Influence of Salt Concentration—The effect of ionic strength on the capacity factor for I, V, and X was studied (Fig. 5). The mobile phases used were 0.05 *M* phosphate buffers at pH 2.5, 3.5, and 7.0; the ionic strength was varied from 0.51 to 2.0 for each pH value. The influence of the ionic strength on capacity factors at pH 2.5 and 3.5, where I, V, and X are in cationic or zwitterion forms, was very small. At pH 7.0, where these substances are in anionic form, this influence was important, especially for V; it decreased in the order V > X > I.

According to Horvath *et al.* (6), the increase in k' with ionic strength can be attributed to an increase in water surface tension when the salt concentration increases. On the contrary, the ionic form of cephalosporin C does not affect the influence of ionic strength on capacity factors. The k'/μ plots are straight lines of similar slope for each pH value studied, except at pH 2.5 and a very low ionic strength (Fig. 6).

The influence of ionic strength on the retention of II and XII–XIV also was studied at pH 2.6 and 6.0 (Fig. 7). The mobile phase was a mixture of 0.05 *M* phosphate buffer and methanol (2:1 v/v). Plotting k'/μ resulted in lines with negative slopes at the lowest acid pH, where the penicillins are in cationic or undissociated form. At pH 6, where the penicillins and the cephalosporins are in anionic form, the slopes of the k'/μ lines are positive.

It must be emphasized that the ionic strength of the mobile phase has a greater influence on the capacity factors of charged forms than on those of uncharged ones, and it is in the opposite direction. In fact, an increase of the ionic strength increases the retention of the charged forms while decreasing the retention of the uncharged acid forms.

CONCLUSION

The effect of cephalosporin and penicillin ionization on the chromatographic retention by nonpolar stationary phases can be interpreted in terms of hydrophobic interactions between the solute and the hydrocarbon function bound to the support surface. This quantitative study permitted determination of the capacity factors of each molecular form (k'_0, k'_{-1}, and k'_{+1}) of the investigated drugs.

The results given in this work will aid in the separation and analysis of some of the investigated substances.

The logarithms of the capacity factors of each molecular form, being independent of pH, probably will represent more adequately the lipophilic or hydrophobic characteristic of a compound having ionizable groups.

Hypocholesterolemic Agents VII: Inhibition of β-Hydroxy-β-methylglutaryl-CoA Reductase by Monoesters of Substituted Glutaric Acids

MARVIN R. BOOTS ˣ, YEONG-MAW YEH, and SHARON G. BOOTS *

Received August 23, 1979, from the *Department of Pharmaceutical Chemistry, Medical College of Virginia, Health Sciences Division, Virginia Commonwealth University, Richmond, VA 23298.* Accepted for publication November 26, 1979.

*Present address: Department of Chemistry, Stanford University, Stanford, CA 94305.

Abstract □ A series of 1-(4-biphenylyl)pentyl hydrogen 3-alkylglutarates and 3-hydroxy-3-alkylglutarates was synthesized and assayed for inhibition of rat liver β-hydroxy-β-methylglutaryl-CoA reductase. Limited solubility of the monoesters in the enzyme assay system prevented the determination of the I_{50} values. However, the limited data indicated no significant changes in the activity of the analogs when they were assayed at identical concentrations.

Keyphrases □ Hypocholesterolemic agents—inhibition of β-hydroxy-β-methylglutaryl-CoA reductase, monoesters of substituted glutaric acids, rat liver microsomes □ Microsomes, rat liver—inhibition of cholesterol biosynthesis, monoesters of substituted glutaric acids □ Enzyme inhibition—effect of monoesters of glutaric acids on cholesterol biosynthesis, rat liver microsomes

An approach to the design of cholesterol biosynthesis inhibitors as potential hypocholesterolemic agents was discussed previously (1, 2). The rationale for the inhibition of the enzyme β-hydroxy-β-methylglutaryl-CoA reductase was presented (1). Structure–activity relationships indicated that maximum activity was observed when R_1 = biphenylyl, R_2 = *n*-butyl, and n = 1–4 in a series of arylalkyl hydrogen alkanedioates (I). In addition, the incorporation of a β-hydroxy-β-methyl moiety into the acid portion of the glutarate analog provided II, which was seven times more active than the glutarate analog of I.

This paper describes the synthesis and assay of a series of 1-(4-biphenylyl)-*n*-pentyl hydrogen 3-alkylglutarates (III) and 3-hydroxy-3-alkylglutarates (IV). The 3-alkyl series (III) was designed specifically to determine if there was a hydrophobic binding site on the enzyme where the 3-alkyl group of the glutaric acid moiety could bind. The

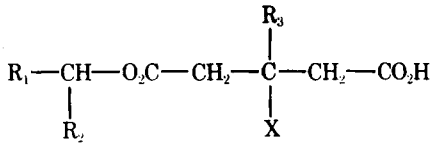
II

3-hydroxy-3-alkyl series (IV) was synthesized and evaluated to determine if binding to the hydrogen-bonding site *via* the hydroxyl group and to the hydrophobic site *via* the 3-alkyl group on the enzyme could occur simultaneously.



III: R_3 = alkyl, X = H
IV: R_3 = alkyl, X = OH

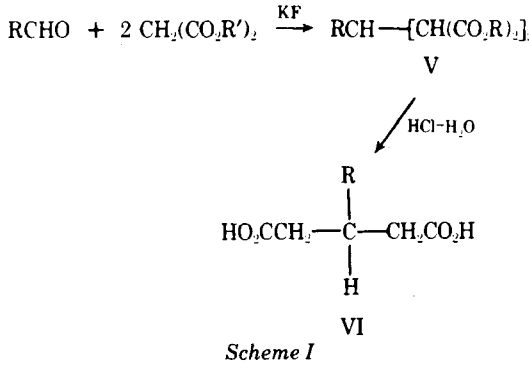
EXPERIMENTAL[1]

Chemistry—The desired monoesters (III and IV) were prepared from 1-(4-biphenylyl)-*n*-pentanol (1) and the appropriate substituted glutaric acid using the method of Büchi *et al.* (3). Synthesis of the required 3-alkylglutaric acids (VI) was performed *via* the pathway illustrated in Scheme I. Condensation of diethyl malonate with aliphatic aldehydes in the presence of potassium fluoride gave the alkylidenedimalonates (V) (4) in 25–85% yields. Acid hydrolysis and decarboxylation of V afforded the desired acids (VI) in 60–80% yields.

The 3-hydroxy-3-alkylglutaric acids (VIII) were synthesized using the pathway illustrated in Scheme II. Treatment of the appropriate ester with the allyl Grignard reagent, as described by Tschesche and Machleidt (5), gave the 4-hydroxy-4-alkyl-1,6-heptadienes (VII) in good yields (80–87%). Ozonolysis of VII followed by treatment with hydrogen peroxide gave the required hydroxy acids (VIII) in 70% yields.

1-(4-Biphenylyl)-n-pentyl Hydrogen 3-Alkyl- and 3-Hydroxy-3-alkylglutarates—The monoesters (IIIa–IIId and IVa–IVd) of the 3-alkylglutaric acids (VI) and 3-hydroxy-3-alkylglutaric acids (VIII) were prepared using the procedure of Büchi *et al.* (3) as described previously (2). The crude oily monoesters were chromatographed on silicic acid. Elution with 20% ether–petroleum ether (bp 60–75°) afforded colorless oily monoesters. The monoesters were characterized as their solid *S*-benzylthiuronium salts using the method of Donleavy (6) as described previously (1). Table I lists the analytical data.

3-Alkylglutaric Acids (VI)—The 3-*n*-propyl- (7), 3-isopropyl- (8), and 3-isobutyl- (9) glutaric acids were prepared by acid hydrolysis and decarboxylation of the appropriate tetraethyl alkylidenedimalonate (4). The preparation of 3-*n*-butylglutaric acid serves as an example.



Scheme I

A mixture of 26.0 g (0.067 mole) of tetraethyl *n*-butylidenedimalonate (4), 250 ml of water, and 250 ml of concentrated hydrochloric acid was refluxed for 24 hr. The resulting solution was extracted with ethyl acetate. The organic phase was washed three times with water, washed with a saturated sodium chloride solution, and then dried over anhydrous sodium sulfate. The solvent was removed to give 9.9 g (78%) yield of a pale-yellow oil; NMR ($CDCl_3$): δ 0.35–0.82 (m, 9H, C_4H_9), 1.2 (s, 4H, CH_2CCH_2), 1.93–2.17 (m, 1H, CH), and 5.80 [s, 2H, $(CO_2H)_2$] ppm. The oil was characterized analytically as the white *S*-benzylthiuronium salt (1), mp 165–167°.

Anal.—Calc. for $C_{25}H_{36}N_4O_4S_2$: C, 57.7; H, 6.9; N, 10.8. Found: C, 57.8; H, 7.1; N, 10.8.

3-Hydroxy-3-alkylglutaric Acids (VIII)—The acids were prepared by ozonolysis followed by hydrogen peroxide oxidation of the appropriate 4-hydroxy-4-alkyl-1,6-heptadiene to afford the desired 3-hydroxy-3-alkylglutaric acid (VIII). The 4-hydroxy-4-alkyl-1,6-heptadienes were prepared using the method of Tschesche and Machleidt (5). The preparation of 4-hydroxy-4-isobutyl-1,6-heptadiene serves as an example.

To a stirred suspension of 4.62 g (0.19 g atom) of magnesium turnings in 8 ml of dry ether, 8 ml of dry tetrahydrofuran, and a crystal of iodine was added dropwise a solution of 6.5 g (0.05 mole) of ethyl isovalerate and 14 ml (0.16 mole) of allyl bromide in 19 ml of dry ether and 56 ml of dry tetrahydrofuran. The reaction mixture was maintained at a gentle reflux during the addition and was refluxed for 3 hr after the addition was complete. The resulting mixture was poured onto ice–hydrochloric acid and then extracted with ether.

The organic phase was washed with water, 5% NaOH, water, and finally saturated sodium chloride solution. It then was dried over anhydrous sodium sulfate and concentrated under reduced pressure to give 9.4 g of an orange liquid. Vacuum distillation afforded 7.8 g (81% yield) of a colorless liquid, bp 50–51° (0.65 mm Hg); NMR ($CDCl_3$): δ 0.95 [d, 6H, $C(CH_3)_2$], 1.39 (d, 2H, CH_2), 1.56 (s, 1H, OH), 1.69 (m, 1H, R_3CH), 2.25 [d, 4H, $(C{=}CCH_2)_2$], 4.89–5.43 [m, 4H, $(C{=}CH_2)_2$], and 5.54–6.31 [m, 2H, $(C{=}CH)_2$] ppm.

Anal.—Calc. for $C_{11}H_{20}O$: C, 78.5; H, 12.0. Found: C, 78.4; H, 12.0.

The following 4-hydroxy-4-alkyl-1,6-heptadienes were prepared using the described procedure: 4-hydroxy-4-*n*-propyl-1,6-heptadiene, bp 39–41° (2.0 mm Hg) [lit. (10) bp 70° (17 mm Hg)]; 4-hydroxy-4-isopropyl-1,6-heptadiene, bp 48–51° (1.5 mm Hg) [lit. (10) bp 43–45° (1.3 mm Hg)]; and 4-hydroxy-4-*n*-butyl-1,6-heptadiene, bp 93–95° (6 mm Hg) [lit. (10) bp 90–92° (6 mm Hg)].

3-Hydroxy-3-n-propylglutaric Acid—The method of Tschesche and Machleidt (5) was used. A solution containing 4.16 g (0.027 mole) of 4-hydroxy-4-*n*-propyl-1,6-heptadiene, 3.5 ml of acetic acid, and 43 ml of methylene chloride was cooled in an isopropanol–dry ice bath. Ozone was passed through the solution for 2 hr, and the resulting blue solution was allowed to warm to 25°. To the clear, colorless solution was added 25 ml of acetic acid, and the methylene chloride was removed under reduced pressure.

To the residue were added 25 ml of acetic acid and 25 ml of 30% H_2O_2. The solution was heated at reflux for 8 hr, and removal of the solvent under reduced pressure afforded 3.69 g of a colorless oil. Trituration with petroleum ether (bp 60–75°) afforded 3.6 g (70% yield) of a white solid, mp 90–94°. Two recrystallizations from ether–petroleum ether (bp 60–75°) afforded a white solid, mp 96–98°; NMR (dimethyl sulfoxide-d_6): δ 0.54–1.77 [m, 7H, $CH_3(CH_2)_2$], 2.51 [s, 4H, $(CH_2COO)_2$], and 6.11 [broad s, 3H, OH, $(COOH)_2$] ppm.

Scheme II

[1] Melting points were determined with a Thomas-Hoover capillary apparatus and are uncorrected. Elemental analyses were carried out by Atlantic Microlaboratories, Atlanta, Ga. IR spectra were determined using a Perkin-Elmer model 257 spectrophotometer. NMR spectra were obtained using a Perkin-Elmer model R-24 spectrometer in the solvent specified with tetramethylsilane as the internal reference.

[a] The inhibition index, I/S, equals the ratio of the micromolar concentration of the inhibitor to the micromolar concentration of the substrate required to give the percentage inhibition shown. At least two sets of duplicate determinations were used. [b] I/S = 9 as reported previously (2). [c] I/S = 1.5 as reported previously (2). [d] A standard inhibitor used routinely to provide comparability of each assay set (2); I/S = 7.

3-hydroxy-3-*n*-propylglutaric acid was used to give 3-hydroxy-3-isopropylglutaric acid (73% yield) as a white solid, mp 87–92°. Two recrystallizations from ethyl acetate–petroleum ether (bp 60–75°) afforded a white solid, mp 99–101°; NMR (dimethyl sulfoxide-d_6): δ 0.93 [d, 6H, $C(CH_3)_2$], 1.30–2.12 (m, 2H, OH, R_3CH), 2.63 [s, 4H, $(CH_2COO)_2$], and 8.00 [broad s, 3H, OH, $(COOH)_2$] ppm.

Anal.—Calc. for $C_8H_{14}O_5$: C, 50.5; H, 7.4. Found: C, 50.4; H, 7.4.

*3-Hydroxy-3-*n*-butylglutaric Acid*—The procedure described for 3-hydroxy-3-*n*-propylglutaric acid was used to give 3-hydroxy-3-*n*-butylglutaric acid (68% yield) as a white solid, mp 66–76°. Two recrystallizations from ethyl acetate–petroleum ether (bp 60–75°) afforded a white solid, mp 76–78°; NMR ($CDCl_3$): δ 0.67–2.23 [m, 9H, $CH_3(CH_2)_3$], 2.78 (s, 4H, $(CH_2COO)_2$], and 8.70 [broad s, 3H, OH, $(COOH)_2$] ppm.

3-Hydroxy-3-isobutylglutaric Acid—The procedure described for 3-hydroxy-3-*n*-propylglutaric acid was used to give 3-hydroxy-3-isobutylglutaric acid (70% yield) as a white solid, mp 90–98°. Recrystallization from ethyl acetate–petroleum ether (bp 60–75°) afforded a white solid, mp 106–108°; NMR (dimethyl sulfoxide-d_6): δ 0.93 [d, 6H, $C(CH_3)_2$], 1.49 (d, 2H, CH_2), 2.06 (m, 1H, R_3CH), 2.61 [s, 4H, $(CH_2COO)_2$], and 5.66 [broad s, 3H, OH, $(COOH)_2$] ppm.

Anal.—Calc. for $C_9H_{16}O_5$: C, 52.9; H, 7.9. Found: C, 52.8; H, 7.9.

Preparation of Rat Liver Microsomes—Rat liver microsomes containing β-hydroxy-β-methylglutaryl-CoA reductase activity were prepared according to the method of Shapiro and Rodwell (11) as described previously (2).

Enzyme Activity and Inhibition—The assay (2) was modified with regard to the isolation of mevalonolactone. The enzyme incubation mixture consisted of $NADP^+$ (9.7 μmoles)[2], glucose-6-phosphate[2] (59.7 μmoles), torula yeast glucose-6-phosphate dehydrogenase[2] (5 units), microsomal protein (2 mg) as determined by a modification of the method of Lowry *et al.* (2, 12), 0.1 ml of ethylene glycol monoethyl ether containing the inhibitor, and sufficient assay buffer [30 m*M* ethylenediaminetetraacetic acid, 70 m*M* NaCl, and 10 m*M* β-mercaptoethanol (pH 6.8)] to give a total volume of 2.9 ml.

Enzymatic activity was initiated by the addition of 0.1 ml of a solution containing 94 nmoles (31 μ*M*) of *dl*-β-hydroxy-β-methyl[3-^{14}C]glutaryl-CoA[3] (specific activity of 920 dpm/nmole). After 25 min of shaking incubation at 37°, the reaction was stopped by the addition of 0.2 ml of concentrated hydrochloric acid. Fifty microliters of an acetone solution containing 7×10^5 dpm (24 μmoles) of *dl*-4-[^{3}H]mevalonolactone[4] was added to the incubation mixture, and the mixture was incubated at 37°

[2] Sigma Chemical Co.
[3] P-L Biochemicals.
[4] Amersham Corp.

for 30 min. To the mixture was added 3.2 g of anhydrous sodium sulfite, and this mixture was extracted twice with 10-ml portions of benzene (13).

The benzene extract was evaporated to dryness in a liquid scintillation vial at 50° under a nitrogen stream. Twenty milliliters of Bray's scintillation solution (14) was added, and tritium and carbon 14 were determined simultaneously in a liquid scintillation counter[5]. Counting efficiency was determined by the external standard method. Some variability in the inhibition data was noted between tubes of microsomes (even from the same liver preparation). For this reason, a standard inhibitor, 1-(4-biphenylyl)pentyl hydrogen succinate (IX), was utilized routinely.

RESULTS AND DISCUSSION

The activity of IIIa–IIId and IVa–IVd as inhibitors of rat liver β-hydroxy-β-methylglutaryl-CoA reductase is shown in Table II. Unfortunately, the low solubility of these compounds in the enzyme assay prevented the determination of I/S values required for 50% inhibition. Thus, no definite conclusions can be made concerning the effect of increasing the size of the alkyl group at the C-3 position of the glutaric acid moiety with or without a C-3 hydroxyl group. However, the limited data do indicate that no substantial changes in inhibitory activity resulted from these modifications [compare 3-hydroxy-3-methyl (X) to 3-hydroxy-3-*n*-propyl (IVa) and the similar degree of inhibition shown by the analogs when assayed at identical I/S values].

Comparison of Dye Dilution Method to Radionuclide Techniques for Cardiac Output Determination in Dogs

SAM SUN-CHONG ENG *x, JUAN R. ROBAYO ‡, WILLIAM PORTER §, and ROBERT E. SMITH ¶

Received July 2, 1979, from the **Faculty of Pharmacy, Wayne State University, and the Department of Pharmacy, Children's Hospital of Michigan, Detroit, MI 48201*, the ‡*College of Pharmacy, University of Oklahoma, Oklahoma City, OK 73190*, the §*Faculty of Pharmacy, Wayne State University, and the Department of Nuclear Medicine, William Beaumont Hospital, Royal Oak, MI 48072*, and the ¶*School of Pharmacy, Creighton University, Omaha, NE 68178.* Accepted for publication November 26, 1979.

Abstract □ A study was undertaken to identify the most accurate ^{99m}Tc-labeled radiopharmaceutical and to determine the accuracy of a noninvasive radionuclide technique (antecubital injection and precordial detection) for cardiac output determinations. Phase I employed sodium pertechnetate, stannous pyrophosphate with sodium pertechnetate, technetium-99*m* red blood cells, and technetium-99*m* human serum albumin as radionuclide tracers. Cardiac output was determined by the dye dilution method and then by the invasive radionuclide technique. The radiopharmaceutical was injected into the same intracardiac catheter used in the dye dilution method. Seven to 10 mongrel dogs were used to test the accuracy of each radiopharmaceutical. A paired *t* test and regression analysis indicated that technetium-99*m* human serum albumin was the most accurate radiopharmaceutical for cardiac output determinations, and the results compared favorably to those obtained by the dye dilution method. In Phase II, technetium-99*m* human serum albumin was used as the radionuclide tracer for cardiac output determinations with the noninvasive technique. The results compared favorably to those obtained by the dye dilution method. Regression analysis indicated a correlation coefficient of 0.91. A paired *t* test demonstrated that the difference between the two methods was not statistically significant ($p > 0.05$). The data suggest that a noninvasive radionuclide technique using an intravascular radiopharmaceutical may be safe and nontraumatic for cardiac output determinations in humans.

Keyphrases □ Cardiac output—determination, comparison of dye dilution method and radionuclide techniques, dogs □ Dye dilution method—determination of cardiac output, comparison to radionuclide techniques, dogs □ Radionuclides—use in determination of cardiac output, comparison to dye dilution method, dogs

Measurement of cardiac output using readily detectable tracers such as indocyanine green[1] or suitable radionuclides is based on the principle of conservation of mass (1–3). The direct Fick method involves measuring the amount of oxygen extracted from the inspired air by the lungs and the arteriovenous oxygen difference (4–6). The Stewart–Hamilton dye dilution method is analogous to the direct Fick method (7–9). The validity and reproducibility of this method were verified by several investigators (10–14). The relative ease of detection and quantitation of radioactive tracers have resulted in the use of radiopharmaceuticals for cardiac output determinations (15–29). However, the necessity for cardiac catheterization and cannulation usually limits their usefulness.

for 30 min. To the mixture was added 3.2 g of anhydrous sodium sulfite, and this mixture was extracted twice with 10-ml portions of benzene (13).

The benzene extract was evaporated to dryness in a liquid scintillation vial at 50° under a nitrogen stream. Twenty milliliters of Bray's scintillation solution (14) was added, and tritium and carbon 14 were determined simultaneously in a liquid scintillation counter[5]. Counting efficiency was determined by the external standard method. Some variability in the inhibition data was noted between tubes of microsomes (even from the same liver preparation). For this reason, a standard inhibitor, 1-(4-biphenylyl)pentyl hydrogen succinate (IX), was utilized routinely.

RESULTS AND DISCUSSION

The activity of IIIa–IIId and IVa–IVd as inhibitors of rat liver β-hydroxy-β-methylglutaryl-CoA reductase is shown in Table II. Unfortunately, the low solubility of these compounds in the enzyme assay prevented the determination of I/S values required for 50% inhibition. Thus, no definite conclusions can be made concerning the effect of increasing the size of the alkyl group at the C-3 position of the glutaric acid moiety with or without a C-3 hydroxyl group. However, the limited data do indicate that no substantial changes in inhibitory activity resulted from these modifications [compare 3-hydroxy-3-methyl (X) to 3-hydroxy-3-*n*-propyl (IVa) and the similar degree of inhibition shown by the analogs when assayed at identical I/S values].

Comparison of Dye Dilution Method to Radionuclide Techniques for Cardiac Output Determination in Dogs

SAM SUN-CHONG ENG *x, JUAN R. ROBAYO ‡, WILLIAM PORTER §, and ROBERT E. SMITH ¶

Received July 2, 1979, from the **Faculty of Pharmacy, Wayne State University, and the Department of Pharmacy, Children's Hospital of Michigan, Detroit, MI 48201*, the ‡*College of Pharmacy, University of Oklahoma, Oklahoma City, OK 73190*, the §*Faculty of Pharmacy, Wayne State University, and the Department of Nuclear Medicine, William Beaumont Hospital, Royal Oak, MI 48072*, and the ¶*School of Pharmacy, Creighton University, Omaha, NE 68178.* Accepted for publication November 26, 1979.

Abstract □ A study was undertaken to identify the most accurate ^{99m}Tc-labeled radiopharmaceutical and to determine the accuracy of a noninvasive radionuclide technique (antecubital injection and precordial detection) for cardiac output determinations. Phase I employed sodium pertechnetate, stannous pyrophosphate with sodium pertechnetate, technetium-99*m* red blood cells, and technetium-99*m* human serum albumin as radionuclide tracers. Cardiac output was determined by the dye dilution method and then by the invasive radionuclide technique. The radiopharmaceutical was injected into the same intracardiac catheter used in the dye dilution method. Seven to 10 mongrel dogs were used to test the accuracy of each radiopharmaceutical. A paired *t* test and regression analysis indicated that technetium-99*m* human serum albumin was the most accurate radiopharmaceutical for cardiac output determinations, and the results compared favorably to those obtained by the dye dilution method. In Phase II, technetium-99*m* human serum albumin was used as the radionuclide tracer for cardiac output determinations with the noninvasive technique. The results compared favorably to those obtained by the dye dilution method. Regression analysis indicated a correlation coefficient of 0.91. A paired *t* test demonstrated that the difference between the two methods was not statistically significant ($p > 0.05$). The data suggest that a noninvasive radionuclide technique using an intravascular radiopharmaceutical may be safe and nontraumatic for cardiac output determinations in humans.

Keyphrases □ Cardiac output—determination, comparison of dye dilution method and radionuclide techniques, dogs □ Dye dilution method—determination of cardiac output, comparison to radionuclide techniques, dogs □ Radionuclides—use in determination of cardiac output, comparison to dye dilution method, dogs

Measurement of cardiac output using readily detectable tracers such as indocyanine green[1] or suitable radionuclides is based on the principle of conservation of mass (1–3). The direct Fick method involves measuring the amount of oxygen extracted from the inspired air by the lungs and the arteriovenous oxygen difference (4–6). The Stewart–Hamilton dye dilution method is analogous to the direct Fick method (7–9). The validity and reproducibility of this method were verified by several investigators (10–14). The relative ease of detection and quantitation of radioactive tracers have resulted in the use of radiopharmaceuticals for cardiac output determinations (15–29). However, the necessity for cardiac catheterization and cannulation usually limits their usefulness.

BACKGROUND

Technetium-99*m* as the pertechnetate ion and ^{99m}Tc-labeled human serum albumin and red blood cells have been investigated as tracers for cardiac function determinations. Technetium-99*m* was used in its pertechnetate form for cardiac output studies (30). Invasive arterial cannulation was used to inject pertechnetate into the external jugular vein, and blood samples were drawn at a constant rate from the femoral artery. This technique may distort the radionuclide dilution curve and render the results inaccurate due to the distance between the injection and sampling sites.

Schelbert *et al.* (31) reported a correlation coefficient of 0.94 for the left ventricular ejection fraction between the radionuclide method and cineangiocardiography. Although precordial recording was utilized, technetium-99*m* human serum albumin was injected into a central venous catheter at the superior vena cava. Antecubital injection and precordial recording of dilution curves for cardiac function determinations have been studied (32–34); however, the validity of this technique has not been established.

In radionuclide cardioangiography, intravascular agents are preferred. Technetium-99*m* human serum albumin and technetium-99*m* red blood cells have been the two most commonly studied intravascular agents. In this study, sodium pertechnetate was used because the leakage of pertechnetate ions from the vascular compartment was not thought to be significant. Stannous pyrophosphate plus sodium pertechnetate was selected as a tracer following reports on the *in vivo* labeling of red blood cells (35, 36).

Four technetium-99*m* radiopharmaceuticals were studied to determine which one correlated best with the dye dilution method for cardiac output determination. The superior radiopharmaceutical, technetium-99*m* human serum albumin, then was used to determine the reliability of a relatively noninvasive radionuclide technique.

EXPERIMENTAL

Technetium-99*m* was eluted from a molybdenum-99–technetium-99*m* generator[2] as sodium pertechnetate. Technetium-99*m* human serum albumin was prepared by the electrolytic method (37, 38). Technetium-99*m* red blood cells were prepared by pretinning red blood cells with stannous glycoheptonate and then were mixed with technetium-99*m* as the pertechnetate (39).

In Phase I, 37 mongrel dogs were anesthetized with pentobarbital, 35 mg/kg, by intravenous bolus injection. The injection catheter was inserted *via* the right femoral vein to the right ventricle, and the sampling catheter was inserted *via* the right femoral artery to the aorta. Catheter placement was verified by radiological examination. A 25-mg vial of indocyanine green was reconstituted aseptically with 10 ml of diluent to yield a solution of 2.5 mg/ml.

The densitometer[3] was calibrated with a known concentration of indocyanine green in 10 ml of mongrel dog blood. After calibration, a bolus of 2.5 mg (1.0 ml) of indocyanine green was injected *via* the injection catheter using a 1.0-ml syringe[4], a three-way stopcock, and a 5-ml saline flush. The dilution was traced on the densitometer, and the computed cardiac output was displayed at the lighted digital window.

Immediately following the determination of cardiac output by the dye dilution method and while the animal was still anesthetized, the dog was placed in the supine position with its four extremities held toward the four corners of a stretcher. The detector of the mobile radioisotopic camera[5] was positioned at a left anterior oblique view with a 60° angle for proper recording of cardiac anatomy and bolus passage through the cardiopulmonary circulation. Before the radiopharmaceutical injection, the videotape system of the mobile camera was activated. A 5–10-mCi dose of a ^{99m}Tc-radiopharmaceutical was injected *via* the injection catheter in the identical manner as the dye dilution method.

The bolus passage, which gives the radionuclide dilution curve, was recorded by the videostorage system of the camera. Five minutes after the ^{99m}Tc-radiopharmaceutical bolus injection, an equilibrium count rate, C_e, was recorded. Then ^{125}I-radioiodinated serum albumin was injected *via* a peripheral vein for blood volume determination (40). The data from individual videotapes were transferred to a large magnetic storage tape through the computer-attached recording unit.

After individual animal data were fed to the computer[6] for analysis, the bolus passage through the cardiopulmonary circulation was framed by the computer into multiple 1-sec frames; the equilibrium study appeared as a single frame. For each set of animal data, four regions of interest were selected using a light pen and the oscilloscope of the computer. In the flow study and the equilibrium study, the left ventricle was labeled as Regions 1 and 3, respectively. The backgrounds surrounding the left ventricle in the flow study and in the equilibrium study were labeled Regions 2 and 4, respectively. The criteria for the selection were that there should be no overlap between regions of interest of the left ventricle and the background and that the point area of the background should be half that of the left ventricle on integration.

Once the four regions were selected and the data were entered into the computer, the computer utilized these data to calculate the area under the total dilution curve. The area of the background curve subsequently was subtracted from the total dilution curve to give the actual radionuclide dilution curve. The computer program excluded secondary recirculation from the primary dilution curve by extrapolation. It converted the points of the original curve to their semilog counterparts that were shown at the computer oscilloscope. The slope of each individual point was printed on a computer sheet. After the investigators selected the points that gave the best semilog extrapolation, the computer integrated the area under the radionuclide dilution curve. The blood volume was entered, and the offset for the curve was selected to eliminate interference by counts derived from the passage of radiopharmaceuticals through the injection catheter. The computer calculated the cardiac output of each animal using:

$$Q_r = \frac{C_e BV}{A} \qquad \text{(Eq. 1)}$$

where A is the area under the radionuclide dilution curve, Q_r is the cardiac output in liters per minute, C_e is the equilibrium in counts per minute, and BV is the total blood volume.

Subsequent to the selection of the most appropriate radiopharmaceutical, seven mongrel dogs were anesthetized with pentobarbital, and the cardiac output was determined by the dye dilution method as in Phase I. Immediately following the determination of cardiac output by the dye dilution method, technetium-99*m* human serum albumin was injected *via* an antecubital vein, and the radionuclide dilution curve was traced precordially by the radionuclide camera and recorded onto the videotape. The data then were analyzed as described.

RESULTS AND DISCUSSION

In Phase I, cardiac output determinations were obtained in 37 mongrel dogs. In Group I, the cardiac output measurements determined by the dye dilution method had a mean of 2.33 ± 0.71 liters/min (mean ± *SD*); results of the pertechnetate radionuclide method had a mean of 1.66 ± 0.46 liters/min (Table I). For individual data pairs, the radionuclide cardiac output values were consistently lower than those obtained by the dye dilution method. This result might have been due to the rapid extravascularization of the pertechnetate ions after injection. On regression analysis, cardiac output data determined by the radionuclide method, Q_r, were assigned as the independent variable, and the data obtained by the dye dilution method, Q_d, were assigned as the dependent variable. The regression line of best fit was $Q_d = -0.08 + 1.46Q_r$. The correlation coefficient was 0.93, which may be due to the consistently lower radionuclide determinations. A paired *t* test indicated that the difference between the radionuclide method and the dye dilution method was statistically significant ($p < 0.05$).

In Group 2, stannous pyrophosphate was injected 10 min prior to the sodium pertechnetate injection to pretin the erythrocytes and to facilitate subsequent *in vivo* labeling of erythrocytes by the pertechnetate. The mean cardiac output value obtained by the radionuclide method (1.63 ± 0.71 liters/min) again was consistently lower than that obtained by the dye dilution method (2.38 ± 0.48 liters/min) (Table II). This result may have been due to the incomplete *in vivo* labeling of erythrocytes. Consequently, part of the injected sodium pertechnetate escaped to the extravascular compartments. This loss resulted in low equilibrium counts and low cardiac output determinations. The regression line of best fit was $Q_d = 1.51 + 0.53Q_r$. The correlation coefficient was lower ($F = 0.79$), possibly because of greater intrapair variations. A paired *t* test also indicated that the difference between the two methods was statistically significant ($p < 0.05$).

For Group 3, data obtained by using technetium-99*m* red blood cells as the tracer in the radionuclide method were compared to those obtained by the dye dilution method (Table III). Although there was a small difference between the mean cardiac output value determined by the radionuclide method (2.75 ± 0.51 liters/min) and the dye dilution method (2.44 ± 0.54 liters/min), individual data pairs varied greatly. Therefore, the correlation coefficient ($F = 0.43$) was significantly lower than that of the previous two groups, and the regression line of best fit was $Q_d = 1.19 + 0.45Q_r$. A paired *t* test indicated that the difference between the two methods was not statistically significant ($p > 0.05$).

In Group 4, the mean cardiac output obtained by using technetium-99*m* human serum albumin as a tracer in the radionuclide method (2.20 ± 0.44 liters/min) was close to the value of the dye dilution method (2.24 ± 0.46 liters/min). The difference between the individual data pairs also was very small (Table IV). Regression analysis gave a correlation coefficient of 0.85 and a regression line of best fit of $Q_d = 0.31 + 0.88Q_r$. The difference between the values in cardiac output by the two methods was not statistically significant ($p > 0.05$).

When all of the results from Phase I of the study were examined, cardiac output determinations using technetium-99*m* human serum albumin as the radionuclide tracer compared favorably to the dye dilution method. The correlation coefficient between the two methods was 0.85, and a paired *t* test indicated that the difference between these two methods was not statistically significant ($p > 0.05$). Sodium pertechnetate and stannous pyrophosphate plus sodium pertechnetate gave significantly different results when compared to the dye dilution method ($p < 0.05$). Even though cardiac output determinations using technetium-99*m* red blood cells were not significantly different from the cardiac output determined by the dye dilution method, regression analysis of the data gave a correlation coefficient of 0.43. Therefore, technetium-99*m* red blood cells appeared to be an inferior tracer.

In Phase II of the study, technetium-99*m* human serum albumin was injected antecubitally, and the dilution curve was recorded precordially. The mean cardiac output by the noninvasive radionuclide method was 2.22 ± 0.57 liters/min and that of the dye dilution method was 2.24 ± 0.54 liters/min. The intrapair differences (Table V) were small and could be explained as physiological occurrences.

Regression analysis gave a correlation coefficient of 0.91 and a regression line of best fit of $Q_d = 0.31 + 0.87Q_r$. A paired *t* test also revealed that the difference in cardiac output determinations between the noninvasive radionuclide method, using technetium-99*m* human serum albumin as the tracer, and the dye dilution method was not statistically significant ($p > 0.05$).

Various investigators reported favorable results using the radionuclide technique for cardiac flow studies when compared to the currently accepted methods. Zekert *et al.* (19) reported a correlation coefficient of 0.80 between the dye dilution method and the radionuclide method, and the difference between the pairs was not statistically significant. Campione and Steiner (20) observed good correlation between cardiac indexes determined simultaneously by the Fick method and the radionuclide technique after antecubital injections and precordial recording using ^{131}I-radioiodinated serum albumin as the tracer. Falch and Norman (28) reported a correlation coefficient of 0.96 between the dye dilution technique and the radionuclide technique using indium-113*m* as the tracer. Van Dyke *et al.* (41) also reported that cardiac output determined by the radionuclide method using technetium-99*m* human serum albumin showed good agreement with cardiac output determined by the Fick method. In the determination of the left ventricular ejection fraction, Strauss *et al.* (34) and Groch *et al.* (42) found that the correlation coef-

2	3.38	3.44
3	2.06	1.78
4	2.62	2.45
5	1.88	1.55
6	1.93	2.02
7	1.75	2.19
Mean	2.24	2.22
SD	0.54	0.57

Paired *t* test
mean of difference = 0.02
standard deviation of difference = 0.25
t test = 0.20

ficients between contrast angiocardiography and the radionuclide technique were 0.92 and 0.90, respectively.

The radionuclide technique employed by most of these investigators used intracardiac catheters for the injection of radiopharmaceuticals. The data from this animal model clearly demonstrated that noninvasive peripheral injection of an intravascular radiopharmaceutical yields results that are not significantly different from the widely used dye dilution method for cardiac output determinations. Although additional investigations are necessary, this study suggests that a noninvasive radionuclide technique may be safe, relatively nontraumatic, and accurate for cardiac output determinations in humans.

Micromeritic Properties of Sulfamethoxazole Microcapsules Prepared by Gelatin–Acacia Coacervation

H. TAKENAKA, Y. KAWASHIMA ˣ, and S. Y. LIN

Received December 14, 1978, from the *Gifu College of Pharmacy, Mitahora, Gifu 502, Japan.* Accepted for publication November 26, 1979.

Abstract □ Micronized sulfamethoxazole particles were microencapsulated using the gelatin–acacia complex coacervation method. The effects of the coacervation pH and the amount of formaldehyde used on the micromeritic parameters of the microcapsules were investigated. The particle-size and the wall thickness distributions were log-normal forms. As the pH was increased, the particle size decreased (8.5–28.5 μm). The porosity of various pH-adjusted microcapsules was between 0.158 and 0.277. The particle size of formalized microcapsules was larger than that of the unformalized microcapsules because formalization prevents shrinking of microcapsules during the dehydration and drying process. A smooth surface appeared on the unformalized microcapsule, but a net-like wrinkled structure was observed upon scanning the formalized one. Moreover, folding and invaginating structures were found on the spray-dried microcapsules. The optimum coacervation pH value was 3.5, at which the highest core content was obtained (77.5% w/w). Approximately 6.73 μg of formaldehyde remained in 1 g of the microcapsules formalized with 50 ml of formaldehyde. The crystalline sulfamethoxazole in the microcapsules prepared by spray drying the coacervate slurries was changed into the amorphous form, while the microcapsules dried in the conventional manner showed the same sulfamethoxazole form as the starting substance.

Keyphrases □ Sulfamethoxazole—microcapsules, prepared by gelatin–acacia coacervation □ Microencapsulation—sulfamethoxazole, gelatin–acacia coacervation □ Antibacterial agents—sulfamethoxazole, microencapsulation by gelatin–acacia coacervation

Microencapsulation is an attractive tool for the preparation of dosage forms to control the release rate, to separate incompatible materials in compounding, and to protect against moisture and oxidation. Many microencapsulation processes have been described (1). One accepted technique is gelatin–acacia complex coacervation, which was developed initially for processing carbonless copy paper (2–5). Various studies were reported later (6–8) on the effect of physical factors such as stirring speed, molecular weight of gelatin, and temperature on coacervation behavior. However, few studies have been published on the effects of the optimum coacervation pH and the amount of cross-linking agents used on the micromeritic parameters such as particle size, particle distribution, wall thickness, and porosity of the microcapsules.

The objective of the present study was to elucidate the effects of these factors on the preparation of sulfamethoxazole microcapsules. The effects of spray drying as an alternative to conventional drying of the coacervates on the surface characteristics and on the crystalline form of the microencapsulated sulfamethoxazole also were investigated. The remaining amounts of formaldehyde used as a hardening agent and the content of sulfamethoxazole in the microcapsules prepared under various conditions were determined.

EXPERIMENTAL

Materials—Gelatin[1] and acacia[2] were used as 3% (w/w) solutions. Micronized sulfamethoxazole[3] was used as a model drug. Acetic acid (10%), formaldehyde solution[4] (5, 15, 30, and 50 ml), isopropanol (70%), acetylacetone reagent solution[5], and formaldehyde standard solution[6] were JP grade and were used as received without further purification or recrystallization.

Microencapsulation—The microcapsules were prepared by the method of Green and Schleicher (2, 3) as modified by Luzzi and Gerraughty (8–10). In these experiments, gelatin and acacia solutions were prepared by dissolving 3.0 g of gelatin and 3.0 g of acacia each in 100 ml of purified distilled water. Five grams of micronized sulfamethoxazole was suspended in acacia solution at 50° for 5 min; an equal amount of gelatin solution, which was thermally controlled at 50°, was added gradually, with stirring at 620 rpm, to the acacia suspension. This suspension was maintained for 5 min, and the pH of the mixture was adjusted gradually by dropwise addition of diluted acetic acid with stirring. At the desired pH (2.5–4.0), the gelatin particles were positively charged and were attracted to the negatively charged acacia particles. Coacervation occurred, and a gelatin coating was formed (Fig. 1A). This mixture was cooled to 5° by immersion in a water bath.

A part of the mixture was withdrawn directly onto a slide glass for analysis of the particle size of the coacervate droplets. The rest of the coacervates was isolated from the equilibrium system and washed with 1 liter of distilled water to remove the excess colloid liquid. A part of the coacervated aggregates was retained for examination of the internal texture with a scanning electron microscope. Figure 1B shows the nest-like structure in which many crystals were encapsulated by a surrounding wall. The coacervates were hardened with formaldehyde solution (5, 15, 30, or 50 ml) for ~2 hr. Then the hardened coacervates were filtered and washed with distilled water. The wet mass was added, with stirring, to 70% isopropanol solution (11); stirring was continued for 30 min.

The sediments were filtered and dried at 40° by the conventional method for 2 hr to yield free-flowing discrete particles. The spray-drying technique (12) also was applied to prepare dried discrete microcapsule powders. The aqueous slurries containing the unformalized coacervates were atomized into a drying chamber at 140 ± 10° by a centrifugal wheel atomizer. Two batches for the preparation of microcapsules were run. The maximum batch-to-batch differences in the micromeritic properties of the microcapsules are indicated in Table I.

Measurement of Micromeritic Properties—Particle size was determined by a photographic counting method using a particle-size ana-

lyzer[7]. Not less than 600 particles were measured for each batch. The coating thickness of the microcapsules was determined by direct measurement after microtome slicing of the microcapsules embedded in paraffin (mp 48–50°). The microcapsules were added to melted paraffin solution, and this mixture immediately was immersed into an ice bath and hardened. The paraffin masses subsequently were sliced with a congelation microtome. The slice thickness was ~10 μm. Each slice was placed on an object slide and mounted with liquid paraffin. Approximately 100 specimens were tested to measure the coating thickness, and the averaged value represented the wall thickness. The sections that came from the extremes of the microcapsules may have given somewhat high values for the wall thickness. However, comparison of the relative differences is valid.

The particle densities of various microcapsules and raw materials (*e.g.*, gelatin and micronized sulfamethoxazole) were measured with a helium–air comparison pycnometer[8].

The surface topography of the microcapsules was investigated by a scanning electron microscope[9]. The microcapsule samples were mounted on a sample stub with double-sided adhesive tape and were vacuum coated with carbon and gold.

The crystalline form of the microcapsulated sulfamethoxazole was determined with an X-ray diffractometer[10] with CuKα radiation (1.5418 Å). The IR spectrum was recorded with an IR spectrometer[11].

Assay of Sulfamethoxazole Content and Remaining Formaldehyde—The sulfamethoxazole content in the microcapsules was assayed by the following method. Approximately 100 mg of each sample was weighed accurately, extracted with pH 7.5 solution (simulated intestinal fluid of JP IX), and then determined spectrophotometrically at a suitable UV wavelength using a double-beam spectrophotometer. Ten 100-mg samples from two batches were tested, and the mean was obtained.

The remaining amount of hardening agent was determined by the modified acetylacetone method (13–15). One gram of each sample (*e.g.*, gelatin, acacia, sulfamethoxazole, and formalized microcapsules using 50 ml of formaldehyde) was extracted for ~2 hr with 100 ml of distilled water by shaking the sample at 40 ± 1° in a water bath, and the sample was filtered with a millipore filter (3 μm). Ten milliliters of the extracted sample solutions and of the formaldehyde standard solution were pipetted into separate 50-ml volumetric flasks containing 10 ml of acetylacetone reagent solution, and the flasks were shaken for 30 min at 40 ± 1° in a water bath. A blank test using 10 ml of distilled water instead of acetylacetone reagent solution also was undertaken. The absorbance of each extracted sample solution was determined at 415 nm by a spectrophotometer[12].

RESULTS AND DISCUSSION

Particle-Size Distribution of Gelatin–Acacia Coacervates and Dried Microcapsules Made Conventionally—The cooled coacervate droplets in equilibrium solution and the dried microcapsules prepared under the various pH adjustments without formalization were placed on a slide glass for particle-size measurements. These data are shown graphically in Figs. 2A and 2B, respectively. The sizes of the coacervates and the microcapsules followed a log-normal distribution. As the pH was increased from 3.3 to 4.2 in the equilibrium liquid, the geometric mean particle diameter of the microcapsules decreased (Table I). This result may have been due to the electrophoretic characteristic of gelatin–acacia coacervates. Electrophoretic data of coacervates obtained previously[13] showed that, at a pH above 3.5, the coacervates were electronegatively charged and the charges increased with increasing pH. This finding indicates that, at the higher pH range, the small coacervates could be formed due to the strong repulsive force between the coacervates. In addition, the reduced amounts of gelatin in the coacervates formed at the lower pH region enhanced the swelling of gelatin below pH 3.5–4.0 (16), leading to the formation of larger coacervates.

The unformalized microcapsules prepared at pH values higher than 3.5 were larger than the corresponding coacervates. The coacervates used for measuring the size were taken directly from the coacervation system prior to further processing. The rest of the coacervates were washed with 1 liter of distilled water, during which swelling occurred. The following drying process, *i.e.*, isopropanol treatment and air drying at 40°, contributed to the shrinkage of the microcapsules and offset the enlargement of the microcapsules caused by swelling. The coacervate with a thicker

[a] All data show the average values from two batches. Key: D_g^1, D_g^2, geometric mean diameter of unformalized and formalized dried microcapsules, respectively; ρ, particle density; l, wall thickness of unformalized dried microcapsules; and ϵ, porosity. [b] Final pH of equilibrium solution. [c] Geometric mean diameter of coacervates.

wall at the higher pH region (Table I) might retard shrinkage during the drying process, leading to the described results (Figs. 2A and 2B and Table I). For the microcapsule with a thinner wall at pH 3.0, the shrinking effects compared to the swelling might result in a size that is smaller than the coacervate (Table I). This expectation also was confirmed using a scanning electron microscope by the detection of a smooth surface on the microcapsule at the higher pH and a wrinkled surface at the lower pH.

The particle-size distributions of the unformalized and formalized microcapsules are seen in Figs. 2B and 2C, respectively. Upon formalizing the coacervates, some differences were observed in the particle-size distribution of microcapsules. An increase in the size of the microcapsules was found as more hardening agent was used (Table I). The hardened wall may prevent the shrinkage that occurs during the dehydration and drying process.

Microcapsule Wall Thickness and Porosity—The influence of pH on the wall thickness of dried microcapsules is shown in Table I. The wall of the dried microcapsules made at the higher pH was thicker than that of microcapsules made at the lower pH. Previous investigators (17–19) concluded that gelatin–acacia coacervates have a gelatin structure in which acacia is attracted by ionic bonds only and does not participate in the gel structure formation. At high pH values, NH_3^+ groups of gelatin are comparatively few but COO^- groups of acacia are numerous. To prepare coacervates, a larger amount of gelatin is required to interact with acacia, therefore leading to a thicker wall.

The particle densities (1.02–1.19) of the microcapsules, as measured by a helium–air comparison pycnometer, were smaller than those of the raw materials, *i.e.*, gelatin (1.27) and sulfamethoxazole (1.53). This result is reasonable because the microcapsule film may prevent helium penetration into the internal matrix of the microcapsule. If it is assumed that the microcapsule film is composed of gelatin alone (16, 17), the porosity, ϵ, of the microcapsule can be determined by inserting the density values into:

$$\epsilon = 1 - \frac{(C_g\rho_s + C_s\rho_g)\rho_m}{\rho_s\rho_g} \qquad \text{(Eq. 1)}$$

where C_g is the weight percent of gelatin, C_s is the weight percent of drug, ρ_s is the density of the drug particles, ρ_g is the density of the gelatin particles, and ρ_m is the density of the microcapsule particles. The porosity of the microcapsules was 0.158–0.277 (Table I).

Microcapsule Surface Topography—The surface of the unformalized microcapsules (Fig. 3A) was smooth and had no cracking or pore penetration. Evidence of folding and invagination was absent. The formalized microcapsules (Fig. 3B) also had a partially smooth surface and were free from structural defects. However, miscellaneous matter was seen occasionally on the capsule surface, which may have been due to crystals or polymer remaining in the medium during hardening. Another partial surface appearance showed a net-like wrinkled structure, which also was observed on the simple coacervated microcapsules during formalizing (23).

Adhesive sundries and crystals on the surface can be attributed to the soluble complex formed by the interaction between the formaldehyde and the primary amino groups of sulfamethoxazole, which was leached out to the surface during the washing process (24). These surface aberrations also may be the partially ruptured coacervates formed during hardening or dehydration, with the unencapsulated crystals adhering to the surface. The shrinking structure, which was not found on the unformalized microcapsules, may suggest that crossover linkage occurred during the formalizing procedure. Reaction of the gel with formaldehyde caused a high degree of insolubility as a result of intermolecular crosslinkage formation. Adhesive polymer sundries could be due to the ruptured fractions of coacervates or the remaining gelatin fractions that were crosslinked with formaldehyde upon hardening.

Drug Content and Remaining Amounts of Hardening Agents—The extraction of sulfamethoxazole microcapsules showed that >45% (w/w) of sulfamethoxazole was contained in the microcapsules (Table I). The microcapsules adjusted to pH 3.5 had the highest content. This result may have been due to the high volume of coacervates formed when the pH was adjusted to 3.5, at which point the positive and negative charges were equivalent (25). According to these data and those from a previous report (26), pH 3.5 is the optimum pH for coacervation in the present system where the acacia is strongly negative and the gelatin is strongly positive. Table I illustrates that the content of the unformalized microcapsules was higher than that of the formalized microcapsules. Because of the interaction between formaldehyde and sulfamethoxazole, this soluble complex was leached out and lost in the medium, resulting in a drug content of ~55% in the formalized microcapsules, which was 22% less than the unformalized content.

Approximately 6.73 μg of formaldehyde remained in 1 g of the formalized microcapsules prepared with 50 ml of formaldehyde. If 710 mg of these microcapsules (56.4%) is administered orally, according to the

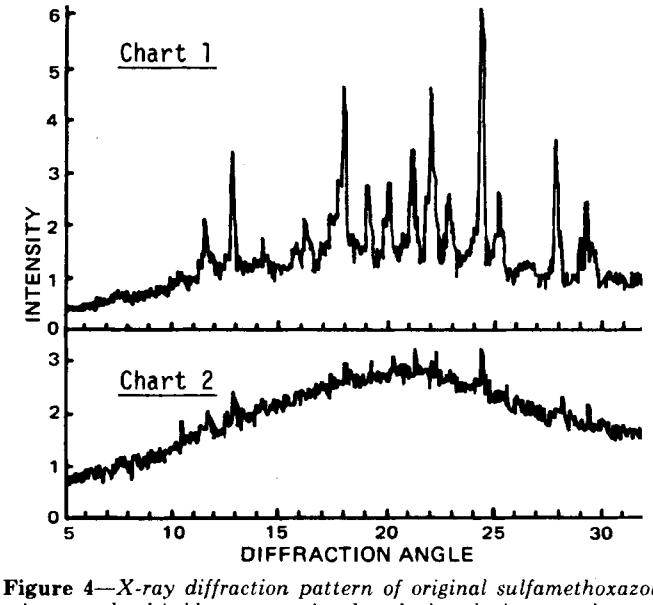

Figure 4—*X-ray diffraction pattern of original sulfamethoxazole, microcapsules dried by a conventional method, and microcapsules spray dried after coacervation. Key: Chart 1, original sulfamethoxazole or dried microcapsules by a conventional method; and Chart 2, spray-dried microcapsules. (Intensity scale: 1 = 10 Hz.)*

formulation of co-trimoxazole tablets[14] (BP 1973), it is predicted that no side effects would occur since only 4.75 μg of formaldehyde is contained in this formulation. The other formalized microcapsules may have a lower amount of remaining formaldehyde, although no such data are available. The method of removing the remaining formaldehyde from the formalized microcapsules also is important for microencapsulation if formaldehyde is applied as a hardening agent.

Effect of Spray-Drying Procedure on Microcapsule Surface Topography and Crystalline Drug Form—On the surface of the spray-dried microcapsules prepared from the unformalized coacervates (Fig. 3C), a smooth surface with some fissures of the coating was observed. Moreover, a few microcapsules possessed a characteristically folded and invaginated surface. This phenomenon may be deduced from a diagram (20–22) of a spray-dried slurry droplet.

X-ray diffraction patterns of the ground microcapsules were obtained to investigate the crystalline forms of sulfamethoxazole in the microcapsule prepared by conventional and spray-drying techniques. The intensities of the diffraction peaks of the spray-dried sulfamethoxazole were weaker than those of the original material. A rapid evaporation of solvent from spray droplets might change the crystalline form to the disordered form (Fig. 4). On the other hand, the intensities of the peaks found in the microcapsules dried by the conventional method coincided with those of the original sulfamethoxazole. This result may be explained in that, although the coacervation temperature was 50°, the crystalline forms could not be disordered due to the mild drying process employed. In addition, the IR spectrum of all of the microcapsules coincided with that of the original sulfamethoxazole, indicating that complexes between sulfamethoxazole and the polymers (gelatin or acacia) were not formed through spray drying and the complex coacervation processes.

Effects of Dansylated Acetylcholine Analogs on *Schistosoma mansoni*

G. R. HILLMAN *x, S.-H. CHU ‡, and M. J. DOTSON *

Received April 18, 1979, from the **Department of Pharmacology and Toxicology, University of Texas Medical Branch, Galveston, TX 77550,* and the ‡*Division of Biomedical Sciences, Brown University, Providence, RI 02912.* Accepted for publication December 3, 1979.

Abstract □ A series of dansylated fluorescent analogs was synthesized and tested for cholinergic and anticholinergic activity in *Schistosoma mansoni*. The compounds were compared with a previously reported analog, 5-(dimethylamino)-*N*-(2-dimethylaminoethyl)naphthalenesulfonamide hydrochloride (I). All of the compounds produced some fluorescent labeling of a structure in the head region of the worms. Major differences were not seen among the compounds. The compounds also were tested as antagonists of carbachol-induced paralysis in an activity monitor. Significant carbachol antagonism was seen for all compounds. Effects on the serotonin response also were recorded. Only one compound, a dibutylaminopropylamine derivative, produced striking antagonism of serotonin-induced motor activity.

Keyphrases □ Cholinergics—antagonists, dansylated acetylcholine analogs, *in vitro* scanning fluorescence method, neuroactive drugs in schistosomes □ Carbachol—effect on schistosomes, effect of anticholinergic agents, scanning fluorescence method, motility studies □ Serotonin—effect on schistosomes, anticholinergic agents, scanning fluorescence method □ Structure–activity relationships—dansylated acetylcholine analogs, effect on motility and neuroactivity in schistosomes, scanning fluorescence method, motility studies

Various cholinomimetic and anticholinergic drugs affect the nervous system of schistosomes. However, some drugs, such as muscarine, nicotine, and tubocurarine, which are highly active at mammalian cholinergic synapses, are conspicuously inactive in schistosomes (1), although acetylcholine and carbachol are effective immediately. This finding suggests that sensitivity to cholinergic drugs in schistosomes is different from that in nicotinic or muscarinic mammalian synapses.

The intensities of the diffraction peaks of the spray-dried sulfamethoxazole were weaker than those of the original material. A rapid evaporation of solvent from spray droplets might change the crystalline form to the disordered form (Fig. 4). On the other hand, the intensities of the peaks found in the microcapsules dried by the conventional method coincided with those of the original sulfamethoxazole. This result may be explained in that, although the coacervation temperature was 50°, the crystalline forms could not be disordered due to the mild drying process employed. In addition, the IR spectrum of all of the microcapsules coincided with that of the original sulfamethoxazole, indicating that complexes between sulfamethoxazole and the polymers (gelatin or acacia) were not formed through spray drying and the complex coacervation processes.

Effects of Dansylated Acetylcholine Analogs on *Schistosoma mansoni*

G. R. HILLMAN *x, S.-H. CHU ‡, and M. J. DOTSON *

Received April 18, 1979, from the **Department of Pharmacology and Toxicology, University of Texas Medical Branch, Galveston, TX 77550,* and the ‡*Division of Biomedical Sciences, Brown University, Providence, RI 02912.* Accepted for publication December 3, 1979.

Abstract □ A series of dansylated fluorescent analogs was synthesized and tested for cholinergic and anticholinergic activity in *Schistosoma mansoni*. The compounds were compared with a previously reported analog, 5-(dimethylamino)-*N*-(2-dimethylaminoethyl)naphthalenesulfonamide hydrochloride (I). All of the compounds produced some fluorescent labeling of a structure in the head region of the worms. Major differences were not seen among the compounds. The compounds also were tested as antagonists of carbachol-induced paralysis in an activity monitor. Significant carbachol antagonism was seen for all compounds. Effects on the serotonin response also were recorded. Only one compound, a dibutylaminopropylamine derivative, produced striking antagonism of serotonin-induced motor activity.

