodinated by a modification of the Hunter–Greenwood method (22). Each serum sample was assayed in duplicate, and the average was taken as representative of the true prolactin concentration[11]. All test and control samples were determined concurrently for each drug. The intra- and interassay variations were 4.2 and 9.4%, respectively.

RESULTS

Time Course of Prolactin Response to Neuroleptics—Evaluation of the serum prolactin levels over 180 min following intraperitoneal injection of the various neuroleptic agents indicated that statistically significant ($p < 0.01$) maximum serum prolactin elevations occurred at the following times: chlorpromazine hydrochloride, 30–90 min; chlorprothixene and trifluoperazine hydrochloride, 30–150 min; fluphenazine hydrochloride, 90–150 min; haloperidol, 90 min; loxapine succinate, 30 min; molindone hydrochloride, 30 and 60 min; and perphenazine and prochlorperazine edisylate, 30–180 min (Figs. 1–3).

For drugs that exhibited statistically indistinguishable maximum serum prolactin elevations at more than one sampling time, one of these times was selected arbitrarily for each drug for subsequent experiments performed in Stage 2. Thirty minutes was utilized for loxapine succinate and molindone hydrochloride, and 90 min was used otherwise.

[11] All results are expressed in terms of NIAMDD rat prolactin.

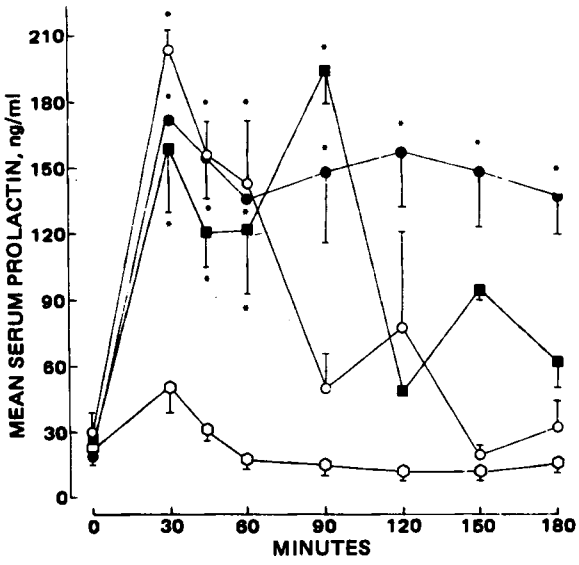

Figure 1—*Effect of intraperitoneally administered chlorpromazine hydrochloride (■), molindone hydrochloride (○), and prochlorperazine edisylate (●) on serum prolactin levels in male rats over 180 min. The control groups received normal saline (○). Each point is the mean for six animals. Vertical lines show the standard error of the means. Maximum serum prolactin elevations ($p < 0.01$) as determined by a one-way analysis of variance and the Newman–Keuls test are indicated by asterisks.*

Neuroleptic Dose–Prolactin Response Curves at Times of Maximum Serum Prolactin Elevation—Figures 4 and 5 show the log dose–prolactin response curves for the nine drugs studied as calculated by standard linear regression analyis (23). The slopes of the regression lines were: chlorpromazine hydrochloride, fluphenazine hydrochloride, haloperidol, and prochlorperazine edisylate, 1.9; chlorprothixene, loxapine succinate, and perphenazine, 1.8; and molindone hydrochloride and trifluoperazine, 1.6. The correlation coefficients for the log dose–prolactin curves were significant ($df = 4$) as follows: chlorpromazine, 0.91 ($p < 0.005$); chlorprothixene, 0.93 ($p < 0.005$); fluphenazine hydrochloride, 0.97 ($p < 0.005$); haloperidol, 0.95 ($p < 0.005$); loxapine succinate, 0.87 ($p < 0.01$); and prochlorperazine edisylate and trifluoperazine hydrochloride, 0.94 ($p < 0.005$).

Prolactin-Releasing Potency of Neuroleptics at Times of Maxi-

mum Serum Prolactin Elevation—Doses (milligrams per kilogram) of neuroleptics calculated from log dose–response curves (Figs. 4 and 5) that were equipotent to 5.0 mg of chlorpromazine hydrochloride/kg in releasing prolactin are presented in Table I. In addition, the clinically defined therapeutic potencies of these drugs are compared on a weight to weight basis and related to their prolactin-stimulating potency. A commonly used chlorpromazine hydrochloride dose was selected as the reference because comparison of the activity of other antipsychotics to this neuroleptic is common (24–26).

DISCUSSION

Neuroleptic drugs belonging to three chemical groups, prochlorperazine, haloperidol, and thiothixene, produce parallel log dose–prolactin response curves in humans, presumably due to their antidopaminergic effects (10). When nine representative drugs belonging to five chemical classes of neuroleptics were administered to rats at experimentally determined times of maximum serum prolactin elevation [which do not vary

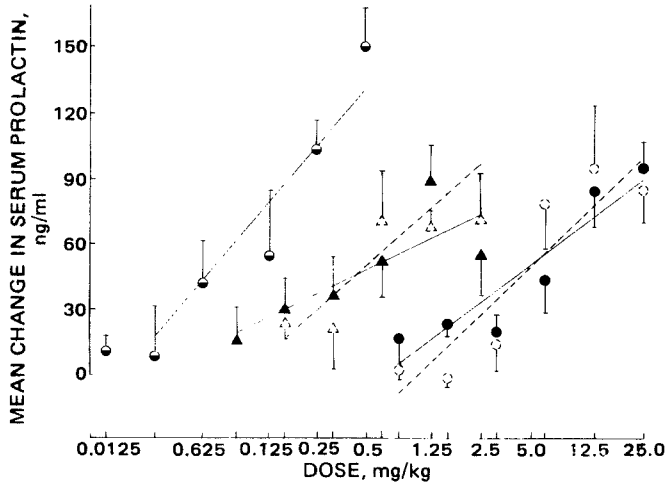

Figure 4—*Log dose–prolactin regression lines of chlorpromazine hydrochloride (○), chlorprothixene (●), haloperidol (◒), loxapine succinate (△), and molindone hydrochloride (▲). The y axis (mean change in serum prolactin) expresses the mean elevation of the prolactin concentration above the mean of the corresponding control group values. Each point represents the mean response of six experiments; vertical lines show the standard error of the means.*

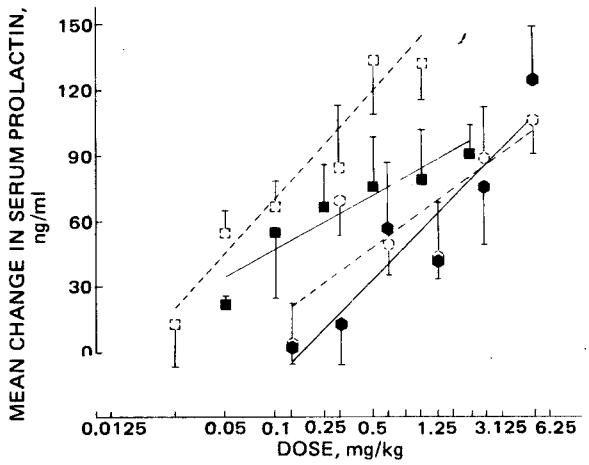

Figure 5—*Log dose–prolactin regression lines of fluphenazine hydrochloride (□), perphenazine (○), prochlorperazine edisylate (●), and trifluoperazine hydrochloride (■). significantly for an individual neuroleptic in response to dose variations (6, 10)], nine nearly parallel log dose–prolactin response regression lines were calculated. The correlation coefficient for each drug was highly significant and indicated excellent linear fit. These results indicate that there also is a common mechanism for inducing prolactin release in rats, presumably due to their antidopaminergic effects.

To evaluate the prolactin-releasing potency of each drug at an experimentally determined time of maximum serum prolactin elevation, the log dose–prolactin response curves were utilized. Based on these curves, the calculated ratio of the neuroleptic to the chlorpromazine hydrochloride prolactin-stimulating potency was compared to its reported antipsychotic potency ratio. For seven of the nine drugs, the neuroleptic to chlorpromazine potency ratios in rats were consistent with the accepted neuroleptic to chlorpromazine potency relationships for humans. The prolactin potency ratios of perphenazine and prochlorperazine to chlorpromazine were only slightly below the accepted clinical potency relationships.

The data indicated a better relationship between the prolactin-releasing potency of neuroleptics in rats and the clinically accepted therapeutic potency in humans than was reported elsewhere in an animal system (18). For example, haloperidol was reported to be only 16.6 times more potent than chlorpromazine in inducing prolactin secretion using a fixed 30-min comparison of serum prolactin levels (18). For the experimentally derived 90-min maximum elevation of serum prolactin for haloperidol, which also was its peak prolactin response time observed in humans following intramuscular adminstration (10), a much better correlation was obtained between prolactin stimulation potency and the accepted clinical potency range (19, 24).

Due to the variability in the time–serum prolactin profiles of the individual neuroleptics following intraperitoneal administration, their potency and prolactin response ratios would have been altered if a fixed time comparison of all prolactin levels was made rather than a comparison at the time of each drug's maximum serum prolactin elevation. The different times for maximum elevation of serum prolactin observed for several neuroleptics in this study, as well as those cited by other investigators but involving humans (6), suggest a variation in the onset of action for different drugs due to their molecular characteristics. Future work should evaluate this possible relationship.

For the nine drugs studied, which represent all chemical classes of antischizophrenic agents approved for clinical use in the United States, there is evidence to suggest that clinically accepted neuroleptic potency relationships in humans closely correlate with prolactin-stimulating properties in male rats when measured at a time of maximum serum prolactin elevation. This technique may be a convenient alternative to the proposed use of normal volunteers (6, 10) as a screening test for establishing the potency of new neuroleptics.

Further Considerations on Model-Independent Bioavailability Estimation

S. HWANG ˣ and K. C. KWAN

Received December 8, 1978, from *Merck Sharp & Dohme Research Laboratories, West Point, PA 19486.* Accepted for publication July 31, 1979.

Abstract □ Assumptions attendant to model-independent bioavailability estimation were reexamined. Particular attention was given to the situation where an intravenous reference is not available and nonrenal clearance is assumed to be constant between treatments. Under these circumstances, the previously proposed approximation was compared with other bioavailability estimators. On the basis of error analysis, a procedure was devised to yield optimal relative bioavailability estimates.

Keyphrases □ Bioavailability—model-independent estimation □ Drug availability—model-independent estimation □ Models—bioavailability estimation, equations

In a previous report (1), a model-independent method to assess bioavailability was suggested. The procedure calls for an initial determination of plasma clearance from an intravenous reference and assumptions concerning changes therein following the test dose(s). The proposed solutions are exact except when an intravenous reference is not available and nonrenal clearance is assumed to be unchanged between treatments. For this latter situation, an approximate solution was suggested initially with the support of a simulated example (1) and verified subsequently with experimental results (2).

This report provides a rigorous analysis of this approximation and the means to optimize its solutions. Its merits are examined relative to those of the dose-adjusted ratio of urinary recoveries of unchanged drug and of the area under the plasma concentration–time curve. It will be shown that where the nonrenal clearances are unchanged, the proposed approximation (1) is always superior to area ratios and often is better than urine ratios. Conditions under which relative bioavailability estimates should be optimal are discussed.

THEORETICAL

Bioavailability following a nonintravascular treatment, x, can be estimated by:

$$F^x = \frac{\dot{V}^x_{cl,p} AUC^x_\infty}{D^x} = \frac{\dot{V}^x_{cl,p} U^x_\infty}{D^x \dot{V}^x_{cl,r}} \qquad \text{(Eq. 1)}$$

where F is the fraction of the dose, D, absorbed; AUC_∞ is the total area under the plasma concentration–time curve; U_∞ is the total amount of unchanged drug excreted in the urine; and $\dot{V}_{cl,p}$ and $\dot{V}_{cl,r}$ are the plasma and plasma renal clearances, respectively. Except for $\dot{V}^x_{cl,p}$, the terms on the right side of Eq. 1 are known or can be calculated from plasma and/or urinary excretion data following treatment x.

On the other hand, plasma clearance must be determined by an independent experiment. Ideally, an intravenous tracer dose is administered concurrently with x such that the plasma clearance of the labeled drug becomes the estimate of $\dot{V}^x_{cl,p}$. An alternative solution was proposed (3, 4) whereby plasma clearance is estimated from separate treatments in which the renal drug clearance is perturbed in a controlled manner. The assumptions are that the perturbing influence on the kidney remains constant with time and that the same dose fraction is absorbed between

Further Considerations on Model-Independent Bioavailability Estimation

S. HWANG ˣ and K. C. KWAN

Received December 8, 1978, from *Merck Sharp & Dohme Research Laboratories, West Point, PA 19486.* Accepted for publication July 31, 1979.

Abstract □ Assumptions attendant to model-independent bioavailability estimation were reexamined. Particular attention was given to the situation where an intravenous reference is not available and nonrenal clearance is assumed to be constant between treatments. Under these circumstances, the previously proposed approximation was compared with other bioavailability estimators. On the basis of error analysis, a procedure was devised to yield optimal relative bioavailability estimates.

Keyphrases □ Bioavailability—model-independent estimation □ Drug availability—model-independent estimation □ Models—bioavailability estimation, equations

In a previous report (1), a model-independent method to assess bioavailability was suggested. The procedure calls for an initial determination of plasma clearance from an intravenous reference and assumptions concerning changes therein following the test dose(s). The proposed solutions are exact except when an intravenous reference is not available and nonrenal clearance is assumed to be unchanged between treatments. For this latter situation, an approximate solution was suggested initially with the support of a simulated example (1) and verified subsequently with experimental results (2).

This report provides a rigorous analysis of this approximation and the means to optimize its solutions. Its merits are examined relative to those of the dose-adjusted ratio of urinary recoveries of unchanged drug and of the area under the plasma concentration–time curve. It will be shown that where the nonrenal clearances are unchanged, the proposed approximation (1) is always superior to area ratios and often is better than urine ratios. Conditions under which relative bioavailability estimates should be optimal are discussed.

THEORETICAL

Bioavailability following a nonintravascular treatment, x, can be estimated by:

$$F^x = \frac{\dot{V}^x_{cl,p} AUC^x_\infty}{D^x} = \frac{\dot{V}^x_{cl,p} U^x_\infty}{D^x \dot{V}^x_{cl,r}} \qquad \text{(Eq. 1)}$$

where F is the fraction of the dose, D, absorbed; AUC_∞ is the total area under the plasma concentration–time curve; U_∞ is the total amount of unchanged drug excreted in the urine; and $\dot{V}_{cl,p}$ and $\dot{V}_{cl,r}$ are the plasma and plasma renal clearances, respectively. Except for $\dot{V}^x_{cl,p}$, the terms on the right side of Eq. 1 are known or can be calculated from plasma and/or urinary excretion data following treatment x.

On the other hand, plasma clearance must be determined by an independent experiment. Ideally, an intravenous tracer dose is administered concurrently with x such that the plasma clearance of the labeled drug becomes the estimate of $\dot{V}^x_{cl,p}$. An alternative solution was proposed (3, 4) whereby plasma clearance is estimated from separate treatments in which the renal drug clearance is perturbed in a controlled manner. The assumptions are that the perturbing influence on the kidney remains constant with time and that the same dose fraction is absorbed between

0022-3549/80/0100-0077$01.00/0
© 1980, American Pharmaceutical Association

treatments. More typically, however, the intravenous reference is administered to the test subject separately so that some assumption must be made concerning the constancy of plasma clearance between treatments. For example, if plasma clearance remains unchanged, *i.e.*, $\dot{V}^x_{cl,p} = \dot{V}^{iv}_{cl,p}$, the bioavailability of x is given by the dose-adjusted ratio of the areas under the plasma concentration curve:

$$F^x = \frac{D^{iv}(AUC^x_\infty)}{D^x(AUC^{iv}_\infty)} \qquad \text{(Eq. 2)}$$

However, if plasma clearance changes in proportion to the observed renal clearance change[1], the dose-adjusted ratio of urinary recoveries is the more accurate estimator, *i.e.*:

$$F^x = \frac{D^{iv}U^x_\infty}{D^xU^{iv}_\infty} \qquad \text{(Eq. 3)}$$

Finally, if nonrenal clearance is constant between treatments:

$$F^x = \frac{AUC^x_\infty}{D^x}(\dot{V}^{iv}_{cl,p} - \dot{V}^{iv}_{cl,r} + \dot{V}^x_{cl,r}) \qquad \text{(Eq. 4}a\text{)}$$

$$F^x = \frac{U^x_\infty}{D^x\dot{V}^x_{cl,r}}(\dot{V}^{iv}_{cl,p} - \dot{V}^{iv}_{cl,r} + \dot{V}^x_{cl,r}) \qquad \text{(Eq. 4}b\text{)}$$

In the absence of an intravenous reference and when $\dot{V}_{cl,p}$ is assumed constant, the bioavailability of treatment x relative to another nonintravascular treatment, s, is given by:

$$\frac{F^x}{F^s} = \frac{D^sAUC^x_\infty}{D^xAUC^s_\infty} \qquad \text{(Eq. 5)}$$

and when the ratio of $\dot{V}_{cl,r}/\dot{V}_{cl,p}$ remains constant between treatments:

$$\frac{F^x}{F^s} = \frac{D^sU^x_\infty}{D^xU^s_\infty} \qquad \text{(Eq. 6)}$$

By analogy to Eqs. 4*a* and 4*b*, the corresponding expression for relative bioavailability when nonrenal clearance remains constant is:

$$\frac{F^x}{F^s} = \frac{U^x_\infty}{D^x\dot{V}^x_{cl,r}}\left[\frac{\dot{V}^s_{cl,p}}{F^s} - \frac{(\dot{V}^s_{cl,r} - \dot{V}^x_{cl,r})}{F^s}\right] \qquad \text{(Eq. 7)}$$

Equations 2–7 are exact insofar as their respective assumptions hold. While the application of Eqs. 2–6 is straightforward, Eq. 7 cannot be evaluated because of the presence of unknowns $\dot{V}^s_{cl,p}$ and F^s on the right side. As an approximation to Eq. 7, it was suggested by Kwan and Till (*K–T*) that (1):

$$\left(\frac{F^x}{F^s}\right)_{K-T} = \frac{1}{[\dot{V}^x_{cl,p}]_{ex}}([\dot{V}^s_{cl,p}]_{ex} - \dot{V}^s_{cl,r} + \dot{V}^x_{cl,r}) \qquad \text{(Eq. 8)}$$

where $[\dot{V}_{cl,p}]_{ex}$ is defined as an experimentally derivable clearance such that:

$$[\dot{V}^{niv}_{cl,p}]_{ex} = \frac{\dot{V}^{niv}_{cl,p}}{F^{niv}} = \frac{D^{niv}(\dot{V}^{niv}_{cl,r})}{U^{niv}_\infty} \qquad \text{(Eq. 9)}$$

and niv refers to a nonintravascular treatment such as x or s. The error incurred by the use of Eq. 8 instead of Eq. 7 therefore is:

$$|(F^x/F^s)_{K-T} - (F^x/F^s)_{Eq.\ 7}| = \frac{|\delta|}{[\dot{V}^x_{cl,p}]_{ex}}\left(\frac{1}{F^s} - 1\right) \qquad \text{(Eq. 10)}$$

where:

$$\delta = \dot{V}^s_{cl,r} - \dot{V}^x_{cl,r} \qquad \text{(Eq. 11)}$$

Since treatments x and s are nonintravascular, one should be able to estimate the bioavailability of s relative to that of x by the same approximate method:

$$\left(\frac{F^s}{F^x}\right)_{K-T} = \frac{1}{[\dot{V}^s_{cl,p}]_{ex}}([\dot{V}^x_{cl,p}] - \dot{V}^x_{cl,r} + \dot{V}^s_{cl,r}) \qquad \text{(Eq. 12)}$$

in which treatment x is designated as the reference for calculation purposes. Then, the bioavailability of x relative to s is simply the reciprocal of $(F^s/F^x)_{K-T}$:

$$\frac{1}{(F^s/F^x)_{K-T}} = \frac{[\dot{V}^s_{cl,p}]_{ex}}{[\dot{V}^x_{cl,p}] - \dot{V}^x_{cl,r} + \dot{V}^s_{cl,r}} \qquad \text{(Eq. 13)}$$

The error resulting from the use of Eq. 13 as an approximation to Eq. 7 is:

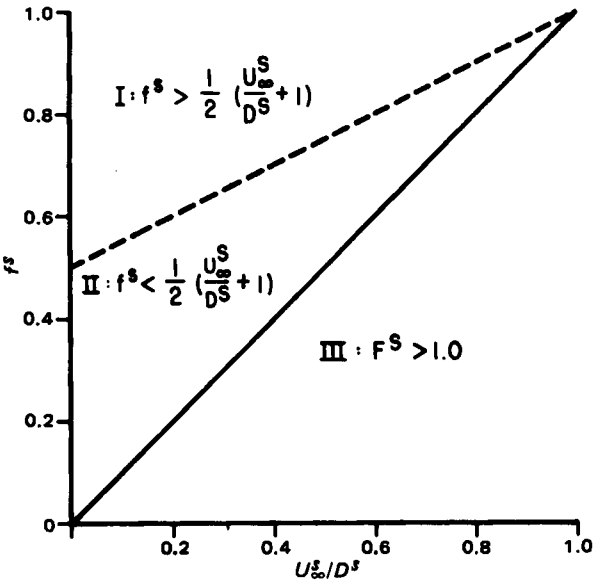

Figure 1—*Plot of* f^s versus U^s_∞/D^s. *On the dashed line,* $f^s = 0.5 + 0.5(U^s_\infty/D^s)$, *the errors associated with the uses of* $(U^x_\infty D^s/U^s_\infty D^x)$ *and* $(F^x/F^s)_{K-T}$ *are equal. In Region I,* $(U^x_\infty D^s)/(U^s D^x)$ *is preferred over* $(F^x/F^s)_{K-T}$, *and vice versa in Region II.*

$$\left|\frac{1}{(F^s/F^x)_{K-T}} - \left(\frac{F^x}{F^s}\right)_{Eq.\ 7}\right| = \frac{|\delta|}{[\dot{V}^x_{cl,p}]_{ex}}\frac{[\dot{V}^x_{cl,p}]_{ex} - \dot{V}^x_{cl,p}}{F^s([\dot{V}^x_{cl,p}]_{ex} + \delta)} \qquad \text{(Eq. 14)}$$

In addition to the trivial case where $\delta = 0$, it is evident from Eqs. 10 and 14 that the error term vanishes as F^s approaches 1.0 and as $[\dot{V}^x_{cl,p}]_{ex}$ approaches $\dot{V}^x_{cl,p}$, respectively. Equation 15 shows that estimates of bioavailability from Eq. 8 generally will differ from those from Eq. 13. The choice between the two can be made by considering the difference between their respective errors, Eqs. 14 and 10:

$$\left|\frac{1}{(F^s/F^x)_{K-T}} - \left(\frac{F^x}{F^s}\right)_{Eq.\ 7}\right| - \left|\left(\frac{F^x}{F^s}\right)_{K-T} - \left(\frac{F^x}{F^s}\right)_{Eq.\ 7}\right| = \frac{|\delta|}{[\dot{V}^x_{cl,p}]_{ex}([\dot{V}^x_{cl,p}]_{ex} + \delta)}|([\dot{V}^x_{cl,p}]_{ex} - \dot{V}^x_{cl,r}) - ([\dot{V}^s_{cl,p}]_{ex} - \dot{V}^s_{cl,r})| \qquad \text{(Eq. 15)}$$

All terms on the right side of Eq. 15 are experimentally derivable. Since the quotient preceding the braces, { }, always is positive, the sign of Eq. 15 is determined by the relative magnitude of $[\dot{V}_{cl,p}]_{ex} - \dot{V}_{cl,r}$ for the two treatments. If $[\dot{V}^x_{cl,p}]_{ex} - \dot{V}^x_{cl,r}$ is greater than $[\dot{V}^s_{cl,p}]_{ex} - \dot{V}^s_{cl,r}$, $(F^x/F^s)_{K-T}$ is closer to the true value and is preferred. If the converse holds, $1/(F^s/F^x)_{K-T}$ should be chosen. In the unlikely event that the two quantities within braces are identical, the same relative bioavailability estimate would result. The same criteria apply in studies involving three or more nonintravascular dosages. In other words, the treatment yielding the smallest value for $[\dot{V}_{cl,p}]_{ex} - \dot{V}_{cl,r}$ should be the reference for calculation.

According to Eq. 15, the first step in the estimation of relative bioavailability under the assumption of constant nonrenal clearance is to calculate $[\dot{V}_{cl,p}]_{ex} - \dot{V}_{cl,r}$ for all treatments in all subjects. For each subject, the treatment with the smallest $[\dot{V}_{cl,p}]_{ex} - \dot{V}_{cl,r}$ then is selected as the reference to which the bioavailability of all other treatments is compared. The resulting bioavailability ratios are rearranged or combined so that the desired reference, s, appears in the denominator.

In view of the approximate nature of Eqs. 8 and 13, their merits relative to other estimators should be examined. Conceivably, either the ratio of the dose fraction recovered in the urine or the ratio of the area under the plasma curve may be similarly adequate as an approximation even though nonrenal clearance is unchanged between treatments. Therefore, if nonrenal clearance truly is constant between treatments, the error associated with the use of the dose-adjusted area ratio (*i.e.*, Eq. 5) as a relative bioavailability estimate would be:

$$\left|\frac{AUC^x_\infty/D^x}{AUC^s_\infty/D^s} - \left(\frac{F^x}{F^s}\right)_{Eq.\ 7}\right| = \frac{|\delta|}{F^s[\dot{V}^x_{cl,p}]_{ex}} \qquad \text{(Eq. 16)}$$

Comparison of the uncommon terms on the right side of Eq. 10 with those of Eq. 16 shows that $(1/F^s) > (1/F^s) - 1$. Thus, under the prescribed

[1] This assumption is synonymous with saying that the fractional urinary recovery, $f = \dot{V}_{cl,r}/\dot{V}_{cl,p}$, remains constant between treatments.

Table I—Simulated Data for Relative Bioavailability Calculation

Oral Treatment	Dose, mg	Dose Fraction Absorbed, F^a	Dose Fraction Excreted in Urine, U_∞/D	Renal Clearance $\dot{V}_{cl,r}$, ml/min	$[\dot{V}_{cl,p}]_{ex} - \dot{V}_{cl,r}$
1	500	0.536	0.265	223.1	618.8
2	500	0.680	0.306	186.6	423.2

[a] As estimated in Table II of Ref. 1.

conditions, Eq. 8 estimates the true bioavailability better than does the ratio of dose-adjusted areas under the plasma curve. In light of the previous discussion on optimization, estimates by Eq. 13, when applicable, should be even better than those by Eq. 8.

Similarly, the absolute difference between the dose-adjusted ratio of urinary recoveries (*i.e.*, Eq. 6) and the true value is:

$$\left|\frac{U^x_\infty/D^x}{U^s_\infty/D^s} - \left(\frac{F^x}{F^s}\right)_{Eq.\ 7}\right| = \frac{|\delta|}{[\dot{V}^x_{cl,p}]_{ex}}\left(\frac{D^s}{U^s_\infty} - \frac{1}{F^s}\right) \quad \text{(Eq. 17)}$$

Comparison of the uncommon terms on the right side of Eqs. 10 and 17 shows that $(D^s/U^s_\infty) - (1/F^s)$ may be greater than, equal to, or less than $(1/F^s) - 1$. Thus, even when the nonrenal clearance is constant between treatments, the urinary excretion ratio approximates relative bioavailability better than does Eq. 8 in some situations. Intuitively, such situations prevail when renal excretion is the dominant drug elimination route. A quantitative assessment of situations in which one method is superior to the other is as follows.

The difference between Eqs. 10 and 17 can be expressed as:

$$\left|\left(\frac{F^x}{F^s}\right)_{K\text{-}T} - \left(\frac{F^x}{F^s}\right)_{Eq.\ 7}\right| - \left|\frac{U^x_\infty/D^x}{U^s_\infty/D^s} - \left(\frac{F^x}{F^s}\right)_{Eq.\ 7}\right| = \frac{|\delta|}{[\dot{V}^x_{cl,p}]_{ex}}\frac{D^s}{U^s_\infty}\left(2f^s - 1 - \frac{U^s_\infty}{D^s}\right) \quad \text{(Eq. 18)}$$

where f^s is the ratio of the renal clearance to plasma clearance. When the right side of Eq. 18 is positive, the urinary recovery ratio is better; when it is negative, $(F^x/F^s)_{K\text{-}T}$ is preferred. Whether Eq. 18 is greater or less than zero depends on the relative magnitude of f^s and U^s_∞/D^s. When Eq. 18 is zero:

$$f^s = \tfrac{1}{2}\left(1 + \frac{U^s_\infty}{D^s}\right) \quad \text{(Eq. 19)}$$

A plot of f^s *versus* U^s_∞/D^s is shown in Fig. 1, which is clearly divided into three regions. Equation 19 separates Region I, representing situations where $f^s > \frac{1}{2}[1 + (U^s_\infty/D^s)]$ when urinary excretion ratios should be used,

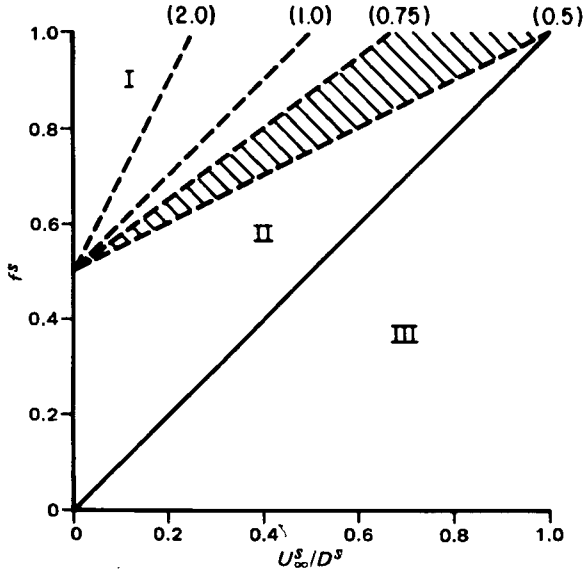

Figure 2—*Plot of* $f^s = 0.5 + \alpha(U^s_\infty D^s)$ *(Eq. 20). The* α *value for each line is specified in parentheses. The shaded area indicates the expansion of Region II by using* $1/(F^s/F^x)_{K\text{-}T}$ *instead of* $(F^x/F^s)_{K\text{-}T}$ *as* α *increases from 0.5 to 0.75.*

Table II—Sample Calculation of Relative Bioavailability of Oral Treatment 1 to Oral Treatment 2

True Value F^1/F^2	$\frac{AUC^1_\infty}{AUC^2_\infty}$[a]	$\frac{U^1_\infty}{U^2_\infty}$	$\left(\frac{F^1}{F^2}\right)_{K\text{-}T}$	$\frac{1}{(F^2/F^1)_{K\text{-}T}}$
0.788	0.724	0.866	0.768	0.757

[a] The *AUC* values were estimated by dividing total urinary recovery by renal clearance.

from Region II, where $f^s < \frac{1}{2}[1 + (U^s_\infty/D^s)]$ when $(F^x/F^s)_{K\text{-}T}$ should be favored. Region III, representing $f^s < (U^s_\infty/D^s)$ (or $\dot{F}^s > 1$), is not experimentally relevant.

In accord with the preceding discussion on the optimal choice of a reference in relative bioavailability calculations, there will be times when $1/(F^s/F^x)_{K\text{-}T}$ is a better estimator than $(F^x/F^s)_{K\text{-}T}$. Under these circumstances, the demarcation between Regions I and II must change so as to enlarge Region II. Therefore, the difference between Eqs. 14 and 17 is:

$$\left|\frac{1}{(F^s/F^x)_{K\text{-}T}} - \left(\frac{F^x}{F^s}\right)_{Eq.\ 7}\right| - \left|\frac{U^x_\infty/D^x}{U^s_\infty/D^s} - \left(\frac{F^x}{F^s}\right)_{Eq.\ 7}\right| = \frac{|\delta|}{[\dot{V}^x_{cl,p}]_{ex}}\frac{D^s}{U^s_\infty}\left\{2f^s - 1 - \frac{U^s_\infty}{D^s} - \frac{U^s_\infty}{D^s}\frac{([\dot{V}^s_{cl,p}]_{ex} - \dot{V}^s_{cl,r}) - ([\dot{V}^x_{cl,p}]_{ex} - \dot{V}^x_{cl,r})}{[\dot{V}^x_{cl,p}]_{ex} - \dot{V}^x_{cl,r} + \dot{V}^s_{cl,r}}\right\} \quad \text{(Eq. 20)}$$

Evidently, the critical value at which Eq. 20 becomes zero is when:

$$f^s = \frac{1}{2} + \left\{\frac{([\dot{V}^s_{cl,p}]_{ex} - \dot{V}^s_{cl,r}) - ([\dot{V}^x_{cl,p}]_{ex} - \dot{V}^x_{cl,r})}{[\dot{V}^x_{cl,p}]_{ex} - \dot{V}^x_{cl,r} + \dot{V}^s_{cl,r}} + \frac{1}{2}\right\}\frac{U^s_\infty}{D^s} \quad \text{(Eq. 21)}$$

Like Eq. 19, Eq. 21 is a straight line with an intercept of 0.5. Unlike Eq. 19, the slope of Eq. 21 varies with each specific pair of treatments x and s. However, since $1/(F^s/F^x)_{K\text{-}T}$ is used only when $[\dot{V}^s_{cl,p}]_{ex} - \dot{V}^s_{cl,r}$ is greater than $[\dot{V}^x_{cl,p}]_{ex} - \dot{V}^x_{cl,r}$, a positive contribution to the slope is assured. Thus, Eq. 20 represents a family of lines with slopes equal to or greater than 0.5 and a common intercept at $x = 0, y = 0.5$. Figure 2 illustrates the moving boundary between Regions I and II for a range of slopes. The shaded area in Fig. 2 represents the expansion of Region II at the expense of Region I if the slope increases from 0.5 to 0.75.

Application of Eqs. 19 and 21 requires some knowledge of the excretion characteristics of the drug. In the absence of an intravenous reference, f^s is an unknown, while all terms on the right side of Eqs. 19 and 21 are experimental observations. If it is known from previous studies that f generally is less than 0.5, Eq. 8 or 13 clearly is preferable to urinary excretion ratios. For given f values greater than 0.5, the superior estimator can be deduced from observed U_∞/D values with the aid of Eqs. 15, 19, and 21 and Fig. 2. That is to say, the choice between $(F^x/F^s)_{K\text{-}T}$ and $1/(F^s/F^x)_{K\text{-}T}$ depends on the criterion set by Eq. 15. Whether either of these terms is preferable to the urinary recovery ratio then depends on f for the drug and the actual observations, *e.g.*, U_∞ and $\dot{V}_{cl,r}$, for a given subject.

For comparisons involving $(F^x/F^s)_{K\text{-}T}$, Eq. 19 or the line having a slope equal to 0.5 in Fig. 2 applies. When $1/(F^s/F^x)_{K\text{-}T}$ is more appropriate, a slope first must be calculated in accordance with Eq. 21, and the proper line must be constructed in Fig. 2. For example, when $U^s_\infty/D^s = 0.4$ and the slope by Eq. 21 is 1.0, Fig. 2 shows that the urinary excretion ratio would be a better estimator of relative bioavailability than $(F^x/F^s)_{K\text{-}T}$ if f^s is >0.7 and superior to $1/(F^s/F^x)_{K\text{-}T}$ if f^s is >0.9.

EXAMPLE

To test the conclusions from the forgoing error analyses, it is necessary to use an example for which the correct answer is known. The simulated data from the previous report (1) are suitable for this purpose because all aspects of drug disposition except renal clearance were kept constant between treatments and the bioavailability of the two oral treatments was fixed *a priori* (and confirmed by comparison to the intravenous reference). Table I summarizes the information necessary to the present discussion.

Various bioavailability estimates of Treatment 2 relative to Treatment 1 are shown in Table II. The accuracy of each approximation can be ranked according to its proximity to the true value, which is the ratio of their absolute bioavailabilities. Since $[\dot{V}_{cl,p}]_{ex} - \dot{V}_{cl,r}$ is smaller after Treatment 2, $(F^1/F^2)_{K\text{-}T}$ should be closer to the true value than $1/(F^2/F^1)_{K\text{-}T}$. This is the case. Also, as predicted, the result by the *AUC*

ratio is worse than that by $(F^1/F^2)_{K\text{-}T}$. Finally, the urinary recovery ratio is the worst approximation of all, which is not unexpected since renal excretion is only a minor elimination route ($f < 0.50$).

DISCUSSION

An approximate solution for relative bioavailability estimation between nonintravascular doses was suggested previously (1). Since then, numerous inquiries have been received concerning the nature and source of its inexactitude, particularly under the assumption of constant nonrenal clearance between treatments. Simulation studies were not revealing; reasonably accurate estimates usually were obtained except when unrealistically large perturbations were considered. On the other hand, the present theoretical analysis appears to offer new insights.

Whereas the ratio of areas under the plasma curve and of urinary excretions are exact relative bioavailability determinants when their respective assumptions prevail, Eqs. 8 and 13 are only approximations when nonrenal clearance remains constant between treatments. In addition, Eqs. 8 and 13 give different answers for a given data set. However, criteria were established so that the more accurate of the two estimates always can be identified. The choice of reference for calculations should be made for each comparison within a study to ensure the best possible estimates.

Despite their approximate nature, Eqs. 8 and 13 always are preferable to area ratios and often are superior to urinary excretion ratios when nonrenal clearance is constant. The only exception is when the drug is eliminated predominantly by renal excretion. Predominance now has been defined as when $\dot{V}_{cl,r}/\dot{V}_{cl,p}$ is greater than either $\frac{1}{2}(1 + U^s_\infty/D^s)$ or:

$$\frac{1}{2} + \left\{\frac{1}{2} + \frac{([\dot{V}^s_{cl,p}]_{ex} - \dot{V}^s_{cl,r}) - ([\dot{V}^x_{cl,p}]_{ex} - \dot{V}^x_{cl,r})}{[\dot{V}^x_{cl,p}]_{ex} - \dot{V}^x_{cl,r} + \dot{V}^s_{cl,r}}\right\} \frac{U^s_\infty}{D^s}$$

depending on whether Eq. 8 or 13 is to be used, respectively. Thus, given some idea of the usual fraction excreted unchanged following an intravenous dose, a decision can be made whether the urinary excretion ratio, Eq. 8, or Eq. 13 should be chosen.

The constant nonrenal clearance assumption ordinarily is favored for another reason. Given that observed renal clearances differ between treatments, the likelihood that compensatory nonrenal clearance changes will occur to maintain a constant plasma clearance or a constant ratio of renal to plasma clearance seems remote. On the other hand, adjustments in plasma clearance based only on observed changes in renal clearance simply corroborate experimental evidence.

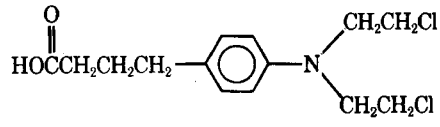
Abstract □ A sensitive and specific method for the determination of chlorambucil and its metabolite in biological fluids is reported. The method is based on selected-ion monitoring detection following simple extraction of the parent compound, its metabolite, and an internal standard (chlorambucil-d_8) from plasma and urine samples. The precision (reproducibility) of the method was 94.3 ± 1.3% with 200 ng of chlorambucil added to 1 ml of plasma. Chlorambucil degradation or alkylation of plasma proteins was minimal with plasma incubated at 24° for 4 hr. However, chloroambucil recovery decreased to 56% after plasma incubation at 37° for 4 hr. Three chlorambucil degradation products in ethyl acetate solution were found, and their structures were studied by mass spectrometry.

Keyphrases □ Chlorambucil—analysis, mass spectrometry, degradation products and metabolite, human plasma and urine □ Antineoplastic agents—chlorambucil, degradation products and metabolite, mass spectrometry, human plasma and urine □ Mass spectrometry, selected-ion monitoring—chlorambucil, degradation products and metabolite, human plasma and urine

The anticancer drug chlorambucil (I) is useful in the treatment of chronic lymphocytic leukemia, ovarian carcinoma, nodular lymphocytic lymphoma, and myelocytic leukemia (1, 2). Various analytical methods were reported for the quantitation of I, including the colorimetric determination of 4-(*p*-nitrobenzyl)pyridine derivatives (3, 4) and UV spectrophotometric (5) and chlorine titrimetric (6) methods. None of these methods provides the sensitivity and accuracy needed to study I pharmacokinetics and metabolism in humans. The mass spectrometric determination of I in plasma was reported recently (7). This



I

method requires several extraction steps, including a back-extraction of I from the aqueous solution at alkaline pH.

The quantitative method presented here is based on a one-step extraction followed by a determination of I and a metabolite in plasma and urine by mass spectrometry using a deuterated I internal standard. This method was used to study the *in vitro* I stability in plasma as well as to characterize the *in vitro* degradation products. The method was applied to the quantitation of I and a metabolite in human plasma and urine samples.

EXPERIMENTAL

Chlorambucil-d_8 Synthesis—The synthesis of chlorambucil-d_8 (labeled at *N*-chloroethyl) was adapted from a literature method (8). 4-(*p*-Nitrophenyl)butyric acid[1], 500 mg, was reacted with ethereal diazomethane[1]. The resulting methylnitrophenylbutyrate was dissolved in ethyl acetate–methanol (9:1 v/v) through which hydrogen gas was bubbled continuously for 8 hr in the presence of palladium[2] with the solvent

ratio is worse than that by $(F^1/F^2)_{K\text{-}T}$. Finally, the urinary recovery ratio is the worst approximation of all, which is not unexpected since renal excretion is only a minor elimination route ($f < 0.50$).

DISCUSSION

An approximate solution for relative bioavailability estimation between nonintravascular doses was suggested previously (1). Since then, numerous inquiries have been received concerning the nature and source of its inexactitude, particularly under the assumption of constant nonrenal clearance between treatments. Simulation studies were not revealing; reasonably accurate estimates usually were obtained except when unrealistically large perturbations were considered. On the other hand, the present theoretical analysis appears to offer new insights.

Whereas the ratio of areas under the plasma curve and of urinary excretions are exact relative bioavailability determinants when their respective assumptions prevail, Eqs. 8 and 13 are only approximations when nonrenal clearance remains constant between treatments. In addition, Eqs. 8 and 13 give different answers for a given data set. However, criteria were established so that the more accurate of the two estimates always can be identified. The choice of reference for calculations should be made for each comparison within a study to ensure the best possible estimates.

Despite their approximate nature, Eqs. 8 and 13 always are preferable to area ratios and often are superior to urinary excretion ratios when nonrenal clearance is constant. The only exception is when the drug is eliminated predominantly by renal excretion. Predominance now has been defined as when $\dot{V}_{cl,r}/\dot{V}_{cl,p}$ is greater than either $\frac{1}{2}(1 + U^s_\infty/D^s)$ or:

$$\frac{1}{2} + \left\{\frac{1}{2} + \frac{([\dot{V}^s_{cl,p}]_{ex} - \dot{V}^s_{cl,r}) - ([\dot{V}^x_{cl,p}]_{ex} - \dot{V}^x_{cl,r})}{[\dot{V}^x_{cl,p}]_{ex} - \dot{V}^x_{cl,r} + \dot{V}^s_{cl,r}}\right\} \frac{U^s_\infty}{D^s}$$

depending on whether Eq. 8 or 13 is to be used, respectively. Thus, given some idea of the usual fraction excreted unchanged following an intravenous dose, a decision can be made whether the urinary excretion ratio, Eq. 8, or Eq. 13 should be chosen.

The constant nonrenal clearance assumption ordinarily is favored for another reason. Given that observed renal clearances differ between treatments, the likelihood that compensatory nonrenal clearance changes will occur to maintain a constant plasma clearance or a constant ratio of renal to plasma clearance seems remote. On the other hand, adjustments in plasma clearance based only on observed changes in renal clearance simply corroborate experimental evidence.

at constant volume. The ethyl acetate then was evaporated using nitrogen gas, yielding the reddish-brown aminophenylbutyric acid methyl ester, which was dissolved immediately in 20 ml of 50% acetic acid (CH_3COOD[3] in D_2O[3]). In a cold room (4°), 2 ml of ethylene oxide-d_4[3] (99% isotopic purity) was added.

The reaction mixture was allowed to stand at room temperature for 24 hr. The reaction was terminated by adding ~10 ml of water and sodium bicarbonate until no significant carbon dioxide evolved. The yellowish solution was extracted with 5 × 8 ml of ethyl acetate, and the ethyl acetate was dried with anhydrous sodium sulfate and then evaporated using nitrogen gas. All traces of water were removed by azeotroping with methylene chloride.

The gummy, dark-brown product was refluxed with 4 ml of freshly distilled phosphorus oxychloride for 45 min. Excess reagent was removed by partitioning several times with water–methylene chloride. The methylene chloride layer was evaporated using a nitrogen stream and refluxed with concentrated hydrochloric acid for 6 hr at 100°. The product was extracted with ethyl acetate–hexane (1:1) and partitioned with 0.01 *M* phosphate buffer (pH 9.0)–0.01 *M* NaCl. The aqueous phase was removed and washed twice with methylene chloride, and the pH was adjusted to 3 using 2 *N* HCl.

Chlorambucil-d_8 was extracted from the acidic aqueous solution with methylene chloride. The final product in methylene chloride was examined by high-performance liquid chromatography[4] and mass spectrometry[5]. The product had >95% chemical purity and >99% isotope purity as revealed by mass spectrometry for the molecular and base ions of deuterated and undeuterated chlorambucil. The yield was ~30%.

Chlorambucil-d_8 Standardization—Synthetic chlorambucil-d_8 was used as an internal standard without further purification. Its chlorambucil-d_8 concentration was determined against a known amount of I[6] by monitoring *m/e* 326 (M − CH_2Cl) and 328 for I and *m/e* 332 (M − CD_2Cl) and 334 for chlorambucil-d_8. Also, *m/e* 326 and 328 of I were monitored against *m/e* 383 and 385 of chlorambucil-d_8. Interferences due to other ions were not observed.

Extraction of I—Deuterated I (five to 10 times the maximum I amount expected) and 0.5 ml of 4% perchloric acid were added to 0.5 ml of plasma or urine. Ethyl acetate–hexane (1:1 v/v), 0.75 ml, was added to the precipitated sample, and I was extracted into the organic layer. The sample was centrifuged for 5 min at 3000 rpm[7], and the organic layer was transferred into a 1-ml microvial with a polytef-lined cap[8]. The solvent was evaporated with purified nitrogen gas at room temperature, and several drops of dry methylene chloride were added to the dried residue. Any water present in the dried residue was removed azeotropically with methylene chloride.

Derivatization of I—Dried samples were converted to their trimethylsilyl (TMS) derivatives for GLC–mass spectrometric analysis. *N,O* - Bis(trimethylsilyl)trifluoroacetamide[8]–acetonitrile–methylene chloride (20:10:1 v/v/v) solution, 100 μl, was added to the samples and allowed to react at 100° for 10 min. The trimethylsilyl derivatives were analyzed by GLC–mass spectrometry.

GLC–Mass Spectrometry—A mass spectrometer[5] was interfaced with a gas–liquid chromatograph[9]. All analyses were performed at 70 ev. The derivatized samples were injected directly onto a GLC column (0.5 m × 2 mm, 3% OV-17 on 100–120-mesh Gas Chrom Q) at 190°. After the solvent was vented for 45 sec at 190°, the column temperature was raised directly to 310°. A I trimethylsilyl derivative eluted at 230°.

Trimethylsilyl I was monitored at *m/e* 326 (M − CH_2Cl) and 328, and the internal standard (trimethylsilyl chlorambucil-d_8) was monitored at *m/e* 383 (M^+) and 385. Deuterated I was monitored at its molecular and chlorine isotope ions (*m/e* 383 and 385) instead of at its most intense fragment ions [*m/e* 332 (M − CD_2Cl) and 334] due to an interfering ion at *m/e* 332. Because *m/e* 383 was ~10 times less abundant than *m/e* 332, 10 times more of the internal standard relative to the expected I concentration was added to give an approximately equal height compared to that of *m/e* 326.

Animal and Human Studies—Rats were given 5.6 mg of I/kg by intravenous bolus injections over 1 min into a jugular venous catheter (9) Patients were given 0.6 mg of oral I[10]/kg. Animal and human plasma and urine samples were kept on ice during collection and stored at −70° until extracted for I.

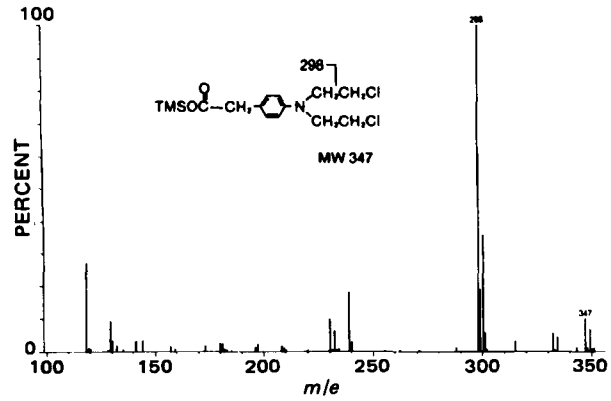

Figure 1—*Mass spectrum of metabolite, p-[4-N,N-bis(2-chloroethyl)]aminophenylacetic acid, isolated from human plasma and urine.*

Recovery Studies—Quantitative extraction was studied with ^{14}C-labeled I. ^{14}C-I[11] (505 ng, 3.5 × 10^4 cpm) was added to 1 ml of plasma, the solution was extracted three times, and the ^{14}C-recovery in the organic layer was examined in each extraction. The precision (reproducibility) of the recovery was studied by mass spectrometry. At least three samples of 5 and 1 μg and 200, 100, and 50 ng of I and appropriate amounts of the internal standard were added to 1-ml plasma samples. A single extraction was then carried out. The expected ratio of I to the internal standard was used to calculate recovery precision.

Stability of I—The I stability (10 μg/ml) in plasma at 37° was studied. At designated times, a sample was taken, the internal standard was added, and the extraction, derivatization, and analyses were performed. The disappearance rate constant, κ, of I was calculated according to $\kappa = 2.3 \log([C]_0/[C]_t)/t$, where $[C]_0$ and $[C]_t$ are the concentrations of I in the medium at times zero and t.

Drug stability in a nonaqueous medium also was studied. A solution of I in ethyl acetate was left at room temperature under ordinary laboratory conditions (with fluorescent light) for 2 weeks. The intensity of the brown color of the ethyl acetate solution increased with prolonged exposure to light. This brownish I solution was examined by GLC–mass spectrometry as the trimethylsilyl derivatives.

Calculations—The I concentrations in plasma and urine were calculated as follows:

$$\text{nanograms of I/aliquot} = \frac{\text{response of I sample}}{\text{response of internal standard sample}} \times \frac{1}{\text{relative equal weight response}} \times \text{nanograms of internal standard} \quad \text{(Eq. 1)}$$

where:

$$\text{relative equal weight response} = \frac{\text{response of I}}{\text{response of internal standard}} \quad \text{(Eq. 2)}$$

for standards of equal weight.

Identification and Determination of Phenylacetic Acid Mustard (p-[4-*N,N*-Bis(2-chloroethyl)]aminophenylacetic Acid)—Plasma and urine samples were extracted and derivatized as described for chlorambucil. Trimethylsilyl derivatives of samples were introduced directly into the GLC system, and the mass spectra of the resolved peaks were examined. Phenylacetic acid mustard was synthesized and highly purified.

The spectrum of the trimethylsilyl derivative of synthetic phenylacetic acid was compared directly to the GLC spectra of plasma and urine. The trimethylsilyl derivative of phenylacetic acid mustard eluted earlier than that of chlorambucil. For routine analysis of phenylacetic acid mustard in biological samples, *m/e* 298 (M − CH_2Cl) was monitored simultaneously with chlorambucil. The quantitation was performed as with

chlorambucil. The initial calibration was carried out using the synthetic compound against chlorambucil-d_8.

Linearity—Linearity of the I determination was studied at 1 μg and 100, 50, 10, 5, 2, 1, and 0.5 ng. Each sample was derivatized independently along with the appropriate amount of internal standard and analyzed. The linearity was evaluated against $y = x$.

Since an excess of the internal standard was used, the dynamic range of the relative equal weight response also was examined. Both a 100-fold excess of the internal standard to I and a fivefold excess of I to the internal standard were studied. The concentration range used was 5 μg–0.5 ng for I and 10 μg–50 ng for the internal standard.

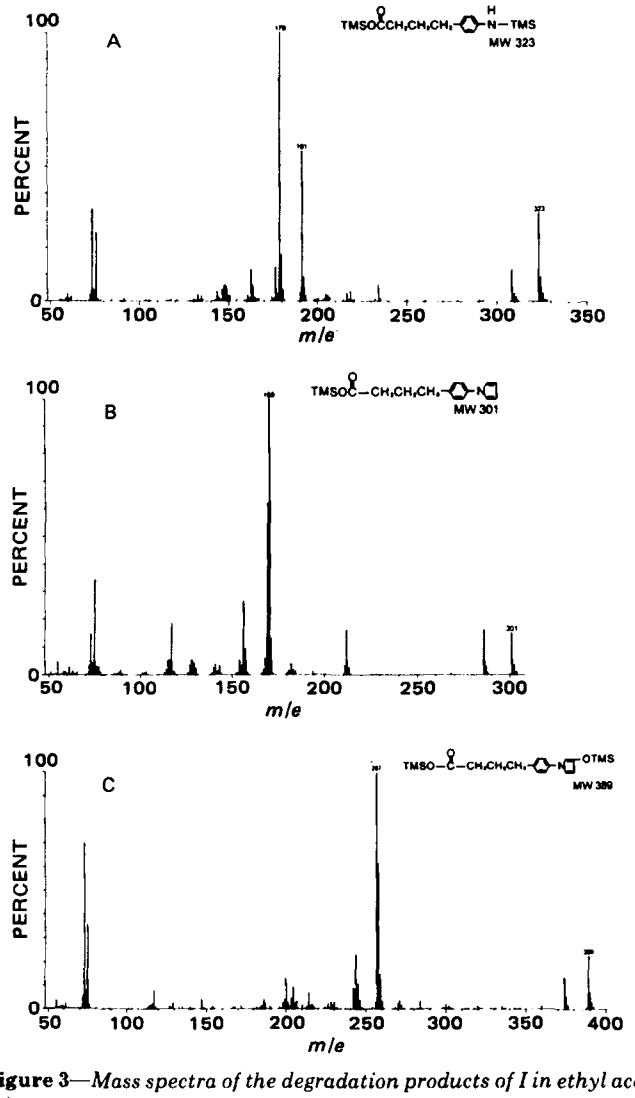

Figure 3—*Mass spectra of the degradation products of I in ethyl acetate.*

RESULTS

The spectrum of *p*-[4-*N*,*N*-bis(2-chloroethyl)]aminophenylacetic acid, a metabolite detected in human plasma and urine (Fig. 1), was identical to that of the synthesized compound.

Studies with ^{14}C-labeled I indicated that more than 70% of added I was recovered from plasma at 25°. Eighty-four percent of the I was recovered when the extraction was repeated three times. The extraction of I at concentrations of 5 and 1 μg and 200, 100, and 50 ng added to 1 ml of plasma showed percent recoveries and standard deviations of 100.4 ± 2.0, 90.5 ± 3.0, 94.3 ± 1.3, 88.2 ± 4.2, and 91.3 ± 12.8, respectively. At least three samples of each concentration were used for statistical calculations.

The linearity of the I determination between 1 μg and 500 pg showed a correlation coefficient, r, of 0.999. There was no statistical difference from $y = x$ ($p > 0.05$). The relative equal weight response calculated from either a 100-fold excess of the internal standard to I or a fivefold excess of I to the internal standard was consistent.

The disappearance of I incubated in plasma (10 μg/ml) is shown in Fig. 2. The disappearance rate constant of I was $\kappa = 0.09\ hr^{-1}$ for the plasma (Fig. 2). The correlation coefficient, r, for all data points to $C = C_0e^{-kt}$ was 0.993. Depending on the source of the plasma used, there was an ~10% variation in the disappearance rate constant.

In contrast to its degradation in an aqueous medium, I stored in a nonaqueous solution (ethyl acetate) at room temperature under fluorescent light resulted in three major products (Fig. 3). With deuterated *N*,*O*-bis(trimethylsilyl)trifluoroacetamide-d_8, the number of trimethylsilyl groups per molecule was two for Compound A (Fig. 3A), one for Compound B (Fig. 3B), and two for Compound C (Fig. 3C).

Stability data for I in plasma at 25 and 37° are presented in Table I. About 90% of the I was recovered from the plasma after 4 hr of incubation at 25° whereas only 56% of the I was recovered at 37° after that time.

Figure 4 shows a plasma I disappearance curve following an intravenous bolus injection of 5.6 mg/kg in a rat. The plasma disappearance of 0.55 mg of I/kg given orally and of *p*-[4-*N*,*N*-bis(2-chloroethyl)]aminophenylacetic acid in a patient with chronic lymphocytic leukemia is shown in Fig. 5. The selected-ion chromatograms of plasma I and the background are shown in Fig. 6.

DISCUSSION

The method presented is based on a one-step extraction from biological fluids, and the selected-ion monitoring method was used for the subsequent determination of I and a metabolite. The method can be used to study pharmacokinetics and metabolism in cancer patients. Compound I was monitored at *m/e* 326 and 328 with deuterated I at *m/e* 383 and 385. When 500 pg was derivatized and analyzed, there was sufficient sensitivity to detect quantities at the 100-pg level. However, to prevent I adsorption, the column had to be preconditioned with two to three repeated injections of I (~0.5 μg). The chlorine isotope ratio gave additional selectivity. The deuterated I synthesis can be carried out in most laboratories using basic organic chemistry techniques and starting materials readily available commercially.

A method for the determination of I in plasma was published recently (7) that depends on several extraction steps followed by mass spectrometric analysis. This method is not only lengthy, but it also requires back-extraction from the buffer at pH 9.0. The instability of the chloroethyl group at alkaline pH is well documented (6, 10, 11). At room temperature, there was ~13% hydrolysis of I in aqueous solution at pH 9.0 over 30 min (7). Alkaline exposure at higher temperatures could result in even greater hydrolysis. Although such hydrolysis is a spontaneous phenomenon observed in *in vitro* situations, the *in vivo* hydrolysis rate may be far greater. Quantitative determination of the formation of hydroxy products is necessary for an overall understanding of the pharmacokinetic behavior of I.

Table I shows the effect of the incubation time and temperature on the stability and recovery of plasma I. Compound I was stable in plasma at room temperature, but recovery decreased significantly at 37°. This low recovery probably resulted from both alkylation and hydrolysis. There

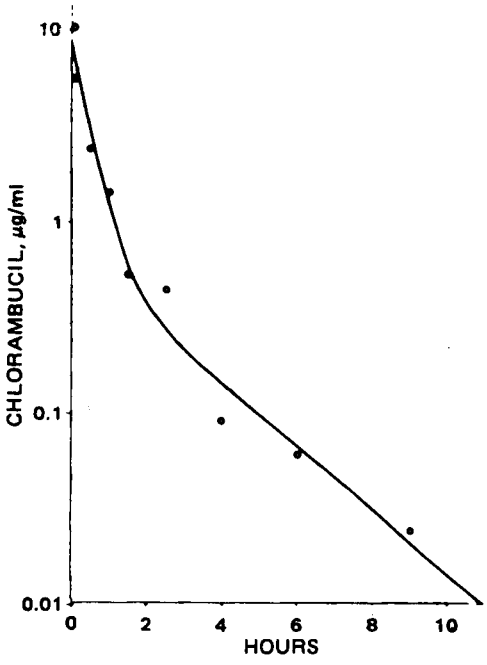

Figure 4—*Disappearance of I in rat plasma.*

may be a protective effect against hydrolysis by plasma proteins, as was shown previously for I and phenylalanine mustard (6, 12).

Three major compounds were observed in the nonaqueous system. The mass spectra with deuterated *N,O*-bis(trimethylsilyl)trifluoroacetamide

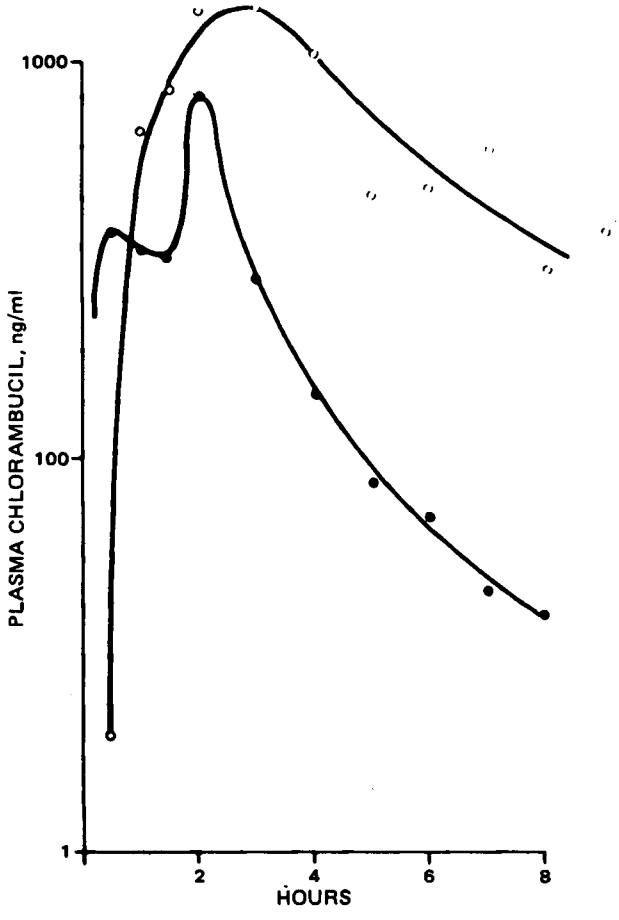

Figure 5—*Plasma I disappearance in a patient with chronic lymphocytic leukemia. The patient was given 0.55 mg/kg orally, and samples were drawn at designated times and analyzed for* p-*[4-*N,N-*bis(2-chloroethyl)]aminophenylacetic acid (○) and I (●).*

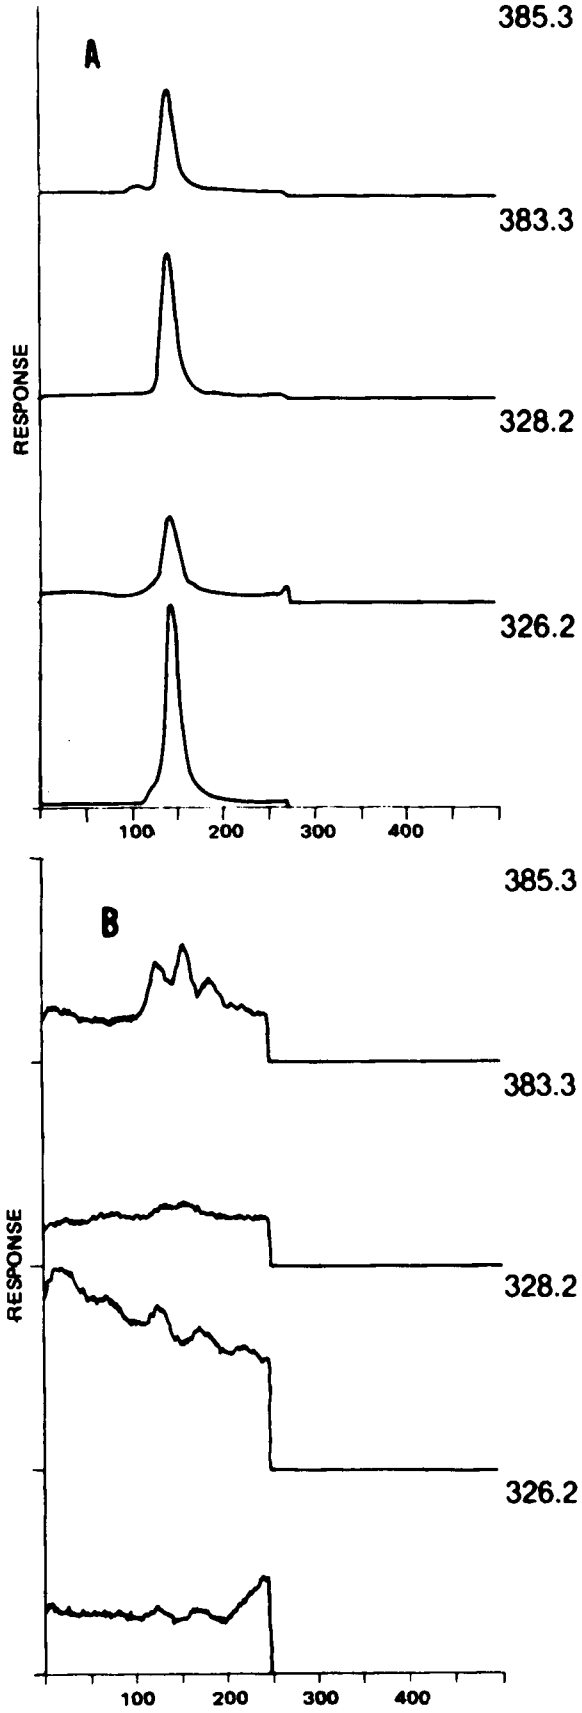

Figure 6—*Ion chromatograms of plasma I and plasma background. Compound I, 200 ng, and 2.0 μg of the internal standard were added to 1.0 ml of plasma. After extraction and derivatization, 0.1 ml of equivalent plasma was analyzed (Fig. 6A). In Fig. 6B, 1.0 ml of plasma was extracted and derivatized, and 0.5 ml of equivalent plasma was analyzed.*

Table I—Temperature and Time Effects on I Recovery from Plasma

Hours	Recovery[a] 25°	37°
0.0	90.5 ± 3.0	80.4 ± 3.0
0.5	82.5 ± 4.8	76.6 ± 3.7[b]

of Compound A indicated that there were two replaceable hydrogens. The highest mass observed was 323 (odd mass), indicating that *m/e* 323 was either a fragment produced from a higher even mass or a molecular ion containing an odd number of nitrogens. Furthermore, there was no indication of chlorine in *m/e* 323. When compared to the chlorambucil molecule, it is most likely that *m/e* 323 was the molecular ion and the chlorambucil nitrogen was preserved. The carbon isotope ratio ($^{12}C/^{13}C$) indicated that 16 carbons was a reasonable assignment. Two major fragments, *m/e* 191 and 179, most likely were due to a highly stable styrene-like fragment and the *p*-aminobenzyl ion.

All three compounds showed the loss of 131 amu [$(CH_3)_3SiOCOCH_2$], indicating that the carboxyl group of I was intact. Based on these observations, Compound A (Fig. 3A) was suggested to be *p*-aminophenylbutyric acid. From similar observations, Compounds B and C (Figs. 3B and 3C) were suggested to be 4-pyrrolylphenylbutyric acid and 4-[3-(hydroxy)pyrrolyl]phenylbutyric acid. No *p*-aminobenzyl-like ion was observed in Compound B or C, probably due to the stabilization by the pyrrole group. The dark-brown color observed in the nonaqueous solution as well as in powdered preparations such as ^{14}C-I most likely was due to these pyrrole derivatives.

The α,β-unsaturated compounds 2-[4-*N*,*N*-bis(2-chloroethyl)]-aminophenyl-2-butenoic acid and 2-[4-bis(2-chloroethyl)]aminophenylacetic acid were found in rats given 8 mg of I/kg ip (13). Both compounds are products of the β-oxidation of I. The phenylacetic acid derivative in human urine and plasma was found (Figs. 1 and 5), and attempts to find the α,β-unsaturated compound were unsuccessful. More extensive studies of I metabolism are in progress.

Antiradiation Compounds XVII: Binding Ability of Radiation-Protective *N*-Heterocyclic Aminoethyl Disulfides and Thiosulfates to DNA

WILLIAM O. FOYE ˣ, MAHRUKH M. KARKARIA, and WILLIAM H. PARSONS

Received August 2, 1979, from the *Samuel M. Best Research Laboratory, Massachusetts College of Pharmacy, Boston, MA 02115.* Accepted for publication August 22, 1979.

Abstract □ Binding parameters for a series of *N*-heterocyclic aminoethyl disulfides and thiosulfates to DNA were determined at different ionic strengths and pH values. None of the thiosulfates showed any binding ability, but the disulfides revealed DNA binding abilities that were suppressed both by increased ionic strength and hydrogen-ion concentration. No correlation between DNA binding ability and radiation protective activity in mice was evident.

Keyphrases □ Antiradiation compounds—binding ability of radioprotective *N*-heterocyclic aminoethyl disulfides and thiosulfates to DNA □ Radioprotective compounds—*N*-heterocyclic aminoethyl disulfides and thiosulfates, DNA binding ability □ DNA—binding by radioprotective *N*-heterocyclic aminoethyl disulfides and thiosulfates □ *N*-Heterocyclic aminoethyl disulfides and thiosulfates—DNA binding ability, radiation protection evaluated

The ability of the radioprotective aminothiols cystamine and bis(2-guanidinoethyl) disulfide to bind reversibly to DNA, RNA, and other nucleoproteins has been demonstrated (1), but the significance of this ability in radiation protection of mammals is not clear. Evidence has accumulated that the aminothiol protecting agents cause a temporary inhibition of nucleoprotein synthesis and facilitate repair of radiation damage (2–5), but the necessity for complexation in this process has not been shown.

To demonstrate whether or not DNA binding is important to radiation protection or repair, a series of *N*-heterocyclic substituted aminoethyl disulfides and thiosulfates showing varying degrees of radiation protection to mice was observed for the ability to bind to DNA. A correlation with protecting ability could show DNA-binding ability to be essential to the protective or repair process.

Most studies of the mechanism of radiation protection in mammals utilized the *N*-unsubstituted aminothiols and simple *S*-derivatives, such as 2-mercaptoethylamine, its phosphorothioate, thiosulfate, or disulfide (cystamine), or 2-mercaptoethylguanidine. Since *N*-substituted de-

[a] All compounds were prepared using 1.1 ml of sodium ^{35}S-thiosulfate solution; these quantities represent equal moles (0.8 mmole).

rivatives of 2-mercaptoethylamine have shown greater protection in mammalian tests and provided compounds having activities ranging from good to nonprotective, such a series should be suitable for observing a possible correlation between DNA binding ability and radiation protective ability. Accordingly, a series of *N*-heterocyclic substituted 2-mercaptoethylamine derivatives (6) having the $HetNHCH_2CH_2SX$ structure (I) was utilized (Het = aromatic or alicyclic heterocycle and X = SO_3H, SCH_2CH_2NHHet). The possible mechanisms by which the aminothiols act as radiation-protective agents were reviewed (7).

EXPERIMENTAL[1]

Synthesis of Radiolabeled Thiosulfates and Disulfides—Synthesized compounds were identified[2] by comparison of IR spectra with those of authentic samples (6). Purity was checked by TLC on silica gel plates with detection of spots by exposure to iodine vapor. Both radiolabeled and nonradiolabeled compounds were prepared on a small scale.

Preparation of Sodium ^{35}S-Thiosulfate Solution—An ampul of sodium ^{35}S-thiosulfate[3] (22.5 mCi/mmole) was broken, and ~0.0074 g was weighed and spiked with cold sodium thiosulfate to give a weight of 0.5745 g (3.6 mmoles). The sodium thiosulfate was transferred to a 5-ml volumetric flask, and distilled water was added to the mark. Each milliliter of this solution contained 0.114 g (0.72 mmole) of sodium thiosulfate. The remaining sodium thiosulfate was stored *in vacuo* over phosphorus pentoxide.

The synthetic procedures for the organic thiosulfates were essentially those already described (6). Weights of starting materials, yields, and melting points are listed in Table I. The disulfides were prepared as follows.

2-Aminoethyl ^{35}S-Disulfide Dihydrochloride—A solution of iodine (0.2487 g, 0.98 mmole) in 5 ml of alcohol was added dropwise to a solution of ^{35}S-2-aminoethanethiosulfuric acid in 1 ml of water. The solution was refluxed for 90 min, and ethanol was removed by distillation. The aqueous residue was extracted with chloroform after the pH was adjusted to 9.0 with 10% NaOH.

The chloroform extract was dried over magnesium sulfate, and the chloroform was evaporated under reduced pressure (40°). The resulting oil was treated with hydrochloric acid in ethanol, and the hydrochloride was twice recrystallized from absolute ethanol, giving 0.042 g (20% yield), mp 219–221° dec. [lit. (8) mp 211°].

2-(N-Morpholinyl)ethyl ^{35}S-Disulfide Dihydrochloride—A solution of ^{35}S-2-(*N*-morpholinyl)ethanethiosulfuric acid (0.449 g, 1.96 mmoles) and potassium iodide (0.065 g, 0.392 mmole) in 1 ml of water was heated, and a solution of iodine (0.2487 g, 0.98 mmole) in 5 ml of alcohol was added dropwise. The solution was refluxed for 90 min, and the ethanol was removed under vacuum at 40° in a rotary evaporator. A little water was added, the solution was filtered, and the filtrate was extracted with ether after the pH was adjusted to 9.0 with 10% NaOH.

The ether layer was dried over magnesium sulfate and evaporated under reduced pressure to an oil, which was treated with hydrochloric acid in ethanol. The solution was evaporated to dryness, and the residue was twice recrystallized from absolute ethanol, giving 0.1056 g (30% yield) of white crystals, mp 225–226° dec. [lit. (9) mp 229–230°]; R_f 0.53 (methanol–water, 6:4).

2-(N-Piperidinyl)ethyl ^{35}S-Disulfide Dihydrochloride—The preceding procedure was followed with ^{35}S-2-(*N*-piperidinyl)ethanethiosulfuric acid (0.441 g, 1.96 mmoles), giving 0.11 g (31% yield) of white crystals, mp 267–269° dec. [lit. (9) mp 270–271°]; R_f 0.28 (*n*-butanol–water–acetic acid, 49.5:49.5:1).

Anal.—Calc. for $C_{14}H_{28}N_2S_2{\cdot}2HCl$: C, 46.52; H, 8.37; N, 7.75; S, 17.74. Found: C, 46.6; H, 8.5; N, 7.7; S, 17.4.

2-(N-Pyrrolidinyl)ethyl ^{35}S-Disulfide Dihydrochloride—The preceding procedure was used with ^{35}S-2-(*N*-pyrrolidinyl)ethanethiosulfuric acid (0.4135 g, 1.96 mmoles), giving 0.067 g (20% yield), mp 231–233° dec. [lit. (9) mp 227–228°]; R_f 0.25 (*n*-butanol–water–acetic acid, 49.5:49.5:1).

Preparation of Stock DNA Solutions—Stock solutions of DNA[4] were prepared in phosphate buffers of the following ionic strengths and pH:

Ionic Strength 0.14, pH 7.2—potassium phosphate (monobasic), 0.0158 *M*; sodium phosphate (dibasic), 0.0404 *M*; sodium diethylenediaminetetraacetate, 0.003 *M*; and carbon dioxide-free distilled water, *qs*, 1000 ml.

Ionic Strength 0.021, pH 7.2—phosphate buffer of ionic strength 0.14 and pH 7.2, 75 ml; and carbon dioxide-free distilled water, *qs*, 1000 ml.

Ionic Strength 0.02, pH 6.0—potassium phosphate (monobasic), 0.0132 *M*; sodium phosphate (dibasic), 0.0013 *M*; sodium diethylenediaminetetraacetate, 0.003 *M*; and carbon dioxide-free distilled water, *qs*, 1000 ml.

The DNA concentration was measured[5] at 259 nm using the molar absorptivity $E(P)$ = 6650 (10). Appropriate dilutions were made, and a Beer–Lambert plot was constructed using the regressed absorption values. Spectral scans of DNA in the different stock solutions were identical. The DNA concentration in micromoles of DNA phosphorus per milliliter was determined:

$$\text{concentration of DNA phosphorus } (\mu\text{moles/ml}) = \frac{1000}{6650} \times 12.5 \times \text{dilution factor} \times \text{absorbance} \quad \text{(Eq. 1)}$$

The concentration values ranged from 1.7 to 2.1 μmoles of DNA phosphorus/ml for the different stock solutions.

Preparation of Stock Solutions of Radiolabeled Thiosulfates and Disulfides—Stock solutions containing 3 μmoles/ml of radiolabeled thiosulfates and disulfides were prepared in the appropriate phosphate buffer and stored at 4°. For the equilibrium dialysis experiments, concentrations of 0.5, 1.0, 1.5, 2.0, and 2.5 μmoles/ml were prepared at the time of the experiments.

Equilibrium Dialysis—The equilibrium dialysis experiments were performed as described by Wagner and Arav (11), using 5-ml glass or acrylic dialysis cells (12). A cellular dialysis membrane (mol. wt. cutoff 12,000) was pretreated by five consecutive 30-min boilings in distilled water and storage at 4° in phosphate buffer for 3–4 hr. The filled dialysis cells were immersed in a thermostated shaker bath at 37 ± 0.5° and shaken until equilibrium was reached (generally 24 hr).

The concentrations of compound in each chamber were determined by radioactivity measurements, or by absorbance measurements in the case of the quinoxalinyl derivative. For radioactivity determinations, 2-ml aliquots from each chamber were transferred to liquid scintillation vials (20 ml). To each was added 15 ml of a liquid scintillation cocktail[6], and the solution was shaken vigorously and counted[7]. An average of five readings was taken, and experiments were carried out in triplicate.

Concentrations of free (C_F) and bound (C_B) species were calculated:

$$C_F = \frac{CT_F}{CT_T} \times \text{total concentration of radiolabeled compound} \quad \text{(Eq. 2)}$$

$$C_B = \frac{CT_T - CT_F}{CT_T} \times \text{total concentration of radiolabeled compound} \quad \text{(Eq. 3)}$$

[1] Elemental analyses were carried out by Dr. F. B. Strauss, Oxford, England. Melting points were determined on a Mel-Temp capillary melting-point block.

Table II—Binding Parameters of Disulfides with DNA [a]

pH	Ionic Strength	Compound	K_a, mM^{-1}	$1/n$	n
7.2	0.14	2-Aminoethyl disulfide	0.51	3.57	0.28
		2-(*N*-Morpholinyl)ethyl disulfide	0.0	0.0	—
		2-(*N*-Piperidinyl)ethyl disulfide	0.40	3.70	0.27
		2-(*N*-Pyrrolidinyl)ethyl disulfide	0.49	5.05	0.20
7.2	0.021	2-Aminoethyl disulfide	10.84	2.48	0.41
		2-(*N*-Morpholinyl)ethyl disulfide	0.0	0.0	—
		2-(*N*-Piperidinyl)ethyl disulfide	5.22	1.81	0.55
6.0	0.020	2-Aminoethyl disulfide	6.93	1.65	0.61

[a] The values were determined from reciprocal (Klotz) plots.

The mathematical treatment of the dialysis experiment data to give association constants, if all binding sites of DNA exhibit the same affinity toward a small molecule, can be expressed as:

$$K_a = \frac{r}{C_F(n - r)} \quad \text{(Eq. 4)}$$

where K_a is the intrinsic association constant, r is the number of adsorbates bound per reference unit (DNA base pair), n is the number of available binding sites per reference unit (DNA base pair), and C_F is the equilibrium concentration of free unbound species.

Plots of both r/C_F *versus* r according to Scatchard (13):

$$r/C_F = nK_a - rK_a \quad \text{(Eq. 5)}$$

and $1/r$ *versus* $1/C_F$ according to Klotz (14):

$$1/r = 1/n + 1/K_a(n)(C_F) \quad \text{(Eq. 6)}$$

were used to determine K_a and n. The binding data were plotted according to both equations. Both gave linear plots, but the correlation coefficient for the Klotz equation was better (>0.91). Values of K_a and n are listed in Table II as determined by the Klotz equation.

DISCUSSION

Binding studies of the heterocyclic aminoethyl disulfides and thiosulfates were carried out by equilibrium dialysis (11), and the concentrations of free and bound species at equilibrium were determined by radioactivity measurements. Radiolabeled thiosulfates were synthesized using sodium ^{35}S-thiosulfate and the heterocyclic aminoethyl chlorides where the heterocycles were morpholine, piperidine, and pyrrolidine; 2-bromoethylamine was also converted to the thiosulfate. The thiosulfates were converted to the radiolabeled disulfides by oxidation with iodine (15) since the thiosulfate was labeled on the outer sulfur atom. Yields from both reactions were generally in the 30–40% range, but piperidinyl thiosulfate was obtained in an 83% yield.

2-(2-Quinoxalinyl)aminoethanethiosulfuric acid (6) also was studied but was not labeled with sulfur 35. It exhibited strong UV absorption at 249 and 359 nm, which did not interfere with the absorption peak of DNA (256 nm at pH 7.2) and could be used as such. The concentration of bound compound was found by breaking the complex with dimethyl sulfoxide (16).

The results of the equilibrium dialysis experiments for the *N*-heterocyclic aminoethyl thiosulfates indicate that no binding took place with DNA. In mice (Table III), the quinoxalinyl derivative and aminoethanethiosulfuric acid had high radiation protective activity (>50% survival at 30 days), the piperidinyl derivative had moderate radiation protective activity, and the morpholinyl and pyrrolidinyl derivatives were inactive. Apparently, DNA binding is not a requirement for protective activity by the aminoalkyl thiosulfates, at least of the intact molecule. The negatively charged thiosulfate probably is repelled by the phosphate groups of DNA and the positively charged amino groups probably remain associated with the thiosulfate groups. *In vivo*, it is possible that the thiosulfates are metabolized to the disulfides, a reaction that occurs readily under hydrolytic conditions (17).

The binding parameters for the heterocyclic aminoethyl disulfides are listed in Table II. Comparison of the radioprotective activities (Table III) with the DNA binding data indicates that the heterocyclic compound with good activity (morpholinyl) did not exhibit binding ability whereas

Compound	Drug Dose, mg/kg	Radiation Dose, rads[a]	Survival at 30 Days, %
2-Aminoethanethiosulfuric acid[b]	150	800R[c]	73
2-(*N*-Morpholinyl)ethanethiosulfuric acid	100	849	0
2-(*N*-Piperidinyl)ethanethiosulfuric acid	60	849	20
2-(*N*-Pyrrolidinyl)ethanethiosulfuric acid	70	849	0
2-(*N*-Quinoxalinyl)ethanethiosulfuric acid	400	849	70
2-Aminoethyl disulfide[d]	146	650R[c]	60
2-(*N*-Morpholinyl)ethyl disulfide	20	849	50
2-(*N*-Piperidinyl)ethyl disulfide	30	849	10
2-(*N*-Pyrrolidinyl)ethyl disulfide	20	849	10

[a] Radiation dosage was from ^{137}Cs γ-irradiation given at a rate of 141.5 rads/min except where indicated otherwise. [b] Data from D. L. Klayman, M. M. Grenan, and D. P. Jacobus, *J. Med. Chem.*, **12**, 510 (1969). [c] Dose is expressed in roentgens of X-radiation. [d] Data from M. L. Beaumariage, *C. R. Soc. Biol.*, **151**, 1788 (1957), using rats.

the poor protective agents (piperidinyl and pyrrolidinyl) showed some binding at ionic strength 0.14 and good binding at ionic strength 0.021. However, 2-aminoethyl disulfide showed both good binding ability and radioprotective ability, although the binding ability was depressed at the higher ionic strength which would resemble physiological conditions more closely. Obviously, no correlation can be drawn between DNA binding ability and radiation protective ability for the disulfides.

Some useful information may be deduced from the binding parameters. Straight-line plots were obtained with both Scatchard and Klotz equation, but the Klotz equation, after linear regression analysis, gave the best correlation coefficient (>0.91). The linear binding isotherms for the disulfides indicate that only one type of binding site on the DNA molecule interacted with these compounds. Comparison of the association constants at two different ionic strengths, 0.14 and 0.021, shows that binding at the higher ionic strength was suppressed, probably through competition with other ions. Comparison of the n values also indicates that the number of available binding sites was reduced. In addition, the lower binding constants at pH 6.0, in comparison to those at pH 7.2, indicate competition with hydrogen ions. At the lower pH, the greater degree of protonation of the amino groups might be expected to lead to greater association with phosphate groups of DNA.

The inability of the morpholine derivative to bind to DNA might be assumed to result from the polar nature of the hetero oxygen atom. However, the fact that the piperidinyl derivative gave lower association constants than the unsubstituted 2-aminoethyl disulfide at both ionic strengths suggests that steric hindrance prevented the association of the charged nitrogen with DNA phosphate groups. Apparently, only ionic interactions occurred. Also, since the association constants were suppressed at the higher ionic strength, it is questionable that the disulfides, including cystamine, would bind to DNA appreciably under physiological conditions. From the effects of ionic strength and pH on the binding constants and the lack of correlation with radiation protective activity, it may be concluded that binding to DNA is not a requisite for radiation protection or nucleic acid repair.

Biodistribution of ^{14}C-Lomustine in an Animal Tumor Model

FRANK P. CASTRONOVO, Jr.[x], MAJIC S. POTSAID, and SUSAN Y. KOPIWODA

Received May 14, 1979, from the *Department of Radiology, Massachusetts General Hospital, Boston, MA 02114.* Accepted for publication August 13, 1979.

Abstract □ A formulation of ^{14}C-lomustine in propylene glycol–ethanol (4:1) was administered intravenously to rats infiltrated with glioma tumors of the astrocytic series (RT6). The organ and tumor distribution of this agent was followed at 1, 4, 12, and 24 hr. Rapid blood disappearance (0–1 hr) of the label concomitant with an increase in all organs except the lung, muscle, and brain was observed. Only the blood, liver, and muscle contained >1% of the dose after 24 hr. The bladder, liver, small bowel, and kidneys concentrated the highest percentages throughout the study. The distribution of ^{14}C-lomustine in the tumor relative to the brain, muscle, and blood showed a maximum 4–12 hr after administration.

Keyphrases □ Lomustine, ^{14}C-labeled—biodistribution, rat tumor model □ Antineoplastic agents—^{14}C-lomustine, biodistribution, rat tumor model □ Biodistribution—^{14}C-lomustine, rat tumor model

Early detection of malignant tumors serves as a basis for improving cancer control. One experimental approach is to label minute quantities of antineoplastic drugs with appropriate radionuclides and to follow their biodistribution in a suitable animal tumor model. One example involved the *N*-nitrosoureas, a class of chemotherapeutic drugs for various malignant tumors (1). The structures of several *N*-substituted nitrosoureas are shown in Table I, where the chlorine- or fluorine-substituted haloethyl derivatives are the most active, with the methyl-substituted nitrosourea possessing the least chemotherapeutic activity (2).

The agent investigated in this study, lomustine [1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea[1], CCNU, I], is an asymmetrical *N*-substituted nitrosourea used for the palliative treatment of primary and metastatic brain tumors and for Hodgkin's disease (3). This investigation followed the radiopharmacodynamics of ^{14}C-I in tumor-bearing rats for 24 hr after intravenous injection.

EXPERIMENTAL

Materials and Methods—The *N*-nitrosoureas are lipophilic agents whose solubility characteristics require formulations with hydroalcoholic vehicles (4). Propylene glycol–ethanol (4:1) was the vehicle chosen for intravenous administration of ^{14}C-I[1] (5).

The ^{14}C-I [1-(2-chloroethyl-U-^{14}C)-3-cyclohexyl-1-nitrosourea] had a specific activity of 12.156 mCi/mmole (52.017 μCi/mg; 1.0195 mCi in 19.6 mg) and a radiochemical purity of 99.7%. The ^{14}C-I was labeled at the chloroethyl moiety (Table I). Prior to the animal studies, the ^{14}C-I was added to 10 ml of the propylene glycol–ethanol mixture.

Tissue Distribution—The rat tumor model (RT6) was a brain malignancy induced by repeated intravenous injections of *N*-nitrosomethylurea (6). The induced tumors were gliomas of the astrocytic series, the histology of which did not vary significantly with serial passage through tissue culture, subcutaneous implantation, or freezing (6). This model was used previously for the determination of the tumor affinity of various ^{99m}Tc-labeled compounds (7). Early detection of this type of tumor in patients with glioblastoma multiforme would be advantageous since the current survival estimate for this pathology 2 years after surgery is ~10% (8).

To determine the pharmacodynamics of ^{14}C-I, 0.2 ml was injected intravenously *via* the tail vein in adult male rats. Three rats were sacrificed at 1, 4, 12, and 24 hr postadministration. Each 0.2 ml of solution had 0.385 mg (1.65 μmoles) of ^{14}C-I (20 μCi of ^{14}C).

At the time of sacrifice, the blood (7% of the body weight), brain, liver, spleen, pancreas, lungs, small bowel, kidneys, heart, bladder, bone marrow, muscle, and tumor fluid, capsule, and necrotic center were isolated from each animal, and their radioactivity content was measured. The dose percentage per gram of tissue, the dose percentage per organ, and the mean ± standard deviation (n = 3) were calculated.

Activity Measurement—Approximately 100 mg of each tissue was placed in a glass scintillation vial containing 2 ml of tissue solubilizer (9).

Each sample was minced with a scissors, and the capped vials were stored at room temperature until dissolution occurred. A toluene-based scintillation solution [4.2 mg of 2,5-diphenyloxazole/ml and 52.5 mg of 1,4-bis[2-(5-phenyloxazolyl)]benzene/ml], 15 ml, was added to each vial, and the radioactivity content was determined for each sample (10).

RESULTS

The initial biodistribution (1 hr) and subsequent translocation data for 24 hr for ^{14}C-I are shown in Tables II and III and are illustrated in Figs. 1–3. The data are displayed *versus* time as the mean dose percentage per organ (±*SD*) (Table II), the log of the mean dose percentage per gram (Figs. 1–3), and the dose percent per gram ratio of the tumor to the brain, muscle, and blood (Table III). Each point represents the mean for three determinations.

After intravenous administration, the whole body blood level of ^{14}C-I dropped rapidly from ~8% after 1 hr to <3% after 4 hr (Table II); therefore, the amount of tracer in the vascular compartment remained constant through the termination of the experiment at 24 hr. Concomitant with its clearance from the blood, the ^{14}C-I activity showed an increased concentration in all organs except for the brain, lungs, and muscle. Thereafter, the remaining organs exhibited a tracer concentration decrease. The muscle, liver, small bowel, and kidneys concentrated the highest dose percentage after 1 hr whereas the blood, liver, and muscle contained >1% of the dose after 24 hr (Table II).

The bladder and kidney cortex contained the greatest quantity of activity per gram (Fig. 1), emphasizing the rapid kidney excretion of ^{14}C-I. In fact, the bladder activity remained maximum up to 24 hr whereas the other organs decreased to a greater extent. Figure 2 illustrates the ^{14}C-I change per gram in the blood, muscle, and brain with time. The vascular compartment remained constant after 4 hr (protein binding), but the muscle and brain decreased rapidly up to 24 hr.

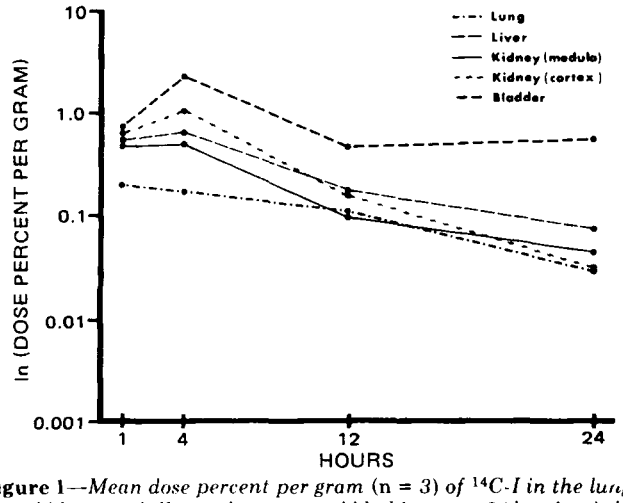

Figure 1—*Mean dose percent per gram* (n = 3) *of* ^{14}*C-I in the lungs, liver, kidney medullar and cortex, and bladder up to 24 hr after injection.*

For the tumor, a consistent ^{14}C-I uptake was observed at all times in the order: fluid > capsule > necrotic portion (Table II). The dose percentage per gram ratio of the tumor capsule to the brain rose rapidly to a maximum of 8.31 after 12 hr and decreased thereafter (Table III). Tumor to muscle and tumor to blood ratios were maximum after 4 hr and also decreased rapidly thereafter.

DISCUSSION

The localization and sizing of neoplasms were demonstrated with various tumor-specific radiopharmaceuticals (11). However, current radiodiagnostic agents are limited in their ability to be specific markers for tumors. Better definition not only could help in the identification of the histology but also could more precisely delineate and assist with effective treatment. Tumors may be defined better if radiopharmaceuticals are developed whose structures are based on chemotherapeutic agents.

The *N*-substituted nitrosoureas, a class of synthetic drugs currently studied for their anticancer properties (12), were selected for study. Their structural diversity (Table I) and limited chemical stability *in vivo* led investigators to hypothesize that their mechanism of action is alkylation (13–15). The 1-alkyl-1-nitrosoureas are believed to decompose under physiological conditions to yield alkyl diazohydroxides, which are progenitors of carbonium ions, and isocyanic acid or alkyl isocyanates, which undergo further reaction (13).

Compound I initially metabolizes to an alkyl diazohydroxide and an alkyl isocyanate. The former structure undergoes further decomposition to yield a vinyl carbonium ion, which eventually breaks down to acetaldehyde. The alkyl isocyanate reacts with water to form the corresponding carbamic acids, which decompose to yield cyclohexylamine. If the concentration of the latter compound is high, as is the case when therapeutic amounts are administered, a symmetrical urea is formed. Under the conditions of this investigation, nontherapeutic amounts of I were administered (0.385 mg of I/0.3-kg rat or 1.28 mg/kg), thus reducing the probability of a symmetrical urea. The production of alkylating agents during the *in vivo* decomposition of I results in the attack of nucleophilic

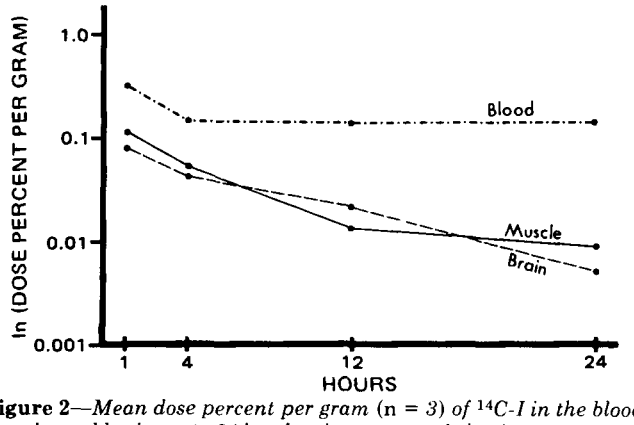

Figure 2—*Mean dose percent per gram* (n = 3) *of* ^{14}*C-I in the blood, muscle, and brain up to 24 hr after intravenous injection.*

Table III—Dose Percent Mean ^{14}C-I per Gram Ratios of Tumor to Various Organs (n = 3)

Hours	Tumor / Brain	Tumor / Muscle	Tumor / Blood
1	0.765	0.566	0.153
4	5.94	4.58	1.66
12	8.31	1.36	1.25
24	6.41	3.77	0.238

centers of biologically important molecules by these products. Reactions with amino, sulfhydryl, or hydroxyl groups yield alkylated materials, which alter the functional ability of biological materials. Such alkylation is thought to produce the mutagenic, teratogenic, carcinogenic, and cytotoxic activity of this class of chemotherapeutic agents (16).

Previous work with ^{14}C-chloroethyl-labeled I showed the label to be bound to nucleic acids and proteins both *in vitro* and *in vivo* (17). Specifically, the carbon-14 attached to nucleic acid bases and tRNA. Several investigators studied cyclohexyl derivatives of I in aninals, where extensive fixation of the label to the plasma proteins was found (18, 19). The tissue biodistribution of ^{14}C-cyclohexyl-I was studied in rabbits, where most of the label was found in the plasma, liver, kidneys, and lungs; after 12 hr, almost all of the carbon-14 label was eliminated *via* the kidneys and bile (5). The preparation and biodistribution of ^{13}N-bis(2-chloroethyl)nitrosourea, labeled primarily to the nitroso group, was reported recently (20). This positron-labeled agent was detected in a human neuroblastoma (mouse model) shortly after administration.

The results with ^{14}C-I correlate well with the literature relative to rapid blood disappearance and uptake in the liver and intestine (5, 18). The maximum tumor to organ ratios (Table III) suggest that γ-emitting radionuclides such as ^{99m}Tc ($t_{1/2p}$ = 6 hr) and ^{111}In ($t_{1/2p}$ = 2.6 days) labeled to I have potential as brain tumor scanning agents.

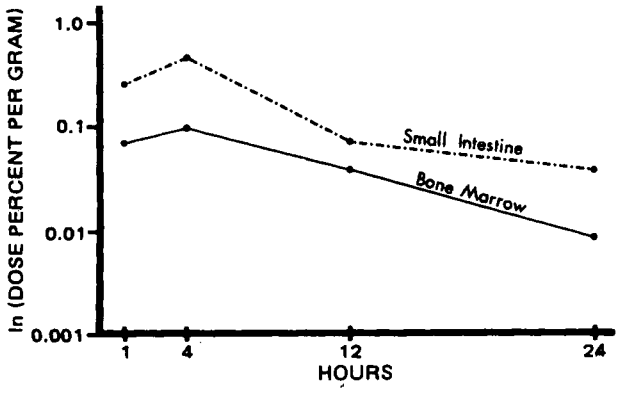

Figure 3—*Mean dose percent per gram* (n = 3) *of* ^{14}*C-I in the small intestine and bone marrow up to 24 hr after intravenous injection.*

New Calculation Method of Mean Total Body Clearance of Drugs and Its Application to Dosage Regimens

WIN L. CHIOU

Received May 17, 1979, from the *Clinical Pharmacokinetics Laboratory and Department of Pharmacy, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612.* Accepted for publication July 3, 1979.

Abstract □ A new method for calculating the mean total body drug clearance is proposed for determining the mean dosing rate for patients. In this method, the mean clearance can be calculated from the individual clearance values by the harmonic mean method, or it can be determined by dividing the same absorbed dose by the arithmetic mean of the areas under the plasma level–time curve from time zero to infinity from all of the subjects or patients studied. In this method, the arithmetic mean method is assumed to have been used for calculation of literature mean plasma levels. Various methods for calculating mean clearances also are evaluated. These methods yield different mean clearance values from the same set of individual data, resulting in different dosage regimen recommendations.

Keyphrases □ Total body clearance—mean calculation, harmonic mean method, dosage rate □ Pharmacokinetics—mean total body clearance, calculation, harmonic mean method □ Dosage regimens—mean total body clearance, calculation, harmonic mean method

The total body clearance, Cl_p, of drugs is an important clinical pharmacokinetic parameter since, in linear pharmacokinetics, the intravenous dosing rate for maintaining the desired steady-state plasma level in an ith patient, C_{pi}^{ss}, is theoretically equal to the product of C_{pi}^{ss} and the total body drug clearance of the patient, Cl_{pi} (1). This principle also should be applied to the mean dosing rate for achieving a certain mean plasma level in multiple dosing after correction for the dose fraction absorbed.

BACKGROUND

Although it occasionally is feasible to individualize a patient's dosage regimen by studying or predicting the patient's Cl_p of the drug (1), the mean total body clearance obtained from group studies of normal subjects or patients often is used as a guide for initiating drug therapy (1–8). Therefore, proper calculation of the mean total body clearance might be important in pharmacokinetic studies.

There appear to be no serious questions in the literature regarding the validity of methods for calculating the individual Cl_p from plasma data obtained after intravenous administration. For example, the individual Cl_p can be calculated by any of the following three equations, which should yield the same result in linear pharmacokinetics (6, 7):

$$Cl_p = \frac{\text{intravenous dose}}{AUC} \qquad \text{(Eq. 1)}$$

$$Cl_p = V_{d,\text{area}}\beta \qquad \text{(Eq. 2)}$$

$$Cl_p = V_p K_{el} \qquad \text{(Eq. 3)}$$

where AUC is the area under the plasma level–time curve from time zero to infinity, $V_{d,\text{area}}$ is the apparent volume of distribution determined by the area method, β is the terminal exponential rate constant in the plasma level decay profile, V_p is the apparent volume of distribution of the central compartment, and K_{el} is the first-order elimination rate constant from the central compartment in a multicompartmental open model (7, 9). In a one-compartment open model system, Cl_p can be calculated by Eq. 1 or as the product of the apparent volume of distribution, V_d, and the apparent first-order elimination rate constant, K. Such methods will be referred to as the product-of-means method.

The arithmetic mean method is commonly used for calculating the mean Cl_p from a group of subjects (8, 10–19). In this method, all of the individual clearance values ($Cl_{p1}, Cl_{p2}, \ldots, Cl_{pn}$) are added and the sum is divided by the total number of subjects, n. In another commonly used method, apparently based on Eq. 3, the arithmetic mean V_p is multiplied by the arithmetic mean K_{el} (10). A recent study (10) on theophylline clinical pharmacokinetics reported that, depending on which of the two methods was used for calculation of the mean Cl_p, a 25–30% difference could occur. Therefore, depending on the method used, the recommended intravenous theophylline infusion rate can vary similarly (10). This inconsistency was considered to be unfortunate by the authors (10). Undoubtedly, different mean Cl_p values also will result for other drugs when these two methods are employed.

The purpose of this note is to propose a new method for calculation of the mean total body clearance that might be useful for the determination of mean dosage regimens in patients. In addition, several existing methods will be evaluated.

THEORETICAL

There are many ways to calculate the mean value of a data set. For example, the mean can be determined by the arithmetic mean, geometric mean, and harmonic mean methods (20). In pharmacokinetic studies, the arithmetic mean method has been used almost exclusively to calculate the means of the steady-state trough, peak, or averaged plasma drug levels after multiple or constant-rate dosing. This method also is used most often in calculation of the mean plasma levels of many endogenous substances such as creatinine and urea. Therefore, it is logical to propose that when a mean dosage regimen is recommended to obtain a targeted mean steady-state plasma level, $\overline{C_p^{ss}}$, for a group of patients, the arithmetic mean of the individual steady-state plasma levels achieved should be used to evaluate the recommended dosage regimen. Based on this assumption, it will be shown that the harmonic mean method should be used for calculating the mean total body clearance to achieve the desired arithmetically averaged steady-state blood, plasma, or serum level.

Since:

$$C_{pi}^{ss} = \frac{K_{0i}}{Cl_{pi}} \qquad \text{(Eq. 4)}$$

where K_{0i} is the zero-order dosing rate for the ith patient, therefore:

$$\overline{C_p^{ss}} = \frac{1}{n}\sum_{i=1}^{n} C_{pi}^{ss} \qquad \text{(Eq. 5)}$$

$$\overline{C_p^{ss}} = \frac{1}{n}\sum_{i=1}^{n} \frac{K_{0i}}{Cl_{pi}} \qquad \text{(Eq. 6)}$$

If $K_{01} = K_{02} = \ldots = K_{0n} = K_0$, then:

$$\overline{C_p^{ss}} = \frac{K_0}{n}\sum_{i=1}^{n} \frac{1}{Cl_{pi}} \qquad \text{(Eq. 7)}$$

$$\overline{C_p^{ss}} = \frac{K_0}{\overline{Cl_p}} \qquad \text{(Eq. 8)}$$

where:

$$\frac{1}{\overline{Cl_p}} = \frac{1}{\text{harmonic mean } Cl_p} = \frac{1}{n}\sum_{i=1}^{n} \frac{1}{Cl_{pi}} \qquad \text{(Eq. 9)}$$

Since for each individual the Cl_p also is related to the dose and to the AUC according to Eq. 1, Eq. 9 becomes:

$$\frac{1}{\overline{Cl_p}} = \frac{1}{n}\left(\frac{AUC_1}{\text{dose}_1} + \frac{AUC_2}{\text{dose}_2} + \ldots + \frac{AUC_n}{\text{dose}_n}\right) \qquad \text{(Eq. 10)}$$

Arithmetic mean	0.162	0.312	0.277	0.0676	0.4209	10.00	10.63	13.58	10.72

[a] Data from Ref. 18. [b] Determined by $(K_{el}V_p)/\beta$. [c] Based on the mean Cl_p calculated by the harmonic mean method (0.0636 liter/kg/hr). [d] Based on the mean Cl_p calculated by the arithmetic mean method (0.0676 liter/kg/hr). [e] Based on the mean Cl_p calculated by the $\overline{K}_{el}\overline{V}$ method (0.0864 liter/kg/hr). [f] Based on the mean Cl_p calculated by the $\overline{V}_{d,area}\overline{\beta}$ method (0.0682 liter/kg/hr).

When all of the doses used are the same or all of the obtained AUC values are corrected for the same dose when different doses are used, Eq. 10 can be simplified and rearranged to:

$$\overline{Cl}_p = \frac{\text{dose}}{(AUC_1 + AUC_2 + \ldots + AUC_n)/n} \qquad \text{(Eq. 11)}$$

$$\overline{Cl}_p = \frac{\text{dose}}{\text{arithmetic mean } AUC} \qquad \text{(Eq. 12)}$$

The method employing Eq. 12 for calculating the mean Cl_p will be referred to as the mean area method. This method and the harmonic mean (Eq. 9) method theoretically should yield the same mean Cl_p.

DISCUSSION

An example based on reported theophylline data (18) illustrates the consequence of employing different methods for the calculation of the mean total body clearance when the targeted mean blood level is set at 10 mg/liter. Relevant pharmacokinetic data in seven asthmatic subjects and analytical results are summarized in Table I. The mean Cl_p values determined by the harmonic mean, arithmetic mean, and two product-of-means ($\overline{K}_{el}\overline{V}_p$ and $\overline{V}_{d,area}\overline{\beta}$) methods are 0.0636, 0.0676, 0.0864, and 0.0682 liter/kg/hr, respectively. The largest difference among these methods is 35.8%.

Only the newly proposed harmonic method results in a correct arithmetic mean of 10 mg/liter of the steady-state blood level. The $\overline{K}_{el}\overline{V}_p$ method yields a mean blood level of 13.5 mg/liter. These results are based on the assumption that the dosing rate for all patients is equal to 10 mg/liter times the mean Cl_p. The difference in the mean Cl_p of propranolol in three subjects (14) estimated by the harmonic and arithmetic mean methods is 41.8%. In all of the methods studied, the harmonic mean method yields the lowest mean clearance values in the discussed and other simulated examples.

When employing the mean AUC method (Eqs. 11 and 12), the dose used for the entire test population should be the same. If not, the AUC for each individual should be corrected to the same dose in terms of the total dose or dose per unit of body weight or body surface area. The potential error of using the linear trapezoidal rule method for the estimation of the AUC was discussed recently (21). In estimating the individual total body drug clearance after oral dosing, the potential first-pass effect in the liver and lungs was ignored in many pharmacokinetic studies. Appropriate equations for such corrections are available (22–24).

It was pointed out recently (24) that the conventional concept for obtaining the initial plasma level at time zero after intravenous bolus dosing by the summation of the exponential coefficients (*i.e.*, $\Sigma_{i=1}^{n} A_i$ in $\Sigma_{i=1}^{n} A_i e^{-K_i t}$) and also for obtaining the AUC by $\Sigma_{i=1}^{n} (A_i)/(K_i)$ is not correct in terms of absolutes and could result in serious errors under certain circumstances. However, such conventional methods of pharmacokinetic analysis might be adequate as a reasonable approximation for most studies (24).

This discussion is based on the assumption that the arithmetic mean method is used for averaging the steady-state blood or plasma level data. Statistically speaking, if other methods such as the harmonic or geometric mean methods could be shown to be superior for averaging these blood or plasma data, a different conclusion regarding the best approach for estimating the mean Cl_p could be reached. Based on the rationale discussed under *Theoretical*, it also was concluded recently that the harmonic mean method is best for calculating the mean volumes of distribution for designing a rational dosage regimen (25). For general purposes, the conventional arithmetic mean method is acceptable for averaging the apparent volumes of distribution and the total body clearances of drugs. The harmonic mean method has been recommended for calculation of the mean biological half-life of drugs (12).

Simultaneous GLC Determination of Clofibrate and Clofibric Acid in Human Plasma

MICHAEL S. WOLF and JAMES J. ZIMMERMAN ˣ

Received February 6, 1979, from the *Department of Pharmaceutics, School of Pharmacy, Temple University, Philadelphia, PA 19140.* Accepted for publication July 24, 1979.

Abstract □ A simultaneous assay for the detection of clofibrate and its metabolite, clofibric acid [2-(*p*-chlorophenoxy)-2-methylpropionic acid], is described. This GLC method is rapid and does not require a derivatization step. It is sensitive to 1-μg/ml levels of either compound in biological samples and can be used to characterize the *in vivo* conversion of clofibrate ester to the free acid.

Keyphrases □ Clofibrate—simultaneous GLC assay with clofibric acid, human plasma □ Clofibric acid—simultaneous GLC assay with clofibrate, human plasma □ Hypolipemic agents—clofibrate, simultaneous GLC assay with clofibric acid, human plasma

Clofibrate, an oral hypolipemic agent, is administered traditionally as the intact ester and assayed as the free acid, clofibric acid [2-(*p*-chlorophenoxy)-2-methylpropionic acid]. In the past decade, considerable attention has been devoted to the development of assays for these compounds (1–12). These methods have been used to generate pharmacokinetic data for clofibric acid.

Clofibric acid assays include spectrophotometric (1), radiometric (2), GLC (3–8), and high-pressure liquid chromatographic (9) techniques, all having approximately the same sensitivity. Clofibrate can be assayed easily by both spectrophotometric and GLC (1) methods, but clofibric acid determinations usually are tedious and time consuming, involving numerous extraction and evaporation steps. A major obstacle in the development of a GLC method for the simultaneous determination of clofibrate and clofibric acid has been the lack of a liquid phase sufficiently polar to yield reproducible clofibric acid peaks without derivatization. A flash derivatization would be ideal for the simultaneous determination, but the heat required would degrade the parent ester.

This paper describes a simultaneous assay method for clofibrate and clofibric acid that is rapid and does not require a derivatization step. It is sensitive to 1-μg/ml levels of either compound in biological samples and can be used to characterize the conversion of clofibrate to clofibric acid.

EXPERIMENTAL

Reagents—Fresh reagent grade ether was used without prior distillation. Purified granular ammonium sulfate was used in the salting-out procedure, and a 50% (w/v) NaF solution was used for plasma esterase deactivation. Commercially available benzocaine was recrystallized and used as the internal standard.

Clofibric acid was prepared by alkaline hydrolysis of clofibrate[1]. Clofibrate, 10 g, was combined with 80 ml of 30% KOH and 40 ml of alcohol USP, and the solution was refluxed for 4 hr as described previously (10). The hydrolysate was cooled to room temperature, extracted with 20 ml of ether to remove any remaining clofibrate, and acidified with 5% H_2SO_4 until litmus paper showed it to be strongly acidic. The acidified solution was extracted with ether (3 × 15 ml), and the extracts were combined and evaporated to dryness. The resulting crystalline residue was recrystallized with hot methanol, yielding ~70%, mp 118–118.5°. Qualitative confirmation was obtained by mass spectrometry[2] and NMR spectroscopy[3].

Sample Preparation—Human plasma, 1 ml, spiked with clofibrate and clofibric acid was added to a 10-ml test tube containing 20 μl of sodium fluoride solution and 550 mg of ammonium sulfate. The mixture was agitated for 30 sec with a vortex mixer[4] and then centrifuged for 10 min at 3500 rpm. The supernate (0.5 ml) was transferred to a fresh test tube, and 100 μg of benzocaine was added. The resulting solution was extracted with 1 ml of ether by agitating for 3 min. The sample tubes were sealed[5] and then centrifuged at 3500 rpm for 30 min to separate the phases. After centrifugation, the ether layer was withdrawn, and 1 μl was injected into the gas chromatograph.

GLC Conditions—The gas chromatograph[6] was equipped with a hydrogen flame-ionization detector. The glass column (1 m × 2 mm i.d.) was packed with 100–120-mesh Gas Chrom Q coated with 10% Silar 10 C[7]. Nitrogen was used as the carrier gas at a 24-ml/min flow rate. The oxygen and hydrogen flow rates were 240 and 40 ml/min, respectively; the injection port, oven, and detector temperatures were 200, 220, and 250°, respectively.

Hydrolysis—A 250-ml three-necked flask was placed in a heating mantle supported on a magnetic stirrer. Two necks were sealed, and a thermometer was placed in the third neck. The temperature control was calibrated and maintained at 37°. Clofibrate, 5 mg, was added within the reaction vessel to a pH 10.5 buffer system consisting of 0.1 *N* Na_2CO_3 and 30 ml of 0.1 *N* $NaHCO_3$. Samples were withdrawn and assayed by the simultaneous method.

RESULTS

Clofibric Acid Identification—The free acid of clofibrate, clofibric acid, when subjected to chemical-ionization mass spectrometry, provided a M + H ion at *m/e* 216. This mass is consistent with the formula of clofibric acid and is supported further by abundant ions at *m/e* 169 (equivalent to the loss of –COOH from the protonated compound) and at *m/e* 128 (corresponding to *p*-C_6H_4ClOH). The structure was confirmed further by other small peaks corresponding to the expected mass fragments.

Further confirmation was provided by an independent NMR spectrum. NMR demonstrated the presence of an aromatic ring (δ 6.75–7.3), –COOH (δ 10.1), and $-C(CH_3)_2-$ (δ 1.55), consistent with the clofibric acid structure. Chloroform was the solvent.

Assay—Under the described GLC conditions, clofibrate and clofibric acid eluted with retention times of 1.8 and 2.5 min, respectively (Fig. 1). Blank plasma samples did not produce any interfering peaks with retention times similar to either clofibrate or clofibric acid.

The standard curves of peak height ratio *versus* concentration in the 10–200-μg/ml range were linear for both compounds. The least-squares estimate for the line fitting a plot of the mean of the peak height ratios obtained on different days *versus* the clofibric acid concentration ($n = 7$, $r = 0.999$) was $y = (6.17 \times 10^{-3})x + 0.024$. For clofibrate ($n = 9$, $r = 0.999$), the regression line was $y = (3.04 \times 10^{-2})x - 0.012$. The standard errors of the estimate were 1.53×10^{-2} and 1.02×10^{-1}, respectively. There was a systematic reduction in all peak height ratios over 1 month, but the change was not statistically significant.

While the assay as outlined has a lower sensitivity limit of ~10 μg/ml for both compounds, the sensitivity can be increased 10-fold to ~1 μg/ml by evaporating the solvent after extraction and redissolving the residue in 100 μl of ether.

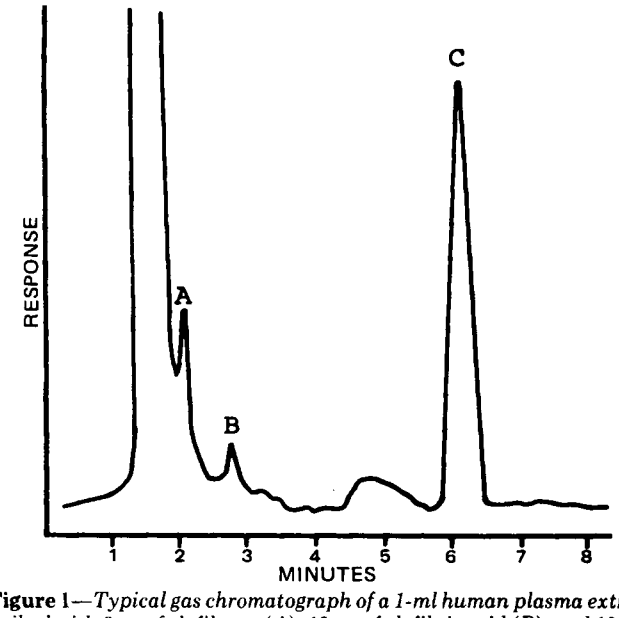

Figure 1—*Typical gas chromatograph of a 1-ml human plasma extract spiked with 6 μg of clofibrate (A), 10 μg of clofibric acid (B), and 100 μg of benzocaine (C).*

Recovery—To achieve maximum recovery of both the ester and the acid, a salting-out technique was utilized. The technique was based on a literature method (11) in which the efficacy of ammonium chloride as an agent for salting drugs out of plasma was examined. A later study (12) showed the effectiveness of ammonium sulfate for the same purpose. A standard mixture of 200 μg of clofibrate and 50 μg of benzocaine was used to study this technique for clofibrate recovery from aqueous solution and plasma. A peak height ratio of 12 was obtained from 1 ml of an aqueous solution of this mixture. For the plasma determination, varying amounts of ammonium sulfate were used to determine the amount needed to achieve the same peak height ratio. Amounts ranged from 300 (ratio of 9.45) to 900 (ratio of 6.65) mg/ml, with the maximum peak height ratio of 11.95 obtained using 550 mg of ammonium sulfate/ml of plasma.

Table I—Recovery of Clofibrate and Clofibric Acid after Alkaline Hydrolysis at 37° and pH 10.51 [a]

Minutes	Clofibrate, μmole/ml	Clofibric Acid, μmole/ml	Recovery, μmole/ml	Percent of Initial Concentration
10	0.190	0.019[b]	0.190	101
20	0.161	0.051	0.212	102
30	0.149	0.060	0.209	101
45	0.145	0.069	0.214	103
60	0.128	0.079	0.207	100
90	0.099	0.102	0.201	97
120	0.074	0.133	0.207	100

[a] Initial clofibrate concentration was 0.207 μmole/ml. Constant pH was maintained with a carbonate buffer. [b] This value was close to the assay sensitivity limit and could not be measured as accurately as other values.

Hydrolysis—The accuracy of the simultaneous assay was tested by following the disappearance of clofibrate and the appearance of clofibric acid during alkaline hydrolysis of the ester at pH 10.51 and 37°. There was excellent recovery at each period, indicating that the assay accurately measured the ester and the hydrolysis product simultaneously (Table I). Degradation of the ester followed pseudo-first-order kinetics over the 2-hr run, yielding a least-squares estimate for the degradation rate constant of 7.98×10^{-3} min^{-1}.

DISCUSSION

The described GLC method has several advantages over previously described assays. It is fast and specific. About 10 samples can be determined in 1 hr by one person. Its specificity is of particular interest because the disappearance of the parent ester and the appearance of the acid metabolite can be followed simultaneously, facilitating the determination of their respective pharmacokinetic parameters. The method does not require derivatization, which can introduce an additional variable.

The method sensitivity may be increased severalfold by evaporating the solvent and redissolving the residue in an appropriate amount of solvent. Column degradation by the free acid cannot be avoided. Under heavy use and with an overnight oven temperature of 200° or greater, column repacking may be necessary every 6–8 weeks.

Cactus Alkaloids XLII: 3,4-Dimethoxy-β-phenethylamine and Heliamine from the Mexican Cereoid *Backebergia militaris*

RACHEL MATA and JERRY L. McLAUGHLIN ˣ

Received May 31, 1979, from the *Department of Medicinal Chemistry and Pharmacognosy, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.* Accepted for publication July 16, 1979.

Abstract □ *Backebergia militaris* (Andot) Bravo ex Sánchez Mejorada yielded alkaloid crystals from a fractionated ethanol extract of only 20 g of plant material. The alkaloid was identified as heliamine (6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline) hydrochloride. A second alkaloid, 3,4-dimethoxy-β-phenethylamine hydrochloride, was crystallized after preparative TLC of the mother liquors. Both compounds were isolated previously from other cactus species.

Keyphrases □ Alkaloids, cactus—heliamine, 3,4-dimethoxy-β-phenethylamine, isolation, identification □ Heliamine—isolation from cacti, identification, 3,4-dimethoxy-β-phenethylamine □ 3,4-Dimethoxy-β-phenethylamine—isolation from cacti, identification, heliamine □ Cactus alkaloids—heliamine, 3,4-dimethoxy-β-phenethylamine, isolation, identification

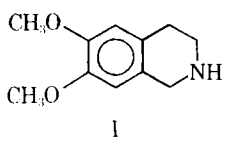
In a chemotaxonomic analysis of several giant Mexican cereoid species of cacti, the new technique of mass-analyzed, ion kinetic energy spectrometry was used to detect and identify alkaloids in ethanol extracts of small (1-g) samples of dried cactus material (1). This survey included *Backebergia militaris* (Andot) Bravo ex Sánchez Mejorada, in which alkaloids at *m/e* 194 and 208 were detected; the major components at these peaks were identified on the basis of fragmentation patterns as heliamine (6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline) and *N*-methylheliamine (oxymethylcorypalline). Both alkaloids were identified previously in other cactus species (2–4). Alkaloid ions at *m/e* less than 194 were not examined.

DISCUSSION

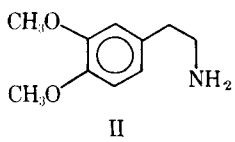
In a previous TLC screening of this species as part of a continuing search for cactus alkaloids, two major compounds (a primary amine and a secondary amine) were detected in the screening extracts. Subsequently, an ethanol extract of only 20 g of plant material was subjected to anion exchange chromatography to resolve phenolic and nonphenolic alkaloids (5). Analytical TLC of the phenolic fraction was negative for any major alkaloids, but analytical TLC of the nonphenolic fraction detected two major and at least two minor alkaloid components. After acid–base partitioning of the nonphenolic fraction, one of the major alkaloids (I) crystallized directly as the hydrochloride. Preparative TLC of the mother liquor permitted resolution of the second major alkaloid from I and a third unidentified minor alkaloid; the second major alkaloid (II) then crystallized as the hydrochloride.

Analytical TLC of I with a series of reference cactus alkaloids suggested that it was heliamine (6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline); this identification was confirmed by melting-point comparisons, IR spectroscopy, and electron-impact mass spectrometry. TLC of II tentatively identified it as 3,4-dimethoxy-β-phenethylamine, and this identification was confirmed by its melting point and its IR and electron-impact mass spectra. Heliamine was reported initially as a natural product from the related cereoid cactus, *Pachycereus pecten-aboriginum* (Engelm.) Br. and R. (2); concurrently, it was crystallized from another Mexican cereoid, *Lemaireocereus weberi* (Coult.) Br. and R. (3). 3,4-Dimethoxy-β-phenethylamine was detected or isolated previously from several cactus species representing all three major cactus tribes (6–8).

Heliamine biogenesis would likely involve cyclization of a primary amine such as 3,4-dimethoxy-β-phenethylamine (or, perhaps, its 3-*O*-demethylated derivative) (9); consequently, the cooccurrence of heliamine and 3,4-dimethoxy-β-phenethylamine is not surprising. Heliamine reportedly has inhibitory activity against sarcoma 45 in rats (10), while 3,4-dimethoxy-β-phenethylamine has questionable involvement in certain mental processes (11).



I



II

EXPERIMENTAL

Plant Material—Cuttings of fresh *B. militaris* (2.8 kg) conforming to published taxonomic descriptions (12) were obtained[1]. The fresh sections were sliced, frozen, freeze dried, and reduced to a powder through a 2-mm screen in a Wiley mill.

Alkaloid Extraction and Fractionation—Twenty grams of the powdered plant material was macerated with stirring in 1 liter of ethanol for 24 hr. After filtration to remove the marc, the ethanol extract was concentrated and subjected to anion-exchange chromatography on 20 g of resin[2] prepared in the hydroxide form (5). Upon analytical TLC using solvent systems and procedures as described previously (14), the phenolic fraction was devoid of any major alkaloids while the nonphenolic fraction contained two major and at least three minor compounds.

The residue from the nonphenolic extract was dissolved in 100 ml of 1 *N* HCl and partitioned with chloroform and ether (three times with 100 ml of each solvent). The aqueous solution pH was adjusted to 9.5 with sodium hydroxide, and the partitions were repeated. The combined chloroform–ether extracts from the basic solutions were dried over anhydrous sodium sulfate, concentrated, and acidified with 5% HCl in ethanol.

Isolation and Identification—*Heliamine (I)*—Upon further concentration of the acidic solution and addition of ether, a precipitate (300 mg) of alkaloid hydrochlorides formed. This precipitate was recrystallized (ethanol–ether) to produce 150 mg (0.75% yield) of the hydrochloride of I (mp 255°)[3]. Analytical TLC with Systems A, B, F, and G (14) identified I as heliamine; when the plate was sprayed with fluorescamine, the purple chromophore observed under UV light was diagnostic for the secondary amine function (15). IR[4] and electron-impact mass[5] spectra were essentially identical to those observed with previously isolated (mp 248°) and synthesized (mp 252°) heliamine hydrochloride (3).

3,4-Dimethoxy-β-phenethylamine (II)—The mother liquors from the crystallization of I were subjected to preparative TLC [eight plates, Solvent A (14)]. Three bands were scraped from the plates and eluted with ethanol: one was additional heliamine; a second was an unidentified compound which failed to crystallize; and the third, II, formed a crystalline hydrochloride (8 mg). Recrystallizations (ethanol–ether) raised the melting point to 149° (5 mg, 0.025% yield). Analytical TLC (14) identified II as 3,4-dimethoxy-β-phenethylamine; when the plate was sprayed with fluorescamine, the bright-yellow fluorescence observed under UV light was diagnostic for the primary amine function (15). IR and electron-impact mass spectra were indistinguishable from those of reference 3,4-dimethoxy-β-phenethylamine hydrochloride[6] (mp 150°).

Determination of Two Fenamates in Plasma by High-Performance Liquid Chromatography

CHIEN K. LIN, CHING S. LEE ˣ, and JOHN H. PERRIN

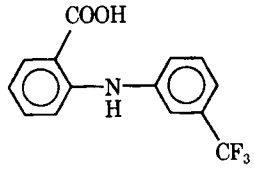
Received March 6, 1979, from the *Department of Pharmacy, College of Pharmacy, University of Florida, Gainesville, FL 32610.* Accepted for publication July 2, 1979.

Abstract □ A high-performance liquid chromatographic determination of two fenamates in human plasma is described. Plasma samples, 1.0 ml, to which 4 μg of internal standard had been added, were extracted with carbon tetrachloride under acidic conditions. Portions of the organic layer were transferred and evaporated to dryness under nitrogen. Residues were dissolved in methanol, and an aliquot was injected into the liquid chromatograph. An intermediate polarity, bonded cyanopropylsilane column was used with a mobile phase of water–acetonitrile–acetic acid (60:30:10 v/v/v). The flow rate was 1 ml/min, and the effluent was monitored at 254 nm. Flufenamic acid and mefenamic acid had retention times of 10.4 and 9.2 min, respectively. In the 1–10-μg range, the mean flufenamic acid recovery from control plasma was 100.7 ± 3.4% (n = 18). A typical calibration curve had a regression equation of $y = 0.132x - 0.04$ with $\gamma^2 = 0.99$. Preliminary stability tests showed that flufenamic acid is stable for at least 2 weeks in plasma after freezing.

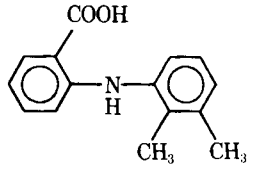
Keyphrases □ Flufenamic acid—analysis, high-performance liquid chromatography, plasma, rats, humans □ Mefenamic acid—analysis, high-performance liquid chromatography, plasma, rats, humans □ High-performance liquid chromatography—analysis, flufenamic acid, mefenamic acid, plasma, rats, humans

Flufenamic acid[1] (I) and mefenamic acid[1] (II) are potent nonsteroidal analgesic and anti-inflammatory agents used in the management of rheumatoid arthritis. Spectrophotometric (1, 2), colorimetric (3), and fluorometric (2, 4, 5) methods have been applied for fenamate analysis in aqueous solution and in biological samples such as plasma, urine, and milk. A fluorometric method for the determination of I in the nanogram range used a chamber paper analysis apparatus (6). A convenient TLC technique was reported for screening three fenamates and their metabolites (7).

Only one GLC method (8) utilizing electron-capture detection has been reported. Although it was described for II, it could be adapted to the analysis of I in blood and urine. However, details of the assay were not provided (8).



I



II

This article describes the high-performance liquid chromatographic (HPLC) determination of plasma fenamate levels. A single extraction step is followed by reversed-phase chromatography, eliminating the tedious and time-consuming procedures required by the previously reported methods (3, 7). Flufenamic acid and mefenamic acid can be internal standards for each other during either assay. The use of an internal standard improves both the precision and the accuracy of plasma level determination.

EXPERIMENTAL

Apparatus—Fenamate analyses were carried out on a liquid chromatograph[2] equipped with dual-delivery pumps[3], a single injector[4], and a single-chamber UV absorbance detector[5].

Reagents—Carbon tetrachloride[6], acetic acid[6], and sulfuric acid[7] were analytical reagent grade. Methanol[8] and acetonitrile[8] were distilled in glass. Solvents including distilled, deionized water were filtered routinely through 0.45-μm filters[9] prior to use in the liquid chromatograph.

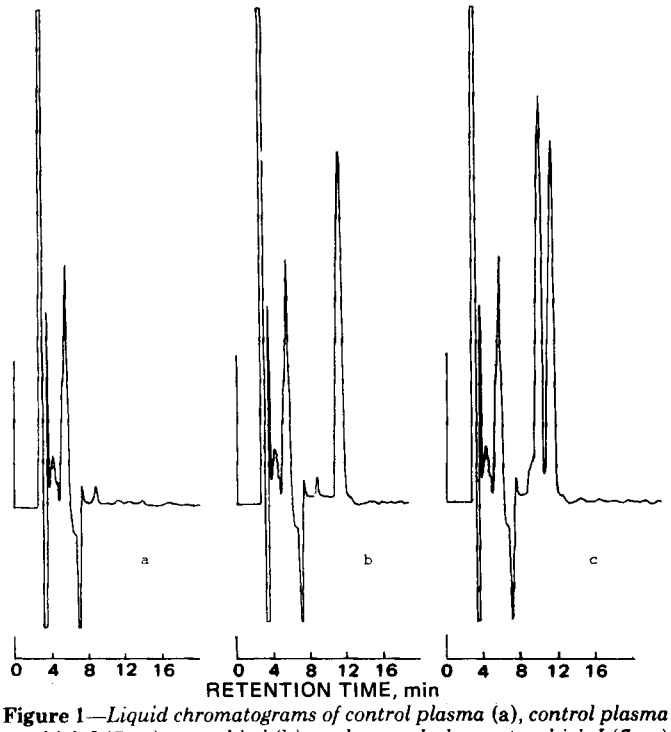

Figure 1—*Liquid chromatograms of control plasma* (a), *control plasma to which I* (7 μg) *was added* (b), *and control plasma to which I* (7 μg) *and II* (4 μg) *were added* (c).

Preparation of Standards—Ten milligrams of each fenamate was dissolved in methanol to yield a 100-μg/ml stock solution. Working standard solutions of I containing 1, 2, 3, 5, 7, and 10 μg/ml were prepared by diluting the stock solution with methanol–water (1:1 v/v). Six calibration samples were used in each run to establish the HPLC standard curve and to determine recovery reproducibility. Mefenamic acid solution, 4 μg/ml, served as the internal standard.

Measurement of Plasma I—Plasma samples, 1.0 ml, to which 4 μg of internal standard had been added, were mixed thoroughly by hand shaking and acidified with 0.9 *M* H_2SO_4. After the addition of 8 ml of carbon tetrachloride, the sample tubes were spun on a test tube rotator for 15 min and centrifuged. The aqueous phase was removed by aspiration. Portions of the carbon tetrachloride were transferred to another tube and evaporated to dryness under nitrogen. Residues were dissolved in 0.5 ml of methanol, and a 40-μl aliquot was injected into the liquid chromatograph.

The standard plasma curve was constructed by plotting the peak height ratios (I/II) *versus* the weight content of I. The peak height ratio of an unknown sample was used to determine the amount of I present. The standard samples were run concurrently with the unknown samples as described previously.

Chromatographic Conditions—A stainless steel column (30 cm × 4 mm i.d.) was packed with a stable reversed-phase stationary phase of porous silica beads (mean diameter 10 μm) coated with chemically bonded cyanopropylsilane monolayers[10]. The mobile phase was water–acetonitrile–acetic acid (60:30:10 v/v/v). The operating temperature was ambient, and the flow rate was 1 ml/min with an operating pressure of 1000 psi. The column effluent was monitored continuously at 254 nm with a full-scale deflection of 0.02 aufs. A short wash (acetonitrile for 15 min followed by chloroform for 10 min at 1 ml/min) at the end of each analytical day removed strongly retained solutes.