Keyphrases □ Cholinergics—antagonists, dansylated acetylcholine analogs, *in vitro* scanning fluorescence method, neuroactive drugs in schistosomes □ Carbachol—effect on schistosomes, effect of anticholinergic agents, scanning fluorescence method, motility studies □ Serotonin—effect on schistosomes, anticholinergic agents, scanning fluorescence method □ Structure–activity relationships—dansylated acetylcholine analogs, effect on motility and neuroactivity in schistosomes, scanning fluorescence method, motility studies

Various cholinomimetic and anticholinergic drugs affect the nervous system of schistosomes. However, some drugs, such as muscarine, nicotine, and tubocurarine, which are highly active at mammalian cholinergic synapses, are conspicuously inactive in schistosomes (1), although acetylcholine and carbachol are effective immediately. This finding suggests that sensitivity to cholinergic drugs in schistosomes is different from that in nicotinic or muscarinic mammalian synapses.

methylammonium perchlorate, a dansylated choline derivative, acts as a fluorescent probe of acetylcholine receptors (2, 3). Related compounds having selective agonist or antagonist properties also have been studied (4), as has fluorescein-conjugated snake toxin (5). An analog of this compound, 5-(dimethylamino)-*N*-(2-dimethylaminoethyl)naphthalenesulfonamide hydrochloride (I), is a more effective labeling agent (6–8). For the present study, a series of dansylated fluorescent acetylcholine analogs was synthesized having systematic variations in the choline-like portions of the molecule.

A scanning fluorescence method and a technique for monitoring the movements of adult schistosomes *in vitro* (8, 9) are two approaches for assessing the effects of neuroactive drugs. With these methods, it was hypothesized (10) that hycanthone has selective anticholinergic action in schistosomes. This finding suggests that the cholinergic pharmacology of schistosomes may be important in chemotherapy, and the cholinomimetic or anticholinergic actions of structurally related compounds therefore are being studied. These structure–activity relationships are intended to suggest molecular variations that may lead to selective toxicity in schistosomes. This information will be used as a guide in the synthesis of other compounds.

EXPERIMENTAL[1]

Compound I and its analogs were synthesized by a method related to that reported previously (5, 7). 5-(Dimethylamino)-1-naphthalenesulfonyl (dansyl) chloride was refluxed with the appropriate *N,N*-dialkylethylenediamines, *N,N*-dialkylpropylenediamines, or 1-methylpiperazine in 50 ml of acetone for 1 hr. The acetone was evaporated to dryness at reduced pressure, and the resulting residue was washed with 100 ml of ether. The resulting hydrochloride was neutralized with 20 ml of 3% Na_2CO_3. Then it was repeatedly extracted with ether and dried over magnesium sulfate.

The solid was removed by filtration, and the filtrate was cooled in an ice bath and bubbled with excess hydrogen chloride gas. On cooling, it solidified slowly to yield analytically pure material. The product was highly hydroscopic and tended to form an oil on exposure to air. It was homogeneous by paper electrophoresis and had fluorescence excitation and emission spectra similar to those reported for dimethylaminonaphthalene-5-sulfonamidoethyltrimethylammonium perchlorate. The analyses and physical properties are given in Tables I and II.

[a] TLC was run on silica gel and developed with ethanol.

Mice infested with *Schistosoma mansoni* were obtained from a mouse–snail cycle[2]. The adult, paired schistosomes were removed 45–60 days postinoculation. The infected mice were administered heparin and ether before being sacrificed by cervical dislocation. Using gentle-hook dissection, the adult, paired schistosomes were removed from the portal and mesenteric veins. The worms were maintained at 37° and pH 7.4 in cell culture medium[3] with added antibiotics and buffering (11). About 1 ml of culture medium was used per worm pair.

For scanning fluorescence measurements, the worm pairs from a mouse were divided into test and control groups and incubated at 37° for 60 min in a culture medium containing the appropriate compound. Each test group was paired with a control group of worms incubated in I. After incubation, the worms were rinsed with saline and placed under a cover slip on a microscope slide for evaluation of fluorescence as described previously (8).

The mounted schistosome was placed on the microscope[4] stage and aligned in the field of view. A small synchronous motor attached to the stage controlled the movement of the image of the worm across the light-sensitive spot of the photometer. As the microscope stage moved, the fluorescence (as a function of distance across the specimen) was recorded from the photometer output. The photometric information was entered directly into a computer for interpretation. The computer au-

[1] Melting points were determined on a Gallenkamp apparatus and are uncorrected. UV spectra were determined on a Perkin-Elmer model 402 spectrophotometer. Elemental analyses were performed by Baron Consulting Co., Orange, Conn. TLC was run on silica gel, and the plates were developed with ethanol.

[4] Olympus model BMB with vertical fluorescence illumination. Emitted fluorescent light, returning through the microscope objective, was directed to the camera port at the top of the microscope. On the camera port, a Farrand MSA microscope spectrum analyzer was mounted. An Aminco potted 1P21 photomultiplier was adapted to the Farrand housing. The photomultiplier was connected to an Aminco J-22A photometer. The photometer output was directly connected to a Hewlett-Packard 9825A computer.

Table III—Specific Fluorescence and Partition Coefficients of the Compounds

Compound	Specific Fluorescence, % transmittance	Partition Coefficient (P)
I	26.0	0.0941
II	31.0	0.2374
III	40.0	0.0190
IV	46.5	0.0345
V	14.0	0.6108
VI	46.5	0.0676

tomatically recorded 250 fluorescence values for each scan, located the fluorescent peak, and determined the height and area of the scanned fluorescent region.

Schistosomes were routinely scanned twice: once across the esophageal region and once across the region of maximal brightness posterior to the esophagus (Fig. 1). Only male schistosomes were scanned due to the small size of the females. The data obtained included the peak height or maximum recorded fluorescence intensity at any point in the scanned region and the peak area or total fluorescence over the scanned region. Both parameters were used to evaluate the esophageal and central regions of the head.

The specific fluorescence of the compounds was compared by two methods. The fluorescence of a 10^{-6} M solution of each compound in pH 7.4 phosphate buffer was measured using a spectrophotofluorometer. The maximum excitation and emission wavelengths for each compound were used to determine the fluorescence. The compounds also were compared using the microfluorometer. A 2-mm thick plastic ring[5] was placed on a microscope slide, filled with drug solution, and covered with a cover slip; this procedure gave a reproducible depth of solution for observation. The specific fluorescence of each compound at 10^{-3} M in phosphate buffer (pH 7.4) was recorded and evaluated at an emission wavelength of 530 nm.

Figure 1—*Fluorescence micrograph of the head region of a male* S. mansoni *labeled with II. The worm was incubated for 1 hr in cell culture medium with* 1×10^{-5} M *II.*

[5] Delrin.

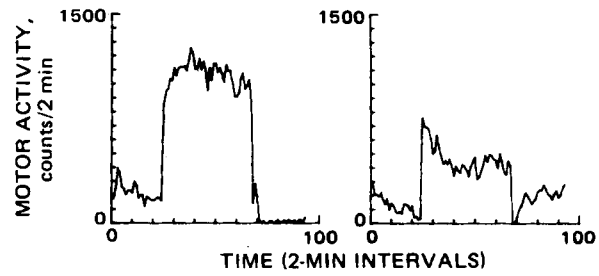

Figure 2—*Effects of IV on carbachol-induced paralysis. Serotonin (1* $\times 10^{-3}$ M*) was added after 18 intervals to produce stimulation. Carbachol (1* $\times 10^{-4}$ M*) was added later, producing paralysis in the control (left). Compound IV (1* $\times 10^{-4}$ M*) was present throughout the experiment (right).*

The motor response of paired *S. mansoni* to the compounds was measured in a specially constructed activity cage described previously (9, 11–13). The apparatus contained four chambers mounted in a temperature-regulated block. Two worm pairs were placed in each glass-bottom chamber, which was located directly above an array of fiberoptics connected to photocells. Movement of the worms in the chamber obscured a light beam, producing a change in the light intensity measured by the photocells. The resultant electronic changes registered by the photocells were translated into numerical counts that were proportional to the total amount of movement. The counts for each chamber were accumulated for 2 min, and the data were automatically transferred to a computer. The data were collected and plotted automatically by the computer.

Four experiments were run simultaneously in the presence and absence of the test compounds. The test compounds, serotonin and carbachol, in culture medium solution were perfused through the 37° chambers, and the response data were accumulated. The activity of the worm was plotted as a function of time.

The partition coefficient was determined for each compound. Equal amounts of pH 7.4 phosphate buffer and ether were shaken for 30 min and allowed to equilibrate. The equilibrated phosphate buffer was used to make a 10^{-4} M solution of each compound. The absorbance of these solutions at 350 nm was recorded. A combination of 4.5 ml of the drug solution and 0.5 ml of the buffer-saturated ether was vortexed for 3 min. The absorbance of the aqueous phase of the mixture was measured after mixing.

The partition coefficient was calculated from:

$$p = \frac{V_2(x - y)}{V_1 y} \qquad \text{(Eq. 1)}$$

where V_1 is the volume of the aqueous phase of the mixture, V_2 is the volume of ether, x is the absorbance of the compound in the buffer before partitioning, and y is the absorbance of the aqueous phase of the buffer

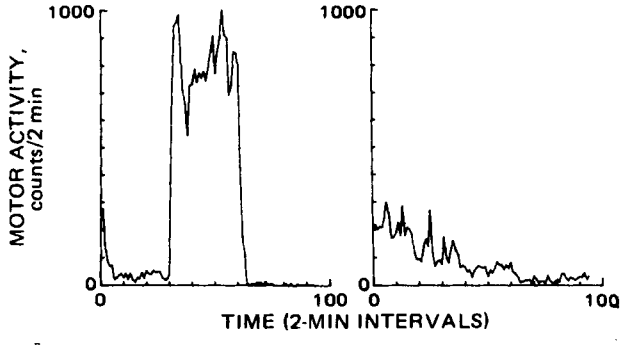

Figure 3—*Effects of VI on serotonin-induced motility. Serotonin (1* $\times 10^{-3}$ M*) was added to the basal medium at 30 intervals, and carbachol (3* $\times 10^{-4}$ M*) was added at 60 intervals. Key: left, normal response; and right, VI present throughout the experiment.*

[a] Numbers are the mean and standard deviation of four or more experiments. Each experimental value is the percent change in average motor activity from 46 min before to 46 min after the addition of carbachol. [b] This value could not be determined since the activity of the worms had already been diminished such that a carbachol effect could not be measured.

after partitioning. The absorbance was assumed to be directly proportional to the compound concentration.

RESULTS

Specific Fluorescence—The relative fluorescences observed using the fluorescence microscope were in excellent agreement with those recorded using the spectrophotometer. However, due to the dependence of these measurements on variables such as microscope focus, the spectrophotofluorometric measurements were used for further calculations. The specific fluorescence measurements are shown in Table III.

Schistosome Fluorescence—Both test and control (I) schistosomes were from the same mouse and were measured in the same experiment. The fluorescence of the esophageal region and the region of maximal brightness posterior to the esophagus of the schistosome was measured with each fluorescent compound. The maximum fluorescence intensity (scanning peak height) and integrated total fluorescence (scanning peak area) were calculated for both regions. All fluorescence values then were corrected by the specific fluorescence of the tested compound. Each test value was compared to the corresponding mean value from a group of scanned I-labeled worms from the same host to determine a fluorescence intensity ratio. Table IV summarizes the ratios of the fluorescence intensity of the test compounds to that of I. All compounds fluorescently labeled specific regions in the schistosome in a manner similar to I (7).

The fluorescent labeling of worms by each compound relative to labeling by I was calculated according to:

$$\bar{F} = \frac{1}{N_2}\sum_{1}^{N_2}\left(\frac{1}{N_0}\sum_{1}^{N_0}\frac{F_{\text{compound}}}{\bar{F}_I}\right) \qquad \text{(Eq. 2)}$$

where N_0 is the number of test worms (*i.e.*, exposed to the compound being tested) in an experiment, F_{compound} is the fluorescence of a test worm adjusted for specific fluorescence of the compound, $\bar{F}_I$ is the mean fluorescence of all I-treated (control) worms in the same experiment adjusted for the specific fluorescence of I (usually equal in number to N_0), and N_2 is the number of experiments conducted with the same test compound.

Table IV gives the values for N_1 where $N_1 = \Sigma_1^{N_2} N_0$. The standard error of $\bar{F}$ for $n = N_2$ also is shown in Table IV.

Motility—The acetylcholine-like drug carbachol was used to evaluate the anticholinergic effect of the compounds on the schistosomes in the activity monitor (Table V). Carbachol has a paralytic effect on schistosomal movements (1). Worm pairs were exposed to a 1 m*M* solution of serotonin to stimulate the worm activity maximally (10). Carbachol at 10^{-4} or 3×10^{-4} *M* then was added, and the activity response of the schistosomes was recorded with and without the test compound.

The movement of the worms was monitored in 2-min intervals. The values for these intervals were averaged for each period (at least 36 min) of drug exposure. The percent decrease in movement due to carbachol administration was calculated from these means. This experiment was conducted in the presence and absence of the test drug on different worms from the same host. The effect of carbachol on motility with and without each test drug is shown in Table V. The difference between the carbachol effect with and without the test drug was tested for significance by the t test with n as the number of repetitions of the experiments. The p value derived from the t test also is shown in Table V.

All compounds were effective in blocking the carbachol action. Since VI had a strong paralytic action of its own, its effects on the carbachol response could not be assessed reliably at higher concentrations.

The effects of the drugs on the serotonin response could be assessed by the same technique. However, since the percent increase with serotonin was more variable (from 60 to 2000%, depending critically on the value of the motility rate before serotonin) than the decrease with carbachol (reliably about 90%), quantitation of drug effects on the serotonin response was difficult. However, it was clear that VI strongly blocked the response to serotonin. None of the other compounds had this effect.

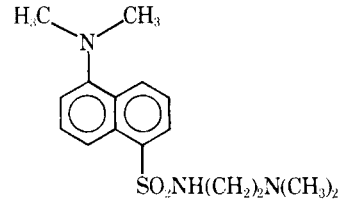
Typical experiments are shown in Figs. 2 and 3. The reduction of the carbachol response by IV and the inhibition of the serotonin response by VI can be seen clearly.

Partition Coefficients—Table III shows the partition coefficients for each drug solution. Compound V demonstrated the highest lipid solubility. The lipid solubility was not related in any obvious way to the structure of the drugs.

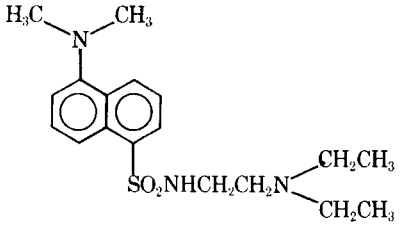
DISCUSSION

Previous studies showed that a dansylated choline analog (I) fluorescently labels schistosomes in regions containing nerve endings and behaves as an antagonist at acetylcholine receptors. In view of the evidence that some antischistosomal drugs (*e.g.*, hycanthone and metrifonate) may act by affecting the cholinergic nervous system, this study was conducted to determine the structural requirements for anticholinergic activity in schistosomes. This problem was approached by the synthesis of structurally related analogs of I, with testing of the compounds in two independent schistosomal experimental systems.

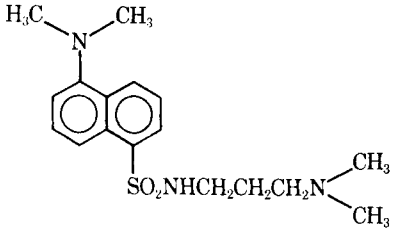
The fluorescent labeling experiments were conducted on the premise that I and its analogs label the physiological acetylcholine binding sites. This hypothesis is supported by prior observations that dansylated compounds not resembling acetylcholine, such as dansyl glycine, do not label specific structures in schistosomes and that anticholinergic drugs



I

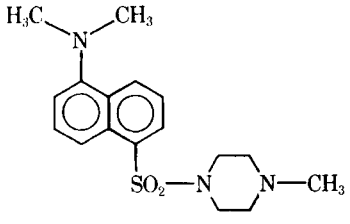


II

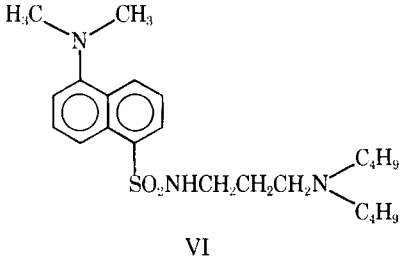


III

IV



V



VI

such as atropine and mecamylamine block labeling of schistosomes by I. The results (Table IV) indicate that there were some differences among the compounds. Analogs with two-carbon chains (I and V, in which the chain is part of a piperazine ring) gave more effective labeling; the three-carbon analogs (III and IV) were less effective as labels.

Addition of larger groups to the terminal nitrogen produced some increase in labeling effectiveness. Compound VI shows that large *N*-substitutions result in increased labeling, even with a three-carbon aliphatic chain. The variations do not correlate in an obvious way with lipid solubility, as shown in Table III. It is suggested that the labeling site preferentially binds molecules with an aliphatic two-carbon side chain and may have a hydrophobic region near an anionic site; more extensive structure–activity studies are needed to characterize this site.

The motility (activity cage) studies provide an independent approach to measuring the neuroactivity of drugs by allowing observation of the antagonism of acetylcholine or serotonin responses. The ability of I to block carbachol-induced paralysis is reported in Table V. All compounds produced a significant block of the carbachol response under at least one set of conditions, indicating that the compounds do have anticholinergic activity. Compound IV had the most clearcut effect. Because IV was one of the less effective fluorescent labels, some of the sites involved in the control of body movements probably are not labeling sites. Only VI effectively blocked the serotonin response. This drug had strong paralytic effects of its own, which made it impossible to determine its ability to block carbachol paralysis.

The structural series reported here is too small to provide a full description of activity requirements in the schistosome system, particularly since several compounds had very similar activity. However, the results with VI suggest that the addition of bulkier groups on the amine nitrogen may be a useful modification. In future studies, similar compounds, with or without the fluorescent dansyl group, will be tested *in vivo* for toxicity to schistosomes within the host animal.

Thermal Decomposition of Ibuproxam

S. CHIMICHI *, F. INNOCENTI ‡, and G. ORZALESI ‡x

Received July 5, 1979, from the *Instituto Medicina del Lavoro, University of Florence, Largo Palagi 1, Florence, Italy, and the ‡Società Italo-Britannica L. Manetti-H. Roberts, Florence, Italy. Accepted for publication November 26, 1979.

Abstract □ The thermal behavior of ibuproxam was studied at several temperatures, and the degradation products were separated by column chromatography and ethereal extractions. The resulting products were ibuprofen [2-(4-isobutylphenyl)propionic acid], 1-(4-isobutylphenyl)-ethylamine, 4-isobutylacetophenone, and 4-isobutylacetophenone oxime. The compounds were identified by IR, UV, and NMR spectroscopy and elemental analyses. 4-Isobutylacetophenone was treated with hydroxylamine to give 4-isobutylacetophenone oxime.

Keyphrases □ Thermal decomposition—ibuproxam, analysis of degradation products □ Ibuproxam—thermal decomposition, identification of thermal degradation products □ Anti-inflammatory agents—ibuproxam, identification of thermal degradation products

Ibuproxam [(*RS*)-2-(4-isobutylphenyl)propiohydroxamic acid, I] is a potent oral nonsteroidal anti-inflammatory agent (1, 2). The pharmacology of ibuproxam was described previously (3), and absorption, metabolism, and extraction patterns in animals (4) and humans (5–7) were reported. Ibuproxam is safe and effective in the treatment of rheumatic diseases. Preclinical pharmacology has indicated the utility of oral dosage forms; this paper identifies the compounds arising from thermal decomposition of ibuproxam.

RESULTS AND DISCUSSION

The stability studies showed that I was thermally unstable (Table I). This instability initially was ascribed to the impurities of the technical grade product, but further testing of the analytical grade substance led to the conclusion that the observed trend was characteristic of the compound (Fig. 1). Ibuproxam, heated over 70°, decomposed to give four products; during these preliminary tests, the presence of water and metals (particularly iron) due to the manufacturing process did not substantially alter the decomposition (Table II).

[a] Samples were analyzed with a Perkin-Elmer 990 gas–liquid chromatograph on a 2-m × 6.35-mm 3% Dexil on Anachrom AB column at 180° with nitrogen as the carrier gas at 30 ml/min.

From a preliminary examination of the crude decomposition product, it was possible to separate two main products: a white sublimate (insoluble in most organic solvents but soluble in water) and a sticky yellow mass that still contained the nondecomposed product (TLC controls) (Fig. 2). Chemical and spectroscopic properties of the sublimate gave evidence of its saline structure, which was confirmed by isolation of II and III; further evidence (melting point and IR spectrum) was obtained by treatment of a commercial sample of II with III.

By column chromatography of the oily mass, IV and V were obtained together with a small amount of I. The structure of V was confirmed chemically by reaction of ketone IV with hydroxylamine (Scheme I).

[a] Obtained at 90 MHz; δ values are expressed in parts per million; tetramethylsilane was the internal reference, and deuterated chloroform was the solvent. [b] Signal disappears on deuteration. [c] For these signals, a progressive change was noted from a pattern type of *AA'BB'* to *AA'XX'*.

EXPERIMENTAL[1]

Thermal Degradation—Ibuproxam (I) (4 g) was sublimed at 110° and 760 mm Hg for 24 hr to yield a white product (1.5 g) and a pale-yellow residue. This residue was extracted with ether (50 ml), and evaporation of the extracts gave an oil (2.3 g).

Ibuprofen [2-(4-Isobutylphenyl)propionic Acid, II]—The sublimate (1 g), purified by several washings with ether (mp 124–125°), was dissolved in water (25 ml). Acidification with concentrated hydrochloric acid (pH 1–2) precipitated a white solid (0.48 g, 90% yield), mp 76–77° (after crystallization from ethyl acetate).

Anal.—Calc. for $C_{13}H_{18}O_2$: C, 75.73; H, 8.73. Found: C, 75.81; H, 8.75.

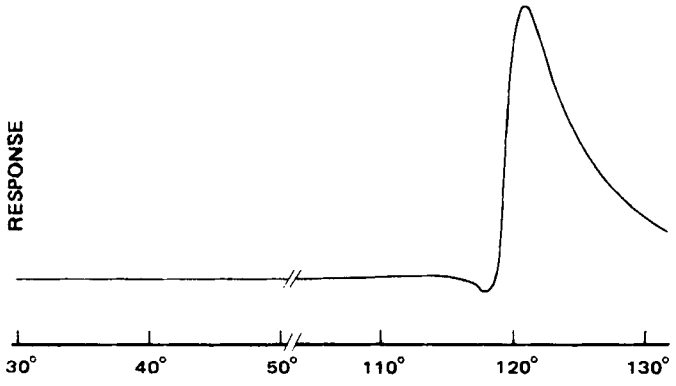

Figure 1—*Thermal decomposition of I. The scan speed was 4°/min, R = 500 μv, and the nitrogen gas flow rate was 20 ml/min.*

[1] Unless otherwise stated, IR spectra were measured for dispersions in Nujol with a Perkin-Elmer 457 spectrometer, and UV spectra were measured for solutions in ethanol with a Perkin-Elmer 124 recording spectrophotometer. ^{1}H-NMR spectra were recorded with a Perkin-Elmer R 32 instrument; chemical shifts are reported in parts per million downfield from the internal standard, tetramethylsilane. Thermal analysis was taken with a TA 2000 Mettler apparatus. Silica gel plates (Merck F_{254}) were used for analytical TLC, and the spots were detected by their UV absorption. Column chromatography was carried out with silica gel (Merck kieselgel 60, 70–230 mesh, ASTM). The extracts were dried over sodium sulfate, and the solvents were removed under reduced pressure. Melting points (uncorrected) were determined by the capillary method.

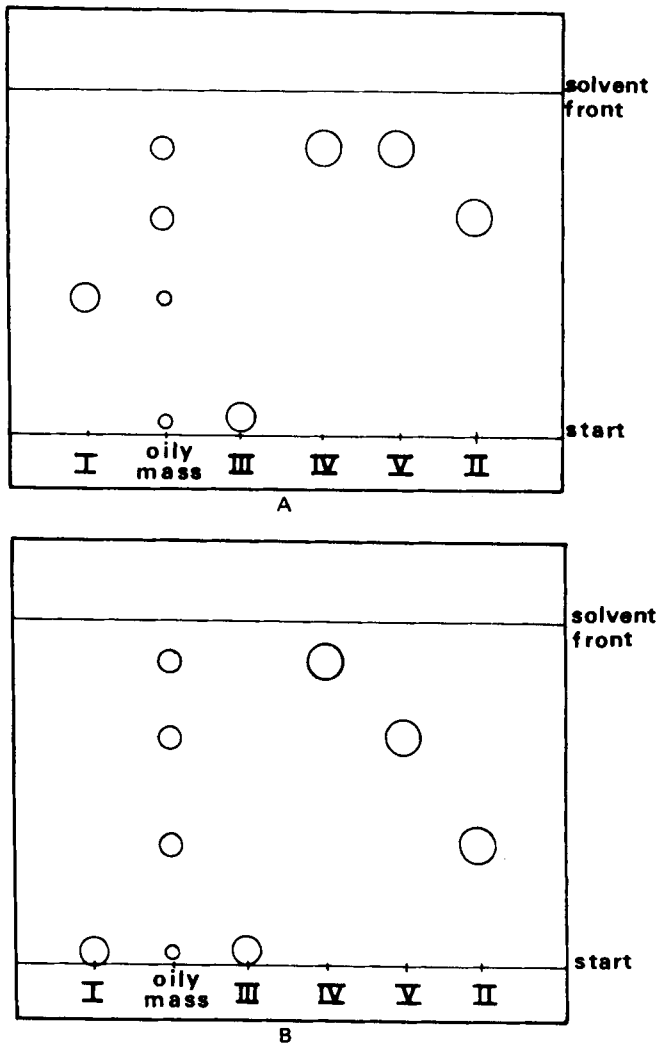

Figure 2—*TLC of the decomposition products of I. Key: A, eluent of benzene–ethyl acetate (1:1 v/v); and B, eluent of benzene–cyclohexane–ethyl acetate (5:5:1 v/v). The spot for I was detected best by spraying with sodium sulfate solution in methanol to give a characteristic green color.*

The product was identical to a commercial sample on the basis of mixed melting-point, IR, UV, and NMR analyses.

1-(4-Isobutylphenyl)ethylamine (III)—The sublimate (1 g), purified as described, was dissolved in water (25 ml); the solution was made alkaline with 10% NaOH and extracted with ether (3 × 30 ml). Removal of the solvent left an oil, which was purified by column chromatography with methanol as the eluent. Compound III (0.35 g, 75% yield) is a colorless liquid whose hydrochloride melts at 178–180°; IR: ν_{max} 3370, 3280, 2955, and 2860 cm^{-1}; UV: λ_{max} 263 (log ϵ 2.20), 272 sh (2.09), 252 (1.97), and 258 (2.12) nm.

Anal.—Calc. for $C_{12}H_{19}N$: C, 81.35; H, 10.73; N, 7.90. Found: C, 81.50; H, 10.95; N, 8.05.

4-Isobutylacetophenone (IV)—The oily residue (2 g) from thermal degradation was resolved into two products by column chromatography with benzene as the eluent. The first fractions gave IV (0.44 g, 50% yield) as a yellow liquid, bp 248°; IR: ν_{max} 2955, 2920, 2860, 1680, and 1608 cm^{-1}; UV: λ_{max} 254 nm (log ϵ 3.94).

Anal.—Calc. for $C_{12}H_{16}O$: C, 81.81; H, 9.09. Found: C, 82.05; H, 9.28.

4-Isobutylacetophenone Oxime (V)—*Method A*—The second product of the oily residue, treated as described, gave V as a white solid (0.57 g, 60% yield), mp 64–65° (after crystallization from *n*-hexane); IR: ν_{max} 3500–2800 br, 2955, 2920, and 2860 cm^{-1}; UV: λ_{max} 250 nm (log ϵ 3.86).

Anal.—Calc. for $C_{12}H_{17}NO$: C, 75.39; H, 11.80; N, 7.32. Found: C, 75.32; H, 11.60; N, 7.46.

Method B—A solution of IV (0.2 g) in methanol (20 ml) was treated with hydroxylamine (0.1 g) and refluxed gently for 6 hr. Removal of the solvent left a white solid (0.2 g, 90% yield), which was identical (melting point, IR, and NMR analyses) with the material obtained by Method A.

High-Performance Liquid Chromatographic Analysis of Griseofulvin in Drug Substance and Solid Dosage Forms: Separation of Impurities and Metabolites

EDWARD TOWNLEY * **and PAUL RODEN** *

Received July 30, 1979, from the *Physical and Analytical Chemical Research and Development Department, Schering-Plough Corporation, Bloomfield, NJ 07003.* Accepted for publication December 5, 1979.

*Present address: Duke University, Durham, NC 27706.

Abstract □ A high-performance liquid chromatographic (HPLC) system, consisting of a methanol–water (3:2 v/v) mobile phase and a Zorbax CN column with *m*-phenylphenol as the internal standard, was utilized to determine the purity of griseofulvin bulk drug substance, to assay griseofulvin in powders, tablets, capsules, and boluses, and to separate griseofulvin from its metabolites. The method was tested on commercial griseofulvin samples, griseofulvin tablets, and a mixture of griseofulvin and its metabolites. The HPLC method is compared to a GLC method.

Keyphrases □ Griseofulvin—high-performance liquid chromatographic analysis, purity and stability of drug substance, powders, tablets, capsules, and boluses, metabolites □ High-performance liquid chromatography—analysis, griseofulvin, purity and stability of griseofulvin dosage forms, metabolites □ Antifungal agents—griseofulvin, high-performance liquid chromatographic analysis of powders, tablets, capsules, and boluses

Griseofulvin has well-established fungistatic activity against various species of *Microsporum, Epidermophyton,* and *Trichophyton.* Usual dosage forms are powders, capsules, tablets, and boluses. Liquid–solid extraction methods for the preparation of griseofulvin for subsequent analysis include extraction of griseofulvin from tablets with boiling alcohol (1) and extraction from tablets with warm chloroform (2, 3).

The drug substance has been determined by several methods, the most common of which is a simple UV analysis (1, 4, 5). Other methods include polarography (6), GLC (2, 3), spectrofluorometry (7, 8), colorimetry (9–11), iodimetry (12), paper chromatography (13), and TLC (14–17). Liquid chromatography has been useful for the analysis of griseofulvin in crude mycelium (18) and in plasma (19).

This report describes a specific, simple, and robust high-performance liquid chromatographic (HPLC) procedure. It is applicable to the drug substance and solid dosage forms and to the separation of griseofulvin from its metabolites. The procedure is offered as an alternative to the GLC method (2), which suffers from the difficulty of drug analysis at high temperatures.

EXPERIMENTAL

Materials—*m*-Phenylphenol[1], reagent grade dichloromethane[2], sodium chloride[3], and anhydrous sodium sulfate[4] were obtained from commercial sources.

Apparatus—The modular high-pressure liquid chromatograph was equipped with a constant-flow pump[5], a valve-type injector[6], a fixed-wavelength (254-nm) UV detector[7], and a strip-chart recorder[8]. Stainless steel columns (4.6 mm × 30 cm) were packed with fully porous 10-μm silica particles to which a monomolecular layer of cyanopropylsilane[9] was chemically bonded. A rotating mixing wheel[10] and centrifuge tubes[11] were used to extract the samples. A data acquisition system[12] was used for both peak height and area measurements.

Chromatographic Conditions—The mobile phase was methanol–water (3:2). This solution was passed through a 0.45-μm filter[13], degassed, and then pumped through the HPLC system at a rate of 1 or 2 ml/min.

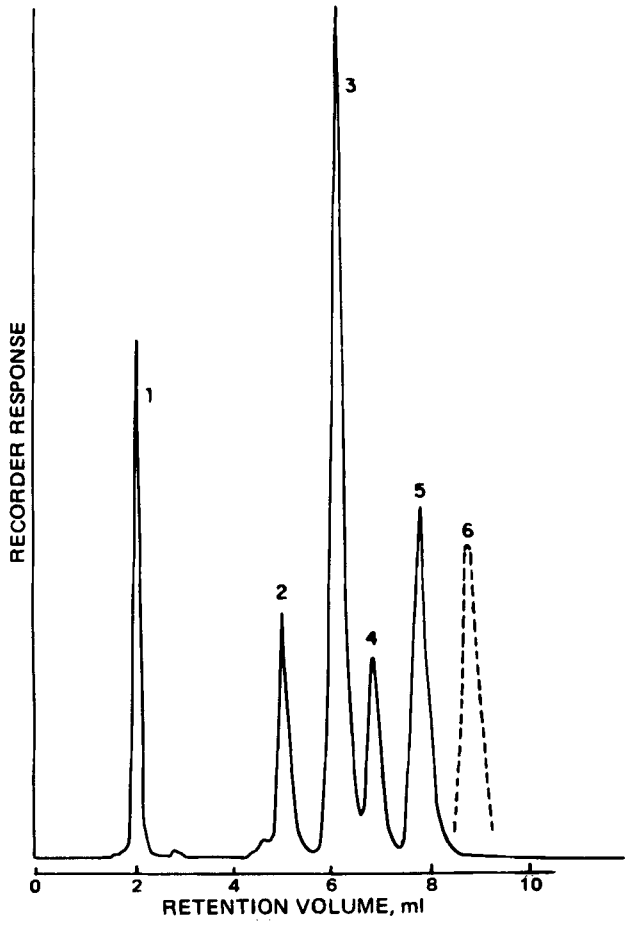

Figure 1—*HPLC separation of biosynthetic impurities (substances identified in the fermentation broth). Key: 1, griseofulvic acid; 2, dechlorogriseofulvin; 3, griseofulvin; 4, isogriseofulvin; 5, tetrahydrogriseofulvin; and 6,* m*-phenylphenol.*

Internal Standard Solution—The internal standard was *m*-phenylphenol prepared as a 1-mg/ml solution in methanol.

Standard Solution—Griseofulvin standard, ~60 mg, was weighed accurately into a 50-ml volumetric flask and was dissolved and diluted to 50 ml with methanol. Five milliliters of this solution was pipetted into a 50-ml volumetric flask. Four milliliters of the internal standard solution also was added by pipet, and the solution was diluted to 50 ml with methanol.

Standard Chromatogram—Twenty microliters of the standard solution was injected into the liquid chromatograph, and the chromatogram was recorded. The peak heights obtained were used in the calculations for griseofulvin.

Griseofulvin Samples—Griseofulvin samples were obtained from England[14] (Batches UGFP-1961 and UGRB-505), Japan[15] (Batches GU-4830S and GU-4910S), Rumania[16] (Batches 26 and 5209), Austria[17] [Batch 15 (805/7)], and the USP reference file[18] (Batch 0672-F2).

Impurities—Isogriseofulvin[14], dechlorogriseofulvin[14], griseofulvic acid[14], and tetrahydrogriseofulvin[19,20] were obtained. Dihydrogriseofulvin and additional tetrahydrogriseofulvin were synthesized[21] *via* the catalytic reduction of griseofulvin (19). The metabolites, 4-demethylgriseofulvin and 6-demethylgriseofulvin, were obtained as a result of previous research (20, 21). Identities were confirmed by comparison of the IR spectra to

authentic references (isogriseofulvin, dechlorogriseofulvin, and griseofulvic acid) or by mass spectral studies (dihydrogriseofulvin, tetrahydrogriseofulvin, 4-demethylgriseofulvin, and 6-demethylgriseofulvin).

Accelerated Decomposition Studies—Accelerated, extreme degradation of griseofulvin was accomplished by several methods:

1. Griseofulvin drug substance was heated at 75° for 3 weeks.
2. Griseofulvin (0.25 mg/ml) was dissolved in methanol–0.1 *N* NaOH (4:1) and allowed to stand for 7 days.
3. Griseofulvin (0.25 mg/ml) was dissolved in methanol–0.1 *N* HCl (4:1) and allowed to stand for 7 days.
4. Griseofulvin was dissolved in methanol–water (4:1) in a Pyrex volumetric flask and exposed to daylight for 14 days through window glass.

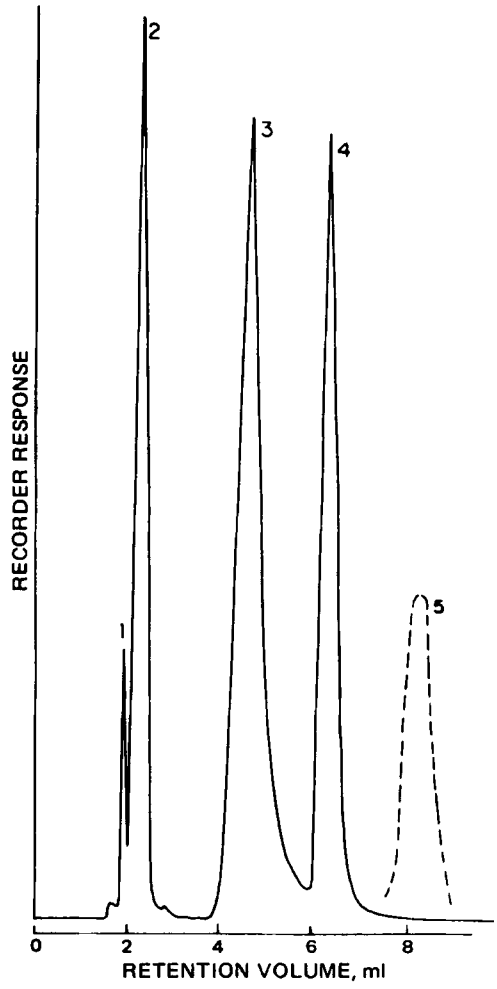

Figure 3—*HPLC separation of 4-demethylgriseofulvin and 6-demethylgriseofulvin metabolites. Key: 1, griseofulvic acid (impurity); 2, 6-demethylgriseofulvin; 3, 4-demethylgriseofulvin; 4, griseofulvin, and 5,* m*-phenylphenol.*

Griseofulvin Drug Substance Purity Determination—Approximately 60 mg of a griseofulvin test sample was weighed accurately into a 50-ml volumetric flask and dissolved and diluted to volume with methanol. Five milliliters of the sample solution was pipetted into a 50-ml volumetric flask. Four milliliters of the internal standard solution was added, and the solution was diluted to volume. Then 20 μl of the sample was injected into the liquid chromatograph operating at the described conditions. The percent purity was calculated from:

$$\text{percent griseofulvin} = \left(\frac{P'_{sple}}{P'_{is}}\right)\left(\frac{P_{is}}{P_{std}}\right)\left(\frac{W_{std}}{W_{sple}}\right) \times 100 \qquad \text{(Eq. 1)}$$

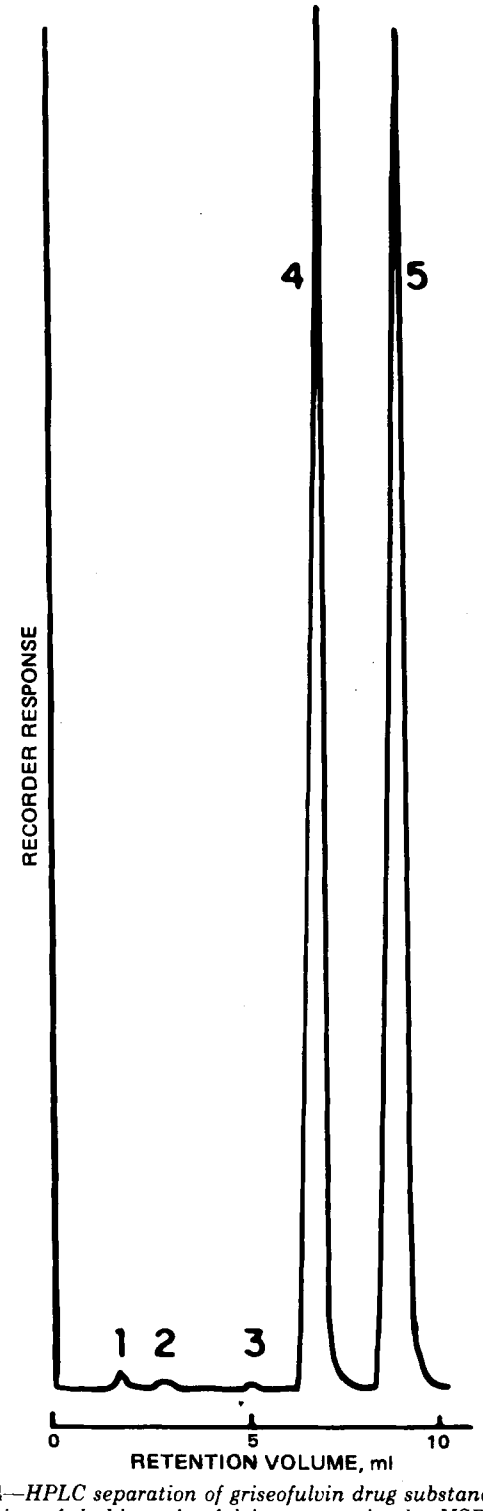

Figure 4—*HPLC separation of griseofulvin drug substance and demonstration of dechlorogriseofulvin content in the USP standard (Batch 0672-F2). Key: 1, solvent; 2, griseofulvic acid; 3, dechlorogriseofulvin; 4, griseofulvin; and 5,* m*-phenylphenol.*

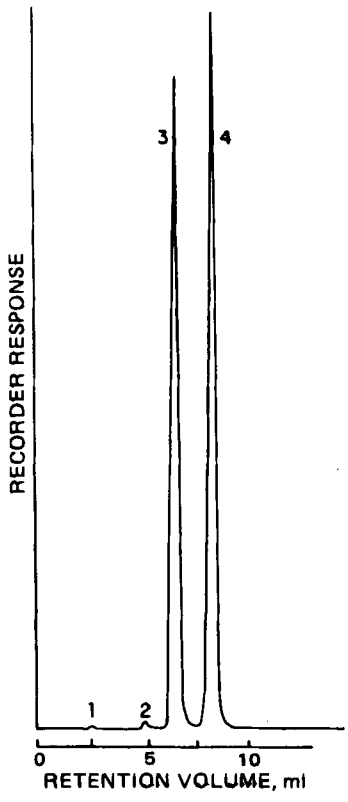

Figure 5—*High-performance liquid chromatogram of griseofulvin extracted from tablets (Batch 7934-45A). Key: 1, griseofulvic acid; 2, dechlorogriseofulvin; 3, griseofulvin; and 4,* m*-phenylphenol.*

where P'_{sple} is the peak height of the sample in the sample chromatogram, P'_{is} is the peak height of the internal standard in the sample chromatogram, P_{is} is the peak height of the internal standard in the standard chromatogram, P_{std} is the peak height of the standard in the standard chromatogram, W_{std} is the weight of the standard, and W_{sple} is the weight of the sample.

Griseofulvin in Solid Dosage Form Determination—A sample of well-mixed ground powder (from powders, tablets, capsules, or boluses) containing 250 mg of griseofulvin was weighed accurately into a 50-ml screw-capped centrifuge tube[11]. Then 20 ml of 10% aqueous sodium chloride solution and 20 ml of dichloromethane were added. Mixing resulted in extraction of the griseofulvin into the dichloromethane after the tube was placed on a rotating wheel[10] for 10 min.

The dichloromethane layer was transferred with a 20-ml syringe and a 16-gauge needle and filtered through ~200 mg of anhydrous sodium sulfate into a 200-ml volumetric flask. The extraction was performed three times and the extracts were combined (total of 60 ml) and diluted to volume. A 5.0-ml portion was transferred to a 50-ml volumetric flask and evaporated to dryness. The *m*-phenylphenol internal standard solution, 4.0 ml, was added, and the griseofulvin residue was dissolved in methanol and diluted to 50 ml. Then 20-μl portions were injected into the liquid chromatograph.

The griseofulvin content was calculated from:

$$\text{milligrams per unit} = \left(\frac{P'_{sple}}{P'_{is}}\right)\left(\frac{P_{is}}{P_{std}}\right)\left(\frac{W_{std}}{W_{sple}}\right)(W_{avg}) \times 4 \qquad \text{(Eq. 2)}$$

where W_{avg} is the average weight of the sample unit (gram, tablet, capsule, or bolus).

Table II—Comparison of the Accuracy of the HPLC and GLC (2) Methods for Griseofulvin Drug Substance

Batch	Mean Purity, %: HPLC Method (n = 4)	Mean Purity, %: GLC Method (n = 2)
S-03294	99.4 (99.3–99.6)	99.7 (99.6, 99.8)
3-2-58161	98.2 (97.9–98.4)	99.1 (98.9, 99.3)
UGRB-505	96.6 (96.3–96.9)	97.1 (96.8, 97.5)

Table III—Comparison of the Accuracy of the HPLC and GLC (2) Methods for Griseofulvin Tablets

Griseofulvin Tablets, mg	Content, mg/tablet	
	HPLC Method (n = 12)	GLC Method (n = 4)
125	125 (122–127)	126 (125–127)
250	247 (244–253)	250 (249–251)

Dechlorogriseofulvin Content Determination—The area under the dechlorogriseofulvin and griseofulvin peaks was obtained using a suitable area measurement integrator[12]. The percent dechlorogriseofulvin content was calculated according to:

$$\text{percent dechlorogriseofulvin} = \frac{\left[A_{DCG}\left(\frac{a_2}{a_1}\right)\right]}{\left[A_{DCG}\left(\frac{a_2}{a_1}\right)\right] + A_G} \times 100 \quad \text{(Eq. 3)}$$

where A_{DCG} is the area of the dechlorogriseofulvin peak, A_G is the area of the griseofulvin peak, a_2 is the absorptivity of griseofulvin at 254 nm, and a_1 is the absorptivity of dechlorogriseofulvin at 254 nm.

RESULTS AND DISCUSSION

The HPLC separation of biosynthetic impurities that were identified in the fermentation broths (18, 22) is demonstrated in Fig. 1. The HPLC separation of decomposition impurities that result when griseofulvin is subjected to accelerated, extreme decomposition is demonstrated in Fig. 2. The separation of 4-demethylgriseofulvin (23) and 6-demethylgriseofulvin (13) metabolites is shown in Fig. 3. The system is applicable to the determination of nonconjugated metabolites.

The data presented in Figs. 1–3 show that an internal standard eluting with a retention volume of ~10 ml will not interfere with a common biosynthetic impurity, decomposition product, or metabolite. *m*-Phenylphenol, whose retention is demonstrated in Figs. 1–3, meets this criterion.

To ascertain the purity of commercial griseofulvin, eight batches were obtained from worldwide sources and then were assayed by the described method. The purity data are given in Table I. The present study showed, as was reported previously (2, 18), that dechlorogriseofulvin was the major impurity and that it was common to all of the batches tested. The USP standard (Fig. 4) contained 0.6% of this impurity. Dechlorogriseofulvin also was separated by TLC using a silica gel adsorbent and ethyl acetate developing solvent. The absence of other significant impurities was confirmed. Table II compares the accuracy of the HPLC results to those of a GLC method (2) for griseofulvin drug substance.

The analysis of griseofulvin in both fresh and aged samples of powders, tablets, capsules, and boluses was performed by the extraction and HPLC procedures described previously. The analysis of griseofulvin tablets[22], 125 and 250 mg, serves as an example. The sample HPLC curve for griseofulvin extracted from griseofulvin tablets is given in Fig. 5. The extraction efficiency was 98% for a single extraction and 100% for the described method. A linear plot of peak height *versus* griseofulvin concentration response was obtained for griseofulvin in ground tablet powder from 62.5 to 500 mg of griseofulvin/sample. The least-squares coefficient was 0.99995. A system suitability test (reproducibility of six samples analyzed on the liquid chromatograph described) gave a relative standard deviation of ±0.3%.

The accuracy of the method was tested by the addition of griseofulvin to a placebo (procedural amount) and analysis by the described method. Recoveries were 100% with respect to a similarly chromatographed standard. The assay results are compared to those obtained by the GLC method of Margosis (2) in Table III.

Calculation of Partition Coefficient of an Unstable Compound Using Kinetic Methods

PETER R. BYRON *, ROBERT E. NOTARI ˣ, and ERIC TOMLINSON

Received June 27, 1979, from the *College of Pharmacy, Ohio State University, Columbus, OH 43210.* Accepted for publication December 6, 1979. *Present address: Department of Pharmacy, University of Aston in Birmingham, Birmingham, B4 7ET, England.

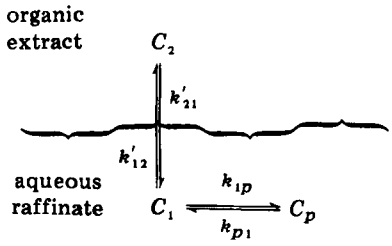
Abstract □ A stirred transfer cell containing equal volumes of light liquid paraffin and an aqueous phase at 37° was used to demonstrate the feasibility of calculating the partition coefficient of an unstable compound by kinetic analysis. Cyclohept-2-enone was chosen since it is a neutral molecule and, therefore, should have a pH-independent oil–water partition coefficient, K_D. Moreover, this cyclic α,β-unsaturated ketone undergoes hydrogen-ion-catalyzed hydration but is sufficiently stable at neutral pH to determine K_D. The model system chosen represents first-order transfer between the aqueous (C_1) and organic (C_2) phases with simultaneous, reversible, first-order hydration. The transfer constants, k'_{12} and k'_{21}, were determined at 37° in the absence of degradation where asymptotic values for C_1 agreed with the observed equilibrium values in nonkinetic partitioning studies. The first-order rate constants for hydration in 0.1 *N* HCl were determined at 37° in the absence of the organic phase. Partitioning with simultaneous hydration then was studied using 0.1 *N* HCl and light liquid paraffin. Data were analyzed by nonlinear regression based on the equation for C_1 as a function of time. The values for k'_{12} and k'_{21} from these experiments were comparable to the estimates obtained under stable conditions. This agreement demonstrates that simultaneous degradation and partitioning can be analyzed for k'_{12} and k'_{21}, thus permitting calculation of the partition coefficient (*i.e.*, $K_D = k'_{12}/k'_{21}$) that would be observed if the drug were stable.

Keyphrases □ Partition coefficients—unstable compounds, cyclohept-2-enone, calculation by kinetic methods □ Cyclohept-2-enone—partition coefficient, calculation by kinetic methods □ Drug partitioning—unstable compounds, cyclohept-2-enone, calculation of partition coefficient by kinetic methods

The two-film theory proposed by Lewis and Whitman (1, 2) for the kinetics of solute transfer between two liquid phases was first experimentally verified by Gordon and Sherwood (3, 4) using a stirred transfer cell (Fig. 1). Since then, both the cell and the theory have been studied extensively and discussed (5–7). A transfer cell was employed to measure the rates of helium and isobutane mass transfer from water to toluene and decahydronaphthalene (8). The diffusion of salts across a butanol–water interface was studied at 13–40°, and the Arrhenius parameters were compared with those for uptake of ions by frog muscle (9). An interesting application of this cell to a drug involved a study that demonstrated ion-pair formation in the transfer of dextromethorphanium ions from water to chloroform (10). McNulty (11) employed a stirred transfer cell to study the effect of polysorbate 60 on the cholesterol uptake by vegetable oil from an aqueous solution containing 5% isopropanol.

The three-phase transfer cell of Rosano *et al.* (12) frequently has been applied to pharmaceutical problems. Lippold and Schneider (13–16) determined the forward (k_f; aqueous to organic) and reverse (k_r) rate constants for a homologous series of benzilic acid quaternary esters. Kubinyi (17) used these data to show that log k_f and log k_r can be defined as a function of the number (n) of CH_2 groups in a homologous series, provided that log K_D also is a simple function of n, where K_D is the partition coefficient.

This report demonstrates that the partition coefficient



Scheme I

may be calculated from data representing the partitioning kinetics in a simple transfer cell (Fig. 1) when a drug undergoes simultaneous degradation in the aqueous phase. The two-phase cell was chosen to accommodate the added complexity introduced by drug instability in the aqueous phase. The model system (cyclohept-2-enone partitioning between liquid petrolatum and water or aqueous hydrochloric acid) chosen to test this theory allows independent evaluation of each rate constant in Scheme I, which represents partitioning in a stirred transfer cell with a competing reversible reaction in the aqueous phase. The concentration of cyclohept-2-enone in the extract (liquid petrolatum) is represented by C_2, and that in the raffinate (aqueous phase) is represented by C_1. The concentration of the degradation product, C_p, is limited to the aqueous phase, which is consistent with the experimental results. Rate constants are apparent first order, and the initial conditions are $C_1 = C_1^0$ with $C_2 = C_p = 0$.

THEORY

Partitioning Kinetics with Stable Drug—For the case where the partition coefficient, K_D, remains constant over the concentration range of the transfer experiment, the observed value may be defined by:

$$K_D = C_2^\infty / C_1^\infty \qquad \text{(Eq. 1)}$$

where C_2^∞ and C_1^∞ are the equilibrium concentrations in the raffinate (C_1) and the organic extract (C_2). At any time during a kinetic run (according to the two-film theory):

$$K_D = C_2^*/C_1 = C_{2i}/C_{1i} = C_2/C_1^* \qquad \text{(Eq. 2)}$$

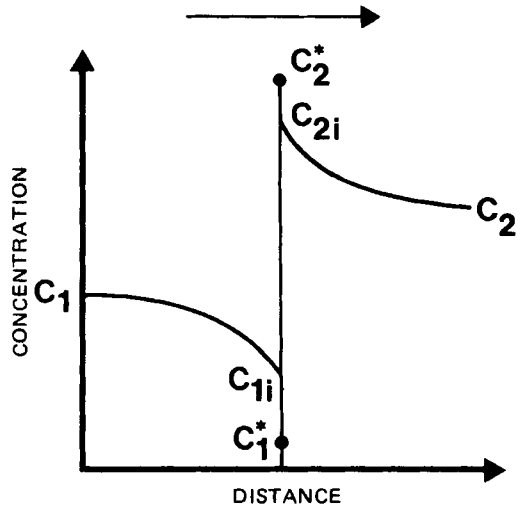

Figure 2—*Concentration gradients in a two-phase transfer cell. The arrow at the top indicates the direction of mass transfer. The concentration of diffusing solute in various regions is defined as: the average or mixed concentration in the stirred raffinate* (C_1) *and extract* (C_2); *at the interface on the raffinate side* (C_{1i}) *and extract side* (C_{2i}); $C_1^* = C_2/K_D$; *and* $C_2^* = C_1/K_D$.

The symbols are defined in Fig. 2. The solute transfer rate from the bulk of the raffinate to the interface through the diffusion layer is dependent on Fick's first law and may be written as:

$$J = -da/dt = V_1(-dC_1/dt) = (C_1 - C_{1i})(D_1A/h_1) \quad \text{(Eq. 3)}$$

where a is the amount of solute in the raffinate, V_1 is the volume of the raffinate, A is the interfacial area, and D_1 and h_1 are the diffusion coefficient and thickness of the diffusion layer in the raffinate, respectively. Similarly, the transfer rate from the interface to the bulk of the extract may be written as:

$$J = (C_{2i} - C_2)(D_2A/h_2) \quad \text{(Eq. 4)}$$

Provided that the interfacial barrier has no significant resistance and that thermal, electrical, and osmotic gradients are absent, then application of the two-film theory enables the *overall* transfer rate to be defined in terms of the overall concentration gradient $[C_1 - (C_2/K_D)]$ as:

$$J = k_{12}A(C_1 - C_1^*) \quad \text{(Eq. 5)}$$

since C_1^* is defined as (C_2/K_D) in Eq. 2. According to Flynn *et al.* (18), the *overall* rate constant for transfer from the raffinate to the extract, k_{12}, can be calculated from:

$$R_T = \frac{1}{k_{12}} = \frac{h_1}{D_1} + \frac{h_2}{D_2K_D} \quad \text{(Eq. 6)}$$

where R_T (the diffusional resistance) is the sum of the individual resistances. Equation 6 assumes the validity of the two-film theory and allows the derivation of Eq. 5 from Eqs. 2–4. Equation 5 is the form of the rate expression generally found in the literature (1–7). Its use requires analysis of both the raffinate and extract to determine $C_1 - C_1^*$ experimentally.

Since $C_1^* = C_2/K_D$ and the amount of solute in the extract, b, may be calculated from $b = a_0 - a$, Eq. 5 also may be written as:

$$J = \frac{-da}{dt} = k_{12}A\left[\left(\frac{a}{V_1}\right) - \left(\frac{(a_0 - a)}{K_DV_2}\right)\right] \quad \text{(Eq. 7)}$$

where V_2 is the volume of the extract, and the amount of solute in the interface is negligible. Integration of Eq. 7 from $t = 0$ to t and from $a = a_0$ to a, followed by substitution of a_∞ for $[a_0V_1/(K_DV_2 + V_1)]$, yields:

$$\ln(a - a_\infty) = \ln(a_0 - a_\infty) - St \quad \text{(Eq. 8)}$$

which also may be written as:

$$(a - a_\infty) = (a_0 - a_\infty)e^{-St} \quad \text{(Eq. 9)}$$

Dividing by V_1 allows conversion of Eq. 9 to concentration:

$$(C_1 - C_1^\infty) = (C_1^0 - C_1^\infty)e^{-St} \quad \text{(Eq. 10)}$$

Thus, a plot of $\ln(a - a_\infty)$ or $\ln(C_1 - C_1^\infty)$ *versus* time is linear with a negative slope, S, defined by:

$$S = \left[\frac{A(K_DV_2 + V_1)}{K_DV_1V_2}\right]k_{12} \quad \text{(Eq. 11)}$$

which may be used to calculate the *overall* rate constant for transfer from the raffinate to the extract. The S value is equivalent to the stirred cell transfer rate constant, S_{SC}, calculated by McNulty (11).

Solving for k_{12} in Eq. 6 and substituting in Eq. 11 yield:

$$S = \frac{D_1D_2A(K_DV_2 + V_1)}{V_1V_2(D_2K_Dh_1 + D_1h_2)} \quad \text{(Eq. 12)}$$

In a transfer cell, the interfacial area, phase volumes, and stirring rate may be kept constant throughout the experiment. In these studies, $V_1 = V_2 = V$, while D_1, D_2, h_1, h_2, and A remain constant, which leads to:

$$S = \left[\frac{A(K_D + 1)}{VK_D}\right]k_{12} = \frac{k'_{12}(K_D + 1)}{K_D} \quad \text{(Eq. 13)}$$

where k'_{12} is expressed in reciprocal time and is the apparent first-order forward rate constant for the partitioning process (Scheme I). Thus:

$$k'_{12} = D_1D_2AK_D/V(D_2K_Dh_1 + D_1h_2) = k_{12}A/V \quad \text{(Eq. 14)}$$

For data representing the extract, an equation similar to Eq. 5 may be written:

$$J = k_{21}A(C_2^* - C_2) \quad \text{(Eq. 15)}$$

Since $C_2^* = C_1K_D$ and $a = a_0 - b$, Eq. 15 may be rewritten as:

$$\frac{db}{dt} = k_{21}A\left[\frac{(a_0 - b)K_D}{V_1} - \left(\frac{b}{V_2}\right)\right] \quad \text{(Eq. 16)}$$

which, after integrating between the limits $t = 0$ to t and $b = 0$ to b and substituting b_∞ for $[a_0K_DV_2/(K_DV_2 + V_1)]$, yields:

$$\ln(b_\infty - b) = \ln b_\infty - S't \quad \text{(Eq. 17)}$$

Division of the exponential form of Eq. 17 by V_2 allows conversion to C_2. A plot of $\ln(b_\infty - b)$ or $\ln(C_2^\infty - C_2)$ *versus* time is linear with a negative slope, S', defined by:

$$S' = \left[\frac{A(K_DV_2 + V_1)}{V_1V_2}\right]k_{21} \quad \text{(Eq. 18)}$$

With the assumption that $V_1 = V_2 = V$, Eq. 18 reduces to:

$$S' = \left[\frac{A(K_D + 1)}{V}\right]k_{21} \quad \text{(Eq. 19)}$$

and the apparent first-order reverse rate constant for the partitioning process (Scheme I) is:

$$k'_{21} = \frac{S'}{(K_D + 1)} \quad \text{(Eq. 20)}$$

where $k'_{21} = k_{21}A/V$. Since mass balance requires that:

$$\frac{-da}{dt} = \frac{db}{dt} \quad \text{(Eq. 21)}$$

then $S = S'$, and the observed slopes of first-order plots based on Eqs. 8 and 17 are equal. Therefore, Eq. 13 equals Eq. 19 and:

$$S = S' = \left[\frac{A(K_D + 1)}{VK_D}\right]k_{12} = \left[\frac{A(K_D + 1)}{V}\right]k_{21} \quad \text{(Eq. 22)}$$

Therefore:

$$K_D = (k_{12}/k_{21}) = (k'_{12}/k'_{21}) \quad \text{(Eq. 23)}$$

Thus, the partition coefficient, K_D, is the ratio of the forward and reverse rate constants.

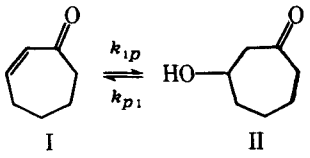
From Eqs. 13 and 20, it can be shown that:

$$(k'_{12} + k'_{21}) = S = S' \quad \text{(Eq. 24)}$$

Thus, the negative slope of a first-order plot for concentration in the raffinate (Eq. 10) or the extract (Eq. 17) equals the observed first-order rate constant, k_{obs}, which is the sum of the constants, $k'_{12} + k'_{21}$, whose ratio (k'_{12}/k'_{21}) is the partition coefficient, K_D.

Simultaneous Partitioning and Reversible Aqueous Degradation—Scheme I represents simultaneous first-order partitioning with reversible aqueous degradation to a nonpartitioning product. Solving (19) the corresponding equation for $-dC_1/dt$ and setting A constant and $V_1 = V_2$ yields:

$$C_1 = Xe^{-\gamma t} + Ye^{-\delta t} + Z \quad \text{(Eq. 25)}$$



Scheme II

where $X = C_1^0(k'_{21} - \gamma)(k_{p1} - \gamma)/\gamma(\gamma - \delta)$, $Y = C_1^0(k'_{21} - \delta)(k_{p1} - \delta)/\delta(\delta - \gamma)$, $Z = C_1^0 k'_{21} k_{p1}/\gamma\delta$, $\gamma = 0.5(K_1 + \sqrt{K_1^2 - 4K_2})$, $\delta = 0.5(K_1 - \sqrt{K_1^2 - 4K_2})$, $K_1 = (k'_{12} + k'_{21} + k_{1p} + k_{p1})$, and $K_2 = (k'_{12}k_{p1} + k'_{21}k_{p1} + k'_{21}k_{1p})$. If partitioning of the product into the organic extract is significant, then Scheme I and Eq. 25 must be modified to include the additional compartment, C_{2p}. The aqueous degradation of drugs usually goes to completion (*i.e.*, apparent irreversibility), and the time course for C_1 therefore is independent of C_p. This case, in which the partitioning behavior of the product is immaterial, is discussed later.

Nonlinear regression of data for a system described by Scheme I using Eq. 25 with known values for k_{1p} and k_{p1} allows estimation of k'_{12} and k'_{21}. The ratio (k'_{12}/k'_{21}) should estimate the partition coefficient, K_D (Eq. 23).

EXPERIMENTAL

Ideal properties to test the theory were defined as follows. The solute should not contain any acidic or basic groups but should remain neutral throughout the pH range studied. (Alternatively, it should have a constant ionic form throughout the studies.) This condition eliminates the complication of a pH-dependent distribution coefficient. A simple stability-indicating assay is required. It must be possible to determine K_D, k'_{12}, and k'_{21} under conditions where the solute is stable. The value for K_D must be sufficiently small to allow accuracy in the estimation of both k'_{12} and k'_{21}. Sink conditions ($k'_{12} \gg k'_{21}$), which prevent the estimation of k'_{21}, eliminated the use of several nonaqueous solvents. The rate constants for degradation, k_{1p} and k_{p1}, must be on the same order of magnitude as k'_{12} and k'_{21} to prevent domination by either extraction or degradation. The solute should not undergo self-association so that K_D remains constant throughout the experiment.

UV absorption[1] was automatically recorded with a flowcell to monitor the C_1 time course continuously. Absorbance at a single wavelength was related directly to C_1 by selecting a solute whose degradation product did not interfere.

The α,β-unsaturated ketone, cyclohept-2-enone (I), was chosen since it was expected to undergo hydrogen-ion-catalyzed hydration to the nonchromophoric compound, 3-hydroxycycloheptanone (II). Previous studies indicated that the process is reversible and that some reaction conditions do not favor complete hydration (20, 21).

In Scheme II, the concentration of I is given by:

$$C_1 = \frac{C_1^0 k_{1p}}{(k_{1p} + k_{p1})} e^{-(k_{1p}+k_{p1})t} + \frac{C_1^0 k_{p1}}{(k_{1p} + k_{p1})} \qquad \text{(Eq. 26)}$$

The negative slope, k_{app}, of a plot of $\ln(C_1 - C_1^\infty)$ *versus* t, where $C_1^\infty = C_1^0 k_{p1}/(k_{1p} + k_{p1})$, is the sum of the first-order rate constants $(k_{1p} + k_{p1})$. The reverse and forward constants may be calculated from:

$$k_{p1} = k_{app} C_1^\infty / C_1^0 \qquad \text{(Eq. 27)}$$

and:

$$k_{1p} = k_{app} - k_{p1} \qquad \text{(Eq. 28)}$$

The 233-nm absorption maximum of cyclohept-2-enone decreased to <5% of its initial value in 1 *N* HCl at 37° within 24 hr. A similar trial using cyclohex-2-enone produced a 32% reduction in 60 hr. The percent residual absorption of cyclohept-2-enone increased with decreasing acid strength.

The theory relating to Scheme I indicates that nonlinear regression based on Eq. 25 can be used to estimate k'_{12} and k'_{21} if the values for k_{1p} and k_{p1} (which may be assessed independently) are known. Equation 23 shows that the partition coefficient may be calculated from the ratio of the distribution constants, $K_D = (k'_{12}/k'_{21})$.

Estimates for K_D were similar at three initial concentrations, representing the range observed in the aqueous phase during partitioning kinetics. Determinations were made by equilibration of cyclohept-2-enone between equal volumes of water and light liquid petrolatum at 37° using the UV absorbance of the solute in the aqueous phase (λ_{max} = 233 nm, ϵ = 10,182). Control experiments to determine the partitioning of the solute between potassium chloride solutions of varying ionic strength (μ = 0–1) and light liquid petrolatum at 37° showed that K_D was independent of μ. Prior to use, the light liquid petrolatum was extracted repeatedly with double-distilled water until the extracts showed no absorption at 233 nm and both phases were preequilibrated.

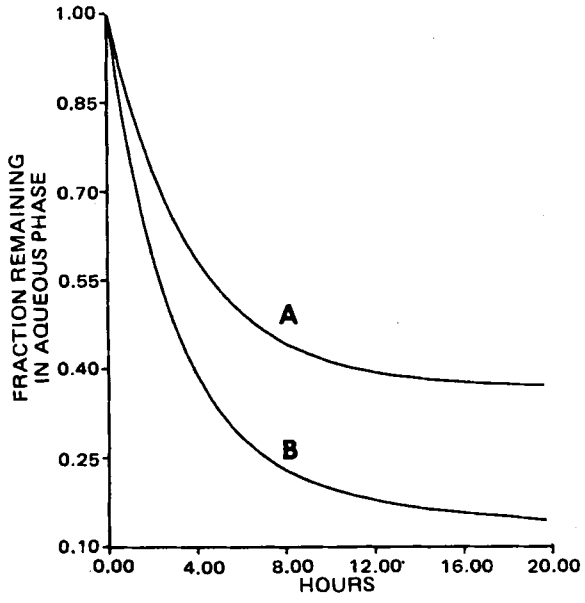


Figure 3—*Fraction of the initial concentration of cyclohept-2-enone remaining in the raffinate as a function of time at 37° under stable (curve A) and unstable (curve B; 0.1 N HCl at 37°) conditions at 50 rpm in the transfer cell. The continuous data presented in the figure are indistinguishable from the theoretical curves obtained using Eq. 10 (curve A) and Eq. 25 (curve B) when* k'_{12}, k'_{21}, k_{1p}, *and* k_{p1} *values are as given in Table I.*

Distribution rate constants were estimated by introducing the solute into the aqueous phase of a transfer cell (Fig. 1) containing 90 ml of each preequilibrated phase, stirred[2] at 50 or 100 rpm and maintained at 37°. The initial concentration in the aqueous phase was 1.4×10^{-4} *M*. The aqueous phase was pumped[3] through a flowcell in the thermally controlled spectrophotometer. The 233-nm absorbance was recorded automatically as a function of time until equilibrium was attained. Final values agreed with the nonkinetic partitioning studies. Cyclohept-2-enone underwent <3% hydration after 96 hr under the study conditions. First-order plots based on Eq. 10 were linear for >95% of the process; k'_{12} and k'_{21} were calculated from Eqs. 23 and 24.

The kinetics of cyclohept-2-enone hydration were studied as a function of the hydrochloric acid concentration at 37°. Rate constants, k_{1p} and k_{p1}, were calculated from Eqs. 27 and 28; those in 0.1 *N* HCl were considered best for the evaluation of k'_{12} and k'_{21} under competing conditions. The residual absorbance after equilibration in 0.1 *N* HCl was 10.3% and is attributed to I since the contribution by II is negligible (20, 21).

The kinetics of hydration in 0.1 *N* HCl with simultaneous partitioning into light liquid petrolatum were measured in a stirred transfer cell at 50 or 100 rpm at 37°. Absorbance data (A at λ_{max} = 233 nm) were analyzed by nonlinear regression (22) based on Eq. 25 where $C_1 = A/\epsilon$. Equilibration studies of I between 0.1 *N* HCl and light liquid petrolatum gave observed values for Z similar to those calculated from $Z = C_1^0 k'_{12} k_{p1}/\gamma\delta$ (Eq. 25). This agreement is consistent with the formation of a nonchromophoric product that does not partition significantly (Scheme I). The values for k'_{12} and k'_{21}, obtained in these experiments with simultaneous partitioning and hydration, were compared to those determined in the absence of hydration.

RESULTS AND DISCUSSION

Curve A in Fig. 3 shows a typical time course for the fraction of solute remaining in the aqueous phase of a stirred transfer cell containing equal volumes of water and light liquid petrolatum at 37° and 50 rpm. The

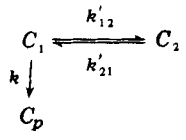

Scheme III

negative slope, S, of a first-order plot based on Eq. 10 was used to calculate k'_{12} and k'_{21} (Eqs. 23 and 24) from such data. Since cyclohept-2-enone is a neutral molecule, its K_D value should be independent of pH. Thus, the values determined for k'_{12} and k'_{21} under stable conditions should be the same as those determined in the presence of simultaneous degradation.

When the experiment was repeated with 0.1 *N* HCl as the aqueous phase, cyclohept-2-enone loss (Fig. 3, curve B) was described by Eq. 25 in accordance with Scheme I. Data were analyzed by nonlinear regression (22) of the entire time course to reiterate the values for k'_{12} and k'_{21} while assigning to k_{1p} and k_{p1} the values determined independently in 0.1 *N* HCl saturated with light liquid petrolatum at 37°. The agreement between the regression estimates and those determined independently (Table I) supports the proposed theory in which $K_D = k'_{12}/k'_{21}$.

The calculation of K_D under unstable conditions may be important to the chemist concerned with its modification. This approach can provide values that may be needed for structural correlations on partitioning. It may not be possible to determine K_D independently as was done with cyclohept-2-enone. For example, the solute may exist as a different charge species at pH values where it is stable, or conditions sufficiently stable for equilibration may not exist.

Partitioning Kinetics with Simultaneous Irreversible Loss of Drug—The present study demonstrated that biexponential loss from the aqueous phase of Scheme I can be analyzed for k'_{12} and k'_{21} whose ratio (k'_{12}/k'_{21}) is K_D. This theory can be extended to Scheme III, which shows the irreversible loss of drug competing with the process of distribution as discussed previously (23) in reference to apomorphine distribution into the brains of mice. This process is analogous to the reversible first-order transfer of a compound between the aqueous phase, C_1, and the organic phase, C_2, of a stirred transfer cell with simultaneous, irreversible, first-order degradation to the product, C_p, in the aqueous phase. Applying the initial conditions of $C_1 = C_1^0$ and $C_2 = C_p = 0$ and again assuming that $[A/V_1] = [A/V_2]$ remains constant provide:

$$C_1 = X'e^{-\alpha t} + Y'e^{-\beta t} \qquad \text{(Eq. 29)}$$

Table I—Comparison of the Rate Constants k'_{12} and k'_{21} for Distribution of Cyclohept-2-enone between Light Liquid Petrolatum and Water to the Estimates Obtained with Simultaneous Hydration and Partitioning (Light Liquid Petrolatum–0.1 *N* HCl) in a Stirred Transfer Cell at 37°

Revolutions per Minute	Stable Conditions			Simultaneous Loss[a]		
	k'_{12}	k'_{21}	K_D[b]	k'_{12}	k'_{21}	Percent Error[c]
50	0.168	0.098	1.7	0.163	0.105	−5.9
100	0.206	0.120	1.7	0.210	0.130	−5.9

[a] The k'_{12} and k'_{21} values were determined by nonlinear regression based on Eq. 25; k_{1p} and k_{p1} were held constant at 0.117 and 0.0134 hr^{-1}, respectively. [b] $K_D = C_2^\infty/C_1^\infty = k'_{12}/k'_{21}$. [c] $|[(k'_{12}/k'_{21})^a - K_D]/K_D{}^b| \times 100$ = percent error.

where $X' = C_1^0(\alpha - k'_{21})/(\alpha - \beta)$, $Y' = C_1^0(k'_{21} - \beta)/(\alpha - \beta)$, $\alpha = 0.5(K_3 + \sqrt{K_3^2 - 4k'_{21}k})$, $\beta = 0.5(K_3 - \sqrt{K_3^2 - 4k'_{21}k})$, and $K_3 = (k'_{12} + k'_{21} + k)$. The time course for solute concentration in the extract may be defined by:

$$C_2 = Z'(e^{-\beta t} - e^{-\alpha t}) \qquad \text{(Eq. 30)}$$

where $Z' = C_1^0 k'_{12}/(\alpha - \beta)$. Such a system, involving the simultaneous partitioning and hydrolysis of ampicillin and amoxicillin in isobutanol–aqueous hydrochloric acid, was investigated (24).

The observed phase ratio, C_2/C_1, will change as a function of time. The time required for this ratio to approach a constant value during an experiment depends on the values for k'_{12}, k'_{21}, and k. When the contribution of the first term in Eq. 29 ($X'e^{-\alpha t}$) becomes insignificant relative to the second term ($Y'e^{-\beta t}$), the ratio approaches a constant. The time required for this result to occur, t_d, may be estimated from:

$$t_d \approx [\ln(F/R)]/(\beta - \alpha) \qquad \text{(Eq. 31)}$$

where $R = (k'_{21} - \alpha)/(k'_{12} - \beta)$ and F is the fraction of C_1 (Eq. 29) at t_d that is due to $X'e^{-\alpha t}$ (25). If, for example, a contribution of 1% is considered insignificant, then $F = 0.01$. At $t > t_d$, C_2/C_1 (Scheme III) approaches a constant distribution ratio, which may be estimated from:

$$r = k'_{12}/(k'_{21} - \beta) \qquad \text{(Eq. 32)}$$

in the limit as $Xe^{-\alpha t}$ approaches zero. Provided that t_d is not too large, C_2/C_1 will approach r during the experiment. However, the value for r will not approximate K_D except under conditions in which the drug is relatively stable and $(k'_{21} - \beta) \to k'_{21}$.

The situation in which C_2/C_1 may be described by r rather than by K_D is referred to as kinetic control of distribution in contrast to thermodynamic control (23). Although many successful biological correlations have been achieved using K_D values, there may be situations where kinetic control dominates. It was noted (23) that the distribution of norapomorphine to the brain [reported by Burkman *et al.* (26)] might be an example where competing kinetic processes controlled the brain–blood ratios, r, due to simultaneous drug loss by glucuronidation. It was suggested that t_d was too large to allow the observation of a constant r value before complete loss of the drug from the animal.

Another example where r may be of greater value than K_D is in simultaneous first-order absorption and degradation. This situation might occur through chemical degradation caused by stomach acidity or metabolism by intestinal flora. Tomlinson *et al.* (24) compared r and K_D values for amoxicillin and ampicillin under unstable conditions and discussed the potential significance of kinetic control of the phase ratios.

Figure 4 illustrates the relationship between r and K_D as a function of selected relative values for k'_{12}, k'_{21}, and k (Scheme III). When $k = 0$, $r = K_D$. From a practical viewpoint, $r \approx K_D$ (within 5%) when $(k'_{12} + k'_{21}) \geq 20k$. As the k value increases, r increases relative to K_D, and kinetic control becomes increasingly significant.

Conclusion—A stirred transfer cell has been employed to calculate the partition coefficient, K_D, for a compound that is unstable in the aqueous phase. Equations for drugs that degrade *irreversibly* in one of the transfer cell phases (Scheme III) can simultaneously estimate the first-order rate constants for both degradation and distribution. This calculation, using kinetic methods, provides K_D values under conditions where equilibration experiments are not possible. These constants may be used to calculate K_D, r, and the time at which distribution is considered complete ($t > t_d$, $F = 0.01$) as simultaneous irreversible degradation competes with partitioning. The difference between r and K_D indicates the degree of kinetic control for the system.

Abstract □ With ^{14}C-urea as the starting material, 2-^{14}C-1-(2′-deoxy-β-D-ribofuranosyl)-5-ethyluracil [2-^{14}C-β-5-ethyl-2′-deoxyuridine] was synthesized for metabolic studies. After intravenous administration in rats, the radioactivity disappeared in the blood within 72 hr, being eliminated primarily in the urine (97%). The major elimination took place in the first 24 hr (92%). Little radioactivity was detected in the organs and tissues after 3 days. Approximately 50% of the urine radioactivity probably was due to an unidentified conjugate, 30% was due to Metabolite II, and 20% was unchanged drug. Metabolite II was identified as 5-ethyluracil by mass and ^{1}H-NMR spectra and by comparison with an authentic sample.

Keyphrases □ Ethyldeoxyuridine—synthesis, biotransformation in rats, metabolites □ Antiviral agents—ethyldeoxyuridine, synthesis, biotransformation in rats, metabolites

1-(2′-Deoxy-β-D-ribofuranosyl)-5-ethyluracil (β-5-ethyl-2′-deoxyuridine[1], VIII) has shown promising therapeutic activity against herpes simplex and vaccina viruses (1, 2) and against herpes keratitis in rabbits (3). Due to its compatibility with the ophthalmic mucous membrane, VIII is particularly suitable for the treatment of herpetic eye disease (4–7). Its excretion, distribution, and biotransformation were studied in rats using ^{14}C-VIII.

EXPERIMENTAL[2]

Synthesis—For metabolic studies, ^{14}C-β-5-ethyl-2′-deoxyuridine (VIII), specific activity 0.168 mCi/mmole, was synthesized (Scheme I). The starting material was ^{14}C-urea[3], specific activity 5.13 mCi/mmole.

2-^{14}C-5-Ethylbarbituric Acid (III)—Diethyl ethylmalonate (II) (9.4 g, 0.05 mole) was added dropwise to 10 ml of a 30% methanolic sodium methoxide solution. The reaction mixture was refluxed for 30 min with constant stirring. Then the ^{14}C-urea solution (3 g, 0.05 mole) in 10 ml of methanol was added quickly. The reaction mixture was refluxed with stirring for 6 hr under anhydrous conditions.

After cooling, the solvent was evaporated to dryness, and the residue was dissolved in 30 ml of hot water. The solution was acidified to pH 1–2 with 10 ml of concentrated hydrochloric acid. Crystals that precipitated overnight under refrigeration were filtered off, washed with ice water, and dried to yield 6.1 g of 2-^{14}C-III (78.3% based on ^{14}C-urea), mp 195–197° [lit. (8) mp 194–195°, (9) mp 193–194°].

2-^{14}C-5-Ethyl-6-chlorouracil (IV)—Phosphoryl chloride (14 ml) was added dropwise into a mixture of III (6.1 g, 0.035 mole) and water (0.5 ml). The reaction mixture temperature was slowly raised to 100° with constant stirring. After heating on an oil bath for 90 min at 90–100°, the reaction mixture was cooled. The remaining phosphoryl chloride was decomposed carefully with 25 ml of water.

The cooled mixture was stirred for 1 hr and allowed to stand in the refrigerator overnight. The white crystalline precipitate was filtered off, washed with ice water, and dried to yield 6.1 g of 2-^{14}C-IV (70% based on ^{14}C-urea), mp 215–217° [lit. (10) mp 215–217°].

2-^{14}C-5-Ethyluracil (V)—The solution of IV (6.1 g, 0.035 mole) in 2 *N* NaOH (58 ml) and 1% palladium-on-charcoal was hydrogenated at 60°. The hydrogen uptake virtually ceased after 3 hr. The catalyst was filtered off, and the filtrate was acidified with concentrated hydrochloric acid. After cooling, the precipitated crystals were filtered off, washed with cold water, and dried to yield 3.6 g of 2-^{14}C-V (51.4% based on ^{14}C-urea), mp 308–309° [lit. (8) mp 302–303°, (11, 12) mp 300–303°, (13) mp 300°, (14, 15) mp 308–309°].

2-^{14}C-2,4-Bis-O-(trimethylsilyl)-5-ethylpyrimidine (VI)—Compound V (3.6 g, 25.5 mmoles), hexamethyldisilazane (21 ml), and dimethylformamide (1.8 ml) were heated on an oil bath for 12 hr at 160–170° with constant stirring under anhydrous conditions. After cooling, the solvent was removed under reduced pressure. The residue, an oily yellow liquid, was used without further purification in the next step.

2-^{14}C-1-(3′,5′-Di-O-p-chlorobenzoyl-2′-deoxy-α,β-D-ribofuranosyl)-5-ethyluracil (VIIa and VIIb)—The reaction of VI with 3,5-di-*O*-*p*-chlorobenzoyl-2′-deoxy-α,β-D-ribofuranosyl chloride (16) to produce 1-(3′,5′-di-*O*-*p*-chlorobenzoyl-2′-deoxy-α,β-D-ribofuranosyl)-5-substi-

Its excretion, distribution, and biotransformation were studied in rats using ^{14}C-VIII.

EXPERIMENTAL[2]

Synthesis—For metabolic studies, ^{14}C-β-5-ethyl-2′-deoxyuridine (VIII), specific activity 0.168 mCi/mmole, was synthesized (Scheme I). The starting material was ^{14}C-urea[3], specific activity 5.13 mCi/mmole.

2-^{14}C-5-Ethylbarbituric Acid (III)—Diethyl ethylmalonate (II) (9.4 g, 0.05 mole) was added dropwise to 10 ml of a 30% methanolic sodium methoxide solution. The reaction mixture was refluxed for 30 min with constant stirring. Then the ^{14}C-urea solution (3 g, 0.05 mole) in 10 ml of methanol was added quickly. The reaction mixture was refluxed with stirring for 6 hr under anhydrous conditions.

After cooling, the solvent was evaporated to dryness, and the residue was dissolved in 30 ml of hot water. The solution was acidified to pH 1–2 with 10 ml of concentrated hydrochloric acid. Crystals that precipitated overnight under refrigeration were filtered off, washed with ice water, and dried to yield 6.1 g of 2-^{14}C-III (78.3% based on ^{14}C-urea), mp 195–197° [lit. (8) mp 194–195°, (9) mp 193–194°].

2-^{14}C-5-Ethyl-6-chlorouracil (IV)—Phosphoryl chloride (14 ml) was added dropwise into a mixture of III (6.1 g, 0.035 mole) and water (0.5 ml). The reaction mixture temperature was slowly raised to 100° with constant stirring. After heating on an oil bath for 90 min at 90–100°, the reaction mixture was cooled. The remaining phosphoryl chloride was decomposed carefully with 25 ml of water.

The cooled mixture was stirred for 1 hr and allowed to stand in the refrigerator overnight. The white crystalline precipitate was filtered off, washed with ice water, and dried to yield 6.1 g of 2-^{14}C-IV (70% based on ^{14}C-urea), mp 215–217° [lit. (10) mp 215–217°].

2-^{14}C-5-Ethyluracil (V)—The solution of IV (6.1 g, 0.035 mole) in 2 *N* NaOH (58 ml) and 1% palladium-on-charcoal was hydrogenated at 60°. The hydrogen uptake virtually ceased after 3 hr. The catalyst was filtered off, and the filtrate was acidified with concentrated hydrochloric acid. After cooling, the precipitated crystals were filtered off, washed with cold water, and dried to yield 3.6 g of 2-^{14}C-V (51.4% based on ^{14}C-urea), mp 308–309° [lit. (8) mp 302–303°, (11, 12) mp 300–303°, (13) mp 300°, (14, 15) mp 308–309°].

2-^{14}C-2,4-Bis-O-(trimethylsilyl)-5-ethylpyrimidine (VI)—Compound V (3.6 g, 25.5 mmoles), hexamethyldisilazane (21 ml), and dimethylformamide (1.8 ml) were heated on an oil bath for 12 hr at 160–170° with constant stirring under anhydrous conditions. After cooling, the solvent was removed under reduced pressure. The residue, an oily yellow liquid, was used without further purification in the next step.

2-^{14}C-1-(3′,5′-Di-O-p-chlorobenzoyl-2′-deoxy-α,β-D-ribofuranosyl)-5-ethyluracil (VIIa and VIIb)—The reaction of VI with 3,5-di-*O*-*p*-chlorobenzoyl-2′-deoxy-α,β-D-ribofuranosyl chloride (16) to produce 1-(3′,5′-di-*O*-*p*-chlorobenzoyl-2′-deoxy-α,β-D-ribofuranosyl)-5-substi-

[1] Edurid, Robugen GmbH, 7300 Esslingen/Neckar, West Germany.

[2] Melting points were taken on a Tottoli (Büchi, Switzerland) apparatus and are uncorrected. Mass spectra were measured at an ionizing potential of 70 ev with a CH-7 Varian MAT spectrometer using a direct evaporator inlet system. ^{1}H-NMR spectra were recorded on a Varian T-60 spectrometer using dimethyl sulfoxide-d_6 as the solvent and trimethylsilane as the internal standard.

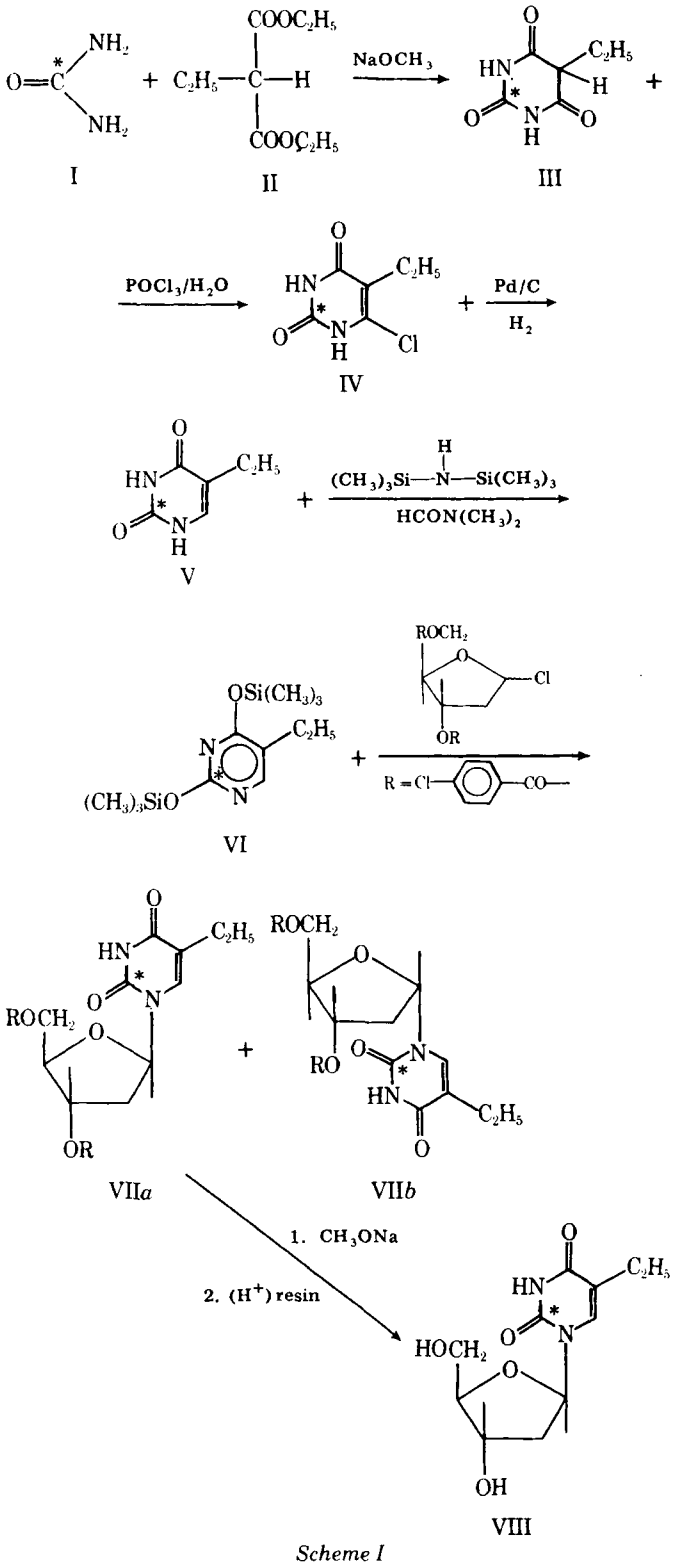

Scheme I

tuted pyrimidines is reported in the literature (17–21). With this method, ^{14}C-labeled VII*a* and VII*b* were synthesized in 43.4% yield based on ^{14}C-urea, mp 169–174°. The mixture of the blocked anomers was crystallized fractionally from toluene, yielding the pure α- and β-anomers: VII*a* (β-anomer), mp 196–197° [lit. (22) mp 195–196°]; and VII*b* (α-anomer), mp 186–188° [lit. (22) mp 186.5–187.5°].

2-^{14}C-1-(2′-Deoxy-β-D-ribofuranosyl)-5-ethyluracil (VIII)—To a suspension of the protected nucleoside VII*a* (3.6 g, 6.75 mmoles) in anhydrous methanol (35 ml), 30% methanolic sodium methoxide (0.65 ml) was added. The solution was stirred at room temperature for 4 hr, and methanol was evaporated under reduced pressure. Water (15 ml) was added to the oily residue. The formed ester was removed by extracting

Table I—Elimination of Radioactivity in Urine and Feces of Rats after 20 mg of 2-^{14}C-β-5-Ethyl-2′-deoxyuridine/kg iv

Sample	Hours	Radioactivity, % of applied dose
Urine	24	92
	48	5.1
	72	0.1
	96	—
Feces	24	0.5
	48	0.3
	72	0.1
	96	—

several times with methylene chloride. To the resulting solution an ion-exchange resin[4] (H^+), previously washed with methanol, was added. Stirring was continued for 5 min.

The solution was filtered from the resin, the filtrate was evaporated *in vacuo* to dryness, and acetone (25 ml) was added to the residue. After overnight refrigeration, the crystalline product was collected by filtration to yield 1.59 g of VIII (92% based on the blocked nucleoside VII*a*), mp 152–153° [lit. (22) mp 152–153°], specific activity 0.168 mCi/mmole. Radiochemical purity was checked by radioscanning of the TLC plates.

Radioactivity Measurements—The radioactive zones on TLC plates were located with a thin-layer scanner[5]. The radioassay in the solution was carried out in a two-canal liquid scintillation counter[6], using a scintillation solution of 1000 ml of dioxane, 180 g of naphthalene, 8 g of 2,5-diphenyloxazole, and 0.1 g of 1,4-bis[2-(4-methyl-5-phenyloxazolyl)]benzene. The external standardization technique was employed.

Application—A 1% solution of ^{14}C-VIII was made in normal saline. One-half milliliter was injected into the tail vein of 250-g male Wistar rats. The animals were kept in metabolic cages, which enabled collection of feces and urine separately. They were given free access to food[7] and water and were kept at 22° temperature and 55% humidity.

Sample Preparation—*Feces, Organs, and Tissues*—For qualitative and quantitative determination of the radioactivity, the fecal samples were dried at 60°, powdered, homogenized, and extracted with methanol in a soxhlet apparatus for 48 hr. The organs and tissues were cut into fine pieces and extracted with methanol for 72 hr. An aliquot (0.1 ml) of these samples was taken for required measurements.

Urine—An aliquot (0.1–0.2 ml) was mixed directly into the scintillation solution, and radioactivity was measured.

Chromatography—Analytical TLC was performed on 20 × 5-cm silica gel plates[8]. Solvent systems were (volume per volume): (*a*) chloroform–ether (8:2) for the blocked nucleoside, (*b*) chloroform–isopropanol (7:3) for the deblocked nucleoside, and (*c*) chloroform–isopropanol (5:5) for the metabolites.

Column chromatography was carried out on 0.05–0.2-mm silica gel with increasing proportions of isopropanol in chloroform.

Metabolite Isolation—The urine radioactivity could not be extracted with ether. The urine was evaporated to dryness, and the residue was extracted three times with isopropanol, yielding about 50% of the radioactivity (Extract A). The rest of the radioactivity could not be removed with organic solvents and possibly was due to conjugates (Extract B). The hydrolysis of the conjugate with β-glucuronidase and arylsulfatase[9] and subsequent isolation and identification of the fractions presented some difficulties and is in progress.

Extract A TLC showed radioactive peaks I and II in a 4:6 ratio, I being more polar than II. Extract A was concentrated to dryness and taken up in chloroform. It was loaded on a glass column (80 × 3 cm) filled with silica gel and eluted with increasing proportions of isopropanol in chloroform using a automatic fraction collector. Three hundred 20-ml fractions were collected. A radioassay was carried out with each fraction. The loaded radioactivity was recovered fully. Eluates 107–172 (7.5% isopropanol in chloroform) were pooled and concentrated to dryness, and the residue was recrystallized twice from methanol, mp 302–303°. It was designated Metabolite II.

Eluates 228–307 (20% isopropanol in chloroform) were concentrated, the solvent was removed, and the residue was recrystallized from toluene,

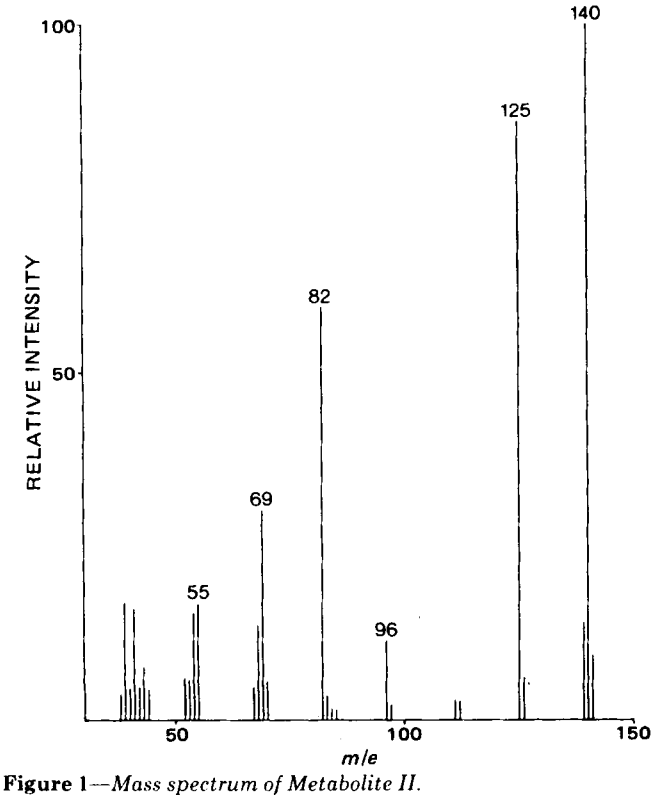

Figure 1—*Mass spectrum of Metabolite II.*

mp 152–153°. It was designated Metabolite I. By mixed melting-point determination and by comparison of the R_f values and mass spectra with an authentic VIII sample, Metabolite I could be identified as unchanged β-5-ethyl-2′-deoxyuridine (VIII).

RESULTS AND DISCUSSION

Excretion—Table I shows the elimination of urine and feces radioactivity up to 96 hr. Almost all of the radioactivity (98%) was extracted within 3 days. Moreover, the major part of the activity (92%) was excreted in the first 24 hr. Therefore, the kidneys are the main elimination organs in the excretion of β-5-ethyl-2′-deoxyuridine and its metabolites. Only a small amount of radioactivity could be found in the feces.

Distribution—In most organs and tissues as well as in the blood, <0.1% of the radioactivity could be found after 72 hr. After intravenous administration, VIII spontaneously disappeared from the blood and was completely eliminated.

Identification of Metabolite II—Metabolite II showed R_f values identical with those of 5-ethyluracil. In the mass spectrum (Fig. 1), the metastable peaks established the following fragmentation:

$$m/e\ 140 \xrightarrow{m^*\ 111.6} m/e\ 125 \xrightarrow{m^*\ 53.9} m/e\ 82$$

This pattern is characteristic of 5-ethyluracil, in which a methyl group is cleaved first. The hydrogen isocyanate (HCNO) loss in the final sequence is characteristic of uracil and barbituric acid derivatives in a retro-Diels-Alder fragmentation (23–25). For comparison, the mass spectrum of VIII was recorded (Fig. 2). The fragmentation of VIII can be formulated according to Scheme II.

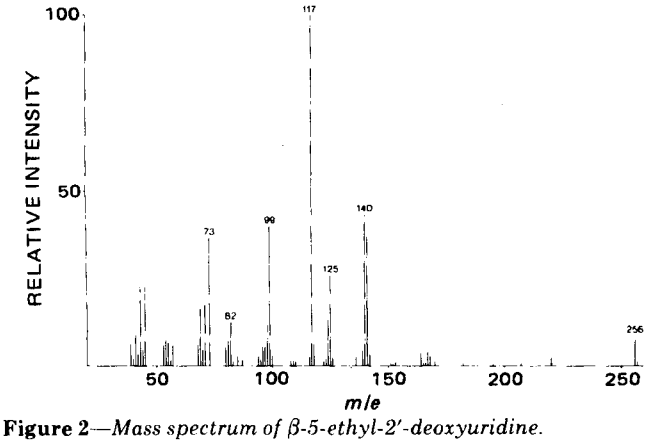

Figure 2—*Mass spectrum of β-5-ethyl-2′-deoxyuridine.*

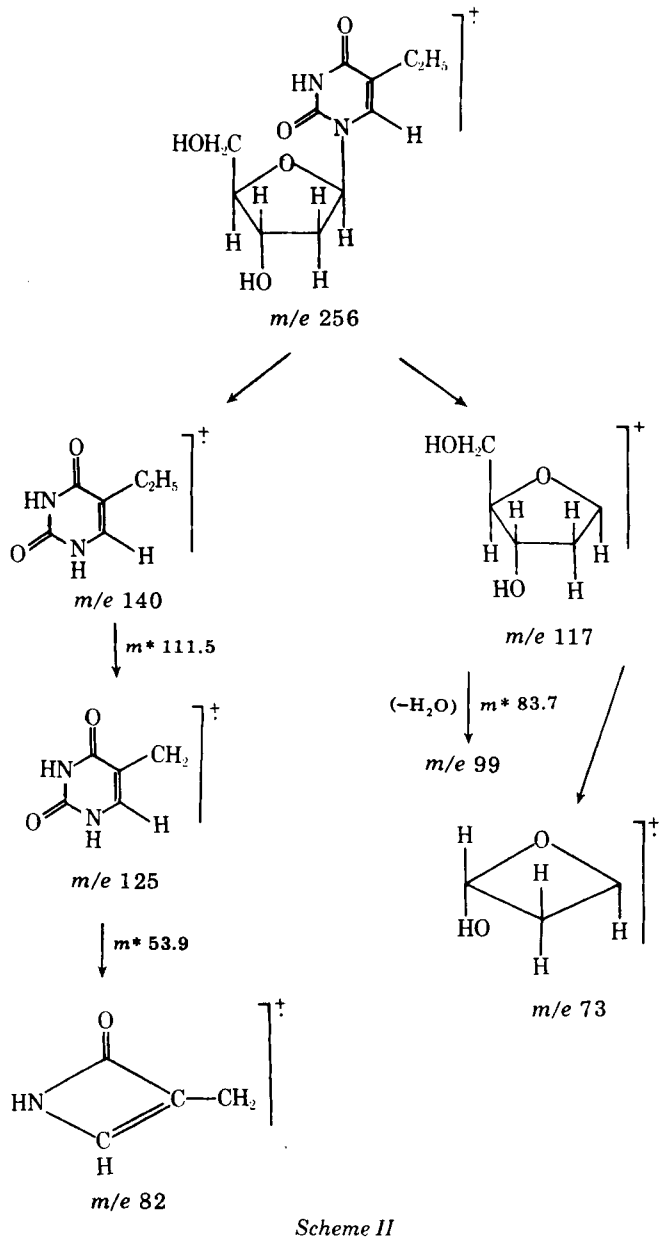

Scheme II

The ^{1}H-NMR spectrum of II in dimethyl sulfoxide-d_6 showed the presence of eight protons. Three protons appeared as a triplet at δ 1.02 ppm, and two protons appeared as a quadruplet at δ 2.2 ppm. The broad doublet (one proton) appeared at δ 7.17 ppm ($J_{6\text{-H/N}^1\text{-H}}$ = 6 Hz). The broad lower field signals at δ 10.26 and 10.66 ppm were in close agreement with the N^1- and N^3-protons of thymine (N^1-H 10.55 ppm, N^3-H 10.95 ppm, dimethyl sulfoxide-d_6), respectively.

These data establish Metabolite II as 5-ethyluracil. The metabolite structure was further confirmed by an independent synthesis; the synthetic 5-ethyluracil mass spectrum and ^{1}H-NMR data were identical with those of II.

Antimuscarinic Agents: Furan Analogs of Benzilate Esters

JAMES F. STUBBINS ˣ, PATRICIA M. HUDGINS *, and DAGMAR C. MURPHY

Received July 23, 1979, from the *Departments of Pharmaceutical Chemistry and Pharmacology, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.* Accepted for publication November 29, 1979. *Present address: Department of Pharmacology, Kirksville College of Osteopathic Medicine, Kirksville, MO 63501.

Abstract □ The methiodide and ethiodide salts of 5-(dimethylaminomethyl)- and 5-(diethylaminomethyl)-α,α-diphenylfurfuryl alcohol were prepared. These compounds may be considered as furan analogs of dialkylaminoethyl benzilate alkiodides. The pA_2 values of these compounds as antagonists of acetylcholine were determined on rat jejunum preparation. All four compounds were significantly less potent than the analogous ester antimuscarinic lachesine. The furan ring cannot be substituted for the ester moiety of typical antimuscarinics. Possible modes of binding by antagonists to the receptor proposed previously are considered that might account for this less-than-expected antimuscarinic activity.

Keyphrases □ Antimuscarinic agents—furan analogs of benzilate esters, synthesis and activity □ Furan analogs—of benzilate esters, synthesis and antimuscarinic activity □ Benzilate esters, furan analogs—synthesis and antimuscarinic activity □ Structure-activity relationships—effect of furan analogs of benzilate esters on receptor binding activity, synthesis of antimuscarinic agents

A fundamental problem in medicinal chemistry is the determination of the topography of drug receptors, *i.e.*, the nature and relative position of groups (subsites) on the receptor that interact with groups on the drug molecule. Knowledge of receptor topography usually comes from the study of the relative activities of structurally different drugs that are used as probes of the receptor surface. In general, present knowledge of topography for the autonomic drug receptors is unsatisfactory.

BACKGROUND

An example is the muscarinic cholinergic receptor. For typical potent agonists such as acetylcholine, Bovet's acetal (I), and methylfurtrethonium (II), it usually is assumed that each compound combines with the same receptor site by interaction of the positive nitrogen with an anionic subsite and with the ester group, acetal group, or a portion of the furan ring interacting with an ester binding subsite.

Several investigators noted that extension of the carbon chain in potent muscarinic agonists caused a progressive decline in agonist potency and the appearance of competitive antagonist properties (1–3). It is uncertain just how the competitive antagonists combine with the muscarinic receptor relative to the acetylcholine receptor site. In the classical view, the competitive antagonists can bind to the anionic and ester binding subsites in the same manner as acetylcholine. The hydrocarbon rings then are believed to bind to a hydrophobic area located just beyond the ester binding subsite (Fig. 1).

Several discrepancies in the known structure–activity relationships are difficult to explain according to this classical view. Many potent antagonists do not contain an ester or comparable group between the nitrogen and the hydrophobic rings. The distance between the nitrogen and the rings is too short in many cases to bind as shown in Fig. 1. Even in ester-type antagonists, many changes in structure or stereochemistry cause changes in activity that do not parallel the effect of that change on agonist activity (4).

As a possible means of explaining the discrepancies between muscarinic agonist and antagonist structure–activity relationships, an alternative mode of binding for the antagonists was proposed (5, 6). In this view, the antagonist is believed to bind so that the cationic head overlaps the anionic subsite used by acetylcholine but the remainder of the molecule does

not cover the ester binding subsite. The lipophilic and hydrogen bonding moieties in the antagonist may bind to other subsites as shown in Fig. 2.

Moran and Triggle proposed a third possible view of the antagonist binding to the receptor (7). They proposed a distinct site on the receptor for the antagonists that is near but does not overlap the acetylcholine binding site. Occupation of the antagonist site results in a perturbation of the acetylcholine binding site so that the affinity is lowered and the antagonism is still competitive.

The most potent muscarinic antagonists derived from acetylcholine generally are obtained by replacement of the acetyl group by benzilyl or similar groups containing two hydrophobic rings and a hydroxyl group attached to the α-carbon atom such as is found in lachesine (III) (8). If methylfurtrethonium and lachesine both bind to the anionic and ester binding subsites utilized by acetylcholine, in accord with the classical view, then substitution of two phenyl groups and a hydroxyl group on the terminal carbon atom of methylfurtrethonium (II) to give Type IV compounds should produce potent antagonists. In the present study, a series of such compounds with different substituents on the cationic nitrogen was prepared and examined for antimuscarinic activity.

RESULTS AND DISCUSSION

Chemistry—The desired compounds were prepared by a method used (9) to prepare the bromide salt of IV*c* as illustrated in Scheme I, except that the methyl ester rather than the ethyl ester was the starting material. Chloromethylation of methyl 2-furoate (V) with paraformaldehyde, zinc chloride, and anhydrous hydrogen chloride yielded VI. Treatment of VI with dimethylamine or diethylamine gave VII*a* or VII*b*, respectively. An attempt to prepare VII*a* directly from V by a Mannich-type reaction, utilizing conditions employing 2-methylfuran (10), was unsuccessful. The ring-inactivating effect of the ester substituent apparently is too strong in this case.

Reaction of VII*a* or VII*b* with commercially prepared phenylmagnesium bromide gave the 5-(dialkylaminomethyl)-α,α-diphenyl-2-furfuryl alcohols (VIII*a* and VIII*b*). Alkylation of VIII*a* and VIII*b* with methyl iodide and ethyl iodide produced the desired alkiodide compounds. Properties of the new compounds are presented in Table I.

Pharmacology—To evaluate the affinity of the compounds for the muscarinic receptor, pA_2 values were measured by standard techniques. The method used was described previously in detail (11). Briefly, segments of rat jejunum were placed in an isolated organ bath containing Tyrode's solution at 25° and aerated with 95% oxygen–5% carbon dioxide. Cumulative dose–response curves to acetylcholine were obtained on each segment. These curves then were repeated in the presence of three or four different concentrations of the compound being evaluated. Segments of rat jejunum from six to eight animals were used with each compound. Linear regression analysis of the data according to the method of Arunlakshana and Schild (12) yielded the pA_2 values.

Because methylfurtrethonium is a more potent agonist than acetylcholine, it seems that the furan ring must bind well to a subsite on the receptor. If methylfurtrethonium binds to the same set of subsites as does acetylcholine, it would be reasonable to expect that the addition of two phenyl rings and a hydroxyl group to the terminal methyl group would produce a potent antagonist comparable to lachesine (III). An examination of Table I shows that the affinities of IV*a*–IV*d* are much less than those of lachesine; they are ~23–90-fold less potent as antagonists on rat

jejunum. The furan ring clearly cannot be substituted for the ester group in the antagonists in the same manner as with the agonists. The classical view of antagonist binding to receptors does not explain the reason for this difference.

If antagonists bind in the manner proposed by Ariëns (5, 6) (Fig. 2), the relatively poor activity of the furan analogs could be explained. In such a case, the furan ring in the antagonists would not occupy a position on the receptor comparable to the furan ring in methylfurtrethonium. Earlier work by Stubbins and coworkers (11, 13, 14) was directed at finding evidence for the correctness of Ariëns' view. Since the ester binding subsite was not involved in binding antagonists according to this theory, it was proposed that addition of a properly placed agonist moiety on typical antagonists might increase the affinity and selectivity for the muscarinic receptor compared to antagonists lacking such a feature. A series of ester-type antagonists with moieties added to resemble acetylcholine, carbachol, or methylfurtrethonium was synthesized and compared in activity to lachesine. The binding of such compounds might be typified as shown in Fig. 3. In fact, the addition of the agonist moiety lowered the affinity in all compounds (13).

Ariëns' proposal might not apply to ester-type antagonists (which resemble acetylcholine more closely) but only to nonester antagonists. Therefore, a second series of 11 compounds having agonist moieties attached to typical nonester antagonist molecules was prepared and tested. A member of this series might bind as illustrated in Fig. 4. No consistent increase in affinity was found (14). Therefore, evidence in support of Ariëns' theory was not found, but this theory cannot be excluded.

Another possible way in which the difference could be explained is on the basis of the suggestion by Moran and Triggle (7) that methylfurtrethonium might bind to the receptor differently from acetylcholine. They suggested that the cationic head of all agonists binds to the anionic subsite but that the remainder of the molecule changes its position on the receptor depending on its relative lipophilic or hydrophilic character. According to this theory, methylfurtrethonium might bind as shown in Fig. 5. In this case, addition of two phenyl rings and a hydroxyl group to the two agonists would not be expected to affect affinity in the same way. Alternatively, the suggestion of Moran and Triggle that antagonists bind to entirely different sites than acetylcholine might account for the result.

In summary, the furan ring cannot replace the ester group in antimuscarinics without a significant loss in affinity for the receptor. The classical view of antagonist binding to the receptor is inadequate to explain this observation, but several alternative hypotheses might account for the results. More work is needed to determine the topography of the muscarinic receptor sites for agonists and antagonists.

EXPERIMENTAL

Methyl 5-Chloromethyl-2-furoate (VI)—Methyl 2-furoate (17.6 g, 140 mmoles) was dissolved in 50 ml of methylene chloride. Paraformaldehyde (6.0 g, 200 mmoles of formaldehyde) and zinc chloride (5.0 g, 37 mmoles) were added, and the mixture was warmed to 35°. Anhydrous hydrogen chloride gas was passed through the mixture until the exothermic reaction subsided. The mixture was poured into 300 ml of water. The organic layer was separated, washed twice more with water, and dried over potassium carbonate. The solvent was removed *in vacuo*, and the residual oil was distilled to give 16.2 g (66% yield) of VI, bp 86–88°/0.2 mm [lit. (15) bp 116–117°/2 mm].

Methyl 5-Dimethylaminomethyl-2-furoate (VII*a*)—Dimethylamine gas was bubbled slowly through a solution containing 15.0 g (86 mmoles) of VI in 130 ml of dry benzene for 2 hr. The mixture was allowed to stand overnight and was filtered. The solvent was evaporated from the filtrate, and the residue was distilled. Compound VII*a*, 11.5 g (73% yield), was obtained, bp 72–78°/0.2 mm.

Methyl 5-Diethylaminomethyl-2-furoate (VII*b*)—A solution of 16.2 g (93 mmoles) of VI in 35 ml of benzene was added dropwise to a stirred solution, heated to reflux, of diethylamine (17.4 g, 238 mmoles) in 30 ml of benzene. Heating was continued for 5 hr after addition was completed, and the mixture was allowed to stand at room temperature overnight. The solid by-product was removed by filtration, and the filtrate was evaporated. The residual oil was distilled to obtain 15.8 g (81% yield) of VII*b*, bp 94–98°/0.2 mm.

5 - Dimethylaminomethyl - α,α - diphenylfurfuryl Alcohol (VIII*a*)—Methyl 5-dimethylaminomethyl-2-furoate (11.1 g, 61 mmoles) dissolved in 30 ml of ether was added dropwise to a 2.07 *M* ethereal solution of phenylmagnesium bromide (120 ml, 241 mmoles) with stirring. After the addition was completed, the mixture was allowed to stand at room temperature for 1 hr and was heated to reflux for 2 hr. The mixture then was poured slowly into 350 ml of water containing 214 g of ethylenediaminetetraacetic acid and 117 g of sodium hydroxide. The ether layer was separated, and the aqueous layer was extracted three times with ether. The ethereal solutions were combined and dried over magnesium

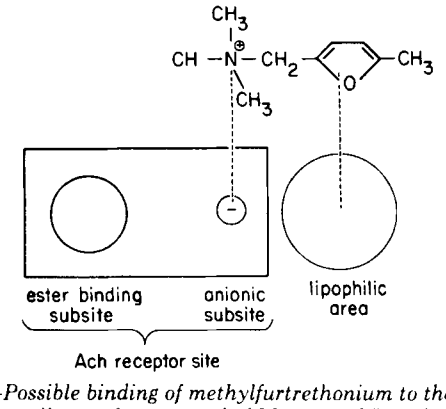

Figure 5—*Possible binding of methylfurtrethonium to the muscarinic receptor according to the proposal of Moran and Triggle (7).*

sulfate. Solvent removal left an oily residue, which crystallized upon trituration with petroleum ether. Recrystallization of the solid from benzene–petroleum ether yielded 7.6 g (41% yield) of VIII*a*, mp 122–124°.

5 - Diethylaminomethyl - α,α - diphenylfurfuryl Alcohol (VIII *b*)—Methyl 5-diethylaminomethyl-2-furoate (15.8 g, 75 mmoles) was reacted with phenylmagnesium bromide (300 mmoles) as in the preparation of VIII*a*. Compound VIII*b*, 10.0 g (40% yield), was obtained, mp 110–111.5° [lit. (9) mp 112–113°].

5-Dialkylaminomethyl-α,α-diphenylfurfuryl Alcohol Alkiodides (IV*a*–IV*d*)—Two grams of the tertiary amine (VIII*a* or VIII*b*) was dissolved in a minimum quantity of benzene. Methyl iodide or ethyl iodide (2 ml) was added, and the mixture was allowed to stand overnight. The product was removed by filtration and recrystallized from isopropanol. The physical properties of the compounds are given in Table I; NMR (dimethyl sulfoxide-d_6): 7.32–7.34 (s, 10H, phenyl), 6.83–6.88 (d, 1H, furan), 6.67–6.70 (s, 1H, OH), 6.17–6.27 (d, 1H, furan), and 4.59–4.68 (s, 2H, furfuryl methylene). In addition, the different compounds exhibited appropriate NMR peaks for the *N*-alkyl groups: 3.18–3.28 (m, NCH_2C), 2.91–3.04 (s, NCH_3), and 1.16–1.22 (t, CCH_3).

Mode of Action of Sesquiterpene Lactones as Anti-Inflammatory Agents

I. H. HALL *x, C. O. STARNES, Jr. *, K. H. LEE *, and T. G. WADDELL ‡

Received July 29, 1979, from the **Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514,* and the ‡*Department of Chemistry, University of Tennessee at Chattanooga, Chattanooga, TN 37401.* Accepted for publication December 7, 1979.