RESULTS AND DISCUSSION

Acceptable separation of the fenamates in this reversed-phase system was dependent on the amount of organic solvent in the mobile phase and on the effective pH of the aqueous component. A simple acetonitrile–water system (30:70 v/v) with an effective pH of 5.5 did not resolve the solutes. Since the fenamates are moderate acids (pKa 3.9 for I and 4.2 for II), their capacity factors were increased by lowering the effective pH of this solvent, and the water–acetonitrile–acetic acid system (60:30:10 v/v/v, effective pH 2.7) resolved the two solute peaks.

Table I—Flufenamic Acid (I) Recovery from Human Plasma (n = 3)

I Added, μg	I Found, μg	Recovery[a], %
1	1.028 ± 0.031	102.8 ± 3.1
2	2.090 ± 0.430	104.5 ± 4.3
3	2.760 ± 0.079	92.0 ± 7.9
5	5.260 ± 0.051	105.0 ± 5.0
7	7.000 ± 0.000	100.0 ± 0.0
10	10.000 ± 0.000	100.0 ± 0.0
1–10[b]	—	100.7 ± 3.4

[a] Expressed as mean ± *SD*. [b] n = 18.

Table II—Peak Height Ratios for the Calibration Curve

I Added, μg	Peak Height Ratios	*SD*
1	0.099	0.003
2	0.230	0.010
3	0.355	0.026
5	0.605	0.025
7	0.857	0.015
10	1.297	0.021

Figure 1 presents liquid chromatograms of control human plasma, control plasma to which I was added, and control plasma to which both fenamates were added. As indicated in Fig. 1*a*, negligible interfering peaks were found in the control plasma specimens. Under the described chromatographic conditions, I and II had retention times of 10.4 and 9.2 min, respectively. Better resolution for the two fenamates can be obtained at a slower flow rate. However, no real benefits (*e.g.*, precision in the measurement of peak height ratios) were gained using prolonged retention times.

The results obtained following analyses of various amounts of I in control human plasma are summarized in Table I. In the 1–10-μg range, the mean I recovery from control plasma was 100.7 ± 3.4% (n = 18). Table II contains peak height ratios obtained from calibration curves prepared with human plasma. Each value represents the average of four samples at each concentration. A typical calibration curve prepared by extracting human plasma samples containing different concentrations of I and 4 μg of II had a regression equation of $y = 0.132x - 0.04$ with $\gamma^2 = 0.99$. The UV absorption was linear between 1 and 10 μg, where therapeutic concentrations can be interpolated conveniently. The lower detection sensitivity limit was 1 μg/ml of plasma.

When UV absorption spectra of I and II were obtained in methanolic solutions, the maximum absorption wavelength, λ_{max}, was 290 nm. Since the chromatograph was equipped with a single-wavelength detector at 254 nm, the optimal condition has not yet been achieved in this assay. Higher detecting sensitivity can be obtained by monitoring the absorption at 290 nm with a variable-wavelength UV detector.

Preliminary 2-week stability tests were performed by dissolving 1–10 μg of I in 1 ml of plasma, which was then frozen for 3, 7, or 15 days; I was stable in frozen plasma for at least 2 weeks (Table III).

Table III—Effect of Frozen Storage on the Flufenamic Acid Stability in Human Plasma

I Added, μg	Days			
	0	3	7	15
1	0.98	1.20	1.04	1.00
2	1.91	2.35	2.19	1.93

10	10.07	9.85	10.57	9.76

Table IV—Plasma Flufenamic Acid Levels in Two Rats at Various Times after Intravenous Sublingual Administration of 5 mg of I/kg in 0.2 *N* NaOH

Minutes	Plasma Levels, μg/ml	
	Rat 1	Rat 2
15	—	120
20	134	—
30	110	128
60	82.3	90.6

Experiments utilizing this procedure in animals are in progress. Plasma flufenamic acid levels in two rats at various times after intravenous sublingual administration of 5 mg of I/kg in 0.2 *N* NaOH are shown in Table IV. Due to the high plasma I concentrations at the dose administered, only 50 μl of the plasma sample was taken for analysis. The assays described here may be used to measure therapeutic levels of I in patients.

Antitumor Activity of Hydrazones and Adducts between Aromatic Aldehydes and *p*-(3,3-Dimethyl-1-triazeno)benzoic Acid Hydrazide

TULLIO GIRALDI *, PHYLLIS M. GODDARD ‡, CARLO NISI §x, and FABIO SIGON §

Received May 3, 1978, from the **Istituto di Farmacologia, Università di Trieste, I 34100, Trieste, Italy, the* ‡*Chester Beatty Research Institute, Institute of Cancer Research, Royal Cancer Hospital, London SW3 6JB, England,* and the §*Istituto di Chimica Farmaceutica, Università di Trieste, I 34100, Trieste, Italy.* Accepted for publication June 1, 1979.

Abstract □ Hydrazones and adducts between aromatic aldehydes and *p*-(3,3-dimethyl-1-triazeno)benzoic acid hydrazide were synthesized and tested for antitumor activity. Two adducts derived from 2,6-dinitro- and 4-cyanobenzaldehyde were active against TLX5 lymphoma in mice. The hydrazone of the latter aldehyde was significantly more active than the adducts.

Keyphrases □ *Antineoplastic agents, potential*—hydrazones and adducts between aromatic aldehydes and *p*-(3,3-dimethyl-1-triazeno)-benzoic acid hydrazide, structure–activity relationships □ *p*-(3,3-Dimethyl-1-triazeno)benzoic acid hydrazide—antineoplastic activity, hydrazones and adducts with aromatic aldehydes, structure–activity relationships

A series of 1-aryl-3,3-dimethyltriazene derivatives, characterized by the presence of a carbonyl group and a triazene function in the *para*-position on the aromatic nucleus, was previously synthesized and examined for antitumor activity against TLX5 lymphoma in mice (1). Among these compounds, the *o*-nitrophenylhydrazone of the *p*-(3,3-dimethyl-1-triazeno)benzoic acid hydrazide and the adduct between this hydrazide and *p*-nitrobenzaldehyde showed considerable activity. Therefore, a further group of adducts and related hydrazones carrying electron-withdrawing substituents was synthesized and tested for their antitumor activity. Their structures and activities are reported in Tables I and II.

EXPERIMENTAL[1]

Adducts I–IV—Adducts I, II, and IV were prepared by the addition of a solution of the aldehyde in hot ethanol to an equimolar solution of *p*-(3,3-dimethyl-1-triazeno)benzoic acid hydrazide (2) in the same solvent. After standing for a few minutes, the products precipitated and were washed with a few milliliters of cold ethanol. Methanol was used as a solvent for preparing adduct III, and this reaction mixture was heated gently for 15 min before allowing the precipitation.

The structures assigned to I–IV are in accordance with their elemental analyses and are supported by the following data:

1. When these substances were heated to 120°, they lost a molecule of water, yielding the corresponding hydrazone, except for III which decomposed.

2. TLC mobilities and UV spectra of these compounds were quite different from those of the relevant hydrazones, so they cannot be simply monohydrates of these substances. Furthermore, all of these compounds exhibited a strong characteristic band at 1040 cm^{-1} attributable to CO stretching, which disappeared after heating. In addition, the UV spectra of I–IV in ethanol corresponded to the sum of the spectra of the starting hydrazide and aldehydes. TLC on silica gel of these substances at very low concentrations showed that they are split, giving two spots corresponding to the starting reagents; the hydrazones, however, gave single spots. The very poor solubilities of these substances did not allow any NMR investigations of their structures.

Hydrazones V–VII—These hydrazones were prepared by heating the corresponding adducts for a few hours at 120°. The completion of the conversion was determined by TLC and by the disappearance of the strong characteristic band at ~1040 cm^{-1}; the yield was quantitative since no further recrystallization was required.

RESULTS AND DISCUSSION

Tests of the triazene derivatives against TLX5 lymphoma[2] in mice are reported in Table III. The activities observed for each compound were compared on the basis of the number of dose levels at which an ILS of ~50% was observed and by considering also the maximum ILS values obtained when >50%. The compounds carrying nitro groups as substit-

[1] Melting points were determined in open glass capillaries using a Büchi apparatus and are uncorrected. IR spectra were recorded on a Perkin-Elmer model 225 spectrophotometer, and UV spectra were determined on a Hitachi Perkin-Elmer model 124. Kieselgel HF 254 + 366 (Merck) and methanol–ethyl acetate–ligroin (3:2:1) were used for TLC.

[2] TLX5 lymphoma cells (10^5) were injected subcutaneously in the inguinal region of CBA/LAC female mice, 20–25 g, bred in the Chester Beatty Research Institute. The drugs were used as a solution freshly prepared by sonication in acetone–arachis oil (10:90 v/v); the treatment was performed by daily intraperitoneal administration from Day 3 to 7 after tumor inoculation. For each substance, 10 control mice and groups of five mice for each dose level were used. ILS is the percent increase of the mean survival time of each treated group to that of the relevant controls.

Experiments utilizing this procedure in animals are in progress. Plasma flufenamic acid levels in two rats at various times after intravenous sublingual administration of 5 mg of I/kg in 0.2 *N* NaOH are shown in Table IV. Due to the high plasma I concentrations at the dose administered, only 50 μl of the plasma sample was taken for analysis. The assays described here may be used to measure therapeutic levels of I in patients.

uents (I, II, V, and VI) were inactive over a dosage range that included maximum tolerated doses, with the exception of III which was effective at three dose levels. The adduct of *p*-cyanobenzaldehyde (IV) also was active at three dose levels, whereas the corresponding hydrazone (VII) was effective at the five highest dosages employed. An analysis of variance (3) indicated that the ILS values obtained for this compound at 50 and 100 mg/kg/day were significantly higher than those observed for the other compounds tested ($F = 17.2$, $p < 0.0002$).

These results, together with those already reported for a related series of compounds (1), indicate a marked antileukemic activity for derivatives characterized by single electron-withdrawing substituents in either the *ortho*- or *para*-position. High activity does not appear to be peculiar for hydrazones or adducts. In this series, the hydrazone derived from *p*-cyanobenzaldehyde (VII) was significantly more active than the corresponding adduct (IV). For the previously examined *p*-nitro-substituted derivatives, the hydrazone proved completely inactive and the adduct showed remarkable activity. The effects of these compounds on other experimental tumors is being examined.

Electron-Capture GLC Determination of Bromhexine in Human Plasma

A. P. De LEENHEER ˣ **and L. M. R. VANDECASTEELE-THIENPONT**

Received March 26, 1979, from the *Laboratoria voor Medische Biochemie en voor Klinische Analyse, Faculteit van de Farmaceutische Wetenschappen, Rijksuniversiteit, Academisch Ziekenhuis, 135 De Pintelaan, 9000-Gent, Belgium.* Accepted for publication July 12, 1979.

Abstract □ A specific and sensitive GLC analysis of bromhexine in human plasma is described. After addition of the internal standard and an aqueous triethanolamine solution, bromhexine is extracted at alkaline pH into *n*-hexane, transferred to an acidic aqueous solution, and back-extracted into *n*-hexane after alkalinization. Both compounds are derivatized with trifluoroacetic anhydride and quantified by GLC using a ^{63}Ni-electron-capture detector. The method has a sensitivity of ~1.0 ng/ml of plasma. Linearity of plasma working curves was good. The extraction recovery from spiked plasma was 90.1 ± 5.68% (*SD*). The within-run and within-day precisions (*CV*) were 6.0% (4.3 ng/ml, $n = 8$) and 8.6% (11.0 ng/ml, $n = 13$), respectively. The procedure was applied successfully to measurement of the plasma concentration–time profile in a human volunteer after oral drug administration.

Keyphrases □ Bromhexine—electron-capture GLC analysis, human plasma □ GLC—bromhexine, electron-capture detection, human plasma □ Mucolytic agents—bromhexine, electron-capture GLC analysis, human plasma

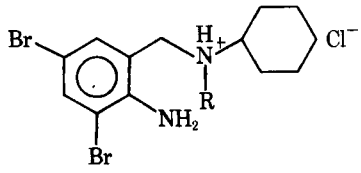
Bromhexine hydrochloride[1] [*N*-cyclohexyl-*N*-methyl-2-(2-amino-3,5-dibromo)benzylammonium chloride] (I) is used as a mucolytic agent (1, 2). The low drug dosage (3) sufficient for pharmacological effectiveness and its extensive metabolism (4, 5) result in low levels in circulating blood (nanograms per milliliter) (6, 7). Thus, to follow the rapidly declining levels of the unchanged drug, highly sensitive and specific methodology is required.

Studies on the absorption, metabolism, and excretion of ^{14}C-labeled I were performed by liquid scintillation spectrometry after extraction of the plasma and urine samples and TLC separation of the drug and metabolites (6–8). Eichler and Kreuger (9) described an electron-capture GLC assay for the quantitation of I residues in the milk and tissues of treated animals. A previous paper[2] described a new GLC assay for the determination of standard I solutions at the nanogram level. The chromatographic properties and electron-capture sensitivity of the trifluoroacetyl derivatives of I and a synthesized, structurally analogous internal standard, *N*-cyclohexyl-*N*-*n*- propyl-2-(2-amino-3,5-dibromo)benzylammonium chloride (II) were investigated.

The present report describes a GLC assay with electron-capture detection for the determination of plasma bromhexine in the low nanogram range.

EXPERIMENTAL

Reagents and Materials—The hydrochloride of I[3] was used as received, and II was synthesized as described (10). Pesticide grade *n*-hexane[4] and methanol[5], fluorometric grade ethyl acetate[6], and trifluoroacetic anhydride[7], obtained in 1-ml sealed glass ampuls, were used as supplied.



I: R = CH_3
II: R = $CH_2CH_2CH_3$

Aqueous 5 *N* NaOH[6], 2 *N* HCl[6], and 1 *N* triethanolamine[6] solutions were prepared with freshly double-distilled water.

Apparatus—GLC was conducted on a gas chromatograph[8] equipped with a 15-mCi ^{63}Ni-electron-capture detector[9] (pulsed, variable-frequency type). The stationary liquid phase, 4% SE-30[10], was coated on 100–120-mesh Gas Chrom Q[11] and packed into a 2.2-m × 2-mm i.d. spiral silanized glass column. The temperatures were: oven, 255°; injection port, 280°; and detector, 330°. Argon–methane (95:5) was the carrier and purge gas at a total flow rate of 28 ml/min.

Extraction—Plasma, 1.0 ml, was placed in a 20-ml polytef screw-capped test tube. The following were added by pipet: 80 μl of internal standard solution (1.2 ng of II/μl in methanol), methanol to a total volume of 200 μl/ml of plasma, 2 ml of 1.0 *N* aqueous triethanolamine, and 0.1 ml of 5.0 *N* NaOH. The solution was mixed well. *n*-Hexane, 15 ml, was added, and the tube contents were mixed on a rotary mixer[12] for 20 min. After centrifugation, the *n*-hexane was transferred to a tube containing 2 ml of 2.0 *N* HCl. The tube was shaken for 20 min, and the *n*-hexane was discarded after separation of the two layers. The extraction was repeated with 10 ml of *n*-hexane.

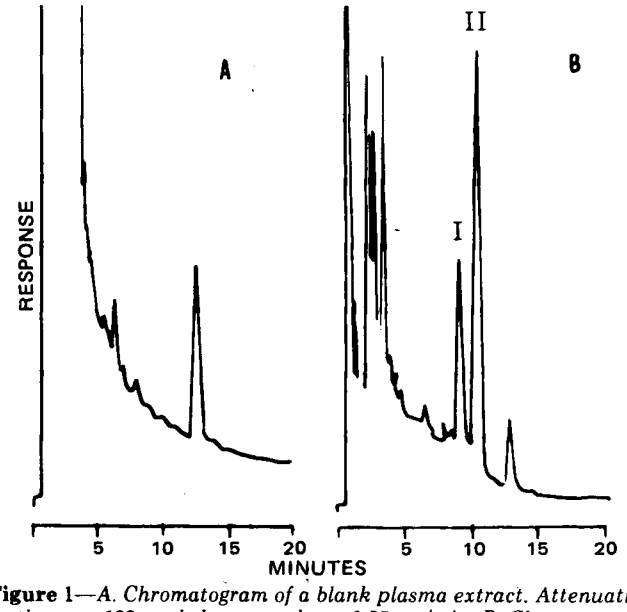


Figure 1—*A. Chromatogram of a blank plasma extract. Attenuation setting was 128, and chart speed was 0.25 cm/min. B. Chromatogram of a plasma extract 90 min after oral administration of 4 mg of bromhexine hydrochloride, representing a level of 3.9 ng of I/ml. Attenuation setting was 256.*

Table I—Recovery of I in Human Plasma by Electron-Capture GLC Analysis (n = 3)

I Added to 1.0 ml of Plasma, mg	Mean I Amount Recovered after Extraction, ng	Mean Recovery ± *SD*, %
6.6	6.5	98.5 ± 3.02
13.3	11.6	87.5 ± 8.90
26.6	23.4	88.0 ± 1.84
53.1	45.9	86.3 ± 4.75
Mean		90.1 ± 5.68

The acid solution was made basic with 1.5 ml of 5 *N* NaOH and was extracted twice with 5 ml of *n*-hexane during 20 min. After centrifugation, the organic layer was evaporated in a 3-ml glass-stoppered conical vial in a heating block[13] at 45° under a nitrogen stream. The residue was redissolved in ~100 μl of ethyl acetate. A slight excess of trifluoroacetic anhydride was added and mixed. After 5 min, excess trifluoroacetic anhydride was removed at 45° under nitrogen. The residue was dissolved in 100 μl of methanol, and ~2 μl was injected with a 10-μl syringe[14] onto the GLC column.

Linearity—Linearity was tested from 1.6 to 12.7 ng/ml and from 7.0 to 115.8 ng/ml. Solutions of I in methanol were added to plasma to give 1.6, 3.2, 6.4, and 12.7 ng/ml and 7.0, 11.6, 23.2, 46.3, 69.5, 92.7, and 115.8 ng/ml. An adjusted constant amount of II was added. The samples were extracted as described and analyzed by GLC. Peak height ratios of I to II were plotted *versus* the concentration ratio of I to II.

Recovery—Known I amounts were added to 1.0 ml of drug-free plasma to give drug concentrations as detailed in Table I. The internal standard was added after the extraction just before derivatization. Percentage recoveries were calculated from a standard curve of the same amounts of I and II derivatized without extraction.

RESULTS AND DISCUSSION

Figures 1A and 1B show representative chromatograms of drug-free plasma and an extract after a single 4-mg oral dose, respectively. Back-extraction from an organic solvent into an acidic aqueous solution was essential for sample cleanup prior to electron-capture GLC. Based on its retention on the 4% SE-30 stationary phase, the extraneous peak at a retention time of 12.6 min was supposed to represent dioctyl phthalate, used as a plasticizer. The component also was present after extraction

of an aqueous solution. Therefore, it was not an endogenous compound. This peak can be eliminated by solvent distillation and storage in glass equipment.

Compound II was synthesized and chosen as the internal standard for GLC experiments[2] on the basis of its structural similarity to I. However, the extraction characteristics from plasma of I and II were different. In contrast, the extraction recovery from water was the same for I and II. Plasma extracts alkalinized only with sodium hydroxide without the triethanolamine solution afforded a relative recovery for II of only 32.1 ± 2.70% (*SD*); after the addition of the triethanolamine solution, the recovery increased to 81.3 ± 6.51% (*SD*). A plot of the response ratios of I to II *versus* the plasma concentration ratio of I to II in the 1.6–12.7- and 7.0–115.8-ng/ml ranges demonstrated a linear relationship (regression lines: $y = 2.5x + 0.04$, $r = 0.9997$, and $y = 2.3x + 0.01$, $r = 0.9996$, respectively).

A detection limit of ~1.0 ng of I/ml was obtained using 1.0 ml of plasma for the analysis.

The within-run precision of the overall procedure (*CV*) of 6.0% was obtained on analyzing eight samples of pooled plasma having a mean value of 4.3 ± 0.26 (*SD*) ng/ml. The day-to-day precision (*CV*) over 8 weeks was 8.6% at a mean concentration of 11.0 ± 0.95 (*SD*) ng/ml. For this study, plasma samples were stored at −20°. These data are presented in Table II. The I recovery studies in the 6.6–53.1-ng/ml range showed a mean of 90.1 ± 5.68% (*SD*) (Table I).

The utility of the technique developed for the determination of I was demonstrated in the establishment of plasma levels in a volunteer after oral administration of 24 mg of I as tablets. Two standard curves were constructed by adding quantities of I to plasma samples in the range of the expected levels, as mentioned under the linearity experiments. A typical time course for the I concentration is shown in Fig. 2. For an exact estimate of the pharmacokinetics of the drug after oral administration in humans, the levels below 3 ng/ml are of limited value since they are too close to the detection limit.

Quantitative Determination of Titanium in a Commercial Sunscreen Formulation by Atomic Absorption Spectrometry

JAMES T. MASON, Jr.

Received May 7, 1979, from *Texas Pharmacal Company, San Antonio, TX 78296.* Accepted for publication June 29, 1979.

Abstract □ An atomic absorption spectrophotometric method was developed for the determination of titanium in a sunscreen formulation containing iron oxides and a complex organic base. Matrix matching between the samples and the standard was essential. A recovery study was conducted using a placebo base. Standard absorbance–concentration curves were linear in the 0–120-ppm range.

Keyphrases □ Titanium—analysis, atomic absorption spectrometry, sunscreens □ Atomic absorption spectrometry—analysis, titanium in sunscreens □ Sunscreens—titanium, analysis, atomic absorption spectrometry

Titanium dioxide is an effective sunscreen (1) for the prevention of sunburn and suntan. It reflects and scatters UV and visible light rays, providing a protective physical barrier against the damaging effects of the sun. The increasing use of sunscreens, along with the stringent and changing regulations on their use, makes a simple method for quantitating titanium dioxide desirable.

The commercial formulation[1] examined was a viscous, oil-in-water cream tinted with synthetic iron oxides. The analysis of titanium dioxide in the presence of iron oxides and a complex organic base requires either an intricate separation or a highly specific method to obtain significant results. Atomic absorption spectrometry promises a simple and specific analytical technique for pharmaceutical analyses. This technique offers an accurate and precise alternative to the titrimetric (2) and colorimetric (3) methods used to analyze titanium compounds. No atomic absorption spectrophotometric method was reported previously for the determination of titanium in pharmaceuticals.

EXPERIMENTAL

Equipment—The atomic absorption spectrophotometer[2] was equipped with a heavy solids, nitrous oxide burner head and a single-element titanium hollow cathode lamp[3]. The instrument settings were: wavelength, 364.3 nm; spectral band width, 0.3 nm; lamp current, 10 mamp; nitrous oxide flow, 10 SCFH; and acetylene flow, 9 SCFH.

Reagents—All reagents were ACS or USP grade. Purified water, USP grade, was used to make the solutions and to rinse the glassware.

Titanium Stock Solution—A standard stock solution containing 1000 ppm of titanium was prepared by heating vigorously 1.6681 g of titanium dioxide[4] with 40 g of ammonium sulfate and 200 ml of concentrated sulfuric acid until dissolution was complete. The solution was transferred to a 1000-ml volumetric flask and diluted to volume with purified water.

Iron Stock Solution—A stock solution containing 1000 ppm of iron was prepared by dissolving 0.50 g of iron wire in 20 ml of dilute nitric acid (1:1) and diluting to 500.0 ml with purified water.

Titanium Standards—The titanium stock solution was diluted to 80.0, 100.0, and 120.0 ppm. All standards were made to contain 0.8% (w/v) ammonium sulfate and 16 ppm of iron by the addition of appropriate quantities of ammonium sulfate and the iron stock solution.

2	80	0.175	0.172	0.154
3	100	0.211	0.201	0.182
4	120	0.253	0.237	0.221
Correlation coefficient		0.9996	0.9980	0.9993

Table II—Titanium Dioxide Recovery from Placebo

Sample	Titanium Dioxide, mg Theoretical	Experimental	Recovery, %
1	47.5	48.0	101.0
2	39.6	39.5	99.7
3	49.0	47.9	97.8
4	34.7	35.6	102.6
5	43.3	42.2	97.5
6	37.3	37.3	100.0
Mean			99.8
RSD			1.9

Placebo—A placebo was prepared utilizing the ingredients and the manufacturing procedure prescribed for the commercial product but omitting the titanium dioxide.

Sample Preparation—Known titanium dioxide quantities, 35–50 mg, were weighed into separate 250-ml erlenmeyer flasks. Approximately 800 mg of placebo was added to each flask to approximate the commercial product at various strengths. After the addition of 7 ml of concentrated sulfuric acid and 2.0 g of ammonium sulfate, each flask was subjected to wet oxidation (4) to destroy the organic matter.

Each sample was digested on a hot plate in a fume hood until charring began. After the sample was decomposed initially by the acid, 30% hydrogen peroxide was added, dropwise, until all organic matter was destroyed and the solution was not more than slightly brown[5]. Fifty milliliters of water was added, and the solution was filtered through filter paper[6] into a 250-ml volumetric flask and brought to volume with purified water.

Procedure—The instrument was allowed to warm up for a minimum of 1 hr or until a stable absorbance reading was obtained using the 100-ppm standard. The nebulizer flow, lamp position, fuel flow, and burner head position were adjusted for maximum absorption. The absorbances of the sample and standard solutions were determined alternately, using the 10 read-average mode and 1-sec integration time, to verify conformance with the standard curve.

Each solution was aspirated at least three times, and the absorbance values were averaged. The two-variable linear regression of the absorbance–concentration curve through zero was determined for the standards using a statistical calculator[7]. The calibration curve was redetermined for each sample run.

RESULTS AND DISCUSSION

Table I contains the absorbance data obtained for three typical standard curves; the relationship of titanium to absorbance was linear in the 0–120-ppm range. This linearity permits the use of these data in determining the titanium in unknown samples, provided the instrument conditions remain unchanged.

Table II contains the titanium dioxide recovery data obtained from

[5] The solution was orange until all hydrogen peroxide was removed.

Table III—Iron Interference on 100 ppm of Titanium

Iron, ppm	Absorbance Increase, %
25	2
50	4
100	7
300	11
500	13
1000	13
3000	26

samples of placebo-prepared sunscreen product. In all samples, the placebo weight was the same.

Iron in the presence of sulfuric acid concentrations below 1 *N* was reported to depress titanium absorption (5). Iron at 2000 ppm in the presence of 2% HF enhanced titanium absorption, while iron at 200 ppm had no detectable effect (6). A third study indicated no interference on the absorbance of a 100-ppm titanium sample by 50 ppm of iron but a depression of absorbance by iron above 200 ppm (7). Attempts to determine the degree of interference caused by the presence of iron yielded the results in Table III. The iron amount present in the final dilutions varied from 11 to 22 ppm, depending on the shade[8] of the sunscreen. Iron, 16 ppm, was added to the standards to approximate the quantity in the samples to match the matrix and to minimize enhancement.

[8] Neutral and dark shades; iron levels were determined by the atomic absorption spectrophotometric method.

Examination of the effects on titanium absorption caused by a difference in the ammonium sulfate or sulfuric acid levels between the standards and the samples showed that a twofold increase in sulfuric acid produced a 2% enhancement of absorbance while a twofold increase in ammonium sulfate produced a 3% enhancement.

The fuel to oxidizer ratio was verified to be critical (5); when the flow rate of one gas varied slightly, the flame condition and the titanium absorption value changed significantly.

The described atomic absorption spectrophotometric method for the determination of titanium is simple, reliable, and accurate. The procedure, including standard preparation, can be performed in ~3 hr.

Surface Activities of Barbital, Phenobarbital, and Pentobarbital and Their Interaction Energies with Phospholipid Monolayers

FEDERICO A. VILALLONGA ˣ and E. W. PHILLIPS

Received December 18, 1978, from the *College of Pharmacy, University of Florida, Gainesville, FL 32610.* Accepted for publication July 3, 1979.

Abstract □ The adsorption free energies of barbital, phenobarbital, and pentobarbital at the air–water interface were estimated from plots of the surface pressure ($\pi \leq 5$ dynes/cm) against the bulk concentration. Their energies of interaction with dipalmitoylphosphatidylethanolamine and dipalmitoyllecithin monolayers spread at the air–water interface were estimated from the surface pressure increase with increasing concentrations of the subphase-injected barbituric acid derivatives. Adsorption free energies and interaction energies were barbital < phenobarbital < pentobarbital, which correlate with their nerve blocking concentration.

Keyphrases □ Barbiturates—adsorption free energy, phospholipid monolayers, barbital, phenobarbital, pentobarbital □ Free energy—adsorption, barbital, phenobarbital, pentobarbital, phospholipid monolayers □ Phospholipid monolayers—adsorption free energy, barbital, phenobarbital, pentobarbital □ Surface activity—barbital, phenobarbital, pentobarbital, interaction with phospholipid monolayers

The interaction energies of procaine, lidocaine, and tetracaine with phospholipid monolayers were correlated recently with their anesthetic and nerve conduction blocking potencies (1).

The present work concerned the surface activities of barbital, phenobarbital, and pentobarbital at the air–water interface and their interaction energies with dipalmitoylphosphatidylethanolamine and dipalmitoyllecithin monolayers spread at the air–water interface.

EXPERIMENTAL

Reagents—Sodium salts of barbital[1], phenobarbital[1], and pentobarbital[1] were used without further purification. Dipalmitoyllecithin[2], dipalmitoylphosphatidylethanolamine[3], the hexane[4] used to prepare the phospholipid spreading solutions, and the water used to prepare the solutions fulfilled the requirements previously specified (2, 3). Analytical reagent grade sodium chloride[1] was roasted for 6 hr at 700° prior to preparation of the aqueous solutions to remove surface-active impurities.

Instruments and Methods—The instruments and methods for the measurement of the surface tension of aqueous solutions (γ) and of the surface pressure change ($\Delta\pi$) of the phospholipid monolayer after drug injection in the subphase already were described (2, 3). The experiments reported here were performed in 0.15 *M* NaCl at 20 ± 1°. In the injection experiments, the initial surface pressure of the phospholipid monolayer was 5 dynes/cm (±0.1 dyne/cm). Surface pressures (π) of the 0.15 *M* NaCl drug solutions were fitted to a function of the logarithm of the drug concentration, *C*, by digital-computerized, nonlinear regression (1, 4). Drug solution densities were determined using 10-ml specific gravity bottles.

RESULTS

Adsorption at Air–Aqueous Interface—Typical plots of the surface pressure (π) against the logarithm of the concentration (*C*, moles per liter)

Table I—Adsorption Free Energies at the Air–Water Interface (ΔG_{ad}), Interaction Energies with Phospholipid Monolayers (Ψ), and Free Energies of Transfer (ΔG_{tr}) to Erythrocyte Membranes and to Octanol of Barbital, Phenobarbital, and Pentobarbital

Barbiturate	Air–0.15 *M* NaCl, ΔG_{ad}, kcal/mole	Dipalmitoyllecithin–0.15 *M* NaCl, Ψ, kcal/mole	Dipalmitoylphosphatidylethanolamine–0.15 *M* NaCl, Ψ, kcal/mole	Erythrocyte[a] Membrane–Buffer Solution, ΔG_{tr}, kcal/mole	Octanol[b]–Water, ΔG_{tr}, kcal/mole	Nerve Blocking[c] Concentration (Frog, Sciatic), mole/liter
Barbital	−4.0	−3.2	−4.0	+0.2	+0.2	28×10^{-3}
Phenobarbital	−4.6	−4.2	−5.2	−1.1	−0.2	5.7×10^{-3}
Pentobarbital	−6.4	−6.0	−5.7	−1.3	−0.4	1.7×10^{-3}

[a] Calculated from Ref. 10. [b] Calculated from Ref. 9. [c] From Ref. 10.

for barbital, phenobarbital, and pentobarbital in 0.15 *M* NaCl are given in Fig. 1.

The adsorption free energy at the air–aqueous solution interface can be estimated from (1, 4, 5):

$$\Delta G = -RT \ln \frac{\pi}{X_2^*} \qquad \text{(Eq. 1)}$$

where ΔG is the standard free energy change associated with solute adsorption at the air–water interface, π is the surface pressure, X_2^* is the solute activity, R is the universal gas constant, and T is the absolute temperature.

The ΔG value can be calculated from the slope (π/X_2^*) of a linear plot of the surface pressure (π) against the solute mole fraction (X_2) in the bulk solution when $X_2 \rightarrow 0$ and $X_2 \rightarrow X_2^*$ at low mole fractions. Plots of the surface pressure (π) against the mole fraction (X_2) for barbital, phenobarbital, and pentobarbital were linear in the region $\pi \leq 5$ dynes/cm (regression coefficients of 0.9988, 0.9918, and 0.9975, respectively). The estimated ΔG values from such plots are given in Table I and were barbital < phenobarbital < pentobarbital.

Interaction with Phospholipid Monolayers—The interaction of the subphase-injected drugs with dipalmitoylphosphatidylethanolamine and dipalmitoyllecithin was virtually completed in the first 15–25 min. The equilibrium criterion was the constancy (±0.1 dyne/cm) of the surface pressure increment ($\Delta\pi$) during 30 min. The interaction energies (Ψ) were estimated (1–4, 6) from the slopes of the linear plots of the reciprocals of the equilibrium surface pressures ($\Delta\pi_{eq}$) against the reciprocals of the final concentrations (n, molecules per cubic centimeter) of the subphase-injected drug. Such energies (Table I) were barbital < phenobarbital < pentobarbital for both monolayers.

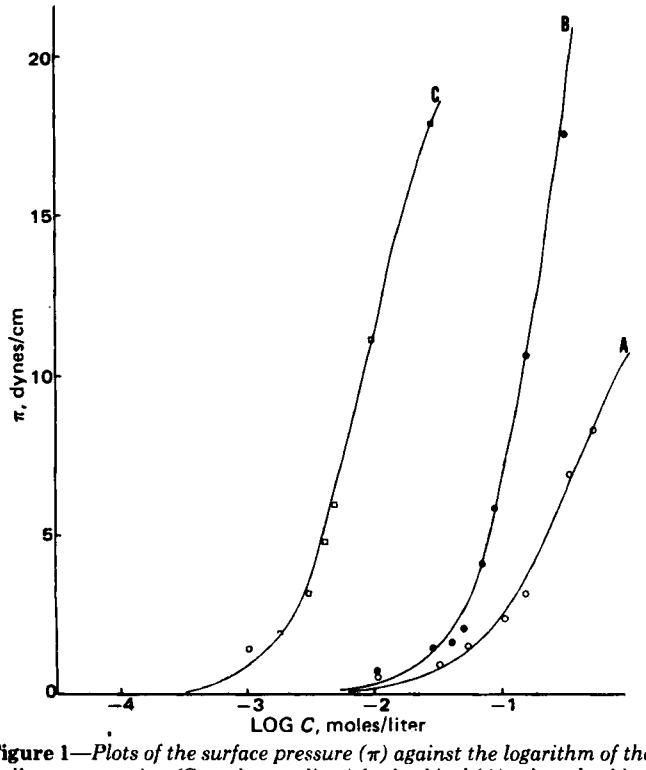

Figure 1—*Plots of the surface pressure (π) against the logarithm of the bulk concentration (C, moles per liter) for barbital (A), phenobarbital (B), and pentobarbital (C). The lines drawn through the experimental points were the best fit obtained from the computer.*

DISCUSSION

The amount of surfactant ions in an adsorbed monolayer at the air–water interface can be estimated directly from measurements of the surface tension variation with surfactant bulk concentration at a constant counterion concentration (1, 7):

$$\Gamma_2^m = \left(\frac{1}{RT}\right)\left(\frac{d\pi}{d \ln m_2}\right)_{m_3} \qquad \text{(Eq. 2)}$$

where Γ_2^m is the monolayer surface concentration of surfactant (moles per square centimeter), R is the universal gas constant (ergs per degree per mole), T is the absolute temperature (degrees Kelvin), π is the surface pressure (dynes per centimeter), and m_2 and m_3 are the molalities (moles per kilogram) of the surfactant ion and the counterion in the bulk solution.

The computed derivative ($d\pi/d \ln m_2$) of the exponential equation that characterized the surface pressure dependence on the concentration permitted (1–4, 6) calculation of the surfactant ion amount in the monolayer (Γ_2^m, moles per square centimeter) at any bulk concentration. Apparent molecular volume calculations performed using crystal density values (8) and space-filling molecular models indicate that the molecular dimensions of these barbituric acid derivatives can be accommodated into a thin interfacial region 8–12 Å thick. On the premises that the barbituric acid derivatives that form the adsorbed monolayer at the air–aqueous interface are immersed completely in the aqueous phase and that the average thickness is 10 Å, the volume, V_s, of the interfacial region that contains the amount of barbituric acid derivative, Γ_2^m (moles per square centimeter), can be estimated reasonably for comparison.

Concentration plots in such a thin interfacial region ($\Gamma'_2 = \Gamma_2^m/V_s$, in moles per liter) estimated from these volumes and from the surface concentration (Γ_2^m, mole per square centimeter) against the bulk concentration C (moles per liter) are given in Fig. 2 for barbital, phenobarbital, and pentobarbital and indicate that the adsorbed pentobarbital concentration at the thin interfacial region could be up to 500 times

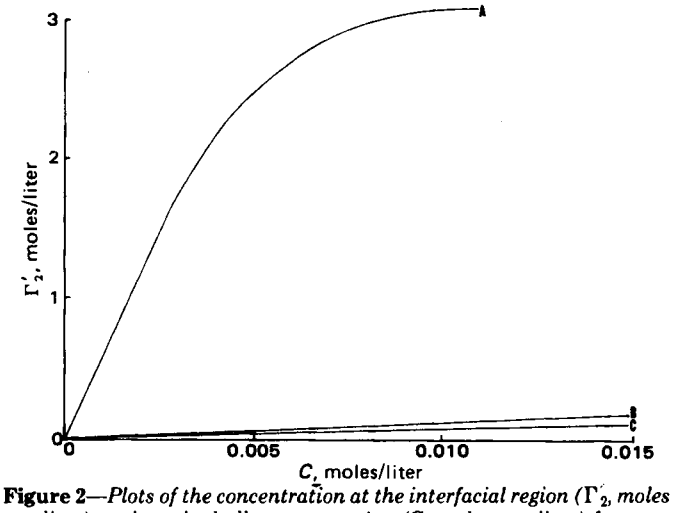

Figure 2—*Plots of the concentration at the interfacial region (Γ'_2, moles per liter) against the bulk concentration (C, moles per liter) for pentobarbital (A), phenobarbital (B), and barbital (C).*

greater than that of phenobarbital and barbital at the same conditions.

Partition coefficients have been measured between octanol–aqueous solution (9) and between erythrocyte membrane–buffer solution (10) for barbital, phenobarbital, and pentobarbital. With the assumptions that the numerical values of the interaction energies of barbital, phenobarbital, and pentobarbital are valid estimates (*i.e.*, the entropies are invariant) and that the same energies are operative for comparative purposes under the conditions in which partition coefficients were measured, the corresponding changes in free energies of transfer to the nonaqueous phase were calculated from literature data (9):

$$\Delta G_{tr} = RT \ln P \qquad \text{(Eq. 3)}$$

where P is the partition coefficient and ΔG_{tr} is the standard free energy associated with solute transfer from the aqueous to the nonaqueous phase. The order of such energies (ΔG_{tr}) (Table I) correlates with the interaction energies of barbital, phenobarbital, and pentobarbital with dipalmitoylphosphatidylethanolamine and with dipalmitoyllecithin monolayers and with their blocking concentrations.

These results show that the interaction energies of pentobarbital with the phospholipid monolayers are higher than those of barbital and phenobarbital and seem to indicate that its increased nerve blocking potency may be due to the comparatively greater interfacial concentration.

Rationalization of Drug Complexation in Aqueous Solution by Use of Hückel Frontier Molecular Orbitals

M. B. FAWZI, E. DAVISON, and M. S. TUTE ˣ

Received May 31, 1979, from *Pfizer Central Research, Sandwich, Kent, CT13 9NJ, England.* Accepted for publication July 25, 1979.

Abstract □ The complexation of certain drug molecules with niacinamide in aqueous solution was explained by the application of Hückel frontier molecular orbital calculations. A linear relationship was observed between the association constants derived from phase solubility studies and the interaction energy predicted by frontier molecular orbital calculations.

Keyphrases □ Niacinamide—complexation with drug molecules, aqueous solution, frontier molecular orbital calculations □ Complexation—of niacinamide with drug molecules, aqueous solution, frontier molecular orbital calculations □ Solubility—modification, niacinamide complexation with drug molecules, aqueous solution, frontier molecular orbital calculations

The solubility of drug substances often is modified by the use of additives. The discovery of the solubilizing (or solubility inhibiting) action of these additives frequently is made empirically; but in many cases, the system can be described by specific interactions between the drug and additive molecules. The use of phase solubility techniques to derive the association constants that quantitatively define the extent of interaction between the species involved was established (1). The nature of the specific interaction often is well understood.

Many potential interactions can be exploited to modify drug solubility. The present work concerns the use of Hückel frontier molecular orbital (FMO) calculations to confirm a π-donor–π-acceptor mechanism for the interaction of 6,7-dimethoxy-1-[4-(ethylcarbamoyloxy)piperidino]phthalazine (I), 2-[4-(2-furoyl)piperazin-1-yl]-4-amino-6,7-dimethoxyquinazoline (II), 4-(4-amino-6,7,8-trimethoxyquinazolin-2-yl)piperazine-1-carboxylic acid 2-methyl-2-hydroxypropyl ester (III), and 6,7-dime-

greater than that of phenobarbital and barbital at the same conditions.

Partition coefficients have been measured between octanol–aqueous solution (9) and between erythrocyte membrane–buffer solution (10) for barbital, phenobarbital, and pentobarbital. With the assumptions that the numerical values of the interaction energies of barbital, phenobarbital, and pentobarbital are valid estimates (*i.e.*, the entropies are invariant) and that the same energies are operative for comparative purposes under the conditions in which partition coefficients were measured, the corresponding changes in free energies of transfer to the nonaqueous phase were calculated from literature data (9):

$$\Delta G_{tr} = RT \ln P \qquad \text{(Eq. 3)}$$

where P is the partition coefficient and ΔG_{tr} is the standard free energy associated with solute transfer from the aqueous to the nonaqueous phase. The order of such energies (ΔG_{tr}) (Table I) correlates with the interaction energies of barbital, phenobarbital, and pentobarbital with dipalmitoylphosphatidylethanolamine and with dipalmitoyllecithin monolayers and with their blocking concentrations.

These results show that the interaction energies of pentobarbital with the phospholipid monolayers are higher than those of barbital and phenobarbital and seem to indicate that its increased nerve blocking potency may be due to the comparatively greater interfacial concentration.

Rationalization of Drug Complexation in Aqueous Solution by Use of Hückel Frontier Molecular Orbitals

M. B. FAWZI, E. DAVISON, and M. S. TUTE ˣ

Received May 31, 1979, from *Pfizer Central Research, Sandwich, Kent, CT13 9NJ, England.* Accepted for publication July 25, 1979.

Abstract □ The complexation of certain drug molecules with niacinamide in aqueous solution was explained by the application of Hückel frontier molecular orbital calculations. A linear relationship was observed between the association constants derived from phase solubility studies and the interaction energy predicted by frontier molecular orbital calculations.

Keyphrases □ Niacinamide—complexation with drug molecules, aqueous solution, frontier molecular orbital calculations □ Complexation—of niacinamide with drug molecules, aqueous solution, frontier molecular orbital calculations □ Solubility—modification, niacinamide complexation with drug molecules, aqueous solution, frontier molecular orbital calculations

The solubility of drug substances often is modified by the use of additives. The discovery of the solubilizing (or solubility inhibiting) action of these additives frequently is made empirically; but in many cases, the system can be described by specific interactions between the drug and additive molecules. The use of phase solubility techniques to derive the association constants that quantitatively define the extent of interaction between the species involved was established (1). The nature of the specific interaction often is well understood.

Many potential interactions can be exploited to modify drug solubility. The present work concerns the use of Hückel frontier molecular orbital (FMO) calculations to confirm a π-donor–π-acceptor mechanism for the interaction of 6,7-dimethoxy-1-[4-(ethylcarbamoyloxy)piperidino]phthalazine (I), 2-[4-(2-furoyl)piperazin-1-yl]-4-amino-6,7-dimethoxyquinazoline (II), 4-(4-amino-6,7,8-trimethoxyquinazolin-2-yl)piperazine-1-carboxylic acid 2-methyl-2-hydroxypropyl ester (III), and 6,7-dime-

IV

thoxy-4-[4-(3-*n*-butylureido)piperidino]quinazoline (IV) with niacinamide in aqueous solution. The association constants derived from phase solubility experiments were linearly related to the interaction energy predicted by frontier molecular orbital calculations.

EXPERIMENTAL

The phase solubility technique described previously (1) was used to investigate the influence of niacinamide on the solubility of Compounds I–IV. Aqueous niacinamide solutions of known concentration were equilibrated with the test compound by stirring at 25° for 24 hr so that a small excess of compound remained undissolved. The total concentration of the test compound in the filtered solutions was measured by UV spectrophotometry after dilution in methanolic hydrochloric acid. Suitable blanks were prepared from the niacinamide solutions.

RESULTS AND DISCUSSION

Association Constants—The phase solubility diagram of I–IV in niacinamide solution showed increased test compound solubility as the niacinamide concentration increased. The slight pH change accompanying the increased concentrations of niacinamide and the test compound did not explain the increased compound solubility since previous experiments showed the solubility of I–IV to be independent of pH in this region. The phase solubility diagrams all showed positive deviations from linearity. This behavior has been interpreted in terms of first- and second-order interactions between the compound (S) and the solubilizing agent (L):

$$S + L \rightleftharpoons SL$$

Scheme I

$$K_{1:1} = \frac{[SL]}{[S][L]} \qquad \text{(Eq. 1)}$$

$$SL + L \rightleftharpoons SL_2$$

Scheme II

$$K_{1:2} = \frac{[SL_2]}{[SL][L]} \qquad \text{(Eq. 2)}$$

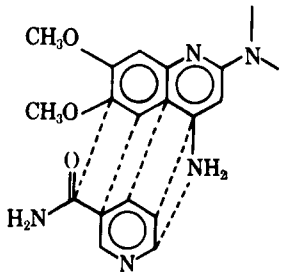
The equations for the association constants $K_{1:1}$ and $K_{1:2}$ involve the free solubilizing agent concentration, $[L]$, in solution. Since only the total concentration of solubilizing agent can be defined, an iterative procedure was developed to isolate values for $K_{1:1}$ and $K_{1:2}$ (2). The values obtained by a similar iterative procedure are shown in Table I.

Molecular Orbital Calculations—The expected π-donor nature of the methoxy-substituted heteroaromatic centers in I–IV led to the choice of the π-acceptor niacinamide as a potential solubilizing agent. The remarkable successes of the simple Hückel frontier molecular orbital approach in rationalizing not only the classical cycloaddition reaction (3) but also numerous other organic reactions (4) encouraged the exploration of a frontier molecular orbital correlation based on the perturbation approach.

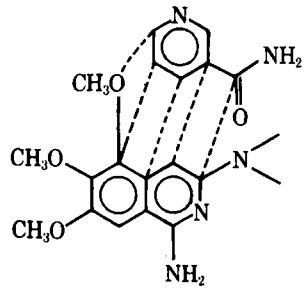
Table I—Equilibrium Constants and Calculated Stabilization Energies for Niacinamide [a] Complexes

Compound	$K_{1:1}$	$K_{1:2}$	ΔE	log $K_{1:1}$	Calculated Log $K_{1:1}$
I	12.31	14.76	0.598	1.090	1.022
II	7.36	0.33	0.561	0.861	0.876
III	18.45	0.51	0.660	1.266	1.267
IV	9.88	2.26	0.607	0.995	1.058

[a] Niacinamide concentration was 0.0–2.0 M for II and 0.0–0.2 M otherwise.



V



VI

In Eq. 3, ΔE is a partial measure of stabilization of the complex between a drug molecule S and the additive L (niacinamide in this case):

$$\Delta E = 2\gamma^2 \left[\frac{(\sum C_s^O C_l^U)^2}{E_s^O - E_l^U} + \frac{(\sum C_s^U C_l^O)^2}{E_l^O - E_s^U} \right] \qquad \text{(Eq. 3)}$$

The ΔE value is analogous to the stabilization energy of the transition state between two reactants (5). Positions s of S and l of L are juxtaposed, and γ is the resonance integral for the interacting molecular orbital lobes at each site. The C and E values are eigenvectors and eigenvalues appropriate to the occupied (O) and unoccupied (U) interacting frontier orbitals. Consideration of secondary orbital overlap was necessary to rationalize certain cycloaddition reactions (6). Similarly, the highest and the next-to-highest occupied orbitals as well as the lowest unoccupied orbitals are included in the summation.

Several assumptions are inherent in the use of Eq. 3:

1. Electrostatic force variations are small compared with frontier molecular orbital interactions (7) so coulombic interaction is neglected.
2. Only the delocalized π-electron systems are involved in complexation.
3. Because the complexing agent is constant, changes in solvation from one complex to another can be considered constant.

In using Eq. 3, the overlap and orientation principle (8) is invoked, and it is considered that the ring systems of the two partners occupy parallel planes for complexes in water (9).

The program used to obtain molecular orbital indexes was developed previously (10). The coulombic and resonance values were obtained from the literature (11). The maximum ΔE value corresponds to the most favorable overlap of orbitals; V shows the most favorable overlap for I, II, and IV; and VI shows the most favorable overlap for the trimethoxy Compound III. The ΔE values obtained from Eq. 3 for these overlaps are shown in Table I.

Equation 4 gives the regression line for the $K_{1:1}$ association constants and the ΔE values for these four complexes ($n = 4$, $r = 0.95$, $p < 0.05$):

$$\log K_{1:1} = 3.95\,\Delta E - 1.34 \qquad \text{(Eq. 4)}$$

This result is believed to justify the assumptions made and is sufficient to encourage further use of frontier molecular orbital theory in attempting to rationalize solution complexation.

The complexation of III shown in VI demonstrates that a simple change in substituent position can alter totally the complexation topology. The frontier molecular orbital theory applied to drug–receptor interactions could throw light on structure–activity relationships. Previously inexplicable "outliers" in regression analyses between biological activity and linear combinations of free energy-related parameters, as used in pioneering methods (12), now might be explained in terms of orbital symmetry if the receptor contains a conjugated π-electron system.

Fluorescence Assay of Nitrofurantoin with *o*-Aminothiophenol in Plasma and Urine

NOBUTOSHI WATARI, TOMOO FUNAKI, and NOBUYOSHI KANENIWA ˣ

Received February 1, 1979, from the *School of Pharmaceutical Sciences, Showa University, Hatanodai, Shinagawa-ku, Tokyo, 142, Japan.* Accepted for publication August 1, 1979.

Abstract □ A fluorescence method is presented for the determination of nitrofurantoin based on conversion of the drug to a fluorescent substance. The method requires 0.1–0.5 ml of plasma or diluted urine and is 10 times more sensitive than the commonly used colorimetric method.

Keyphrases □ Nitrofurantoin—fluorescence assay, plasma and urine □ Spectrophotofluorometry—analysis, nitrofurantoin, plasma and urine □ Antibacterials—nitrofurantoin, fluorescence assay, plasma and urine

Nitrofurantoin, 1-(5-nitro-2-furfurylideneamino)hydantoin (I), is used to treat urinary tract infections. The determination of drug levels in body fluids is important for pharmacokinetic and bioavailability studies. The content of I in plasma and urine commonly is determined by a colorimetric method based on the formation of a hyamine complex of I after its extraction into nitromethane (1, 2).

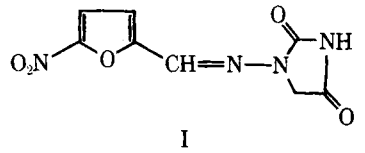
An electrochemical determination of I in urine that is faster and more accurate than the colorimetric method was reported (3). However, both methods require large sample volumes and are insufficiently sensitive for pharmacokinetic studies.

The reaction products obtained by heating some aromatic aldehydes with *o*-aminothiophenol (II) are fluorescent (4), and some drugs were assayed with II utilizing this reaction (5, 6). This paper discusses the application of this reaction to the fluorescence assay of I in plasma and urine.

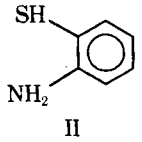
EXPERIMENTAL

Reagents—Nitrofurantoin[1] (I) was obtained commercially. *o*-Aminothiophenol hydrochloride was prepared by recrystallization of crude crystals obtained from a mixture of 1 ml of hydrochloric acid/g of *o*-aminothiophenol[2] (II) in ethanol (4). The other reagents were reagent grade.

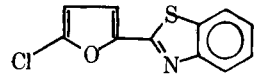
Procedure—Plasma, 0.1–0.5 ml, was deproteinized by mixing with 1 ml of ethanol. After centrifugation at 3000 rpm for 10 min, 0.5 ml of the supernate was transferred to a 15-ml test tube. Then 1 ml of 0.001% sodium nitrite, 2 ml of hydrochloric acid, 1 ml of 0.1% *o*-aminothiophenol hydrochloride, and 0.5 ml of distilled water were added. After mixing, the solution was heated at 70° in a water bath for 10 min. After cooling to room temperature, UV irradiation was carried out for 3 min; the relative fluoresence intensity was measured with excitation and emission at 375 and 422 nm, respectively.



I



II



III

The content of I in urine was determined similarly. If the urine was diluted eightfold or more with distilled water, 1 ml of the diluted urine could be assayed directly without deproteinization.

The spectrophotofluorometer[3] was standardized with quinine sulfate[4] in 0.1 *N* H_2SO_4.

The concentration of I in a sample was determined by comparing its fluorescence intensity with that of a standard solution prepared by adding a known concentration of I dissolved in ethanol to plasma or urine free of I and processing it in the same way as the test sample.

RESULTS AND DISCUSSION

A fluorescent substance, 2-(5-chloro-2-furyl)benzothiazole (III), was formed by the reaction of the 2-furaldehyde obtained by hydrochloric acid hydrolysis of I with II (6). However, the conversion of I to III varied due to a steric effect of the side chain of I (7) and incomplete replacement of the nitro group of 2-(5-nitro-2-furyl)benzothiazole with chlorine to give III (6). The nitro group can be replaced with chlorine by UV irradiation (6). The hydrolysis of I is reversible and is promoted by sodium nitrite, acetylacetone, formaldehyde, *etc.*

The maximum relative intensity of fluorescence was obtained in the presence of 0.001% sodium nitrite and with UV irradiation after heating. Therefore, these conditions were adopted for the assay of I with II. Typical results are summarized in Table I.

A linear relationship was obtained between the relative fluorescence intensity and the I concentration up to 5 μg/ml. The means of the relative fluorescence intensity of plasma samples varied slightly within a given analysis, but the standard deviations were similar. For this reason, it is necessary to run a standard I solution with each plasma and urine analysis. Under these conditions, quantitative measurements are possible.

Table I—Fluorescence Method for Nitrofurantoin Determination (Relative Fluorescence Intensity per Microgram [a])

Sample[b]	Trial[c]	Nitrofurantoin Reacted, μg							
		0.25	0.50	0.75	1.00	5.00	10.00	Mean[d]	SD
Water (1.0 ml)	1	124.8	100.7	99.9	100.3	100.1	62.7	106.4	10.7
	2	95.1	100.3	99.1	94.1	109.2	90.0	99.6	6.0
	3	113.3	93.6	93.9	92.9	88.6	72.5	96.5	9.7
Rabbit plasma (0.1 ml)	1	109.5	95.1	95.8	108.3	94.1	84.0	100.6	7.6
	2	109.5	119.5	107.8	119.3	115.9	107.5	114.4	5.5
	3	75.9	88.3	79.5	85.0	84.5	64.8	82.6	4.9
Rabbit plasma (0.5 ml)	1				87.3				
	2				99.0				
	3				102.5				

[a] Blank values were subtracted. [b] Blank values for water and 0.1 and 0.5 ml of rabbit plasma were 7.8, 10.6, and 27.6 relative fluorescence intensity units, respectively. [c] $n = 3$. [d] The mean and standard deviation were calculated between 0.25 and 5 μg since the 10-μg values seemed unreliable.

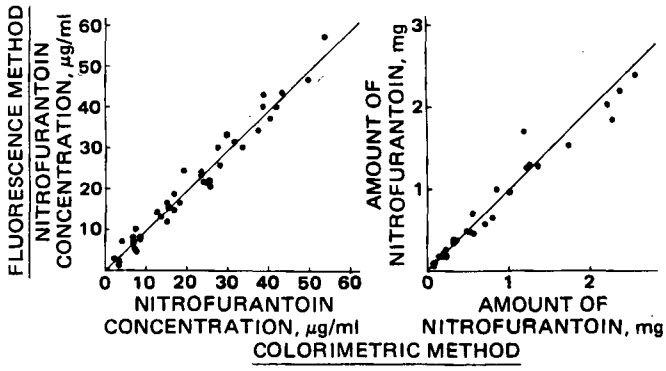

Figure 1—*Comparison of values obtained by the fluorescence and colorimetric methods for the determination of I in plasma (left) and urine (right).*

three rabbits dosed with I were assayed by the fluorescence and colorimetric methods. Figure 1 shows that good correlations were obtained for the values determined by the two methods in both plasma ($y = 0.980x + 0.125$, $r = 0.982$) and urine ($y = 0.980x - 0.026$, $r = 0.999$).

The fluorescence method for I is 10 times more sensitive than the colorimetric method, and it appears to be specific for I. It should be useful for the determination of microamounts of the drug for pharmacokinetic studies and other purposes.

Phenylfurans IV: Spasmolytic 3-Diethylamino-2,2-(dimethyl)propyl Esters of 5-Substituted Phenyl-2-furancarboxylic Acids

HOMER A. BURCH *x, RONALD E. WHITE *, GEORGE C. WRIGHT *, and MARVIN M. GOLDENBERG ‡

Received February 15, 1979, from the **Chemical Research Division and the* ‡*Biological Research Division, Norwich-Eaton Pharmaceuticals, Division of Morton-Norwich Products, Inc., Norwich, NY 13815.* Accepted for publication August 1, 1979.

Abstract □ A series of 3-diethylamino-2,2-(dimethyl)propyl 5-substituted phenyl-2-furancarboxylates was prepared and found to be pharmacologically active *in vitro* as GI tract nonanticholinergic smooth muscle spasmolytic agents. One of the more active compounds in the series contained the 5-(4-nitrophenyl) group.

Keyphrases □ Phenylfurans—3-diethylamino -2,2- (dimethyl)propyl esters of 5-substituted phenyl-2-furancarboxylic acids, synthesis, potential use as spasmolytic agents □ Spasmolytic agents—3-diethylamino-2,2-(dimethyl)propyl esters of 5-substituted phenyl-2-furancarboxylic acids, synthesis and pharmacological properties

The syntheses and pharmacological properties of 1- and 3-amino- and 1-amino-5-hydroxy-2,4-imidazolidinedione derivatives of 5-phenyl-2-furancarboxaldehydes have been described (1–3). This paper discusses the synthesis and *in vitro* pharmacological evaluation of a series of esters (I) derived from 3-diethylamino-2,2-(dimethyl)propanol (III) and 5-phenyl-2-furancarboxylic acids (II) (4). These compounds have potential use as spasmolytic agents (5).

DISCUSSION

Synthesis—The key intermediates in the synthesis of the esters were the appropriately substituted 5-phenyl-2-furancarboxylic acids (II). The acids generally were obtained in modest yields through the coupling of a substituted phenyldiazonium salt with 2-furancarboxylic acid. Several acids were prepared by oxidation of the corresponding 5-phenyl-2-fur-

[d] The mean and standard deviation were calculated between 0.25 and 5 μg since the 10-μg values seemed unreliable.

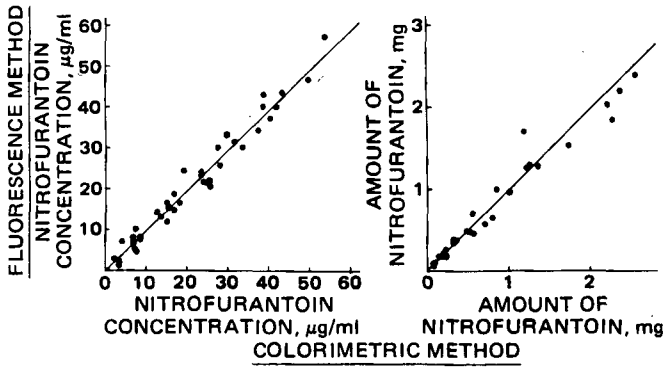

Figure 1—*Comparison of values obtained by the fluorescence and colorimetric methods for the determination of I in plasma (left) and urine (right).*

three rabbits dosed with I were assayed by the fluorescence and colorimetric methods. Figure 1 shows that good correlations were obtained for the values determined by the two methods in both plasma ($y = 0.980x + 0.125$, $r = 0.982$) and urine ($y = 0.980x - 0.026$, $r = 0.999$).

The fluorescence method for I is 10 times more sensitive than the colorimetric method, and it appears to be specific for I. It should be useful for the determination of microamounts of the drug for pharmacokinetic studies and other purposes.

Phenylfurans IV: Spasmolytic 3-Diethylamino-2,2-(dimethyl)propyl Esters of 5-Substituted Phenyl-2-furancarboxylic Acids

HOMER A. BURCH *x, RONALD E. WHITE *, GEORGE C. WRIGHT *, and MARVIN M. GOLDENBERG ‡

Received February 15, 1979, from the **Chemical Research Division and the* ‡*Biological Research Division, Norwich-Eaton Pharmaceuticals, Division of Morton-Norwich Products, Inc., Norwich, NY 13815.* Accepted for publication August 1, 1979.

Abstract □ A series of 3-diethylamino-2,2-(dimethyl)propyl 5-substituted phenyl-2-furancarboxylates was prepared and found to be pharmacologically active *in vitro* as GI tract nonanticholinergic smooth muscle spasmolytic agents. One of the more active compounds in the series contained the 5-(4-nitrophenyl) group.

Keyphrases □ Phenylfurans—3-diethylamino -2,2- (dimethyl)propyl esters of 5-substituted phenyl-2-furancarboxylic acids, synthesis, potential use as spasmolytic agents □ Spasmolytic agents—3-diethylamino-2,2-(dimethyl)propyl esters of 5-substituted phenyl-2-furancarboxylic acids, synthesis and pharmacological properties

The syntheses and pharmacological properties of 1- and 3-amino- and 1-amino-5-hydroxy-2,4-imidazolidinedione derivatives of 5-phenyl-2-furancarboxaldehydes have been described (1–3). This paper discusses the synthesis and *in vitro* pharmacological evaluation of a series of esters (I) derived from 3-diethylamino-2,2-(dimethyl)propanol (III) and 5-phenyl-2-furancarboxylic acids (II) (4). These compounds have potential use as spasmolytic agents (5).

DISCUSSION

Synthesis—The key intermediates in the synthesis of the esters were the appropriately substituted 5-phenyl-2-furancarboxylic acids (II). The acids generally were obtained in modest yields through the coupling of a substituted phenyldiazonium salt with 2-furancarboxylic acid. Several acids were prepared by oxidation of the corresponding 5-phenyl-2-fur-

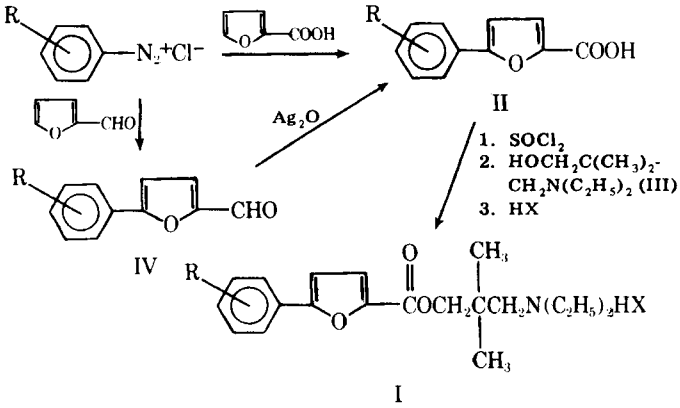
[a] E = ethanol, I = 2-propanol, A = acetone, BP = benzene–petroleum ether, and EA = ethyl acetate. [b] As determined by the ratio of two frequencies of electrical stimulation, one before and one after the drug, that caused equal muscle contraction (8). The estimation of inhibition is predicted on the lines representing contractions (at frequencies of electrical stimulation of 0.3, 1, 3, and 10 Hz) being parallel before and after drug administration. Two to 10 ileal strips were used to ascertain the activity of each compound. [c] Concentration of acetylcholine in the bath was 0.01 μg/ml. [d] The estimate of activity given in this case applied only to a frequency of 1 Hz and is different at other frequencies of stimulation because the lines are nonparallel. [e] Water by Karl Fischer method: calc., 2.20; found, 2.0%. [f] The frequency–response lines are nonparallel, and values do not apply.

ancarboxaldehydes (IV). Evidence for arylation of the furan ring at the 5-position was presented previously (6).

Subsequent ester formation occurred readily *via* the reaction of the acid chloride of II with III (Scheme I).

Pharmacology—This series of compounds was evaluated to discover



I

Scheme I

nonanticholinergic therapeutic agents capable of exerting a spasmolytic effect through inhibition of contraction of the small and large intestines induced by motor nerve electrical stimulation. The activity of each compound was determined initially by using the isolated rabbit ileum following transmural electrical- and acetylcholine-induced excitation of the smooth muscle (7).

A compound's efficacy was judged by whether it caused parallel displacement or depression of the contractile responses of the isolated rabbit ileum evoked by increasing electrical stimulation frequencies. An inactive compound did not shift the frequency–response line. If the contractile responses at any particular stimulation frequency were equal before and after drug administration, a numerical value of 1 was assigned to describe the lack of response change. An active inhibitory compound had a value of <1. A nonspecific depression of contractile responses following the various stimulation frequencies elicited a nonparallel shift of these responses.

The results of *in vitro* pharmacological testing are found in Table I. When tested at 1 μg/ml, six esters (Ia, If, and Ii–Il) displaced contractile responses of the isolated rabbit ileum. The estimation of inhibitory action for these compounds was ≤0.7. Increasing the concentration of each agent to 3 or 10 μg/ml shifted the frequency–response curves and caused profound inhibition by nearly all of the esters.

Another criterion for evaluating activity was the ability of the compound not to exhibit substantial antagonism of acetylcholine-induced

contractions. All esters failed to cause a dose-related inhibition of acetylcholine-induced contractions.

These findings demonstrate this class of compounds to be pharmacologically active as GI tract nonanticholinergic smooth muscle spasmolytic agents. The spectra of pharmacological effectiveness of I*f* were reported elsewhere (8).

EXPERIMENTAL[1]

5-Substituted Phenyl-2-furancarboxylic Acids (II)—*Method A*—To the diazonium salt of 2,3-dichloroaniline (289 g, 1.78 moles) in a mixture of 400 ml of water and 900 ml of concentrated hydrochloric acid at 0° were added a solution of 2-furancarboxylic acid (184 g, 1.6 moles) in 660 ml of acetone and a solution of cupric chloride (40 g) in 80 ml of water. Cooling was necessary to keep the temperature below 35°. After the exothermic reaction ceased, the mixture was stored at room temperature for 2 days; it was then poured into 6 liters of water, and the resulting mixture was stirred for 2 hr. The crude II*d* was collected by filtration, washed with water, and dried at 60°. Purification was achieved by recrystallization.

Compounds II*a*–II*h* were prepared similarly from the appropriately substituted anilines.

Method B—A solution of silver nitrate (120 g, 0.71 mole) in 243 ml of water was added with stirring to a solution of sodium hydroxide (56 g, 1.4 moles) in 243 ml of water. 5-Phenyl-2-furancarboxyaldehyde (6) (63 g, 0.37 mole) was added in portions to the resulting brown mixture. The reaction mixture was stirred for 0.5 hr at room temperature and filtered, and the residue was washed with 500 ml of hot water. The chilled filtrate was acidified to pH 2 with concentrated hydrochloric acid. The product was collected by filtration, washed with water, and recrystallized. Compound II*m* was described previously as an oil, bp 120–122°/30 mm (9).

Compounds II*i*–II*l* were prepared similarly from the appropriately substituted 5-phenyl-2-furancarboxaldehydes.

The IR spectra of II showed broad carbonyl absorption (COOH) at 5.85–6.0 μm. Other pertinent data are summarized in Table II.

Procedure for 5-Substituted Phenyl-2-furancarboxaldehydes (IV)—Thirty minutes after the formation of the diazonium salt from the appropriately substituted aniline (1.0 mole), the mixture was gravity filtered; the filtrate was added to a mixture of 2-furancarboxaldehyde (123 g, 1.28 moles) in 200 ml of water. A solution of cupric chloride (46 g) in 200 ml of water was added. The resulting mixture was heated with stirring at 56° for 4 hr and then stirred overnight at room temperature.

The product was extracted with 1 liter of chloroform in portions. After the extracts were dried over anhydrous magnesium sulfate and charcoal, the product was isolated by filtration and evaporation under reduced pressure. The crude aldehydes were obtained in 9–40% yields and were used for Method B without further purification.

5-(4-Trifluoromethyl)phenyl-, 3,4-difluorophenyl-, 4-methoxyphenyl- (10), and 3-methoxyphenyl-2-furancarboxaldehydes were prepared in this manner.

3-Diethylamino-2,2-(dimethyl)propyl-5-(4-nitrophenyl) -2- furancarboxylate Hydrochloride (I*f*)—Acid II*f* (55 g, 0.24 mole) was added with rapid stirring at room temperature to 84 ml of thionyl chloride. The resulting mixture was heated until dissolution occurred (~45 min), refluxed for an additional 0.5 hr, and cooled. Excess thionyl chloride was evaporated under reduced pressure. The residue was taken up in 1.3 liters of dry benzene, and III (11) (38.5 g, 0.24 mole) was added. The resulting solution was heated under reflux for 3 hr, cooled, diluted with 750 ml of petroleum ether, and allowed to stand overnight.

After removal of the benzene–petroleum ether by decantation, the residue was suspended in 2 liters of water containing 4 ml of concentrated hydrochloric acid. The mixture was stirred for 0.5 hr, and the pH was adjusted to ~8 by the cautious addition of 200 ml of saturated aqueous sodium carbonate solution. The mixture was extracted with 2.1 liters of benzene in portions, and the extracts were dried over anhydrous magnesium sulfate. The benzene extracts were treated with an ethereal hydrogen chloride solution to pH 3, diluted with 800 ml of petroleum ether, and allowed to stand for 1 hr. After filtration and recrystallization of the residue, I*f* was obtained as colorless needles.

The remaining I esters were prepared similarly from the appropriately substituted II acids. Ester I*k* was isolated as the fumarate salt rather than as the hydrochloride salt as follows. The benzene extracts, containing the free base of I*k*, were evaporated to dryness under reduced pressure. The residue was dissolved in 2-propanol and treated with a 2-propanol solution of fumaric acid. After cooling, the precipitated I*f* was isolated by filtration; IR: 6.8 (I*a*–I*d* and I*f*–I*m*) and 6.9 (I*e*) (ester carbonyl) μm; NMR (dimethyl sulfoxide-d_6): I*f*: δ 0.78 [s, 6, $C(CH_3)_2$], 0.89 (t, 6, J = 7

[1] All melting points were determined using a hot-stage apparatus and are uncorrected.

Hz, CH_2CH_3), 2.74 [m, 6, $N(CH_2)_3$], 3.9 (s, 2, OCH_2), 7.06, 7.18 (doublets, J = 3.5 Hz, 2, 3,4-furan CH), 7.61, 7.89 (doublets, J = 9.0 Hz, 4, phenyl CH), and 10.8 (b, 1, HCl)

Other I esters had similar NMR spectra except for expected variations due to various phenyl substitutents. Other pertinent data are summarized in Table I.

The I esters were evaluated initially *in vitro* on the rabbit ileum as described previously (7). Each drug was dissolved in distilled water for administration.

Simultaneous Quantitation of Acetaminophen, Aspirin, Caffeine, Codeine Phosphate, Phenacetin, and Salicylamide by High-Pressure Liquid Chromatography

V. DAS GUPTA

Received May 7, 1979, from the *Department of Pharmaceutics, College of Pharmacy, University of Houston, Houston, TX 77004.* Accepted for publication July 31, 1979.

Abstract □ A method for the simultaneous quantitation of acetaminophen, aspirin, caffeine, codeine phosphate, phenacetin, and salicylamide was developed. The method is based on reversed-phase high-pressure liquid chromatography with a mobile phase buffered with phosphate (pH 2.3). The procedure not only separated these six active ingredients but also salicylic acid, the major decomposition product of aspirin. The method gave excellent results for three commercial products and a synthetic mixture containing four active ingredients. Lowering the pH increased the retention time of some weak acids and decreased that of some weak bases. Only these changes in the retention times made the separation possible.

Keyphrases □ High-pressure liquid chromatography—simultaneous quantitation of acetaminophen, aspirin, caffeine, codeine phosphate, phenacetin, and salicylamide □ Acetaminophen—simultaneous quantitation with aspirin, caffeine, codeine phosphate, phenacetin, and salicylamide, high-pressure liquid chromatography □ Aspirin—simultaneous quantitation with acetaminophen, caffeine, codeine phosphate, phenacetin, and salicylamide, high-pressure liquid chromatography □ Caffeine—simultaneous quantitation with acetaminophen, aspirin, codeine phosphate, phenacetin, and salicylamide, high-pressure liquid chromatography □ Codeine phosphate—simultaneous quantitation with acetaminophen, aspirin, caffeine, phenacetin, and salicylamide, high-pressure liquid chromatography □ Phenacetin—simultaneous quantitation with acetaminophen, aspirin, caffeine, codeine phosphate, and salicylamide, high-pressure liquid chromatography □ Salicylamide—simultaneous quantitation with acetaminophen, aspirin, caffeine, codeine phosphate, and phenacetin, high-pressure liquid chromatography

About 80 commercially available nonprescription drugs (1) contain one or more pain relievers such as acetaminophen, aspirin, phenacetin, and salicylamide. Many of them also contain caffeine and buffering agents such as aluminum hydroxide and magnesium hydroxide (1). At least two commercial products contain a combination of acetaminophen, aspirin, caffeine, and salicylamide (1). Other products contain a combination of acetaminophen or aspirin, caffeine, phenacetin, and salicylamide (1). Many prescription drugs contain codeine phosphate, usually combined with aspirin, caffeine, and phenacetin.

BACKGROUND

The simultaneous quantitation of these ingredients is difficult. The NF methods (2) for the quantitation of aspirin, caffeine, codeine phosphate, and phenacetin in combination are tedious and time consuming. The colorimetric (3) and fluorometric (4) methods for aspirin quantitation are based on its hydrolysis to salicylic acid. Since salicylic acid is the principal decomposition product of aspirin, these methods are not specific. The GLC method (5) for aspirin quantitation is more specific but requires derivatization, which takes ~1 hr and can be complicated by the hydrolysis of aspirin to salicylic acid.

Previous investigators (6) reported that aspirin-containing combinations were difficult to chromatograph using nonpolar solvents and normal-phase chromatography. They preferred (7) paired-ion chromatography using the tetrabutylammonium ion to separate aspirin from muscle relaxants. They did not apply this method to separate combinations of the various pain relievers mentioned.

An automated high-pressure liquid chromatographic (HPLC) method (8) for the quantitation of aspirin, caffeine, and phenacetin was reported. The investigators used a controlled pore glass support as the stationary column and 8% acetic acid in chloroform as the mobile phase. This method was not tried on other pain relievers or in the presence of codeine phosphate.

Another HPLC method (9) analyzed small aspirin quantities in plasma in the presence of large salicylic acid quantities. However, the salicylic acid quantity is very small and the aspirin quantity is high in the dosage forms.

One study (10) used macroporous poly(methyl methylacrylate) resin to assay aspirin. This method was tedious and complicated. Two columns and two solvents were used to analyze some pain reliever combinations.

The purposes of the present investigations were to: (*a*) develop a rapid

Simultaneous Quantitation of Acetaminophen, Aspirin, Caffeine, Codeine Phosphate, Phenacetin, and Salicylamide by High-Pressure Liquid Chromatography

V. DAS GUPTA

Received May 7, 1979, from the *Department of Pharmaceutics, College of Pharmacy, University of Houston, Houston, TX 77004.* Accepted for publication July 31, 1979.

Abstract □ A method for the simultaneous quantitation of acetaminophen, aspirin, caffeine, codeine phosphate, phenacetin, and salicylamide was developed. The method is based on reversed-phase high-pressure liquid chromatography with a mobile phase buffered with phosphate (pH 2.3). The procedure not only separated these six active ingredients but also salicylic acid, the major decomposition product of aspirin. The method gave excellent results for three commercial products and a synthetic mixture containing four active ingredients. Lowering the pH increased the retention time of some weak acids and decreased that of some weak bases. Only these changes in the retention times made the separation possible.

Keyphrases □ High-pressure liquid chromatography—simultaneous quantitation of acetaminophen, aspirin, caffeine, codeine phosphate, phenacetin, and salicylamide □ Acetaminophen—simultaneous quantitation with aspirin, caffeine, codeine phosphate, phenacetin, and salicylamide, high-pressure liquid chromatography □ Aspirin—simultaneous quantitation with acetaminophen, caffeine, codeine phosphate, phenacetin, and salicylamide, high-pressure liquid chromatography □ Caffeine—simultaneous quantitation with acetaminophen, aspirin, codeine phosphate, phenacetin, and salicylamide, high-pressure liquid chromatography □ Codeine phosphate—simultaneous quantitation with acetaminophen, aspirin, caffeine, phenacetin, and salicylamide, high-pressure liquid chromatography □ Phenacetin—simultaneous quantitation with acetaminophen, aspirin, caffeine, codeine phosphate, and salicylamide, high-pressure liquid chromatography □ Salicylamide—simultaneous quantitation with acetaminophen, aspirin, caffeine, codeine phosphate, and phenacetin, high-pressure liquid chromatography

About 80 commercially available nonprescription drugs (1) contain one or more pain relievers such as acetaminophen, aspirin, phenacetin, and salicylamide. Many of them also contain caffeine and buffering agents such as aluminum hydroxide and magnesium hydroxide (1). At least two commercial products contain a combination of acetaminophen, aspirin, caffeine, and salicylamide (1). Other products contain a combination of acetaminophen or aspirin, caffeine, phenacetin, and salicylamide (1). Many prescription drugs contain codeine phosphate, usually combined with aspirin, caffeine, and phenacetin.

BACKGROUND

The simultaneous quantitation of these ingredients is difficult. The NF methods (2) for the quantitation of aspirin, caffeine, codeine phosphate, and phenacetin in combination are tedious and time consuming. The colorimetric (3) and fluorometric (4) methods for aspirin quantitation are based on its hydrolysis to salicylic acid. Since salicylic acid is the principal decomposition product of aspirin, these methods are not specific. The GLC method (5) for aspirin quantitation is more specific but requires derivatization, which takes ~1 hr and can be complicated by the hydrolysis of aspirin to salicylic acid.

Previous investigators (6) reported that aspirin-containing combinations were difficult to chromatograph using nonpolar solvents and normal-phase chromatography. They preferred (7) paired-ion chromatography using the tetrabutylammonium ion to separate aspirin from muscle relaxants. They did not apply this method to separate combinations of the various pain relievers mentioned.

An automated high-pressure liquid chromatographic (HPLC) method (8) for the quantitation of aspirin, caffeine, and phenacetin was reported. The investigators used a controlled pore glass support as the stationary column and 8% acetic acid in chloroform as the mobile phase. This method was not tried on other pain relievers or in the presence of codeine phosphate.

Another HPLC method (9) analyzed small aspirin quantities in plasma in the presence of large salicylic acid quantities. However, the salicylic acid quantity is very small and the aspirin quantity is high in the dosage forms.

One study (10) used macroporous poly(methyl methylacrylate) resin to assay aspirin. This method was tedious and complicated. Two columns and two solvents were used to analyze some pain reliever combinations.

The purposes of the present investigations were to: (*a*) develop a rapid

and simple HPLC method for the simultaneous quantitation of six active ingredients (acetaminophen, aspirin, caffeine, codeine phosphate, phenacetin, and salicylamide), and (*b*) develop a method free of interference from salicylic acid, the principal aspirin decomposition product.

EXPERIMENTAL

Reagents and Chemicals—All reagents and chemicals were ACS, USP, or NF quality and were used without further purification.

Apparatus—The high-pressure liquid chromatograph[1] was connected to a multiple-wavelength[2] detector, a recorder[3], and an integrator[4].

Column—The nonpolar column[5] (30 cm × 4 mm i.d.) consisted of a monomolecular layer of octadecyltrichlorosilane permanently bonded by silicone–carbon bonds.

Chromatographic Conditions—Solvent A consisted of 0.01 *M* KH_2PO_4 in water with 19% (v/v) methanol (±1%) whose pH[6] was adjusted to 2.3 with an 85% aqueous phosphoric acid solution (~1.1 ml/liter was required). Any methanol concentration between 18 and 20% could be used, but the retention times differed slightly. The exact concentrations used were reported with the sample chromatograms. Solvent B was the same as Solvent A, except that no phosphoric acid was added and the pH was ~4.85.

The temperature was ambient. The flow rate was 2.0 ml/min. The detector sensitivity was 0.04 (254 nm), except for acetaminophen peaks where it was 0.2. For the phenacetin analysis, the sensitivity was 0.1. For codeine analysis, 285 nm was preferred due to greater sensitivity. The chart speed was 30.5 cm/hr.

Solution Preparation—The stock solutions of acetaminophen (I), aspirin (II), salicylamide (III), and salicylic acid (IV) were prepared by dissolving 0.100 g in 5 ml of ethanol and bringing the solution to 100.0 ml with water. Aspirin solutions always were prepared immediately before use. Similar stock solutions of caffeine (V) and codeine phosphate (VI) were prepared without ethanol. The stock solution of phenacetin (VII) was prepared by dissolving 0.05 g of the drug in 5 ml of ethanol and bringing the solution to 100.0 ml with water. The lower concentration was used due to its poor water solubility. The standard solutions and mixture of solutions were prepared as needed by diluting the stock solutions with water.

Synthetic Mixture Preparation—A synthetic mixture was prepared by mixing 1.0 g each of I, II, and III and 0.3 g each of V and VII.

Preparation of Assay Solutions of Commercial Dosage Forms and Synthetic Mixture—For VI, an appropriate quantity of the powder representing 10.0 mg of VI was mixed with enough water to bring to 100.0 ml. The mixture was shaken for a few minutes and filtered. The first 15–20 ml of the filtrate was rejected, and a sample was collected for analysis.

For the other compounds, an appropriate quantity of the fine powder was stirred thoroughly with 5 ml of ethanol and brought to 100.0 ml with water. The mixture was filtered, the first 15–20 ml of the filtrate was rejected, and a sample was collected for further dilution. In general, 10.0 ml of the clear filtrate was diluted to 50.0 ml with water. For aspirin-containing products, the solution always was prepared fresh.

The appropriate quantity of the powder required was determined based on the concentrations of various active ingredients in multicomponent dosage forms. In general, the final dilution(s) for analysis contained the following active ingredient concentrations (micrograms per milliliter): I, 30–50; II, 100–250; III, 100–200; V, 15–30; and VII, 30–50. With these concentrations, sensitivity was 0.2 for I and 0.04 for all others. With one commercial dosage form containing I, V, and VII, instead of preparing another dilution for the analysis of VII, a higher concentration (~2.5 times more) was assayed at a sensitivity of 0.1. The standard mixtures used for comparison contained identical or similar concentrations of all active ingredients. The exact ingredient concentrations used for the sample chromatograms are reported in the figures.

Assay—A 20.0-μl aliquot of the assay solution was injected into the chromatograph using the described conditions (Solvent A). An identical volume of the appropriate standard solution or mixture was injected for comparison after the assay solution was eluted. The standard solution or mixture contained identical or similar active ingredient concentrations.

Calculations—Since preliminary investigations indicated that the peak heights (and the peak areas) were directly related to the concentrations tested (in micrograms: I, 0.5–1.2; II, 1.6–6.0; III, 1.6–5.0; V,

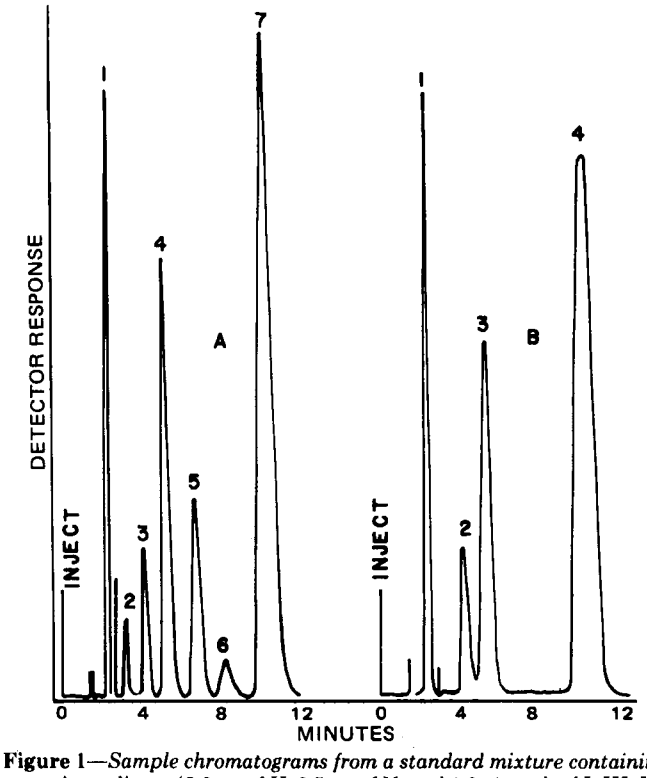

Figure 1—*Sample chromatograms from a standard mixture containing seven ingredients (2.0 μg of II, 0.5 μg of V, and 1.0 μg each of I, III, IV, VI, and VII). Chromatogram A was developed using Solvent A (20% methanol) and chromatogram B was developed using Solvent B. The sensitivity was 0.2 for peak 1 and 0.04 otherwise. The lines after peak 1 indicate the time when the sensitivity was changed. Peaks 1–7 in chromatogram A are from I, VI, III, V, II, IV, and VII, respectively. In chromatogram B, peak 1 is from I, II, and IV; peak 2 is from VI and III; peak 3 is from V; and peak 4 is from VII.*

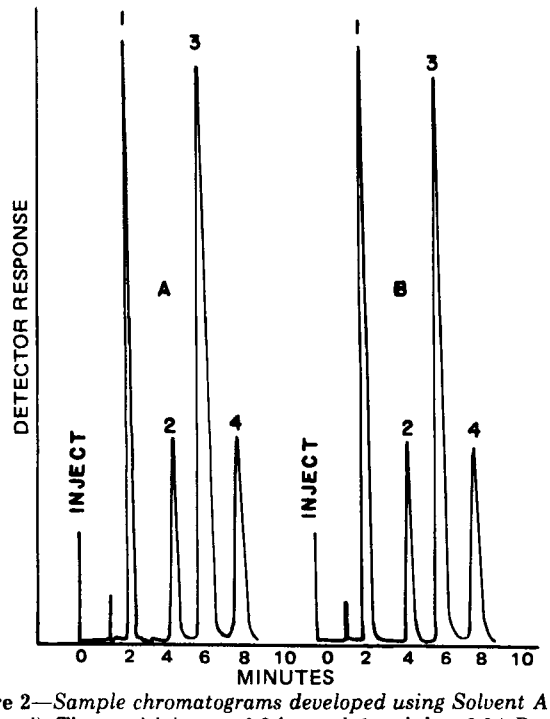

Figure 2—*Sample chromatograms developed using Solvent A (18% methanol). The sensitivity was 0.2 for peak 1 and then 0.04. Peaks 1–4 are from I (0.972 μg), III (1.296 μg), V (0.648 μg), and II (1.944 μg), respectively. Chromatogram A is from a standard mixture, and chromatogram B is from a commercial product.*

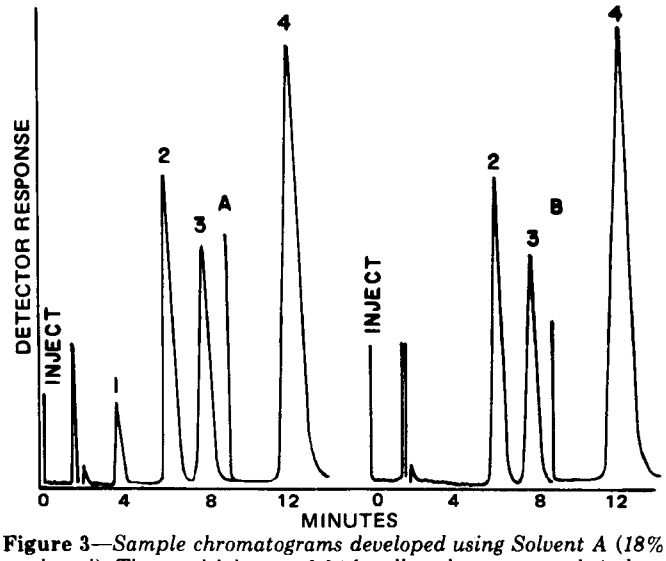

Figure 3—*Sample chromatograms developed using Solvent A (18% methanol). The sensitivity was 0.04 for all peaks except peak 4 where it was 0.1. The lines after peak 3 indicate the time when sensitivity was changed. Peaks 2–4 in both chromatograms are from V, II, and VII, respectively. Peak 1 in chromatogram A is from VI (1.0 μg). The quantities of II, V, and VII injected in chromatogram A (from a standard mixture) were 2.36, 0.32, and 1.56 μg, respectively. In chromatogram B (from a commercial product), the quantities were 2.268, 0.324, and 1.62 μg, respectively.*

0.2–0.7; VI, 1.5–4.0; and VIII, 0.5–1.2), the results were calculated using:

$$\frac{Ph_a}{Ph_s} \times 100 = \% \text{ label claim} \qquad \text{(Eq. 1)}$$

where Ph_a is the peak height of the assay solution and Ph_s is the peak height of the standard.

The ranges given are for a sensitivity of 0.2 for I and 0.04 for all other ingredients. In one commercial sample, VII was assayed using a sensitivity of 0.1. In this assay, peak heights *versus* concentrations were linear between 1.25 and 3.0 μg.

Two sample chromatograms (Fig. 1) were developed by injecting a 20-μl aliquot of a mixture containing 50 μg/ml each of I, III, IV, VI, and VII, 100 μg/ml of II, and 25 μg/ml of V. In the first chromatogram (Fig. 1A), Solvent A containing 20% (v/v) methanol was used; Solvent B (20% methanol) was used in the second chromatogram (Fig. 1B). The results are presented in Table I, and some sample chromatograms are shown in Figs. 2 and 3.

RESULTS AND DISCUSSION

Figure 1A clearly indicates that it is possible to separate seven active ingredients, I–VII, from each other using Solvent A, whose pH was adjusted to 2.3. The same ingredients could not be separated (Fig. 1B) using Solvent B (pH 4.85), which was similar to Solvent A but whose pH had not been adjusted with phosphoric acid. Figure 1B shows only four peaks since aspirin (II) and salicylic acid (IV) were eluted with acetaminophen (I) (peak 1) and codeine phosphate (VI) was eluted with salicylamide (III) (peak 2). The separation between peaks 2 and 3 also was not as good as in Fig. 1A.

By adjusting the solvent pH, the retention times of II and IV were increased and that of VI was decreased, which made the separation possible. Apparently, these changes result because, at a lower pH, both II and IV are predominantly in the undissociated forms while codeine is in the dissociated form. The undissociated forms were expected to be retained for longer times than dissociated forms on a nonpolar column.

With a solvent pH of 2.6–2.7, the retention times of II and IV increased, but these compounds did not separate from one another. It was important to separate these two compounds since IV is the major decomposition product of II. As the pH was decreased, separation became more effective. The pH is very important and functions similar to paired-ion chromatography, in which the retention times are increased.

The analytical results of three commercial dosage forms and a synthetic mixture (Table I and Figs. 2 and 3) indicate that the proposed method can be used for the simultaneous quantitation of active ingredients in various commercial products. Since none of the commercial dosage forms contain all seven ingredients, it is easy to select an internal standard if desired. The peak heights (also peak areas) *versus* concentrations were followed in wide ranges (see *Calculations*). These investigations were not intended to assay IV. Salicylic acid (IV), a major decomposition product of II, was investigated to determine its interference with the analysis of II. It is obvious (Fig. 1A) that it did not interfere. Investigators (11) reported recently that the USP method (12) for the quantitation of II in dosage forms is not stability indicating.

The standard and assay solutions can be prepared in ethanol if desired. Since peak heights vary with the solvent used, both the standard and assay solutions should be prepared in the same solvent. The peak heights were slightly smaller with ethanol as the solvent. Ethanol may be preferred for products containing II since it is less susceptible to hydrolysis in ethanol than in water. The solutions containing II must be prepared immediately before use. Since the optimum stability of II is at about pH 2.3 (13), the mobile phase should have a minimal adverse effect on hydrolysis. With ethanol as the solvent for the assay solution, I did not separate from the ethanol peak. Therefore, ethanol should not be used if I is to be assayed.

The possibilities of assaying very small quantities of IV (0.1% or more) in products containing II are now being studied since USP (12) requires such analysis.

High-Pressure Liquid Chromatographic Determination of Salicylic Acid in Aspirin Powder and Pharmaceutical Dosage Forms

V. DAS GUPTA

Received May 10, 1979, from the *Department of Pharmaceutics, College of Pharmacy, University of Houston, Houston, TX 77004.*
Accepted for publication July 31, 1979.

Abstract □ A sensitive, simple, and rapid method for the quantitation of salicylic acid in aspirin powders and its dosage forms was developed. The method is based on reversed-phase high-pressure liquid chromatography using a mobile phase containing 20% methanol in aqueous phosphate buffer of pH 2.3. Other common ingredients present with aspirin such as acetaminophen, caffeine, codeine phosphate, phenacetin, and salicylamide do not interfere. Salicylic acid quantities as low as 0.1 μg can be assayed with a relative standard deviation of ±2.3%. Sensitivity can be increased by using lower sensitivity settings. The method was tried on numerous commercial products and an old aspirin powder. The results generally were excellent, except that all of the aspirin and salicylic acid could not be extracted from suppositories. The old aspirin powder failed the USP limit test for salicylic acid. The powder apparently absorbed moisture and contained salicylamide as an impurity.

Keyphrases □ High-pressure liquid chromatography—analysis, salicylic acid in aspirin powder and dosage forms □ Aspirin—powder and dosage forms, analysis of salicylic acid, high-pressure liquid chromatography □ Salicylic acid—analysis in aspirin powder and dosage forms, high-pressure liquid chromatography

Salicylic acid is the major decomposition product of aspirin. Because free salicylic acid can cause gastric upset, the USP (1) prescribes limit tests for salicylic acid in aspirin powder and in pharmaceutical dosage forms containing aspirin. The limits are 0.1% for aspirin powder, 0.3% for tablets without buffers, 3.0% for buffered aspirin dosage forms, and 1.0% for suppositories. However, the USP method for the quantitation of salicylic acid in aspirin dosage forms is tedious and time consuming. For aspirin powder, the test is qualitative.

A high-pressure liquid chromatographic (HPLC) method (2) was reported which analyzes small aspirin quantities in the presence of large salicylic acid quantities in plasma. However, in dosage forms and aspirin powder, the assay of small salicylic acid quantities in the presence of large aspirin quantities was a problem. A tedious and complicated method was used for the separation of salicylic acid from aspirin (3).

The simultaneous quantitation of acetaminophen, aspirin, caffeine, codeine phosphate, phenacetin, and salicylamide was reported (4). In this method, the salicylic acid did not interfere. Small salicylic acid quantities could not be determined due to a lack of sensitivity in the analytical method. The purpose of these investigations was to develop a simple and rapid HPLC method for the quantitation of small salicylic acid quantities in aspirin powder and its pharmaceutical dosage forms.

EXPERIMENTAL

Reagents and Chemicals—All reagents and chemicals were ACS, USP, or NF quality and were used without further purification.

Apparatus—The high-pressure liquid chromatograph[1] was connected to a multiple-wavelength[2] detector, a recorder[3], and an integrator[4].

Column—The nonpolar column[5] (30 cm × 4 mm i.d.) consisted of a monomolecular layer of octadecyltrichlorosilane permanently bonded by silicone–carbon bonds.

Chromatographic Conditions—The solvent consisted of 0.01 *M* KH_2PO_4 in water with 20% (v/v) methanol, and its pH[6] was adjusted to 2.3 with an 85% aqueous phosphoric acid solution (~1.1 ml/liter). The temperature was ambient. The flow rate was 2.0 ml/min. The detector sensitivity was 0.04 (300 nm), and the chart speed was 30.5 cm/hr.

Solution Preparation—A stock solution of salicylic acid was prepared by dissolving 0.100 g in enough ethanol to bring to 100.0 ml. This solution was diluted with ethanol for the preparation of the standard solution or other solutions.

A stock solution of a standard mixture was prepared by dissolving 48.6 mg of acetaminophen, 97.2 mg of aspirin, 32.4 mg of caffeine, 50.0 mg of phenacetin, 64.8 mg of salicylamide, and 25.0 mg of salicylic acid in 10 ml of ethanol and bringing the solution to 100.0 ml with water. A solution of the standard mixture was prepared by diluting 10.0 ml of the stock solution to 100.0 ml with water. Both the stock and standard mixture solutions were prepared immediately before use.

Preparation of Assay Solutions from Aspirin Powder—All solutions were prepared immediately before injection into the chromatograph. Aspirin powder, 250.0 mg, was dissolved in enough ethanol to bring to 25.0 ml. Another solution of identical strength was prepared from an old aspirin powder (~10 years), which appeared to have decomposed. These solutions were used for the free salicylic acid determination.

Two other aspirin solutions were prepared by diluting the first solution to 250 μg/ml. Solution 1 was prepared by diluting with water, and Solution 2 was prepared with ethanol. These solutions were allowed to stand for ~50 hr and were then analyzed for free salicylic acid. This analysis was done to compare the hydrolysis rate of aspirin in water *versus* ethanol.

Assay Solutions from Solid Dosage Forms—An appropriate quantity of the fine powder was mixed with enough ethanol to bring to 25.0 ml, and the mixture was shaken for 2–3 min and filtered. The first 5–8 ml of the filtrate was rejected, and samples were collected for analysis. The solutions were prepared immediately before analysis. The quantity of the powder weighed represented at least 80 mg (for all nonbuffered tablets) or 50 mg (for buffered tablets) of aspirin. These quantities were determined by considering USP (1) salicylic acid limits. Exact concentrations of the aspirin solutions are reported in Table I.

Suppository Assay Solutions—A suppository containing 600 mg of aspirin was transferred to a 150-ml beaker. The beaker was warmed by

The powder apparently absorbed moisture and contained salicylamide as an impurity.

Keyphrases □ High-pressure liquid chromatography—analysis, salicylic acid in aspirin powder and dosage forms □ Aspirin—powder and dosage forms, analysis of salicylic acid, high-pressure liquid chromatography □ Salicylic acid—analysis in aspirin powder and dosage forms, high-pressure liquid chromatography

Salicylic acid is the major decomposition product of aspirin. Because free salicylic acid can cause gastric upset, the USP (1) prescribes limit tests for salicylic acid in aspirin powder and in pharmaceutical dosage forms containing aspirin. The limits are 0.1% for aspirin powder, 0.3% for tablets without buffers, 3.0% for buffered aspirin dosage forms, and 1.0% for suppositories. However, the USP method for the quantitation of salicylic acid in aspirin dosage forms is tedious and time consuming. For aspirin powder, the test is qualitative.

A high-pressure liquid chromatographic (HPLC) method (2) was reported which analyzes small aspirin quantities in the presence of large salicylic acid quantities in plasma. However, in dosage forms and aspirin powder, the assay of small salicylic acid quantities in the presence of large aspirin quantities was a problem. A tedious and complicated method was used for the separation of salicylic acid from aspirin (3).

The simultaneous quantitation of acetaminophen, aspirin, caffeine, codeine phosphate, phenacetin, and salicylamide was reported (4). In this method, the salicylic acid did not interfere. Small salicylic acid quantities could not be determined due to a lack of sensitivity in the analytical method. The purpose of these investigations was to develop a simple and rapid HPLC method for the quantitation of small salicylic acid quantities in aspirin powder and its pharmaceutical dosage forms.

EXPERIMENTAL

Reagents and Chemicals—All reagents and chemicals were ACS, USP, or NF quality and were used without further purification.

Apparatus—The high-pressure liquid chromatograph[1] was connected to a multiple-wavelength[2] detector, a recorder[3], and an integrator[4].

Column—The nonpolar column[5] (30 cm × 4 mm i.d.) consisted of a monomolecular layer of octadecyltrichlorosilane permanently bonded by silicone–carbon bonds.

Chromatographic Conditions—The solvent consisted of 0.01 *M* KH_2PO_4 in water with 20% (v/v) methanol, and its pH[6] was adjusted to 2.3 with an 85% aqueous phosphoric acid solution (~1.1 ml/liter). The temperature was ambient. The flow rate was 2.0 ml/min. The detector sensitivity was 0.04 (300 nm), and the chart speed was 30.5 cm/hr.

Solution Preparation—A stock solution of salicylic acid was prepared by dissolving 0.100 g in enough ethanol to bring to 100.0 ml. This solution was diluted with ethanol for the preparation of the standard solution or other solutions.

A stock solution of a standard mixture was prepared by dissolving 48.6 mg of acetaminophen, 97.2 mg of aspirin, 32.4 mg of caffeine, 50.0 mg of phenacetin, 64.8 mg of salicylamide, and 25.0 mg of salicylic acid in 10 ml of ethanol and bringing the solution to 100.0 ml with water. A solution of the standard mixture was prepared by diluting 10.0 ml of the stock solution to 100.0 ml with water. Both the stock and standard mixture solutions were prepared immediately before use.

Preparation of Assay Solutions from Aspirin Powder—All solutions were prepared immediately before injection into the chromatograph. Aspirin powder, 250.0 mg, was dissolved in enough ethanol to bring to 25.0 ml. Another solution of identical strength was prepared from an old aspirin powder (~10 years), which appeared to have decomposed. These solutions were used for the free salicylic acid determination.

Two other aspirin solutions were prepared by diluting the first solution to 250 μg/ml. Solution 1 was prepared by diluting with water, and Solution 2 was prepared with ethanol. These solutions were allowed to stand for ~50 hr and were then analyzed for free salicylic acid. This analysis was done to compare the hydrolysis rate of aspirin in water *versus* ethanol.

Assay Solutions from Solid Dosage Forms—An appropriate quantity of the fine powder was mixed with enough ethanol to bring to 25.0 ml, and the mixture was shaken for 2–3 min and filtered. The first 5–8 ml of the filtrate was rejected, and samples were collected for analysis. The solutions were prepared immediately before analysis. The quantity of the powder weighed represented at least 80 mg (for all nonbuffered tablets) or 50 mg (for buffered tablets) of aspirin. These quantities were determined by considering USP (1) salicylic acid limits. Exact concentrations of the aspirin solutions are reported in Table I.

Suppository Assay Solutions—A suppository containing 600 mg of aspirin was transferred to a 150-ml beaker. The beaker was warmed by

Table I—Assay Results of Aspirin Powders and Commercial Dosage Forms

Sample	Claim per Dosage Form, mg	Concentration of Aspirin in Assay Solution, mg/ml	Assay Results	
			Aspirin, % label claim	Salicylic Acid[a] Based on Percent Label Claim of Aspirin
Aspirin powder	—	10.0	—	0.07
Old aspirin powder	—	10.0	95.6[b]	0.61
Tablet 1	Aspirin, 325	10.0	99.8	0.06
Tablet 2	Aspirin, 325; magnesium-aluminum hydroxide, 300	2.6	100.4	0.41
Tablet 3	Aspirin, 600; magnesium hydroxide, 150; aluminum hydroxide dried gel, 150	2.4	99.6	0.54
Tablet 4	Aspirin, 227; phenacetin, 162; caffeine, 32	6.8	100.0	0.14
Tablet 5	Aspirin, 195; acetaminophen, 97; caffeine, 65; salicylamide, 130	7.8	100.1	0.13
Suppository	Aspirin, 600	1.0	31.4	0.64[c]
Aspirin solution (50 hr old)				
In ethanol	—	0.25	—	2.8
In water	—	0.25	—	6.6[d]

[a] Relative standard deviation based on five injections was ±2.3%. [b] This old aspirin powder apparently had absorbed moisture. It also failed the USP limit test for salicylic acid. [c] Calculated based on label claim of aspirin; percent found was divided by 0.314. Since the salicylic acid peak was small, the margin of error is ~3.8%. [d] To determine salicylic acid in a water solution, the standard salicylic acid solution also was made in water by diluting the stock solution. The peaks were slightly higher for the standard solution in water *versus* in ethanol.

immersion in a water bath (~50°) to melt the suppository, and the melt was mixed with enough ethanol to make 60.0 ml of mixture. The mixture was shaken for 4–5 min, and the decanted alcoholic solution was diluted (from 10.0 to 100.0 ml) with ethanol to prepare the assay solution.

Assay Method—A 20.0-μl aliquot of the assay solution was injected into the chromatograph using the described conditions. An identical volume of salicylic acid solution in ethanol (10.0 μg/ml) was injected for comparison after the assay solution eluted.

Two chromatograms (Fig. 1) were developed by injecting a 20.0-μl aliquot of the standard mixture. One chromatogram used a detector wavelength of 300 nm, and the other chromatogram used 254 nm.

Calculations—Since preliminary investigations indicated that peak heights were directly related to concentrations (0.10–0.6 μg) of salicylic acid, the results were calculated by:

$$\frac{Ph_a}{Ph_s} \times 10 = \text{micrograms of salicylic acid per milliliter of solution} \quad \text{(Eq. 1)}$$

where Ph_a is the peak height of the assay solution and Ph_s is the peak height of the standard solution. To ensure quantitative extraction of aspirin from the dosage forms, aspirin was assayed using the method reported previously (4) (Table I and Figs. 2–4).

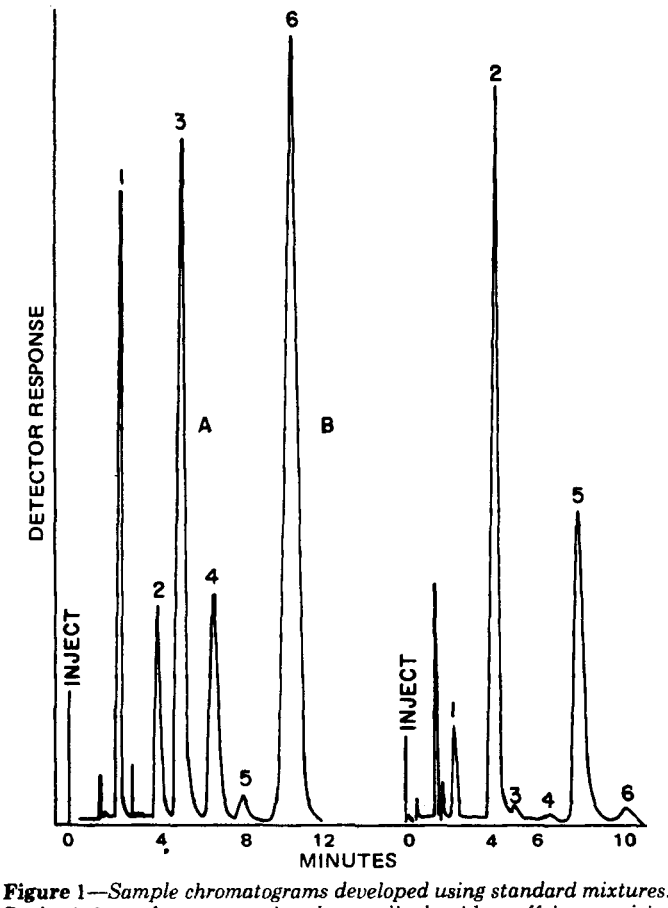

Figure 1—*Sample chromatograms developed using standard mixtures. Peaks 1–6 are from acetaminophen, salicylamide, caffeine, aspirin, salicylic acid, and phenacetin, respectively. Chromatogram A was developed at 254 nm, and B was developed at 300 nm.*

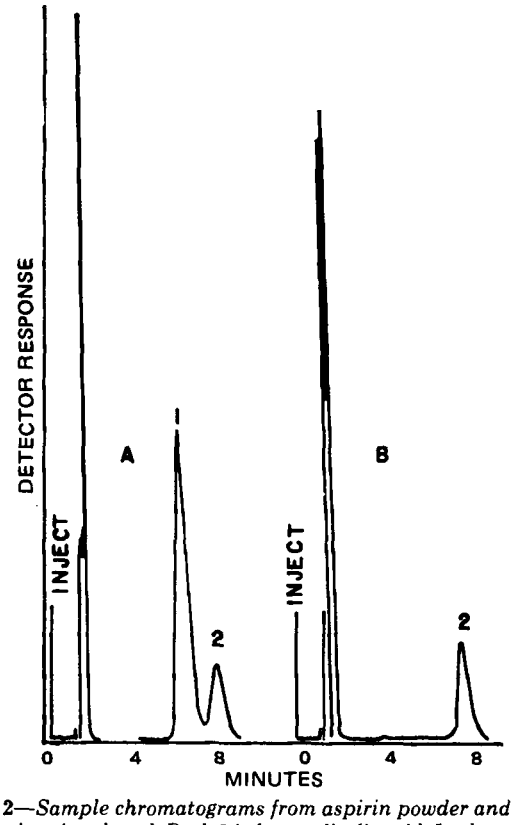

Figure 2—*Sample chromatograms from aspirin powder and salicylic acid solutions in ethanol. Peak 2 is from salicylic acid. In chromatogram A, peak 1 is from aspirin (0.2 mg). In B, 0.2 μg of salicylic acid was injected.*

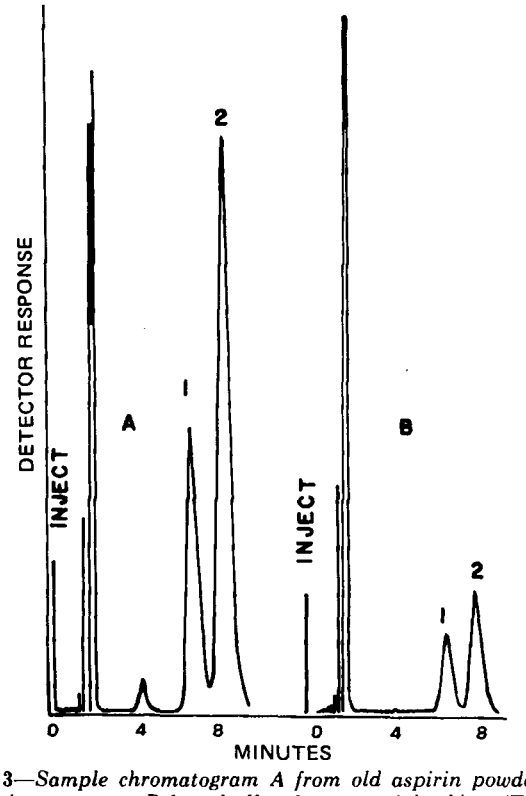

Figure 3—*Sample chromatogram A from old aspirin powder and sample chromatogram B from buffered commercial tablets (Tablet 3 in Table I). Peak 1 is from aspirin, and 2 is from salicylic acid. In A, there is an additional peak after ~4 min, which may be due to salicylamide impurity.*

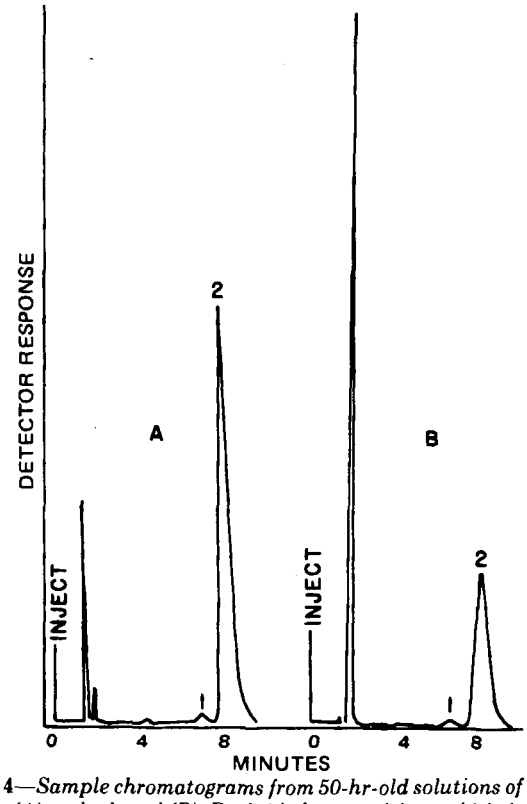

Figure 4—*Sample chromatograms from 50-hr-old solutions of aspirin in water (A) and ethanol (B). Peak 1 is from aspirin, and 2 is from salicylic acid.*

RESULTS AND DISCUSSION

It was reported (4) that it was not possible to assay salicylic acid using the solvent system developed for the simultaneous quantitation of acetaminophen, aspirin, caffeine, codeine phosphate, phenacetin, and salicylamide due to the lack of sensitivity at 254 nm (sensitivity 0.04). Otherwise, separation of salicylic acid from the six active ingredients was excellent (4). Preliminary investigations subsequently indicated that the spectral absorption of salicylic acid solution in the mobile phase was very high at 300 nm, the wavelength of maximum absorption. When considering weight per weight concentrations, the absorption of aspirin solution at 300 nm was almost negligible (Fig. 1B, peak 4). For comparison, chromatograms A and B (Fig. 1) were developed at 254 and 300 nm, respectively. In A, peak 1 was obtained at a sensitivity of 0.2; the sensitivity for peak 1 in B was 0.04. A sensitivity of 0.04 was used otherwise. Even with a sensitivity of 0.04, peak 1 (from acetaminophen) in chromatogram B was very small as compared with peak 1 in chromatogram A (Fig. 1).

The results (Table I) and the sample chromatograms indicate that very small quantities of salicylic acid can be assayed in aspirin powder and its dosage forms using a simple HPLC method. The mobile phase pH (2.3) was almost the optimum pH for aspirin stability (5). Therefore, the adverse effect from the mobile phase was minimal. Aspirin could not be extracted from the suppositories quantitatively with ethanol (Table I). Chloroform was not used for this extraction because it is not miscible with the mobile phase.

Salicylic acid determinations were made at a sensitivity of 0.04. The sensitivity of this method can be increased by changing the setting to 0.01; however, there was some noise problem at this low sensitivity. In the proposed assay, salicylic acid concentrations as low as 5 μg/ml can be determined with a relative standard deviation of ±2.3%. If the salicylic acid assay results are less than 5 μg/ml, the error could be higher. Therefore, the assay should be repeated either with a higher aspirin concentration or with a lower sensitivity.

The old aspirin powder did not pass the USP limit test (Table I) of 0.1% for salicylic acid. Moreover, the old aspirin powder assayed only 95.6%, which may have been due to the moisture absorption. Also, it showed an additional peak (Fig. 3A) after 4 min, which may have been due to salicylamide as an impurity since the retention time of the peak was identical to that of salicylamide (Fig. 1). Although no internal standard was used, one of the following (if not present in the dosage form) may be used as an internal standard: caffeine, 1–2 mg/ml; phenacetin, 1–2 mg/ml; and salicylamide, ~20 μg/ml.

Dipole Moments and Conformational Structures of 2-Substituted Phenothiazines as Solutes

C. LEVAYER *, A.-M. GALY ‡, and J. BARBE ‡x

Received April 4, 1979, from the *Service de Chimie Minérale, U.E.R. de Pharmacie, Rue Gaston-Veil, B.P. 1024, 44035 Nantes Cedex, France, and the ‡Service de Chimie Minérale, U.E.R. de Pharmacie, Boulevard Jean-Moulin, 13385 Marseille Cedex 4, France. Accepted for publication August 7, 1979.

Abstract □ Experimental dipole moments measured in anhydrous benzene and dioxane are compared to the calculated values of some 2-substituted phenothiazine derivatives. The dipole moments and the solvent effects support the existence of a conformational mixture of these compounds as solutes.

Keyphrases □ Phenothiazines—2-substituted, dipole moments and conformational structures as solutes □ Dipole moments—of 2-substituted phenothiazines as solutes □ Conformations—of 2-substituted phenothiazines as solutes

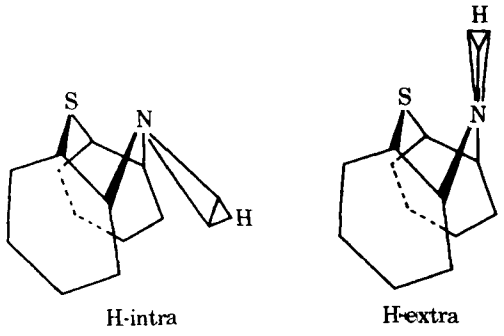
A previous report (1) on *N*-methylphenothiazine and its 2-chloro derivative suggested a mixture of conformers of these compounds in solution. This finding is important for a possible conformational explanation of phenothiazine polybiovalency. The conformational structures of some other 2-substituted molecules, which are the chemical forerunners of the clinically used phenothiazine drugs, were determined by comparing the theoretical dipole moments of peculiar conformations to experimental values. The experiment dipole moments were measured with the compounds as solutes due to the physical state of the biophase.

EXPERIMENTAL

Materials—The following compounds[1] were studied: phenothiazine (I), 2-chlorophenothiazine (II), 2-cyanophenothiazine (III), 2-methoxyphenothiazine (IV), 2-thiomethylphenothiazine (V), 2-acetylphenothiazine (VI), and 2-propionylphenothiazine (VII).

Method—The dipole moments of the compounds as solutes in anhydrous benzene and in anhydrous dioxane were measured at different temperatures. The permittivity[2] and refractive index[3] of the solutions were extrapolated to infinite dilution according to Guggenheim (2) and Smith (3). The quantity $(\epsilon_{12} - n_{12}^2) - (\epsilon_1 - n_1^2)$ was plotted *versus* the molar concentration, C, of the solute. The slope of the curve at $C = 0$ then was used to calculate the dipole moment, μ, by:

$$\mu^2 = \frac{9kT}{4\pi N} \frac{3}{(\epsilon_1 + 2)(n_1^2 + 2)} \frac{(\epsilon_{12} - n_{12}^2) - (\epsilon_1 - n_1^2)}{C} \quad \text{(Eq. 1)}$$



where k is the Boltzmann constant, N is Avogadro's number, T is the absolute temperature, and ϵ_i and n_i are the permittivities and refractive indexes, respectively, of the solutes (Index 1) and of the solutions (Index 12).

[a] When necessary, H-intra structures (i) are distinguished from H-extra structures (e).

RESULTS AND DISCUSSION

The experimental dipole moments are given in Table I. The theoretical values were calculated using a vectorial incremental addition. The molecular increments and their dipole moments (4, 5) are listed in Table II.

Because folding along an NS axis is well known in phenothiazine derivatives (6–8), calculations were performed for different values of the angle, α, between each aromatic moiety of the heterocycle. Both H-intra (quasiequatorial) and H-extra (quasiaxial) limit conformations (9) were considered. Consequently, the following assumptions were used (10): $\mu_{CN\ conjugated}$ (*e.g.*, H-intra structure) = 1.7 *D*, and $\mu_{CN\ unconjugated}$ (*e.g.*, H-extra structure) = 0.8 *D*. Such values followed from a study of dipole moment geometrical structural relationships (Table III).

Theoretical dipole moments of the studied compounds are presented in Table IV.

The comparison between experimental and theoretical dipole moments agreed with a folded structure for these molecules. However, there were different α values with each. Compounds I–V sometimes had a quasiaxial structure and sometimes a quasiequatorial one, demonstrated by the dielectric behavior of the compounds in dioxane. Dioxane interacts with conformable solutes by hydrogen bonds (11). Such an interaction is included in the dipole moment value of the solute. Here, there were solute–solvent interactions only with an H-intra conformation because of the electronic hindrances of the H-extra conformer, as can be shown by a molecular framework. Dipole moments measured in benzene and dioxane must agree with one another only for an H-extra structure. The experimental values agreed. Unfortunately, the structures of VI and VII could not be elucidated by correlating experimental and calculated dipole moments except when the following classical relation was used:

$$\mu^2_{experimental} = \mu^2_{H\text{-intra structure}} x_1 + \mu^2_{H\text{-extra structure}} x_2 \qquad \text{(Eq. 2)}$$

Table V—Molar Fractions of the H-Intra Structure Calculated for Several α Values

α	I	II	III	IV	V	VI or VII
142°	0.65	0.67	0.21	0.60	0.67	0.46
146°	0.66	0.67	0.22	0.62	0.69	0.49
150°	0.69	0.68	0.23	0.64	0.71	0.52
154°	0.72	0.70	0.23	0.66	0.74	0.55
158°	0.77	0.73	0.19	0.69	0.78	0.58

where x_1 and x_2 are the molar fractions of the selected conformers. Thus, a conformational mixture was admitted. Results obtained by applying this conclusion to all of the compounds are listed in Table V.

These results were in agreement with those of the previous study of *N*-methylphenothiazine derivatives (1). Moreover, contradictory results about NH phenothiazine compounds from theoretical calculations (9), NMR studies (12, 13), and crystallographic data (14) could be explained if the prevalence of this or that conformer was considered for each molecule. Thus, a mixture of conformations is suggested for dibenzoparathiazine and its substituted derivatives in solution. This result supports the action pattern proposed (15, 16) for phenothiazine drugs.

GLC–Mass Spectral Determination of Mescaline in Plasma of Rabbits after Intravenous Injection

C. VAN PETEGHEM [x], A. HEYNDRICKX, and W. VAN ZELE

Received February 21, 1978, from the *Toxicology Laboratory, University of Ghent, 9000 Ghent, Belgium.* Accepted for publication August 7, 1979.

Abstract □ A GLC–mass spectral analysis with a deuterated internal standard was developed to measure plasma mescaline concentrations after intravenous administration to rabbits. The drug and the internal standard were extracted with benzene, derivatized with trifluoroacetic acid anhydride, and chromatographed on 2.5% QF-1 with mass fragmentographic detection. The detection limit is 5 ng/ml of plasma. The relative standard deviation was ~5%. The main advantage of this method is that it combines the specificity of the GLC retention time and mass spectral fragmentation pattern with the sensitivity of the mass fragmentographic detection.

Keyphrases □ Mescaline— GLC–mass spectral determination, rabbit plasma, intravenous injection □ Hallucinogenics—mescaline, GLC–mass spectral determination, rabbit plasma, intravenous injection □ GLC–mass spectrometry—analysis, mescaline in rabbit plasma

Mescaline (3,4,5-trimethoxyphenethylamine), an alkaloid isolated in 1896 from the peyote cactus *Lophophora Williamsii*, causes unusual psychic effects and visual hallucinations. In the United States, it is not considered a narcotic drug; but in most countries, it is on the list of illicit drugs. A review of its chemistry, biogenesis, and biological effects was published previously (1).

In clinical toxicological laboratories, identification and quantitation of mescaline are sometimes requested. Only a few methods relate to biological samples (2–4). Most references concern systematic mescaline identification by combined TLC (5–7), GLC and/or mass spectrometry (8–10), or high-pressure liquid chromatography (11). A radioimmunological method also was described (12).

Mescaline is excreted primarily in the urine in humans: subjects given 500 mg po excreted 87% of the dose in 24 hr. The unchanged compound accounted for 60%, and 3,4,5-trimethoxyphenylacetic acid accounted for ~30% (13).

This paper reports a specific and sensitive method for the quantitative determination of mescaline as trifluoroacetylmescaline (I) with trifluoroacetyl-$^2H_2$-mescaline (II) as the internal standard.

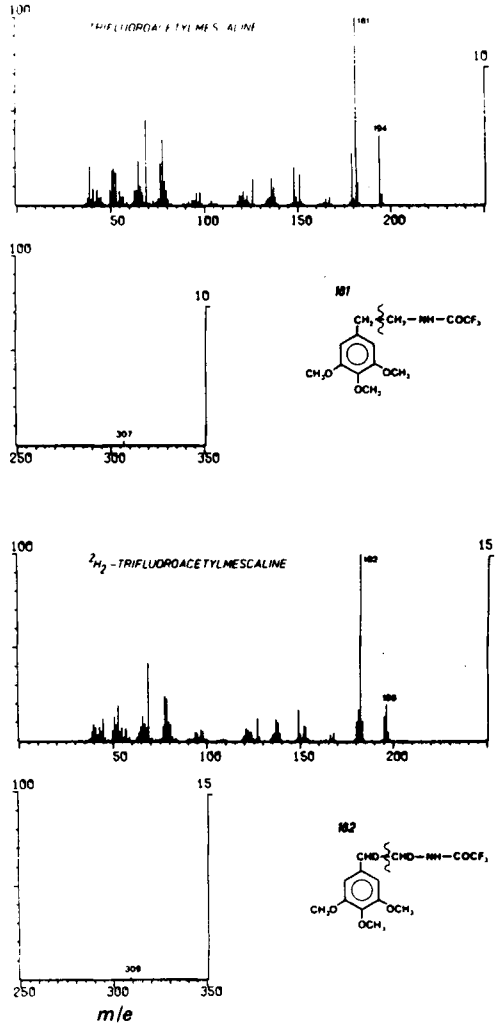

Figure 1—*The 70-ev electron-impact mass spectra of I (top) and II (bottom).*

EXPERIMENTAL

Materials—All chemicals were analytical reagent grade and used as received. Mescaline[1] was 99% pure. ^2H-Labeled mescaline was synthesized from 3,4,5-trimethoxybenzaldehyde by condensation with nitromethane and subsequent reduction with lithium aluminum deuteride. All labeled and nonlabeled standards were prepared in methanol at concentrations permitting use of 10–50-μl aliquots.

Table I—Influence of Overnight Storage Temperature (4 or −18°) on Plasma Mescaline Contents

Sample	Corrected Areas Ratio: Storage at 4°	Corrected Areas Ratio: Storage at −18°
1	0.416	0.417
2	0.443	0.455
3	0.441	0.458
4	0.464	0.471
5	0.457	0.487
6	0.444	0.460
$\bar{x}$	0.444	0.458
σ	0.017	0.023
CV	3.7%	5.1%

Subjects—Rabbits, 2 ± 0.1 kg, were given 1 ml of an aqueous solution of mescaline at a 10-mg/kg dose by rapid intravenous injection in the ear. Blood (1 ml) was drawn from the other ear and collected in heparinized tubes. The samples were centrifuged, and the plasma was stored at 4° until analysis on the next day.

Apparatus—Determinations were performed by GLC[2] with a mass spectrometer as a specific detector[3] coupled to a data system[4]. A silanized

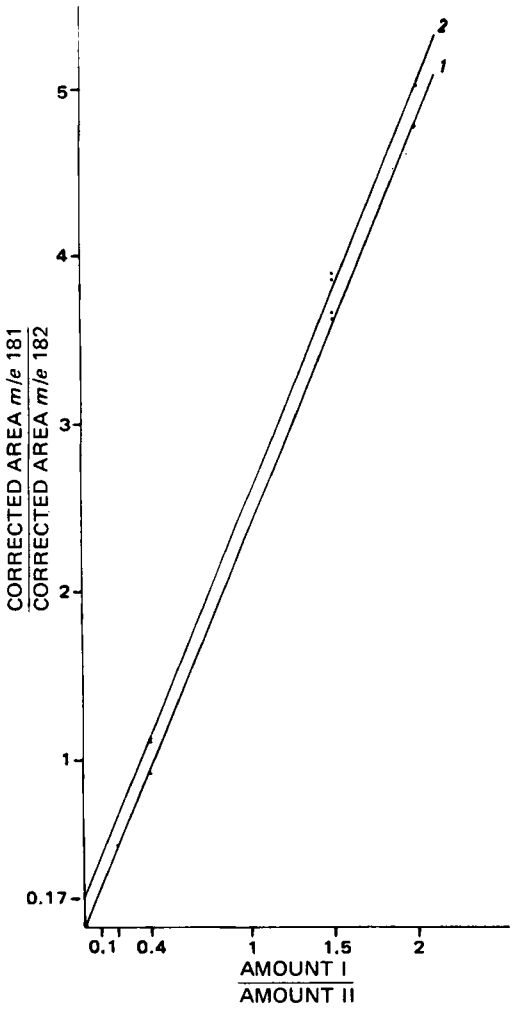

Figure 2—*Calibration graphs after correction for mutual contribution (1) and for the contribution of I to II (2) only.*

glass column, 1.5 m × 0.63 cm, was packed with 2.5% QF-1 on 100–120-mesh Varaport. Helium carrier gas flow was maintained at 30–35 ml/min. Injection port and oven temperatures were 210 and 195°, respectively. The mass spectrometer was operated at a pressure of 5×10^{-6} torr; the ionizing energy in the ion source was 70 ev.

Extraction—To 0.5 ml of plasma was added 20 μl of internal standard solution (200 ng of II). The pH was adjusted to 10 with 1 ml of ammonia–ammonium chloride buffer. The sample was then extracted with 4 ml of benzene. The extracts were dried over anhydrous sodium sulfate (~2 g) and evaporated to dryness under nitrogen.

The residue was dissolved in 0.2 ml of ethyl acetate and 0.2 ml of trifluoroacetic acid anhydride. The solution was allowed to react at 60° in a warm water bath for 30 min, after which the solvents were evaporated with a nitrogen stream. Then the residue was dissolved in 10–20 μl of methanol, and 1–2-μl aliquots were analyzed. The retention time for mescaline and the internal standard was 2.60 min.

Quantitation—Standard solutions in methanol, containing quantities equivalent to 20, 40, 80, 200, and 400 ng of mescaline/μl and 200 ng of internal standard/μl, were used to establish the calibration curve.

RESULTS AND DISCUSSION

The mass spectra of mescaline and of the internal standard are shown in Fig. 1. From the intensity ratio of the *m/e* 181 and 182 ions, the plasma concentrations could be calculated. The problem was that the *m/e* 181 ion in the mescaline spectrum had an isotopic peak at *m/e* 182, while the fragmentation pattern of the internal standard showed both *m/e* 181 and 182 peaks. Consequently, the standard calibration graph shows a curved line with an intercept different from zero, depending on the relative intensity of the *m/e* 181 ion to the *m/e* 182 ion in the mass spectrum of the internal standard. However, this problem could be overcome by correcting

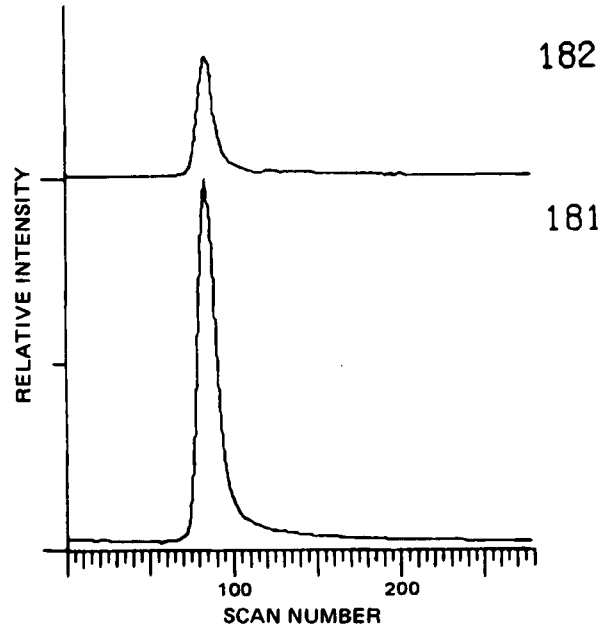

Figure 3—*Mass fragmentogram of a plasma extract (*m/e *181 = trace of I, and* m/e *182 = trace of II).*

for those mutual interferences using:

$$S_{181} = (f_x)(C_x) + (a)(f_s)(C_s) \quad \text{(Eq. 1)}$$

$$S_{182} = (f_s)(C_s) + (b)(f_x)(C_x) \quad \text{(Eq. 2)}$$

where:

C_x = amount of mescaline present in the extract
f_x = factor relating concentration to intensity of the *m/e* 181 ion in the mescaline spectrum
C_s = amount of internal standard in the extract
f_s = factor relating concentration to intensity of the *m/e* 182 ion in the internal standard spectrum
a = relative intensity of the *m/e* 181 ion to the *m/e* 182 ion in the mass spectrum of the internal standard
b = relative intensity of the *m/e* 182 ion to the *m/e* 181 ion in the mescaline mass spectrum
S_{181} = integrated area of the 181 channel
S_{182} = integrated area of the 182 channel

Equations 1 and 2 can be rewritten as:

$$\frac{S_{181} - (a)(S_{182})}{S_{182} - (b)(S_{181})} = (A)(C_x) \quad \text{(Eq. 3)}$$

where:

$$A = \left(\frac{f_x}{f_s}\right)\left(\frac{1}{C_s}\right) \quad \text{(Eq. 4)}$$

The ratio of the corrected areas is now directly proportional to the concentration of the unknown in the standard (Fig. 2). Curve 1 is calculated

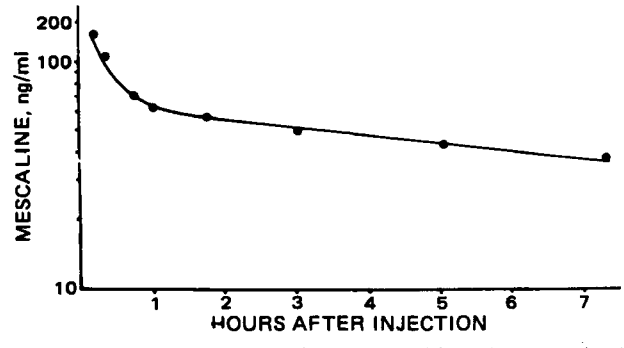

Figure 4—*Profile curve of mescaline in one subject after 10 mg/kg iv.*

by linear regression from the experimental data with $a = 0.165$ and $b = 0.105$. The latter values are obtained by injecting standard solutions of I and II and measuring the ratios of *m/e* 182 to 181 and of *m/e* 181 to 182, respectively. The equation is given by:

$$y = 0.05x + 0.0013 \qquad \text{(Eq. 5)}$$

where y is the corrected areas ratio and x is the mescaline concentration.

Curve 2 is calculated with $a = 0$ and $b = 0.105$ when no corrections are made for the constant contribution of the internal standard's *m/e* 181 ion to the compound to be measured. In this case, the intercept is 0.17, which is in reasonably good agreement with the expected value of 0.165.

An example of a mass fragmentogram of a plasma extract is shown in Fig. 3. No coeluting substances were found when blank plasma samples were analyzed. Therefore, the method, due to the combined specificity of both retention time and mass spectrometric fragmentation pattern, is suitable for pharmacokinetic studies.

The influence of the overnight storage temperature was examined by analyzing a 0.05-ppm spiked pool serum sample, part of which had been kept at 4° and another part at −18° overnight (Table I). The mean values ($n = 6$) of each set of assays were not significantly different (Student *t* test).

The precision of this analytical procedure, expressed as the coefficient of variation, is on the order of 5%. For the GLC–mass spectral quantitative assay, it was 1.7% (six repetitive injections of the same extract).

Although the apparent extraction efficiency with a labeled internal standard added before the extraction was 100%, the actual efficiency was checked; it was about 95% for spiked serum samples. To illustrate that the method is suitable for biological profile studies, the profile curve of one subject is shown in Fig. 4.

New Compounds: Reissert Compound Studies XXXII: Facile Synthesis of 3-Azapapaverine

DEBKUMAR BHATTACHARJEE and F. D. POPP ˣ

Received June 18, 1979, from the *Department of Chemistry, University of Missouri–Kansas City, Kansas City, MO 64110.* Accepted for publication July 31, 1979.

Abstract □ 6,7-Dimethoxyphthalazine was obtained in four steps from veratric acid and converted to its Reissert compound. Alkylation of this Reissert compound with 3,4-dimethoxybenzyl chloride followed by hydrolysis gave 3-azapapaverine.

Keyphrases □ Reissert compounds—synthesis of 3-azapapaverine from veratric acid □ 3-Azapapaverine—synthesis from veratric acid *via* a Reissert compound □ Phthalazines—synthesis of 3-azapapaverine from veratric acid *via* Reissert compound derivative of 6,7-dimethoxyphthalazine

The application of Reissert compounds (1, 2) to the synthesis of natural products and compounds of potential medicinal interest is well documented (2, 3) in the field of quinolines and, particularly, isoquinolines. Although phthalazine also yields a Reissert compound (4, 5), its use in the synthesis of potential medicinal agents has not been studied. This paper reports a convenient synthesis of 3-azapapaverine (I) using the Reissert compound (II) of 6,7-dimethoxyphthalazine (III) and demonstrates the potential utility of Reissert compounds derived from phthalazine.

DISCUSSION

A convenient synthesis of III from commercially available veratric acid (IV) was developed using modifications of several literature procedures. Chloromethylation of IV gave the lactone (V) (6), which yielded 4,5-dimethoxyphthalyl alcohol (VI) on reduction with lithium aluminum hydride (7). Oxidation of VI with activated manganese dioxide gave 4,5-dimethoxyphthalaldehyde (VII). Treatment of this dialdehyde (VII) with hydrazine hydrate gave III (8). The overall yield of III from IV was 36%.

Compound III was converted to its Reissert compound (II) by a phase transfer procedure (5) or by a trimethylsilyl cyanide procedure (9). Alkylation of II with 3,4-dimethoxybenzyl chloride in the presence of sodium hydride gave the alkylated Reissert compound VIII. Hydrolysis of VIII with potassium hydroxide gave I.

This procedure should be valuable in the synthesis of phthalazine analogs of isoquinolines of medicinal interest.

EXPERIMENTAL

***m*-Meconin (V)**—Formaldehyde (230 ml, 37% solution) was saturated with hydrogen chloride gas at 15–20°, and 32 g (0.176 mole) of IV[1] was added. The mixture was heated to 60–70° for 7 hr, during which hydrogen chloride gas was bubbled slowly through it. The mixture was cooled, kept overnight, and concentrated *in vacuo*. Water, 100 ml, was added, and the mixture was neutralized with 2:3 dilute ammonium hydroxide. A solid formed and was filtered, washed several times with water, and dried. Recrystallization from methanol gave 22.4 g (65.6%) of V, mp 154–155° [lit. (6) mp 154–156°]; IR (KBr): 3080, 3020 (m), 2940 (w), 1755–1740 (s), 1600 (s), 1500 (s), 1350 (s), and 1300 (s) cm^{-1}.

4,5-Dimethoxyphthalyl Alcohol (VI)—A warm solution of 14 g (0.072 mole) of V in 150 ml of anhydrous tetrahydrofuran was added continuously to a suspension of 7.5 g of lithium aluminum hydride in 80 ml of tetrahydrofuran, and the mixture was refluxed for 4 hr. The mixture was cooled in an ice bath, and the excess lithium aluminum hydride was

decomposed by the dropwise addition, with stirring, of 7.5 ml of water, 7.5 ml of 15% NaOH, and 22.5 ml of water. The precipitate was extracted with hot tetrahydrofuran, the combined tetrahydrofuran solutions were evaporated, and the residue was extracted with chloroform. Evaporation of the dried chloroform extract gave 13 g (91%) of VI, mp 110–111° (from benzene) [lit. (7) mp 111°].

4,5-Dimethoxyphthalaldehyde (VII)—To a vigorously stirred suspension of 20 g of activated manganese dioxide in 200 ml of chloroform was added 3 g of VI, and the mixture was stirred at room temperature for 3 days. The manganese dioxide was filtered and washed several times with chloroform, and the combined solvent was distilled to give 1.9 g (64.6%) of VII, mp 168–169° (from benzene) [lit. (7) mp 165°]; IR (KBr): 3100, 3000, 2930, 2870 (w), 1675 (vs), 1585 (s), 1510–1500 (s), 1460 (s), 1440 (s), and 1285 (s) cm^{-1}; NMR ($CDCl_3$): δ 10.7 (s, 2H), 7.36 (s, 2H), and 3.98 (s, 6H).

6,7-Dimethoxyphthalazine (III)—Compound VII (3.5 g, 0.018 mole) was warmed with 175 ml of absolute ethanol, and 1.1 g of 85% hydrazine hydrate was added dropwise with stirring. When VII had dissolved, the solution was refluxed for 5 hr and concentrated *in vacuo* to give 3.2 g (93.4%) of III, mp 198–200° (from chloroform–benzene) [lit. (8) mp 181–183°]; IR ($CHCl_3$): 3050 (m), 1605 (w), 1505 (m), 1470 (m), 1430 (s), 1335 (m), 1250 (s), 1225 (vs), and 1160 (s) cm^{-1}; NMR ($CDCl_3$): δ 9.27 (s, 2H), 7.1 (s, 2H), and 4.04 (s, 6H).

Anal.—Calc. for $C_{10}H_{10}N_2O_2$: C, 63.14; H, 5.30. Found: C, 63.41; H, 5.53.

1-Cyano-2-benzoyl-6,7-dimethoxy-1,2-dihydrophthalazine (II)—To a solution of 3.2 g (0.0168 mole) of III in 200 ml of dry methylene chloride were added a catalytic amount (50 mg) of anhydrous aluminum chloride and 5 g (0.0504 mole) of trimethylsilyl cyanide. After 10 min, 7.1 g (0.0504 mole) of benzoyl chloride was added, and the mixture was stirred at room temperature for 24 hr. The mixture was washed with water, 5% HCl, water, 5% NaOH, and water. The mixture was dried, and the solvent was removed. The residue was recrystallized from benzene–chloroform to give 5 g (92.6%) of II, mp 204–207°; IR (KBr): 3080 (w), 2975 (m), 2945 (w), 1640 (s), 1600 (s), 1570 (w), 1515 (s), 1450 (s), 1380 (s), 1315 (s), 1280 (s), 1250 (s), 1130 (s), 1010 (s), and 910 (s) cm^{-1}; NMR ($CDCl_3$): δ 7.78–7.20 (m, 6H), 6.86 (s, 1H), 6.82 (s, 1H), 6.55 (1H), 3.95 (s, 3H), and 3.92 (s, 3H).

Anal.—Calc. for $C_{18}H_{15}N_3O_3$: C, 67.28; H, 4.70; N, 13.08. Found: C, 67.28; H, 4.63; N, 13.02.

1-Cyano-1-(3,4-dimethoxybenzyl) -2- benzoyl-6,7-dimethoxy-1,2-dihydrophthalazine (VIII)—To a stirred solution of 3.21 g (0.01 mole) of II in 30 ml of dimethylformamide at −15° under a nitrogen atmosphere were added 1.87 g (0.01 mole) of 3,4-dimethoxybenzyl chloride and 0.48 g of 50% NaH in oil. The mixture was allowed to warm to room temperature and was stirred for an additional 2 hr. Then the solution was poured onto 300 g of ice. The product was filtered, washed with water, and dried to give 4.48 g (95%) of VIII, mp 198–201° (from chloroform–methanol); IR (KBr): 3070 (w), 3045 (w), 3010 (m), 2945 (w), 2850 (m), 1655 (s), 1600 (s), 1570 (m), 1510 (s), 1410 (s), 1330 (s), 1260 (s), 1240 (s), and 1120 (s) cm^{-1}; NMR ($CDCl_3$): δ 7.78–6.20 (m, 11H), 3.9 (s, 3H), 3.8 (s, 6H), 3.65 (s, 3H), and 3.56 (s, 2H).

Anal.—Calc. for $C_{27}H_{25}N_3O_5$: C, 68.78; H, 5.34; N, 8.91. Found: C, 68.85; H, 5.24; N, 8.88.

3-Azapapaverine (I)—A solution of 4.4 g of VIII and 47 g of potassium hydroxide in 140 ml of ethanol and 140 ml of water was refluxed for 3 hr. The mixture was concentrated *in vacuo* to less than half the volume, and 140 ml of water was added. The mixture was extracted with chloroform, and the dried chloroform extract was evaporated to give I (74% yield), mp 120° (from ethyl acetate–petroleum ether) [lit. (10) mp 120–121°].

Treatment of I in methanol with methyl iodide gave I methiodide, mp 203–208° (from ethanol); IR (KBr): 3010 (m), 2965 (m), 2920 (w), 2850 (m), 1595 (s), 1510 (vs), 1415 (s), 1300 (s), 1220 (s), 1150 (s), and 1030 (s) cm^{-1}; NMR (acetone-d_6): δ 10.35 (s, 1H), 7.98 (s, 1H), 7.9 (s, 1H), 7.05 (s, 1H), 6.83 (broad s, 2H), 4.73 (s, 2H), 4.68 (s, 3H), 4.11 (s, 3H), 4.08 (s, 3H), and 3.71 (s, 6H).

Anal.—Calc. for $C_{20}H_{23}IN_2O_4$: C, 49.80; H, 4.80; N, 5.80. Found: C, 49.77; H, 4.81; N, 5.89.

New Compounds: Derivatives of Fluorene XXXVII: 9-Substituted 3-Nitrofluorenes

HSI-LUNG PAN, CAROL-ANN COLE, and T. LLOYD FLETCHER ˣ

Received April 30, 1979, from the *Department of Oncological Organic Chemistry, The Fred Hutchinson Cancer Research Center, Seattle, WA 98104.* Accepted for publication July 10, 1979.

Abstract □ New 9-substituted 3-nitrofluorenes were prepared as potential intermediates in a study of modified electrophilicity and mutagenicity of the carcinogen 3-*N,O*-diacetylhydroxylaminofluorene. The reported derivatives, together with some already known 9-substituted 3-nitrofluorenes, were too unstable to survive the reducing conditions required to transform the nitro group to the corresponding hydroxylamine.

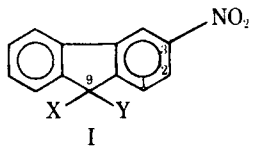
Keyphrases □ Fluorenes—synthesis of 3-nitro-9-substituted derivatives, potential enhancement of 3-*N,O*-diacetylhydroxylaminofluorene carcinogenicity □ 3-*N,O*-Diacetylhydroxylaminofluorene—synthesis of 9-substituted 3-nitrofluorene intermediates, effect on carcinogenicity □ Carcinogens—synthesis of 9-substituted 3-nitrofluorene intermediates for study of 3-*N,O*-diacetylhydroxylaminofluorene mutagenicity

Oncogenic arylamines and amides generally are believed to exert their baneful effects by undergoing enzymatic oxidation to an *N*-hydroxy derivative (a proximate carcinogen) and then by further reaction to form an ester such as the acetate or sulfate (1). Many of these esters are ultimate carcinogens, and they cleave heterolytically, with differing facility, at the nitrogen–oxygen bond. The electron-deficient nitrogen atom is left as an electrophilic center (acetamidonium ion). Such moieties are capable of an *in vivo* attack on various nucleophiles in tissue constituents such as DNA, RNA, and proteins. Some of these reactions appear to be crucial in carcinogenesis.

DISCUSSION

Much of the knowledge supporting the foregoing concepts was developed from studies on 2-fluorenamine and *N*-acetyl-2-fluorenamine, a strong hepatocarcinogen (1). A closely related isomer, *N*-acetyl-3-fluorenamine, is of interest because its *N*-acetoxy derivative, 3-*N,O*-diacetylhydroxylaminofluorene, is a much weaker carcinogen (mammary) and is not hepatocarcinogenic (2). It is possible that one major reason for this difference in biological activity between the 2-substituted and 3-substituted compounds is simply the lower tendency of the acetoxy group of the latter to act as a leaving group and the lower electrophilicity of the resulting acetamidonium ion.

Accordingly, 3-nitrofluorene (I) derivatives were designed with various 9-substituents to increase the leaving group facility of the acetoxy group and, after reduction and acetylation to the *N*-acetoxyamide, to produce a compound with enhanced mutagenicity and carcinogenicity. The presence of an electron donor group in the single-ring compound *O*-acetyl-*N*-benzoylphenylhydroxylamine was shown to enhance heterolytic acyloxy migration to a nucleophilic carbon (3). 2-Methoxy-3-*N,O*-diacetylhydroxylaminofluorene showed slightly enhanced mutagenicity over that of 3-*N,O*-diacetylhydroxylaminofluorene[1]. Since it was assumed that the effect sought was lessened by steric hindrance and since other methoxylated 3-nitrofluorenes were not readily available, the 9-position was investigated.



I

Ia: X = H, Y = Br
Ib: X = H, Y = OCH_3
Ic: X = H, Y = OC_2H_5
Id: X = H, Y = $P^+(C_6H_5)_3Br^-$
Ie: X = H, Y = $SC(NH_2)=N^+H_2Br^-$
If: XY = $=NNHSO_2C_6H_4CH_3$-*p*

Unfortunately, *Ia–If* were either too unstable for the reducing conditions required to transform the nitro group to the corresponding hydroxylamine (ammonium sulfide in ethanol–dimethylformamide) (4) or gave relatively intractable mixtures in the workup. Since these compounds may be of interest in other areas and since known 3,9-disubstituted fluorenes are comparatively few, this report is pertinent. Ways of stabilizing the 9-position are being studied and will be the subject of a future article.

Attempts to make 9-methoxy-3-nitrofluorene (*Ib*) from 3-nitrofluorene-9-ol (5) with methyl iodide, dimethylformamide, and silver oxide (6) or with trimethylsulfoxonium iodide and silver oxide (7) led to recovery of 3-nitrofluorenone as the only recognizable product.

Attempts to make an ylid from *Id* (8) failed, as did efforts to produce 9-mercapto-3-nitrofluorene from *Ie* (9). Attempts to prepare 9-fluoro- or 9-cyano-3-nitrofluorene did not yield the desired products. Previously known 9-chloro-3-nitrofluorene and 9-acetoxy-3-nitrofluorene were included in the nitro reduction attempts.

EXPERIMENTAL[2]

9-Bromo-3-nitrofluorene (Ia)—3-Nitrofluoren-9-ol (7.5 g, 0.033 mole), prepared by sodium borohydride reduction of 3-nitrofluoren-9-one (5), was mixed with 100% acetic acid (120 ml). Aqueous 48% HBr (16 ml) was added to the stirred mixture all at once. The mixture was heated with stirring to boiling, and the solvent was distilled off. The residue was allowed to cool to room temperature and then was dissolved in hot benzene. The benzene solution was treated with activated charcoal[3], filtered, and concentrated to a small volume. Addition of petroleum ether (bp 30–60°) caused the product to crystallize as white needles, 9.5 g (99%), mp 154.5–156°. Recrystallization from benzene–petroleum ether (bp 30–60°) gave 9.1 g, mp 157–158°.

Anal.—Calc. for $C_{13}H_8BrNO_2$: C, 53.82; H, 2.78; Br, 27.54; N, 4.83. Found: C, 53.81; H, 2.81; Br, 27.75; N, 4.86.

9-Methoxy-3-nitrofluorene (Ib)—9-Chloro-3-nitrofluorene (10) (1 g, 0.004 mole) was mixed with powdered silver nitrate (0.7 g, 0.004 mole) and absolute methanol (40 ml). The mixture was refluxed under dry nitrogen for 2 hr and cooled to room temperature. The suspension was filtered into a slurry of crushed ice and water. The crystallized product in the ice slurry then was collected, washed with water, and dried over concentrated sulfuric acid *in vacuo* to give 0.9 g. Chromatography on silica gel and recrystallization from methanol–water gave a pure product, 0.45 g (47%), mp 103.5–104.5°; IR (mineral oil): 1060 cm^{-1}.

Anal.—Calc. for $C_{14}H_{11}NO_3$: C, 69.70; H, 4.60; N, 5.81. Found: C, 69.87; H, 4.37; N, 5:62.

9-Ethoxy-3-nitrofluorene (Ic)—In a manner similar to that for *Ib*, equimolar amounts of 9-chloro-3-nitrofluorene and silver nitrate in refluxing absolute ethanol gave crude *Ic*. Chromatography and recrystallization from ethanol–water gave a 40% yield of pure product, mp 88–89°; IR (mineral oil): 1060 cm^{-1}.

Anal.—Calc. for $C_{15}H_{13}NO_3$: C, 70.58; H, 5.13; N, 5.49. Found: C, 70.52; H, 5.01; N, 5.42.

9-(3-Nitrofluorenyl)triphenylphosphonium Bromide (Id)—To a stirred solution of *Ia* (1.5 g, 0.005 mole) in benzene (50 ml) was added triphenylphosphine (1.3 g, 0.005 mole) in one portion. The mixture was

[1] H.-L. Pan, C.-A. Cole, and T. L. Fletcher, unpublished results.

[2] Melting points were determined on a Fisher-Johns apparatus and are corrected. IR spectra were obtained using a Beckman IR-33 spectrophotometer. Elemental analyses were performed by commercial analytical laboratories.

stirred further in nitrogen for 1 hr and then refluxed for 0.5 hr and stirred to cool. After filtration from the reaction mixture, the gray solid (0.7 g, 25%) was washed twice with benzene and then with ether and dried *in vacuo*, mp 210–214° dec.

Anal.—Calc. for $C_{31}H_{23}BrNO_2P$: C, 67.40; H, 4.20; N, 2.54. Found: C, 67.27; H, 4.18; N, 2.64.

9-(3-Nitrofluorenyl)isothiuronium Bromide (Ie)—Compound Ia (2.9 g, 0.01 mole) and thiourea (0.76 g, 0.01 mole) were ground together thoroughly. To the mixture were added 1-butanol (8 ml) and aqueous 48% HBr (1 ml). The mixture was refluxed with occasional shaking for 0.5 hr and cooled. The crystalline product was collected, washed successively with small amounts of 1-butanol, carbon tetrachloride, chloroform, and ether, and air dried, giving 3.45 g (93%), mp 210–215° dec.

Anal.—Calc. for $C_{14}H_{12}BrN_3O_2S$: C, 45.91; H, 3.30; N, 11.47; S, 8.75. Found: C, 45.77; H, 3.22; N, 11.28; S, 8.76.

3-Nitrofluoren-9-*p*-toluenesulfonylhydrazone (If)—*p*-Toluenesulfonylhydrazine (11) (15.4 g, 0.083 mole) and 3-nitrofluoren-9-one (15 g, 0.067 mole) were suspended in absolute ethanol (150 ml). The suspension was heated with stirring under reflux for 1.5 hr and cooled. The brown crystalline product was collected, washed with 100 ml of boiling ethanol, and dried, giving 20.5 g (78%), mp 194–197° dec.

The product (0.5 g) was purified by repeated washing with boiling ethanol and recrystallization from chloroform–benzene to give lustrous orange crystals, 0.3 g, mp 205–206° dec.; IR (mineral oil): 3230, 1583, 1515, 1365, 1330, and 1150 cm^{-1}.

Anal.—Calc. for $C_{20}H_{15}N_3O_4S$: C, 61.06; H, 3.84; N, 10.68. Found: C, 60.94; H, 3.93; N, 10.24.

Decarboxylation Kinetics of 5-(Tetradecyloxy)-2-furoic Acid

Keyphrases □ Decomposition—solid-state reactions, decarboxylation kinetics, hypolipidemic agent, 5-(tetradecyloxy)-2-furoic acid □ Kinetics—solid-state activation energy, decarboxylation, decomposition, 5-(tetradecyloxy)-2-furoic acid □ 2-Furoic acid, 5-tetradecyloxy—hypolipidemic agent, solid-state decomposition, kinetics

To the Editor:

Single-component solid reactions are of several types: *e.g.*, a solid can form a solid and a gas (type I) or a liquid and a gas (type II). A type I reaction is exemplified by oxygen formation from permanganates, whereas the formation of liquid aniline and gaseous carbon dioxide from decarboxylation of *p*-aminobenzoic acid denotes a type II reaction. This paper reports a type II reaction of a pharmaceutical solid, 5-(tetradecyloxy)-2-furoic acid[1], which is a novel hypolipidemic agent (1).

Decarboxylation kinetics in the solid state have been reported (2–7), and several reported reactions (3, 5, 6) were type II. This paper deals with carboxylic acid, RCOOH, where R = $C_{14}H_{29}O$–(C_4H_2O)– and where (C_4H_2O)– is a furan moiety. The compound decomposes *via* the reaction shown in Scheme I, where RH is liquid in the temperature range studied; hence, the reaction is type II.

$$RCOOH \rightarrow RH + CO_2$$

Scheme I

An apparatus such as the one described by Carstensen and Musa (Fig. 6 of Ref. 3) was constructed for the studies at each temperature. The assembly was completely tight since it was fused by glass blowing and sealed under vacuum (<0.1 μm Hg). The entire assembly was placed in a thermostated mineral oil bath or, for lower temperatures, in a water bath. The pressure evolution was followed as a function of time with a cathetometer[2]. All pertinent volumes were determined by water weight calibration. With knowledge of the volumes, the pressures were converted to moles of gas, thus yielding a decomposition *versus* time curve (Fig. 1). The gas evolution eventually accounted for 100% decomposition.

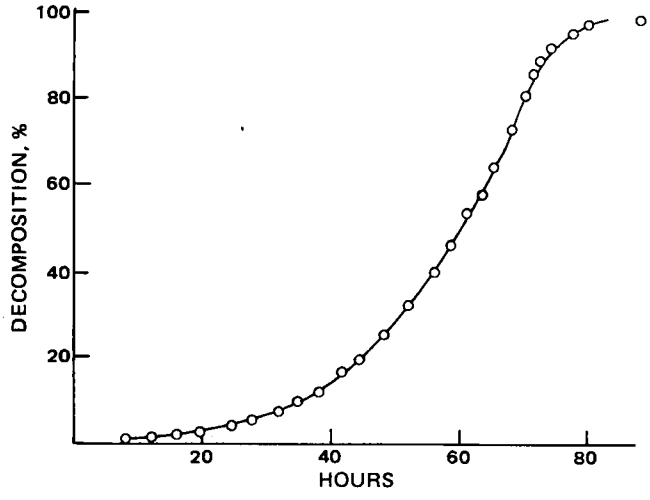

Figure 1—*Percent of parent compound decomposed as a function of time at 90°.*

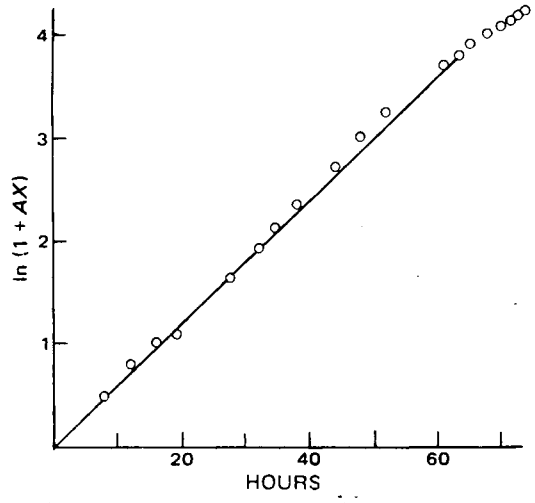

Figure 2—*Data from Fig. 1 treated according to Eq. 3* (A = 70).

The data treatment (3–6) of the curve is as follows. If the amount is n moles and if there are x moles decomposed at time t, then x is present as liquid. If the solubility of parent compound in the liquid is S moles of RCOOH/mole of RH, then the amount of solid present is $n - x - Sx$; the rate equation then is:

$$dx/dt = -k_s(n - X - Sx) - k_lSx \qquad \text{(Eq. 1)}$$

where k_s and k_l are solid and liquid first-order rate constants, respectively. If the mole fraction $X = x/n$ is used in place of moles decomposed, the equation becomes:

$$dX/dt = -k_s(1 - x - SX) - k_lSX \qquad \text{(Eq. 2)}$$

By integration:

$$\ln(1 + AX) = -\alpha t \qquad \text{(Eq. 3)}$$

where $A = \alpha/k_s$ and $\alpha = k_lS - k_sS - k_s$. The value of A is found by iteration, and linearization according to Eq. 3 is shown in Fig. 2. Once all solid has disappeared, the model no longer holds and simply reverts to solution kinetics as pointed out by Carstensen and Musa (3).

The values at four temperatures are shown in Table I. The least-squares fit for the Arrhenius plot (Fig. 3) is:

$$\ln k_s = (-38{,}650/R)(1/T) + 46.25 \qquad \text{(Eq. 4)}$$

with a correlation coefficient of −0.992. The activation

energy for k_s is high compared to usual solution kinetics (although within range) but is lower than that for, for instance, the solid-state decomposition of substituted benzoic (3) or salicylic (6) acids. Solid-state activation energies are extremely high (3–7, 9–13). When they are wholly dictated by physical propagation (type I), the energy of activation supersedes the normal range for solution kinetics by a factor of two to three. Type II reactions usually have intermediate activation energies.

the activity of the molecules whose structures are shown in Table I. Electronic effects, reflected in polarographic half-wave potentials, and steric effects were the most important parameters examined in the correlations. It was concluded that the monoamine oxidase inhibitory activity of the series was due to the hydrazide group, which could form an unstable diazene with the monoamine oxidase flavine coenzyme before rearrangement to bind on the enzyme.

An alternative approach to determining structure–activity relationships and to improving the understanding of the mechanism of action of a series of compounds evolved from the work of Kier and Hall (4, 5) and has been used extensively in structure–activity analyses (6–8). This approach, the molecular connectivity method, has its roots in the topology of the molecules, from which a set of indexes may be calculated. These indexes encode molecular structural information into the regression analysis. The indexes may be used alone or in conjunction with other physical parameters to discover correlations concerning biological or chemical activity within a series of molecules.

Molecular connectivity indexes were calculated for the monoamine oxidase inhibitors of Fulcrand *et al.* (1). Linear regression analysis by computer search for the three variables that gave the best correlation with activity as monoamine oxidase inhibitors yielded:

$$pI_{50} = -5.2 - 29E - 0.82\,{}^2\chi + 1.8\,{}^3\chi_p^v \qquad \text{(Eq. 1)}$$
$$n = 24 \quad r = 0.941 \quad s = 0.201 \quad F = 52$$

where E represents the half-wave potential; the other indexes calculated for the molecules were shown previously (4). This equation clearly indicates that electronic effects contribute to the monoamine oxidase inhibitor activity of the hydrazides, in agreement with Fulcrand *et al.* (1). The ${}^2\chi$ index gives weight to structural features of two-bond lengths in the molecules, whereas the ${}^3\chi_p^v$ index represents three-bond path lengths within the molecules and also emphasizes the importance of the heteroatoms in the substituents.

To gain further insight into structural influences on the interaction between the inhibitors and the active enzyme site, regression analyses were run on a subseries of molecules formed by the deletion of certain substituent groups. In particular, the nitrogen substituent (R_6) was kept constant with the isopropyl group to determine if this substituent was governing the inhibitory potency. This subset of 17 molecules correlates with pI_{50}:

$$pI_{50} = -4.1 + 0.59\,{}^0\chi^2 - 0.94\,{}^2\chi - 23E \qquad \text{(Eq. 2)}$$
$$n = 17 \quad r = 0.951 \quad s = 0.134 \quad F = 41$$

Again, E and ${}^2\chi$ emerge as significant parameters, but ${}^3\chi_p^v$ is replaced by ${}^0\chi^v$. However, this new valency chi index retains an indication of a contribution of heteroatoms in the substituents to activity. If the R_4 and R_5 substituents are limited to hydrogen while R_6 is kept as isopropyl, then only 10 molecules remain and the correlation is:

$$pI_{50} = -34 - 94E - 2.6\,{}^4\chi_{pc}^v \qquad \text{(Eq. 3)}$$
$$n = 10 \quad r = 0.923 \quad s = 0.100 \quad F = 20$$

Electronic effects again contribute to the relationship. The ${}^4\chi_{pc}^v$ index relates well to systems where ring substitutions have been made and indicates that monoamine oxidase inhibitor activity of the hydrazides is related to the ring in some fashion, perhaps indirectly through its effects on the neighboring ether linkage. A further argument can be made for this point if all substituents from R_1 through R_5 are restricted to hydrogen and R_6 is varied. Only four molecules remain in the set, but there is no hint of correlation with electronic or chi parameters to the monoamine oxidase inhibitor activity.

Although the R_6 substituents certainly must affect the hydrazide, these observations would clearly argue against the hydrazide moiety as the sole contributor to biological activity. Therefore, it may be concluded that monoamine oxidase inhibitor activity of these hydrazides depends

largely on the nature of the ring substitution as well as on the half-wave reduction potential of the ring, its substituents, or the ether oxygen.

Calculation of Cutaneous Metabolic Rate Constant from Diffusion Model

Keyphrases □ Rotating disk—analysis, cutaneous metabolism of vidarabine, guinea pig, *in vitro* study □ Skin—metabolism of vidarabine, rotating-disk method, guinea pig, *in vitro* study □ Antiviral agents—vidarabine, cutaneous metabolism, rotating-disk method, guinea pig, *in vitro* study □ Vidarabine—cutaneous metabolism, analysis by rotating-disk method, guinea pig, *in vitro* study

To the Editor:

A method for the determination of the cutaneous metabolic rate constant for vidarabine (I) from a rotating-disk diffusion model was reported recently by Leung and Ando (1). They calculated the enzyme rate constant from the observed flux using:

$$k_m = 1 \Big/ \left[\frac{C_A(h)}{-F_A} - \frac{h}{D_{aqA}}\right](m) \qquad \text{(Eq. 1)}$$

where k_m is the first-order enzyme rate constant, $C_A(h)$ is the initial substrate concentration, F_A is the flux of the substrate in the system, h is the aqueous diffusion layer thickness, D_{aqA} is the aqueous diffusion coefficient, and m is the membrane thickness. Equation 1 was derived from Eq. 25 of a previous publication by Ando *et al.* (2) by taking the limit of $\theta \to 0$ such that $\tanh \theta \to \theta$:

$$\frac{1}{\kappa} = C_1 \tanh \kappa m \qquad \text{(Eq. 2)}$$

where:

$$\kappa = \sqrt{k_m/D_A}$$

$$C_1 = D_A\left[\frac{C_A(h)}{-F_A} - \frac{h}{D_{aqA}}\right]$$

$$\theta = \kappa m$$

and D_A is the diffusion coefficient of the substrate for the cutaneous tissue.

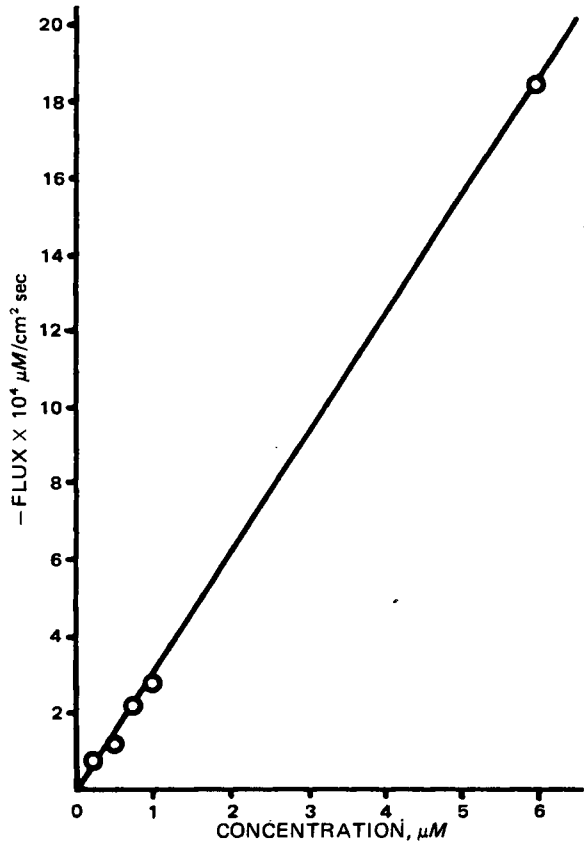

Figure 1—*Plot of flux* versus *substrate concentration. The slope of the linear regression line is 3.11 × 10⁻⁴ cm⁻² sec⁻¹ (r = 0.9997).*

The k_m of the deaminase enzyme in guinea pig epidermis was calculated to be 0.156 sec^{-1}, which contradicts the $\theta \to 0$ assumption by giving θ values of 0.25 and 24.9 for D_A values of 1.0×10^{-5} and 1.0×10^{-9} cm^2/sec, respectively. Obviously, the validity of Eq. 1 is questionable when D_A is smaller than 1.0×10^{-5} cm^2/sec. Strictly speaking, the $\theta \to 0$ assumption should never be valid because it leads to either $D_A \to \infty$, *i.e.*, no diffusional barrier exists, or $m \to 0$, *i.e.*, no membrane exists, since k_m is finite. In neither case will the simultaneous diffusion and metabolism theory

Calculation of Cutaneous Metabolic Rate Constant from Diffusion Model

Keyphrases □ Rotating disk—analysis, cutaneous metabolism of vidarabine, guinea pig, *in vitro* study □ Skin—metabolism of vidarabine, rotating-disk method, guinea pig, *in vitro* study □ Antiviral agents—vidarabine, cutaneous metabolism, rotating-disk method, guinea pig, *in vitro* study □ Vidarabine—cutaneous metabolism, analysis by rotating-disk method, guinea pig, *in vitro* study

To the Editor:

A method for the determination of the cutaneous metabolic rate constant for vidarabine (I) from a rotating-disk diffusion model was reported recently by Leung and Ando (1). They calculated the enzyme rate constant from the observed flux using:

$$k_m = 1 \Big/ \left[\frac{C_A(h)}{-F_A} - \frac{h}{D_{aqA}}\right](m) \qquad \text{(Eq. 1)}$$

where k_m is the first-order enzyme rate constant, $C_A(h)$ is the initial substrate concentration, F_A is the flux of the substrate in the system, h is the aqueous diffusion layer thickness, D_{aqA} is the aqueous diffusion coefficient, and m is the membrane thickness. Equation 1 was derived from Eq. 25 of a previous publication by Ando *et al.* (2) by taking the limit of $\theta \to 0$ such that $\tanh \theta \to \theta$:

$$\frac{1}{\kappa} = C_1 \tanh \kappa m \qquad \text{(Eq. 2)}$$

where:

$$\kappa = \sqrt{k_m/D_A}$$

$$C_1 = D_A\left[\frac{C_A(h)}{-F_A} - \frac{h}{D_{aqA}}\right]$$

$$\theta = \kappa m$$

and D_A is the diffusion coefficient of the substrate for the cutaneous tissue.

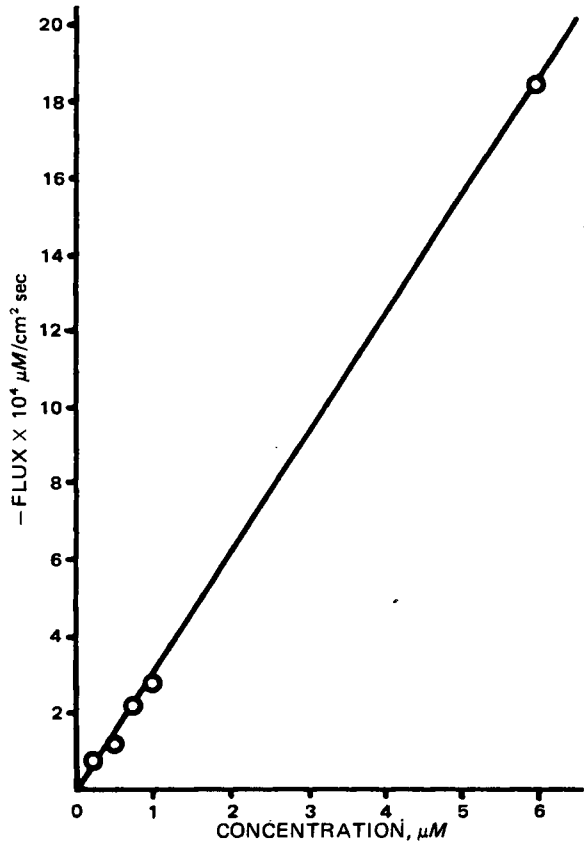

Figure 1—*Plot of flux* versus *substrate concentration. The slope of the linear regression line is 3.11 × 10⁻⁴ cm⁻² sec⁻¹ (r = 0.9997).*

The k_m of the deaminase enzyme in guinea pig epidermis was calculated to be 0.156 sec^{-1}, which contradicts the $\theta \to 0$ assumption by giving θ values of 0.25 and 24.9 for D_A values of 1.0×10^{-5} and 1.0×10^{-9} cm^2/sec, respectively. Obviously, the validity of Eq. 1 is questionable when D_A is smaller than 1.0×10^{-5} cm^2/sec. Strictly speaking, the $\theta \to 0$ assumption should never be valid because it leads to either $D_A \to \infty$, *i.e.*, no diffusional barrier exists, or $m \to 0$, *i.e.*, no membrane exists, since k_m is finite. In neither case will the simultaneous diffusion and metabolism theory

apply. It would be a surprise if the calculation of k_m did not require a D_A value, as in the use of Eq. 1, since the model is based on the simultaneous diffusion and metabolism process.

The correct estimation of k_m can be drawn only from Eq. 2. From Eq. 2, one expects F_A to be a linear function of $C_A(h)$ for a given membrane. Figure 1 shows a plot of F_A *versus* $C_A(h)$. The data were taken from Table III of Leung and Ando's report (1) with a column added to list the mean fluxes in micromolar per square centimeter per second (Table I). With Eq. 2, the reciprocal of the slope of the line in Fig. 1 gives k_m values of 0.207, 1.148, 11.48, and 114.8 sec^{-1} for D_A values of 10^{-6}, 10^{-7}, 10^{-8}, and 10^{-9} cm^2/sec, respectively.

A Rebuttal and Some Insights into Cutaneous Metabolism and Diffusion

Keyphrases □ Rotating disk—analysis, cutaneous metabolism of vidarabine, guinea pig, *in vitro* study □ Skin—metabolism of vidarabine, rotating-disk method, guinea pig, *in vitro* study □ Antiviral agents—vidarabine, cutaneous metabolism, rotating-disk method, guinea pig, *in vitro* study □ Vidarabine—cutaneous metabolism, analysis by rotating-disk method, guinea pig, *in vitro* study

To the Editor:

Dr. Yu's communication (1) refers critically to the report of Leung and Ando (2); the basis for this criticism evidently stems from some of his recent research (3).

It appears from Dr. Yu's communication (1) that this research was based on a model derived by Ando *et al.* (4). One must assume that Dr. Yu used this model to measure k_m for the same enzyme and for the same drug as in the paper of Leung and Ando (2). The methodology is not stated; however, it is a good assumption that he used a diffusion cell similar to that used by Ando *et al.* (4) instead of the rotating disk in our system. It will be assumed that the D_A values for the epidermis that Dr. Yu cites for hairless mice skin were obtained after removal of the stratum corneum.

The basis of Dr. Yu's criticism is our interpretation of Eq. 25 of the model (4). His Eq. 2 is a rearrangement of this equation. In my comments, I shall show that Dr. Yu made two classical errors. First, he applied a model verbatim without due cognizance of the stated limitations of the model. Second, he made inappropriate comparisons.

The basic equation Dr. Yu disagrees with is Eq. 1 in his communication. We arrived at this equation by taking the limit of tanh $\theta \rightarrow 0$. The basic validity of this approximation is evident from the nature of the power series expansion for tanh θ (5):

$$\tanh\theta = \theta - \frac{\theta^3}{3} + \frac{2}{15}\theta^5 - \frac{17}{315}\theta^7 + \ldots + (-1)^{n-1}\frac{2^{2n}(2^{2n}-1)}{(2n)!}B_{2n-1}\theta^{2n-1} + \ldots \quad \text{(Eq. 1)}$$

where $|\theta| < \pi/2$ and B_{2n-1} are Bernoulli's numbers. The approximation of:

$$\tanh\theta \simeq \theta \quad \text{(Eq. 2)}$$

as $\theta \rightarrow 0$ is one of the most common forms of linearization. The basis for this approximation is that as θ becomes small, θ^3 decreases much more rapidly. For this reason, in the simple pendulum (6, 7):

$$F = mg\sin\theta \quad \text{(Eq. 3)}$$

can be replaced by:

$$F = -mg\theta \quad \text{(Eq. 4)}$$

for small θ since (5):

$$\sin\theta = \theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \frac{\theta^7}{7!} + \ldots \quad \text{(Eq. 5)}$$

Using this approximation, $\theta \times \tanh\theta$ of Dr. Yu's Eq. 2 becomes:

$$\theta \times \tanh\theta = \theta^2 - \frac{\theta^4}{3} + \frac{2}{15}\theta^6 - \frac{17}{315}\theta^8 + \ldots \quad \text{(Eq. 6)}$$

In Table I, we show the percent error in using θ^2 instead of $\theta \times \tanh\theta$ computed from the first four terms of the series. Although θ^2 always overestimates $\theta \times \tanh\theta$, values of $\theta > 0.75$ are reasonable considering that the biological variability in determining the skin thickness in unmatched guinea pigs has a standard deviation of 18% for eight or more animals (8). Note also that $\theta = 0.11$ gives a 0.0% error.

The major thrust of Dr. Yu's criticism is that he believes that D_A must be measured to determine the linear metabolic rate constant, k_m. Current methodology, including Dr. Yu's, does not justify this degree of refinement. He is, as I have stated before, applying the model verbatim without due cognizance of the stated limitations of the model. In the model that I derived (4), the skin was envisioned as a two-ply laminate composed of the relatively impermeable stratum corneum and the viable epidermis. The distribution of enzymes in the epidermis was assumed to be homogeneous. A caveat was given: "The epidermis contains most of the catabolic enzymes that render the drug inactive by metabolism, but it is not clear how the distribution of catabolic enzymes might vary with epidermal depth. Presumably, one would expect a gradual increase in metabolic activity as the basal epithelial layer is approached from the stratum corneum."As we shall see, the distribution of the enzyme adenosine deaminase, the most likely catabolic enzyme responsible for the metabolism of 9-β-D-arabinofuranosylhypoxanthine (I), is not homogeneous; apparently, there is not even a gradual

$$F = mg\sin\theta \quad \text{(Eq. 3)}$$

can be replaced by:

$$F = -mg\theta \quad \text{(Eq. 4)}$$

for small θ since (5):

$$\sin\theta = \theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \frac{\theta^7}{7!} + \ldots \quad \text{(Eq. 5)}$$

Using this approximation, $\theta \times \tanh\theta$ of Dr. Yu's Eq. 2 becomes:

$$\theta \times \tanh\theta = \theta^2 - \frac{\theta^4}{3} + \frac{2}{15}\theta^6 - \frac{17}{315}\theta^8 + \ldots \quad \text{(Eq. 6)}$$

In Table I, we show the percent error in using θ^2 instead of $\theta \times \tanh\theta$ computed from the first four terms of the series. Although θ^2 always overestimates $\theta \times \tanh\theta$, values of $\theta > 0.75$ are reasonable considering that the biological variability in determining the skin thickness in unmatched guinea pigs has a standard deviation of 18% for eight or more animals (8). Note also that $\theta = 0.11$ gives a 0.0% error.

The major thrust of Dr. Yu's criticism is that he believes that D_A must be measured to determine the linear metabolic rate constant, k_m. Current methodology, including Dr. Yu's, does not justify this degree of refinement. He is, as I have stated before, applying the model verbatim without due cognizance of the stated limitations of the model. In the model that I derived (4), the skin was envisioned as a two-ply laminate composed of the relatively impermeable stratum corneum and the viable epidermis. The distribution of enzymes in the epidermis was assumed to be homogeneous. A caveat was given: "The epidermis contains most of the catabolic enzymes that render the drug inactive by metabolism, but it is not clear how the distribution of catabolic enzymes might vary with epidermal depth. Presumably, one would expect a gradual increase in metabolic activity as the basal epithelial layer is approached from the stratum corneum."As we shall see, the distribution of the enzyme adenosine deaminase, the most likely catabolic enzyme responsible for the metabolism of 9-β-D-arabinofuranosylhypoxanthine (I), is not homogeneous; apparently, there is not even a gradual

Table I—Approximation of $\theta \times \tanh\theta$ by θ^2 and Percent Error

θ	θ^2	$\theta^4/3$	$2(\theta^6/15)$	$17(\theta^8/315)$	$\theta \times \tanh\theta$	Percent Error

distribution of the enzyme from the stratum corneum to the basal layer.

Adenosine deaminase is a salvage pathway enzyme in the skin (9) and converts the purine nucleoside adenosine to inosine. This intermediate may be degraded or possibly converted by other salvage pathway enzymes in the skin into guanosine (10). These salvage pathways permit reutilization of purines and may be necessary since the continuous cellular renewal occurring in the epidermis requires active synthesis and breakdown of nucleic acids. Indeed, the absence of effective salvage pathways for the reutilization of inosine forms the biochemical basis for some inherited disorders (11, 12). Similar salvage pathways exist for the synthesis of pyrimidines in the skin (13, 14).

With respect to Dr. Yu's comments, there is every reason to believe that there is not a homogeneous or even a gradual distribution of the enzyme adenosine deaminase in the skin; rather, there is every reason to believe that the enzyme resides exclusively in the basal layer of the epidermis. The basal layer of the epidermis can be separated from the upper differentiated spinous and granular layers (15). Studies with these cells have shown that only the basal cells have proliferative capabilities and that only the basal cells can be used to establish successful primary cultures. Irreversible changes in the spinous and granular cells of the upper epidermal layers probably are responsible for the absence of mitosis in these cells. A concomitant change with this loss of mitotic ability in the upper epidermal layer is the complete loss of salvage pathway pyrimidine enzymes (16). Only the basal cells have these enzymes. For this reason, only the basal cells probably contain the purine salvage enzyme, adenosine deaminase.

Studies have shown that the basal cells incorporate thymidine 205-fold faster than do the upper epidermal cells in the spinous and granular layers (16). This observation raises serious questions as to the utility of measuring the epidermal diffusion coefficient, D_A, for the entire epidermis, as Dr. Yu evidently has done. The fact that the diffusion coefficient for a drug would be much slower in the spinous and granular layers is reasonable from considerations of epidermal differentiation. Basal cells would be expected to be the most permeable because they are the only cells undergoing mitosis. Essential nutrients must permeate these cells from the dermal capillaries. For this reason, one would suppose that the diffusion coefficient of the basal cells would be on the order of the diffusion coefficient of the dermis. In this way, nutrient transport would be optimized. The diffusion coefficient of the differentiating spinous and granular layer cells of the upper epidermis should be *intermediate* between that of the basal cells and that of the very impermeable stratum corneum.

Further support for a faster diffusion coefficient for the basal cells is evident from a comparison of the unesterified cholesterol content (with respect to total lipid) of the epidermal cells (17): basal cells, 8.4 ± 0.3; granular cells, 18.0 ± 2.6; and stratum corneum, 23 ± 4.7. Since unesterified cholesterol is found primarily in the plasma membrane of these cells (18) and since levels of unesterified cholesterol and sphingomyelin render membranes more lipophilic, less permeable, and less easily degraded (19), one might justifiably conclude that the basal cells are much more permeable than the spinous and granular cells.

With these facts on hand, let us examine Dr. Yu's criticisms. Dr. Yu assumed D_A values of 1.0×10^{-5} and 1.0×10^{-9} cm^2/sec and, using the value for the membrane thickness that we used, 20.85×10^{-4} cm, and our value of k_m, he computed θ values of 0.25 and 24.9, respectively. He claims that this result contradicts our $\theta \to 0$ assumption. This is not true. Dr. Yu is making an inappropriate comparison. We viewed the epidermal layer as a whole and felt that it would be pedantic to try to define the model any further experimentally because of the inherent limitations of the model. The distribution of the enzyme, adenosine deaminase, is not homogeneous throughout the epidermal layer but rather resides exclusively in the basal cell layer.

Furthermore, a determination of D_A for the entire epidermis, exclusive of the stratum corneum, as Dr. Yu evidently has done experimentally, is equally pedantic and misleading. As we have shown, the diffusion coefficient of the basal cell layer where the enzyme almost exclusively resides is most likely on the order of the diffusion coefficient of the dermis and not the epidermis as a whole. Therefore, determination of D_A for the entire epidermis as Dr. Yu has done is in error, because D_A is defined as the diffusion coefficient in the region of a homogeneous enzyme distribution.

Dr. Yu also questions the validity of our approximation since the $\theta \to 0$ assumption, strictly speaking according to him, implies that either $D_A \to \infty$, *i.e.*, no diffusional barrier exists, or $M \to 0$, *i.e.*, no membrane exists. This conclusion is incorrect; as shown in Table I, the error in our approximation is less than 0.0% for a value of $\theta = 0.11$. It is not necessary for the θ value to equal 0 for this accuracy. Therefore, one would never reach Dr. Yu's conclusion. Moreover, the condition $\theta \to 0$ does not necessarily mean that either $D_A \to \infty$ or $M \to 0$. In real skin, all of these variables change because real skin is not homogeneous. If we chose to make a Yu-type computation of θ, a more appropriate calculation would be based on the evidence I have presented. The thickness of guinea pig epidermis has been determined from the upper border of the stratum granulosum to the lower border of the basal cell layer (8). This measurement included one basal cell layer, one or two spinous cell layers, and one to three granular cell layers or a range of three to six cell layers (20, 21). If we take the number of cell layers to be four and divide the number of cell layers into the thickness of the epidermis, 20.85 μm (*SE* 0.40, $n = 39$), we obtain an approximate thickness for the basal cell layer of 5.21 μm. Since we have argued that this layer is the only one containing the enzyme adenosine deaminase and that the diffusion coefficient in this layer would be very close to the dermis, we can calculate θ using Dr. Yu's value for D_A for the dermis of 1.34×10^{-6} cm^2/sec from:

$$\theta = M\sqrt{k_m/D_A} \qquad \text{(Eq. 7)}$$

This calculation yields a θ value of 0.178. From Table I, we see that a θ of 1.8 will only produce an error of 0.9%. We can even improve on this result. In the previous calculation, we used the reported k_m value of 0.156 cm^{-1}, which was based on a membrane thickness of 20.85 μm. If k_m is recomputed based on a membrane thickness of 5.21 μm, then

θ = 0.039. The approximation that we have made then gives an error of 0.05%.

Elimination of Tablet Air Entrapment Using USP 1 Rotating-Basket Dissolution Apparatus

Keyphrases □ Drug dissolution—USP 1 rotating-basket dissolution testing apparatus, modification to eliminate tablet air entrapment □ Rotating-basket apparatus—dissolution testing, modification to eliminate tablet air entrapment

To the Editor:

Dissolution testing using the USP 1 rotating-basket apparatus (1) is subject to variability due to an artifact of the method. For certain dosage forms, this artifact results in entrapment of the test specimen in an air bubble at the top of the basket assembly. This air bubble is entrapped if the 2-mm vent hole in the top of the basket assembly is blocked by the tablet as the assembly is lowered into the dissolution fluid or if the bubble is positioned elsewhere on the top of the assembly and does not migrate toward the vent.

Since the rim around the detachable part of the basket protrudes below the top of the assembly by about 3 mm, a dead space is available to prevent the bubble from migrating out of the basket at the edge (Fig. 1C). When a tablet is entrapped in this way, the apparent dissolution rate is very low and the dissolution run is invalid.

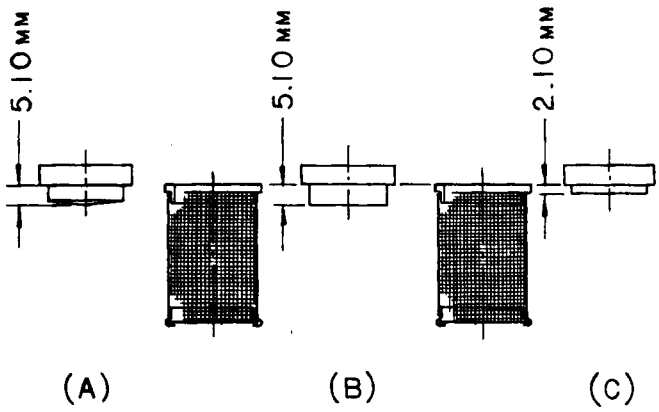

Figure 1—*Conical head design (A), extended head design (B), and conventional head design (C).*

It was noted in our laboratories that this air entrapment occurred occasionally during dissolution tests on the nondisintegrating USP dissolution calibrator salicylic acid 300-mg tablet. A basket top was fabricated to eliminate the dead space around the basket rim (Fig. 1B), and this simple modification essentially eliminated the problem. However, the problem recurred during testing of an experimental film-coated tablet. For the film-coated tablets, the problem was so severe that several runs were needed to obtain valid six-tablet results. Use of the modified design (Fig. 1B) did not totally eliminate the problem.

To circumvent air entrapment with the film-coated tablets, the top of the basket assembly was modified further by fabricating a slight conical shape such that the center protrudes about 1 mm below the edge. This shape imparts enough of a slope to permit an entrapped bubble to escape and to allow the tablet to return to the bottom of the basket (Fig. 1A). The improvement is dramatic. For example, in one series of six-tablet runs, seven of 18 USP salicylic acid calibrators were air entrapped with the conventional head while the conical head design completely eliminated the problem. For the experimental film-coated tablets, 10 of 18 tablets were air entrapped with the conventional head but only one of 18 was air entrapped with the conical head design.

The conical head modification of the basket top design (Fig. 1A) may be of sufficient utility to warrant general use. It is not inconsistent with the present apparatus description (1); however, it may be advantageous to define explicitly the dimensions in the USP to permit its use.

REVIEWS

Handbook of Aerosol Technology, 2nd Ed. By P. A. SANDERS. Van Nostrand Reinhold Co., 135 W. 50th St., New York, NY 10020. 1979. 526 pp. 15 × 25 cm. Price $27.50

This book is an updated version of "Principles of Aerosol Technology," which was published in 1970. It has become available at a time when the aerosol industry has completed the changeover from the predominant use of fluorocarbons as the propellant to other alternative propellant systems. The "Handbook of Aerosol Technology" is the first book that considers the development of aerosols in the light of the restrictions placed on the use of fluorocarbons as propellants.

The text is divided into three major sections: homogeneous systems and their properties; emulsions, foams, and suspensions; and miscellaneous. While Dr. Sanders is the major author, five chapters were written by several of his former associates from the Freon Products Division of Du Pont, and much of the new experimental data presented was developed at Du Pont.

Chapters 3 and 4 will be particularly valuable to the experienced aerosol chemist in that the use of the fluorocarbon and hydrocarbon propellants for aerosol products is discussed in light of the restricted use of fluorocarbon propellants. The chapters include all of the necessary physicochemical data of value to those formulating aerosol products. While the author includes much information about the fluorocarbon propellants, these propellants can be used only for inhalation-type aerosol products that are covered by a New Drug Application and for an extremely limited number of vaginal foams.

The chapters on containers and valves have been updated and supply the reader with the required knowledge of these components. The chapter on filling methods is adequate but should have included greater details about the filling of products utilizing hydrocarbon propellants. Since the hydrocarbon propellants are flammable, they must be handled differently from the fluorocarbons. A thorough discussion of vapor pressure, spray characteristics, solvency, viscosity, and density is presented. Much of the data in these chapters deal with fluorocarbons and are of limited value based on present regulations. However, data are given for other fluorocarbons such as fluorocarbon 22, which may be approved for use in the future.

The chapter on stability is especially well written and includes the various test methods used to determine the stability of aerosols. Since aerosols now utilize a hydrocarbon propellant, the chapter concerned with flammability is essential. Dr. Sanders also indicates the various regulations involved.

Section II deals with emulsions, foams, and suspensions. The basic aspect of emulsion technology is covered, and much research data of tremendous value to the formulating chemist are supplied. Both aqueous and nonaqueous foams and other systems are discussed, which should interest developers of pharmaceutical aerosol dosage foams. This section alone is worth more than the cost of the book. The material presented is of value to anyone interested in surface chemistry and emulsions, not only to those interested in aerosols.

Section III concerns fluorocarbons in the atmosphere and technical programs in the atmospheric sciences. These chapters are of limited value but present the concerns of various organizations as to the use of fluorocarbons as propellants. However, the final chapters dealing with the sampling and analysis of aerosol products and the toxicity of fluorocarbon propellants are related to the development of these products and are of interest.

This book is recommended for use by both the experienced and the newcomer and should be part of the required library of all laboratories.

Alicyclic Chemistry, Vol. 6. (A Specialist Periodical Report). Edited by M. A. McKERVEY *et al.* The Chemical Society. 1978. 357 pp. 13 × 22 cm. Price $56.00. (Available from Special Issues Sales, American Chemical Society, 1155 16th St., N.W., Washington, DC 20036.)

This sixth volume of an annual series is devoted to a summary of the literature of 1976 describing the chemistry of alicyclic compounds. Each chapter is devoted to a different alicyclic system, beginning in Chapter 1 with three-membered rings and progressing through four-, five-, and six-membered ring systems in subsequent chapters. The last two chapters in the book deal with surveys of literature describing the chemistry of medium- and large-ring compounds and bridged carbocyclic compounds.

Each chapter contains summaries of the literature dealing with structural studies of the various alicyclic systems including both molecular orbital and spectroscopic investigations. The literature of 1976 describing conformational aspects of a variety of alicyclic systems also is summarized in the appropriate chapters. In addition, reports of novel syntheses and chemical reactions of the various alicyclic systems are provided.

Each chapter is well illustrated with structural and chemical formulas. The literature citations are provided conveniently on the same page as the text material. While this book does not have a subject index, a useful author index is included.

Volume 6 of "Alicyclic Chemistry" would be a useful addition to the personal library of chemists and spectroscopists interested in having a concise and thorough review of the literature (of 1976) in this area. Natural products chemists should find this publication useful in terms of an annual review of the chemistry of a variety of alicyclic compounds of natural origin. It is refreshing to note that the current volume of this series sells for the same price as Volume 5.

Forensic Toxicology: Controlled Substances and Dangerous Drugs. By W. T. LOWRY and J. C. GARRIOTT. Plenum Press, 227 W. 17th St., New York, NY 10011. 1979. xvii + 445 pp. 15 × 23 cm. Price $37.50.

A retrieval of archival data organized in alphabetical order is the purpose of this new hard-covered book. After eight introductory and explanatory chapters comprising 116 pages, the book covers information in monograph form. For each drug entity, which includes both American and foreign manufacturers, the structural formula is presented along with its synonyms, chemical name, trade name, pharmacological classification, biochemical consideration, toxicity data with blood levels, when available, and even some pharmacognosy data where applicable. In addition, each drug is boldly classified as: (*a*) noncontrolled, (*b*) dangerous, or (*c*) scheduled with the specific schedule.

The title is misleading in that one does not find classical forensic toxicology, but the authors did not intend it to be a forensic toxicology text. Apparently, the authors used the title for lack of a better description. It is a reference book intended for attorneys, toxicologists, or chemists who need legal, chemical, and toxicity information on various drugs.

For pharmacists who know the drug laws, the introductory chapters are of little value. The first seven chapters, covering some 100 pages, include definitions and explanations of pharmaceutical dosage forms (from aerosols to tinctures) and scheduled, legend, excluded, and excepted substances. Chapter 4 deals specifically with the regulation of controlled

Much of the data in these chapters deal with fluorocarbons and are of limited value based on present regulations. However, data are given for other fluorocarbons such as fluorocarbon 22, which may be approved for use in the future.

The chapter on stability is especially well written and includes the various test methods used to determine the stability of aerosols. Since aerosols now utilize a hydrocarbon propellant, the chapter concerned with flammability is essential. Dr. Sanders also indicates the various regulations involved.

Section II deals with emulsions, foams, and suspensions. The basic aspect of emulsion technology is covered, and much research data of tremendous value to the formulating chemist are supplied. Both aqueous and nonaqueous foams and other systems are discussed, which should interest developers of pharmaceutical aerosol dosage foams. This section alone is worth more than the cost of the book. The material presented is of value to anyone interested in surface chemistry and emulsions, not only to those interested in aerosols.

Section III concerns fluorocarbons in the atmosphere and technical programs in the atmospheric sciences. These chapters are of limited value but present the concerns of various organizations as to the use of fluorocarbons as propellants. However, the final chapters dealing with the sampling and analysis of aerosol products and the toxicity of fluorocarbon propellants are related to the development of these products and are of interest.

This book is recommended for use by both the experienced and the newcomer and should be part of the required library of all laboratories.

Alicyclic Chemistry, Vol. 6. (A Specialist Periodical Report). Edited by M. A. McKERVEY *et al.* The Chemical Society. 1978. 357 pp. 13 × 22 cm. Price $56.00. (Available from Special Issues Sales, American Chemical Society, 1155 16th St., N.W., Washington, DC 20036.)

This sixth volume of an annual series is devoted to a summary of the literature of 1976 describing the chemistry of alicyclic compounds. Each chapter is devoted to a different alicyclic system, beginning in Chapter 1 with three-membered rings and progressing through four-, five-, and six-membered ring systems in subsequent chapters. The last two chapters in the book deal with surveys of literature describing the chemistry of medium- and large-ring compounds and bridged carbocyclic compounds.

Each chapter contains summaries of the literature dealing with structural studies of the various alicyclic systems including both molecular orbital and spectroscopic investigations. The literature of 1976 describing conformational aspects of a variety of alicyclic systems also is summarized in the appropriate chapters. In addition, reports of novel syntheses and chemical reactions of the various alicyclic systems are provided.

Each chapter is well illustrated with structural and chemical formulas. The literature citations are provided conveniently on the same page as the text material. While this book does not have a subject index, a useful author index is included.

Volume 6 of "Alicyclic Chemistry" would be a useful addition to the personal library of chemists and spectroscopists interested in having a concise and thorough review of the literature (of 1976) in this area. Natural products chemists should find this publication useful in terms of an annual review of the chemistry of a variety of alicyclic compounds of natural origin. It is refreshing to note that the current volume of this series sells for the same price as Volume 5.

Forensic Toxicology: Controlled Substances and Dangerous Drugs. By W. T. LOWRY and J. C. GARRIOTT. Plenum Press, 227 W. 17th St., New York, NY 10011. 1979. xvii + 445 pp. 15 × 23 cm. Price $37.50.

A retrieval of archival data organized in alphabetical order is the purpose of this new hard-covered book. After eight introductory and explanatory chapters comprising 116 pages, the book covers information in monograph form. For each drug entity, which includes both American and foreign manufacturers, the structural formula is presented along with its synonyms, chemical name, trade name, pharmacological classification, biochemical consideration, toxicity data with blood levels, when available, and even some pharmacognosy data where applicable. In addition, each drug is boldly classified as: (*a*) noncontrolled, (*b*) dangerous, or (*c*) scheduled with the specific schedule.

The title is misleading in that one does not find classical forensic toxicology, but the authors did not intend it to be a forensic toxicology text. Apparently, the authors used the title for lack of a better description. It is a reference book intended for attorneys, toxicologists, or chemists who need legal, chemical, and toxicity information on various drugs.

For pharmacists who know the drug laws, the introductory chapters are of little value. The first seven chapters, covering some 100 pages, include definitions and explanations of pharmaceutical dosage forms (from aerosols to tinctures) and scheduled, legend, excluded, and excepted substances. Chapter 4 deals specifically with the regulation of controlled

REVIEWS

Handbook of Aerosol Technology, 2nd Ed. By P. A. SANDERS. Van Nostrand Reinhold Co., 135 W. 50th St., New York, NY 10020. 1979. 526 pp. 15 × 25 cm. Price $27.50

This book is an updated version of "Principles of Aerosol Technology," which was published in 1970. It has become available at a time when the aerosol industry has completed the changeover from the predominant use of fluorocarbons as the propellant to other alternative propellant systems. The "Handbook of Aerosol Technology" is the first book that considers the development of aerosols in the light of the restrictions placed on the use of fluorocarbons as propellants.

The text is divided into three major sections: homogeneous systems and their properties; emulsions, foams, and suspensions; and miscellaneous. While Dr. Sanders is the major author, five chapters were written by several of his former associates from the Freon Products Division of Du Pont, and much of the new experimental data presented was developed at Du Pont.

Chapters 3 and 4 will be particularly valuable to the experienced aerosol chemist in that the use of the fluorocarbon and hydrocarbon propellants for aerosol products is discussed in light of the restricted use of fluorocarbon propellants. The chapters include all of the necessary physicochemical data of value to those formulating aerosol products. While the author includes much information about the fluorocarbon propellants, these propellants can be used only for inhalation-type aerosol products that are covered by a New Drug Application and for an extremely limited number of vaginal foams.

The chapters on containers and valves have been updated and supply the reader with the required knowledge of these components. The chapter on filling methods is adequate but should have included greater details about the filling of products utilizing hydrocarbon propellants. Since the hydrocarbon propellants are flammable, they must be handled differently from the fluorocarbons. A thorough discussion of vapor pressure, spray characteristics, solvency, viscosity, and density is presented. Much of the data in these chapters deal with fluorocarbons and are of limited value based on present regulations. However, data are given for other fluorocarbons such as fluorocarbon 22, which may be approved for use in the future.

The chapter on stability is especially well written and includes the various test methods used to determine the stability of aerosols. Since aerosols now utilize a hydrocarbon propellant, the chapter concerned with flammability is essential. Dr. Sanders also indicates the various regulations involved.

Section II deals with emulsions, foams, and suspensions. The basic aspect of emulsion technology is covered, and much research data of tremendous value to the formulating chemist are supplied. Both aqueous and nonaqueous foams and other systems are discussed, which should interest developers of pharmaceutical aerosol dosage foams. This section alone is worth more than the cost of the book. The material presented is of value to anyone interested in surface chemistry and emulsions, not only to those interested in aerosols.

Section III concerns fluorocarbons in the atmosphere and technical programs in the atmospheric sciences. These chapters are of limited value but present the concerns of various organizations as to the use of fluorocarbons as propellants. However, the final chapters dealing with the sampling and analysis of aerosol products and the toxicity of fluorocarbon propellants are related to the development of these products and are of interest.

Forensic Toxicology: Controlled Substances and Dangerous Drugs. By W. T. LOWRY and J. C. GARRIOTT. Plenum Press, 227 W. 17th St., New York, NY 10011. 1979. xvii + 445 pp. 15 × 23 cm. Price $37.50.

A retrieval of archival data organized in alphabetical order is the purpose of this new hard-covered book. After eight introductory and explanatory chapters comprising 116 pages, the book covers information in monograph form. For each drug entity, which includes both American and foreign manufacturers, the structural formula is presented along with its synonyms, chemical name, trade name, pharmacological classification, biochemical consideration, toxicity data with blood levels, when available, and even some pharmacognosy data where applicable. In addition, each drug is boldly classified as: (*a*) noncontrolled, (*b*) dangerous, or (*c*) scheduled with the specific schedule.

The title is misleading in that one does not find classical forensic toxicology, but the authors did not intend it to be a forensic toxicology text. Apparently, the authors used the title for lack of a better description. It is a reference book intended for attorneys, toxicologists, or chemists who need legal, chemical, and toxicity information on various drugs.

For pharmacists who know the drug laws, the introductory chapters are of little value. The first seven chapters, covering some 100 pages, include definitions and explanations of pharmaceutical dosage forms (from aerosols to tinctures) and scheduled, legend, excluded, and excepted substances. Chapter 4 deals specifically with the regulation of controlled

substances and includes a copy of the Drug Enforcement Administration form for registration under the Controlled Substances Act of 1970. It also includes general information known to all practicing pharmacists concerning security requirements, order forms, *etc.*

Chapter 6 gives the requirements for exception of a preparation from all or part of the Act. This information is followed by 21 pages of alphabetically listed drug preparations indicating which are excepted. For some preparations, an indication is given that none is excepted. Chapter 5 (3 pages long) lists preparations that are excluded from any schedule and that can be sold over the counter, such as Vicks Inhaler which contains L-methamphetamine (L-desoxyephedrine). Some of these items are excluded from the Act only in a given preparation; L-methamphetamine is a Schedule II substance but is excluded only in a preparation like Vicks Inhaler.

Chapter 8 deals with the analytical techniques used for drug identification and serves only to familiarize the reader with the names of the techniques and with what might be accomplished by a chemist using the instrument or technique.

Chapter 9 is the bulk of the book and deviates from the subtitle because it includes controlled and noncontrolled substances. The implication from the title of Chapter 9 is that commonly abused substances are included. However, many listings do not constitute abused drugs; misused but not abused! For example, the noncontrolled substances acetaminophen, acetanilide, lactose, and salicylate are included. The information supplied is useful from a clinical or forensic view point.

During the 1st week that I had the book, I referred to it twice and both times I found the data and/or information I needed on a specific drug. The book is useful in my work; the same may not be true for the community or hospital pharmacist.

The Family Prescription & Medication Guide. By ALBERT M. PAWLINA. Prentice-Hall, Englewood Cliffs, NJ 07632. 1979. 367 pp. 15 × 21 cm. Price $13.95 hard cover, $6.95 soft cover.

This nontechnical book is intended to guide the individual patient on appropriate drug use. The first section lists alphabetically about 250 commonly used drugs and summarizes their brand names, medical use, and possible side effects. An alphabetical arrangement of both generic and brand names, identifying the manufacturers and components of each product, follows. Common medical and pharmaceutical terms are defined in the third section. The Appendix tables list some common and serious food–drug and drug–drug interactions.

Applied Therapeutics for Clinical Pharmacists. 2nd Ed. Edited by MARY ANNE KODA-KIMBLE, LLOYD Y. YOUNG, and S. KATCHER. Applied Therapeutics Inc., P.O. Box 31-747, San Francisco, CA 94131. 1978. 944 pp. 20 × 26 cm. Price $31.50.

Molecular Structure by Diffraction Methods. Vol. 6. By L. E. SUTTON *et al.* The Chemical Society. 1979. 338 pp. 13 × 22 cm. Price $72.50. (Available from the American Chemical Society, 1155 16th St., N.W., Washington, DC 20036.)

Piroxicam. No. 1. International Congress and Symposium Series. Edited by W. M. O'BRIEN and E. H. WISEMAN. The Royal Society of Medicine. 1978. 111 pp. 16 × 24 cm. Price $10.25. (Available from Grune and Stratton, 111 5th Ave., New York, NY 10003.)

Pregnancy Metabolism, Diabetes and the Fetus. Ciba Foundation Symposium 63 (new series). Elsevier/North-Holland, 52 Vanderbilt Ave., New York, NY 10017. 1979. 326 pp. 16 × 24 cm. Price $39.50.

Principles of Organic Stereochemistry. Vol. 6. Studies in Organic Chemistry Series. By BERNARD TESTA. Dekker, 270 Madison Ave., New York, NY 10016. 1979. 248 pp. 15 × 23 cm. Price $14.50.

The Alkaloids. Chemistry and Physiology. Vol. XVII. Edited by R. H. F. MANSKE and R. G. A. RODRIGO. Academic, 111 5th Ave., New York, NY 10003. 1979. 611 pp. 15 × 23 cm. Price $55.00.

Progress in Pharmacology. Vol. 2, No. 2. Action of Cardiac Glycosides on the Excitation–Contraction Coupling in Heart Muscle. By HEINZ LULLMANN and THIES PETERS. *Drug Absorption from Abnormal Gastrointestinal Tract.* By M. J. MATTILA and V. M. K. VENHO. Gustav Fischer Verlag, Postfach 72 0143, D 7000 Stuttgart 70, West Germany. 1979. 86 pp. 16 × 24 cm. Price DM 41.50 (for the series).

Advances in Cancer Chemotherapy. Vol. 1. Edited by ANDRE ROSOWSKY. Dekker, 270 Madison Ave., New York, NY 10016. 1979. 297 pp. 15 × 23 cm. Price $29.75.

Disposition of Toxic Drugs and Chemicals in Man. Vol. 2. Peripherally-Acting Drugs and Common Toxic Chemicals. By RANDALL C. BASELT. Biomedical, P.O. Box 495, Davis, CA 95676. 1978. 281 pp. 15 × 23 cm. Price $22.50.

Carbohydrate Chemistry. Vol. 10. A Specialist Periodical Report. By J. S. BRIMACOMBE *et al.* The Chemical Society. 1978. 524 pp. 13 × 22 cm. Price $64.00. (Available from the American Chemical Society, 1155 16th St., N.W., Washington, DC 20036.)

Carbon-13 NMR Shift Assignments of Amines and Alkaloids. By MAURICE SHAMMA and DAVID M. HINDENLANG. Plenum, 227 W. 17th St., New York, NY 10011. 1979. 303 pp. 15 × 23 cm. Price $29.50.

Central Nervous System Pharmacology: A Self-Instruction Text, 2nd Ed. By DONALD E. McMILLAN. Little, Brown, 34 Beacon St., Boston, MA 02106. 1979. 166 pp. 21 × 26 cm. Price $12.50.

A Color Atlas Of The Rat. Dissection Guide. By RONALD J. OLDS and JOAN R. OLDS. Wiley, 605 Third Ave., New York, NY 10016. 1979. 112 pp. 13 × 19 cm.

Handbook on Drug Abuse. Edited by ROBERT I. DUPONT, AVRAM GOLDSTEIN, and JOHN O'DONNELL. National Institute on Drug Abuse, U.S. Department of Health, Education, and Welfare and Office of Drug Abuse Policy. 1979. 452 pp. 19 × 26 cm.

IARC Monographs on the Evaluation of the Carcinogenic Risk of Chemicals to Humans. Vol. 19. Some Monomers, Plastics and Synthetic Elastomers, and Acrolein. World Health Organization, 1211 Geneva 27, Switzerland. 1979. 513 pp. 17 × 24 cm. Price Sw. fr. 60.

Issues in Pharmaceutical Economics. Edited by ROBERT I. CHIEN. Lexington Books, D.C. Heath, Lexington, MA 02173. 1979. 246 pp. 16 × 23 cm. Price $17.95.

The Alkaloids. Vol. 8. By M. F. GRUNDON *et al.* The Chemical Society. 1978. 276 pp. 13 × 22 cm. Price $52.75. (Available from the American Chemical Society, 1155 16th St., N.W., Washington, DC 20036.)

Biosynthetic Products for Cancer Chemotherapy. Vol. 3. By GEORGE R. PETTIT and RICHARD H. ODE. Plenum, 227 W. 17th St., New York, NY 10011. 1979. 15 × 23 cm. 197 pp. Price $32.50.

Quantitative Structure Activity Relationships of Analgesics, Narcotic Antagonists, and Hallucinogens. National Institute on Drug Abuse. U.S. Government Printing Office, Washington, DC 20402 (Stock No. 017-024-00786-2). 487 pp. 14 × 23 cm.

substances and includes a copy of the Drug Enforcement Administration form for registration under the Controlled Substances Act of 1970. It also includes general information known to all practicing pharmacists concerning security requirements, order forms, *etc.*

Chapter 6 gives the requirements for exception of a preparation from all or part of the Act. This information is followed by 21 pages of alphabetically listed drug preparations indicating which are excepted. For some preparations, an indication is given that none is excepted. Chapter 5 (3 pages long) lists preparations that are excluded from any schedule and that can be sold over the counter, such as Vicks Inhaler which contains L-methamphetamine (L-desoxyephedrine). Some of these items are excluded from the Act only in a given preparation; L-methamphetamine is a Schedule II substance but is excluded only in a preparation like Vicks Inhaler.

Chapter 8 deals with the analytical techniques used for drug identification and serves only to familiarize the reader with the names of the techniques and with what might be accomplished by a chemist using the instrument or technique.

Chapter 9 is the bulk of the book and deviates from the subtitle because it includes controlled and noncontrolled substances. The implication from the title of Chapter 9 is that commonly abused substances are included. However, many listings do not constitute abused drugs; misused but not abused! For example, the noncontrolled substances acetaminophen, acetanilide, lactose, and salicylate are included. The information supplied is useful from a clinical or forensic view point.

During the 1st week that I had the book, I referred to it twice and both times I found the data and/or information I needed on a specific drug. The book is useful in my work; the same may not be true for the community or hospital pharmacist.

Encyclopaedia of Antibiotics, 2nd Ed. By JOHN S. GLASBY. Wiley, One Wiley Drive, Somerset, NJ 08873. 1979. 467 pp. 18 × 26 cm. Price $60.00.

The second edition has been expanded to include over 400 new antibiotics which have been discovered since publication of the first edition. As in the previous edition, formulas, structures, melting points, origin, methods of purification and preparation, and patent references are given for the antibiotics. Toxicity and activity are indicated for many of the antibiotics. This book would be a valuable reference source for scientists and students working with antibiotics.

CARCINOGENICITY TESTING—A NATIONAL CATASTROPHE

"What you have described to us is a national catastrophe!"

That strong language was used by a prominent clinical researcher who had just heard a presentation by a National Cancer Institute (NCI) staff scientist at a meeting of the National Council on Drugs (NCD). In an audio-visual presentation, the NCI scientist had provided a rather complete description of the NCI's Carcinogenicity Testing Program, and the apparent unanimous reaction of the NCD members present closely corresponded to that articulated by the clinical scientist quoted above.

In late spring 1979, the NCI released to the public press the test results on several well-known and long-used drugs which had been studied under that Institute's Carcinogenicity Testing Program. Included among those drugs was reserpine, and it was assigned a positive classification as a carcinogenic substance. Because of the current wide use of reserpine in medical treatment, classification of this drug as a carcinogenic agent caused considerable anxiety, apprehension, concern, and confusion among health care practitioners, as well as the general public including many patients under treatment with the drug.

Subsequent reports regarding the potential risks involving reserpine seemed only to confuse the matter further rather than to clarify it. Hence, the NCD invited the NCI to provide the group with a first-hand, detailed explanation of the entire testing program.

Beyond hearing that the project costs approximately 65 million dollars a year to conduct the screening program to detect possible carcinogenic effects of chemicals (including drugs), the NCD was also informed regarding the test protocol in use. The latter essentially involves the administration of maximally tolerated doses of the test chemical to two species of rodents for one generation.

Beyond the general view that such testing is virtually meaningless by itself, the NCD was shocked to learn, among other things, that the NCI has not:

(*a*) done any studies to correlate their animal results to humans;

(*b*) tested any known human carcinogens in animals to ascertain whether common relationships exist;

(*c*) attempted to establish whether there is any dose relationship for known carcinogens, much less what such a relationship might be;

(*d*) ascertained "background effects" for the test animals in their test environment—that is, the frequency of tumors in control animals due to heredity, feed, drinking water, or other factors; and

(*e*) conducted any replicate experiments whatsoever to confirm their initial findings—hence, even such questionable "positives" as reserpine have never been repeated.

During the ensuing discussion, the NCI official was subjected to sharp questioning regarding the basic scientific faults and omissions in the program. And incredibly, he clarified that he and his associates equally recognized those deficiencies, but they were constrained by legislative factors to follow their present course.

Incidentally, more than half of the substances tested in the NCI's bioassay program provided some evidence of carcinogenicity. Projections are that this is probably an accurate forecast of the eventual outcome of the total program. Imagine the devastating consequences on life as we know it if half the chemicals to which we are presently exposed are summarily banned from further use. The very thought is mind-boggling!

Yet such disproportionate findings of carcinogenicity potential should not be too surprising considering the massive doses used, the lifetime of exposure, and the other radical conditions comprising the "test protocol" employed.

But as explained by the NCI official, the agency is primarily restricted by the unrealistic provisions in the legislation Congress enacted. Given such a mandate, the Institute has little choice. Moreover, the enormous cost to conduct such tests on even a single chemical means that only a relatively few substances can be tested, thereby making simple retesting an "unaffordable luxury."

Clearly, Congressional review, restudy, reconsideration, and amendment of this law are in order to rectify what, in this writer's view, was accurately labeled "a national catastrophe."

And incredibly, he clarified that he and his associates equally recognized those deficiencies, but they were constrained by legislative factors to follow their present course.

Incidentally, more than half of the substances tested in the NCI's bioassay program provided some evidence of carcinogenicity. Projections are that this is probably an accurate forecast of the eventual outcome of the total program. Imagine the devastating consequences on life as we know it if half the chemicals to which we are presently exposed are summarily banned from further use. The very thought is mind-boggling!

Yet such disproportionate findings of carcinogenicity potential should not be too surprising considering the massive doses used, the lifetime of exposure, and the other radical conditions comprising the "test protocol" employed.

But as explained by the NCI official, the agency is primarily restricted by the unrealistic provisions in the legislation Congress enacted. Given such a mandate, the Institute has little choice. Moreover, the enormous cost to conduct such tests on even a single chemical means that only a relatively few substances can be tested, thereby making simple retesting an "unaffordable luxury."

Clearly, Congressional review, restudy, reconsideration, and amendment of this law are in order to rectify what, in this writer's view, was accurately labeled "a national catastrophe."

Effect of Self-Association of Phenol on Its Transport across Polyethylene Film

T. J. MIKKELSON ˣ, S. WATANABE *, J. H. RYTTING, and T. HIGUCHI

Received July 30, 1979, from the *Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66044.* Accepted for publication September 10, 1979. *Present address: Eisai Co. Ltd., Tokyo, Japan.

Abstract □ Phenol diffusion across a high density polyethylene film from isooctane, in which phenol self-associates, demonstrated nonideal behavior. The steady-state flux of phenol across the film was not directly proportional to its concentration in the donor phase. At higher donor phase concentrations, negative steady-state flux deviations were observed. These negative deviations were due to phenol self-association in the donor phase and the resulting decreases in thermodynamic activity. By using a monomer–pentamer model for phenol self-association in isooctane, the steady-state flux was shown to be directly proportional to the phenol monomer concentration in the donor phase. Although steady-state flux concentration deviations were observed, the diffusion time lag was independent of the permeant concentration and reflected the intrinsic diffusivity of the film to phenol.

Keyphrases □ Phenol—effect of self-association on transport across polyethylene film □ Self-association—phenol, effect on transport across polyethylene film □ Mass transfer—phenol self-association, effect on membrane transport □ Diffusion—phenol self-association, effect on membrane transport □ Flux, steady state—effect of phenol self-association on transport across polyethylene film

Mass transfer processes in drug delivery include those that are involved in drug release from a dosage unit and those that are involved in drug transport across biological membranes. The rate and extent of these processes depend on the film or absorbing membrane, the physicochemical characteristics of the permeating drug, and the properties of the drug delivery unit. The dependency of these mass transfer processes on physicochemical drug properties and membrane characteristics has been extensively studied because it is an integral part of drug research and development. Determinants such as molecular size, crystalline form, solubility, pH and ionization, charge, complexation, and partitioning have been identified and continue to be characterized relative to their significance.

There is continuing interest in these laboratories in the effects of specific molecular interactions in solution. For example, many molecules with polar functional groups undergo pronounced self-association in nonpolar solvent systems, resulting in changes in thermodynamic activity (1–3).

The properties of alcohols in hydrocarbon solvents have been studied extensively. Self-association is a dominant factor in the lower than expected vapor pressures of alcohols (1–3). The anomalous solubility behavior of phenol in hydrocarbon solvents is a function of self-association (3). Furthermore, dissolution characteristics of an alcohol deviating from a modified Noyes–Whitney prediction (4) can be rationalized on the basis of self-association.

This report describes specifically the effects of phenol self-association in isooctane on phenol transport across a high density polyethylene film. The effect of self-association on transport was described previously only in general and descriptive terms (5–7). This report describes quantitatively the changes in transport properties resulting from the self-association of a permeating species in the donor phase of a diffusion assembly in terms of an exact molecular association model.

THEORETICAL

Steady-State Permeation—Fick's first law was formulated as:

$$J = -D\left(\frac{dC}{dx}\right) \qquad \text{(Eq. 1)}$$

where J is the flux of material across a unit area of film, D is the diffusion coefficient, and (dC/dx) is the concentration differential across the film. The negative sign implies that the material flow is from an element of higher concentration to an element of lower concentration. For an isotropic or homogeneous film of a given cross-sectional area and a constant thickness, Fick's law can be expressed as:

$$J = PA\,\Delta C \qquad \text{(Eq. 2)}$$

where J is the net flux of material or the appearance of permeant on the receptor side, P is the permeability coefficient, A is the cross-sectional area of the film or membrane, and ΔC is the concentration difference across the total film thickness.

0022-3549/80/0200-0133$01.00/0
© 1980 American Pharmaceutical Association

Under sink conditions, ΔC is replaced with the concentration of permeant in the donor phase, C_d, and the permeability coefficient or permeability, P, becomes:

$$P = \frac{D_m K}{h_m} \qquad \text{(Eq. 3)}$$

where D_m is the permeant diffusivity or diffusion coefficient in the membrane, K is the membrane–donor phase partition coefficient, and h_m is the membrane thickness. This development assumes a partition–diffusion mass transfer mechanism, in contrast to a pore permeation mechanism. A partition–diffusion mechanism has been demonstrated for polyethylene films and the transport of numerous solute materials of general and pharmaceutical interest (8–10).

From measurements of the permeant concentration appearing in the receptor phase as a function of time, the parameters descriptive of the transfer process can be obtained readily, in part from the steady-state permeation. By utilizing the expression:

$$J = \frac{dQ}{dt} = V\left(\frac{dC}{dt}\right) \qquad \text{(Eq. 4)}$$

(where Q is the amount of permeant reaching the receptor site, V is the volume of the receptor phase or compartment, and C is the permeant concentration reaching the receptor side), and combining it with the expression $\Delta C = C_d$ and with Eq. 2, the result is:

$$\frac{V}{A}\left(\frac{dC}{dt}\right) = PC_d \qquad \text{(Eq. 5)}$$

In a steady-state experiment, where C_d remains essentially unchanged (*i.e.*, where the amount of permeant transported or the concentration of permeant achieved in the receptor phase is small compared to C_d), a plot of C *versus* t following an initial time lag will be linear. From the slope, dC/dt, of the linear portion of the plot, the steady-state flux, SSF, is obtained by:

$$SSF = \frac{V}{A}\left(\frac{dC}{dt}\right) \qquad \text{(Eq. 6)}$$

which, in turn, results in:

$$SSF = PC_d \qquad \text{(Eq. 7)}$$

allowing for the determination of permeability by:

$$P = \frac{SSF}{C_d} \qquad \text{(Eq. 8)}$$

Equations 6 and 8 provide a means of computing the steady-state flux and permeability from observed data obtained in a steady-state experiment. Further system elucidation is achieved by defining and solving the permeability coefficient, P, which is a function of the diffusion coefficient of the permeant in the membrane, D_m, the thickness of the membrane, h_m, and the membrane–donor phase partition coefficient, K. The contribution of the partition coefficient to permeability results from use of the donor phase concentration as a reference to the actual concentration of the permeant in the membrane at the donor phase–membrane interface. The relationship is presented in Eq. 3. Of these three parameters (D_m, h_m, and K), only the h_m term, which is experimentally defined, is known. To obtain values of D_m and K, one of them must be independently determined; evaluation of the nonsteady-state data from the same experiments permits the calculation of D_m. Therefore, to elucidate the mass transfer process taking place, an analysis of nonsteady-state permeation is used.

Nonsteady-State Permeation—The necessary equation for determining the diffusivity, D_m, from the nonsteady-state permeation characteristics across an isotropic or homogeneous film was reported (11) and is:

$$t_L = \frac{h_m^2}{6D_m} \qquad \text{(Eq. 9)}$$

where t_L is the diffusion time lag. From Eq. 9, it can be seen that, for a homogeneous film, the time lag is a function only of the membrane thickness and the membrane diffusivity. The time lag is obtained by extrapolation of the linear steady-state data back to its time axis intercept. As a result, for a membrane of known thickness, the membrane diffusivity can be computed. With this information, the membrane–donor phase partition coefficient can be computed using Eq. 3.

Self-Association—The mass transfer characteristics of a self-associating permeant may demonstrate nonideal behavior when interpreted directly through Fick's laws. The nonideal behavior arises from a dependency on the effective concentration (thermodynamic activity or chemical potential) of the permeant, rather than the total concentration, and/or a dependency on the effective diffusion coefficient, which changes as a function of the size of the associated species and the extent of its formation. The contribution of self-association to a particular mass transfer process depends on the experimental conditions. Self-association can potentially occur in the phases contacting a membrane, such as the donor phase, and/or within the membrane itself, depending on donor phase and membrane characteristics.

For a nonassociating permeant diffusing through a homogeneous membrane in the steady state, Eq. 1 is directly applicable. For this simple system, the activity or concentration gradient across the film is linear.

For a system of a self-associating solute diffusing through a homogeneous membrane, Eq. 1 is not directly applicable. If it is assumed that this self-association is an equilibrium between a monomer and a single polymer species, there exists a gradient of each species, monomer and polymer, across the film, and the reaction between them will be at equilibrium within all elements within the film. As a result, the gradients of the two species across the film are nonlinear.

Approaches to quantitating the system can be empirical or modelistic. In the empirical approach, the total flux of permeant (monomer and polymer) can be described in terms of an observed or apparent diffusion coefficient, which is concentration dependent. Such an approach was suggested by Barrer (12); the equation for the diffusivity relates diffusivity to concentration:

$$D = BRT\frac{d\ln a}{d\ln c} \qquad \text{(Eq. 10)}$$

where R and T have their usual meaning, a is activity, and B is a coefficient reflecting the mobility of the permeant. Barrer (12) pointed out that both B and $(d\ln a/d\ln c)$ can depend on permeant concentration. Such an approach was taken by Longsworth (5), who interpreted the mass transfer of self-associating acids and alcohols in carbon tetrachloride in terms of an apparent diffusion coefficient, which decreases as a function of increasing total permeant concentration.

Under experimental conditions where permeant self-association occurs in the donor phase but only the monomeric species diffuses across the film, the observed nonideal characteristics of transport are explained in terms of effective concentration or chemical potential of permeant in the donor phase. This type of system is being reported here. The experimental results indicate that only the phenol monomer is transported across the polyethylene film and that the intrinsic membrane permeability remains unchanged. However, over the donor concentrations studied, phenol self-association in the isooctane donor phase, which decreases the effective donor phase concentration or activity of the permeant, appreciably influences mass transfer.

The literature affords significant data on the self-association of alcohols and its effect on vapor pressure (1, 2), spectral properties (13), solubility (3), and transport characteristics from an empirical standpoint (5). The effect of donor phase self-association on permeation characteristics across a membrane can be more systematically described by incorporation of a model describing the donor phase self-association rather than interpretation of experimental results in terms of a changing apparent or observed diffusion coefficient.

Phenol self-association in isooctane and cyclohexane has been studied in detail (3). These systems are adequately described in terms of a monomer–pentamer model. Given the information that a monomer–pentamer model is appropriate ($n = 5$) and given the equilibrium or association constant, $K_{1,5}$, monomer concentrations for a given total concentration can be calculated.

Permeation Model—The system of a solute that self-associates in a donor solvent but permeates a membrane only in its monomer form can be described by extending Eq. 7 to account for self-association. This system is diagrammed in Scheme I. A mathematical description of Scheme I is given in the following two equations:

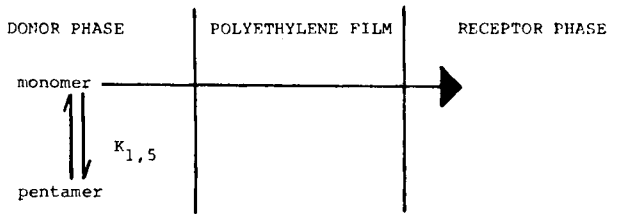
$$SSF = PC_{\text{mon}} \qquad \text{(Eq. 11)}$$

$$SSF = \left(\frac{D_m K}{h_m}\right) C_{\text{mon}} \qquad \text{(Eq. 12)}$$

where P is the intrinsic membrane permeability and K is the intrinsic membrane–donor phase partition coefficient. These equations relate the steady-state flux to the monomer concentration of permeant in the donor phase. The expression $C_{\text{mon}} = (f_{\text{mon}})(C_T)$ allows Eq. 11 to be written as:

$$SSF = (P_{\text{obs}})(C_T) \qquad \text{(Eq. 13)}$$

where P_{obs} is the observed permeability and is related to the other pa-



Scheme I

rameters by $P_{obs} = (D_m K/h_m)(f_{mon})$. This relationship indicates that the the observed permeability is equal to the product of the intrinsic permeability and the monomer fraction of permeant in the donor phase, $P_{obs} = Pf_{mon}$. This approach allows the system to be interpreted in terms of an observed permeability.

The system can also be interpreted in terms of an apparent or observed partition coefficient, K_{obs}. This approach results in:

$$SSF = \left(\frac{D_m}{h_m}\right)(K_{obs})(C_T) \qquad \text{(Eq. 14)}$$

where $K_{obs} = Kf_{mon}$.

This approach, beginning with Eq. 13, allows studies (permeant self-association in the donor phase, but membrane transport of only the monomer species) to be described in terms of an observed permeability or an observed partition coefficient when the reference concentration parameter is the total permeant concentration, C_T, in the donor phase. However, the most precise description is in terms of the intrinsic parameters, the intrinsic permeability, P, and the intrinsic partition coefficient, K, and by fully describing the donor phase self-association in terms of n and $K_{1,n}$.

The system can be resolved partially using only permeation data, without precise knowledge of the self-association equilibrium. The full mathematical expression for the system in terms of permeation is:

$$SSF = \left(\frac{D_m K}{h_m}\right)(f_{mon})(C_T) \qquad \text{(Eq. 15)}$$

From each experiment in a series of permeation experiments, SSF is determined as a function of C_T. Since the membrane thickness, h_m, is defined experimentally, the measured diffusion time lags permit calculation of D_m using Eq. 9; K and f_{mon} remain unsolved. However, K can be obtained by proper experimental design. Since f_{mon} goes to unity at low concentrations, experimental runs at low concentrations, where the self-association is negligible, allow determination of K; *i.e.*, $K_{obs} = K$ as f_{mon} goes to unity. As a result, experiments conducted at higher C_T can be interpreted in terms of f_{mon}, P, and K using the information obtained from the experiments conducted at low concentrations.

The approach of resolving the system only from interpretation of permeation data permits an estimation of f_{mon}, which is, however, a general description of the self-association. An accurate and complete understanding of the processes, both permeation and self-association, is best provided by a direct and independent equilibrium determination of C_{mon} as a function of C_T, such that n and $K_{1,n}$ are precisely known. For the phenol–isooctane mixtures used as the donor phases in this study, the values of n and $K_{1,n}$ were measured independently (3). This information permitted the processes to be more readily interpreted and modeled by providing independent verification of the experimental results.

EXPERIMENTAL

Materials—High density polyethylene films[1] were used. Phenol[2], analytical reagent grade, was used without further purification. The isooctane[3] had a labeled purity of 99+ mole %. It was stored over a molecular sieve and otherwise used as received. All other chemicals were analytical reagent grade.

Analytical Method—All phenol concentrations were determined by direct spectrophotometric[4] measurement at 269 nm ($\log \epsilon = 3.18$) in 0.1 M aqueous sulfuric acid.

Diffusion Cells—Pyrex glass diffusion cells were constructed. They consisted of identical cylindrical half-cells between which the polyethylene film was mounted. The half-cell chambers were slightly tapered and had a mean inside diameter of approximately 5.5 cm and an inside height or depth of approximately 6.0 cm, resulting in a half-cell volume of 145 ml. Each half-cell was constructed with a cylindrical portal extending off the cylinder side, allowing for filling of the compartments and withdrawing of samples. The open or contact end of the half-cells was of ground glass and grooved to accept an O-ring. The sequence of half-cell–O-ring–polyethylene membrane–O-ring–half-cell was firmly maintained using a metal clamp.

The assembled cell was immersed in a well-stirred constant-temperature bath, and the contents were well stirred by positioning magnetic stirrers directly below the half-cells beneath the water bath. Rapid mixing and homogeneity of the half-cell solutions were verified visually by use of a dye.

The cross-sectional area of the membrane over which the transport occurred was 29.7 cm^2, which resulted in an area to volume ratio of 0.20 cm^{-1}.

Diffusion Study—Prior to assembly, the polyethylene films were soaked to an equilibrium swelling in isooctane. The swelled film thickness was determined to be 0.078 ± 0.002 cm using a screw micrometer graduated to 0.001 cm.

Following assembly, the cell was immersed in a constant-temperature bath maintained at 25.0 ± 0.1°. The receptor compartment was filled with 145 ml of an aqueous solution of 0.1 M H_2SO_4. The donor compartment was filled with 145 ml of the test solutions of phenol in isooctane. The stir bars were immediately rotated at greater than 200 rpm, which commenced the experiment. This degree of stirring ensured membrane, and not diffusion layer, rate-limited transport.

At preselected intervals, 1.0-ml samples were withdrawn from the receptor compartment and immediately analyzed spectrophotometrically for phenol. The receptor compartment volume was maintained at 145 ml by addition of 1.0 ml of 0.1 M H_2SO_4 following sample removal. Aqueous sulfuric acid was used as the receptor phase to facilitate the analytical measurement for greater chemical stability and to suppress phenol ionization.

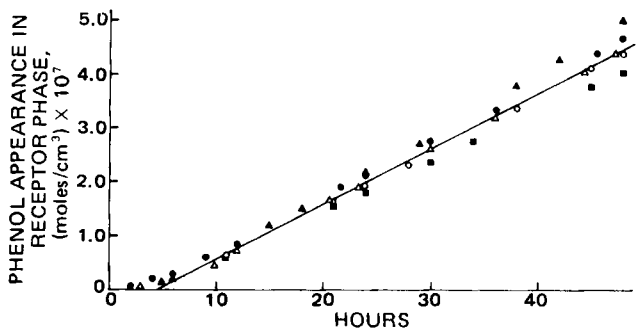


Figure 1—*Phenol concentration appearing in the receptor phase as a function of time. The donor phase phenol concentration was 2.00 × 10^{-4} mole/cm³. The different symbols represent five individual experiments. The drawn line is that obtained by linear regression analysis of the data points for times equal to or greater than 15 hr from all five individual experiments.*

RESULTS AND DISCUSSION

Permeation studies were conducted at 12 donor phase concentrations of phenol in isooctane over 0.05–2.00 × 10^{-4} mole/cm³. Figure 1, a plot of the phenol concentration in the receptor phase as a function of time, shows the data from five runs using a donor phase concentration of 2.0 × 10^{-4} mole/cm³. The linear steady-state portion and the time lag, which are typical of an experiment conducted under sink conditions with a constant donor phase concentration, are evident.

From the data obtained at each donor phase concentration, the steady-state flux was determined from the slope of the linear portion of the curve using Eq. 6 and linear regression data analysis. Since the experimental time lags were approximately 5 hr at each donor phase concentration, only data obtained at times greater than 15 hr were used in calculating the steady-state flux values. The line drawn in Fig. 1 is the regression line and corresponds to a steady-state flux of 1.36 × 10^{-11} mole/sec/cm². The 32 data points obtained at 15 hr or longer from the five experiments gave a correlation coefficient of 0.987. Extrapolation of the regression line to the time axis resulted in a time lag of 4.6 hr.

The steady-state flux and the extrapolated time lag, t_L, values calculated for the 12 donor phase concentrations are given in Table I. Figure

[g] The K_{obs} values used to calculate the mean value of 0.24.

2*a* shows the steady-state permeation data given in Table I, where the calculated steady-state flux values are plotted as a function of the total phenol concentration in the donor phase. This plot is linear at low donor phase concentrations up to ~0.25 × 10⁻⁴ mole/cm³. At donor phase concentrations greater than 0.25 × 10⁻⁴ mole/cm³, a negative deviation from linearity is observed, which increases in severity at larger values of C_T.

The time lags, t_L, at each donor phase concentration (Table I) are plotted in Fig. 2*b* as a function of C_T. The time lag is seen to be independent of the donor phase permeant concentration. An averaged value of the time lag computed from the experiments at the 12 donor phase concentrations is 5.2 ± 0.3 hr. By using this value and applying Eq. 9, the membrane diffusion coefficient for phenol was found to be 5.4 × 10⁻⁸ cm²/sec.

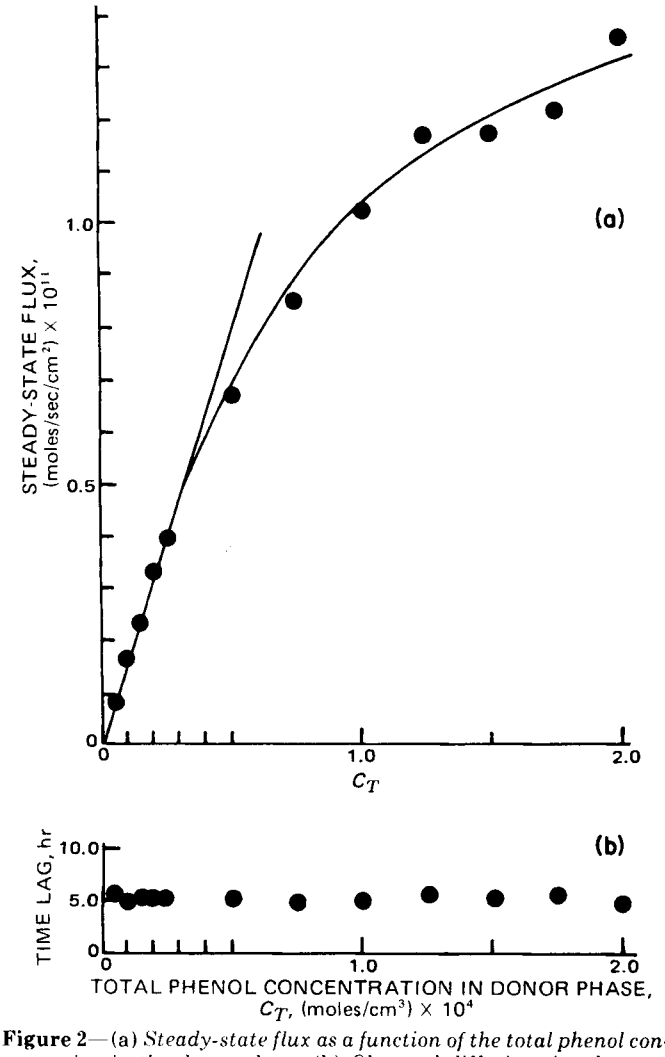

Figure 2—(a) *Steady-state flux as a function of the total phenol concentration in the donor phase.* (b) *Observed diffusion time lag as a function of the total phenol concentration in the donor phase.*

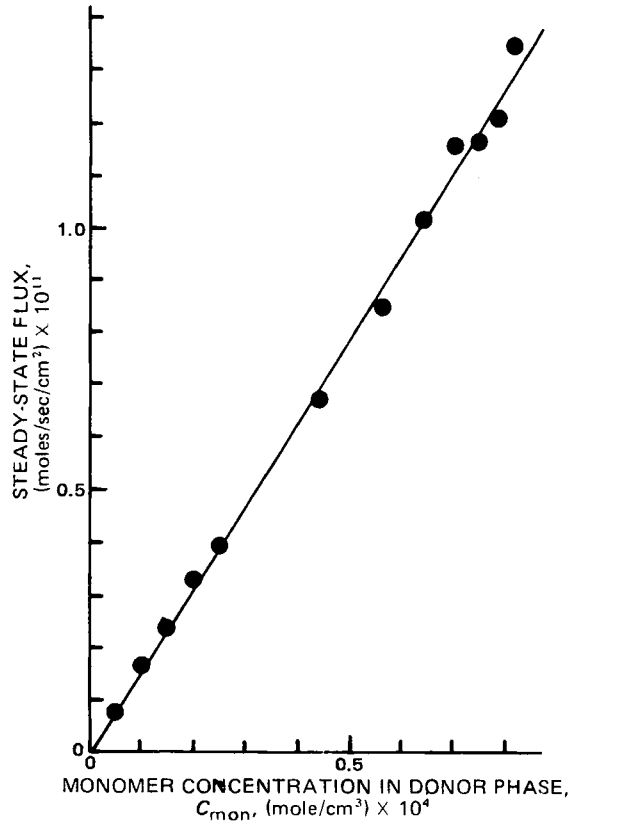

Figure 3—*Steady-state flux as a function of the donor phase phenol monomer concentration. The slope of the line, which was obtained by regression analysis, equals 15.9 × 10⁻⁸ cm/sec and represents the intrinsic permeability of the film to phenol contained in a donor phase of isooctane.*

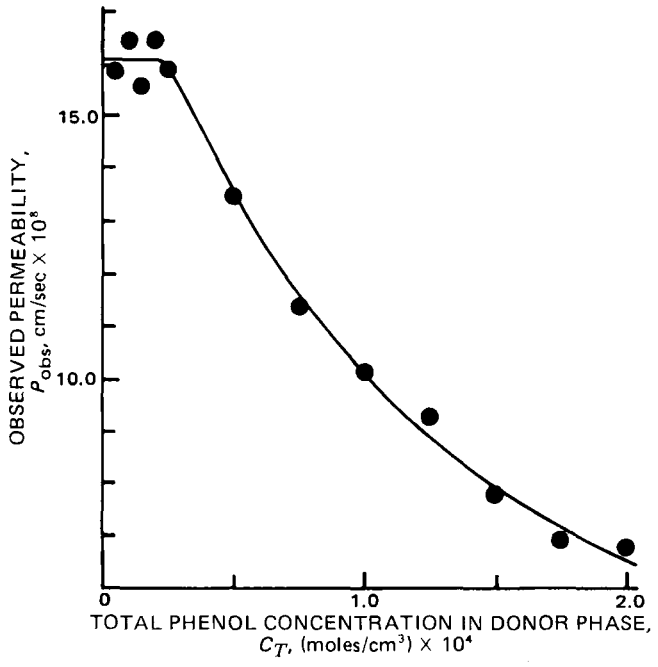

Figure 4—*Observed permeability coefficients as a function of the total phenol concentration in the donor phase.*

Ideally, these experiments would conform with Eq. 7, which predicts linearity in a plot of steady-state flux against donor phase concentration. The resulting slope would equal membrane permeability. Equation 7 is an expression of Fick's first law and includes the term C_d, the concentration difference across the film, which is typically taken to be the driving force for diffusion. However, as pointed out by Flynn *et al.* (14), the fundamental flux determinant is the chemical potential difference across the film. The nonlinearity actually observed was accounted for by relating the steady-state flux to the concentration gradient of the phenol monomer rather than to its total concentration.

With recently published data (3) on phenol self-association, the phenol monomer concentration in the isooctane donor solutions was calculated using an association constant, $K_{1,5}$, of 6.26×10^3 liters^4/mole^4. These concentrations and the fraction of phenol monomer, f_{mon}, are given in Table II. In the concentrations studied, the phenol exists totally as a monomer (negligible self-association) at or below 0.25×10^{-4} mole/cm^3.

A plot of the steady-state flux as a function of the donor phase concentration of the phenol monomer, C_{mon}, is presented in Fig. 3. The figure, a plot of Eq. 11 or 12, is linear. The slope of the line equals 15.9×10^{-8} cm/sec (correlation coefficient of 0.998) and represents the intrinsic permeability of the polyethylene film under the experimental conditions. This slope or intrinsic permeability value obtained from Fig. 3 should be identical to the initial slope value in Fig. 2, where the total phenol concentration is plotted as the abscissa, because at the phenol concentrations corresponding to the first five data points in Fig. 2, the phenol exists in effect totally as a monomer. This can be demonstrated by two different calculations. From the initial slope in Fig. 2, generated using the paired (C_T, SSF) data points for the five lowest phenol concentrations, a permeability of 16.0×10^{-8} cm/sec is obtained, in comparison to the value of 15.9×10^{-8} cm/sec obtained from the slope in Fig. 3. Alternatively, as can be seen in Table II, the individual P_{obs} values corresponding to the five lowest phenol concentrations yield an average value of 16.1×10^{-8} cm/sec.

Apparent or observed permeability values, P_{obs}, were calculated from the steady-state flux values at each donor phase concentration using Eq. 13 (Table II). These P_{obs} values are plotted in Fig. 4 as a function of C_T. This plot displays the significant decline in the apparent permeability at the higher donor phase concentrations where there is significant phenol self-association. The dependence of permeation on the monomer concentration is further substantiated by comparing the observed permeabilities to the monomer fractions. For the data in Table II, at a C_T of 2.00×10^{-4} mole/cm^3, the monomer fraction is 0.41. By comparison, the P_{obs} is 6.8×10^{-8} cm/sec, 0.43 times the value of 15.9×10^{-8} cm/sec obtained from the slope of Fig. 3. Similarly, at a C_T of 1.00×10^{-4} mole/cm^3, the monomer fraction is 0.65. In comparison, the P_{obs} is 10.2×10^{-8} cm/sec, 0.64 times the Fig. 3 slope value.

The data in Fig. 2*a* indicate that permeant self-association decreases the ability of the phenol to undergo transport across the polyethylene film. At total phenol concentrations greater than 0.25×10^{-4} mole/cm^3, there is not a proportionate increase in its steady-state flux across the polyethylene film. However, these steady-state flux data do not indicate whether the self-association effect is restricted only to the level of the donor phase or also occurs within the membrane.

An interpretation of the nonsteady-state data provides insight into the location of the self-association effect. As is evident in Fig. 2*b*, the experimentally determined time lags are independent of the donor phase phenol concentration, which indicates that the membrane diffusion coefficient is concentration independent. If permeant self-association occurred within the membrane, it would occur to an increasing extent as the donor phase permeant concentration increased. This increasing occurrence in the membrane of a polymer species at higher levels of C_T should increase the experimentally observed time lag. The time lag increase would result from a decrease in the effective diffusion coefficient, because of the inverse dependency of a diffusion coefficient on the effective molecular weight. However, since the diffusion coefficient is concentration independent, it can be concluded that (*a*) phenol self-association does not occur within the polyethylene film, or (*b*) if self-association is occurring within the membrane, its extent is negligible or the transport of the polymer species across the membrane is not sufficient to affect transport parameters, *i.e.*, it does not alter the diffusion coefficient.

The linearity seen in Fig. 3 suggests that the contribution of the self-association is restricted to the donor phase. Since there is an apparent direct dependency of the steady-state flux on the monomer concentration of phenol in the donor phase, it appears that only the monomer is partitioning into the membrane. This interpretation is further supported by the K_{obs} values found in Table II. The K_{obs} values, which are the experimentally observed polyethylene–isooctane partition coefficients, are closely approximated by calculating the product of the independently calculated f_{mon} values and the average intrinsic partition coefficient of 0.24, which is the observed value obtained from the experiments at the five lowest donor phase concentrations.

Simultaneous High-Performance Liquid Chromatographic Determination of Chlordiazepoxide and Amitriptyline Hydrochloride in Two-Component Tablet Formulations

D. BURKE and H. SOKOLOFF ˣ

Received December 5, 1978, from the *Quality Control Department, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication August 21, 1979.

Abstract □ A rapid, precise, and accurate high-performance liquid chromatographic procedure is presented for the simultaneous determination of amitriptyline hydrochloride and chlordiazepoxide in two-component tablet formulations. The impurities and decomposition products of both components were separated, making the determination specific for amitriptyline hydrochloride and chlordiazepoxide. The method was used for the assay, content uniformity, and dissolution testing of dosage forms containing 5–30 mg of chlordiazepoxide and 12.5–75 mg of amitriptyline.

Keyphrases □ Chlordiazepoxide—simultaneous determination with amitriptyline hydrochloride, high-performance liquid chromatography □ Amitriptyline hydrochloride—simultaneous determination with chlordiazepoxide, high-performance liquid chromatography □ High-performance liquid chromatography—simultaneous determination of chlordiazepoxide and amitriptyline hydrochloride

Numerous high-performance liquid chromatographic (HPLC) methods for the determination of amitriptyline hydrochloride (V), chlordiazepoxide (III), and related compounds have been reported (1–4). However, none of the methods is applicable to the simultaneous determination of these compounds in two-component tablet formulations.

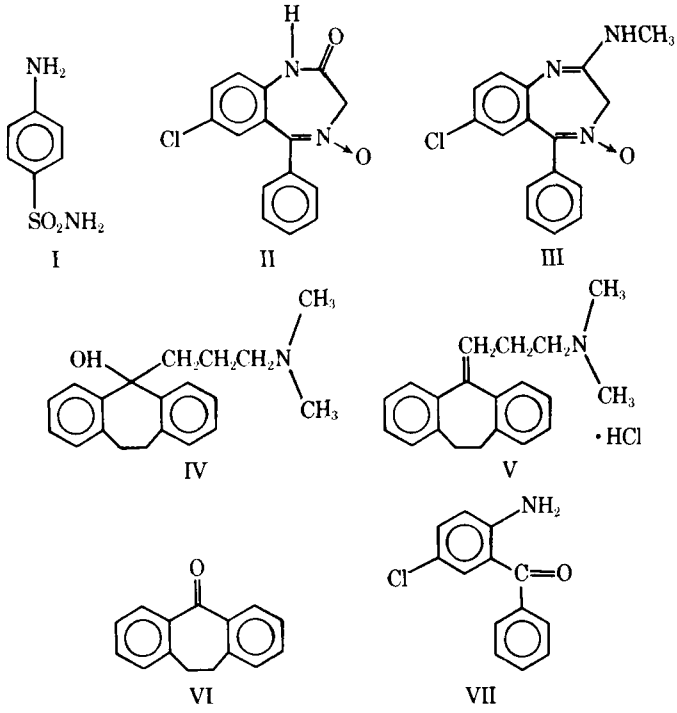
Conventional analyses, such as pharmacopeial procedures for the individual drugs (5), also are not suited for simultaneous determination. Traditional procedures, such as the spectrophotometric determination of the bromcresol green complex of amitriptyline hydrochloride and of the diazotization and coupling product of chlordiazepoxide, are tedious and time consuming, especially for content uniformity and dissolution testing.

This report presents an HPLC method for the quantitative determination of both substances in two-component tablet formulations. The analysis can be performed in a reasonable time and eliminates interference due to possible impurities: 10,11-dihydro-5-[3-(dimethylamino)propyl]-5*H*-dibenzo[*a*,*d*]cycloheptene-5-ol (IV) and 10,11-dihydro-5*H*-dibenzo[*a*,*d*]cycloheptene-5-one (VI) in amitriptyline hydrochloride and 7-chloro-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepin-2-one-4-oxide (II) and 2-amino-5-chlorobenzophenone (VII) in chlordiazepoxide.

EXPERIMENTAL

Apparatus—The liquid chromatograph consisted of a pump[1] with a flow capacity of 16–160 ml/hr and a fixed-wavelength UV detector[2] (254 nm). Solutions were injected with a valve loop[3] with a capacity of 20 or 50 μl. A 30 × 0.39-cm i.d. column containing an octadecyl bonded-phase packing[4] was used.

Chromatographic Conditions—The mobile phase consisted of 0.01 *M* sodium lauryl sulfate in tetrahydrofuran–methanol–pH 2.5 Britton–Robinson buffer (120:30:150). A flow rate of ~1 ml/min was established.



Reagents and Samples—The solvents were commercial analytical grade, and the water was double distilled. The Britton–Robinson buffer was prepared by adding 10.5 ml of 0.2 *N* NaOH to 100 ml of stock solution consisting of 0.04 *M* acetic acid, 0.04 *M* phosphoric acid, and 0.04 *M* boric acid to obtain pH 2.5 (6). The sample solvent was water–tetrahydrofuran–methanol (150:120:30). Sulfanilamide[5] (I) solution in the sample solvent at ~1 mg/ml was the internal standard. The standard solution contained ~0.3 mg of amitriptyline hydrochloride[6]/ml, 0.1 mg of chlordiazepoxide[7]/ml, and 0.1 mg of sulfanilamide/ml.

All standard and sample solutions were prepared and stored in low-actinic glassware.

Assay and Calculation—For the content uniformity test and tablet composite assay, one tablet or the equivalent tablet mass was triturated with the sample solvent and transferred quantitatively to a volumetric flask. The internal standard was added, and the flask contents were diluted to volume with the sample solvent to obtain ~0.3 mg of amitriptyline hydrochloride/ml, 0.1 mg of chlordiazepoxide/ml, and 0.1 mg of sulfanilamide/ml. An aliquot was filtered, and 20 μl was injected.

For analysis of the tablets after dissolution, a portion of the sample solution was withdrawn after an appropriate time and filtered, and an aliquot was transferred to a volumetric flask. The pH was adjusted to 2.5, and the aliquot was diluted to volume with the sample solvent to obtain 0.011 mg of amitriptyline hydrochloride/ml and 0.004 mg of chlordiazepoxide/ml. A solution of reference standards of the same amitriptyline hydrochloride and chlordiazepoxide concentrations was prepared similarly, and 50 μl of each solution was injected.

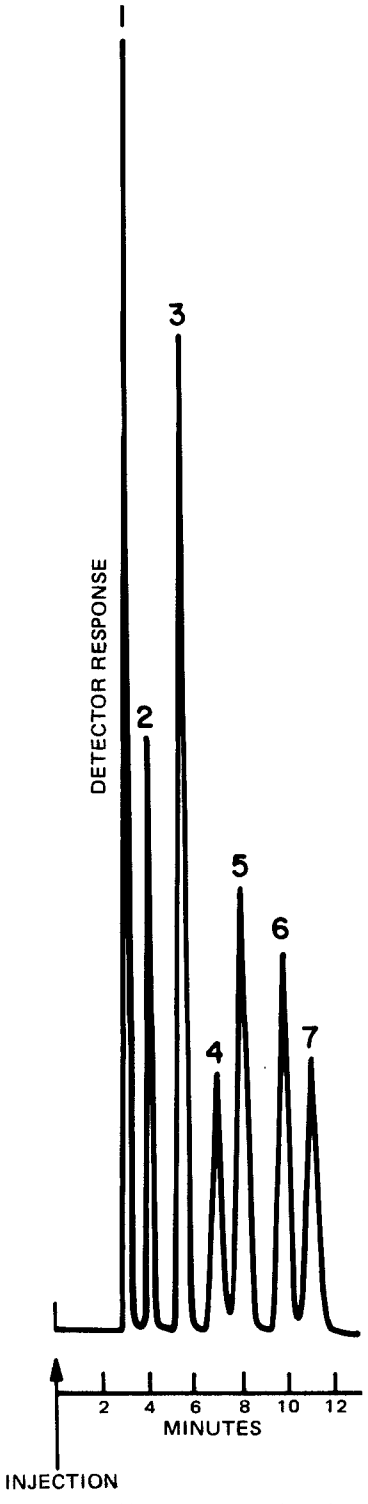

Figure 1—*Chromatogram of a mixture of I (1), II (2), III (3), IV (4), V (5), VI (6), and VII (7).*

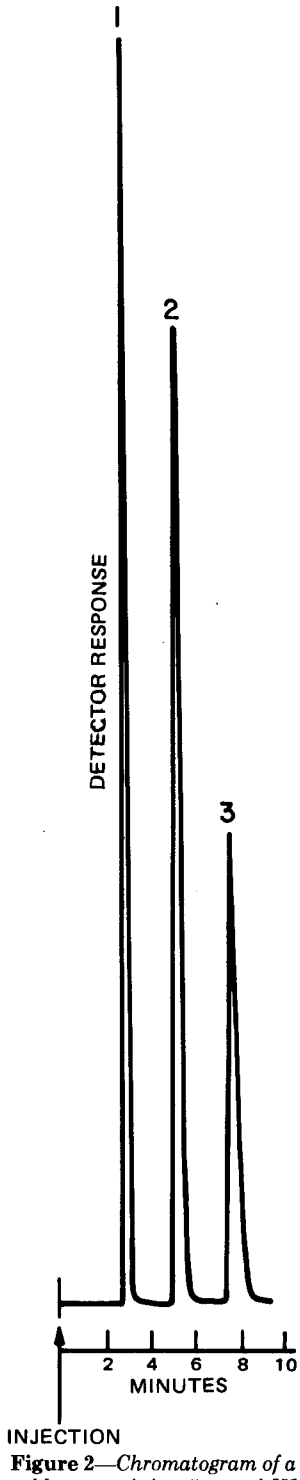

Figure 2—*Chromatogram of a tablet containing 5 mg of III (2) and 12.5 mg of V (3) with I (1) (internal standard) added.*

Quantitation was by the peak height ratio of the reference standards and sample to the internal standard for the content uniformity test and tablet composite assay and by comparison of the peak height of the sample to that of the external standard for dissolution calculations.

RESULTS AND DISCUSSION

This investigation was initiated for use in control laboratories where rapid and simple methods are required. Simple and rapid sample preparation was needed, particularly for content uniformity and dissolution tests. The aqueous sample solution in the latter test can be used as is or with minimal sample treatment for reversed-phase chromatography.

To determine the appropriate HPLC parameters, some preliminary TLC was performed using silica gel plates coated with silicone oil. A mobile phase containing tetrahydrofuran and pH 3 Britton–Robinson buffer was selective in the migration of the six compounds chromatographed. The use of a μBondapak C_{18} column with the buffered mobile phase failed to separate V, II, and IV from each other. Variation of the mobile phase composition was unsuccessful. Complete separation was achieved by the addition to a mobile phase of sodium lauryl sulfate and methanol and by adjustment of the pH to 2.5. The paired-ion species were eluted within 12 min.

Table I—Chromatographic Characteristics of Amitriptyline Hydrochloride, Chlordiazepoxide, Their Impurities, and the Internal Standard

Compound[a]	Retention Time, min	Number of Theoretical Plates, N^b	Capacity Factor, k^c	Selectivity, α
I	3.0	580	0.6	
				1.9
II	4.5	660	1.1	
				1.6
III	5.5	780	1.8	
				1.4
IV	7.5	730	2.6	
				1.2
V	8.0	960	3.1	
				1.3
VI	10.0	1440	4.1	
				1.2
VII	11.0	1870	4.8	

[a] The calculations were made from the chromatogram in Fig. 1. [b] The number of plates was calculated from $N = 16\ (t_r/t_w)^2$. [c] The column void volume was 2.0 ml.

Table II—Comparison of HPLC and Spectrophotometric Tablet Assays

	Amitriptyline Found, %		Chlordiazepoxide Found, %

RSD, %	0.96	0.84	0.36	1.3

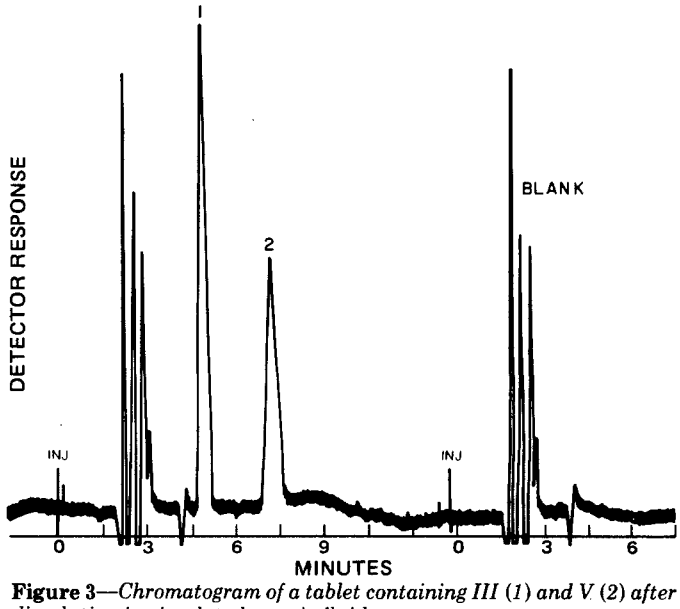

Figure 3—*Chromatogram of a tablet containing III (1) and V (2) after dissolution in simulated gastric fluid.*

Several tricyclic compounds and benzodiazepine derivatives were chromatographed in the selection of the internal standard necessary for the quantitation of amitriptyline hydrochloride and chlordiazepoxide, but a stable material with a suitable retention time was not found. Sulfanilamide eluted before amitriptyline hydrochloride and chlordiazepoxide and was well separated from their respective impurities, so it was chosen as the internal standard. Separation of the compounds including sulfanilamide is shown in Fig. 1, and the calculated chromatographic characteristics are listed in Table I.

Linearity—A plot of peak height *versus* the amount of the two components injected was linear between 0.3 and 11 μg of amitriptyline hydrochloride and 0.13 and 4 μg of chlordiazepoxide. The working concentration was ~5.7 μg of amitriptyline hydrochloride and 2 μg of chlordiazepoxide for the content uniformity test and assay. For dissolution measurements, the working concentration was 0.6 μg of amitriptyline hydrochloride and 0.2 μg of chlordiazepoxide.

Precision—Chromatographic system reproducibility was determined by injecting six 20-μl aliquots of a sample solution containing 0.1 mg of internal standard/ml, 0.3 mg of amitriptyline hydrochloride/ml, and 0.1 mg of chlordiazepoxide/ml as well as corresponding amounts of the reference standards. The relative standard deviation was ±0.16 and ±0.18% for amitriptyline hydrochloride and chlordiazepoxide, respectively. Six replicate samples of composite tablet mass also were assayed. The relative standard deviations were 0.96% for amitriptyline hydrochloride and 0.36% for chlordiazepoxide.

Recovery—A known amount of both active components was added to an assayed sample, and 97.7% of the amitriptyline hydrochloride and 100.2% of the chlordiazepoxide were recovered.

Figure 2 shows a typical chromatogram of the tablet assay. No interference due to a placebo was found. The completeness of the extraction of the tablet mass during sample preparation was checked; no active components remained in the tablet mass after filtering. Good agreement was obtained between the HPLC method and the spectrophotometric procedures, *i.e.*, measurements of the bromcresol green complex of amitriptyline hydrochloride and of the diazotization and coupling product of chlordiazepoxide (Table II).

For the dissolution test, external rather than internal standards were used since, at low concentrations, the sensitivity had to be increased and the blank interfered in the region of the internal standard. A typical chromatogram is shown in Fig. 3.

The described procedure subsequently was used for experimental tablet and capsule formulations containing only amitriptyline hydrochloride. The assay and content uniformity results correlated well with the data obtained using the pharmacopeial (5) procedures.

Validation of Washing Procedures for Maintaining a Microbiologically Clean Gel Filtration Column

L.-F. WEN ˣ, T. BOHANNON, A. CRABB, S. NG, and F. MAMARIL

Received March 26, 1979, from the *Quality Control Department, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication September 10, 1979.

Abstract □ Chromatographic gel filtration matrixes used in various separation techniques are subject to microbial contamination. The need for a microbe-free column is critical when preparing materials that require a low or zero microbial count. This report proposes two alternative washing systems: 0.02 *N* HCl containing 0.81% NaCl, and 0.1 *M* tromethamine–hydrochloride buffer (pH 7.0) containing 0.81% NaCl and 0.02% thimerosal. These washing systems were validated using a 100 × 2.6-cm column packed with a modified dextran gel slurry previously inoculated with known counts of USP test organisms. After each wash, the column separation characteristics were verified further with appropriate test proteins.

Keyphrases □ Chromatography—gel filtration, washing procedures for columns contaminated with microorganisms □ Contamination—microorganisms in gel filtration columns, washing procedures for column disinfection

Chromatographic column packing materials such as gel filtration and ion-exchange matrixes used in separation and the buffer systems usually employed with such matrixes are subject to microbial contamination and proliferation. Excessive microbial growth obstructs the flow, affects the chromatographic properties of these columns, and contaminates material that is affected adversely by microorganisms.

Gel filtration matrixes can be sterilized in the wet or dry state by autoclaving (1, 2), but such techniques are not feasible for a working column. Gaseous sterilization with formaldehyde or ethylene oxide is ineffective and unsafe due to the limited sterilant penetration and the residual toxic effects (2, 3). Organic solvents such as chloroform and toluene are incompatible with the matrixes and some column components. Several antimicrobial agents are compatible with the column packing matrixes. Thimerosal is one of the most commonly used preservatives because of its highly biostatic effect (2, 4). Its routine use as an applicable and effective antimicrobial agent in chromatographic columns has to be evaluated.

The present investigation was undertaken to develop effective methods to minimize or eliminate microbial contamination in a gel filtration column and to validate the antimicrobial effectiveness and applicability of these methods.

Organic solvents such as chloroform and toluene are incompatible with the matrixes and some column components. Several antimicrobial agents are compatible with the column packing matrixes. Thimerosal is one of the most commonly used preservatives because of its highly biostatic effect (2, 4). Its routine use as an applicable and effective antimicrobial agent in chromatographic columns has to be evaluated.

The present investigation was undertaken to develop effective methods to minimize or eliminate microbial contamination in a gel filtration column and to validate the antimicrobial effectiveness and applicability of these methods.