Abstract □ Sesquiterpene lactones containing an α-methylene-γ-lactone moiety were shown to be potent inhibitors of carrageenan-induced edema and chronic adjuvant-induced arthritis in rodents at 2.5 mg/kg/day. The mode of action of sesquiterpene lactones as anti-inflammatory agents appeared to be at multiple sites; for example, at 5×10^{-4} *M*, the sesquiterpene lactones effectively uncoupled the oxidative phosphorylation of human polymorphonuclear neutrophils and elevated the cyclic adenosine monophosphate levels of rat neutrophils and rat and mouse liver cells. Free and total lysosomal enzymatic activity was inhibited by these agents at 5×10^{-4} *M* in both rat and mouse liver and rat and human neutrophils. Furthermore, the structure–activity relationships for the stabilization of lysosomal membrane for rat liver cathepsin activity followed the same structural requirement necessary for anti-inflammatory activity; *i.e.*, the α-methylene-γ-lactone moiety contributed the most activity, whereas the β-unsubstituted cyclopentenone and α-epoxycyclopentanone contributed only minor activity. Human polymorphonuclear neutrophil chemotaxis was inhibited at low concentrations (*i.e.*, 5×10^{-5} and 5×10^{-6} *M*), whereas prostaglandin synthetase activity was inhibited at a higher concentration (*i.e.*, 10^{-3} *M*) by the sesquiterpene lactones.

Keyphrases □ Anti-inflammatory agents—sesquiterpene lactones, mode of action determined *in vitro* and *in vivo* □ Sesquiterpene lactones—anti-inflammatory agents, antiarthritic agents, mode of action determined in rat and human neutrophils and rat and mouse liver cells □ Oxidative phosphorylation—uncoupling effect of sesquiterpene lactones, mode of action determined in inflammation process □ Lysosomal membrane—effect of sesquiterpene lactones on membrane stability, hydrolytic enzyme release, mode of action in inflammation process □ Cyclic adenosine monophosphate—effect of sesquiterpene lactones on *in vitro* levels, role in inflammation process □ Structure–activity relationships—effect of sesquiterpene lactones on inflammation process, several modes of action determined *in vitro* and *in vivo*

The anti-inflammatory activity of sesquiterpene lactones in rodents was reported previously (1). An α-methylene-γ-lactone moiety within the structure of the pseudoguaianolide and germacranolide derivatives was required for activity against edema-induced carrageenan inflammation. Saturation of the 11,13-double bond of the methylene group of the lactone resulted in a loss of activity (1).

In the chronic adjuvant-induced arthritic screen, compounds containing the α-methylene-γ-lactone, the β-unsubstituted cyclopentenone, and α-epoxycyclopentanone afforded significant inhibitory activity at 2.5 mg/kg/day (1). In addition, these derivatives also suppressed the writhing reflex, induced pleurisy, delayed hypersensitivity, and passive cutaneous anaphylaxis and were mild immunostimulants of immunoglobulins (1). sesquiterpene lactones on metabolic events associated with the inflammation process are reported here.

EXPERIMENTAL

Test Compounds—Twenty sesquiterpene lactones and related compounds were chosen. Some of the compounds were natural products isolated from plant species by literature techniques (2): helenalin (I) from *Balduina angustifolia* (3); tenulin (II) (4) and aromaticin (IV) (4, 5) from *Helenium amarum;* eupaformosanin (XIV) from *Eupatorium formosanum* (6); eupahyssopin (XV) from *E. hyssopifolium* (7); molephantinin (XVI) (8), molephantin (XVII) (9), and phantomolin (XIX) (10) from *Elephantopus mollis;* deoxyelephantopin (XVIII) from *El. carolinianus* (11); and eupatolide (XX) from *E. formosanum* (12).

2,3-Dihydrohelenalin (V), 2,3-epoxyhelenalin (VIII), and 2,3,11,13-tetrahydrohelenalin (XI) were modified chemically from helenalin (13). 2,3-Dihydrotenulin (VI), 2,3-epoxytenulin (IX), isotenulin (III), 2,3-dihydroisotenulin (VII), and 2,3-epoxyisotenulin (X) were prepared by a literature method (14), as was α-methylene-γ-lactone (XII) (15). The 2-cyclopentenone[1] and indomethacin[2] were purchased commercially.

Anti-Inflammatory Screen—Sprague–Dawley male rats (~160 g) were administered test compounds at 2.5 mg/kg ip in 0.05% polysorbate 80–water 3 hr and 30 min prior to injection of 0.2 ml of 1% carrageenan in 0.9% saline into the plantar surface of the right hindfoot. Isotonic saline was injected into the left hindfoot, which served as a baseline. After 3 hr, both feet were excised at the tibiotarsal (ankle) joint according to a modified method (16, 17), resulting in an average net increase of 0.655 g for the control animals.

Antiarthritic Screen—Male Sprague–Dawley rats (~160 g) were injected at the base of the tail with 0.2 ml of light mineral oil containing 1 mg of dried *Mycobacterium butyricum* and 0.4 mg of digitonin. The test drugs were administered on Days 3–20 at 2.5 mg/kg/day ip. Animals were sacrificed on Day 21, and the feet were excised and weighed (18). The control animals achieved an average net weight increase of 0.830 g.

Cell Preparation—Metabolic studies were conducted on CF_1 male mouse (~30 g) and Sprague–Dawley male rat (~180 g) liver homogenates (10%) in 0.25 *M* sucrose and 0.001 *M* ethylenediaminetetraacetic acid at pH 7.2. Polymorphonuclear neutrophils were collected from the peripheral blood of healthy human males (25–28 years) and separated by Ficol–Hypaque density gradient centrifugation by the technique of English and Anderson (19). The neutrophils were aspirated from the lower density gradient level; after water lysis of the red blood cells, the neutrophils constituted 99.9% of the cells.

Polymorphonuclear neutrophils were collected from the peritoneal cavity of male Sprague–Dawley rats (~280 g) ~4 hr after injection of 35 ml of 0.5% oyster glycogen in isotonic saline. The neutrophils were centrifuged at 800×*g* for 20 min, washed, and resuspended in pH 7.4 minimum essential medium and 10% fetal calf serum (20). The neutrophil concentration was ~80% of the cell content.

Oxidative Phosphorylation Studies—Basal and adenosine diphosphate-stimulated respiration of the 10% liver homogenates of rats and mice or 10^6 human polymorphonuclear neutrophils was measured using succinate or α-ketoglutarate as the substrate (21). The reaction vessel contained sucrose (55 μmoles), potassium chloride (22 μmoles), dibasic potassium phosphate (22 μmoles), sodium succinate (90 μmoles) or α-ketoglutarate (60 μmoles), and the test compounds at 5×10^{-4} *M* in 0.05% polysorbate 80–water in a total volume of 1.8 ml.

Oxygen consumption was measured using a Clark electrode connected to an oxygraph. After the basal metabolism (state 4) level was obtained, 0.257 μmole of adenosine diphosphate was added to obtain the adenosine diphosphate-stimulated respiration rate (state 3). The respiration rate was calculated in microliters of oxygen consumed per hour per milligram of wet weight of rat or mouse liver homogenates or 10^7 human polymorphonuclear neutrophils.

In vivo oxidative phosphorylation studies were conducted on mice and rats treated with helanalin (I) at 6 mg/kg or tenulin (II), eupahyssopin (XV), and deoxyelephantopin (XVIII) at 12.5 mg/kg for 3 days. Animals were sacrificed on Day 4, and liver homogenates were prepared for the respiration studies.

Lysosomal Hydrolytic Enzymatic Activities—Free and total acid phosphatase activities were studied using 0.1 *M* β-glycerol phosphate in pH 5.0, 0.1 *M* acetate buffer on CF_1 mouse liver homogenates for 20 min or rat polymorphonuclear neutrophils for 60 min (22). The test drugs were incubated *in vitro* at 5×10^{-4} *M* in 1% carboxymethylcellulose. The total enzymatic activity was obtained by treating the liver homogenates or neutrophils with 0.02% alkylphenoxypolyethoxyethanol 100 to release the bound hydrolytic enzymes from the lysosomal membrane. The reaction was terminated with 10% trichloroacetic acid, and the mixture was centrifuged.

Inorganic phosphate was determined by the method of Chen *et al.* (23). Free, total, and percent released acid phosphatase activities were calculated after correcting for the blank values. Free and total cathepsin activities were determined in an analogous manner on mouse and rat liver homogenates and on rat polymorphonuclear neutrophils with 2% azocasein as the substrate in pH 5.0, 0.1 *M* acetate buffer (24). The supernate was assayed for acid-soluble peptide fragments at 366 nm. Free, total, and percent released cathepsin activities were calculated after correcting for the blank values.

The effects of the drugs on lysosomal membrane stabilization were studied on rat liver homogenates by incubating the test drugs (5×10^{-4} *M*) for 20 min at 37° prior to measuring the enzymatic catalytic activity (25). Free and total aryl sulfatase activities were determined on mouse liver homogenates with 0.72 μmole of *p*-nitrocatechol sulfate as the substrate in pH 5.8, 0.2 *M* acetate buffer. The reaction was conducted for 20 min at 37° and terminated with 4 *N* NaOH. The formation of 4-nitrocatechol in the supernate was measured at 510 nm spectrophotometrically (25).

Cyclic Adenosine Monophosphate Levels—Isolated rat polymorphonuclear neutrophils were incubated with the test drugs at 5×10^{-4} *M* for 1 hr at 37° in pH 7.4 minimum essential medium. The reaction was stopped with 6% trichloroacetic acid, and the cyclic adenosine monophosphate levels were determined by radioimmunoassay[3] using ^{125}I-2-*O*-succinyl cyclic adenosine monophosphate tyrosine methyl ester and cyclic adenosine monophosphate antibody (26). Results were calculated in picomoles of cyclic adenosine monophosphate per 10^7 polymorphonuclear neutrophils.

Cyclic adenosine monophosphate levels also were determined after treating the mice or rats *in vivo* with helenalin (I) at 6 mg/kg or tenulin (II), eupahyssopin (XV), and deoxyelephantopin (XVIII) at 12.5 mg/kg for 3 days. The animals were sacrificed on the 4th day, and a 10% liver homogenate was prepared for the radioimmunoassay. Results were calculated as picomoles per milligram of wet liver.

Prostaglandin Synthetase Activity—The incubation medium of Tomlinson *et al.* (27) was used to determine the [^{3}H]prostaglandin for-

[1] Aldrich.

[3] Becton Dickinson.

mation from [^{3}H](N)-arachidonic acid (86.2 Ci/mmole) and 10 mg of purified commercial prostaglandin synthetase from bovine seminal vesicles[4]. After 1 hr at 37°, the reaction was terminated with 1 *N* HCl, and the mixture was extracted with ether and evaporated. The residue was dissolved in ethyl acetate and spotted on silica gel TLC plates, which were eluted with chloroform–methanol–water–acetic acid (90:8:1:0.8) (28). The plates were dried and developed in iodine vapor; with the use of prostaglandin standards, the appropriate areas were scraped and counted for tritium content. Indomethacin was used as an internal standard at 10^{-4} and 10^{-6} *M*. Helenalin (I) and tenulin (II) were tested at 10^{-3} and 10^{-4} *M*.

Polymorphonuclear Neutrophil Chemotaxis—Isolated human polymorphonuclear neutrophils were utilized to measure the inhibition of chemotaxis and migration to *Escherichia coli* bacterial culture filtrate, as the chemotactant agent, by the method of Nelson *et al.* (29) on agarose tissue culture plates. The test drugs at 10^{-4}, 5×10^{-5}, and 10^{-6} *M* were incubated for 30 min at 37° with the neutrophils in pH 7.4 minimum essential medium prior to the assay. The plates were incubated in a carbon dioxide incubator at 37° for 2.5 hr and fixed in methanol overnight. After staining with Wright's stain, the migration from the wells was measured in micrometers. The migration for the control neutrophils was 991 ± 52 μm. Indomethacin was used as an internal standard at 10^{-3} *M*.

RESULTS

The sesquiterpene lactone analogs containing an α-methylene-γ-lactone moiety (I, IV, and V) possessed potent anti-inflammatory activity in rodents at a relatively low dose of 2.5 mg/kg (Table I); II, III, VI, VII, and XI were inactive. Administration of helenalin (I) resulted in the best inhibitory activity of the sesquiterpene lactones both in the carrageenan-induced screen (75%) and the chronic adjuvant-induced arthritic screen (77%). Compounds V, VIII, IX, XV, XVIII, and XIX caused 43–57% inhibition of the carrageenan-induced edema. In the chronic arthritic screen, treatment with the simple α-methylene-γ-lactone (XII) resulted in 83% inhibition. Compounds IX, X, XV, and XVIII resulted in 63–69% inhibition of induced arthritis; II, III, VIII, and indomethacin caused 45–53% inhibition of arthritis.

Representative compounds were selected for the biochemical studies. Helenalin (I) and tenulin (II) were selected from the pseudoguaianolides,

and eupahyssopin (XV) and deoxyelephantopin (XVIII) were selected from the germacranolides. The *in vitro* mouse and rat liver oxidative phosphorylation studies demonstrated that these compounds at 5×10^{-4} *M* only marginally altered the basal respiration (state 4) and the adenosine monophosphate-stimulated respiration (state 3), utilizing as the substrates either succinate, a flavin adenine dinucleotide-linked dehydrogenase, or α-ketoglutarate, a nicotinic adenine dinucleotide-linked dehydrogenase (Table II).

In vivo administration of the sesquiterpene lactones for 3 days significantly increased rat and mouse basal respiration with succinate; although not significant, the trend followed the same pattern with α-ketoglutarate. Adenosine monophosphate-stimulated respiration was reduced drastically in mouse liver with I using succinate (Table III). Human polymorphonuclear neutrophil basal respiration (Table IV) was increased significantly with I, II, XV, and XVIII at 5×10^{-4} *M* using either succinate or α-ketoglutarate as the substrate, whereas the adenosine diphosphate-stimulated respiration was reduced significantly with both succinate and α-ketoglutarate as the substrate. These studies indicate that the respiration of human neutrophils was uncoupled by these four sesquiterpene lactones.

Liver hydrolytic enzyme studies *in vitro* showed that the sesquiterpene lactones were potent inhibitors of lysosomal enzyme activities (Table V). Helenalin (I) and tenulin (II) suppressed mouse liver free acid phosphatase, cathepsin, and aryl sulfatase activities at pH 5.0 and 5×10^{-4} *M*. The total enzymatic activities were suppressed by I for acid phosphatase and cathepsin, whereas the total cathepsin activity was inhibited by II. Both I and II reduced the percent of cathepsin and aryl sulfatase enzymes released into the cytoplasm.

The structure–activity study of sesquiterpene lactones *in vitro* on rat liver free cathepsin and the percent of cathepsin released demonstrated that all of the sesquiterpene lactones tested were active at 5×10^{-4} *M* (Table VI). Helenalin caused a maximum inhibition of 92%, with IV, IX, X, XII, and XIV–XIX resulting in 64–88% inhibition. The internal standard, indomethacin, resulted in 33% inhibition of free cathepsin activity at 5×10^{-4} *M*. Masking of the α-methylene-γ-lactone (compare I to II) or alteration from the *cis*- to the *trans*-fused ring (compare I to IV) also resulted in loss of activity. The 2,3-epoxy derivatives (VIII–X) improved the ability to inhibit the free cathepsin activity, with the exception of the helenalin epoxy derivative (VIII). Loss or acetylation of the 6-hydroxyl group of the cycloheptane ring along with the *trans*-fused orientation of the α-methylene-γ-lactone moiety (III and IV) resulted in an even greater loss of activity. The effects of the sesquiterpene lactones on the precent release of the cathepsin enzyme from the bound lysosomal membrane demonstrated that the sesquiterpene lactones probably stabilized the membrane and reduced the release of the enzyme.

Helenalin (I) reduced the percent of lysosomal enzyme release from 24 to 2%; the reduction for XV was to 3%, and the reduction for IX, X, XIV, and XVI–XIX was to 6–8%. Compounds that were not active in the anti-inflammatory screen had minimal effects on reducing the lysosomal enzyme release (*e.g.*, II, III, VI, VII, XI, and XIII were essentially inactive). Compounds that demonstrated potent anti-inflammatory activity also significantly reduced the lysosomal enzyme release (*e.g.*, I, IV, V, VIII–X, XII, and XIV–XIX). The lysosomal enzymatic activities of rat polymorphonuclear neutrophils also were reduced by sesquiterpene lactones at 5×10^{-4} *M* (Table VII). Helenalin (I) demonstrated 93% inhibition of free acid phosphatase activity, 94% inhibition of total acid phosphatase activity, 84% inhibition of free cathepsin activity, and 73% inhibition of total cathepsin activity. Compounds III, IV, IX, X, and XIII–XVI caused 70–87% inhibition of the free acid phosphatase activity, whereas IV, VIII–X, XII, and XIV–XVIII caused 54–88% inhibition of the total acid phosphatase activity. Free cathepsin activity was suppressed 55–67% by II, IV, V, VIII, XII, XVI, XVII, XIX, and XX. Total cathepsin activity was inhibited 51–63% by IV, VIII, XIII, and XVII.

The inhibition of lysosomal enzymatic activities of rat polymorphonuclear neutrophils correlated more with the ability to inhibit chronic arthritis than the anti-inflammatory screen. Masking of the α-methylene-γ-lactone (compare I to II), loss of the free 6-hydroxyl group, or alteration from a *cis*- to a *trans*-fusion of the α-methylene-γ-lactone moiety to the cycloheptane backbone (compare I to III and IV) again reduced the ability to inhibit the free and total lysosomal enzymatic activity.

In vivo treatment with helenalin (I) at 6 mg/kg/day for 3 days resulted in a 61 and a 51% increase in mouse liver and in rat liver cyclic nucleotide levels, respectively. Tenulin (II) at 12.5 mg/kg had little effect in mouse

[a] Expressed as mean ± *SD*, $n = 6$. [b] $p \leq 0.001$. [c] $p \leq 0.010$. [d] 0.272 μg of phosphate released/hr/10^7 cells. [e] 0.347 μg of phosphate released/hr/10^7 cells. [f] 0.147 mg of protein released/hr/10^7 cells. [g] 0.183 mg of protein released/hr/10^7 cells.

or rat liver. Eupahyssopin (XV) and deoxyelephantopin (XVIII) followed essentially the same pattern as I but with a slightly lower magnitude (Table VIII). The cyclic adenosine monophosphate levels of rat polymorphonuclear neutrophils were elevated 158% by I (Table IX). Compounds II, IV, V, VIII, IX, and XIII elevated the cyclic nucleotide level significantly. The isotenulin series (III, VII, and X) and the germacranolides (XIV–XX) in general lowered the cyclic nucleotide levels in neutrophils.

Sesquiterpene lactones containing an α-methylene-γ-lactone or an α-epoxycyclopentanone ring successfully inhibited polymorphonuclear neutrophil chemotaxic migration (Table X). Compounds I, IV, VIII–X, XV, XVIII, and XX caused 100% inhibition or paralysis of neutrophil migration at 5×10^{-5} *M*. At a lower concentration—*viz.*, 10^{-6} *M*, I, X, XVIII, and, surprisingly, XX caused significant inhibition.

In vitro prostaglandin synthetase activity (Table XI) was suppressed 29% by I and 8% by II at 10^{-3} *M*. These two sesquiterpene lactones had no inhibitory effects at $^{-4}$ *M*. Indomethacin caused 38 and 24% inhibition at 10^{-4} and 10^{-6} *M*, respectively.

DISCUSSION

The pseudoguaianolide (I, IV, and V) and germacranolide (XIV–XX) sesquiterpene lactones at 2.5 mg/kg significantly suppressed induced inflammation in rats. In the carrageenan-induced edema screen, the α-methylene-γ-lactone moiety plays a major role in affording anti-inflammatory activity, demonstrated by these sesquiterpene lactones. In addition, the α-epoxycyclopentanone system contributed to the anti-inflammatory activity (VIII–X) of these compounds against the induced edema. In the chronic adjuvant-induced arthritic screen, not only did the α-methylene-γ-lactone moiety and the α-epoxycyclopentanone system contribute significantly to the antiarthritic activity, but the β-unsubstituted cyclopentenone ring (II and III) also instilled antiarthritic activity for the sesquiterpene lactones.

Sesquiterpene lactones affected a number of biochemical parameters that influence the inflammation process. The synthesis of the chemical mediator, prostaglandin, was suppressed in the presence of sesquiterpene lactones at 10^{-3} *M* compared to indomethacin at 10^{-4} *M* in this isolated enzyme system. Dithiothreitol and mercaptoethanol, thiol-blocking reagents, are known to inhibit prostaglandin synthesis from arachidonic acid (30). Sesquiterpene lactones have been shown to inhibit sulfhydryl-bearing enzymes, supposedly through a Michael addition of the cyclopentenone ring and the α-methylene-γ-lactone moiety (4). It was noted that saturation of the 2,3-double bond of the cyclopentenone and the 11,13-double bond of the α-methylene-γ-lactone of helenalin resulted in a loss of anti-inflammatory activity (1).

Whereas it was difficult to demonstrate the effects of sesquiterpene lactones on mouse and rat liver oxidative phosphorylation processes, these agents definitely uncoupled the *in vitro* oxidative phosphorylation respiration of polymorphonuclear neutrophils of humans. The concentration (5×10^{-4} *M*) of sesquiterpene lactones necessary to cause uncoupling compared favorably with standard anti-inflammatory agents, *e.g.*, salicylates at 10^{-3} *M* (31) and phenylbutazone at 10^{-4} *M* (32). Suppression of oxidative phosphorylation processes of neutrophils may be associated with the lack of an efficient energy-generating system necessary for leukocyte chemotaxis, microtubular contraction, and migration to the inflammation site. A relatively low concentration of sesquiterpene lactones, *i.e.*, 5×10^{-5} and 10^{-6} *M*, was required to inhibit neutrophil chemotaxis and migration to the chemoattractant *E. coli* bacterial culture filtrate. Bryant *et al.* (33) demonstrated that sodium arsenite, which uncoupled oxidative phosphorylation at 2.5×10^{-4} *M*, also inhibited neutrophil migration. Likewise, the uncouplers iodoacetamide and dinitrophenol blocked chemotaxis partially at 10^{-4} *M* (34).

Standard anti-inflammatory drugs have been shown to inhibit liver

Table VIII—Cyclic Adenosine Monophosphate Levels [a] of Rodent Liver after 3 Days of Treatment with Sesquiterpene Lactones

lysosomal aryl sulfatase enzymatic activity and lysosomal rupture; *e.g.*, at 10^{-3} *M*, indomethacin, acetyl salicylate, and phenylbutazone caused 18, 13, and 42% inhibition, respectively (25). The sesquiterpene lactones, helenalin and tenulin, at 5×10^{-4} *M* suppressed liver lysosomal aryl sulfatase enzymatic activity and rupture by 75%. Higher magnitudes of inhibition were observed with helenalin and tenulin on mouse liver cathepsin activity and rupture of lysosomes. Structure–activity studies on rat liver free cathepsin activity correlated positively with the anti-inflammatory activity of the sesquiterpene lactones. Furthermore, cathepsin D enzymatic activity has been implicated in the inflammation process as causing the release of vasoamine peptides and chemotactic factors, which are chemical mediators that can attract phagocytic cells to the site of inflammation (35). Rupture of the lysosomal membrane to release hydrolytic enzymes, *i.e.*, cathepsin, appeared to be retarded drastically by the sesquiterpene lactones. Again, there was a strong positive correlation between lysosomal membrane stabilization and the anti-inflammatory activity of the sesquiterpene lactones.

A similar pattern was observed with the incubation of sesquiterpene lactones with polymorphonuclear neutrophils. Free and total acid phosphatase and cathepsin activities were inhibited significantly following generally the same structural requirements for inhibition. The neutrophils (leukocytes) supposedly contain high concentrations of hydrolytic enzymes that are released at the sites of inflammation, causing the spread of infection and digestion of tissue cellular components. Inhibition of lysosomal release and catalytic activity will reduce the spread of inflammation and tissue damage. Both acid phosphatase (36) and crude cathepsin (37) enzymatic activities can be blocked by thiol-blocking reagents.

Elevated levels of cyclic adenosine monophosphate have been correlated with the stabilization of lysosomal membranes; *e.g.*, 10^{-6} *M* cyclic adenosine monophosphate inhibited the release of β-glucuronidase from human neutrophils (38). High cyclic adenosine monophosphate levels inhibited rabbit (39) and human (40) polymorphonuclear neutrophil chemotaxis and migration. In addition, elevated levels of cyclic adenosine monophosphate or its derivatives were associated with the blockage of allergen-mediated immunoglobulin E hypersensitivity, T-cell-mediated cytolysis, formation of migration inhibitory factor, activation of phagocytic cell function, and release of histamine, slow-reacting substances, and prostaglandins (38, 41–43). Furthermore, induced chronic arthritis was related to decreased cyclic adenosine monophosphate levels, increased lysosomal enzymatic activity, and release in the paw (44).

Helenalin, the most potent sesquiterpene lactone anti-inflammatory agent, as well as eupahyssopin and deoxyelephantopin, was observed to elevate the cyclic adenosine monophosphate level of mouse and rat liver significantly after *in vivo* administration whereas tenulin had little effect. The pseudoguaianolide sesquiterpene lactones, except the isotenulin series, significantly elevated the cyclic adenosine monophosphate levels of polymorphonuclear neutrophils whereas the germacranolide sesquiterpene lactones either had no effect or the opposite effect.

The mode of action of sesquiterpene lactones as anti-inflammatory agents appeared to be similar to commercially available agents. These agents were shown to be potent inhibitors of neutrophil migration, lysosomal rupture and enzymatic activity, and prostaglandin synthesis, which was linked to elevated cyclic adenosine monophosphate levels.

Aspirin—A National Survey I: Semiautomated Determination of Aspirin in Bulk and Tablet Formulations and Salicylic Acid in Tablet Formulations

WILLIAM E. JUHL ˣ **and ROSS D. KIRCHHOEFER**

Received October 29, 1979, from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication December 14, 1979.

Abstract □ A semiautomated assay to determine aspirin (acetylsalicylic acid) in aspirin tablets, powdered tablet composites, and pure drug substances is presented. The sample was dissolved in alcoholic buffer, diluted, and extracted with chloroform. The absorbance of the chloroform solution was read at 280 nm. Results obtained by the USP XIX and semiautomated methods are compared. The proposed method is accurate and precise, and common excipients do not interfere. Recoveries of 100% were obtained. A semiautomated assay for salicylic acid in aspirin tablets also is presented. The sample was dissolved in alcoholic buffer, ferric nitrate was added, and the absorbance of the resulting purple color was read at 532 nm. The method is suitable as a rapid screening procedure for testing the salicylic acid content of aspirin products. Results obtained by the USP XIX and semiautomated methods are compared, and the accuracy and precision of the proposed method are given. One hundred seventy tablet samples and 34 bulk drug substances were analyzed for aspirin and salicylic acid content. Approximately 5% of the tablet samples failed to meet the USP XIX limits for aspirin content, and 10% failed to meet the limits for salicylic acid.

Keyphrases □ Salicylic acid—semiautomated colorimetric determination in tablet formulations □ Analgesics—determination of aspirin and salicylic acid □ Aspirin—semiautomated UV determination in bulk and tablet formulations

A national survey of aspirin products and formulations was conducted in this laboratory. The survey consisted of the analysis of 170 samples of tablets, representing 58 formulations from 38 manufacturers, and 34 samples of bulk aspirin from 12 manufacturers. The purpose was to evaluate the quality of aspirin products on the market and the adequacy of present standards. Methodology was developed in these laboratories for the semiautomated analysis of the content uniformity test for aspirin (acetylsalicylic acid) and the limit test for salicylic acid, for the determination of impurities (1) and salicylic acid by high-pressure liquid chromatography (HPLC) (2), and for the determination of dissolution rates using semiautomated procedures (3). This paper presents the data on the determination of aspirin and salicylic acid.

Previously developed methods (4–11), including semiautomated procedures for the determination of aspirin (4, 5), were rejected for various reasons. The method of Hubin and Ganshirt (4) was not suitable because it involves the hydrolysis of aspirin itself. The method of Oydvin and Sapiraa (5) was not tried because it involves the use of chloroform, which is not a practical solvent to use in a semiautomated system with a liquid sampler. The Clayton and Thiers (6) manual spectrophotometric procedure determines up to five compounds simultaneously and thus appeared to be too complicated to automate. Other methods were eliminated because of the described problems or other practical considerations.

This paper describes a semiautomated UV method for the determination of aspirin and a semiautomated colorimetric method for the determination of salicylic acid. The aspirin method is applicable to plain and buffered tablets, powdered composites, and bulk drug substances and is free from the influence of excipient interferences. The salicylic acid procedure is based on the method of Cullen *et al.* (12) and can be used as a rapid screening assay. This method is applicable to plain, buffered, and pediatric aspirin tablets. Results are compared with the official USP XIX (13) procedures.

EXPERIMENTAL

Aspirin

Apparatus—An automatic analyzer with a sampler[1], pump[2], manifold, and timer[3] was used. The manifold was connected to a spectrophotometer[4] equipped with a quartz flowcell[5]. A 100-mv recorder[6] was connected to the spectrophotometer.

Reagents—Ethanol, 95%, was used. Chloroform, ACS grade, was washed with water and filtered through paper on the day of use. The pH 2.2 buffer solution was prepared by diluting 250.0 ml of 0.2 *M* KCl and 39.0 ml of 0.2 *M* HCl to 1 liter with water. The 0.2 *M* KCl was prepared by dissolving 14.911 g of potassium chloride in water and diluting to 1 liter with water. The 0.2 *M* HCl was prepared by diluting 17.0 ml of concentrated hydrochloric acid to 1 liter with water. The buffer–ethanol solution was prepared by mixing equal volumes of pH 2.2 buffer solution and ethanol.

Standard Preparation—About 324 mg of USP aspirin reference standard was weighed accurately and dissolved in 50.0 ml of buffer–ethanol (1:1). It was prepared fresh daily.

Sample Preparation—*324-mg Tablets*—One tablet was placed in a snap-cap vial or erlenmeyer flask. Three or four drops of water were placed on each tablet, and 50.0 ml of buffer–ethanol (1:1) was added. The solution was shaken or treated ultrasonically until the tablet disintegrated. Samples were analyzed within 6 hr of preparation. For buffered tablets, 1 ml of dilute hydrochloric acid (15:85 v/v) was added.

Powdered Composites or Bulk Drug Substances—An amount equivalent to 325 mg of aspirin was dissolved in 50.0 ml of buffer–ethanol (1:1). The sample was shaken mechanically or placed in an ultrasonic generator for ~5 min.

Semiautomated Determination—The automated system was assembled as shown in Fig. 1. The solutions were sampled at a rate of 30 cups/hr with a sample-to-wash ratio of 2:1. A sampling pattern of three standards, five samples, one standard, five samples, *etc.*, was used. Two cups of standard were placed at the end. The first two standards and the last standard were not included in the calculations. A polytetrafluoroethylene[7] strip was inserted into the BO fitting to direct the organic phase downward.

To start the system, ethanol was pumped through the chloroform pump tube for 5 min and then the tube was pumped dry. The chloroform line

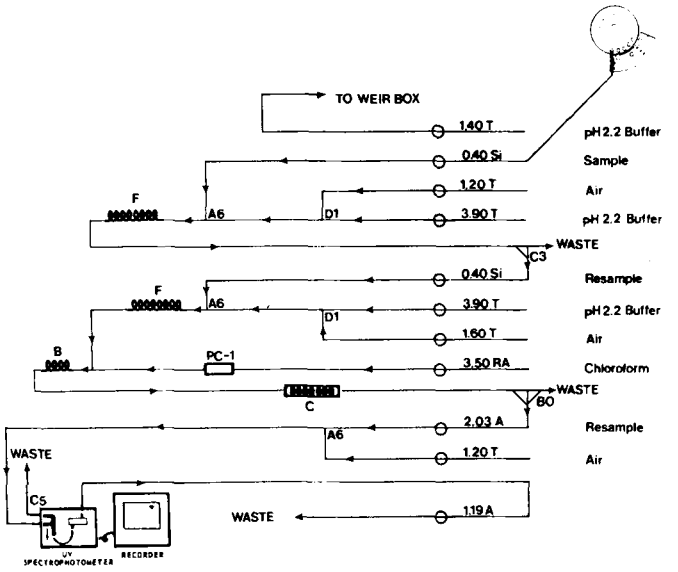

Figure 1—*Flow diagram of an automated system for aspirin. Key: Si, silicon pump tube; T, Tygon pump tube; RA, red Acidflex pump tube; A, Acidflex pump tube; F, 28-turn × 2.4-mm i.d. mixing coil; B, 28-turn × 2.4-mm i.d. mixing coil with one double end; and C, 5.5-turn settling coil.*

was placed in its solution and pumped until the solution reached the spectrophotometer cell. The pH 2.2 buffer line was placed in its solution, and the system was allowed to equilibrate. In the manifold, the sample stream was diluted twice with pH 2.2 buffer and chloroform was added. The chloroform containing the extracted drug was pumped through a flowcell, and the absorbance of the drug was read at 280 nm.

Salicylic Acid

Apparatus—The same type of automatic analyzer was connected to a spectrophotometer[8] equipped with a quartz flowcell[9] and a 100-mv recorder[6].

Reagents—Ethanol, 95%, was used. The pH 2.2 buffer solution was prepared as described. The ferric nitrate hexahydrate was prepared by adding 10 g of ferric nitrate and 5.0 ml of concentrated nitric acid to a 1-liter volumetric flask and diluting to volume with water.

Standard Preparation—*Plain Tablets*—About 20 mg of salicylic acid standard was weighed accurately and dissolved in 100 ml of pH 2.2 buffer–ethanol (3:1).

Table I—Comparison of Results (Percent of Label Claim) Obtained by USP XIX and Automated Procedures for Aspirin in Aspirin Tablets

Tablet	USP[a]	Automated[b]
324 mg, plain	101.2	101.5 (1.11, 1.09)[c]
324 mg, plain	97.9	99.0 (0.69, 0.70)
324 mg, buffered	98.2	100.1 (1.36, 1.36)
324 mg, buffered	95.3	94.2 (0.75, 0.79)
81 mg, pediatric	103.3	103.3 (0.75, 0.73)
81 mg, pediatric	105.4	106.1 (1.08, 1.01)

[a] Average of four results. [b] Average of 10 results. [c] Values in parentheses are standard deviations and coefficients of variation, respectively.

Buffered Tablets—About 200 mg of salicylic acid standard was weighed accurately and dissolved in 100 ml of pH 2.2 buffer–ethanol (3:1).

Sample Preparation—*Plain Tablets*—Ten tablets were placed in an erlenmeyer flask, 25 ml of buffer–ethanol (1:1) was added, and the flask was shaken for 5 min. Then 25 ml of pH 2.2 buffer was added and mixed. The solution was filtered through paper, and the first 10 ml was discarded.

Buffered Tablets—Ten tablets were placed in an erlenmeyer flask, 10 ml of ethanol was added, and the flask was shaken for 5 min. Then 40 ml of pH 2.2 buffer was added and mixed. The solution was filtered through paper, and the first 10 ml was discarded.

Semiautomated Determination—The automated system was assembled as shown in Fig. 2. The solutions were sampled at a rate of 30 cups/hr with a sample-to-wash ratio of 2:1. A sampling pattern of three standards, two samples, and two standards was used. The first two standards and the last standard were not included in the calculation.

To start the system, the pH 2.2 buffer and ferric nitrate reagent lines were placed in their respective solutions and the pump was started. The sample stream was introduced and then segmented with air, and ferric nitrate reagent was added. The absorbance of the colored solution was read at 532 nm.

RESULTS AND DISCUSSION

Aspirin—*Validation Tests*—A series of validation tests was performed on the automated system. A linear response was obtained when four standard solutions containing 3–13 mg of aspirin/ml (corresponding to 50–200% of declaration) were tested. A standard solution containing 6.5 mg of aspirin/ml gave reproducible peaks whose heights reached ~95% of the steady state. The assay of 20 individual cups of solution exhibited a relative standard deviation of 1.0%.

Hydrolysis—There was concern that the aspirin might hydrolyze to salicylic acid in the solvent, thus giving erroneous results. A sample solution of powdered aspirin tablet composite was prepared and assayed with freshly prepared aspirin standard solutions for 6 hr, and the assay results did not change significantly.

Composite Assays—Portions of tablet composites equivalent to single tablets were analyzed by the proposed method and the USP XIX (13) method. The ground tablet composites were prepared from available commercial samples. Table I shows the close agreement between the two methods and the precision of the automated procedure.

Interferences—Separate tests were performed to check for interferences from impurities, dyes, and common excipients. Two known impurities and one postulated impurity from aspirin formulations were tested: acetylsalicylsalicylic acid, acetylsalicylic anhydride, and *O*-salicylsalicylic acid. The interferences by impurities were measured by spiking standard solutions of aspirin with weighed amounts of each im-

Table II—Comparison of Results (Percent of Label Claim) Obtained by USP XIX and Automated Procedures for Salicylic Acid in Aspirin Tablets

Tablet	USP[a]	Automated[a,b]
324 mg, plain	0.073	0.089 (0.01)
324 mg, plain	0.036	0.050 (0.01)
324 mg, buffered	0.580	0.420 (0.05)
324 mg, buffered	3.400	3.480 (0.14)
81 mg, pediatric	0.230	0.620 (0.02)
81 mg, pediatric	0.264	0.421 (0.01)

[a] Average of three or more determinations. [b] Values in parentheses are standard deviations.

[e] Buffered tablets. [f] No result obtained.

purity and comparing the response with that from the standard solution. No interferences were found.

Colorimetric interference from the dye in a manufactured tablet was checked by adding chloroform to an aqueous sample solution of the tablet in a separator and shaking manually. All of the color from the dye remained in the aqueous layer. Since the drug is extracted into the chloroform layer on the automated system, there is no interference from the dye at 280 nm.

Common excipients were examined and found not to interfere. A recovery of 99.9% was obtained with a mixture of 90% aspirin and 10% starch. A mixture of aspirin, cornstarch, lactose, and magnesium stearate gave a recovery of 99.8%. With a mixture of aspirin and magnesium carbonate, the recovery was 101.0%.

Evaporation Test—Since 50% ethanol was the sample solvent, the possibility of evaporation during the time required to analyze a number of solutions on the automated system was investigated. Twenty cups of a sample solution were loaded on the system and analyzed, and then three fresh cups were loaded just after sampling the 20th cup. There was no difference in absorbance between the first 20 cups and the last three cups. Thus, there was little evaporation over a 1-hr period.

Solvent Selection—Several solvents were tested for this method, including 95% ethanol, pH 2.2 buffer–ethanol (1:1), and buffer–ethanol (3:1). Results indicated that the buffer–ethanol (1:1) was the best solvent. If the alcohol concentration was too low, the aspirin did not completely dissolve. If the pH of the sample solution was too high, aspirin was hydrolyzed to salicylic acid.

Buffered Aspirin Preparation—With some buffered aspirin formulations, it was necessary to add acid to decrease the pH of the solution to that of the standard solution to prevent low recoveries. Usually 1 ml of dilute hydrochloric acid was sufficient.

Salicylic Acid—*Validation Tests*—A series of validation tests was performed on the automated system. A linear response was obtained when solutions of salicylic acid standard containing 0.1–0.4 and 1.0–4.0 mg/ml were tested. The absorbance of 30 individual cups of solution exhibited a relative standard deviation of 1.4%.

Composite Assays—Portions of tablet composites equivalent to 10 tablets were analyzed by the proposed method and the USP XIX method. The ground tablet composites were prepared from available commercial samples. Table II shows the results obtained by both methods and the precision of the automated procedure.

Recovery of Standards—Recovery assays, using the proposed method, were made on simulated mixtures of aspirin based on the manufacturers' formulations. Recoveries were obtained by spiking standard solutions of salicylic acid with weighed amounts of excipient materials and comparing the results with those from the standard solution. A recovery of 101.0% salicylic acid was obtained from a mixture of 90% aspirin and 10% starch. A mixture of aspirin, cornstarch, lactose, and magnesium stearate gave a recovery of 100.7% salicylic acid.

Interferences—Interference from the impurities acetylsalicylsalicylic acid, acetylsalicylic anhydride, and *O*-salicylsalicylic acid was measured by spiking standard solutions of salicylic acid with weighed amounts of each impurity and comparing the response with that of the standard solution. No impurity interference was found.

Solvent Selection—Aspirin is stable at pH 2.2 but is not very soluble in a pH 2.2 buffer; ethanol is needed to increase the solubility. When a solvent containing >25% ethanol was used, a brown hazy solution resulted when the ferric nitrate reagent was added. Cullen *et al.* (12) reported that a violet color resulted with the addition of ferric nitrate. A series of tests using different percentages of ethanol was performed to obtain the violet color. As a result, 25% ethanol in pH 2.2 buffer was selected as the solvent. Buffered tablets first were dissolved in 95% ethanol. When they were dissolved in 50% ethanol, a mass of undissolved flocculent material formed, which made it difficult to obtain sufficient filtered solution for analysis on the automated system.

Sensitivity Adjustment—Different levels of salicylic acid were found in plain as opposed to buffered tablets. Therefore, it was necessary to use a spectrophotometer with adjustable sensitivity.

Filtering—All solutions of plain or buffered tablets were filtered through paper since insoluble excipient materials present in the sample solutions interfered with the automated procedure.

Hydrolysis—Because of possible hydrolysis of the aspirin to salicylic acid in the solvent, tests were performed to check the hydrolysis. Aspirin was added to a standard salicylic acid solution, and this solution was compared to the unspiked standard solution. There was no detectable hydrolysis on the automated system. To limit the hydrolysis that would occur with time, all solutions were analyzed within 30 min after the solvent addition to the tablets.

Table III lists the results obtained from the national survey by the automated methods for aspirin and salicylic acid. It also shows comparisons with the USP methods for some samples. One hundred seventy tablet samples were analyzed for aspirin and salicylic acid content, and 34 bulk drug substances were analyzed for aspirin content. Four tablet samples failed to meet the USP XIX limits for aspirin content. Eighteen tablet samples failed to meet the USP XIX limits for salicylic acid content.

Aspirin—A National Survey II: Determination of Salicylic Acid in Bulk Aspirin and Aspirin Formulations by High-Pressure Liquid Chromatography Using a Fluorescence Detector

ROSS D. KIRCHHOEFER ˣ **and WILLIAM E. JUHL**

Received October 29, 1979, from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication December 14, 1979.

Abstract □ A quantitative high-pressure liquid chromatographic method, using a reversed-phase column coupled to a fluorescence detector, was developed to determine salicylic acid in bulk aspirin and plain and buffered aspirin tablets. The aspirin was dissolved, filtered, and injected into the chromatograph; the fluorescence of the salicylic acid was measured at ~425 nm. Excipients and impurities did not interfere, and recoveries of 100% were obtained. The method was used to analyze 84 aspirin samples.

Keyphrases □ Salicylic acid—high-pressure liquid chromatography, fluorescence detection and measurement □ Analgesics—determination of salicylic acid in aspirin by high-pressure liquid chromatography □ Aspirin—determination of salicylic acid by high-pressure liquid chromatography □ High-pressure liquid chromatography—determination of salicylic acid in aspirin

The nonaspirin salicylate test in USP XIX (1) is required for the assay of bulk aspirin and plain and buffered aspirin tablets. The official monograph test for salicylic acid in bulk aspirin is a tube comparison based on the color of the complex formed by ferric ion and salicylic acid and has only a pass–fail requirement at a limit of 0.1%. The plain tablet test, based on the method of Weber and Levine (2), uses a ferric chloride–urea trap of the salicylic acid on a diatomaceous earth[1] column with subsequent elution and measurement of salicylic acid at ~306 nm. The absorbance of the standard is only ~0.1 absorbance unit; samples with low levels of salicylic acid give very low absorbance readings, making accurate measurements difficult. The limit for salicylic acid in plain tablets is 0.3%. The buffered tablet assay, based on the method of Guttman and Salomon (3), uses the same column but can accommodate higher concentrations of salicylic acid. The limit in buffered tablets is 3.0%.

[1] Celite.

Salicylic acid and other impurities in aspirin products have been determined by high-pressure liquid chromatography (HPLC) (4, 5). As part of a national survey, the screening of many aspirin samples for salicylic acid was desired; therefore, a suitable HPLC procedure was needed. The method of Jansson and Andersson (5) was not suitable because of the *in situ* column preparation, which could cause reproducibility problems. The method of Ali (4) was chosen because of the commercial availability of the reversed-phase column and because the solvent system was compatible with aspirin solubility. However, preliminary experiments showed that salicylic acid was not easily determined at 254 nm at levels of 0.3% or lower in aspirin products.

Shane and Stillman (6) determined salicylic acid in the presence of aspirin by fluorescence in chloroform solution. The work of Shane and Miele (7) indicated that salicylic acid could be determined fluorometrically in the presence of aspirin using a pH 4 aqueous buffer solution.

An aqueous–alcoholic solvent of pH 3.4 is obtained when acetic acid is added to the HPLC mobile phase used by Ali (4). This solvent causes salicylic acid to fluoresce and is an excellent solvent for aspirin formulations.

The procedure described in this paper combines HPLC with a fluorescence detector and accurately measures the salicylic acid content of bulk, plain, and buffered aspirin formulations. The samples were prepared in methanol–water–acetic acid and injected into the chromatograph, and the salicylic acid was measured by the fluorescence detector. The results were compared with those obtained using the official USP XIX procedure and a semiautomated colorimetric procedure (8). The procedure was used successfully to analyze 34 bulk and 50 tablet aspirin formulations.

Table I—Comparison of Results (Percent of Label Claim) Obtained by USP XIX and Fluorometric HPLC Methods for Salicylic Acid in Aspirin Tablets

Tablet	USP[a]	Fluorometric HPLC[a]
324 mg, plain	0.073	0.088
324 mg, plain	0.036	0.048
324 mg, buffered	0.580	0.420
81 mg, pediatric	0.230	0.492[b]
81 mg, pediatric	0.264	0.372[b]

[a] Average of four determinations. [b] Average of five to seven determinations.

EXPERIMENTAL

Apparatus—The high-pressure liquid chromatograph[2] was coupled to a ratio fluorometer[3] equipped with a quartz flowcell[4], a primary 5 × 5-cm glass filter[5], and a secondary 5 × 5-cm glass filter[6]. A 100-mv recorder[7] was connected to the fluorometer. Standard 0.2-cm small-bore polytetrafluoroethylene[8] tubing connected the liquid chromatograph to the fluorometer.

A 250 × 4.6-mm column, packed with octadecylsilane bonded to 10-μm silica[9], was used at ambient temperature. The flow rate was 1.5 ml/min, and column pressure was ~1600 psi. The volume of the sample and standard solutions introduced on the column was 40 μl. Methanol was used to rinse the column.

Reagents—Methanol and acetic acid were ACS reagent grade. The methanol and deionized water were filtered with suction through 0.6[10]- and 0.45[11]-μm filters, respectively, before use. The mobile phase, consisting of 54% methanol and 46% water that contained 2.5% acetic acid, was degassed on the instrument at 40° for 20 min before use.

The mobile phase for the liquid chromatograph can be made independently from the sample solvent. The mobile phase should not be left on the column overnight.

The same batch of mobile phase was used to dilute the sample and standard.

Standard Salicylic Acid Solutions—*Stock Solution*—Approximately 100 mg of salicylic acid[12] of known purity was weighed accurately, transferred to a 100-ml volumetric flask, and dissolved in and diluted to volume with methanol.

Working Solution—A 1.0-ml aliquot of the stock solution was transferred to a 50-ml volumetric flask and diluted to volume with the mobile phase. This concentration should be 0.972 mg/50 ml to be equivalent to the 0.3% limit for salicylic acid in plain 324-mg tablets.

Sample Solution—*Bulk and Plain Tablets*—An amount of aspirin or ground composite equivalent to 324 mg of aspirin was transferred to a 50-ml volumetric flask, and 25–30 ml of the mobile phase was added. Then the solution was either treated ultrasonically for 30–90 sec or shaken vigorously for 60–120 sec, diluted to volume with the mobile phase, mixed, and filtered[13,14]. After the first 5 ml was discarded, the HPLC vial was filled and capped, and the solution was injected. The total time for manipulation should be <3 min.

Buffered Tablets—An amount of aspirin formulation equivalent to 324 mg of aspirin was transferred to a 100-ml volumetric flask. Fifty milliliters of the mobile phase was added, and the sample was treated as outlined under *Bulk and Plain Tablets*. Then a 10.0-ml aliquot was transferred to a 100-ml volumetric flask, diluted to volume with the mobile phase, and mixed. The solution was filtered and injected as outlined under *Bulk and Plain Tablets*. The total time for manipulation should be <4 min.

The fluorometer response and/or the standard concentration were adjusted when salicylic acid levels greatly exceeded 0.3% for plain tablets or 3.0% for buffered tablets.

[b] USP XIX modified; tablet material was mixed for 10 min with chloroform before being poured onto column. [c] Average of four or more results. [d] Results due to difference in salicylic acid content of individual tablets. Results reported are from separate prepared composites. [e] USP modified; formic acid was used to free salicylic acid from the formulation (see Ref. 11). [f] Method lacked sensitivity for proper analysis. [g] Passed USP XIX limit test of 0.1%.

Quantitation—Quantitation was achieved by measuring peak height with the 100-mv recorder. The column and detector were primed with two or three injections of a salicylic acid solution before a standard was injected. The first injection of the standard and sample was used to calculate the salicylic acid content.

RESULTS AND DISCUSSION

Salicylic acid can be determined even if the HPLC column does not separate salicylic acid and aspirin. When the HPLC column fails to separate these compounds, any interference with the salicylic acid peak height due to aspirin should be checked. This problem did not arise in this study since the C_{18} reversed-phase column separated the salicylic acid from aspirin; the retention times of aspirin and salicylic acid were 3.9 and 5.0 min, respectively.

Salicylic acid was detected at 40 pg/40-μl injection at a signal-to-noise ratio of 100:1, indicating a detection limit of ~1 pg/40 μl. This procedure is at least 100 times more sensitive than the procedures of Peng *et al.* (9) and Terweij-Groen *et al.* (10), who determined salicylic acid in plasma and deproteinized serum, respectively, by the use of HPLC with UV detectors at 237 and 235 nm.

Salicylic acid gave a linear response over almost the full range of the fluorometer, *i.e.*, 0–9 mg/50 ml. The fluorometer was normally operated on midrange with the salicylic acid peak height adjusted to ~75% full scale. Since the relative fluorescence of salicylic acid is pH dependent (6), the standard and samples must be prepared with the same mobile phase solution. The reproducibility of 11 salicylic acid standard injections calculated from the peak heights was ±1.2 fluorescence units with an average peak height of 67.3 fluorescence units. Recoveries of salicylic acid in the presence of aspirin from simulated formulations ranged from 101.0 to 105.5%. Recoveries of salicylic acid from buffered aspirin samples ranged from 100.0 to 117.0%. With some buffered tablet formulations,

it may be necessary to add a small amount of formic acid to the tablet material to release salicylic acid into the solution (3, 11).

The average result for 10 individual weighings from a prepared 325-mg commercial sample composite was 0.048% salicylic acid with a relative standard deviation of 3.9%.

Table I shows a comparison of the results of the fluorometric HPLC procedure with the official USP XIX procedure. The samples are the same as those reported in Table II in Ref. 8. The results were obtained on composites prepared from commercial tablet samples.

Table II shows a comparison of the fluorometric HPLC procedure with the USP XIX method and with a semiautomated colorimetric procedure (8) for samples collected during the aspirin survey. The results listed for each manufacturer were not determined on the same composite.

Baum and Cantwell (12) recently reported the simultaneous determination of salicylic acid in aspirin formulations by HPLC with UV detection. The Baum and Cantwell method was noted only after the HPLC procedure was being used routinely on manufactured formulations in this laboratory.

The hydrolysis of aspirin to salicylic acid (12) is well recognized. For this reason, a time limit was placed on the sample preparation in the procedure. Sample preparation times exceeding 10 min were unsatisfactory for accurate and precise recoveries.

Aspirin—A National Survey III: Determination of Impurities in Bulk Aspirin and Aspirin Formulations by High-Pressure Liquid Chromatography and Spectrophotometry

ROSS D. KIRCHHOEFER ˣ, JOHN C. REEPMEYER, and WILLIAM E. JUHL

Received October 29, 1979, from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication December 14, 1979.

Abstract □ A quantitative high-pressure liquid chromatographic method, using a reversed-phase column and an aqueous acetic acid–methanol solution as the mobile phase, was employed for the determination of *O*-acetyl-*O*-salicylsalicylic acid and *O*-salicylsalicylic acid in pharmaceutical aspirin preparations. The aspirin was dissolved, filtered, and injected into the chromatograph. The absorbance of the impurities was measured at 254 nm. Acetylsalicylic anhydride was determined by a spectrophotometric method. The aspirin was dissolved in pH 11.3 buffer and extracted with benzene. An aliquot of the benzene was evaporated, and the residue was dissolved in α-benzamidocinnamate–pyridine reagent. The acetylsalicylic anhydride was measured using the difference between the absorbance at 362 and 372 nm. Possible interference of aspirin with the procedure is discussed. Thirty-four bulk aspirin and 172 tablet formulations were examined. Results for *O*-acetyl-*O*-salicylsalicylic acid, *O*-salicylsalicylic acid, and acetylsalicylic anhydride are given.

Keyphrases □ *O*-Acetyl-*O*-salicylsalicylic acid—high-pressure liquid chromatographic determination □ Analgesics—determination of impurities in aspirin □ Aspirin—determination of impurities □ *O*-Salicylsalicylic acid—high-pressure liquid chromatographic determination □ Acetylsalicylic anhydride—spectrophotometric determination

Acetylsalicylic anhydride (I), *O*-acetyl-*O*-salicylsalicylic acid (II), and salicylic acid have been determined in aspirin tablets by high-pressure liquid chromatography (HPLC) (1–5), GLC (1, 3, 6–9), TLC (10, 11), and spectrophotometry (12, 13).

The HPLC procedure of Ali (1) was used in these laboratories to determine impurities in aspirin products. However, certain reversed-phase HPLC columns did not separate I from another impurity, which was isolated and identified as *O*-salicylsalicylic acid (III) (14). Compound I also is decomposed rapidly while in contact with the mobile phase. Therefore, this procedure was used only for the measurement of II and III. Additional impurities were found in commercial samples but have not been identified.

Bundgaard (5) postulated the presence of III and *p*-acetoxybenzoic acid in aspirin formulations based on their HPLC retention times. Bundgaard indicated that these

Aspirin—A National Survey III: Determination of Impurities in Bulk Aspirin and Aspirin Formulations by High-Pressure Liquid Chromatography and Spectrophotometry

ROSS D. KIRCHHOEFER ˣ, JOHN C. REEPMEYER, and WILLIAM E. JUHL

Received October 29, 1979, from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis, MO 63101.* Accepted for publication December 14, 1979.

Abstract □ A quantitative high-pressure liquid chromatographic method, using a reversed-phase column and an aqueous acetic acid–methanol solution as the mobile phase, was employed for the determination of *O*-acetyl-*O*-salicylsalicylic acid and *O*-salicylsalicylic acid in pharmaceutical aspirin preparations. The aspirin was dissolved, filtered, and injected into the chromatograph. The absorbance of the impurities was measured at 254 nm. Acetylsalicylic anhydride was determined by a spectrophotometric method. The aspirin was dissolved in pH 11.3 buffer and extracted with benzene. An aliquot of the benzene was evaporated, and the residue was dissolved in α-benzamidocinnamate–pyridine reagent. The acetylsalicylic anhydride was measured using the difference between the absorbance at 362 and 372 nm. Possible interference of aspirin with the procedure is discussed. Thirty-four bulk aspirin and 172 tablet formulations were examined. Results for *O*-acetyl-*O*-salicylsalicylic acid, *O*-salicylsalicylic acid, and acetylsalicylic anhydride are given.

Keyphrases □ *O*-Acetyl-*O*-salicylsalicylic acid—high-pressure liquid chromatographic determination □ Analgesics—determination of impurities in aspirin □ Aspirin—determination of impurities □ *O*-Salicylsalicylic acid—high-pressure liquid chromatographic determination □ Acetylsalicylic anhydride—spectrophotometric determination

Acetylsalicylic anhydride (I), *O*-acetyl-*O*-salicylsalicylic acid (II), and salicylic acid have been determined in aspirin tablets by high-pressure liquid chromatography (HPLC) (1–5), GLC (1, 3, 6–9), TLC (10, 11), and spectrophotometry (12, 13).

The HPLC procedure of Ali (1) was used in these laboratories to determine impurities in aspirin products. However, certain reversed-phase HPLC columns did not separate I from another impurity, which was isolated and identified as *O*-salicylsalicylic acid (III) (14). Compound I also is decomposed rapidly while in contact with the mobile phase. Therefore, this procedure was used only for the measurement of II and III. Additional impurities were found in commercial samples but have not been identified.

Bundgaard (5) postulated the presence of III and *p*-acetoxybenzoic acid in aspirin formulations based on their HPLC retention times. Bundgaard indicated that these

[f] Sample from which *O*-salicylsalicylic acid was isolated and identified.

impurities were present in salicylic acid, the starting material for aspirin. The presence of III in aspirin formulations was confirmed in this laboratory and was determined to be a commonly occurring impurity in commercial aspirin preparations. This paper presents the first procedure for the quantitation of III in aspirin and its formulations.

The spectrophotometric procedure of Bundgaard and Bundgaard (13) was modified and used to determine I in bulk aspirin and in plain and buffered tablets, and an HPLC method was used to determine II and III in these products. Thirty-four bulk aspirin products, representing 12 foreign and domestic bulk drug suppliers, and 172 tablet formulations, representing 38 manufacturers, were analyzed for I–III.

EXPERIMENTAL

Chromatographic Method—*Apparatus*—A high-pressure liquid chromatograph[1] with a single-wavelength 254-nm detector was used. The operating conditions, column, and reagents were as described previously (15), except that the flow rate was 1.5 ml/min and the amount of acetic acid was increased to 2.5%.

Standard Stock Solution—Approximately 10 mg of *O*-acetyl-*O*-salicylsalicylic acid, synthesized according to the general method of Chattaway (16), and 10 mg of *O*-salicylsalicylic acid[2] were weighed accurately, transferred to a 10-ml volumetric flask, and dissolved in and diluted to volume with methanol.

Standard Working Solution—A 1.0-ml aliquot of the stock solution was transferred to a 10-ml volumetric flask and diluted to volume with the mobile phase. This solution was transferred to the HPLC vial, the vial was capped, and 40 μl of the solution was injected.

Sample Preparation—An amount of powder equivalent to 324 mg of aspirin for tablet formulations or 700 mg for bulk aspirin was transferred to a 25-ml erlenmeyer flask. The mobile phase (10.0 ml) was added, and the solution was shaken or treated ultrasonically for 2–3 min. The solution was filtered, if needed, through a 0.6-μm filter[3]. After the first milliliter was discarded, the HPLC vial was filled and capped, and 40 μl of the solution was injected.

[a] See Table I, footnote *a*. [b] MA = Monsanto Chemical Co., St. Louis, Mo.; and XX = Graynor Chemical Co., Pine Brook, N.J., supplier Poland. [c] Trace = <0.003% of II or <0.01% of III. [d] Not detected. [e] Buffered formulation. [f] Salicylic acid content of 2.1%, limit 3.0%. [g] No valid reading was obtained.

tracted from a powdered sample containing 500 mg of aspirin. To an evaporated portion of the benzene extract was added 3 ml of α-benzamidocinnamate–pyridine reagent, producing an azlactone. The solution was read in the UV region after 25 and 60 min.

The method of calculation was changed from the given procedure by subtracting the absorbance of the minimum at 372 nm from the absorbance of the maximum at 362 nm and using this net absorbance. The standard was synthesized according to Bundgaard and Bundgaard (13).

RESULTS AND DISCUSSION

Compounds II and III were stable in the chromatographic solvents and were determined by this procedure; I was unstable in the mobile phase and decomposed rapidly during analysis. Therefore, I could not be determined by HPLC. While attempting to measure I, it was found that some C_{18} reversed-phase HPLC columns would not separate I from III. However, the column (15) used in the present work separated I and III. Compound III has not previously been identified in aspirin formulations, but its presence was postulated by Bundgaard (5) based on its retention time on silica gel HPLC. Compound III has been identified in these laboratories by IR, UV, and mass spectrometry and TLC after isolation (14).

The original spectrophotometric procedure (13) gave results that indicated that aspirin did not interfere with the determination of I. However, aspirin itself will react with the reagent but at a much slower rate than I. When as little as 0.044% (0.22 mg) aspirin was extracted with I, it contributed to an artificially high value of I by 0.004% (additive with the percentage of I present) after a 30-min reaction period and by 0.008% after 60 min. During the survey, results for I averaged ~0.015%.

Aspirin interference in this analysis can be determined by following the reaction over a period of time. Absorbance readings were taken at 25 and 60 min. A continual increase in absorbance indicated the presence of aspirin, and the quantitation was considered invalid. Thorough shaking of the pH 11.3 buffer solution with benzene, followed by centrifugation, usually removed the aspirin to permit determination of I.

Table I lists the amounts of I–III found in a national survey of aspirin formulations, and Table II lists the amounts found in bulk aspirin. The levels of I–III listed for bulk aspirin from the same bulk drug suppliers sometimes were different, presumably because they were from different lots.

Linearity for II and III was established at levels down to 0.003 and 0.01% (0.01 and 0.03 mg/10 ml) of declared aspirin, respectively. A recovery (from a synthetic starch–lactose formulation) of 100% for II and III was obtained at the 0.03% level relative to aspirin.

Table III shows the only correlations available to match the same lot of bulk aspirin to the finished tablets. Bundgaard (5) stated that the levels of I and II found in tablets originate from the starting bulk aspirin. In general, the level of II was lower in bulk aspirin than in tablets manufactured from that bulk, indicating that aspirin is converted to II during or after tablet manufacture (Table III).

Synthesis and Anticancer Activity of Asparagine Analogs

MICHAEL J. MURPHY and JAMES F. STUBBINS ˣ

Received August 31, 1979, from the *Department of Pharmaceutical Chemistry, School of Pharmacy, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.* Accepted for publication December 12, 1979.

Abstract □ A series of 11 asparagines substituted on N^4 was prepared and evaluated for their ability to inhibit the growth of L5178Y leukemia cell cultures. These cells require an exogenous source of L-asparagine and should be sensitive to an asparagine antimetabolite. The compounds were prepared by reaction of phthalylaspartic anhydride with a primary or secondary amine, followed by removal of the phthalyl group with hydrazine. One compound, *N,N*-dibenzylasparagine, showed significant activity. Additional study of asparagine derivatives bearing large, lipophilic groups at N^4 is warranted.

Keyphrases □ Asparagine analogs—synthesis and anticancer activity □ Anticancer activity—asparagine analogs □ Antileukemic activity—asparagine analogs

There has been great interest in the enzyme L-asparaginase (L-asparagine amidohydrolase, E.C. 3.5.1.1) since it was shown (1) to be the active antitumor agent found in guinea pig serum. Several tumor cell types are sensitive to L-asparaginase treatment, including some human leukemias (2–4). Dramatic remissions were obtained with sensitive tumors, but resistance to the L-asparaginase treatment developed rapidly (4).

BACKGROUND

L-Asparaginase acts on sensitive tumors by removing the required exogenous supply of L-asparagine (I), whereas most normal cells and resistant tumors can synthesize L-asparagine (5). Large doses of injected L-asparaginase rapidly reduced L-asparagine below detectable levels in the plasma, but extracellular fluid concentrations were reduced by only 70% (6). Thus, leukemic cells in the bloodstream generally are killed, but some inaccessible cells have a good chance of survival on the remaining tissue levels of L-asparagine. Furthermore, those cells that survive long

enough produce asparagine synthetase and are resistant to subsequent treatment with L-asparaginase (7).

To circumvent the development of resistance with L-asparaginase, an asparagine analog given concomitantly might be of value if the analog would distribute throughout the body fluid and act as an antimetabolite. Cultured asparagine-requiring tumor cells have been shown (8) to possess an active uptake system that might be inhibited by such an analog without affecting normal cells. An antimetabolite also might block the incorporation of asparagine into protein. Although such an action also might affect normal cells, cells that require an exogenous metabolite generally are more susceptible to an antimetabolite. Nonrequiring cells generally can overcome a competitive block simply by increasing their synthesis of the metabolite (9).

Several simple analogs of asparagine have been reported to possess some *in vivo* antitumor activity. L-Aspartic acid β-hydrazide (II), for example, showed weak activity (10). It was shown (11) that 5-diazo-4-oxo-L-norvaline (III) has an irreversible inhibitory effect against L5178Y tumor cells requiring L-asparagine, but it also inhibits the nonrequiring cells, probably by blocking asparagine synthesis.

In the present study, a series of substituted asparagines (IV) was prepared as an initial approach to finding selective inhibitors of asparagine-requiring cancers that will be minimally toxic to normal cells.

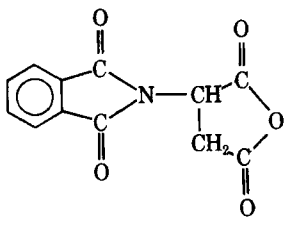
$HOOCCH(NH_2)CH_2COX$

I: X = NH_2
II: X = $NHNH_2$
III: X = CHN_2
IV: X = NR_1R_2

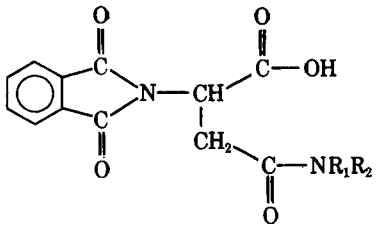
RESULTS AND DISCUSSION

Chemistry—The desired mono- and disubstituted asparagines were prepared by a modification of the method of Tanenbaum (12). L-Aspartic acid was heated with phthalic anhydride in pyridine to give the phthalyl-blocked derivative. The aspartic acid was not isolated but was converted to the N^2-phthalylaspartic anhydride (V) by treatment with acetic anhydride. The product had racemized completely, and no optical rotation was observable.

The direction of ring opening of V with ammonia was shown to be dependent on the solvent polarity (12). Only the N^2-phthalylasparagine and none of the isomeric α-amides were obtained in ether. When V was treated with a series of primary amines, the substituted N^2-phthalylasparagines (VI) were prepared in a similar fashion. The properties of the compounds are listed in Table I. The compounds displayed IR absorption bands near 1160, 1630, and 1560 cm^{-1}, indicative of the secondary amide structure, and the bands at 1780 and 1710 cm^{-1} indicated the presence of imide carbonyl groups. The NMR spectra were consistent with the assigned structure and included a doublet near 3.5 ppm and a triplet near 5.7 ppm associated with the asparagine moiety.



V



VI

Treatment of the phthalylasparagines (VI) with hydrazine removed the phthalyl group to give the N^4-substituted asparagines (IV) in reasonable yield. For preparation of the tertiary amides, the intermediate phthalylasparagines were not isolated; the crude products were treated directly with hydrazine. The properties of the compounds are given in Table II. The products all displayed NMR signals at ~4.50 and 3.30 ppm for the asparagine methine and methylene protons, respectively; otherwise, the spectra were consistent with the assigned structures. The considerably higher melting point of IV*d* compared to that reported previously (13) could not be explained.

Biology—The compounds were tested for their ability to inhibit the growth of L5178Y cells grown in McCoy's 5A medium. The desired quantity of each compound was dissolved in ethanol and diluted with sterile distilled water. A portion of this solution, 0.1 ml, was added to 5 ml of cell suspension containing ~2.5×10^5 leukemic cells. Duplicate tubes were used with a final compound concentration of 10 or 100 μg/ml and an ethanol concentration of <1%.

The tubes were placed in a carbon dioxide incubator at 36–38° for 96 hr. The contents of the tubes were counted[1] to determine inhibition of cell growth. Under the experimental conditions, L-asparaginase at a concentration of 1×10^{-3} μg/ml gave 100% inhibition.

Only one test compound had significant activity. At a concentration of 100 μg/ml, *N,N*-dibenzylasparagine (IV*k*) inhibited growth by 96%. The ID_{50} value was estimated to be 55 μg/ml. The drug concentration needed for appreciable inhibition was rather high; however, the culture medium contained 45 μg of L-asparagine/ml. Therefore, if the drug were acting as a competitive antimetabolite of L-asparagine, there was considerable metabolite with which to compete. Furthermore, the analog is racemic, and only the enantiomer with the L-configuration probably is an effective inhibitor.

Since the initiation of this study, Uren *et al.* (14) reported the testing of 19 asparagine analogs for inhibition of growth of a subline of L5178Y capable of asparagine synthesis and for inhibition of isolated asparagine synthetase. Of the 19 analogs studied, four were *N*-alkylasparagines. *N*-Methylasparagine was the most active inhibitor of asparagine synthetase and also actively inhibited L5178Y cell growth in the absence of asparagine. Inhibition was reversed completely in the presence of 1 m*M* asparagine. The *N*-ethyl, *N*-isopropyl, and *N,N*-dimethyl (IV*g*) analogs were completely inactive.

Inhibition of asparagine synthetase seems limited to analogs that have no more bulk than one methyl group on the amide nitrogen. The activity found in the present study of the dibenzyl analog (IV*k*) was not an inhibition of asparagine synthetase since these cells lack this synthetic capability. The analog must be interfering with asparagine uptake or utilization.

The only distinctive structural feature of IV*k* that might account for its activity is the dibenzyl moiety, which provides the highest lipophilicity of any of the analogs examined. Therefore, other asparagine derivatives

[a] Yields are based on the purified N^2-phthalylasparagines. [b] Lit. (15) mp 265° (crude material). [c] Lit. (16) mp 255°. [d] Lit. (13) mp 265°. [e] Yields are based on N^2-phthalylaspartic anhydride.

with large lipophilic substituents on the amide nitrogen should be prepared. By testing these additional compounds in a medium deficient in L-asparagine, it might be possible to find a prospective anticancer agent for use in combination with L-asparaginase.

EXPERIMENTAL[2]

N^2-Phthalylaspartic Anhydride (V)—L-Aspartic acid (13.3 g, 100 mmoles) and phthalic anhydride (14.8 g, 100 mmoles) were heated under reflux in 200 ml of pyridine for 2 hr. The mixture was cooled to room temperature, and the undissolved solids were removed by filtration. The filtrate was concentrated under reduced pressure to a yellow oil. Acetic anhydride (50 ml) was added to the oil with vigorous agitation, and the mixture was chilled at 0° for 2 hr. The resulting precipitate was collected, washed with anhydrous ether, and recrystallized from *p*-dioxane to give 17.1 g (70% yield) of V, mp 224–226° [lit. (12) mp 224–225°]; IR: 1875, 1210, 932 (COOCO), 1795 (C=O), 1785, and 1705 (CONRCO) cm^{-1}; NMR (dimethyl sulfoxide-d_6): 3.53 (d, 2H, CH_2), 5.77 (t, 1H, CH), and 8.00 (s, 4H, C_6H_4).

N^2-Phthalyl-*N*-substituted Asparagines (VI)—N^2-Phthalylaspartic anhydride (3.0 g, 12 mmoles) was suspended in 75 ml of anhydrous ether. Then 25 mmoles of the appropriate amine was added, and the mixture was stirred at room temperature for 24 hr. The solvent was evaporated under reduced pressure. The residue was dissolved in water, and the solution was acidified with 6 *N* HCl to pH 2. The resulting precipitate was removed by filtration. The compounds derived from primary amines were recrystallized from aqueous ethanol (Table I). For compounds derived from secondary amines, the crude product was used directly in the succeeding step.

N^4-Substituted Asparagines (IV)—Either the purified or crude preparation of N^2-phthalyl-N^4-substituted asparagine was dissolved in 25 ml of 20% aqueous hydrazine hydrate solution. The solution was stirred at room temperature for 24 hr. The reaction mixture was acidified with dilute hydrochloric acid to pH 5–6. The resulting precipitate was collected and recrystallized to give the pure product (Table II).

[2] Melting points were obtained with a Thomas-Hoover capillary apparatus and are uncorrected. Combustion analyses were performed using a Perkin-Elmer 240 elemental analyzer. IR spectra were obtained using a Perkin-Elmer model 257 grating spectrophotometer on samples prepared in a potassium bromide pellet. NMR spectra were obtained using a Hitachi Perkin-Elmer R-24 high-resolution spectrometer. Compounds were dissolved in deuterated solvents from commercial sources with tetramethylsilane as the internal standard.

Mercapto Steroids in Protection against Mercury and Lead Poisoning

ROBERT T. BLICKENSTAFF *§x, BRIAN COX ‡, EMERSON FOSTER §, LESLIE ROBERTS *, and LARRY K. STEINRAUF *‡

Received October 10, 1979, from the *Department of Biochemistry and the ‡Department of Biophysics, Indiana University School of Medicine, and the §Veterans Administration Hospital, Indianapolis, IN 46202. Accepted for publication December 18, 1979.

Abstract □ When thiocholesterol is administered as liposomes, it provides significant protection against methylmercuric chloride in mice when given in three intraperitoneal injections, 0.5 hr before and 2 and 8 hr after the methylmercuric chloride. Thiositosterol, 5α-cholestane-2β,3α-dithiol, and 5β-cholane-3β,24-dithiol also are active, but 3α-mercapto-5α-pregnan-20-one, 6β-mercapto-5α-cholestane-3β,5α-diol, 3β-mercapto-5β-cholanic acid, and adamantanethiol are ineffective under these conditions. Adamantanethiol is somewhat effective when administered in soybean oil. Cholestanyl amine was treated with acetylthiosuccinic anhydride to give the half amide; cleavage with hydroxylamine liberated the thiol group. This product is active against both methylmercuric chloride and lead nitrate.

Keyphrases □ Methylmercuric chloride toxicity—protection by mercapto steroids □ Steroids—mercapto compounds, protection against mercury and lead poisoning □ Heavy metal poisoning—protection by mercapto steroids

In a study to identify lipophilic therapeutic agents for heavy metal poisoning that would minimize the burden placed on the kidney, thiocholesterol was found to be superior to dimercaprol and penicillamine in protecting mice against methylmercuric chloride toxicity (1). An investigation of how alterations in the structure of the molecule might alter activity then was desired. Compounds were synthesized containing, in addition to the thiol group, a hydroxyl, a carboxyl, or a second thiol group. A thiosemicarbazone, synthesized in connection with another problem and lacking a mercapto group, was included because it forms a precipitate with methylmercuric chloride *in vitro*. Several nonsteroidal mercaptans also were studied.

EXPERIMENTAL[1]

Thiositosterol (II)—Tosylation of 20.0 g of β-sitosterol[2] in 140 ml of pyridine[3] with 20 g of *p*-toluenesulfonyl chloride in the refrigerator overnight gave 28.7 g of crude product, mp 130°. Recrystallization from 2-butanone–acetone–water gave β-sitosteryl *p*-toluenesulfonate[4], 24.0 g (89% yield), mp 130–132°; IR: 1601 (benzene ring), 1198 and 1180 (SO_3), 950, 900, 878, 820, and 675 cm^{-1}.

Anal.—Calc. for $C_{36}H_{50}O_3S$: C, 76.00; H, 9.92; S, 5.64. Found: C, 76.24; H, 10.19; S, 5.64.

The tosylate (24.0 g) was treated with thiourea (24.0 g) in 248 ml of 95% alcohol and 25 ml of pyridine at reflux for 4.5 hr. Water precipitated the crude product, 22.8 g (82% yield), mp 233–239°. Two recrystallizations from methanol gave β-sitosteryl isothiouronium tosylate, mp 238–239°; IR: 3300–3000 (NH), 1675, 1230, 1181 (SO_3), 1139, 1050, 1025, 822, and 698 cm^{-1}.

Anal.—Calc. for $C_{37}H_{60}N_2O_3S_2$: C, 68.90; H, 9.38; N, 4.34; S, 9.94. Found: C, 68.60; H, 9.61; N, 4.14; S, 9.72.

Hydrolysis of 7.753 g of the isothiouronium salt in alcoholic sodium hydroxide (2.46 g/180 ml, 5 hr reflux) followed by precipitation with cold water and dilute hydrochloric acid gave the crude product, 4.594 g (89% yield), mp 61–65°. Two crystallizations from acetone–water gave II, mp 70–71°; IR: 1200, 968, and 802 cm^{-1}.

Anal.—Calc. for $C_{29}H_{50}S$: C, 80.86; H, 11.70; S, 7.44. Found: C, 80.59; H, 11.95; S, 7.29.

3α-Mercapto-5α-pregnan-20-one (V)—A comparable reaction of 3β-tosyloxy-5α-pregnan-20-one, mp 131.5–133° [lit. (4) mp 132–135°], with thiourea gave the corresponding isothiouronium tosylate, mp 270–272°; IR: 3275 (NH), 1701 (C=O), 1180 (SO_3), 1090, 1041, 1005, and 819 cm^{-1}.

Anal.—Calc. for $C_{29}H_{44}N_2O_4S_2$: C, 63.47; H, 8.08; N, 5.10; S, 11.67. Found: C, 63.73; H, 8.31; N, 4.90; S, 11.82.

Alkaline hydrolysis of the isothiouronium salt gave V in an 89% yield, mp 123–125° (methanol–water); IR: 1710 (C=O), 1208, 1160, and 978 cm^{-1}.

Anal.—Calc. for $C_{21}H_{34}OS$: C, 75.39; H, 10.24; S, 9.58. Found: C, 75.59; H, 10.34; S, 9.36.

***N*-(5α-Cholestan-3α-yl)mercaptosuccinic Acid Monoamide (VIII)**—A solution of 16.0 g of 5α-cholestan-3α-yl amine and 14.2 g of *S*-acetylmercaptosuccinic anhydride in acetic acid was held under nitrogen at 90–100° for 15 min. The solution was cooled to 35° and poured onto ice. The solid was filtered, the filtrate was extracted with ether, and the ethereal solution and solid were combined and evaporated. The solid residue was dissolved in 75 ml of tetrahydrofuran, 30 ml of methanol, and 10 ml of water. Hydroxylamine hydrochloride was added, and the solution was saturated with gaseous ammonia.

After standing at room temperature for 1.5 hr, the solution was made acidic with cold dilute hydrochloric acid. The precipitate was filtered, washed with water, and dried to give 20.0 g (93% yield), mp 113–118°. The analytical sample was precipitated from acidic methanol–water to yield VIII, mp 117–121°; IR: 3300 and 3170 (NH), 1710 (acid C=O), 1635 (amide C=O), 1540, 1220, and 1175 cm^{-1}.

Anal.—Calc. for $C_{31}H_{53}NO_3S$: C, 71.61; H, 10.28; N, 2.60; S, 6.16. Found: C, 71.26, 71.92; H, 10.46, 10.84; N, 2.48; S, 5.74.

3β-Hydroxy-5-androstene-16,17-dione 16-Oxime 17-Thiosemicarbazone (XI)—3β-Hydroxy-5-androsten-17-one tetrahydropyranyl ether (5, 6) (IX, 23.40 g) was added to a stirred solution of 5.89 g of potassium in 262 ml of *tert*-butanol under nitrogen. The mixture was stirred 1 hr, and 22.0 ml of isopentyl nitrite was added. The contents of the flask solidified within 2 min. After standing overnight at room temperature, the solid mass was dissolved in 1300 ml of cold water and extracted three times with ether.

Table I—Effect of Timing on Intraperitoneal Thiocholesterol Therapy for Methylmercuric Chloride Toxicity

Steroid[a]	Hours before First Injection[b]	Hours after Second Injection[b]	Hours after Third Injection[b]	Survivors	p^c
Cholesterol	24	24	48	3/20, 15%	—
Thiocholesterol	24	24	48	3/16, 19%	—
Thiocholesterol	2	24	48	9/16, 56%	<0.0093
Thiocholesterol	0.5	24	48	8/16, 50%	<0.0278
Cholesterol	0.5	2	8	1/15, 7%	—
Thiocholesterol	0.5	2	8	13/16, 81%	<0.0001
Thiocholesterol	0.25	2	4	0/16, 0%	—
Thiocholesterol	0.25	2	8	0/16, 0%	—

[a] Steroids were administered as liposomes with 400 mg of steroid/kg of body weight. [b] Before and after intraperitoneal injection of 25 mg of methylmercuric chloride/kg of body weight. [c] Normal difference test as compared to appropriate cholesterol control (13).

[1] Melting points were obtained on a Thomas-Hoover melting point apparatus and are corrected. IR spectra were taken as smears or mineral oil mulls on a Perkin-Elmer 247 spectrophotometer. Microanalyses were performed by Galbraith Laboratories, Knoxville, Tenn.

[2] Mann, dried by benzene azeotropy.

[3] Dried over molecular sieve.

[4] Reported without the melting point by Stoll (2) and possibly the same as the compound with a melting point of 123–124.5° reported by Rathmann and Morrow (3).

Table II—Activity of Compounds against Methylmercuric Chloride Toxicity [a]

	Compound [b]	Survivors	p [c]
	Cholesterol	15/78, 19%	—
I	Thiocholesterol	16/22, 73%	<0.0001
II	Thiositosterol	13/30, 43%	<0.0124
III	5α-Cholestane-2β,3α-dithiol	17/22, 77%	<0.0001
IV	6β-Mercapto-5α-cholestane-3β,5α-diol	0/10, 0%	—
V	3α-Mercapto-5α-pregnan-20-one	3/10, 30%	—
VIII	*N*-(5α-Cholestan-3α-yl)mercaptosuccinic acid monoamide	16/36, 44%	<0.0069
XI	3β-Hydroxy-5-androstene-16,17-dione 16-oxime 17-thiosemicarbazone	2/9, 22%	—
XII	3β-Mercapto-5β-cholanic acid	4/10, 40%	<0.1936
XIII	5β-Cholane-3β,24-dithiol	6/10, 60%	<0.0001
XIV	1-Adamantanethiol	1/10, 10%	—

[a] All mice received 20 mg of methylmercuric chloride/kg of body weight by intraperitoneal injection. [b] Administered as liposomes injected intraperitoneally 0.5 hr before and 2 and 8 hr after methylmercuric chloride injection at the level of 400 mg of steroid or 170 mg of adamantanethiol/kg of body weight. [c] Normal difference test (13) as compared to the control group.

The combined ethereal layer was washed with water; the water wash was added to the original alkaline layer, which then was cooled and acidified with acetic acid. Filtration of the mixture after several hours of refrigeration gave 22.36 g of crude product, mp 161–166° (88% yield). Three recrystallizations in methanol–water gave 3β-hydroxy-5-androstene-16,17-dione 16-oxime 3-tetrahydropyranyl ether (X), mp 176–191°; IR: 3245 (OH), 1735 (C=O), 1632, 1135, 1112, 1058, 1022, 974, 940, 908, and 868 cm^{-1}.

Anal.—Calc. for $C_{24}H_{35}NO_4$: C, 71.79; H, 8.79; N, 3.49. Found: C, 71.69; H, 8.78; N, 3.64.

The thiosemicarbazone was prepared in the usual way with 5 ml of concentrated hydrochloric acid, 2.00 g of the oxime (X), and 1.50 g of thiosemicarbazide in 39 ml of boiling 95% ethanol and 6 ml of water. Two recrystallizations from methanol–dimethylformamide–water gave XI[5], mp 296–298° dec.; *IR*: 3408 (OH), 3230 (OH), 3145 (NH), 1580, 1300, 1080, and 968 cm^{-1}.

Anal.—Calc. for $C_{20}H_{30}N_4O_2S$: C, 61.51; H, 7.74; N, 14.35; S, 8.21. Found: C, 61.32; H, 7.91; N, 14.37; S, 8.10.

Assays—Assays were conducted with male, Swiss–Webster mice, 22–25 g. Liposomes were prepared as described previously (1); with VIII and XI, cholesterol was added (compound to cholesterol, 4:1) to obtain stable liposomes. 1-Dodecanethiol was tested in cottonseed oil because it would not form liposomes under these conditions. Methylmercuric chloride was dissolved in warm water at a concentration of 1 mg/ml, and lead nitrate was dissolved at a concentration of 20 mg/ml. Mice were injected with test compounds in the left groin and with mercury or lead in the right groin.

RESULTS AND DISCUSSION

Thiositosterol (II) was synthesized from sitosterol and 3α-mercapto-5α-pregnan-20-one (V) was synthesized from 3β-hydroxy-5α-pregnan-20-one *via* the corresponding tosylates and isothiouronium salts in a sequence comparable to the synthesis of thiocholesterol (7). Cholestane-2β,3α-dithiol (III) (8), 6β-mercapto-5α-cholestane-3β,5α-diol (IV) (9), and 1-adamantanethiol (XIV) (10) were synthesized by literature methods. 5α-Cholestan-3α-yl amine (VI) reacted with *S*-acetylmercaptosuccinic anhydride to give the corresponding hemiamide (VII) following a reported method (11). The product was deacylated with hydroxylamine to give the mercapto compound (VIII). The mercapto group may be on the carbon adjacent to either the carboxyl or the amide group, and, although the product exhibited a single spot by TLC, it may be a mixture of the two isomers. The tetrahydropyranyl ether (IX) of androstenolone was oximated with isopentyl nitrite and potassium *tert*-butoxide (12). When the intermediate (X) was converted to the corresponding thiosemicarbazone (XI), the tetrahydropyranyl ether group was cleaved, giving the 3-hydroxy derivative. Compounds XII and XIII were reported previously.

[5] Mixing equal volumes of 0.01 *N* mercuric acetate in 70% alcohol and 0.01 *N* XI in alcohol caused a rapid precipitation.

Table III—Activity against Methylmercuric Chloride of Compounds Tested in Vegetable Oil [a]

Compound [b]	Survivors	p [c]
Soybean oil	2/20, 10%	—
III	5/10, 50%	<0.0594
XIV	5/10, 50%	<0.0594
1-Dodecanethiol	0/13, 0%	—

[a] All mice received 20 mg of methylmercuric chloride/kg of body weight by intraperitoneal injection. [b] Administered in soybean oil solution by intraperitoneal injection 0.5 hr before and 2 and 8 hr after the methylmercuric chloride injection at the level of 400 mg (of steroid or 1-dodecanethiol) or 170 mg (of adamantanethiol)/kg of body weight. [c] Normal difference test (13) as compared to the control group.

Table IV—Activity of VIII against Lead Nitrate Toxicity [a]

Compound	Dose [b], mg/kg	Survivors	p [c]
Cholesterol	400	2/10, 20%	—
VIII	292	9/10, 90%	<0.0019

[a] All mice received 180 mg of lead nitrate/kg of body weight by intraperitoneal injection. [b] Administered as liposomes injected 0.5 hr before and 2 and 8 hr after lead acetate injection. [c] Normal difference test (13) as compared to the control group.

The desirability of having an assay in which the test compound is administered only following administration of the toxic dose of the heavy metal, thereby mimicking real life conditions, is obvious. However, in earlier work (1), thiocholesterol was an effective protective agent when given 24 and 48 hr *before* methylmercuric chloride but not when given 0, 12, 24, and 36 hr *after* methylmercuric chloride. To decrease the time between pretreatment and the toxic dose, the comparisons in Table I were carried out. Significant protection was afforded when the first of three injections of thiocholesterol was given 0.5 or 2 hr before the methylmercuric chloride but not when given 0.25 or 24 hr before. The highest survival rate was obtained with the sequence 0.5 hr before and 2 and 8 hr after the toxic dose, and this regimen was used in subsequent assays.

The results reported in Table II are composites of a series of assays and illustrate that II, III, VIII, and XIII are active in addition to thiocholesterol. 3β-Mercapto-5β-cholanoic acid (XII) was active when tested under a less stringent protocol (1). Adamantanethiol, inactive under these conditions, exhibited some activity when administered in soybean oil (Table III), but 1-dodecanethiol was totally inactive.

The hemisuccinamide (VIII) exhibited high protective activity when tested against lead nitrate (Table IV).

While there are too few examples for extensive structure–activity generalizations, it is useful to note that 3-mercapto (but not 6-mercapto) steroids were active against methylmercuric chloride. The 2,3- and 3,24-dithiols also were active. The high activity of the hemisuccinamide against lead may be the result of coordination of the lead to both carboxyl and thiol groups. These observations provide leads for the synthesis of other mercapto steroids for heavy metal therapy.

Application of Queueing Theory to Pharmacokinetics

P. H. BRILL *x **and R. E. MOON** ‡

Received October 30, 1978, from the *Department of Quantitative Methods, University of Illinois at Chicago Circle, Chicago, IL 60680, and the ‡Institute of Biomedical Engineering and Department of Medicine, University of Toronto, Toronto, Canada. Accepted for publication December 20, 1979.

Abstract □ This paper considers the steady-state plasma drug concentration in a one-compartment, open pharmacokinetic model with multiple doses and first-order kinetics using a classical deterministic technique as well as a queueing theoretical stochastic analysis. The stochastic analysis employs a new method for obtaining the steady-state probability distribution of the content of a dam with compound Poisson input and a general release rule. It is shown that if the deterministic steady-state average concentration exists, it is equal to the mean value of the steady-state concentration, the probability distribution of which is obtained using the stochastic model. Moreover, the steady-state probability distribution of the concentration and its mean always exist in the stochastic model. Ramifications of the stochastic method of analysis are discussed.

Keyphrases □ Pharmacokinetics—steady-state plasma drug concentration, queueing theory □ Models, pharmacokinetic—steady-state plasma drug concentration, queueing theory □ Queueing theory—application to pharmacokinetics, steady-state plasma drug concentration

This paper introduces a method of analyzing drug accumulation based on a stochastic model of multiple-dosing regimens. In classical pharmacokinetic theory, transient and steady-state drug concentrations in the blood for multiple-dosing regimens are derived from knowledge of the deterministic dose sizes, intervals between doses, volumes of distribution, and kinetics of elimination and transfer between body compartments (1–4). This analysis may be clinically useful only if two major conditions are true: (*a*) the dosage intervals are known, and (*b*) the amount of drug absorbed as a consequence of each dose is known.

These conditions rarely are met in practice. As noted previously (2), nonstandard definitions of *bid*, *tid*, and *qid* may lead to varying dosage intervals. Family physicians and drug package inserts often direct that drugs should be taken near meal times, bed time, or three or four times daily without defining these terms specifically (2). Patients rarely take drugs on schedule unless they are in the hospital. Furthermore, dose size may vary because the initial dose or other doses may be different from the usual maintenance dose. The fractional absorption of oral drugs depends on several factors. For drugs administered intramuscularly, the fractional absorption partially depends on the injection site (1). Moreover, completeness of drug absorption always is clinically important (1, 5).

These observations suggest the desirability of obtaining the drug concentration in the plasma when the dose intervals, doses, or absorption fractions are subject to random fluctuations and must be considered random variables. Accounting for such random variations in these parameters leads to the consideration of a stochastic analysis of pharmacokinetic models. This paper emphasizes the new technique itself rather than its application to general multiple-dosing models. The model presented is a one-compartment, open model with instantaneous input and first-order elimination. A classical, well-known deterministic method of analysis is presented for convenience of reference, and a stochastic, queueing theoretical approach for studying the same model then is given. The latter technique is based on a new method of analyzing the model of a dam with a general release rule[1], which was studied previously in stochastic processes using other approaches.

THEORETICAL

The Model—The model treated is a one-compartment, open model with multiple dosing and first-order kinetics (1–4, 6). For clarity and to focus attention on the new technique, very rapid administration of each dose directly into and instantaneous distribution throughout the compartment is assumed. This assumption is a good approximation for intravenous bolus dosing. For outpatient oral dosing (to which the stochastic technique is more applicable), first-order absorption may be a more appropriate assumption. However, for many drugs in common clinical use, the absorption constant is appreciably larger than the elimination constant. Examples are digoxin, sublingually administered nitrites, salicylates, and phenylbutazone. For such drugs, the assumption of instantaneous absorption, although only approximate, is not entirely unreasonable.

The following notations are used in both the deterministic and stochastic analyses:

V = volume of compartment
K_e = elimination rate constant (time^{-1})
$t_{1/2e}$ = elimination half-life; $1/k_e = t_{1/2e}/\ln 2 = 1.44t_{1/2e}$
τ_n = administration time of nth dose, $n = 1, 2, 3, \ldots$; $\tau_1 = 0$
T_n = nth dosage interval; $T_n = \tau_{n+1} - \tau_n$
D_n = amount of nth dose
F_n = fraction of D_n distributed throughout V
E_n = effective increase in drug concentration at time τ_n; $E_n = F_nD_n/V$
$C(t)$ = drug concentration at time t; $t \geq 0$
C_n = drug concentration at time τ_n; $C_1 = C(0) = 0$
λ = rate of administration of doses
B = common distribution function of effective increases in concentration, E_n, independent of n; $B(0) = 0$
$r(x)$ = drug elimination rate when the concentration is x (mass times volume^{-1} times time^{-1})

Deterministic Analysis—The following well-known deterministic analysis is presented for comparison with the stochastic analysis. Vari-

Abstract □ This paper considers the steady-state plasma drug concentration in a one-compartment, open pharmacokinetic model with multiple doses and first-order kinetics using a classical deterministic technique as well as a queueing theoretical stochastic analysis. The stochastic analysis employs a new method for obtaining the steady-state probability distribution of the content of a dam with compound Poisson input and a general release rule. It is shown that if the deterministic steady-state average concentration exists, it is equal to the mean value of the steady-state concentration, the probability distribution of which is obtained using the stochastic model. Moreover, the steady-state probability distribution of the concentration and its mean always exist in the stochastic model. Ramifications of the stochastic method of analysis are discussed.

Keyphrases □ Pharmacokinetics—steady-state plasma drug concentration, queueing theory □ Models, pharmacokinetic—steady-state plasma drug concentration, queueing theory □ Queueing theory—application to pharmacokinetics, steady-state plasma drug concentration

This paper introduces a method of analyzing drug accumulation based on a stochastic model of multiple-dosing regimens. In classical pharmacokinetic theory, transient and steady-state drug concentrations in the blood for multiple-dosing regimens are derived from knowledge of the deterministic dose sizes, intervals between doses, volumes of distribution, and kinetics of elimination and transfer between body compartments (1–4). This analysis may be clinically useful only if two major conditions are true: (*a*) the dosage intervals are known, and (*b*) the amount of drug absorbed as a consequence of each dose is known.

These conditions rarely are met in practice. As noted previously (2), nonstandard definitions of *bid*, *tid*, and *qid* may lead to varying dosage intervals. Family physicians and drug package inserts often direct that drugs should be taken near meal times, bed time, or three or four times daily without defining these terms specifically (2). Patients rarely take drugs on schedule unless they are in the hospital. Furthermore, dose size may vary because the initial dose or other doses may be different from the usual maintenance dose. The fractional absorption of oral drugs depends on several factors. For drugs administered intramuscularly, the fractional absorption partially depends on the injection site (1). Moreover, completeness of drug absorption always is clinically important (1, 5).

These observations suggest the desirability of obtaining the drug concentration in the plasma when the dose intervals, doses, or absorption fractions are subject to random fluctuations and must be considered random variables. Accounting for such random variations in these parameters leads to the consideration of a stochastic analysis of pharmacokinetic models. This paper emphasizes the new technique itself rather than its application to general multiple-dosing models. The model presented is a one-compartment, open model with instantaneous input and first-order elimination. A classical, well-known deterministic method of analysis is presented for convenience of reference, and a stochastic, queueing theoretical approach for studying the same model then is given. The latter technique is based on a new method of analyzing the model of a dam with a general release rule[1], which was studied previously in stochastic processes using other approaches.

THEORETICAL

The Model—The model treated is a one-compartment, open model with multiple dosing and first-order kinetics (1–4, 6). For clarity and to focus attention on the new technique, very rapid administration of each dose directly into and instantaneous distribution throughout the compartment is assumed. This assumption is a good approximation for intravenous bolus dosing. For outpatient oral dosing (to which the stochastic technique is more applicable), first-order absorption may be a more appropriate assumption. However, for many drugs in common clinical use, the absorption constant is appreciably larger than the elimination constant. Examples are digoxin, sublingually administered nitrites, salicylates, and phenylbutazone. For such drugs, the assumption of instantaneous absorption, although only approximate, is not entirely unreasonable.

The following notations are used in both the deterministic and stochastic analyses:

V = volume of compartment
K_e = elimination rate constant (time^{-1})
$t_{1/2e}$ = elimination half-life; $1/k_e = t_{1/2e}/\ln 2 = 1.44t_{1/2e}$
τ_n = administration time of nth dose, $n = 1, 2, 3, \ldots$; $\tau_1 = 0$
T_n = nth dosage interval; $T_n = \tau_{n+1} - \tau_n$
D_n = amount of nth dose
F_n = fraction of D_n distributed throughout V
E_n = effective increase in drug concentration at time τ_n; $E_n = F_nD_n/V$
$C(t)$ = drug concentration at time t; $t \geq 0$
C_n = drug concentration at time τ_n; $C_1 = C(0) = 0$
λ = rate of administration of doses
B = common distribution function of effective increases in concentration, E_n, independent of n; $B(0) = 0$
$r(x)$ = drug elimination rate when the concentration is x (mass times volume^{-1} times time^{-1})

Deterministic Analysis—The following well-known deterministic analysis is presented for comparison with the stochastic analysis. Vari-

ations and generalizations of this analysis were given previously (1–4, 6). Equations 1–9 in the present discussion parallel formulas presented previously. All of the parameters are considered deterministic so that T_n, D_n, F_n, E_n, and C_n are real nonnegative constants for $n = 1, 2, 3, \ldots$. The deterministic differential equations of elimination are:

$$\frac{dC(t)}{dt} = -K_e C(t) \qquad \tau_n < t \leq \tau_{n+1} \qquad \text{(Eq. 1)}$$

with initial conditions $C(\tau_n^+) = C_n + E_n$, $n = 1, 2, 3, \ldots$ (3). It then follows that:

$$C(t) = (C_n + E_n) \exp[-K_e(t - \tau_n)] \qquad \tau_n < t \leq \tau_{n+1},\ n = 1, 2, 3, \ldots \qquad \text{(Eq. 2)}$$

and thus:

$$C_{n+1} = C(\tau_{n+1}) = (C_n + E_n) \exp(-K_e T_n) \qquad n = 1, 2, 3, \ldots \qquad \text{(Eq. 3)}$$

Three sequences are of interest in pharmacokinetics: minimum (or infimum), maximum (or supremum), and average concentrations during each dosage interval, which are C_n, $C_n + E_n$, and $\overline{C}_n = (1/T_n) \int_{t=\tau_n}^{\tau_{n+1}} C(t)\, dt$, respectively. Consideration of general constraints on the parameters E_n and T_n that are necessary and sufficient for the convergence of these sequences to limiting values is outside the scope of this paper. However, a sufficient (but not necessary) condition for any of these sequences to converge is monotonicity (*i.e.*, always increasing or always decreasing) after some finite value of n. For different dosing regimens, the limits of all three, any two, only one, or none of these sequences may exist. In the remainder of this section, all limits are taken as $n \to \infty$.

If $\lim C_n$ exists, Eq. 3 yields:

$$\lim C_n = \lim\{E_n/[\exp(K_e T_n) - 1]\} \qquad \text{(Eq. 4)}$$

If $\lim (C_n + E_n)$ exists, Eq. 3 yields:

$$\lim (C_n + E_n) = \lim\{E_{n+1}/[1 - \exp(-K_e T_n)]\} \qquad \text{(Eq. 5)}$$

Using Eq. 2 and substituting from Eq. 3 result in:

$$\overline{C}_n = (1/T_n) \int_{t=\tau_n}^{\tau_{n+1}} C(t)\, dt = (1/K_e)(C_n + E_n - C_{n+1})/T_n \qquad \text{(Eq. 6a)}$$

and, hence, if $\lim \overline{C}_n$ exists:

$$\lim \overline{C}_n = (1/K_e) \lim [(C_n + E_n - C_{n+1})/T_n] \qquad \text{(Eq. 6b)}$$

With the assumption that $\lim \overline{C}_n$ and $\lim C_n$ exist, it follows from Eq. 6*b* that:

$$\lim \overline{C}_n = (1/K_e) \lim (E_n/T_n) = (1/K_e) \lim (F_n D_n/T_n) \qquad \text{(Eq. 7)}$$

If both $\lim \overline{C}_n$ and $\lim (C_n + E_n)$ exist, then:

$$\lim \overline{C}_n = (1/K_e) \lim (E_{n+1}/T_n) = (1/K_e) \lim (F_{n+1} D_{n+1}/T_n) \qquad \text{(Eq. 8)}$$

In Eqs. 4–8, E_n and T_n must be known to predict whether the sequences will converge or oscillate. Knowledge of these parameters rarely is obtainable, except possibly in controlled hospital situations or laboratory studies. In pharmacokinetic literature, analytical results for these limits usually are derived by assuming uniform dosing, *i.e.*, $F_n = F$, $D_n = D$, and $T_n = T$, so that the E_n values all are equal. The condition of uniform dosing is sufficient but not necessary for the limits in Eqs. 4–8 to exist. Under uniform dosing, the steady-state average concentration is given by:

$$\lim \overline{C}_n = 1.44 t_{1/2e} E/T = 1.44 t_{1/2e} FD/(VT) \qquad \text{(Eq. 9)}$$

Since actual dosing rarely is uniform in ambulatory patients, even when it is the intended therapy, nonuniform dosing must be considered. A generalization of Eq. 9 holds for nonuniform dosing of the following type. Both $\lim C_n$ and $\lim \overline{C}_n$ are assumed to exist, so Eq. 7 holds. In addition, let the average increase in drug concentration per dose after n intervals, which is given by $(\sum_{i=1}^n E_i)/n$ (or equivalently by $\sum_{i=1}^n F_i D_i/n$), and the average dose interval after n intervals, $(\sum_{i=1}^n T_i)/n$, tend to the limits E' $[\equiv (FD)']$ and T', respectively, as $n \to \infty$. Then, with Eq. 7 and the fact that both E_n and T_n are bounded away from zero and also bounded above, the following is obtained:

$$\lim \overline{C}_n = (1/K_e) \lim (E_n/T_n) \qquad \text{(Eq. 10a)}$$

$$\lim \overline{C}_n = (1/K_e) E'/T' \qquad \text{(Eq. 10b)}$$

$$\lim \overline{C}_n = 1.44 t_{1/2e} E'/T' \qquad \text{(Eq. 10c)}$$

$$\lim \overline{C}_n = 1.44 t_{1/2e} (FD)'/T' \qquad \text{(Eq. 10d)}$$

The introduction of this type of nonuniform dosing model serves a dual purpose. First, it leads to Eqs. 10*c* and 10*d*, which demonstrate that the limiting average concentration depends on the effective increases in concentration and the dose intervals only through their respective limiting average values. Second, it links the deterministic models of this section to the stochastic model. The latter model also possesses the property established in Eqs. 10*c* and 10*d*.

Stochastic Analysis—In this section, a completely different method for analyzing the present model is introduced. The parameters T_n, D_n, and F_n, $n = 1, 2, \ldots$, are considered to be sequences of independently, identically distributed, random variables, so that $E_n = F_n D_n/V$ is a random variable. Hence, $\{C_n, n \geq 1\}$ and $\{C(t), t \geq 0\}$ are stochastic processes.

Furthermore, it is assumed that $\{N(t), t \geq 0\}$ is a Poisson process with arrival rate λ, where $N(t)$ denotes the number of doses in the time interval $[0, t]$. Note that $P[N(t) = k] = [e^{-\lambda t}(\lambda t)^k]/k!$, $k = 0, 1, 2, \ldots$. Thus, $\{T_n, n \geq 1\}$ is a sequence of exponentially distributed random variables with the common probability distribution function $1 - \exp(-\lambda x)$, $x \geq 0$. The sequence $\{E_n, n \geq 1\}$ is assumed to have common probability distribution, B, with $B(0) = 0$. The mean value of the random variable with distribution B is denoted by $E'' = \int_{z=0}^{\infty} z\, dB(z)$. The drug elimination is described by a general release function, r, with $r(c) > 0$ for $c > 0$ and $r(0) = 0$, where c denotes the concentration level. Therefore, the pharmacokinetic system previously modeled deterministically is modeled stochastically as a dam with a general release rule[1] (7–9). Hence, in general, the following analysis is not constrained to first-order kinetics of elimination. Sample functions of the process $\{C(t), t \geq 0\}$ satisfy the differential equations:

$$dC(t)/dt = -r[C(t)] \qquad \tau_n < t \leq \tau_{n+1} \qquad \text{(Eq. 11)}$$

with initial conditions $C(\tau_n^+) = C_n + E_n$, $n = 1, 2, 3, \ldots$.

The relation $\lim_{c \to \infty} r(c) > \lambda \int_0^\infty z B(dz) = \lambda E''$ guarantees the existence of the steady-state probability distribution function of the drug concentration (8). This result implies, as will be seen following Eq. 15, that for first-order kinetics the steady-state concentration, its probability distribution, and its average always exist. This probability distribution function is denoted by G having the probability density function g. An equation for G that is well known in the literature of stochastic processes (7–9) now is derived by a new method[1]. The present investigators believe that this method has strong intuitive appeal as well as other desirable properties that are outside the scope of this paper. This method differs from one given previously (9), which counts crossings of levels during regenerative cycles of the process rather than during time intervals of the form $(0, t]$, as is done here. Let $E[D_t(c)]$ and $E[U_t(c)]$ denote the expected values of the number of times that a sample function of the process $\{C(t), t \geq 0\}$ downcrosses and upcrosses level c, respectively, during time interval $(0, t]$. The theorems given previously[1] state that:

$$\lim_{t \to \infty} E[D_t(c)]/t = r(c) g(c) \qquad c > 0 \qquad \text{(Eq. 12)}$$

and:

$$\lim_{t \to \infty} E[U_t(c)]/t = \lambda \int_{z=0}^{c} \overline{B}(c - z) G(dz) \qquad \text{(Eq. 13)}$$

where $\overline{B}(x) = 1 - B(x)$, $x \geq 0$. Since the number of downcrossings and upcrossings cannot differ by more than one during any time interval, it follows that the right sides of Eqs. 12 and 13 must be equal, so that[1] Eq. 14 holds:

$$r(c) g(c) = \lambda \int_{z=0}^{c} \overline{B}(c - z) G(dz) \qquad \text{(Eq. 14)}$$

This relation is the well-known equation in stochastic processes referred to previously (7–9). Up to this point, the release function, r, has not been specified so that Eq. 14 holds for non-first-order kinetics of elimination. At this stage, Eq. 14 is specialized to first-order kinetics of elimination by assuming that:

$$r(c) = K_e c \qquad c \geq 0 \qquad \text{(Eq. 15)}$$

Notice that $\lim_{c \to \infty} K_e c = \infty$, which is greater than $\lambda E''$ since E'' is finite. Therefore, with first-order elimination, the limiting probability distribution and its average always exist (8). This property of the stochastic model obviates the need to consider the convergence properties of the sequences in Eqs. 4–8. The actual observed increases in concentration per dose and actual observed dosage intervals encountered in any particular therapy will vary in accordance with sampling from distribution B and from an exponential distribution, respectively. Due to the law

of large numbers, their averages will tend to E'' and $1/\lambda$, respectively, as the number of doses increases. Therefore, this model is the stochastic analog of a deterministic model with the type of nonuniform dosing considered preceding Eq. 10*a*. Thus, the stochastic model does not assume that the intended therapy must involve uniform dosing, but it also applies if the intended therapy actually happens to comprise uniform dosing. This result follows since uniform dosing is just a special type of deterministic nonuniform dosing considered following Eq. 9. To apply the stochastic model for drug management in a given therapy, it must be established that there is a known probability distribution, B, and that the number of doses in any time interval has a Poisson distribution.

With Eq. 15, Eq. 14 reduces to:

$$K_e c g(c) = \lambda \int_{z=0}^{c} \overline{B}\,(c - z) g(z)\, dz \qquad \text{(Eq. 16)}$$

whose tractability without using integral transforms depends on the nature of the function B. Even if Eq. 16 is not readily solvable for g, the steady-state mean value of the concentration with probability density g can be found immediately by integrating both sides of Eq. 16 with respect to the variable c over the range $(0, \infty)$. This integration leads to:

$$\overline{C} = \lambda E''/K_e = 1.44 t_{1/2e} E'' \lambda \qquad \text{(Eq. 17)}$$

where $\overline{C}$ is the mean value of the steady-state probability distribution of the drug concentration. If D_n and F_n are completely independent sequences of random variables, then $E'' = F''D''/V$, where F'' and D'' are the mean fractional absorption and mean dosage, respectively. In this case, setting $\lambda = 1/T''$ transforms Eq. 17 into:

$$\overline{C} = 1.44 t_{1/2e} F''D''/(VT'') \qquad \text{(Eq. 18)}$$

Comparison of Eqs. 9, 10*c*, and 10*d* with Eqs. 17 and 18 demonstrates that $\lim \overline{C}_n = \overline{C}$, provided $\lim \overline{C}_n$ exists. A complete solution of Eq. 16 is given when the effective increases in concentration at dose times are exponentially distributed with the mean $1/\mu$, *i.e.*, $B(x) = 1 - \exp(-\mu x), x \geq 0$. Substitution of this B into Eq. 16 yields:

$$K_e c g(c) = \lambda \int_{z=0}^{c} \exp[-\mu(c - z)] g(z)\, dz \qquad \text{(Eq. 19)}$$

Operating on Eq. 19 with differential operator $\langle D + \mu \rangle$, solving the resulting differential equation, and using the normalizing condition $\int_{z=0}^{\infty} G(dz) = 1$ (or proceeding as in Example 1 of Ref. 7) result in the following solution:

$$g(c) = \exp(-\mu c)(\mu c)^{(\lambda/K_e - 1)}\, \mu/\Gamma(\lambda/K_e) \qquad c > 0 \quad \text{(Eq. 20)}$$

where Γ denotes the gamma function. This result was obtained previously by several investigators (8, 10). In this example, Eq. 17 becomes $\overline{C} = 1.44 t_{1/2e} \lambda/\mu = 1.44 t_{1/2e} F''D''/(VT'')$ as in Eq. 18. This relation expresses the fact that $\overline{C}$ is exactly the same as the classical steady-state average concentration in Eq. 9 or its generalization in Eq. 10*d*, if the latter limits exist.

DISCUSSION

The steady-state probability distribution function of drug concentration and its average always exist and have been calculated under the assumptions that dose administrations occur in a Poisson process, fractional absorptions and dose amounts are independent random variables, the common probability distribution of the resulting drug concentration increases at dose times is known, and elimination is first order. The probabilistic approach presented might be used to predict the percentage of the time that a patient's drug concentration will be below or above any level in the steady state. Imprecise knowledge of the deterministic sequences of doses, dosage intervals, and the resulting limiting behavior of the concentration in the compartment is quantified by exact knowledge of the steady-state probability distribution function.

Using classical theory, one simply predicts a patient's minimum, maximum, or average drug concentration; in addition, it is assumed that the dosage intervals and absorption characteristics are precisely known constants. In classical theory, one can predict, for example, that if a patient takes 500 mg of procainamide every 4 hr, his or her serum level will "likely" be therapeutic because these constants are rarely known exactly. It would be more informative and useful to know that if the patient takes the drug *approximately* every 4 hr and if drug absorption is subject to chance variations, then the serum will contain an established therapeutic concentration 95% of the time.

The latter type of prediction might allow more rational therapy with drugs taken by ambulatory patients for which the therapeutic effect is close to toxicity or for which it is essential to maintain a therapeutic serum level. Digoxin, antiarrhythmics, anticonvulsants, certain antibiotics, antineoplastics, aminophylline, salicylates in the therapy of rheumatic disorders, antihypertensives, and corticosteroids are examples of medications belonging to this class. The particular stochastic analysis presented here may be directly applicable to some of these agents, particularly those with relatively rapid absorption and first-order elimination kinetics.

Similarly, the stochastic approach can be used to predict caffeine levels in coffee and tea drinkers since these beverages usually are imbibed at random intervals and by sipping random amounts. Carbon monoxide and nicotine levels in tobacco users and ethanol levels in partygoers might be predicted in the same manner. The exponential dam described by Eq. 19 might be a good model for these situations, and Eq. 20 then would be an exact analytical solution for the steady-state probability distribution of the serum concentration. The dosage rate, λ, and the average increase in concentration, $1/\mu$, would have to be determined experimentally.

Extension of the present analysis to include first-order absorption would make the probabilistic technique applicable to a broader class of drugs. Moreover, development of similar queueing theoretical methods for multicompartment models with more general dosing regimens is of interest.

TLC Determination of Griseofulvin in Plasma and 6-Demethylgriseofulvin in Urine

Y. GARCEAU, J. BRISSON, I. DAVIS, R. L. DeANGELIS *, and J. HASEGAWA ˣ

Received February 26, 1979, from the *Biopharmacy Section, Pharmacy Research and Development Division, Ayerst Laboratories, Inc., Rouses Point, NY 12979.* Accepted for publication December 21, 1979. *Present address: Wellcome Research Laboratories, Research Triangle Park, NC 27709.

Abstract □ Fluorometric TLC procedures are described for the determination of griseofulvin in human plasma and 6-demethylgriseofulvin in human urine. Griseofulvin is extracted from plasma with ether, and its metabolite, 6-demethylgriseofulvin, is extracted from urine with benzene. Both compounds are subjected to TLC on silica gel plates. The plates are scanned using the fluorescent mode of a spectrodensitometer. For griseofulvin, the quantitation limit is 20 ng/ml of plasma and the recovery is 100%; for 6-demethylgriseofulvin, the limit is 1 μg/ml of urine and the recovery is 96%. The methods were used to determine the plasma levels of griseofulvin and the amount of 6-demethylgriseofulvin excreted in the urine of human volunteers after a single oral dose of griseofulvin.

Keyphrases □ Griseofulvin—TLC determination in plasma □ 6-Demethylgriseofulvin—TLC determination in urine □ TLC—determination of griseofulvin in plasma and 6-demethylgriseofulvin in urine □ Antifungal agents—TLC determination of griseofulvin in plasma and 6-demethylgriseofulvin in urine

The antifungal agent griseofulvin is metabolized mainly to 6-demethylgriseofulvin and 6-demethylgriseofulvin glucuronide in humans (1–3). Following oral griseofulvin administration to human volunteers, intact griseofulvin and 6-demethylgriseofulvin were measured in plasma (3). In urine, <0.2% of an oral dose was excreted as unchanged griseofulvin (3); the main urinary metabolites were 6-demethylgriseofulvin and its glucuronide, and together they accounted for 65% of an intravenous dose and 34–64% of an oral dose (4).

Plasma levels of unchanged griseofulvin and the urinary excretion of 6-demethylgriseofulvin have been used to estimate griseofulvin bioavailability (4–7). Griseofulvin has been measured in plasma using spectrophotofluorometry (8), GLC (9, 10), and high-pressure liquid chromatography (11, 12). The metabolite 6-demethylgriseofulvin has been measured in urine using UV spectrophotometry (13) and GLC (5, 14). A qualitative TLC procedure also was described and used to identify griseofulvin and its metabolites in urine (15).

This paper describes quantitative fluorometric TLC procedures that have the simplicity of a spectrophotometric method as well as the sensitivity and specificity of a GLC assay.

EXPERIMENTAL

Materials—All reagents and solvents were analytical reagent grade. Commercial silica gel TLC plates[1], 20 × 20 cm (without fluorescent indicator), were used. The plates were divided into 20 channels of 1-cm width with a scoring device[2].

Solutions of griseofulvin and 6-demethylgriseofulvin were prepared in methanol. Acetate buffer (0.1 *M*, pH 4.7) was prepared by dissolving 0.37 g of sodium acetate in 100 ml of distilled water and adjusting to pH 4.7 with acetic acid. Enzyme solutions of β-glucuronidase[3] from beef liver were prepared in this acetate buffer. 6-Demethylgriseofulvin was obtained by extraction from dog urine according to a published procedure (15).