EXPERIMENTAL

Microbial Inoculum Suspension Preparation—The bacterial cultures, *Staphylococcus aureus* (ATCC 6538), *Escherichia coli* (ATCC

0022-3549/80/0200-0140$01.00/0

© 1980, American Pharmaceutical Association

8739), and *Pseudomonas aeruginosa* (ATCC 9027), were grown for 24 hr at 35° on soybean–casein digest agar[1] slants. The yeast culture, *Candida albicans* (ATCC 10231), was grown for 48 hr at 23° on Sabouraud dextrose agar[2] slants. On the slurry inoculation day, individual culture suspensions were prepared in 0.9% NaCl[3] contained in sterile colorimeter tubes (150 × 15 mm). Each culture was scraped aseptically with a loop from the agar slants and carefully emulsified in colorimeter tubes until the uniform turbidity, as determined at 420 nm[4], equaled an approximate viability count of 1–5 × 10^8 organisms/ml of suspension.

The bacterial culture, *Bacillus subtilis* (ATCC 9372), and the mold culture, *Aspergillus niger* (ATCC 16404), were prepared as spore suspensions in 0.9% NaCl solution, with the later suspension containing 0.05% polysorbate 80[5]. These spore suspensions had viability counts of ~1–5 × 10^8 organisms/ml.

Quantitative Determination of Microbial Viability—The individual inoculum suspensions and the initially inoculated samples of slurry and effluents were diluted serially in 10-fold increments to 10^{-9} in pH 7.2 phosphate buffer[6]. All other samples of effluents and slurry were similarly diluted to 10^{-5}. Then, in duplicate, 1.0 ml of each diluted sample was placed in sterile plastic petri dishes (150 × 25 mm) with a sterile glass serological pipet (1 in 1/100 ml). In addition, 1.0- and 0.1-ml quantities of each undiluted sample were placed aseptically in plastic petri dishes with glass serological pipets (1 in 1/100 ml and 1/10 in 1/100 ml, respectively).

For samples without thimerosal[7], Sabouraud dextrose agar was added to one set of plates to enumerate molds or yeasts, and soybean–casein digest agar was added to the other set of plates to enumerate bacteria. In the samples containing thimerosal, the appropriate media were supplemented with sodium thioglycolate[8] (500 mg/liter). After incubation of the soybean–casein digest agar plates for 3–5 days at 35° and the Sabouraud dextrose agar plates at room temperature for 7–11 days, colony-forming units were counted.

Qualitative Determination of Microbial Viability—To monitor the viability of *S. aureus*, *E. coli*, and *P. aeruginosa*, 0.1 ml of each sample was placed onto mannitol salt[9], MacConkey[10], and cetrimide[11] agar plates, which were incubated for ≥3 days at 35° and checked by Gram-stain or appearance for characteristic growth. In addition, the viability count plates were checked for colonies characteristic of each inoculated contaminant.

pH Determination—The pH of each sample was determined with a digital pH meter[12].

Mercury Determination—To monitor mercury as thimerosal in the effluents and slurries treated with the tromethamine–thimerosal wash solution, flameless atomic absorption spectroscopy was used.

Reagent blanks were prepared by pipetting water, 3 ml, into 300-ml bottles[13]. A working standard solution of 0.5 ppm of mercury was prepared by diluting a 1000-ppm mercury standard solution. Then 1.0, 2.0, and 3.0 ml of the working standard were pipetted into one of three 300-ml bottles[13].

Each sample from the tromethamine–thimerosal wash solution was acidified with an equal volume of concentrated nitric acid to kill any microorganisms. All samples were stored at 5° prior to the atomic absorption analyses. At that time, each sample was diluted with double-distilled water to obtain ~1 ppm of mercury, and 1-ml samples were pipetted into 300-ml bottles[13].

To each blank, standard, and sample solution were added 5 ml of 35% HNO_3, 5 ml of 50% (v/v) H_2SO_4, and 5 drops of 5.0% potassium permanganate to produce a purple color. After standing for 30 min, each preparation was diluted to volume (100 ml) with distilled water. Hydroxylamine hydrochloride (1.5%), 5 ml, was added to decolorize each solution, the solution was treated with 5 ml of 10.0% stannous chloride, and the flask was stoppered immediately with the aspirator tube of the instrument[14]. The enclosed atmosphere of each solution was circulated through the apparatus drying train using the electric pump. The maximum absorbance was recorded when the mercury vapor concentration reached an equilibrium value. Between runs of each solution, the vapor was circulated through the mercury scrubber to clean the system.

The average blank absorbance was subtracted from the standard and sample absorbances. The quantity of mercury in each diluted sample was read from a calibration curve prepared by plotting the mercury quantities in the standards in micrograms against the corrected standard absorbances. The mercury concentration in the original sample was calculated by:

$$\text{concentration (ppm) of mercury} = \frac{C \times D}{S} \qquad \text{(Eq. 1)}$$

where C is the amount of mercury (parts per million) in 1 ml of diluted sample, D is the dilution factor, and S is the amount of sample (milliliters).

Antimicrobial Activity Determination of Acid Wash Solution—Dry modified polymeric dextran gel[15] (~50 g) was added to ~1500 ml of sterile distilled water. After 3 days of equilibration at room temperature, the distilled water in the slurry was decanted and replaced with sterile 0.81% NaCl. Following an additional 2-day equilibration at room temperature, the supernate was decanted, leaving ~1000 ml of slurry. This slurry was inoculated with either 10 ml of each inoculum suspension (*S. aureus*, *E. coli*, *P. aeruginosa*, and *C. albicans*) or 10 ml of each spore suspension (*A. niger* and *B. subtilis*).

Over 24 hr, the inoculated slurry was packed by gravity into the column[16] to a height of ~95 cm. The column was maintained at 5° by circulating controlled-temperature water through the column jacket. The slurry and column effluent were sampled immediately and tested for microbial count and pH.

The packed column, continuously maintained at 5°, was washed with ~3–4 liters of the sterile, filtered, pH 1.8 acid wash solution at a flow rate of ~0.8 ml/min. Column effluent samples were collected in sterile screw-capped test tubes (150 × 20 mm) after 1 and 4 days to determine the microbial count and pH. The remaining effluent was pooled for determining the total acid wash elution volume.

After this acid wash treatment, the column was rinsed by washing with 1.5–2.5 liters of 0.1 *M* tromethamine–hydrochloride buffer (pH 7.0) containing 0.81% NaCl and 0.02% sodium azide (rinsing buffer) at the same flow rate.

After 1 and 2 days of rinsing, the column effluent samples were collected in sterile screw-capped test tubes for microbial counting and pH determination. The remaining effluent was pooled for determination of the total rinsing buffer elution volume. Five days after the rinse termination, a sample of the effluent was aseptically collected for microbial counting and pH determination. The slurry was removed immediately from the column and sampled aseptically from the top, middle, and bottom for the microbial count and pH determination.

Antimicrobial Activity Determination of Tromethamine–Thimerosal Wash Solution—The described washing and rinsing protocol and the time schedule were followed in using the tromethamine–thimerosal wash solution to clean the inoculated columns. In addition to the microbial count and pH determination, column effluents and slurry were assayed for mercury by flameless atomic absorption spectroscopy to monitor the thimerosal concentration.

Separation Properties of Columns Treated with Acid and Tromethamine–Thimerosal Wash Solution—Two milligrams each of cytochrome c[17], bovine serum albumin[18], and a dextran indicator[19] were added separately to 2-ml aliquots of the rinsing buffer. The test solution was prepared by combining 1.0 ml of each of these solutions. This test solution was fractionated on the same uninoculated column after each of the following procedures: (*a*) rinsed and equilibrated with ~2 liters of rinsing buffer over 24 hr (control run); (*b*) rinsed and equilibrated with

[a] Standing in the slurry.

~2 liters of rinsing buffer and treated with ~1 liter of the acid wash solution over 24 hr followed by rinsing and equilibration with ~2 liters of rinsing buffer over 48 hr (acid wash run); and (c) rinsed and reequilibrated with ~2 liters of rinsing buffer and treated with ~1 liter of the tromethamine–thimerosal wash solution over 24 hr followed by rinsing and equilibration with ~2 liters of rinsing buffer over 48 hr (tromethamine–thimerosal wash run). These solutions were allowed to flow through the slurry in the column by gravity at 0.8 ml/min.

After each of the three column treatments, the test solution was added to the column and was allowed to flow ~2.5 cm into the slurry before initiation of the rinsing buffer eluent, which flowed by gravity at a similar rate. Six-milliliter fractions were collected[20], and each fraction was monitored visually and/or spectrophotometrically[21] for components of the test solution.

The column void volume was estimated from the elution volume of the blue dextran, which was detected spectrophotometrically by its absorbance at 625 nm and visually by its blue color. The elution volume of cytochrome c was determined spectrophotometrically from its absorbance at 407 nm and visually by its red color. The elution volume of bovine serum albumin was determined by its absorbance at 280 nm. Then the relative elution volumes were calculated after each run by dividing the elution volume of each test protein, V_e, by the respective void volume, V_0, for each respective run. In addition, the Ouchterlony double-diffusion technique was used to confirm the separation of bovine serum albumin from cytochrome c.

Ouchterlony Double-Diffusion Technique—In the Ouchterlony technique, 50 μl from each of the three fractions of the bovine serum albumin peak was added to each of three outer wells of an Ouchterlony plate[22]. Fifty microliters from each of the two fractions of the cytochrome c peak was added to each of two additional outer wells on the same Ouchterlony plate. Fifty microliters of a control solution (2 mg of bovine serum albumin/ml) was added to the sixth outer well of the Ouchterlony plate. Fifty microliters of rabbit antibovine serum albumin[23] (2 mg/ml) was added to the center well of the plate, which was incubated for 24 hr in a moisture chamber at room temperature and subsequently examined for precipitin bands.

RESULTS

Validation of Antimicrobial Activity of Column Wash Solutions—The results indicate that both the acid wash and the tromethamine–thimerosal wash solutions are capable of eliminating microbial contamination from the gel filtration slurry packed into a column maintained at 5°. The acid wash was more effective than the tromethamine–thimerosal wash solution against both the nonspore-forming bacteria and the spores of *B. subtilis* (Tables I–IV). The acid wash solution was extremely active against the nonspore-forming bacteria since the combined bacterial count of *S. aureus* (Gram-positive cocci), *E. coli*, and *P. aeruginosa* (both Gram-negative bacilli) was reduced from 5.0×10^6 bacteria/ml of effluent to zero in 1 treatment day (Table I).

In comparison, the combined viability count for a mixture of the same three nonspore-forming bacteria was reduced from 3.8×10^6 to 1.6×10^3 organisms/ml of effluent sample following 4 days of treatment with the tromethamine–thimerosal wash (Table III). Visual (qualitative) examination of the viability count plates indicated that, after 4 days of treatment, *P. aeruginosa* was eliminated completely, that *E. coli* contamination was reduced significantly, and that most of the remaining nonspore-forming contamination was *S. aureus*.

The acid wash produced almost a 100,000-fold reduction in the number of *B. subtilis* spores per milliliter of effluent with 4 days of treatment (Table II). On the other hand, only a 1000-fold reduction in the number of *B. subtilis* spores per milliliter of effluent was produced with 4 days of treatment with the tromethamine–thimerosal wash solution (Table IV).

The tromethamine–thimerosal wash solution was more effective than the acid wash solution against yeast and the *A. niger* mold spores. *A. niger* spores, initially at concentrations of 1.5×10^6/ml of slurry and of 1.5×10^4/ml of effluent, were reduced to zero per milliliter of effluent with 1 day of treatment with the tromethamine–thimerosal wash solution (Table IV). This reduction was permanent since no mold spores were recovered from the treated slurry. Similarly, this same wash produced a 100,000-fold reduction in the *C. albicans* count per milliliter of effluent (Table III).

Table III—Tromethamine–Thimerosal Wash Treatment of a Column Slurry Contaminated with Nonspore-Forming Bacteria and Yeast

Sampling Time, days	Column Eluting Solution Used between Sampling	Total Effluent Volume between Sampling, ml	Sample Analyses				
			Nature of Sample	pH	Mercury Content, %	Microorganism Count per Milliliter	
						Total Bacteria	Yeast
0	Tromethamine–thimerosal wash solution	0	Slurry	6.6	—[a]	3.8×10^6	3.5×10^6
			Effluent	6.4	—[a]	3.8×10^6	2.4×10^6
1	Tromethamine–thimerosal wash solution	1000	Effluent	7.0	0.01	3.8×10^4	4.0×10^3
4	Rinsing buffer	2720	Effluent	7.1	0.01	1.6×10^3	3.5×10^1
5	Rinsing buffer	1000	Effluent	7.0	—[a]	7.6×10^2	1.0×10^1

11	Rinsing buffer[b]	0	Effluent	7.0	—[a]	1.2×10^3	0
			Slurry from top	7.0	—[a]	1.6×10^3	0
			Slurry from middle	7.0	—[a]	3.2×10^3	0
			Slurry from bottom	7.0	—[a]	3.2×10^4	0

[a] Negligible mercury content. [b] Standing in the slurry.

Table IV—Tromethamine–Thimerosal Wash Treatment of a Column Slurry Contaminated with Bacterial and Mold Spores

Sampling Time, days	Column Eluting Solution Used between Sampling	Total Effluent Volume between Sampling, ml	Sample Analyses				
			Nature of Sample	pH	Mercury Content, %	Microorganism Count per Milliliter	
						Bacteria Spores	Mold Spores
0	Tromethamine–thimerosal wash solution	0	Slurry	6.4	—[a]	1.5×10^6	1.5×10^6
			Effluent	6.5	—[a]	2.0×10^6	1.5×10^4
1	Tromethamine–thimerosal wash solution	825	Effluent	7.0	0.01	5.5×10^3	0
4	Rinsing buffer	2250	Effluent	7.0	0.01	2.4×10^3	0
5	Rinsing buffer	1000	Effluent	7.0	—[a]	1.2×10^3	0
6	Rinsing buffer[b]	1150	Effluent	7.0	—[a]	8.0×10^2	0
11	Rinsing buffer[b]	0	Effluent	6.8	—[a]	9.0×10^4	0
			Slurry from top	6.8	—[a]	3.5×10^5	0
			Slurry from middle	6.8	—[a]	5.6×10^5	0

[a] Negligible mercury content. [b] Standing in the slurry.

Table V—Relative Elution Volumes of the Test Solution Components after Each Run

Test Solution Components	Relative Elution Volumes (V_e/V_0)[a]		
	Control Run	Acid Wash Run	Tromethamine–Thimerosal Wash Run
Bovine serum albumin[b]	1.04	1.05	1.00
Cytochrome c[b]	2.07	2.56	2.60

[a] The column void volume (V_0) was determined using blue dextran; V_e is the test protein elution volume. [b] Fractions were verified further by the Ouchterlony double-diffusion technique.

At the conclusion of this experiment, no viable *C. albicans* cells were recovered from the slurry (Table III).

The acid wash solution produced a less dramatic reduction in the number of yeast and mold spores. The yeast spore count per milliliter of effluent was reduced 10,000-fold with 4 days of treatment, although the count increased after the treatment ended (Table I). The mold spore count per milliliter of effluent was reduced almost 10,000-fold with 1 day of treatment, and as with the *C. albicans*, the number of colony-forming units of *A. niger* increased following termination of the 4-day flow of the acid wash solution (Table II).

Each wash solution was eliminated from the column within ~24 hr by continuous elution with the rinsing buffer, as shown by the pH or mercury determination (Tables I–IV). Only a trace of mercury was detected in the gel slurry after rinsing the column previously treated with the tromethamine–thimerosal wash (Tables III and IV).

Validation of Separation Properties of Treated Column—The test protein elution patterns (bovine serum albumin and cytochrome c) obtained from the control run, the acid wash run, and the tromethamine–thimerosal run showed no significant differences, indicating that the column separation properties were not affected by either washing procedure. The relative elution volumes of the test proteins after both the acid wash run and the tromethamine–thimerosal wash run were similar to the relative elution volumes obtained after the control run (Table V). In addition, the Ouchterlony double-diffusion technique verified that there was no cross-contamination of the cytochrome c fraction with bovine serum albumin.

DISCUSSION

Selection of Suitable Wash Solutions—Several disinfectant solutions other than the tromethamine–thimerosal and the acid wash solutions were considered, but they were not studied because of their undesirable characteristics. Formaldehyde (3–8%) and glutaraldehyde (2%) were reported to be sporocidal (4), but formaldehyde is corrosive and damaging to the plastic parts of the column equipment, and glutaraldehyde is expensive and unstable upon storage (4). Other substances, such as chloroform, butanol, and toluene, cause the gel particles of certain gel filtration matrixes to shrink (2), are effective only at high concentrations (2, 5), and are incompatible with the plastic parts of the column equipment (2).

Thimerosal, a well-known antimicrobial agent (4), commonly is used as a preservative in multiple-dose containers and in topical preparations (4, 6). Furthermore, it is compatible with gel filtration and cation-exchange matrixes (2, 5). Dilute hydrochloric acid was examined since its acidity is expected to be antimicrobial and since gel filtration matrixes can be exposed to 0.02 *N* HCl for at least 6 months without deleterious effects (2). The 0.02% sodium azide included in the rinsing buffer does not interact with proteins or carbohydrates or affect their chromatographic behavior (2). The inclusion of isotonic sodium chloride concentrations in the wash solutions and rinsing buffer keeps the ionic strengths constant to avoid gel volume shrinkage or swelling upon changes in the eluents.

Antimicrobial Activity Determination and Monitoring of Wash Solution Removal—The washing procedures were examined under working conditions in a typical gel filtration column maintained at 5°. To investigate their antimicrobial effectiveness, the gel slurry was inoculated with high counts of the five test microorganisms recommended by USP XIX for antimicrobial effectiveness testing (7). To ensure meaningful results with the tromethamine–thimerosal wash, the static effects of mercury (7, 8) were neutralized by the addition of sodium

thioglycolate to a final concentration of 500 mg/liter (7) to all culture media possibly containing thimerosal. To substantiate the microbial counts and pH or mercury concentrations of effluent samples taken at the end of each wash and rinse cycle, column slurry samples were also analyzed at the conclusion of each antimicrobial effectiveness test.

To monitor the acid wash removal, pH determination was the most appropriate method. Since thimerosal contains ~50% mercury by weight (9), the tromethamine–thimerosal wash removal was monitored by cold vapor, flameless atomic absorption spectroscopy (10).

Washing Solution Effects on Treated Column Separation Properties—The proteins cytochrome c and bovine serum albumin were selected because, based on their respective molecular weights of 12,400 and 67,000, they can be readily fractionated by the slurry used in this investigation (2). Each protein, as well as the blue dextran void volume indicator, was readily assayed spectrophotometrically. In addition, the Ouchterlony double-diffusion procedure, based on a literature method (11), confirmed the clear separation of bovine serum albumin and cytochrome c in the control column and in treated columns.

It is feasible to apply both wash solutions, 0.02 *N* HCl containing 0.81% NaCl and the 0.1 *M* tromethamine–hydrochloride buffer (pH 7.0) containing 0.81% NaCl and 0.02% thimerosal, for disinfecting a modified gel filtration slurry under typical working conditions. Both wash solutions demonstrate antimicrobial activity against high concentrations of various microorganisms in the gel slurry packed into a column maintained at 5°.

Since the acid wash is more effective against nonspore-forming bacteria, including the more resistant species *P. aeruginosa* (4), and since the tromethamine–thimerosal wash is more active against mold and yeast, both wash solutions can be used routinely on an alternating basis or as needed. The wash solutions cannot be used in combination, however, since thimerosal is unstable in acidic solutions (4). In addition, both wash solutions can be removed from the slurry within 24 hr with no more than 1 liter of the rinsing buffer. Both wash solutions do not adversely affect the matrix separation properties and should be compatible with similar column packing materials.

High-Performance Liquid Chromatographic Analysis of Trimethoprim and Sulfamethoxazole in Dosage Forms

R. O. SINGLETARY, Jr., and F. D. SANCILIO ˣ

Received April 29, 1979, from *Burroughs Wellcome Co., Greenville, NC 27834.* Accepted for publication August 30, 1979.

Abstract □ A rapid, sensitive, and automatable high-performance liquid chromatographic method is presented for the determination of sulfamethoxazole, trimethoprim, and a preservative in dosage forms in the presence of excipients and degradation products.

Keyphrases □ Trimethoprim—simultaneous analysis with sulfamethoxazole and methylparaben, high-performance liquid chromatography, oral suspension and solid dosage forms □ Sulfamethoxazole—simultaneous analysis with trimethoprim and methylparaben, high-performance liquid chromatography, oral suspension and solid dosage forms □ Antibacterial agents—trimethoprim and sulfamethoxazole, simultaneous high-performance liquid chromatographic analysis, oral suspension and solid dosage forms

The antibacterials sulfamethoxazole and trimethoprim are the active ingredients in several oral suspension and solid dosage forms. The official analyses of their dosage forms are spectrophotometric methods following extraction (1, 2). These methods are time consuming and relatively difficult. A high-performance liquid chromatographic (HPLC) method, presented for the analysis of various sulfonamides in combination with trimethoprim, does not separate the various degradation products and the active components and cannot be used as a stability-indicating assay (3).

This study was undertaken to establish a rapid, quantitative, and stability-indicating procedure for routine quality control testing of trimethoprim and sulfamethoxazole in dosage forms. Methylparaben, a commonly used preservative, also may be determined in the analysis of the oral suspension.

EXPERIMENTAL

Apparatus—A high-pressure liquid chromatograph[1] with a 254-nm detector and a stainless steel column (30 cm × 4 mm i.d.) was used. The column packing[2] was porous silica particles with an octadecylsilane-bonded coating. The system was operated at 2.0 ml/min with a column pressure of ~1800 psi for solid dosage forms and at 3.0 ml/min with a column pressure of ~2800 psi for oral suspensions.

Samples were injected by an autosampler[3] equipped with a 10-μl loop, and all analyses were performed at ambient temperature. A laboratory computer system[4] was used to gather data and to calculate the percentage of the theoretical component amounts.

Materials—Methanol[5], methylparaben[6], phenacetin[6], trimethoprim[6], sulfamethoxazole[6], acetonitrile[7], and acetic acid[8] were used as received. The oral suspensions and tablets were obtained from marketed batches[9].

Mobile Phase—The mobile phase was degassed acetonitrile–1% aqueous acetic acid (16:84) for tablets and degassed acetonitrile–1% aqueous acetic acid (10:90) for oral suspensions.

Internal Standard Solution—A 2-mg/ml solution of phenacetin in methanol was prepared as the internal standard.

Reference Standard Solution—Approximately 20 mg of trimethoprim and 100 mg of sulfamethoxazole were weighed accurately into a 100-ml volumetric flask. After 6.0 ml of the internal standard was added and the trimethoprim and sulfamethoxazole were dissolved in methanol[10], the flask was filled to volume with methanol.

Sample Preparation for Solid Dosage Forms—Twenty intact tablets from each sample were weighed accurately to obtain the average tablet weight and were ground to a fine powder. An amount of the powder equivalent to 100 mg of sulfamethoxazole was weighed accurately and placed in a 100-ml volumetric flask. Sufficient methanol to dissolve the active ingredients[10] and 6.0 ml of the internal standard solution were added, and the solution was diluted to volume with methanol. A portion of this solution was centrifuged or filtered before use.

Sample Preparations for Oral Suspension—Approximately 2.7 g of the oral suspension sample was weighed accurately and placed in a 100-ml volumetric flask. After 6.0 ml of the internal standard solution was added and the active ingredients were dissolved in methanol[10], the flask was diluted to volume with methanol. A portion of this solution was filtered or centrifuged before use. The specific gravity of the suspension was required for the calculations.

Chromatography—Each sample analysis consisted of two 10-μl injections of the sample solution bracketed by two 10-μl injections of a standard solution. Sample chromatograms for the oral suspension and tablet samples are shown in Figs. 1 and 2, respectively. The detector attenuation was 0.1 aufs.

The peak area or height ratios were used to quantitate the chromatograms. The ratios were calculated by:

$$SP \text{ or } ST = \frac{PA_1}{PA_2} \qquad \text{(Eq. 1)}$$

where SP is the sample ratio, ST is the standard ratio, PA_1 is the area or height of the sample or standard component peak, and PA_2 is the area or height of the internal standard peak. The percent of the theoretical amount of each component was calculated by:

$$\left(\frac{SP}{ST}\right)\left(\frac{W_1}{W_2}\right)\left(\frac{AS}{TA}\right) \times 100 = \% \text{ of theoretical amount} \qquad \text{(Eq. 2)}$$

where W_1 and W_2 are the standard and sample weights, respectively; AS is the average tablet weight or specific gravity; and TA is the theoretical amount per tablet or milliliter. Peak areas were used in the trimethoprim and sulfamethoxazole calculations, and peak heights were used in the methylparaben calculations.

RESULTS AND DISCUSSION

A nonpolar column was selected due to the polarity of the components to be determined. The high efficiency of the reversed-phase, small particle column resolved all of the formulation components and potential degradation products.

The presence of methylparaben as a preservative in the oral suspension required a different mobile phase from that used for the tablets. A slightly more polar mobile phase was used to resolve methylparaben from sulfamethoxazole in the oral suspension to quantitate both components accurately. The less polar mobile phase allowed faster analysis for the tablets.

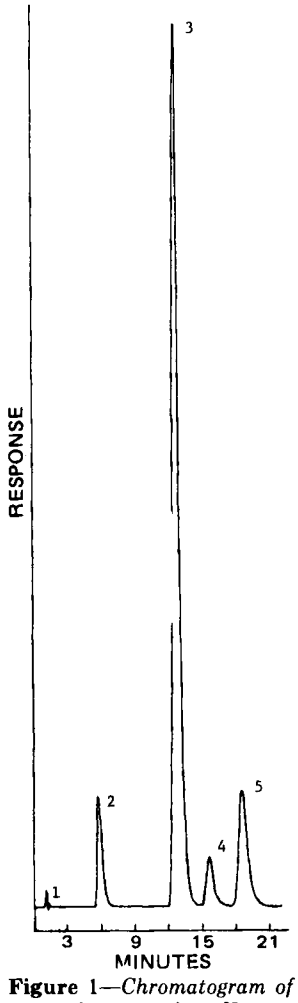

Figure 1—*Chromatogram of an oral suspension. Key: 1, solvent; 2, trimethoprim; 3, sulfamethoxazole; 4, methylparaben; and 5, phenacetin.*

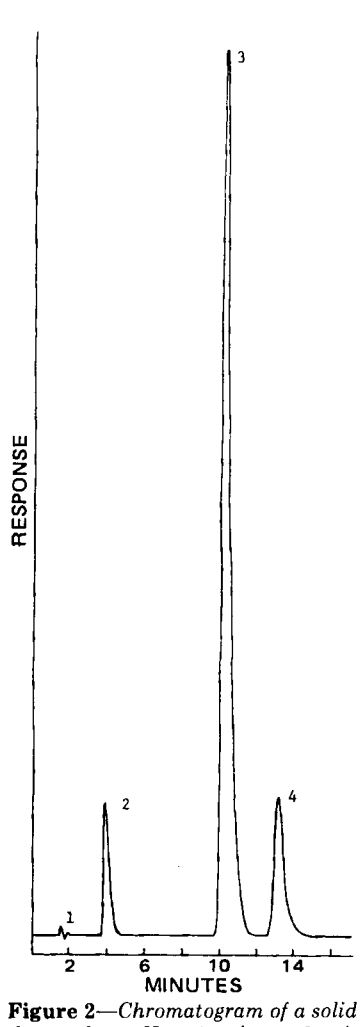

Figure 2—*Chromatogram of a solid dosage form. Key: 1, solvent; 2, trimethoprim; 3, sulfamethoxazole; and 4, phenacetin.*

An internal standard method was chosen to minimize errors resulting from both the apparatus and the injection technique. The peak exhibited by phenacetin, the internal standard, was resolved well from the peaks exhibited by trimethoprim, sulfamethoxazole, methylparaben, and the degradation products.

Linearity of the method for sulfamethoxazole and trimethoprim was determined by plotting the peak area response *versus* the concentration of each component. Peak height response was plotted *versus* concentration for the methylparaben linearity determination. Solutions containing various amounts of the component and a constant amount of the internal standard were chromatographed. The results proved that the method was linear in accordance with Beer's law.

Method reproducibility was determined by 13 consecutive injections of a standard solution equivalent to 100% of the theoretical amount of each component. The relative standard deviations were 0.16, 0.36, and 5.30%, using the peak area for sulfamethoxazole, trimethoprim, and methylparaben, respectively. The relative standard deviation for methylparaben was 0.97% using peak height measurements. Since this reproducibility is greater than that obtained using peak area, peak heights were used for the methylparaben calculations.

Each component was heat degraded in acid, base, and water. These solutions were chromatographed to show the retention times for the degradation products. Sulfamethoxazole exhibited no noticeable degradation, and trimethoprim exhibited two peaks identified as 2-amino-4-hydroxy-5-(3′,4′,5′-trimethoxybenzyl)pyrimidine and 4-amino-2-hydroxy-5-(3′,4′,5′-trimethoxybenzyl)pyrimidine. The retention times of the two degradation products using the mobile phase for solid dosage

[a] Each assay result is an average of two analyses. Samples were weighed for each analysis. The percent of the theoretical amount is the amount of active ingredient found based on the amount claimed.

forms were ~4.9 and 3.1 min, respectively. The retention times using the mobile phase for the oral suspension were ~10.0 and 4.2 min, respectively. These degradation products were identified by chromatographing standard solutions containing the impurities, the degradation solutions containing the products of interest, and degradation solutions spiked with these products and noting the retention times of the peaks. Placebos were chromatographed and showed that the excipients did not interfere.

The values obtained using the HPLC method compared favorably with those obtained using the extraction–spectrophotometric determination (Table I). In most cases, the HPLC assay gave slightly higher values than the extraction method. This difference may have been caused by a loss of sample during the extraction. In some cases, absorbing impurities or degradation products may have caused the extraction–spectrophotometric method to give a higher result than the more specific HPLC method. The HPLC assay was performed on 2 days and showed that the precision of the instrumentation and the assay reproducibility results were good. A different sample was weighed each day the assay was performed (Table II).

The HPLC method is accurate and is shorter and easier than the extraction–spectrophotometric method. In addition, the HPLC method can be automated easily using automatic samplers and laboratory computers or integrators.

Stability-Indicating Assay for Tolmetin Sodium in Solid Dosage Forms

CASIMIR A. JANICKI ˣ **and KATHERINE F. DALY** *

Received December 12, 1978, from the *Pharmacy Research Department, McNeil Laboratories, Fort Washington, PA 19034.* Accepted for publication August 22, 1979. *Present address: Instrument Products, E. I. du Pont de Nemours and Co., Wilmington, DE 19898.

Abstract □ A spectrophotometric assay for determining tolmetin sodium in pharmaceutical solid dosage forms is described. Tolmetin sodium is separated from common pharmaceutical excipients and probable degradation products. Recovery, precision, and accuracy data are provided. Two TLC methods are included which can be used to monitor qualitatively the stability of aged dosage forms.

Keyphrases □ Tolmetin sodium—stability-indicating assay, solid dosage forms □ Anti-inflammatory agents—tolmetin sodium, stability-indicating assay, solid dosage forms □ Stability—tolmetin sodium, spectrophotometric assay, solid dosage forms

Tolmetin[1] sodium [sodium 1-methyl-5-(4-methylbenzoyl)-1*H*-pyrrole-2-acetate dihydrate] was introduced commercially as an anti-inflammatory drug for the treatment of rheumatoid arthritis. Since it is a pyrrole derivative (1), it differs chemically from other anti-inflammatory agents. During the development of a suitable dosage form, a precise and accurate stability assay was needed. GLC and spectrophotometric assays were developed (2–4) to evaluate the absorption, distribution, and excretion of tolmetin sodium in human subjects. High-pressure liquid chromatographic methods were developed recently for assessing the purity of tolmetin sodium (5) and for determining tolmetin and its major metabolite in plasma (6).

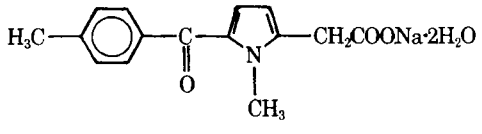
A spectrophotometric assay is described that can determine tolmetin sodium in the presence of probable degradation products and common pharmaceutical tablet and capsule excipients. Precision and accuracy data also are provided. The method is quick and simple, requires only readily available equipment, and has the specificity needed for stability studies. Two TLC methods also are included which can be used to monitor qualitatively the stability of aged dosage forms.

EXPERIMENTAL

Reagents—All reagents met ACS specifications. Reference standard tolmetin sodium[2] was used as the standard. The TLC plates were 5 × 20-cm precoated silica gel GF[3]. Commercial tolmetin sodium tablets containing the equivalent of 200 mg of tolmetin were used[2].

Standard Preparation—Tolmetin sodium reference standard, 122.6 mg (equivalent to 100.0 mg of tolmetin), was placed in a 120-ml screw-capped bottle. Water, 25 ml, was added, and the mixture was swirled. Ethylene dichloride, 50 ml, and 5 ml of 6 *N* HCl were added by pipet. The standards were analyzed as described under *Procedure*.

Procedure—At least 20 tablets were weighed and finely powdered. A portion of the powder equivalent to 100 mg of tolmetin was weighed accurately and transferred to a 120-ml screw-capped bottle. Ethylene dichloride, 50 ml, and 25 ml of 1 *N* HCl were added by pipet, and the mixture was shaken mechanically[4] for 15 min.



tolmetin sodium dihydrate

The solution was centrifuged to separate the phases and aspirated, and the aqueous layer was discarded. Five milliliters of the ethylene dichloride layer (2 mg/ml) was pipetted into a 100-ml volumetric flask, and the solution was diluted to volume with ethylene dichloride and mixed (0.1 mg/ml). Five milliliters of this solution was pipetted into a 120-ml screw-capped bottle containing exactly 50 ml of 0.1 *N* NaOH. The solution was shaken mechanically for 30 min and centrifuged. Then the sodium hydroxide layer was transferred to a clean container (0.01 mg/ml).

The UV absorption spectrum of the sample was recorded concomitantly with the reference standard in 1-cm cells, using 0.1 *N* NaOH saturated with ethylene dichloride as the blank. The percent tolmetin was calculated by:

$$\% \text{ tolmetin} = \frac{A_u}{A_s} \times \frac{C_s}{C_u} \times 100 \qquad \text{(Eq. 1)}$$

where A_u and A_s are the absorbances of the sample and standard, respectively, at the wavelength of maximum absorbance near 322 nm and C_s and C_u are the concentrations in milligrams per milliliter of the standard and sample, respectively.

Recovery—A stock solution of 24.6 mg of tolmetin sodium/ml of methanol was prepared. Two 5-ml samples were evaporated to dryness. One sample was assayed by the described procedure, and the second sample was diluted directly to the same final concentration with 0.1 *N* NaOH. Thirteen such experiments were run by five analysts.

Specificity—Twenty-five milligrams of I (*p*-toluic acid), III, IV, IX, and XI (Table I) were weighed directly into 120-ml screw-capped bottles and assayed as described.

Precision and Accuracy—An aqueous stock solution containing 1.23 mg of tolmetin sodium/ml was prepared, and 25-ml portions were assayed. The dilution was changed accordingly in the second assay step. Twelve assays were performed by six analysts.

In a second experiment, 40 tablets from a stability test program were ground to a fine powder and samples were assayed. Sixteen assays were performed by seven analysts.

Hydrolysis—Tolmetin sodium samples, 250 mg, were added to separate round-bottom flasks containing 50 ml of 1 *N* NaOH, water, or 1 *N* HCl. The samples were refluxed for 72, 72, or 24 hr, respectively.

Another sample of 615 mg of tolmetin sodium was dissolved in 500 ml of water and placed in a water-jacketed quartz immersion well and irradiated with a high-pressure mercury arc lamp for 24 hr. The resulting solutions and precipitants were assayed for intact tolmetin.

TLC—Tolmetin sodium and the 10 test compounds (Table I) were dissolved in methanol. The TLC chambers were 1.89-liter, wide-mouth Mason jars fitted with standard lids. The solvent systems were acetic acid–chloroform (5:95 v/v) (A) and *n*-butanol saturated with ammonia test solution (USP XIX) (B). For the *n*-butanol–ammonia solution, the plates were developed in preequilibrated paper-lined jars. Each plate was developed until the solvent front was ~2.5 cm from the top. The plates were air dried and viewed under short-wavelength UV light. The plates then were stained with iodine vapor. The plates also may be scanned with a densitometer[5].

RESULTS AND DISCUSSION

To determine the specificity of the assay for tolmetin sodium, I, III, IV, IX, and XI were assayed. The resulting UV spectra showed absorbance only from the sample derived from I. Since there was no interference

[a] Detection limits under UV light ranged from 0.1 to 0.5 μg.

from *p*-toluic acid from 360 to 275 nm (Fig. 1), this compound does not interfere in the tolmetin sodium assay. The other compounds either did not extract into the sodium hydroxide layer or, in the case of IV, did not have any UV absorbance.

Compound I is *p*-toluic acid, and IV is the pyrrole acetic acid fragment of the tolmetin molecule. Both compounds are probable degradation products of tolmetin sodium. Compound III is the methyl ester of tolmetin, IX is the amide of tolmetin and a precursor in tolmetin synthesis, and XI is the decarboxylated tolmetin product. Compound III was used as a model compound in the event that esterification became a degradation route.

Since the five model compounds could be considered only as possible degradation or reaction products, attempts were made to degrade tolmetin sodium. Tolmetin sodium solutions were hydrolyzed as discussed under *Experimental*. The alkaline hydrolysis solution assayed 88% for intact tolmetin sodium, while the water hydrolysis solution assayed 94%. The solution from the attempted UV light degradation assayed 82%. TLC data showed many minor degradation products, but their identification was not attempted.

The acid solution was orange and contained a violet precipitate. The acid hydrolysis mixture assayed 64% for intact tolmetin sodium. The major TLC spots were at the origin and at R_f 0.5 and 0.7 using acetic acid–chloroform. With UV and IR, the sample at R_f 0.5 was identified as tolmetin, and the spot at R_f 0.7 was *p*-toluic acid. The spot at the origin was believed to be a highly polar molecule or a species of relatively high molecular weight containing many polar groups. *N*-Methylpyrroles are known to form polymers in acidic media, which are highly colored when polymerized under aerobic conditions (7).

To demonstrate the efficiency of the tolmetin sodium extraction, an aqueous stock solution of tolmetin sodium was prepared. Five analysts assayed 13 portions of it as directed for the tablets, and other portions were diluted simultaneously with 0.1 *N* NaOH. The data (Table II) indicated essentially complete drug extraction.

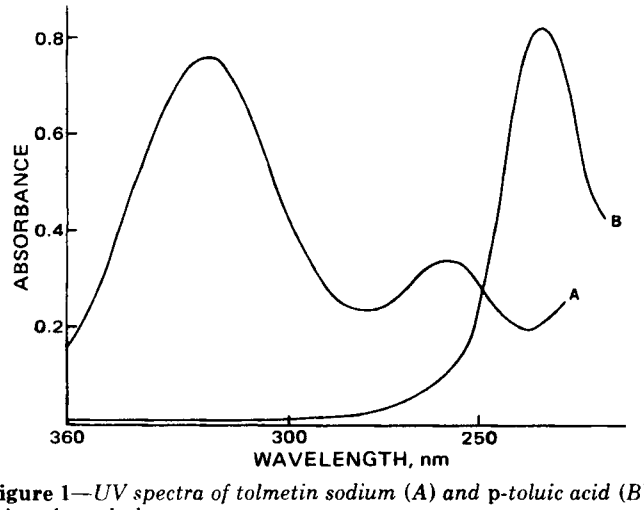

Figure 1—*UV spectra of tolmetin sodium (A) and p-toluic acid (B) taken through the assay.*

Another experiment was conducted to demonstrate the efficiency of the extraction for powdered tablet samples. Duplicate tablet powder samples were taken through the assay along with duplicate samples extracted with 25- and 75-ml samples of ethylene dichloride. The acid solution volume remained as described. The assay varied only in the dilution step with the last extraction step remaining as described. The mean of the six assays was 99.7% label with a standard deviation of 0.16.

To show that the initial extraction step in the assay did not affect tolmetin stability, reference standard tolmetin sodium was treated as described under *Experimental*, except that sufficient 12 *N* HCl was added to make the aqueous layer 3 *N* instead of 1 *N*. The solution was shaken, and samples were removed after 1 and 24 hr for TLC analysis. Using a densitometer, <0.2% degradation was determined after 1 hr and <0.8% was determined after 24 hr. Less than 0.1% degradation was detected by TLC using the method under *Procedure*.

Precision and accuracy were tested initially on an aqueous tolmetin

SD	0.47	1.07

sodium solution. The data had an accuracy of 100.2% with a standard deviation of 0.47% for the 12 assays (Table III). The experiment was conducted over 18 days. A precision study was conducted on a composite sample obtained by grinding 40 commercial tablets. The mean from the 16 assays was 99.8% over 2 months with a standard deviation of 1.07%. The data demonstrated that the method gives precise and accurate data.

Common tablet and capsule excipients such as starch, lactose, cellulose, and stearate lubricants were taken through the assay and did not interfere.

The assay was used to follow the stability of aged tablets and capsules containing up to an equivalent of 400 mg of tolmetin (490.1 mg of tolmetin sodium). Tablets were assayed for up to 5 years at room temperature and at various temperatures up to 80° for 3 months. The stability data demonstrated that the tablets and capsules were very stable. TLC was conducted on the aged samples using the two solvent mixtures. The data showed that tolmetin sodium remained intact in the dosage forms even after aging for 5 years at room temperature and accelerated aging at temperatures up to 80°. Less than 2% degradation was noted under the accelerated conditions.

Two solvent mixtures of different polarity were chosen for TLC to minimize the possibility of unresolved degradation products that could not be predicted. The compounds chosen to demonstrate the specificity of the TLC methods were, with one exception, previously postulated to be theoretical impurities in tolmetin sodium (5). The data (Table I) demonstrated that the solvent systems are suitable for separating tolmetin sodium from possible degradation products as well as theoretical impurities. Further confirmation was made on an aged tablet sample that was chromatographed and isolated from the TLC plate. The material was found to be identical to tolmetin sodium by UV, IR, and mass spectrometry.

The assay was used additionally to follow the stability of tolmetin sodium solutions buffered from pH 4.5 to 10.0 at 80°[6]. The data supported the reflux experiments, which showed that tolmetin sodium is relatively stable at neutral and alkaline pH values but unstable at acidic pH.

The data demonstrated that the method is capable of monitoring the stability of tolmetin sodium in solid dosage forms. The method is precise and accurate and utilizes common laboratory equipment. The hydrolysis experiments illustrated that tolmetin is stable under neutral and alkaline conditions but not under acidic conditions. The TLC methods can monitor qualitatively tolmetin sodium stability in aged dosage forms.

Preparation and Biological Actions of *N*-2,2,2-Trifluoroethyl-2-(3,4-dihydroxyphenyl)ethylamine

JOHN P. O'DONNELL *x, A. J. AZZARO ‡, and P. R. URQUILLA ‡

Received April 9, 1979, from the **School of Pharmacy and the* ‡*Departments of Neurology and Pharmacology, School of Medicine, West Virginia University Medical Center, Morgantown, WV 26506.* Accepted for publication August 22, 1979.

Abstract □ *N*-2,2,2-Trifluoroethyl-2-(3,4-dihydroxyphenyl)ethylamine was synthesized and compared to *N*-ethyl-2-(3,4-dihydroxyphenyl)-ethylamine and dopamine for activity on adenylate cyclase in the rat striatum. Both dopamine and *N*-ethyl-2-(3,4-dihydroxyphenyl)ethylamine stimulated adenylate cyclase activity in a dose-dependent fashion. The *N*-trifluoroethyldopamine analog at 1×10^{-4} *M* induced a weak effect. The compounds were evaluated further by studying their relaxant effects in isolated rabbit renal and ear arteries. Both the *N*-ethyl- and *N*-trifluoroethyldopamine analogs produced a relaxant effect but demonstrated no selectivity for dopamine receptors.

Keyphrases □ Adenylate cyclase activity—dopamine, *N*- and *N,N*-substituted dopamine analogs, peripheral and central dopamine receptors, isolated striata and blood vessels □ Dopamine—antiparkinson drug, adenylate cyclase activity, dopamine analogs □ *N*-Ethyl-2-(3,4-dihydroxyphenyl)ethylamine—dopamine analog, adenylate cyclase activity □ *N*-2,2,2-Trifluoroethyl-2-(3,4-dihydroxyphenyl)ethylamine—dopamine analog, adenylate cyclase activity

The treatment of parkinsonism with levodopa has beneficial effects; however, in some patients with severely impaired dopaminergic neurons, the use of levodopa may be ineffective because the tissue cannot perform the necessary enzymatic decarboxylation to form dopamine (1, 2). An effort to generate new dopaminergic drugs for parkinsonism led to the synthesis of *N*- and *N,N*-substituted dopamine analogs (3–9). The binding of simple dopaminergic ligands to the receptor appears to be independent of substitution on the nitrogen (5). Unlike dopamine, the *N*- and *N,N*-substituted dopamine analogs cross the blood–brain barrier (3, 4). In addition, these agents are resistant to deamination by monoamine oxidase since they are secondary and tertiary amines. Moreover, these *N*- and *N,N*-substituted dopamine analogs act in the central nervous system as direct acting dopamine receptor agonists and, therefore, are independent of prejunctional dopaminergic mechanisms (4, 8).

To improve absorption and distribution of the *N*-alkyl-substituted dopamine analogs, *N*-2,2,2-trifluoroethyl-2-(3,4-dihydroxyphenyl)ethylamine (I) was prepared. The 2,2,2-trifluoroethyl group is well suited to replace the ethyl group because of similar steric properties and because the fluorine atom increases both lipid solubility and membrane penetration.

The agonistic properties of I, *N*-ethyl-2-(3,4-dihy-

sodium solution. The data had an accuracy of 100.2% with a standard deviation of 0.47% for the 12 assays (Table III). The experiment was conducted over 18 days. A precision study was conducted on a composite sample obtained by grinding 40 commercial tablets. The mean from the 16 assays was 99.8% over 2 months with a standard deviation of 1.07%. The data demonstrated that the method gives precise and accurate data.

Common tablet and capsule excipients such as starch, lactose, cellulose, and stearate lubricants were taken through the assay and did not interfere.

The assay was used to follow the stability of aged tablets and capsules containing up to an equivalent of 400 mg of tolmetin (490.1 mg of tolmetin sodium). Tablets were assayed for up to 5 years at room temperature and at various temperatures up to 80° for 3 months. The stability data demonstrated that the tablets and capsules were very stable. TLC was conducted on the aged samples using the two solvent mixtures. The data showed that tolmetin sodium remained intact in the dosage forms even after aging for 5 years at room temperature and accelerated aging at temperatures up to 80°. Less than 2% degradation was noted under the accelerated conditions.

Two solvent mixtures of different polarity were chosen for TLC to minimize the possibility of unresolved degradation products that could not be predicted. The compounds chosen to demonstrate the specificity of the TLC methods were, with one exception, previously postulated to be theoretical impurities in tolmetin sodium (5). The data (Table I) demonstrated that the solvent systems are suitable for separating tolmetin sodium from possible degradation products as well as theoretical impurities. Further confirmation was made on an aged tablet sample that was chromatographed and isolated from the TLC plate. The material was found to be identical to tolmetin sodium by UV, IR, and mass spectrometry.

The assay was used additionally to follow the stability of tolmetin sodium solutions buffered from pH 4.5 to 10.0 at 80°[6]. The data supported the reflux experiments, which showed that tolmetin sodium is relatively stable at neutral and alkaline pH values but unstable at acidic pH.

The data demonstrated that the method is capable of monitoring the stability of tolmetin sodium in solid dosage forms. The method is precise and accurate and utilizes common laboratory equipment. The hydrolysis experiments illustrated that tolmetin is stable under neutral and alkaline conditions but not under acidic conditions. The TLC methods can monitor qualitatively tolmetin sodium stability in aged dosage forms.

Preparation and Biological Actions of *N*-2,2,2-Trifluoroethyl-2-(3,4-dihydroxyphenyl)ethylamine

JOHN P. O'DONNELL *x, A. J. AZZARO ‡, and P. R. URQUILLA ‡

Received April 9, 1979, from the **School of Pharmacy and the* ‡*Departments of Neurology and Pharmacology, School of Medicine, West Virginia University Medical Center, Morgantown, WV 26506.* Accepted for publication August 22, 1979.

Abstract □ *N*-2,2,2-Trifluoroethyl-2-(3,4-dihydroxyphenyl)ethylamine was synthesized and compared to *N*-ethyl-2-(3,4-dihydroxyphenyl)-ethylamine and dopamine for activity on adenylate cyclase in the rat striatum. Both dopamine and *N*-ethyl-2-(3,4-dihydroxyphenyl)ethylamine stimulated adenylate cyclase activity in a dose-dependent fashion. The *N*-trifluoroethyldopamine analog at 1×10^{-4} *M* induced a weak effect. The compounds were evaluated further by studying their relaxant effects in isolated rabbit renal and ear arteries. Both the *N*-ethyl- and *N*-trifluoroethyldopamine analogs produced a relaxant effect but demonstrated no selectivity for dopamine receptors.

Keyphrases □ Adenylate cyclase activity—dopamine, *N*- and *N,N*-substituted dopamine analogs, peripheral and central dopamine receptors, isolated striata and blood vessels □ Dopamine—antiparkinson drug, adenylate cyclase activity, dopamine analogs □ *N*-Ethyl-2-(3,4-dihydroxyphenyl)ethylamine—dopamine analog, adenylate cyclase activity □ *N*-2,2,2-Trifluoroethyl-2-(3,4-dihydroxyphenyl)ethylamine—dopamine analog, adenylate cyclase activity

The treatment of parkinsonism with levodopa has beneficial effects; however, in some patients with severely impaired dopaminergic neurons, the use of levodopa may be ineffective because the tissue cannot perform the necessary enzymatic decarboxylation to form dopamine (1, 2). An effort to generate new dopaminergic drugs for parkinsonism led to the synthesis of *N*- and *N,N*-substituted dopamine analogs (3–9). The binding of simple dopaminergic ligands to the receptor appears to be independent of substitution on the nitrogen (5). Unlike dopamine, the *N*- and *N,N*-substituted dopamine analogs cross the blood–brain barrier (3, 4). In addition, these agents are resistant to deamination by monoamine oxidase since they are secondary and tertiary amines. Moreover, these *N*- and *N,N*-substituted dopamine analogs act in the central nervous system as direct acting dopamine receptor agonists and, therefore, are independent of prejunctional dopaminergic mechanisms (4, 8).

To improve absorption and distribution of the *N*-alkyl-substituted dopamine analogs, *N*-2,2,2-trifluoroethyl-2-(3,4-dihydroxyphenyl)ethylamine (I) was prepared. The 2,2,2-trifluoroethyl group is well suited to replace the ethyl group because of similar steric properties and because the fluorine atom increases both lipid solubility and membrane penetration.

droxyphenyl)ethylamine, and dopamine at central and peripheral dopamine receptors were analyzed pharmacologically. These studies measured the effects of each agent on the activity of dopamine-sensitive adenylate cyclase in rat neostriatum and evaluated their relaxant effects on isolated rabbit renal and ear arteries.

EXPERIMENTAL

Chemistry[1]—*N-Trifluoroacetyl -2- (3,4-dimethoxyphenyl)ethylamine (III)*—Trifluoroacetic anhydride (20 ml, 0.129 mole) was added very slowly, with stirring, to 20 g (0.115 mole) of 2-(3,4-dimethoxyphenyl)ethylamine. The resulting glassy solid was allowed to set overnight. Trituration of the solid mass with water gave a white suspension, which was filtered and washed with water. The crude amide was recrystallized from benzene–hexane to afford 27.4 g (86%), mp 84°; IR (neat): 1715 cm^{-1} (C=O); NMR ($CDCl_3$): δ 2.60–3.70 (m, 4H, CH_2), 3.84 (s, 6H, OCH_3), and 6.60–6.80 (m, 3H, 3 aromatic H).

Anal.—Calc. for $C_{12}H_{14}F_3NO_3$: C, 51.99; H, 5.08; N, 5.05. Found: C, 51.89; H, 5.11; N, 5.04.

N-(2,2,2-Trifluoroethyl) -2- (3,4-dimethoxyphenyl)ethylamine (IV)—To an ice-chilled mixture of tetrahydrofuran (100 ml) and 27.4 g of III (0.999 mole) was added slowly, with stirring, 233 ml (0.23 mole) of 1 *M* diborane in tetrahydrofuran[2] under nitrogen. The resulting mixture was stirred at 0° for 1 hr and then refluxed for 12 hr. The reaction mixture again was cooled to 0°, 50 ml of water was added, and the volatiles were removed from the reaction mixture. The residue was taken up in water and extracted three times with chloroform. The combined chloroform extracts were dried over magnesium sulfate and filtered, and the filtrate was treated with anhydrous hydrochloric acid. The volatiles were again removed, and the residue was recrystallized from ether to afford 27.8 g (90%) of crystals, mp 208°; NMR (free base) ($CDCl_3$): δ 2.50–3.45 (m, 6H, CH_2), 3.85 (s, 6H, OCH_3), and 6.68 (s, 3H, aromatic H).

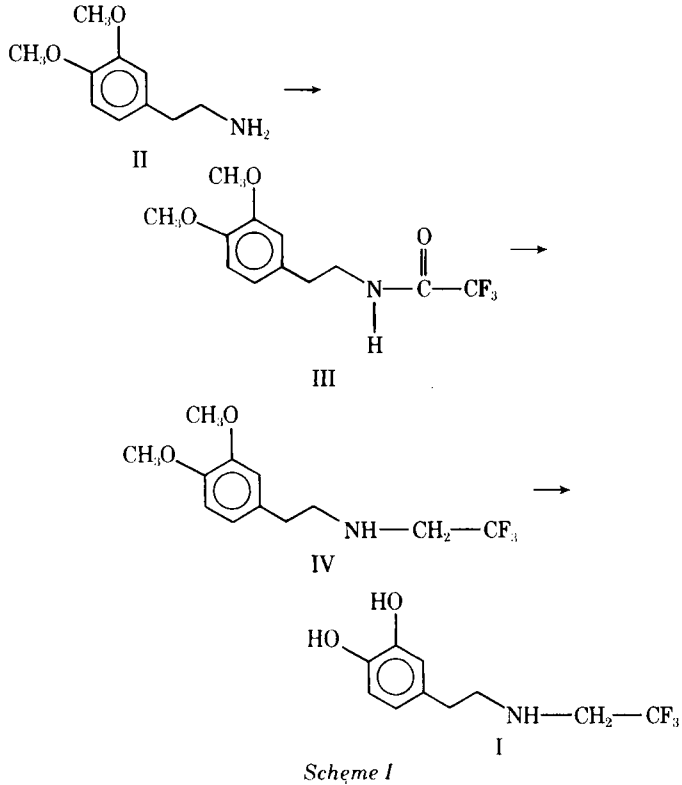
Anal.—Calc. for $C_{12}H_{17}ClF_3NO_2$: C, 48.25; H, 5.39; N, 4.69. Found: C, 48.27; H, 5.48; N, 4.63.

N-(2,2,2-Trifluoroethyl)-2-(3,4-dihydroxyphenyl)ethylamine (I)—Compound IV (3.0 g, 0.01 mole) was dissolved in 48% HBr (20 ml). The system was flushed with nitrogen for 0.25 hr and then heated to 150° for 2 hr. Excess acid was removed under reduced pressure to give a residue. Two recrystallizations from isopropyl alcohol–ether afforded 2.12 g (70%) of product, mp 179–180°. The pKa of I was determined by titration (10); IR (KBr): 3250 cm^{-1} (broad, OH); NMR (D_2O): δ 2.60–4.20 (m, 6H, CH_2) and 6.62–6.80 (m, aromatic H).

Anal.—Calc. for $C_{10}H_{13}BrF_3NO_2$: C, 37.99; H, 4.11; N, 4.28. Found: C, 37.95; H, 4.22; N, 4.41.

Adenylate Cyclase Activity—Adult male Sprague–Dawley rats[3], 200–250 g, were decapitated, and their brains were removed rapidly and placed in ice-cold saline. Each corpus striatum was dissected in the cold, as described by Glowinski and Iverson (11), and placed in ice-cold pH 7.4 Krebs–Henseleit bicarbonate buffer. A cell-free striatal homogenate was prepared in 25 volumes (w/v) of 2 m*M* tris(hydroxymethyl)aminomethane maleate buffer (pH 7.4) containing 2 m*M* edetic acid (ethylenediaminetetraacetic acid) using a polytef–glass tissue homogenizer[4]. Aliquots (50 μl) of this cell-free homogenate were assayed for adenylate cyclase activity using the procedure of Kebabian *et al.* (12). 3-Isobutyl-1-methylxanthine[5] (1 m*M*) was used to inhibit phosphodiesterase activity. A 25-μl aliquot of each sample was assayed for cyclic AMP content by the method of Gilman (13) as modified by Tovey *et al.* (14).

A wide concentration range (*i.e.*, 10^{-7}–10^{-3} *M*) of dopamine and of each experimental agent was tested for striatal adenylate cyclase activity. Haloperidol[6] was dissolved in propylene glycol–3 *N* HCl. The haloperidol solution was adjusted to pH 7.4 and brought to 50 ml with normal saline. In experiments where haloperidol was employed, an equal volume of the vehicle used to dissolve haloperidol was added to samples without haloperidol.



Scheme I

Statistical analysis to determine differences between sample means was performed using the Student *t* test or the Student *t* test for paired sample comparisons (15).

Isolated Rabbit Renal and Ear Arteries—Albino rabbits, 3–4 kg, were killed by air embolism, and the left renal artery and the central ear arteries were removed carefully. Two cylindrical segments (5 mm × 0.5 mm o.d.) were taken from each artery. The cylinders were set up for isometric recording of tension changes in the manner described for cerebral vessels (16, 17). The recording system included a polygraph[7] and force-displacement transducer[8]. A resting tension of 0.5 g was applied to the tissue and readjusted every 15 min during the initial 1-hr equilibration. The organ bath (pH 7.3–7.4) contained 10 ml of Krebs–Henseleit buffer continuously bubbled with 95% O_2–5% CO_2 and maintained at 37°. Edetic acid (30 m*M*) was added to minimize oxidation of dopamine and its analogs. Solutions of dopamine and its analogs were prepared in saline containing 0.01% (w/v) ascorbic acid.

To avoid possible concomitant activation of α- and β-adrenergic receptors by dopamine and the test compounds, the experiments were carried out in tissues pretreated with 29 m*M* phenoxybenzamine for 0.5 hr and in the presence of propranolol (3.4×10^{-7} *M*). Since phenoxybenzamine also has been reported (18) to inhibit neuronal uptake of catecholamines, its use in this study might have the additional advantage of preventing dopamine diversion from the receptor region toward the adrenergic nerve endings.

Active development of tension to 0.99 ± 0.089 g (mean ± *SEM*) was induced with 28–38 m*M* KCl. At the plateau level of the response to potassium chloride, dopamine and its analogs were added in increasing concentrations (*i.e.*, 10^{-7}–10^{-4} *M*) to the tissue segment, while the other segment served as a control to check for a decline of the plateau tension that might have occurred with time. Only one analog was tested in each segment. The plateau tension was stable, and no correction of the changes observed with dopamine was necessary. Dose–response curves for sodium nitrite also were determined in both arteries to assess vascular relaxation independently of the dopaminergic mechanism.

DISCUSSION

N-(2,2,2-Trifluoroethyl)-2-(3,4-dihydroxyphenyl)ethylamine (I) was prepared according to Scheme I. 2-(3,4-Dimethoxyphenyl)ethylamine (II) was reacted with trifluoroacetic anhydride to form the amide III, which was reduced with diborane to give the amide IV. The methyl ethers

[1] Melting points were determined in open glass capillaries using a Thomas-Hoover Uni-Melt apparatus and are uncorrected. IR absorption spectra were recorded on a Beckman model 18A spectrophotometer on liquid films or as potassium bromide pellets. NMR spectra were recorded on a Varian T-60 spectrometer with tetramethylsilane as the internal standard. Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tenn.

Sodium nitrite	45.5 ± 2.1	89.1 ± 1.6	1.9	4

[a] Values are means ± *SEM*.

of IV were cleaved with hydrobromic acid. *N*-Ethyl-2-(3,4-dihydroxyphenyl)ethylamine (V) was prepared in an analogous procedure and also was evaluated for biological activity as a structural comparison to I.

One problem in characterizing dopaminergic activity in isolated blood vessels is the lack of a specific dopamine antagonist. Recent work (19) demonstrated that typical dopamine antagonists cannot be used to characterize peripheral dopamine activity in isolated vessels. In contrast, the induced vasodilator activity in dogs may be attenuated selectively by butyrophenone and phenothiazine neuroleptic agents (20). An alternative to the lack of vascular specificity and a specific dopamine antagonist is the use of two vascular preparations with different sensitivities to dopamine (19). The ED_{40} values and the ratios of rabbit ear arteries to renal arteries for dopamine and analogs are presented in Table I. The ED_{40} was selected because certain dopamine analogs at doses above the ED_{40} demonstrated contractile effects. A comparison of the relaxation ratio in the very responsive renal artery *versus* the less responsive ear artery for dopamine and the specific renal dopamine agonist, 6,7-dihydroxy-2-aminotetrahydronaphthalene (21), gave a similar ratio for dopamine receptor agonist activity. A nonspecific relaxant, sodium nitrite, has a similar potency on both vessels. Since the effect of I and V was comparable to that of sodium nitrite, these compounds demonstrated no specific activity.

The activity of dopamine-sensitive adenylate cyclase in rat neostriatum is a useful biochemical measure of the effectiveness of agents as agonists or antagonists at central dopamine receptors (3, 22–24). Agents that act as dopamine receptor agonists stimulate striatal adenylate cyclase activity (12). In addition, dopamine receptor antagonists attenuate the stimulating effect of dopamine or other dopamine receptor agonists on striatal adenylate cyclase activity.

Dopamine, I, and V were tested for their ability to enhance adenylate cyclase activity in rat corpus striatum (Table II). Dopamine and V stimulated the adenylate cyclase activity in a dose-dependent fashion. In this regard, both agents were similar in potency. Compound I induced only a weak stimulating effect on adenylate cyclase at $1 \times 10^{-4} M$.

To determine the specificity of dopamine and V on adenylate cyclase activity, both agents were tested in the presence of haloperidol, a dopamine receptor antagonist (12, 25, 26). Haloperidol ($10^{-4} M$) did not alter the control level of adenylate cyclase activity (Fig. 1). However, haloperidol completely attenuated the stimulating action of dopamine and *N*-ethyldopamine on striatal adenylate cyclase. Although not shown here, the weak stimulation of adenylate cyclase activity by I ($10^{-4} M$) was attenuated completely by haloperidol ($10^{-4} M$).

Table II—Adenylate Cyclase Activity in Striatal Homogenates [a]

Agent	Concentration, μM	Cyclic AMP[b], pmoles above control	Percent of Control
Dopamine	10	3.6 ± 2.4	105
	100	28.8 ± 3.9[c]	138
	1000	33.8 ± 6.3[c]	144
Compound V	10	13.0 ± 5.4[c]	117
	100	23.3 ± 4.5[c]	131
	1000	27.6 ± 4.3[c]	137
Compound I	10	7.4 ± 4.8	108
	100	11.7 ± 3.0[c]	113
	1000	−0.8 ± 3.4	99

[a] Cell-free homogenates of rat corpus striatum were assayed for adenylate cyclase activity by measuring the conversion of ATP (0.5 m*M*) to cyclic AMP. [b] Mean ± *SEM* of six to eight experiments. Controls for each agent were as follows: dopamine, 76.7 ± 5.2 pmoles/mg/2.5 min; V, 75.3 ± 8.1 pmoles/mg/2.5 min; and I, 89.7 ± 5.1 pmoles/mg/2.5 min. [c] $p < 0.05$ as compared to control.

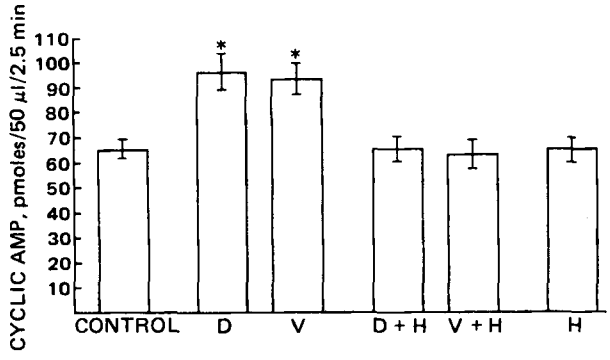

Figure 1—*Effect of haloperidol (H) (10^{-4} M) on the dopamine (D) and Compound V stimulation of adenylate cyclase in striatal homogenates. Cell-free homogenates of rat corpus striata were assayed for adenylate cyclase activity. Each value for cyclic AMP represents the mean* ± SEM *of five experiments. A concentration of 1×10^{-4} M dopamine or V was used to stimulate adenylate cyclase activity (* = $p < 0.05$ with respect to control).*

These results show that even if I would demonstrate improved absorption and distribution characteristics, it cannot stimulate adenylate cyclase. However, V stimulated adenylate cyclase but to a lesser degree than dopamine. These findings were unexpected due to the close structural similarity of I to V. An explanation for the lack of dopaminergic activity may be attempted by comparing the ionization ratios of the amine groups. The amine groups of dopamine (10) and V have pKa values of 9.74 and 10.61, respectively. Compound I has a pKa value of 5.10. Thus, altering the alkyl substitution by replacement of the protons with the electronegative fluorine atoms changes the ratio at physiological pH from the zwitterion to predominantly the uncharged species, in contrast to dopamine and V at physiological pH, at which the predominant species is the phenolic ammonium salt.

It was proposed recently (10) that the active species at dopamine receptors may be the neutral uncharged form of dopamine. The limited data of this study suggest that the activity of dopaminergic agonists may depend on the ability of the dopamine ligand to undergo readily an equilibrium transformation on the receptor between the zwitterion and the uncharged species.

High-Performance Liquid Chromatographic Analysis of Codeine in Syrups Using Ion-Pair Formation

E. J. KUBIAK and J. W. MUNSON ˣ

Received July 25, 1979, from *Quality Control, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication September 13, 1979.

Abstract □ The chromatographic behavior of morphine, codeine, and ethylmorphine was examined using reversed-phase high-performance liquid chromatography and ion-pair formation. Alkyl sulfonates and sulfates significantly increased the retention times for these compounds. The carbon chain length of the pairing ions was linearly related to the log of the capacity factors of these amine drugs. A mechanism for the increased retention based on ion-pair formation in the mobile phase is proposed. The use of dioctyl sodium sulfosuccinate as a pairing ion for codeine is described, and a method utilizing this pairing ion was developed for the quantitation of codeine in syrups. This method was applied successfully to various syrups containing codeine or codeine phosphate.

Keyphrases □ Codeine—analysis, high-performance liquid chromatography, ion-pair formation, effect of carbon chain length of pairing ions, syrups □ Ethylmorphine—analysis, high-performance liquid chromatography, ion-pair formation, effect of carbon chain length of pairing ions □ Morphine—analysis, high-performance liquid chromatography, ion-pair formation, effect of carbon chain length of pairing ions □ High-performance liquid chromatography, ion-pair formation—analysis of codeine, ethylmorphine, and morphine, effect of carbon chain length of pairing ion

The use of ion-pair formation to enhance retention time is becoming popular in reversed-phase high-performance liquid chromatography (HPLC). The counterions used to form ion-pairs generally are detergents such as alkyl sulfates and sulfonates or tetraalkylammonium salts. Anionic surfactants (sulfates and sulfonates) generally are used to form ion-pairs with cationic eluates, and cationic tetraalkylammonium salts are used with anionic eluates. By formation of the ion-pair, the apparent polarity of the eluate is decreased, leading to increased retention times in reversed-phase HPLC.

Since many drugs contain either acidic or basic functional groups, pH conditions can be chosen such that numerous drugs will form ion-pairs with these surfactants. The surfactant molecule often is referred to as the pairing ion, which gives rise to the term ion-pair HPLC. While ion-pair formation can be used in normal-phase HPLC, it is used more widely in reversed-phase HPLC. This technique also has been called soap chromatography (1, 2) because of the surfactants used.

BACKGROUND

The mechanism of retention enhancement has been attributed to two phenomena. The original concept closely follows classical ion-pair extraction techniques in which two oppositely charged molecules form an ion-pair in an aqueous solution and then partition as a complex into a nonpolar organic solvent. In the chromatographic analog of this concept, the analyte forms a complex with a pairing ion added to the mobile phase. The complex then partitions into the stationary phase (nonpolar), thus accounting for the increased analyte retention. An alternative mechanism suggests that the pairing ion first binds to the stationary phase to form an ion-exchanging surface due to the adsorbed charged pairing ions (3). Complex formation at the surface of the stationary phase thus is responsible for the increased analyte retention. Recently, application of solvophobic theory to a reversed-phase ion-pair chromatographic study led to the conclusion that the retention of the analyte involves ion-pair formation in the mobile phase and subsequent partitioning of the neutral complex to the stationary phase (4).

Codeine analysis by HPLC has been of interest. An early study (5) utilized columns of pellicular silica gel coated with polyethylene glycol 300 with an ethanol–heptane (1:10) mobile phase saturated with the stationary phase. In this system, codeine was well resolved from morphine, thebaine, and papaverine. However, quantitative codeine analysis at levels near 3 μg gave a relative error of ~9%. In a study of the liquid chromatographic behavior of alkaloids, the retention times of codeine and morphine on a microparticulate silica column were measured (6). Codeine eluted slightly before morphine with mobile phases of chloroform–methanol (three volume ratios) and ether–methanol (three volume ratios).

The quantification of morphine, codeine, and thebaine was accomplished by isocratic reversed-phase HPLC (7). With a microparticulate (10-μm) octadecylsilane column and a mobile phase of 0.1 *N* monobasic sodium phosphate in 25% acetonitrile–water, codeine in gum opium was measured with a relative standard deviation of 1.3%. Codeine also was separated from other opium alkaloids using a pellicular silica column and

High-Performance Liquid Chromatographic Analysis of Codeine in Syrups Using Ion-Pair Formation

E. J. KUBIAK and J. W. MUNSON ˣ

Received July 25, 1979, from *Quality Control, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication September 13, 1979.

Abstract □ The chromatographic behavior of morphine, codeine, and ethylmorphine was examined using reversed-phase high-performance liquid chromatography and ion-pair formation. Alkyl sulfonates and sulfates significantly increased the retention times for these compounds. The carbon chain length of the pairing ions was linearly related to the log of the capacity factors of these amine drugs. A mechanism for the increased retention based on ion-pair formation in the mobile phase is proposed. The use of dioctyl sodium sulfosuccinate as a pairing ion for codeine is described, and a method utilizing this pairing ion was developed for the quantitation of codeine in syrups. This method was applied successfully to various syrups containing codeine or codeine phosphate.

Keyphrases □ Codeine—analysis, high-performance liquid chromatography, ion-pair formation, effect of carbon chain length of pairing ions, syrups □ Ethylmorphine—analysis, high-performance liquid chromatography, ion-pair formation, effect of carbon chain length of pairing ions □ Morphine—analysis, high-performance liquid chromatography, ion-pair formation, effect of carbon chain length of pairing ions □ High-performance liquid chromatography, ion-pair formation—analysis of codeine, ethylmorphine, and morphine, effect of carbon chain length of pairing ion

The use of ion-pair formation to enhance retention time is becoming popular in reversed-phase high-performance liquid chromatography (HPLC). The counterions used to form ion-pairs generally are detergents such as alkyl sulfates and sulfonates or tetraalkylammonium salts. Anionic surfactants (sulfates and sulfonates) generally are used to form ion-pairs with cationic eluates, and cationic tetraalkylammonium salts are used with anionic eluates. By formation of the ion-pair, the apparent polarity of the eluate is decreased, leading to increased retention times in reversed-phase HPLC.

Since many drugs contain either acidic or basic functional groups, pH conditions can be chosen such that numerous drugs will form ion-pairs with these surfactants. The surfactant molecule often is referred to as the pairing ion, which gives rise to the term ion-pair HPLC. While ion-pair formation can be used in normal-phase HPLC, it is used more widely in reversed-phase HPLC. This technique also has been called soap chromatography (1, 2) because of the surfactants used.

BACKGROUND

The mechanism of retention enhancement has been attributed to two phenomena. The original concept closely follows classical ion-pair extraction techniques in which two oppositely charged molecules form an ion-pair in an aqueous solution and then partition as a complex into a nonpolar organic solvent. In the chromatographic analog of this concept, the analyte forms a complex with a pairing ion added to the mobile phase. The complex then partitions into the stationary phase (nonpolar), thus accounting for the increased analyte retention. An alternative mechanism suggests that the pairing ion first binds to the stationary phase to form an ion-exchanging surface due to the adsorbed charged pairing ions (3). Complex formation at the surface of the stationary phase thus is responsible for the increased analyte retention. Recently, application of solvophobic theory to a reversed-phase ion-pair chromatographic study led to the conclusion that the retention of the analyte involves ion-pair formation in the mobile phase and subsequent partitioning of the neutral complex to the stationary phase (4).

Codeine analysis by HPLC has been of interest. An early study (5) utilized columns of pellicular silica gel coated with polyethylene glycol 300 with an ethanol–heptane (1:10) mobile phase saturated with the stationary phase. In this system, codeine was well resolved from morphine, thebaine, and papaverine. However, quantitative codeine analysis at levels near 3 μg gave a relative error of ~9%. In a study of the liquid chromatographic behavior of alkaloids, the retention times of codeine and morphine on a microparticulate silica column were measured (6). Codeine eluted slightly before morphine with mobile phases of chloroform–methanol (three volume ratios) and ether–methanol (three volume ratios).

The quantification of morphine, codeine, and thebaine was accomplished by isocratic reversed-phase HPLC (7). With a microparticulate (10-μm) octadecylsilane column and a mobile phase of 0.1 *N* monobasic sodium phosphate in 25% acetonitrile–water, codeine in gum opium was measured with a relative standard deviation of 1.3%. Codeine also was separated from other opium alkaloids using a pellicular silica column and

gradient elution with hexane and chloroform–methanol–diethylamine (400:300:1) (8). This methodology was applied to the analysis of morphine, cryptopine, thebaine, papaverine, codeine, and noscapine in opium (9).

The liquid chromatographic behavior of opium alkaloids using ion-pairing reagents in the mobile phase has been studied. With a microparticulate (10-μm) octadecylsilane column and a mobile phase of 0.005 *M* *n*-heptanesulfonic acid in methanol–water (40:60), several morphinan derivatives were separated (10). In this system, morphine eluted before codeine. Mixtures of morphine, codeine, thebaine, noscapine, and papaverine were separated with a similar chromatographic system (11). Codeine also was analyzed in liquid dosage forms with an octadecylsilane (10-μm) column and a water–methanol (87:13) mobile phase containing 0.05 *M* dibasic potassium phosphate (12). With this system, codeine was analyzed in the presence of guaifenesin, pheniramine maleate, phenylpropanolamine hydrochloride, and pyrilamine maleate.

This paper describes the effects of the carbon chain length of the pairing ion on the capacity factors for codeine, morphine, and ethylmorphine. Mechanisms are proposed to account for the retention of these compounds in reversed-phase ion-pair HPLC. The properties of dioctyl sodium sulfosuccinate as a pairing ion for codeine are described. An HPLC method for codeine syrups that requires minimum sample treatment is presented.

EXPERIMENTAL

Materials—Methanesulfonic acid[1], ethanesulfonic acid[1], sodium butanesulfonate[1], sodium hexanesulfonate[1], sodium hexanesulfate[1], sodium octanesulfonate[1], sodium decylsulfate[1], sodium dodecylsulfate[1], sodium tetradecylsulfonate[2], sodium tetradecylsulfate[1], sodium hexadecylsulfate[1], dioctyl sodium sulfosuccinate[3], codeine *N*-oxide[4], morphine hydrochloride[5], codeine phosphate[5], and ethylmorphine hydrochloride[5] were used as received.

Distilled-in-glass acetonitrile[6] and deionized water were used for all mobile phase preparations. The internal standard, diphenylamine, also was used as received. All other chemicals were reagent grade. Codeine syrups were obtained from a local drug wholesale distributor.

Apparatus—The modular high-performance liquid chromatograph consisted of a reciprocating piston pump equipped with a pulse dampener[7], an automated loop injector[8], a UV detector[9] (254 nm), and a recorder[10]. For quantitative measurements, data were collected and processed by a digital computer[11].

Mobile Phase—All mobile phases contained 0.005 *M* pairing ion and 0.01 *M* ammonium nitrate in acetonitrile–water (375:625). After mixing, the mobile phases were adjusted to pH 3.3 with acetic acid and filtered through a 5-μm filter. (Considerable foaming was observed with most mobile phases upon filtration.)

Columns—A microparticulate octadecylsilane column[12] (10 μm, 30 cm × 4 mm) and a microparticulate octasilane column[13] (10 μm, 25 cm × 4.6 mm) were obtained commercially. When not in use, these columns were flushed with acetonitrile–water (80:20) and stored in the same solvent. Flow rates of 2–3 ml/min gave adequate resolution with reasonable analysis time.

Quantitation of Codeine in Syrups—*Internal Standard Method*—Exactly 5.0 ml of the syrup was transferred quantitatively to a 125-ml erlenmeyer flask containing 40.0 ml of the internal standard solution (diphenylamine, 0.05 mg/ml in the mobile phase). After thorough mixing, 25-μl aliquots were chromatographed with a detector setting of 0.032 aufs. Concentrations were determined by comparison of the peak height ratios from sample preparations to those from a standard preparation (USP codeine phosphate reference standard).

External Standard Method—Exactly 5.0 ml of the syrup was added to 40.0 ml of the mobile phase and chromatographed in the same manner as the internal standard method. Concentrations were calculated by comparison of the peak heights of the codeine peaks.

RESULTS AND DISCUSSION

In preliminary studies, nitrate ions (as ammonium or sodium salts) significantly improved the peak shape and reduced tailing. This effect possibly was due to occupation of uncoated sites on the solid support

material by the nitrate ions. Consequently, all mobile phase solutions contained 0.01 *M* ammonium nitrate. The mobile phase pH was adjusted to 3.3 to ensure that the amines would be protonated.

The effects of the carbon chain length of the pairing ion on the capacity factors of morphine, codeine, and ethylmorphine are shown in Fig. 1. Relatively minor effects were observed as the chain length was increased to eight carbons (octanesulfonate). Above this point, the capacity factors increased dramatically as the chain length was increased. The elution order for all systems was morphine, codeine, and ethylmorphine. This order is consistent with the polarity of the substitution on the aromatic ring (hydroxy, methoxy, and ethoxy, respectively). The shape of this curve suggests that the capacity factors are related logarithmically to the number of carbons in the pairing ions.

A plot of the log of the capacity factors of morphine, codeine, and ethylmorphine *versus* the carbon chain length of the pairing ion is shown in Fig. 2 (octadecylsilane column). A similar plot is shown in Fig. 3 for the octasilane column. The slopes of both plots are similar. The distinct break between the two linear portions of the curve suggests that two mechanisms may be operative in analyte retention.

Two distinct ion-pair mechanisms can be postulated to explain the behavior shown in Figs. 2 and 3. The first mechanism involves ion-pair formation in the mobile phase with subsequent partitioning into the stationary phase. This process is outlined in Scheme I, where D^+ is the protonated form of the amine drug, A^- is the anionic form of the pairing ion, and DA is the charge neutralized ion-pair:

$$D^+_M + A^-_M \rightleftharpoons DA_M$$

$$DA_M \rightleftharpoons DA_S$$

Scheme I

The subscripts *M* and *S* refer to the species in the mobile phase and the stationary phase, respectively.

The second mechanism, dynamic ion exchange, involves adsorption of the pairing ion onto the stationary phase surface followed by ion-pair formation at the interface (Scheme II):

$$A^-_M \rightleftharpoons A^-_S$$

$$A^-_S + D^+_M \rightleftharpoons DA_S$$

Scheme II

If the first mechanism is operative, one would expect the capacity factor to increase as the pairing-ion size increases. The increased chain length of the pairing ion should cause an increase in the hydrophobicity of the complex, thus favoring partitioning into the stationary phase. The portions of the curves in Figs. 2 and 3 that lie above a chain length of eight carbons show this behavior. This portion of the curve shows that each two additional methylene groups in the pairing ion increase the capacity by a factor of 2.2 (for the octadecylsilane column). This increase is in good agreement with the predicted value of 2.5 obtained from consideration of enhancement factors in a study of chromatographic retention of catecholamines paired with alkyl sulfates (4). In the same study, solvophobic theory was employed to deduce that ion-pair formation in the mobile phase was the primary mechanism for analyte retention.

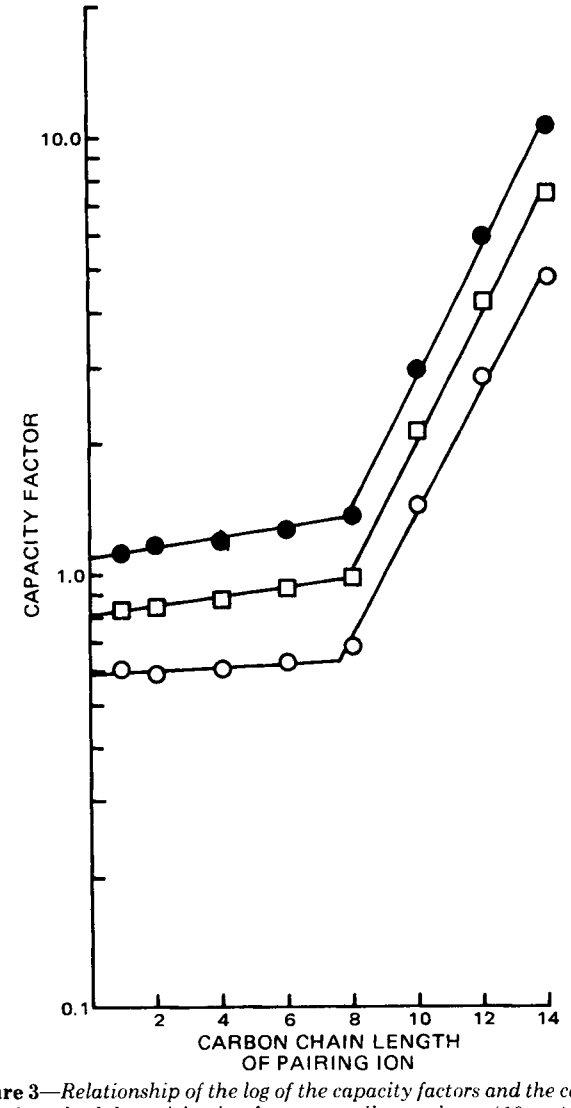

Figure 3—*Relationship of the log of the capacity factors and the carbon chain length of the pairing ion for an octasilane column (10 μm). Key:* ○, *morphine;* □, *codeine; and* ●, *ethylmorphine.*

The retention mechanism when the ion-pairing reagent contains eight carbons or less is not straightforward. Since the shorter chain pairing ions were sulfonates and the longer chain pairing ions were sulfates, the possibility of sulfonates behaving differently from sulfates was considered. However, capacity factors measured with sodium hexanesulfonate and sodium hexanesulfate were the same (within experimental error); they also were the same for sodium tetradecylsulfonate and sodium tetradecylsulfate.

One is tempted to attribute this behavior to an ion-exchange mechanism, but the similarity of the curves in Figs. 2 and 3 weigh against it. If pairing-ion adsorption is significant, a difference in behavior when the chain length of the alkyl portion of the stationary phase is changed from eight to 18 would be expected. The plots presented in Figs. 2 and 3 are too similar to suggest that this mechanism is important. The behavior of the short chain pairing ions may be due to the ion-pair complex formed. Since there appears to be little increase in complex hydrophobicity with an increasing chain length up to eight, a mechanism is proposed to account for this behavior.

Examination of molecular models of codeine and octanesulfonate suggests that these molecules could form an ion-pair complex in which the hydrocarbon chain of the pairing ion aligns along the carbon backbone of the codeine molecule (ionic moieties of each molecule are juxtaposed), with essentially no portion of the carbon chain protruding beyond the codeine molecule. This type of complex formation would minimize the hydrophobic interactions of each molecule with the primarily aqueous solvent. For short carbon chains (eight or less), the ion-pair apparently is not appreciably less polar than the ion-pair formed from methanesulfonate and the protonated amine. In other words, the polarity is controlled primarily by the amine molecule. Consequently, little change in the capacity factor (Figs. 2 and 3) is observed with short pairing ions. On the other hand, pairing ions that contain more than eight carbon atoms would form ion-pairs in which the alkyl chain of the pairing ion would protrude beyond the codeine molecule. This protrusion results in greater complex hydrophobicity and hence greater retention. While these arguments can explain qualitatively the observed behavior, they do not rule out the possibility of dynamic ion exchange.

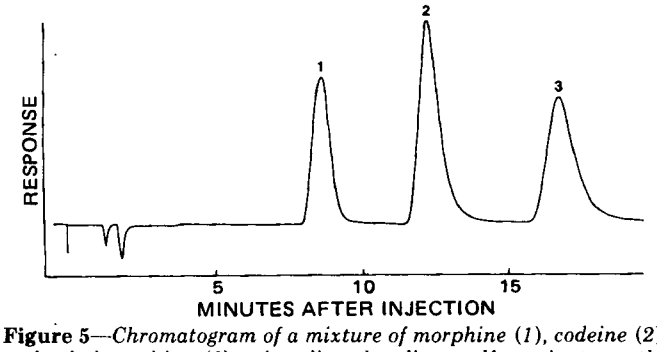

Figure 5—*Chromatogram of a mixture of morphine (1), codeine (2), and ethylmorphine (3) using dioctyl sodium sulfosuccinate as the pairing ion.*

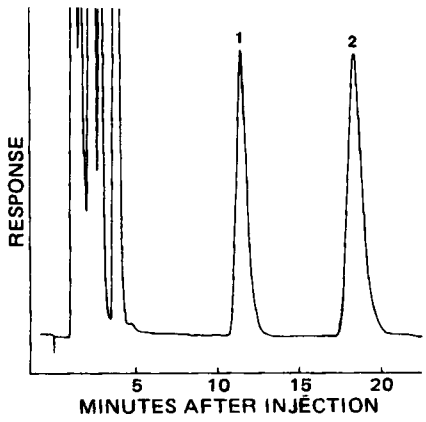

Figure 6—*Chromatogram of a codeine syrup using dioctyl sodium sulfosuccinate as the pairing ion. Peak 1 is codeine and peak 2 is diphenylamine, the internal standard (0.032 aufs).*

Data obtained in a study of the ion-pairing behavior of 4-methyl-1-tetradecylpyridinium chloride (I) lend support to the arguments presented here[14]. In this study, the capacity factor was measured as a function of the carbon chain length of the pairing ion (octadecylsilane column). Alkyl sulfates and sulfonates ranging from butanesulfonate to octadecylsulfate were used as pairing ions. No significant increase in capacity factor was observed until the alkyl chain length exceeded 12 carbons. These data are consistent with the concept of complex formation with association of the alkyl portions of both molecules of the ion-pair.

The effect of pairing ion chain length on compound resolution is shown in Fig. 4. Hexanesulfonate did not adequately resolve morphine, codeine, and ethylmorphine under these conditions, while decylsulfate and tetradecylsulfate gave resolutions adequate for peak height and peak area measurements, respectively. Furthermore, increasing the chain length increased the retention time to such an extent that nonionic species would have eluted well ahead of the amines. This latter aspect is important when direct injections of diluted syrups are contemplated.

In early studies, problems with pairing-ion solubilization were encountered with tetradecyl- and hexadecylsulfates. To circumvent this problem, dioctyl sodium sulfosuccinate (II) was investigated as a possible pairing ion for codeine. This molecule has the requisite solubility and a sufficiently long alkyl chain to produce adequate retention for codeine. Furthermore, this compound is readily available at low cost. The chromatogram for a morphine, codeine, and ethylmorphine mixture using II as the pairing ion is shown in Fig. 5. Under these conditions, II produced capacity factors similar to those produced by tetradecylsulfate. Also, II solubilization in the mobile phase was accomplished easily with stirring. Consequently, all assay development for codeine syrups was carried out using II as the pairing ion.

[a] Internal standard method.

Table II—Analyses of Codeine Syrups (Milligrams per 5 ml)

Sample	Trial 1	Trial 2
A[a]	9.69[b]	9.66
B[c]	9.96[d]	9.99
C[e]	10.02	9.92
D[f]	10.21	10.05
E[g]	10.10	9.97

[a] Syrup contained 85 mg of terpin hydrate/5 ml and 10 mg of codeine/5 ml. [b] Expressed as free base. [c] Syrup contained (in 5 ml) 12.5 mg of phenylpropanolamine hydrochloride, 6.25 mg of pheniramine maleate, 6.25 mg of pyrilamine maleate, 100 mg of guaifenesin, and 10 mg of codeine phosphate. [d] Expressed as phosphate salt. [e] Syrup contained 100 mg of guaifenesin/5 ml and 10 mg of codeine phosphate/5 ml. [f] Syrup contained (in 5 ml) 5 mg of promethazine, 44 mg of potassium guaiacolsulfonate, and 10 mg of codeine phosphate. [g] Syrup contained (in 5 ml) 2 mg of brompheniramine maleate, 5 mg of phenylephrine hydrochloride, 5 mg of phenylpropanolamine hydrochloride, 100 mg of guaifenesin, and 10 mg of codeine phosphate.

Figure 6 shows a typical chromatogram of a 5.0-ml syrup sample (10.0 mg of codeine phosphate and 100 mg of guaifenesin/5 ml) diluted with 40.0 ml of the internal standard solution (diphenylamine, 0.05 mg/ml in the mobile phase). Excellent separation was obtained, with all syrup excipients (and guaifenesin) eluting at or near the solvent front. Codeine phosphate recovery from spiked placebo syrups averaged 100.5% with a relative standard deviation of 0.5% (n = 13) over 2.2–16.4 mg/5 ml (internal standard method). Replicate analyses of one lot of codeine syrup gave an average value of 9.95 mg/5 ml (theory is 10.0 mg/5 ml) with a relative standard deviation of 0.4% (n = 8). Analysis of the same lot on a different day gave an average of 10.10 mg/5 ml with a relative standard deviation of 0.3% (n = 6). The overall average of these data is 10.0 mg/5 ml with a relative standard deviation of 0.8% (n = 14) (Table I).

Five samples of syrups containing codeine or codeine phosphate were obtained through commercial sources and analyzed by the external standard method (Table II). Excellent agreement with the labeled codeine content was obtained. Even though some products contained other

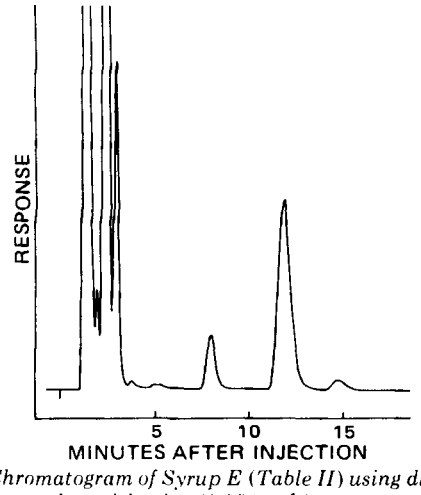

Figure 7—*Chromatogram of Syrup E (Table II) using dioctyl sodium sulfosuccinate as the pairing ion (0.064 aufs).*

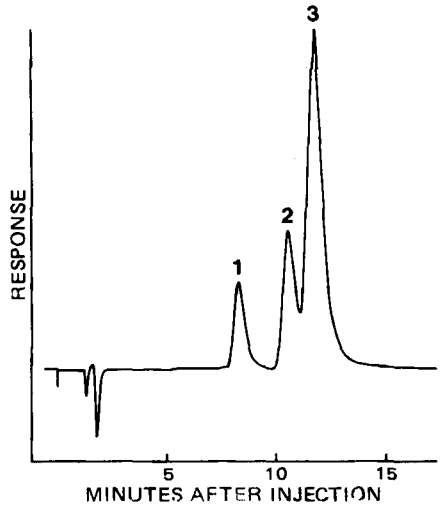

Figure 8—*Chromatogram of a mixture of morphine (1), codeine N-oxide (2), and codeine (3) using conditions used for the codeine assay.*

amine drugs, adequate resolution was obtained in all cases without modification of the mobile phase. The chromatographic tracing of the most complex mixture is shown in Fig. 7 (Product E).

The separation of codeine from its synthetic precursor, morphine, and a possible oxidation product, codeine N-oxide, is shown in Fig. 8. Even though the N-oxide was not completely resolved from codeine, it did not interfere when peak height measurements were used. No extraneous peaks were observed in any samples analyzed by this method, even though some samples were >1 year old.

The method described here is precise and accurate. Since the codeine elutes well after the solvent front, simple dilution of the syrups was the only sample preparation necessary. Total sample preparation and chromatographic analysis time is <20 min/sample. Dioctyl sodium sulfosuccinate has been shown to be a useful, inexpensive pairing ion for codeine analysis.

Tissue Distribution and Metabolism of Drugs VI: Effect of Second Drugs on Pancreatic Distribution and Insulin-Releasing Activity of Sulfonylureas in Perfused Rat Pancreas

KATSUHIKO OKUMURA *, MASATO ARAKAWA *§, and RYOHEI HORI ‡×

Received June 25, 1979, from the *Institute of Pharmaceutical Sciences, Hiroshima University School of Medicine, Hiroshima 734, Japan, and the ‡Department of Pharmacy, Kyoto University Hospital, Sakyo-ku, Kyoto, 606, Japan. Accepted for publication September 13, 1979. §Present address: General Research Center, Wakunaga Pharmaceutical Co. Ltd., Kotachi, Hiroshima, 729-64, Japan.

Abstract □ The distribution of sulfonylureas and their insulin-releasing potency as a pharmacological response were studied in isolated perfused rat pancreas. Sulfonylurea concentrations in the perfused pancreas in the presence or absence of a second drug were determined after perfusion for 15 min. Sulfonylureas could be distributed throughout the pancreas readily, and the tissue sulfonylurea concentration was reduced by the addition of sulfaphenazole, sulfadimethoxine, and salicylic acid. The insulin secretion rate stimulated by tolbutamide also was reduced by these three drugs; sulfanilamide, which could not displace the tolbutamide distribution, did not affect the tolbutamide-mediated secretion of insulin. These results document the importance of drug concentration in the tissue or receptor site with regard to insulin secretion and show that the sulfonylurea-mediated secretion of insulin can be modified easily by concomitant perfusion of a second drug that displaces sulfonylurea in the pancreas. These findings suggest that the drug interaction at the target organ or receptor site should be understood to provide adequate drug therapy.

Keyphrases □ Pancreas—distribution of sulfonylureas, displacement of sulfonylurea by second drug □ Distribution—sulfonylureas in the perfused pancreas, correlation with pharmacological response □ Sulfonylureas—distribution in pancreas, displacement by second drug □ Insulin secretion—stimulation by sulfonylurea, inhibition by presence of second drug

Hypoglycemic sulfonylureas are generally accepted to bind strongly to serum protein (1, 2). In 5% albumin solution, only 10% or less of tolbutamide was present in active unbound molecules at clinical levels (1, 2).

Even minute alteration of the protein binding capability changes the amount of the active unbound form of sulfonylureas. Clinically, ineffective therapy or toxic responses could result.

Displacement of such sulfonylurea–protein binding by other drugs has been demonstrated in plasma and in albumin solutions (3, 4). These phenomena may also occur in various organs or tissues (5, 6), but little is known about drug binding in tissues. The displacement at the receptor or binding site in the target organ may directly reflect therapeutic efficacy.

It has been generally accepted that the distribution dynamics of a drug are closely related to its efficacy or adverse reaction (6). However, technical difficulties in performing such investigations have limited available information. It is difficult to determine accurately the drug concentration in organs as compared to the blood, and it is almost impossible to measure the amount at isolated receptors. Moreover, it is particularly hard to obtain a simple and precise pharmacological marker.

In a previous paper (7), drug disposition dynamics in the exocrine pancreas were reported. Drugs are transported to the pancreas through the lipid barrier and excreted into the pancreatic juice through the rather tight lipoid and molecular sieve barriers.

In the present paper, the pancreatic distribution of sulfonylureas is correlated with insulin secretagogic capacity as the pharmacological marker using isolated perfused rat pancreas.

EXPERIMENTAL

Materials—Dextran (mol. wt. 60,000–90,000) was purchased in powder[1] or liquid[2] form (dextran 70 JP IX). Tolbutamide[3] and carbutamide[4] were the sulfonylureas studied. All other chemicals were obtained from commercially available sources and were analytical reagent grade.

Animals—Male Wistar rats, 200–300 g, were housed in a constant-temperature room with free access to water and food.

Procedure—The technique for pancreas isolation was practically the same as the reported pancreas–duodenum isolation method (8). The insertion of the cannulas was modified and directed upward just below the superior mesenteric artery. Furthermore, to simplify the procedure, the left renal, internal spermatic, and iliolumbar vessels were not occluded. The pancreas–duodenum was isolated from the rat and perfused on a constant-temperature table (37.4°).

The perfusion medium was Krebs–Henseleit bicarbonate solution supplemented with glucose (100 mg %). Colloidal osmotic pressure was maintained by the addition of dextran (4.5%) in accordance with the method of Toyota *et al.* (9). The perfusate was supplied by a peristaltic pump at the rate of 2 ml/min (net perfusion pressure was 30–60 mm Hg) and oxygenated with 95% O_2–5% CO_2 through a fiber-type oxygenator[5]. The perfusion time was 15 min for study of the pancreatic uptake of sulfonylureas. The perfusion experiment was carried out for 45 min to permit comparative study of insulin secretion stimulated by sulfonylureas with or without second drugs. The first 10 min was used as a stabilizing control period, and the next three 10-min periods and the last 5 min served as the experimental period to determine the effect of sulfonylurea and second drugs.

Four kinds of experiments were conducted in this comparative study. The first was a control experiment using basal Krebs–Henseleit bicarbonate solution, the second determined the direct effect of second drugs, the third was the tolbutamide control study, and the last was a combined experiment using tolbutamide and a second drug. Every 2.5 min, samples of effluent from the cannula in the portal vein were collected for insulin assay.

Analytical Methods—Tolbutamide and carbutamide were determined by the methods of Martin and Rowland (10) and of Bratton and Marshall (11), respectively, after Somozyi's deproteinization. Insulin secreted in each experimental period was assayed as immunoreactive insulin (IRI) by a single-antibody precipitation method using polyethylene glycol (12). Rat insulin was used as the reference standard. Aprotinin[6] was added to each borosilicated culture tube[7] (1.2 × 75 mm) in accordance with the method of Toyota *et al.* (13).

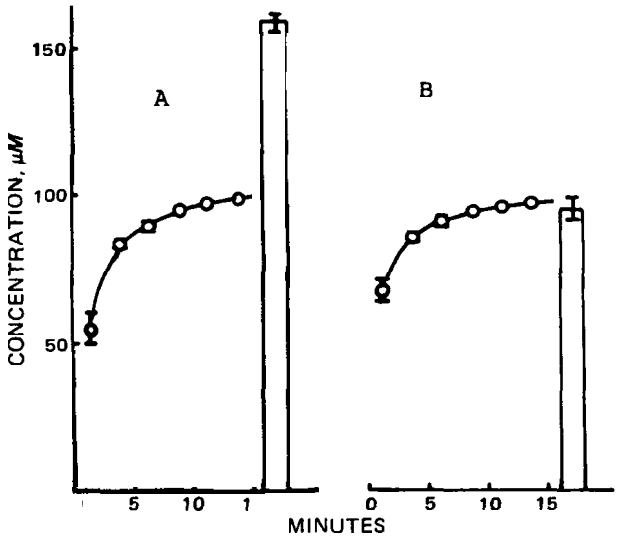

Figure 1—*Concentration profile of sulfonylureas in the portal effluent of the perfusate. Key: A, tolbutamide (100 μM) perfused; and B, carbutamide (100 μM) perfused. Open bars denote drug concentration in the pancreas.*

The effect of the second drug on the insulin secretion stimulated by tolbutamide was judged by the total amount of insulin secreted during the perfusion period of 15–45 min, because the insulin secretion stimulated by tolbutamide alone was almost stable during this period. The insulin secretion from 15 to 20 min and from 30 to 40 min was expressed as secretion in a combined experiment (microunits per minute), and the insulin secretion from 20 to 30 min and from 40 to 45 min was adopted as the control experiment in which only tolbutamide was perfused. The two values obtained from the two periods were compared. Statistical analysis was performed using the Student t test of paired samples.

RESULTS AND DISCUSSION

The concentration profile of tolbutamide and carbutamide in the effluent of the perfusate from the cannula in the portal vein when both drug solutions of 100 μM were perfused in the pancreas is shown in Fig. 1. After perfusion for 15 min, the sulfonylurea concentration in the whole pancreas was determined since equilibrium between the perfusate and the pancreas was nearly achieved within 15 min. The control data of pancreatic uptake of tolbutamide and carbutamide were 158 and 95 μM, respectively. These values were compared with the data based on concomitant use of second drugs.

Although serum albumin is used in almost every laboratory to maintain the colloidal osmotic pressure in the perfused pancreas, dextran was selected to differentiate between effects caused by competition for plasma protein binding sites as opposed to β-cell binding sites. The fact that dextran had no binding capacity with tolbutamide was confirmed by an ultrafiltration technique (14). Next, the effects of sulfaphenazole, sulfadimethoxine, sulfanilamide, and salicylic acid were examined to determine how they affect sulfonylurea distribution in the pancreas. Sulfaphenazole, sulfadimethoxine, and salicylic acid inhibited the pancreatic uptake of sulfonylureas by 30–40% (Table I), but sulfanilamide had little or no effect on the pancreatic uptake of tolbutamide.

These results correlated well with the displacement phenomenon of these drugs in the plasma or in an albumin solution (3). Christensen *et al.* (15) reported on the severe hypoglycemia provoked by the concomitant administration of tolbutamide and sulfaphenazole. Other investigators (16, 17) also reported that a similar phenomenon occurred with phenylbutazone or dicumarol. Hypoglycemia was attributable to a

Table I—Effect of the Second Drug on the Pancreatic Uptake of Sulfonylureas

Sulfonylurea	Second Drug	Pancreatic Uptake[a], μM	Uptake Ratio, %
Tolbutamide (100 μM)	None	158 ± 3[b] (6)[c]	100
	Sulfanilamide (2.5 mM)	150 ± 7 (3)	95

combination of causes, *i.e.*, inhibition of hepatic metabolism, increased protein-unbound sulfonylurea, and its displacement from tissue-binding sites in the liver (18). The displacement phenomenon in the blood is one main cause of hypoglycemia, but it is not totally responsible. The results of the present study showed that the pancreatic uptake of sulfonylureas decreased in accordance with their displacement phenomenon in plasma by the addition of second drugs with high hydrophobicity.

In considering the action site of sulfonylureas in the pancreas, the possibility that drug binding to the β-cell membrane may be related to secretagogic action (19–23) has received much attention. Drug displacement may occur at the receptor site as demonstrated in plasma or in the whole pancreas, and a converse pharmacological effect of what happened as a result of displacement in plasma may be seen. The possibility of displacement of tolbutamide at the receptor or binding site also was investigated in this study using the secreted insulin as a marker of the pharmacological effect. The basal pattern and tolbutamide-stimulated pattern are illustrated in Fig. 2.

Since it has been considered that sulfonylurea binding to the β-cell membranes is closely related to the secretagogic potency, it was expected that the drug interaction at the receptor level might be detected effectively by this experimental system. Sulfaphenazole, sulfadimethoxine, and salicylic acid, which inhibited the pancreatic uptake of tolbutamide, were investigated to determine their effect on the insulin secretion stimulated by tolbutamide. As shown in Fig. 3, the insulin secretory rate during the concomitant perfusion of tolbutamide and sulfaphenazole was significantly lower than that obtained during tolbutamide perfusion alone. When only sulfaphenazole was perfused, no significant effect was detected in the insulin secretory rate (Table II).

The effect of sulfadimethoxine and salicylic acid on insulin secretion stimulated by tolbutamide also was examined; smaller, but significant, inhibitory effects were observed. Insulin secretion rates when tolbutamide alone was perfused and when tolbutamide and a second drug were perfused are listed in Table III. These results are well explained by the hypothesis that expects competition at the binding or receptor site between tolbutamide and the second drug on the β-cell membrane.

Hellman *et al.* (22) reported on a similar phenomenon using 4-acetamide-4′-isothiocyanate-stilben-2,2′-disulfonic acid in incubated rat Langerhans islet. It depressed the islet uptake of glyburide (glibenclamide) and, when present solely with the islets, it activated the insulin secretion strongly. When it coexisted with glyburide, the two secretagogues acted less actively than the additive effect of glyburide and 4-acetamide-4′-isothiocyanate-stilben-2,2′-disulfonic acid. Hellman *et al.* (22) pointed out the possibility that 4-acetamide-4′-isothiocyanate-stilben-2,2′-disulfonic acid, a membrane probe, prevented the secretagogic recognition of glyburide by displacing this sulfonylurea from the β-cell membranes. Although their hypothesis may explain the present data, tolbutamide possibly could react directly with sulfaphenazole, sulfadimethoxine, or salicylic acid and form a less active complex compound. To exclude this possibility, the complex formation of these drugs was examined by the solubility method (24). The complex formation was no more than merely 1% of tolbutamide in the perfusate (stability constant = 5.3 M^{-1}). Thus, it could not explain the remarkably decreased insulin secretion.

On the other hand, the finding that tolbutamide-mediated secretion was inhibited by the addition of these three drugs could have been caused by their direct action if they had the capacity to inhibit insulin secretion. A perfusion study indicated that these drugs made a small, but insignificant, change in the insulin secretion (Table II). Consequently, direct inhibition of insulin secretion by these drugs apparently was not the reason for this phenomenon.

When sulfanilamide was perfused concomitantly with tolbutamide, the insulin secretion rate was slightly, but not significantly, stimulated (Table III). Since sulfanilamide was hardly able to displace the pancreatic uptake of tolbutamide, this result is consistent with the hypothesis that drug concentration at the tissue level might reflect the pharmacological response.

The importance of the drug protein binding in plasma has been stressed. It has been postulated widely that the unbound free fraction of a drug in plasma could serve as the marker of therapeutic efficacy. However, a correlation between the serum free fraction value and the tissue free fraction value is unlikely in the presence of some specific accumulation of drug in the tissue. From this point of view, drug–tissue binding or interaction in connection with pharmacological or toxicological response has received attention recently. The presented data show the important role of drug disposition dynamics in tissues, especially in target organs. Thus, drug disposition in target organs or receptor sites should always be considered when preparing a dosing regimen for optimal therapy.

Serum Levels of Butorphanol by Radioimmunoassay

KENNETH A. PITTMAN ˣ, ROBERT D. SMYTH, and ROBERT F. MAYOL *

Received March 19, 1979, from *Bristol Laboratories, Syracuse, NY 13201.* Accepted for publication September 18, 1979. *Mead-Johnson Research Center, Evansville, IN 47721.

Abstract □ A radioimmunoassay was developed for the analysis of butorphanol in human serum. The procedure involves extraction of serum with hexane containing 2% isoamyl alcohol, followed by evaporative solvent removal and radioimmunoassay of the reconstituted residue. The antibody significantly cross-reacts with unidentified butorphanol metabolites but not with two known metabolites, hydroxybutorphanol and norbutorphanol. Extraction eliminated interference from the butorphanol metabolites normally present in serum. The antibody also cross-reacts with pentazocine and cyclazocine but not with morphine, hydromorphone, oxymorphine, codeine, methadone, and meperidine. Butorphanol tartrate was administered intravenously (2 mg) to normal male volunteers. Serum butorphanol levels declined biexponentially with an average terminal half-life of 2.7 hr. Enzymatic serum hydrolysis prior to extraction yielded additional butorphanol, indicating the presence of butorphanol conjugates. The specificity of the assay for butorphanol was confirmed by GLC–mass fragmentography.

Keyphrases □ Butorphanol—radioimmunoassay in human serum, pharmacokinetics in human serum □ Pharmacokinetics—butorphanol in human serum □ Radioimmunoassay—butorphanol in human serum □ Narcotic agonist–antagonist—serum butorphanol pharmacokinetics by radioimmunoassay

Butorphanol (I), a totally synthetic morphinan (1) with narcotic agonist–antagonist properties, has been shown to be a potent analgesic in animals (2) and humans (3–5). Studies with ^{3}H-butorphanol in normal human subjects demonstrated the presence of hydroxybutorphanol (II), norbutorphanol (III), and conjugates of I, II, and III as metabolites of I[1]. Additional unidentified metabolites were present. The plasma I levels indicated that conventional GLC or high-pressure liquid chromatographic procedures could not achieve the detection level necessary to define fully the serum concentration profile after parenteral administration. A specific radioimmunoassay procedure was needed to determine the pharmacokinetics and bioavailability of I.

Rabbit antibutorphanol antibody was prepared *via* I conjugation to bovine serum albumin, followed by injection of this antigen into rabbits to obtain the antiserum[2]. Radiolabeled antigen was prepared by a chloramine-T procedure for the introduction of iodine 125 into the aromatic ring of I, and this hapten was bound by the antiserum and displaced by comparable amounts of pure I. The conventional second antibody (goat antirabbit globulin) technique was utilized to separate free from bound antigen. No significant cross-reactivity with the butorphanol metabolites II or III was observed. Cross-reactivity from unknown metabolites, however, necessitated the development of a technique specific for I, so an extraction procedure prior to radioimmunoassay was included.

A combined GLC–mass fragmentography assay was developed to demonstrate that the final method was specific for I in the presence of its metabolites.

The purposes of these studies were to develop and validate a radioimmunoassay method for I and to demonstrate the utility of the method in the determination of serum levels of I after administration of therapeutic doses.

EXPERIMENTAL

Chemicals and Reagents—Na^{125}I (carrier free)[3], *N*-chloro-4-methylbenzenesulfonamide sodium salt[4] (chloramine-T), diethylamine[4], normal human serum[5], normal rabbit serum[5], goat antirabbit γ-globulin antiserum[6], 3,14-dihydroxy-*N*-cyclobutylmethylmorphinan hydrogen tartrate[7] (butorphanol tartrate, I-tartrate, lot 75F1355-2), 3,14-dihydroxy-*N*-(*trans*-3′-hydroxycyclobutylmethyl)morphinan hydrogen tartrate[7] (hydroxybutorphanol tartrate, II-tartrate, lot 1099-21), 3,14-dihydroxymorphinan[7] (norbutorphanol, III, lot 923-19), 3,14-dihydroxy-*N*-cyclopropylmethylmorphinan hydrogen tartrate[7] (internal standard, IV, lot 75F1878), *N,O*-bis(trimethylsilyl)trifluoroacetamide[8] (V), *N,O*-bis(perdeuterotrimethylsilyl)trifluoroacetamide[9] (VI), and rabbit antibutorphanol antiserum[2] were used as received.

All other chemicals and reagents were USP, NF, or ACS grade or better and were used without further purification.

Radioiodinated Butorphanol Hapten—To a 1-dram vial with a stirring bar were added, with stirring, 20 mCi of Na^{125}I (200 μl), 3.5 μl of a solution of 1.46 mg of I-tartrate (1 mg of base)/ml of distilled water, and 100 μl of 0.25 *M*, pH 7.6 phosphate buffer. Then 10 μl of a fresh solution of 3 mg of chloramine-T/ml was added, followed within 5–10 sec by 10 μl of a fresh solution of 7 mg of sodium metabisulfite/ml. Carbonate buffer (50 μl) and hexane (2 ml) were added, and stirring was continued for 10 min.

The aqueous phase was frozen on dry ice; the hexane phase was removed, washed once with 1 ml of distilled water, and aliquoted into individual vials after its activity was determined. The iodinated butorphanol was stored at −20°, and aliquots were reconstituted with radioimmunoassay buffer just prior to use. After 1–3 months, the stock preparation becomes unsatisfactory due to the accumulation of degradation products.

Solutions—The butorphanol standard solution was prepared to yield 145.8 pg of I-tartrate (100 pg of base)/ml; 1-ml amounts were transferred to 0.5-dram vials and stored at −20°. The radioimmunoassay buffer was 0.05 *M*, pH 7.6 phosphate buffer. It was prepared fresh for use. The carbonate buffer was a saturated solution of sodium bicarbonate and sodium carbonate. The extraction solvent was 2 parts (v/v) of isoamyl alcohol to 98 parts (v/v) of hexane. The protein solution consisted of 4 parts (v/v) of normal rabbit serum diluted with 96 parts (v/v) of radioimmunoassay buffer. It was prepared from frozen (−20°) serum aliquots and kept on ice[6].

Rabbit antibutorphanol antiserum was diluted in protein solution in the ratio of 1 μl to 5 ml, respectively. It was made fresh from frozen (−20°) antiserum aliquots and kept on ice. [Other lots of antibody than the one used may require a different dilution to obtain useful standard curves (7).] The goat antirabbit γ-globulin solution was prepared by diluting the antiserum in radioimmunoassay buffer to obtain about 13 units/ml, *e.g.*, 8 ml of antiserum plus 22 ml of buffer. It was made fresh from frozen (−20°) antiserum aliquots and kept on ice[8].

To prepare the radioiodinated butorphanol hapten solution, the ethanolic stock solution of ^{125}I-butorphanol was diluted to obtain (*a*) about 180,000 cpm/ml or (*b*) about 100,000 cpm, depending on whether

[a] Mean coefficient of variation for triplicate samples. [b] Coefficient of variation for all samples (three times number of curves).

a high or low standard curve was prepared. It was made fresh and kept on ice. The counts per minute may need to be adjusted if a different γ-counter is used.

Radioimmunoassay—For a given analytical run, a constant volume of serum was taken from all samples, and the same volume of human serum was used for the standard curve, because of the variable effect of serum volume on nonspecific and control binding values. Volumes of human serum from 0.1 to 0.5 ml were suitable; 0.2 ml is used as an example.

Into sets of triplicate extraction tubes[10] were pipetted[11] 0.25, 0.50, 1.0, 1.5, 2.0, 2.5, and 3.0 μl of butorphanol standard solution. Three additional sets of tubes were reserved for background (BKG), nonspecific binding (NSB), and maximum binding (B_0). Human serum (0.2 ml) was pipetted[12] into all of the tubes, and duplicate 0.2-ml portions of the desired test samples were pipetted into additional tubes. Carbonate buffer (50 μl) and the extraction solvent (2 ml) were added; then the tubes were racked, and each rack was shaken gently by hand for 1 min. The racks were centrifuged[13] for 10 min at 3000 rpm at −5° and then placed in a shallow bath of dry ice–ethanol for about 3 min.

Each organic phase was decanted into a clean tube[14] and reduced to dryness, using a manifold[15] supplied with dry, filtered nitrogen gas. All subsequent solutions were added to the tubes with a diluter–pipeter[16] set to deliver 0.1 ml of reagent solution followed by 0.4 ml of radioimmunoassay buffer. The final volume in each tube was 1.5 ml. Solutions were kept in an ice bath when not in use. Radioiodinated hapten was added to all tubes except the background tubes, to which extra radioimmunoassay buffer was added. Antibutorphanol antiserum was added to all tubes except the nonspecific binding tubes, to which protein solution was added. Antirabbit serum antibody was added to all tubes.

The tubes were centrifuged at 3000 rpm for 3 min at −5° and stored at 5–7° for 16 hr (overnight). Free and bound haptens were separated by centrifugation at 3000 rpm for 30 min, and 1.0 ml of each supernate was transferred to fresh tubes. The ^{125}I-activity was determined in a γ-counter[17] with automatic correction for background. Calculations were carried out automatically in the system by a modified log–logit analysis (6). In this procedure, the bound radioactivity for each sample or standard (B) was estimated, and the ratio:

$$y = \frac{B - \text{NSB}}{B_0 - \text{NSB}} \qquad \text{(Eq. 1)}$$

was calculated and transformed to:

$$\text{logit } y = \ln\left(\frac{y}{1-y}\right) = \ln\left(\frac{B - \text{NSB}}{B_0 - B}\right) \qquad \text{(Eq. 2)}$$

The slope and intercept were obtained by linear regression for logit y *versus* ln p, where p equals the amount of standard in each tube. The amount of I in each sample tube was estimated by standard inverse prediction techniques.

Cross-Reactivity—Fifty micrograms each of II, III, morphine sulfate, hydromorphone, oxymorphone hydrochloride, codeine, pentazocine, cyclazocine, methadone hydrochloride, and meperidine hydrochloride were dissolved in 500 ml of 0.01 *N* HCl. Amounts of each of these solutions were added to control human serum to give concentrations of 0.2, 2, and 20 ng/ml, and the serum samples were carried through the radioimmunoassay as unknowns to determine the relative ability of the compounds to displace radioiodinated hapten from the antibutorphanol antibody.

Enzymatic Hydrolysis—To 1.0-ml samples of spiked or test human plasma were added 25 μl of enzyme solution[18], 5 μl of chloroform, and 4.0 ml of 0.1 *M*, pH 5.5 acetate buffer. The samples were incubated at 37° for 72 hr under a nitrogen atmosphere, and portions were carried through the radioimmunoassay.

GLC–Mass Fragmentography—To 3-ml samples of spiked or test human plasma was added 0.3 μg of IV. The samples were made basic and extracted with chloroform. The chloroform was extracted with 0.1 *N* H_2SO_4, which, in turn, was made basic and extracted with chloroform, which was reduced to dryness under a nitrogen stream. Compound V (25 μl) was added to each sample, and the samples were agitated and held at room temperature for 30 min to form the trimethylsilyl derivatives of I and IV. To each sample was added 2 μl of a solution containing 25 ng of I/ml of VI. This addition of the perdeuterotrimethylsilyl derivative of I provided a carrier for the picogram amounts of the trimethylsilyl derivative of I so that it was not lost in the chromatographic system.

The instrument used was a gas chromatograph[19] coupled to a quadrupole mass spectrometer[20] equipped with a chemical-ionization source. Conditions were: carrier–reactant gas, methane; injection port temperature, 250°; oven temperature, 235°; transfer line temperature, 250°; ion chamber pressure, 0.5–1 torr; and electron beam intensity, 100 ev. The methane flow rate was adjusted to maximize the mass 29 ion in the methane spectrum, resulting in a carrier gas flow rate between 10 and 20 ml/min. Four microliters from each sample was injected into a 91-cm × 2.5-mm i.d. column containing 3% OV-1 on Gas Chrom Q[21].

The column effluent was scanned continuously in the single-ion monitoring mode using a cycle time of 1 sec. Three mass numbers were monitored in each cycle, corresponding to the pseudomolecular ions (MH^+) of the trimethylsilyl derivative of IV (386.4 amu), the trimethylsilyl derivative of I (400.4 amu), and the perdeuterotrimethylsilyl derivative of I (409.4 amu). The derivatives of I eluted at 3.5 min, and the derivative of IV eluted at 2.0 min. A response ratio of the trimethylsilyl derivative of I to the trimethylsilyl derivative of IV was calculated, and the regression of the ratio on the I concentration in the plasma standards was used to calculate the I concentration in the test samples by inverse prediction.

Subjects—A signed informed consent was obtained from each normal, healthy, adult male subject. Complete physical examinations, hematology, blood chemistries, and urinalysis were performed on each subject on the day prior to the 1st study day. All parameters were within the normal range.

In Study 1, each subject in one group received 2 mg of butorphanol tartrate intramuscularly whereas each subject in the other group received 16 mg of butorphanol tartrate orally. Subjects were fasted overnight prior to drug administration in the morning. Blood samples were obtained at 0, 2, 4, and 8 hr.

In Study 2, subjects received 2 mg of butorphanol tartrate intravenously. Blood samples were obtained 0.5 hr prior to drug administration and at 5, 10, 15, 20, 30, and 45 min and at 1, 1.25, 2, 3, 4, 6, and 8 hr. Subjects abstained from solid food and liquid, except water, from midnight of the beginning of the test day. Subjects were instructed to walk around for at least 5 min after each blood collection. They received a light breakfast 4 hr after dose administration and were discharged after the

last blood sample was obtained.

Blood samples were obtained in plain evacuated tubes, allowed to clot at room temperature for 30 min, and centrifuged at 5°. Serum samples were removed and immediately flash frozen, stored, and shipped frozen; they were maintained frozen at −20° until analyzed.

Pharmacokinetic Analysis—The serum concentration data for each subject in Study 2 were plotted on semilog paper with time as the abscissa. Judgments then were made as to the nature and trend of the time course of serum concentration; also at this time, certain data points were judged to be outliers if they deviated widely (by ~25%) from the general trend. With the outliers excluded, all of the data sets were run through the program CSTRIP (7) to obtain initial polyexponential parameter estimates. These estimates were then passed, along with their associated data sets, to the program GUESS (8) for parameter optimization by a nonlinear technique. The optimized polyexponential parameters then were used to calculate pharmacokinetic parameters.

RESULTS AND DISCUSSION

Preliminary experiments[22] showed that increasing amounts of human serum or of the residue of hexane extracts of human serum increasingly reduced the binding of radioiodinated hapten to the antibody. For a given serum volume, there was little variability in the reduction of this binding; for serum volumes of ≤0.5 ml, the effect was not of sufficient magnitude to interfere with the usefulness of the radioimmunoassay. Data on the accuracy and precision of the radioimmunoassay are presented in Table I. The data were obtained from the same standard curves used to estimate butorphanol concentrations in the discussed serum samples. As expected, the best precision was obtained for samples near the center of the range of the standard curve.

The potential interference of known[1] metabolites of butorphanol (II and III) and of various narcotics and agonist–antagonists (see *Experimental*) was tested at levels up to 20 ng/ml. Only pentazocine and cyclazocine cross-reacted; they gave apparent butorphanol values of 0.1–0.2 ng/ml at their highest level of 20 ng/ml. Therefore, misleading values for butorphanol may be observed in any subject who may have received large doses of pentazocine within 24 hr of assaying for butorphanol by the radioimmunoassay.

The plasma I concentrations as determined by the radioimmunoassay in human subjects after intramuscular and oral dosing (Table II) and those determined by GLC–mass fragmentography (Table III) were compared by least-squares analysis, assuming a linear relationship between the two analytical methods. The slope, y-intercept, and regression coefficient were calculated, and the null hypotheses that the slope was equal to unity and that the y-intercept was equal to zero were tested. The results (Table IV) indicate that the methods are equivalent and that the radioimmunoassay is specific for butorphanol in the presence of its metabolites.

Table IV—Correlation of Radioimmunoassay and GLC–Mass Fragmentography Methods for Determination of Serum Butorphanol [a]

Sample Source (n)	Slope ± 95% Confidence Interval	Intercept ± 95% Confidence Interval	Correlation Coefficient
Oral (16)	0.98 ± 0.18	0.24[b] ± 0.05	0.96
Intramuscular (15)	0.87 ± 0.19	0.01 ± 0.08	0.94
Oral plus intramuscular (31)	0.92 ± 0.14	0.13[b] ± 0.04	0.93

[a] Each value obtained by GLC–mass fragmentography was used as an independent variable (x values), and the corresponding value obtained by radioimmunoassay was used as the dependent variable (y value). [b] Significantly different than 0 ($p < 0.05$).

The slight, but significant, intercept in the radioimmunoassay results on subjects given I orally could indicate that the radioimmunoassay was measuring an immunoreactive moiety other than butorphanol, but one that was present in the serum in a constant amount. Or it could indicate that there was a slight positive bias in the radioimmunoassay for the analyses run on that day. Subsequent experience with many other subjects given oral butorphanol suggests that the latter explanation is

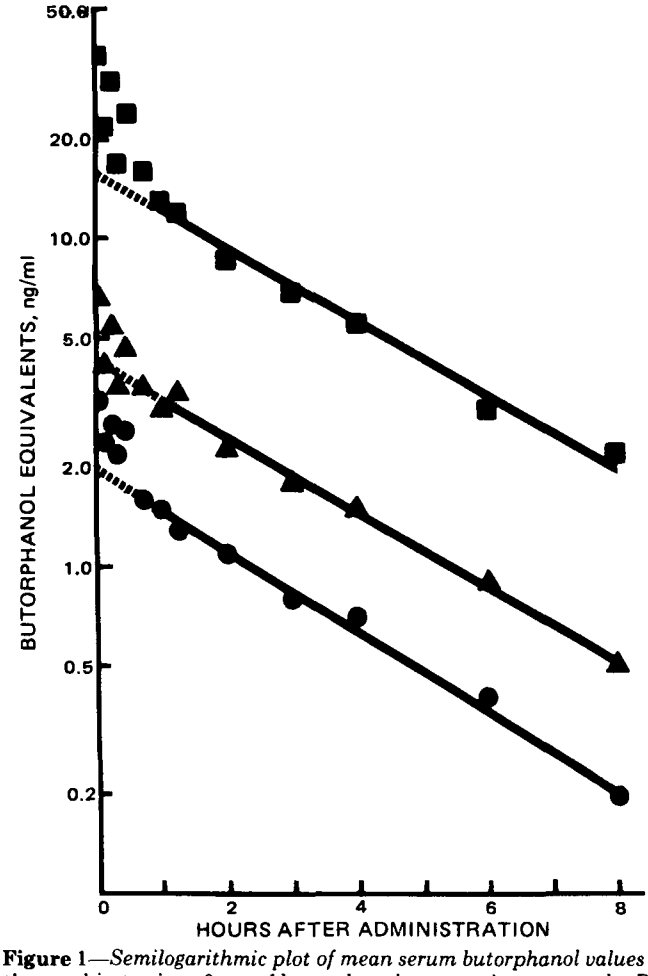

Figure 1—*Semilogarithmic plot of mean serum butorphanol values in three subjects given 2 mg of butorphanol tartrate intravenously. Butorphanol was determined by a complete radioimmunoassay (●) involving an extraction to separate butorphanol from its metabolites, by radioimmunoassay directly on serum (▲), and by radioimmunoassay after enzymatic hydrolysis to release butorphanol from conjugates (■), followed by extraction. Least-squares lines (solid and dashed) were calculated for log serum value* versus *time from 1 to 8 hr after dosing.*

[a] Determinations were made by a complete radioimmunoassay (RIA) involving an extraction to remove butorphanol from its metabolites, by radioimmunoassay directly on serum, and by radioimmunoassay after enzymatic hydrolysis of conjugates and extraction of butorphanol. See *Experimental* for details.

correct. Regression, using the log–logit transformation of Hatch *et al.* (6), often leads to an overestimate of very low concentrations, especially those below the lowest standard. Particular caution must be taken when estimating values between zero and the low standard with this procedure.

Serum samples for three subjects who received intravenous butorphanol were analyzed directly by the radioimmunoassay by omitting the extraction procedure. The values obtained (Table V) for serum butorphanol were 1.5–3 times higher (average 2.1 ± *SE*) than the values obtained (Table V) by including hexane extraction in the radioimmunoassay. The same samples also were analyzed by the radioimmunoassay after being subjected to enzymes (β-glucuronidase and arylsulfatase), which hydrolyze common conjugates of phenolic drugs. The values obtained (Table V) were 5–15 times higher (average 9.5 ± *SE* = 0.4) than those obtained without enzymatic hydrolysis.

Semilog plots of the mean serum butorphanol concentrations for those three subjects as determined by the complete radioimmunoassay, the radioimmunoassay without the extraction step, and the complete radioimmunoassay preceded by enzymatic hydrolysis are shown in Fig. 1. Lines of best fit were calculated for each set of data from 1 to 8 hr after dose administration. The slopes were not significantly different, suggesting that butorphanol elimination may be rate limiting in the clearance of it and its metabolites from the body.

When the data for each of the 18 subjects given butorphanol intravenously (Study 2) were plotted as log concentration *versus* time, log serum concentration in most subjects appeared to decline biexponentially, showing a rapid distributive phase (α-phase) and a slower postdistributive phase (β-phase). When the data for each subject were analyzed using CSTRIP, the decline in serum concentration was biexponential for 17 of the data sets and monoexponential for one in which the distributive phase was missed entirely. The equation used for biexponential decline was:

$$C_s = Ae^{-\alpha t} + Be^{-\beta t} \quad \text{(Eq. 3)}$$

where C_s is the serum concentration in nanograms per milliliter and A and B are the y-intercepts and α and β are the slopes of the fastest declining and the slowest declining exponentials, respectively; A and B are in nanograms per milliliter, and α and β are in reciprocal hours. Similarly, the equation used for the monoexponential decline observed for one subject was:

$$C_s = Be^{-\beta t} \quad \text{(Eq. 4)}$$

where B and β describe the same exponential (β-phase) as in Eq. 3.

The initial estimates for A, B, α, and β otained by CSTRIP were optimized to obtain a curve of best fit by GUESS. The average values and their standard errors for α, β, and the serum half-life (0.693/β) were 7.7 ± 2.5 hr^{-1}, 0.262 ± 0.009 hr^{-1}, and 2.70 ± 0.09 hr, respectively. As the standard errors indicate, the values for α were quite variable from subject to subject while those for β were consistent. Pharmacokinetic studies of narcotics and other narcotic agonists and antagonists have revealed polyexponential declines in plasma concentration following intravenous administration. Meperidine (9, 10), naloxone (11), and pentazocine (12, 13), for example, declined exponentially while fentanyl (14) and morphine (15, 16) declined triexponentially. Terminal plasma or serum half-lives for codeine (17), meperidine (9, 10), morphine (15, 16), and pentazocine (12, 13, 18) fell in the 2–4-hr range, as did butorphanol. In pharmacokinetic terms, the behavior of butorphanol after intravenous dosing appears to be typical of the narcotic and narcotic agonist–antagonist drugs.

Metabolites and Analogs of 2-Ethyl-2,3-dihydro-5-benzofuranacetic Acid (Furofenac): Chemical and Pharmacological Properties

CLAUDIO CASALINI *, GIUSEPPE MASCELLANI *x, GIANFRANCO TAMAGNONE *, GIULIA CESARANO *, and ANGELO GIUMANINI ‡

Received April 11, 1979, from the **Alfa Farmaceutici Research Laboratories, 40133 Bologna, Italy,* and the ‡*Centre for Gas Chromatography and Mass Spectrometry, University of Bologna, 40126 Bologna, Italy.* Accepted for publication September 19, 1979.

Abstract □ The *in vivo* metabolism of 2-ethyl-2,3-dihydro-5-benzofuranacetic acid (furofenac), a new drug, was studied in rats, dogs, and humans. The drug has antiplatelet-aggregation activity and anti-inflammatory activity combined with low ulcerogenic power. Hydroxylated derivatives and analogous compounds were prepared, and their syntheses and chemical characteristics are described. TLC, GLC, high-pressure liquid chromatography, and GLC–mass spectrometry were applied to urine extracts, and authentic synthetic specimens were used for comparison. The products identified in human and dog urine were mainly conjugation compounds of the drug, while the products in rat urine were hydroxylated derivatives. Some pharmacological characteristics of the metabolites are discussed.

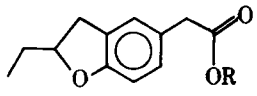
Keyphrases □ 2-Ethyl-2,3-dihydro-5-benzofuranacetic acid—*in vivo* metabolism, rats, dogs, humans □ Drug metabolism—2-ethyl-2,3-dihydro-5-benzofuranacetic acid, *in vivo*, rats, dogs, humans □ Anti-inflammatory agents—2-ethyl-2,3-dihydro-5-benzofuranacetic acid, *in vivo* metabolism, rats, dogs, humans

2-Ethyl-2,3-dihydro-5-benzofuranacetic acid[1] (furofenac, I) was synthesized during a research project aimed at finding compounds with potential anti-inflammatory activity (1, 2). Pharmacotoxicological investigations showed that I has marked anti-inflammatory and antiplatelet-aggregation activity, low toxicity, and very slight ulcerogenicity. It interferes with the biosynthesis of prostaglandins (3), and some *in vivo* pharmacological tests showed that it has good inhibitory activity against thromboxane synthetase (4).

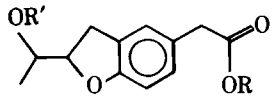
The synthesis of I was optimized (5, 6) in view of clinical trials, and pharmacokinetic studies were undertaken to define its metabolic fate and to search for metabolites of pharmacological interest. The purposes of the present study were to identify and synthesize some of the metabolites of I and to evaluate their anti-inflammatory activity.