Determination of Plasma Griseofulvin—One milliliter of human plasma was shaken with 5 ml of ether for 15 min to extract the drug. After centrifugation, a 3-ml aliquot of the ether phase was transferred to a clean centrifuge tube and evaporated to dryness under nitrogen[4] at 40–45°. The residue was dissolved in 100 μl of chloroform, and a 40-μl aliquot from this solution was spotted on a TLC plate along with standard griseofulvin solutions.

The plate was developed to a height of 10 cm in a saturated tank containing 100 ml of the ether–acetone (80:20) solvent system. Then the plate was air dried and scanned in a spectrodensitometer[5] containing a 200-w xenon–mercury lamp[6] and coupled to a density computer[7]. The instrument was operated in the fluorescence mode with excitation at 305 nm and emission at 650 nm. Quantitation was achieved by a computing digital integrator[8].

Determination of 6-Demethylgriseofulvin in Urine—For the determination of free 6-demethylgriseofulvin, 1 ml of urine was acidified with 0.1 ml of 1 *N* HCl and shaken with 2 ml of benzene for 15 min. The mixture was centrifuged to obtain a clear benzene phase. Ten-microliter aliquots of the benzene solution were spotted on a TLC plate along with standard solutions of 6-demethylgriseofulvin. The plate was developed to 10 cm in a saturated tank containing 100 ml of the chloroform–ether–acetone–acetic acid (65:20:15:0.5) solvent system. Then the plate was air dried and read in the fluorescence mode of a spectrodensitometer as described.

To assay conjugated 6-demethylgriseofulvin, 1 ml of urine was mixed with 0.5 ml of 0.1 *M* acetate buffer containing 430 units of β-glucuronidase. The solution was incubated at 37° for 90 min. After incubation, 0.1 ml of 1 *N* HCl was added, and the sample was shaken with 10 ml of benzene for 15 min. The mixture was centrifuged to obtain a clear benzene phase, and 20-μl aliquots of this phase were analyzed as described for the determination of free 6-demethylgriseofulvin. This procedure measures total (free and conjugated) 6-demethylgriseofulvin. To determine the amount of conjugated 6-demethylgriseofulvin, the free metabolite is subtracted from the total.

Recovery Experiments—Samples of human plasma were spiked with solutions of various griseofulvin concentrations, and urine samples were spiked with 6-demethylgriseofulvin. The spiked samples were assayed by the described procedure and compared to absolute standards.

Linearity of Response and Quantitation Limit of Absolute Standards—Solutions with different concentrations of griseofulvin and 6-demethylgriseofulvin were spotted on TLC plates and chromatographed to determine the linear ranges of instrument response. The quantitation limit was set as an "area under the peak" of 25,000 units,

which corresponded to 5 ng of griseofulvin or 6-demethylgriseofulvin/spot.

***In Vivo* Experiment**—To demonstrate the applicability of the methods, a plasma level profile of griseofulvin and a urinary excretion profile of 6-demethylgriseofulvin were obtained in human volunteers. One volunteer received 250 mg of griseofulvin[9], and blood samples were drawn before and 1, 2, 4, 8, and 24 hr after medication. Blood was transferred to tubes containing ethylenediaminetetraacetic acid, and the contents were mixed and centrifuged. Plasma was kept frozen until it was analyzed. A second volunteer received griseofulvin as one 500-mg tablet[10], and urine was collected for 72 hr after drug administration in pools at 24,

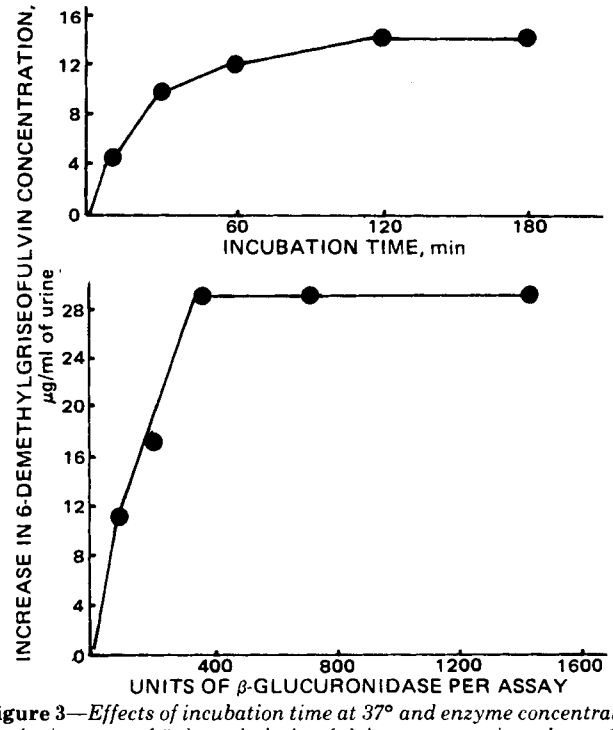

Figure 3—*Effects of incubation time at 37° and enzyme concentration on the increase of 6-demethylgriseofulvin concentration when a 1-ml urine sample was subjected to hydrolysis by β-glucuronidase. Top: time of incubation of urine sample in the presence of 430 units of β-glucuronidase. The urine specimen (0–24 hr) was collected from a volunteer receiving a daily dose of 125 mg of griseofulvin. Bottom: incubation of urine sample at 37° for 90 min in the presence of various concentrations of β-glucuronidase. Enzyme activity is expressed in Fishman units. The urine specimen (0–24 hr) was obtained from a volunteer who had received one oral dose of 450 mg of griseofulvin.*

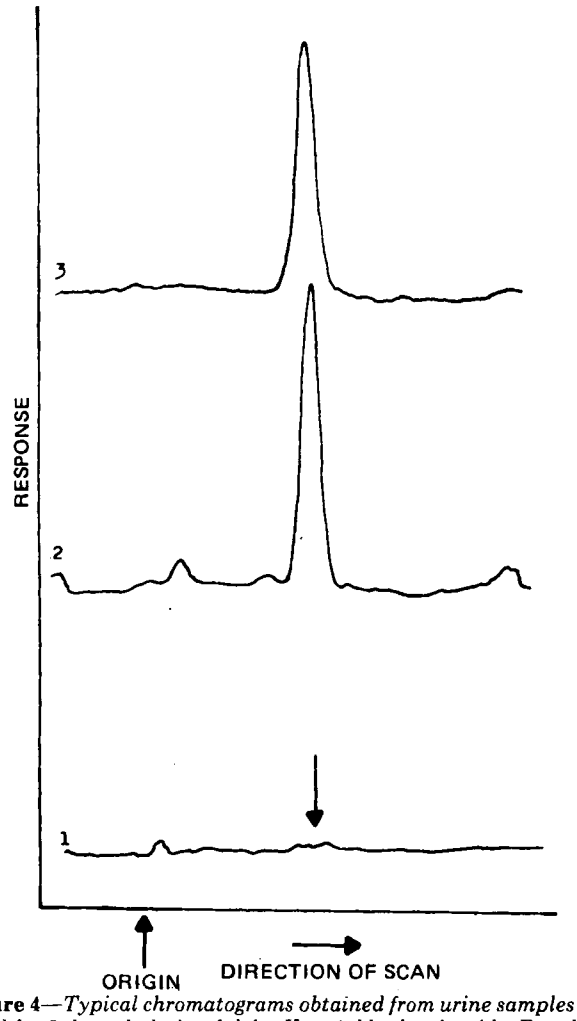

Figure 4—*Typical chromatograms obtained from urine samples analyzed for 6-demethylgriseofulvin. Key: 1, blank urine (the R_f value of 6-demethylgriseofulvin is indicated by the arrow); 2, pooled urine (0–24 hr) from a volunteer who received one single oral 500-mg dose of griseofulvin; and 3, standard of 6-demethylgriseofulvin with 100 ng/spot.*

48, and 72 hr. A preadministration urine sample also was obtained. The samples were kept frozen until they were analyzed.

RESULTS AND DISCUSSION

Plasma Griseofulvin—Griseofulvin had an R_f value of 0.25 in the TLC system and could be quantitated to 5 ng/spot. In terms of assay sensitivity in plasma, the limit of reliable quantitation was set at 20 ng/ml. Instrument response, as determined by the area under the peak, was linear from 0 to at least 300 ng/spot. In terms of concentrations in plasma, linearity was observed from 10 to at least 1000 ng/ml. The assay was free of interference from extractable plasma impurities and from the metabolite 6-demethylgriseofulvin (R_f 0.05).

Chromatograms of extracts from human plasma obtained before and after griseofulvin administration are shown in Fig. 1. Recoveries obtained from plasma samples spiked with griseofulvin over the 20–1500-ng/ml range varied between 93 and 109%, with a mean of 99.9% (Table I). The reproducibility was ±3.9% (*SD*), n = 22. The absolute accuracy of the mean was calculated using the expression $\overline{X} - \hat{X}$, where $\overline{X}$ is the mean of the set and $\hat{X}$ is the true value, defined here as 100% recovery. Therefore, the absolute accuracy of the mean was 99.9% − 100.0% = −0.1%. A plasma griseofulvin concentration–time curve obtained in a volunteer following oral administration of a single 250-mg dose is shown in Fig. 2.

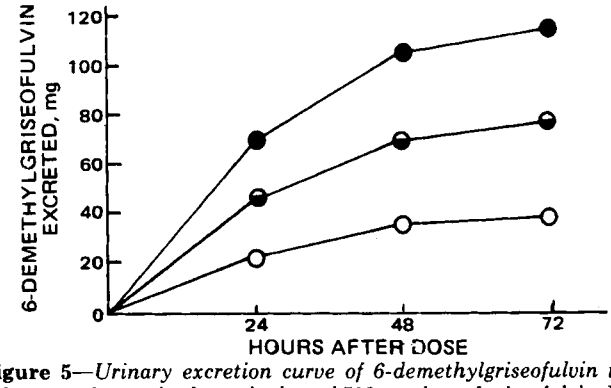

Figure 5—*Urinary excretion curve of 6-demethylgriseofulvin in a volunteer who received one single oral 500-mg dose of griseofulvin. Key: ●, total 6-demethylgriseofulvin; ⊖, free 6-demethylgriseofulvin; and ○, conjugated 6-demethylgriseofulvin.*

6-Demethylgriseofulvin in Urine—In the system used, 6-demethylgriseofulvin (R_f 0.26) was well separated from urine impurities and from the parent drug, griseofulvin (R_f 0.47). Instrument response, as measured by the areas under the peaks, was linear over the range tested, 0–600 ng/spot or 0–120 μg/ml of urine when expressed in concentration units. The detection limit was 5 ng/spot or 1 μg/ml. Recoveries obtained from urine samples spiked with 6-demethylgriseofulvin over the 10–80-μg/ml range varied between 88 and 108%, with a mean of 95.9% (Table II). The reproducibility was ±9.6% (*SD*), n = 14. The absolute accuracy of the mean was −4.1%.

In the determination of total (free and conjugated) 6-demethylgriseofulvin, it was essential to establish that the incubation period and the enzyme concentration used were adequate to hydrolyze all glucuronide present. Since no standard material of 6-demethylgriseofulvin glucuronide was available, urine samples from volunteers dosed with griseofulvin were subjected to hydrolysis using various β-glucuronidase concentrations and incubation times. As seen in Fig. 3, a glucuronidase concentration of 370 units in the 1.5-ml incubation mixture and an incubation time of 1.5 hr were sufficient to liberate the maximum amount of free 6-demethylgriseofulvin from the sample.

Chromatograms of a blank human urine sample and of a postdosing urine sample are shown in Fig. 4.

Figure 5 shows the 72-hr urinary excretion profile of 6-demethylgriseofulvin of a volunteer following oral administration of a single 500-mg dose of griseofulvin.

The described methods are sensitive, specific, and reproducible. In addition, they are simple, relatively rapid, and especially useful when a large number of samples must be analyzed.

Stoichiometric Model of α-Cyclodextrin Complex Formation

THOMAS W. ROSANSKE and KENNETH A. CONNORS ˣ

Received October 9, 1979, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication January 7, 1980.

Abstract □ The solubility, spectral, and kinetic methods were used to study complexing between α-cyclodextrin (ligand, L) and 3,5-dimethoxycinnamic acid, benzalacetone, and methyl cinnamate (substrates, S). In aqueous solution at 25° and with an ionic strength of 0.01 *M*, the following stability constants were found (K_{11} for SL and K_{12} for SL_2): 3,5-dimethoxycinnamic acid, $K_{11} = 1965\ M^{-1}$ and $K_{12} = 0$; benzalacetone, $K_{11} = 105\ M^{-1}$ and $K_{12} = 15\ M^{-1}$; and methyl cinnamate, $K_{11} = 1200\ M^{-1}$ and $K_{12} = 50\ M^{-1}$. A model of complex formation is proposed that can account for the observed stoichiometry and that yields stability estimates for two isomeric 1:1 complexes in the systems in which a 1:2 complex forms. For cinnamic acid, benzalacetone, and methyl cinnamate, stability constants are inversely correlated with the substrate dipole moment.

Keyphrases □ α-Cyclodextrin—complexation with 3,5-dimethoxycinnamic acid, benzalacetone, and methyl cinnamate, stoichiometric model □ Stability constants—complexes of α-cyclodextrin with cinnamic acid, benzalacetone, and methyl cinnamate □ Complexation—α-cyclodextrin, stoichiometric model

A previous study (1) showed that *trans*-cinnamic acid forms 1:1 (SL) and 1:2 (SL_2) complexes[1] with α-cyclodextrin (cyclohexaamylose) in aqueous solution. Therefore, knowledge of the factors that influence the stoichiometric relationships in such a system and that control the magnitudes of the complex stability constants was desired. For this purpose, the complexing of several substrates structurally related to cinnamic acid was studied in aqueous α-cyclodextrin solutions. These substrates are 3,5-dimethoxy-*trans*-cinnamic acid (I), benzalacetone (*trans*-4-phenyl-3-buten-2-one, II), and methyl *trans*-cinnamate (III). The complexing behavior was studied by the solubility, spectral, and kinetic techniques.

EXPERIMENTAL

Materials—3,5-Dimethoxy-*trans*-cinnamic acid[2] was recrystallized twice from water, mp 174.6–175°. Benzalacetone[2] was recrystallized twice from *n*-hexane, mp 39.7–40.7° [lit. (2) mp 41–42°]. Methyl *trans*-cinnamate[3] was distilled under reduced pressure, bp 95–97° (10–12 mm Hg), mp 32.9–33.9° [lit. (3) mp 33.5–34.5°]. α-Cyclodextrin[4] was used directly; drying to constant weight at 90° indicated 9.77% water content, corresponding closely to the hexahydrate (9.99% water); $[\alpha]_D^{25}$ +150.4 ± 2.2° (10 measurements) [lit. (4) $[\alpha]_D^{25}$ +150.5°].

Procedures—The solubility and spectral studies were carried out as described for cinnamic acid (1), except that in the solubility technique the supernatant solution was analyzed spectrophotometrically after appropriate dilution. For the 3,5-dimethoxycinnamic acid, this dilution was made a basic pH to minimize spectral perturbations caused by complexing since it is known (5) that acid anions complex less strongly than the parent carboxylic acid.

A kinetic method was used to study methyl cinnamate. Increasing amounts of α-cyclodextrin were weighed accurately into a series of 10-ml volumetric flasks and were dissolved in pH 10.36 carbonate buffer. To each flask, 0.2 ml of a saturated aqueous solution of methyl cinnamate was added. The solutions were brought to volume with the carbonate buffer. At recorded times, samples were analyzed spectrophotometrically at 295 nm. The kinetics were apparent first order.

All studies were carried out at 25.0° and an ionic strength of 0.01 *M*. The stability constants are defined by:

$$K_{11} = \frac{[SL]}{[S][L]} \qquad \text{(Eq. 1)}$$

$$K_{12} = \frac{[SL_2]}{[SL][L]} \qquad \text{(Eq. 2)}$$

RESULTS

3,5-Dimethoxycinnamic Acid—UV spectra of 3,5-dimethoxycinnamic acid with varying concentrations of α-cyclodextrin revealed isosbestic points at 231, 240, and 300 nm; these isosbestic points were preserved even at high ligand concentrations. This behavior is consistent with 1:1 stoichiometry, and the Benesi–Hildebrand double-reciprocal plot is shown in Fig. 1. Least-squares analysis gave $K_{11} = 1970\ M^{-1}$.

Figure 2 is the solubility diagram for this system. The linear rise in total solubility is consistent with 1:1 complexing, and the stability constant evaluated from the line (excluding the three highest points) was $K_{11} = 1960\ M^{-1}$, in excellent agreement with the result from the spectral study. (The deviation of the three terminal points is attributed to a small spectral perturbation caused by complexation in the analytical solution.) The well-behaved isosbestic points, the linear spectral and solubility plots, and the agreement of K_{11} values from the independent spectral and solubility studies all indicate that this system is described fully by 1:1 stoichiometry.

Benzalacetone—Figure 3 shows the solubility diagram for the benzalacetone system. The initial rising portion is followed by a plateau region, and then a decrease in S_t occurs with a shoulder unusual in such diagrams. The shape of this curve will be discussed. Analysis of the solid phases gave the following results for $10^2 L_t$ and x_L, where x_L is the mole fraction of cyclodextrin in the solid: 2.90, 0.26; 4.90, 0.60; 6.01, 0.61; 6.90, 0.65; 8.02, 0.66; and 10.1, 0.67. These data show that at least one complex with a stoichiometric L to S ratio of greater than unity must be present.

Interpretation of the initial rising portion in terms of 1:1 plus 1:2 complexes, as described previously (1, 6), shows that the slope of the line is 0.50, which implies that $K_{11} = 1/s_0$, where s_0 is the solubility at $L_t = 0$. This relationship gives $K_{11} = 105\ M^{-1}$; with $K_{11} = 1/s_0$, the data can be fitted regardless of the value of K_{12}. Thus, the solubility study showed that a complex of higher L to S stoichiometry must be present and yielded an estimate of K_{11}.

The spectral data showed isosbestic points at 241 and 304 nm; these points were lost at cyclodextrin concentrations of greater than ~0.007

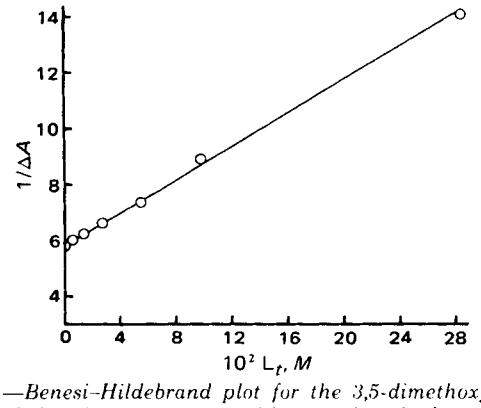

Figure 1—*Benesi–Hildebrand plot for the 3,5-dimethoxycinnamic acid–α-cyclodextrin system at 25° with a wavelength of 291 nm, a path length of 1 cm, a total substrate concentration of 4.54 × 10⁻⁵ M, and a pH of 2.3; L_t represents the total ligand concentration (moles per liter), and ΔA is the change in absorbance.*

[1] The substrate (cinnamic acid in this example) is represented by S, and the ligand (cyclodextrin) is represented by L.

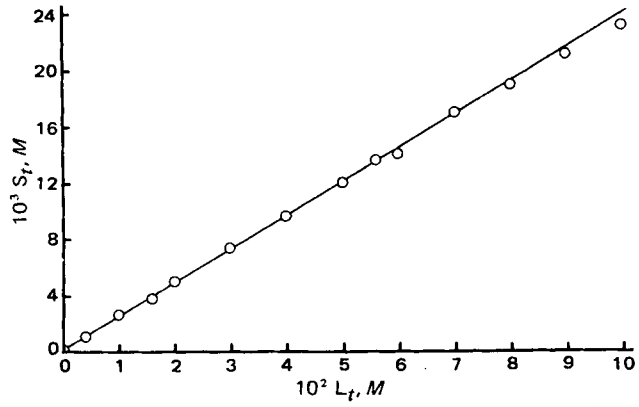

Figure 2—*Solubility study of the 3,5-dimethoxycinnamic acid–α-cyclodextrin system at 25°. The substrate solubility at $L_t = 0$ is 1.51×10^{-4} M; S_t represents the total substrate concentration.*

M, indicating the presence of at least two complexes. The spectral results at 291 nm are given in Fig. 4. The smooth curve was calculated by assuming 1:1 and 1:2 complexes, fixing K_{11} at 105 M^{-1} (from the solubility data), and allowing K_{12} and the complex molar absorptivities to function as adjustable parameters, as described previously (1). The resulting values were $K_{11} = 105\ M^{-1}$, $K_{12} = 15\ M^{-1}$, $\Delta a_{11} = 4500$, and $\Delta a_{12} = 6600$, where $\Delta a_{11} = a_S - a_{11}$, *etc.*, with *a* representing the designated molar absorptivity.

Methyl Cinnamate—The solubility plot for methyl cinnamate (Fig. 5) is qualitatively similar to that of benzalacetone. The solid phase analysis again gave evidence of a 1:2 complex ($10^2 L_t$ and x_L): 2.00, 0.17; 4.01, 0.56; 4.90, 0.60; 6.01, 0.62; 6.80, 0.66; and 10.1, 0.67. Treatment of the initial rising portion in terms of SL and SL_2 complexes gives $K_{11} = 1200\ M^{-1}$ and $K_{12} = 50\ M^{-1}$.

The kinetic method used to study this system is based on the inhibitory effect of cyclodextrin on the rate of alkaline hydrolysis of methyl cinnamate. Scheme I shows the assumed kinetics.

$$S + OH^- \xrightarrow{k_S} \text{products}$$

$$SL + OH^- \xrightarrow{k_{11}} \text{products}$$

$$SL_2 + OH^- \xrightarrow{k_{12}} \text{products}$$

Scheme I

The following equations then are readily derived, as was shown previously (6, 7):

$$L_t = [L] + \frac{S_t(K_{11}[L] + 2K_{11}K_{12}[L]^2)}{1 + K_{11}[L] + K_{11}K_{12}[L]^2} \qquad \text{(Eq. 3)}$$

$$\frac{k_S - k'_S}{k_S} = \frac{q_{11}K_{11}[L] + q_{12}K_{11}K_{12}[L]^2}{1 + K_{11}[L] + K_{11}K_{12}[L]^2} \qquad \text{(Eq. 4)}$$

where L_t is the total ligand concentration, [L] is the free (uncomplexed) ligand concentration, k'_S is the apparent second-order rate constant in the presence of ligand, $q_{11} = 1 - k_{11}/k_S$, and $q_{12} = 1 - k_{12}/k_S$. It is not practical to obtain an expression for k'_S as an explicit function of L_t, so a curve-fitting procedure is used. Figure 6 shows the kinetic data; the smooth line was calculated with Eqs. 3 and 4, taking $K_{11} = 1200\ M^{-1}$ and $K_{12} = 50\ M^{-1}$ (from the solubility study) and treating q_{11} and q_{12} as adjustable parameters. The method is used to assign reasonable values to [L] and to calculate corresponding values for L_t and k'_S for comparison with the experimental results. The line in Fig. 6 was obtained using $q_{11} = 0.75$ and $q_{12} = 0.86$.

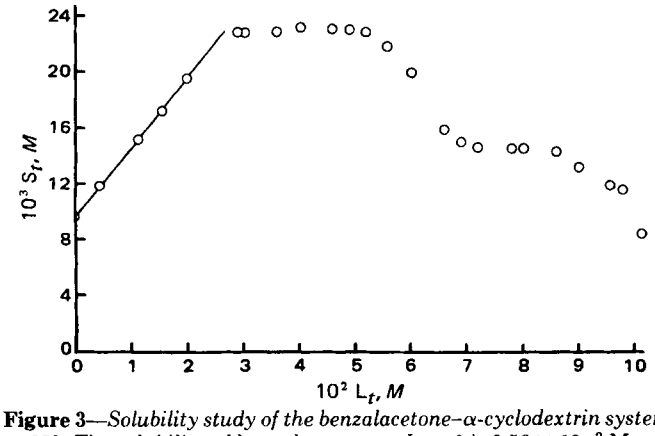

Figure 3—*Solubility study of the benzalacetone–α-cyclodextrin system at 25°. The solubility of benzalacetone at $L_t = 0$ is 9.56×10^{-3} M.*

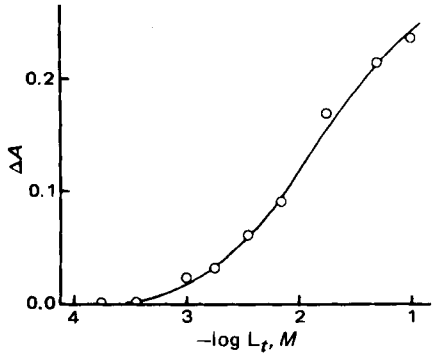

Figure 4—*Change in absorbance at 291 nm in the benzalacetone–α-cyclodextrin system with a path length of 1 cm, a total substrate concentration of 4.39×10^{-5} M, and a pH of 2.3.*

DISCUSSION

Complex Stoichiometry and Stability—Each substrate was investigated by two experimental techniques because such comparative studies have been effective in elucidating stoichiometric relationships (1, 7). The important pieces of information are the isosbestic point behavior, the solid phase compositions, and the quantitative consistency between the two methods. The essential conclusion is that solutions of α-cyclodextrin with 3,5-dimethoxycinnamic acid can be described fully in terms of 1:1 complex formation whereas the benzalacetone and methyl cinnamate systems require 1:1 and 1:2 stoichiometries for their description.

The shapes of the solubility curves for benzalacetone and methyl cinnamate have not been explained fully. In systems containing 1:1 and 1:2 complexes, there are several possibilities for solubility behavior: (*a*) the solubility of SL will be reached first, (*b*) the solubility of SL_2 will be reached first, (*c*) the solubilities of SL and SL_2 will be reached essentially simultaneously, and (*d*) SL and SL_2 will form solid solutions. Case *a* is observed with cinnamic acid and apparently does not apply here (1). Cases *b* and *c* both require, as argued previously (6), that $x_L = 0.67$ at the point terminating the plateau; hence, these cases do not account for the solid phase analyses. The formation of a solid solution from solid SL and SL_2 does not seem unlikely if these are inclusion complexes; X-ray evidence for solid cyclodextrin complexes with channel-like structures was reported (8, 9). This reaction decreases the number of solid phases by one; then upon depletion of solid S, only one solid phase remains (the solid solution), and the constraint on S_t is removed.

The q_{11} and q_{12} values obtained from the kinetic analysis may be interpreted as the fractional decrease in reactivity of the complexed substrate relative to the uncomplexed substrate. If the system actually contains two isomeric 1:1 complexes, then q_{11} is a weighted average of the corresponding quantities for the individual complexes (7). It is quite possible for one of these quantities to be positive ($k_{11} < k_S$) while the other is negative ($k_{11} > k_S$). The value of q_{12} seems somewhat low

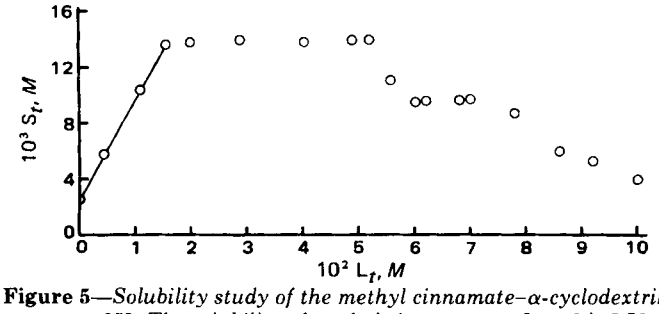

Figure 5—*Solubility study of the methyl cinnamate–α-cyclodextrin system at 25°. The solubility of methyl cinnamate at $L_t = 0$ is 2.50×10^{-3} M.*

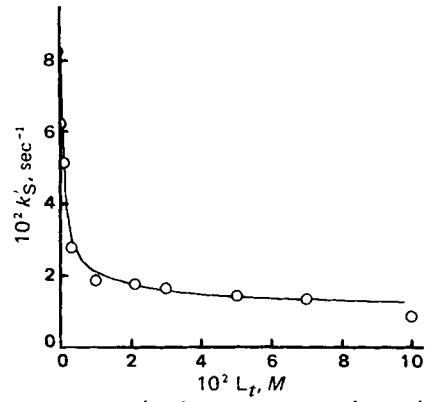

Figure 6—*Apparent second-order rate constants for methyl cinnamate hydrolysis as a function of the α-cyclodextrin concentration; the rate constant at* $L_t = 0$ *was* 8.33×10^{-2} M^{-1} sec^{-1}.

(complete inhibition, $q_{12} = 1$, is anticipated for the fully included substrate); however, as Fig. 6 shows, considerable uncertainty (at least 10%) may be associated with this value because of imprecision in the rate data. Table I summarizes the stability constant findings for these substrates.

Stoichiometric Model of Complexing—As a framework for describing and explaining complex stoichiometry and stability in these systems, the following argument may be useful. Let h-H represent the cyclodextrin (host) molecule, the lower and upper case letters indicating that the two ends of the cavity are structurally different, and let g-G represent a linear nonsymmetrical substrate (guest) molecule. Then all possible 1:1 inclusion complexes may be represented as follows, where it is assumed that, within each orientation, the energy distribution of positional isomers is narrow so that only a single complex need be considered:

1:1 complexes	symbol
g-G h-H	gH
g-G H-h	gh
G-g h-H	GH
G-g H-h	Gh

It also is possible, in principle, to form 2:1 and 1:2 inclusion complexes:

2:1 complexes	symbol
g-G G-g H-h	HGGh
g-G g-G H-h	HGgh
G-g g-G H-h	Hggh
G-g G-g H-h	HgGh

1:2 complexes	symbol
g-G h-H h-H	gHhG
g-G H-h h-H	ghhG
G-g h-H H-h	GHHg
G-g H-h H-h	GhHg

Now suppose that, for the systems being considered, no 2:1 complexes exist. In the present study, there was no necessity to invoke S_2L complexes, and there appears to be no literature report of S_2L complexes with α-cyclodextrin. Then it is reasonable to infer that the guest molecule can enter only one end of the host. As a consequence of this inference, there can be only two 1:1 complexes and only one 1:2 complex. For example, suppose only the H end of the host can be entered. In this case, the only possible complexes are gH, GH, and GHHg. The model thus has led, for this experimental case, to a great simplification of the stoichiometric possibilities. Other special cases of the general model can be described but are not required in this treatment.

Table I—Stability Constants for α-Cyclodextrin Complexes at 25°

Substrate	K_{11}, M^{-1}	K_{12}, M^{-1}
Cinnamic acid[a]	2260	60
Cinnamate ion[a]	110	15
3,5-Dimethoxycinnamic acid	1965	0
Benzalacetone	105	15
Methyl cinnamate	1200	50

[a] From Ref. 1.

It is known (7) that the observed K_{11} value obtained from any experimental technique is the sum of the stability constants for all isomeric 1:1 complexes; hence, for the case being considered:

$$K_{11} = K_{gH} + K_{GH} \qquad \text{(Eq. 5)}$$

To carry the analysis further, the assumption is made that the 1:2 complex is formed by adding a host molecule to a 1:1 complex without perturbing the structure (or energy) of the 1:1 complex. The 1:2 complex can be formed *via* the gH route (Scheme II) or the GH route (Scheme III).

$$gH + h\text{-}H \overset{K'}{\rightleftharpoons} GHHg$$

Scheme II

$$GH + h\text{-}H \overset{K''}{\rightleftharpoons} GHHg$$

Scheme III

The observed stability constant for 1:2 complex formation therefore is given by:

$$K_{12} = \frac{[GHHg]}{([gH] + [GH])[h\text{-}H]} \qquad \text{(Eq. 6)}$$

which becomes:

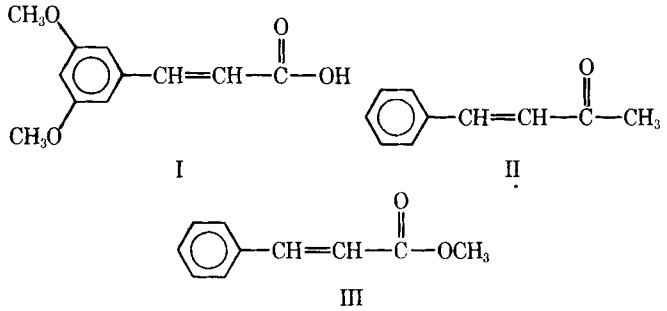
$$K_{12} = \frac{K'K''}{K' + K''} \qquad \text{(Eq. 7)}$$

The assumption that addition of the second host molecule does not perturb the preformed 1:1 complex structure is equivalent to assuming $K' = K_{GH}$ and $K'' = K_{gH}$; thus:

$$K_{12} = \frac{K_{gH}K_{GH}}{K_{gH} + K_{GH}} \qquad \text{(Eq. 8)}$$

With Eqs. 5 and 8, K_{gH} and K_{GH} can be evaluated[5].

Table II lists K_{gH} and K_{GH} values for the substrates of Table I. The assignment of symbols is arbitrary. Because of the structural likenesses among the members of this series of substrates, it seems reasonable to attribute all larger values to one mode (K_{GH}) and the smaller constants to the other (K_{gH}).



Interpretation of the data for these substrates (I–III) in terms of the model suggests that the two isomeric 1:1 complexes are formed by inclusion of either the side chain or the phenyl ring in the cyclodextrin cavity. Molecular models indicate that the disubstituted phenyl ring of I cannot penetrate the ligand cavity; hence, the stoichiometric model predicts that one of the isomeric 1:1 constants will be zero and, therefore, that $K_{12} = 0$. This behavior is observed; therefore, the assignments in Table II signify that K_{GH} describes binding of the side chain whereas K_{gH} describes binding of the phenyl ring. A further prediction is that K_{GH} for I should be very similar to that for cinnamic acid, as is seen.

[5] Equation 8 can be written as $1/K_{12} = 1/K_{gH} + 1/K_{GH}$; *i.e.*, the 1:2 dissociation constant is equal to the sum of the 1:1 dissociation constants.

Table II—Calculated Isomeric 1:1 Stability Constants [a]

Substrate	K_{GH}, M^{-1}	K_{gH}, M^{-1}
Cinnamic acid	2199	61.5
Cinnamate ion	92.1	17.9
3,5-Dimethoxycinnamic acid	1965	0
Benzalacetone	86.9	18.1
Methyl cinnamate	1148	52.3

[a] Calculated with Eqs. 5 and 8 from the data in Table I.

All substrates in Table II other than I evidently offer the possibility of binding at both sites, so significant values of both K_{11} and K_{12} are anticipated and observed. Since the model has no provision for substituent effects, it does not provide quantitative predictions for these substrates. The advantages of the model are in transforming a potentially very complicated system into a fairly simple one on the basis of experimental observation and reasonable approximations and in providing qualitative stoichiometric predictive ability and a means for deriving quantitative estimates of isomeric stability constants when certain assumptions are met.

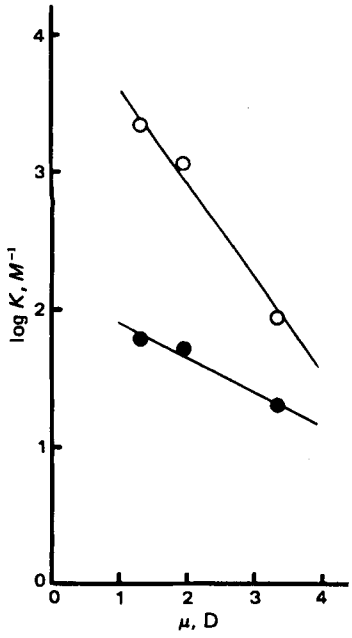


Figure 7—*Plot of log* K_{GH} (○) *and log* K_{gH} (●) *against the substrate dipole moment for II (μ = 3.34 D), III (μ = 1.95 D), and cinnamic acid (μ = 1.31 D). Dipole moments are from Ref. 10. The lines have no theoretical significance.*

Dipole Moment Correlation—The stability constants for the substrates in Table II, particularly K_{GH}, vary more than might be expected based on the apparent structural similarity of these compounds. The behavior of benzalacetone, in particular, seems anomalous. However, the constants in Table II for II, III, and cinnamic acid correlate well with the substrate dipole moment, as shown in Fig. 7; the larger the dipole moment, the smaller is the stability constant. This behavior is consistent with the view that the interior of the cyclodextrin cavity is less polar than the surrounding aqueous medium; hence, the more polar the substrate, the less is its tendency to partition into the ligand cavity.

The relative slopes of the plots for K_{GH} and K_{gH} in Fig. 7 substantiate the structural assignments of these quantities, the more sensitive quantity (K_{GH}) representing the side chain upon which the structural change is made and, therefore, responding more to the change than does K_{gH}, which describes binding far removed from the structural alteration. That the constant assigned to the side chain, which is the more polar end of the substrate molecule, is larger than that for the phenyl ring may seem inconsistent, but the comparison overlooks other factors, particularly the sizes of these two binding sites.

The cinnamate-ion system is qualitatively consistent with this interpretation. The essentially identical stability constants for cinnamate and benzalacetone suggest that a methyl ketone may be a good model for the polarity of a carboxylate ion.

Rate and Pattern of Gastric Emptying in Humans Using ^{99m}Tc-Labeled Triethylenetetraamine–Polystyrene Resin

MICHAEL C. THEODORAKIS *x, GEORGE A. DIGENIS ‡, ROBERT M. BEIHN ‡, MANVENDRA B. SHAMBHU ‡, and FRANK H. DeLAND ‡

Received September 17, 1979, from the **Department of Veterinary Biosciences, Division of Nuclear Medicine, College of Veterinary Medicine, University of Illinois at Urbana–Champaign, Urbana, IL 61801,* and the ‡*Divisions of Medicinal Chemistry and Nuclear Medicine, Colleges of Pharmacy and Medicine, University of Kentucky, Lexington, KY 40506.* Accepted for publication December 26, 1979.

Abstract □ The preparation and application of a new radiopharmaceutical used in the investigation of the rate and pattern of gastric emptying by external scintigraphy are described. Triethylenetetraamine was bound covalently to cross-linked chloromethylated polystyrene. The triethylenetetraamine–polystyrene resin tenaciously and rapidly bound technetium 99*m*. The gastric emptying rate was evaluated in normal adult volunteers and patients by serially recording the gastric radioactivity after ingestion of a test meal mixed with ^{99m}Tc-labeled triethylenetetraamine–polystyrene resin. The data indicated that ^{99m}Tc-labeled triethylenetetraamine–polystyrene resin was an ideal agent for assessing the rate and pattern of gastric emptying in humans. The gastric emptying half-time ($t_{1/2}$GE) in normal subjects ranged from 25 to 75 min.

Keyphrases □ Radiopharmaceuticals—^{99m}Tc-labeled triethylenetetraamine–polystyrene resin, determination of gastric emptying rate and pattern, humans □ GI motility—determination of gastric emptying rate and pattern, radionuclide imaging, humans □ Triethylenetetraamine–polystyrene resin, ^{99m}Tc-labeled—determination of gastric emptying rate and pattern, humans

The introduction of γ-emitting short-lived radionuclides and the development of the scintillation camera connected to a fast-acquisition digital data processor, multimode analyzer, and videotape recorder permit the noninvasive investigation of the rate and pattern of gastric emptying by external scintigraphy. Quantitative dynamic data and excellent scintigraphic images of the stomach, intestines, and colon can be obtained without physical or physiological influences on the GI tract.

BACKGROUND

In several clinical situations, detailed information about abnormalities in the pattern and rate of gastric emptying would be helpful. Such abnormalities already are recognized as being concomitant with certain diseases. For instance, hypermotility has been associated with duodenal ulcers, while diminished gastric peristalsis has been associated with gastric ulcers (1, 2). Furthermore, delayed gastric emptying has been observed in malignant diseases of the stomach and in pyloric stenosis (3, 4).

Measurement of gastric emptying is not only an important aid to the clinician studying gastroduodenal disease, dumping syndrome, and postvagotomy disturbances but also is a major determinant in the absorption rate of drugs. Individual variations in the drug absorption rate from any dosage form may be due largely to differences in the rate of gastric emptying (5, 6).

Since sodium [^{51}Cr]chromate and a rectilinear scanner first were used to measure the gastric emptying rate (7), several other radiopharmaceutical preparations have been used for the same purpose, including: ^{113m}In- and ^{99m}Tc-labeled diethylenetriaminepentaacetic acid (8, 9), a ^{113m}In-labeled microcolloid (10), a ^{99m}Tc-labeled colloid of antimony sulfide (11), ^{99m}Tc-labeled human albumin microspheres (12), cesium 129 adsorbed onto a suspension of zirconium phosphate (13), and their combinations (8, 13).

The disadvantages of these radiopharmaceutical preparations are well known. For instance, ^{113m}In- and ^{99m}Tc-labeled diethylenetriaminepentaacetic acid are water soluble and remain in the liquid phase of the gastric content, which is discharged through the pylorus more rapidly than the solid phase, and thus lower half-time values of gastric emptying result. Colloidal preparations are difficult to prepare, and their physicochemical properties offer disadvantages such as the formation of micelles and coagulation. The adsorption or absorption of the radiopharmaceutical by the stomach walls also provides an opportunity for error.

The recently introduced radiopharmaceutical ^{99m}Tc-labeled triethylenetetraamine–polystyrene resin (I) (14, 15) is free of these shortcomings and approximates the characteristics of an ideal radiopharmaceutical for assessing the rate and pattern of gastric emptying. These characteristics are: (*a*) not to influence the osmolality of the stomach content, (*b*) to be nonabsorbable and nonadsorbable, (*c*) to bind the radionuclide tenaciously and not to exchange it with food particles or the stomach wall, (*d*) to possess ideal food-mixing characteristics and have a particle size comparable to that of foods, and (*e*) to be nontoxic and inert and give reproducible and noninvasive estimates of the gastric emptying time without exposing the patient to a high radiation dose.

EXPERIMENTAL

Preparation of Popcorn Polystyrene—The polymer was prepared according to the procedure described by Letsinger *et al.* (16). It was washed three times with chloroform, dried, and broken down in a blender.

Preparation of Chloromethylated Polystyrene—Popcorn polystyrene (70 g, 40–100 mesh) was allowed to swell in 550 ml of chloroform for 1 hr. A mixture of 100 ml of chloromethyl methyl ether and 40 ml of stannic chloride was added to the polystyrene, and the contents were stirred at 25° for 2 hr. After filtration, the resin was washed with chloroform, dioxane, dioxane–water, water, and acetone. The product was dried at 60° under vacuum for 24 hr, yielding 86 g.

Anal.—Calc. for chloromethyl groups on 50% of the resin rings: Cl, 13.4%. Found: Cl, 13.3%.

Preparation of Triethylenetetraamine–Polystyrene Resin (I)—Chloromethylated polystyrene (10 g) was added to 30 ml of pyridine. After 30 min, a 10-fold excess of the amine was added; the mixture was maintained at 95° in an oil bath under a calcium chloride drying tube. The resin was recovered by filtration and washed with pyridine, water, and methanol. It was dried at 60° under vacuum.

Anal.—Calc. for: N, 14.87; Cl, 0.0. Found: N, 9; Cl, 0.08.

Uptake of Sodium [^{99m}Tc]Pertechnetate by Triethylenetetraamine–Polystyrene Resin—Triethylenetetraamine–polystyrene resin (0.20 g), with a bead size ranging between 0.16 and 0.4 mm, was placed in a 150-ml beaker, and 50 ml of double-distilled water was added. The pH was adjusted to a predetermined value with 0.1 *N* HCl. A 50-ml aliquot of sodium [^{99m}Tc]pertechnetate (52 μCi) in distilled water was added. The mixture was stirred magnetically, and the pH was kept constant and monitored by a pH meter[1]. The temperature was maintained at 23–25°. At the appropriate time intervals, 1-ml samples were withdrawn and counted by a γ-ray well counter[2].

Preparation of ^{99m}Tc-Labeled Triethylenetetraamine–Polystyrene Resin—Triethylenetetraamine–polystyrene resin (0.25 g, 40–100 mesh) was placed in a 50-ml beaker with 20 ml of distilled water and stirred for 1 min. A solution of sodium pertechnetate[3] (20 μCi–1 mCi) was added. The mixture was stirred for 10 min, and the labeled resin was

recovered by filtration. The resin was washed with two 50-ml aliquots of distilled water and subsequently was counted to determine the specific activity.

Stability of ^{99m}Tc-Labeled Triethylenetetraamine–Polystyrene Resin in Simulated Gastric Juice—The ^{99m}Tc-labeled triethylenetetraamine–polystyrene resin (0.4 g, 2 μCi/g) was introduced in a beaker containing 50 ml of simulated gastric juice[4] (pH 1.4). The mixture was stirred magnetically, and the temperature was maintained at 25°. Samples of 0.5 ml were withdrawn at predetermined time intervals.

Human Testing—To evaluate the new radiodiagnostic agent, 20 adult male and female hospital patients were studied. Normal subjects who had never undergone GI tract surgery and subjects who had had surgery of the upper GI tract participated in the study. None of the subjects was treated with anticholinergic drugs prior to or during the study. No special preparation of the subject was needed. Two reference points were drawn on the abdominal skin of the subject and on the oscilloscope by the radioactive marker, cobalt 57, to ensure reproducibility of the position of the subject relative to the camera.

The ^{99m}Tc-labeled triethylenetetraamine–polystyrene resin was mixed with a test meal consisting of 33.3 g of cream of wheat and 2.4 g of sodium chloride in 235 ml of water. After the subject ingested the labeled test meal, the time was recorded and the subject was placed under the γ-camera[5,6] in the supine position. The positions of the γ-camera and the subject were adjusted so that the entire stomach appeared in the center of the monitoring oscilloscope. Several scintiphotographs of the stomach were obtained at certain time intervals.

In each time interval, four to nine points were collected. Each point represented the integrated relative radioactivity per minute of the desired flagged area of the stomach. The data were stored on a magnetic tape for future reference. The logarithm of the relative radioactivity of the stomach was plotted against time. From the slope of the graph, the half-time of the gastric emptying ($t_{1/2}$GE) of the test meal and the ^{99m}Tc-labeled triethylenetetraamine–polystyrene resin beads was determined. A whole-body survey at the end of each study failed to show any detectable activity outside of the GI tract.

RESULTS

Popcorn polystyrene, an opaque, low-density polymer, was prepared by copolymerization of styrene and divinylbenzene (99.8:0.2) according to a literature procedure (16). The particle size was reduced after a chloroform wash, and 40–100-mesh beads were used.

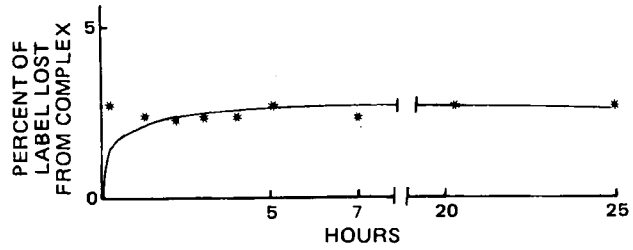

Figure 2—*Percent of radioactivity lost from ^{99m}Tc-labeled triethylenetetraamine–polystyrene in simulated gastric juice (pH 1.4).*

Introduction of chloromethyl functions into the insoluble polymer was carried out by reaction with chloromethyl methyl ether in the presence of anhydrous stannic chloride. The degree of chloromethylation of popcorn polystyrene was controlled by the amounts of stannic chloride and chloromethyl methyl ether and the reaction time. Chloromethyl groups were introduced in 50% of the polystyrene rings, producing a resin with 3.6 mEq of chloride/g.

Attachment of triethylenetetraamine was performed by swelling of the chloromethylated resin beads (40–100 mesh) in pyridine, followed by treatment with a 10-fold excess of triethylenetetraamine at 95°. Elemental analysis for nitrogen and chlorine indicated that triethylenetetraamine was bound to polystyrene by more than one attachment (17).

Triethylenetetraamine–polystyrene resin beads (40–100 mesh) efficiently and quantitatively bound the [^{99m}Tc]pertechnetate anions from aqueous solutions of ~10^{-9} *M* sodium [^{99m}Tc]pertechnetate. The anion uptake at three pH values (1.4, 4.0, and 6.0) was complete in 10 min (Fig. 1). When the popcorn polystyrene and chloromethylated polystyrene resins were used, the uptake of pertechnetate anions was 8.4 and 8.6%, respectively, after 60 min.

The ^{99m}Tc-labeled resin was stable in simulated gastric juice, releasing only 2.0% of the radioactivity in 25 hr at 37° (Fig. 2). The results of experiments in humans showed that <0.2% of the ingested radioactivity appeared in the blood and urine during the passage of the resin throughout the entire GI tract. A whole-body survey at the end of each study failed to show any detectable activity outside of the GI tract.

Twenty healthy adult volunteers were studied to establish a normal range of the gastric emptying rate (Table I). Invariably, the subjects exhibited a monoexponential pattern of gastric emptying. A typical curve is shown in Fig. 3. The ordinate represents the logarithm of relative radioactivity (expressed as counts per minute) and the abscissa denotes the time (minutes). The relative radioactivity was determined by selecting, with an electronic cursor, a region of interest over the whole gastric area excluding the pylorus and intestines. The slope of the curve was equal to $-\lambda\text{eff}/2.303$.

The observed constant, λeff, was equal to the sum of the technetium 99*m* decay constant, λ, and the rate constant of gastric emptying, λGE, where $\lambda\text{eff} = 0.693/t_{1/2}\text{eff}$, $\lambda = 0.693/t_{1/2}$, and $\lambda\text{GE} = 0.693/t_{1/2}\text{GE}$. The half-time of gastric emptying, $t_{1/2}$GE, was calculated from the following equation: $t_{1/2}\text{eff} = (t_{1/2}t_{1/2}\text{GE})/(t_{1/2} + t_{1/2}\text{GE})$. With this technique, the $t_{1/2}$GE for normal individuals ranged from 25 to 75 min (Table I). This

range was in agreement with results obtained using other radiopharmaceuticals (11). The $t_{1/2}$eff was not affected by the duodenal or jejunal overlap with the stomach (9). The gradual movement of radioactivity from the stomach through the pylorus into the intestines was indicated by a series of sequential scintigraphic images (Fig. 4). The entire stomach and the intestines were visualized. The absorbed radiation dose by the stomach was 102 mrads/250 μCi.

A second group of three individuals suffering from various disorders of the GI tract was used to demonstrate the difference in gastric emptying rates between normals and patients. Two patients suffering from pyloric stenosis exhibited a monoexponential pattern of gastric emptying with half-times of 115 and 136 min, respectively. A third patient with a 70% gastric resection and gastrojejunostomy exhibited a gastric emptying pattern consisting of two components: a component with a high rate of decrease, $t_{1/2}$GE = 5 min, representing dumping, and a component with a low rate of decrease, $t_{1/2}$GE = 91 min (Fig. 5).

DISCUSSION

The purpose of this study was to demonstrate the suitability of ^{99m}Tc-labeled triethylenetetraamine–polystyrene resin as an agent for investigating the pattern and rate of gastric emptying in humans. This study ascertained that the ^{99m}Tc-labeled resin was an ideal agent for measuring the gastric emptying rate of a solid meal in normal subjects and patients. The agent fulfilled the criteria of an ideal agent. It tenaciously bound [^{99m}Tc]pertechnetate anions; it was not absorbed or adsorbed on the gastric mucosa; the polystyrene beads had a particle size comparable to that of solid food and mixed homogeneously with the solid phase of the gastric content; it was nontoxic; it was an easily prepared radiopharmaceutical with the ideal radiation characteristics of technetium 99*m*; and, finally, the technique was noninvasive and comfortable to the patient. The use of the γ-camera coupled with a fast data-acquisition device allowed rapid and convenient observation of second-by-second alterations in the pattern and rate of gastric emptying.

Two fundamental assumptions were made in using this technique: the stomach was presumed to remain in the same position and retain the same shape throughout the study, and no correction was made for changes of depth of the radioisotope below the abdominal wall. The error that was

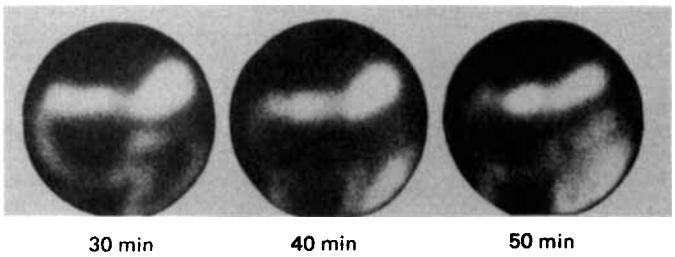

Figure 4—*Anterior scintigraphic series at 10-min intervals illustrating the gastric elimination and bowel distribution of the ^{99m}Tc-labeled triethylenetetraamine–polystyrene resin, $t_{1/2}GE$ = 36 min.*

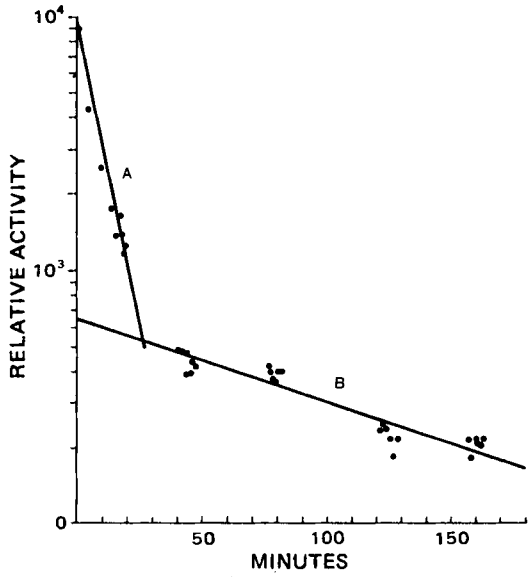

Figure 5—*Clearance rate of ^{99m}Tc-labeled triethylenetetraamine–polystyrene from the stomach of a male patient with Billroth II. Key: A, $t_{1/2}GE$ = 5 min; and B, $t_{1/2}GE$ = 99 min.*

introduced by these assumptions was minimal (13). Another source of error was the variations in tissue absorption of the γ-rays and the overlap of the duodenal–jejunal flexure with the gastric antrum, which tended to increase the count when, at the time of reading, the labeled gastric contents went through the duodenum or jejunum. However, this error did not change the slope of the linear logarithmic equation that described the gastric emptying process (3).

This study demonstrated that the gastric emptying of the solid phase of the ^{99m}Tc-labeled triethylenetetraamine–polystyrene gastric content can be described by a monoexponential function, at least for the first 120 min for normal subjects and patients suffering from pyloric stenosis. Moreover, it was shown that GI surgery, such as gastrojejunostomy, may drastically change the pattern and rate of gastric emptying (Fig. 5). Since the gastric emptying rate was affected by various factors, the position of the patient, the test meal, the position of camera, and the administered radioactivity dose were kept as constant as possible.

The use of ^{99m}Tc-labeled triethylenetetraamine–polystyrene in combination with a scintillation camera is a better technique than the isotopic and nonisotopic techniques that have been used for the investigation of the pattern and rates of gastric emptying of the solid phase of the gastric content. The disadvantages of the previous techniques and agents were discussed extensively elsewhere (9). Clinicians may use this technique to study GI diseases such as gastric and duodenal ulcers, gastric neoplasms, pyloric stenosis, dumping syndrome, and postsurgical status of gastrectomy, gastrojejunostomy, vagotomy, and pyloroplasty.

Preliminary Evaluation of Furosemide–Probenecid Interaction in Humans

DAVID E. SMITH *, WINNIE LIANG GEE *, D. CRAIG BRATER ‡§, EMIL T. LIN *, and LESLIE Z. BENET *x

Received October 5, 1979, from the **Department of Pharmacy, School of Pharmacy, and the* ‡*Division of Clinical Pharmacology, School of Medicine, University of California, San Francisco, CA 94143.* Accepted for publication December 28, 1979. §Present address: Department of Pharmacology, Division of Clinical Pharmacology, University of Texas Health Science Center at Dallas, Southwestern Medical School, Dallas, TX 75235.

Abstract □ The pharmacokinetics and pharmacodynamics of intravenous furosemide, 40 mg, were studied in four healthy male subjects in a crossover fashion with and without probenecid pretreatment. In each study, 16 plasma and 10 urine samples were collected over 24 hr. Fluid and electrolyte urinary losses were replaced orally throughout the study. Unchanged furosemide and probenecid were measured using high-pressure liquid chromatography; urinary sodium was measured by flame photometry. Although probenecid caused marked changes in the pharmacokinetic parameters of furosemide (increased area under the curve, decreased plasma and renal clearance, increased half-life, and decreased fraction excreted unchanged in the urine), there was no significant difference in its gross 8-hr natriuretic and diuretic effect. However, analysis of the time course of natriuresis showed a pattern similar to that of the urinary furosemide excretion rate, whereas the plasma concentration was poorly correlated over the entire dose–response curve.

Keyphrases □ Furosemide—pharmacokinetics and pharmacodynamics with and without probenecid pretreatment, humans □ Probenecid—pharmacokinetics and pharmacodynamics of furosemide with and without probenecid pretreatment, humans □ Drug–drug interactions—pharmacokinetics and pharmacodynamics of furosemide with and without probenecid pretreatment, humans □ Pharmacokinetics—furosemide with and without probenecid pretreatment, humans

Furosemide is an anthranilic acid derivative used to treat edematous states of hepatic, cardiac, and renal origin (1–3). It is believed to act at the luminal surface of the nephron where it inhibits the active reabsorption of chloride in the ascending limb of the loop of Henle (4–7). Since furosemide is highly protein bound (8, 9), access to the lumen occurs primarily through active secretion *via* the nonspecific organic acid secretory pathway (5, 6, 10). Thus, any drug or chemical substance that competes for this pathway could prevent furosemide from reaching its site of action and thereby attenuate its diuretic response.

Probenecid is a weak organic acid that competes with furosemide for active secretion into the kidney lumen. This competition can prevent furosemide from achieving an adequate cellular or luminal concentration and thereby diminish its natriuretic and diuretic response. Previous studies in experimental animals supported this hypothesis and showed that probenecid can decrease the natriuretic action of furosemide (10, 11). Studies in humans evaluating the effect of probenecid on the pharmacokinetics and pharmacodynamics of furosemide are limited and less clear (12–14).

The present investigation was undertaken to clarify the mechanism by which probenecid alters the diuretic response of furosemide. An additional objective was to define, in humans, a relationship between the dose of furosemide, its concentration or amount in a measurable sampling compartment, and its diuretic effect.

EXPERIMENTAL

Materials and Methods—Four males, 21–33 years and 65–77 kg, participated as outpatients in this study. Each subject had a normal medical history, physical examination, and standard laboratory tests. Each subject received 40 mg of furosemide alone and after pretreatment with probenecid. An interval of at least 1 week elapsed between studies. Subjects fasted the night before and until at least 2 hr after administration of the diuretic. Identical lot numbers for each drug were used throughout the study.

Furosemide was administered intravenously over ~3 min, with the midpoint of the infusion considered as time zero. Probenecid (1 g) was ingested at bedtime the night before and on arising the morning of the study (30–60 min prior to furosemide administration). Blood samples (3 ml) to determine the drug concentration were obtained with an indwelling heparinized scalp vein needle at 0, 5, 10, 20, 30, 45, 60, 80, 100, 120, 180, 240, 300, 360, and 480 min and ~24 hr.

Voided urine was collected at 0, 0.5, 1.0, 1.5, 2.0, 3.0, 4.0, 5.0, 6.0, 8.0, and 24 hr and at two times of spontaneous voiding at home between the 8- and 24-hr collections. After each voiding, subjects drank a volume of balanced electrolyte solution flavored with fruit syrup equal to their urinary volume to avoid dehydration and electrolyte depletion.

All 24-hr blood samples showed normal electrolytes, urea nitrogen, and creatinine. Sodium concentrations were measured with a flame photometer[1]. Statistical differences were determined using a paired t test.

Plasma samples of furosemide, with and without probenecid pretreatment, were analyzed using a rapid, sensitive, and specific high-pressure liquid chromatographic[2] (HPLC) assay developed in this laboratory (15). Samples were run on a μBondapak C_{18} reversed-phase column[3] (30 cm × 3.9 mm i.d.) using dual-channel UV detection[4] (0.01 aufs). A 20-μl aliquot containing the internal standard, phenobarbital sodium (0.25 mg/ml), was added to 0.20-ml plasma furosemide samples. The mixture was vortexed, and 0.40 ml of acetonitrile was added. The mixture was vortexed again and then centrifuged for 10 min. The supernate was transferred to a clean test tube and evaporated under nitrogen gas until ~0.15 ml of the solution remained. A solvent system of 25% acetonitrile in 0.01 *M* acetic acid, adjusted to pH 5.0 with sodium hydroxide, was employed to measure furosemide at 280 nm and pheno-

Received October 5, 1979, from the **Department of Pharmacy, School of Pharmacy, and the* ‡*Division of Clinical Pharmacology, School of Medicine, University of California, San Francisco, CA 94143.* Accepted for publication December 28, 1979. §Present address: Department of Pharmacology, Division of Clinical Pharmacology, University of Texas Health Science Center at Dallas, Southwestern Medical School, Dallas, TX 75235.

Abstract □ The pharmacokinetics and pharmacodynamics of intravenous furosemide, 40 mg, were studied in four healthy male subjects in a crossover fashion with and without probenecid pretreatment. In each study, 16 plasma and 10 urine samples were collected over 24 hr. Fluid and electrolyte urinary losses were replaced orally throughout the study. Unchanged furosemide and probenecid were measured using high-pressure liquid chromatography; urinary sodium was measured by flame photometry. Although probenecid caused marked changes in the pharmacokinetic parameters of furosemide (increased area under the curve, decreased plasma and renal clearance, increased half-life, and decreased fraction excreted unchanged in the urine), there was no significant difference in its gross 8-hr natriuretic and diuretic effect. However, analysis of the time course of natriuresis showed a pattern similar to that of the urinary furosemide excretion rate, whereas the plasma concentration was poorly correlated over the entire dose–response curve.

Keyphrases □ Furosemide—pharmacokinetics and pharmacodynamics with and without probenecid pretreatment, humans □ Probenecid—pharmacokinetics and pharmacodynamics of furosemide with and without probenecid pretreatment, humans □ Drug–drug interactions—pharmacokinetics and pharmacodynamics of furosemide with and without probenecid pretreatment, humans □ Pharmacokinetics—furosemide with and without probenecid pretreatment, humans

Furosemide is an anthranilic acid derivative used to treat edematous states of hepatic, cardiac, and renal origin (1–3). It is believed to act at the luminal surface of the nephron where it inhibits the active reabsorption of chloride in the ascending limb of the loop of Henle (4–7). Since furosemide is highly protein bound (8, 9), access to the lumen occurs primarily through active secretion *via* the nonspecific organic acid secretory pathway (5, 6, 10). Thus, any drug or chemical substance that competes for this pathway could prevent furosemide from reaching its site of action and thereby attenuate its diuretic response.

Probenecid is a weak organic acid that competes with furosemide for active secretion into the kidney lumen. This competition can prevent furosemide from achieving an adequate cellular or luminal concentration and thereby diminish its natriuretic and diuretic response. Previous studies in experimental animals supported this hypothesis and showed that probenecid can decrease the natriuretic action of furosemide (10, 11). Studies in humans evaluating the effect of probenecid on the pharmacokinetics and pharmacodynamics of furosemide are limited and less clear (12–14).

The present investigation was undertaken to clarify the mechanism by which probenecid alters the diuretic response of furosemide. An additional objective was to define, in humans, a relationship between the dose of furosemide, its concentration or amount in a measurable sampling compartment, and its diuretic effect.

EXPERIMENTAL

Materials and Methods—Four males, 21–33 years and 65–77 kg, participated as outpatients in this study. Each subject had a normal medical history, physical examination, and standard laboratory tests. Each subject received 40 mg of furosemide alone and after pretreatment with probenecid. An interval of at least 1 week elapsed between studies. Subjects fasted the night before and until at least 2 hr after administration of the diuretic. Identical lot numbers for each drug were used throughout the study.

Furosemide was administered intravenously over ~3 min, with the midpoint of the infusion considered as time zero. Probenecid (1 g) was ingested at bedtime the night before and on arising the morning of the study (30–60 min prior to furosemide administration). Blood samples (3 ml) to determine the drug concentration were obtained with an indwelling heparinized scalp vein needle at 0, 5, 10, 20, 30, 45, 60, 80, 100, 120, 180, 240, 300, 360, and 480 min and ~24 hr.

Voided urine was collected at 0, 0.5, 1.0, 1.5, 2.0, 3.0, 4.0, 5.0, 6.0, 8.0, and 24 hr and at two times of spontaneous voiding at home between the 8- and 24-hr collections. After each voiding, subjects drank a volume of balanced electrolyte solution flavored with fruit syrup equal to their urinary volume to avoid dehydration and electrolyte depletion.

All 24-hr blood samples showed normal electrolytes, urea nitrogen, and creatinine. Sodium concentrations were measured with a flame photometer[1]. Statistical differences were determined using a paired t test.

Plasma samples of furosemide, with and without probenecid pretreatment, were analyzed using a rapid, sensitive, and specific high-pressure liquid chromatographic[2] (HPLC) assay developed in this laboratory (15). Samples were run on a μBondapak C_{18} reversed-phase column[3] (30 cm × 3.9 mm i.d.) using dual-channel UV detection[4] (0.01 aufs). A 20-μl aliquot containing the internal standard, phenobarbital sodium (0.25 mg/ml), was added to 0.20-ml plasma furosemide samples. The mixture was vortexed, and 0.40 ml of acetonitrile was added. The mixture was vortexed again and then centrifuged for 10 min. The supernate was transferred to a clean test tube and evaporated under nitrogen gas until ~0.15 ml of the solution remained. A solvent system of 25% acetonitrile in 0.01 *M* acetic acid, adjusted to pH 5.0 with sodium hydroxide, was employed to measure furosemide at 280 nm and pheno-

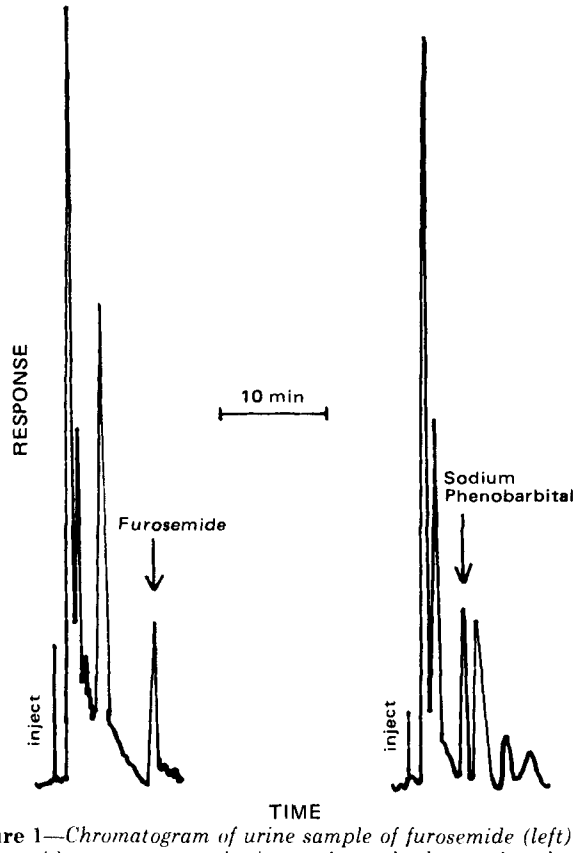

Figure 1—*Chromatogram of urine sample of furosemide (left) with probenecid pretreatment; the internal standard was phenobarbital sodium (right).*

barbital sodium at 254 nm. Urine samples of furosemide administered alone were prepared in a similar fashion, except that the addition of acetonitrile and the evaporation step were omitted.

During the assay of urine furosemide samples obtained following probenecid pretreatment, interfering peaks (possibly from probenecid metabolites) occurred in both the 280- and 254-nm detection channels. Therefore, it was necessary to develop a new assay system to separate the interfering peaks from those of furosemide and the internal standard, phenobarbital sodium. These urine samples were assayed for furosemide by HPLC[5] on a C_{18} reversed-phase column[3] using fluorescence detection[6]. The excitation and emission wavelengths of furosemide were set at 345 and 405 nm, respectively. The photomultiplier gain was set at 4, and the sensitivity range was set at 10. A 20-μl aliquot of the internal standard, phenobarbital sodium (2.5 mg/ml), still was measured by UV detection[7] at 254 nm (0.05 aufs).

With a solvent system of 30% acetonitrile in 0.015 *M* aqueous phosphoric acid solution at a flow rate of 2.0 ml/min, furosemide and phenobarbital sodium had retention times of 9.0 and 5.0 min, respectively (Fig. 1). A typical standard curve of the peak height ratio of furosemide to phenobarbital sodium over the concentration range of 0.82–20.50 μg/ml resulted in a linear least-squares regression equation of $y = 0.205x + 0.008$ ($r^2 = 0.999$). With fluorescent detection, concentrations as low as 8.20 ng/ml were measured.

Plasma samples of probenecid were prepared in a similar fashion to furosemide. A 40-μl aliquot of phenobarbital sodium (4 mg/ml) was used as the internal standard, and the solvent system (30% acetonitrile in 0.01 *M* acetic acid, adjusted to pH 5.0 with sodium hydroxide) had a flow rate of 2.0 ml/min. Both probenecid and phenobarbital sodium were measured using UV detection[7] at 254 nm. Plasma probenecid concentrations were fairly constant during the entire study and ranged from 100 to 165 μg/ml (Fig. 2).

Calculations—The half-life of furosemide, $t_{1/2}$, was determined by linear regression from the terminal portion of the urinary excretion rate *versus* midpoint time plots. The area under the plasma concentration–time curve, *AUC*, was calculated using the trapezoidal rule, extrapolated to infinity from the last measured concentration.

The volume of distribution at steady state, Vd_{ss}, was determined by the compartment-independent method of Benet and Galeazzi (16):

$$Vd_{ss} = \text{dose } (AUMC)/(AUC)^2 \qquad \text{(Eq. 1)}$$

where *AUMC* is the area under the curve of the first moment of the concentration–time curve, *i.e.*, $\int_0^\infty tC_p\,dt$. The total plasma clearance of furosemide, Cl_p, was calculated from:

$$Cl_p = \text{dose}/AUC \qquad \text{(Eq. 2)}$$

The total renal clearance, Cl_r, was estimated from:

$$Cl_r = Ae_\infty/AUC \qquad \text{(Eq. 3)}$$

where the amount of unchanged drug recovered in the urine at time infinity is represented by Ae_∞. The fraction of furosemide excreted unchanged in the urine, f_e, was calculated by dividing Ae_∞ by the intravenous dose. Nonrenal plasma clearance, Cl_{nr}, was calculated as the difference between the plasma and renal clearances. The fraction excreted by nonrenal routes, f_{nr}, was calculated by dividing the nonrenal clearance by the total plasma clearance.

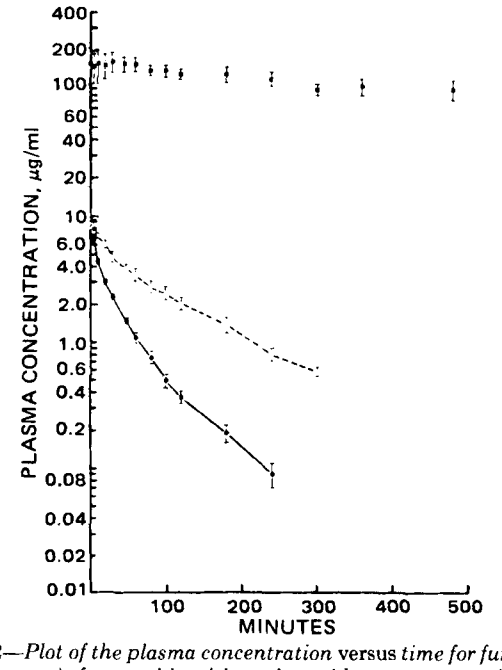

Figure 2—*Plot of the plasma concentration* versus *time for furosemide alone (●——●), furosemide with probenecid pretreatment (○- - -○), and probenecid (■). Data are expressed as the mean ± SEM (n = 4).*

RESULTS

The effects of probenecid on the pharmacokinetics of furosemide were analyzed in both plasma and urine (Table I). Mean plasma concentrations of furosemide with probenecid pretreatment were significantly increased at all time points except at 5 min (Fig. 2). The significant increase in *AUC* supports this observation [252 ± 24 (μg min)/ml for furosemide alone (Treatment I) and 785 ± 87 (μg min)/ml for furosemide with probenecid pretreatment (Treatment II); $p < 0.001$]. In addition, the total plasma clearance of furosemide was decreased significantly in the presence of probenecid (160 ± 15 ml/min for Treatment I and 51.4 ± 5.3 ml/min for Treatment II; $p < 0.001$). This difference in total plasma clearance was reflected by the significant increase in the half-life of furosemide (82 ± 5 min for Treatment I and 175 ± 17 min for Treatment II; $p < 0.001$) since the Vd_{ss} value was not altered significantly (8.44 ± 0.93 liters for Treatment I and 6.66 ± 1.78 liters for Treatment II; $p > 0.20$).

The total renal clearance of furosemide was reduced markedly with probenecid pretreatment (118 ± 17 ml/min for Treatment I and 23.1 ± 1.0 ml/min for Treatment II; $p < 0.002$), while the nonrenal plasma clearance did not change significantly (42 ± 12 ml/min for Treatment I and 28.3 ± 4.9 ml/min for Treatment II; $p > 0.10$). In addition, the fraction of furosemide excreted unchanged in the urine in the presence of probenecid was reduced significantly (0.74 ± 0.07 for Treatment I and 0.46 ± 0.05 for Treatment II; $p < 0.01$) with a corresponding increase in

the fraction excreted by nonrenal routes (0.26 ± 0.07 for Treatment I and 0.55 ± 0.04 for Treatment II; $p < 0.01$).

Analysis of the urinary excretion rate of furosemide, with and without probenecid pretreatment, is shown in Fig. 3. Initially, the urinary excretion rate of furosemide with probenecid was significantly lower than that of furosemide when administered alone. However, after ~125 min, the two curves (Treatments I and II) intersect; at subsequent times, probenecid caused a significant increase in the furosemide excretion rate. This result was primarily due to the large difference in plasma furosemide concentrations at subsequent times between Treatments I and II (Fig. 2) since the renal clearance was reduced but was constant throughout each study.

The effect of probenecid on furosemide-induced natriuresis is shown in Fig. 4. The initial natriuretic response to furosemide when it was given concomitantly with probenecid was reduced compared to that of furosemide administered alone. The two curves (Treatments I and II) intersect at 100 min; at subsequent times, probenecid caused an increase in furosemide-induced natriuresis, similar to that seen for the urinary excretion rate of furosemide. Although differences in the sodium excretion rate were seen with and without probenecid pretreatment, they did not appear to be statistically different. Table II shows that the 8-hr sodium excretion (milliequivalents) was 291 ± 53 for Treatment I and 323 ± 106 for Treatment II ($p > 0.50$). The diuretic response (milliliters per 8 hr) was 2257 ± 422 for Treatment I and 2637 ± 632 for Treatment II ($p > 0.20$).

DISCUSSION

Experiments in animals suggested that the luminal concentration or amount of furosemide rather than its plasma concentration may be the critical determinant with respect to its natriuretic and diuretic effect (10, 11, 17, 18). Hook and Williamson (10) and Friedman and Roch-Ramel (11) demonstrated in the dog and cat, respectively, that probenecid (50 mg/kg iv) significantly inhibited furosemide-induced natriuresis. Since probenecid is highly secreted (19), it can compete for active transport and prevent furosemide from reaching the tubular fluid, thereby attenuating its natriuretic effect. However, human studies (12–14) do not

corroborate these findings in animals. In contrast, probenecid caused either no change or a significant increase in the natriuretic response to furosemide.

The first study of the effect of probenecid on furosemide kinetics and natriuretic response in humans showed that probenecid significantly decreased the total plasma clearance (155 ml/min for Treatment I and 85 ml/min for Treatment II) and the total renal clearance (134 ml/min for Treatment I and 63 ml/min for Treatment II) of furosemide, and significantly increased the furosemide half-life (35.8 min for Treatment I and 60.8 min for Treatment II) (12). However, the 6-hr urine volume (5098 ml for Treatment I and 6164 ml for Treatment II) and the sodium excretion (578 mEq for Treatment I and 694 mEq for Treatment II) were not significantly different between treatments. In addition, the fraction of the dose excreted unchanged in the urine was not statistically altered with probenecid pretreatment, although three of the four subjects studied did excrete a smaller percentage. Therefore, the investigators (12) concluded that their results were consistent with the findings of a previous study (10), which suggested that the amount of furosemide in the tubular fluid is the main determinant of furosemide diuresis. Although we do not disagree with their conclusions, the previous investigators did not fully characterize the mechanism of this interaction between furosemide and probenecid. Since the time course of the natriuretic and diuretic response was not described, the previous investigators were considering only gross effects.

Homeida *et al.* (13) also demonstrated marked changes in furosemide pharmacokinetics with probenecid pretreatment. Similarly, these investigators noted that since the total proportion of unchanged drug reaching the renal tubule was not changed markedly, the total diuretic effect remained unaltered. However, this conclusion is suspect since our calculations of their data show an approximate 41% decrease in the fraction of the furosemide dose excreted unchanged in the urine (from 0.34 to 0.20) when the subjects were pretreated with probenecid. In addition, furosemide was assayed spectrofluorometrically, which is rather nonspecific, especially in urine. This method may account for the unusual values for the total, renal, and nonrenal plasma clearances reported in their control subjects, as suggested by Benet (20).

In a more recent study, the pharmacodynamic effect of probenecid on the response to furosemide in humans was quantified (14). Analysis of the time course of natriuresis and diuresis showed that probenecid actually decreased the response of furosemide for the first 60–90 min but increased the subsequent response sufficiently to result in a statistically greater overall effect. However, it was noted (14) that since the concentrations or amounts of furosemide in the urine were not compared with the response, a unifying hypothesis to explain the mechanism of a furosemide–probenecid interaction was not possible[8].

In the present investigation, the time course of furosemide in plasma and urine was compared with that of the natriuretic effect in an attempt to explain the mechanism for a furosemide–probenecid interaction. Although probenecid caused marked changes in the pharmacokinetic parameters of furosemide (Table I), there was no significant difference in its gross natriuretic and diuretic effect (Table II). Analysis of the time course for natriuresis (Fig. 4) shows that probenecid actually decreased the response for the first 100 min after furosemide administration. However, the subsequent response was increased sufficiently to result in no statistical difference in the mean 8-hr value for sodium excretion. Although a similar pattern was seen with respect to the urinary excretion of furosemide, the magnitude of this difference between treatments was statistically significant (Fig. 3).

Figure 5 shows that probenecid caused a significant shift to the right in the relationship between the plasma concentration of furosemide and its natriuretic effect. This observation suggests that higher plasma furosemide concentrations are needed in the presence of probenecid to produce a natriuretic response equivalent to that produced by lower concentrations when probenecid is absent. Figure 6 shows the relationship between the urinary furosemide excretion rate and the natriuretic effect. Although Treatments I and II were not parallel over the entire dose–response curve, the amount of furosemide excreted into the urine was better correlated with response than was the plasma furosemide concentration.

The shift to the left between the urinary excretion rate of furosemide and the effect (upper portion of Fig. 6) may be real or may be an artifact due to the limited number of subjects. However, a possible explanation for this finding may involve an interaction between probenecid and prostaglandins. Previous investigators hypothesized that prostaglandins mediate the natriuretic–diuretic effect of furosemide (21–25). Renal prostaglandins are synthesized primarily in the medulla (24, 26–28) and are released into the extracellular fluids (29). *In vitro* studies showed that prostaglandins accumulate in several tissues, including the renal cortex, as a result of an active transport mechanism (30, 31). In addition, it was shown that probenecid can inhibit the renal tubular transport of prostaglandins, presumably by competing for active transport into the urine (32, 33). Although this conclusion is speculation, this inhibition by probenecid of prostaglandin transport may result in a tubule that is more responsive to smaller amounts of furosemide in the urine and thus account for the shift to the left as described.

CONCLUSIONS

The mechanism by which probenecid alters furosemide-induced natriuresis is consistent with *in vitro* studies (6) indicating that furosemide acts at the luminal surface of the nephron. This study in humans, as well as previous animal studies (18), demonstrates that the urinary excretion rate of furosemide is a better indicator of natriuresis and diuresis than is the plasma concentration.

Syntheses and Evaluation of Ketals, Hemithioketals, and Dithioketals of Conjugated Styryl Ketones Principally for Antineoplastic Activity

J. R. DIMMOCK ˣ and L. M. SMITH

Received November 6, 1979, from the *College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan, S7N OWO, Canada.* Accepted for publication January 7, 1980.

Abstract □ Ketals, hemithioketals, and dithioketals of nuclear-substituted styryl ketones were prepared as latentiated forms of the ketones. This undertaking was based on the premise that there is increased acidity in tumors compared to normal tissue, and thus preferential regeneration of the ketone in neoplastic tissue may occur. Attempts to form 1,3-dioxolans of Mannich bases were unsuccessful. The prepared compounds did not possess significant anticancer properties, but analgesic, anti-inflammatory, antihistaminic, and antimicrobial activities were found in the prepared Mannich bases.

Keyphrases □ Antineoplastic activity—ketals, hemithioketals, and dithioketals of conjugated styryl ketones, synthesis and evaluation of activity □ Styryl ketones, conjugated—synthesis of ketals, hemithioketals, and dithioketals, evaluation for antineoplastic activity □ Mannich bases—synthesized from conjugated styryl ketones and acetophenones, evaluation for antineoplastic activity

A recurrent problem in the design of compounds for cancer chemotherapy is the synthesis of derivatives possessing selective toxicity for tumors. Biochemical differences between cancerous and normal cells have been claimed (1), including the increased acidity of certain malignant cells compared to normal tissue (2–4). The increased acidity of tumors has been ascribed to the greater rate of aerobic glycolysis in neoplastic tissue (5), which leads to increased lactic acid production. The pH of a number of tumors has been reported to be ~7.0 (2–4), although such measurements probably recorded the extracellular pH. Therefore, the pH of the intracellular fluid probably is even lower (6), and an average pH value for a number of tumorous tissues has been considered to be ~6.5 (7). Hence, a prodrug permitting the release of a cytotoxic agent under acidic conditions may afford selective lethality of tumors with ameliorated toxicity for normal tissue. Only a few attempts have been made to design compounds based on this pH differential (8–11).

Several investigations in this laboratory involved the preparation of some nuclear-substituted styryl ketones (I) and related Mannich bases (II) for evaluation as anticancer agents (12–14) and in other screens (15–17). While the ketones have not been evaluated against P-388 lymphocytic leukemia, some of the Mannich bases showed promising levels of activity in this screen (12); one compound (IIe) increased the mean survival time in mice by >40% (12). However, murine toxicity was found in II due at least partially to interference with mitochondrial function (18, 19). Therefore, prodrugs of both I and II were prepared, and both I and the prodrugs were evaluated in the P-388 screen so that anticancer activities and murine toxicities of the ketones (I and II) and their latentiated precursors could be compared. Since ketals, hemithioketals, and dithioketals are known to hydrolyze under acidic conditions but are stable in neutral or alkaline media (20), the preparation of these derivatives from I and II may

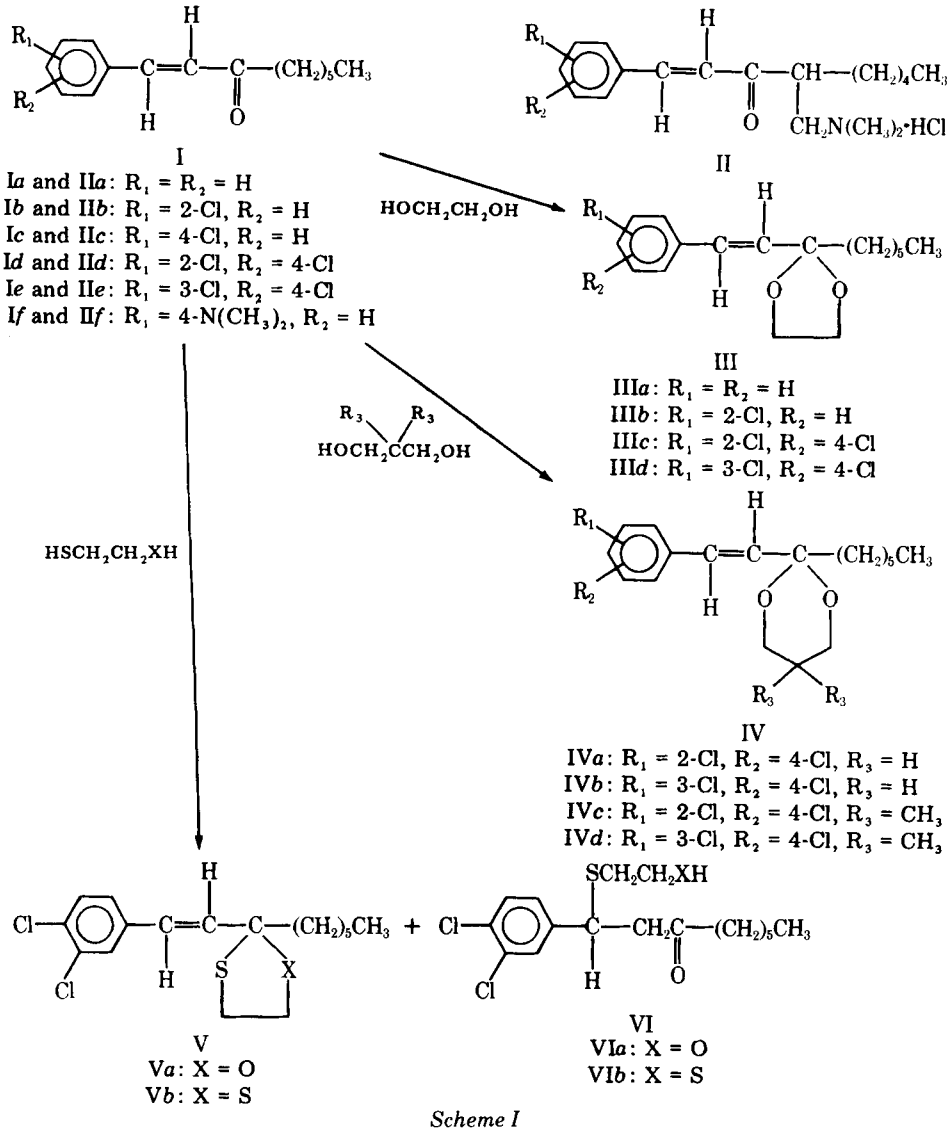


Scheme I

permit selective regeneration of these ketones in neoplastic tissue.

DISCUSSION

A review of synthetic methods available for preparing ketals, hemithioketals, and dithioketals, including the synthesis of these heterocycles derived from α,β-unsaturated ketones (20), outlined various reaction conditions that may be employed.

Initially, several abortive attempts were made to prepare the ketal IIIa from ethylene glycol and 1-phenyl-1-nonen-3-one (Ia) using different catalysts, solvents, and reaction times. However, prolonged heating of the reactants in benzene or toluene using *p*-toluenesulfonic acid as the catalyst led to the successful preparation of III–V, although there occasionally were low yields (Scheme I). The preparation of VII also was undertaken to examine the effect on biological activity of replacing the *n*-hexyl chain by a methyl group. Preliminary attempts to prepare Va and Vb by using milder reaction conditions and piperidine as the catalyst led to the Michael adducts (VIa and VIb) in low yields.

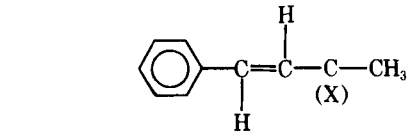
Attempts to react 4-dimethylaminomethyl-1-phenyl-1-nonen-3-one with ethylene glycol to produce the desired ketal were unsuccessful. The only product found on some occasions was the diolefin, 4-methylene-1-phenyl-1-nonen-3-one, which must have originated by the loss of dimethylamine hydrochloride from the Mannich base IIa. To eliminate this deamination process, the Mannich bases IXa and IXb were prepared as shown in Scheme II, but no reaction between IXa and ethylene glycol occurred under the conditions employed.

The antineoplastic evaluation of I and III–IX is shown in Table I. Unless otherwise stated, none of the compounds caused mortalities to mice at a dose of 200 mg/kg. Therefore, the styryl ketones (I) do not have marked murine toxicity, unlike the Mannich bases (II) (12), but only marginal levels of anticancer activity were seen. However, modification of the *n*-hexyl group of Ia led to the analogs VIIa and VIIIa with perceptible beneficial responses in the P-388 lymphocytic leukemia screen.

The lack of antineoplastic activity of the heterocycles III–V and VIIb is not surprising if reversion to the ketones (I) occurs. But the question may be posited as to whether these compounds are stable under neutral or acid conditions and if this is the case, any biological response or lack of activity may be due to the heterocycles *per se*. Seven representative compounds (IIIa, IIId, IVb, IVd, Va, Vb, and VIIa) were hydrolyzed to only a minute extent in buffer solutions of pH 7.0 and 6.4 for 20 hr at 37°; therefore, reversion of these compounds to the precursor ketones may not occur.

Compounds III–IX, with the exception of those indicated under *Experimental*, were evaluated for analgesic, anti-inflammatory, antidepressant, and antihistaminic properties. Of the 15 compounds examined, four met the criterion for analgesic activity, defined as protection of 50% or more in the phenylquinone writhing test (Table I). Compound Va displayed algesic properties. The unsubstituted 1,3-dioxolan (IIIa) showed higher activity than the chlorinated analogs (IIIb–IIId). However, expansion of the dioxolan ring of IIIc and IIId to the 1,3-dioxan heterocycles (IVa and IVb) led to compounds with improved analgesic activities, although insertion of geminal dimethyl groups onto the heterocyclic rings led to virtually inactive compounds, IVc and IVd.

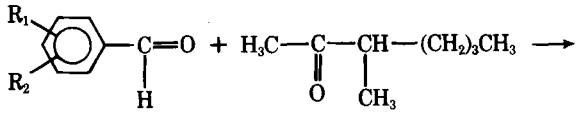
The most active analgesic was the Mannich base IXa; it had an ED_{50} of 20 mg/kg. The analgesic activity of codeine, expressed as an ED_{50} value, is 14.2 mg/kg in the hot plate test (21); although the compounds listed

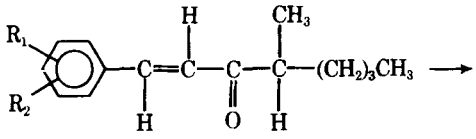


VII

VII*a*: X = =O

VII*b*: X = OCH_2CH_2O

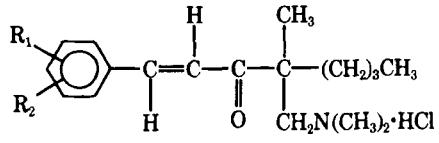




VIII

VIII*a*: $R_1 = R_2 = H$

VIII*b*: R_1 = 3-Cl, R_2 = 4-Cl



IX

IX*a*: $R_1 = R_2 = H$

IX*b*: R_1 = 3-Cl, R_2 = 4-Cl

Scheme II

in Table I were evaluated differently, it appears that IX*a* and codeine have comparable potencies. As noted previously for III, the presence of chlorine atoms in the aromatic ring reduced analgesic potency, and the dichlorinated analog of IX*a*, IX*b*, did not have analgesic activity. It is conceivable that the bulky chlorine atoms hinder alignment of the aromatic ring at a nonpolar area of a receptor.

In certain pathological conditions, an analgesic possessing anti-inflammatory properties can be a useful therapeutic agent. However, III–IX were inactive in the anti-inflammatory screen except for the Mannich base IX*b*, which at a dose of 120 mg/kg showed antagonism to carrageenan-induced rat paw edema of 100 and 17% at 3 and 5 hr, respectively, after treatment[1]. In addition, IX*b* was the only compound that met the criterion for activity[2] in the antidepressant screen, showing antagonism to tetrabenazine-induced ptosis in mice of 50 and 63% at the end of 0.5 and 1 hr, respectively, at a dose of 120 mg/kg. The only other compound with slight activity was IV*c*, which showed antagonism of 54 and 11% at the end of 0.5 and 1 hr, respectively.

All compounds examined in the antihistaminic screen showed activity (Table I), with the two Mannich bases IX*a* and IX*b* showing the greatest potencies. These two derivatives may be regarded as substituted propylamines, which is a class of compounds known to possess antihistaminic activity. Halogenation in the aromatic ring in the antihistaminic propylamines generally enhances activity (22), as was observed with these two compounds.

Some of the series III–IX compounds were examined for antimicrobial activity and were shown to be inactive with the exception of III*a*, which inhibited the growth of *Trichophyton mentagrophytes* at 10 μg/ml, and the Mannich bases IX*a* and IX*b*. Certain Mannich bases display antimicrobial activities (23), and this class of compounds is known to undergo facile deamination (24, 25). Therefore, the antimicrobial activities of Mannich bases may be due to the compound *per se* or to the corresponding deaminated product, *i.e.*, the analogous α,β-unsaturated ketone (26). The Mannich bases IX*a* and IX*b* are incapable of undergoing deamination. Evaluation of simpler Mannich bases (X) in this screen

[1] The reference compound, indomethacin, showed antagonism of 17 and 83% at the end of 3 and 5 hr, respectively, at a dose of 32 mg/kg. Values obtained in excess of 30% are considered to indicate anti-inflammatory activity.

[2] The reference compound was amitriptyline, which showed antagonism at 8 mg/kg of 90 and 49% at the end of 0.5 and 1 hr, respectively. A compound is considered active if it shows an antagonistic effect to tetrabenazine in excess of 50 and 25% after 0.5 and 1 hr, respectively.

IX*a*	105 (50)[f]	ED_{50} = 20 mg/kg[g]		50
IX*b*	113 (12.5)[h]	120	1[g]	100

[a] The figures are the ratios of the survival time of treated animals to control animals expressed as a percentage. A compound should increase the mean survival time by 20% to be considered active. [b] Analgesic activity was measured by the percentage protection in the phenylquinone writhing test in mice. Protection in excess of 50% indicates an active compound. [c] The figures indicate the percentage protection of a compound at a concentration of 0.1 mg/ml against a standard dose of histamine. A compound is considered active if 50% or more protection is found. [d] There were 1/6 and 6/6 survivors on Day 5 at dose levels of 200 and 100 mg/kg, respectively. [e] The percentage increase in writhes for this compound was 58%. [f] There were 5/6 and 6/6 survivors on Day 5 at dose levels of 200 and 100 mg/kg, respectively. [g] This compound elicited a Straub tail response. [h] There were 0/6, 1/6, 5/6, and 6/6 survivors on Day 5 at dose levels of 200, 100, 50, and 25 mg/kg, respectively.

where deamination could occur was desired, and it has been claimed that antimicrobial activity is increased as the facility for deamination is enhanced (27). Table II shows that IX and X showed both antibacterial and antifungal activities; while the unsubstituted Mannich bases IX*a* and X*a* had similar activity, the chlorinated compounds in series X showed lower potency than IX*b*.

The levels of analgesic, anti-inflammatory, antidepressant, and antihistaminic activities displayed by IX*a* and IX*b* also were found in X (Table III). All of the series X derivatives showed anti-inflammatory and analgesic properties and, as noted in series IX, X*a*, which has no nuclear halogen, was more potent as an analgesic than were the chlorinated analogs X*b*–X*d*. Series X compounds, like IX, showed antidepressant and antihistaminic activities, but unlike the IX derivatives, the chlorinated compounds, X*b*–X*d*, had lower antihistaminic activity than the unsubstituted compound, X*a*.

In conclusion, this study outlined a synthetic route for the preparation of some potential prodrugs of certain nuclear-substituted styryl ketones and recorded some of the failures to synthesize 1,3-dioxolan derivatives from Mannich bases. The prepared heterocycles did not show improved antineoplastic activity over the precursor α,β-unsaturated ketones, probably due to the inactivity of the compounds *per se* or to the lack of activity of the ketones. Some of the heterocyclic compounds displayed analgesic and antihistaminic activities, although these were of a lower magnitude than some Mannich bases synthesized in this study. While

[a] Analgesic activity was measured by the percentage protection in the phenylquinone writhing test using mice. Protection in excess of 50% indicates an active compound. [b] The anti-inflammatory activity was measured by the percentage protection afforded by the compound to carrageenan-induced edema in rats. Compounds showing greater than 30% protection are considered active. [c] The antidepressant screen measured the antagonism of a compound to tetrabenazine-induced ptosis in mice. A compound is considered active if >50 and >25% protection are obtained at the end of 0.5 and 1 hr, respectively. [d] The antihistaminic screen was undertaken by measuring the effect of the compound (0.1 mg/ml) on a guinea pig ileum preparation. A compound is considered active if 50% protection or more to a standard dose of histamine (0.5 mg/ml) is obtained. The reference compound, diphenhydramine, gives 100% protection at a dose of 0.01 mg/ml. [e] These compounds elicited a Straub tail response. [f] The reference compounds in the analgesic, anti-inflammatory, antidepressant, and antihistaminic screens were aspirin, indomethacin, amitriptyline, and diphenhydramine, respectively.

little antimicrobial activity was found in the nonnitrogenous derivatives, some of the Mannich bases displayed activity against certain pathogenic bacteria and fungi.

EXPERIMENTAL[3]

Melting points and boiling points are uncorrected. Organic extracts were washed with water and dried over anhydrous magnesium sulfate. The solvent was removed using a water aspirator. The boiling point of the petroleum ether was 30–60°. TLC was carried out on all of the compounds, which were purified by column chromatography using aluminum oxide sheets[4] and petroleum ether as the solvent to confirm the homogeneity of the product. The 60-MHz NMR spectra[5] were determined in deuterochloroform with tetramethylsilane as the internal standard. Mass spectra[6] were run at 70 ev, and IR spectra[7] were determined as films.

Syntheses of Compounds—Compounds I*a*–I*f* (28) and II*a* (29) were prepared by literature methods.

*Ketals, Hemithioketals, and Dithioketals (III–V and VII*b)—The general synthetic procedure was as follows. A mixture of the ketone (I) (0.1 mole), the appropriate alcohol or thiol (0.125 mole), and a catalytic quantity of *p*-toluenesulfonic acid (0.1 g) in benzene (200 ml) was heated under reflux for 48 hr. A Dean-Stark trap attached to the apparatus collected the water formed during the reaction. Upon cooling, the mixture was extracted with ether to give viscous yellow oils.

Modifications of this general synthetic route were employed in the preparation of IV, for which toluene was used as the solvent in place of benzene, and for V, for which the length of time of heating under reflux in benzene was reduced to 24 hr. The ketals III and VII*b* derived from ethylene glycol were purified by distillation, while attempts to effect purification in this manner with some of the other compounds (IV and V) invariably led to decomposition to the starting reactants.

The boiling points of III*a*–III*d* and VII*b* were 151°/0.1 mm, 155°/0.15 mm, 161°/0.1 mm, 167°/0.1 mm, and 133°/0.1 mm, respectively. Compounds IV and V were purified by column chromatography using neutral aluminum oxide[8] and eluting the compounds with petroleum ether to give viscous yellow oils. For IV*d*, colorless granular crystals, mp 65–67°, were obtained after chromatography. Attempts to use basic aluminum oxide[9] followed by elution with petroleum ether led to the decomposition of the dioxolan on the column.

NMR and IR spectroscopy and mass spectrometry were carried out on III–V and VII*b*, and the spectra obtained were consistent with the proposed structures. The NMR spectroscopy data found for five representative compounds are: III*a*: δ 7.23 (m, 5, C_6H_5), 6.68 (d, 1, C_1H), 6.02 (d, 1, C_2H), 3.85 (s, 4, OC_2H_4O), 2.12–1.08 [m, 10, $(CH_2)_5$], and 0.88 (t, 3, C_9H_3); IV*b*: δ 7.38–6.78 (m, 3, C_6H_3), 6.45 (d, 1, C_1H), 5.95 (d, 1, C_2H), 3.92 (m, 2, $OCH_2CH_2CH_2O$), 3.78 (t, 4, $OCH_2CH_2CH_2O$), 2.35–1.05 [m, 10, $(CH_2)_5$], and 0.88 (t, 3, C_9H_3); IV*d*: δ 7.48–6.91 (m, 3, C_6H_3), 6.48 (d, 1, C_1H), 5.94 (d, 1, C_2H), 3.48 [q, 4, $OCH_2C(CH_3)_2CH_2O$], 2.04–1.04 [m, 10, $(CH_2)_5$], 1.21 (s, 3, $OCH_2CH_3(-C-)CH_3-CH_2O$), 0.88 (t, 3, C_9H_3), and 0.68 (s, 3, $OCH_2CH_3(-C-)CH_3-CH_2O$); V*a*: δ 7.51–6.91 (m, 3, C_6H_3), 6.44 (d, 1, C_1H), 6.04 (d, 1, C_2H), 4.11 (octet, 2, OCH_2CH_2S), 3.01 (t, 2, OCH_2CH_2S), 2.21–1.08 [m, 10, $(CH_2)_5$], and 0.88 (t, 3, C_9H_3); V*b*: δ 7.45–6.97 (m, 3, C_6H_3), 6.60 (d, 1, C_1H), 6.20 (d, 1, C_2H), 3.25 (s, 4, SCH_2CH_2S), 2.27–1.05 [m, 10, $(CH_2)_5$], and 0.90 (t, 3, C_9H_3). The coupling constant for the olefinic protons in these five compounds was 16 Hz.

IR spectroscopy of the ketals III and IV showed loss of the α,β-unsaturated carbonyl peak of I in the region of 1700–1600 cm^{-1}, while the strong absorption at ~965 cm^{-1} due to the out-of-plane methine deformation band of the olefinic group (30) was present. Peaks at ~1190 (w), 1170 (s), and 1095 (w) cm^{-1} were assigned to the carbon–oxygen stretching vibrations associated with the ketal group (31). In the sulfur analogs (V), the absence of carbonyl absorption was noted and the peak at 965 cm^{-1}, while retained, was of diminished intensity compared to III and IV. The sulfur–carbon absorption in the region of 700–590 cm^{-1} (32) was not observed.

Examination of the mass spectrum of a representative ketal (IV*a*) showed that loss of the *n*-hexyl group occurred, producing an ion (A) at *m/e* 175 that was derived from the molecular ion (*m/e* 260). Ion A lost 44 mass units and yielded an ion (B) at *m/e* 131, whose structure was considered to be $C_6H_5CH{=}CHC{\equiv}O^+$. Ion B lost carbon monoxide to form the styrenoid ion $C_6H_5CH{=}C^+H$. Metastable peaks were observed, which supported this fragmentation pathway, and all of the ketals fragmented to give analogous ions. The analytical data and the yields of these compounds are summarized in Table IV.

Initial attempts to prepare the ketal III*a* were either unsuccessful or unsatisfactory. When the reactants were heated in benzene for 4 or 8 hr, little or no reaction product was obtained. When either stannic chloride or boron trifluoride etherate replaced *p*-toluenesulfonic acid (heating under reflux for 48 hr in benzene), no product was obtained. When the reactants were heated under reflux for 48 hr in methanol or chloroform in place of benzene, no reaction occurred, even if anhydrous magnesium sulfate or anhydrous sodium sulfate was added to the reaction mixture. When toluene replaced benzene as the solvent, III*a* was formed in greater yield than when benzene was used as the solvent, but there was an increase in tar formation.

Adducts (VI)—A mixture of 1-(3,4-dichlorophenyl)-1-nonen-3-one (0.1 mole), 2-mercaptoethanol (0.25 mole), and 2 or 3 drops of piperidine in ethanol (100 ml) was heated at 40° for 24 hr. The solvent was removed to give a pale-yellow oil, which was purified by chromatography using aluminum oxide[8]. Elution with petroleum ether gave 1-(3,4-dichlorophenyl)-1-(2-hydroxyethylthio)-3-nonanone (VI*a*) as a colorless oil in a 13% yield; mass spectrum: *m/e* 362 (M^+).

Anal.—Calc. for $C_{17}H_{24}Cl_2O_2S$: C, 56.20; H, 6.66. Found: C, 55.10; H, 6.57.

The thio analog (VI*b*) was prepared in a similar fashion, except that a colorless solid was obtained after completion of the reaction and removal of the solvent. Recrystallization of the solid from acetone produced 1-(3,4-dichlorophenyl)-1-(2-mercaptoethylthio)-3-nonanone (VI*b*) as fluffy, colorless crystals, mp 84–85°, in an 18% yield.

Anal.—Calc. for $C_{17}H_{24}Cl_2OS_2$: C, 53.82: H, 6.38. Found: C, 54.03; H, 6.43.

Styryl Ketones (VIII) and Related Mannich Bases (IX)—1-Phenyl-4-methyl-1-octen-3-one (VIII*a*) was prepared by the literature method (28) as a pale-yellow oil, bp 132°/0.8 mm, in a 64% yield.

Anal.—Calc. for $C_{15}H_{20}O$: C, 83.28; H, 9.32. Found: C, 83.42; H, 9.53.

1-(3,4-Dichlorophenyl)-4-methyl-1-octen-3-one (VIII*b*) was prepared in a similar fashion as a pale-yellow oil, bp 151–153°/0.75 mm, in a 52% yield; mass spectrum: *m/e* 284 (M^+).

Anal.—Calc. for $C_{15}H_{18}Cl_2O$: C, 63.17; H, 6.36. Found: C, 62.35; H, 6.42.

4-Dimethylaminomethyl-4-methyl-1-phenyl-1-octen-3-one hydrochloride (IX*a*) was prepared from VIII*a* by the literature procedure (29) with crystallization from acetone to give fluffy, colorless crystals, mp 153.5–154°, in a 53% yield.

Anal.—Calc. for $C_{18}H_{28}ClNO$: C, 69.77; H, 9.11; N, 4.52. Found: C, 70.12; H, 9.08; N, 4.58.

The corresponding 3,4-dichloro analog (IX*b*), prepared in a similar fashion from VIII*b*, crystallized from acetone as fluffy, colorless crystals, mp 126.5–127°, in a 56% yield.

Anal.—Calc. for $C_{18}H_{26}Cl_3NO$: C, 57.07; H, 6.92; N, 3.70. Found: C, 56.61; H, 6.94; N, 3.67.

Dioxolan Derivative of 4-Dimethylaminomethyl-1-phenyl-1-nonen-3-one—A mixture of 4-dimethylaminomethyl-1-phenyl-1-nonen-3-one hydrochloride (II*a*, 0.1 mole), ethylene glycol (0.125 mole), and a catalytic quantity of *p*-toluenesulfonic acid in benzene (200 ml) was heated under reflux for 48 hr. Water did not appear to collect in a Dean-Stark trap attached to the reaction vessel but the pH of the benzene in the trap was ~1 after 4 hr of heating. After the solvent was removed, a mixture of equal volumes of water and ether was added to the reaction product.

The organic extract was separated and revealed the presence of a compound whose mass spectral, NMR, IR, and TLC characteristics were identical with those of an authentic specimen of 4-methylene-1-phenyl-1-nonen-3-one (29). The aqueous layer was cooled in ice, made basic with aqueous sodium hydroxide solution (10% w/v), and extracted with ether; the product that was isolated was shown by mass spectrometry and IR and NMR spectroscopy to be an unreacted Mannich base.

Other attempts to prepare this ketal used ratios of the Mannich base hydrochloride (II*a*), ethylene glycol, and solvent similar to those described; unless otherwise stated, the reaction proceeded for 24 hr.

1. A catalytic quantity of anhydrous stannic chloride in dry chloroform was used, and the reaction mixture was kept at 40° overnight, from which only unreacted starting material was isolated.

2. The previous experiment was repeated, except that anhydrous magnesium sulfate was added as a drying agent. No reaction occurred.

3. When the reactants were heated under reflux in benzene with anhydrous stannic chloride, the olefin 4-methylene-1-phenyl-1-nonen-3-one and a viscous oil were found.

4. A mixture of Mannich base hydrochloride (0.1 mole), ethylene glycol (0.125 mole), and anhydrous stannic chloride (0.1 g) was heated under reflux in benzene (20 ml) and produced a tarry oil.

5. The reactants were heated under reflux in chloroform containing a catalytic quantity of anhydrous zinc chloride in the presence of molecular sieves[10], from which only unreacted material was isolated.

6. When the previous reaction was repeated using benzene as the solvent and eliminating the molecular sieves, 4-methylene-1-phenyl-1-nonen-3-one was isolated.

7. When boron trifluoride etherate in dry ether was employed and the reaction mixture was heated overnight at 30°, no reaction occurred.

8. The reactants were heated overnight under reflux in chloroform to which adipic acid has been added as the catalyst. The isolated product was 4-methylene-1-phenyl-1-nonen-3-one.

9. Instead of the hydrochloride salt, the free Mannich base was used; the same results were produced.

Dioxolan Derivative of 4-Dimethylaminomethyl-4-methyl-1-phenyl-1-octen-3-one—A mixture of IX*a* (0.1 mole), ethylene glycol (0.125 mole), and a catalytic quantity of *p*-toluenesulfonic acid in benzene (200 ml) was heated under reflux for 48 hr. The mixture was treated as described previously, and only unreacted materials were isolated.

Mannich Bases (X)—The Mannich bases (X) were prepared by the literature method (29) and gave the required derivatives as fluffy, colorless crystals, which were recrystallized from acetone. 3-Dimethylamino-1-phenyl-1-propanone hydrochloride (X*a*) was prepared in a 41% yield, mp 159–160° [lit. (33) mp 160°]. The *p*-chloro analog (X*b*) was obtained in a 43% yield, mp 171–173° [lit. (34) mp 170°]. Compound X*c* was synthesized in a 15% yield, mp 193–195° [lit. (35) mp 193–195°]. Compound X*d* was prepared in a 22% yield, mp 138–139° [lit. (35) mp 138–139°].

Table IV—Ketals, Hemithioketals, and Dithioketals of Conjugated Styryl Ketones

Compound	Yield, %	Formula		Analysis, % Calc.	Found
III*a*	68	$C_{17}H_{24}O_2$	C	78.46	78.56
			H	9.23	9.23

[10] Molecular sieves (type 4A, grade 514, 8–12 mesh), Fisher Scientific Co.

Hydrolyses of the Ketals (IIIa, IIId, IVb, IVd, Va, Vb, and VIIb)—The acetonitrile–buffer solutions were prepared as follows. A solution of monobasic sodium phosphate monohydrate (9.30 g) in double-distilled water was adjusted to 1000 ml (Solution A), and a solution of dibasic sodium phosphate heptahydrate was prepared by dissolving the salt (17.88 g) in water and diluting to 1000 ml (Solution B). A mixture of acetonitrile (500.0 ml) and Solution A (389.0 ml) was placed in a 1000-ml volumetric flask, and Solution B was added to 1000 ml. The pH of the resultant solution was 7.00. The acetonitrile–buffer solution of pH 6.40 was prepared in a similar manner, except that the amount of Solution A was 464.0 ml.

The appropriate ketal (10^{-3} g) was dissolved in acetonitrile–buffer (100.0 ml) at pH 7.00 and 6.40 and heated in a constant-temperature bath at 37° for 20 hr. At the commencement of the experiment and also at the end of 20 hr, 1.0-ml aliquots were withdrawn and diluted to 10.0 ml with the same solvent. The UV spectrum[11] was observed at the λ_{max} of both the ketal and the corresponding ketone. The percentage hydrolysis was obtained by noting the ketone absorption (A), and since there is some end-absorption of the ketal in the region of the λ_{max} of the ketone, the extent of the hydrolyses was obtained from:

$$\% \text{ hydrolysis} = \frac{A_{obs} - A_{\text{end-absorption of ketal}}}{A_{\text{pure ketone}}} \qquad \text{(Eq. 1)}$$

The percentage hydrolyses of IIIa, IIId, IVb, IVd, Va, Vb, and VIIb at pH 7.00 were 3.53, 4.29, 2.23, 1.30, 0.21, 0, and 3.81, respectively. At pH 6.40, the percentage hydrolyses of the same compounds were 1.68, 3.07, 0.13, 0, 0, 0, and 2.75, respectively.

Screening of Compounds—The anticancer screening was carried out by the Drug Research and Development Division of the National Cancer Institute, Bethesda, Md., using their protocols (36). In the P-388 screen, the compounds were administered by the intraperitoneal route into either male or female CD_2F_1 mice, although on rare occasions the $B_6D_2F_1$ strain was employed. The compounds were administered for 9 consecutive days, except for Ia and VIa, for which injections were made every 4 days with a total of two and three injections, respectively. The derivatives were administered in saline (Va, VIb, VIIIb, and IXb), saline with polysorbate 80[12] (Ia–If, IIIa, IVd, VIIa, VIIb, VIIIa, and IXa), saline with alcohol (IVa–IVc), or hydroxypropylcellulose (IIIb–IIId) or as a suspension in saline (VIa). Compound Vb was administered either in saline or in saline containing polysorbate 80.

All of the series III–X compounds, except where noted, were evaluated[13] for analgesic, anti-inflammatory, antidepressant, and antihistaminic activities by previously reported procedures (37). Compounds Vb, VIa, and VIIa were not included in any of these screens; IIIc and Va were not assessed for antidepressant and antihistaminic activities, respectively. The antimicrobial screen[13] was performed by the literature method (37) on the series III–IX compounds with the exception of IVa and VIIa.

Localization of Technetium 99m–Ethylenediamine-*N,N'*-bis(α-2-hydroxy-5-bromophenyl)acetic Acid and Technetium 99m–*N*-(2-Mercapto-1-oxopropyl)glycine in Hepatobiliary System

MICHAEL C. THEODORAKIS *x, WILLIAM C. GROUTAS ‡, ALEX J. BERMUDEZ *, DAVID MAGNIN ‡, and STAVROULA-VANI S. STEFANAKOU *

Received September 17, 1979, from the *Division of Nuclear Medicine and Radiopharmacology, College of Veterinary Medicine, University of Illinois at Urbana-Champaign, Urbana, IL 61801, and the ‡College of Chemistry, University of Wisconsin at Eau Claire, Eau Claire, WI 54701. Accepted for publication January 4, 1980.

Abstract □ Two radiopharmaceuticals, technetium 99m–*N*-(2-mercapto-1-oxopropyl)glycine (^{99m}Tc-I) and technetium 99m–ethylenediamine-*N,N'*-bis(α-2-hydroxy-5-bromophenyl)acetic acid (^{99m}Tc-II), were prepared and evaluated in dogs, rabbits, and rats. Both agents gave good scintigraphic images of the liver and gallbladder in dogs. The cumulative amount of ^{99m}Tc-I and ^{99m}Tc-II excreted in the bile of dogs and the physiological disposition data in rats revealed slight, inconclusive differences in their distributions. However, the scintigraphic images and physiological disposition data in rabbits revealed gross differences in the distribution pattern of the two agents. The observed similarities in the biliary excretion of both agents in dogs and rats were attributed to the fact that these species are relatively good biliary excretors, and both agents therefore were excreted extensively. However, rabbits, which are poor biliary excretors relative to dogs and rats, excreted ^{99m}Tc-II more extensively than ^{99m}Tc-I because of the favorable molecular characteristics of ^{99m}Tc-II.

Keyphrases □ Radiopharmaceuticals—technetium 99m complexes of *N*-(2-mercapto-1-oxopropyl)glycine and ethylenediamine-*N,N'*-bis(α-2-hydroxy-5-bromophenyl)acetic acid, localization in hepatobiliary system □ Technetium 99m—complexes with *N*-(2-mercapto-1-oxopropyl)glycine and ethylenediamine-*N,N'*-bis(α-2-hydroxy-5-bromophenyl)acetic acid, localization in hepatobiliary system □ Scintigraphic imaging agents—complexes of technetium 99m with *N*-(2-mercapto-1-oxopropyl)glycine and ethylenediamine-*N,N'*-bis(α-2-hydroxy-5-bromophenyl)acetic acid, localization in hepatobiliary system

External scintigraphic diagnosis of gallbladder pathology has been the subject of several investigations. Application of the intravenous radionuclide cholangiogram has saved time in routine hepatobiliary function tests, demonstrating the patency of the cystic duct in patients with suspected acute cholecystitis, and also in evaluating the patency of surgically devised drainage pathways of the biliary system, particularly after liver transplantation and after the Kusai procedure for biliary atresia (1).