EXPERIMENTAL[2]

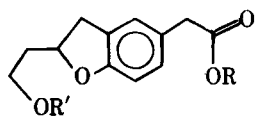
2-(1-Acetoxyethyl)-2,3-dihydrobenzofuran-5-ylacetic Acid Methyl Ester (IV)—2-(1-Acetoxyethyl)-2,3-dihydrobenzofuran (3.3 g, 16 mmoles) (7) was added at 5° to a solution of zinc chloride (2.5 g, 18 mmoles) in acetic anhydride (5 ml) with stirring. The reaction mixture was poured into 0.5 *N* HCl after 4 hr at 5°, and the methylene chloride extract was dried over sodium sulfate and filtered over 70–230-mesh silica gel (5 g). The solvent was distilled off.



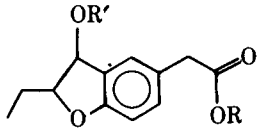
I: R = H
II: R = CH_3



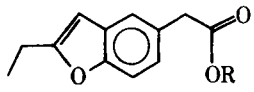
IV: R = CH_3, R′ = CH_3CO
V: R = R′ = H



IX: R = CH_3, R′ = CH_3CO
X: R = R′ = H



XV: R = R′ = H
XVII: R = CH_3, R′ = CH_3CO



XVI: R = H
XVIII: R = CH_3

2-(1-Acetoxyethyl)-5-acetyl-2,3-dihydrobenzofuran (III), bp 155–158°/2 mm Hg, was obtained in a 58% yield. Compound III (1.6 g, 6.5 mmoles) was added at 5° to a solution of thallium trinitrate (3.1 g, 7 mmoles) in methanol (20 ml) and 70% perchloric acid (4 ml). After 3 hr at 5°, the mixture was kept at room temperature for 2 hr. The mixture then was filtered, diluted, and finally extracted with methylene chloride. The solvent was evaporated to give IV (79% yield).

2-(1-Hydroxyethyl)-2,3-dihydrobenzofuran-5-ylacetic Acid (V)—A mixture of IV (1.6 g, 7 mmoles) and sodium bicarbonate (1.6 g, 19 mmoles) in methanol–water was refluxed for 4 hr. It then was cooled to room temperature and extracted with ethyl acetate. The organic layer was washed (2 *N* HCl and water) and dried over sodium sulfate, and the solvent was evaporated.

Crystallization of the residue from hexane–methylene chloride gave pure V (78% yield), mp 85–87°; IR: 3400, 2960, 2900, 1690, 1490, 1410, 1255, 1210, and 1085 cm^{-1}; UV (CH_3OH): 232 (log ϵ 3.801) and 286 (3.468) nm; mass spectrum: *m/e* 131 (100%) and 222 (M^+, 13); ^1H-NMR: δ 6.60–7.10 (m, 3), 4.59 (m, 1), 3.85 (m, 1), 3.50 (s, 2), 3.14 (d, 2), and 1.22 (d, 3) ppm.

Anal.—Calc. for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35. Found: C, 65.06; H, 6.31.

2-(2-Acetoxyethyl)-2,3-dihydrobenzofuran-5-ylacetic Acid Methyl Ester (IX)—A solution of 2,3-dihydrobenzofuran-2-ylacetic acid ethyl ester (6.9 g, 33.5 mmoles) (8) in ether was added to a slurry of lithium aluminum hydride (2.5 g, 66 mmoles) in ether (50 ml) over 30 min. The reaction mixture was refluxed for 10 hr and then chilled and quenched with 2 *N* HCl. 2-(2-Hydroxyethyl)-2,3-dihydrobenzofuran (VI), obtained from evaporation of the ether extract, was treated with acetic anhydride (10 ml) and pyridine (8 ml). The mixture was heated at 40° for 1 hr, and then ether and 0.5 *N* HCl were added. Usual workup gave 2-(2-acetoxyethyl)-2,3-dihydrobenzofuran (VII) (87% yield), bp 140–142°/2 mm Hg. The IR and UV spectra were as expected.

Compound VII (6 g, 29 mmoles) was added to a solution of anhydrous zinc chloride (4.8 g, 36 mmoles) in acetic anhydride (12 ml, 128 mmoles) with stirring over 30 min at 5°. After 2.5 hr at this temperature, the reaction mixture was extracted with ether. The workup gave 2-(2-acetoxyethyl)-5-acetyl-2,3-dihydrobenzofuran (VIII), bp 202–204°/2 mm Hg, mp 43–44°. The IR and UV spectra agreed with the expected structure.

[1] Furofenac has been patented by Schiapparelli, Turin, Italy.

[2] Melting points were determined in open capillary tubes and are uncorrected. IR spectra were obtained with a Perkin-Elmer 257 spectrophotometer in a potassium bromide disk. UV spectra were obtained with a Perkin-Elmer 550 spectrophotometer in methanol. ^1H-NMR spectra were obtained in deuteromethanol with a Jeol 60 HL spectrometer with tetramethylsilane as the internal standard. Mass spectra were obtained with an LKB 9000 gas–liquid chromatograph–mass spectrometer. GLC analyses were carried out on a Perkin-Elmer 3920 instrument equipped with a flame-ionization detector. HPLC analyses were performed on a Perkin-Elmer 601 instrument equipped with a UV/visible variable-wavelength detector. Elemental analyses were performed by Istituto di Chimica degli Intermedi, University of Bologna. All reagents and solvents were of analytical reagent grade and were used without further purification.

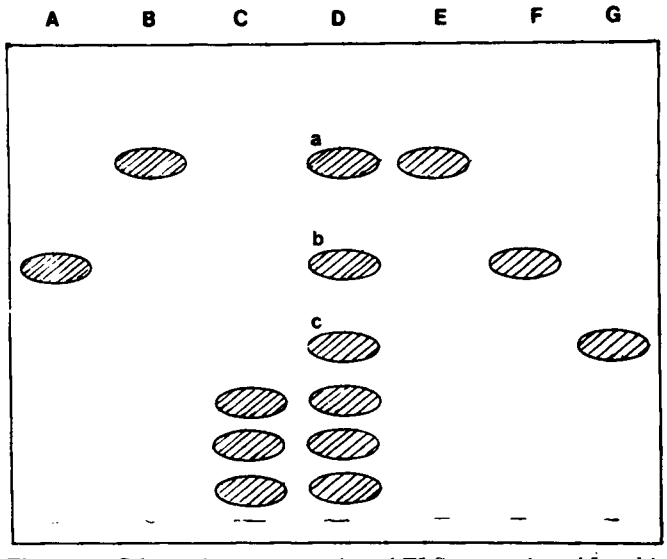

Figure 1—*Schematic representation of TLC separation of I and its metabolites. Key: A, XV; B, I; C, urine blank; D, chloroform extract A of rat urine samples; E, XVI; F, V; and G, X.*

Compound IX was obtained (85% yield) from VIII by treatment with thallium trinitrate as described for the preparation of IV.

2-(2-Hydroxyethyl)-2,3-dihydrobenzofuran-5-ylacetic Acid (X)—Crude IX was hydrolyzed with sodium hydroxide in ethanol–water to afford X (77% yield), mp 111–113° (dichloroethane); IR: 3400, 2920, 1690, 1495, 1410, 1255, 1210, and 1055 cm^{-1}; UV (CH_3OH): 232 (log ϵ 3.823) and 286 (3.475) nm; mass spectrum: *m/e* 222 (M^+, 100%); ^1H-NMR: δ 6.54–7.05 (m, 3), 4.93 (m, 1), 3.73 (t, 2), 3.48 (s, 2), 3.00 (m, 2), and 1.90 (m, 2) ppm.

Anal.—Calc. for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35. Found: C, 64.58; H, 6.34.

2-Ethyl-3-hydroxy-2,3-dihydrobenzofuran-5-ylacetic Acid (XV)—Butyryl chloride (10.5 g, 0.1 mole) was added to a solution of *p*-hydroxyphenylacetic acid ethyl ester (18 g, 0.1 mole) and pyridine (7.9 g, 0.1 mole) in methylene chloride (50 ml) over 30 min. The mixture was refluxed for 2 hr and worked up to give *p*-butyryloxyphenylacetic acid ethyl ester (XI).

Compound XI (25 g, 0.1 mole) and aluminum chloride (32 g, 0.24 mole) were heated at 120–130°. The mixture was stirred with 2 *N* HCl, and the precipitate obtained was filtered. Crystallization from carbon tetrachloride yielded 3-butyryl-4-hydroxyphenylacetic acid (XII) (69% yield), mp 115–117°.

Bromine (8.3 g, 52 mmoles) was added to a solution of XII (11.1 g, 0.05 mole) in dichloroethane (60 ml) over 2.5 hr. After standing overnight, the solution was treated with hexane to afford 3-[(α-bromo)butyryl]-4-hydroxyphenylacetic acid (XIII) (88% yield), mp 135–137°.

Treatment of XIII (13 g, 43 mmoles) with a solution of sodium bicarbonate (13 g, 0.15 mole) in water (90 ml) gave 2-ethyl-3-oxo-2,3-dihydrobenzofuran-5-ylacetic acid (XIV) (78%), mp 118–120° (cyclohexane–ethyl acetate).

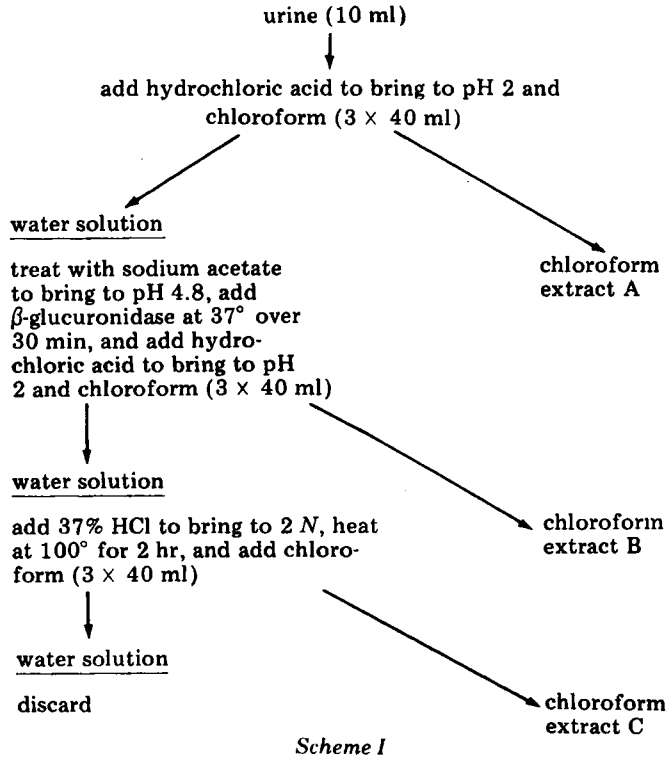
A solution of XIV (6.6 g, 33 mmoles) and sodium bicarbonate (2.8 g, 33 mmoles) in 30 ml of water was treated slowly with sodium borohydride (0.8 g, 21 mmoles). After 1.5 hr at room temperature, the reaction mixture was quenched with ethanol (8 ml) and chloroacetic acid (8.5 g, 90 mmoles) to give XV, mp 122–123° (80% yield); IR: 3200, 2940, 1680, 1625, 1485, 1415, 1300, 1270, 1240, 1210, 1145, 1060, 1025, 980, 925, 890, 815, 785, 755, and 710 cm^{-1}; UV: 232 (log ϵ 3.850) and 286 (3.426) nm; ^1H-NMR: δ 7.30–6.60 (m, 3), 4.20 (m, 1), 3.42 (s, 2), 1.70 (m, 2), and 1.00 (t, 3) ppm; mass spectrum: *m/e* 189 (100%) and 222 (M^+, 98).

Anal.—Calc. for $C_{12}H_{14}O_4$: C, 64.85; H, 6.35. Found: C, 65.25; H, 6.26.

After heating in 2 *N* HCl for 0.5 hr, XV was dehydrated to XVI.

2-Ethylbenzofuran-5-ylacetic Acid (XVI)—*N*-Bromosuccinimide (1.8 g, 10 mmoles) was added over 30 min to a carbon tetrachloride solution (30 ml) of I (2.05 g, 10 mmoles) and a catalytic amount of benzoyl peroxide. The mixture was refluxed for 1 hr, cooled, and filtered on a small silica gel column, from which XVI was eluted with methylene chloride–methanol (50:1, v/v). Pure XVI was obtained (60% yield) by crystallization from cyclohexane, mp 90–92°; IR: 2960, 2900, 1690, 1590, 1465, 1410, 1295, 1265, 1235, 1190, 1150, and 930 cm^{-1}; UV: 249 (log ϵ 4.129), 281 (3.514), and 288 (3.537) nm; mass spectrum: *m/e* 159 (100%) and 204 (M^+, 71); ^1H-NMR (*d*-chloroform): δ 10.86 (s, 1), 7.10–7.48 (m, 3), 6.38 (s, 1), 3.70 (s, 2), 2.81 (s, 2), and 1.30 (t, 3) ppm.

Anal.—Calc. for $C_{12}H_{12}O_3$: C, 70.57; H, 5.92. Found: C, 70.90; H, 5.99.



Scheme I

***In Vivo* Metabolism**—Adult male rats (Wistar), 250 g, and male beagle dogs, ~12 kg, were fed normally during drug administration. The cages were equipped with a urine–feces separator. No metabolic inducers were used. Tests also were performed on human volunteers in good health.

Compound I was administered orally in single doses to rats (500 mg/kg in arabic gum), dogs (100 mg/kg in a jelly capsule), and human volunteers (6.5 mg/kg in a hard jelly capsule). Individual 24-hr urine was collected after administration.

Urine Extraction—The drug and metabolites were extracted from collected urine according to Scheme I. Each chloroform extract was dried

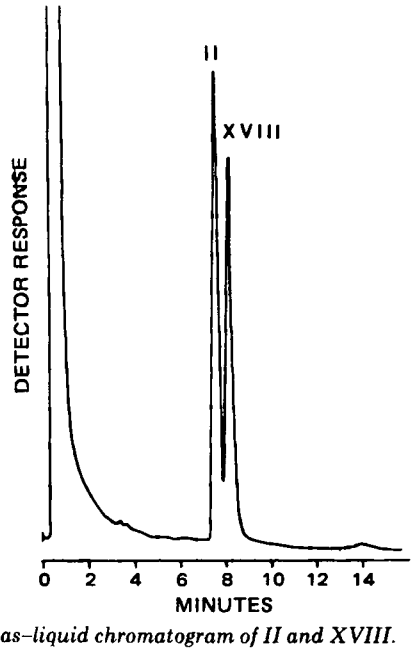


Figure 2—*Gas–liquid chromatogram of II and XVIII.*

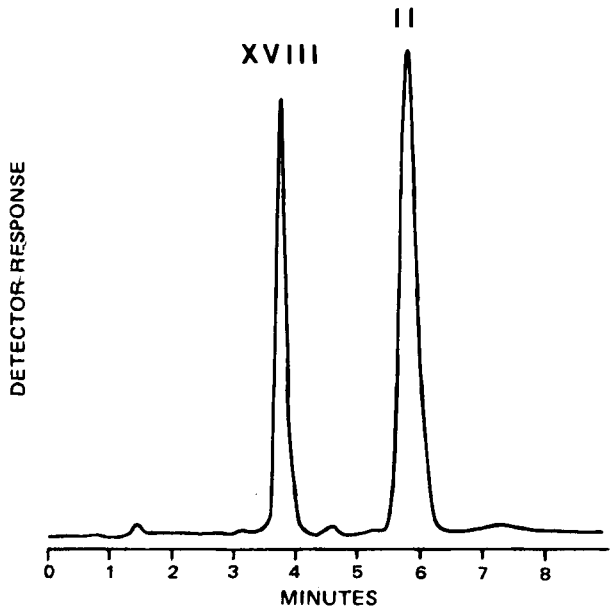

Figure 3—*High-pressure liquid chromatogram of II and XVIII.*

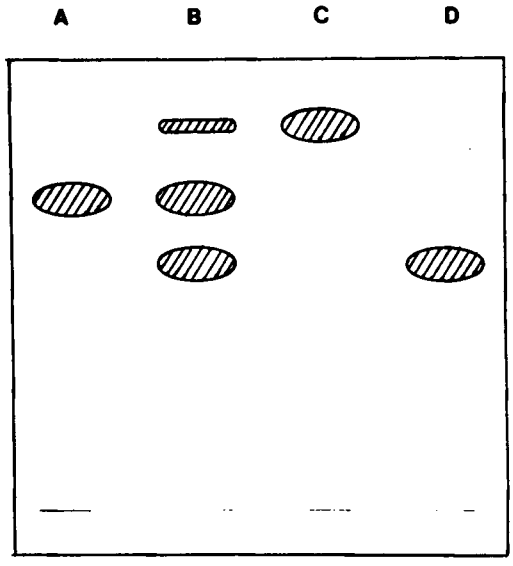

Figure 4—*Schematic representation of the TLC separation of IV, XVII, and XVIII. Key: A, XVII; B, urine band with* R_f *equal to that of V and XV eluted from the plate and treated with diazomethane and then acetic anhydride; C, XVIII; and D, IV.*

over sodium sulfate and concentrated to about 1 ml. The blanks were obtained according to the same procedure.

TLC—The chloroform extract (0.3 ml of the concentrated solution) was deposited on silica gel F-254 layers using benzene–dioxane–acetic acid (90:10:2, v/v/v) as the eluent and appropriate blanks and authentic samples for comparison.

TLC spots other than those common to the blank were scraped off and extracted with methanol. A UV spectrum was recorded for each solution, which was evaporated subsequently to dryness and then treated with an ether solution of diazomethane. The methyl esters were acetylated at 40° over 2 hr with pyridine and acetic anhydride, the excess of which was destroyed with methanol.

Derivatives IV, IX, XVII, and XVIII thus were obtained from V, X, XV[3], and XVI, respectively. These derivatives were analyzed for homogeneity by GLC, TLC, and high-pressure liquid chromatography (HPLC). Final identification was by mass spectrometry, with the appropriate inlet (direct or GLC), through comparison with the corresponding authentic sample.

Derivatives IV, XVII, and XVIII also were separated by TLC using a 0.75% solution of ethanol in chloroform as the eluent.

GLC—Compounds II and XVIII were separated using a steel column (2 m × 2.5 mm i.d.), packed with SP-1000 (3%) on Chromosorb HP (80–100 mesh) at 190°, with nitrogen as the carrier gas (30 ml/min). An E-301 (3%) on Chromosorb G (80–100 mesh) packing was used for IV and IX at 170°.

HPLC—Separations were performed with a steel column (25 × 0.26 cm) packed with Cyano-Sil-X-1 and set at 40° with a UV detector (285 nm). Chloroform–hexane (1:4, v/v, 1 ml/min) was the eluent.

Mass Spectrometry—Electron-impact mass spectra at 70 ev (source temperature 270–290°) were recorded *via* direct inlet at room temperature. When suitable, previous GLC separation was performed using helium as the carrier gas and a Ryhage separator at 300°. The spectral characteristics were reported previously (9).

Pharmacological and Toxicological Evaluations—The activity of the metabolites was tested in the carrageenan edema test (10). Mouse LD_{50} was determined according to the Spearman–Kärber procedure (11). All metabolites were less active than I and had similar toxicity.

RESULTS AND DISCUSSION

The preliminary data obtained by examination of the thin-layer chromatogram of the urine of rats treated with I suggested the likely formation of metabolites with the same dihydrobenzofuranic structure as I but with higher polarity. However, the neat benzofuranic UV spectrum of the spot corresponding to I was unexpected. The high reactivity toward acetic anhydride of the more polar metabolites and other chemical evidence, as well as known pharmacokinetic transformations [*e.g.*, benzylic hydroxylation (12) and ω and $\omega - 1$ side-chain hydroxylations (13)], indicated that the more polar metabolites were hydroxylated, nonphenolic compounds.

The puzzle of the benzofuranic spot was resolved upon observation of its variable intensity in different extraction conditions of the same urine pool. In particular, a nearly complete disappearance of the benzofuranic spot, accompanied by a slight increase in intensity of one of the polar spots, was observed under strictly defined extraction conditions. This observation suggested that it was a possible chemical artifact due to the decomposition of one of the actual metabolites to the benzofuranic analog of I. The following procedure was followed specifically for the identification of metabolites.

Chloroform extract A of rat urine was resolved into three TLC spots (a, b, and c in Fig. 1) which were not present in the chromatograms of the corresponding blanks. Spot a consisted of two components that could be separated and identified by GLC (Fig. 2) and HPLC (Fig. 3) of the corresponding methyl esters by comparison of their behavior with that of the analogous derivatives of authentic specimens of I and XVI. Spot b was resolved after the methylation–acetylation procedure into two spots (Fig. 4) with R_f values identical to those of independently prepared XVII and IV. Mass spectral analysis confirmed that spot b consisted of XV and

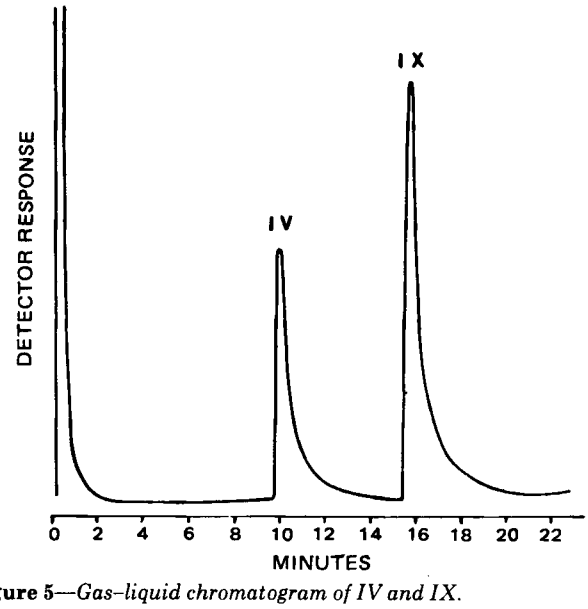

Figure 5—*Gas–liquid chromatogram of IV and IX.*

[3] On methylation and acylation, XV gave rise to XVII and to small amounts of XVIII.

Table I—Drug and Urinary Metabolites Separated from Different Animal Species [a]

Compound	Rats	Dogs	Humans
I	Trace	+	Trace
I glucuronide	−	+++	+++++
I labile acid derivative	−	+++++	++++
XV	+++	+	+
V	+++	+	−
X	++++	++	−

[a] The + indicates the relative abundance of the metabolites in the species.

V. Finally, spot c proved to be X on the basis of TLC and GLC data. The gas–liquid chromatogram of IV and IX is shown in Fig. 5.

In chloroform extracts B and C of rat urine, neither I nor compounds structurally related to I could be detected; a single spot with the same R_f as I was observed in the thin-layer chromatogram of the chloroform extracts B and C of both humans and dogs.

The mass spectra of the compounds extracted from the urine samples were identical to those of the derivatives of I, V, X, XV, and XVI. A comparative examination of the results obtained by the various techniques showed that rats metabolize I to the hydroxylated Compounds X, V, and XV.

Compound XVI is not a true metabolite, and its formation was due to a chemical artifact. In fact, it was only present in substantial amounts when the extraction was made in strongly acidic conditions, whereas the true Metabolite XV was detected in the extracts obtained in weakly acidic conditions. Compound XVI is formed from XV by dehydration.

In rat urine, traces of I also were present. In contrast to the findings for rats, the qualitative pattern of the metabolites of I in dogs was closer to that found in humans. Compound I was eliminated in a form conjugated with glucuronic acid, as shown by TLC of the extracts before and after treatment with β-glucuronidase.

Another conjugate, which gives I when treated with acid, was found in the urine of dogs and humans, but its identity was not elucidated. Amino acid conjugation is a possibility and was observed previously in the metabolism of other arylacetic anti-inflammatory drugs (14, 15). The results of the metabolism of I in different species are shown in Table I.

The initial stage of many biological oxidations is believed to be the abstraction of a hydrogen atom from the substrate. Lowering of the activation barrier for the homolytic cleavage of the CH bonds in I is expected only for the benzylic positions and the CH bond alpha to the ether oxygen. Interestingly, only the ring benzylic position was hydroxylated.

The toxicities of the metabolites were on the same order as the toxicity of the parent drug, and their activities in the carrageenan edema test were lower. Further detailed pharmacological and pharmacokinetic studies on I and its analogs are in progress in these laboratories.

GLC Determination of α- and β-Tribenosides in Human Plasma

ANTOINE SIOUFI ˣ and FRANÇOISE POMMIER

Received July 6, 1979, from the *Biopharmaceutical Research Center, Ciba-Geigy, B.P. 308, 92506 Rueil-Malmaison, France.* Accepted for publication August 30, 1979.

Abstract □ The determination of α-tribenoside at concentrations down to 10 ng/ml and β-tribenoside at concentrations down to 5 ng/ml in human plasma is described. After addition of an internal standard, α- and β-tribenosides are extracted at basic pH into benzene. Both compounds are derivatized with *N*-heptafluorobutyrylimidazole. The derivatives are determined by GLC using a ^{63}Ni-electron-capture detector.

Keyphrases □ Tribenoside—GLC determination of α- and β-anomers, human plasma □ Anti-inflammatory agents—tribenoside, GLC determination of α- and β-anomers, human plasma □ Antiphlebotic agents—tribenoside, GLC determination of α- and β-anomers, human plasma

Tribenoside[1] (ethyl 3,5,6-tri-*O*-benzyl-D-glucofuranoside) is an anti-inflammatory and antiphlebotic agent. It is a mixture of about 33% of the α-anomer and 67% of the β-anomer.

No analytical technique is available for the quantitative assay of the two anomers in plasma. Tribenoside metabolism was studied in rats and dogs after administration of the ^{14}C-labeled drug (1); the blood concentration of the β-anomer remained higher than that of the α-anomer for the first few hours, but the situation was reversed after 20 hr. Metabolism splits the three benzyl groups and the ethyl group, giving several metabolites from each anomer.

This paper describes the GLC determination in plasma of α-tribenoside down to 10 ng/ml and of β-tribenoside down to 5 ng/ml, using β-clobenoside as the internal standard.

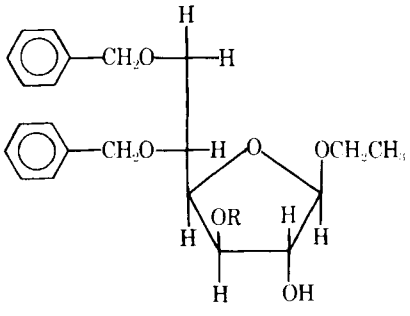
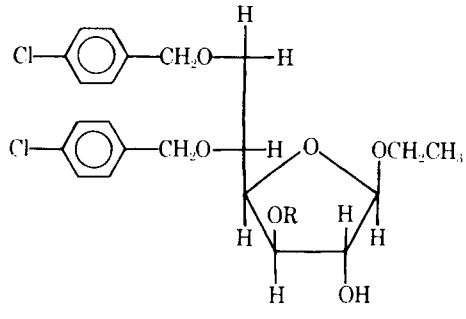
α-tribenoside: R = —CH_2—



β-tribenoside: R = —CH_2—



β-clobenoside: R = —C_7H_7

EXPERIMENTAL

Reagents—The benzene[2], sodium hydroxide[3], and heptane[3] were analytical grade. *N*-Heptafluorobutyrylimidazole[4] was stored at 4° in glass ampuls under nitrogen. The methanolic internal standard solution contained 500 ng of β-clobenoside[5]/ml.

Materials—The glassware was washed for 30 min in an ultrasonic bath, first with water and then with methanol.

The gas chromatograph[6] was equipped with a 15-mCi-^{63}Ni-electron-capture detector[7]. Peak areas were given by an electronic integrator[8]. The column was operated at 270°, the injector temperature was 300°, and the detector was set at 300° with argon–methane (90:10) at a 60-ml/min flow rate.

Glass columns (2 m × 3 mm i.d.) were washed with 1 *M* HCl, distilled water, acetone, and benzene and then were silanized with a 1% (v/v) solution of hexamethyldisilazane in benzene. The columns were washed again with benzene and dried at 100°.

The column packing[9] was 3% OV-17 on 100–120-mesh Gas Chrom Q. The filled columns were flushed with the carrier gas at a flow rate of 40 ml/min and heated to 300° at 1°/min. The column temperature was held overnight at 300° and at 270° throughout the next day. The temperature then was increased repeatedly from 150 to 250° for 24 hr. During these programmed cycles, the columns were conditioned further by the injection of 100 μl of a silylating agent[10] in portions between 150 and 220°. After this procedure, the columns were ready for use.

Extraction—The internal standard solution, 300 μl, was measured into a stoppered glass tube and dried under a nitrogen stream in a water bath at 37°. One milliliter of the sample, 2 ml of 0.1 *M* NaOH, and 4 ml of benzene were added. The tube was shaken mechanically[11] for 15 min and centrifuged at 5000 rpm for 10 min.

An aliquot of the benzene phase was transferred to another tube and dried under a nitrogen stream in a water bath at 37°.

Derivatization and Chromatography—To the dry residue were added 100 μl of heptane and 50 μl of *N*-heptafluorobutyrylimidazole. The solution was mixed thoroughly[12] for 30 sec and allowed to stand for 10 min at room temperature. Then 3 ml of water and 2 ml of heptane were added, and the tube was shaken thoroughly[12] for 30 sec and centrifuged for 3 min at 4000 rpm.

An aliquot of the heptane phase was transferred to another tube and dried under a nitrogen stream in a water bath at 37°; 500 μl of heptane was added, and the tube was shaken on a mixer[12].

Table III—α- and β-Tribenosides (Nanograms per Milliliter) in the Plasma of a Human Subject Given 800 mg of Tribenoside Orally for 7 Days

Anomer	Time after Administration								
	0 hr	1 hr	2 hr	3 hr	4 hr	6 hr	8 hr	Day 2	Day 8
α-Tribenoside	ND[a]	41	53	20	10	6	6	11	14
β-Tribenoside	ND	94	92	51	36	24	24	52	47

[a] ND = not detected.

A 2-μl portion of the heptane solution was injected into the gas chromatograph by the solvent flush technique.

The α- and β-tribenoside content was calculated from the ratio of the peak areas by reference to a calibration curve prepared from a series of dried methanolic α- and β-tribenoside solutions to which plasma was added to yield concentrations between 2 and 150 ng/ml.

Human Subject—A healthy male subject, who had not received any drug for 8 days prior to the experiment and did not take any other drug during the study, received two 400-mg tribenoside capsules before breakfast for 7 days.

Blood samples were collected on the 1st day before and 1, 2, 3, 4, 6, and 8 hr after drug administration. Blood was collected on Days 2 and 3, just before the morning drug administration.

RESULTS AND DISCUSSION

Reaction Time—The derivatization was applied to 10, 25, and 500 ng of α- and β-tribenosides, and the reaction time was varied from 1 to 30 min. Derivative formation was evaluated by peak areas; derivatization was immediate, and the yield of the α- and β-tribenosides was the same over 1–30 min. For convenience and safety, the suggested derivatization time is 10 min.

Sensitivity and Precision—Tables I and II show that when the concentrations of α- and β-tribenosides reached the lower limits, the coefficient of variation increased to ~10. These lower concentrations (10 and 5 ng/ml for α- and β-tribenosides, respectively) may be taken as the assay sensitivity limits; lower concentrations could be detected but could not be determined accurately.

Plasma Interferences—Figures 1*a* and 1*b* show the chromatograms of a blank human plasma extract and the same plasma spiked with 100 ng of α- and β-tribenosides and 150 ng of β-clobenoside, respectively. No interference of the normal plasma components was noted.

Specificity—The four main metabolites (all a mixture of the corresponding α- and β-anomers) were derivatized under the same conditions as tribenoside. These metabolites were ethyl 3,5-di-*O*-benzyl-D-glucofuranoside, ethyl 3,6-di-*O*-benzyl-D-glucofuranoside, ethyl 5,6-di-*O*-benzyl-D-glucofuranoside, and 3,5,6-tri-*O*-benzyl-D-glucofuranoside. Their derivatives were not recorded when chromatographed under the same conditions as tribenoside at concentrations of ≤1 mg/ml.

Application—The technique was used to study the elimination of α- and β-tribenosides after daily oral administration to humans. The plasma concentrations of α- and β-tribenosides are given in Table III. The determinations were done in duplicate.

Effect of Polyols on Interaction of Paraben Preservatives with Polysorbate 80

JAMES BLANCHARD

Received April 3, 1979, from the *Department of Pharmaceutical Sciences, College of Pharmacy, University of Arizona, Tucson, AZ 85721.* Accepted for publication September 14, 1979.

Abstract □ A quantitative study of the interaction of the methyl, ethyl, propyl, and butyl esters of *p*-hydroxybenzoic acid with polysorbate 80 in the presence and absence of two polyols (propylene glycol and glycerol), which were potential competitors, was performed. The results indicate that neither competitor displaced significant amounts of the parabens from their binding sites on polysorbate 80. The previously observed synergistic antimicrobial effects of these polyols appear to be due to a mechanism other than the displacement of the parabens from their micellar binding sites.

Keyphrases □ Polyols—effect of propylene glycol and glycerol on interaction of parabens with polysorbate 80 □ Propylene glycol—effect on interaction of parabens with polysorbate 80 □ Glycerol—effect on interaction of parabens with polysorbate 80 □ Parabens—interaction with polysorbate 80, effect of propylene glycol and glycerol □ Preservatives—parabens, interaction with polysorbate 80, effect of propylene glycol and glycerol □ Polysorbate 80—interaction with paraben preservatives, effect of propylene glycol and glycerol

Several reports described the ability of nonionic surfactants (including polysorbates) to interfere with the activity of phenolic preservatives such as the parabens (1–4). This inactivation is believed to be due to the formation of a complex between the preservative molecules and the surfactant micelle, based on the assumption that the preservative antimicrobial activity is primarily due to the unbound form (3).

Previous work indicated that polyols such as propylene glycol or glycerol could function as preservatives or synergists to preservatives (5–7). Since these studies were designed to determine only whether preservative activity was enhanced by polyol addition, a systematic study was needed to evaluate the mechanism underlying the increased preservative activity associated with the polyols. Thus, a model system was developed to evaluate the ability

Table III—α- and β-Tribenosides (Nanograms per Milliliter) in the Plasma of a Human Subject Given 800 mg of Tribenoside Orally for 7 Days

Anomer	Time after Administration								
	0 hr	1 hr	2 hr	3 hr	4 hr	6 hr	8 hr	Day 2	Day 8
α-Tribenoside	ND[a]	41	53	20	10	6	6	11	14
β-Tribenoside	ND	94	92	51	36	24	24	52	47

[a] ND = not detected.

A 2-μl portion of the heptane solution was injected into the gas chromatograph by the solvent flush technique.

The α- and β-tribenoside content was calculated from the ratio of the peak areas by reference to a calibration curve prepared from a series of dried methanolic α- and β-tribenoside solutions to which plasma was added to yield concentrations between 2 and 150 ng/ml.

Human Subject—A healthy male subject, who had not received any drug for 8 days prior to the experiment and did not take any other drug during the study, received two 400-mg tribenoside capsules before breakfast for 7 days.

Blood samples were collected on the 1st day before and 1, 2, 3, 4, 6, and 8 hr after drug administration. Blood was collected on Days 2 and 3, just before the morning drug administration.

RESULTS AND DISCUSSION

Reaction Time—The derivatization was applied to 10, 25, and 500 ng of α- and β-tribenosides, and the reaction time was varied from 1 to 30 min. Derivative formation was evaluated by peak areas; derivatization was immediate, and the yield of the α- and β-tribenosides was the same over 1–30 min. For convenience and safety, the suggested derivatization time is 10 min.

Sensitivity and Precision—Tables I and II show that when the concentrations of α- and β-tribenosides reached the lower limits, the coefficient of variation increased to ~10. These lower concentrations (10 and 5 ng/ml for α- and β-tribenosides, respectively) may be taken as the assay sensitivity limits; lower concentrations could be detected but could not be determined accurately.

Plasma Interferences—Figures 1*a* and 1*b* show the chromatograms of a blank human plasma extract and the same plasma spiked with 100 ng of α- and β-tribenosides and 150 ng of β-clobenoside, respectively. No interference of the normal plasma components was noted.

of various polyols to inhibit the complexation of several paraben preservatives with polysorbate 80.

In initial efforts (8), sorbitol was the polyol chosen for study because of its compatibility with ingredients common to pharmaceutical formulations. Since sorbitol proved to be an ineffective competitive complexing agent, presumably because of its relatively high polarity, less polar polyols such as propylene glycol and glycerol were selected; these agents had previously been reported to act as synergists to preservatives (6, 7).

EXPERIMENTAL

Reagents—The following were used: methylparaben[1] (I), mp 130°; ethylparaben[2] (II), mp 117°; propylparaben[3] (III), mp 96–97°; butylparaben[4] (IV), mp 70°; polysorbate 80[5]; propylene glycol (reagent grade)[6]; and glycerol[7] (spectrophotometric grade).

The parabens were recrystallized from distilled water (9, 10) and dried in a desiccator for at least 48 hr prior to use. Polysorbate 80, propylene glycol, and glycerol were used without further purification. All solutions were prepared with double-distilled water from an all-glass apparatus.

Procedures—The dialysis procedures and equipment were similar to those described previously (8). Commercially available[8] acrylic plastic dialysis cells were employed. Nylon[9] membranes, previously washed for 1 hr in distilled water and heated to 80° to remove contaminants, were satisfactory. These membranes were previously shown to be impermeable to the polysorbate yet permeable to the parabens, thereby allowing equilibration of the latter (2, 11).

After the cells were assembled, 5 ml of distilled water was added to one cell compartment (the aqueous compartment) and 5 ml of a mixture of varying volume ratios of preservative in 10% (w/v) polysorbate 80 and polysorbate 80 (10% w/v) was added to the other cell compartment (the surfactant compartment). This procedure was employed to vary the amount of preservative present in the surfactant compartment while maintaining the polysorbate concentration constant at 10% (w/v). The cells were then placed on a shaker bath[10] and agitated at 120 oscillations/min for 20 hr at room temperature (23–25°) to achieve equilibrium.

Samples of preservative were removed from both sides of the membrane and assayed spectrophotometrically at 255 nm (2, 12) against blanks prepared identically, except for the omission of the parabens. This procedure was essential to compensate for any polysorbate absorption. Polysorbate 80 solutions stored for more than 4 weeks sometimes gave evidence of microbial growth. To avoid this problem, fresh polysorbate 80-containing solutions were prepared every 3 weeks.

In developing the spectrophotometric assay, it was noted that the absorption spectra of the parabens were pH dependent. As the pH was increased, the peak at 255 nm gradually decreased in intensity and a peak, centered at about 296 nm (13–15), increased in intensity. This second peak was likely due to the ionization of the weakly acidic phenolic proton of the parabens, which have pKa values of 8.4–8.5 (14). The simultaneous existence of the two paraben forms (*i.e.*, ionized and unionized) was undesirable in assaying the solutions accurately and in studying the binding of only the more active unionized form (16, 17), which reportedly binds more avidly to polysorbate 80 than the ionic form (18).

In addition, the parabens are reported to be relatively unstable at pH values above 6 (18, 19). Since the absorption spectra of the parabens should be pH independent at pH 6 or below (where they would be essentially 100% unionized), a study was performed to determine whether the paraben binding profile in a system buffered to pH 5.5 (0.1 *M* acetate) would differ significantly from that observed with an aqueous unbuffered system, as employed by Patel and Kostenbauder (2). The results of this comparison indicated that the use of unbuffered aqueous systems provides binding data that are equivalent to data obtained using a pH 5.5 system. Thus, in subsequent experiments, unbuffered aqueous systems were employed. Measurements at the start and completion of several

experimental runs indicated that the pH remained relatively constant (pH ≤ 6).

Propylene glycol and glycerol were added as possible competitors to the preservative in 10% (w/v) polysorbate 80 solution such that, in any aliquot portion, the molar ratio of polyol to paraben was constant at either 10:1 (propylene glycol) or 5:1 (glycerol). The assays were identical to those in the experiments involving no competitor since neither polyol interfered with the preservative assay at the dilutions necessary to assay for the parabens.

RESULTS AND DISCUSSION

The degree of interaction of each paraben with polysorbate 80 was determined by assaying spectrophotometrically the surfactant compartment of the dialysis cell to determine the total paraben concentration, D_t, and then assaying the aqueous compartment to determine the free (unbound) paraben concentration, D_f. The bound paraben concentration, D_b, was calculated as the difference between these two values.

To obtain information about the binding mechanism, the following mass action treatment was employed (20). It is applicable to binding phenomena in undersaturated systems such as those utilized here.

For a macromolecule with m classes of independent and equivalent binding sites, with each class i having n_i sites with an intrinsic association (binding) constant K_i, the following expression may be written:

$$r = \frac{[D_b]}{[M_t]} = \sum_{i=1}^{m} \frac{n_i K_i [D_f]}{1 + K_i [D_f]} \qquad \text{(Eq. 1)}$$

where r is the number of moles of paraben bound per mole of surfactant; $[D_b]$ and $[D_f]$ are the concentrations of bound and free (unbound) paraben, respectively; and $[M_t]$ is the concentration of macromolecule (surfactant). Theoretically, $[M_t]$ should be the micelle concentration, n the number of binding sites per micelle, and K the association constant for the reaction with the micelles since the binding interaction reportedly occurs between the preservative and the surfactant micelles rather than the monomer surfactant molecules (11, 21). From a practical standpoint, however, it is more convenient to express K, n, and M_t in terms of the surfactant concentration since the micellar molecular weight is not known precisely. Since the critical micelle concentration of polysorbate 80 is very low (21, 22), the monomer concentration may be neglected (11). In analyzing the data, the molecular weight of polysorbate 80 was assumed to be 1470[11].

A Scatchard (23) plot results when $r/[D_f]$ *versus* r is plotted. By rearranging Eq. 1, it can be observed that this type of plot should be linear with a slope of $-K$ and ordinate and abscissa intercepts of nK and n, respectively, when only one class of binding sites is present.

This simplest of binding models is referred to as the "two-parameter model" (24) since only n and K need to be determined to describe the binding adequately. However, as noted previously (9, 11, 25), Scatchard plots frequently exhibit curvature indicative of more than one class of binding sites. To describe these more complex binding processes, Eq. 1 may be rewritten as:

$$r = \sum_{i=1}^{m-1} \frac{n_i K_i [D_f]}{1 + K_i [D_f]} + n_m K_m [D_f] \qquad \text{(Eq. 2)}$$

when one association constant becomes very small. This can occur when the second class of binding sites is not saturable within the experimentally investigated range of ligand concentrations. In such instances, $[D_t] \ll 1/K_2$, where $[D_t]$ = the total drug (ligand) concentration employed. The second term on the right-hand side of Eq. 2 is, therefore, indicative of a class of binding sites that possesses an "infinite" (nonsaturable) binding capacity but "zero" affinity, thereby producing a horizontal asymptote on the Scatchard plot. This binding process can be described by a three-parameter model, which corresponds to a value of $m = 2$ in Eq. 2, and may be written as:

$$\frac{r}{[D_f]} = \frac{n_1 K_1}{1 + K_1 [D_f]} + C \qquad \text{(Eq. 3)}$$

where $C = n_2 K_2$. Often these two different classes of binding sites are designated as "specific" (subscript 1) and "nonspecific" (subscript 2) binding (26).

As illustrated by Winkler and Hubner (26), it is often necessary to use other plots in conjunction with the Scatchard plot to ascertain the binding models correctly. For example, if it is assumed that the smallest unbound ligand (preservative) concentration in the experiment is large relative to $1/K_1$, Eq. 3 can be rewritten as:

$$r = n_1 + C[D_f] \qquad \text{(Eq. 4)}$$

Equation 4 indicates that a plot of r *versus* $[D_f]$ should produce a straight line of slope C and an ordinate intercept of n_1.

To determine the applicability of Eq. 4 in describing the binding, the equation was fitted to the data plotted in Figs. 1–4. These plots illustrate the interaction between 10% (w/v) polysorbate 80 and I–IV, alone and in the presence of propylene glycol or glycerol. The best-fit binding parameters for the interaction of the various parabens with polysorbate 80 (Table I) were calculated by least-squares linear regression.

The linearity of these plots, as indicated by the high coefficients of determination for the linear regressions, is good evidence of the adherence of the binding data to Eq. 4. The values of C listed in Table I may be interpreted as being indicative of a weak, nonspecific (nonsaturable) type of binding analogous to a partitioning of the preservative between the micellar and aqueous phases (17, 21). In a Scatchard plot, they would

[a] Molar ratio of competitor to preservative is shown in parentheses (r^2, n_1, and C are derived from r *versus* D_f plots). [b] Octanol–water partition coefficient data from Ref. 27. [c] All parameter uncertainties are expressed as standard errors.

represent a constant value of $r/[D_f]$ (*i.e.*, a horizontal asymptote) at large r values. The partitioning phenomenon may be envisioned as a process whereby preservative molecules, in an attempt to lower their free energy, migrate from a thermodynamically less stable aqueous environment in the bulk phase to a more stable (less polar) micellar phase, with the degree of penetration and affinity being proportional to their lipophilicity.

The data also indicate that the values of C observed for the parabens are in excellent agreement with their reported (27) octanol–water partition coefficients (Fig. 5), which further substantiates that the binding process described by the term C is a type of partitioning phenomenon. The coefficient of determination for the regression of the calculated values of C on the partition coefficients was 0.9968. This excellent agreement between C and the lipophilicity of the preservative molecules also supports the notion that the binding sites are less polar than their surrounding aqueous environment.

The values of C obtained for each of the four parabens are also illustrated in Fig. 6 since the values of C plotted as the ordinate in Fig. 5 are equal to the slopes of the respective lines plotted in Fig. 6. This plot illustrates that the relative binding affinities of the four parabens for polysorbate 80 are in the order butyl > propyl > ethyl > methyl. This relative binding order was previously noted by other investigators (28–30).

In addition to the simple partitioning mechanism described, Higuchi and Lach (31) proposed that phenolic compounds that possess an acidic hydrogen could associate with electrophilic atoms such as oxygen, found in the polyether ethylene oxide chains of nonionic surfactants. They suggested that this type of interaction could be enhanced by the "squeezing together" of the hydrophobic portions of the interacting molecules by water molecules. This rationale provides a possible explanation for the progressive increase in binding to polysorbate 80 observed as the nonpolar character of the paraben was increased from the methyl to the butyl esters. The relative binding affinities based on the data of Fig. 6 (*i.e.*, the slopes of each plot) are in the order 1:2.5:7.8:21.5, from the methyl to the butyl esters, respectively.

Barr and Tice (4) and deNavarre (32) postulated that the inactivation of phenolics by nonionic surfactants was due to this type of complex formation. Other investigators, however, postulated that these interactions may be explained adequately in terms of solubilization within surfactant micelles (33). Some investigators (34, 35) suggested that, because inactivation occurs between preservatives and surfactants of extremely diverse chemical structure, solubilization is a more probable explanation than specific complex formation.

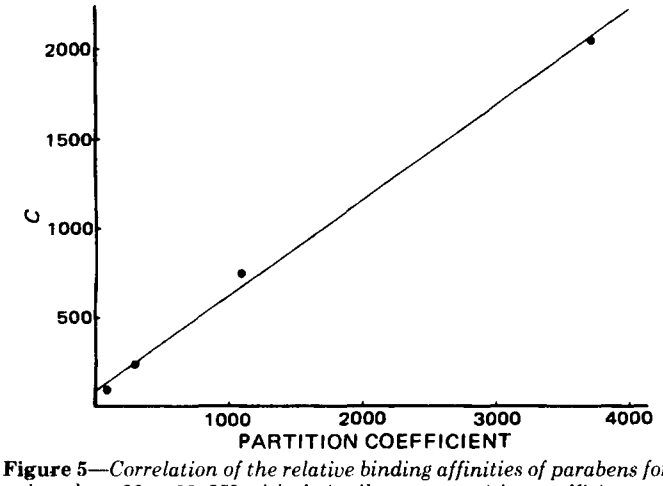

Figure 5—*Correlation of the relative binding affinities of parabens for polysorbate 80 at 23–25° with their oil–water partition coefficients.*

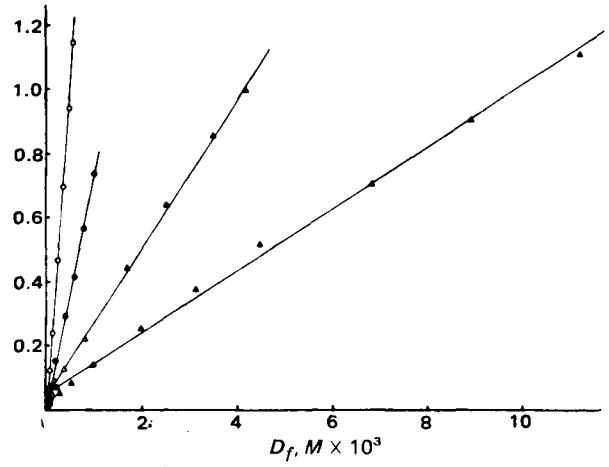

Figure 6—*Relative binding affinities of parabens to polysorbate 80 at 23–25°. Key: ▲, methylparaben; △, ethylparaben; ●, propylparaben; and ○, butylparaben. All data points represent the average of duplicate determinations.*

The literature indicates that a significant preservative–surfactant interaction requires micelles regardless of which mechanism is operative. In fact, micelles of nonionic surfactants probably provide an environment highly suited for both hydrogen bonding and micellar solubilization to operate simultaneously.

The r *versus* $[D_f]$ plots (Figs. 1–4) that illustrate the binding of the various paraben derivatives to polysorbate 80 also indicate that neither propylene glycol or glycerol displaced significant amounts of bound preservative from the polysorbate micelle. This result is shown by the virtual superimposability of these plots and the close agreement of the binding parameters (Table I) in the presence and absence of either polyol. These polyols probably are too polar to partition deeply enough into the polysorbate 80 micelle to displace the bound preservative. The previously reported synergistic antimicrobial effects of these polyols with the parabens apparently occur *via* a mechanism other than the simple displacement of the preservative molecules from their micellar binding sites. The antimicrobial activity enhancement associated with these agents possibly may be due to an osmotic effect or to their ability to hydrogen bond preferentially with available water, thereby preventing microorganism metabolism (5, 36–38) even though the polyol concentrations used (<6% w/v for propylene glycol and <5% w/v for glycerol) were considerably less than the levels (20–50%) described by Barr and Tice (37). An alternative possibility is that the polyol concentrations were too low to produce a measurable displacement of the bound paraben species.

trans-Cinnamic Acid–α-Cyclodextrin System as Studied by Solubility, Spectral, and Potentiometric Techniques

KENNETH A. CONNORS ˣ **and THOMAS W. ROSANSKE**

Received July 18, 1979, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication September 19, 1979.

Abstract □ Complex formation in aqueous solutions of *trans*-cinnamic acid or *trans*-cinnamate ion (the substrate, S) and α-cyclodextrin (the ligand, L) can be described quantitatively as the 1:1 and 1:2 complexes, SL and SL_2. The solubility, spectral, and potentiometric data over a wide range of ligand concentrations yielded consistent estimates of the complex association constants. For cinnamic acid at 25°, $K_{11} = 2260\ M^{-1}$, $\Delta H^\circ_{11} = -9.3$ kcal/mole, and $\Delta S^\circ_{11} = -8$ e.u.; and $K_{12} = 60\ M^{-1}$, $\Delta H^\circ_{12} = -12$ kcal/mole, and $\Delta S^\circ_{12} = -26$ e.u. For cinnamate ion at 25°, $K_{11} = 110\ M^{-1}$, $\Delta H^\circ_{11} = -1.9$ kcal/mole, and $\Delta S^\circ_{11} = +11$ e.u.; and $K_{12} = 15\ M^{-1}$, $\Delta H^\circ_{12} = -9$ kcal/mole, and $\Delta S^\circ_{12} = -15$ e.u. (all entropy changes are unitary quantities). Thermodynamic cycles for the complexes, using solubility data, reveal that complex formation in the solid phase is thermodynamically spontaneous but that complex stability is greater in aqueous solution than in the solid phase.

Keyphrases □ Complexation—*trans*-cinnamic acid with α-cyclodextrin, thermodynamic analysis, stoichiometry, stability equilibria, determined by spectral, solubility, and pH measurements □ Thermodynamics—complexation analysis, determined by spectral, solubility, and pH measurements, *trans*-cinnamic acid–α-cyclodextrin complex □ *trans*-Cinnamic acid—analysis of complexation with α-cyclodextrin, thermodynamics □ α-Cyclodextrin—analysis of complexation with *trans*-cinnamic acid, thermodynamics □ Solubility measurements—complexation of *trans*-cinnamic acid with α-cyclodextrin □ UV spectrometry—complexation of *trans*-cinnamic acid–α-cyclodextrin □ pH measurements—complexation of *trans*-cinnamic acid–α-cyclodextrin

The chemical and physical properties of *trans*-cinnamic acid and its derivatives make these compounds highly useful substrates[1] in studies of molecular complex formation (1–7). Preliminary studies in this laboratory on the *trans*-cinnamic acid–α-cyclodextrin (cyclohexaamylose) system in aqueous solution showed that simple 1:1 stoichiometry in the complex does not adequately describe the equilibrium system. This observation seemed to be worth pursuing because cinnamic acid reportedly forms a 1:1 complex with α-cyclodextrin (8) and because this substrate does not seem to be an atypical one in such studies; hence,

[1] The substrate is the compound whose measured properties constitute the dependent variable; the ligand is the substance (α-cyclodextrin in this case) whose concentration is the independent variable.

trans-Cinnamic Acid–α-Cyclodextrin System as Studied by Solubility, Spectral, and Potentiometric Techniques

KENNETH A. CONNORS ˣ **and THOMAS W. ROSANSKE**

Received July 18, 1979, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication September 19, 1979.

Abstract □ Complex formation in aqueous solutions of *trans*-cinnamic acid or *trans*-cinnamate ion (the substrate, S) and α-cyclodextrin (the ligand, L) can be described quantitatively as the 1:1 and 1:2 complexes, SL and SL_2. The solubility, spectral, and potentiometric data over a wide range of ligand concentrations yielded consistent estimates of the complex association constants. For cinnamic acid at 25°, $K_{11} = 2260\ M^{-1}$, $\Delta H^\circ_{11} = -9.3$ kcal/mole, and $\Delta S^\circ_{11} = -8$ e.u.; and $K_{12} = 60\ M^{-1}$, $\Delta H^\circ_{12} = -12$ kcal/mole, and $\Delta S^\circ_{12} = -26$ e.u. For cinnamate ion at 25°, $K_{11} = 110\ M^{-1}$, $\Delta H^\circ_{11} = -1.9$ kcal/mole, and $\Delta S^\circ_{11} = +11$ e.u.; and $K_{12} = 15\ M^{-1}$, $\Delta H^\circ_{12} = -9$ kcal/mole, and $\Delta S^\circ_{12} = -15$ e.u. (all entropy changes are unitary quantities). Thermodynamic cycles for the complexes, using solubility data, reveal that complex formation in the solid phase is thermodynamically spontaneous but that complex stability is greater in aqueous solution than in the solid phase.

Keyphrases □ Complexation—*trans*-cinnamic acid with α-cyclodextrin, thermodynamic analysis, stoichiometry, stability equilibria, determined by spectral, solubility, and pH measurements □ Thermodynamics—complexation analysis, determined by spectral, solubility, and pH measurements, *trans*-cinnamic acid–α-cyclodextrin complex □ *trans*-Cinnamic acid—analysis of complexation with α-cyclodextrin, thermodynamics □ α-Cyclodextrin—analysis of complexation with *trans*-cinnamic acid, thermodynamics □ Solubility measurements—complexation of *trans*-cinnamic acid with α-cyclodextrin □ UV spectrometry—complexation of *trans*-cinnamic acid–α-cyclodextrin □ pH measurements—complexation of *trans*-cinnamic acid–α-cyclodextrin

The chemical and physical properties of *trans*-cinnamic acid and its derivatives make these compounds highly useful substrates[1] in studies of molecular complex formation (1–7). Preliminary studies in this laboratory on the *trans*-cinnamic acid–α-cyclodextrin (cyclohexaamylose) system in aqueous solution showed that simple 1:1 stoichiometry in the complex does not adequately describe the equilibrium system. This observation seemed to be worth pursuing because cinnamic acid reportedly forms a 1:1 complex with α-cyclodextrin (8) and because this substrate does not seem to be an atypical one in such studies; hence,

[1] The substrate is the compound whose measured properties constitute the dependent variable; the ligand is the substance (α-cyclodextrin in this case) whose concentration is the independent variable.

knowledge of its stoichiometric relationships may be of wider utility. Attempts to correlate and to explain complex stability or to explicate complex structures and the forces involved cannot be successful unless the stoichiometries and stabilities of the complexes are known.

Although 1:1 stoichiometric ratios commonly are found for cyclodextrin complexes, different ratios have been reported for some substrates. Among organic acids and acid anions, solid phase stoichiometries other than 1:1 have been found for cinnamic acid (acid–β-cyclodextrin, 2:1) (9), salicylic acid (acid–β-cyclodextrin, 3:1) (10), and some normal aliphatic acids (11). More recently, Laufer and coworkers (12–14) studied some acids and acid anions and found 1:2 (SL_2) complexes of 4-biphenylcarboxylate and *p*-methylcinnamate ions with α-cyclodextrin in aqueous solution.

The present approach to sorting out stoichiometric relationships in complex systems is to use more than one experimental technique capable of providing estimates of stability constants (15). Disagreement of apparent 1:1 stability constants evaluated by several methods is definitive evidence for the presence of at least one complex with a stoichiometry other than 1:1; quantitative agreement among several methods strengthens the argument for a model leading to such consistency. In this study, solubility (16), spectral (17), and potentiometric (18) methods were used.

EXPERIMENTAL

Materials—α-Cyclodextrin[2] was used directly. Drying to constant weight at 90° indicated 9.77% water, corresponding closely to the hexahydrate[3] ($[\alpha]_D^{25} = 150.4 \pm 2.1°$). *trans*-Cinnamic acid was recrystallized from water, mp 133.5–133.7° [lit. (19) mp 133–134°]. Tris(hydroxymethyl)aminomethane base and hydrochloride[4] were used directly. Other chemicals were reagent grade. Water was deionized and distilled from alkaline permanganate.

Apparatus—Spectrophotometric measurements were made on spectrophotometers[5] fitted with jacketed cell compartments for temperature control. The pH measurements were made with a combination electrode[6]. Solubility studies were carried out in a constant-temperature water bath equipped to rotate the sample vessels end-over-end at 32 rpm.

Solubility Method—Equal amounts (50 mg) of cinnamic acid were weighed into each of several 10-ml glass ampuls. To each ampul were added 0.50 ml of 0.10 *M* HCl and graded measured volumes of an aqueous stock solution of α-cyclodextrin. Water was added to make the total volume 5.0 ml. The ampuls were sealed and rotated end-over-end in a 25.0° water bath until solubility equilibrium was reached. (Twenty-four hours was adequate in the initial rising portion of the phase diagram, whereas 10 days was necessary in the plateau regions, as determined by numerous trials.)

The ampuls then were placed upright and motionless at 25° overnight to permit the precipitate to settle. A portion of the clear supernate was withdrawn with a 1-ml disposable syringe equipped with a 3.8-cm (1.5-in.) 20-gauge needle. A 2.0-ml sample of the supernate was titrated to the phenolphthalein end-point with standard sodium hydroxide; a correction was applied to account for the hydrochloric acid present in the sample solution.

The solid phases in the ampuls were collected by filtration and were dried; weighed samples were analyzed for cinnamic acid by titration. The cyclodextrin content was obtained by difference.

Spectral Method—Unionized cinnamic acid was studied by weighing increasing amounts of α-cyclodextrin into each of several 10-ml volumetric flasks; to each flask were added 1.0 ml of 0.1 *M* HCl, 5.0 ml of a stock solution of cinnamic acid, and water to bring to volume. Reference solutions were prepared for each sample solution, containing the same concentrations of cyclodextrin and hydrochloric acid but no cinnamic acid. Absorbance was measured at 279 nm in a 1.0-cm cell. For studies at temperatures other than 25°, concentrations at the experimental temperature were corrected from the concentrations at the temperature of preparation using the density of water.

Cinnamate anion was studied similarly, except that the pH was brought to 9 with tris(hydroxymethyl)aminomethane buffer, ensuring that essentially all of the substrate (pKa 4.35) was ionized whereas essentially none of the α-cyclodextrin (pKa 12) (20) was in anionic form. [Separate potentiometric measurements showed that this buffer does not significantly complex with α-cyclodextrin[7].] Measurements were made at 269 nm. The ionic strength in these and all studies was constant at 0.01 *M*. Control of pH with sodium hydroxide led to essentially the same results as with tris(hydroxymethyl)aminomethane buffers.

Potentiometric Method—A stock solution was prepared to contain equal concentrations of cinnamic acid and sodium cinnamate by exactly half-neutralizing a weighed sample of cinnamic acid with standard sodium hydroxide. The ionic strength was brought to 0.01 *M* with sodium chloride. Increasing amounts of α-cyclodextrin were weighed into each of several flasks, to which equal volumes of the cinnamic acid–cinnamate-ion stock solution were added. The pH of each solution, measured at 25°, was interpreted as pKa′, the apparent pKa of cinnamic acid in that solution.

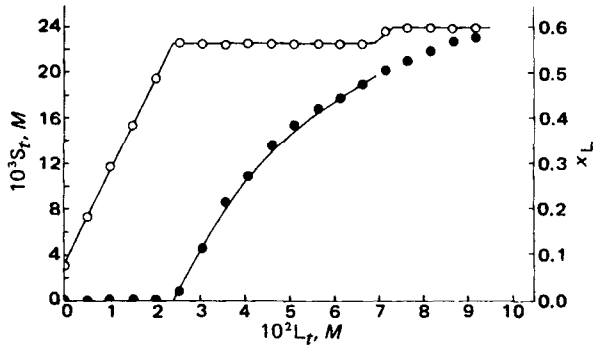

Figure 1—*Solubility of the* trans*-cinnamic acid–α-cyclodextrin system at 25°. Key:* ○ *(left vertical axis), total solution phase concentration of substrate; and* ● *(right vertical axis), mole fraction of cyclodextrin in the solid phase. The total added concentration of ligand (cyclodextrin) is given on the horizontal axis. The smooth lines were calculated as described in the text.*

RESULTS

Solubility Study—Figure 1 shows the experimental results of the solubility study. On the abscissa is specified L_t, the total molar concentration of ligand (α-cyclodextrin) in the system. The left-hand ordinate gives S_t, the total molar concentration of substrate found in the solution phase after equilibration. The right-hand ordinate gives the mole fraction of ligand in the solid phase.

The appearance of the solution phase diagram proves that at least two complexes of different stoichiometry are present, and the solid phase data indicate that a complex is present with an L/S ratio greater than unity. Therefore, these observations suggest that the simplest description of the system will invoke the complexes SL and SL_2. This conclusion may seem inconsistent with the linear nature of the initial rising portion of the solution data, but this will be shown not to be a problem.

To extract numerical estimates from Fig. 1, a quantitative description is required. The complex formation equilibria and stability constants are defined as:

$$S + L \rightleftharpoons SL$$

Scheme I

$$SL + L \rightleftharpoons SL_2$$

Scheme II

$$K_{11} = \frac{[SL]}{[S][L]} \qquad \text{(Eq. 1)}$$

[2] Lot 106C-0046-1, Sigma.
[3] Aldrich.
[4] Sigma.
[5] Cary model 14 or 16.
[6] Orion model 801 pH meter.
[7] A. B. Wong, unpublished results in these laboratories.

$$K_{12} = \frac{[SL_2]}{[SL][L]} \qquad \text{(Eq. 2)}$$

where K_{11} and K_{12} are concentration constants at the experimental ionic strength of 0.01 *M*. Assumptions include the constancy of activity coefficients, a negligible general medium effect, and negligible volume changes (this last assumption was the least well founded but was a relatively unimportant factor).

The following variables need to be defined: S_t is the total solution molar concentration of S, L_t is the total formal molar concentration of L, s_0 is the molar solubility of free S, s_{11} is the molar solubility of SL, and s_{12} is the molar solubility of SL_2. Throughout the initial rising portion of the solution phase diagram, solid substrate is present; hence, the concentration of S is held constant at the solubility limit. The mass balance on S gives:

$$S_t = [S] + [SL] + [SL_2] \qquad \text{(Eq. 3)}$$

which, with the given condition and Eqs. 1 and 2, becomes:

$$S_t = s_0 + K_{11}s_0[L] + K_{11}K_{12}s_0[L]^2 \qquad \text{(Eq. 4)}$$

where [L] is the free ligand concentration. The mass balance on L gives:

$$L_t = [L] + [SL] + 2[SL_2] \qquad \text{(Eq. 5)}$$

which becomes:

$$L_t = [L] + K_{11}s_0[L] + 2K_{11}K_{12}s_0[L]^2 \qquad \text{(Eq. 6)}$$

Eliminating [L] between Eqs. 4 and 6 yields:

$$S_t = s_0 + \frac{L_t}{2} + \frac{ab}{c} - \frac{b}{c}(a^2 + 8K_{11}K_{12}s_0L_t)^{1/2} \qquad \text{(Eq. 7)}$$

where:

$$a = 1 + K_{11}s_0$$

$$b = \frac{a}{2K_{11}s_0} - 1$$

$$c = 4K_{12}$$

Equation 7, which is valid only for finite values of K_{11} and K_{12}, is the equation of the rising portion of the solubility curve for the SL + SL_2 system before the solubility limit of either complex has been reached. The slope is given by dS_t/dL_t (Eq. 8):

$$\frac{dS_t}{dL_t} = \frac{1}{2}\left[1 - \frac{8bK_{11}K_{12}s_0}{c(a^2 + 8K_{11}K_{12}s_0L_t)^{1/2}}\right] \qquad \text{(Eq. 8)}$$

Since a and c must be positive, the curvature in the slope depends upon the sign of b. If $b = 0$, the slope is constant with the value 0.5; this implies that $K_{11} = 1/s_0$. If b is negative, the slope decreases as L_t increases; if b is positive, the slope increases as L_t increases. Whether these cases can be distinguished experimentally will be determined by the magnitudes of the parameters and the range of L_t over which the variable S_t can be observed. The value of the slope at $L_t = 0$ obtained from Eq. 9 is:

$$\left(\frac{dS_t}{dL_t}\right)_{L_t=0} = \frac{1}{2} - \frac{1}{2}\left[\frac{1 - K_{11}s_0}{1 + K_{11}s_0}\right] \qquad \text{(Eq. 9)}$$

The discontinuity giving rise to the segment that is invariant in S_t (the first plateau) needs to be considered. As L_t increases, S_t rises because of the formation of soluble SL and SL_2 complexes. Ultimately, the solubility limit of one of these complexes is reached (as long as the solid S phase is not exhausted first and the solubility limit of L is not reached). Suppose that the solubility of SL is reached before that of SL_2. Then [S] = s_0 and [SL] = s_{11}, and from Eq. 3 one gets:

$$S_t = s_0 + s_{11} + \frac{K_{12}(s_{11})^2}{K_{11}s_0} \qquad \text{(Eq. 10)}$$

That is, S_t becomes invariant as soon as one of the complexes reaches its solubility limit, with the complexation equilibria ensuring that the second complex concentration then also is fixed. This conclusion is general for any number of complexes and no matter which complex reaches its solubility first as long as solid S is present. Thus, the first plateau is accounted for. Of course, the interpretation of S_t in this region depends on which complex has reached its solubility limit. Because of the solid phase data, the argument leading to Eq. 10 appears to apply to Fig. 1.

As L_t continues to increase, the solid S eventually is depleted by its conversion into complexes and its precipitation as solid SL. At the point where solid S disappears, the constraint on S_t is lost (although the condition [SL] = s_{11} still applies). An equation for the dependence of S_t on L_t can be obtained (21); but since it plays no role in the quantitative interpretation of the present data, it can be overlooked. The S_t value rises until the solubility limit of the second complex (SL_2) is reached, when S_t again becomes invariant; its value, given by Eq. 11, is reached by an argument similar to that leading to Eq. 10:

$$S_t = \frac{K_{12}(s_{11})^2}{K_{11}s_{12}} + s_{11} + s_{12} \qquad \text{(Eq. 11)}$$

Thus, a "second plateau" is observed. (If L_t could be made sufficiently large, eventually all solid SL would disappear, and S_t would decrease to a final value approximately equal to s_{12}.)

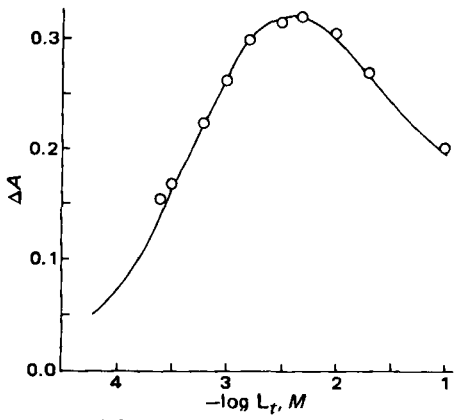

Figure 2—*Spectra of the* trans*-cinnamic acid–α-cyclodextrin system at 25°. The vertical axis gives the change in absorbance in a 1-cm path length of cinnamic acid at 279 nm produced by a total concentration L_t of ligand. The total substrate concentration, S_t, was 8.48 × 10^{-5} M. The ΔA values at the two points corresponding to the highest L_t were corrected for a general medium effect based on an equivalent weight/volume concentration of α-methylglucoside; at L_t = 0.1 M, this correction was 0.009 aufs. The smooth curve was calculated with Eqs. 15 and 16.*

The composition of the solid phase is now considered. From $L_t = 0$ up to the discontinuity marking the beginning of the first plateau, it is postulated that the complex species are soluble so that only solid substrate is present; thus, the mole fraction of cyclodextrin in the solid phase, x_L, should be zero, as is found experimentally (Fig. 1). Throughout the first plateau, the essential feature is that solid S is being replaced by solid SL; therefore, at the beginning of the plateau, $x_L = 0$; at the end of this plateau, $x_L = 0.5$, as is observed. At the beginning of the second plateau, the value of x_L should begin to rise as solid SL is replaced by solid SL_2, the eventual value of x_L being 0.667 (if L_t can be made large enough). Figure 1 shows that x_L does increase in this region, reaching a value of 0.58 at the highest ligand concentration studied.

Equations can be derived relating x_L to L_t in these regions (21), and the smooth line in the first plateau region was calculated with one of these equations, the experimental quantities, and system parameters estimated from the solution phase data. Some ambiguity is introduced by the varying solution phase and total system volumes in these calculations; hence, the qualitative interpretation previously given will suffice for present purposes.

The solubility data were not interpreted independently of the spectral and potentiometric data; rather, for unionized cinnamic acid, the solubility and spectral studies were analyzed to give K_{11} and K_{12} values that best fit both sets of results. These K_{11} and K_{12} values then were imposed as constraints on the potentiometric results. Therefore, uncertainties attached to these values represent limits outside of which the quantitative consistency among the independent sets of data is seriously degraded. These results are obtained at 25°: $K_{11} = 2260 \pm 50\ M^{-1}$, $K_{12} = 60 \pm 5\ M^{-1}$, $s_0 = 3.01 \pm 0.05 \times 10^{-3}\ M$ (the uncertainty is the standard deviation of 11 determinations for s_0), $s_{11} = 1.7 \pm 0.2 \times 10^{-2}\ M$, and $s_{12} = 5.5 \pm 0.5 \times 10^{-3}\ M$ or $1.4 \pm 0.6 \times 10^{-3}\ M$ (because of the ambiguity in a quadratic solution).

Spectral Study—The UV spectrum of cinnamic acid is altered in the presence of α-cyclodextrin. At low cyclodextrin concentrations, isosbestic points are observed at 231 and 296 nm, but these isosbestic points are lost at ligand concentrations greater than ~0.003 *M*. (At such low ligand concentrations, a general medium effect on the spectra cannot account for departure from the isosbestic behavior, as demonstrated by incorporation of α-methylglucoside.) This finding is evidence for at least two

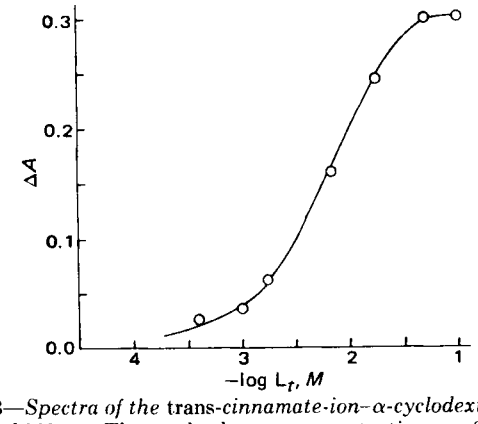

Figure 3—*Spectra of the* trans-*cinnamate-ion–α-cyclodextrin system at 25° and 269 nm. The total substrate concentration was 8.56 × 10^{-5} M. The smooth curve was calculated with Eqs. 15 and 16.*

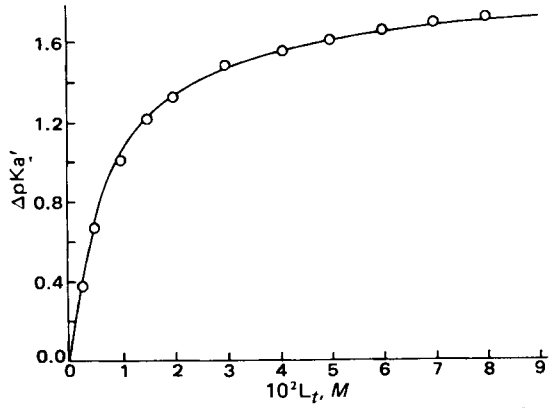

Figure 4—*Potentiometric study of the* trans-*cinnamic acid–α-cyclodextrin system at 25°. The smooth curve was calculated with Eqs. 26 and 34. The total substrate concentration, A_t, was 4.83 × 10^{-3} M.*

complexes. Figure 2 shows the change in absorbance at a fixed wavelength produced by α-cyclodextrin over a wide concentration range.

The analysis of this system assumes SL plus SL_2 complexes for consistency with the solubility results. This system has been treated before (15, 22) but primarily in terms of conventional double-reciprocal graphical analysis, which is not effective for extracting the stability constants. If adherence to Beer's law is assumed for all species, the absorbance for unit path length in a substrate solution containing nonabsorbing ligand is:

$$A = \epsilon_S[S] + \epsilon_{11}[SL] + \epsilon_{12}[SL_2] \qquad \text{(Eq. 12)}$$

In a solution without ligand, it is:

$$A_0 = \epsilon_S S_t \qquad \text{(Eq. 13)}$$

where ϵ_i is the molar absorptivity of species i. The total substrate concentration, S_t, is held constant. Defining $\Delta A = A_0 - A$, $\Delta\epsilon_{11} = \epsilon_S - \epsilon_{11}$, and $\Delta\epsilon_{12} = \epsilon_S - \epsilon_{12}$ and incorporating the relationship between S and free S:

$$S_t = [S](1 + K_{11}[L] + K_{11}K_{12}[L]^2) \qquad \text{(Eq. 14)}$$

relates ΔA to the free ligand concentration:

$$\Delta A = \frac{S_t K_{11}[L](\Delta\epsilon_{11} + \Delta\epsilon_{12}K_{12}[L])}{1 + K_{11}[L] + K_{11}K_{12}[L]^2} \qquad \text{(Eq. 15)}$$

From the mass balance on L:

$$L_t = [L] + \frac{S_t K_{11}[L](1 + 2K_{12}[L])}{1 + K_{11}[L] + K_{11}K_{12}[L]} \qquad \text{(Eq. 16)}$$

It is not practical to express ΔA as an explicit function of L_t, but a numerical curve-fitting procedure is straightforward. Estimates of K_{11}, K_{12}, $\Delta\epsilon_{11}$, and $\Delta\epsilon_{12}$ are obtained from preliminary trials or from supplementary data (*i.e.*, the solubility study). An arbitrary but realistic value of [L] is selected, and the corresponding quantities ΔA and L_t are calculated with Eqs. 15 and 16. These quantities are compared with the experimental values, and the parameters are adjusted until a satisfactory agreement is achieved. As noted earlier, K_{11} and K_{12} were not permitted to vary freely but were constrained by the condition that the final values must account for both the spectral and the solubility data. The smooth curve in Fig. 2 was calculated in this way; at 25°, the results are $K_{11} = 2260\ M^{-1}$, $K_{12} = 60\ M^{-1}$, $\Delta\epsilon_{11} = 4700$, and $\Delta\epsilon_{12} = 1900$. (At 279 nm, $\epsilon_S = 1.98 \times 10^4$.)

Figure 3 is the plot of ΔA *versus* log L_t for the cinnamate-ion–α-cyclodextrin system at 25°. This curve has a sigmoidal shape characteristic of simple 1:1 complexing, and a Benesi–Hildebrand plot of $1/\Delta A$ *versus* $1/L_t$ is linear; evidently, the system can be described in terms of a 1:1 complex. The potentiometric data, however, appear to require the presence of both the SL and SL_2 complexes in the cinnamate-ion system; hence, both complexes are considered to be present in the spectral study. The K_{11} and K_{12} values were required to give consistent fits to both the spectral and the potentiometric data. The smooth curve in Fig. 3 was drawn with Eqs. 15 and 16 and the values $K_{11} = 110 \pm 3\ M^{-1}$, $K_{12} = 15 \pm 2\ M^{-1}$, $\Delta\epsilon_{11} = 4300$, and $\Delta\epsilon_{12} = 3300$. (At 269 nm, $\epsilon_S = 2.04 \times 10^4$.)

Potentiometric Study—The potentiometric method for studying cyclodextrin complexes of weak acids was introduced in 1976 and applied to some 1:1 complexing systems (18). Let pKa represent the negative logarithm of the dissociation constant of the weak acid in the absence of ligand (pKa refers to the experimental conditions and is not the thermodynamic constant), and let pKa′ be the corresponding quantity in the presence of cyclodextrin. Define ΔpKa = pKa′ − pKa. Figure 4 shows the dependence of ΔpKa′ on L_t for the cinnamic acid–α-cyclodextrin system. This curve cannot be accounted for satisfactorily in terms of only 1:1 complexes between cyclodextrin and the unionized and ionized forms of the substrate. Therefore, the theory of this method for the SL + SL_2 case was developed.

Let HA, A^-, and L represent cinnamic acid, cinnamate ion, and cyclodextrin, respectively. Then the three acid–base equilibria are presented as:

$$HA \rightleftharpoons H^+ + A^-$$
Scheme III

$$HAL \rightleftharpoons H^+ + AL^-$$
Scheme IV

$$HAL_2 \rightleftharpoons H^+ + AL_2^-$$
Scheme V

with their acid–base dissociation constants given by:

$$K_a = \frac{[H^+][A^-]}{[HA]} \qquad \text{(Eq. 17)}$$

$$K_{a11} = \frac{[H^+][AL^-]}{[HAL]} \qquad \text{(Eq. 18)}$$

$$K_{a12} = \frac{[H^+][AL_2^-]}{[HAL_2]} \qquad \text{(Eq. 19)}$$

The four complexation equilibria are given by:

$$HA + L \rightleftharpoons HAL$$
Scheme VI

$$A^- + L \rightleftharpoons AL^-$$
Scheme VII

$$HAL + L \rightleftharpoons HAL_2$$
Scheme VIII

$$AL^- + L \rightleftharpoons AL_2^-$$
Scheme IX

with their corresponding stability constants:

$$K_{11a} = \frac{[HAL]}{[HA][L]} \qquad \text{(Eq. 20)}$$

$$K_{11b} = \frac{[AL^-]}{[A^-][L]} \qquad \text{(Eq. 21)}$$

$$K_{12a} = \frac{[HAL_2]}{[HAL][L]} \qquad \text{(Eq. 22)}$$

$$K_{12b} = \frac{[AL_2^-]}{[AL^-][L]} \qquad \text{(Eq. 23)}$$

The apparent acid dissociation constant, K_a', is defined by:

$$K_a' = \frac{[H^+][A^-]_{total}}{[HA]_{total}} = \frac{[H^+]([A^-] + [AL^-] + [AL_2^-])}{[HA] + [HAL] + [HAL_2]} \qquad \text{(Eq. 24)}$$

Table I—Thermodynamic Quantities for Cinnamic Acid–α-Cyclodextrin and Cinnamate-Ion–α-Cyclodextrin Complexes

T, °K	Complex[a]	K, M^{-1}	ΔH°, kcal/mole	ΔS°, e.u. Molar Basis	ΔS°, e.u. Mole Fraction Basis
		trans-Cinnamic Acid			
289	SL	3700 ± 100	−9.3 ± 0.6	−16 ± 2	−8
298	SL	2260 ± 50			
308	SL	1350 ± 80			
318	SL	850 ± 50			
289	SL_2	120 + 10	−12 ± 1	−34 ± 4	−26
298	SL_2	60 ± 5			
308	SL_2	30 ± 3			
318	SL_2	17 ± 2			
		trans-Cinnamate Ion			
298	SL	110 ± 3	−1.9 ± 0.6	+3 ± 2	+11
308	SL	100 ± 3			
318	SL	90 ± 3			
298	SL_2	15 ± 2	−9 ± 3	−23 ± 9	−15
308	SL_2	10 ± 1			
318	SL_2	6 ± 1			

[a] S = substrate (cinnamic acid or anion) and L = ligand (cyclodextrin).

Substitution leads to:

$$K_a' = K_a \frac{[1 + K_{11b}[L] + K_{11b}K_{12b}[L]^2]}{[1 + K_{11a}[L] + K_{11a}K_{12a}[L]^2]} \quad \text{(Eq. 25)}$$

or:

$$\Delta pKa' = \log \frac{[1 + K_{11a}[L] + K_{11a}K_{12a}[L]^2]}{[1 + K_{11b}[L] + K_{11b}K_{12b}[L]^2]} \quad \text{(Eq. 26)}$$

As in the spectral study, it is not feasible to find ΔpKa′ as an explicit function of L_t, but L_t can be related to [L] to give a practical method for evaluating the stability constants. The mass balances on ligand and substrate are written as:

$$L_t = [L] + [HAL] + [AL^-] + 2[HAL_2] + 2[AL_2^-] \quad \text{(Eq. 27)}$$

$$A_t = [HA] + [A^-] + [HAL] + [AL^-] + [HAL_2] + [AL_2^-] \quad \text{(Eq. 28)}$$

Substitution with the equilibrium expressions yields functions of L_t and A_t in terms of the variables [L], [HA], and [H^+]. Under the experimental conditions, [H^+] = K_a', so:

$$C = \frac{K_a}{[H^+]} = \frac{K_a}{K_a'} = \frac{1 + K_{11a}[L] + K_{11a}K_{12a}[L]^2}{1 + K_{11b}[L] + K_{11b}K_{12b}[L]^2} \quad \text{(Eq. 29)}$$

giving:

$$L_t = [L] + [HA](K_{11a}[L] + CK_{11b}[L] + 2K_{11a}K_{12a}[L]^2 + 2CK_{11b}K_{12b}[L]^2) \quad \text{(Eq. 30)}$$

and:

$$A_t = [HA](1 + C + K_{11a}[L] + CK_{11b}[L] + K_{11a}K_{12a}[L]^2 + CK_{11b}K_{12b}[L]^2) \quad \text{(Eq. 31)}$$

Define:

$$K_{11}' = K_{11a} + K_{11b}C \quad \text{(Eq. 32)}$$

and:

$$K_{12}' = K_{11a}K_{12a} + K_{11b}K_{12b}C \quad \text{(Eq. 33)}$$

Then Eq. 34 is obtained:

$$L_t = [L]\left[1 + \frac{K_{11}'A_t + 2K_{12}'A_t[L]}{1 + C + K_{11}'[L] + K_{12}'[L]^2}\right] \quad \text{(Eq. 34)}$$

The procedure is to assign a value to [L] and, with Eqs. 26 and 34 and estimates of the stability constants, to calculate ΔpKa′ and L_t for comparison with the experimental results.

Not all of the constants defined for the system are independent. From the definitions, one obtains:

$$K_{11a}K_{a11} = K_aK_{11b} \quad \text{(Eq. 35)}$$

and:

$$K_{12a}K_{a12} = K_{a11}K_{12b} \quad \text{(Eq. 36)}$$

The smooth curve in Fig. 4 was calculated with Eqs. 26 and 34. In this calculation, K_{11a} and K_{12a} were fixed at 2260 and 60 M^{-1}, respectively, as determined from the solubility and spectral studies; thus, only K_{11b} and K_{12b} were treated as adjustable parameters. Even these parameters, however, were not completely free since they had to account for both the potentiometric data and the spectral study on the cinnamate ion. The final values, as given previously, were K_{11b} = 110 M^{-1} and K_{12b} = 15 M^{-1}. It was necessary to incorporate a finite value for K_{12b} to achieve a satisfactory fit at the higher L_t range in Fig. 4.

Thermodynamic Quantities—Since the comparative studies demonstrated that these systems can be described in terms of SL and SL_2 complexes, any of the experimental techniques suffices to make subsequent estimates of the stability constants. The spectral technique was applied to the cinnamic acid–α-cyclodextrin and cinnamate-ion–α-cyclodextrin systems at several temperatures to obtain enthalpy and entropy changes for the complexation equilibria. The data were analyzed in terms of SL and SL_2 complexes (Table I). Entropy changes on a mole fraction basis (unitary entropy changes) (23) were obtained for Schemes I and II from:

$$\Delta S° \text{ (unitary)} = \Delta S° \text{ (molar)} + 8.0 \text{ e.u.} \quad \text{(Eq. 37)}$$

DISCUSSION

Complex Stoichiometry and Stability—Several kinds of evidence show that the cinnamic acid–α-cyclodextrin system cannot be described solely in terms of 1:1 complexes:

1. The isosbestic points seen at low ligand concentrations are lost at higher concentrations.
2. The shape of the plot of Δ*A versus* log L_t (Fig. 2) requires some process in addition to 1:1 complexation.
3. Apparent 1:1 stability constants, evaluated assuming only 1:1 stoichiometry and using data at low ligand concentration, are 1300 M^{-1} for the solubility method and 2900 M^{-1} for the spectral method, the disagreement being inconsistent with the assumption.
4. The increase of total dissolved substrate after the initial plateau portion of the solubility diagram cannot occur if only 1:1 complexation occurs.
5. The solid phase composition in the solubility study requires an L/S ratio greater than 1:1.
6. The potentiometric curve cannot be fitted with the assumption of 1:1 stoichiometry.

Few modern workers use the solubility method to study molecular complexes, and the technique has been criticized because it does not permit the estimation of stability constants unless the stoichiometry of the interaction is known. This criticism is correct, but the limitation applies equally to every other experimental technique. In the present investigation, the solubility method was the single most useful tool because it not only showed that more than one type of complex must be present, but it also indicated the probable stoichiometric ratios. But the strongest evidence for the interpretation of the cinnamic acid–α-cyclodextrin system in terms of SL and SL_2 complexes is the quantitative

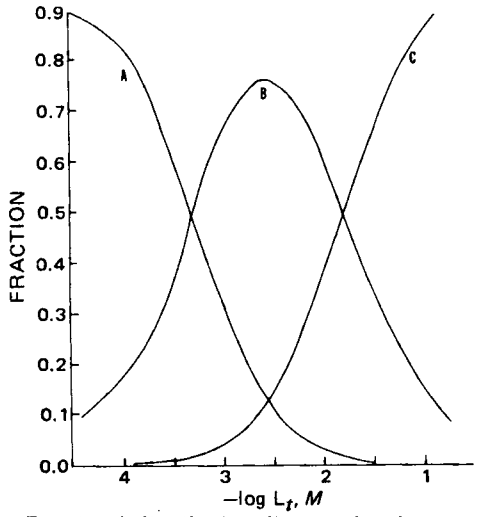

Figure 5—*Fractional distribution diagram for the* trans-*cinnamic acid–α-cyclodextrin system at 25°. The total cinnamic acid concentration was 8.5 × 10⁻⁵* M. *Curves A, B, and C are S, SL, and SL_2, respectively.*

agreement among the three experimental techniques when analyzed according to this model. Such comparative study by independent techniques is one desirable feature of investigations into complex stoichiometries and stabilities; another advantage is extension of the measurements over as wide a range of ligand concentrations as is feasible, preferably over essentially the full binding isotherm.

Should the small values of K_{12} relative to K_{11} (Table I) be thought to render the incursion of SL_2 formation negligible except at a high ligand concentration, it should be noted that the fractional distribution of species S, SL, and SL_2 depends on the product $K_{11}K_{12}$. These distributions (*e.g.*, for SL_2) can be calculated with Eqs. 16 and 38:

$$\text{fraction of } SL_2 = \frac{[SL_2]}{S_t} = \frac{K_{11}K_{12}[L]^2}{1 + K_{11}[L] + K_{11}K_{12}[L]^2} \quad \text{(Eq. 38)}$$

Figure 5 is a fractional distribution diagram for the cinnamic acid–α-cyclodextrin system at 25° with $S_t = 8.5 \times 10^{-5}$ *M*, corresponding to the conditions for the spectral study. At the relatively low total cyclodextrin concentration of 0.01 *M*, about 37% of the cinnamic acid is present as the ternary SL_2 complex. Diagrams of this type should be valuable in selecting experimental conditions for studying complex properties.

The evidence for a ternary SL_2 complex in the cinnamate-ion system is less compelling, consisting of the need to include the term containing K_{12b} in Eq. 26 to achieve a satisfactory fit to the potentiometric data.

Complex Properties and Structures—The symbolism of Schemes VI–IX is adopted here to discuss the several complexes with brevity and without ambiguity. Thus, HA represents cinnamic acid and A^- is cinnamate ion.

Several properties of the complexes (other than the standard thermodynamic quantities to be considered later) were measured in the present study and may be helpful in determining the complex structures. The complex molar absorptivities for HAL, HAL_2, AL^-, and AL_2^- were obtained but only at a single wavelength. The general spectral shifts in the presence of cyclodextrin are not dramatic and do not seem helpful at this point.

With Eqs. 35 and 36, one calculates $pKa_{11} = 5.66$ and $pKa_{12} = 6.27$, compared with pKa = 4.35 for uncomplexed cinnamic acid. Complexing between carboxylic acids and α-cyclodextrin leads to a decrease in the acid strength of the substrate; this is equivalent to saying that the unionized carboxylic acid complexes more strongly than does the carboxylate ion (18). Since the two statements are equivalent, a rationalization of one of them equally accounts for the other. Consider the acidity of HAL (*i.e.*, the acidity of complexed cinnamic acid) relative to that of cinnamic acid in water. Spectroscopic data (24) indicate that the α-cyclodextrin cavity is apolar. If the cinnamic acid group is included within the ligand cavity, it experiences an environment that is comparable (except for "end" effects and restricted molecular motion) to that provided by a solvent such as dioxane or a ketone. In such a medium, having an effective dielectric constant smaller than that of water, the extent of ionization of the carboxylic acid will be less than in water. Therefore, it is anticipated that $K_{a11} < K_a$ for neutral carboxylic acids, from which it follows that $K_{11a} > K_{11b}$, as is observed for these substrates[8]. The same argument applies to the ternary complex HAL_2, which also must be an inclusion complex[9].

The solubility of HAL was determined to be 1.7×10^{-2} *M*. If the substrate HA is included within the cavity, it is not surprising that HAL would have a solubility intermediate to that of the hydrophobic HA ($s_0 = 3.01 \times 10^{-3}$ *M*) and the hydrophilic L ($s_L = 0.125$ *M*). The solubility of HAL_2 is 5.5×10^{-3} *M* (or 1.4×10^{-3} *M*), considerably smaller than that of L or HAL and comparable with that of HA. If HA is included in a channel formed by an end-to-end association of two cyclodextrins, the solubility of HAL_2 will be determined in part by solvent interactions with a dimer-like species L_2; this species is twice as large as L or HAL and provides no additional sites for solvent interaction; hence, its solubility probably will be smaller.

The solubility of the cinnamate-ion–α-cyclodextrin complex was not determined; if it is an inclusion complex with the carboxylate group buried in the cavity, its solubility might be as low as that of HAL. On the other hand, if the carboxylate function is exposed, the complex may be as soluble as the substrate; sodium cinnamate had a solubility of 0.505 *M*. These limits will be used later.

The picture that results from these several kinds of evidence and lines of reasoning is of binary (1:1) inclusion complexes, probably with the side chain in the cavity. The ternary (1:2) complexes may have the substrate in a cavity formed by two ligand molecules associated end-to-end. Although α-cyclodextrin does not form a dimer (28), the SL_2 complex is formed in the presence of cinnamic acid or cinnamate ion. In a sense, cyclodextrin dimerization is promoted by the substrate molecule, the complex structure possibly being much like a dowel joint. Such SL_2 complexes are formed by cinnamic acid, cinnamate ion, *p*-methylcinnamate ion (13), and 4-biphenylcarboxylate ion (12) whereas benzoic acid, benzoate ion (14), and *p*-nitrophenolate ion (18, 27) apparently form only 1:1 complexes. The length of the substrate molecule is possibly a factor determining whether an SL_2 complex forms (11).

Thermodynamic Analysis—The values of free energy and entropy changes depend on the concentration units used in evaluating them, and these quantities can be corrected for the entropy of mixing if the concentrations are expressed on the mole fraction scale (29). The resulting values are called unitary quantities. Table I gives unitary entropy changes (in the last column) for the process studied here[10].

The favorable free energy changes are manifested for the HAL, HAL_2, and AL_2^- complexes as favorable $\Delta H°$ and unfavorable $\Delta S°$ values; for the AL^- complex, the entropy change is favorable and the enthalpy change is very small. Another observation is that, for each substrate, $\Delta H°$ is more favorable and $\Delta S°$ is less favorable for the 1:2 complexes than for the 1:1 complex. (The $\Delta H°$ and $\Delta S°$ for the 1:2 complexes refer to the stepwise process, $SL + L \rightleftharpoons SL_2$, not to the overall process, $S + 2L \rightleftharpoons SL_2$.)

The conventional interpretation of favorable enthalpy changes and of entropy decreases invokes the role of water structure or ordering in the complexation. The negative $\Delta S°$ may signify an increase in solvent ordering in the product state (complex) compared with the individual solvated species. Nonpolar solutes, upon association, show entropy increases, but moderately polar solutes lead to entropy decreases. Jencks (31) pointed out that a favorable $\Delta H°$ may result from solute–solute interactions or from increased solvent–solvent interactions, which are made possible by the greater solvent order. Cyclodextrins are rather special solutes because the cavity contains highly ordered solvent molecules, which must be displaced upon inclusion of a substrate. Van Etten *et al.* (24) suggested that these water molecules cannot form the normal complement of hydrogen bonds because of steric restrictions and that

[8] The same argument applied to phenols may seem to lead to the same prediction. However, phenols behave differently from carboxylic acids in nonaqueous media. For example, in pyridine, the acid strengths of phenols are enhanced relative to those of carboxylic acids, with the result that, for example, *p*-nitrophenol is a stronger acid than is benzoic acid in this solvent (25). Similar behavior is seen in acetone (26). Thus, it is likely that phenol acidity will be increased in the cyclodextrin cavity, with the consequence that $K_{11b} > K_{11a}$, as is seen (18, 27).

[9] The conclusion that HAL and HAL_2 are inclusion complexes follows from the abnormally large equilibrium constants for their formation. (The overall constant for $HA + 2L \rightleftharpoons HAL_2$ is equal to $K_{11}K_{12}$.) When two species interact noncovalently in solution in a simple stacking manner, the stability constant for the process is proportional to the area of contact between the molecules (6). For a molecule the size of cinnamic acid, the maximum value to be expected is on the order of $10^2\ M^{-1}$. Since K_{11} for cinnamic acid–α-cyclodextrin is much higher that this value, some extraordinary stabilizing phenomenon, presumably inclusion, must be occurring. The ternary complex HAL_2 is formed from L and the inclusion complex HAL, so it too is an inclusion complex.

[10] For other discussions of unitary quantities, see Refs. 23 and 30. The authors thank Professor P. Mukerjee, who first called their attention to unitary quantities.

Table II—Thermodynamic Analysis of the Cinnamic Acid–α-Cyclodextrin System

Process[a]	$\Delta G°$ (unitary)[b], cal/mole
1. $S(s) \rightleftharpoons S(aq)$	$+5820 \pm 10$
2. $L(s) \rightleftharpoons L(aq)$	$+3610 \pm 50$
3. $SL(aq) \rightleftharpoons SL(s)$	-4800 ± 70
4. $S(aq) + L(aq) \rightleftharpoons SL(aq)$	-6950 ± 15
5. $S(s) + L(s) \rightleftharpoons SL(s)$	-2320 ± 90
6. $SL(s) \rightleftharpoons SL(aq)$	$+4800 \pm 70$
7. $L(s) \rightleftharpoons L(aq)$	$+3610 \pm 50$
8. $SL_2(aq) \rightleftharpoons SL_2(s)$	-5460 ± 100 (-6280 ± 260)
9. $SL(aq) + L(aq) \rightleftharpoons SL_2(aq)$	-4810 ± 50
10. $SL(s) + L(s) \rightleftharpoons SL_2(s)$	-1860 ± 140 (-2680 ± 280)

[a] The *s* represents solid phase and aq represents solution. [b] Uncertainties represent standard deviation estimates calculated from experimental estimates of the uncertainties in the solubilities and stability constants.

Table III—Thermodynamic Analysis of the 1:1 Cinnamate-Ion–α-Cyclodextrin Complex

Process	$\Delta G°$ (unitary)[a], cal/mole
1. $M^+S^-(s) \rightleftharpoons M^+S^-(aq)$	$+2790 \pm 120$
2. $L(s) \rightleftharpoons L(aq)$	$+3610 \pm 50$
3. $M^+SL^-(aq) \rightleftharpoons M^+SL^-(s)$	[-2790 ± 120 to -4800 ± 70][b]
4. $M^+S^-(aq) + L(aq) \rightleftharpoons M^+SL^-(aq)$	-5160 ± 20
5. $M^+S^-(s) + L(s) \rightleftharpoons M^+SL^-(s)$	[-1550 ± 200 to -2430 ± 150]

[a] Uncertainties represent standard deviation estimates calculated from experimental estimates of the uncertainties in solubilities and stability constants. [b] Estimated limits.

their release to bulk solvent is manifested as a favorable enthalpy change for complex formation. Restriction of rotational motion of an included substrate molecule could lead to an entropy decrease.

Such rationalizations do not provide much predictive power. For the AL^- complex, an entropy increase is seen, and the enthalpy change is very small. If the carboxylate enters the cavity, the net result may be a considerable decrease in solvent order by release of water from the cavity and from the carboxylate group. Presumably, the counterion remains outside the cyclodextrin. Komiyama and Bender (32) interpreted similar $\Delta H°$ and $\Delta S°$ values in complexation of 1-adamantanecarboxylate with α-cyclodextrin as evidence for apolar binding of the nonpolar substrate to the top of the cavity. This interpretation does not seem applicable to the cinnamate-ion system.

The $\Delta H°$ and $\Delta S°$ values for HAL_2 and AL_2^- are similar, considering the uncertainties. In each case, the process may be much the same: a ligand cavity is evacuated, the ligand slides over the portion of substrate protruding in an SL complex, S readjusts its position within the L_2 aggregate, and solvent reordering occurs.

The solubility data provide an opportunity for a different kind of analysis. Table II gives unitary free energy changes for the processes described in this paper. Processes 1–4 are for the formation of complex HAL; these processes, when added, give the net Process 5. Process 5 is solvent independent (if solid L is understood to represent the hydrated ligand); it is expected that the same value would be obtained for its $\Delta G°$ if corresponding experimental values were available for Processes 1–4 in another solvent (such as a mixed aqueous–organic solvent). Thus, $\Delta G°$ for Process 5 can be compared with $\Delta G°$ for Process 4, indicating that the complex formation is more favorable in water than in the solid state. Tables II and III show a similar relationship for the HAL_2 and AL^- complexes. Formation of these complexes in the solid phase is thermodynamically favorable.

These processes can be represented as a cycle as for the complex SL (Scheme X):

$$\begin{array}{ccccc} S(aq) & + & L(aq) & \rightleftharpoons & SL(aq) \\ \Updownarrow & & \Updownarrow & & \Updownarrow \\ S(s) & + & L(s) & \rightleftharpoons & SL(s) \end{array}$$

Scheme X

Just as other solvents should lead to the same free energy change for the solid phase process, the solid phases in this cycle also could be replaced by liquid phases, and rather than using solubilities in the model, partition coefficients would be employed. This cycle suggests why, for a series of closely related compounds, limited correlations between complex stability constants and substrate solubility or partition coefficient may be observed.

This analysis suggests new lines of experimental work. It will be necessary to establish that the free energy change for the solid phase process is, in fact, independent of the solvent used. It will be interesting to partition this free energy change into enthalpy and entropy changes. Since a long-term goal is to predict complex stability constants in aqueous solution (*i.e.*, Process 4 in Table II), these thermodynamic cycles offer a promising route; after study of numerous systems, it may be easier to estimate the free energy change of Process 5 than of Process 4. The cycle then provides a path for the calculation of the free energy change of Process 4.

NMR Spectral Study of Proton Transfer in Amitriptyline Hydrochloride–Chlordiazepoxide Hydrochloride Combinations in Dipolar Aprotic Solvent

PRANAB K. BHATTACHARYYA

Received July 9, 1979, from the *Quality Control Department, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication September 19, 1979.

Abstract □ The singlet resonance due to the two equivalent methyl groups of amitriptyline hydrochloride in dimethyl sulfoxide-d_6 solution changed into a doublet with the addition of chlordiazepoxide hydrochloride. A spin decoupling experiment revealed that the doublet originated because of the emergence of observable spin–spin coupling between the tertiary amine proton and the methyl groups. The phenomenon was interpreted to be due to the nature of proton transfer caused by the relative magnitudes of the basicities of the amines in these compounds, which were determined by the inductive and steric effects of the substituents, leading to the formation of hydrogen-bonded ion-pairs in the aprotic diluent. The enthalpy of the exchange process was 6.4 ± 0.5 kcal/mole.

Keyphrases □ NMR spectroscopy—proton transfer in amitriptyline hydrochloride–chlordiazepoxide hydrochloride mixtures, dipolar aprotic solvent □ Amitriptyline hydrochloride—effect of chlordiazepoxide hydrochloride on NMR spectra, proton transfer in a dipolar aprotic solvent □ Chlordiazepoxide hydrochloride—effect of amitriptyline hydrochloride on NMR spectra, proton transfer in a dipolar aprotic solvent

The relative magnitudes of the basicities of amines in solution essentially determine the outcome of the competition between the bases for available acidic protons. In an analytical study with a formulation containing amitriptyline hydrochloride and chlordiazepoxide free base, it was observed that mixtures of the hydrochloride salts of amitriptyline and chlordiazepoxide provide an interesting example of the proton exchange equilibrium caused by the relative orders of basicities of the amines in these compounds. However, since hydrogen bonding plays a vital role in acid–base behavior leading to the formation of many types of aggregates, which vary widely in stability, the protic solvents such as water and alcohols are not suitable for such an investigation because they are actively involved in hydrogen bonding and exchange reactions.

EXPERIMENTAL

The hydrochloride samples were prepared in NMR grade dimethyl sulfoxide-d_6 (99.8 atom % D), which was shaken with molecular sieves type 13 X. Spectra were obtained with an NMR spectrometer[1] equipped with accessories for performing double-resonance and temperature-dependence experiments.

RESULTS

The NMR spectra of chlordiazepoxide hydrochloride and amitriptyline hydrochloride in dimethyl sulfoxide-d_6 are presented in Figs. 1A and 1B. Table I contains the assignments of the NMR spectra of the hydrochloride salts and free bases of amitriptyline and chlordiazepoxide. The NMR spectrum (Fig. 1C) shows that the singlet resonance due to the two equivalent *N*-methyl groups of amitriptyline hydrochloride changes strikingly into a doublet when chlordiazepoxide hydrochloride is added to the amitriptyline hydrochloride solution. The doublet is observed when the mole ratio of chlordiazepoxide hydrochloride to amitriptyline hydrochloride is ≥0.1. The doublet (splitting ~4.5 Hz) collapses into a singlet (Fig. 2) when the tertiary amine proton resonance region (δ ~10.5–11.5 ppm) in amitriptyline hydrochloride is saturated by the double-resonance technique.

[1] Varian XL-100/Nicolet TT-100.

Table I—Assignments[a] of the PMR Spectra of Amitriptyline Hydrochloride and Free Base and of Chlordiazepoxide Hydrochloride and Free Base

Compound	Proton	δ, ppm (in Dimethyl Sulfoxide-d_6) HCl Salt	Free Base
Amitriptyline	$>CH_2 \times 4$	2.3–3.5 (m)	2.0–3.4 (m)
	$-CH_3 \times 2$	2.64 (s)	2.0 (s)
	$=CH-$	5.82 (t, 7.5 Hz)	5.8 (t, 7.5 Hz)
	Aromatic	6.9–7.4 (m)	$6.9–7.3_5$ (m)
	HCl	10.8–11.4 (b)	
Chlordiazepoxide	$-CH_3$	3.28 (s)	2.83 (d, 4.5 Hz)
	$>CH_2$	5.0 (s)	4.4 (s)
	Aromatic	$6.3–7.0_5$ (m)	6.3–7.7 (m)
	>NH	11.4 (b)	8.08 (q, 4.5 Hz)
	HCl	11.4 (b)	

[a] Multiplicities and, where applicable, coupling constants in Hertz are noted within parentheses; s = singlet, d = doublet, t = triplet, m = multiplet, and b = broad peak.

This experiment conclusively proves that the doublet in the NMR spectrum of amitriptyline hydrochloride is caused by the protons in the methyl groups becoming spin-coupled to the tertiary amine proton when chlordiazepoxide hydrochloride is added. This finding is confirmed by the experiments where the doublet collapses into a singlet when the amine proton is deuterated by the addition of deuterium oxide. The splitting does not arise from nonequivalent *N*-methyl groups or from stereoisomers protonated on opposite sides of the nitrogen atom.

The spin–spin coupling originates because of the emergence of the following predominant rate-determining step (Scheme I) in the acid–base equilibrium of amitriptyline hydrochloride in the presence of chlordiazepoxide hydrochloride in dimethyl sulfoxide-d_6 solvent:

$$N\text{:}\cdots HCl \rightarrow N^+H\cdots Cl^-$$

Scheme I

where the N:- - -H bond is electrostatic with no charge transfer and the N^+H bond is covalent with charge transfer.

With amitriptyline hydrochloride, the proton donor and acceptor are both strong enough so that the proton shifts toward the nitrogen nucleus under the condition where slightly more than one acid is attracted (probably by aggregation) per amine molecule. The product, symbolized by $N^+H\cdots Cl^-$, is called a hydrogen-bonded ion-pair (1). Thus, the transfer of acidity between the two compounds results in the neutral molecule changing into a positive ion where the intermolecular distance between the nitrogen and the proton is smaller than in the neutral molecule.

Since the doublet formation indicating that protonation has occurred on the nitrogen atom is a reflection of ion-pair formation, the criterion of splitting is a qualitative indication of the covalent character of the bond between the nitrogen atom and proton. Since the precise character of the sp^3 orbital occupied by the lone pair of electrons of the nitrogen atom depends on the groups linked to this atom, the energy of the N^+H bond produced and the thermodynamic stability of the positive ion depend on the nature of these groups.

The spin–spin coupling is an interaction that provides two magnetic environments for the *N*-methyl protons, depending on the spin state of the N^+H proton. Whether or not the *N*-methyl protons of amitriptyline appear as a doublet depends on the lifetime of the spin states of the N^+H protons. Development of the theory for intermediate rates of exchange was first published by Gutowsky *et al.* (2). Later extension of the theory

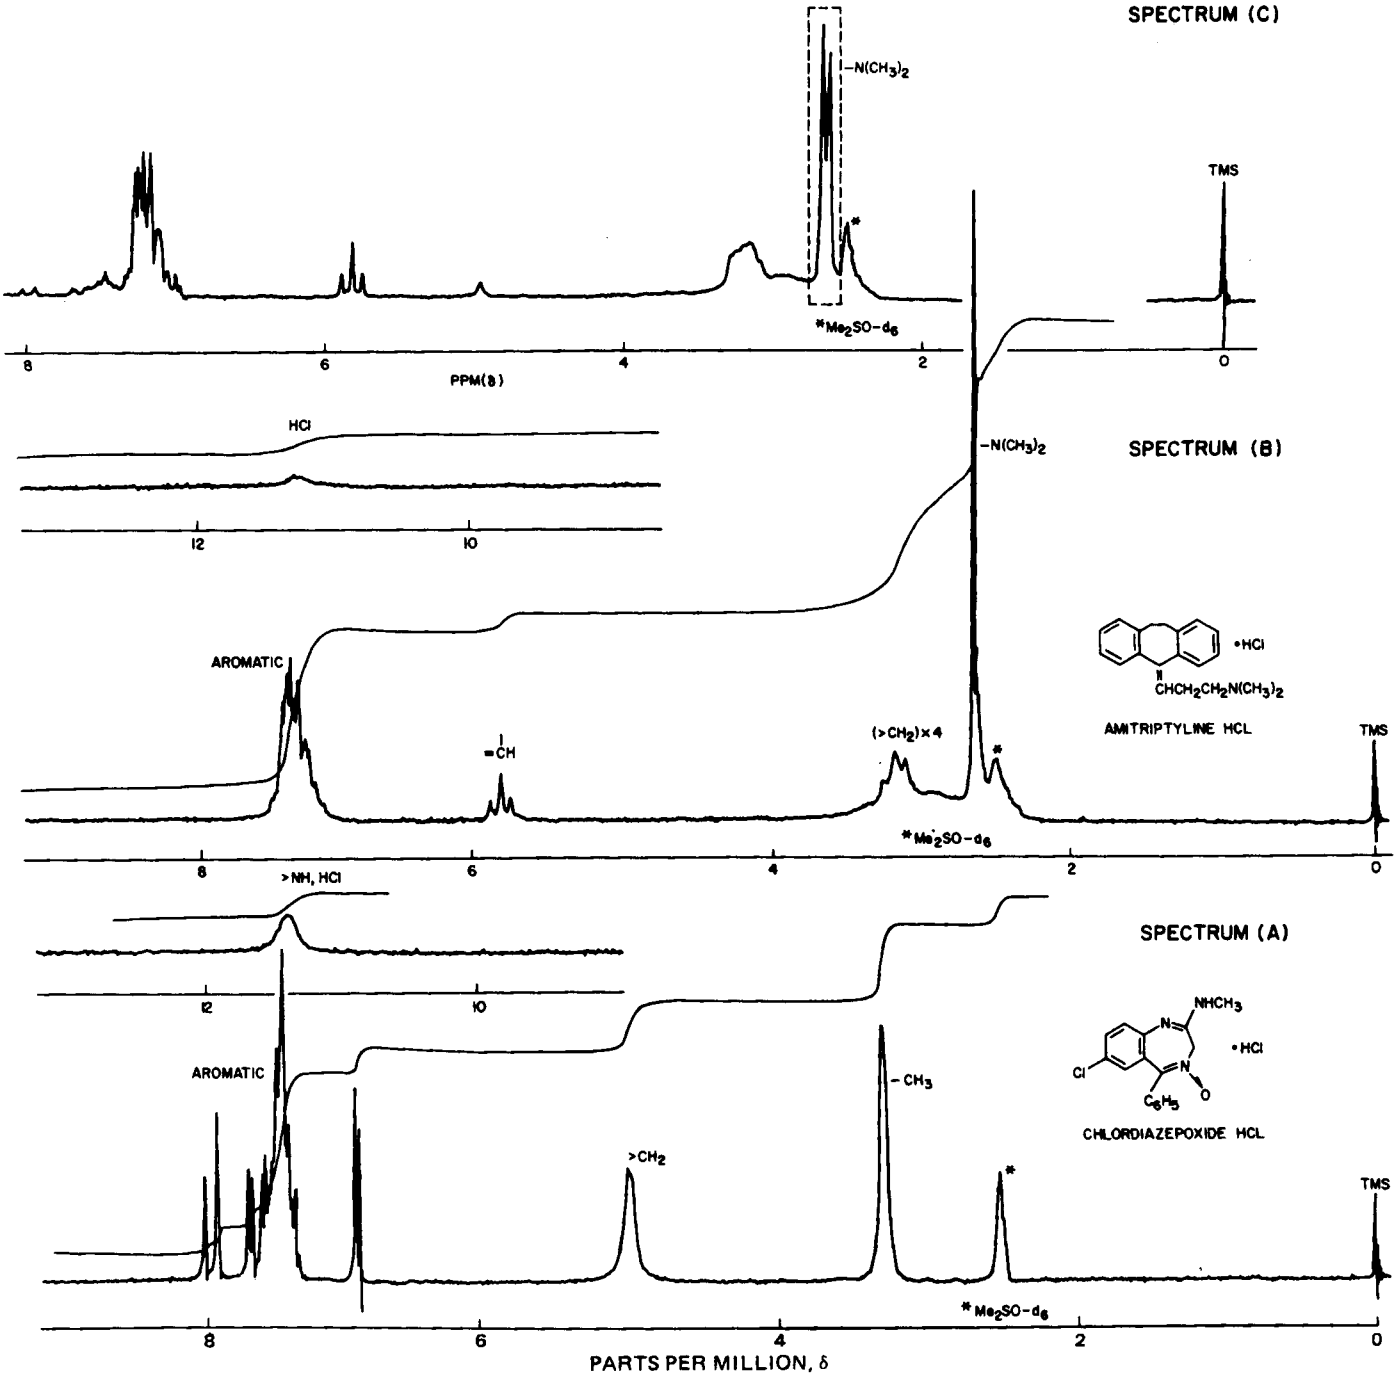

Figure 1—*PMR spectra (A) of chlordiazepoxide hydrochloride (50 mg) in 0.5 ml of dimethyl sulfoxide-d_6 solvent, (B) of amitriptyline hydrochloride (50 mg) in 0.5 ml of dimethyl sulfoxide-d_6 solvent, and (C) of the combination of amitriptyline hydrochloride (50 mg) and chlordiazepoxide hydrochloride (5 mg) in 0.5 ml of dimethyl sulfoxide-d_6 solvent. The doublet is marked with a dashed rectangle. (TMS = tetramethylsilane.)*

(3) was not very general in that it did not account for an asymmetric pair of lines. Rogers and Woodbrey (4) developed a general treatment in which a precise measure of lifetime, τ, is obtained from the line shape parameter, p. In the case of a doublet, the lifetime is given by the following expression:

$$2\pi\tau|J| = \pm[2p \pm 2(p^2 - p)^{1/2}]^{1/2} \quad \text{for } \sqrt{2}\pi\tau|J| > 1 \quad \text{(Eq. 1)}$$

where p is the ratio of the mean of the peak maxima to the minimum between them and J is the spin–spin coupling constant.

At the point of coalescence, the lifetime is given by:

$$2\pi\tau|J| = \sqrt{2} \quad \text{(Eq. 2)}$$

The proton exchange rates are obtained from the relation:

$$r = \frac{1}{\tau} \quad \text{(Eq. 3)}$$

The exchange process can be accelerated by raising the temperature (Fig. 3). Increasing the temperature increases r since a heat of activation, ΔH, is associated with it according to the Arrhenius equation:

$$r \propto \exp(-\Delta H/RT) \quad \text{(Eq. 4)}$$

where T is the absolute temperature and R is the gas constant.

The values of the lifetime and proton transfer rate of the positive ions at different temperatures, which are calculated from Eqs. 1–3, are listed in Table II. The doublet collapses into a singlet when the probe temperature is raised to 50° or higher (ambient probe temperature is 32°). The activation energy associated with the exchange process is obtained from the slope of the plot of:

$$\ln\frac{r(322)}{r(T)} = -\frac{\Delta H}{R}\left(\frac{1}{322} - \frac{1}{T}\right) \quad \text{(Eq. 5)}$$

The ΔH value is determined to be 6.4 ± 0.5 kcal/mole. In this example,

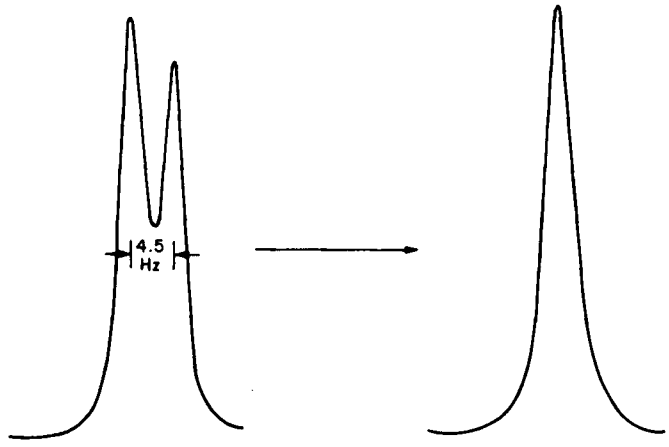

Figure 2—*Transformation of the doublet into a singlet when the tertiary amine proton resonance is decoupled.*

the spin–spin splitting averages to zero by the transfer process having a mean lifetime in the various states of <0.05 sec. Incidentally, the chemical shifts of the singlet and doublet due to the methyl groups of amitriptyline in the forms of associated complex and ion-pairs, respectively, are essentially the same (2.64 ppm), probably because (5) of the similar wave functions of the species rather than lack of sensitivity of the nuclei to changes in electron densities in the two forms of the compound.

It is also obvious from Figs. 1B and 1C that the *N*-methyl doublet splitting, which stands out as an observable effect caused by the intermolecular competition for acidic protons in this experiment, is not detectable in the following combinations since the amount of available exchangeable acidic protons is below the necessary threshold: amitriptyline hydrochloride and chlordiazepoxide base, amitriptyline base and chlordiazepoxide hydrochloride, and amitriptyline base and chlordiazepoxide base. This finding is confirmed by the doublet splitting in the competition-free model experiment where 5 μl of 0.01 *N* HCl is added to 20 mg of amitriptyline hydrochloride in dimethyl sulfoxide-d_6 solvent.

DISCUSSION

The overall acid–base behavior of compounds and, therefore, the observed competitive behavior of amines for acidic protons are determined by the relative proton donor–acceptor affinities and the role of intermolecular hydrogen bonding in dimethyl sulfoxide-d_6. The relative orders of basicities of amines, which can be considered as nucleophilic agents whose exact nature depends on the position of the unshared electron pair at the coordinatively active nitrogen atom, are determined (6) by the inductive and steric effects of the substituents attached to this atom. The introduction of electron donor groups with positive inductive effects into the tertiary amine molecule increases the basicity, and the introduction of electron acceptor groups with negative inductive effects lowers the basicity. Thus, in one direction, the increasing substitution of the nitrogen atom in going from the primary to tertiary amine results in an increase in base strength because of the electron-donating property of the alkyl group. In the other direction, the increasing steric hindrance due to the bulk of the alkyl groups decreases the apparent basicity. With amitriptyline, there is a fairly large amount of positive inductive effect on the tertiary nitrogen owing to the methylene and two methyl groups. The doublet splitting indicates that the steric hindrance is not large enough to neutralize this increase of basicity. In chlordiazepoxide, on the other hand, the positive inductive effect induced by the methyl group on the nitrogen atom of the secondary amine is reduced by the neighboring unsaturation in the ring. Thus, a significant difference in the electronic contributions to base strengths exists in the two compounds. The imines of chlordiazepoxide, which are expected to be comparatively weak in the relative order of basicity, will have a negligible influence on the competitive acid–base behavior in this study because the competition for the acidic protons obviously will be restricted mainly to the secondary amine proton of chlordiazepoxide and the tertiary amine proton of amitriptyline.

At this point, it is important to remember that the dipolar aprotic solvents such as dimethyl sulfoxide-d_6 are not truly inert but show proton donor–acceptor behavior, thus affecting quantitative relationships (7) observed in studying interactions between bases and acids. The aprotic solvents are thus admirably suited for ascertaining differentiating kinds of acid–base behavior, which are masked in amphiprotic and other active solvents. These solvents display significant and differing hydrogen bonding tendencies since the interactions of principal interest in such solvents are the much stronger interactions between dissolved species, including long-range Coulomb effects caused by the general electrostatic

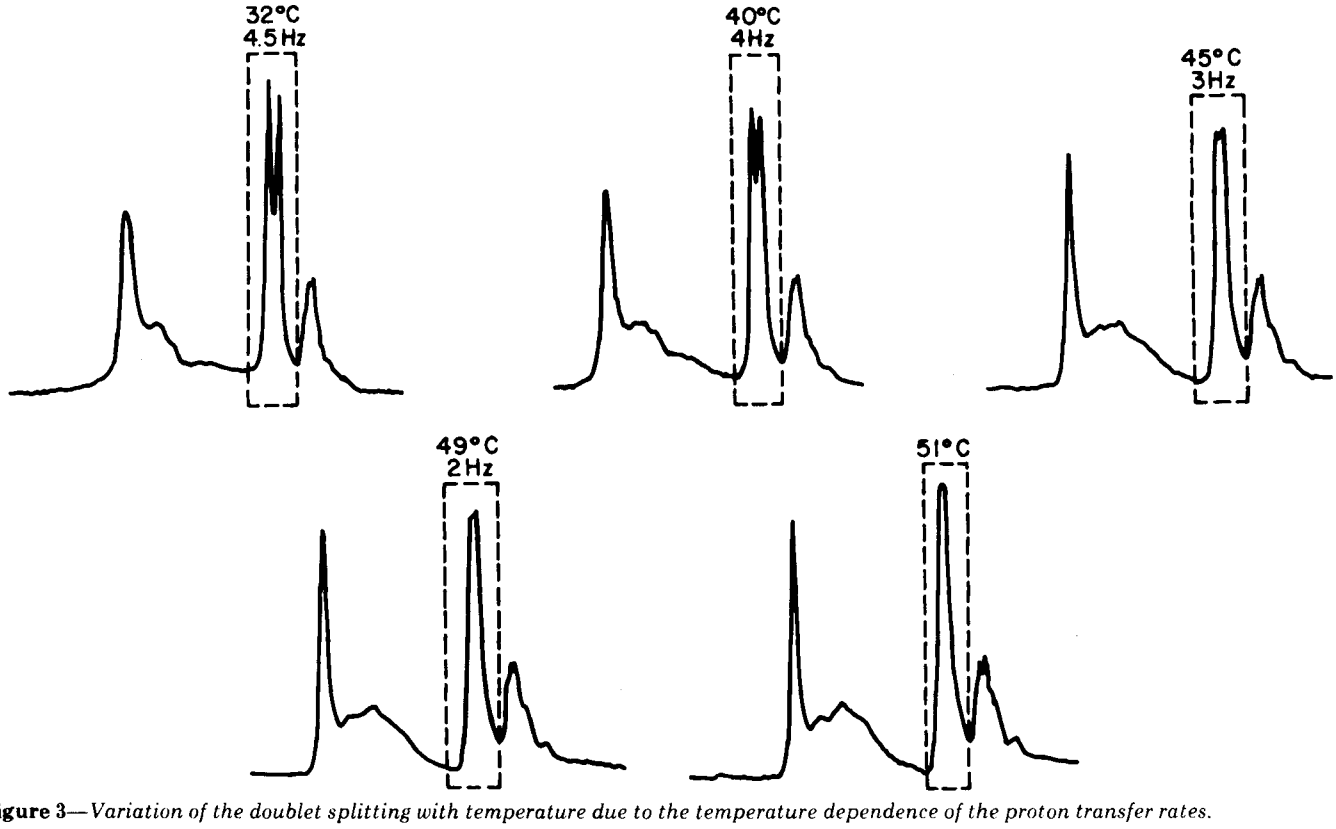

Figure 3—*Variation of the doublet splitting with temperature due to the temperature dependence of the proton transfer rates.*

Table II—Temperature Dependence of the Proton Exchange Rate (r) and Mean Lifetime (τ) of the Positive Ion

Temperature	$2\pi\tau\lvert J\rvert$[a]	τ, sec	r, sec^{-1}
32°	2.5	0.09	11
40°	2.0	0.07	14
45°	1.6	0.06	17
49°	1.4	0.05	20

[a] $|J|$ = 4.5 Hz.

solvation of the ammonium cation or the ion-pair by both the static and induced moments of the diluent molecules. Consequently, intermolecular hydrogen bonding assumes greater importance in aprotic solvents than in leveling solvents in the detection of competitive basic sites.

The relative degree of dissociation exhibited by amitriptyline hydrochloride and chlordiazepoxide hydrochloride in dimethyl sulfoxide-d_6 results from two opposing effects: the positive inductive effect, which tends to increase the stability of the salts, and the steric influence, which tends to decrease the stability. The observed base strengths are determined by the relative ease by which the respective amine hydrochlorides can form aggregates of ion-pairs by intermolecular hydrogen bonding (8). The tertiary amine hydrochlorides have one proton, which is presumably bonded to the chloride and unavailable for participation in aggregate formation. This condition delays aggregation until a higher concentration of acidic protons is reached by transfer of acidity caused by the migration of acidic protons from chlordiazepoxide molecules to amitriptyline molecules, particularly in a high dielectric constant solvent like dimethyl sulfoxide-d_6. When this happens, owing to the mobility of protons (9) within the hydrogen bonds, proton transfer can occur within the hydrogen bond representing the joining of the Brönsted acid–base pair N- - -HCl to yield the polar form N^+H- - -Cl^-.

At this time, the tertiary amine hydrochlorides are induced to form aggregates of ion-pairs (7) by intermolecular hydrogen bonding in response to the need to stabilize the ion-pairs of the salt. Therefore, the proton exchange equilibrium shifts toward the direction of reduced proton mobility of the tertiary amine proton of the amitriptyline salt, which results in the covalent N^+H bond being time resolved in the NMR spectrum. This phenomenon is reinforced by the fact that the tertiary amine forms stronger N^+H- - -Cl^- bonds than does the secondary amine due to the greater concentration of positive charge in the tertiary ammonium ion (10). The stronger the cation–anion hydrogen bonding, the less is the extent of the aggregation of the resulting ion-pairs by electrostatic solvation. While the number of molecules forming an aggregate is not determined in this example, it is disrupted when the temperature is raised. The existence of a doublet splitting requires that the N-methyl protons with fixed orientations of the magnetic moment vector remain coupled with the spin state of the N^+H group for a time greater than τ (Table II). The value of the heat of activation for the exchange process (~6.4 kcal/mole) probably leads to the suggestion of dimeric aggregates being the means of effecting exchange (11).

In conclusion, NMR spectroscopy is a useful tool for investigating proton exchange equilibrium between compounds possessing basic sites that compete for acidic protons, particularly in an aprotic solvent. An indication of the formation of ion-pairs and, hence, the covalent character of the nitrogen–proton bond are provided by the appropriate line splitting, which also gives an estimate of the mobility of protons existing in the exchange environment influenced by varied types of intermolecular hydrogen bonding and solute-solvent interactions.

Rapid Determination of Chlorpromazine Hydrochloride and Two Oxidation Products in Various Pharmaceutical Samples Using High-Performance Liquid Chromatography and Fluorescence Detection

DAVID M. TAKAHASHI

Received June 11, 1979, from the *Food and Drug Administration, 50 United Nations Plaza, San Francisco, CA 94102.* Accepted for publication September 20, 1979.

Abstract □ A rapid, simple, and accurate high-performance liquid chromatographic procedure using an amino-bonded microparticulate column is reported for the determination of chlorpromazine hydrochloride (I) and its two oxidation products, the sulfoxide (II) and the sulfone (III), in commercially available pharmaceutical dosage preparations. Simultaneous identification and quantitation of II and III in the presence of at least 100 times the amount of parent compound were achieved with selective fluorometric detection. Identification and quantitation of I were achieved by changing the fluorescence detection mode. A typical chromatographic run was completed within 15 min. The described procedure is simpler, more sensitive, and more accurate than the USP XIX methods, particularly for the analysis of II in injectables. Quantitation of II and III at levels as low as 0.1 μg, representing 0.1% contamination, was demonstrated.

Keyphrases □ Chlorpromazine hydrochloride—and oxidation products, high-performance liquid chromatography and fluorescence detection, dosage forms □ High-performance liquid chromatography—rapid determination of chlorpromazine hydrochloride and two oxidation products, dosage forms □ Phenothiazines—chlorpromazine hydrochloride and two oxidation products, rapid determination by high-performance liquid chromatography and fluorescence detection, dosage forms

Tricyclic antidepressants of the phenothiazine type are important psychopharmacological agents in modern psychotherapy and have continuously attracted interest since their discovery. One clinically useful member of this class is chlorpromazine hydrochloride (I). It readily undergoes sulfoxidation at the sulfur atom in position 5 to form the sulfoxide (II), which may be further oxidized to the sulfone (III).

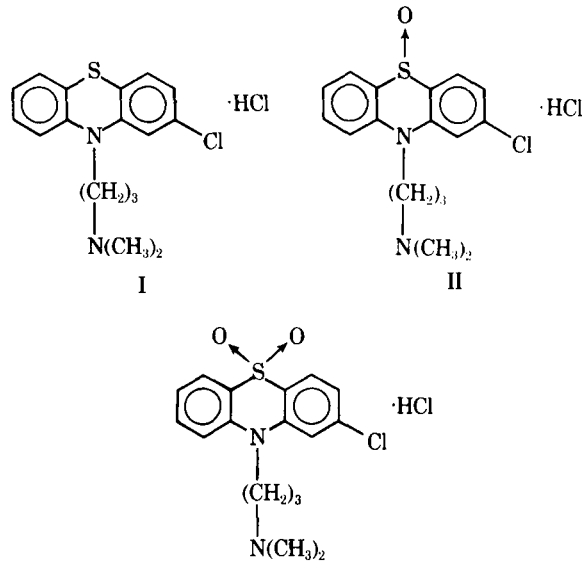
BACKGROUND

The USP XIX monographs (1) specify limits for certain impurities and degradation products in various dosage formulations of chlorpromazine and its hydrochloride salt. For instance, a maximum of 0.5% for "other alkylated phenothiazines" is allowed. Although the widespread occurrence of both alkylated and nonalkylated compounds was recently demonstrated in various tablet formulations, many of the impurities found are also used as therapeutic agents and thus were not considered as a health hazard (2). However, the presence of these artifacts deserves attention during manufacturing quality control procedures (2) as an index to adherence with recognized Current Good Manufacturing Practices.

The USP XIX permits II in injectables up to a maximum of 5%, but the TLC identification test used is only semiquantitative at best. Furthermore, this test lacks the specificity desired since the comparison is made with the TLC spot of the USP chlorpromazine hydrochloride reference standard and not with that of the sulfoxide reference material. Similar TLC identification tests are also used for the other alkylated phenothiazines. One is never certain whether II, III, the other alkylated or nonalkylated phenothiazines, or other degradation products are being determined.

The quantitative determination of chlorpromazine and its hydrochloride salt in dosage preparations is based on the differential UV absorption of the drug using two absorption maxima (254 and 277 nm). Pure drug substances are assayed by perchloric acid titration.

In general, it is inherently more desirable to use simpler and more accurate techniques and to avoid complex and nonspecific analytical methods. Thus, there is a need for developing a suitable analytical method to identify and quantitate I and its degradation products rapidly (especially II).



Many procedures have been reported for the determination of I and its metabolites. Previously reported fluorescence properties of phenothiazine drugs (3–6) indicate spectrofluorometry to be useful for qualitative and quantitative analyses of these compounds. The differences in the fluorescence spectra of I and its *S*-oxidation products may be particularly useful in the development of a rapid and simultaneous determination. However, it has been virtually impossible to differentiate between II and III by conventional spectrofluorometry when present in a mixture (6).

In recent years, high-performance liquid chromatography (HPLC) has been employed in the determination of I and its derivatives (7–11). In general, UV detection has been used. However, a method for the simultaneous determination of I–III has not been previously reported. This article describes the development of such a method, combining both the HPLC separation and fluorescence detection techniques for determining these three compounds in mixtures with other constituents normally present in commercial pharmaceutical preparations.

EXPERIMENTAL

Reagents and Chemicals—Compounds I[1], II[2], and III[2] were used as received. All other reagents were analytical reagent grade except *d*-araboascorbic acid[3]. All solvents were glass distilled[4].

Apparatus—The liquid chromatograph[5] was equipped with reciprocating dual-piston constant-flow rate pumps, a rotary valve injector[6],

[1] United States Pharmacopeial Convention, Rockville, Md.
[2] Smith Kline and French Laboratories, Philadelphia, Pa.
[3] Eastman Kodak Co., Rochester, N.Y.

a filter fluorescence detector[7], a variable-wavelength UV detector[8], a computing integrator[9], and a recorder[10]. The HPLC columns were: (*a*) a 25-cm × 4.6-mm i.d. stainless steel column commercially packed with 10-μm amino-bonded microparticle packing[11] and (*b*) a 30-cm × 4-mm i.d. stainless steel column commercially packed with 10-μm amino-bonded microparticle packing[12]. Ambient temperature was used throughout these experiments.

Mobile Phase—The mobile phase consisted of acetonitrile–benzene–water (16:4:1), with the water containing 0.01% each of sodium metabisulfite and *d*-araboascorbic acid as antioxidants. The prepared mobile phase was filtered[13], degassed, and stored in the solvent reservoir of the instrument.

Standard Solutions—All standard materials were dissolved in and made to volume with acetonitrile. All solutions were protected from light.

Linearity Standards—Five standard solutions, ranging in concentration from 1.00 to 50.0 μg/ml, were individually prepared in acetonitrile for II or III. The I standard solutions (10.0–500 μg/ml) also were prepared in acetonitrile. Duplicate 100-μl aliquots of each solution were chromatographed.

Daily Calibration Standard Mixture—A mixture of the three standard materials in acetonitrile was made fresh each day and contained 10.0 μg/ml each of II and III and 1000 μg/ml of I.

Analysis of Pharmaceutical Dosage Preparations—For II or III determination, sample solutions were accurately prepared as indicated so that the final concentration of I, based on the declared potency, was 1 mg/ml. For I determination, sample solutions were accurately prepared so that the final concentration of I, based on the declared potency, was 100–250 μg/ml.

Injectables—A sample aliquot was diluted and made to volume with acetonitrile.

Tablets—Tablets were powdered, weighed, warmed over a steam bath in acetonitrile, and shaken vigorously for 1 min. The solution was allowed to cool and then was filtered and made to volume with acetonitrile.

Concentrates—An aliquot was diluted and made to volume with acetonitrile.

Syrup—An aliquot was mixed with acetonitrile, warmed over a steam bath, and shaken vigorously for 1 min. The solution was allowed to cool and then was filtered and concentrated under nitrogen to volume before injection.

Suppositories—A sample was warmed over a steam bath in acetonitrile until dissolution was complete. After cooling, the sample solution was filtered and made to volume with acetonitrile.

Detection—The HPLC eluates were monitored by the UV absorption at 345 nm and by fluorometry with excitation at 280 nm and emission at 385 nm for II and III or at 450 nm for I. All three compounds in approximately equal amounts can be simultaneously detected by fluorometry if the emission detection is set at 400 nm. Peak height was used for quantitation.

RESULTS AND DISCUSSION

HPLC Column—Polar bonded phases used in the normal mode frequently produce separations similar, but often more efficient, to those obtained on silica gel packings. One highly polar hydrogen bonded phase that is readily available commercially is a chemically bonded aminosilane. It is stable toward hydrolysis, can be used for normal or reversed-phase chromatography, and is less sensitive to water adsorption than is silica gel.

This material performed well in the normal phase HPLC separation of I and its two oxidation products, II and III (Fig. 1). Its unique selectivity and speed were amply demonstrated. Since these materials eluted rapidly, the expenditure of time and expensive organic solvents was greatly minimized.

HPLC Mobile Phase—Various isocratic and gradient mobile phase systems were tried before acetonitrile–benzene–water (16:4:1) was selected. Water-free mobile phases were undesirable since the elution of II was delayed considerably. They also resulted in a badly tailing peak. With the addition of water to the mobile phase, II rapidly eluted in a sharp and symmetrical peak. The amount of water added was carefully controlled as soon as it was optimized since varying the amount of water produced changes in the retention time of II. However, unlike silica gel, the amino-bonded packing was less sensitive to water adsorption, and lengthy equilibration was not required as the water content of the mobile phase was varied.

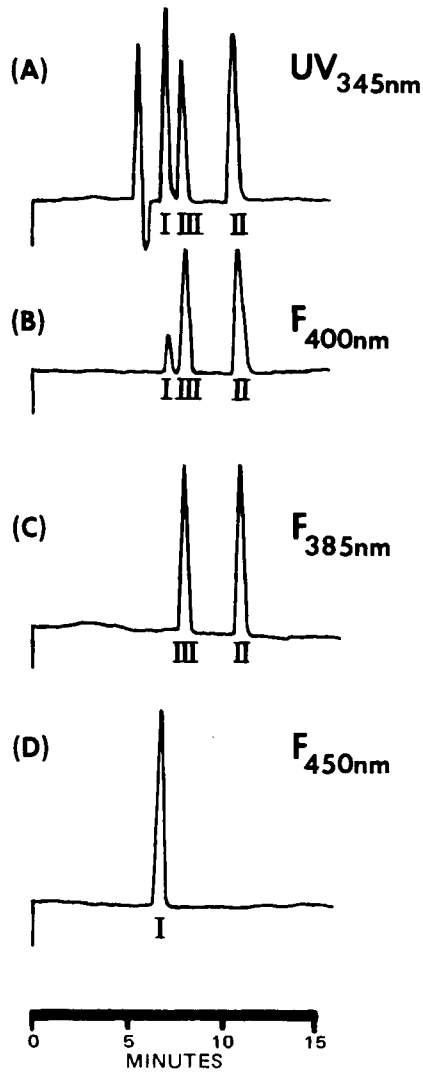

Figure 1—*Chromatograms of standard mixtures of chlorpromazine hydrochloride (I) and its two S-oxidation products, sulfoxide (II) and sulfone (III) (5 μg each). UV absorption was at 345 nm (A) and fluorescence emission was at 400 (B), 385 (C), or 450 (D) nm. The HPLC column was μBondapak NH_2, the pressure was 140 psi, and the flow rate was 1.0 ml/min.*

The inclusion of benzene in the mobile phase also was desirable to stabilize the retention time of II. Without benzene, II always eluted a little slower when injected in a mixture with I (a 100:1 ratio) and III. When the amount of benzene in the mobile phase was increased, the resolution of the three compounds greatly improved, although it took longer for a complete chromatographic run (*e.g.*, 12 *versus* 30 min). However, an increase in the amount of benzene limited the amount of water that could be mixed into the mobile phase. For instance, when benzene was increased from 20 to 50%, water had to be reduced to ~1% to keep the mobile phase homogeneous.

Selection of Fluorescence Detection Mode—Compound I displayed three UV maxima while II and III each had four UV maxima (12, 13). Since benzene was used as a component of the HPLC system, the absorbance below 280 nm of these phenothiazine derivatives was lost. However, this loss did not present problems since the compounds were monitored at wavelengths longer than 280 nm.

Simultaneous quantitation of I and its two oxidation products was possible with the aid of a UV detector only when all three compounds were present in approximately equal amounts and were completely free

Table I—Analysis of Pharmaceutical Dosage Preparations [a]

Dosage Preparation	Declared Potency of Chlorpromazine Hydrochloride	Number of Samples Analyzed	Chlorpromazine Hydrochloride Content (Average), %	Chlorpromazine Sulfoxide Content, %
Tablet	10 mg/tablet	2	100	ND[b]
Suppository[c]	25 mg/suppository	4	99	ND
Syrup	10 mg/5 ml	4	95	ND
Injection, single dose (1 ml)	25 mg/ml	10	103	ND
Injection, multiple dose (10 ml)	25 mg/ml	2	102	ND
Concentrate (120 ml)	30 mg/ml	4	102	1.03, 0.69, 0.73, 0.90

[a] Chlorpromazine sulfone was not detected in any pharmaceutical dosage preparation tested. [b] ND = none detected. [c] Contained chlorpromazine.

from other UV-absorbing interferences. When I was present in a 100-fold excess, III was completely obscured by I. Furthermore, when such a large amount of I was chromatographed, other strong UV-absorbing impurities, although present in small amounts relative to the parent compound, became detectable and interfered with the determination of II.

Fluorescence detection is more selective and, therefore, better suited for this type of analysis. The differences in the fluorescence characteristics of I, II, and III were useful in developing this rapid HPLC procedure for their determination. To determine II and III, the fluorescence emission signal of I was completely eliminated by selectively choosing the emission signals of the oxidation products at 385 nm while I was similarly determined by switching to an emission wavelength of 450 nm. The impurities in I observed in its UV chromatogram were completely eliminated in its fluorescence chromatogram when the emission signal was set at 385 nm.

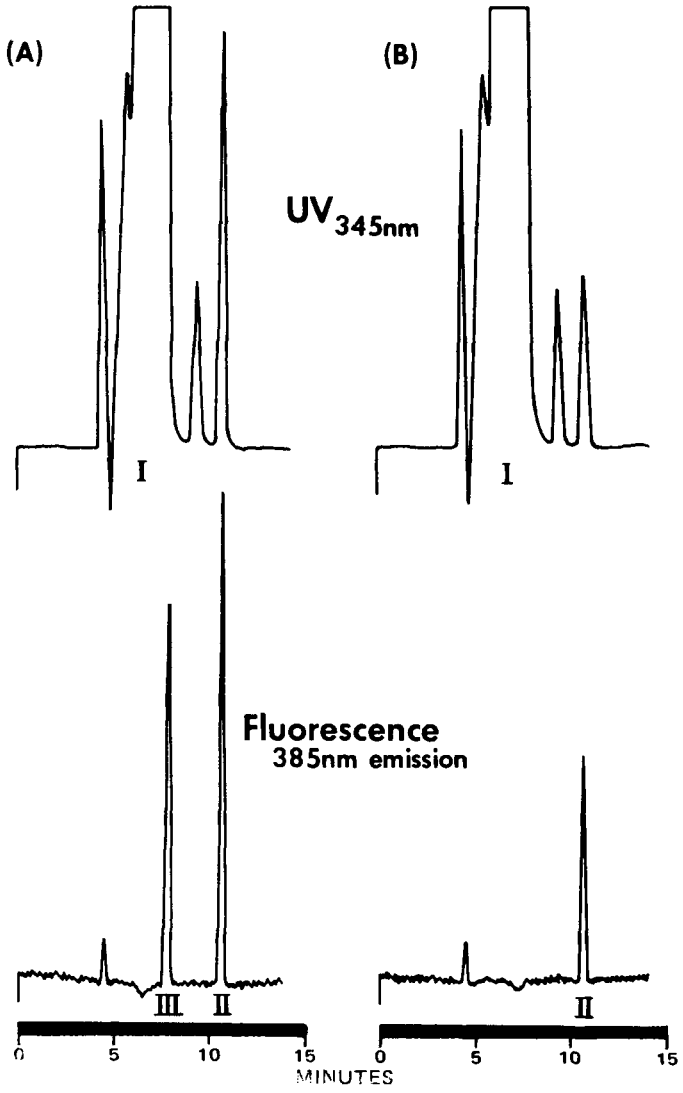

Figure 2—*Typical chromatograms of chlorpromazine hydrochloride (I) concentrate. Key: A, sample spiked with sulfoxide (II) and sulfone (III) at 1% (1 μg) level; and B, unspiked sample. The HPLC column was Lichrosorb NH_2, the pressure was 110 psi, and the flow rate was 1.0 ml/min.*

An alternative means of quickly and simultaneously identifying these three compounds was to determine selectively their fluorescence emission at 400 nm. At this wavelength, all three compounds could be detected if they were present in approximately equal amounts.

One problem encountered in the quantitative fluorescence determination of very low concentrations of phenothiazines is the interference from Raman scattering (3). This interference becomes particularly critical in the determination of II (6) or III. In the HPLC procedure described, a deuterium lamp source was used at 280 nm to lessen the Raman scatter influence. It also provided the stronger energy available at this wavelength.

The detection limit for UV and fluorescence modes remained about the same for I. For II and III, fluorescence was relatively more sensitive. However, unlike UV photometric detection, fluorescence detection is generally free from interferences caused by pump pulses and changes in the refractive index due to solvent peaks. Fluorescence detection also provides a convenient option of selectively eliminating all unwanted signals. All peaks obtained were well defined, sharp, and symmetrical and eluted within 15 min.

Linearity, Reproducibility, and Sensitivity—Fluorescence response curves of I–III were all linear in the ranges examined (1–50 μg for I and 0.1–5 μg for both II and III).

Good reproducibility of the described HPLC procedure using fluorescence detection was demonstrated when six 100-μl aliquots of a standard mixture containing 1.0 μg each of II and III in the presence of 100 μg of I were chromatographed. The relative standard deviations were 1.5 and 2.1% for II and III, respectively. This standard mixture was then diluted with acetonitrile so that each 100-μl injection represented 25 μg of I. The reproducibility of the method for I was determined by chromatographing six 100-μl diluted aliquots. The relative standard deviation was 1.2%.

The minimum detectable limit of I–III under the fluorescence conditions described was 0.05 μg for all three compounds. Under the sample conditions described, this limit represents, in most cases, a minimum detectable contamination level of 0.05% for II and III with respect to the parent compound.

Sample Analysis and Recovery—Various I formulations (Table I) were analyzed by this HPLC procedure using fluorescence detection. The UV detection mode was useless for III since it was completely obscured by the 100-fold amount of the parent drug. Furthermore, UV-absorbing impurities of the parent drug interfered with the determination of II. In addition, the UV detection mode was sensitive to changes in the refractive index of the solvent passing through it.

Table I indicates that, in almost all samples analyzed, neither II nor III was detected at the detection limit of 0.05%, even though the samples assayed were a few years old and were not representative of current formulations. (All samples were obtained during December 1975 and stored intact in the dark at room temperature. Samples were analyzed during November 1977.) The notable exceptions were the four samples of I concentrate that contained 0.7–1.0% of II. Figure 2 shows a typical chromatogram of I concentrate containing a low level of II.

All samples were also analyzed for I; the diluted aliquots of the sample solutions prepared for II and III assays were used. The same HPLC parameter was used throughout, except that the fluorometric detection was monitored at the 450-nm emission. All pharmacopeial samples were

within the USP XIX monograph limits. The I content of nonpharmacopeial concentrate was also satisfactory.

For a recovery study, five samples (tablet, concentrate, suppository, single-dose injectable, and multiple-dose injectable) were each spiked at 1% levels of II and III and analyzed. The mean recoveries ($n = 5$) were 98.3 and 97.5% with relative standard deviations of 1.8 and 2.4% for II and III, respectively. A syrup sample was spiked at 5% levels of II and III; 104 and 103% recoveries were obtained, respectively.

USP Reference Standard—Analysis of freshly obtained USP I reference standard (200 μg) by the UV absorption mode revealed 0.18% of "apparent" II. However, this peak was totally absent in the fluorescence chromatogram, proving that no II was present in the reference standard. The minimum detection level in this case was at 0.025%. When this standard solution was again analyzed 10 days later, its fluorescence chromatogram demonstrated the presence of II (0.03%). This change appeared to be due to the autoxidation of I. Although the solution was stored in the dark when not in use, dissolved oxygen was not purged and the solution was under a normal atmosphere at room temperature during its storage.

CONCLUSIONS

A novel approach of using an amino-bonded HPLC packing for the rapid and quantitative determination of I and two of its oxidation products was presented. Unlike the UV photometric determination, the selective fluorescence detection approach permitted a fast, qualitative, and quantitative determination of a mixture of trace components, II and III, in the presence of at least a 100-fold excess of parent drug. It also permitted a fast and selective determination of the major component, I. Interferences from other impurities were not encountered. A typical HPLC analysis was completed within 15 min. For all three compounds, the fluorescence response was linear in the ranges tested, and the minimum detectable amount was 0.05 μg.

The described HPLC procedure allows the injection of diluted raw samples directly into the HPLC system. The recoveries of II and III from commercial samples at 1% contamination levels were satisfactory. The described method is also simpler, more sensitive, and more accurate than the USP XIX methods for determining I or II.

Impurities in Drugs IV: Indomethacin

N. M. CURRAN, E. G. LOVERING, K. M. McERLANE *, and J. R. WATSON ˣ

Received July 27, 1979, from the *Pharmaceutical Chemistry Division, Drug Research Laboratories, Health Protection Branch, Tunney's Pasture, Ottawa, Ontario K1A 0L2, Canada.* Accepted for publication September 20, 1979. *Present address: Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, British Columbia, Canada.

Abstract □ One lot of indomethacin raw material, five lots of capsule preparations, and three lots of suppository formulations were screened for impurities by TLC. Only the suppository products exhibited impurities above trace levels. The two main impurities were present at levels estimated at ~0.5 and 2%. After isolation from preparative TLC plates, they were identified by NMR, IR, and mass spectroscopy as the α-substituted monoglyceryl esters of 4-chlorobenzoic acid and indomethacin, respectively.

Keyphrases □ Indomethacin—impurities, detection by NMR, IR, and mass spectroscopy □ Anti-inflammatory agents—indomethacin, detection of impurities by NMR, IR, and mass spectroscopy

Indomethacin is an analgesic and anti-inflammatory agent used to treat rheumatoid arthritis and other joint diseases. The NF XIV (1) contains monograph specifications for the drug substance and capsules, and BP 1973 (2) includes monograph specifications for the drug substance, capsule, and suppository. However, the compendia do not contain tests and limits for impurities in indomethacin formulations, nor are there publications dealing with their occurrence in commercial preparations. Indomethacin may be synthesized by several routes (3–7). However, these methods are generally modifications of the original procedure described by Shen *et al.* (3).

This paper deals with impurities observed in a routine TLC screening program of indomethacin drug substances and formulations. The main impurities found in suppository preparations were isolated and identified and serve to underline a classical instance of drug–excipient interaction.

EXPERIMENTAL

Materials—All drug substances (one sample) and formulations (five capsule and three suppository samples) were obtained directly from the manufacturers. Indomethacin [1-(4-chlorobenzoyl)-5-methoxy-2-methylindole-3-acetic acid] (I) was the NF reference standard material. 4-Chlorobenzoic acid[1] (II), 4-chlorobenzoyl chloride[1], 5-methoxy-2-

VI	0.64	0.53	—
VII	0.70	0.55	—

[a] In ether–acetic acid (100:3). [b] In benzene–methanol–acetic acid (90:10:3).

methyl-3-indoleacetic acid, (III), glycerin[1] (ACS grade), pyridine[1] (ACS grade), ether[2] (USP grade), acetic acid[3] (ACS grade), benzene[4] (ACS grade), methanol[4] (ACS grade), anhydrous sodium sulfate[4] (ACS grade), and sodium hydrogen carbonate[4] (analytical reagent) were obtained commercially.

TLC plates were precoated with silica gel 60 F-25[4] (20 × 20 cm, 0.25 mm) or silica gel GF[5] (20 × 20 cm, 1.0 mm).

Standard Solutions—Ether solutions of the following were prepared: I, 20 mg/ml; II, 0.25 mg/ml; and III, 0.25 mg/ml.

TLC Systems—Two developing systems were used: A, ether–acetic acid (100:3); and B, benzene–methanol–acetic acid (90:10:3). Both solutions were placed in filter paper-lined chromatographic tanks and allowed to equilibrate for 1 hr prior to use. Spots were visualized with UV light at 254 nm.

Drug Substance, Capsule, and Suppository Extraction—About 100 mg of indomethacin drug substance, accurately weighed, was dissolved in 5 ml of ether. The solution was analyzed by TLC.

The contents of 10 capsules were emptied and weighed. An amount of powder equivalent to about 100 mg of indomethacin was accurately weighed into a screw-capped tube, 10 ml of ether–water (1:1) was added, and the mixture was shaken vigorously for 15 min and then centrifuged. A portion of the ether layer was used for TLC analysis.

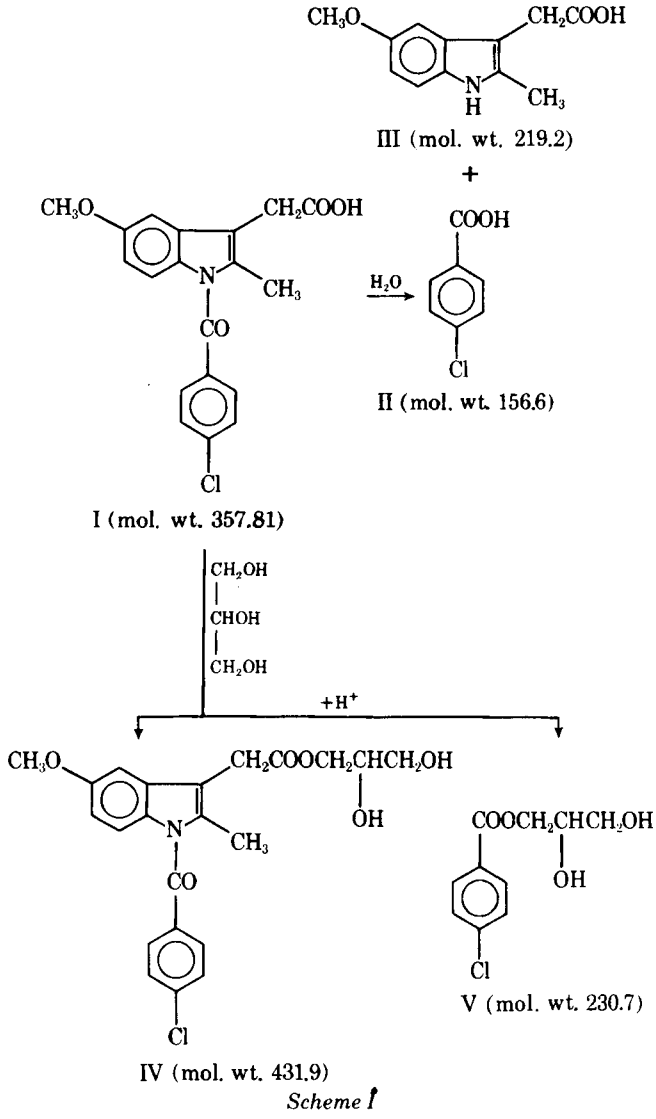
Five suppositories, equivalent to 500 mg of drug, were stirred vigorously in a stoppered flask for 30 min in 50 ml of ether–water (1:1). The heterogeneous solution was transferred to a screw-capped tube and centrifuged. The ether layer was used for TLC analysis.

Screening for Impurities—The R_f values of the drug and each impurity were determined in both TLC systems, and the lower limits of detectability of I, II, III, IV (indomethacin-α-monoglyceride), and V (4-chlorobenzoic acid-α-monoglyceride) were established (Table I). Aliquots of 1, 10, and 25 μl (20, 200, and 500 μg of I) of the ether extracts of each formulation and drug substance were spotted (0.25-mm plate) beside 1-, 10-, and 25-μl (20-, 200-, and 500-μg) aliquots of the standard solution of I and 1-, 5-, 10-, and 20-μl (0.25-, 1.25-, 2.5-, and 5-μg) portions of each standard solution of II and III.

The concentrations of impurities in the formulations (Table II) were estimated by comparison of the spot diameters and intensities with the corresponding spots of the standard solutions.

Isolation of Impurities—Impurities IV and V (Tables I and II) were isolated from Suppository Formulation A using the following procedure. Ten suppositories were shaken vigorously for 30 min in 100 ml of ether–water (1:1) in a separator. The ether layer was transferred to an erlenmeyer flask and dried over anhydrous sodium sulfate for 15 min. The mixture was filtered, and 1 ml of the filtrate was applied to a silica gel GF (1.0-mm) plate using a commercial TLC sample streaker[6]. The streaking operation was repeated on several plates. Each plate was developed in System A until the solvent front reached the top of the plate.

After development and hot air drying of each plate, the bands corresponding to IV and V were scraped off the plate into separate flasks; the total scrapings of each of these impurities were stirred in 75 ml of ether for 2 hr. The mixtures were filtered, and the filtrates were dried over anhydrous sodium sulfate and filtered again. The plate extract solutions of impurities IV and V were brought to dryness under a stream of pure dry nitrogen, and the separate residues were dried *in vacuo* at 60° overnight. Pale-yellow oils were obtained. The purity of each compound as isolated was checked by TLC in both solvent systems.



Scheme I

Synthesis of 4-Chlorobenzoic Acid-α-monoglyceride (V in Scheme I)—4-Chlorobenzoyl chloride (3.5 g, 0.02 mole) was slowly added dropwise with constant stirring to a solution of glycerin (4.0 g, 0.04 mole) in dry pyridine (10 ml) at 0°. Then the solution was allowed to warm to ambient temperature for 2 hr. The reaction mixture was diluted to 30 ml with water and extracted with three 25-ml portions of ether. The ether extracts were combined and shaken with four 15-ml portions of 5% aqueous sodium bicarbonate solution followed by two 10-ml portions of water. The ether layer was dried for 30 min over anhydrous sodium sulfate, the mixture was filtered, and the filtrate was evaporated to dryness under a stream of pure dry nitrogen. The oily residue was dried overnight *in vacuo* over phosphorus pentoxide at 50°. Recrystallization from benzene afforded white crystals (mp 88–89°).

The product was checked by TLC in both solvent systems against impurity V isolated from the plates and was subjected to NMR[7], IR[8], and mass spectral[9] analyses.

Characterization and Elucidation of IV and V Structures—*Indomethacin-α-monoglyceride (IV)*—IR (liquid film): 3200 (OH, br), 1725 (ester carbonyl), 1670 (amide carbonyl), and 1500 cm^{-1}; NMR[10] ($CDCl_3$): δ 7.69 [d, 2H, ArH (2′,6′), J = ~9 Hz], 7.47 [d, 2H, ArH (3′,5′), J = ~9 Hz], 6.97 [d, 1H, ArH (4), J = ~2.5 Hz], 6.90 [d, 1H, ArH (7), J = ~9 Hz], 6.67 [d, d, 1H, ArH (6), J = ~9 and 2.5 Hz], 4.22 (d, 2H, $COOCH_2$, J = ~5 Hz), 3.84 (s, 3H, OCH_3), 3.72 (s, 2H, CH_2COO), 3.62–3.53 (m, 3H, $OCHCH_2O$), 2.39 (s, 3H, CH_3), and 2.05 (s, 2H, OH, disappears on D_2O exchange) ppm;

4-Chlorobenzoic Acid-α-monoglyceride (V) (TLC Isolate and Synthesized Product)—IR (liquid film): 3200 (OH, br) and 1725 (ester carbonyl) cm^{-1}; NMR[11] ($CDCl_3$): δ 8.01 [d, 2H, ArH (2, 6), J = ~9 Hz], 7.43 [d, 2H, ArH (3, 5), J = ~9 Hz], 4.44 (d, 2H, $COOCH_2$, J = ~5 Hz), 4.09–3.48 (m, 3H, $OCHCH_2O$), and 2.05 (s, 2H, OH, disappears on D_2O exchange) ppm; mass spectrum: chemical-ionization mode (CH_4), *m/e* 231/233 ($M^+ + 1$, 100/35%) and 213/215 ($M^+ + 1 - H_2O$, 93/31).

RESULTS AND DISCUSSION

The ethereal indomethacin solutions used were saturated and, as such, were prone to precipitation if not kept well capped. Alternatively, more dilute solutions could be prepared by increasing the amount of ether for dissolution or extraction by 50%. However, for application of the same amounts of drug to the TLC plates, the larger sample volumes required resulted in somewhat more diffuse spots and bands.

[11] The aromatic protons are designated as *ortho* (2 and 6) and *meta* (3 and 5) to the carbonyl group.

Table II—Impurity Levels in Indomethacin Drug Substance and Formulations

Form	Dosage Level, mg/unit	Impurities[a], % II	III	IV	V	VI	VII

Capsule	25	Tr	Tr	ND	ND	ND	ND
Capsule	50	Tr	Tr	ND	ND	ND	ND
Suppository	100	Tr	Tr	2	0.5	Tr	Tr
Suppository	100	Tr	Tr	2	0.5	Tr	Tr
Suppository	100	Tr	Tr	2	0.5	Tr	Tr

[a] Estimated by TLC and expressed as a percentage of the label claim of drug. [b] Trace (<0.05%). [c] None detected.

The data given in Table II indicate that only the suppository products exhibited impurities (IV and V) above trace levels. Compounds IV and V were estimated by TLC to be present at levels of ~2 and 0.5%, respectively. Both impurities are formed through chemical interaction of the drug with glycerin present in the suppository. Indomethacin produced these materials in significant amounts when heated with glycerin in the presence of trace mineral acid at 80° for 24 hr. Moreover, when reacted with glycerin under the same conditions, 4-chlorobenzoic acid gave appreciable amounts of V. Reaction of III with glycerin gave rise to an oily product (R_f 0.19, System A), which did not correspond to any of the observed impurities but which was consistent (NMR and IR) with an α-monoglyceride structure. In addition to IV and V and trace levels of II and III, two other impurities (VI and VII) were observed in the suppositories. Since only traces of these impurities appeared to be present, they were not investigated further.

The bulk drug sample and the capsule formulations gave traces of II and III, confirmed by comparison of R_f values in the two solvent systems with authentic specimens of these compounds. No other impurities were observed in the bulk drug and capsule preparations.

Synthesis of Propranolol Mustard as a Possible Lung-Specific Antitumor Agent

L. V. FEYNS *, J. A. BEISLER *x, J. S. DRISCOLL *, and R. A. ADAMSON ‡

Received September 4, 1979, from the **Laboratory of Medicinal Chemistry and Biology and the* ‡*Laboratory of Chemical Pharmacology, Division of Cancer Treatment, National Cancer Institute, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication September 28, 1979.

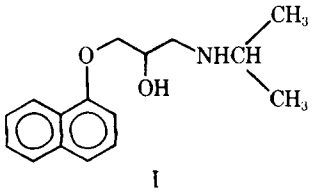
Abstract □ A nitrogen mustard analog of propranolol was synthesized as a potential lung-specific antitumor agent. Since *dl*-propranolol concentrates in lung tissue and β-blocking activity resides only with the *l*-enantiomer, the *d*-modification could serve as a lung-directed carrier for a cytotoxic group. Reaction of 1-(1-naphthyloxy)-3-[bis(2-hydroxyethyl)amino]-2-propanol with thionyl chloride resulted in replacement of all three hydroxyl groups with chlorine. The necessary chlorination selectivity was achieved with *p*-toluenesulfonyl chloride in dimethylformamide solution to provide propranolol mustard, 1-(1-naphthyloxy)-3-[bis(2-chloroethyl)amino]-2-propanol. Both the trichloro compound and propranolol mustard showed reproducible activity against P-388 leukemia. Neither compound was active against the B16 tumor or Lewis lung carcinoma.

Keyphrases □ Propranolol—nitrogen mustard analog, synthesis, potential lung-specific antitumor activity □ Antitumor agents, potential—lung specific, propranolol mustard, synthesis □ Alkylating agents—propranolol mustard, synthesis, potential lung-specific antitumor activity

Alkylating agents, especially the nitrogen mustards, continue to be an important class of drugs in the management of clinical cancer. Although early analogs involved the attachment of the mustard group to carriers seemingly randomly selected (1), cancer chemotherapists of the last decade have attempted to design new mustard derivatives based on exploitable differences between cell types and with the best attainable cytotoxic specificity toward neoplastic tissue (2).

A carrier moiety that has potential for selectively directing a mustard group to lung tissue was suggested recently (3) as having possible utility in the treatment of pulmonary carcinoma. It was reported (4) that high levels of *dl*-propranolol (I) concentrate in the lungs. Although the *l*-enantiomer produces a β-adrenergic blockade, the antipode is inactive as a β-blocker. Therefore, *d*-propranolol might serve effectively as a carrier for lung-directed alkylating agents that would be devoid of undesired effects on the peripheral autonomic nervous system. For example, replacement of the isopropylamino substituent of I with a bis(2-chloroethyl)amino group would result in mustard V shown in Scheme I.

As a continuation of the development of drugs for the treatment of lung cancer (5), the synthesis of a propranolol mustard (V) was initiated. Although the preliminary plan called for working with racemic synthetic intermediates leading to racemic V, the synthetic sequence (Scheme I) provided the option of resolution of optical isomers if biological test data of the racemic mixtures were encouraging.



I

RESULTS AND DISCUSSION

Chemistry—Condensation of (1-naphthyloxy)methyloxirane (II) with diethanolamine (Scheme I) gave a triol (III), which was isolated in excellent yield as the hydrochloride salt. Conversion of III to V necessitated a regioselective chlorination of the two primary hydroxyl groups to generate the mustard functionality. Chlorination of III with thionyl chloride, using a procedure (6) that was utilized successfully in the preparation of a similar nitrogen mustard, nonspecifically gave the trichloro compound IV as the only isolated product.

The ^{13}C-NMR spectrum[1] of IV showed chemical shifts at 42.0 and 57.2 ppm due to the carbon atoms bearing the chlorine substituents and the carbon atoms bonded to the nitrogen atom of the mustard group, respectively. These assignments compare well with those reported (7) for the bis(2-chloroethyl)amino group of cyclophosphamide. The remaining aliphatic carbon atoms gave resonance signals at 69.2 (OCH_2), 58.6 (ClCH), and 57.5 (CH_2N) ppm. These assignments were verified by observing the chemical shift multiplicities in a spectrum obtained in the partially decoupled mode. The shifts recorded for the carbon atoms of the aromatic nucleus were in line with those reported (8) for I.

The necessary regiospecific chlorination of III was obtained using *p*-toluenesulfonyl chloride in dimethylformamide solution to provide the targeted compound, propranolol mustard (V). The poor water solubility of the hydrochloride salt of V allowed it to be separated easily in a 44% yield from other reaction products. Although used to advantage in the present work, the formation of alkyl chlorides first was reported (9) as a side reaction occurring with the tosylation of primary alcohols with *p*-toluenesulfonyl chloride in dimethylformamide solution.

The mass spectra of mustards IV and V showed molecular ions at *m/e* 359 and 341, respectively, and both gave their base peaks at *m/e* 154 due to the $[CH_2{=}N(CH_2CH_2Cl)_2]^+$ ion, which resulted from cleavage of the

[a] The percentage increase (decrease) of the median lifespan of test animals beyond the median survival time of untreated control animals was used to evaluate antitumor activity. Activity is defined as a percentage increase of lifespan of ≥25%. [b] Drugs were suspended in 0.9% saline with hydroxypropylcellulose and administered daily for 9 days after tumor implantation. [c] The T indicates that deaths occurred due to drug-related toxicity.

carbon–carbon bond located α,β to the nitrogen atom. The ^{1}H-NMR spectra of IV and V were consistent with the structures assigned.

Antitumor Evaluation—Propranolol mustard (V) as well as the trichloro Compound IV was evaluated extensively *in vivo* for antitumor activity using three transplantable murine tumors: P-388 leukemia (PS), B16 melanoma (B16), and Lewis lung carcinoma (LL). The last tumor was employed in one system (10) where Lewis lung carcinoma tumor cells were given intravenously and in another system (11) where the Lewis lung carcinoma tumor inoculum was implanted subcutaneously. The P-388 and B16 test systems were used according to established protocols (12). In each of the four test systems, test compounds were administered intraperitoneally daily for 9 days beginning 24 hr after tumor implantation. Dose–response data for IV and V against each test system are recorded in Table I; duplicate determinations were carried out for each system.

Both IV and V prolonged the lifespan of mice bearing P-388 leukemia beyond that of untreated control animals. The percentage increase of lifespan achieved in leukemic mice by IV was between 34 and 41% at a dosage of 20 mg/kg/day. Propranolol mustard (V) gave a somewhat more potent antileukemic effect than IV since just 10 mg/kg/day was sufficient to produce a similar range increase (44–49%). That the bis(2-chloroethyl)amino group is necessary for activity was supported by the lack of activity observed with triol III against P-388 leukemia over a dose range of 400–12.5 mg/kg/day.

Neither IV nor V gave significant activity indications against B16 melanoma, a test system model for solid tumors (Table I). Table I also indicates that neither IV nor V was active in the lung tumor models. The Lewis lung tumor, both in the subcutaneous and intravenous implantation procedures, was completely unaffected by mustards IV and V.

The absence of activity shown by propranolol mustard in the Lewis lung system could be attributed to the net increase in the partition coefficient (log P) resulting from replacement of the $NHCH(CH_3)_2$ group in propranolol with the more lipophilic $N(CH_2CH_2Cl)_2$ group. However, the lack of activity also could be ascribed to an inappropriate utilization of propranolol as a carrier moiety. If the aliphatic portion of I is the essential element in the molecule to effect preferential concentration in lung tissue, then a rational design of a lung-specific antitumor agent would suggest attachment of the cytotoxic mustard group at a point distant from the side chain. Future work also might consider the use of a nitrosourea substituent as the cytotoxic functionality since members of the nitrosourea series have greater incidence of activity against the Lewis lung tumor than do the nitrogen mustards (13).

EXPERIMENTAL[2]

(1-Naphthyloxy)methyloxirane (II)—A literature method (14) was used to convert 110 g (0.76 mole) of 1-naphthol into II. It was obtained as a pale-yellow oil in a 21% yield after distillation, bp 141–144° (0.07 mm) [lit. (15) bp 140° (2 mm)]. The integrated NMR spectrum (60 Hz) was consistent with the assigned structure.

1-(1-Naphthyloxy)-3-[bis(2-hydroxyethyl)amino]-2-propanol (III)—A solution of 16.0 g (0.08 mole) of II and 10.1 g (0.096 mole) of diethanolamine in 200 ml of 1-propanol was refluxed for 2 hr. The reaction solution was concentrated under vacuum at 40°, and the residue was treated with excess methanolic hydrogen chloride. Four volumes of ether were added, and the mixture was allowed to stand overnight at 4°, giving 24.8 g (91% yield) of III as the crystalline hydrochloride salt, mp 140–142°. The melting point was raised to 142–142.5° after recrystallization from methanol–ether (1:2).

Anal.—Calc. for $C_{17}H_{23}NO_4$·HCl: C, 59.73; H, 7.08; Cl, 10.37; N, 4.10. Found: C, 59.71; H, 6.88; Cl, 10.13; N, 4.13.

The free base was extracted with chloroform from an aqueous solution of III·HCl, which was made basic with dilute sodium hydroxide solution. Evaporation of the dried extracts gave the liberated base (III) as a pale-yellow syrup. This syrup could not be induced to crystallize but was homogeneous by TLC; IR: 3360, 1627, 1596, 1579, 1458, 1397, 1262, 1100, 1066, and 1033 cm^{-1}; NMR (60 MHz): δ 2.68 (t, J = 5.5 Hz, 4H, NCH_2CH_2) and 3.52 (t, J = 5.5 Hz, 4H, CH_2OH).

The picrate of III was formed from ethanol and gave a melting point of 161–162° after recrystallization from ethanol [lit. (16) mp 161–163°].

1-(1-Naphthyloxy)-2-chloro-3-[bis(2-chloroethyl)amino]propane (IV)—To a solution of purified (17) thionyl chloride (16.3 g, 0.137 mole) in 60 ml of dry (sodium) benzene, which was stirred and cooled to 2°, was added dropwise a solution of II (10.45 g, 0.0342 mole) in 60 ml of dry benzene at a rate such that the solution temperature did not exceed 5°. After the addition was complete, the reaction solution was refluxed and stirred for 2.5 hr and then evaporated under reduced pressure at room temperature. Thionyl chloride traces were removed by codistillation with two 100-ml portions of dry benzene.

The residue was partitioned between 100 ml of benzene and 100 ml of 2 N aqueous NaOH solution. The layers were separated, and the aqueous layer was saturated with sodium chloride and extracted twice with benzene. The combined benzene solutions were washed twice with water, dried with anhydrous sodium sulfate, treated with activated charcoal, and evaporated to give 9.5 g of an oil. The oil was distilled in a short-path apparatus (150–170°, 0.2 mm) in 0.5–1.7-g portions to give a combined distillate of 7.0 g as a pale-yellow oil. The oil was extracted with hot petroleum ether.

Storage of the extract overnight at ~−15° gave 4.72 g (38%) of white crystals (IV), mp 45–46°; IR: 1583, 1510, 1460, 1404, 1267, 1240, and 1103 cm^{-1}; NMR (100 MHz): δ 2.96 (t, J = 6 Hz, 4H, NCH_2CH_2), 3.08–3.26 (m, 2H, $CHCH_2N$), 3.48 (t, J = 6 Hz, 4H, CH_2Cl), 4.23–4.56 (m, 3H, $ArOCH_2CH$), and 6.78–8.30 (m, 7H, aromatic); mass spectrum: m/e 359 (M^+, 4.4%), 323 (M − HCl, 1.2), 310 (M − CH_2Cl, 8.8), 216 (8.2), 202 (M − $CH_2OC_{10}H_7$, 8.2), 183 (13), 154 [$CH_2{=}N(CH_2CH_2Cl)_2$, 100], 144 (20), 127 (9.8), and 115 (32).

Anal.—Calc. for $C_{17}H_{20}Cl_3NO$: C, 56.61; H, 5.59; Cl, 29.49; N, 3.88. Found: C, 56.71; H, 5.62; Cl, 29.44; N, 4.02.

The picrate of IV was formed from chloroform and gave a melting point of 123–124° after recrystallization from ethanol.

[2] PMR spectra were determined with a Varian T-60 or HA100 spectrometer in deuterochloroform solution. Chemical shifts are reported in parts per million (δ) downfield from tetramethylsilane, which was used as an internal standard. IR spectra were recorded in chloroform solution with a Perkin-Elmer model 621 spectrophotometer. Mass spectra were obtained by direct probe insertion with a DuPont 21-492 spectrometer operated with a 75-ev ionizing voltage. Melting points were measured on a Thomas-Hoover capillary melting-point apparatus and are uncorrected. Elemental analyses were performed by the Section on Microanalytical Services and Instrumentation, National Institute of Arthritis, Metabolism, and Digestive Disease, National Institutes of Health.

Anal.—Calc. for $C_{17}H_{20}Cl_3NO \cdot C_6H_3N_3O_7$: C, 46.84; H, 3.93; Cl, 18.03; N, 9.50. Found: C, 46.87; H, 4.09; Cl, 17.83; N, 9.45.

1-(1-Naphthyloxy)-3-[bis(2-chloroethyl)amino] -2- propanol (V)—*p*-Toluenesulfonyl chloride (6.25 g, 0.0328 mole) was added to a solution of III (5.0 g, 0.0164 mole) in 50 ml of dry (molecular sieves) dimethylformamide. The reaction mixture was stirred and heated for 2 hr at 55–65°. The solvent was removed under reduced pressure at 40° with a rotary evaporator, and the residual syrup was partitioned between 250 ml of benzene and 100 ml of 1 *N* aqueous NaOH solution. The benzene layer was separated, washed with water, and dried over anhydrous sodium sulfate.

Under vigorous stirring, 250 ml of 2 *N* HCl was added dropwise over 30 min to the benzene solution. The stirring was continued for an additional hour after the addition was completed. The white crystals that formed were removed by filtration and washed with 2 *N* HCl, benzene, and ether to give 2.71 g (44% yield) of V as the hydrochloride salt, mp 149–153°. Analytically pure hydrochloride was obtained by chromatographing the free base and by converting the purified base back to the hydrochloride. Accordingly, the base was liberated by benzene extraction from 1 *N* NaOH.

After evaporation of the dried extracts, the residue was chromatographed over silica[3]. Elution of the column with chloroform gave V as a noncrystallizable oil, which was treated with ethanol saturated with hydrogen chloride. The resulting crystalline hydrochloride was recrystallized from the same solvent, mp 155.5–157°; IR (mineral oil mull): 3260 (br), 2580 (br), 1580, 1400, 1391, 1270, 1239, 1126, and 1100 cm^{-1}.

Anal.—Calc. for $C_{17}H_{21}Cl_2NO_2 \cdot HCl$: C, 53.91; H, 5.86; Cl (total), 28.08; Cl (ionic), 9.36; N, 3.70. Found: C, 53.80; H, 5.83; Cl (total), 27.98; Cl (ionic), 9.50; N, 3.70.

The free base appeared as one spot when analyzed by TLC (silica, chloroform); NMR (100 MHz): δ 2.78 (d, J = 7 Hz, 2H, $CHCH_2N$), 2.95 (t, J = 6 Hz, 4H, NCH_2CH_2), 3.55 (t, J = 6 Hz, 4H, CH_2Cl), 4.02–4.32 (m, 3H, $ArOCH_2CH$), and 6.76–8.26 (m, 7H, aromatic); mass spectrum: *m/e* 341 (M^+, 2.3%), 305 (M − HCl, 2.1), 292 (M − CH_2Cl, 1.7), 256 (M − CH_2Cl − HCl, 3.3), 198 (1.1), 186 (2.3), 183 (2.9), 154 [$CH_2{=}N(CH_2CH_2Cl)_2$, 100], 144 (13), and 115 (17).

Centrally Active *N*-Substituted Analogs of 3,4-Methylenedioxyphenylisopropylamine (3,4-Methylenedioxyamphetamine)

ULRICH BRAUN *, ALEXANDER T. SHULGIN ‡x, and GISELA BRAUN *

Received April 29, 1979, from the **Institute of Pharmacology, University of Bonn, 53 Bonn, West Germany*, and ‡*1483 Shulgin Road, Lafayette, CA 94549.* Accepted for publication September 20, 1979.

Abstract □ The known central nervous system activity of 3,4-methylenedioxyphenylisopropylamine and its *N*-methyl homolog prompted the synthesis of a series of analogs with substituents on the nitrogen atom. Most of these analogs (R = alkyl, alkenyl, hydroxy, alkoxy, and alkoxyalkyl) were prepared by the reductive alkylation of 3,4-methylenedioxyphenylacetone with the appropriate amine and sodium cyanoborohydride. Hindered isomers were synthesized indirectly. Measurements of their pharmacological activity in several animal assays and in human subjects indicated that the central activity decreased with the increasing bulk of the *N*-substituent.

Keyphrases □ Amines, phenylalkyl, substituted—*N*-substituted analogs of psychotomimetic agents □ Psychotomimetic agents—*N*-substituted analogs of known centrally active agents □ 3,4-Methylenedioxyphenylisopropylamine—synthesis of centrally active *N*-substituted analogs

The structural nucleus of amphetamine has served as the basis of numerous compounds of pharmacological interest. Amphetamine itself is a sympathomimetic stimulant at nominal dosages and leads to a psychotomimetic syndrome only at high dose levels (1). Nuclear alkyl substitution maintains the stimulant properties of the parent compound (2, 3), but the substitution of methoxyl groups leads to compounds that are primarily psychotomimetic

Anal.—Calc. for $C_{17}H_{20}Cl_3NO \cdot C_6H_3N_3O_7$: C, 46.84; H, 3.93; Cl, 18.03; N, 9.50. Found: C, 46.87; H, 4.09; Cl, 17.83; N, 9.45.

1-(1-Naphthyloxy)-3-[bis(2-chloroethyl)amino] -2- propanol (V)—*p*-Toluenesulfonyl chloride (6.25 g, 0.0328 mole) was added to a solution of III (5.0 g, 0.0164 mole) in 50 ml of dry (molecular sieves) dimethylformamide. The reaction mixture was stirred and heated for 2 hr at 55–65°. The solvent was removed under reduced pressure at 40° with a rotary evaporator, and the residual syrup was partitioned between 250 ml of benzene and 100 ml of 1 *N* aqueous NaOH solution. The benzene layer was separated, washed with water, and dried over anhydrous sodium sulfate.

Under vigorous stirring, 250 ml of 2 *N* HCl was added dropwise over 30 min to the benzene solution. The stirring was continued for an additional hour after the addition was completed. The white crystals that formed were removed by filtration and washed with 2 *N* HCl, benzene, and ether to give 2.71 g (44% yield) of V as the hydrochloride salt, mp 149–153°. Analytically pure hydrochloride was obtained by chromatographing the free base and by converting the purified base back to the hydrochloride. Accordingly, the base was liberated by benzene extraction from 1 *N* NaOH.

After evaporation of the dried extracts, the residue was chromatographed over silica[3]. Elution of the column with chloroform gave V as a noncrystallizable oil, which was treated with ethanol saturated with hydrogen chloride. The resulting crystalline hydrochloride was recrystallized from the same solvent, mp 155.5–157°; IR (mineral oil mull): 3260 (br), 2580 (br), 1580, 1400, 1391, 1270, 1239, 1126, and 1100 cm^{-1}.

Anal.—Calc. for $C_{17}H_{21}Cl_2NO_2 \cdot HCl$: C, 53.91; H, 5.86; Cl (total), 28.08; Cl (ionic), 9.36; N, 3.70. Found: C, 53.80; H, 5.83; Cl (total), 27.98; Cl (ionic), 9.50; N, 3.70.

The free base appeared as one spot when analyzed by TLC (silica, chloroform); NMR (100 MHz): δ 2.78 (d, J = 7 Hz, 2H, $CHCH_2N$), 2.95 (t, J = 6 Hz, 4H, NCH_2CH_2), 3.55 (t, J = 6 Hz, 4H, CH_2Cl), 4.02–4.32 (m, 3H, $ArOCH_2CH$), and 6.76–8.26 (m, 7H, aromatic); mass spectrum: *m/e* 341 (M^+, 2.3%), 305 (M − HCl, 2.1), 292 (M − CH_2Cl, 1.7), 256 (M − CH_2Cl − HCl, 3.3), 198 (1.1), 186 (2.3), 183 (2.9), 154 [$CH_2{=}N(CH_2CH_2Cl)_2$, 100], 144 (13), and 115 (17).

Centrally Active *N*-Substituted Analogs of 3,4-Methylenedioxyphenylisopropylamine (3,4-Methylenedioxyamphetamine)

ULRICH BRAUN *, ALEXANDER T. SHULGIN ‡x, and GISELA BRAUN *

Received April 29, 1979, from the **Institute of Pharmacology, University of Bonn, 53 Bonn, West Germany*, and ‡*1483 Shulgin Road, Lafayette, CA 94549.* Accepted for publication September 20, 1979.

Abstract □ The known central nervous system activity of 3,4-methylenedioxyphenylisopropylamine and its *N*-methyl homolog prompted the synthesis of a series of analogs with substituents on the nitrogen atom. Most of these analogs (R = alkyl, alkenyl, hydroxy, alkoxy, and alkoxyalkyl) were prepared by the reductive alkylation of 3,4-methylenedioxyphenylacetone with the appropriate amine and sodium cyanoborohydride. Hindered isomers were synthesized indirectly. Measurements of their pharmacological activity in several animal assays and in human subjects indicated that the central activity decreased with the increasing bulk of the *N*-substituent.

Keyphrases □ Amines, phenylalkyl, substituted—*N*-substituted analogs of psychotomimetic agents □ Psychotomimetic agents—*N*-substituted analogs of known centrally active agents □ 3,4-Methylenedioxyphenylisopropylamine—synthesis of centrally active *N*-substituted analogs

The structural nucleus of amphetamine has served as the basis of numerous compounds of pharmacological interest. Amphetamine itself is a sympathomimetic stimulant at nominal dosages and leads to a psychotomimetic syndrome only at high dose levels (1). Nuclear alkyl substitution maintains the stimulant properties of the parent compound (2, 3), but the substitution of methoxyl groups leads to compounds that are primarily psychotomimetic

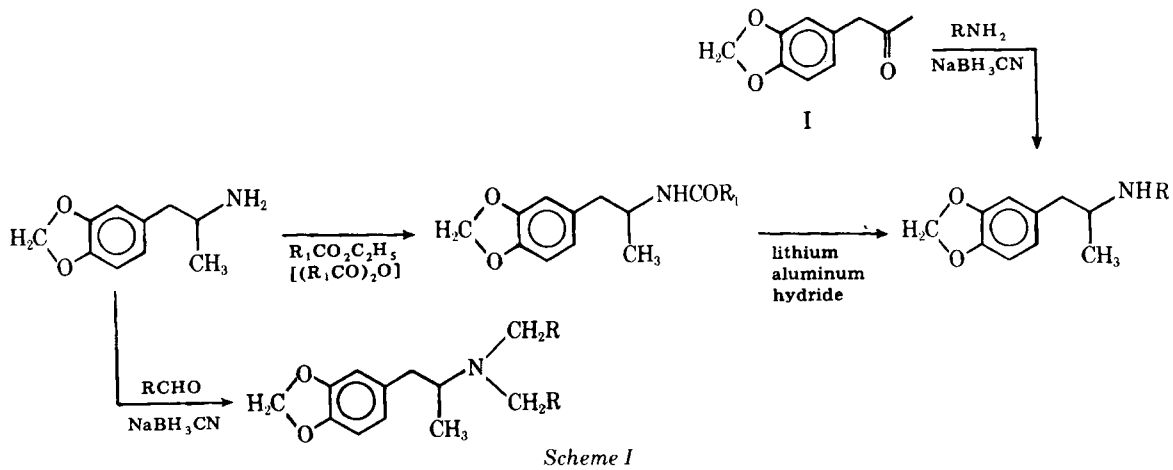

Scheme I

(4); this property is enhanced by the additional inclusion of alkyl (5), halo (6), or alkylmercapto (7) groups. A methylenedioxy group on the aromatic nucleus, either without (8, 9) or with (10) methoxyl groups, maintains this latter pharmacological property. Removal of the α-methyl group of these substituted amphetamine analogs inevitably decreases potency but leaves their qualitative nature intact (11).

Less is known about the effects of *N*-substitution. With amphetamine itself, *N*-methylation provides methamphetamine, which is similar to amphetamine in both potency and action (12), but only sparse information exists concerning the human pharmacology of higher homologs (13). One psychotomimetic (methylenedioxyphenylisopropylamine, IIa) is known to maintain its central action in humans with both *N*-methylation (7) and *N*-ethylation (14).

This report describes the preparation of some related *N*-substituted analogs of IIa and outlines their pharmacological properties with respect to motor activity and analgesia in animals and central activity in humans.

RESULTS AND DISCUSSION

Several bases were prepared by one or more of the three general procedures shown in Scheme I. Procedure I, employing the reductive amination of a ketone with amines in the presence of sodium cyanoborohydride (15), gave acceptable yields with piperonylacetone (I) and most primary amines as their hydrochloride salts in methanol. The products were isolated conventionally except for the long chain homologs which, as salts, were extremely water insoluble but soluble in methylene chloride. This procedure was unsatisfactory with hindered primary amines (*tert*-butylamine and 4-aminoheptane); with the secondary amines studied, it was effective only with dimethylamine.

The simpler homologs could be prepared by acylation of IIa itself, followed by reduction of the resulting amide with lithium aluminum hydride (Procedure II). The *N,N*-diethyl homolog IIv could not be formed from I and diethylamine, and it was prepared by the reductive alkylation of IIa with an excess of acetaldehyde and with sodium cyanoborohydride (Procedure III). Compound IIr formed readily from I and hydroxylamine, but attempts to distill the isolated product led to an erratic degree of decomposition by disproportionation, in part, to IIa. An alternative procedure leading to IIr was the reduction of the I oxime. The product amines and their physical properties are shown in Table I. Representative synthetic procedures are outlined under *Experimental*.

Several bases were evaluated as centrally active drugs in assays that measured analgesia or motor stimulation. Analgesia studies included hot-plate and light–warmth stimuli, as well as diminished response to injected acetic acid as determined by the loss of the stretch reflex response. Motor stimulation was determined in automated activity cages. Human psychotomimetic efficacy was determined for several of these materials by standard procedures (4).

In all animal assays, IIa was significantly more active as an analgesic than control saline. The results (Table II) were normalized with IIa as a standard, with increasing values indicating increased effectiveness. The motor stimulation observed in mice and the effective psychotomimetic levels found in humans are given in Table III. A full report of the pharmacological procedures and related experimental details was published separately (19).

The direct determination of central activity of these materials in animal studies is compromised by the use of dosages close to the LD_{50} values and may represent a more generalized somatic challenge than simple analgesia or stimulation. This problem was apparent for higher dosages of IIa and IIb but not for IIm and IIo where there was little stimulation despite high LD_{50} levels. Throughout these assays, it was apparent that the simplest homologs of IIa (IIb, IIc, and IIr) were somewhat similar in action and efficacy. The two simplest compounds (IIa and IIb) have been studied most frequently, and the reported facts are compared with the results of this study in Table IV. Generally, both the toxicity (and the risk) of a drug and its central activity decrease with homologation, maintaining a constant therapeutic index. The metabolic explanation that the activity of IIb in humans is due to its conversion to IIa is contradicted by the qualitative differences of their actions and by the fact that opposite optical isomers are responsible for their actions (22). Compound IIr, a potential metabolite of IIa, has been studied only as the racemate.

EXPERIMENTAL

Melting points were determined in open capillaries and are uncorrected. Boiling points were recorded from bulb-to-bulb distillation. Microanalyses of all new compounds are included in Table I. All new compounds had IR and NMR spectra consistent with the assigned structures[1].

N-Ethyl-3,4-methylenedioxyphenylisopropylamine (IIc)—*Procedure I*—To a solution of 31.0 g of ethylamine hydrochloride in 110 ml of methanol were added 6.6 g of piperonylacetone (I, 37 mmoles) and then 3 g of sodium cyanoborohydride. The mixture was stirred at ambient temperature, and 12 *N* HCl was added as required to maintain the pH at neutrality (determined by the use of external damp universal pH paper). The reaction was complete in 36 hr. Following addition to 1 liter of water containing 5 ml of 12 *N* HCl, the reaction mixture was extracted twice with 150 ml of methylene chloride (discarded), made basic with 25% NaOH, and reextracted with 3 × 150 ml of methylene chloride. The extracts were pooled, and the solvent was removed *in vacuo*.

Distillation of the residual oil (8.3 g) at 0.20 mm Hg yielded 6.0 g of product as a viscous colorless oil, bp 85–95°. This product was dissolved in 60 ml of isopropanol and acidified with 12 *N* HCl (titration end-point determined with external damp universal pH paper), and an equal volume of ether was added. There was a spontaneous crystallization of the product as a white solid. It was removed by filtration and washed first

[1] IR spectra were obtained on a Perkin-Elmer Infracord spectrophotometer, and NMR spectra were obtained on a Perkin-Elmer 60-mHz permanent magnet NMR spectrometer. Microanalyses were performed by Galbraith Laboratories, Knoxville, TN 37921.

[a] Compound IIa has been referred to in the literature as MDA and EA-1299. Compound IIb has been referred to in the literature as MDM, MDMA, and EA-1475. The EA codes are from the Edgewood Arsenal, U.S. Army Chemical Warfare Service. [b] Ammonia was employed as the acetate salt. [c] The conventional preparation of IIa by the lithium aluminum hydride reduction of 1-(3,4-methylenedioxyphenyl)-2-nitropropene gave a yield of 87%. [d] Lit. (16) mp 186–187°. [e] Lit. (17) mp 148–149° and mp 147–148° (18). [f] Overall yield from IIa, with isolation and purification of the intermediate formamide. [g] Overall yield from IIa, with isolation and purification of the intermediate acetamide. [h] The major product was IIa from ammonia formed by the *in situ* decomposition of cyanomethylamine. [i] Unstable to distillation (see text). Free base from isopropanol, mp 94–95°. Nitrogen analysis was: calc., 7.08; found, 7.09.

with isopropanol–ether and finally with ether alone, giving 6.1 g of the air-dried product (68% yield), mp 201–202°.

Procedure II—A solution of 3.6 g of IIa as the free base (20 mmoles) in 20 ml of pyridine was treated with 2.4 ml of acetic anhydride and stirred at ambient temperature for 18 hr. The reaction mixture was added to 200 ml of water, stirred several hours, acidified with hydrochloric acid, and extracted with 2 × 80 ml of methylene chloride. The extracts were pooled, and the solvent was removed *in vacuo* to yield an off-white solid (mp 89–90°), which crystallized from 80 ml of ethyl acetate–hexane (1:1). The acetamide was obtained as white crystals (2.6 g, 58% yield, mp 92–93°).

A solution of 1.7 g of the acetamide (7.7 mmoles) in 8 ml of dry tetrahydrofuran was added to a solution of 1.6 g of lithium aluminum hydride in 150 ml of tetrahydrofuran and stirred at reflux temperature. After being held at reflux with stirring for 72 hr, the reaction mixture was cooled (external ice water), and treated sequentially with 1.6 ml of water in several milliliters of tetrahydrofuran, 1.6 ml of 15% NaOH, and finally with 4.8 ml of additional water. The white solids were removed by filtration and washed with tetrahydrofuran. The filtrate and washes were combined, and the solvent was removed *in vacuo*.

The residual oil was distilled (90–100° at 0.2 mm Hg), dissolved in 8 ml of isopropanol, acidified with 12 *N* HCl (external damp pH paper), and diluted with ether. Resulting white solids were filtered, washed with isopropanol–ether and then with ether, and air dried. The product weighed 1.0 g, mp 198–199° (mixed melting point with the product from Procedure I, 198–199°); the yield was 53% from the acetamide and 31% overall from IIa.

***N* - Cyanomethyl - 3,4 - methylenedioxyphenylisopropylamine (III)**—The crude reaction product (following Procedure I) obtained from I (2.67 g, 15 mmoles), cyanomethylamine sulfate (20 g, 130 mmoles) in 100 ml of methanol adjusted to neutral pH with 25% NaOH, and 1.3 g of sodium cyanoborohydride was a mixture of III and IIa. The latter was undoubtedly formed by the *in situ* decomposition of free cyanometh-

[a] Published literature data have been commingled with results from this study for comparison. [b] *R* and *S* represents the absolute configurations of the pharmacologically active isomers, and are the levo- and dextrorotatory forms, respectively.

ylamine to ammonia. Upon distillation, the first fraction (1.3 g, bp 90–110° at 0.4 mm Hg) was substantially free of the cyanomethylene group (by NMR), but the second fraction (0.8 g, bp 150–160° at 0.3 mm Hg) had the proper NMR spectrum in deuterium oxide as the hydrochloride salt: δ 1.30 and 1.42 (2s, 3H, CH_3), 3.00 (m, 2H, aromatic CH_2), ~3.6 (m, 1H, CH), 4.38 (s, 2H, CH_2CN), 4.75 (s, NH and DOH), 6.05 (s, 2H, OCH_2O), and 6.95 (s, 3H, aromatic H). The analytical sample was recrystallized from boiling isopropanol (50 ml/g).

***N*-Hydroxy-3,4-methylenedioxyphenylisopropylamine (IIr)**—The crude reaction product (*via* Procedure I) obtained from I (7.2 g, 40 mmoles), hydroxylamine hydrochloride in methanol (29.6 g in 240 ml), and sodium cyanoborohydride (2 g) gave evidence, on attempted distillation, of the generation of water by pyrolytic disproportionation. At bath temperatures of <90°, the distillate was mainly IIt; but above 100°, there was extensive decomposition to IIa, which was the major product isolated (verified by IR spectral comparison of the hydrochloride salt with reference IIa·HCl). The free base could be obtained as a solid and was best purified by recrystallization as described below.

Compound IIr also could be prepared *via* the I oxime. A solution of 10 g of I (56 mmoles) and 10 g of hydroxylamine hydrochloride in 50 ml of pyridine and 50 ml of ethanol was held at reflux for 2 hr. Removal of the solvents *in vacuo* left an oil, which crystallized upon trituration under water. The crude oxime was removed by filtration and recrystallized from ethanol–water to yield 5.5 g (51% yield) of a white crystalline product, mp 84–87°. The oxime was dissolved in 50 ml of methanol and treated with 2.5 g of sodium cyanoborohydride. While being stirred at ambient temperature, 12 *N* HCl was added dropwise (about 10 drops every 12 hr) over 3 days. The methanol was removed *in vacuo*, and the residue was suspended in acidified water (5 ml of 12 *N* HCl in 500 ml). The reaction mixture was extracted with 3 × 100 ml of methylene chloride (unreacted oxime was discarded), made basic with sodium hydroxide, and reextracted with 3 × 100 ml of methylene chloride. The extracts were pooled, and the solvent was removed *in vacuo* to provide IIr (free base) as a white solid (1.4-g crude yield after vacuum drying at 0.2 mm Hg).

After recrystallization from isopropanol (6 ml/g), the product had a melting point of 92–94° (mixed melting point with the oxime, 56–62°). In the IR spectrum, both the NH and the OH stretch vibration absorptions were visible at 3040 (broad) and 3135 (sharp) cm^{-1} (in mineral oil). The free base was converted to the hydrochloride salt by dissolution in 20 ml of warm isopropanol, acidification with 12 *N* HCl (external damp pH paper), and the addition of 200 ml of ether. The clear solution slowly deposited white crystals of IIr·HCl, 0.8 g (12% yield from the oxime, overall yield of 6%), mp 149–150° (mixed melting point with IIa·HCl was 128–138°).

***N,N*-Diethyl-3,4-methylenedioxyphenylisopropylamine (IIv) (Procedure III)**—A stirred solution of 1.4 g of IIa·HCl (6.5 mmoles) in 30 ml of methanol was treated with 7.0 g of acetaldehyde and 1.5 g of sodium cyanoborohydride. Then 12 *N* HCl was added dropwise as needed to maintain the pH at neutrality (as determined by external damp universal pH paper). After 48 hr, the reaction mixture was added to 600 ml of water, acidified with hydrochloric acid (5 ml), and extracted with 2 × 100 ml of methylene chloride. The residual aqueous phase was made basic with 25% NaOH and reextracted with 3 × 100 ml of methylene chloride. The extracts were combined and the solvent was removed *in vacuo*. The residual pale-yellow oil (1.1 g of crude weight) was distilled (85–88° at 0.15 mm Hg) to yield 1.0 g of a colorless oil. This oil was dissolved in 8 ml of isopropanol, acidified with 12 *N* HCl, and diluted with 30 ml of ether. After the product had crystallized completely, it was removed by filtration and washed first with 75% ether (with isopropanol) and finally with ether. Air drying yielded 1.1 g of IIv·HCl as white crystals (62% of theory), mp 177–178°.

Abstract □ Numerous cyclic analogs of lactic acid were synthesized to ascertain whether they might act as agonists or antagonists of lactic acid, a known attractant for mosquitoes. These compounds were evaluated with an *in vitro* blood-feeding test system and an *in vivo* cloth test. Two of the compounds in the blood-feeding test system showed biphasic results, acting as attractants at low concentrations and as repellents at higher concentrations. Several compounds (III, V, VII, and X) repelled *Aedes aegypti* mosquitoes in the blood-feeding test system. However, in the *in vivo* cloth test system, only III repelled the mosquitoes significantly.

Keyphrases □ Lactic acid cyclic analogs—topical mosquito repellents, *in vivo* testing, humans □ Mosquitoes—topical repellents, lactic acid cyclic analogs, *in vivo* testing, humans □ Repellents, mosquito—topical use in humans, lactic acid cyclic analogs

Numerous cyclic analogs of lactic acid have been synthesized and evaluated as mosquito repellents using an *in vitro* blood-feeding test system (1). Some of these compounds also were evaluated by an *in vivo* cloth test[1].

In addition to L-lactic acid, several compounds related to lactic acid attract *Aedes aegypti* mosquitoes (2). Certain receptors on the antennae of the female *A. aegypti* mosquito respond to lactic acid, but *N,N*-diethyl-*m*-toluamide blocks this response (3). Thus, an antagonist to lactic acid may exhibit repellent activity and an agonist may attract the mosquitoes.

A survey of chemical classes with repellent behavior (4, 5) indicated that α-keto and α-hydroxy carbonyl compounds were among those showing increased frequency of repellent activity.

The structure–activity relationships of these compounds were investigated in structures that varied in the separation of the oxygen functions (hydroxyl or RO) from the carbonyl functions. The alkyl substituents were varied to give a boiling-point range since volatility is an important variable affecting the duration of topical repellency. Table I indicates the structures, boiling points or melting points, and repellency data for compounds used against *A. aegypti* (yellow fever) mosquitoes.

EXPERIMENTAL[2]

Chemistry—*Ethyl 2-Butyl-1-hydroxycyclopentanecarboxylate (6) (IV)*—2-*n*-Butyl-1-hydroxycyclopentanecarbonitrile (7) (5.0 g, 29.9 mmoles), anhydrous ethanol (1.38 g, 29.9 mmoles), *p*-toluenesulfonic acid monohydrate (5.69 g, 29.9 mmoles), and 5 ml of anhydrous benzene were stirred overnight at 90°. Water and benzene were added, the organic layer was washed with 20% Na_2CO_3 and water and then dried over sodium sulfate, and the solvent was evaporated. Distillation of the residue afforded IV (bp 71–72°/0.5 mm Hg) as a colorless liquid, 1.0 g (16% yield); IR (film): 3460, 2900, 2830, 1720, 1430, 1370, 1230, 1050, 880, and 760 cm^{-1}; NMR ($CDCl_3$): δ 4.27 (q, 2H), 3.1 (s, 1H), 1.6–2.2 (m, 7H), 1.27 (t, 3H), 1.05–1.4 (m, 6H), and 0.87 (t, 3H) ppm.

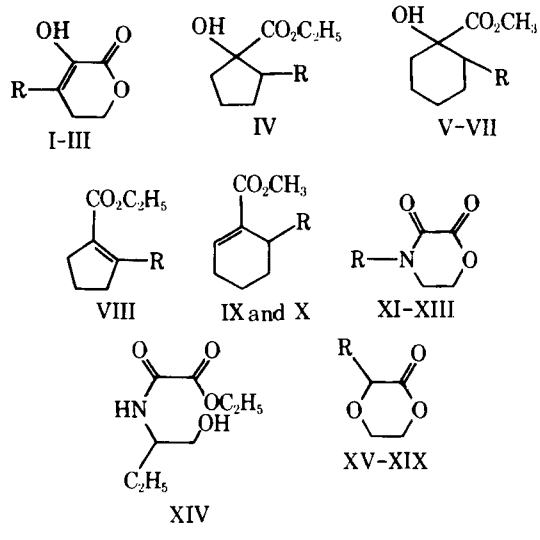
Anal.—Calc. for $C_{12}H_{22}O_3$: C, 67.25; H, 10.35. Found: C, 67.70; H, 10.60.

Methyl 2-Butyl-1-hydroxycyclohexanecarboxylate (V)—2-*n*-Butyl-1-hydroxycyclohexanecarbonitrile (7) (7.2 g, 39.7 mmoles) and 20 volume % H_2SO_4 (26 ml) in acetic acid (35 ml) were stirred at 110° for 27 hr. After cooling, the reaction mixture was poured into cold water and extracted with ether. The carboxylic acid was extracted with dilute sodium hydroxide, the aqueous alkaline solution was acidified with concentrated hydrochloric acid, and the solution was extracted with ether. The combined ether layers were dried over sodium sulfate–charcoal and were concentrated to yield 0.91 g of a yellow oil.

A solution of diazomethane in ether was added slowly at 0° to a stirred solution of 2-*n*-butyl-1-hydroxycyclohexanecarboxylic acid (0.91 g, 4.54 mmoles) in 10 ml of ether until nitrogen evolution ceased. The reaction mixture was stirred for 40 min at 0° and for 30 min at room temperature. After the addition of 1 ml of 3 *N* acetic acid, the solution was extracted with sodium bicarbonate and water, and the extract was dried over magnesium sulfate and concentrated. Distillation afforded V (bp 85–86°/0.5 mm Hg) as a colorless liquid, 0.90 g (93% yield); IR (film): 3480, 2920, 2850, 1730, 1460, 1390, 1240, 1160, 1100, and 1020 cm^{-1}; NMR ($CDCl_3$): δ 3.76 (s) and 3.64 (s, 3H), 3.36 (s, 1H), 2.2–2.5 (m, 3H), 1.0–1.9 (m, 12H), and 0.86 (t, 3H) ppm.

Anal.—Calc. for $C_{12}H_{22}O_3$: C, 67.26; H, 10.35. Found: C, 67.20; H, 10.22.

(1-Acetoxy-2-heptylcyclohexyl)carbonitrile—Five grams (0.022 mole) of (2-heptyl-1-hydroxycyclohexyl)carbonitrile was dissolved in 50 ml of acetic anhydride. After addition of 0.1 g of 4-dimethylaminopyridine as a catalyst, the mixture was allowed to stand at room temperature for 2 days. The excess acetic anhydride was removed *in vacuo*. The residue was taken up with saturated sodium bicarbonate and extracted three times with ether. After drying with anhydrous magnesium sulfate and



[1] The *in vivo* cloth test system was developed by the Agricultural Research Laboratories, U.S. Department of Agriculture, Gainesville, Fla.

[2] Melting points were determined on a capillary melting-point apparatus and are uncorrected. Boiling points were determined using a short-path distillation apparatus and are uncorrected. IR (Perkin-Elmer 735B) and NMR (Varian Associates T-60 or EM-390) spectra were taken of all compounds and were completely consistent with the assigned structures. Elemental analyses were performed by the Microanalytical Laboratory, Department of Chemistry, Stanford University, Stanford, Calif.

evaporating, 5.3 g of a yellow oil was obtained and was sufficiently pure for the following reaction.

(2-Heptyl-1-hydroxycyclohexyl)carbonitrile—A mixture of 15 g (0.076 mole) of 2-heptylcyclohexanone, 19 g (0.22 mole) of acetone cyanohydrin, and 0.3 g of triethylamine was allowed to stand at room temperature for 2 hr. After acidification with sulfuric acid in acetone, the excess acetone cyanohydrin was distilled *in vacuo* (60°/1.0 mm Hg). The residue was taken up in ether and washed with water. After drying over sodium sulfate and evaporating, 15 g of a reddish oil was obtained and was sufficiently pure for further reactions.

Methyl (2-Heptyl-1-hydroxycyclohexyl)carboxylate (VII)—Five grams (0.0187 mole) of (1-acetoxy-2-heptylcyclohexyl)carbonitrile was dissolved in a mixture of 19 ml of acetic acid, 1 ml of acetic anhydride, and 4 ml of sulfuric acid. After standing at room temperature for 4 hr, 3 ml of water was added. Three grams (0.0435 mole) of granular sodium nitrite was added slowly to the cooled and stirred mixture. The suspension was stirred under cooling for 30 min and at room temperature for 1 hr. The mixture was poured into ice water and extracted three times with ether.

The combined extracts were evaporated *in vacuo*, and the residue was taken up with 20 ml of methanol. After addition of 10 ml of 40% KOH, the mixture was refluxed for 1 hr, poured into water, and extracted three times with ether. The aqueous phase was acidified with 10% H_2SO_4 and extracted three times with dichloromethane. After drying with anhydrous magnesium sulfate, an ethereal solution of diazomethane was added slowly to the stirred and cooled acid solution. After decolorization with activated charcoal and evaporation, the crude product was distilled *in vacuo* to give 2.5 g of a colorless oil (130° air bath temperature/0.35 mm Hg). A second distillation gave 2.4 g (50% yield) of pure product, bp 118°/0.3 mm Hg.

Anal.—Calc. for $C_{15}H_{28}O_3$: C, 70.27; H, 11.01. Found: C, 69.42; H, 10.70.

Ethyl 2-Butyl-1-cyclopentene-1-carboxylate (VIII)—Compound IV (2.3 g, 10.73 mmoles) in 2.5 ml of pyridine was treated dropwise at 0° with 1.4 ml of thionyl chloride, heated for 1 hr at 140° (oil bath temperature), and poured after cooling into ice water. The ester was extracted with ether, and the extract was dried over sodium sulfate–charcoal and concentrated *in vacuo*. Distillation (bp 74–75°/0.5 mm Hg) afforded VIII as a colorless liquid, 1.8 g (86% yield); IR (film): 2940, 2850, 1700, 1640, 1470, 1380, 1270, 1210, 1105, and 1045 cm^{-1}; NMR ($CDCl_3$): δ 4.18 (q, 2H), 1.6–2.8 (m, 8H), 1.26 (t, 3H), 1.1–1.16 (m, 4H), and 0.9 (t, 3H) ppm.

Anal.—Calc. for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27. Found: C, 73.03; H, 10.03.

Methyl 6-Heptyl-1-cyclohexene-1-carboxylate (X)—2-*n*-Heptyl-1-hydroxycyclohexanecarbonitrile (7) (2.0 g, 8.95 mmoles) in 2.2 ml of pyridine was treated dropwise at 0° with 1.2 ml of thionyl chloride, and the mixture was heated for 1 hr at 140° (oil bath temperature) and poured after cooling into ice water. The desired product was extracted with ether, and the extract was dried over sodium sulfate–charcoal and concentrated *in vacuo* to yield 1.6 g of a light-yellow oil.

A solution of 6-*n*-heptylcyclohex-1-enecarbonitrile (1.3 g, 6.33 mmoles) in 2.6 ml of 50 volume % H_2SO_4 and 6.5 ml of acetic acid was stirred at 110° for 18 hr. To this ice-cooled and well-stirred reaction mixture, a solution of sodium nitrite (0.52 g, 7.6 mmoles) in 2 ml of water was added slowly. After stirring for 20 min at room temperature and 1.5 hr at 80°, the reaction mixture was poured into water and extracted with ether. The ether solution was extracted several times with dilute sodium hydroxide, and the combined alkaline layers were acidified with concentrated hydrochloric acid and extracted with ether. The ether layers were dried over sodium sulfate–charcoal and concentrated to yield 0.93 g of a yellow oil.

Esterification of 6-*n*-heptylcyclohex-1-enecarboxylic acid (0.93 g, 4.14 mmoles) with diazomethane (as described for V) afforded X after distillation (bp 124°/0.5 mm Hg) as a light-yellow oil, 0.84 g (95% yield); IR (film): 2900, 2840, 1715, 1645, 1440, 1390, 1360, 1250, 1090, and 770 cm^{-1}; NMR ($CDCl_3$): δ 6.84 (t, 1H), 3.7 (s, 3H), 2.4–2.65 (m, 1H), 2.0–2.3 (m, 2H), 1.1–1.7 (m, 16H), and 0.87 (t, 3H) ppm.

Anal.—Calc. for $C_{13}H_{26}O_2$: C, 75.58; H, 10.99. Found: C, 75.34; H, 10.82.

4-Butyl-2,3-morpholinedione (XII)—A mixture of diethyl oxalate (6.24 g, 42.7 mmoles), 2-(butylamino)ethanol (5.0 g, 42.7 mmoles), and potassium hydroxide (0.1 g) was heated at 110° for 2 hr, and the ethanol

that formed was distilled off. To remove all of the ethanol, the reaction mixture was heated for another 2 hr at 100° under reduced pressure (40 mm). After cooling to room temperature, the partially crystallized residue was acidified by the addition of 0.2 ml of concentrated sulfuric acid and dissolved in methylene chloride. The solution was washed several times with water, dried over sodium sulfate, and concentrated *in vacuo*. Recrystallization from ether afforded XII as colorless flakes, 5.5 g (75% yield); IR (KBr): 2920, 2840, 1745, 1670, 1480, 1440, 1360, 1180, 1070, 1030, and 940 cm^{-1}; NMR ($CDCl_3$): δ 4.53 (t, 2H), 3.70 (t, 2H), 3.50 (t, 2H), 1.14–1.8 (m, 4H), and 0.93 (t, 3H) ppm.

Anal.—Calc. for $C_8H_{13}NO_3$: C, 56.13; H, 7.65. Found: C, 56.39; H, 7.77.

Ethyl [[1-(Hydroxymethyl)propyl]amino]oxoacetate (XIV)—2-Amino-1-butanol (5.0 g, 56.1 mmoles) in 70 ml of anhydrous ethanol was added over 2.5 hr to a stirred solution of diethyl oxalate (8.2 g, 56.1 mmoles) in 50 ml of anhydrous ethanol at 50°. After cooling, some crystalline by-product was filtered off, and the solution was concentrated *in vacuo*. The residue was purified by low-pressure liquid chromatography (8% ethanol in dichloromethane) to give XIV as a light-yellow oil, 5.2 g (49% yield); IR ($CDCl_3$): 3370, 2960, 2880, 1740, 1690, 1540, 1470, 1385, 1320, 1280, 1220, and 1040 cm^{-1}; NMR ($CDCl_3$): δ 7.7 (d, 1H), 4.4 (q, 2H), 3.5–4.2 (m, 4H), 1.35 (t, 3H), 1.2–1.8 (m, 2H), and 0.93 (t, 3H) ppm.

Anal.—Calc. for $C_8H_{15}NO_4$: C, 50.78; H, 7.99; N, 7.40. Found: C, 50.65; H, 8.01; N, 7.30.

***In Vivo* Testing Cloth Test**—The cloth test screens limited quantities of chemicals as mosquito repellents. The test compound (50 mg) was placed in a 2-dram vial to which 0.75 ml of acetone or other solvent was added. When the chemical was thoroughly dissolved, a 50-cm^2 (5 × 10-cm) piece of muslin bandage was rolled, placed in the vial, and mixed with the solution, and the vial was sealed until the chemicals were tested. The rate of cloth treatment was 1.0 mg/cm^2. After treatment, the cloths were kept refrigerated in the vials for at least 24 hr.

At the start of a test, vials were removed from the refrigerator and allowed to warm to room temperature. The cloth then was removed from the vial, stapled over a 4 × 9-cm opening cut into a 12.7 × 20.3-cm file card, and allowed to dry for 15 min before testing.

The subject testing the compounds covered his or her arm with a nylon stocking and wore a rubber glove over the hand and wrist to protect against bites. The card and attached cloth patch were then taped over the nylon-covered forearm so that only the treated cloth allowed access to the skin by the mosquitoes. The arm was then exposed to a stock cage of *A. aegypti* mosquitoes (~1500) for 1 min. More than three bites through the treated cloth in 1 min denoted failure of the chemical. If the chemical did not fail, it was stored at room temperature and retested in 24 hr and daily thereafter until it failed. Two standard repellents, diethyltoluamide and dimethyl phthalate, were tested concurrently.

When a sufficient quantity of the candidate material was available, the minimum effective dose (MED) was determined. The testing method was the same, but the treatment rate was reduced by one-half until more than three bites per minute were received at the lowest dose. The minimum effective doses were determined only on the fresh (air dried for 15 min) and 1-day-old treatments.

RESULTS AND DISCUSSION

Several of the synthesized compounds were solids; and although two compounds (I and XII) were evaluated in the membrane feeder test (1), the others (XI, XIII, and XVII–XIX) were not evaluated since solids with melting points greater than 40° do not repel significantly.

Two compounds (IX and XII) showed weak repellent activity at high concentrations and attracted the mosquitoes at lower concentrations in the membrane feeder test. These compounds are under study in these laboratories for their effects on the lactic acid receptor of *A. aegypti* mosquitoes.

There is not always good agreement between the *in vitro* membrane feeder test and the *in vivo* cloth test. However, the membrane feeder test is useful as a rapid screening method when many compounds are studied.

The most interesting compounds from this series were III and VII, which will be studied further on mice and Mexican hairless dogs prior to any human skin tests. From the cloth test results, III seems to be the most promising.

Tissue Distribution of Antitumor Drugs Associated with Polyalkylcyanoacrylate Nanoparticles

P. COUVREUR *x, B. KANTE *, V. LENAERTS *, V. SCAILTEUR *, M. ROLAND *, and P. SPEISER ‡

Received July 26, 1979, from the **Laboratoire de Pharmacie Galénique, Faculté de Médecine, Université Catholique de Louvain, 1200 Brussels, Belgium*, and the ‡*School of Pharmacy, Federal Institute of Technology, 8006 Zürich, Switzerland.* Accepted for publication September 24, 1979.

Abstract □ Polymethylcyanoacrylate nanoparticles, polyethylcyanoacrylate nanoparticles, and free ^{3}H-dactinomycin and ^{3}H-vinblastine were studied with emphasis on their distribution pattern in rat tissues after intravenous administration. The adsorption of cytostatic drugs to polyalkylcyanoacrylate nanoparticles can modify drug distribution in tissues. Particularly with vinblastine, modification of drug disposition is important. Data are given concerning the formation and stability of nanoparticle–drug complexes. Polyalkylcyanoacrylate nanoparticles seem to be an interesting drug carrier owing to their size, structure, degradability, and drug sorptive properties.

Keyphrases □ Polymethylcyanoacrylate nanoparticles—with adsorbed dactinomycin and vinblastine, distribution patterns in rats, compared to polyethylcyanoacrylate nanoparticles □ Polyethylcyanoacrylate nanoparticles—with adsorbed dactinomycin and vinblastine, distribution patterns in rats, compared to polymethylcyanoacrylate nanoparticles □ Dactinomycin—on polymethylcyanoacrylate and polyethylcyanoacrylate nanoparticles, distribution patterns in rats □ Vinblastine—on polymethylcyanoacrylate and polyethylcyanoacrylate nanoparticles, distribution patterns in rats □ Drug carriers—polymethylcyanoacrylate and polyethylcyanoacrylate nanoparticles, distribution patterns of adsorbed dactinomycin and vinblastine in rats

The problem of directing a cytostatic agent to specific sites is a current topic of research. Specific targeting of drug carriers may improve the anticancer activity and lower the general toxicity.

The use of endocytizable and lysosomotropic carriers such as liposomes (1–3) and DNA complexes (4, 5) appears promising, and new lysosomotropic carriers like albumin microspherules (6) and acrylic nanocapsules (7, 8) have been developed. Entrapment of fluorescein in such polyacrylamide nanocapsules significantly increases dye uptake by cultured fibroblasts and allows its accumulation into lysosomes, which are cell compartments in which fluorescein does not spontaneously accumulate (9, 10). However, the polymer used to prepare nanocapsules is unlikely to be digested by lysosomal enzyme, which might restrict its clinical use.

It has been demonstrated that polyalkylcyanoacrylate nanoparticles are potential lysosomotropic carriers because of their size, structure, and sorptive properties (11, 12). Such degradable nanoparticles are able to adsorb various molecules, including antimitotic drugs, reproducibly (11, 13, 14). The hydrolysis rate is dependent on the alkyl chain length of the cyanoacrylic monomer, which allows the drug release kinetics to be selected (13).

This study compared the tissue distribution of free dactinomycin and vinblastine with that of the adsorbed drugs on polymethylcyanoacrylate and polyethylcyanoacrylate nanoparticles after intravenous administration to rats.

EXPERIMENTAL

Preparation of ^{3}H-Dactinomycin and ^{3}H-Vinblastine Nanoparticles—Either ^{3}H-dactinomycin[1] (40 μl) or ^{3}H-vinblastine[1] (75 μl) was added to 1.5 ml of an aqueous solution containing 0.5% polysorbate[2] 20 in 0.01 *M* HCl. Then 17 μl of monomer[3] (methyl- or ethylcyanoacrylate) was dispersed under mechanical stirring.

After polymerization (30 min), the milky suspensions obtained were buffered to pH 7 using 0.05 ml of 1.0 *M* NaOH and 2.0 ml of phosphate buffer [containing 25% (v/v) of 0.2 *M* KH_2PO_4 and 15% (v/v) of 0.2 *M* NaOH]. The colloidal suspension obtained after filtration through a 0.8-μm filter[4] was diluted with an equal volume of the phosphate buffer.

The solutions of free ^{3}H-dactinomycin and ^{3}H-vinblastine were prepared as described for the nanoparticles but without monomer addition.

Determination of Drug Adsorbed on Nanoparticles—*Dactinomycin*—Dactinomycin (3.3 mg) and ^{3}H-dactinomycin (20 μl) were dissolved in 50 ml of acid containing polysorbate 20. Monomers were then added and polymerized as already described.

The nanospherule suspensions (10 ml) were centrifuged at 20,000 rpm. After separation and dissolution of the sediment in dimethylformamide, the ^{3}H-dactinomycin was measured in both the sediment and the supernate by scintillation counting as described.

Vinblastine—Vinblastine (17.5 mg) and ^{3}H-vinblastine (20 μl) were dissolved in 50 ml of acid containing polysorbate 20. The determination of the amount of vinblastine adsorbed on polymethyl- and polyethylcyanoacrylate nanoparticles was made in the same manner as for ^{3}H-dactinomycin.

Sample Preparation for Scintillation Counting—One milliliter of the supernatant and sediment solutions was pretreated with 0.5 *N* quaternary ammonium hydroxide in toluene[5] (0.75 ml). Isopropanol (0.75 ml) and 30% H_2O_2 (0.5 ml) were added to decolorize the samples. After 60 min, xylol–0.5 *M* HCl[6] (9:1) (15 ml) was added, and counting was performed in a liquid scintillation counter[7]. Quench correction was obtained using a channels ratio method. The results are expressed in percent of the drug adsorbed on the nanospherules.

Injection of ^{3}H-Dactinomycin and ^{3}H-Vinblastine in Free Form and Nanoparticle-Associated Forms—Three groups of 20 male Wistar rats (180–220 g), anesthetized with ether, were injected by puncture in femoral vena. Each group received one of the following forms of ^{3}H-dactinomycin in a single injection of 0.80 ml: free drug and polymethyl- and polyethylcyanoacrylate nanoparticles. At 0.5, 3, and 24 hr, six, eight, and six rats, respectively, were killed by decapitation in each of the three groups. Samples of blood and various tissues were removed for ^{3}H-analysis.

The differential tissue distribution of ^{3}H-vinblastine was determined in the same manner on two groups of 18 rats. Each group received free or adsorbed ^{3}H-vinblastine, and six rats were killed in each of the two groups at the same time intervals.

Preparation of Rat Tissues for ^{3}H-Analysis—Samples of fresh tissues including spleen, small intestine, muscle, kidneys, liver, and lungs were taken. For each organ except the spleen, three samples weighing 45–55 mg were each solubilized in 1 ml of 0.5 *N* quaternary ammonium hydroxide. For the spleen, 20-mg samples were used. After solubilization (about 4 hr), samples were decolorized using 0.2 ml of 30% H_2O_2, followed by warming at 40° for 30 min.

For the blood analysis, 200 μl was solubilized in 1.5 ml of quaternary

Table I—Efficiency of Drug Sorption on Nanoparticles

Drug	Concentration of Suspension, μg/ml	Sorption, % Polymethyl-cyanoacrylate	Sorption, % Polyethyl-cyanoacrylate
Dactinomycin	55	92.8	86.5
Vinblastine	350	35.8	80.0
Vinblastine	45	67.2	85.0

ammonium hydroxide in toluene–isopropanol (1:1) and decolorized with 0.5 ml of 30% H_2O_2.

After cooling at room temperature, 15 ml of the scintillation fluid was added to each sample, and counting was performed in the liquid scintillation analyzer.

For each form of ^{3}H-dactinomycin or ^{3}H-vinblastine used, the amount of radioactivity injected was calculated on the basis of analysis of triplicate samples of 0.2 ml measured with the same syringe used for injection. These samples were treated as described for the tissues.

Drug concentration in each tissue analyzed was expressed in microcuries × 10^{-3} per gram of tissue and per microcurie injected in the whole animal.

RESULTS AND DISCUSSION

Formation and Stability of Nanoparticle–Drug Complexes—Dactinomycin and vinblastine were adsorbed on the nanoparticles with high efficiency (Table I). Although the percentage of adsorbed drug declined with increasing amounts, substantial amounts of dactinomycin and vinblastine can be sorbed. The percentages of drug adsorbed to the nanoparticles were in all cases higher than those obtained with entrapment in liposomes (15, 16). Furthermore, the amounts of drug adsorbed on nanoparticles were reproducible.

For a 55-μg/ml suspension of dactinomycin, 92.8 and 86.5% of the drug were adsorbed on polymethyl- and polyethylcyanoacrylate nanoparticles, respectively, when the drug was incorporated before polymerization. In contrast, when a suspension of prepared nanoparticles was mixed with an aqueous solution of free dactinomycin, the percentage of the drug adsorbed on the particles decreased to 66.0 and 64.5% for polymethyl- and polyethylcyanoacrylate nanoparticle forms, respectively. These results are in agreement with the porous structure of particles observed after cryofracture by electron microscopy (11). Indeed, when the drug is added after the nanoparticles are formed, the inner surface of the carrier probably is no longer available for adsorption.

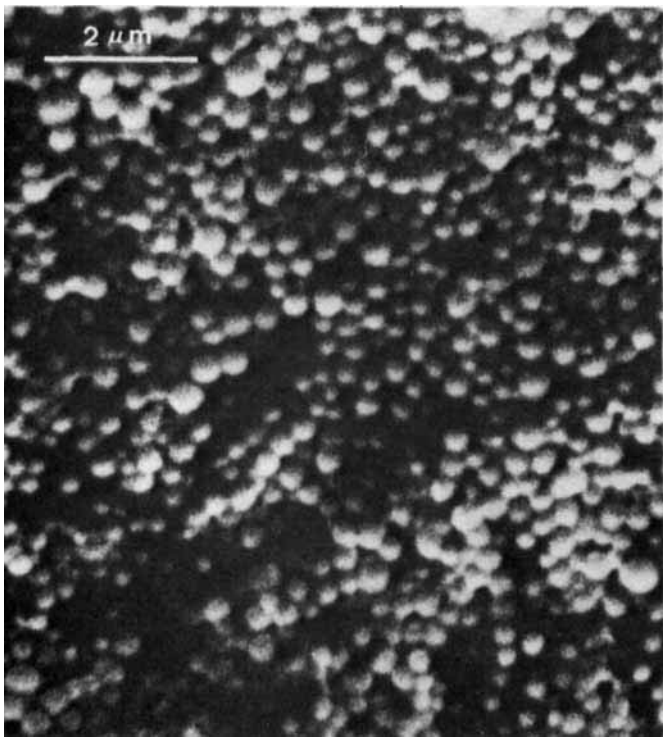

Figure 1—*Morphological appearance of dactinomycin associated to polymethylcyanoacrylate nanoparticles at the scanning electron microscope. Thickness of the gold layer was 100 nm.*

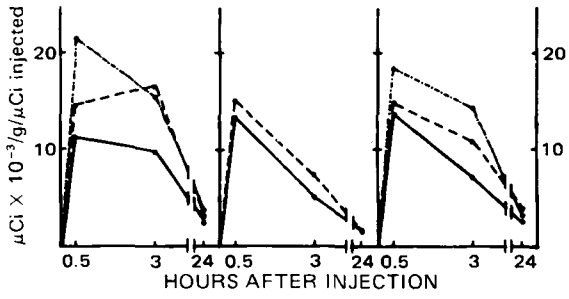

Figure 2—*Tissue concentrations [small intestine (left), liver (center), and lungs (right)] in rats at various times after administration of ^{3}H-dactinomycin. A single intravenous injection of polymethyl- (·–·) or polyethyl- (– –) cyanoacrylate nanoparticles or free (—) dactinomycin was given to each rat. Each point is the mean value from at least six animals.*

A scanning electron microscopic[8] study showed that drug adsorption at the surface of the particles induces no morphological modification of these nanoparticles. Figure 1 shows spherical dactinomycin–polymethylcyanoacrylate nanoparticles with a diameter of ~200–300 nm, considering the thickness of the gold layer (100 nm) used for sample preparation.

Dactinomycin Distribution in Rat Tissues—Table II shows the concentrations of ^{3}H-dactinomycin found in the blood, spleen, small intestine, muscle, kidney, liver, and lung samples after administration of either free dactinomycin or nanoparticle-adsorbed forms. Each value at various times after the injection represents a mean result obtained with six or eight animals and with three pretreatment levels from each tissue analyzed. A statistical analysis (Student t test) was carried out to determine, with a probability of 0.975, the significant differences in the tissue distributions induced by adsorption.

Significant increases of ^{3}H-dactinomycin uptake were obtained for the small intestine and lungs of polymethylcyanoacrylate nanoparticle-injected rats at 0.5 hr (Fig. 2). Three hours after the injection, the ^{3}H-dactinomycin content in both of these two tissues decreased, but the radioactivity levels remained higher than those found in the small in-

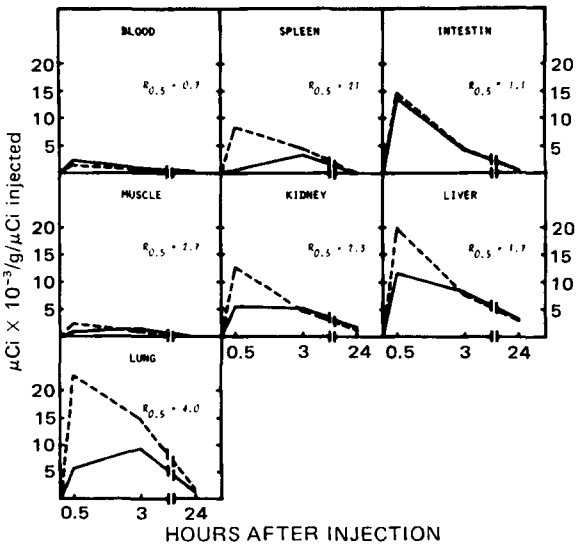

Figure 3—*Tissue concentrations (blood, spleen, intestine, muscle, kidneys, liver, and lungs) of free (—) and polyethylcyanoacrylate nanoparticle (– –) ^{3}H-vinblastine forms at various times after intravenous administration. Each point is the mean value from a minimum of six animals. The $R_{0.5}$ represents the relation between vinblastine adsorbed on polyethylcyanoacrylate nanoparticles and free vinblastine tissue concentration at 30 min after injection ($R_{0.5} = PEN_{0.5}/F_{0.5}$).*

Liver	4.9	5.6	6.9	0.93	3.69	1.14	1.41
Lungs	6.8	14.3	10.5	3.85	3.80	2.10	1.54

[a] Units are microcuries × 10^{-3} per gram per microcurie injected. t_{stud} ($p = 0.975$) represents the results of the statistical analysis (Student test) for a probability of 0.975. Underlined numbers correspond to a significant difference between free (F), polymethyl- (PMN), and polyethyl- (PEN) cyanoacrylate nanoparticle forms for the chosen probability.

testine and lungs of rats injected with the free drug. No significant difference was found 24 hr after injection.

Similar observations were made for polyethylcyanoacrylate nanoparticles. Thus, the small intestine and lungs of the injected rats showed significantly higher contents of ^{3}H-dactinomycin at 3 hr in comparison with free drug. Furthermore, the ^{3}H-dactinomycin concentration in the liver was higher for the polyethylcyanoacrylate nanoparticle form; this observed difference was slight but significant (Table II).

In both the spleen and kidneys, the decrease of radioactivity remained similar for all three forms of ^{3}H-dactinomycin during the experiment. Except for the lungs and small intestine, the tissue distribution of ^{3}H-dactinomycin was poorly modified by adsorbing it on nanoparticles, in spite of generally higher drug levels in tissues of rats injected with nanoparticles. Previous studies on dactinomycin tissue distribution in mice showed that the small intestine retains high dactinomycin concentrations (17, 18). The present results are similar to these observations, but it was surprising to find still higher concentrations of radioactivity in the intestinal wall of rats injected with ^{3}H-dactinomycin adsorbed on nanoparticles. Likewise, the poor accumulation of the nanoparticle forms in the liver and the spleen is difficult to explain. The tissue distribution of dactinomycin nanoparticles was comparable to that observed when the drug was incorporated into the aqueous phase of multilamellar liposomes (18).

^{3}H-Vinblastine in Rat Tissues—Table III lists the ^{3}H-concentration after the injection of free drug or polyethylcyanoacrylate nanoparticle–^{3}H-vinblastine. Concentrations of ^{3}H-vinblastine found in tissues after administration of nanoparticles were generally higher than those obtained with the free form. This result was particularly remarkable at 0.5 hr after the injection and for tissues rich in reticuloendothelial macrophage cells such as the liver, spleen, and lungs (Fig. 3). Thus, 0.5 hr after injection, the spleen accumulated 21-fold more nanoparticles with adsorbed ^{3}H-vinblastine than free drug. Likewise, after the same time, the drug concentrations observed with nanoparticles were 1.7-fold higher in the liver, fourfold higher in the lungs, and 2.3-fold higher in the kidneys compared to levels with free vinblastine.

More surprising was the higher concentration of the nanoparticles compared to the free form in the muscle. Indeed, the muscle retained 2.7-fold more vinblastine when the drug was adsorbed on polyethylcyanoacrylate nanoparticles. At 30 min after injection, the tissue concentrations observed with nanoparticles were generally two- to 20-fold higher than with the free drug (Table III). Thus, the kinetics of tissue uptake of the nanoparticles were quite different compared to those of the free form (Fig. 3). Maximum levels were observed after 0.5 hr for the nanoparticle formulation and after 3 hr for the free form, except for the liver and blood. Differences in the tissue drug concentrations were more marked a short time after injection.

Table III—Tissue Accumulation of Drug at 0.5 hr Postinjection

Organ	F^a	PEN[a]	t_{stud} ($p = 0.975$)	PEN / F
Blood	2.2	1.5	1.54	0.7
Spleen	0.4	8.4	6.17	21.0
Small intestine	13.8	14.9	0.17	1.1
Muscle	0.8	2.2	4.69	2.7
Kidneys	5.5	12.8	8.34	2.3
Liver	11.6	20.0	3.84	1.7
Lungs	5.6	22.7	8.97	4.0

[a] Units are microcuries × 10^{-3} per gram per microcurie injected. t_{stud} ($p = 0.975$) represents the results of the statistical analysis (Student test). Underlined numbers correspond to a significant difference between free (F) and polyethylcyanoacrylate nanoparticle (PEN) forms for a probability of 0.975.

Earlier studies with liposomes (19, 20) showed preferential cellular capture by the liver and spleen. The present results show that the ^{3}H-vinblastine nanoparticles have a broader tissue distribution than liposomes and provide evidence that nanoparticles can be used to modify tissue distribution of vinblastine. The significant difference in the accumulation in the muscle between free and nanoparticle-adsorbed vinblastine cannot now be explained, but it is interesting to note that cultured fibroblasts, which have a moderate endocytic capacity, accumulate polyacrylamide nanoparticles (9).

These results agree qualitatively with previous reports in that the favored sites for free vinblastine include the spleen, intestine, lungs, and liver (19, 21).

CONCLUSIONS

The present study provides evidence that the adsorption of cytotoxic drugs to polyalkylcyanoacrylate nanoparticles can modify the drug distribution pattern in tissues. This effect was particularly marked for the vinblastine nanoparticles. Furthermore, the results obtained with dactinomycin and vinblastine show that the differential tissue distribution (between free and adsorbed forms) was not only related to the carrier but also depended on the active molecule. For example, both free vinblastine and dactinomycin had a marked affinity for the small intestine, which was enhanced with dactinomycin adsorbed on nanoparticles but unchanged with vinblastine nanoparticles. In contrast, the increase of the uptake of nanoparticle-adsorbed drugs by the liver and spleen was more marked, comparatively, for vinblastine than for dactinomycin.

Such results are in agreement with the observations reported for liposomes (22, 23). Indeed, 3 hr after injection of radiolabeled free drug or the liposome-encapsulated form, the tissue distribution was quite different for dactinomycin, cytosine arabinose, vinblastine, $^{86}Rb^+$, or ethylenediaminetetraacetate.

All modifications of distribution patterns of the examined drugs were observed at the earlier times after administration (0.5 or 3 hr). Thus, the effect of the carrier seems rapid, especially with vinblastine nanoparticles. Such observations are compatible with the rapidity of endocytosis, which may be carried out in minutes (24).

Moreover, these results show that there is a general increased uptake of cytostatic drugs when they are adsorbed on nanoparticles. But this increase is not uniform for all tissues. Differential and selective increases in tissue uptake of cytotoxic drugs will be of interest in cancer chemotherapy. Polyalkylcyanoacrylate nanoparticles could be useful in this area. The action of nanoparticles associated with cytostatic agents on tumor-bearing animals and the selective uptake by different cell types will be investigated.

Effect of Carnitine Analogs on Carnitine Acetyltransferase

MARVIN R. BOOTS *x, MARY LYNN WOLFE ‡, SHARON G. BOOTS *§, and JESSE L. BOBBITT ‡

Received June 1, 1979, from the **Department of Pharmaceutical Chemistry, Health Sciences Division, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298*, and the ‡*Biochemical Research Department, Lilly Research Laboratories, Division of Eli Lilly and Company, Indianapolis, IN 46240.* Accepted for publication September 20, 1979. §Present address: Department of Chemistry, Stanford University, Stanford, CA 94305.

Abstract □ Carnitine analogs with various substituents on the nitrogen were tested for their effect on carnitine acetyltransferase from rat sperm and pigeon breast. A radiometric assay was used to measure the formation of acetylcarnitine in the presence of other enzymes that competed for acetyl coenzyme A in the sperm preparation. The apparent enzyme inhibition caused by the analogs was explained by the analogs serving as alternative substrates with higher K_m and lower V_{max} values. The analogs had no effect on whole sperm.

Keyphrases □ Carnitine analogs—effect on carnitine acetyltransferase, spectrophotometric and radiometric measurements, kinetic parameters, *in vitro* □ Kinetics—analysis of carnitine analogs on carnitine acetyltransferase activity, spectrophotometric and radiometric measurements □ Spectrophotometry—analysis of carnitine analogs on carnitine acetyltransferase activity, kinetics

The primary importance of carnitine acetyltransferase (EC 2.3.1.7) in mitochondria is not known. Since the enzyme is found in high levels in cells that derive much of their energy requirements from lipid metabolism, it was thought that its major function was in lipid metabolism (1). For example, pigeon breast and heart muscle are common sources of the enzyme. The enzyme also is abundant in sperm (2), where the acetylation of carnitine may serve as an important regulator of both lipid and carbohydrate metabolism (3, 4).

Carnitine analogs that inhibit the enzyme may alter the path of energy metabolism (5). Rat and mouse sperm offer a convenient means of testing the biological activity of carnitine analogs. Carnitine appears to be important for sperm metabolism. Not only are carnitine acetyltransferase levels high in sperm, but carnitine is also in high concentration in epididymal fluid (6). The sperm can be isolated easily with little contamination by other cells, and they can be checked easily for viability by examining their motility under a microscope.

Unfortunately, the most commonly used spectrophotometric assay for carnitine acetyltransferase cannot be used with crude sperm enzyme; this assay measures the disappearance of the thiol ester bond of acetyl coenzyme A, and competing reactions using acetyl coenzyme A interfere with this measurement unless the enzyme is purified. However, crude enzyme can be assayed by measuring the transfer of labeled acetate to acetylcarnitine, which can be precipitated as the periodide (7). Since carnitine acetyltransferase probably is essential for sperm function, any inhibitor also should be detected with whole sperm by changes in the fertilization rate.

In this study, carnitine analogs were examined for their effect on the enzyme in both crude sperm preparations and crystalline pigeon breast enzyme. In addition, selected analogs were examined in various test systems to determine the cellular effects of the analogs.

EXPERIMENTAL

Carnitine Analogs—The *dl*-carnitine analogs (I–VII) were prepared as described previously (5).

Spectrophotometric Assay—The spectrophotometric assay of carnitine acetyltransferase activity measured the decrease in absorbance[1] of the thiol ester bond of acetyl coenzyme A at 232 nm (8). The reaction mixture in each cell contained 1.0 m*M* L-carnitine[2], 0.1 m*M* acetyl coenzyme A[2], and the carnitine analog of the desired concentration. The reaction was carried out at 25° in 100 m*M* tromethamine buffer, pH 8.0,

VI	5	12	38	10	20	30
VII	0	5	12	5	12	25

after addition of ~20 microunits (80 units/mg of protein) of pigeon breast enzyme[3].

Radiometric Assay—The assay using precipitation of labeled acetylcarnitine was a modification of the semimicro method described by McCaman *et al.* (7). The 0.25-ml reaction mixture contained 24 m*M* DL-carnitine (4.8 mg/ml), 0.5 m*M* ^{3}H-acetyl coenzyme A[4] tritium-labeled to ~1 mCi/mmole, the carnitine analog at various concentrations, and 0.1 *M* phosphate buffer, pH 7.5, with 0.5 m*M* ethylenediaminetetraacetate. The exact amount of sperm or pigeon breast enzyme was adjusted to stay within the linear portion of the standard curve.

After 30 min at 37°, the reaction was stopped, and the solution was deproteinized with 10 μl of cold 50% (w/v) trichloroacetic acid. After centrifugation, 0.20 ml of the supernate was transferred to another small centrifuge tube, and 0.30 ml of potassium iodide–iodine solution was added to precipitate the carnitine, labeled acetylcarnitine, and carnitine analogs as the periodides. The precipitate usually was allowed to stand overnight at 4° to ensure precipitation when the analogs were present. The precipitate was washed with 0.6 ml of cold 2 *N* H_2SO_4, dissolved in 10 ml of scintillator solution[5], and decolorized with 0.3 ml of an organic base[6].

Enzymes—Crystalline pigeon breast carnitine acetyltransferase was purchased[3]. The sperm enzyme was obtained from the mitochondria of rat or mouse epididymal sperm using a differential centrifugation procedure similar to that described previously (2). Fat-free epididymal tissue was homogenized in 0.25 *M* sucrose (5 ml/rat) and centrifuged for 10 min at 1000×*g*. The pellet was rehomogenized, and the combined supernate was centrifuged for 15 min at 10,000×*g* to sediment the mitochondria.

The mitochondria were homogenized twice at 20-min intervals with pH 8.0 phosphate buffer–ethylenediaminetetraacetate solution containing 0.1% deoxycholate (2), using 2 ml of buffer/rat. The homogenate was centrifuged at 10,000×*g* for 20 min. The enzyme was in the supernate, and the protein concentration was ~10 mg/ml. The preparation was stable in the frozen state.

Kinetic Measurements—Kinetic parameters for the carnitine analogs were determined spectrophotometrically using substrate concentrations less than or equal to 1 m*M*. Both K_m and V_{max} values were determined graphically from Lineweaver–Burk plots.

Whole Sperm Effects—Epididymal sperm from mice were expressed and washed twice in Tyrode's solution containing 0.1% glucose and 0.1% bovine serum albumin. The sperm were resuspended in the modified Tyrode's solution. To this suspension was added, in the desired concentration, the analog adjusted to neutral pH.

After 15 min at 37°, the sperm were washed again, and the enzyme was extracted for assay as already described. Comparison was made with control sperm without analog.

***In Vitro* Fertilization and Egg Culture**—Some analogs were tested in an assay designed to detect substances that interfered with sperm function, egg fertilization, or early embryo development. The system contained a measured number of mouse sperm and mouse eggs in an appropriate medium cultured under normal conditions (9). In the absence of test substances, the eggs were fertilized and developed to the morula stage at a known rate. Compounds that interfered with any part of the process, *i.e.*, from sperm viability to early egg metabolism, could be detected by an analysis of the cell types present at the end of the culture period. At 1 μg of the test substance/ml, ~14% of 1000 randomly selected organic compounds showed some activity. At 10 mg/ml, ~40% of the tested compounds interfered with some aspect of egg development.

VII	$CH_2CH_2CH_2CH_2$		H	2.0	<1

[a] Data was obtained *via* the spectrophotometric assay using crystalline pigeon breast enzyme.

RESULTS

The radiometric assay for carnitine acetyltransferase, based on precipitation of acetylcarnitine, was linear with the amount of sperm enzyme until ~40% of the labeled acetyl coenzyme A was consumed. It also was linear with time until the same amount of acetyl coenzyme A was consumed. Acetyl coenzyme A was limiting under the assay conditions since excess carnitine was needed to get complete precipitation. The amount of enzyme used for assaying the inhibitory properties of the analogs was adjusted to give 25–30% conversion of acetyl coenzyme A (corresponding to approximately 3 milliunits of the commercial pigeon breast enzyme). Addition of the analogs to the reaction mixture appeared to inhibit the sperm enzyme (Table I). The same inhibition patterns were seen with purified pigeon breast enzyme using the precipitation assay (Table I): I–III were better inhibitors than V–VII.

When the analogs were tested as substrates for the enzyme in the absence of carnitine, they served as substrates to varying degrees. The precipitation of the acetyl analog as the periodide was more variable, however, and K_m and V_{max} values for each analog were determined spectrophotometrically using concentrations up to 1 m*M* (Table II).

Whole Sperm Enzyme Effects—Analogs IV and V were tested for their effect on carnitine acetyltransferase levels in whole sperm. Enzyme levels were unchanged in sperm incubated for 15 min with the analogs and then washed. Compound V was tested at 1 μ*M* and IV was tested at concentrations as high as 100 m*M* without effect on the enzyme extracted from treated sperm.

Effect on *In Vitro* Sperm and Egg Culture—Compounds III–V and VII were tested at 0.1, 1.0, and 10 μg/ml of media. The fertilization rate in the presence of the analogs was indistinguishable from controls.

DISCUSSION

The radiometric assay permitted the measurement of small amounts of sperm carnitine acetyltransferase without extensive purification. Enzyme levels in the epididymal sperm of one mouse could be measured, and numerous assays could be made without large numbers of animals.

Under the usual assay procedures, the analogs first appeared to be typical competitive inhibitors except that inhibition leveled off at high levels. When examined as substrates, the apparent inhibition occurred because they were poorer substrates than carnitine. The 4-mg/ml analog concentration was about twice the concentration of L-carnitine in the radiometric assay. Exact kinetics of the radiometric assay were obscured by the presence of D-carnitine (also an inhibitor) and the variables introduced by the precipitation of the acetyl analog periodides. The spectrophotometric system was used to measure K_m and V_{max} of the analogs with the purified pigeon breast enzyme. The similarity of the enzymes toward the analog effects in the radiometric assay suggested that the data obtained spectrophotometrically with the crystalline enzyme were applicable to the crude sperm enzyme.

The K_m value generally increased and the V_{max} value decreased with increasing bulk and rigidity of the nitrogen substituents. Analogs I–IV accepted the transfer of the acetyl group to the β-hydroxyl if the posi-

tively charged nitrogen atom of the analog fit the binding site on the enzyme. Attempts to isolate the labeled, acetylated analog from the reaction mixture were unsuccessful. The label trailed badly in all separation systems tried.

Although the analogs acted as enzyme inhibitors, they had no effect on the sperm. Whether the analogs were excluded from the cells or entered the cell and were ineffective in altering the enzyme activity cannot be discerned from the available data. These studies confirmed previous work that showed that the analogs had no biological activity (5).

Pharmacokinetics of Doxycycline Reabsorption

PETER VENG PEDERSEN [*x] **and RAYMOND MILLER** [‡]

Received August 20, 1979, from the [*]*Department of Pharmacy, School of Pharmacy, and the* [‡]*Division of Clinical Pharmacology, Department of Medicine, University of California, San Francisco, CA 94143.* Accepted for publication September 28, 1979.

Abstract □ Two cyclic linear compartment models are proposed to investigate the reabsorption mechanism of doxycycline. In one model, reabsorption is considered to be continuous; in the other model, it is discontinuous. The continuous model, when fitted, leads to one real and two complex conjugate eigenvalues, corresponding to a regression equation consisting of a regular exponential term and an exponentially damped trigonometric expression. In spite of the apparent oscillatory nature of this regression equation, the fitted curves show no secondary peaks or humps apparent in the data. Simulation studies indicate that it may not be possible to get response profiles showing secondary peaks or humps that are experimentally detectable with linear compartment systems with cyclic pathways and continuous transfer. The model with discontinuous cyclic transfer was more flexible in describing the discrepancies in the data and appeared to be preferable to the continuous cyclic transfer model judged by the Akaike information criterion.

Keyphrases □ Doxycycline—pharmacokinetics of reabsorption, two cyclic linear compartment models proposed □ Pharmacokinetics—doxycycline reabsorption, two cyclic linear compartment models proposed □ Models—pharmacokinetics of doxycycline reabsorption

There does not appear to be general agreement about the pharmacokinetic behavior of doxycycline in humans. Gibaldi (1) claimed that the persistence of serum doxycycline levels is due to a relatively slow absorption compounded by enterohepatic cycling, while other authors proposed that it is due to an intrinsically slow rate of elimination (2, 3). The pharmacokinetic parameters for doxycycline were calculated from the data of Fabre *et al.* (3), assuming a single-compartment model (1). The elimination rate was calculated using the data points from 35 to 72 hr after administration; these values were assumed to be true postabsorptive data (1). The mean half-life for doxycycline of 9.8 hr obtained in this way does not differ greatly from the half-life of other tetracyclines. An apparent absorption half-life of 5.3 hr was calculated by the method of residuals. It was suggested (1) that the persistence of appreciable serum concentrations of doxycycline relative to other tetracyclines is a function of absorption kinetics rather than elimination kinetics.

Using the same data, a subsequent investigator (2) calculated a substantially different absorption half-life of 50 min and a quite different elimination half-life of 22–24 hr and suggested that the persistent serum levels are primarily due to slow elimination. Schach von Witteman (2) pointed out that the low values found 72 hr after dosing are not very accurate and that the emphasis placed on this limited segment of the data is not justified. However, this investigator ignored the last two data points entirely in calculating the elimination rate constant. Inclusion of these two data points results in a considerably shorter half-life.

Although it is difficult to resolve properly the absorption and elimination kinetics from oral data alone, the data (3) show signs of secondary peaks, which support the hypothesis of reabsorption. This hypothesis is further supported by a high affinity to the bile reported for doxycycline and other tetracyclines (4). If reabsorption occurs, then the calculation of intrinsic absorption and elimination half-lives using classical pharmacokinetic approaches as discussed may not apply. It is not valid to assume a postabsorptive phase in a pharmacokinetic system with significant reabsorption.

Therefore, it is of interest to investigate the kinetic behavior of doxycycline using kinetic models that do consider the drug's reabsorption. It is also valuable to investigate whether the reabsorption occurs through a continuous process as suggested previously (4) or whether it is of a discontinuous nature, possibly related to biliary intestinal secretion that occurs primarily in the form of squirts of bile into the intestine (5). This work proposes two simple pharmacokinetic models to investigate these matters using the data of Fabre *et al.* (3).

THEORY

The two linear pharmacokinetic models proposed represent simple forms of drug reabsorption. Both models contain a cyclic disposition and do not belong to the categories of models (mammillary, catenary, and other noncyclic systems) proposed most frequently in pharmacokinetics.

Model 1—This linear model proposes first-order absorption, central

Gibaldi (1) claimed that the persistence of serum doxycycline levels is due to a relatively slow absorption compounded by enterohepatic cycling, while other authors proposed that it is due to an intrinsically slow rate of elimination (2, 3). The pharmacokinetic parameters for doxycycline were calculated from the data of Fabre *et al.* (3), assuming a single-compartment model (1). The elimination rate was calculated using the data points from 35 to 72 hr after administration; these values were assumed to be true postabsorptive data (1). The mean half-life for doxycycline of 9.8 hr obtained in this way does not differ greatly from the half-life of other tetracyclines. An apparent absorption half-life of 5.3 hr was calculated by the method of residuals. It was suggested (1) that the persistence of appreciable serum concentrations of doxycycline relative to other tetracyclines is a function of absorption kinetics rather than elimination kinetics.

Using the same data, a subsequent investigator (2) calculated a substantially different absorption half-life of 50 min and a quite different elimination half-life of 22–24 hr and suggested that the persistent serum levels are primarily due to slow elimination. Schach von Witteman (2) pointed out that the low values found 72 hr after dosing are not very accurate and that the emphasis placed on this limited segment of the data is not justified. However, this investigator ignored the last two data points entirely in calculating the elimination rate constant. Inclusion of these two data points results in a considerably shorter half-life.

Although it is difficult to resolve properly the absorption and elimination kinetics from oral data alone, the data (3) show signs of secondary peaks, which support the hypothesis of reabsorption. This hypothesis is further supported by a high affinity to the bile reported for doxycycline and other tetracyclines (4). If reabsorption occurs, then the calculation of intrinsic absorption and elimination half-lives using classical pharmacokinetic approaches as discussed may not apply. It is not valid to assume a postabsorptive phase in a pharmacokinetic system with significant reabsorption.

Therefore, it is of interest to investigate the kinetic behavior of doxycycline using kinetic models that do consider the drug's reabsorption. It is also valuable to investigate whether the reabsorption occurs through a continuous process as suggested previously (4) or whether it is of a discontinuous nature, possibly related to biliary intestinal secretion that occurs primarily in the form of squirts of bile into the intestine (5). This work proposes two simple pharmacokinetic models to investigate these matters using the data of Fabre *et al.* (3).

THEORY

The two linear pharmacokinetic models proposed represent simple forms of drug reabsorption. Both models contain a cyclic disposition and do not belong to the categories of models (mammillary, catenary, and other noncyclic systems) proposed most frequently in pharmacokinetics.

Model 1—This linear model proposes first-order absorption, central

0022-3549/80/0200-0204$01.00/0

© 1980, American Pharmaceutical Association

elimination, and drug distribution into an intermediate compartment. The intermediate compartment can be considered to be either the bile or a virtual compartment representing a secreted nonabsorbable compound or complex that releases the drug to the "absorption compartment" where it is subject to reabsorption.

The equation for this model is readily derived by the Veng Pedersen approach[1] (6). Equation 12 from Ref. 6 gives:

$$x_1 = L^{-1}\sum_{j=1}^{3}\frac{|\mathbf{S}|_{1j}}{|\mathbf{S}|}[x_j(0)+\bar{f}_j] = L^{-1}\frac{|\mathbf{S}|_{13}}{|\mathbf{S}|}D_F \qquad \text{(Eq. 1)}$$

Using Heaviside's expansion theorem and $c = x_1/V$, Eq. 1 becomes:

$$c = \frac{D_F}{V}\sum_{j=1}^{3}P(\lambda_j)\exp\lambda_j(t-T_L)_+ \qquad \text{(Eq. 2)}$$

where:

$$P(s) = |\mathbf{S}(s)|_{13}/|\mathbf{S}'(s)| \qquad \text{(Eq. 3)}$$

$$|\mathbf{S}(s)| = s^3 + a_2s^2 + a_1s + a_0 = (s-\lambda_1)(s-\lambda_2)(s-\lambda_3) \qquad \text{(Eq. 4)}$$

$$|\mathbf{S}'(s)| = 3s^2 + 2a_2s + a_1 \qquad \text{(Eq. 5)}$$

$$a_2 = E_1 + E_2 + E_3 \qquad \text{(Eq. 6)}$$

$$a_1 = E_1E_2 + E_1E_3 + E_2E_3 - (k_{21}k_{12} + k_{31}k_{13} + k_{23}k_{32}) \qquad \text{(Eq. 7)}$$

$$a_0 = E_1E_2E_3 - k_{23}k_{32}E_1 - k_{21}k_{12}E_3 - k_{31}k_{13}E_2 - k_{31}k_{12}k_{23} - k_{13}k_{32}k_{21} \qquad \text{(Eq. 8)}$$

$$|\mathbf{S}|_{13} = k_{31}(s+E_2) \qquad \text{(Eq. 9)}$$

If the system shows significant reabsorption, then two of the eigenvalues of the linear system will be complex conjugate while the third will be real; otherwise, all eigenvalues will be real. In any case, the real part of any eigenvalue is negative. In the complex case, Eq. 2 can also be written:

$$c = \frac{D_F}{V}\{2[Re(P(\lambda))\cos\lambda_{Im}(t-T_L)_+ - Im[P(\lambda)]\sin\lambda_{Im}(t-T_L)_+]\exp\lambda_{Re}(t-T_L)_+ + P(\lambda_1)\exp\lambda_1(t-T_L)_+\} \qquad \text{(Eq. 10)}$$

where λ_1 is the real eigenvalue and λ_{Im} and λ_{Re} are the imaginary and real parts, respectively, of a complex eigenvalue λ satisfying $|\mathbf{S}(\lambda)| = 0$.

Although explicit formulas exist for finding the complex and/or real roots of the characteristic polynomial $|\mathbf{S}(s)|$, it is not advisable to use them because of the possibility of severe numerical instability (10). Instead, the eigenvalues were determined to the proper degree of accuracy using Laguerre's method (11) and the interactive nonlinear regression program FUNFIT (12), which was used for all curve fittings. Equation 2 was programmed to accommodate both the real and complex cases. Therefore, the microparameters and the form of the response function are not constrained but lead to a convergence to either a real or complex case, depending on the data.

Model 2—This model is identical to Model 1, except that drug transfer between Compartments 2 and 3 is not a continuous first-order process but a bolus impulse. At some time, $t = T_b$, some fraction, F_b, of the drug cumulated in the bile is spontaneously released to the intestine by a bile squirt. The equation describing this process is readily derived by standard means (6):

$$c = \left(\frac{D_F}{V}\right)\frac{k_{31}}{k_{31}+\lambda}\{\exp\lambda(t-T_L)_+ - \exp[-k_{31}(t-T_L)_+] + A[\exp\lambda(t-T_b)_+ - \exp[-k_{31}(t-T_b)_+]]\} \qquad \text{(Eq. 11)}$$

where:

$$A = \frac{F_bk_{31}k_{12}}{k_{31}+\lambda}\left\{\frac{1}{\lambda}[\exp\lambda(T_b-T_s)-1] + \frac{1}{k_{31}}[\exp[-k_{31}(T_b-T_L)]-1]\right\} \qquad \text{(Eq. 12)}$$

and:

$$\lambda = E_1 = k_{12} + k_{10} \qquad \text{(Eq. 13)}$$

RESULTS AND DISCUSSION

In the real case with real eigenvalues, the response function for Model 1 consists of three regular exponential terms. However, in the complex case (Eq. 10), the function consists of two terms: an exponentially damped, oscillating trigonometric term superimposed on a regular exponential term. Thus, for a linear system behaving according to Model 1 and showing significant reabsorption, one may believe that the response function will show secondary peaks or humps judged from the functional form of Eq. 10. However, this does not appear to be the case. Although the curve fittings for all subjects using Eq. 2 lead to a convergence with complex eigenvalues (Eq. 10), no secondary peaks or humps were observed in the fitted curves (Fig. 1).

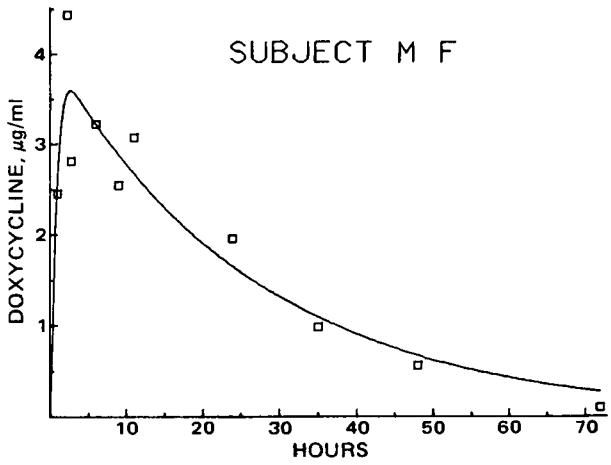

Figure 1—*Least-squares fit of Model 1 (Eq. 2) to plasma doxycycline level data. The fitting resulted in complex eigenvalues, with an estimated response function as given by Eq. 10.*

Extensive simulation studies were done on an interactive computer graphic system to investigate whether any perturbation of the microparameters of the model may result in secondary peaks or humps in the regression curve. Apparently, this effect does not occur even for systems with a substantial degree of reabsorption or for systems constructed numerically by maximizing the "degree of complexity" on the basis of the discriminant of the characteristic polynomial.

From a purely theoretical point of view, some support apparently exists for the claim that linear systems with cyclic pathways and continuous transfer do not give rise to secondary peaks and that humps may be difficult to detect, but there is no formal proof (13). This behavior is related to a relatively long period of the trigonometric expression and a relatively strong exponential damping term inherent in such systems.

When dealing with cyclic models with complex eigenvalues, as opposed to noncyclic systems, it is improper to fit the macroparametric form instead of the microparametric form of the response function. For example, if Eq. 10 is fitted in its macroparametric form, the curve may approximate an extra peak or a hump in the data. However, if the macroparameters are used to calculate the microparameters, then some of them may turn out to be complex or negative, in disagreement with the model proposed.

Table I shows that the reabsorption rate constant k_{23} is relatively large compared to the elimination rate constant k_{el} and k_{12} for all subjects, indicating substantial reabsorption. In spite of this significant reabsorption, the fitted curves do not appear distinguishable from ordinary absorption curves for noncyclic linear systems (Fig. 1). Reabsorption and cyclic transport processes in pharmacokinetics have usually been considered only when dealing with data containing secondary peaks or an extra hump. These results show that a "typical" drug level profile may be associated with a strong degree of reabsorption. Therefore, a greater number of drugs could be subject to reabsorption than currently known.

The average absorption half-life estimated using Model 1 is 0.5 hr (Table I), which is considerably shorter than the 5.3 hr determined by the method of residuals by Gibaldi (1) but comparable to the half-life of 50 min determined by Schach von Witteman (2). The average elimination half-life of 13 hr is larger than the 9–8 hr determined by Gibaldi (1) but considerably shorter than that determined by Schach von Witteman (2). These differences are mainly due to the different models used. Gibaldi (1) suggested that the slow decline of plasma doxycycline levels relative to other tetracyclines is due to relatively slow absorption compounded by enterohepatic cycling. However, the absorption and elimination half-lives were calculated assuming a one-compartment model without considering reabsorption (1, 2).

[1] The model contains a cyclic pathway. Thus, neither the Benet approach (7) nor the Vaughan *et al.* approach (8, 9) can be used for this reabsorption model.

[a] $k_a = k_{31}$. [b] $k_{el} = k_{12} + k_{10}$. [c] RSS = residual sum of squares. [d] Akaike's information criterion.

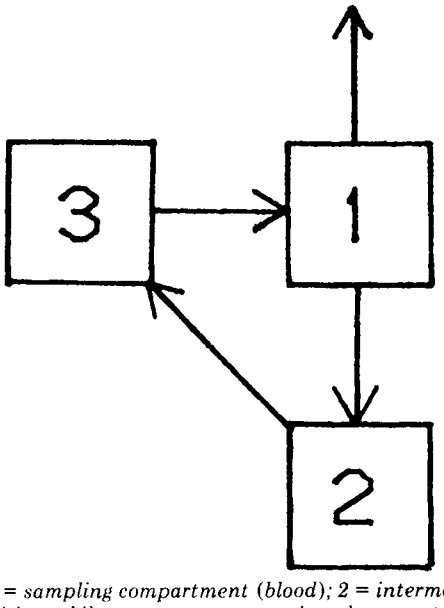
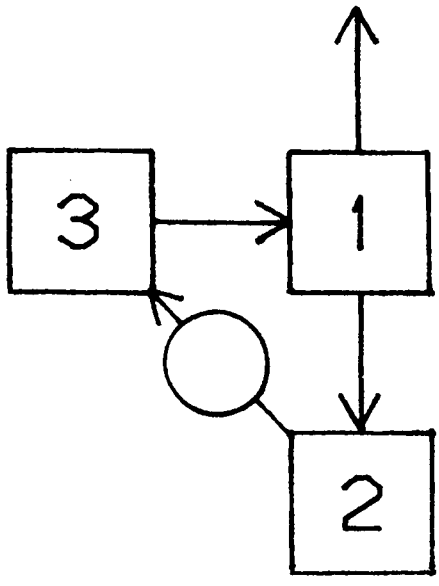
It appears that plasma level data showing secondary peaks or extra humps are not well approximated by linear compartment models with continuous first-order intercompartment drug transfer. However, such behavior may be related to discontinuous transfer processes. The doxycycline data appear to show secondary peaks that are not described by Model 1. Model 2 is identical to Model 1 except that drug transfer back into the intestine is a discontinuous bolus transfer *via* the bile. This model appears physiologically more meaningful than Model 1, considering the discontinuous nature of biliary secretion (5).

The average absorption half-life of 0.4 hr is somewhat smaller than that obtained using Model 1 (0.5 hr) while the average elimination half-life of 14 hr is greater than the 13 hr previously determined (Tables I and II). Although the average absorption and elimination half-lives are not very different from those determined using Model 1, Model 2 fits the data consistently better than Model 1 judged from the residual sum of squares and the Akaike information criterion values (Table II and Fig. 2).

Almost complete absorption takes place from the upper intestine following oral doxycycline administration (4). To account for the 70–80% doxycycline eventually recovered in the feces (14), intestinal secretion has been proposed as primarily responsible with biliary secretion playing a minor role (14, 15). It was proposed that after essentially complete absorption, the drug in the blood diffuses into the alkaline medium of the intestinal lumen where cationic chelation occurs, in which form doxycycline cannot be reabsorbed and is ultimately eliminated in the feces (16). Some investigations indicated that average concentrations of doxycycline are about five times greater than serum concentrations and that bile concentrations of the gallbladder are 10–15 times greater than serum concentrations (4). It was estimated that 10–15% of a 200-mg dose



Model 1—1 = sampling compartment (blood); 2 = intermediate compartment, either a bile compartment or a virtual compartment representing a secreted nonabsorbable compound or complex from which an absorbable form of the drug is released; and 3 = compartment from which absorption takes place.



Model 2—1 = sampling compartment (blood); 2 = bile compartment from which bile containing drug is released spontaneously as a bolus squirt to the absorption compartment; and 3 = compartment from which absorption takes place.

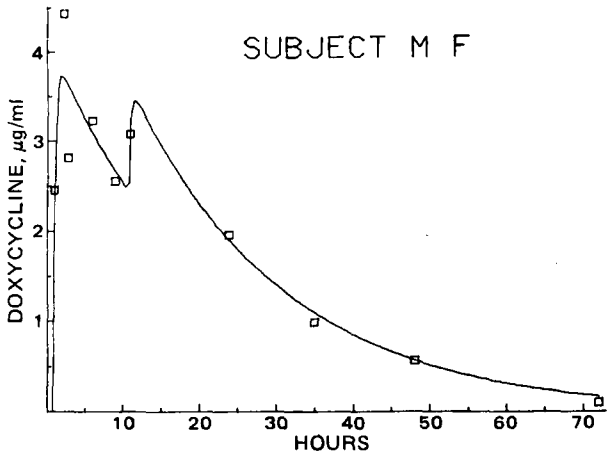


Figure 2—*Least-squares fit of Model 2 (Eq. 11) to plasma doxycycline level data.*

would be eliminated in the bile per day if an average of 500 ml of bile was secreted (4). If doxycycline's metabolism rate, urinary excretion rate, and excretion rate of chelate complex are first-order processes, or if the combined elimination rate by these processes is approximately first order (k_{10}), then Model 2 may be physiologically meaningful if the absorption rate is first order.

In humans, bile is retained in the gallbladder until it is spontaneously released, usually after a meal (5). The estimated times of bile release, T_b, in six subjects varied from 5 to 24 hr. Food and especially fats promote contraction of the gallbladder so that the timing and fat content of the meal play a role in the estimated time and magnitude of bile release.

It is difficult to speculate about the feasibility of these times and the degree of reabsorption because of the limited data and the inaccuracy of the assay methodology and because no specific information is available about the food intake of the subjects after drug administration. However, the data appear to show a consistent trend of reabsorption, and the Akaike information criterion (17, 18) seems to indicate, in comparing the two linear compartment models (Tables I and II), that the reabsorption mechanism is discontinuous rather than continuous.

NOTATIONS

c = drug concentration in sampleable compartment (blood plasma) at time t

D_F = amount of dose available in the compartment where absorption takes place

$E_i = \sum_{j=0}^{n} k_{ij}$, where $n = 3$

$\bar{f}_i$ = Laplace transform of input rate into the ith compartment

F_b = fraction of the amount of drug cumulated in the bile that is released by a squirt of bile at time $t = T_b$

$Im(z)$ = imaginary part of complex number z

k_{ij} = first-order rate constant for drug transfer from compartment i to compartment j

L^{-1} = inverse Laplace transform operator

λ = eigenvalue of linear pharmacokinetic system (real or complex)

$Re(z)$ = real part of complex number z

s = Laplace transform variable

$|\mathbf{S}|$ = $|\mathbf{S}(s)|$, determinant of $\mathbf{S}$ matrix defined in Ref. 6.

$|\mathbf{S}|_{ij}$ = $|\mathbf{S}(s)|_{ij}$ cofactor corresponding to the i,jth position of $\mathbf{S}$ matrix

T_b = time when bile containing drug is released to absorption compartment

T_L = absorption lag time

V = volume of distribution of sampleable compartment

x_i = amount in ith compartment at time t

$(y)_+$ = max(0,y), the "truncation function"

Insulin Permeability of Hydrophilic Polyacrylate Membranes

M. V. SEFTON ˣ **and E. NISHIMURA**

Received May 11, 1979, from the *Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario, M5S 1A4, Canada.* Accepted for publication August 22, 1979.

Abstract □ The diffusive permeability of insulin in polyhydroxyethyl methacrylate (37.1% water), polyhydroxyethyl acrylate (51.8% water), polymethacrylic acid (67.5% water), and cuprophane PT-150 membranes was determined and correlated with the weight fraction of water in the membrane. Insulin diffusivity in the membranes was determined to be 1.0×10^{-6} cm²/sec, which is in reasonable agreement with literature values for insulin diffusivity in water.

Keyphrases □ Polyacrylate membrane—effect on insulin diffusivity, extent of cross-linkage, hydration effect □ Insulin diffusivity—permeability through hydrophilic polyacrylate membranes □ Membrane permeability—hydrophilic polyacrylate membranes, effect on insulin diffusivity, extent of cross-linkage, hydration effect

Controlled-release insulin is desirable because of the recognized relationship between poor glycemia control associated with conventional insulin therapy and the degenerative sequelae of juvenile diabetes (1). Specifically, the development of a micropump for controlled-release delivery of insulin at variable rates (2) necessitated the investigation of the insulin permeability of a series of highly swollen polyacrylate membranes. In this device, basal delivery of insulin occurs through a polymeric membrane under a concentration and/or small pressure gradient while augmented delivery results when the membrane is repeatedly squeezed between the moving core of a solenoid and the membrane support. Augmentations as high as 50 times basal can be achieved to match insulin delivery to the postprandial insulin needs of a diabetic patient.

BACKGROUND

The diffusive permeability of solutes in hydrophilic membranes has been thoroughly studied (3–10). The effects of membrane hydration (3, 4), solute size (5–8), and cross-linker content (9, 10) were investigated. Various models were considered in analyzing the data. According to Yasuda *et al.* (3–5), the diffusive permeability, P, is related to the membrane diffusivity, D, by:

$$P = KD = \alpha HD \qquad \text{(Eq. 1)}$$

where H is the hydration or volume fraction of solvent in the membrane and K is the solute partition coefficient in the membrane. The parameter α reflects the proportionality between the partition coefficient and hydration and is unity for high hydration values (4). The solute diffusivity in the membrane generally is less than that in free solution because of the lower free volume (3) and the sieve effect (5) of the membrane. Yasuda *et al.* (5) found that the sieve effect was not evident for cellulose-based membranes with solutes up to the size of albumin (mol. wt. 66,000).

This study concerned the insulin permeability of highly swollen acrylate-based membranes and the membrane hydration effect on insulin permeability.

EXPERIMENTAL

Materials and Methods—Hydroxyethyl acrylate (I), hydroxyethyl methacrylate (II), and methacrylic acid (III) were polymerized *in situ* between two shim-separated glass plates over 24 hr. Triethylene glycol dimethacrylate was the cross-linking agent. Formulations are presented in Table I. The membranes were equilibrated in 0.9% saline prior to testing. A sample of cuprophane PT-150 was obtained from a Kolff twin-coil dialyzer[1].

The hydration, H, was assumed to be proportional to the weight fraction of water since the membrane densities were all 1.25 ± 0.05 g/cm³. The water fraction was determined by weighing the swollen membrane samples before and after drying *in vacuo*. The swollen membrane thickness was determined with a micrometer.

The membrane was supported by rubber gaskets between two Lucite chambers for permeability testing. It was tested in the horizontal position. The lower chamber, containing 65 ml of a radiolabeled insulin solution, was stirred by a magnetic stirrer. Initially, the upper chamber contained insulin-free saline and was agitated by an overhead stirrer, which was closely controlled because of frothing. The lower chamber was sealed to prevent bulk flow so that samples could be taken from this chamber only at the beginning and end of each run. The concentrations in this chamber were calculated by mass balance. The effective membrane area was 5.07 cm². The initial insulin solution was pH 7.4 phosphate-buffered saline containing 0.4 unit of insulin/ml[2] and 0.5 nCi of I-125 insulin/ml[3]. All experiments were conducted at $22 \pm 1°$.

Samples (1.3 ml) were removed at regular intervals from the upper chamber and were replaced by an equal volume of 0.9% saline. These samples, the two samples from the lower reservoir, and a background sample were each mixed with 10 ml of liquid scintillation cocktail[4] in

Table I—Formulations and Properties of Highly Swollen Polyacrylate Membranes

	Primary Monomer		
	Methacrylic Acid (III)	Hydroxyethyl Acrylate (I)	Hydroxyethyl Methacrylate (II)

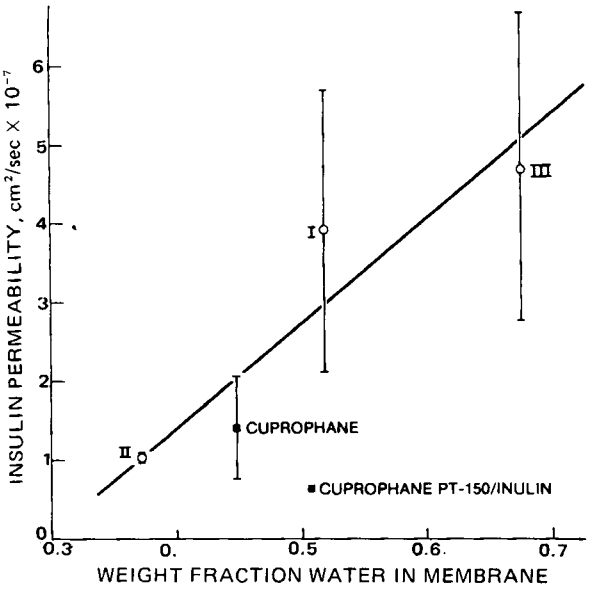

Figure 1—*Effect of weight fraction of water on insulin permeability of highly swollen polyacrylate membranes. Permeability of inulin in cuprophane PT-150(6) (■) is shown for comparison.*

polyethylene vials and counted using a liquid scintillation spectrometer.

Calculation of Membrane Permeability—Permeability was calculated using the following equations (6):

$$\ln \prod_{i=0}^{i=n} \left[\frac{(C_2 - C_1)_{i+1}}{(C_2' - C_1)_i}\right] = \frac{PA}{t_m}\left(\frac{1}{V_1} + \frac{1}{V_2}\right)\theta_n \quad \text{(Eq. 2)}$$

$$C_{2,i}' = (1 - V_r/V_2)C_{2,i} \quad \text{(Eq. 3)}$$

where:

$C_{1,i}$ = concentration of ith sample in lower (concentrated) reservoir, calculated by mass balance
$C_{2,i}$ = concentration of ith sample in upper (dilute) reservoir
$C_{2,i}'$ = concentration in upper reservoir corrected for dilution
V_1 = volume of lower reservoir
V_2 = volume of upper reservoir
V_r = sample volume (1.3 ml)
A = effective membrane area
t_m = membrane thickness
θ_n = time for sample n

The left side of Eq. 2 was plotted against time to determine the slope for calculating the membrane permeability, P. To compensate for mass balance errors, the lower reservoir concentration, C_1, was calculated forward from the initial concentration and backward from the final concentration. These two permeability values rarely differed by more than 10%; this variation was less than the intrasample variation. The averaged results are presented in Table I and were plotted against the weight fraction of water (Fig. 1). At least two experiments were performed for each membrane.

The compression moduli of 2-mm thick samples of I and II water-swollen hydrogels were determined at 10% strain on a tensile testing machine[5] having a crosshead speed of 0.1 cm/min. The hydrogels were prepared as given in Table I in 7-mm o.d. glass tubes at 10°. The molecular weight between cross-links, M_c, was determined (Table I) from these moduli and the hydrogel densities (11).

DISCUSSION

Despite the differences in membrane chemical structure, insulin permeability correlated well with the weight fraction of water in the membrane. Specific interactions between membrane chemical structure and solute were apparently negligible (within experimental error). With the assumption that α (Eq. 1) was unity, the membrane diffusivity of insulin was proportional to the slope of the line (Fig. 1) and was 1.0×10^{-6} cm²/sec. This value agrees with the literature values of 0.73×10^{-6} and 1.6×10^{-6} cm²/sec for insulin diffusivity in water at infinite dilution at 20° measured by ultracentrifugation techniques (12). The differences in the free volume and the molecular state within the membrane relative to that in free solution should account for this deviation.

The effect of cross-linking is as expected. At a higher M_c value (lower extent of cross-linking), the permeability is higher since the membrane swells more. Although the hydrogels absorbed more water than saline, the M_c values should not be different in saline. However, the differences in reaction conditions (temperature and geometry) may be significant despite the longer reaction times; for example, the number of free chain ends was ignored in this calculation. The dramatic increase in permeability at a low extent of cross-linking noted by others (9, 10) was not detected since the extent of cross-linking was greater in this work.

Membrane Transport of Alkyl Homologs: Role of Fluid Flow in Aqueous Diffusion Region

ASHOK C. SHAH *x **and KENNETH G. NELSON** ‡§

Received April 4, 1979, from the *Pharmacy Research Unit, The Upjohn Company, Kalamazoo, MI 49001, and the ‡College of Pharmacy, University of Minnesota, Minneapolis, MN 55455. Accepted for publication August 24, 1979. §Present address: Pharmacy Research Unit, The Upjohn Company, Kalamazoo, MI 49001.

Abstract □ Passive drug transport across a membrane involves the resistances in series offered by the membrane and the liquid layer immediately adjacent to it. The liquid layers generally are referred to as unstirred aqueous diffusion layers, suggesting that solute transport across these layers occurs solely by molecular diffusion. In accord with convective diffusion theory, recent studies showed that the transport from either a dissolving surface or a membrane surface depends not only on molecular diffusion but also on fluid convection in the liquid adjacent to the membrane. Membrane permeation rates were determined for a series of alkyl *p*-aminobenzoates, and the results correlated with a model comprised of membrane diffusion and convective diffusion in the adjacent liquid region.

Keyphrases □ Drug transport—alkyl *p*-aminobenzoates, membrane permeation, fluid flow in aqueous diffusion region □ *p*-Aminobenzoates—membrane permeation, fluid flow in aqueous diffusion region □ Permeation—*p*-aminobenzoates, membrane transport, fluid flow in aqueous diffusion region

Passive drug transport across a membrane involves the resistance offered by the membrane itself as well as by the passage through the liquid immediately adjacent to the membrane. At steady state, the two processes occur simultaneously; because they are in series, limiting cases exist in which one process or the other may be rate limiting. Recent studies demonstrated that under conditions of aqueous boundary layer control, the permeation rate of butamben through a dimethicone membrane was described accurately by a mathematical model based on convective diffusion theory (1).

Models for steady-state transport across membranes generally have been based on the assumption of unstirred solvent layers adjacent to the membrane (2). Such layers are included as a resistance in series with the membrane. However, this concept of a static liquid layer adjacent to a solid and continuous with a moving liquid has been criticized (3) on the basis of empircal evidence as well as hydrodynamic theory.

The purposes of this work were to study the membrane permeation of a series of alkyl *p*-aminobenzoates and to evaluate the data in terms of a model comprised of membrane diffusion and convective diffusion in the adjacent liquid.

EXPERIMENTAL

The permeation studies for the methyl through pentyl *p*-aminobenzoates were carried out using a dimethicone membrane (thickness of 0.0254 cm) in a laminar flowcell (1, 4). On the donor side of the membrane, a well-stirred aqueous suspension of the permeant provided the source at a constant concentration. On the other side, water flowing under laminar conditions removed the solute from the vicinity of the membrane and also served as the means to monitor the permeation rate spectrophotometrically.

Table I gives the aqueous solubilities and partition coefficients for the compounds studied. The aqueous solubilities at 25° were determined previously (4). The partition coefficients were obtained by equilibrating dimethicone membranes with aqueous suspensions of the esters for 48 hr at 25°, extracting the ester from the membrane by successive equilibration with water, and analyzing the extract spectrophotometrically (λ_{max} 285 nm) to determine the ester concentration in the membrane. Partition coefficients were taken as the ratio of the concentration in the membrane to the aqueous solubility.

THEORETICAL

The diffusional resistance, R_m, of the circular membrane is given by:

$$R_m = \frac{h}{D_m K \pi r^2} \qquad \text{(Eq. 1)}$$

where h is the membrane thickness, D_m is the solute diffusivity in the membrane, K is the partition coefficient of the solute in the membrane relative to water, and r is the membrane radius. The analogous resistance term, R_w, for the convective diffusion transport through the liquid adjacent to the membrane may be expressed as:

$$R_w = \frac{1}{2.16 r^{5/3} D_w^{2/3} \alpha^{1/3}} \qquad \text{(Eq. 2)}$$

where D_w is the aqueous diffusivity of the solute and α is the rate of shear adjacent to the membrane which is directly proportional to the fluid flow rate (4). The steady-state permeation rate is given by the concentration difference across the membrane divided by the resistance, which is the sum of the individual layer resistances for a classical composite membrane (5). If it is assumed that the resistances as given in Eqs. 1 and 2 are additive, the steady-state permeation rate, J, may be written as:

$$J = \frac{2.16 \pi r^{11/3} D_w^{2/3} \alpha^{1/3} D_m K C}{\pi r^2 D_m K + 2.16 h r^{5/3} D_w^{2/3} \alpha^{1/3}} \qquad \text{(Eq. 3)}$$

where C is the constant solute concentration on the donor side of the membrane.

Two limiting cases of Eq. 3 are represented schematically in Fig. 1. In one case, diffusion across the membrane becomes rate controlling under conditions that favor minimizing Eq. 2 relative to Eq. 1, *e.g.*, a very large α or h, so that Eq. 3 becomes:

$$J = \frac{\pi r^2 D_m K C}{h} \qquad \text{(Eq. 4)}$$

Alternatively, if the resistance in the membrane (Eq. 1) is minimized with respect to that in the liquid (Eq. 2) by such factors as a small h or a large K, then:

$$J = 2.16 r^{5/3} D_w^{2/3} \alpha^{1/3} C \qquad \text{(Eq. 5)}$$

This limiting case was discussed previously (1) and is the same expression as for the dissolution from a solid solute surface in the cell. Equation 3 in effect is an interpolation formula; it combines the two limiting cases to describe permeation for conditions in which the two resistances are comparable in magnitude.

Figure 1 was drawn ignoring the partitioning effect ($K = 1$). In Case II, the profile in the liquid is dependent on the distance along the mem-

Table I—Aqueous Solubilities and Partition Coefficients of *p*-Aminobenzoate Esters at 25°

Ester	Aqueous Solubility, moles/liter	Partition Coefficient
Methyl	1.04×10^{-2}	0.26
Ethyl	6.19×10^{-3}	0.78
Propyl	2.78×10^{-3}	2.59
Butyl	9.39×10^{-4}	9.61
Pentyl	2.72×10^{-4}	38.11

brane. Thus, the gradient would be steeper and the extent of penetration into the liquid would be less near the upstream edge of the membrane than at points along the membrane further downstream.

RESULTS AND DISCUSSION

The steady-state permeation rates of the methyl through pentyl *p*-aminobenzoates were determined as a function of the fluid flow rate under laminar conditions. These rates are shown in Fig. 2 as the data points. Because the parameters on the right side of Eq. 3 are known independently, the rates predicted by Eq. 3 also are included in Fig. 2 as the solid lines. The experimental results are in reasonably good agreement with

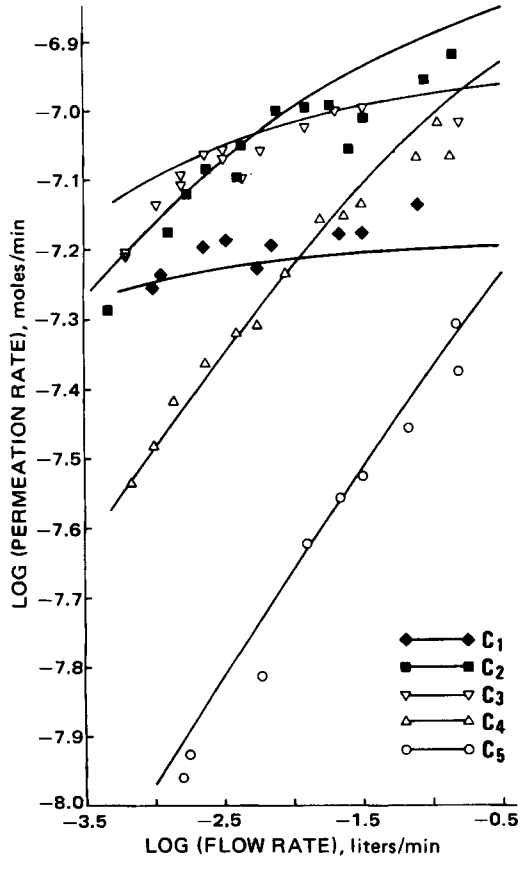

Figure 2—*Permeation rates of C_1–C_5 alkyl homologs of* p-*aminobenzoates determined as a function of the fluid flow rate. Curves represent relationships predicted by Eq. 3.*

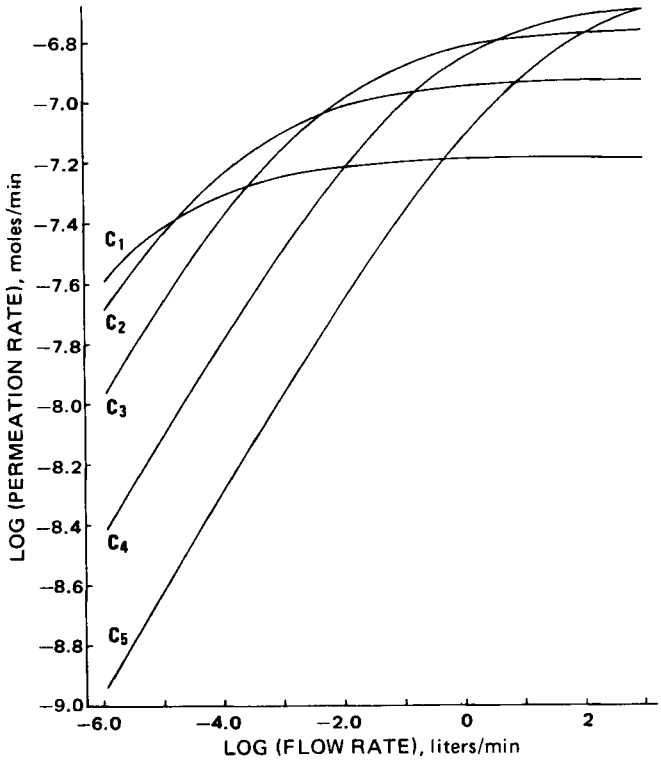

Figure 3—*Permeation rates of C_1–C_5 alkyl homologs of* p-*aminobenzoates estimated by Eq. 3 over a wide range of fluid flow rates.*

Eq. 3, especially for the butyl and pentyl esters. For the others, predicted trends exist in the rates of the various esters relative to each other.

To demonstrate the ramifications of Eq. 3, predicted rates are shown in Fig. 3 for a much wider range of fluid flow rates. At low flow rates, the lines became parallel with a slope of one-third because the solute transport rate was controlled by the simultaneous diffusion and convection in the liquid adjacent to the membrane, which is commonly termed the aqueous boundary layer control. This limiting case is given by Eq. 5. The

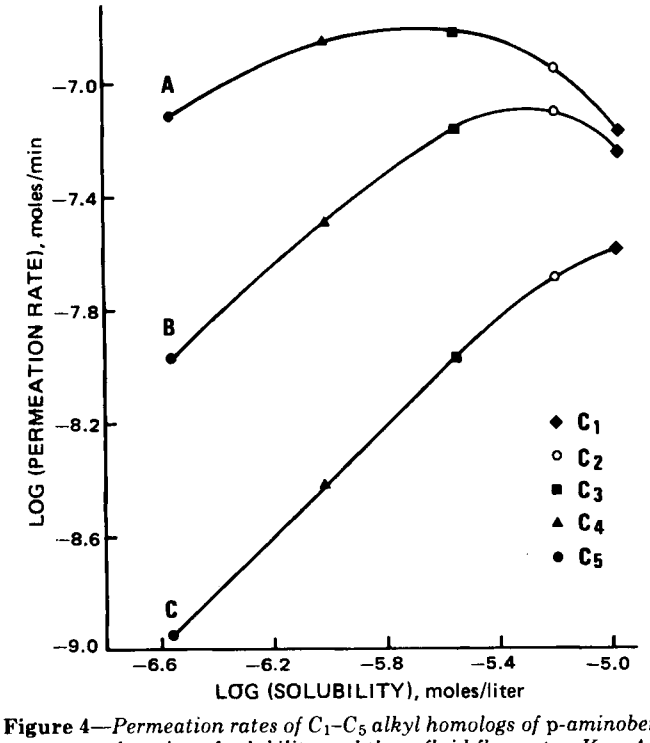

Figure 4—*Permeation rates of C_1–C_5 alkyl homologs of* p-*aminobenzoates as a function of solubility and three fluid flow rates. Key: A, 1 liter/min; B, 1×10^{-3} liter/min; and C, 1×10^{-6} liter/min.*

vertical spacing is governed by the solubilities of the various esters.

At high flow rates, the permeation rates leveled off and became independent of flow in accordance with Eq. 4, wherein the permeation rate becomes only a function of the transport across the membrane. Thus, K and C determined the relative positions of the plateaus in Fig. 3.

In the permeation simulations calculated with Eq. 3, values of D_m and D_w reported previously (2, 4) were assumed to be the same ($D_m = 2.72 \times 10^{-6}$ cm^2/sec and $D_w = 6 \times 10^{-6}$ cm^2/sec) for all members of the series because the change in molecular weight would change the diffusivity insignificantly (6) compared with the order-of-magnitude changes in the other parameters, *e.g.*, solubility and flow rate. Although the diffusivity was not evaluated as an independent parameter in the present work, it has been observed experimentally (7) that the resistance in the aqueous boundary layer film adjacent to a membrane is proportional to the diffusivity raised to the power −0.6. This observation is in reasonably good agreement with Eq. 2.

Equation 3 arises from an assumption that the resistances in the membrane and in the adjacent liquid are additive. This combination permits calculation of the permeation rate under conditions of membrane control or aqueous convective diffusion control or at intermediate points. It is apparent from the permeation data that the predictions were reasonably good. However, in the intermediate region, Eq. 3 should be considered as an interpolation formula rather than as an expression arising directly from basic theory because the instantaneous transport rate decreases somewhat with increasing distance along the membrane in the direction of flow. This decrease is a characteristic of convective diffusion theory. With intermediate cases, there would be a concentration gradient within the membrane in the direction of flow. This gradient is not accounted for in Eq. 3. However, such a gradient would be much smaller than the gradient normal to the membrane because of the relative distances involved and, therefore, may be ignored.

If the data in Fig. 3 are replotted as log permeation rate *versus* log solubility, the curves obtained at different flow rates appear as in Fig. 4. The maximum permeation rate is shifted to the left, *i.e.*, to permeants having a lower solubility, with an increase in flow rate. This is similar to the concepts of Flynn and Yalkowsky (2), who evaluated the effect of fluid flow agitation in terms of a change in the thickness of the stagnant or unstirred layer. The thickness of the unstirred layer is a model-dependent parameter; it cannot be measured independently of permeation experiments. In the present work, the effect of fluid flow is incorporated as the rate of shear adjacent to the membrane. Because hydrodynamic theory permits one to determine the shear rate from the fluid flow rate and the geometry of the cell, the effect of fluid flow on permeation and the position of maximum permeation can be calculated readily *a priori* for a given membrane thickness using Eq. 3.

Simultaneous High-Pressure Liquid Chromatographic Determination of Acetaminophen, Guaifenesin, and Dextromethorphan Hydrobromide in Cough Syrup

W. O. McSHARRY *x and I. V. E. SAVAGE ‡

Received April 12, 1979, from the **Quality Control Department, Hoffmann-La Roche Inc., Nutley, NJ 07110,* and ‡*Roche Products Pty. Ltd., Dee Why 2099, Australia.* Accepted for publication August 23, 1979.

Abstract □ Acetaminophen (I), guaifenesin (II), and dextromethorphan hydrobromide (III) were separated and quantitated simultaneously in cough syrup by high-pressure liquid chromatography. A chemically bonded octadecylsilane stationary phase was used with a mobile phase of 45% (v/v) aqueous methanol. The mobile phase pH was stabilized to 4.2 by adding formic acid–ammonium formate buffer (~0.4%). The internal standard was *o*-dinitrobenzene. Retention volumes were 4 ml for I, 6 ml for II, 11 ml for the internal standard, and 20 ml for III. Inactive syrup components did not interfere, permitting direct diluted sample injection. Results on active ingredients were essentially 100% of the claim, with standard deviations of ±1.5, 1.2, and 2.1% for I, II, and III, respectively.

Keyphrases □ High-pressure liquid chromatography—simultaneous determination of acetaminophen, guaifenesin, and dextromethorphan hydrobromide, analysis of cough syrup active ingredients □ Pharmaceutical preparations—simultaneous determination of cough syrup active ingredients by high-pressure liquid chromatography □ Acetaminophen—simultaneous determination with guaifenesin and dextromethorphan hydrobromide, high-pressure liquid chromatography □ Guaifenesin—simultaneous determination with acetaminophen and dextromethorphan hydrobromide, high-pressure liquid chromatography □ Dextromethorphan hydrobromide—simultaneous determination with acetaminophen and guaifenesin, high-pressure liquid chromatography

Characterization of numerous drugs (1–4) and analyses of specific dosage forms have been conducted through the use of high-pressure liquid chromatography (HPLC). Recent investigations of pharmaceutical preparations included acetaminophen (paracetamol)–chlorpheniramine maleate–dextromethorphan hydrobromide (5) and codeine phosphate–guaifenesin (glyceryl guaiacolate)–pheniramine maleate–phenylpropanolamine hydrochloride–pyrilamine maleate (6). A liquid chromatographic analysis of 29 drug compounds in acidic, neutral, and alkaline media included syrups containing phenylephrine hydrochloride, acetaminophen, guaifenesin, and dextromethorphan hydrobromide (4). However, it was not clear if the last three compounds could be analyzed using a single mobile phase.

Simultaneous determination of acetaminophan (I), guaifenesin (II), and dextromethorphan hydrobromide (III) in a liquid preparation has not been reported. Routine analysis of a cough syrup was required, and HPLC was the method of choice. A chemically bonded nonpolar-sta-

[a] Expressed as percent of claim. [b] Standard deviation of a single determination calculated from six replicates.

tionary phase was chosen because it is not adversely affected by the polar components of the syrup, making prior separation unnecessary. The aim was to develop a procedure in which all three components could be determined simultaneously in a single injection.

EXPERIMENTAL

Reagents—Acetaminophen (paracetamol) BP[1] (I), guaifenesin (glyceryl guaiacolate) BPC[1] (II), dextromethorphan hydrobromide[2] (III), and *o*-dinitrobenzene[3] (the internal standard) were used as supplied.

Mobile Phase Preparation—Thirty-four milliliters of 28–30% ammonia[4] was diluted with 30 ml of water. Then 30 ml of formic acid[4] (minimum 98%) was added slowly with stirring. When cool, the solution (pH ~ 3.9) was diluted to 100 ml with water (ammonium formate buffer).

Ammonium formate buffer (10 ml) was added to 450 ml of methanol[4] (ACS grade) and diluted with water to make 1 liter (pH ~ 4.2) at room temperature. The mobile phase was filtered with vacuum.

Standard Solutions—*Internal Standard Solution Preparation*—*o*-Dinitrobenzene, 50 mg, was dissolved in 125 ml of methanol and diluted to 250 ml.

Standard Solution Preparation—Separate standard stock solutions were prepared in 50% (v/v) methanol in water containing ~9.0 mg of I/ml, 3.7 mg of II/ml, or 0.4 mg of III/ml. A standard solution of all three components was prepared by pipetting 10.0 ml of I solution, 10.0 ml of II solution, 15.0 ml of III solution, and 5.0 ml of internal standard solution into a 50-ml volumetric flask and diluting to volume with 50% (v/v) methanol in water.

Sample Preparation—A 3-ml sample was transferred to a 50-ml volumetric flask and weighed. Then 5 ml of internal standard solution was added, and the mixture was diluted to volume with 50% (v/v) methanol in water.

Instrumentation—The liquid chromatograph consisted of a constant-flow pump[5], a low pressure injector[6], a 30-cm × 4-mm i.d. octadecylsilane column[7], and an absorbance detector[8] at 280 nm. The flow rate was 2.0 ml/min, and the injection volume was 15 μl. Peak heights were monitored with a strip-chart recorder[9] adjusted for maximum on-scale deflection for the internal standard and III. An electronic integrator[10] was used to monitor peak areas. Settings on the integrator were chosen to minimize noise.

Calculations—Results for I and II were calculated from the integrated area relative to the internal standard area. Results for III were calculated from the peak height relative to the height of the internal standard peak.

RESULTS AND DISCUSSION

The simultaneous analysis of all three components in this cough syrup was difficult for two reasons. First, the wide response range between I and III limited the amount of sample that could be injected without either overloading the detector or losing precision in the smaller component measurement. Second, the wide difference in polarity between I and III made it difficult to separate I and II from interfering impurities while eluting III in a reasonable time.

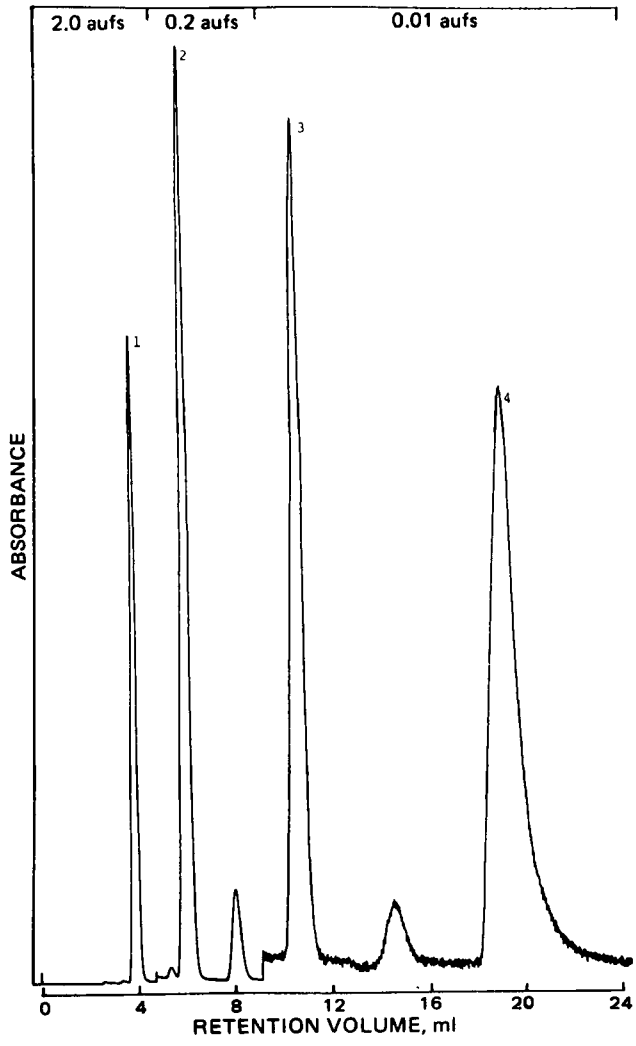

Figure 1—*High-pressure liquid chromatogram of a cough syrup preparation. Peaks 1, 2, and 4 are acetaminophen, guaifenesin, and dextromethorphan hydrobromide, respectively. Peak 3 is the internal standard (o-dinitrobenzene). Other peaks are unidentified components of the syrup. Absorbance units at full scale (aufs) are shown at the top.*

Heptanesulfonic acid and pentanesulfonic acid were tried as ion-pairing agents but retained III at methanol concentrations sufficiently low to separate I and II. Ammonium acetate buffer significantly reduced III retention without affecting I and II. Ammonium formate finally was chosen because it further reduced III retention, again without affecting I and II.

In all mobile phases tried, III tailed badly. Due to the tailing and low concentration of III, electronic integration was not reproducible (coefficient of variation ±5%). Therefore, peak height measurement was used. The possibility of interfering peaks was checked by injecting: a blank syrup preparation containing all ingredients except I, II, and III; a syrup preparation with no internal standard added; and the internal standard only, at a concentration 10 times that used in the analysis.

None of the inactive syrup components coeluted with the active ingredients or internal standard, nor did the internal standard contain any impurities that coeluted with the active ingredients (Fig. 1). Separation of I from its potential hydrolysis product, *p*-aminophenol, was confirmed by injecting a freshly prepared solution of *p*-aminophenol, which eluted separately from I. Detector response was linear within ±2% for all components between 80 and 110% of the claim.

Altogether nine samples were analyzed (Table I). Method precision was evaluated in two ways. The precision of the response ratio mea-

surement was determined by making six replicate injections of a single standard preparation. The overall precision was evaluated by making one injection for each of six separate sample preparations and calculating the result by comparison with the six replicate single injections. Most of the error resulted from the response ratio measurement (Table I), which can be reduced by replicate injections.

Instrument setup and preparation of the standard required ~2 hr. Individual analyses, including calculations, can be carried out at a rate of more than one sample per hour.

Nonvariance of LD_{50} Values of Drugs in Gravid and Nongravid Mice

JAMES A. RUSSELL, MICHAEL P. MAHALIK, JOSEPH M. McDEVITT, and RONALD F. GAUTIERI ˣ

Received April 5, 1979, from the *Department of Pharmacology, School of Pharmacy, Temple University, Philadelphia, PA 19140.* Accepted for publication August 22, 1979.

Abstract □ This study showed that the LD_{50} values for morphine sulfate, cobalt chloride, and phenytoin sodium did not vary significantly on Day 9 of gestation in CF-1 mice when compared to values of nongravid animals.

Keyphrases □ LD_{50} testing—gravid and nongravid mice, morphine sulfate, cobalt chloride, phenytoin sodium, teratological study □ Teratological study—gravid and nongravid mice, morphine sulfate, cobalt chloride, phenytoin sodium, LD_{50} testing □ Morphine sulfate—LD_{50} testing, gravid and nongravid mice □ Phenytoin sodium—LD_{50} testing, gravid and nongravid mice □ Cobalt chloride—LD_{50} testing, gravid and nongravid mice

The LD_{50} value is the dose of a drug that proves lethal to 50% of a population. Despite the frequent use of this parameter to determine dosage schedules in teratological studies, it is often utilized with reservation due to its variance in gravid mice.

Therefore, to determine the LD_{50} variance in gravid and nongravid mice, it was decided to utilize drugs from different classes (morphine sulfate, cobalt chloride, and phenytoin sodium) and to subject the mice to a typical LD_{50} screen. Gravid mice were challenged on Day 9 of gestation, which corresponds to the midpoint in mouse pregnancy and also with the appearance of overt birth defects (1).

EXPERIMENTAL

Male and female CF-1 mice[1], ≥25 g, were utilized. Males were caged individually, and females were maintained in groups of 10 in large aggregate cages until exposure to the males. All mice were allowed water and food[2] *ad libitum*.

For morphine sulfate[3] and cobalt chloride[4] testing, 40 nongravid females were assigned to one of five groups of eight using a table of random numbers. Fifty-five animals, 11 per group, were used for phenytoin sodium testing[5] in the same manner. Dosage levels then were assigned to the groups (Tables I–III). Each mouse was weighed to the closest 0.1 g, caged individually, and administered the respective drug subcutaneously on the medial side of the right inguinal region.

Morphine sulfate (2%) and cobalt chloride (1 or 2%) were prepared daily in double-distilled water; phenytoin sodium (1%) was prepared in 70% propylene glycol in 0.9% NaCl. If the injected volume exceeded 1 ml, it was divided into two equal portions and was injected in separate inguinal regions. After injection, each mouse was observed for 24 hr, at which time the fatalities were observed (Tables I–III).

Breeding was accomplished as follows. Two females were placed

Table I—Observed Deaths [a] with Morphine Sulfate after 24 hr

Mice	Dosage, mg/kg				
	250	400	450	500	750
Nongravid	0/8	2/8	2/8	5/8	8/8
Gravid	0/8	1/8	2/8	5/8	7/8

[a] Deaths per number of mice tested.

Table II—Observed Deaths [a] with Cobalt Chloride after 24 hr

Mice	Dosage, mg/kg				
	100	125	150	200	300
Nongravid	0/8	2/8	4/8	6/8	8/8
Gravid	0/8	1/8	3/8	5/8	8/8

[a] Deaths per number of mice tested.

Table III—Observed Deaths [a] with Phenytoin Sodium after 24 hr

Mice	Dosage, mg/kg				
	200	250	300	325	400

Table IV—Statistical Comparison [a] of Drugs Tested in Gravid and Nongravid CF-1 Mice

Test Group	LD_{50}, mg/kg	Slope	Slope Ratio	Slope Ratio Function	Potency Ratio	Potency Ratio Function
Morphine sulfate			1.11	1.20	1.08	1.22
Nongravid mice	480 (428–538)	1.17				
Gravid mice	520 (488–603)	1.30				
Cobalt chloride			1.04	1.60	1.11	1.26
Nongravid mice	157 (138–179)	1.33				
Gravid mice	174 (144–210)	1.28				
Phenytoin sodium			1.09	1.33	1.11	1.19
Nongravid mice	273 (250–298)	1.16				
Gravid mice	246 (214–283)	1.26				

[a] Values calculated by the method of Litchfield and Wilcoxon (2).

overnight in cages containing one male. On the next morning (Day 0), all females were observed for the presence of coagulated intravaginal semen, which was the criterion used for determining pregnancy. Then all those deemed pregnant were weighed and placed in individual cages. All of the nonpregnant mice were returned to the aggregate cages for later use.

On Day 9, gravid mice were randomly assigned to one of the appropriate dosage groups, and the respective solutions were administered subcutaneously; the same number of animals were used as for the nongravid groups. After 24 hr, fatalities were recorded. All gravid mice then were cervically dislocated and laparotomized to confirm pregnancy by the presence of fetal swellings.

RESULTS AND DISCUSSION

The teratogenic effects of morphine sulfate, cobalt chloride, and phenytoin sodium were reported previously (1, 3, 4). The determination of dosage schedules in these studies was made under the assumption that the LD_{50} of each drug did not vary between gravid and nongravid mice.

The data in Tables I–III were subjected to probit analysis according to the method of Litchfield and Wilcoxon (2). Because the slope ratios were less than the slope ratio functions, it can be concluded, with 95% confidence, that the dose–response curves did not deviate significantly from parallelism (Table IV). Furthermore, because the potency ratios were calculated to be less than the potency ratio functions, it can be concluded, with 95% confidence, that the LD_{50} of the respective drugs did not change significantly on Day 9 of gestation in CF-1 mice.

The range of the conclusions in this study is limited by the strain of mouse and the peculiarities of the drugs. However, because the drugs from three different classes did not vary in gravid and nongravid mice with respect to their LD_{50} curves, these results possibly can be extrapolated to other drugs. Hence, one LD_{50} curve obtained from nongravid mice may serve as a valid reference to determine the dose of an agent to be tested for teratogenicity.

Rapid Colorimetric Analysis of Chlorhexidine in Pharmaceutical Preparations

G. ANDERMANN ˣ, M. O. BUHLER, and M. ERHART

Received April 30, 1979, from the *Analytical Research and Development Department, P.O.S. Laboratories, 68240 Kaysersberg, France.* Accepted for publication August 21, 1979.

Abstract □ A colorimetric determination of chlorhexidine is described. The method is based on the formation of a yellow complex between the drug and bromcresol green. The absorption peak of this complex, extracted by chloroform, is at 410 nm, and linear response is obtained from 2.5 to 30 μg of chlorhexidine/ml. The accuracy and reproducibility of this rapid method make it useful for chlorhexidine determination in the manufacturing control of pharmaceutical mixtures.

Keyphrases □ Chlorhexidine—analysis, colorimetric determination in commercial dosage forms □ Antimicrobial agents—chlorhexidine, colorimetric determination in commercial dosage forms □ Colorimetry—analysis of chlorhexidine in commercial dosage forms

Chlorhexidine (I), an antimicrobial agent, is a common ingredient in antiseptic preparations. The presence of chlorhexidine as a preservative in other pharmaceutical dosage forms (eye drops) and cosmetics necessitated a rapid, economical, and sensitive determination.

BACKGROUND

The primary method available previously was a colorimetric procedure (1), but several components in pharmaceutical formulations interfere in the determination. Another colorimetric assay using *N*-(1-naphthyl)-ethylenediamine was reported for the determination of chlorhexidine in biological fluids (2), but it is time consuming and has background interference. A direct spectrophotometric assay of chlorhexidine using bromthymol blue was reported recently (3). Chlorhexidine is estimated based on differences in the absorbance before and after complexation with the acid dye. These techniques yield rather large errors.

Polarographic estimation (4) and an automated liquid chromatographic determination (5) also were reported recently. Chlorhexidine also has been determined successfully by GLC after hydrolysis to *p*-chloroaniline and suitable derivatization to *p*-chloroiodobenzene (6, 7), but this technique is time consuming and unsuitable for multiple analyses.

This paper describes a rapid colorimetric method that is based on the solvent extraction of a dye complex and is suitable for chlorhexidine analysis in pharmaceutical mixtures and cosmetics.

were used. To prevent adsorption of the drug–dye complex onto the glass, screw-top plastic tubes were required (8).

Reagents—A pH 5.70 buffer was prepared by mixing 100 ml of 0.1 *M* citric acid with 140 ml of 0.2 *M* anhydrous Na_2HPO_4. The bromcresol green solution was prepared by dissolving 30 mg of bromcresol green[3] in 100 ml of the pH 5.70 buffer and filtering. The solution was stable for 1 week. A 1:100 dilution had an absorbance of 0.154 ± 0.003 at 617 nm.

Chlorhexidine digluconate[4], 5 mg, was dissolved in 100 ml of distilled water. This stock solution was diluted to give 2.5–30-μg/ml working standards, which were prepared fresh for each run.

Procedure for Chlorhexidine Standard Solutions—One milliliter of standard solution was transferred to a screw-top plastic tube, and 3 ml of the bromcresol green reagent and 2.5 ml of chloroform were added. The tubes were stoppered, shaken for 3 min, and centrifuged at 3000 rpm for 3 min. The aqueous supernate was discarded. The chloroform layer was transferred carefully with an automatic pipet[5] to a 1-cm light path cell, and the absorbance was measured against a blank (1 ml of distilled water instead of the chlorhexidine solution) at 410 nm.

10	0.132	0.132	0.120
Average	0.126	0.127	0.123
SD	0.003	0.006	0.005
RSD, %	2.4	4.7	4.0

Procedure for Chlorhexidine Viscous Solutions, Shampoos, and Lotions—The chlorhexidine base was extracted from ~10–25 mg of chlorhexidine digluconate-containing samples by adding 50 μl of 10 *N* NaOH and shaking the solution for 15 min with 5 ml of chloroform. After centrifugation for 3 min at 3000 rpm, 2.5 ml of the chloroform layer was transferred to a screw-top plastic tube, 3 ml of bromcresol green reagent was added, and the procedure was followed as described for the standard solutions beginning with: "The tubes were stoppered . . . ."

RESULTS AND DISCUSSION

Color Stability—The yellow color was monitored with a recording spectrophotometer and was stable for 8 hr.

Linearity—The absorption peak of the bromcresol green–chlorhexidine complex was at ~410 nm. At this wavelength, the reaction followed Beer's law to an absorbance of 1.0, and linear response was obtained for 2.5–30 μg of chlorhexidine/ml (Table I).

The linear regression line was $A_{410} = (11.1C + 17.1)\ 10^{-3}$, where A_{410} is the absorbance at 410 nm and C is the concentration expressed in micrograms per milliliter. The calculated molar absorptivity, ϵ, was 11,302 ± 270. The correlation coefficient was 0.998.

Accuracy—The mean recoveries of known chlorhexidine amounts added to the formulations are shown in Table II. The precision was calculated by a literature method (9) as ~3.8% and was similar for viscous solutions and formulated products.

Table III shows the method to be fairly precise for chlorhexidine in eye drops, contact lens cleaning solutions, and shampoos, so the method can be used for manufacturing controls. No interference was observed with formulations of alcoholic solutions, eye drops, viscous solutions, and gels.

Detection Limits—The detection limit, as determined on 20 samples at the 95% confidence level, was 2.5 μg of chlorhexidine digluconate/ml.

Reproducibility—To show the within-batch variation, the chlorhexidine digluconate content of a 10-μg/ml standard solution was determined 12 times (Table IV). To show the between-batch variation, duplicate determinations were carried out on several days. The results were highly reproducible (Table V). Interanalyst variations of five chemists were determined at five levels by the proposed method, and rectilinear results were obtained (Table VI).

Method Limitations—Attempts to extend the method to chlorhexidine creams were unsuccessful due to coextraction of the formulation excipients that complex with bromcresol green. Emulsions also can be formed with the solvent and the chlorhexidine-containing creams.

This colorimetric determination of chlorhexidine salts offers improved precision, convenience, and speed over the previously reported methods. The high color stability offers an advantage over the colorimetric procedure of Holbrook (1). These considerations make the method suitable for the automated analysis of chlorhexidine salt formulations.

Brain-to-Blood and Saliva-to-Blood Mepivacaine Ratios in Rats

KATHLEEN R. GANS, DEBRA J. WOOD, and G. VICTOR ROSSI ˣ

Received June 18, 1979, from the *Department of Biological Sciences, Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104.* Accepted for publication August 24, 1979.

Abstract □ Mepivacaine hydrochloride, 25 and 50 mg/kg sc (with sacrifice at 15 min) produced higher ($p < 0.005$) drug levels in neonate (24–36-hr-old) rat brain and blood than in adult rat brain and blood; however, there was no significant difference in the brain-to-blood ratio of the drug between neonates and adults at either dose level. Intraarterial infusion of mepivacaine hydrochloride (20 μg/min) in adult rats resulted in measurable (GLC) mepivacaine base levels in pilocarpine-induced parotid salivary secretions collected throughout 30- and 45-min infusion periods. The saliva-to-blood ratios (±*SEM*) of mepivacaine base were 0.64 ± 0.13 after a 30-min infusion and 2.13 ± 0.48 after a 45-min infusion.

Keyphrases □ Mepivacaine—brain-to-blood and saliva-to-blood ratios, rats □ Anesthetics—mepivacaine, brain-to-blood and saliva-to-blood ratios, rats □ Models, animal—mepivacaine, brain-to-blood and saliva-to-blood ratios, rats

Several clinical studies demonstrated behavioral deficiencies and toxic manifestations in newborn infants whose mothers received local anesthesia during labor (1–8). Mepivacaine, widely used for such anesthesia, has been implicated in neonatal bradycardia, depression, apnea, convulsions, and death (1–4, 9, 10).

Because critical determinations of drug levels in the blood and tissues of healthy infants rarely are feasible, an animal model was employed to explore quantitative aspects of mepivacaine-related neural toxicity in neonates. Brain-to-blood ratios of mepivacaine base were determined for both neonate (24–36-hr-old) and adult rats after subcutaneous administration (25 and 50 mg/kg) of mepivacaine hydrochloride. Mepivacaine levels in adult rat whole blood and parotid saliva were compared to determine whether the salivary mepivacaine level could serve as an index of the blood drug concentration.

EXPERIMENTAL

Female Sprague–Dawley rats were supplied with food and water *ad libitum*. One group consisted of nonpregnant adult rats (250–300 g). Another group contained newborn rats (6–9 g) which remained with their mothers and nursed freely until drug or saline administration 24–36 hr postpartum.

Adult rats were prepared for saliva collection by anesthetization with urethan (1.2 mg/kg ip) followed by tracheotomy and cannulation of the parotid ducts according to a literature method (11). Tapered polyethylene tubing (PE 50) was inserted into each duct with the aid of a binocular dissecting microscope. Pilocarpine hydrochloride[1], 0.25 mg/ml, was infused at 0.2 ml/min into the right brachial artery to stimulate parotid salivary secretion. Mepivacaine hydrochloride[2], 1 mg/ml, was infused intraarterially (0.2 ml/min) concomitantly with the pilocarpine solution. Saliva was collected continuously throughout either a 30- or 45-min pilocarpine–mepivacaine infusion period, immediately after which 2–4 ml of blood was withdrawn *via* cardiac puncture into a heparinized vacutainer.

In another study, nonpregnant adult female rats were injected subcutaneously with 25 or 50 mg of mepivacaine hydrochloride/kg in 1.0 ml of saline; after 15 min, blood was collected *via* cardiac puncture into a heparinized vacutainer. The animals then were decapitated, and the brain was removed.

Two neonates were selected randomly from each of 15 litters and were injected subcutaneously with mepivacaine hydrochloride; one littermate received 25 mg/kg and the other received 50 mg/kg in 0.1 ml of saline. Animals were sacrificed 15 min after drug administration. Procedures for blood collection from neonates combined two techniques (12, 13). Brain tissue was removed after the spinal cord was severed at the neck.

Newborn and adult rat tissue and fluid samples also were collected from saline-injected animals, spiked with mepivacaine, and extracted for standard curves constructed each day for each tissue type. Mepiva-

Table II—Concentration of Mepivacaine Base in Adult Rat Parotid Saliva and Blood [a]

Infusion Time, min	n[b]	Saliva Mepivacaine, μg/g ± SEM	Blood Mepivacaine, μg/g ± SEM	Mepivacaine Saliva-to-Blood Ratio
30	17	4.79 ± 0.84	8.57 ± 1.07	0.64 ± 0.13
45	12	14.30 ± 4.64	8.10 ± 0.85	2.13 ± 0.48

[a] Mepivacaine hydrochloride was infused intraarterially at 200 μg/min. Pilocarpine hydrochloride (50 μg/min) was infused intraarterially concomitantly to stimulate parotid secretion. [b] Number of animals.

caine hydrochloride concentrations added to control samples ranged from 0.5 to 20 mg/g.

Immediately after collection, the blood, brain, and saliva samples were weighed and frozen (−15°). Because significant deterioration of mepivacaine in biological fluids stored for more than 72 hr was reported (14), extraction was performed within 3 days of tissue collection.

Published procedures were used for mepivacaine extraction from blood and saliva and for GLC analysis (14). Brain samples were homogenized with 1 ml of phosphate buffer (pH 7.4) in ground-glass tubes using a homogenizer[3]. An additional 2 ml of buffer was used to wash tissue from the homogenizing vessel into conical extraction tubes. After centrifugation at 2000 rpm for 10 min, ether was added to the supernate and the standard extraction protocol (14) was commenced.

Following evaporation of the final ether extract, the residue of each sample was reconstituted with 20 μl of chloroform. One microliter of the reconstituted sample was injected into a gas–liquid chromatograph[4] equipped with a hydrogen detector and preset to optimum conditions for detection of mepivacaine and procainamide (internal standard). The free (unbound) mepivacaine concentration (micrograms per gram of tissue) in each sample was determined *via* the method of internal standards with the use of standard curves constructed for each sample species. Relative ratios of brain-to-blood and parotid saliva-to-blood mepivacaine concentrations were calculated.

RESULTS AND DISCUSSION

Acute Mepivacaine Hydrochloride Toxicity—Dose studies (12.5–400 mg/kg) indicated that the approximate subcutaneous LD_{50} of mepivacaine hydrochloride in 24–36-hr-old neonate rats was 150 mg/kg. The subcutaneous LD_{50} of mepivacaine in rats weighing 65–75 g was reported to be 500 ± 53 mg/kg (15). None of the neonates that received 25 mg of mepivacaine hydrochloride/kg sc manifested gross toxic symptoms, but four of the 14 newborns injected with 50 mg/kg exhibited decreased spontaneous motor activity. Subcutaneous doses of 25 and 50 mg/kg produced no remarkable symptomatology in adult female rats. These subtoxic doses resulted in quantifiable mepivacaine levels in neonate and adult rat tissues.

Adult and Neonate Blood Mepivacaine Levels—Concentrations of mepivacaine base in adult and neonate rat whole brain and blood and calculated brain-to-blood ratios of mepivacaine appear in Table I. Following subcutaneous administration of 25- and 50-mg/kg mepivacaine hydrochloride doses, the mepivacaine levels were significantly higher in neonate rat brain and blood than in the corresponding adult female rat tissues. However, there was no significant difference between the brain-to-blood mepivacaine concentration ratios calculated for adults and for neonates at either of the two doses of local anesthetic agent.

Other investigators reported that a significantly greater fraction of bupivacaine, an anesthetic structurally related to mepivacaine, is bound to human maternal plasma proteins than is bound to fetal plasma proteins over a wide drug concentration range (16, 17). Although protein binding determinations were not performed, the slope of standard GLC curves (as determined by linear regression analysis) constructed with mepivacaine-spiked neonate rat brain and blood were consistently steeper than those obtained with adult rat tissue.

Acute neonatal intoxication without concomitant signs of local anesthetic intoxication in the mother was observed in humans born to mothers who received epidural or paracervical block anesthesia with mepivacaine hydrochloride during labor (1, 4, 7, 9, 18). The neurological deficiencies observed in the newborn might be related to incomplete development of the neonatal blood–brain barrier; however, this study revealed no significant differences in the brain-to-blood ratios of mepivacaine between neonate and adult rats. The study did demonstrate considerably higher levels of unbound mepivacaine in the brain tissue and blood of 24–36-hr-old rats than in these tissues of adult female rats 15 min after subcutaneous injection of equivalent body weight doses of the local anesthetic.

Mepivacaine in Adult Rat Blood and Saliva—The saliva-to-blood ratio of mepivacaine was explored to evaluate the sensitivity and reproducibility of this salivary assay as a noninvasive technique relevant to clinical monitoring of the blood level of a local anesthetic in the newborn. Intravenous infusion of mepivacaine hydrochloride (200 μg/min) in adult rats established blood and salivary drug levels well within the quantitation range by the GLC assay (14). The mepivacaine base concentrations in blood and pilocarpine-stimulated parotid saliva collected throughout 30- and 45-min intraarterial mepivacaine hydrochloride infusions and the saliva-to-blood mepivacaine ratio for each collection period are summarized in Table II.

Although the salivary drug concentration data were reasonably consistent within any collection period (*i.e.*, 30 or 45 min), the saliva-to-blood mepivacaine ratio differed considerably, depending on the infusion time and the total dose of local anesthetic. Thus, this study failed to demonstrate a consistent relationship between the mepivacaine level in these two body fluid compartments that would support saliva sampling and analysis as a means of estimating the blood drug level. The salivary secretion rate in the rat necessitated collection of a 20–30-min sample for drug extraction; a larger animal model, permitting simultaneous sampling of saliva and blood, would be advantageous to explore the relative compartmentalization of mepivacaine.

GLC Microdetermination of Indomethacin in Plasma

MICHAEL A. EVANS

Received May 18, 1979, from the *Department of Pharmacology, University of Illinois at the Medical Center, Chicago, IL 60680.* Accepted for publication August 27, 1979.

Abstract □ A GLC method utilizing an electron-capture detector is described for analysis of indomethacin in blood plasma. Indomethacin is extracted with ethyl acetate from plasma buffered to pH 5.0. The ethyl acetate is evaporated to dryness, and indomethacin is derivatized to a pentafluoropropionyl ester prior to chromatography. A GLC standard is used for peak height quantitation of indomethacin. The extraction efficiency from plasma is 92 ± 3%, and as little as 1 ng of indomethacin can be quantitatively determined.

Keyphrases □ Indomethacin—GLC analysis, human plasma □ GLC—analysis, indomethacin in human plasma □ Anti-inflammatory agents—indomethacin, GLC analysis in human plasma

Indomethacin[1] is an extensively used anti-inflammatory drug with potent inhibitory action on prostaglandin synthesis. Recent studies demonstrated that the drug is also successful in the management of patent ductus arteriosus in the premature infant (1). Since complications of indomethacin therapy in the premature infant are associated with high plasma levels, a rapid and sensitive assay was needed for monitoring therapeutic plasma drug levels utilizing small samples. Several investigators recently reported sensitive analytical procedures for indomethacin in biological fluid; however, these procedures require several extractions (2, 3), lack an internal standard (4), and require an initial plasma sample of 0.5 ml (5). Therefore, an electron-capture GLC method was developed for monitoring therapeutic indomethacin levels in limited plasma samples (0.1 ml) utilizing a GLC standard for quantitation.

EXPERIMENTAL

Apparatus—A gas chromatograph[2] equipped with a ^{63}Ni-electron-capture detector was maintained with a high purity nitrogen column gas flow of 70 ml/min. The column oven temperature was 295°; the injection port and detector temperatures were maintained at 310°.

Column—A glass column, 2 m × 2 mm, was packed with 10% SP 2250 on 100–120-mesh Supelcoport[3]. The column was rinsed before packing with methanol and acetone; it was then dried and conditioned for 2 hr with a 20% solution of dimethyldichlorosilane[4] in toluene. Following silylation, the column was rinsed with acetone and dried under nitrogen before packing.

Procedures—Plasma (0.1 ml) was transferred to 1.5-ml polypropylene disposable micro test tubes[5], buffered to pH 5.0 with 0.1 ml of 0.2 *M* acetate buffer, and extracted with 1.0 ml of ethyl acetate. The ethyl acetate (0.9 ml) was transferred by disposable pipet to a dry, clean 1.5-ml micro test tube and evaporated to dryness using a vacuum centrifuge[6]. The residue was mixed with 10 μl of a mixture of 2,2,3,3,3-pentafluoro-1-propanol in pentafluoropropionic anhydride[7] (1:4, v/v) and heated to 75° for 20 min. Following derivatization, the sample was evaporated to dryness using the vacuum centrifuge; the residue was redissolved in 10 μl of ethyl acetate containing 2.5 μg of *p*-bromobenzaldehyde isonicotinoylhydrazone/ml as the internal standard.

One-microliter samples were injected into the gas chromatograph for analysis. The internal standard was prepared according to Timbrell *et al.* (6) by mixing equimolar amounts of isoniazid and *p*-bromobenzaldehyde in methanol and refluxing for 1 hr at 60°. After cooling for 24 hr at −20°, the crystalline product was filtered, washed twice with warm methanol, and recrystallized. The final product, *p*-bromobenzaldehyde isonicotinoylhydrazone, was found to be better than 98% pure by GLC and TLC.

A standard calibration curve was prepared by adding 0.1 ml of plasma to known amounts of indomethacin to give final indomethacin concentrations ranging from 0.01 to 1 μg/ml. Thirty samples, five per concentration, were analyzed to prepare the standard curve. Each sample was injected in duplicate, and the determination of the entire standard curve was replicated at once. 2-^{14}C-Indomethacin[8] was used to estimate the extraction efficiency of indomethacin from plasma by measurement of the total radioactivity in the extract.

RESULTS AND DISCUSSION

The electron-capture GLC retention times for derivatized indomethacin and the internal standard were 5.2 and 6.8 min, respectively. Chromatograms from a control human plasma and a plasma sample containing 31 ng of indomethacin, both with the internal standard, are shown in Fig. 1. Since peaks for both agents were symmetrical, quantitation was made by comparison of peak heights. Detector response and the calibration curve were linear over 0.01–1.0-μg/ml range. Blanks were prepared from plasma of drug-free subjects, and no peaks were observed that would interfere with the measurement of indomethacin or the internal standard. Plasma samples containing 5 μg/ml of salicylate or furosemide also did not interfere with indomethacin quantitation.

Linear regression analysis of the individual data points (n = 60) from the standards plotted as the ratio of the peak height of derivatized in-

GLC Microdetermination of Indomethacin in Plasma

MICHAEL A. EVANS

Received May 18, 1979, from the *Department of Pharmacology, University of Illinois at the Medical Center, Chicago, IL 60680.* Accepted for publication August 27, 1979.

Abstract □ A GLC method utilizing an electron-capture detector is described for analysis of indomethacin in blood plasma. Indomethacin is extracted with ethyl acetate from plasma buffered to pH 5.0. The ethyl acetate is evaporated to dryness, and indomethacin is derivatized to a pentafluoropropionyl ester prior to chromatography. A GLC standard is used for peak height quantitation of indomethacin. The extraction efficiency from plasma is 92 ± 3%, and as little as 1 ng of indomethacin can be quantitatively determined.

Keyphrases □ Indomethacin—GLC analysis, human plasma □ GLC—analysis, indomethacin in human plasma □ Anti-inflammatory agents—indomethacin, GLC analysis in human plasma

Indomethacin[1] is an extensively used anti-inflammatory drug with potent inhibitory action on prostaglandin synthesis. Recent studies demonstrated that the drug is also successful in the management of patent ductus arteriosus in the premature infant (1). Since complications of indomethacin therapy in the premature infant are associated with high plasma levels, a rapid and sensitive assay was needed for monitoring therapeutic plasma drug levels utilizing small samples. Several investigators recently reported sensitive analytical procedures for indomethacin in biological fluid; however, these procedures require several extractions (2, 3), lack an internal standard (4), and require an initial plasma sample of 0.5 ml (5). Therefore, an electron-capture GLC method was developed for monitoring therapeutic indomethacin levels in limited plasma samples (0.1 ml) utilizing a GLC standard for quantitation.

EXPERIMENTAL

Apparatus—A gas chromatograph[2] equipped with a ^{63}Ni-electron-capture detector was maintained with a high purity nitrogen column gas flow of 70 ml/min. The column oven temperature was 295°; the injection port and detector temperatures were maintained at 310°.

Column—A glass column, 2 m × 2 mm, was packed with 10% SP 2250 on 100–120-mesh Supelcoport[3]. The column was rinsed before packing with methanol and acetone; it was then dried and conditioned for 2 hr with a 20% solution of dimethyldichlorosilane[4] in toluene. Following silylation, the column was rinsed with acetone and dried under nitrogen before packing.

Procedures—Plasma (0.1 ml) was transferred to 1.5-ml polypropylene disposable micro test tubes[5], buffered to pH 5.0 with 0.1 ml of 0.2 *M* acetate buffer, and extracted with 1.0 ml of ethyl acetate. The ethyl acetate (0.9 ml) was transferred by disposable pipet to a dry, clean 1.5-ml micro test tube and evaporated to dryness using a vacuum centrifuge[6]. The residue was mixed with 10 μl of a mixture of 2,2,3,3,3-pentafluoro-1-propanol in pentafluoropropionic anhydride[7] (1:4, v/v) and heated to 75° for 20 min. Following derivatization, the sample was evaporated to dryness using the vacuum centrifuge; the residue was redissolved in 10 μl of ethyl acetate containing 2.5 μg of *p*-bromobenzaldehyde isonicotinoylhydrazone/ml as the internal standard.

One-microliter samples were injected into the gas chromatograph for analysis. The internal standard was prepared according to Timbrell *et al.* (6) by mixing equimolar amounts of isoniazid and *p*-bromobenzaldehyde in methanol and refluxing for 1 hr at 60°. After cooling for 24 hr at −20°, the crystalline product was filtered, washed twice with warm methanol, and recrystallized. The final product, *p*-bromobenzaldehyde isonicotinoylhydrazone, was found to be better than 98% pure by GLC and TLC.

A standard calibration curve was prepared by adding 0.1 ml of plasma to known amounts of indomethacin to give final indomethacin concentrations ranging from 0.01 to 1 μg/ml. Thirty samples, five per concentration, were analyzed to prepare the standard curve. Each sample was injected in duplicate, and the determination of the entire standard curve was replicated at once. 2-^{14}C-Indomethacin[8] was used to estimate the extraction efficiency of indomethacin from plasma by measurement of the total radioactivity in the extract.

RESULTS AND DISCUSSION

Peristaltic Dissolution Apparatus: Prediction of Relative *In Vivo* Performance of Prednisone Tablets in Humans

D. L. SIMMONS ˣ, A. A. LEGORE, and P. PICOTTE

Received March 23, 1979, from the *R & D Laboratories, Frank W. Horner Limited, Montreal H3C 2W6, Canada.* Accepted for publication August 29, 1979.

Abstract □ By utilizing a previously established correlation concept, the relative *in vivo* performance in humans of seven unknown prednisone tablets was predicted accurately from peristaltic dissolution rate data. A general discussion is presented on the role of the peristaltic apparatus in selecting a suitable dosage form at the developmental stage.

Keyphrases □ Prednisone—tablets, prediction of relative *in vivo* performance in humans, peristaltic dissolution apparatus □ Dissolution apparatus, peristaltic—prednisone tablets, prediction of relative *in vivo* performance in humans □ *In vitro–in vivo* correlation—prednisone tablets, prediction of relative *in vivo* performance in humans, peristaltic dissolution apparatus

In 1975, a peristaltic dissolution rate apparatus was developed that was capable of predicting the *in vivo* performance of tolbutamide tablets in beagle dogs (1). This work was extended later to include meprobamate tablets (2) and tolbutamide tablets marketed in Canada (3). Despite the excellent *in vitro–in vivo* correlations obtained, a prime concern was the reliance on beagles as an *in vivo* model and the absence of human data in the correlations.

The performance of the apparatus on tablets that had been evaluated in a human bioavailability study was tested in this study. Seven prednisone tablets commercially available in the United States, each containing 5 mg of prednisone, were submitted in coded form by the Food and Drug Administration (FDA). Based on the peristaltic dissolution data, the relative *in vivo* performance of the tablets was predicted accurately.

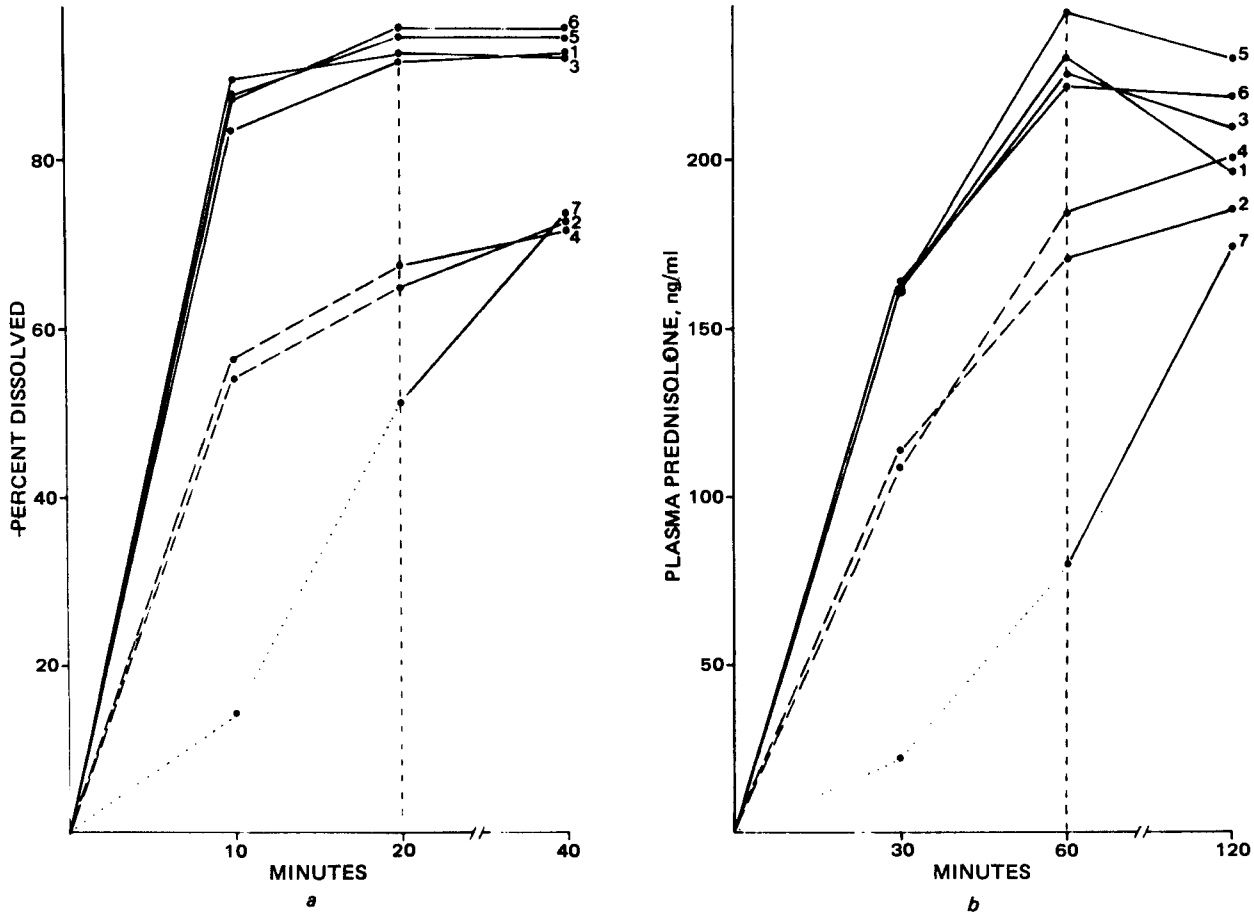

Figure 1—*Peristaltic dissolution plots of prednisone tablets* (a) *and prednisolone concentration–time plots of tablets* (b). *Key: See Table I. Dotted vertical lines at 20 and 60 min represent the maximum time intervals for* in vitro–in vivo *correlation. Relative performances of tablets from 0 to these times are categorized by solid, broken, and dotted lines.*

EXPERIMENTAL

Dissolution Rate Determinations—Dissolution rate profiles (Fig. 1*a*) for the prednisone tablets (5 mg) were obtained from the peristaltic dissolution rate assembly according to the conditions described previously (1). Aliquots (20 ml) of the dissolution medium, pH 7.6 tromethamine buffer, were removed at 10, 20, and 40 min and replenished with fresh buffer. Duplicate filtered aliquots (9 ml) were extracted separately with chloroform (3 × 5 ml), and the combined extracts from each sample were evaporated to dryness under nitrogen on a water bath.

The residues were dissolved in alcohol–chloroform (1:1, 0.5 ml) containing cholesteryl acetate[1] as an internal standard and were assayed for prednisone by GLC. The standard curve was obtained by spiking dissolution medium aliquots with known prednisone[2] quantities and performing the workup as described.

Chromatographic Conditions—The gas–liquid chromatograph[3] was equipped with a flame-ionization detector and a glass column (1.8 m × 6.2 mm o.d.) packed with 3% OV-17 on 80–100-mesh Gas Chrom Q. The column, detector, and injection port temperatures were 265, 295, and 278°, respectively. The carrier gas (nitrogen) flow rate was 48 ml/min. Air and hydrogen flow rates were adjusted for maximum sensitivity. The retention times for prednisone and cholesteryl acetate were 6.1 and 8.4 min, respectively.

RESULTS

In previous *in vitro–in vivo* correlation experiments (1–3) conducted with the peristaltic dissolution rate apparatus and blood drug level studies in beagles during the initial absorption phase, a direct relationship was established between *in vitro* data at t min and *in vivo* data at $3t$ min. By determining the dissolution rate profiles for the tablets during a 40-min period, their relative *in vivo* performance during a corresponding 120-min period was predicted accurately.

In this study, the average percent dissolved values also were obtained during the same *in vitro* period at 10, 20, and 40 min on the seven coded FDA prednisone tablets using the peristaltic dissolution assembly. These values are depicted graphically in Fig. 1*a*. Tablets 1, 3, 5, and 6 demonstrated comparable and excellent dissolution characteristics. Tablets 2 and 4 displayed mediocre dissolution profiles. Tablet 7 provided extremely poor initial performance and showed different intertablet disintegration characteristics, *e.g.*, two tablets in 23 min and one tablet in 32 min.

According to the correlation concept, these dissolution profiles were expected to reflect the relative *in vivo* performance of the tablets during a corresponding 120-min period. Tablets 1, 3, 5, and 6 were expected to exhibit identical drug absorption profiles. Conversely, Tablets 2, 4, and 7 were expected to display delayed drug absorption patterns, with a pronounced difference for Tablet 7.

This information was submitted to the FDA, which subsequently deciphered the code and confirmed that these prednisone tablets were from the same manufacturers and same lot numbers as those utilized in a comparative bioavailability study in human volunteers (4, 5). Figure 1*b* is a plot of the actual plasma prednisolone concentration *versus* time up to 120 min for 12 volunteers administered two 5-mg prednisone tablets. The data revealed that prednisone was absorbed and metabolized rapidly from Tablets 1, 3, 5, and 6 with a peak plasma prednisolone concentration of 222–244 ng/ml at 60 min. Tablets 2, 4, and 7 exhibited delayed drug absorption profiles. An examination of the two profiles in Figs. 1*a* and 1*b* demonstrates the ability of the peristaltic dissolution rate apparatus to simulate effectively the relative *in vivo* performance of the tablets.

Statistical treatment by regression analysis of the percent dissolved values for the tablets at 10 and 20 min *versus* plasma prednisolone concentrations at 30 and 60 min (Table I) revealed an extremely good fit with correlation coefficients of 0.995 and 0.923, respectively.

DISCUSSION

The peristaltic dissolution apparatus has provided the authors with complete assurance that a new product launched on the market is bioequivalent to an originator's product or formulated to present optimum drug release characteristics. This assurance has been demonstrated by the excellent *in vitro–in vivo* correlations obtained in beagle dog studies, comparative bioavailability evaluations in humans, and results from clinical studies.

The utility of the peristaltic apparatus in drug product design can be exemplified in the following manner. If the drug substance (*e.g.*, prednisone) has limited water solubility, a drug suspension is screened for dissolution characteristics in dilute hydrochloric acid solutions (0.1–0.001 *N*), distilled water, and pH 7.6 tromethamine buffer. This procedure is followed in the event that the drug exhibits polymorphism or possesses amphoteric characteristics and because of pH variations observed in gastric fluids (6). If the drug is available commercially, a minimum of six lots of the originator's product is subjected to the same dissolution treatment. Any tablet or capsule formulation developed in the laboratories then must comply with the dissolution profiles exhibited by the originator's product. This routine is followed through to production scaleup, and the first six production batches of a new product are monitored carefully by the peristaltic apparatus. Any formulation change including an increase in batch size is investigated for possible changes in drug release characteristics before the product is released for sale.

Additional *in vitro–in vivo* correlations obtained with the peristaltic dissolution apparatus and initial drug absorption profiles in beagles are under investigation.

High-Performance Liquid Chromatographic Determination of Isoniazid and 1-Isonicotinyl-2-lactosylhydrazine in Isoniazid Tablet Formulations

A. G. BUTTERFIELD ˣ, E. G. LOVERING, and R. W. SEARS

Received August 6, 1979, from the *Drug Research Laboratories, Health Protection Branch, Tunney's Pasture, Ottawa, Ontario K1A 0L2, Canada.* Accepted for publication August 30, 1979.

Abstract □ A high-performance liquid chromatographic procedure is presented for the simultaneous determination of isoniazid and 1-isonicotinyl-2-lactosylhydrazine (I) in isoniazid tablet formulations. An aliquot of a diluted aqueous tablet extract is introduced onto a microparticulate cyanopropyl bonded-phase column using a valve-loop injector and chromatographed using a mobile phase of acetonitrile–0.01 *M*, pH 3.5 aqueous acetate buffer (5:95). Compound I can be determined at levels as low as 0.5% of the isoniazid label claim. The relative standard deviations are 0.4 and 0.7% for the simultaneous determination of isoniazid and I, respectively. Seven commercial tablet formulations contained 93.8–97.0% of the labeled isoniazid amounts and 0.3–5.8% of I, expressed as equivalent isoniazid relative to the labeled isoniazid level.

Keyphrases □ High-performance liquid chromatography—simultaneous determination of isoniazid and 1-isonicotinyl-2-lactosylhydrazine, isoniazid tablet formulation analysis □ Isoniazid—high-performance liquid chromatography, isoniazid tablet formulation analysis, simultaneous determination with 1-isonicotinyl-2-lactosylhydrazine □ 1-Isonicotinyl-2-lactosylhydrazine—high-performance liquid chromatography, isoniazid tablet analysis, simultaneous determination with isoniazid

1-Isonicotinyl-2-lactosylhydrazine (I) has been reported in isoniazid tablets formulated with lactose (1, 2). The formation of I from the interaction of isoniazid and lactose is marked at high humidity and/or elevated temperatures (3). TLC of various isoniazid tablet formulations available in Canada showed appreciable levels of I. The USP XIX (4) nitrite titration assay for isoniazid responds quantitatively to the isoniazid moiety of I (5); therefore, an alternative procedure was required to monitor isoniazid formulations for I. Several colorimetric procedures (2, 6) are specific for isoniazid in the presence of I but cannot directly measure I.

A chromatographic method would be applicable to the rapid, simultaneous determination of isoniazid and I. TLC was unsuitable because of the difficulty in obtaining quantitative data, and GLC was rejected because of chromatographic difficulties with I. High-performance liquid chromatography (HPLC) has been used for isoniazid analysis in single- (1) and dual- (7) component formulations but has not been applied to the analysis of I except (1) to show that such compounds do not interfere with the isoniazid peak. A forward-phase HPLC system was developed recently for the simultaneous analysis of isoniazid and α- and β-1-glucopyranosyl-2-isonicotinylhydrazine

DISCUSSION

The peristaltic dissolution apparatus has provided the authors with complete assurance that a new product launched on the market is bioequivalent to an originator's product or formulated to present optimum drug release characteristics. This assurance has been demonstrated by the excellent *in vitro–in vivo* correlations obtained in beagle dog studies, comparative bioavailability evaluations in humans, and results from clinical studies.

The utility of the peristaltic apparatus in drug product design can be exemplified in the following manner. If the drug substance (*e.g.*, prednisone) has limited water solubility, a drug suspension is screened for dissolution characteristics in dilute hydrochloric acid solutions (0.1–0.001 *N*), distilled water, and pH 7.6 tromethamine buffer. This procedure is followed in the event that the drug exhibits polymorphism or possesses amphoteric characteristics and because of pH variations observed in gastric fluids (6). If the drug is available commercially, a minimum of six lots of the originator's product is subjected to the same dissolution treatment. Any tablet or capsule formulation developed in the laboratories then must comply with the dissolution profiles exhibited by the originator's product. This routine is followed through to production scaleup, and the first six production batches of a new product are monitored carefully by the peristaltic apparatus. Any formulation change including an increase in batch size is investigated for possible changes in drug release characteristics before the product is released for sale.

Additional *in vitro–in vivo* correlations obtained with the peristaltic dissolution apparatus and initial drug absorption profiles in beagles are under investigation.

High-Performance Liquid Chromatographic Determination of Isoniazid and 1-Isonicotinyl-2-lactosylhydrazine in Isoniazid Tablet Formulations

A. G. BUTTERFIELD ˣ, E. G. LOVERING, and R. W. SEARS

Received August 6, 1979, from the *Drug Research Laboratories, Health Protection Branch, Tunney's Pasture, Ottawa, Ontario K1A 0L2, Canada.* Accepted for publication August 30, 1979.

Abstract □ A high-performance liquid chromatographic procedure is presented for the simultaneous determination of isoniazid and 1-isonicotinyl-2-lactosylhydrazine (I) in isoniazid tablet formulations. An aliquot of a diluted aqueous tablet extract is introduced onto a microparticulate cyanopropyl bonded-phase column using a valve-loop injector and chromatographed using a mobile phase of acetonitrile–0.01 *M*, pH 3.5 aqueous acetate buffer (5:95). Compound I can be determined at levels as low as 0.5% of the isoniazid label claim. The relative standard deviations are 0.4 and 0.7% for the simultaneous determination of isoniazid and I, respectively. Seven commercial tablet formulations contained 93.8–97.0% of the labeled isoniazid amounts and 0.3–5.8% of I, expressed as equivalent isoniazid relative to the labeled isoniazid level.

Keyphrases □ High-performance liquid chromatography—simultaneous determination of isoniazid and 1-isonicotinyl-2-lactosylhydrazine, isoniazid tablet formulation analysis □ Isoniazid—high-performance liquid chromatography, isoniazid tablet formulation analysis, simultaneous determination with 1-isonicotinyl-2-lactosylhydrazine □ 1-Isonicotinyl-2-lactosylhydrazine—high-performance liquid chromatography, isoniazid tablet analysis, simultaneous determination with isoniazid

1-Isonicotinyl-2-lactosylhydrazine (I) has been reported in isoniazid tablets formulated with lactose (1, 2). The formation of I from the interaction of isoniazid and lactose is marked at high humidity and/or elevated temperatures (3). TLC of various isoniazid tablet formulations available in Canada showed appreciable levels of I. The USP XIX (4) nitrite titration assay for isoniazid responds quantitatively to the isoniazid moiety of I (5); therefore, an alternative procedure was required to monitor isoniazid formulations for I. Several colorimetric procedures (2, 6) are specific for isoniazid in the presence of I but cannot directly measure I.

A chromatographic method would be applicable to the rapid, simultaneous determination of isoniazid and I. TLC was unsuitable because of the difficulty in obtaining quantitative data, and GLC was rejected because of chromatographic difficulties with I. High-performance liquid chromatography (HPLC) has been used for isoniazid analysis in single- (1) and dual- (7) component formulations but has not been applied to the analysis of I except (1) to show that such compounds do not interfere with the isoniazid peak. A forward-phase HPLC system was developed recently for the simultaneous analysis of isoniazid and α- and β-1-glucopyranosyl-2-isonicotinylhydrazine

in isoniazid sugar syrup formulations[1]. However, this system is not applicable to the determination of I in isoniazid tablet formulations because of the late elution of and low sensitivity for I.

This article describes the HPLC system developed for the quantitation of low levels of I and isoniazid in isoniazid tablet formulations.

EXPERIMENTAL

Reagents and Chemicals—Isoniazid[2] raw material was assayed before use by the USP (4) procedure (100.5%), and its purity was confirmed by HPLC. Compound I was synthesized from 0.2 mole of isoniazid and 0.2 mole of lactose[3] in 200 ml of water at room temperature (23 ± 1°). After 7 days, a white, crystalline product was precipitated by the addition of a small amount of methanol and cooling to 4°. The product was filtered, washed with acetone, and recrystallized from water–methanol until the HPLC[4] and TLC[5] tests for residual isoniazid and lactose, respectively, were negative. The product purity, mp 214–216° (uncorr.) [lit. (8) mp 202°], was determined by the isoniazid moiety titration using the USP XIX (4) nitrite titration procedure.

All other reagents and chemicals were commercial analytical reagent grade except for the distilled water, which was double distilled and filtered through a 0.2-μm filter[6] before use.

Chromatography—The liquid chromatograph consisted of a single-piston metering pump[7], a valve-loop injector[8] equipped with a 10-μl loop, a fixed-wavelength UV detector[9] [254 nm, 0.02 absorbance unit full scale (aufs)], a 10-mv strip-chart recorder[10] connected to the recorder output, and an electronic-computing integrator[11] connected to the detector absorbance terminals.

The mobile phase, aqueous 0.01 *M* acetate buffer (pH 3.5)–acetonitrile (95:5 v/v), was pumped through a 3.2 × 250-mm cyanopropyl bonded-phase column[12] at 1.5 ml/min (80 bar).

Calibration Curves—Aqueous stock solutions of isoniazid, 5.0 mg/ml, and of I, 0.125 mg/ml, were prepared. Standard solutions were prepared by pipetting 1, 2, 3, 5, or 10 ml of the isoniazid stock solution into each of five 50-ml volumetric flasks along with 1, 2, 5, 10, or 20 ml of the I stock solution. Each standard solution was diluted to volume with water, and duplicate 10-μl aliquots of each were chromatographed.

Calibration Standard Solutions—Compound I, ~5 mg, and isoniazid, 50 mg, were weighed accurately, transferred to a 100-ml volumetric flask, dissolved, and diluted to volume with distilled water (Solution A). A second calibration standard was prepared by diluting 5.0 ml of Solution A to 25.0 ml with water (Solution B). Duplicate 10-μl aliquots of each calibration standard were chromatographed periodically to check the slopes of the calibration curves.

Analysis of Pharmaceuticals—*Single-Tablet Assay*—A tablet was placed in a 20 × 150-mm screw-capped culture tube[13] and finely powdered with a glass rod. Sufficient distilled water was added to give a theoretical isoniazid concentration of 5.0 mg/ml, *e.g.*, 20.0 ml of water for a 100-mg tablet. The tightly capped tube was rotated[14] at 30 rpm for 15 min and then centrifuged[15] briefly at 1000 rpm. Five milliliters of the clear aqueous supernate was transferred to a 50-ml volumetric flask and diluted to volume with distilled water. Duplicate 10-μl aliquots of the resulting solution were chromatographed.

Tablet Composite Assay—A tablet composite was prepared by grinding 20 tablets in a mechanical mill[16]. A quantity of powdered tablet material equivalent to 50 mg of isoniazid was transferred to a 20 × 150-mm screw-capped culture tube, 10 ml of water was added, and the sample was centrifuged and chromatographed as described under *Single-Tablet Assay*.

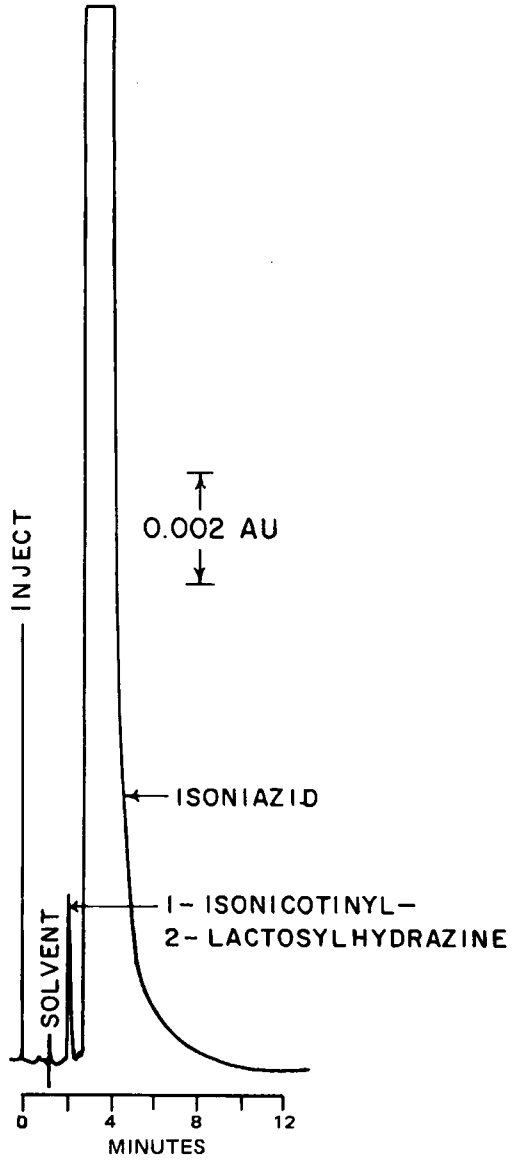

Figure 1—*High-performance liquid chromatogram of a typical isoniazid tablet extract.*

Quantitation—Quantitation was by comparison of the peak height for I and the peak area for isoniazid to the calibration standards and was based on absolute injection of 10-μl samples.

RESULTS AND DISCUSSION

Chromatographic System—Previous reports of HPLC systems for isoniazid analysis either did not describe the chromatographic behavior of I (7) or indicated a long retention time and, therefore, poor sensitivity (1). To achieve maximum sensitivity, reversed-phase HPLC was necessary to elute I ahead of isoniazid. Octadecyl bonded-phase columns[17] provided the desired elution order but gave retention times that decreased over a few days until both I and isoniazid eluted at the solvent front.

A cyanopropyl bonded-phase column[12] gave comparatively good results with the mobile phase described under *Experimental*. Satisfactory separations were obtained on three replicate cyanopropyl columns, each requiring somewhat different mobile phases. A simple water–acetonitrile

Table I—Retention Times for Isoniazid and Various Related Compounds

Compound	Retention Time[a], sec
Isoniazid	258
1-Isonicotinyl-2-lactosylhydrazine (I)	133
Isonicotinic acid	75[b]
Isonicotinamide	184
1-Isonicotinyl-2-glucosylhydrazine (II)	128
1-Isonicotinyl-2-galactosylhydrazine (III)	130
4-Aminosalicylic acid	79
Pyridoxine hydrochloride	>900

[a] The column was a 3.2 × 250-mm Spherisorb CN (5 μm), the flow rate was 1.5 ml/min, and the mobile phase was 5% acetonitrile in aqueous 0.01 *M* sodium acetate buffer (pH 3.5). [b] Solvent front (t_0).

(95:5) mobile phase initially eluted isoniazid as a retained peak, but retention decreased to zero over a few days. Substitution of a dilute aqueous acetate buffer for water in the mobile phase stabilized the retention time at a value dependent on the buffer pH and concentration. Increased retention times were obtained as the pH or ionic strength was decreased. Since retention times also increased as the acetonitrile proportion in the mobile phase was reduced, the separation mode can be described as reverse phase.

After several weeks, the retention times for isoniazid and I decreased to an unacceptable degree. The column was regenerated by pumping 1% aqueous HCl at 1.5 ml/min for 1 hr. On returning to the original mobile phase conditions, this procedure initially led to much longer retention times followed by a slow return to the original separation.

Figure 1 shows a chromatogram obtained when a representative tablet formulation was analyzed. The compounds were eluted in less than 12 min, a major portion of this time being necessary for the elution of the long tail on the isoniazid peak.

Various isoniazid-related compounds were chromatographed (Table I), either because of their possible occurrence as impurities or because they are sometimes formulated with isoniazid in two-component tablets. 1-Isonicotinyl-2-glucosylhydrazine (II) and 1-isonicotinyl-2-galactosylhydrazine (III) may be present in tablet formulations through isoniazid interaction with lactose hydrolysis products, glucose and galactose. Since I–III are not resolved, the procedure is not specific for I in the presence of these impurities. However, since the three compounds exhibited the same molar detector response, due entirely to the isoniazid moiety, total isoniazid in the form of sugar hydrazones may be determined by quantifying the peak at the retention time of I.

Linearity and Standard Curves—The isoniazid standard curve (peak area *versus* amount injected) was linear with a negligible intercept ($y = mx$) over 1.0–10.1 μg/injection (0.1–1.10 mg/ml). Similarly, the I standard curve (peak height *versus* amount injected) was linear with a negligible intercept ($y = mx$) over 25–500 ng/injection (2.5–50 μg/ml). Therefore, the standard curves are applicable to tablets containing 20–200% of the isoniazid label claim level and 0.5–10% of I (or 0.15–3.0% of I expressed as equivalent isoniazid).

Response factors were determined by two or more injections of two calibration solutions at the start of each day or whenever the mobile phase was replenished. Agreement of the response factors within 3% at the two levels was considered adequate but was typically better than 2%. After checking the response at two levels to show linearity, a single calibration standard was chromatographed periodically to check for response changes. Due to gradual hydrolysis of I, calibration standards must be prepared daily.

Sample Preparation—The time required for constant extraction of isoniazid and I from the tablet mass was determined by tumbling crushed single tablets of a representative formulation, 100 mg, for 5, 10, 15, 20, and 30 min in 20 ml of water. Each sample was centrifuged briefly at 1000 rpm, and 1.0 ml was diluted to 10.0 ml with water. Duplicate 10-μl aliquots of each diluted sample were chromatographed. The peak heights for I and the peak areas for isoniazid were the same in all samples, indicating constant extraction of both compounds in less than 5 min. Based on response factor data and the label claim for the formulation used, extraction also appeared to be complete, and a geometric dilution procedure substantiated this finding. When tablet composite samples equivalent to one-half, one, and two tablets were analyzed (15-min tumbling time), the I and isoniazid concentrations were both in the ratio 1:2:4, showing that complete extraction took <15 min.

Table II—HPLC Analysis of Isoniazid Tablet Formulations[a]

Formulation	Label Claim, mg	Compound I[b,c], %	Isoniazid, % label claim[b]
A	50	0.39	93.9
B	300	ND[d]	95.9
C	100	0.35	96.8
D	100	0.31	94.4
E	100	5.81	93.8
F	100	0.29	96.3
G	100	0.96	97.0

[a] Tablet composite assay. [b] Mean of duplicate assays. [c] Based on the isoniazid moiety of I, *i.e.*, isoniazid equivalent. [d] None detected.

Quantitation—Samples, 10 μl, were introduced *via* a valve-loop injector using the loop-fill mode. This absolute injection technique gave precise, accurate results and eliminated the need for an internal standard. Initially, peak area was used for both compounds; but during the procedure testing, the separation of isoniazid and I on different columns was usable over a wider resolution range when peak height was used for quantitation of I. Ten injections of a representative formulation extract gave relative standard deviations of 0.7 and 0.4% for I and isoniazid, respectively.

Analysis of five replicate composite samples of a representative isoniazid tablet formulation containing 3.3% of I (0.96% expressed as equivalent isoniazid) and 97.0% of the isoniazid label claim level gave relative standard deviations of 1.8 and 0.9%, respectively.

Seven commercial formulations were analyzed in duplicate (Table II). In tablets formulated with lactose, the I levels varied between 0.3 and 5.8%, expressed as equivalent isoniazid, while isoniazid levels varied between 93.8 and 97.0% of the label claim.

Comparative Analgesic, Behavioral, and Dependence Properties of Morphine and *O*-(4-Methoxylphenylcarbamoyl)-3-diethylaminopropiophenone Oxime Hydrochloride

NATHAN WATZMAN * **and JOSEPH P. BUCKLEY** ‡x

Received July 9, 1979, from the *Research Laboratories, Department of Pharmacology, School of Pharmacy, University of Pittsburgh, Pittsburgh, PA 15261.* Accepted for publication August 30, 1979. *Present address: Health Resources Administration, Department of Health, Education, and Welfare, Hyattsville, MD 20782. ‡Present address: College of Pharmacy, University of Houston, Houston, TX 77004.

Abstract □ The analgesic activity of *O*-(4-methoxylphenylcarbamoyl)-3-diethylaminopropiophenone oxime hydrochloride was investigated in Swiss–Webster mice using an electroshock technique in which the pain threshold was the minimum voltage producing tonic extension of the hindlimbs in response to an electroshock delivered to the feet. The analgesic potency of *O*-(4-methoxylphenylcarbamoyl)-3-diethylaminopropiophenone oxime hydrochloride was equal to, or greater than, that of morphine. Neither nalorphine nor withdrawal produced visible behavioral effects in rats treated with *O*-(4-methoxylphenylcarbamoyl)-3-diethylaminopropiophenone oxime hydrochloride for 21 days, suggesting that the physical dependency liability of the compound may be less than that of morphine.

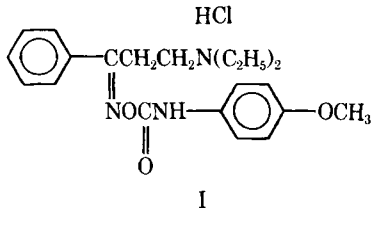
Keyphrases □ Morphine sulfate—comparative effects with *O*-(4-methoxylphenylcarbamoyl)-3-diethylaminopropiophenone oxime hydrochloride in rodents, pain threshold, physical dependency, tolerance, analgesic, withdrawal syndrome □ *O*-(4-Methoxylphenylcarbamoyl)-3-diethylaminopropiophenone oxime hydrochloride—analgesic, behavioral, and dependence properties, compared to morphine sulfate □ Analgesics—morphine sulfate, *O*-(4-methoxylphenylcarbamoyl)-3-diethylaminopropiophenone oxime hydrochloride, comparative studies in rodents

The clinical use of morphine has been limited by its undesirable capacity to induce tolerance and physical and psychogenic dependence. The synthesis of meperidine[1] (1) gave impetus to the search for new chemical molecules possessing the same pharmacological properties as morphine without the undesirable characteristics. Compounds such as methadone[2], unlike morphine in chemical structure, have been reported to possess the same or greater analgesic effects as morphine (2); unfortunately, they also possess the undesirable ability to produce the same three adaptive processes.

The present study investigated the analgesic activity of *O* - (4-methoxylphenylcarbamoyl)-3-diethylaminopropiophenone oxime hydrochloride (I) in rodents.

EXPERIMENTAL

Pain sensitivity was determined in 48 male albino mice[3] utilizing a modified flinch jump method (3). The aluminum test chamber contained four (10.2 × 10.2 × 10.2-cm) compartments with a grid floor designed so that 2-sec shocks of increasing intensity were delivered to the feet every 8 sec; timers and a grid scrambler[4] with a 1.5-megaohm resistor were used. Beginning with 143 v (0.1 mamp), the current was increased progressively until the pain threshold was reached or a maximum of 385 v (0.25 mamp) was applied without the pain response. The threshold was designed as the minimum voltage that produced tonic extension of the hindlimbs and jumping in response to three successive shocks applied at each voltage level. Four of the eight groups (six animals each) received placebo (0.9% saline, 0.1 ml/10 g body weight) or one of three doses of morphine sulfate (2, 5, or 10 mg/kg sc) 30 min before testing; the four other groups received placebo treatment or one of three doses of I identical to morphine.



I

To observe the chronic effects of the two test compounds as well as to monitor the morphine tolerance behavior, male Sprague–Dawley rats were administered the test compounds for 3 weeks in doses regarded as sufficient to produce addiction. Both compounds were administered subcutaneously according to the following dose schedule: 5, 10, and 20 mg/kg twice daily during the 1st, 2nd, and 3rd weeks, respectively. When 20 mg of I/kg was administered on the 15th day (Day 1 of the 3rd week), convulsions and death occurred in three of six animals. A similar morphine sulfate dose did not produce any marked changes.

Based on preliminary trials, 18 male Sprague–Dawley rats were divided into three equal treatment groups. Each group received, subcutaneously, I, morphine sulfate, or normal saline twice daily for 21 consecutive days according to the following morphine dosage schedule utilized by Gunne (4). For I, the initial dose (2.5 mg/kg/injection) was doubled every 7th day so that the dose level for each of the 3 weeks was 2.5, 5.0, and 10

mg/kg/injection, respectively. For morphine sulfate, the initial dose (20 mg/kg/injection) was tripled every 7th day so that the dose level for each of the 3 weeks was 20, 60, and 180 mg/kg/injection, respectively.

One animal died from the initial morphine dose. On the 22nd day (Day 1 of drug withdrawal), half of the animals of each group (two of the morphine-treated animals) were administered a single 10-mg/kg sc dose of the narcotic antagonist nalorphine[5] to precipitate withdrawal symptoms. The other half of the groups (three animals each) received no drugs. All animals were observed for 1 week in their individual observation cages and home cages.

RESULTS

Table I shows the response threshold to electrical shock for each of the 48 mice and the average threshold for each drug dosage. The thresholds for the two saline control groups were similar, and the effects of the compounds did not differ statistically in thresholds produced at the two lowest doses (2 and 5 mg/kg). However, I produced a greater increase in pain threshold than did morphine at the highest dose level (10 mg/kg). Three of six animals receiving the highest dose of I did not reach the response criteria, whereas only one of six animals treated with the same dose of morphine failed to reach the criteria.

The early stages of chronic morphine administration initially produced hyperactivity and headbobbing, with the head carried close to the ground. After 10 min, the hyperactivity was replaced by a cataleptic-like state in which the animals remained in peculiar postures with a fixed stare. By the 16th day (Day 2 of 180-mg/kg dose), the animals were sedated but their bodies were stiff when handled, indicating an increase in muscular tone and stimulation of the spinal cord. Water and food intake decreased with time, and the animals became increasingly more difficult to handle. They were hyperactive only immediately after injection, jumping onto the back of the cage and over each other, and then they assumed trance-like postures similar to the description by Gunne (4). No behavioral effects were noted at any I dose level. Manifestations of central nervous system depression (ataxia, *etc.*) as well as autonomic effects were reported (5) in rhesus monkeys chronically administered I for 40 days.

Figure 1 shows the weight gains for each drug group. Compound I-treated animals and the saline controls had similar weight gains, and their fur appeared normal throughout the study. However, the weight gain of the morphine-treated animals was far below that of the other two groups, and their fur was off-white or brownish. On the last weighing day (19th day), the mean weights ± *SE* for the saline-, I-, and morphine-treated groups were 383 ± 11.9, 341 ± 11.1, and 310 ± 5,1 g, respectively. These data were statistically different ($p < 0.05$) by the Student t test. There were no visible physical effects among the saline control animals.

A single nalorphine injection to the morphine-treated rats on the 1st withdrawal day produced extreme sedation, ptosis, and increased defecation with diarrhea, reflecting the expected precipitation of the withdrawal syndrome (6). These symptoms, except the diarrhea, disappeared by Day 5 of withdrawal. Withdrawn morphine-treated animals (no nalorphine) also showed sedation, ptosis, and diarrhea and they returned to normal by Day 5 of withdrawal. Compound I- and saline-treated animals were not affected visibly by nalorphine, and I did not demonstrate withdrawal-like symptoms. Compound I partially suppressed morphine abstinence in morphine-dependent rhesus monkeys, reflecting some morphine antagonist properties of its own (7).

[5] Nalline, Merck Sharp & Dohme, West Point, Pa.

DISCUSSION

Data from the pain threshold study indicate that I has analgesic potency equal to or greater than morphine. Although the compounds did not differ in the pain thresholds produced at the two lowest doses, I induced a greater threshold increase at the highest dose (10 mg/kg). The differences in potency between the two compounds would have been greater had the trials continued beyond the maximum experimental voltage (385 v) and every animal reached criteria. Three of the six I-treated animals did not reach criteria compared to only one of the six in the morphine group.

The basic behavior elicited by chronic morphine administration to rats was an initial hyperactivity followed by a cataleptic-like immobile state with fixed stare. As the program progressed, the initial hyperactivity increased and the animals became more difficult to handle. The major effects of morphine withdrawal and nalorphine in morphine-treated rats were sedation, ptosis, and increased defecation with diarrhea. No such behavioral effects were produced by chronic I administration.

There were no qualitative differences between the morphine–nalorphine-treated animals and the morphine-withdrawn animals, except that diarrhea persisted longer in the former group. Thus, nalorphine apparently precipitated withdrawal-like symptoms. Neither nalorphine-administered I animals nor withdrawal from I produced any visible behavioral effects. The marked difference between the doses of I and morphine sulfate should not negate the results since, within experimental design limits, the animals did not develop a tolerance to the experimental compounds. Therefore, the data suggest that I does not produce the same autonomic and behavioral effects as morphine, nor do I-treated animals display the same syndrome of effects when withdrawn from the drug.

Oral and Rectal Absorption of Chloral Hydrate and Its Betaine Complex

MICHAEL SIMPSON and EUGENE L. PARROTT ˣ

Received July 30, 1979, from the *Division of Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication September 21, 1979.

Abstract □ Chloral hydrate and its betaine complex were administered orally and rectally to nine healthy male subjects. The urinary excretion, which was a reflection of absorption, of a metabolite, trichloroacetic acid, was determined. No statistically significant difference was found between the oral absorption of chloral hydrate and its betaine complex and between the rectal absorption of chloral hydrate and its betaine complex. A statistical difference was found between the oral and rectal absorption of chloral hydrate and between the oral and rectal absorption of chloral betaine.

Keyphrases □ Chloral hydrate—oral and rectal absorption, compared to chloral betaine □ Chloral betaine—oral and rectal absorption, compared to chloral hydrate □ Absorption—oral and rectal, comparison of chloral hydrate and chloral betaine

The solubility, diffusivity, and lipid–water partition coefficient of drug complexes can differ significantly from these properties of the respective free drug. Therefore, some drug complexes may not penetrate biological membranes and thus have no biological activity (1). Conversely, if a complex is highly dissociated when diluted in biological fluids, complexation has little effect on absorption.

Several derivatives of chloral hydrate have been prepared and tried clinically to reduce or eliminate its bitter taste and gastric irritation (2, 3). Chloral betaine is a 1:1 complex of chloral hydrate and betaine (4). The purpose of this study was to determine if complexation influenced the absorption of an equivalent weight of chloral hydrate and chloral betaine by the oral and rectal routes. The availability of chloral hydrate and chloral betaine from rectal and oral administrations also was compared.

EXPERIMENTAL

Preparation—Chloral betaine was prepared by mixing 135.2 g of betaine monohydrate[1] with 200.2 g of chloral hydrate[2] and warming the mixture on a water bath at 60° (4). The pasty mixture was stirred continuously at 60° for 30 min. The solid residue was crystallized three times from a minimum of distilled water and was stored in a desiccator.

The crystals were compared to the NF reference standard[3] and to NF specifications (5). The melting point of the chloral betaine was determined[4] to be 121.5–123°. With sodium hydroxide TS, the chloral betaine produced chloroform, which was recognized by its odor (5). Measurement[5] of the IR spectra showed that the NF reference standard and the chloral betaine were similar. Differential thermal analysis[6] of the NF reference standard and the chloral betaine showed a single melting point at the same temperature.

The chloral betaine contained 7.97% of moisture by Karl Fischer titration; the NF specification is 5.9–7.5% (5). The excessive moisture was considered in the dose administered, so 881.5 mg of chloral betaine was equivalent to 500 mg of chloral hydrate in this study. The content of chloral hydrate in the chloral betaine assayed as 57.71%, within the NF specification of 56.0–59.5% (5). The amount of betaine was 41.54%, within the NF specification of 40–44% (5).

In the preparation of capsules, each compound was passed through a 60-mesh screen; then 500 mg of chloral hydrate and 881 mg of chloral betaine were placed in 00 and 000 hard gelatin capsules, respectively. Each capsule was stored in a coded, amber, screw-capped bottle.

The suppository base consisted of 24% beeswax[7] in cocoa butter[8] prepared by the fusion method. The base was stored in a cool room for 4 weeks prior to use. In the preparation of suppositories, each compound was passed through a 60-mesh screen; then equivalent weights of chloral hydrate and chloral betaine were manually incorporated in 2.5 g of the base. Each suppository was wrapped in aluminum foil with an inner lining of Parafilm and stored in a screw-capped bottle in a refrigerator until 10–15 min before insertion.

Protocol—All dosage forms were coded and were distributed by a crossover design with overnight fasting; 2 weeks elapsed between the administration of each dosage form. Three subjects did not continue the study after the first dose so the study was completed utilizing nine male subjects from 23 to 39 years of age and weighing 60–73 kg.

Upon arising, the bladder was voided, and a capsule was ingested with 300 ml of water. With rectal administration, the bladder was voided upon arising, the bowel was evacuated, a suppository was inserted high in the rectum, and 300 ml of water was ingested. At least 2 hr was allowed to elapse before food was eaten. Subjects were instructed not to ingest alcoholic beverages and coffee and not to operate machinery during the day.

Urine samples were collected at 2, 4, 6, 8, 10, 12, 16, and 24 hr after drug administration. Volumes were measured, and aliquots were retained in amber vials for analysis. No attempt was made to control the urinary pH. The urinary pH was determined at the time of each sample collection; for a given subject, the fluctuation of pH did not exceed 1.2 pH units.

Analytical Method—Since chloral hydrate has a very short half-life in the body and is not excreted as such, the urine was analyzed for trichloroacetic acid, one of the metabolites. The trichloroacetic acid excreted in the urine was determined by the method of Cabana and Gessner (6).

Statistics—The significance of the difference between the means was calculated using the Student t test, two tail ($p = 0.05$).

RESULTS AND DISCUSSION

Chloral hydrate is rapidly and completely absorbed after oral administration (7, 8), and relatively high concentrations of trichloroacetic acid are found in the blood coincident with the appearance of trichloroethanol after oral administration (9). After rectal administration, chloral hydrate is also converted to trichloroacetic acid and trichloroethanol (10). It appears that chloral hydrate is converted to its metabolites during the first pass through the liver (10), and chloral hydrate is not detectable in the blood at levels as low as 0.5 μg/ml 10 min after administration (10, 11). Chloral hydrate is biotransformed and is excreted as trichloroacetic acid, trichloroethanol, and trichloroethanol glucuronide. Trichloroacetic acid is also formed from trichloroethanol and is excreted in the urine (8, 10, 12).

Since the biotransformation of chloral hydrate is complex with a wide biological variation, a comparative study of chloral hydrate and chloral betaine administered by oral and rectal routes was based on the urinary excretion of trichloroacetic acid with the assumption that in a given subject this biotransformation would be essentially the same. In the crossover study, 500 mg of chloral hydrate or an equivalent weight of chloral betaine was administered in a hard gelatin capsule and in a cocoa butter suppository to nine male subjects. Plots of the milligrams excreted against time to each subject are not given; however, the individual plots

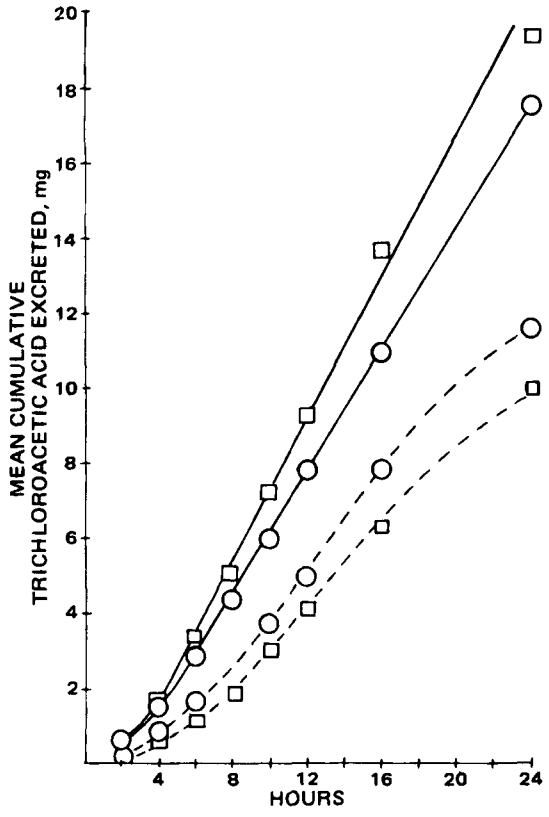

Figure 1—*Mean cumulative milligrams of trichloroacetic acid excreted by nine subjects in 24 hr after administration of 500 mg equivalent of chloral hydrate and chloral betaine in a capsule and in a suppository. Key: —, capsule; – –, suppository; ○, chloral hydrate; and □, chloral betaine.*

follow the general pattern shown in Fig. 1 for the mean cumulative amount of trichloroacetic acid for nine subjects as given in Table I.

It has been observed that complexes may alter absorption (1). Perhaps the most often observed complex formation is between various drugs and macromolecules such as gums, cellulose derivatives, and high molecular weight polyols. The nonabsorbable nature of this type of interaction (amphetamine with carboxymethylcellulose sodium; phenobarbital with polyethylene glycol 4000) provides ample explanation for the nonabsorbable character of the drug complex. With other types of complexes, the dilution of the drug complex in the biological fluids after administration may result in its complete dissociation so that the complexation has little or no effect on absorption. Soci and Parrott (13) noted that methylcellulose and carbomer complexed with nitrofurantoin *in vitro* but that this complexation did not interfere with GI absorption in humans. It was of interest to consider the influence of complexation by comparing the excretion of trichloroacetic acid after the administration of chloral hydrate and its betaine complex.

The significance of the difference between the means in Table I was calculated using the Student *t* test. There was no significant difference between the oral administration of an equivalent weight of chloral hydrate and chloral betaine. Likewise, there was no statistically significant difference between the rectal administration of an equivalent weight of chloral hydrate and chloral betaine (Fig. 1).

Table I—Mean Cumulative Milligrams (±*SD*) of Trichloroacetic Acid Excreted in 24 hr after Oral and Rectal Administration of 500 mg Equivalent of Chloral Hydrate and Chloral Betaine

	Oral		Rectal	
Hours	Chloral Hydrate	Chloral Betaine	Chloral Hydrate	Chloral Betaine
2	0.63 ± 0.52	0.69 ± 0.39	0.29 ± 0.20	0.18 ± 0.17
4	1.52 ± 0.87	1.65 ± 0.63	0.86 ± 0.51	0.51 ± 0.38
6	2.87 ± 0.97	4.44 ± 1.61	1.65 ± 0.81	1.07 ± 0.86
8	4.28 ± 1.74	5.06 ± 1.87	—	1.87 ± 1.45
10	6.01 ± 2.16	7.17 ± 2.55	3.76 ± 1.67	3.04 ± 2.34
12	7.41 ± 2.91	9.31 ± 3.48	4.92 ± 2.08	4.16 ± 3.20
16	11.49 ± 4.58	13.76 ± 4.92	7.84 ± 4.18	6.31 ± 4.53
24	17.17 ± 7.67	19.48 ± 7.15	11.62 ± 6.30	10.04 ± 7.17

Chloral hydrate may be administered rectally, especially in infants and children, to avoid bad taste and gastric irritation (14); however, it may be irritating to the rectal mucosa. The Student *t* test and the data in Table I indicated a significant difference between the oral and rectal administration of chloral hydrate. As shown in Fig. 1, more trichloroacetic acid was excreted after the oral administration of 500 mg of chloral hydrate than after rectal administration by means of a suppository.

There was also a significant difference between the oral and rectal administration of chloral betaine. As shown in Fig. 1, more trichloroacetic acid was excreted after oral administration than after rectal administration. Thus, although the chloral betaine complex is absorbed rectally, it appears that the rectal dose required is somewhat greater than the oral dose.

^{13}C-NMR Spectroscopy of Three Tetracycline Antibiotics: Minocycline Hydrochloride, Meclocycline, and Rolitetracycline

EUGENE P. MAZZOLA *x, JUDITH A. MELIN §, and LOLA G. WAYLAND ‡

Received March 16, 1979, from the **Division of Chemistry and Physics, Bureau of Foods, Food and Drug Administration, Washington, DC 20204,* and the ‡*National Center for Antibiotics Analysis, Bureau of Drugs, Food and Drug Administration, Washington, DC 20204.* Accepted for publication September 13, 1979. §Undergraduate Federal Summer Intern, Radcliffe College, Cambridge, Mass.

Abstract □ ^{13}C-NMR data and spectral assignments are presented for tetracycline antibiotics minocycline hydrochloride, meclocycline, and rolitetracycline.

Keyphrases □ Tetracyclines—^{13}C-NMR spectra, chemical shifts assigned □ ^{13}C-NMR spectroscopy—tetracyclines, chemical shifts assigned □ Antibacterials—tetracyclines, ^{13}C-NMR spectra, chemical shifts assigned

PMR and, recently, ^{13}C-NMR spectroscopy have been widely applied to the characterization of tetracycline antibiotics (1–11). ^{13}C-NMR spectral analyses have been reported for tetracycline hydrochloride (I) and base (II) and the following related hydrochloride salts: chlortetracycline (III), methacycline (IV) (6-methyleneoxytetracycline), oxytetracycline, doxycycline (6-deoxyoxytetracycline), and demeclocycline (demethylchlortetracycline) (12).

This paper reports the ^{13}C-NMR data and spectral assignments for rolitetracycline (V) (*N*-pyrrolidinomethyltetracycline), minocycline hydrochloride (VI) (7-dimethylamino-6-demethyldeoxytetracycline hydrochloride), and meclocycline (VII) (7-chloro-6-methyleneoxytetracycline). These three tetracyclines gave rise to ^{13}C-NMR signals that could be tentatively assigned by virtue of their similarity to those of the six tetracycline antibiotics examined by Asleson and Frank (12). However, because several groups of resonance lines in the three tetracyclines were sufficiently closely spaced and different from those of the previously characterized tetracyclines, further study was necessary to clarify the assignments.

EXPERIMENTAL

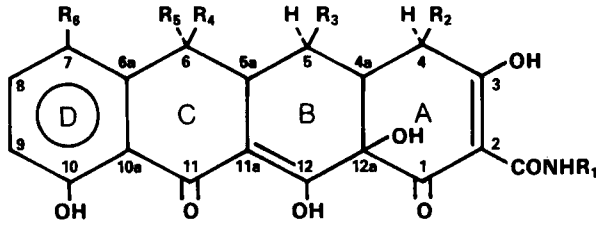
NMR Spectra—^{13}C-NMR spectra, described by 4096 data points, were obtained at 20 MHz[1]. Pulse widths of 10 μsec were used, which correspond to tip angles of 45° with 10-mm sample tubes. Single-frequency off-resonance decoupled (SFORD) ^{13}C-NMR spectra were obtained with proton-decoupling frequencies about 600 Hz upfield from tetramethylsilane and at full decoupling power levels. Spin-lattice relaxation times, T_1, were determined for two particular ^{13}C-nuclei of VII using the inversion–recovery method (13, 14).

The delay time, T, between sequences was 15 sec; the intervals between the 180 and 90° pulses, τ, were 0.1, 0.2, 0.6, 0.8, 1.2, 1.4, 1.8, 2.2, 2.8, and 4.0 sec. Approximately 0.2 *M* solutions of these tetracyclines were prepared in dimethyl sulfoxide-d_6, and ~0.1 *M* solutions were prepared in deuterium oxide. The latter were used to locate carbon signals obscured by the dimethyl sulfoxide-d_6 solvent.

Compounds—Minocycline hydrochloride, meclocyline, and rolitetracycline official and proposed FDA working standards were obtained from the National Center for Antibiotics Analysis.

RESULTS AND DISCUSSION

The ^{13}C-NMR spectrum of V (Table I), as expected, closely resembled that of II, so assignment of most resonance lines was straightforward. One notable exception in terms of chemical shift value was the amide carbon which, at 168.3 ppm, was more shielded than that of II at 172.6 ppm. Such a change in shielding for amide carbons is, however, expected upon conversion of a primary to a secondary amide (15). Four triplet signals at 22.5, 23.6, 50.1, and 56.6 ppm in an SFORD spectrum corresponded to the pyrrolidine α- and β-carbons, C-5, and the pyrrolidino *N*-methylene carbon. The pyrrolidine carbons at 23.6 and 50.1 ppm were readily distinguished from C-5 (22.5 ppm) and the pyrrolidino *N*-methylene carbon (56.6 ppm) on the basis of their double intensities, due to symmetry, in the nuclear Overhauser effect-suppressed proton noise-decoupled spectrum used to count carbon atoms (16). Moreover, the signals at 50.1 and 56.6 ppm were in the range expected for methylene carbons bonded to nitrogen and were so assigned (16).



general tetracycline structure

	R_1	R_2	R_3	R_4	R_5	R_6
I	H	$N(CH_3)_2$·HCl	H	CH_3	OH	H
II	H	$N(CH_3)_2$	H	CH_3	OH	H
III	H	$N(CH_3)_2$·HCl	H	CH_3	OH	Cl
IV	H	$N(CH_3)_2$·HCl	OH	$=CH_2$		H
V	$CH_2NC_4H_8$	$N(CH_3)_2$	H	CH_3	OH	H
VI	H	$N(CH_3)_2$·HCl	H	H	H	$N(CH_3)_2$
VII	H	$N(CH_3)_2$	OH	$=CH_2$		Cl

The carbon spectrum of VI was somewhat different from the spectra of the other tetracyclines (12) partly because VI is the only member of this family possessing methylene carbons in both the B- and C-rings—*viz.*, C-5 and C-6, and a dimethylamino group attached to the D-ring. With respect to the D-ring, the signals at 136.6 and 157.4 ppm are characteristic of quaternary carbons bonded to nitrogen and oxygen, respectively (16), and were assigned to C-7 and C-10, respectively. The two methine carbons in the D-ring, C-8 and C-9, were easily identified in an SFORD spectrum as the doublets at 115.6 and 128.5 ppm. The former was assigned to C-9 by comparison with C-9 signals of the other tetracyclines (16). The latter (C-8) was shielded by the *o*-dimethylamino group relative to the other tetracyclines, as is C-6a, to which the signal at 142.2 ppm was assigned (16).

Assignment of the triplets due to C-5 and C-6 and of the close-lying doublets due to C-4a and C-5a in the SFORD spectrum was developed in the following manner. The triplet at 33.8 ppm was assigned to C-6 because this carbon is benzylic and is expected to be more deshielded than the other methylene carbon, C-5, which appears at 29.6 ppm (16). The doublet at 35.1 ppm was assigned to C-4a by comparison with C-4a signals of the other tetracyclines (12), leaving C-5a at 31.6 ppm. With I as a model, removal of the methyl and hydroxyl groups from C-6 to produce a structure like VI is expected to have a much greater effect on C-5a, which is shielded by about 10 ppm, than on C-4a, which is essentially unchanged. The quartet at 41.2 ppm was assigned to the carbons of the D-ring dimethylamino group, and that at 44.4 ppm was assigned to those of the A-ring dimethylammonium group. The carbons of the latter group are expected to be more deshielded because of the positively charged nitrogen atom.

As anticipated, the carbon spectrum of VII was similar to spectra of III and IV. Like VI, the methine carbons, C-8 and C-9, were readily identified in an SFORD spectrum and assigned to the doublets at 137.8 and 118.3 ppm, respectively, by comparison with corresponding carbon signals of III. Further examination permitted differentiation of the doublet due to C-4 from that of C-5, these two signals being observed at 64.9 and 65.5 ppm, respectively. However, the components of the low-field doublet were relatively sharp while those of the high-field doublet exhibited considerable splitting due to long-range coupling, *i.e.*, two bonds or more. Since C-4 should be coupled to the six methyl protons of the 4-dimethylamino group and C-5 does not appear to have as extensive coupling possibilities, the signal at 64.9 ppm was assigned to C-4. Moreover, the doublets assigned to C-4 in I, III, IV, and VI all displayed similar long-range coupling compared with other doublet signals.

Examination of a fully coupled spectrum of meclocycline allowed the signal of C-7 to be distinguished from that of C-10a. Two singlet signals were observed at 116.6 and 119.6 ppm in the SFORD spectrum and were ascribed to the quaternary carbons C-7 and C-10a. In the fully coupled spectrum, however, the low-field signal appeared as a doublet of doublets, with coupling constants of 4 and 7 Hz, while the high-field signal was observed as a 7-Hz doublet. Since both carbons should exhibit *trans*-oriented three-bond couplings to H-9 and since C-7 should be coupled to H-8 as well, the four-line signal at 119.6 ppm was assigned to C-7 and the doublet at 116.6 ppm was assigned to C-10a. The remaining doublets at 40 and 45.4 ppm were assigned to C-4a and C-5a, respectively, by comparison with analogous carbon signals of the other tetracyclines (12). In these compounds, C-4a resonances were consistently ~5 ppm upfield from those attributed to C-5a carbons; in IV, these two carbons appeared at 41 and 44 ppm, respectively.

Several lines of reasoning led to the assignment of signals at 136.9 and 138.6 ppm to C-6 and C-6a, respectively. First, in the SFORD spectrum the low-field signal was considerably broader than the high-field one, which was only 1 Hz wider than the corresponding resonance line in the proton noise-decoupled spectrum. Inspection of VII revealed that C-6a should be *trans*-coupled to one exocyclic methylene proton and *cis*-coupled to the other and should exhibit a *trans*-oriented three-bond coupling to H-8. While C-6 ought, in principle, to be coupled to these same exocyclic methylene protons, the olefinic *cis* and *trans* three-bond couplings of C-6a should be larger and result in a wider signal for this carbon in the SFORD spectrum (17–19). Therefore, the low-field signal was tentatively assigned to C-6a.

Second, a selective heteronuclear decoupling experiment was carried out in which H-8, at 7.67 ppm, was irradiated while an otherwise fully coupled spectrum of VII was obtained. The signal at 138.6 ppm (tentatively assigned to C-6a) appeared to sharpen compared with the corresponding signal in a control, fully coupled spectrum, while that at 136.9 ppm apparently remained unchanged. Since C-6a is expected to show a larger coupling to H-8 than is C-6 (*trans*-oriented three-bond coupling *versus* allylic-type four-bond coupling) (17–19), the low-field signal was assigned to C-6a, consistent with the first results.

Third, spin-lattice relaxation times, T_1, were determined for the two signals. The resonance at 136.9 ppm had a T_1 value of 0.7 sec while that of the 138.6-ppm signal was 2.5 sec. Examination of a Dreiding model of VII demonstrated that C-6 is situated approximately 2 Å from both the two exocyclic methylene protons and H-5a while C-6a is located about 2.5 Å from the nearer exocyclic methylene proton and about 3 Å, or greater, from H-9, H-5a, and the further exocyclic methylene proton. Due to the substantial decrease in effectiveness of the dipole–dipole relaxation mechanism with increasing internuclear distance (13), C-6 would be expected to have a shorter T_1 value than C-6a. Therefore, the signal at 136.9 ppm was assigned to C-6, again consistent with the initial assignment.

Synthesis of 1-*O*-(2′-Acetoxy)benzoyl-α-D-2-deoxyglucopyranose, a Novel Aspirin Prodrug

J. E. TRUELOVE *, A. A. HUSSAIN ˣ, and H. B. KOSTENBAUDER

Received March 23, 1979, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication September 12, 1979. *Present address: Wyeth Laboratories, Paoli, PA 19301.

Abstract □ The synthesis and characterization of 1-*O*-(2′-acetoxy)-benzoyl-α-D-2-deoxyglucopyranose, a novel aspirin prodrug, are described. 3,4,6-Tri-*O*-benzyl-α-D-2-deoxyglucopyranose was synthesized by methylating the anomeric hydroxyl group of 2-deoxyglucose, benzylating the 3-, 4-, and 6-hydroxy functional groups, and cleaving hydrolytically the anomeric methyl group. Reaction of the tribenzylated sugar with the acid chloride of aspirin and subsequent hydrogenolysis of the benzyl groups resulted in the prodrug, mp 128°. The compound was further characterized by elemental analysis and PMR and ^{13}C-NMR spectroscopy. *In vitro*, the compound cleaved to aspirin with a half-life of 7 min at 37°. Prodrug cleavage was independent of pH over the pH 3–9 range.

Keyphrases □ 1-*O*-(2′-Acetoxy)benzoyl -α-D- 2-deoxyglucopyranose —aspirin prodrug, synthesis □ Aspirin prodrugs—synthesis of 1-*O*-(2′-acetoxy)benzoyl-α-D-2-deoxyglucopyranose □ Prodrugs—aspirin, synthesis of 1-*O*-(2′-acetoxy)benzoyl-α-D-2-deoxyglucopyranose

Aspirin, probably the most widely used drug in the world, is a potent, effective, and low cost medicament. However, it produces occult GI blood loss in a large percentage of patients (1–6). Studies have also shown that gastric irritation is a local effect (6) of contact of the mucosa with the highly acidic aspirin particles or the saturated solution surrounding those particles. Although GI bleeding can be prevented by administration of aspirin in a highly buffered solution (7), the high sodium content of such buffered products makes their chronic use impractical (6).

Previous communications showed that the acylal derivative 1-ethoxy(ethyl-2-acetoxy)benzoate is an oily, insoluble compound which cleaves very rapidly, generating aspirin (8), and that the acylal 1-*O*-(2′-acetoxy)benzoyl-α-D-glucopyranose is a more soluble, crystalline compound which only slowly generates aspirin in solution (9).

The present report describes the synthesis of the prodrug 1-*O*-(2′-acetoxy)benzoyl-α-D-2-deoxyglucopyranose (V), a crystalline compound that cleaves to aspirin *in vitro* in a reaction that is independent of pH; it has a half-life of 7 min at 37° (10). The prodrug, a neutral compound, should generate a nonirritating aspirin solution upon contact with the gastric milieu.

EXPERIMENTAL

Materials—The following materials were reagent grade or equivalent: methanol, sodium carbonate, acetone, absolute ethanol, ethyl acetate, potassium hydroxide, dry dioxane, dry pyridine, ethyl ether, sodium sulfate, acetic acid, sulfuric acid, dichloromethane, sodium bicarbonate, palladium-on-carbon, petroleum ether, and chloroform. 2-Deoxyglucose[1] and *o*-acetylsalicyloyl chloride[2] were used as received. Benzyl chloride[2] was redistilled at 175 ± 0.5°.

Synthesis—The general procedure for the synthesis of the prodrug (V) was a modification of that of Glaudemans and Fletcher (11).

α-Methyl-2-deoxyglucopyranose (I)—A solution of the starting material, 2-deoxyglucose (15 g, 0.09 mole), in 2% methanolic hydrochloric acid (540 ml) was warmed to 40° and shaken for 1 hr. After cooling to 20°, the mixture was stirred with excess sodium carbonate (32 g) for 15 min. After filtration, the solvent was removed under reduced pressure to give an oil containing a small amount of white solid.

The oil was dissolved in acetone (750 ml) and, after filtration and solvent removal, crystallized from 5 ml of ethanol at −5°. The crystalline material (I) was recovered by filtration and washed with cold (−5°) ethyl acetate. The yield was 10 g (61%), mp 91–92°[3] [lit. (12) mp 91–92°]; NMR[4] (dimethyl sulfoxide-d_6): δ 4.1–4.8 (m, 3H, OH), 3.1–4.1 (m, 9H, 3-6-H's, 1-H, OCH_3), and 1.1–2.3 (m, 2H, 2-H's).

*α-Methyl-3,4,6-tri-*O*-benzyl-2-deoxy-D-glucopyranose (II)*—Nine grams (0.05 mole) of I was added to a suspension of finely powdered potassium hydroxide (44.8 g) in dry dioxane (110 ml), and the mixture was warmed to reflux. As soon as reflux was smooth, colorless benzyl chloride (62 ml) was added dropwise over 45 min. After an additional 40 min of refluxing, the dioxane was distilled off during 3 hr. After cooling, the residue was diluted to 350 ml with water and extracted with ether.

The ether portions were dried and, after filtration, evaporated at reduced pressure to give an oil. The oil was subjected to vacuum distillation (bath temperature of 200°, 0.4 mm Hg). The oily product (II) remained in the distillation vessel in ~100% yield; NMR ($CDCl_3$): δ 6.7–7.7 (m, 15H, ArH), 4.2–5.0 (m, 7H, ring-CH_2–, 1-H), 3.3–4.2 (m, 5H, 3-6-H's), 3.2 (s, 3H, OCH_3), and 1.4–2.5 (m, 2H, 2-H's).

*3,4,6-Tri-*O*-benzyl-α-D-2-deoxyglucopyranose (III)*—Compound II (22.3 g, 0.05 mole) was dissolved in hot (70°) acetic acid, slowly treated with hot (70°) 1 *M* H_2SO_4, and stirred at 70° for 1 hr. The reaction mixture was slowly added to cold water (3 liters, 10°), stirred for 2 hr, and kept at 10° for 24 hr. The product (III) was recovered by filtration and washed with methanol. The yield was 14 g (65%), mp 96–97°; NMR ($CDCl_3$): δ 6.7–7.7 (m, 15H, ArH), 5.1–5.4 (s, 1H, 1-H), 4.2–5.1 (m, 6, H ring-CH_2–), 3.2–4.2 (m, 6H, 3-6-H's, 1-OH), and 1.4–2.5 (m, 2H, 2-H's).

1-O-(2′-Acetoxy)benzoyl -3,4,6- tri-O-benzyl-α-D-2-deoxyglucopyranose (IV)—A solution of III (13.7 g, 0.032 mole) in dichloromethane (130 ml) was treated with a solution of *O*-acetylsalicyloyl chloride (6.93 g, 0.035 mole) and pyridine (2.8 ml) in dichloromethane (50 ml) and

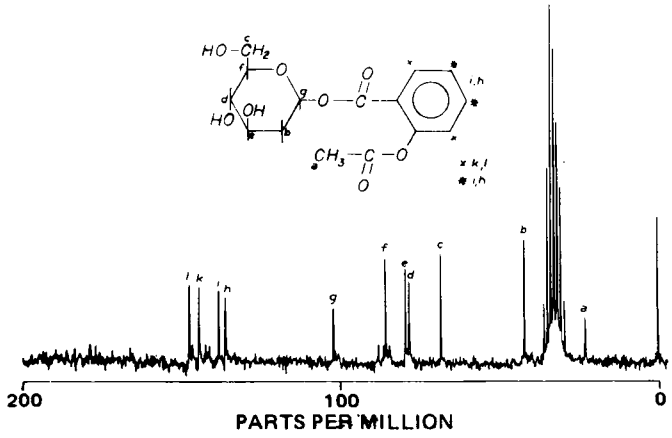

Figure 1—^{13}C-*NMR spectrum of 1-*O*-(2′-acetoxy)benzoyl-α-D-2-deoxyglucopyranose in acetone-*d_6.

stirred at 20° for 23 hr. Then 100 g of ice was added, and the mixture was left for an additional 1 hr. The dichloromethane layer was separated and washed with water, 3 *N* H_2SO_4, water, and a saturated solution of sodium bicarbonate. It then was dried and evaporated under reduced pressure to yield an oil.

The crude product separated as a waxy solid from a solution of the oil in methanol (200 ml). Recrystallization from ethanol gave IV (4.7 g, 25%); NMR ($CDCl_3$): δ 6.7–8.0 (m, 19H, ArH), 5.8 (d, 1H, 1-H), 4.4–4.9 (m, 6H, ring-CH_2–), 3.4–3.9 (m, 5H, 3-6-H's), and 1.0–2.5 (m, 5H, 2-H, –$OCOCH_3$). The ^{13}C-NMR[5] (deuterochloroform) was also consistent with the structure of IV.

1-O-(2′-Acetoxy)benzoyl-α-D-2-deoxyglucopyranose (V)—Compound IV (1 g, 0.002 mole) was dissolved in ethanol (150 ml), and 10% palladium-on-carbon (0.6 g) was added. Hydrogenolysis at 60 psig for 12 hr, filtration, and solvent evaporation at reduced pressure gave an oil. The oil was washed with petroleum ether (50 ml), and it crystallized spontaneously upon the addition of chloroform (15 ml). The yield was 0.52 g (95%), mp 128–129°; NMR (acetone-d_6): δ 7.0–8.2 (m, 4H, ArH), 5.8–5.9 (d, 1H, 1-H), 3.0–4.1 (m, 8H, 3-6-H's, OH's), 2.3 (s, 3H, –$OCOCH_3$), and 1.0–2.3 (m, 2H, 2-H's). The ^{13}C-NMR (acetone-d_6) was also consistent with the structure of V (Fig. 1).

Anal.[6]—Calc. for $C_{15}H_{18}O_8$: C, 55.20; H, 5.57. Found: C, 55.35; H, 5.59.

DISCUSSION

The method described here for Compound V provides a synthetic route for the preparation of acylal prodrugs of aspirin in which the acidic carboxyl function is masked by a sugar molecule. Compound V was characterized by elemental analysis and PMR and ^{13}C-NMR spectroscopy. The ^{13}C-NMR spectrum shown in Fig. 1 is consistent with the assigned structure (V).

Since the regeneration rate of the parent compound from V occurs *in vitro* with a half-life of 7 min at 37° (10) and since preliminary data (9) indicate that the glucose analog hydrolyzes much more slowly, application of the method to other sugars (or other parent drugs) may provide additional useful drug substances.

[5] The ^{13}C-NMR spectra were obtained using a Varian CFT-20 NMR spectrometer.

[6] Elemental analysis was performed by Micro-Analysis, Inc., Wilmington, Del.

New Compounds: Synthesis of 2-Chloromethylbenzo[*b*]furans

WAYNE K. ANDERSON ˣ, JEFFREY C. BOTTARO, and MICHAEL J. HALAT

Received June 20, 1979, from the *Department of Medicinal Chemistry, School of Pharmacy, State University of New York at Buffalo, Buffalo, NY 14260.* Accepted for publication August 8, 1979.

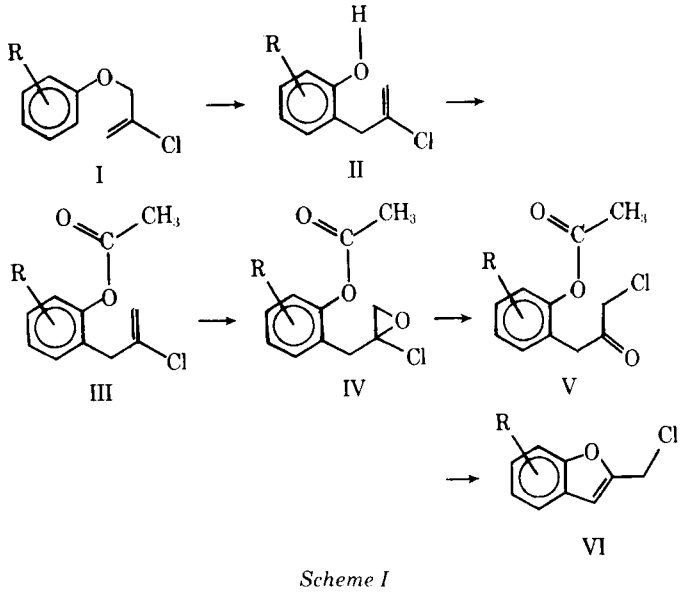
Abstract □ 2-Chloromethylbenzo[*b*]furans were prepared in high overall yield from the corresponding chloroethylphenyl ethers through chloroepoxide and α-chlorophenylacetone intermediates.

Keyphrases □ Benzo[*b*]furans—synthesis of 2-chloromethyl compounds □ 2-Chloromethylbenzo[*b*]furans—synthesis □ Heterocycles—synthesis of 2-chloromethylbenzo[*b*]furans

The benzo[*b*]furan ring system has provided a focus for the development of new agents in several classes, and new synthetic approaches to this heterocyclic system continue to be significant. The synthesis of 2-methylbenzo[*b*]furans from aryl 2-chloroprop-2-enyl ethers was described (1), but low yields were obtained when the starting phenol contained an *o*-chlorine substituent. This report describes an alternative procedure which circumvents this problem and gives a reactive chloromethyl group in the 2-position of the benzo[*b*]furan.

DISCUSSION

The starting phenol was added to a solution of sodium in absolute ethanol. 2,3-Dichloropropene was added, and the mixture was heated under reflux for 24 hr to give the aryl 2-chloroprop-2-enyl ethers (I) in almost quantitative yield. Rearrangement of I to II as described previously (1, 2) and acetylation of II gave III. This acetylation was necessary since the next step, epoxidation, yielded only decomposed material in the presence of the free phenol. Epoxidation of III gave chloroepoxides (IV), usually in crude yields greater than 90%, which were converted directly to the chloroketone (V).



Scheme I

The rearrangement of IV occurred when the chloroepoxide was allowed

[a] IR, UV, and NMR data are consistent with the reported structures and are similar to data reported under *Experimental*. [b] The yield of V is based on III (*i.e.*, on the two-step conversion).

to stand (neat) at room temperature for several days; this reaction was accelerated markedly by a trace of anhydrous hydrogen chloride. The phenylacetone derivatives (V) are potentially useful intermediates in the synthesis of substituted phenethylamines and phenpropylamines.

Treatment of Va or Vb with hot concentrated hydrochloric acid resulted in facile cyclization to VIa or VIb, respectively. Excessive decomposition accompanied attempted cyclization of Vc–Ve.

EXPERIMENTAL

Table I summarizes the yields, physical properties, and microanalyses for the compounds prepared[1]. Scheme I illustrates the steps in the synthesis.

2-(2′-Chloroprop-2-enyl)-4-chlorophenyl Acetate (IIIa)—A solution of IIa (6.09 g, 0.03 mole) and acetic anhydride (10 ml) in anhydrous pyridine (30 ml) was stirred magnetically and allowed to stand for 12 hr at room temperature. The pyridine and excess anhydride were removed *in vacuo*, and the residue was distilled to yield IIIa (7.21 g, 98%), bp 90°/0.20 torr; IR: 2899, 1757, 1634, 1475, 1427, 1404, 1366, 1190 (br), 1164, 1043, 1009, 943, 909, and 890 cm^{-1}; NMR: δ 2.25 (s, 3H), 3.59 (s, 2H), 5.29 (d, J = 13 Hz, 2H), and 7.08–7.60 (m, 3H); UV: λ_{max} 228 (Σ 3170) and 278 (55) nm.

2-(3′-Chloropropan-2′-one)-4-chlorophenyl Acetate (Va)—A stirred solution of IIIa (30 g, 0.115 mole) and *m*-chloroperbenzoic acid (85%, 36 g) in methylene chloride (300 ml) was allowed to stand at room temperature for 9 days. It was then concentrated to dryness *in vacuo*, and the residue was dissolved in ether (200 ml). The ethereal solution was washed successively with saturated aqueous sodium carbonate solution (200 ml), water (200 ml), and 10% aqueous hydrochloric acid (200 ml); the solution was dried over sodium sulfate and concentrated *in vacuo*.

The residual acid catalyzed the conversion of IVa to Va; the reaction was monitored by TLC (silica gel, methylene chloride); after several days, none of the chloroepoxide remained. The product was crystallized from carbon tetrachloride–hexane to yield 21 g (70%) of Va, mp 98–100°; IR: 2907, 1761, 1718, 1481, 1368, 1196, 1163, 1111, 1009, and 881 cm^{-1}; NMR: δ 2.27 (s, 3H), 3.78 (s, 2H), 4.07 (s, 2H), and 6.93–7.43 (m, 3H); UV: λ_{max} 226 (Σ 3260), 270 (550), and 278 (520) nm.

2-Chloromethyl-5-chlorobenzo[*b*]furan (VIa)—A vigorously stirred solution of Va (2.0 g, 7.66 mmoles) in concentrated hydrochloric acid (60 ml) was heated at 90° for 1 hr, and the cooled solution then was extracted with chloroform (3 × 60 ml). The chloroform solution was washed with water (100 ml), dried over sodium sulfate, and concentrated *in vacuo* to give 1.53 g (99%) of VIa, mp 53–55°. Crystallization from hexane at −78° gave VIa, mp 54–55°; IR: 2941, 1855, 1730, 1610, 1577, 1460, 1445, 1429, 1314, 1272, 1263, 1192, 1130, 1064, 961, 925, 889, 870, 833, 719, and 698 cm^{-1}; NMR: δ 4.52 (s, 2H), 6.51 (s, 1H), and 7.13–7.40 (m, 3H); UV: λ_{max} 215 (Σ 19,600), 256 (13,700), 288 (3460), and 298 (2990) nm.

[1] Melting points (uncorrected) were determined in an open capillary with a Thomas–Hoover Unimelt apparatus. IR spectra were determined for carbon tetrachloride solutions (unless otherwise specified) with a Perkin-Elmer 237 spectrophotometer. UV data were determined for 95% ethanol solutions with a Beckman DB-G spectrophotometer. NMR spectra were determined with a Varian T-60 spectrometer for carbon tetrachloride solutions (unless otherwise specified) containing ~1% tetramethylsilane as the internal standard. Microanalyses were performed by Atlantic Microlab, Atlanta, Ga.

Drug Interactions I: Folic Acid and Calcium Gluconate

Keyphrases □ Drug interactions—folic acid and calcium gluconate, low concentrations □ Folic acid—interaction with calcium gluconate, low concentrations □ Calcium gluconate—interaction with folic acid, low concentrations

To the Editor:

The interaction of folic acid and calcium salts is well documented (1–5). These references state that these compounds combine to yield a precipitate, but quantitative information on this interaction is lacking. Thus, it is of interest to determine the extent of this interaction at high dilutions and to investigate its reversibility with ethylenediaminetetraacetic acid (I), a known calcium-sensitive ligand. This study is important in view of the possible use of these agents in intravenous admixtures in pediatric patients in which a precipitate may not be obtained. This communication reports the results of a preliminary study that showed that calcium gluconate does inhibit significantly the reactivity of folic acid at low concentrations when a precipitate is not apparent.

The official assay (6) was modified by replacing the 2-min centrifuge period with a 10-min shaking period on a mechanical shaker[1]. The procedure yielded 4 μg of folic acid (mean = 0.1 μg, n = 16). The interaction procedure was conducted by diluting a volume of the same intravenous solution of folic acid[2] with 3.03% K_2HPO_4 to yield a solution containing 10 μg of folic acid/ml. This solution was treated with a volume of calcium gluconate solution[3], suitably diluted to yield the appropriate concentration of calcium ion (0.5, 1, or 10 μg/ml). This mixture was used as the assay preparation in the official assay after the volume was adjusted to 5 ml with distilled water. The quenching procedure was conducted as follows. After exactly 10 min, a quantity of I equimolar to the calcium concentration was added to the folic acid–calcium assay preparation, the volume was adjusted to 5 ml with distilled water, the preparation was mixed thoroughly, and the assay was followed as indicated previously.

Compound I in the same concentrations did not interfere with the folic acid determination when calcium gluconate was omitted (Fig. 1). As noted, the quantity of folic acid recovered by pretreatment with calcium gluconate diminished linearly (T = 26°, K = 0.228 min^{-1}). Furthermore, this folic acid–calcium interaction can be reversed quantitatively by the addition of I.

This study demonstrates that the folic acid–calcium interaction is significant at all concentrations, regardless of whether the interaction yields a precipitate. The stability constant of the folic acid–calcium interaction and the effect of pH on the reaction are being investigated further.

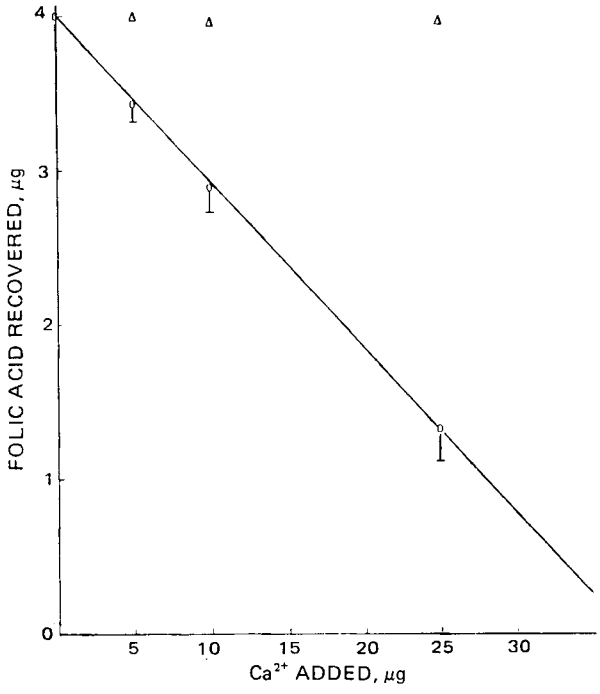

Figure 1—*Effect of calcium gluconate on the folic acid concentration (10 μg/ml). Folic acid concentrations (○) (mean + or − SD, n = 16) are shown as a function of the micrograms of Ca^{2+} added. Pretreatment with ethylenediaminetetraacetic acid (△) also is shown.*

REVIEWS

Textbook of Biopharmaceutics and Clinical Pharmacokinetics. By S. NIAZI. Appleton-Century-Crofts, 292 Madison Ave., New York, NY 10017. 1979. 332 pp. 17 × 23 cm. Price $18.50.

The author claims that this book presents the principles needed to understand and control drug therapy with sufficient depth and breadth for the undergraduate pharmacy student.

The first chapter briefly describes the disciplines of biopharmaceutics, pharmacokinetics, and clinical pharmacokinetics and defines the scope of the book.

Chapters 2–4 concern the introduction of a drug into the body. In Chapter 2, definitions are presented and various formulation factors are described. Chemical form, ionization constant, polymorphism, solvation, complexation, particle size, and surface-active agents are mentioned. Each topic is described, and numerous examples are cited. The evaluation of dosage forms is the topic of Chapter 3. Different types of dosage forms and the various *in vitro* tests required of a dosage form are described. Bioavailability testing and evaluation also are covered. Chapter 4 describes various routes of drug administration with descriptions of numerous factors that can influence absorption.

The distribution of drugs is the subject of Chapter 5. Protein binding, tissue distribution, and volume of distribution are included. Drug excretion and metabolism are included in Chapter 6 as ways in which the body terminates drug action. Factors influencing renal, biliary, salivary, and mammary excretion are detailed and referenced. Metabolism pathways and Michaelis–Menten kinetics also are described.

Pharmacokinetic principles, with full development of numerous useful equations, are the subject of Chapter 7. One- and two-compartment plasma and urine data are treated. Administration as a bolus, infusion or absorption, single and multiple dose is included. The final sections briefly discuss nonlinear, physiologically based, and pharmacological models.

In Chapters 8 and 9, the effect of various factors on the value of pharmacokinetic parameters and the development of suitable dosage regimens for various drug classes based on the clinical status of the patient are described.

This book covers all of the topics of importance in an undergraduate biopharmaceutics and pharmacokinetics course. There are many referenced examples and tables of data given for each phenomenon discussed. Many questions are included at the end of most chapters. Although advanced material is at times given with only brief explanation, this text should serve admirably as a textbook accompanying a lecture course in biopharmaceutics and pharmacokinetics.

Sterile Dosage Forms: Their Preparation and Clinical Application. 2nd ed. By S. TURCO and R. E. KING. Lea & Febiger, Philadelphia, PA 19106. 1979. 456 pp. 15 × 24 cm. Price $18.50.

This book represents an updated version of the text introduced in 1974. The major changes include the addition of a chapter on Blood and Blood Substitutes and an Appendix entitled "Hazards Associated with Parenteral Therapy." Other major revisions include six pages added to the end of Chapter 7 (Biopharmaceutic Factors Influencing Drug Availability), pages 209–225 added to the end of Chapter 8 (Large Volume Sterile Solutions), and a complete rewriting of Chapter 13 (Radiopharmaceuticals). All of these new sections are worthwhile additions, especially the discussions of hospital-based intravenous teams, flow control devices for intravenous therapy, and the work of the National Coordinating Committee on Large Volume Parenterals (NCCLVP). Another significant improvement throughout the text is the use of *numbered* references. In the first edition, it was virtually impossible to match the discussion with the *unnumbered* reference listing at the end of each chapter.

Thus, the second edition of what was a reasonably good text to begin with is improved significantly. However, I feel that a number of considerations could improve the text even further. For example, some additional discussion of parenteral stability and the fundamental equations for calculating the shelflife of various admixtures could have been added to Chapter 11 (Parenteral Admixtures and Incompatibilities). Since the book appears to be directed toward the hospital pharmacist, I believe that it is well within their spectrum of duties to have to research a stability problem. Thus, the fundamental information necessary for performing simple stability studies would have been a worthwhile addition.

In the discussion of osmolality (pp. 262–263), it is stated that 0.9% sodium chloride injection has an osmotic pressure of 308 mOsm/liter since sodium chloride *ionizes* into two ions. In fact, it is only at infinite dilution that discrete "particles" exist since in more concentrated solutions the sodium and chloride ions are not completely *dissociated*. The net effect of this incomplete dissociation is that for electrolytes such as sodium chloride, the osmotic pressure will not normally be equal to the molarity of the salt multiplied by the number of ions formed. Instead, the molarity must be multiplied by an effective concentration or "*i* value" (van't Hoff term), which for 0.9% (w/v) NaCl is ~1.9, thereby producing an osmotic pressure of about 293 mOsm/liter for normal saline.

The discussion of particulate matter provided in Chapter 3 is adequate. It could be improved with a somewhat expanded description of the official standards presently in effect in the United States and other countries and some further mention of the present methodology. This is an area in which hospital pharmacists have made extensive contributions, and additional discussion is warranted.

The bimolecular leaflet model of the cell membrane proposed by Danielli and Davson (p. 148) seems to have fallen into disfavor among membrane biologists and has been largely replaced by the fluid mosaic model of Singer and Nicolson. Thus, a picture of the fluid mosaic model might have been more appropriate for Fig. 7–3.

Some references in the extensive listing on pages 431–441 use *et al.*, presumably because this section is appended since this procedure was not used in earlier sections of the book. I am opposed to the use of *et al.* in reference listings since it fails to give credit to deserving cocontributors.

Finally, some typographical errors noticed are as follows: in the index (p. ix), line 4, Flow Control in I.V. Therapy starts on p. 212, not 203; the caption to Fig. 1–2 in both the first and second editions refers to Johann Daniel "Taylor", which should be Johann Daniel "Major."

In spite of these limitations and suggestions for improvement, I still recommend this text as a major contribution in the area of parenterals. It should find use as a reference work for hospital and research pharmacists and will no doubt become a required text for course offerings in pharmacy and nursing colleges. It is attractively packaged and well illustrated through the use of numerous photographic plates, and the price is reasonable in relation to other texts of comparable size.

Pathophysiology and Pharmacotherapy of Asthma: An Overview

LAWRENCE W. CHAKRIN ˣ and ROBERT D. KRELL

Received May 4, 1979, from the *Department of Biological Research, Section on Respiratory and Allergic Diseases, Smith Kline and French Laboratories, Philadelphia, PA 19101.* Accepted for publication July 27, 1979.

Abstract □ The pathophysiology of allergic and "nonallergic" asthma is presented, and several classes of antiallergic agents are discussed.

Keyphrases □ Antiallergic drugs—cromolyn sodium, adrenergic bronchodilators, corticosteroids, anticholinergic agents □ Pathophysiology—asthma, immunologically induced release of primary and secondary mediators, membrane permeability changes, calcium-ion dependency, antiallergic drugs □ Asthma—review of current theories, clinical evaluation, symposium, antiallergic drugs

Asthma is a disease marked by recurrent, quickly developing, bronchial obstruction leading to paroxysmal dyspnea. The condition results from a spasm of hypersensitive bronchial smooth muscle, generally in the segmental and smaller bronchi. The spasm is often accompanied by a mucosal edema and respiratory mucus hypersecretion. The principal types of the disease are allergic or extrinsic asthma and "nonallergic" or intrinsic asthma, the latter of uncertain origin (1). The prevalence of asthma is slightly higher in children than in adults; ~5% of all children in the United States below the age of 15 suffer from the disease (2).

An early clinical impression of the disease was accurately given by Dr. Michael Ryan, writing in "Observations on the History and Cure of the Asthma" (for review, see Ref. 3), who observed in 1793 that few diseases can be considered more formidable. The prospect of instant suffocation is so alarming as to weaken and depress a mind endowed even with the utmost fortitude and resignation. Dr. Ryan concluded that any remedy capable of permanent relief must be looked upon as of the utmost importance to mankind.

PATHOPHYSIOLOGY

The symptomatology of immediate-type allergic diseases, including extrinsic asthma and allergic rhinitis, presumably results from the immunologically (antigen) induced release of various pharmacologically active substances from mast cells, and basophilic leukocytes previously sensitized with an antibody generally of the immunoglobulin E class (4), and possibly from other cells as well. The substances thus released and referred to as primary mediators of anaphylaxis, *i.e.*, those released as a direct consequence of antigen–antibody interaction, include histamine, slow-reacting substance, eosinophil chemotactic factor, and platelet-activating factor (5). There are probably other primary mediators as well as secondary mediators released indirectly, such as some of the prostaglandins and kinins involved in the modulation of allergic processes (5). The sequence of biochemical events associated with mediator release is not clearly understood and has been the subject of a substantial research effort, particularly during the past decade (5).

Considerable evidence now supports immunoglobulin E (4) as the immunoglobulin class essential to acute allergic reactions, although some data indicate that such reactions also can be mediated by subclasses of immunoglobulin G-type antibodies. Immunoglobulin E may be synthesized locally in the respiratory tract or by the systemic immune system. It is a heat-labile glycoprotein of 198,000 molecular weight, which, as do the other immunoglobulin classes, contains two heavy and two light polypeptide chains linked by sulfhydryl bonds in fundamentally a Y-shaped structure. Presumably, the most significant biological property of the molecule is its ability to bind to homologous mast cells and basophils, thus sensitizing these cells for subsequent allergic reactions (4, 6). The Fc region of immunoglobulin E is that portion of the stem of the immunoglobulin molecule responsible for the highly specific binding to the receptors (4, 6) on the membranes of the tissue-fixed mast cells and blood basophils.

The remaining branched portion of the molecule, the Fab portion, contains the antigen binding sites thought to be made up of parts of the heavy and light chains. While not completely understood, evidence suggests that bridging of two cell-bound immunoglobulin E molecules by antigen (4, 6) is the initial step in a cascade of reactions resulting in mediator release. Presumably, an allosteric change in the structure of the Fc portion of the antibody then leads to the development of activated sites (7) on the mast cell or basophil membrane. Resulting changes in the charge distribution of the membrane are thought to increase the membrane permeability and alter the intracellular ionic milieu, initiating further biochemical steps of which relatively little is known (7).

It has been suggested that an early event in the release is an activation of a membrane-bound chymotrypsin-like proesterase (5). Esterase activation presumably requires calcium ion and results in an enzyme that can be inhibited by isofluorphate (diisopropyl fluorophosphate). Later in the sequence, there appear to be an energy-requiring step that can be inhibited by 2-deoxyglucose, an intracellular calcium-ion-requiring step capable of being suppressed by edetic (ethylenediaminetetraacetic) acid, and a step regulated by the relative levels of cyclic adenosine monophosphate and/or cyclic guanosine monophosphate. Presumbly, the mechanism of action of many compounds clinically effective in asthma is at the cyclic nucleotide step(s) (5).

Moreover, the cellular secretion of histamine, at least, may involve microtubules and microfilaments (7), although the supporting data are generally indirect and involve inhibition of histamine release by the alkaloid colchicine, thought to be an inhibitor of microtubule function. Conversely, heavy water, which is considered to stabilize microtubules, enhances histamine release. Little is known about the process of limiting immunological histamine release, although a series of feedback controls governed by the cyclic nucleotides and histamine itself has been suggested. Somewhat more is known about some mediators of anaphylaxis, which are thought to contribute collectively to the clinical syndrome of the disease (5, 6).

Histamine is β-imidazolylethylamine, and it is synthesized principally by a specific *l*-histidine decarboxylase enzyme. Histamine involved in hypersensitivity reactions of the immediate type appears to be stored in discrete mast cell (or basophil) secretory granules as a complex with heparin and protein. This stored amine undergoes slow turnover by comparison to the extra mast cell histamine of the GI mucosa and the central nervous system.

While still the subject of controversy, it is believed that the immunological, calcium-dependent release of histamine involves two processes, perhaps including the exocytosis of the subcellular cytoplasmic granules and the disassociation of histamine from the granule matrix (7). The heparin–protein complex of mast cell granules has ion-exchange properties, and exposure of the granule matrix to an altered ionic environment results in an exchange of histamine for sodium ions, which have an affinity for the binding sites. Once released, histamine presumably contributes to portions of the clinical syndrome of immediate hypersensitivity reactions. Apart from tissue uptake, histamine then apparently undergoes metabolism by one of two pathways. One, through methylation of the ring structure by imidazole-*N*-methyltransferase, yields methylhistamine, which is then oxidized through monoamine oxidase to methylimida-

0022-3549/80/0200-0236$01.00/0
© 1980, American Pharmaceutical Association

zoleacetic acid. Alternatively, histamine can undergo an oxidative deamination by histaminase or diaminoxidase to imidazoleacetic acid. The products of this metabolism are excreted in the urine.

As with histamine, the mast cell has been implicated as a source of slow-reacting substance of anaphylaxis (5, 8), although other cell types also appear to serve that function. Two experimental systems that generate slow-reacting substance of anaphylaxis are the sensitized fragmented lung and peripheral blood leukocyte preparations. The material is measured by bioassay utilizing the guinea pig ileum, and it produces a sustained contraction in the presence of an H_1-antihistamine and an anticholinergic agent. While the chemical structure of slow-reacting substance of anaphylaxis has only just been disclosed, some information was available concerning its physicochemical and biological properties. Slow-reacting substance of anaphylaxis was thought to be an acidic lipid of ~400–600 molecular weight and presumably contained an esterified sulfate group. It was considered resistant to proteases and phospholipases but labile to arylsulfatases and oxidation (5, 8). Furthermore, it was thought that slow-reacting substance of anaphylaxis could be derived from arachidonic acid, perhaps through a lipoxygenase pathway, but it appeared to be more polar than, and could be separated from, conventional prostaglandins (8).

Recently (9), it was suggested that slow-reacting substance of anaphylaxis may be "identical" to leukotriene C, one of a group of compounds related to the prostaglandins identified by Samuelsson, Borgeat, and colleagues of the Karolinska Institute in Sweden. Leukotriene C contains the amino acid cysteine covalently linked to the 20-carbon fatty acid derivative of the prostaglandin precursor, arachidonic acid. While there have been occasional reports of a small amount of preformed slow-reacting substance of anaphylaxis in lung tissue, it is presumably formed *de novo* and released on immunological challenge.

Eosinophils occur in relatively large numbers in pulmonary tissues and mucosal secretions of asthmatics, although their role is not precisely understood (10). Investigations that demonstrated that neither relatively pure slow-reacting substance of anaphylaxis nor histamine was chemotactic for these cells provided the basis for discovery of eosinophil chemotactic factor of anaphylaxis, another preformed primary mediator. Eosinophil chemotactic factor has a molecular weight of ~500, and chromatographic and electrophoretic evaluation suggests that eosinophil chemotactic factor of anaphylaxis is a low molecular weight acidic peptide. Two tetrapeptides with amino acid sequence Val-Gly-Ser-Glu and Ala-Gly-Ser-Glu were recovered from extracts of human lung fragments and were shown to be chemotactic for eosinophils (5, 10). Whether these tetrapeptides are, in fact, eosinophil chemotactic factor remains to be determined conclusively.

Additionally, other pharmacologically potent materials have been shown to be released from previously sensitized lung tissues on immunological challenge. Prostaglandins of the E and F classes are presumably rapidly synthesized (5, 8) and released, and they affect bronchial smooth muscle in an opposing fashion: prostaglandin E_2 producing relaxation and prostaglandin $F_{2\alpha}$ producing contraction (8). Their pharmacological activities are probably mediated by intracellular messengers, the cyclic nucleotides, cyclic guanosine monophosphate, and cyclic adenosine monophosphate, and they themselves are considered as secondary mediators whose synthesis and release may be governed by histamine or slow-reacting substance of anaphylaxis.

In addition to the prostaglandins, other chemicals, yet poorly characterized, probably contribute to the symptomatology of allergic asthma. Platelet-activating factor is possibly a lipid material, released on an immunoglobulin E–antigen interaction on basophils or lung tissue (5). Platelet-activating factor induces aggregation of platelets and the subsequent release of serotonin, which can cause tracheobronchial smooth muscle contraction.

In addition to the direct spasmogenic effects of many mediators of anaphylaxis, parasympathetic reflexes mediated through the vagus nerve also may contribute to the bronchoconstriction in the human asthmatic. Furthermore, individuals with asthma disclose a substantial hyperresponsiveness of their airways to several pharmacological agents such as histamine, prostaglandins, and cholinergic agonists as well as to such nonspecific irritants as cold air and noxious gases. This hyperresponsiveness may enhance the pathophysiological effects of the mediators released on antigen exposure.

PHARMACOTHERAPY

Following an established diagnosis and evidence for the reversibility of airway obstruction, the process of selecting an appropriate course of pharmacotherapy may be initiated. Management of the acute bronchospasm has the first priority; when it is initially controlled, etiological factors can be determined. In status asthmaticus (1, 11), a severe continuous state of asthmatic dyspnea, hospital management is indicated. Treatment must provide rapid bronchodilation, perhaps best achieved in this instance with intravenous aminophylline.

For less severe clinical situations, new drugs have been introduced during the last decade (11–14). Still others have been reevaluated for their utility among various patient populations.

Cromolyn Sodium—In 1956, a Fisons Pharmaceutical Corporation research team (3) initiated a search for compounds having selective actions on smooth muscle. The team chose khellin, extracted from a Mediterranean plant, as the chemical prototype since its seeds had been used since ancient times as a smooth muscle relaxant. A series of chromone-2-carboxylic acids was developed, but the compounds were inactive as smooth muscle relaxants and as antagonists to chemical spasmogens. However, they did partially inhibit, but not reverse, antigen-induced bronchospasm in an asthmatic volunteer. The interest in chromones led to the bis-chromones (3); in January 1965, one of these bis-chromones, cromolyn sodium (disodium cromoglycate), was synthesized and tested. In January 1968, it was introduced into therapy in the United Kingdom.

Although the cellular events responsible for the release of the mediators of anaphylaxis is not clearly understood (5), inhibition of their release would seem to be effective therapy. Presumably, the effectiveness of cromolyn sodium (3) is based on its ability to inhibit the immunologically induced release of mediators from sensitized cells (15). The compound has no bronchodilator or anti-inflammatory activity, and it is not effective for the treatment of the acute asthmatic episode. Rather, it is a clinically effective, prophylactic antiallergic agent in a limited patient population consisting principally of children. The compound is poorly absorbed from the GI tract, so it is administered as a powder inhalation.

Although some inconvenience and a need for education are associated with its use, cromolyn sodium offers a rather substantial degree of safety, with only occasional cough or bronchospasm generally associated with its use. While enjoying broader use elsewhere, in the United States the compound is indicated as an adjunctive therapy in the management of patients with severe bronchial asthma (3). Cromolyn sodium is continued on a more chronic basis if it significantly reduces the severity of symptoms, allows for a reduction in or elimination of steroids, or allows for satisfactory management of individuals who have "intolerable" side effects to sympathomimetic drugs or the methylxanthines.

The clinical efficacy of cromolyn sodium as an antiasthmatic agent has prompted a significant worldwide research effort directed to the discovery of more potent, orally active antiallergic drugs (15).

In addition to cromolyn sodium, the pharmacological armamentarium for the management of asthma consists of several adrenergic bronchodilators (16) including epinephrine and isoproterenol and the new, β_2-selective adrenergic drugs, theophylline and its several preparations, both systemic and inhaled corticosteroids, and anticholinergic agents such as atropine and its derivatives (11–14, 16, 17). Concern as to potential side effects with some of these agents, as well as the relative inconvenience attendant to cromolyn sodium administration, suggests that an orally active prophylactic antiallergic agent with a rather broad therapeutic index would be of significant value.

Adrenergic Drugs—Adrenergic receptors have been pharmacologically classified into α, β-1, and β-2 types. Among various other activities, adrenergic agents can stimulate α-receptors and cause vasoconstriction, β-1 receptors and cause cardiac stimulation, and β-2 receptors and provide bronchodilation (13, 16).

The use of adrenergic drugs in asthma dates from the use of the herb *Ma Huang* in Chinese folk medicine. The active ingredient, ephedrine, was introduced into Occidental medicine in the 1920's. Ephedrine stimulates α- and β-adrenergic receptors and, apart from its direct actions, releases norepinephrine stores from peripheral sympathetic nerve endings. Tachyphylaxis can develop to its activity, and subsequent doses are less effective, presumably due to norepinephrine depletion.

Epinephrine and isoproterenol, the prototype β-adrenergic stimulant, have been used in the management of bronchospasm for many years. Their use is limited, however, by the occasional development of undesirable side effects of tremor and cardiac stimulation. Beyond their lack of selectivity for β-2 receptors, the compounds have a relatively short duration of action because of rapid tissue inactivation, in part due to catechol-*O*-methyltransferase.

In the mid-1960's, Lands and coworkers demonstrated that a substantial selectivity for β-adrenergic receptors could be realized by chemical modifications of the phenylethylamine moiety of catecholamines (16). More recent attempts to improve selectivity and metabolic

stability have involved altering the catechol structure (16). Thus, in the past few years, some relatively selective β-2 adrenergic agonists have been developed including salbutamol, carbuterol, terbutaline, metaproterenol, and isoetharine (11, 13). Many of these compounds provide prolonged bronchodilation after aerosol or oral administration while producing relatively few cardiovascular side effects at effective bronchodilator dose levels.

Methylxanthine Phosphodiesterase Inhibitors—Theophylline and its various salts (11–13) are presumably effective in asthma by preventing the intracellular conversion of cyclic adenosine monophosphate to 5′-adenosine monophosphate. By elevating cyclic adenosine monophosphate, theophylline is capable of inhibiting immunologically induced mediator release and of potentiating the effect of β-2 selective adrenergic agonists, which stimulate the production of increased concentrations of cyclic adenosine monophosphate. First introduced as a therapy for asthma in the 1930's, oral theophylline now is widely used because it provides effective bronchodilation with minimal side effects in many patients. Occasional side effects with oral administration and, perhaps more frequently, with rapid intravenous administration include insomnia, nervousness, and cardiac arrhythmias.

Corticosteroids—Generally, corticosteroids (11–13) of relatively short duration are highly effective for the clinical management of severe asthma. Such compounds as prednisone, hydrocortisone, and prednisolone provide excellent anti-inflammatory, antiallergic activity in asthma. When utilized in an alternate day therapy, they are less likely to cause adrenal suppression, osteoporosis, or other adverse effects.

Recently, a variety of inhaled steroids have been introduced, and beclomethasone or other compounds have been shown to be locally effective at relatively low doses that do not cause substantial systemic effects. Adrenal insufficiency has occurred in some individuals when transferred to these topical inhaled steroids from systemic dose forms. The mechanisms by which the corticosteroids are effective in allergic inflammation is unknown but may be related in part to adenyl cyclase and the relative levels of cyclic adenosine monophosphate and cyclic guanosine monophosphate.

Anticholinergic Agents—In recent years, there has been a substantial renewal of interest in anticholinergic agents for the clinical management of asthma. It has been suggested that an imbalance of the autonomic nervous system function contributes to the disease. The characteristic hyperirritability of the airway smooth muscle may be due to a parasympathetic nervous system predominance (11–13, 17). Stimulation of subepithelial receptors of tracheobronchial tissue by particulate, gaseous, or immunological irritants can induce vagal reflex-mediated bronchoconstriction. The resulting increase in airway resistance can be reduced by atropine administration. Moreover, cholinergic agonists enhance immunologically induced mediator release, and atropine can inhibit such release, thus suggesting activity at sites other than the muscle. Recent interest has been shown in the bronchodilation produced by ipratropium bromide, an atropine-like investigational drug.

In addition to these classes of compounds, other agents have been studied, including the E-series prostaglandins and α-adrenergic antagonists (8, 13). Prostaglandins E_1 and E_2 are apparently effective bronchodilators in some individuals, but respiratory tract irritation and cough have precluded their extensive study. α-Adrenergic antagonists such as phentolamine may be useful, although the extent of α-adrenergic tone to tracheobronchial smooth muscle is relatively minor. The potential for adverse effects with these antagonists has limited their study.

The selection of appropriate therapy was reviewed recently (11–13, 17). In summary, a substantial number of individuals respond with effective bronchodilation and little adverse reaction to an oral theophylline preparation. Oral, relatively β-2-selective adrenergic drugs provide good bronchodilation, but adverse effects including tremor may limit their use. Asthmatics who fail to achieve adequate relief with either of these classes of drugs may benefit from cromolyn sodium. Individuals with persistent, severe disease likely will require corticosteroids, and aerosols of these agents may preclude the need for larger doses of systemic steroids. Many of the therapies can be combined, and often lower doses of each agent in combination may be *as* effective (and perhaps offer fewer side effects) as single-drug therapy.

The past decade has seen substantial progress in the understanding of cellular processes that presumably account for the clinical syndrome of allergic asthma. As even greater understanding develops, we can expect more sophisticated drugs to supplement the existing agents.

Preclinical Evaluation of Antiallergic Agents

ROBERT D. KRELL and LAWRENCE W. CHAKRIN ˣ

Received May 4, 1979, from the *Department of Biological Research, Section on Respiratory and Allergic Diseases, Smith Kline and French Laboratories, Philadelphia, PA 19101.* Accepted for publication July 27, 1979.

Abstract □ This paper examines the advantages and disadvantages of many *in vivo* and *in vitro* experimental model systems employed in the preclinical testing of antiallergic drugs.

Keyphrases □ Antiallergic drugs—inhibition of mediator release, *in vivo* and *in vitro* models □ α-Adrenoceptor agonist—cyclic adenosine monophosphate levels, effects on mediator release, antiallergic drugs □ β-Adrenoceptor agonists—cyclic guanosine monophosphate levels, effects on mediator release, antiallergic drugs □ Asthma—review of current theories, clinical evaluation, symposium, antiallergic drugs □ Cromolyn sodium—prophylactic antiallergic drug

The primary purpose of this report is to provide insight into the drug discovery process by examining several commonly used animal models as well as to illustrate the type of data that may be obtained. It is not intended as a thorough review of all methods currently available for the detection of antiallergic activity of novel molecules. The merits and limitations of these various systems, at least as presently viewed, are addressed. Allergic asthma will serve as a focus for allergic disorders in general. It is hoped that agents efficacious in this disease will prove beneficial for other allergic conditions as well.

Most experimental animal models commonly are based on the "mediator concept" of allergic disorders discussed in the preceding paper (1). The rationale for this approach to pharmacotherapy lies almost totally with the known pharmacology of the prototype prophylactic antiallergic agent cromolyn sodium and its well-established clinical utility (2).

Before beginning a discussion as to the type of technology employed, it is pertinent to examine the question of why a search for antiallergic agents beyond cromolyn sodium should continue. Cromolyn sodium is not orally active and is, therefore, administered as a powdered aerosol by a clever but cumbersome technique. The drug is efficacious in only a portion of the asthmatic patients for reasons that are not presently understood (2). Consequently, a compound that is orally active or that can be administered by more conventional aerosol techniques and/or that can protect a broader group or preferably all asthmatics would be a significant advance in therapy.

IN VIVO MODELS

By far, the most widely used paradigm is the 48-hr rat passive cutaneous anaphylaxis test (3), which frequently serves as the primary laboratory experimental system (Fig. 1). Briefly, adult female rats are immunized on Day 0 with an appropriate dose of ovalbumin along with *Bordetella pertussis*, which serves as an adjuvant. Often, rats receive a subcutaneous injection of larva from the nematode *Nippostrongylus brasiliensis* several days after primary immunization to enhance the production of antiovalbumin reaginic antibody. The rats are killed and bled 10–14 days later, and serum containing the antibody is prepared.

Appropriate dilutions of the serum are subsequently injected into discrete areas of the dorsal surface of the skin of a recipient rat. Since certain subclasses of immunoglobulin G antibodies may also bind to cutaneous mast cells, a 48-hr period is interposed between sensitization and antigen challenge to allow these antibodies to dissipate. Immunoglobulin E-type antibodies directed against ovalbumin remain firmly fixed to the mast cells for much longer periods (4). Test compounds are administered to the animals immediately prior to challenge with ovalbumin, which is often mixed with Evans blue dye. The short time between administration of the test compound and antigen is essential to ensure optimal activity. Unaccountably, there is a well-established inverse relationship regarding the time interval between drug and antigen administration and efficacy (3).

Upon injection, the antigen interacts with the antibodies fixed to the mast cell surface, which leads to a series of intracellular biochemical events culminating in the release of the vasoactive amines, histamine and serotonin, from the cells. When the animal is killed 30 min later and the dorsal skin reflected, the pharmacological effect of these mediators is visualized as an area of dye infiltration (wheals), which can be quantitated. Antiallergic agents are expected to reduce mediator release, which is manifested as a reduction in wheal size as compared to controls. Those compounds that demonstrate efficacy often undergo secondary testing in the rodent. Wheal size reduction in rats may be brought about by interfering with the antigen-induced release of the mediators of anaphylaxis from mast cells or by antagonizing the ability of histamine and/or serotonin to increase vascular permeability. To discriminate between these types of activity, the ability of the test compound to block wheals produced by the direct intracutaneous injection of histamine and/or serotonin is evaluated. Compounds that antagonize the vascular response to histamine and/or serotonin are often discarded as having a potentially unsuitable mechanism of action. One shortcoming of this approach is the possibility that molecules that possess antiallergic as well as antagonist types of activity may be overlooked.

The principal advantages of the rat passive cutaneous anaphylaxis model are that it is simple, rapid, economical, and semiquantitative. Furthermore, the potential oral efficacy of compounds may be assessed at an early stage in the pharmacological testing sequence. Major disadvantages are that it provides only circumstantial evidence as to the mechanism of action of the compounds and that efficacy is established in cutaneous tissue rather than in the designated therapeutic site, pulmonary and tracheobronchial tissue.

Various *in vivo* models of "allergic asthma" have been developed in several species to gain information on the potential efficacy of compounds in preventing antigen-induced bronchospasm. Since these models are considerably more complex than the rat passive cutaneous anaphylaxis, compound evaluation in these paradigms generally occupies the terminal step in the pharmacological testing sequence. Models have been developed in small animals such as the rat and guinea pig, utilizing either active or passive sensitization, most frequently with ovalbumin or dinitrophenol–ovalbumin combinations (5–7). Antigen may be presented parenterally for precipitation of systemic anaphylaxis or by aerosol to induce pulmonary anaphylaxis. Pretreatment with an efficacious antiallergic agent would be expected to reduce the severity of the response to antigen. The major advantages of these models are that the principal mediators of pulmonary anaphylaxis have been determined in both species (5–7) and that the sensitized animals are easily and economically prepared in large numbers.

A major disadvantage of these models is that, until recently, they have not allowed for the use of sophisticated technology for measurement of pulmonary mechanics due to the small size of the animals (8). Determination of the effects of antigen or drug–antigen combinations usually involves an indirect assessment of lung compliance rather than a true determination of resistance to air flow in large and small airways.

In contrast, some large animal models of allergic asthma are amenable to measurement of large and small airway resistance (9–11). The principal models used are dogs and rhesus monkeys with a spontaneously occurring hypersensitivity to an antigen prepared from *Ascaris suum* roundworms. The basis of the hypersensitivity is believed to involve neonatal infestation by nematodes, which provokes immunoglobulin E-type antibodies directed against the worm. Although neither dogs nor monkeys are normally subject to infestation with *A. suum* roundworms, a cross-reactivity between common antigenic determinants of the host's natural parasite—*viz.*, *Toxocara canis* in the case of the dog, and *A. suum* is assumed

to exist, allowing for the use of this more readily available nematode as an antigen source.

Dogs and rhesus monkeys with hypersensitivity to *Ascaris* antigen are separated from the nonhypersensitive population by a cutaneous testing procedure (Fig. 2). Briefly, the technique consists of injecting Evans blue dye intravenously followed by intracutaneous administration of appropriate dilutions of *Ascaris* antigen. Animals with the appropriate hypersensitivity level respond with wheals and dye infiltration at the antigen injection site. The reaction mechanism is thought to be similar to the rat cutaneous anaphylaxis test in that reaginic antibodies directed against the nematode are firmly fixed to cutaneous mast cells. Subsequent interaction with antigen causes cellular release of the vasoactive substances, leading to an increase in vascular permeability and leakage of dye from the vasculature.

In dogs reared in less than optimal environments, about 50% of adult animals demonstrate a cutaneous hypersensitivity whereas only about 5–10% of the wild adult rhesus monkey population display such hypersensitivity. Animals with appropriate cutaneous sensitivity are subse-

quently challenged with aerosols of the partially purified antigen for determination of airway hypersensitivity. For reasons that are not clear, only a portion of those animals with a cutaneous hypersensitivity demonstrate bronchial responsiveness to the antigen. As with the small animal models, compounds with antiallergic activity are expected to inhibit anaphylaxis when administered prior to antigen provocation. An example of an appropriate pharmacological profile is provided in Figs. 3 and 4 where the antiallergic agent, 5-acetyl-4-hydroxy-3-[1-[(3-amino-4-hydroxyphenyl)amino]ethylidene]-2*H*-pyran-2,6(3*H*)-dione hydrochloride (I) (3), was evaluated against *Ascaris* antigen-induced alterations in pulmonary resistance and dynamic lung compliance in dogs and rhesus monkeys, respectively. Increases in pulmonary resistance and decreases in dynamic lung compliance represent narrowing of large and small airways, respectively. As is apparent, this compound significantly lessened the response in both species.

An alternative to these actively sensitized models is passive sensitization of the airways of nonhypersensitive dogs and monkeys with high titer reaginic serum obtained from hypersensitive donors (10). With monkeys, human serums directed against known allergens may be used because of immunological cross-reactivity between species. Although both systemic and aerosol sensitization may be employed, the latter is most efficient because it requires smaller quantities of serum. While usually successful in the dog, this technique is less applicable to monkeys for unknown reasons, which may relate to the presence or absence of pharmacological airway hyperresponsiveness in the recipient animals.

Rhesus monkeys bronchially hypersensitive to *Ascaris* antigen display an airway hyperresponsiveness to several pharmacological agents including histamine, prostaglandin $F_{2\alpha}$, and cholinergic agonists (12, 13). Dogs do not demonstrate such hyperresponsiveness (14). As noted in the preceding article (1), airway hyperresponsiveness to nonspecific irritants and pharmacological agents is one cardinal clinical feature of the asthmatic. This hyperresponsiveness apparently amplifies the pathophysiological effects of the mediators released on antigen exposure. The demonstration of this phenomenon in monkeys provides an experimental model that may be of utility in uncovering mechanisms underlying this aspect of the disease and perhaps eventually lead to therapeutic agents capable of alleviating the hyperresponsiveness. To date, however, comparatively few investigations have been undertaken with this aspect of the model.

Major disadvantages of large animal models include:

1. Animals with positive bronchial antigen hypersensitivity, particularly rhesus monkeys, are relatively scarce.
2. Antigen challenge can be no more frequent than every 2 weeks. Shorter intervals lead to highly erratic pathophysiological pulmonary responses. Thus, large numbers of animals are required to evaluate reasonable numbers of experimental compounds.
3. Pulmonary responses may be extremely variable, even in the same animal.
4. Large animal models are costly to develop and maintain routinely.
5. No clear insight has yet been gained regarding the biochemical pharmacology underlying the pulmonary pathophysiology. Therefore, unexpected results are difficult to understand.
6. Various pharmacological mechanisms other than inhibition of mediator release can account for a reduction in the response. For example, end-organ antagonism of prominent mediators and smooth muscle bronchodilator activity both reduce response severity.
7. Apparently, humans uniquely suffer from asthma. To our knowledge, no case of allergic asthma in a nonhuman species has been reported. Therefore, while there is presently no alternative, these laboratory models may ultimately prove irrelevant to the clinical syndrome.

For more information regarding these models, the reader is referred to several review articles (9–11, 15).

IN VITRO MODELS

In vitro models of allergic asthma generally occupy an intermediate step in the preclinical pharmacological testing sequence, most often interposed between passive cutaneous anaphylaxis and the more complex *in vivo* models. These systems allow for an assessment of the potential ability of novel molecules to interfere with the antigen-induced release process—the presumed mechanism of action of cromolyn sodium. The most commonly used *in vitro* systems include isolated mast cells (16), blood leukocytes (basophils) (17), and fragment lung tissue (18–21).

A commonly used technique for obtaining a relatively "pure" population of mast cells involves the rat peritoneal cavity. In brief, cells are removed from the peritoneal cavity of actively sensitized rats by a simple washing with a physiological salt solution, and the mast cell population is separated from other peritoneal cell types by centrifugation. Cells are then suspended in an appropriate physiological medium and challenged with antigen to induce histamine release. Preincubation with antiallergic agents is expected to reduce the amount of histamine released on challenge.

Similarly, blood leukocytes (basophils), which also contain histamine and IgE antibody Fc fragment binding sites, may be prepared from actively sensitized animals or allergic human donors, suspended in an artificial medium, and challenged with the appropriate antigen to release the mediators of anaphylaxis. One notable pharmacological peculiarity of human basophils is that immunologically induced mediator release is not susceptible to the inhibitory effect of cromolyn sodium (22). These types of systems are relatively simple and economical, and they provide an essentially homogeneous cell population with which to study antiallergic agents.

The next higher order of complexity in the testing sequence is the *in vitro* fragmented lung model prepared from various species including rats, guinea pigs, dogs, rhesus monkeys, and humans (18–21). Lungs obtained from normal or actively sensitized animals or humans are resected, chopped into small fragments, passively sensitized with high titer reaginic antibody (for those obtained from normal animals), placed in a physiological medium, and then challenged with the appropriate antigen. Many chemical substances can be released on immunological challenge from fragmented lung tissue, and some appear to be species specific. Without regard to species, a partial list of these "mediators" includes: histamine, slow-reacting substance of anaphylaxis, prostaglandins, eosinophil chemotactic factor of anaphylaxis, platelet-activating

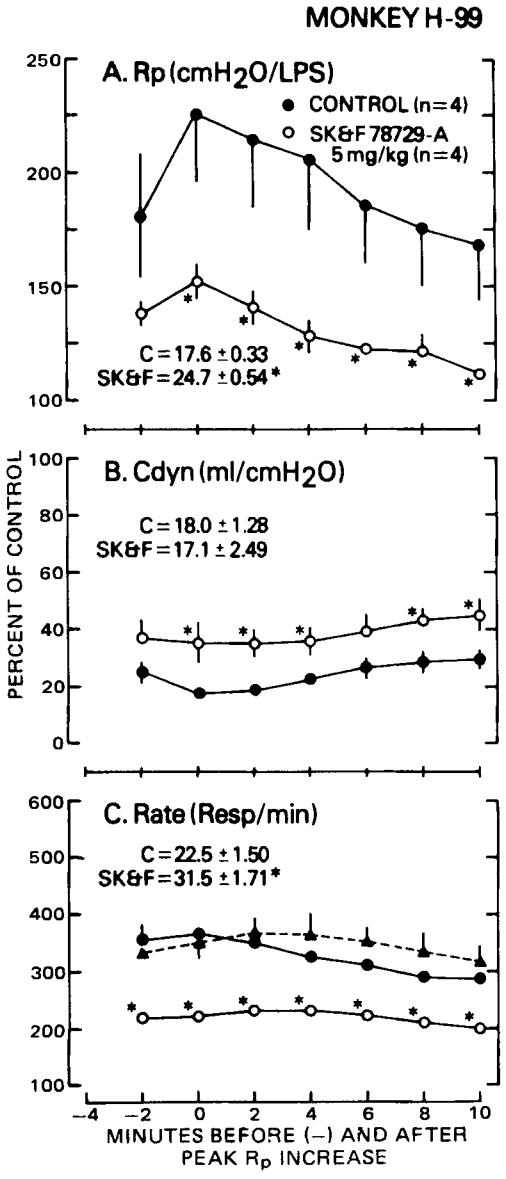

Figure 4—*Effect of I (SK&F 78729-A) on* Ascaris *antigen-induced pulmonary anaphylaxis in the* Ascaris *hypersensitive rhesus monkey model of allergic asthma. Compound I was administered (5 mg/kg iv) 5 min before 15 inhalations of a 1:3 dilution of partially purified* Ascaris *antigen. Rp = pulmonary resistance, and Cdyn = dynamic lung compliance. Baseline values for Rp, Cdyn, and rate immediately prior to antigen challenge are illustrated within the graph. The significant difference in the Rp baseline was not related to the administration of I. Each data point is the mean ± SEM of four separate experiments. factor, kinins, serotonin, rabbit aorta contracting substance releasing factor, and rabbit aorta contracting substance.

The sheer number of substances released, as well as the rather sophisticated technology required to assay each material, precludes the routine analysis of more than two or three substances. Consequently, many laboratories involved in the search for novel antiallergic agents often measure either histamine or slow-reacting substance of anaphylaxis or both. The selection of these two mediators is based on the observation that much of the body's histamine is sequestered within mast cells, the cells believed to play a major role in the pathophysiological process. Thus, inhibition of histamine release by antiallergic agents provides evidence that the molecule is altering the mast cell release process and, hopefully, that the inhibition will extend to all substances eminating from this cell. Unfortunately, recent experiments indicated that this assumption may not be valid.

The pharmacology of mediator release has been far more extensively studied in these models than in the large *in vivo* models of allergic asthma. It appears well established that agents capable of increasing intracellular levels of cyclic 3′,5′-adenosine monophosphate effectively inhibit histamine and slow-reacting substance of anaphylaxis release from most *in vitro* models (20). Such agents include β-adrenoceptor agonists such as isoproterenol and epinephrine, phosphodiesterase inhibitors including theophylline, and other agonists such as prostaglandins and, perhaps, histamine. Conversely, agents that increase intracellular levels of cyclic 3′,5′-guanosine monophosphate, including α-adrenoceptor and cholinergic stimulants, enhance the immunological release of the mediators (23).

Recently, it was demonstrated that slow-reacting substance of anaphylaxis release can be enhanced by several agents with little or no effect on histamine release, whereas amine release may be augmented or inhibited with no discernible effect on slow-reacting substance of anaphylaxis release (21, 24, 25). These observations suggest the lack of a common release process, at least as regards these two substances; the wider implication is that release of other mediators may also be pharmacologically distinct. Hence, inhibition of histamine and/or slow-reacting substance of anaphylaxis release by novel antiallergic agents cannot be extrapolated to other mediators without reservation. The obscurity of the important mediators of allergic asthma makes this observation unsettling to the preclinical pharmacologist because the inhibitory effects of antiallergic agents on histamine or slow-reacting substance of anaphylaxis release in laboratory models may not translate to an inhibition of the relevant mediators of allergic asthma in humans.

STATUS OF PROPHYLACTIC ANTIALLERGIC AGENTS

Several years of laboratory experimentation with these paradigms have led to the clinical introduction of almost 40 chemically novel antiallergic agents. Unfortunately, only one compound, ketotifen, has been added to the armamentarium and even it is currently limited to use in Switzerland (26). These discouraging clinical results have led to a reevaluation of these models, with attempts to determine which, if any, pharmacological commonalities of the 40 molecules may conceivably account for clinical failures. A number have been identified.

A rapid loss of efficacy as well as tachyphylaxis to the activity of these types of compounds is apparent following oral or parenteral administration in some *in vivo* models or on prolonged preincubation in some *in vitro* models. Although not orally active, cromolyn sodium demonstrates a similar pharmacological profile in these models, yet it remains clinically useful. On this basis, one may be tempted to speculate that such liability in laboratory models does not translate to the clinic and could not account for the clinical failures. However, a thorough determination as to whether this phenomenon occurs when compounds are administered by the aerosol route has not been conducted in laboratory models; thus, aerosol administration of cromolyn sodium may obviate tachyphylaxis and rapid loss of efficacy and prove a caveat for those unwilling to accept compounds not orally active.

Another area of concern is the recent demonstration, as already discussed, that some mediators can be selectively modulated (19, 21, 27). Since the important mediators of the allergic syndrome may be unknown, conceivably these compounds are not inhibiting release of the mediators most relevant to the pathophysiology. Alternatively, the major effects of these compounds may be on mediators of only secondary importance to the bronchospasm. Compounds with such activity may demonstrate marginal to no clinical activity.

Another interesting finding is that these types of molecules appear to be more potent inhibitors of histamine than slow-reacting substance of anaphylaxis release (3). In our experience, the concentration–response curve for these agents on histamine release often lies to the left and above that obtained for slow-reacting substance of anaphylaxis. If, as is often assumed, slow-reacting substance of anaphylaxis is an important mediator of human allergic asthma, a compound at least as potent for slow-reacting substance of anaphylaxis release as for histamine release may prove an interesting clinical candidate. Unfortunately, no new molecules appear to offer this profile.

And, finally, with relatively few exceptions, the newer compounds only partially inhibit the release of histamine and slow-reacting substance of anaphylaxis from most *in vitro* preparations. Frequently, "bell-shaped" concentration–response curves with maximal effects of between 40 and 60% inhibition are characteristic (3). However, cromolyn sodium shares this feature in many models but is clinically active. It is possible to compensate for this disparity by suggesting that cromolyn sodium may be completely efficacious in inhibiting other as yet unknown but important mediators of the human pathophysiology. Again, mechanisms

underlying this partial inhibition remain obscure; however, compounds offering 100% inhibition of both mediators or indeed all mediators would offer a potential clinical advantage.

In summary, as laboratory and clinical experience with both cromolyn sodium and novel antiallergic agents increases, a clearer understanding of the mechanism of action of this class of compounds undoubtedly will emerge. When this time approaches, many problems that concern us today will, hopefully, have fallen away and, perhaps, the design of and search for antiallergic drugs will be considerably less confusing and frustrating than they have been for the past decade.

Antiasthmatic Drug Therapy and Calcium Ions: Review of Pathogenesis and Role of Calcium

ELLIOTT MIDDLETON, Jr.

Received May 18, 1979, from the *School of Medicine, State University of New York at Buffalo, Buffalo, NY 14203.* Accepted for publication July 27, 1979.

Abstract □ This paper presents the calcium-dependent pathophysiological features of allergic and nonallergic asthma. Various theories concerning the role of free calcium ions in the pathogenesis of asthma are discussed.

Keyphrases □ Antiallergic drugs—calcium antagonists, inhibition of calcium influx and intracellular calcium movements, inhibition of mediator release □ Calcium-ion dependency—asthma pathophysiology, cyclic adenosine and guanosine monophosphate levels, mediator release, smooth muscle contraction–excitation, mast cell and mucous cell secretion, vagus nerve activation □ Mediator release—antigen dependency, calcium dependency, antiallergic drugs □ Asthma—review of current theories, clinical evaluation, symposium, antiallergic drugs

The principal pathogenetic features of asthma are ultimately calcium-related phenomena: smooth muscle contraction, mast cell chemical mediator secretion, mucous gland secretion, and vagal cholinergic reflex activity. In these cell types, the availability of free calcium ions for excitation–contraction coupling, stimulus–secretion coupling, and nerve impulse conduction determines significantly the smooth muscle contractility, mast cell mediator secretion, mucous gland secretion, and vagus nerve activity. Increased free calcium-ion concentrations might account for heightened smooth muscle contractility and increased mucous gland secretion and perhaps also for an increased mast cell mediator secretion rate and vagal nerve activity.

If the critical pathogenetic pathways in asthma are ultimately related to free calcium-ion availability in smooth muscle, mast cells, mucous glands, and vagus nerve, it follows that effective asthma drug therapy must reduce calcium availability to the essential contractile, secretory, and vagus nerve functions. This concept places altered transmembrane and intracellular calcium movements at the level of final common pathway for the

pathogenesis of asthma, regardless of the proximate stimulus (*e.g.*, allergy, infection, or exercise) and may be considered the *calcium hypothesis of asthma.*

DISCUSSION

Asthma is a clinically heterogeneous disorder. Examples of heterogeneity are noted in nonuniform heredity, variable airways reactivity and physiological abnormalities (large *versus* small airway involvement), immunologic features (allergic *versus* nonallergic asthma and the unique nonimmunologic form of aspirin-induced asthma), and variable therapeutic response with different drug classes. Furthermore, many asthma precipitants are recognized clinically including allergy, certain viral infections, exercise, cold air, respiratory irritants, aspirin (~10% of asthma patients), and emotional state, especially fear and anger. Does each of these aspects of clinical heterogeneity and variable precipitants represent different biochemical pathways? Perhaps in a proximate sense they do, yet the final expression of the pathological changes in asthma must finally be related to the translocation of calcium ions to activate the smooth muscle contractile system, the mast cell and mucous gland secretory systems, and nerve impulse initiation and conduction in vagal fibers.

It is reasonable to consider the interaction between an excitatory agent and specific tissue receptors (*e.g.*, antigen with mast cells or histamine or acetylcholine with smooth muscle) as the stimulus that activates some calcium membrane transport or membrane releasing system, or both. Following activation, the transport (or releasing) system promotes calcium-ion flow from intra- and/or extracellular storage sites into the cytoplasmic matrix. The result is an increase in free calcium ions near the contractile proteins in smooth muscle, the secretory apparatus in mast cells and mucous glands, and the nerve impulse initiation and conduction systems. The interaction of the calcium ions with the relevant specific sites then initiates a response.

When the excitatory agent is removed from the vicinity of the smooth muscle, mast cell, mucous gland, or nerve cell, calcium-ion flow into the cytoplasm is reduced and the cellular response is decreased. With smooth muscle, a gradual reduction in the calcium-ion level is accompanied by a gradual dissociation of calcium from the contractile elements and by a gradual decrease in the capacity of the contractile machinery to maintain increased tension. Removal of free cytoplasmic calcium is considered to be accomplished by a metabolically dependent calcium pump located in the plasma membrane and/or the membranes of intracellular organelles. The pump transports calcium from the cytoplasm to sequestration sites or to the external medium.

Based on these considerations, it is inferred that both the rate of inward flow or the release of calcium ions (from extra- or intracellular calcium stores) initiated by the excitatory agent and the simultaneous removal rate of free cytoplasmic calcium by the energy-linked calcium pump are important in determining the final cytosol calcium concentration. Since the calcium ions enter into a reversible interaction with specific contractile and secretory proteins, depending on cell type, their concentration in the cytoplasm determines the extent to which they elicit a response. It might be assumed, therefore, that the free calcium concentration in the cytoplasmic matrix and, therefore, the rate at which the calcium transport system delivers calcium to the cytoplasmic matrix would be important in the magnitude of the response.

The application of physiological techniques has uncovered energy-dependent calcium-concentrating systems in mitochondrial and microsomal preparations from smooth muscle. Therefore, it can be inferred that these structures possess a calcium-sequestering function, which, in the case of smooth muscle, induces relaxation. Conversely, these structures possibly may function as sites from which activator calcium can be mobilized for contraction. Comparable regulatory mechanisms may exist in mast cells and mucous glands.

The mechanisms by which excitatory agents mobilize calcium from different storage sites apparently vary from tissue to tissue. Vascular and nonvascular smooth muscle studies suggested that membrane depolarization is associated predominantly with the mobilization of extracellular or loosely bound calcium. It is difficult, however, to generalize about the manner in which an excitatory agent mobilizes calcium or about the calcium sources in smooth muscles, mast cells, mucous glands, or nerve tissues.

The manner in which the calcium transport system is coupled to the excitatory agent–receptor complex is not clear, and it is difficult to propose a model that accounts for graded increases in the activation of a calcium transport system that presumably occurs with incremental increases in the excitatory agent concentration (*e.g.*, antigen with mast cells or histamine or acetylcholine with smooth muscle).

Any exciting agent stimulating the relevant cell types in the lung in asthma (smooth muscle, mucous glands, mast cells, and nerve) may involve an induced shift of calcium ions from storage sites to the cytoplasmic matrix; this shift is carried out by a finite number of cellular transport sites which exist in cellular membranes. These calcium transport sites normally function at a low activity level unless activated by two independent cellular reactions. One of these reactions involves calcium transport site activation in an unknown fashion by the interaction of the excitatory agent with specific tissue receptors. The second involves reversible complex formation between calcium in storage depots and the activated calcium transport sites.

The entry rate of free calcium into the cytoplasmic matrix and, ultimately, the cellular response are dependent on the fraction of the total number of calcium transport sites participating in each type of reaction. Calcium transport site activation may be accomplished by a complex interaction between the excitatory agent and specific tissue receptors, which seem to be linked to the transport sites. The increase in calcium conductance that results from transport site activation is usually a graded response. It follows that calcium-ion transport by activated sites must be preceded by the formation of a reversible complex between the calcium transport sites and the calcium ions that are to be transported into the cytoplasmic matrix and, eventually, that are to interact with contractile, secretory, and nerve excitation systems.

Many recognized calcium-dependent processes are important in asthma pathogenesis: excitation–contraction coupling in smooth muscle, stimulus–secretion coupling in secretory cell types including mast cells and mucous glands, and microtubule function and calcium effects on certain enzyme systems such as adenyl cyclase, guanyl cyclase, and phosphodiesterase activator protein.

Currently utilized drugs presumably indirectly affect calcium movement and disposition by acting on the adenyl cyclase–cyclic adenosine monophosphate system (β-agonists) and, perhaps, through phosphodiesterase inhibition (theophylline); cromolyn sodium, however, may have some calcium-antagonistic properties, *i.e.*, inhibition of calcium uptake by activated mast cells. The relationship of the antiasthmatic effects of corticosteroids to calcium movement is obscure. The possibility of developing compounds with calcium-antagonistic properties selective for cells involved in asthma pathogenesis is attractive, and such compounds are being studied.

Calcium antagonists can be defined as compounds that affect the translocation of calcium ions across cell membranes and within cells; certain calcium antagonists appear to act by affecting transmembrane calcium translocations while others affect intracellular calcium movements. Their mechanism of action is complex and ill defined. Some calcium antagonists have been studied for their effects on myocardial and vascular smooth muscle responses to various agonists (and are in use therapeutically, *e.g.*, verapamil), a few have been studied for their effect on nonvascular smooth muscle, and several have been studied for their ability to block specific secretory processes (*e.g.*, catecholamine secretion from the adrenal medulla), but few investigations of calcium antagonists on mediator secretion from mast cells or basophils have been undertaken.

IMMUNOLOGICAL–CHEMICAL MEDIATOR THEORY: REGULATION OF CHEMICAL MEDIATOR RELEASE

Immunoglobulin E-sensitized mast cells and basophils can be triggered to release chemical mediators upon stimulation with a specific antigen, and the release process has an absolute requirement for calcium ions (*cf.*, 1–7). Indeed, calcium microinjection into mast cells provokes local granule extrusion (8). It was believed that the chemical mediators acted locally and directly on smooth muscle, blood vessels, and mucous glands and attracted eosinophils and other inflammatory cells to produce the characteristic pathological changes of asthma in the lung. Not all causes of asthma have an identifiable immunological basis, however, so it is safe to say that allergy is a sufficient, but not an exclusive, explanation for asthma.

The discovery of immunoglobulin E (*cf.*, 9) established the immunological basis of immediate-type hypersensitivity reactions and spurred research on the mechanisms by which chemical mediators are released from mast cells and basophils. It is now well recognized that immunoglobulin E antibody is firmly bound to special receptors in the cell membrane of mast cells and basophils and that interaction of the bound antibody with specific antigen initiates a series of intracellular biochemical reactions, which culminate in the noncytolytic secretion of

preformed mediators and the generation and release of several mediators that exist as precursors (1–7).

The essential role of immunoglobulin E receptors in mediator release from rat mast cells was demonstrated by Ishizaka and Ishizaka (10), who found that antibodies specifically directed against immunoglobulin E receptors caused histamine release and immediate skin reactions in normal rats. This important observation indicates that membrane perturbation, presumably involving the spatial relationships of the immunoglobulin E receptor and subtended functional units, is sufficient to initiate the biochemical sequence required for mediator release.

The list of mast cell- and basophil-derived mediators includes: (*a*) preformed mediators such as histamine, eosinophil chemotactic factor of anaphylaxis, eosinophil chemotactic factor oligopeptides, neutrophil chemotactic factor, heparin, chymase, lung kallikrein of anaphylaxis, superoxide radical, and superoxide dismutase; and (*b*) newly generated mediators such as slow-reacting substance of anaphylaxis, platelet-activating factor(s), lipid chemotactic factors, and prostaglandins. The source, nature, properties, and metabolism of these substances have been reviewed extensively (1–6, 11). Some or all of these substances may participate in the pathogenesis of the acute and chronic aspects of lung pathology and altered physiology in various types of asthma, acting through direct and reflex mechanisms. It is also pertinent that histamine and slow-reacting substance of anaphylaxis require calcium for stimulation of smooth muscle contraction.

Extensive studies (1–6) of immunoglobulin E-dependent immunological release of chemical mediators from mast cells and basophils have provided a partial picture of the biochemical events involved and, thus, the various loci for potential pharmacological intervention. Interaction of specific antigen with mast cell-bound immunoglobulin E antibody presumably results in membrane perturbation associated with extracellular calcium-ion transport into the cell. This initial step is accompanied by the activation of a proesterase, which is converted to an active chymotrypsin-like serine esterase, which subsequently engages in further autocatalytic activation. Possibly, calcium-ion influx is essential for initial activation and autocatalytic activation of the proesterase to the esterase. The active esterase decays quite rapidly.

A subsequent energy-dependent step can be inhibited by 2-deoxyglucose. Precisely what function in the mediator release sequence is subserved by the energy requirement is not certain, but it may be related to the function of a "contractile protein" since dense bands of microfilaments have been observed around mast cell granules, especially during degranulation. Microfilament function is probably involved in mediator release, and the function of microfilaments can be affected by cytochalasins A and B. Studies with these agents indicated that histamine release and slow-reacting substance of anaphylaxis generation and release can be dissociated. Although cytochalasins A and B enhance histamine release, they inhibit the concomitant formation of slow-reacting substance of anaphylaxis. An interesting study (12) indicated a significant difference in the cytochalasin sensitivity of histamine release in a comparison of asthmatic and normal basophils.

Several studies indicated an important function of microtubules in mediator release from mast cells and basophils. Colchicine, a compound that binds to the microtubular subunit protein, thereby preventing microtubule assembly and function, inhibits histamine release. Heavy water (D_2O), on the other hand, favors microtubule subunit aggregation and facilitates histamine release.

The metabolic regulation of chemical mediator release has been investigated intensively. One aspect of metabolic control of mediator release that is quite well worked out in several *in vitro* systems involves the effects of cyclic adenosine monophosphate, cyclic guanosine monophosphate, and agents that affect their intracellular concentration. Numerous studies (1–6) indicated that agents that increase cyclic adenosine monophosphate levels (*e.g.*, β-agonists, histamine, prostaglandin E, and cholera toxin) tend to decrease chemical mediator release, while agents that decrease cyclic adenosine monophosphate levels (*e.g.*, α-adrenergic agonists) tend to increase chemical mediator release. On the other hand, compounds that increase cyclic guanosine monophosphate levels (*e.g.*, cholinergic agents and, perhaps, α-adrenergic compounds) tend to increase chemical mediator release. Indeed, recent evidence appears to establish cyclic guanosine monophosphate as an important mediator of immunological mediator release in human lung (13).

The effect of each adrenergic or cholinergic agonist can be blocked by antagonists such as propranolol, phentolamine, and atropine, substantiating the β- and α-adrenergic and muscarinic cholinergic nature of the receptor systems involved. Thus, chemical mediator release can be modulated by products of the sympathetic and parasympathetic nervous system and other substances acting through specific receptor systems and affecting the intracellular levels of cyclic adenosine monophosphate and cyclic guanosine monophosphate. Calcium plays a critical role in control of intracellular cyclic nucleotide concentrations through its ability to inhibit adenyl cyclase (14), stimulate guanyl cyclase (15), and regulate the phosphodiesterase regulator protein (16).

NEUROGENIC THEORY

The neurogenic theory of asthma pathogenesis is grounded in the observation that stimulation of subepithelial airway receptors by released chemical mediators or other irritants results in a vagally mediated cholinergic bronchoconstrictor reflex, which can be markedly attenuated or abolished by atropine or experimental manipulations that attenuate vagal afferent and efferent impulse transmission. Atropine acts competitively to inhibit the calcium-dependent effects of released acetylcholine on smooth muscle and mucous glands. The asthma-worsening effect of viral respiratory infections that denude the epithelium is thought to be due to sensitization of these rapidly adapting subepithelial sensory receptors; in normal subjects with "colds," a transient (1–6 weeks) hyperirritability of the airways to inhaled histamine or citric acid aerosols has been demonstrated (17). Much evidence supports the neurogenic theory, and it has been reviewed extensively (18–21).

Mediators immunologically released from intraluminal airway mast cells or basophiloid cells (22) may stimulate vagal sensory endings and increase bronchial epithelial permeability to macromolecular antigens, allowing them to gain access to submucosal mast cells where further mediator release might occur. Although cholinergic agents increase immunological mediator release *in vitro*, there is no evidence that cholinergic stimulation *in vivo* does the same thing.

β-ADRENERGIC BLOCKADE THEORY

Another major theory concerned with asthma pathogenesis is that of β-adrenergic blockade proposed by Szentivanyi (23). Briefly, this theory states that there is diminished responsiveness of β-adrenergic receptors to stimulation by β-adrenergic agents. This theory implies that β-receptor-mediated relaxation of smooth muscle and β-receptor-mediated functions of other cells and organ systems might be reduced. It also implies a diminished accumulation of cyclic adenosine monophosphate following stimulation with β-agonists because of the linked relationship of β-receptors and adenyl cyclase to convert adenosine triphosphate to cyclic adenosine monophosphate. Adenyl cyclase is a membrane-bound, magnesium-dependent enzyme and is inhibited by calcium ions. Although not totally conclusive, considerable evidence supports this theory and the data have been reviewed extensively (23–27). An interesting recent supportive observation also was reported: salbutamol inhalation increased plasma and urinary cyclic adenosine monophosphate levels in both normal and asthmatic subjects, but the increase in asthmatics was significantly less (28).

A major objection to the β-adrenergic blockade theory arose when several investigators (29–32) noted that asthmatic patients or normal individuals given β-adrenergic drugs developed subsensitivity of leukocytes to stimulation by isoproterenol as determined by cyclic adenosine monophosphate accumulation. These studies indicated that the apparent state of "β-adrenergic blockade" was, in fact, drug induced. However, Busse (33) later studied asthmatic patients who had not received β-adrenergic drugs for 2 weeks and determined that the isoproterenol-induced inhibition of polymorphonuclear leukocyte lysosomal enzyme release was reduced as well as the isoproterenol-stimulated accumulation of cyclic adenosine monophosphate in these cells. These data are generally consistent with the β-adrenergic blockade theory. Bush *et al.* (34) also found a decreased isoproterenol polymorphonuclear leukocyte response in normal individuals during rhinovirus infection, indicating that the viral infection produces dysfunction of the β-receptor–adenyl cyclase system in nonpulmonary tissues. Thus, viral infections appear to have metabolic effects on cell function and direct airway effects. Precisely what aspect of enzymatic control of cyclic adenosine monophosphate synthesis (or degradation) is affected by the virus or the products of viral infection remains to be determined.

Recent experiments on asthmatic and nonasthmatic dogs (sensitive to *Ascaris suum*) compared trachael ring smooth muscle responsiveness to antigen, methacholine, and isoproterenol; isoproterenol induced consistently greater relaxation in nonasthmatic rings following standardized precontraction with methacholine (35). The finding of isoproterenol hyporesponsiveness in natively asthmatic dogs, under conditions excluding possible receptor densensitization due to prior exposure to β-agonists, is consistent with the β-adrenergic blockade theory but does

not exclude the importance of vagal mechanisms.

In summary, solid evidence apparently substantiates the possibility of β-adrenergic receptor–adenyl cyclase dysfunction in certain cells of asthmatic patients (and dogs). However, the studies do not shed any light on the locus of the biochemical–pharmacological defect. Since the β-receptor–adenyl cyclase system is considered to be composed of a recognition or discriminator (receptor) unit, a transducer unit, and a catalytic unit, dysfunction could occur at any (or all) of these levels.

It is now well recognized that guanosine triphosphate is an important regulator of adenyl cyclase in many hormone-stimulated systems (36). The data indicate that guanylyl nucleotide regulation of adenyl cyclase activity is not only ubiquitous but also independent of the receptor coupled to the enzyme. It is also known that the guanosine triphosphate concentration is under the control of a phosphatase (36–38). Thus, it is possible that cells of asthmatics may have abnormal function of this regulator site or possibly increased phosphatase activity, which would indirectly depress adenyl cyclase function. There are no data to support these ideas, but it is interesting to consider the therapeutic possibilities of agents that might act at the guanosine triphosphate regulator site to increase adenyl cyclase responsiveness to β-agonists or that might inhibit the phosphatase.

REDUCED FUNCTION OF NONADRENERGIC INHIBITORY SYSTEM THEORY

Another theory is reduced function of the nonadrenergic inhibitory system in the lungs of asthmatic patients (39). Human airways, from the midtrachea to the distal bronchi, have been studied *in vitro* for inhibitory nerves (40). Electrical field stimulation of the tissues demonstrated cholinergic excitatory nerves inhibitable by atropine. In the presence of atropine, field stimulation of the tissues relaxed smooth muscle, even when it was contracted by histamine. This relaxation was neither blocked nor modified by adrenergic antagonists. Nerve stimulation involvement in the field stimulation–induced relaxation was established when tetrodotoxin blocked the effect.

This airway relaxation system shares some characteristics of the nonadrenergic inhibitory system in the GI tract and of the comparable system reported in guinea pig tracheal smooth muscle. Moreover, no evidence of adrenergic inhibitory fibers in human bronchial muscle could be found by either pharmacological or histochemical techniques. The nonadrenergic inhibitory system may be the principal inhibitory system of human airway smooth muscle, and a defect in this system might be a possible explanation for the hyperreactivity of the airways noted in asthma patients.

The asthma theories reviewed are not mutually exclusive. Nevertheless, in each case, the final common denominator is considered to be the increased availability of free (activator) calcium ions for excitation–contraction coupling in smooth muscle, stimulus–secretion coupling in mast cells and mucous glands, and nerve impulse initiation and conduction in the vagus.

AIRWAY HYPERIRRITABILITY

Any asthma theory must explain the disease hallmark, namely, hyperirritability of the airways from various stimuli. Hyperirritability has been demonstrated in clinical investigations with various substances that are chemically unrelated but require calcium for their smooth muscle stimulating activity. These agents include acetylcholine, methacholine, histamine, slow-reacting substance of anaphylaxis, prostaglandin $F_{2\alpha}$, and bradykinin.

Airway hyperreactivity suggests that the airway smooth muscle is partially depolarized, *i.e.*, reactive to low doses of various chemically diverse substances or stimuli. The basic cause of the hyperreactivity (or postulated state of partial depolarization) is unknown but certainly suggests an increased permeability of smooth muscle cell membrane to calcium ions, which activate the contractile machinery. The single piece of evidence that possibly supports increased permeability (or partial depolarization) was provided by Simonsson *et al.* (41), who demonstrated that airway smooth muscle from a patient with chronic bronchitis responded *in vitro* to very low doses of carbachol and bradykinin as compared to normal bronchial smooth muscle. Whether such findings might obtain in asthma remains to be determined.

BIOLOGICAL PROPERTIES OF CALCIUM AND CALCIUM ANTAGONISTS

Calcium plays a critical and central role in many biological events at both the intra- and extracellular levels (42, 43). However, calcium distribution across the cell membrane is far from equilibrium; if the testing membrane potential (~−60 mv) were equal to the calcium equilibrium potential, then the intracellular calcium activity should be some 100-fold greater than the extracellular activity. This is clearly not so. Although accurate measurements of free ionized intracellular calcium concentrations have not been made in many systems, the consensus of evidence firmly indicates that the free intracellular calcium concentration is less than 10^{-7} *M* (44–46).

The very large driving force for calcium entry indicates that specific mechanisms must exist for intracellular calcium removal. Subsequent to entry, calcium may be removed through complexation with cytoplasmic constituents (including the internal membrane surface) or by sequestration into the intracellular structures, mitochondria (47, 48), and sarcoplasmic reticulum (49, 50) of smooth muscle, for example.

Although there can be no doubt as to the importance of calcium uptake by the active transport processes mediated by mitochondria and sarcoplasmic reticulum, the cell must, to maintain its total calcium reasonably constant, ultimately transport calcium to the external medium. Two major processes for intracellular calcium removal have been described. In one process, calcium extrusion is directly coupled to adenosine triphosphate hydrolysis; in the second process, calcium extrusion is coupled to an influx of sodium ions.

CALCIUM ENTRY PROCESS

Given the existence of the several mechanisms that operate to maintain a low intracellular free calcium concentration, there must also exist mechanisms that increase intracellular calcium concentrations and couple membrane excitation to intracellular calcium-modulated events. This calcium may be derived from intracellular stores or from extracellular sources. Although initial emphasis was placed by Hodgkin and Huxley (51) on Na^+ and K^+ as the current carrying species during squid axon excitation, there is now substantial evidence for this and many other tissues that calcium entry through "specific calcium channels" also contributes to the total membrane current (44, 46, 52, 53).

Of particular importance, pharmacological differentiation of the Na^+, K^+, and calcium channels is possible with selective antagonists. Tetrodotoxin and tetraethylammonium are well known for their actions on Na^+ and K^+ channels, respectively (54), and the inorganic ions Mg^{2+}, Mn^{2+}, Ni^{2+}, Co^{2+}, and La^{3+} and the organic agents verapamil, methoxyverapamil, and nifedipine have gained prominence as calcium channel antagonists (46, 55, 56). There is an obvious analogy between this differentiation of ion channels and the differentiation of pharmacological receptors through specific antagonist action.

There is not considerable evidence that the calcium entry process similar to that seen in the squid axon occurs in several excitable tissues and that a calcium channel is utilized distinct from that carrying the early sodium current. The basis for the differentiation of such a process rests on the following properties:

1. Membrane currents and potential changes in Na^+-free solution are basically identical to those seen in Na^+-containing media in the presence of tetrodotoxin or in preprations where the Na^+ channel has been inactivated by prior depolarization.
2. The calcium current is insensitive to tetrodotoxin and tetraethylammonium but is sensitive to antagonism by Mg^{2+}, Mn^{2+}, Co^{2+}, La^{3+}, verapamil, methoxyverapamil, and nifedipine.
3. Both Sr^{2+} and Ba^{2+} can substitute for calcium.
4. The threshold voltage- and time-dependent activation and inactivation parameters and gating currents are quite distinct from those determined for the early sodium current.

As judged by these criteria, calcium channels mediating calcium translocation have been described in various preparations, from protozoan to mammalian (57), although complete ionic, electrophysiological, and pharmacological characterization is not available in many instances.

CALCIUM CHANNEL ANTAGONISTS

The di- and trivalent cations Mn^{2+}, Ni^{2+}, Co^{2+}, and La^{3+} and the organic molecules verapamil, methoxyverapamil, and nifedipine are defined as calcium channel antagonists, and their actions serve as one important component of calcium channels. However, neither the sites nor the mechanisms of action of these antagonists have been defined precisely.

Certain data also suggest that the channels may possess gating mechanisms involving phosphatidylinositol breakdown as the initial event

required to open calcium channels following agonist–receptor interaction (58, 59). Phenoxybenzamine, an α-adrenergic blocker with antagonistic effects against several chemically unrelated agonists, was the only one of a number of compounds tested found to block phosphatidylinositol breakdown and to inhibit smooth muscle contraction (60). The nature and controlling mechanisms of calcium gates/channels is far from completely understood, but they are of central importance to the calcium hypothesis of asthma.

Various organic calcium antagonists have been developed which block entry of calcium ions from the outside to the inside of the cell and which can modify the effects of various calcium-dependent agonists (61). Some examples are verapamil, methoxyverapamil, nifedipine, benzyclane, prenylamine, and cinnarizine. These compounds have been studied mainly for their effect on myocardial cell function as well as on coronary and other vascular smooth muscles. Verapamil and methoxyverapamil have potent effects on excitation–contraction coupling in several vascular smooth muscle preparations and also in guinea pig ileal smooth muscle (57). Verapamil and methoxyverapamil are also quite potent inhibitors of stimulus–secretion coupling in several systems (57).

Other calcium antagonists such as the aminoindenes (62, 63) and mecinarone (66) appear not to block the calcium entry process but rather to affect the intracellular sites of calcium action. This was demonstrated in studies of cholinergically stimulated release of catecholamines from the adrenal medulla (62) and also with histamine- and carbachol-induced contraction of different smooth muscle preparations (63). Ketotifen, an effective antiasthmatic drug (64), inhibits calcium 45 uptake by rat mast cells (65) and also possesses antihistaminic activity (H_1). Compounds with such properties are of interest for both theoretical and practical considerations in drug design, *i.e.*, in the search for compounds that affect the essential intracellular calcium movements required for contractile and secretory phenomena. The effects of certain calcium antagonists on rat mast cell mediator release will be described later.

It is plausible that the calcium channel organization is basically similar to that suggested for the sodium channel by Hille (54). An important component of Hille's model is the channel cation coordination site, which constitutes a rate-limiting selectivity filter. The energetics of cation interaction at this site determine whether a cation is a permeant or nonpermeant species. In the case of the sodium channel, Na^+ binds the least well and is the most permeant. The geometry and ligand characteristics of this proposed site determine the selectivity between monovalent and divalent cations (67, 68) and, in the case of the calcium channel, divalent cations with ionic radii similar to those of calcium may be expected to interact with this site and to serve as substitutes for or antagonists of calcium permeation.

Little quantitative data exist for ion interactions at the calcium channel. However, for antagonism, it is clear that $M^{3+} > M^{2+}$ (69) and that among divalent cations the order of permeation is $Ba^{2+} > Sr^{2+} > Ca^{2+} \gg Mg^{2+}$; Ni^{2+} and Co^{2+} serve as antagonists, and Mn^{2+} acts as both an antagonist and permeant species (70). These findings suggest that the ionic radius and hydration energy may be important factors in determining cation interaction and permeation in the calcium channel. Many of these effects of di- and trivalent cations are likely related to a general adsorption to negatively charged membrane sites. Finally, the lanthanide series of cations are calcium channel antagonists, probably by virtue of their rather general ability to substitute for calcium at calcium-binding sites (71, 72).

The organic calcium antagonists verapamil, methoxyverapamil, and, to a lesser extent, nifedipine have achieved prominence recently and are classified, largely on the basis of electrophysiological evidence in cardiac preparations, as specific calcium channel antagonists (55, 56, 73–75). At 10^{-6}–10^{-8} M, these agents produce a selective antagonism of the slow calcium current with minimal effect on the fast sodium current and thus produce electromechanical decoupling of the heart in the activity sequence nifedipine > methoxyverapamil > verapamil (56, 74, 76–79). The effects of these agents are overcome by increased extracellular calcium.

Because of the high activity and apparent selectivity of action of these agents, their activity in other calcium-utilizing systems can be viewed as evidence that basically similar slow calcium channels are operative in secretory and mechanical processes (57). A complete characterization of the calcium current is not available for many of these processes. However, the similar activities of these antagonists in cardiac and smooth muscle and secretory systems certainly indicate a common basis of action. In a few preparations, widely different activities have been noted according to the stimulus employed; this finding is probably indicative of different modes of calcium translocation. Thus, in rabbit mesenteric artery, verapamil is ~1000 times more active against K^+ than against norepinephrine-induced contractions, suggesting that norepinephrine and K^+ employ principally intracellular and extracellular calcium sources, respectively (80). In contrast, K^+ and muscarinic receptor-induced contractions of guinea pig ileal longitudinal smooth muscle appear, as judged by antagonist activities, to employ identical calcium translocation mechanisms.

Where kinetic evidence is available, verapamil, methoxyverapamil, and nifedipine appear to act noncompetitively against agonists and competitively against calcium. An exceptional situation apparently exists in cardiac tissue where the effects of these agents can be overcome by increasing extracellular calcium and by catecholamines (55, 56, 74) so that a competitive relationship appears to exist also between β-agonists and the calcium antagonists (81, 82). A likely explanation is that the action of catecholamines at the cardiac β-receptor is to increase the available calcium channels, perhaps by a cyclic adenosine monophosphate-dependent mechanism (83). Nifedipine, which shows no apparent structural similarity to verapamil or methoxyverapamil, appears to behave similarly.

There is no question but that verapamil, methoxyverapamil, and nifedipine act as potent antagonists of the slow inward calcium current. There is also evidence that these agents may have important effects on other ionic processes. Verapamil and methoxyverapamil, at the fairly high concentrations used in the squid axon (2×10^{-4} M), do reduce the fast Na^+ current; in cardiac fibers, these agents also appear to have some effect on both the Na^+ and K^+ currents (84, 85). However, some part of their effects on K^+ currents probably is due to the dependence of the latter on calcium entry (86).

Whether nifedipine, which is generally assumed to be a calcium channel antagonist acting similarly to verapamil and methoxyverapamil but of higher activity, shares all of the actions of verapamil and methoxyverapamil is not fully established. However, nifedipine does exert a greater depressant effect on the guinea pig atria with increasing stimulus frequency, suggesting that it also modifies the kinetics of the calcium restitution processes (87). That compounds of such differing structure as verapamil and nifedipine exert similar effects on both the calcium permeation and restitution processes is perhaps suggestive that both processes are controlled through interaction at a common site.

EXCITATION–CONTRACTION COUPLING IN SMOOTH MUSCLE

The source of calcium utilized in smooth muscle excitation–contraction coupling remains ill-defined since, unlike fast skeletal muscle, the smaller less well-developed sarcoplasmic reticulum and slower and more sustained contractile responses of smooth muscle do not impose the dominant demands for an intracellular calcium mobilization–sequestration system that is seen in skeletal muscle. Hence, in smooth muscle, intracellular and extracellular sources of calcium may be utilized in excitation–contraction coupling; the relative usage depends on the tissue, the experimental conditions, and the stimulus (88–93).

Sarcoplasmic reticulum does exist in smooth muscle, and studies (94–96) showed that the amounts vary significantly, being greatest in rabbit main pulmonary artery and least in portal anterior mesenteric vein and taenia coli. A correlation exists between the sarcoplasmic reticulum volume and the ability to sustain contraction in the absence of extracellular calcium. Furthermore, the central and peripheral tubules of sarcoplasmic reticulum are continuous with each other, and the peripheral tubules enjoy a close relationship with the surface membrane in some tissues, suggesting that this arrangement may provide the structural basis for calcium release by the invasion of the action potential (94–98). Calcium-sequestering subcellular fractions have been isolated from several smooth muscles (89, 99–101). However, the quantitative contribution of sarcoplasmic reticulum calcium to excitation–contraction coupling is not established, and it is also clear that there is no obligatory association between electrical and mechanical events for some smooth muscles (94, 97, 102–105). Agonist and antagonist actions are identical or very similar to polarized and depolarized tissues, and excitation–contraction coupling can therefore be independent membrane potential changes.

Attempts to define intracellular or extracellular calcium pools as the source of calcium used in smooth muscle excitation–contraction coupling simply on the basis of dependence of responses on extracellular calcium is of questionable value. Thus, Keatinge (104) showed, for norepinephrine-induced contractions of sheep carotid artery, that a 30-min incubation in calcium-free media left sufficient extracellular calcium to sustain excitation–contraction coupling. Furthermore, in any experiments in which calcium is altered, significant "stabilizing" or "labilizing" actions

occur at the cell membrane level and may profoundly alter membrane excitability (105–108).

Finally, even where tissues do show extreme dependence on extracellular calcium, this does not imply equivalent utilization of extracellular calcium. Studies on guinea pig ileal longitudinal and rat vas deferens, both of which are extremely dependent on extracellular calcium, are illustrative of this fact (109, 110). Comparison of the action of calcium antagonists including La^{3+}, methoxyverapamil, nifedipine, 2-diethylaminoethyl-2,2-diphenyl valerate, and local anesthetics revealed significant differences in their activities in these two tissues. It was concluded: "that although qualitative similarities are apparent with respect to the dependence of agonist-induced activity in both the guinea pig ileum and rat vas deferens it is clear that calcium translocation processes in these two tissues, as examined by the use of a variety of calcium antagonists" are both tissue and agonist selective (110). The calcium ionophore A-23187 produces contractile responses in the guinea pig ileal but not in the rat vas deferens smooth muscle (111). Clearly, differences in calcium utilization are involved in these two smooth muscles which, however, show an equal apparent dependence on extracellular calcium.

It has been suggested that the lanthanide cations may provide a method for distinguishing between intracellular and extracellular calcium use (112–116) on the basis that the similar ionic radius of La^{3+} and calcium and the higher charge density of La^{3+} will enable it to replace calcium influx and efflux. If these assumptions are correct (53, 96, 117), then the use of La^{3+} may permit a qualitative diagnosis of intracellular *versus* extracellular calcium use. Moreover, because La^{3+} is presumed to displace the superficial, rapidly exchangeable calcium and prevent calcium flux, it can be used to "trap" intracellular calcium and, hence, to obtain a quantitative estimate of any change in intracellular calcium occurring during excitation–contraction coupling. Thus, in guinea pig ileal longitudinal muscle, phasic and tonic components of the acetylcholine- and K^+-induced responses are equally (and highly) sensitive to La^{3+}, suggesting that a similar or identical calcium source is involved (53). In rat uterus, acetylcholine responses are significantly more resistant than K^+ responses (115). In rabbit aorta, La^{3+} abolishes the slow phase of the norepinephrine response but leaves the fast phase unchanged (114, 115), suggesting that extracellular and intracellular calcium components are utilized, respectively.

The "lanthanum method" has also been used to determine quantitatively extracellular calcium uptake during excitation–contraction coupling. Thus, in rabbit aorta, Van Breemen *et al.* (114) showed that there were parallel changes in tension development and intracellular calcium content during K^+ or Li^+ stimulation but only after the complicating effects of extracellular calcium exchange had been eliminated by La^{3+} treatment.

Although progress is being made in the delineation of the relative use of intracellular and extracellular calcium in smooth muscle excitation–contraction coupling, the mechanisms by which drug–receptor interactions are linked to calcium mobilization are poorly understood. Several mechanisms must be considered:

1. Coupling of membrane potential changes to calcium release from sarcoplasmic reticulum. This may be regarded as some equivalent of skeletal muscle excitation–contraction coupling and may also include an influx of "trigger" calcium that initiates an intracellular calcium release.
2. Direct entry of calcium through action potentials that totally or partially use calcium as the current-carrying species.
3. Mobilization of calcium (intracellular or extracellular) by potential-independent changes, *i.e.*, the pharmacomechanical coupling of Somlyo and Somlyo (94, 97).
4. Influx of calcium through intracellular sodium–extracellular calcium exchange processes.

These processes are not mutually exclusive, and it is entirely possible that their combinations are used in a given smooth muscle. Additionally, it is obviously necessary to consider the roles of cyclic adenosine monophosphate and cyclic guanosine monophosphate because of their well-described relationships to receptor processes, notably to adrenergic (α and β) and cholinergic (muscarinic) processes (*cf.*, 118–121), and because of the mutual interrelationship of calcium and the cyclic nucleotides in many systems (122, 123). Increasing evidence suggests that the cyclic nucleotides may, through their activation of protein kinase, control membrane phosphorylation and that this may serve to control ion permeabilities (124, 125).

Finally, a comment must be made on the possible role of calcium as a component of membrane receptors such that agonist displacement of the calcium serves to labilize the membrane and initiate excitatory events and enhanced calcium binding serves to stabilize the membrane. Some implications of this proposal were considered previously (53, 108, 126).

As noted previously, calcium entry through specific calcium channels is one source of calcium for excitation–contraction coupling in smooth muscle. The guinea pig ileal longitudinal smooth muscle represents one such system (53, 126–128). This tissue is very sensitive to extracellular calcium for both K^+ and acetylcholine responses, and both responses are equally sensitive to La^{3+}, methoxyverapamil, and nifedipine.

Calcium 45 uptake has been measured by the "lanthanum procedure" and is equally sensitive to the calcium antagonists as the mechanical responses. A 1:1 relationship was found for calcium uptake and mechanical response and, in a series of muscarinic agonists and partial agonists, decreased calcium uptake was associated with partial agonists. The guinea pig ileal longitudinal smooth muscle is sensitive to stimulants including K^+, acetylcholine, and histamine, and the responses are all equally sensitive to the calcium antagonists methoxyverapamil and nifedipine. This finding suggests that several stimulants serve to activate a common pool of calcium channels.

Much of the reviewed material with respect to smooth muscle physiology and pharmacology may be relevant to calcium-ion involvement in chemical mediator releasing systems.

CALCIUM AND CHEMICAL MEDIATOR RELEASE

Lichtenstein's studies (129) with the basophil system indicated that the release reaction can be divided into two stages: first, an antigen-dependent, calcium-independent stage, and second, an antigen-independent, calcium-dependent stage. The agents affecting histamine release *via* increased accumulation of cyclic adenosine monophosphate appear to act only in the first stage whereas agents affecting microtubule function (colchicine and deuterium oxide) act in the calcium-dependent second stage.

Further investigation (130) of the mechanism of mediator release from chopped human lung revealed an additional edetic (ethylenediaminetetraacetic) acid-inhibitable, calcium-dependent step beyond the initial immunological stimulation of (presumed) increased permeability of the cell membrane to calcium and ingress of calcium ions. The experiments of Kaliner and Austen (130) also disclosed that isoproterenol increased cyclic adenosine monophosphate concentrations and prevented the observed calcium reversal of edetic acid inhibition of mediator release, suggesting that the second calcium-dependent step might relate to the action of a contractile protein susceptible to inhibition by phosphorylation by the cyclic adenosine monophosphate-dependent protein kinase system (130). In this connection, it is important to recall that calcium plays a critical role in the control of intracellular cyclic adenosine monophosphate and cyclic guanosine monophosphate concentrations through its ability to inhibit adenyl cyclase (14), stimulate guanyl cyclase (15), and control the phosphodiesterase regulator protein (16).

The most familiar pathophysiological stimulus to the mast cell is the antigen–antibody reaction, which leads to the release of histamine and other substances. In 1958, Mongar and Schild (7) observed that calcium was essential for this response. When it became apparent that calcium influx also mediated the effect of the physiological stimulus to adrenal chromaffin cell catecholamine release, Douglas (131) suggested that the role of calcium in immunological mast cell activation might be similar, namely, to act as a coupling agent between stimulus and response. Later, Douglas (132) cited the mast cell as an example of a class of secretory cells using calcium influx to activate exocytosis. Indeed, the microinjection of calcium ions into mast cells caused granule exocytosis (8).

The calcium inophore A-23187 also stimulates mediator release in rat mast cells (133) and human basophils (134). Comparisons of immunological and ionophore-induced mediator release from basophils have been made. Ionophore and antigen-stimulated histamine release in human basophils differ in several respects (134): the kinetics and total quantity of histamine released are different, depending on the concentrations of antigen or ionophore (with low antigen concentrations producing a slower rate and less total histamine release but low ionophore concentrations producing delayed onset but rapid and essentially complete histamine release); antigen-desensitized basophils release histamine with ionophore; cyclic adenosine monophosphate or agents that stimulate increased cyclic adenosine monophosphate concentrations do not reduce ionophore-induced histamine release as with antigen-induced release; the microtubule-active agents colchicine and deuterium oxide inhibit and augment ionophore-induced release, respectively, but quantitatively less so as compared to antigen-stimulated release; and the calcium antagonist lanthanum inhibits both processes, but the ionophore effect is slightly more sensitive. Thus, ionophore and antigen appear to share certain as-

pects of the codependent biochemical mechanisms involved in histamine release but clearly differ in some respects (134). The specific calcium channel(s) involved, their topography in relationship to the cell surface immunological event, and the mechanisms of opening and closing the calcium channels involved in immunological or ionophore-stimulated mediator release remain unknown.

The calcium antagonist lanthanum produces significant inhibition of histamine release not only in basophils but also in mast cells (135) following immunological challenge. Based on a series of experiments, Foreman and Mongar (*cf.*, 136) concluded that mast cell activation (by several different mechanisms) is accompanied by calcium uptake that is temporally and quantitatively related to histamine release, suggesting that the trigger to histamine release from mast cells is an increased mast cell membrane permeability to calcium and an influx of calcium ions to the intracellular compartment. In the stimulated cell, it is supposed that the equilibrium between "open" and "closed" calcium channels is shifted in favor of open, allowing increased influx of calcium, the magnitude of which determines the degree of histamine secretion. In their model, Foreman and Mongar (136) considered that cyclic adenosine monophosphate has an effect that closes calcium channels and reduces calcium influx.

The recent experiments of Payne (137) on histamine release in the rat mast cell system concerned the effects of quercitin, dantrolene sodium, and 8-(*N,N*-diethylamino)-octyl-3,4,5-trimethoxybenzoate, all calcium antagonists (137). Quercitin and a small number of other flavones of plant origin recently were shown to inhibit histamine release by immunological and nonimmunological stimuli (but no ionophore) (138). Flavones are chemically related to cromolyn sodium; it was suggested that they act similarly by interfering with the normal path of calcium entry into stimulated mast cells. Like quercitin, dantrolene sodium (130) and 8-(*N,N*-diethylamino)-octyl-3,4,5-trimethoxybenzoate (140) have been reported to interfere with calcium translocations. Dantrolene sodium is a peripherally acting smooth muscle relaxant thought to prevent intracellular mobilization of calcium. 8-(*N,N*-Diethylamino)-octyl-3,4,5-trimethoxybenzoate is an aliphatic reserpine analog, which has also been suggested to act as an intracellular calcium antagonist based on its inhibitory effects on smooth muscle contraction (140).

Payne's results (137) indicated that histamine release by compound 48/80 from peritoneal and pleural rat mast cells was inhibited in a concentration-dependent manner by quercitin, which also inhibited dextran-induced histamine release. Dantrolene sodium inhibited histamine release by either compound 48/80 or dextran whereas it produced only weak inhibition of histamine release induced by the calcium ionophore A-23187. On the other hand, histamine release by dextran and ionophore A-23187 was strongly inhibited by 8-(*N,N*-diethylamino)-octyl-3,4,5-trimethoxybenzoate. The results were interpreted to suggest that quercitin, dantrolene sodium, and 8-(*N,N*-diethylamino)-octyl-3,4,5-trimethoxybenzoate may act at different sites to inhibit calcium translocations required for histamine release. Also, Barrett-Bee (141) found that the calcium antagonist cinnarizine inhibited antigen-induced histamine release (50%) in the rat mast cell system.

SUMMARY

Asthma may be considered to be a calcium-dependent disease by virtue of the dependency of excitation–contraction coupling in smooth muscle, stimulus–secretion coupling in mast cells and mucous glands, and vagal nerve activity on the availability of increased cytoplasmic calcium-ion concentrations. The nature and regulation of the calcium channels or pathways involved in various cell types are unknown. Whether the increased responsiveness of the relevant cells in asthma is characterized by increased ease of calcium influx, release from intracellular storage sites, or decreased calcium sequestration mechanisms in the plasma membrane or intracellular organelles is a subject for future research.

Effective antiasthmatic therapy must act finally to reduce availability of cytoplasmic calcium to excitation–contraction, stimulus–secretion, and nerve activation systems. Many effective drugs presumably act in this fashion, but the mechanisms are poorly understood.

It is possible that new calcium antagonists could be synthesized that would inhibit calcium influx or intracellular calcium movements in airway smooth muscle, mast cells, mucous glands, and vagus nerve and that might prove of value in asthma treatment.

The author gratefully acknowledges many informative and stimulating conversations with Dr. David Triggle regarding the role of calcium in smooth muscle functions.

Clinical Evaluation of Antiallergic Agents

RICHARD R. ROSENTHAL

Received May 4, 1979, from the *School of Medicine, Johns Hopkins University, and the Good Samaritan Hospital, Baltimore, MD 21239.* Accepted for publication September 10, 1979.

Abstract □ Testing methods used to detect antiallergic activity are described for several pharmacological classes of drugs. The pharmacodynamics of each drug determine the type of testing required to detect antiallergic or antiasthmatic activity.

Keyphrases □ Pharmacokinetics—clinical testing in mildly asthmatic human volunteers, dose–response curve of antiallergic drugs □ Antiallergic drugs—pharmacokinetics, various clinical testing procedures in humans, inhibition of mediator release, cyclic adenosine monophosphate levels, potential asthma inhibitors □ β-Adrenoceptor agonists—antiallergic drug testing, bronchiolar smooth muscle, cyclic adenosine monophosphate levels, effects on mediator release □ Asthma—review of current theories, clinical evaluation, symposium, antiallergic drugs

Hypersensitivity involves an allergic reaction that is an immunological event characterized by the release of a chemical mediator, histamine or slow-reacting substance of anaphylaxis, in response to exposure to a foreign antigen. Foreign (environmental) antigens are usually complex protein mixtures such as cat dander or ragweed pollen. Initial antigen exposure results in the elaboration of antibody of the immunoglobulin E class, which, as circulating specific immunoglobulin E antibody, is in equilibrium with cell-fixed immunoglobulin E on circulating basophils or tissue mast cells. When a subsequent environmental antigenic insult occurs, the antigen combines with the cell-fixed immunoglobulin E antibody, whereupon histamine and other chemical mediators are released to act directly on target tissue. Accordingly, the characteristic allergic reactions seen in asthma, rhinitis, urticaria, and even systemic anaphylaxis reflect the anatomic sites where histamine and other chemical mediators are released as well as their respective tissue responses.

DISCUSSION

Histamine release induced by antigen can be modified by drugs that act on various stages within the release mechanism. For example, the β-agonists, isoproterenol, ephedrine, metaproterenol, and terbutaline, activate adenyl cyclase to increase intracellular levels of cyclic adenosine monophosphate, an enhancement that prevents histamine release. Because phosphodiesterase catalyzes the conversion of cyclic adenosine monophosphate to 5′-adenosine monophosphate, inhibition of this enzyme by drugs such as the xanthines (theophylline) arrests the breakdown of cyclic adenosine monophosphate, thereby preventing histamine release.

Cromolyn sodium is the prototype of a new class of compounds that act presumably by preventing mediator release, although the exact mechanism of action is unknown. The anti-inflammatory steroids appear to stabilize the mast cell membrane and also enhance β-receptor sensitivity. The prostaglandins not only influence intracellular cyclic adenosine monophosphate but also may prevent mediator release, whereas prostaglandin synthetase inhibitors may regulate allergic hypersensitivity reactions in either direction. At the cellular level, α-agonists (phenylephrine) and cholinergic agonists (acetylcholine) may increase intracellular cyclic guanosine monophosphate by stimulating guanyl cyclase and enhancing histamine release. On the basis of experimental evidence, α-blockers and cholinergic antagonists may have some usefulness as antiallergic agents.

The classical antihistamines, exemplified by diphenhydramine, compete with histamine at H_1-receptor sites to allay allergic reactions. This group has a new member with different pharmacological attributes, the H_2-receptor antagonist cimetidine, which blocks gastric acid secretion. Although this kind of blockade has not previously been associated with allergy treatment, preliminary studies suggest that H_1- and H_2-blockers in combination may be effective against urticaria (1–3). Drugs that alter the immune response also may be considered antiallergic. Ragweed extract or denatured antigens can raise the protective immunoglobulin G antibody titers and reduce the severity of an allergic reaction.

A number of clinical testing procedures can be used to evaluate new antiallergic medications. The inhalation challenge method elicits an asthmatic attack under laboratory conditions, enabling a test drug to be evaluated (4). In this technique, mildly asthmatic volunteers with near normal pulmonary function inhale graded doses of antagonists such as antigen, methacholine, or histamine, using a specialized inhalation dosing apparatus, the inhalation dosimeter. Spirometry and specific airway conductance are monitored, and the dose–response curves to the inhaled antagonists indicate patient sensitivity.

The provocation dose, defined as the amount of antagonist causing a 20% fall in forced expiratory volume in 1 sec, is interpolated from the dose–response curve and used as a reproducible index of patient sensitivity to the inhalant.

A change in the dose–response curve or a shift of the provocation dose toward a higher antigen requirement indicates an alteration of antigen sensitivity. By this procedure, antiasthma agents can be evaluated for

relative efficacy and compared pharmacokinetically. Also, the premedication interval can be lengthened to provide information relative to the duration of the blocking activity after the administration of the protective dose of the test drug.

Isoproterenol kinetics have been studied with this procedure. When premedication with isoproterenol was accomplished 1 hr before antigen provocation, the sympathomimetic agent was effective as a bronchodilator but did not act long enough to inhibit the response to inhaled antigen 1 hr later. When isoproterenol was given every 0.5 hr in conjunction with inhaled antigen, the dose–response curve shifted significantly in the direction of increased antigen requirement. However, when isoproterenol was admixed with the antigen and given simultaneously, complete inhibition of the antigen response occurred. These observations correlate well with *in vitro* studies, which revealed that a peak accumulation of cyclic adenosine monophosphate occurred within 5 min of exposure to isoproterenol, as did a concomitant inhibition of antigen-induced histamine release (5).

Similar studies with selective adrenergic agonists have shed light on the pharmacology involved in the bronchomotor response. Phenylephrine, primarily an α-agonist, elicits bronchodilator responses and inhibits inhaled antigen effects in the manner of isoproterenol, a β-agonist, although less effectively. This observation refutes the popular belief that α-adrenergic receptors of bronchiolar smooth muscle cause bronchospasm when activated. On the contrary, the evidence suggests that there are few, if any, α-receptors in bronchiolar smooth muscle and that any activity caused by α-agonistic drugs is due to the unopposed weak β-specificity (6).

Bronchial provocation techniques have been used extensively to study the physiology of asthma and the pharmacology of antiallergic drugs. β-Agonists, xanthines, anticholinergics, prostaglandins, and the cromolyn-type inhibitors have all been evaluated by these methods. The most effective agents in preventing bronchospasm by inhalation are the β-adrenergic agonists. Isoproterenol is the most effective drug in this respect when given simultaneously with the antigen. Metaproterenol and terbutaline, the latter not yet approved for inhalation, have a longer duration (7).

Anticholinergic drugs, including atropine, are not yet available for inhalation in the United States, although they have been evaluated in bronchoprovocation studies. Atropine causes considerable baseline elevation and is a bronchodilator that diminishes the resting bronchial vagal tone (8). Irritant-induced bronchospasm caused by inhalation of dust or cold air is mediated by the vagus nerve, a cholinergic pathway, whose responses are effectively blocked by inhaled atropine (9). Antihistamines (H_1-blockers) are ineffective when inhaled before antigen challenge, suggesting that mediators other than histamine may be involved in allergic bronchospasm. The synthetic prostaglandins, while not yet in the clinical testing stage, represent another class of potential asthma inhibitors.

The exercise challenge is more physiological or "natural" than the inhalation challenge. Exercise protocols require the performance of pulmonary function tests after a suitable patient jogs on a treadmill for 6–8 min. Following this exercise, susceptible patients usually have a significant fall in their pulmonary function. A test drug can be introduced before the exercise challenge, and its inhibitory capabilities can be studied. This procedure seems best suited for evaluation of the cromolyn-type agents. Atropine, while raising the baseline, does not usually prevent the relative drop in pulmonary function that occurs after exercise (10, 11). Some protection is afforded by this anticholinergic, however, because of the elevated baseline pulmonary functions. The β-adrenergic agonists, isoproterenol and terbutaline, are quite effective through mechanisms of baseline elevation as well as prevention of the exercise response (7). On the other hand, inhaled antihistamines are ineffective against exercise challenge, although they possess varying degrees of anticholinergic activity (8).

The most widely employed experimental method of drug evaluation is the maintenance of a symptom diary often supplemented with routine pulmonary function tests. Diaries that measure chronic symptoms of wheezing, shortness of breath, chest tightness, and cough and that assign a score for intensity and duration are quite useful, especially when medication use and pulmonary function are integrated into the diary. Such diaries are also effective for monitoring the effects of immunotherapy (allergy shots) for the treatment of seasonal hay fever (12).

In summary, drugs representative of many pharmacological categories are useful in the treatment of asthma and other allergic illnesses. An understanding of their pharmacodynamics is critical to the design of appropriate clinical trials as well as to proper prescribing. When underlying mechanisms are not understood or are unclear, empiricism may be necessary for drug evaluation. As the mechanisms underlying the asthmatic state become better known, the potential for optimal therapy will emerge.

EVERY FIVE YEARS

A current series on public affairs television is titled "Every Four Years." The series examines various aspects of the presidency of the United States, and specifically the changing style of those who have sought and reached the office as well as the evolving impact those changes have had on the office itself. The title, of course, refers to the presidential term, and the timing of the series is most appropriate with national elections coming up again this fall.

But even sooner, in fact this April, a process will repeat itself, which used to occur every ten years since 1820, but more recently has been taking place at five-year intervals.

We refer to the United States Pharmacopeial Convention, the members of which will be gathering in Washington, D.C., from April 17 through April 19, immediately preceding the APhA Annual Meeting.

As provided for in the USPC Bylaws, a call goes out "*every five years*" to all the recognized organizations in medicine, pharmacy, and several related areas for each of them to appoint delegates who will then convene at the USPC's quinquennial meeting. These delegates are responsible for (*a*) electing a Board of Trustees to oversee the operation, (*b*) selecting a Committee of Revision to undertake the assigned tasks of developing and updating the standards to go into the next edition of the compendia, and (*c*) adopting a series of resolutions to serve as the expression of the will of the assembled convention concerning what particular subjects should be addressed, or what particular tasks should be undertaken, during the upcoming five-year period until the next convention. The delegates also deal with certain other matters such as extending recognition to additional organizations and proposed amendments to the USPC Bylaws.

But the task of broadly laying out the master plan which will point the direction for the coming revision period is a function that should not be taken casually. All too often, organizations fail to recognize ominous signs which suggest the need for corrective action.

In the case of the USPC, we see certain strong indications that the federal government is moving in the direction of impinging on traditional compendia turf. Although there have been a number of such intrusions over the years—such as the antibiotic certification amendments and the authority to establish nonproprietary drug names—the movement was given substantial impetus with the Office of Technology Assessment's Drug Bioequivalence Study Panel report in mid-1974. That report called for the replacement of the USP and NF with a new standards-setting organization.

Changes that occurred in 1975 served to buy some additional time for the official compendia to undertake and complete the job of developing standards and specifications that would pass the scrutiny of discerning critics including the OTA panel. There is, however, some question as to how well the USPC has responded to date in fully satisfying that challenge.

Whatever might be said along that line, the fact remains that significant compendia-related activity has been recently stirring within Food and Drug Administration circles. Indeed, these activities have caused some compendia-watchers to be concerned that the FDA could be laying the groundwork for an Afghanistan-style take-over. Whether or not the FDA may have such designs, we truly don't know.

However, at least two speeches by FDA officials, during recent months, point in the direction of a future turf-battle.

First, the staff director of FDA's new Compendial Monograph Evaluation and Development Program, speaking at the APhA Academy of Pharmaceutical Sciences' November meeting in Kansas City, told the audience that the agency expects his program to produce a "new generation of compendial standards which are highly reflective of both the market and the state-of-the-art." Begun only in late 1978, this program has two professed objectives: (*a*) to evaluate existing selected compendial monographs and to develop or improve analytical testing methods to assure that they will be suitable for regulatory purposes, and (*b*) to develop monographs where none currently exist in order to establish adequate public standards.

Second, the executive director of FDA's regional operations, appearing as a panelist during the Food and Drug Law Institute's annual conference in Washington last December, informed the audience of programs initiated by his department within the past year. One such program he mentioned is a critical review of USP/NF monographs with a view toward developing new and improved test and assay procedures at the various FDA regional laboratories.

Clearly, therefore, in FDA's eyes there is significant room for improvement in the compendial monographs. And how far FDA plans to pursue these projects of "improvement" remains to be seen.

But if the agency were ever to mount a take-over effort, this would clearly be the wisest strategy to follow in initiating such tactics. Consequently, the delegates who soon will be assembling for the USP Convention should be conscious of this possibility and lay out the best possible defense to meet that threat—namely, a program that will produce a new edition of the compendia that is so improved in the standards and specifications area as to approach a level of perfection that it will defy FDA challenges to "improve" it.

In conclusion, we feel it would be tragic if this country ever were to lose the present system whereby drug standards are established within the private sector under legal sanction and recognition. The 1980 USP Convention will have the prime challenge of producing a workable, no-frills blueprint to see that such a loss is not allowed to occur through oversight or neglect.

Fluorescence Properties of Pseudomorphine and Congeners: Structure–Activity Relationships

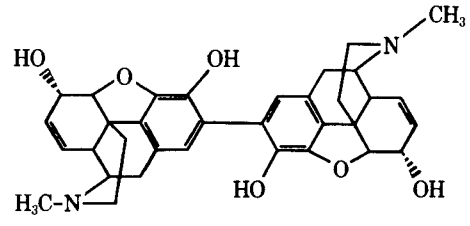
W. D. DARWIN and E. J. CONE ˣ

Received July 23, 1979, from the *National Institute on Drug Abuse, Division of Research, Addiction Research Center, Lexington, KY 40583.*
Accepted for publication October 1, 1979.

Abstract □ The fluorescence properties of morphine congeners oxidized with potassium ferro-ferricyanide are described. Fluorescence did not occur in congeners with the following structural features: an alkyl or acyl group at the 3-*O*-position, a C-6 carbonyl group, or absence of the furan oxygen. Masking the carbonyl group by ethylene ketal formation effectively restored fluorescence. Morphine congeners that fluoresced were most sensitive to structural changes at C-6, C-7, and C-8. Details of effects of structural changes on emission maxima, intensity, and Stokes' shift are reported.

Keyphrases □ Morphine congeners—ferro-ferricyanide oxidation, fluorescence characteristics □ Pseudomorphine—structural variations, fluorescence □ Fluorometry—structural effects, intensity, Stokes' shift, structural analysis □ Structure–activity relationships—pseudomorphine and congeners

Morphine (I, Table I) can be oxidized to the bimolecular base pseudomorphine (II) by reaction with potassium ferricyanide in aqueous solution (1). The structure of this derivative was shown to be 2,2′-bimorphine on the basis of spectral and chemical studies (2). Because of the extended conjugated system, the fluorescence properties of II are greatly enhanced over that of I.



II

Several fluorometric assays of I in biological material are based on the conversion of I to a pseudomorphine derivative (3–6). The occurrence of fluorescence from oxidized solutions containing morphine congeners also has been observed (1) and used for structural verification of metabolites of naltrexone (XVII) (7) and naloxone (XXII) (8). However, a detailed understanding of the structural requirements for fluorescence of pseudomorphine congeners is not available for prediction of fluorescence of new compounds, and there is some ambiguity in the literature concerning the requirements for fluorescence of morphine congeners (1, 8). Consequently, a study was made of the fluorescence properties of a series of morphine analogs to determine their basic structural requirements for fluorescence under oxidizing conditions. An explanation is also proposed for the unusual quenching properties of XVII and XXII.

EXPERIMENTAL

Apparatus—A spectrofluorometer[1] equipped with an *x–y* recorder[2] was used for determining excitation and emission spectra and for measuring fluorescent intensities. Spectra were not corrected for variations in lamp intensity or photomultiplier sensitivity but were calibrated with quinine sulfate at 350 and 450 nm before each measurement.

Chemicals[3]—All chemicals were reagent grade quality.

TLC—Glass fiber sheets[4] were developed with ethyl acetate–methanol–aqueous ammonia (70:10:5 v/v/v). The developing chamber was allowed to equilibrate 10 min prior to elution. After the sheets were developed and dried, they were inspected for fluorescence under 250- and 360-nm UV light. The plates were then sprayed with potassium iodoplatinate solution for visualization of morphine and pseudomorphine-like components.

Preparation of Standard Solutions—Quinine sulfate solutions (1 mg/liter) were prepared in 0.1 *N* H_2SO_4. Solutions of morphine (10 μg/ml) and congeners were prepared in distilled water. The oxidant solution was a mixture of potassium ferricyanide (28.85 mg) and potassium ferrocyanide (2.45 mg) in 50 ml of distilled water (1). The latter solution was prepared fresh daily, and an aliquot was diluted 10-fold before use.

Oxidation and Measurement of Fluorescence—Equal volumes of drug solution (5 ml, 10 μg/ml) and phosphate buffer (5 ml, 0.1 *M* K_2HPO_4, pH 8.5) were mixed and treated with the freshly prepared oxidant solution (0.5 ml). The mixture was allowed to remain at room temperature for 10 min. During the waiting period, the instrument was

[a] The designations — and H_2 represent unsaturation and saturation of the 7,8-bond, respectively. [b] The constants λ_{ex} and λ_{em} are reported in nanometers, and Stokes' shift constant is reported in centimeters^{-1}. Intensity (I^{-1}) is equivalent to the concentration of the compound, in micrograms per milliliter, that will give the same fluorescence intensity as 1 μg/ml of quinine sulfate. The fluorescence of all compounds was measured at pH 8.5 at a concentration of 5 μg/ml, with the exception of XXVII–XXX which were measured at pH 7.0 due to insolubility at higher pH. n.o. indicates that fluorescence was not observed. [c] A small amount of fluorescence was observed due to contamination of VIII by hydrolysis to VII.

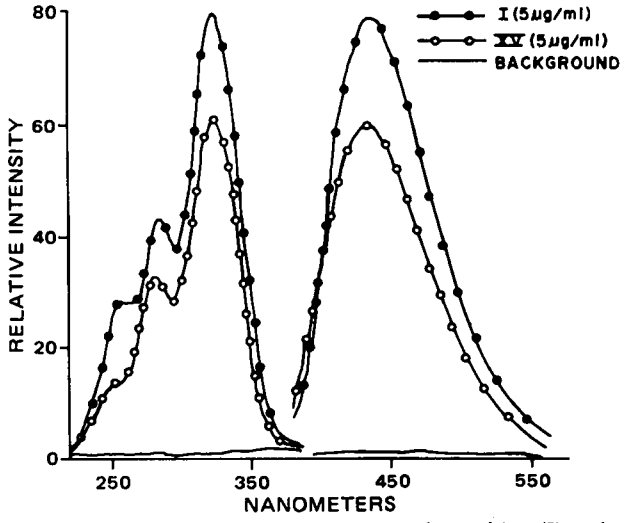

Figure 1—*Excitation and emission spectra of morphine (I) and 6α-naltrexol (XV) oxidized with potassium ferro-ferricyanide at pH 8.5. Both concentrations were 5 μg/ml; λ_{ex} = 324 nm and λ_{em} = 434 for I, and λ_{ex} = 323 nm and λ_{em} = 432 for XV.*

calibrated with quinine sulfate solution for wavelength and intensity corrections.

The excitation maximum, λ_{ex}, of the drug solution was located, and relative intensity was recorded. Background corrections were made using drug solutions treated similarly but without added oxidant. Contributions from background were generally <5%. All drugs were analyzed in triplicate, and the mean of the analyses is reported.

RESULTS AND DISCUSSION

Morphine congeners were oxidized with potassium ferro-ferricyanide solution to form pseudomorphine-like products similar to those formed from reaction of I. Fluorescence properties of these products were measured with a spectrofluorometer calibrated with quinine sulfate solution. The procedure used for the oxidation step was adapted from that of Kupferberg *et al.* (1) for the oxidation of I. Optimum conditions for production of fluorescence (pH and reaction time) were established prior to fluorescence measurement.

Typical excitation and emission spectra of the oxidation products of XV and I are shown in Fig. 1. The spectral similarities of XV to I are apparent. Three absorption bands were observed for all morphine congeners that exhibited fluorescence. Emission spectra characteristically showed a single maximum. The fluorescence properties of the oxidized morphine congeners are presented in Table I. The most intense absorption bands, λ_{ex} and λ_{em}, are reported. In addition, a measure of the reciprocal of the fluorescent intensity, I^{-1} (equivalent to the concentration of the compound in micrograms per milliliter that will give the same fluorescent intensity as 1 μg/ml of quinine sulfate), Stokes' shift constant (9, 10), and a structure are included. The Stokes' shift constant, a measure of the energy dissipated during the lifetime of the excited state before return to the ground state, also reflects energy differences in shifts of equal magnitude at different wavelengths.

Table II—Compounds that Did Not Fluoresce under Oxidizing Conditions and Associated Mechanisms Preventing Fluorescence

Compound	Apparent Structural Feature Involved in Prevention of Fluorescence
Codeine, α-isocodeine, norcodeine, 6α-hydrocodol, 6β-hydrocodol, 6α-oxycodol, 6β-oxycodol, hydrocodone[a], oxycodone[a], *N*-methylcyclopropylnoroxycodone[a], dextromethorphan[a], ethylmorphine, diacetylmorphine, 14-hydroxycodeine	Prevention of dimerization at C-2 by alkylation or acylation of the C-3 phenol group
Levallorphan, pentazocine, cyclazocine	Lack of a furan oxygen
Hydromorphone, naltrexone, naloxone, oxymorphone	Intramolecular quenching by C-6 keto group

[a] These compounds have additional structural features that would prevent fluorescence under these conditions.

Compounds that did not fluoresce under the mild oxidizing conditions of the potassium ferro-ferricyanide solution are listed in Table II. It is apparent that at least three structural features are important in the prevention of fluorescence of morphine congeners under these conditions. The dimerization process can be blocked by introduction of an alkyl or acetyl group at the 3-*O*-position. TLC analyses of the oxidized products of I, X, XII, XIII, XV, XVII, and 6β-hydrocodol for polar, pseudomorphine-like adducts provided evidence for their occurrence for I, X, XII, XV, and XVII. Thus, it is likely that the C-2 position of these compounds is activated by the presence of the C-3 phenolic group through tautomerization to a quinone-like structure, which may then undergo a coupling reaction. Blockade of this process with an alkyl or acyl group would prevent dimerization.

A second structural feature important in the prevention of fluorescence involves quenching by a carbonyl group located at C-6. Both XII and XVII reacted under the standard oxidizing conditions to produce a more polar product, as evidenced by iodoplatinate-positive spots on TLC. Although dimerization apparently occurred for XII and XVII, neither compound fluoresced. In contrast, fluorescence was observed for the 6α- and 6β-carbinol homologs of XII and XVII and for the ethylene ketal XVIII. Protection of the carbonyl group as a ketal, thus providing a fluorescent derivative, is a similar effect to that observed by Crowell and Varsel (11), who reported that the fluorescence quenching effect of aromatic aldehydes could be overcome by acetal formation.

The quenching effects of the carbonyl group result from the nonbonded electrons undergoing $n \rightarrow \pi^*$ transitions at lower energy levels and with lower molar absorptivity than the $\pi \rightarrow \pi^*$ transitions. In addition, the greater degree of *s* character in the sp^2 hybridized nonbinding orbital of the carbonyl oxygen than in the π orbitals of the biphenyl system results in a higher degree of spin-orbit coupling. Intersystem crossing is increased, thereby decreasing fluorescence and increasing the possibility of phosphorescence at lower temperatures. The conversion of XVII to XVIII results in less *s* character for the carbon–oxygen bond at C-6 (sp^3 orbitals) and eliminates the π bond, thereby restoring fluorescence.

The possibility that fluorescence quenching by the carbonyl group was occurring *via* an intermolecular process rather than by intramolecular quenching was ruled out by mixing the fluorescent species and measuring the resultant fluorescence. Three solutions were prepared: A, XVII (20 μg/ml); B, XV (20 μg/ml); and C, XVII (10 μg/ml) and XV (10 μg/ml). The compounds were oxidized and an additional solution, D, was prepared from equal parts of the oxidized Solutions A and B. This procedure gave the same concentration of drug in Solutions C and D.

The fluorescence of each solution was measured (Fig. 2). The fluorescent intensity of Solution D was approximately one-half of that observed for Solution B, as would be expected if intermolecular quenching