Complexes of technetium 99m with mercaptoisobutyric acid (2), dihydrothioctic acid (3), pyridoxylidene glutamate (4), pyridoxal phenylalanine (5), methyliminodiacetic acid (6), and *N*-[[(2,6-dimethyl)phenylcarbamoyl]-methyl]iminodiacetic acid (6) have been used for the intravenous radionuclide cholangiogram in humans and for replacing [^{131}I]rose bengal, which has undesirable radiation characteristics. Complexes of technetium 99m with *N*-(2-mercapto-1-oxopropyl)glycine (7) and ethylenediamine-*N,N'*-bis(α-2-hydroxy-5-bromophenyl)acetic acid (8) have been proposed as possible agents for the intravenous radionuclide cholangiogram.

The purpose of this study was to use animals to explore the relative merit of technetium 99m–*N*-(2-mercapto-1-oxopropyl)glycine (^{99m}Tc-I) and technetium 99m–ethylenediamine-*N,N'*-bis(α-2-hydroxy-5-bromophenyl)acetic acid (^{99m}Tc-II) as diagnostic radiopharmaceuticals in humans. The criteria for selecting the best agent were the quality of the scintigraphic images of the hepatobiliary system in dogs and rabbits and the tissue distribution of both agents in rats and rabbits.

EXPERIMENTAL

***N*-(2-Mercapto-1-oxopropyl)glycine[1] (I)**—Compound I was used without further purification.

Ethylenediamine-*N,N'*-bis(α-2-hydroxy-5-bromophenyl)acetic Acid[2] (II)—A solution of *p*-bromophenol (22.82 g, 0.1319 mole), sodium dichloroacetate (19.92 g, 0.1319 mole), and ethylenediamine (3.96 g, 0.066 mole) in 10 ml of methanol and 6 ml of water was heated to 85° and stirred for 24 hr under nitrogen. The reaction mixture pH was maintained at 9.5 by adding 6 *N* NaOH. After cooling to room temperature, the pH was adjusted carefully to 6.0 with 6 *N* HCl. The precipitated *p*-bromophenol was removed by extraction with ether (3 × 35 ml).

The aqueous solution pH was lowered to 4.0 with 6 *N* HCl, whereupon an orange solid precipitated. The dark supernate was carefully decanted, and the residue was washed repeatedly with methanol and acetone. The solvent finally was removed *in vacuo*, leaving a yellow solid (9.57 g, 30% yield), mp 245° dec. The compound could be purified further by column chromatography with silica gel and methanol–ammonium hydroxide as the eluent; IR (KBr): 3400–2400 (hydrogen-bonded OH) and 1660 (C=O) cm^{-1}; NMR (CF_3COOH–tetramethylsilane): δ 10.56 (s, 4H), 7.0 (s, 4H), 6.34–6.48 (d, 2H), 4.75 (s, 2H), and 3.4 (m, 4H).

Anal.—Calc. for $C_{18}H_{18}Br_2N_2O_6$: C, 41.72; H, 3.50; Br, 30.84; N, 5.4. Found: C, 41.72; H, 3.52; Br, 28.17; N, 6.18.

Technetium 99m-*N*-(2-Mercapto-1-oxopropyl)glycine (^{99m}Tc-I)—The technetium 99m complex of I was prepared by a modification of a reported method (7). Three milliliters of a saline eluate of sodium pertechnetate (III) (1–5 mCi), received from a molybdenum 99-technetium 99m generator[3], was mixed with 0.5 ml of a stock solution of stannous chloride–I, followed by 5–10 min of incubation at room temperature under a nitrogen atmosphere. The stock solution was prepared by mixing 40 ml of 0.15 *M* I in 1 *M* $NaHCO_3$ with 40 ml of 8.4×10^{-3} *M* $SnCl_2 \cdot 2H_2O$ in 0.1 *M* HCl. The stock solution pH was adjusted

to 7.0 with 5 *M* HCl, and it then was filtered through a 0.22-μm membrane filter into a sterile glass container.

All solutions were purged with nitrogen and were prepared fresh prior to each experiment. The molar ratio of I to tin was 18:1.

Technetium 99m-Ethylenediamine-*N,N'*-bis(*α*-2-hydroxy-5-bromophenyl)acetic Acid (^{99m}Tc-II)—The technetium 99m complex of II was prepared under a nitrogen atmosphere by mixing 2 ml of III (1–5 mCi) with 1 ml of a stock solution of stannous chloride–II, followed by 5–10 min of incubation at room temperature. The stock solution was prepared by mixing 100 ml of 2.5×10^{-2} *M* II in 0.1 *M* NaOH with 2.0×10^{-4} mole of stannous chloride dihydrate. After the stannous chloride was dissolved completely, the pH was adjusted to 8.8 with 1 *M* HCl, and the solution was filtered through a 0.22-μm membrane filter into a sterile glass container.

All solutions were purged with nitrogen and were prepared fresh prior to each experiment. The molar ratio of II to tin was 12.5:1.

Labeling Efficiency of ^{99m}Tc-I and ^{99m}Tc-II—Prior to administration, ^{99m}Tc-I was analyzed for unreacted III by TLC on cellulose plates[4] with acetone as the developing solvent. The carrier I and the complex ^{99m}Tc-I remained at the origin, while the unreacted III moved with the solvent front. The unreacted III was always <3%.

The ^{99m}Tc-II was chromatographed on cellulose TLC plates[4] sprayed with 1% (w/v) $BaCl_2$. The developing solvent was prepared by mixing five parts of *n*-butanol with four parts of water and one part of acetic acid in a separator and retaining the organic layer. The R_f values of III and ^{99m}Tc-II were 0.43 and 0.94, respectively. The labeling efficiency was higher than 95%.

Distribution Studies in Animals—An 8-kg fasted beagle was injected intravenously with ^{99m}Tc-I (5×10^{-4} mmole of I, 1 mCi). The same beagle was injected intravenously 15 days later with ^{99m}Tc-II (6.6×10^{-4} mmole of II, 1 mCi). In both instances, the animal was anesthetized with an intramuscular dose of the dissociative anesthetic fentanyl and droperidol[5] (0.12 cm^3/kg); the animal was immobilized on a restrainer and placed under a γ-camera[6]. A series of ventral scintigraphic images was taken using a high-resolution pinhole collimator (Fig. 1).

Table I—Percent of Injected Dose Recovered in Dog Bile[a]

^{99m}Tc-I	^{99m}Tc-II
70.1[a]	48.6
55.9	64.1

[a] Obtained 75 min postinjection; result of one measurement.

For the bile recovery studies, two groups of two beagles each were injected in the forelimb vein with ^{99m}Tc-I (1×10^{-3} mmole, 1 mCi) and ^{99m}Tc-II (1×10^{-3} mmole, 1 mCi), respectively. The animals were anesthetized with pentobarbital sodium (30 mg/kg), the common bile duct was catheterized with a polyethylene catheter, and bile was collected for 75 min (Table I). The cystic duct was ligated.

Two groups, each containing 21 albino New Zealand rabbits (2–3 kg), received by injection into the ear vein freshly prepared ^{99m}Tc-I (6.6×10^{-4} mmole of I/kg, 1 mCi) and ^{99m}Tc-II[7] (6.6×10^{-4} mmole of II/kg, 1 mCi), respectively. Groups of three animals were sacrificed at 0.25, 0.5, 1, 2, 3, 5, and 24 hr after injection of a lethal dose of pentobarbital. Blood samples were obtained by cardiac puncture immediately after death. The blood weight was considered to be 7% of the body weight. Certain organs were excised, wet weighed, and counted by a shielded scintillation crystal

of fixed geometry linked to a counter[8,9]. The results were reported as the percent of total injected radioactivity per gram of organ (Tables II and III). Prior to sacrifice, several scintigraphic images of the abdominal area were taken with a γ-camera[6] shielded with a pinhole collimator (Fig. 1).

Two groups, each containing 18 white rats, received by injection into the tail vein freshly prepared ^{99m}Tc-I (1.3×10^{-3} mmole of I, 0.5 mCi) and ^{99m}Tc-II[10] (1.3×10^{-3} mmole of II, 0.5 mCi), respectively. Prior to experimentation, the animals were housed in groups of three for 3 days. They were allowed free access to food and tap water. The animals were sacrificed in groups of three at 0.5, 1, 2, 3, 5, and 24 hr postinjection. Certain organs were excised and counted in a well counter[9]. The results are reported as the percent of total injected radioactivity (Tables IV and V).

RESULTS AND DISCUSSION

The radioactive sodium pertechnetate (III) reacted with an excess of I. The complexation took place at room temperature in the presence of the oxidizable salt stannous chloride and under a nitrogen atmosphere. Since trace quantities of cations could interfere with the stability of the thiol (I), highly pure reagents and diluents were used. Although the ligand (I) to tin ratio varied from 9:1 to 18:1, this variation did not affect the extent of the complexation with III, as was evident from TLC–radiochromatographic monitoring of the extent of chelation of III.

Ligand II was soluble at pH values lower than 4.0 and higher than 8.0. The complex was formed by reducing III with stannous chloride in the presence of II at pH 8.5. The solutions were purged thoroughly with nitrogen to avoid oxidation of the phenol rings. Although the ligand to tin ratio ranged from 10:1 to 16:1, this variation did not affect the extent of complexation of the reduced technetium with the ligand II.

In both instances, the exact nature of the technetium complexes (^{99m}Tc-I and ^{99m}Tc-II) was uncertain. The presence of a thiol and a carboxyl group in I and the carboxyl, secondary amine, and hydroxyl groups in II were necessary for the formation of stable chelates. The high molecular weight (mol. wt. 518) of ligand II and the presence of two bromophenolic rings rendered the molecule susceptible to extensive biliary excretion. In contrast, ligand I had a lower molecular weight (mol. wt. 163) and lacked lipophilic groups. Therefore, it was expected to be less suitable than II for hepatobiliary excretion.

The sequential scintigraphic images (Fig. 1) of the liver and gallbladder of a beagle indicated that both ^{99m}Tc-I and ^{99m}Tc-II had a similar distribution pattern. Specifically, ^{99m}Tc-I started accumulating in the liver 5 min following intravenous administration. During the same period, the gallbladder became visible, and it was delineated clearly 30 min postinjection. When ^{99m}Tc-II was administered, the gallbladder was clearly delineated in the first 30 min postinjection, and the quality of the scintigraphic images was the same as that received with ^{99m}Tc-I. Upon intravenous administration of 50 μg of cerulein, the gallbladder in both cases contracted and enabled visualization of the common bile duct as the radioactivity was excreted into the intestines. A slight kidney uptake was noted with ^{99m}Tc-I.

The scintigraphic images taken following intravenous administration of ^{99m}Tc-I in rabbits (Fig. 1) indicated rapid accumulation of the radioactivity in the liver 5–15 min postinjection. During the same period, the gallbladder became slightly visible but never was clearly delineated

^{99m}Tc-I	1.4	1.8	4.5	5.3	3.1	1.5	0.0
			Gallbladder to Blood Ratio[a]				
^{99m}Tc-II	1.1	1.0	4.1	3.0	2.6	3.2	0.0
^{99m}Tc-I	0.1	0.2	0.5	0.7	0.9	0.4	0.0

[a] Ratio of percent of dose per gram of tissue to percent of dose per gram of tissue.

during the experiment. The visualization of the kidneys, urinary bladder, and small intestine indicated that part of the radioactivity was shunted through the urinary system and part was excreted through the intestines. The scintigraphic images (Fig. 1) taken when ^{99m}Tc-II was administered indicated a similar distribution pattern, except that the gallbladder was clearly visible and delineated 30 min postinjection and remained as such throughout the experiment.

The distribution of the radioactivity as a function of time in rabbits (Tables II and III) indicated that ^{99m}Tc-II cleared from the blood more rapidly than ^{99m}Tc-I and was accumulated rapidly in the liver. For instance, at 30 min postinjection, the radioactivity levels of ^{99m}Tc-I in the liver and blood were 0.08 and 0.69% of the dose/g, respectively; the corresponding levels for ^{99m}Tc-II were 0.18 and 0.30%, respectively. On the other hand, the urinary excretion, as denoted by the kidney, urine, and bladder levels, was higher for ^{99m}Tc-I than for ^{99m}Tc-II during the same period. In contrast, the levels of the gallbladder and intestines were higher for ^{99m}Tc-II than for ^{99m}Tc-I throughout the testing period. Furthermore, the target organ to nontarget organ ratio, which is the parameter for assessing the imaging capability of any diagnostic radiopharmaceutical, was higher for ^{99m}Tc-II than for ^{99m}Tc-I (Table VI). In particular, the gallbladder to blood ratio of ^{99m}Tc-II was five to 10 times higher than that of ^{99m}Tc-I during the first 30 or 60 min postinjection. The gallbladder to liver ratio of ^{99m}Tc-II was higher than that of ^{99m}Tc-I and remained as such up to 5 hr postinjection.

The distribution of ^{99m}Tc-I and ^{99m}Tc-II in rats (Tables IV and V) indicated that a good portion of ^{99m}Tc-I was excreted through the kidneys while the urinary excretion of ^{99m}Tc-II was lower. The high urinary excretion component of ^{99m}Tc-I was in agreement with observations made by previous investigators that low molecular weight mercaptans are retained in the kidneys and excreted through the urine in rats (9). Liver uptake was appreciable for ^{99m}Tc-II.

The scintigraphic images in dogs (Fig. 1) of both ^{99m}Tc-I and ^{99m}Tc-II were of equivalent quality. In both instances, the liver and gallbladder were delineated clearly and rapidly. The bile collection during the first 75 min postinjection did not reveal appreciable differences in the bile excretion of the two compounds (Table I). The tissue levels in rats revealed certain differences in the distribution of both ^{99m}Tc-I and ^{99m}Tc-II; however, the tissue levels in rabbits revealed gross differences, as was corroborated by the target to nontarget ratios (Table VI) and the differences in the quality of scintigraphic images (Fig. 1).

The *in vivo* distribution data agree with certain observations of previous investigators concerning the hepatobiliary excretion of substances as affected by the species of the experimental animal and the molecular characteristics of the compound. According to one investigator (10), hepatobiliary excretion in both dogs and rats is extensive. These species are classified as good hepatobiliary excretors, while rabbits, humans, and primates are classified relative to dogs and rats as poor hepatobiliary excretors. Furthermore, high lipophilicity and high molecular weight are factors that favor hepatobiliary excretion, while low molecular weight hydrophilic substances are shunted through the urinary pathway of excretion (10).

The exact reason for the higher biliary excretion of ^{99m}Tc-I in dogs and rats is not known. It may be the result of increased lipophilicity and increased molecular weight due to the formation of ^{99m}Tc-I or due to the formation of a complex with two ligands (^{99m}Tc-I_2). Further studies are in progress to investigate the complex. In rabbits, which like humans and primates are poor biliary excretors relative to dogs and rats (10), ^{99m}Tc-II, due to its favorable molecular characteristics, was a better hepatobiliary scintigraphic agent than ^{99m}Tc-I. Finally, in light of the presented data, it is concluded that rabbits are a better model than dogs or rats for evaluating hepatobiliary scintigraphic agents for use in humans.

Binding of Gold to Bovine Serum Albumin Using Flameless Atomic Absorption

SRIKUMARAN MELETHIL *§x, ALPHONSE POKLIS ‡¶, and VIDYA A. SAGAR ‡

Received August 23, 1978, from the *Departments of *Pharmaceutics and Pharmacy Practice and ‡Pharmacology and Toxicology, College of Pharmacy, North Dakota State University, Fargo, ND 58105. Accepted for publication December 3, 1979. §Present address: Division of Pharmaceutical Sciences, Schools of Pharmacy and Medicine, University of Missouri-Kansas City, Kansas City, MO 64111. ¶Present address: Department of Pathology, School of Medicine, St. Louis University, St. Louis, MO 63104.

Abstract □ A graphite furnace atomic absorption spectrophotometric assay capable of accurately determining nanogram amounts of gold in biological fluids was developed. The presence of bovine serum albumin and/or phosphate in the sample reduced the method sensitivity without affecting the linear response. Binding of gold was studied by ultrafiltration using cones with a molecular weight cutoff of 25,000. The binding of gold at various concentrations to 2 and 4% bovine serum albumin in 0.1 *M* phosphate buffer, pH 7.4, was independent of the gold and protein concentrations. In the 2–10-μg/ml range, the overall binding values (mean ± *SD*) of gold to 2 and 4% bovine serum albumin were 98 ± 1.6 (n = 35) and 99 ± 1.0% (n = 15), respectively. When ultrafiltration cones with a molecular weight cutoff of 50,000 were used, the extent of binding to 2% bovine serum albumin was 85.4 ± 1.6% (n = 11). This statistically significant difference ($p < 0.001$) was due to variations in the protein retention of the two cone types. Interaction studies showed that gold was not displaced from the binding sites by salicylic acid (200 μg/ml) or vice versa.

Keyphrases □ Antiarthritis agents—gold, effect of plasma protein and gold concentrations on gold binding, flameless atomic absorption determination of gold in biological fluids □ Aspirin—effect of salicylic acid on binding of gold to bovine serum albumin, flameless atomic absorption determination □ Protein binding—gold to bovine serum albumin, effect of plasma protein and gold concentration on gold binding, effect of salicylic acid on gold bound to albumin, flameless atomic absorption determination □ Salicylic acid—effect on gold bound to serum albumin, flameless atomic absorption determination

Gold salts are widely used in rheumatoid arthritis treatment (1). Although gold has a high affinity for plasma proteins (2–10), the specific protein to which it is bound most extensively is a matter of controversy. Some reports indicated that gold is bound exclusively to albumin (2, 3, 9), while others implicated fibrinogen (5) and α- and β-globulins (8). No data currently are available on the effect of protein concentration on the extent of gold binding. This aspect has important therapeutic implications since hypoalbuminemia often is encountered in arthritic patients (11). The recent observation (12) that aspirin hepatotoxicity increased in patients who were treated simultaneously with gold raises questions about competition for binding sites between salicylic acid and gold.

BACKGROUND

Several analytical methods have been used to determine gold in biological fluids. They include colorimetry (13), neutron activation analysis (14), polarography (15), and flame and carbon rod atomic absorption spectrophotometric techniques (4, 11, 16–21). Colorimetry and polarography require extensive sample manipulation, are time consuming, and suffer from low sensitivity. These disadvantages make these methods inapplicable to the routine determination of therapeutic gold concentrations (1–10 μg/ml). While neutron activation analysis has high sensitivity (0.01 μg/ml), the cost of instrumentation is prohibitive to most clinical laboratories.

Atomic absorption spectrophotometry has greatly facilitated the detection of minute concentrations of metals in biological fluids. Earlier procedures for gold estimation in biological fluids were conducted using flame atomic absorption spectrophotometric techniques (4, 6, 17). However, the required dilution, digestion, and extraction steps resulted in a loss of sensitivity and time. New atomic absorption spectrophotometric techniques using a carbon rod or a graphite furnace atomizer have overcome these problems (18–21). The advantages of these new techniques are high absolute sensitivity, microliter sample size, the potential for analyzing samples without pretreatment, speed of analysis, freedom from introduction of contaminants, and low background noise.

The first objective of this study was to develop a sensitive flameless atomic absorption spectrophotometric assay to determine gold in biological fluids. The second objective was to study the extent of the binding of gold to bovine serum albumin and the effect of salicylate on this interaction.

EXPERIMENTAL

Materials—Graphite tubes[1] for sample atomization, gold standards[2], ultrafiltration membrane cones[3], bovine serum albumin[4], and salicylic acid[5] were obtained commercially. Distilled, deionized water was prepared by passing distilled water through an ion-exchange system[6]. To avoid possible loss of gold by binding to glass, plastic laboratoryware was used.

Instrumentation—An atomic absorption spectrophotometer[7] equipped with a graphite furnace atomizer[8], a deuterium-arc background corrector[9], and an automatic injector system[10] was used for gold determination. A gold hollow cathode lamp[11] was the light source. Atomization peak heights of gold were recorded on a strip-chart recorder[12] at a chart speed of 10 mm/min and a recorder current of 10 mamp.

Operating Conditions—The optimum parameters for gold determination in the test solutions were: drying cycle, 100° for 20 sec with a temperature ramp of 30 sec; charring cycle, 800° for 60 sec with a temperature ramp of 30 sec; and atomization cycle, 2200° for 5 sec. The ramp setting permits gradual rise in the furnace temperature during each run. The carrier gas was argon at a flow rate of 30 ml/min. Atomization peak heights were recorded at 242.8 nm.

Calibration Curves for Gold—A working standard, 100 μg/ml, was prepared by diluting commercially obtained gold solution with distilled, deionized water. This working standard was diluted further with 0.1 *M* phosphate buffer, pH 7.4, to give solutions containing 0.1, 0.2, 0.3, and 0.4 μg of gold/ml. Twenty-microliter aliquots of each solution were in-

0.2% Bovine serum albumin in 0.1 *M* phosphate buffer, pH 7.4	77	1.0	0.996

[a] Expressed in arbitrary units. [b] Gold concentration ranged from 0.1 to 0.4 μg/ml. [c] Correlation coefficient.

jected into the atomic absorption spectrophotometer, and the atomization peak heights were recorded. Calibration plots were prepared on all days of sample analysis using the same graphite tube used for the samples.

Matrix Effects—Gold solutions of 0.1–0.4 μg/ml were prepared by diluting the working standard with (*a*) distilled, deionized water, (*b*) 0.1 *M* phosphate buffer, pH 7.4, or (*c*) 0.2% bovine serum albumin in 0.1 *M* phosphate buffer, pH 7.4. The atomization peak heights of 20-μl aliquots of these gold solutions were obtained as described earlier.

Binding Studies—The binding of gold to bovine serum albumin was studied using a previously reported ultrafiltration technique (22) with minor modifications. The membrane cones, after pretreatment as recommended by the manufacturer, were dried by centrifugation at 2000 rpm (484×*g*) for 25 min. A comparison of cone weights before and after soaking and centrifugation showed that <0.06 ml of distilled, deionized water remained in the cones.

Bovine serum albumin solutions, 2 and 4%, containing various concentrations of gold (2–10 μg/ml) were prepared in 0.1 *M* phosphate buffer, pH 7.4. Following equilibration for 16–24 hr (overnight), 5-ml aliquots were transferred to pretreated cones and centrifuged for 30 sec at 2000 rpm. The filtrate, ~0.1 ml, was discarded to minimize dilution errors that can be expected from the residual water in the cones. A second 0.4-ml aliquot of filtrate was collected, and a 20-μl portion was injected into the atomic absorption spectrophotometer. The atomization peaks at 242.8 nm were recorded and converted into concentrations using calibration plots prepared with standard gold solutions in 0.1 *M* phosphate buffer, pH 7.4.

To determine the nonspecific loss of gold due to binding to the ultrafiltration cones and/or the apparatus, gold solutions in phosphate buffer (2–4 μg/ml) were filtered through the cones in the absence of bovine serum albumin. Gold concentrations in the filtrates were compared to the corresponding concentrations prior to filtration.

Displacement Studies with Salicylic Acid—The procedure was identical to that described under *Binding Studies*, except for the addition of salicylic acid. These studies were conducted with the 2% bovine serum albumin solution. In one set of experiments, salicylic acid was added to bovine serum albumin 24 hr prior to the addition of gold. In the second set, salicylic acid was added 24 hr after the addition of gold to bovine serum albumin.

While gold concentrations varied from 2 to 10 μg/ml, the salicylic acid concentration was 200 μg/ml in all trials. Following the addition of gold in the first set of experiments and salicylic acid in the second set, the solutions were equilibrated overnight. Binding studies then were performed. Salicylate concentrations in the ultrafiltrates were determined by UV spectrophotometry at 295 nm.

RESULTS AND DISCUSSION

Analytical—Atomization peak heights for gold at 242.8 nm were linearly related to concentration in the 0.1–0.4-μg/ml range. Peak heights varied considerably among the graphite tubes. For instance, the slope of the peak height (arbitrary units) *versus* gold concentration (micrograms per milliliter) ranged from 139 to 240 during a 2-month period when most of the samples were analyzed. However, the correlation coefficients of calibration plots obtained during this period were better than 0.990, with very small intercept values that were not statistically significant.

Visual examination of the graphite tubes revealed differences in their thickness. The "thicker" tubes gave erratic results and were not used in the analyses. In view of these problems, the peak heights obtained with test solutions were converted to gold concentrations using calibration plots prepared using the same graphite tube. Under such controlled conditions, the overall coefficient of variation of the technique was <2% (Tables I and II). The life of a tube ranged from 50 to 60 determinations under the conditions used.

Matrix Effects—The medium or matrix in which the gold solutions were prepared also affected the method sensitivity (Table III). A decrease in the slope of the regression line corresponded to a decrease in the peak height. Based on the slope values in Table III, a gold solution prepared in 0.1 *M* phosphate buffer was expected to have a peak height that was ~25% lower than that obtained with an aqueous gold solution of equal concentration. The presence of even small amounts of bovine serum albumin in the buffer resulted in a further decrease in peak heights to ~40% of those obtained in water.

The reasons for these effects remain unclear. However, they emphasize the need to recognize that electrolytes and other normal constituents of biological fluids can interfere with atomic absorption measurements. The interference may be due to molecular absorption of electrolytes at the wavelength of gold absorption or to the physical occlusion of gold in a host of condensing interferent atoms.

While this work was in progress, Kamel *et al.* (11) reported a similar method to determine gold in blood. They reported that the organic matrix of blood reduced the sensitivity of the technique. It was speculated that a stable protein complex that was not destroyed during the charring cycle may have prevented the complete atomization of gold. However, such an explanation does not fit the interference observed with phosphate.

Binding Studies—Small amounts of protein escaped through the ultrafiltration cones used in this study. Depending on this amount and the affinity of the drug for the macromolecule, the values obtained for the extent of binding may have been underestimated. The manufacturer specifies that cones with molecular weight cutoffs of 25,000 (Type 1)[13] and 50,000 (Type 2)[14] retain >95 and 90% of albumin, respectively. For five randomly chosen Type 2 cones, the mean protein leakage was determined to be 11% (range 9–12.5%); these values were obtained by expressing the protein concentration in the filtrate as a fraction of that placed in the cone (2%) prior to ultrafiltration. Protein concentrations were measured by the biuret method (23). In a similar study with Type 1 cones, four cones showed no detectable leak and one had a leak of 5.8%.

The extent of gold binding to 2% bovine serum albumin was 85 ± 1.6% ($n = 11$) with Type 2 cones. The corresponding value with Type 1 cones was 98 ± 1.0% ($n = 15$), which is significantly higher ($p < 0.001$) than the value obtained with the Type 2 cones. The extent of underestimation (13%) is in good agreement with the differences in protein leakage (11%) between these two cone varieties. Therefore, all binding studies used Type 1 cones. Although each cone was not tested for protein leakage, suspiciously low values for binding were always associated with cones that were found to leak, as indicated by the presence of protein in the ultrafiltrate. Such cases were repeated.

A paired *t* test showed that, in the absence of bovine serum albumin,

[13] Centriflo membrane cones, type CF25, Amicon Corp., Lexington, Mass.
[14] Centriflo membrane cones, type CF50, Amicon Corp., Lexington, Mass.

gold concentrations in the ultrafiltrates were not statistically different ($p > 0.05$) from the corresponding concentrations prior to filtration. Hence, no corrections for nonspecific binding were warranted. Gold was almost 100% bound to bovine serum albumin (Table I). These results indicate that gold may be bound exclusively to the albumin fraction of plasma, as was reported earlier (2, 3, 9). However, more definite conclusions can be made only after studies in the presence of other plasma proteins. The overall values for the percent of gold bound to 2 ($n = 35$) and 4% ($n = 15$) bovine serum albumin were 98 ± 1.6 and 99 ± 1.0% (mean ± *SD*), respectively.

Two factors that often determine the extent of binding are the concentrations of the drug and of the protein. The gold concentrations studied were selected to include the plasma concentrations of the drug encountered in chrysotherapy (2, 6, 16, 24, 25). While there is a paucity of data regarding the extent of hypoalbuminemia in arthritis patients, a recent study observed serum albumin levels as low as 2.47 g/100 ml (11). The results of the present work show that, in the clinically important range, the extent of gold binding was independent of gold and bovine serum albumin concentrations. The validity of these results in the *in vivo* situation in humans remains to be examined.

Interaction with Salicylic Acid—Salicylic acid did not compete with gold for binding sites on bovine serum albumin (Table II). Since the sequence of addition of salicylic acid had no significant effect on the affinity of gold for bovine serum albumin, inhibition of a noncompetitive nature also can be ruled out. Similarly, gold did not interfere with salicylate binding; salicylate was 62–70% bound to bovine serum albumin in the absence and presence of gold (2–10-μg/ml range). During aspirin therapy, plasma concentrations of salicylate range from 50 to 200 μg/ml (26). The *in vitro* results suggest that mutual displacement of gold and salicylic acid from plasma proteins may not be a serious drug interaction in arthritis management.

The results of this study show that clinically encountered plasma concentrations of gold, salicylate, and albumin are unlikely to cause statistically significant alterations in the extent of protein binding of these two drugs. However, for drugs that are bound extensively to plasma protein as is gold, minor binding alterations may be clinically significant due to the resulting dramatic changes in the free concentration. For instance, a 1% decrease in the binding of gold (assumed to be 99% bound) results in a twofold (1–2%) increase in the free concentration of gold. Such changes, although extremely difficult to document experimentally, could cause gold toxicity in arthritic patients.

GLC Analysis of Poison Ivy and Poison Oak Urushiol Components in Vegetable Oil Preparations

MAHMOUD A. ELSOHLY ˣ and CARLTON E. TURNER

Received August 6, 1979, from the *Research Institute of Pharmaceutical Sciences, School of Pharmacy, University of Mississippi, University, MS 38677.* Accepted for publication November 26, 1979.

Abstract □ A procedure is described for the analysis of urushiol content of pharmaceutical preparations containing extracts of poison ivy (*Toxicodendron radicans*) and poison oak (*T. diversilobum*) in vegetable oils. The procedure involves extraction of the urushiols from the oily solutions using 90% methanol in water followed by GLC analysis of the extracts. Recoveries of both poison ivy and poison oak urushiols from solutions in corn oil, olive oil, sesame seed oil, and cottonseed oil were calculated. Correlation coefficients (r^2) ranged from 0.97 to 1.00, and the coefficients of variations ranged from 3.08 to 7.90%.

Keyphrases □ Urushiols—GLC analysis, pharmaceutical preparations containing poison ivy and poison oak extracts in vegetable oils □ GLC—analysis, urushiols in pharmaceutical preparations containing poison ivy and poison oak extracts in vegetable oils □ Poison ivy—urushiol components in vegetable oil preparations, GLC analysis

Contact dermatitis due to poison ivy (*Toxicodendron radicans*) and other related *Anacardiaceae* species [*e.g.*, poison oak (*T. diversilobum*) and poison sumac (*T. vernix*)] is a major problem among outdoor workers in the

GLC Analysis of Poison Ivy and Poison Oak Urushiol Components in Vegetable Oil Preparations

MAHMOUD A. ELSOHLY ˣ and CARLTON E. TURNER

Received August 6, 1979, from the *Research Institute of Pharmaceutical Sciences, School of Pharmacy, University of Mississippi, University, MS 38677.* Accepted for publication November 26, 1979.

Abstract □ A procedure is described for the analysis of urushiol content of pharmaceutical preparations containing extracts of poison ivy (*Toxicodendron radicans*) and poison oak (*T. diversilobum*) in vegetable oils. The procedure involves extraction of the urushiols from the oily solutions using 90% methanol in water followed by GLC analysis of the extracts. Recoveries of both poison ivy and poison oak urushiols from solutions in corn oil, olive oil, sesame seed oil, and cottonseed oil were calculated. Correlation coefficients (r^2) ranged from 0.97 to 1.00, and the coefficients of variations ranged from 3.08 to 7.90%.

Keyphrases □ Urushiols—GLC analysis, pharmaceutical preparations containing poison ivy and poison oak extracts in vegetable oils □ GLC—analysis, urushiols in pharmaceutical preparations containing poison ivy and poison oak extracts in vegetable oils □ Poison ivy—urushiol components in vegetable oil preparations, GLC analysis

Contact dermatitis due to poison ivy (*Toxicodendron radicans*) and other related *Anacardiaceae* species [*e.g.*, poison oak (*T. diversilobum*) and poison sumac (*T. vernix*)] is a major problem among outdoor workers in the

United States. Urushiol, the constituent in these plants that causes dermatitis, has been shown to be a mixture of 3-*n*-alk(en)yl catechols with zero, one, two, or three double bonds in the C_{15}-side chain of poison ivy (1–4) and the C_{17}-side chain of poison oak (5, 6).

Extracts of poison ivy and poison oak have been used in the detection and prophylactic treatment of sensitivity (7–9). Solutions of these extracts are provided mainly in vegetable oils, *e.g.*, corn oil (poison ivy–poison oak extract capsules[1]) and olive oil (injection[2]) (10). Although these preparations have been in use for a long time, no procedure is available to determine the concentration of the active component (urushiol) in these formulations. This report describes a simple GLC procedure for the determination of the total urushiol content of preparations containing poison ivy or poison oak extracts in vegetable oils such as corn oil, cottonseed oil, olive oil, and sesame seed oil.

EXPERIMENTAL

Plant Extracts—Poison ivy (*T. radicans*) and poison oak (*T. diversilobum*) extracts were prepared as described previously (6) or were obtained commercially[1]. The extracts were analyzed for urushiol content following the literature procedure (6).

Preparation of Oil Solutions of Poison Ivy and Poison Oak Extracts—Commercially available corn oil, cottonseed oil, olive oil, and sesame seed oil were used for the preparation of the solutions. For each oil, two sets of solutions were prepared containing 1, 2, 4, 7, or 10% of either poison ivy or poison oak extracts corresponding to 0.96–12.0 mg of urushiol/ml. The actual urushiol content of each solution (milligrams per milliliter) was based on the preanalysis of the extracts.

Extraction of Urushiol from Oil Solutions—One-milliliter aliquots of each solution were transferred to 15-ml screw-capped centrifuge tubes. To each oil solution was added 5 ml of methanol–water (9:1). The tubes were capped and vortexed for 20 sec or shaken vigorously for ~1 min and then centrifuged for 5 min. The top layer from each tube was withdrawn carefully into a 10-ml round-bottom flask, and the solvent was evaporated under vacuum at 40°.

The extraction was repeated twice using 5 ml of the same solvent each time. In each case, the top layer was added to the respective flask and the solvent was evaporated. Complete evaporation of the small amount of water remaining in the evaporation flask was achieved by adding ~2 ml each of absolute ethanol and benzene, followed by evaporation. This step was done twice to ensure complete dryness of the extract.

Preparation of Samples for GLC Analysis—*Dilute Samples*—Samples obtained from oil solutions containing <2 mg of urushiol/ml were prepared directly for GLC analysis by the addition of 0.25 ml of pyridine and 0.5 ml of bis(trimethylsilyl)trifluoroacetamide[3] containing 1% trimethylchlorosilane to the residue in the round-bottom flask. Then 0.5 ml of internal standard (dotriacontane, 5 mg/ml in isooctane) was added.

Concentrated Samples—Samples expected to contain >2 mg of urushiol/ml were treated in the following manner. The residue obtained after evaporation of the methanol–water extract was transferred quantitatively to a 5- or 10-ml volumetric flask with chloroform, and the volume was adjusted with the same solvent. A 1-ml aliquot then was withdrawn from the chloroform solution and evaporated, and the residue was treated as described for the dilute samples. The dilution factor was considered in the calculations.

GLC Analysis—The samples were analyzed using a gas–liquid chromatograph[4] and a 5% OV-225 column under the conditions reported previously (6).

Table I—Recovery of Urushiols from Vegetable Oil Solutions of Poison Ivy and Poison Oak Extracts Using 90% Methanol–Water [a]

	Recovery, % [b]	Correlation [b] Coefficient (r^2)	Coefficient of Variation [c], %
Corn oil			
Poison ivy	66.6	1.00	3.55
Poison oak	60.2	0.99	3.70
Olive oil			
Poison ivy	69.3	0.99	4.01
Poison oak	59.6	0.99	3.22
Sesame oil			
Poison ivy	68.4	0.99	3.50
Poison oak	52.0	0.98	3.30
Cottonseed oil			
Poison ivy	64.1	0.97	7.90
Poison oak	49.9	0.99	3.08

[a] The urushiol concentration in the different oils ranged from 0.96 to 12 mg/ml. [b] Calculated from the least-squares line. The correction factor is the reciprocal of the recovery. [c] Mean coefficient of variation of all extractions over the concentration range used.

RESULTS AND DISCUSSION

GLC procedures were described previously for the identification of urushiol (11, 12), and the use of GLC–mass spectrometry for the quantitative determination of the different congeners also was reported (13). A new GLC procedure was reported previously for the quantitation of the different components of poison ivy and poison oak urushiols as their trimethylsilyl derivatives using a 5% OV-225 column (6). The separation of the different congeners allowed the quantitation of each. The procedure was applied for the analysis of poison ivy and poison oak urushiol components in extracts obtained from different plant parts.

Extracts of poison ivy, poison oak, and, in some cases, poison sumac in vegetable oil solutions have been used for prophylactic treatment of Rhus dermatitis. The lack of an analytical procedure to determine the concentration of the active constituent, urushiol, in these preparations prompted the present study.

Corn oil, olive oil, sesame seed oil, and cottonseed oil were selected as representatives of vegetable oils. Solutions of poison ivy and poison oak extracts were made in each oil to contain different amounts of the extracts corresponding to concentrations of 0.94–12.0 mg of urushiol/ml. The extracts were analyzed for urushiol content prior to mixing.

Different cleanup procedures were investigated to separate the urushiol components from the oils prior to analysis. These procedures included column chromatography, TLC, and solvent partitioning. Due to on-column decomposition, column chromatography on silica gel 60 resulted in a loss of a significant amount of the urushiols. The loss was maximized when a large enough column was used (20 g) to permit the clean separation of the urushiol from the oil. Aluminum oxide adsorbents could not be used since urushiol binds irreversibly to alumina. Other chromatographic materials also were tried including polyamide, cellulose, cellulose acetate, and diethylaminoethylcellulose with no success.

Different solvents then were investigated for the extraction of urushiol from the oil solutions of the extracts. These solvents included methanol, ethanol, methanol–butanol mixtures (5–20% butanol), and methanol–water mixtures (2–20% water). A methanol–water mixture (9:1) was the best solvent for extraction since it gave a high percentage recovery of urushiol with the least contamination of the extracts with the oil components. GLC analysis (6) of the 90% methanol–water extracts of the pure vegetable oils showed virtually no peaks that might interfere with the urushiol peaks. Thus, the previously outlined procedure (6) was applicable to the analysis of urushiols in the methanol–water (9:1) extracts of poison ivy and poison oak preparations in vegetable oils. The extraction efficiency of this solvent mixture was determined for each oil by plotting the actual concentration of urushiol (milligrams per milliliter *versus* the observed concentration).

Figure 1 shows the recovery curves for the extraction of urushiol from solutions of poison ivy extract in different vegetable oils; Fig. 2 shows the same curves for poison oak. Each point in these curves is the average of triplicate analyses. The coefficient of variation (CV) for each point was calculated, and a mean CV value was given for each curve (Table I). A linear relationship was shown between the added and observed concentrations in each case with correlation coefficients (r^2) ranging between 0.97 and 1.00 (Table I). This result makes it possible to use this extraction procedure and to compensate for the recovery percentage. The slope of each curve (Figs. 1 and 2) thus represents the correction factor used to compensate for the extraction efficiency in each case. The same correction factors were found when preparations containing a mixture of poison ivy and poison oak extracts were formulated.

The reported procedure can be used for the analysis of the total urushiols content as well as for the percentage of each individual congener.

High-Pressure Liquid Chromatographic Identification of Drugs Used in Management of Arthritis

JOHN K. BAKER ˣ **and E. KIM FIFER**

Received March 19, 1979, from the *Department of Medicinal Chemistry, School of Pharmacy, University of Mississippi, University, MS 38677.* Accepted for publication November 26, 1979.

Abstract □ A screening procedure was developed for the identification of drugs used in the clinical treatment of arthritis. Each glucocorticoid, nonsteroidal anti-inflammatory agent, or tranquilizer was characterized by its retention on a reversed-phase high-pressure liquid chromatographic column and by the ratio of the response of dual UV detectors (254 and 280 nm). Although the retention times of all 14 drugs examined were <4 min, each drug could be distinguished easily from the other drugs in the series.

Keyphrases □ Antiarthritis agents—glucocorticoids, nonsteroidal anti-inflammatory agents, tranquilizers, high-pressure liquid chromatographic identification □ High-pressure liquid chromatography—identification of glucocorticoids, nonsteroidal anti-inflammatory agents, and tranquilizers used in arthritis treatment □ Glucocorticoids—identification by high-pressure liquid chromatography, arthritis treatment □ Anti-inflammatory agents, nonsteroidal—identification by high-pressure liquid chromatography, arthritis treatment □ Tranquilizers—identification by high-pressure liquid chromatography, arthritis treatment

Solid dosage forms obtained from patients who received treatment in specialized arthritis clinics in Mexico have been analyzed in these laboratories. In many cases, the patients were told that these drugs were vitamins or natural products and were given a large supply of two or three different tablets to continue taking on their return to the United States. GLC (1) and standard spectroscopic analyses (2) showed that many of these tablets were a tranquilizer (*e.g.*, diazepam or chlordiazepoxide) and an anti-inflammatory steroid or a tranquilizer and a nonsteroidal anti-inflammatory drug (*e.g.*, phenylbutazone or indomethacin). Although there are many qualitative and quantitative analytical methods reported in the literature for individual drugs, a single analytical method for the screening of such samples has not been reported.

BACKGROUND

Since both types of anti-inflammatory agents require different derivatization methods for GLC analysis, high-pressure liquid chromatography (HPLC) was investigated for the identification of the tranquilizers, steroids, and nonsteroidal anti-inflammatory agents.

One major limitation of any chromatographic method for identifying drugs is that many compounds have identical retention times if a fairly large population of compounds is examined. In a recent study (3) of a diverse group of only 101 narcotics, amphetamines, barbiturates, and tranquilizers, only 9% of the drugs could be identified uniquely by HPLC retention times. In that study, if dual UV detectors were used to measure accurately the absorbance of each chromatographic peak at 254 and 280 nm, 95% of the drugs could be characterized uniquely. Moreover, HPLC retention times and A_{254}/A_{280} ratios as paired discriminators were more useful than HPLC retention times on a silica column and on a reversed-phase column as paired discriminators (3). Because of the utility, speed, and low cost of the technique, its usefulness in aiding in the identification of the present group of drugs was investigated.

It is generally recognized that the utility of HPLC retention times is limited because of the small variations that occur with time when the same column is used and because of the large variations that occur with a new column. Relative retention times are considerably more reproducible, but this measurement also has limitations. For example, when reversed-phase HPLC columns are used and the alcohol content of the mobile phase is increased inadvertently or a new column with a lower percent of the stationary phase is used, the observed relative retention time generally increases.

Many of these problems can be reduced or eliminated through the use of a retention index scale based on the relative retention of a homologous series of C_3–C_{23} 2-ketoalkanes and the drug in question (4). The retention index of a given drug is fairly independent of the mobile phase composition, even when the drug retention time varies by several orders of magnitude. The retention index of many drugs also was found to be nearly the same when a bonded cyanoalkyl reversed-phase column was substituted for a C_{18} reversed-phase column (4). Although the retention index measurements were slightly more time consuming than the conventional relative retention time measurements, the former method was selected for this study because of the greater potential for laboratory-to-laboratory reproducibility of the data.

EXPERIMENTAL

Chromatographic Conditions—A 30-cm × 3.9-mm i.d. octadecyl reversed-phase column[1] with a 10-μm particle size was used. The mobile phase was prepared using 3.3 g of dibasic potassium phosphate, 4.2 g of monobasic potassium phosphate, 2.8 liters of methanol, and 1.2 liters of water. The flow rate was 2.0 ml/min, and the column was operated at room temperature.

An HPLC pump[2] and a microsyringe-loaded loop injector[3] also were used. Two UV detectors[4] were used in series (254-nm detector followed by a 280-nm detector), and they were calibrated with a morphine reference standard (3).

Measurement of Retention Indexes—The method used in this study was essentially the same as that reported previously (4). The retention index scale was based on the relative retention of the drug in question and a series (C_3–C_{23}) of 2-ketoalkanes[5]. The capacity factor, k', of the drugs and the standards was determined from the retention time observed for the compound, t_R, and the retention time of the solvent front, t_0, using Eq. 1:

$$k' = \frac{t_R - t_0}{t_0} \qquad \text{(Eq. 1)}$$

The retention index of a given 2-keto alkane standard was, by definition, equal to 100 times the number of carbons in the compound. Thus, 2-butanone was assigned a value of 400. The retention index, I, of a given drug was calculated from the observed capacity factor for the drug, k'_D, the capacity factor for the standard eluting just before the test compound, k'_N, and the capacity factor for the next higher homolog, k'_{N+1}, using Eq. 2:

$$I = 100\,\frac{\log k'_D - \log k'_N}{\log k'_{N+1} - \log k'_N} + 100N \qquad \text{(Eq. 2)}$$

Each drug was chromatographed as a mixture with the 2-ketoalkane reference compounds to minimize the effect of retention time variations on the precision of the retention index measurements. If the chromatographic peak for the drug could not be resolved from the peaks of the standards, the mixture of the standards was chromatographed immediately after the drug. Because of the much smaller molar absorptivity of the 2-ketoalkane standards, a larger quantity of the ketones (~50 μg each) was injected with the drugs (~1 μg) to obtain comparable peak heights.

Preparation of Solid Dosage Forms for HPLC—The tablets were crushed to a fine powder. Approximately 100 mg of the powder was mixed with 1.0–2.0 ml of methanol, and the mixture was then filtered through

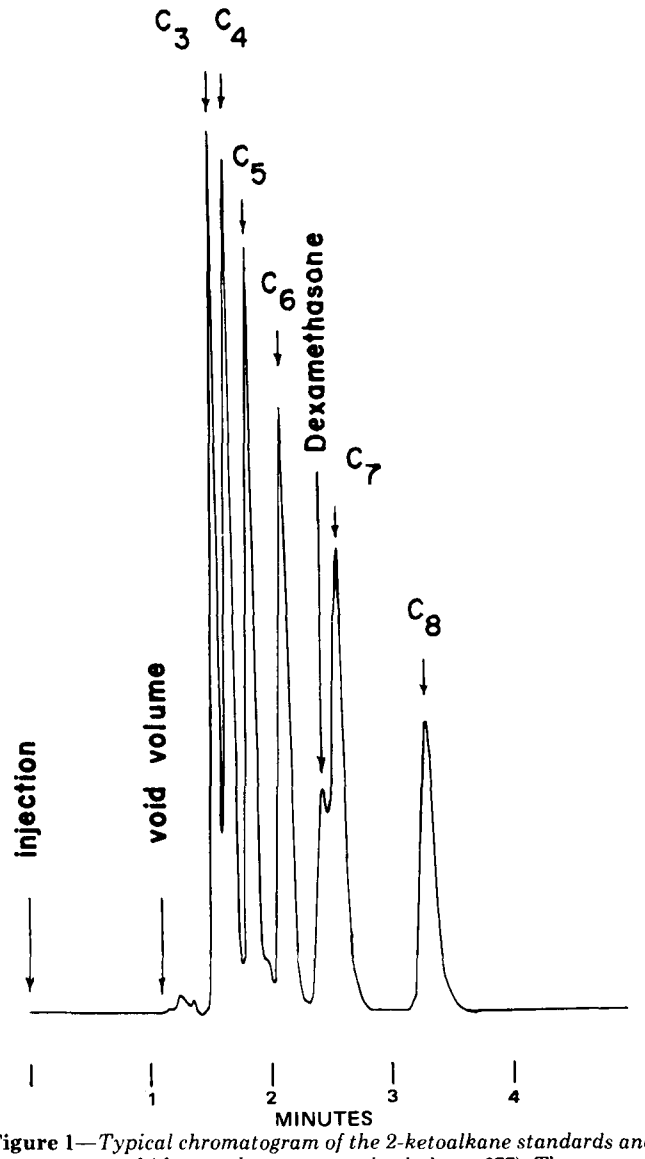

Figure 1—*Typical chromatogram of the 2-ketoalkane standards and a test compound (dexamethasone, retention index = 677). The response of only the 280-nm detector is shown.*

a disposable Pasteur pipet containing a small, tightly packed plug of cotton. Then 0.1–2.0 μl of the methanolic extract was injected into the chromatograph along with the 2-ketoalkane standards mixture.

RESULTS AND DISCUSSION

The chromatogram shown in Fig. 1 for dexamethasone and the 2-ketoalkanes is typical of the results obtained, except that the 254-nm detector response is not shown to simplify the figure. Although the retention times of all of the drugs were fairly short, the drugs were sufficiently removed from the solvent front to obtain precise retention index and absorbance ratio measurements. The longest retention tine was observed for diazepam (3.43 min), the shortest time was observed for naproxen (1.56 min), and the retention time of the solvent front was 1.12 min.

The drugs are listed in Table I in order of increasing retention index, and there is an apparent discrepancy between the retention index and the retention time measurements. Although the short-term reproducibility of the retention time generally was ±0.01 min, the long-term variations were greater. The retention index measurements are considerably more reliable than the retention time measurements (4), and more emphasis was placed on this measurement in the present study.

Although the retention indexes of many drugs in the series were fairly close, each compound could be distinguished from the others if the A_{254}/A_{280} values also were utilized. For example, the retention indexes of fenoprofen and triamcinolone were very close, but the two drugs could be readily distinguished using the absorbance ratio measurements. With

Table I—HPLC Characterization of Various Drugs Used in Management of Arthritis

Drug	Retention Index	A_{254}/A_{280}	Retention Time, min
Naproxen	304	1.61	1.56[a]
Phenylbutazone	363	1.27	1.56
Fenoprofen	439	1.09	1.78
Triamcinolone	463	6.23	1.74
Prednisone	550	6.86	1.97
Ibuprofen	566	6.55	2.03
Mefenamic acid	598	0.51	2.07
Indomethacin	621	1.46	2.16
Prednisolone	625	4.97	2.22
Dexamethasone	677	5.91	2.48
Methylprednisolone	707	5.12	2.64
Chlordiazepoxide	750	1.85	2.91
Methylprednisolone acetate	786	5.06	3.20
Diazepam	812	4.64	3.43

[a] The void volume was 2.24 ml (1.12 min).

methylprednisolone acetate and diazepam, both the retention index and the absorbance ratio measurements were fairly close, but even these two drugs could be differentiated if care was taken in making the measurements. The retention index and absorbance ratio of prednisone and ibuprofen also were grouped closely, but these compounds could be differentiated. The precision of the A_{254}/A_{280} measurements previously was ±1.9% (1), and essentially the same precision was observed in the present study. The short-term precision of the retention index measurements was typically ±5 units. Thus, if the retention index and A_{254}/A_{250} values were used as paired discriminators, all of the drugs in Table I could be distinguished from each other.

All of the steroids had similar absorbance ratio values. The highest value was observed for prednisone (6.86), and the lowest value was observed for prednisolone (4.97). Since all of the steroids in the study had essentially the same chromophore, it was expected that the absorbance ratio also would be similar.

Naproxen, fenoprofen, ibuprofen, mefenamic acid, and indomethacin all contain a carboxylic acid group that is completely ionized at the pH of the mobile phase (7.0). Thus, it was not unexpected that even drugs with a very lipophilic naphthyl group, such as naproxen, had a small retention index. Because of the diversity of the chromophores in this group of drugs, the A_{254}/A_{280} ratios varied greatly.

Although each drug in Table I can be distinguished from the others, other steroids that occasionally were used should have similar indexes and absorbance ratios. The relationship between the drug retention on reversed-phase columns and the lipophilicity of the drug was investigated previously (3, 5–8). Hansch substituent constants, π values, have been used to estimate the lipophilicity of the drugs (9), and these estimates have been used to estimate their HPLC retention indexes (10). The HPLC retention index of a given drug, I_x, could be estimated using the sum of the Hansch substituent values for the drug, π_x, and the experimentally observed index for the reference or parent drug for the series, I_{ref}, by (10):

$$I_x = 200\pi_x + I_{\text{ref}} \qquad \text{(Eq. 3)}$$

With Eq. 3, it is possible to predict other clinically used steroids that might be misidentified as one of the drugs in Table I. It is expected that both the retention index and the absorbance ratio of triamcinolone and meprednisone would be very close. Similarly, there is a potential for interference between dexamethasone (I = 677) and its isomer, betamethasone. Other interferences might be observed between methylprednisolone and triamcinolone diacetate and between methylprednisolone acetate and triamcinolone acetonide.

Other compounds that were not examined in this study also might be misidentified as one of the drugs listed in Table I. Although the absorbance ratio technique greatly reduces the probability of error in the identification of drugs based on retention times alone (3), the methods presented in this study are simple and rapid. As with any analytical method, good laboratory procedures dictate that the initial results should be confirmed by an independent method.

Chemotherapy of Neuroblastoma in Mice with Anticancer Agents

GEORGE C. Y. CHIOU ˣ **and MARILYN K. MARTIN**

Received August 20, 1979, from the *Department of Medical Pharmacology & Toxicology, College of Medicine, Texas A&M University, College Station, TX 77843.* Accepted for publication December 4, 1979.

Abstract □ Neuroblastoma-inoculated A/J mice were treated with various anticancer chemotherapeutic agents, including cyclophosphamide, daunorubicin, vincristine, α-bungarotoxin, dihydroxytryptamine, and diaminopropane. Cyclophosphamide and diaminopropane inhibited neuroblastoma as effectively as bromoacetylcholine and bromoacetate. The effectiveness of these drugs could be related to the inhibition of ornithine decarboxylase, a rate-limiting enzyme for the synthesis of polyamines.

Keyphrases □ Anticancer agents—chemotherapy of neuroblastoma in mice □ Ornithine decarboxylase—inhibition by anticancer agents, chemotherapy of neuroblastoma □ Cyclophosphamide—chemotherapy of neuroblastoma in mice □ Diaminopropane—chemotherapy of neuroblastoma in mice

Despite many efforts, the prognosis of the clinical treatment of neuroblastoma in patients over the age of 1 year is very poor (1). Since the A/J mouse inoculated with C-1300 neuroblastoma cells is considered to be a model of the neuroblastoma disease of humans (2), various anticancer drugs were tested on this animal model to determine an effective way to treat the neuroblastoma disease. Bromoacetylcholine and bromoacetate recently were reported to be effective in inhibiting the neuroblastoma growth *in vivo* (3–6). Therefore, a combination of bromoacetylcholine and other anticancer drugs also was tested in this neuroblastoma mouse model.

METHODS

Adult male A/J mice[1] were inoculated subcutaneously in the interscapular area with 1×10^6 cells of murine C-1300 neuroblastoma cells. Ten days was allowed for a measurable tumor to develop. Drug injections began on the 10th day after neuroblastoma inoculation, and this time was designated as Day 0 of drug treatment. Identical conditions were maintained for the control groups, except that saline was injected instead of drug solutions. Drug treatment was continued for 6 weeks unless otherwise specified. For all injections, the volume of the drug solutions was <50 μl.

Bromoacetylcholine percholate was synthesized by a previously described method (7). Sodium bromoacetate, cyclophosphamide, 1,3-diaminopropane, 5,6-dihydroxytryptamine, α-bungarotoxin, and vincristine were purchased commercially. All drug solutions were freshly prepared at the time of injection.

[1] Jackson Laboratory, Bar Harbor, Me.

RESULTS

It has been established that bromoacetylcholine (30 mg/kg) injected intratumorly one to three times per day and bromoacetate (12 mg/kg) injected intratumorly twice per day inhibit neuroblastoma growth in A/J mice efficiently and prolong the lifespan of these animals by >200% (4, 5). The only anticancer agent that was able to produce an effectiveness equivalent to bromoacetylcholine and bromoacetate was cyclophosphamide (100 mg/kg) injected only once intraperitoneally (Table I). A higher dose (200 mg/kg) of cyclophosphamide reduced its effectiveness due to toxicity. Combination of cyclophosphamide with bromoacetylcholine or bromoacetate did not additionally prolong the lifespan. On the contrary, the lifespan was shortened somewhat as compared to the lifespan of mice receiving the optimal doses of bromoacetylcholine, bromoacetate, and cyclophosphamide administered individually (Table I).

Daunorubicin[2] at a dose of 2 mg/kg injected intravenously twice per week worsened the disease as compared to the control. Combined use of daunorubicin and bromoacetylcholine prolonged the lifespan by only 33%, which was much shorter than the result with bromoacetylcholine alone (Table I).

Vincristine (1 mg/kg) injected intraperitoneally three times daily did not improve the neuroblastoma disease and did not potentiate the effect of bromoacetylcholine (Table I). On the contrary, it shortened the mean lifespan of bromoacetylcholine-treated animals from 73.4 (207% change of lifespan) (5) to 52.1 (129% change of lifespan) days (Table I).

Table II shows the effects of various agents known to inhibit neuroblastoma growth in cell culture on the neuroblastoma growth in A/J mice. α-Bungarotoxin is an inhibitor of neuroblastoma in cell culture (8) but is too toxic to be used *in vivo*. The mice survival rate was shorter than that of the untreated controls (Table II).

5,6-Dihydroxytryptamine has degenerated serotonergic neurons (9, 10) and inhibited gliomas in cell culture (11). However, it did not prolong the lifespan of neuroblastoma-inoculated A/J mice and did not enhance the inhibition of neuroblastoma growth when used in combination with bromoacetylcholine (Table II).

1,3-Diaminopropane was shown to inhibit ornithine decarboxylase, a rate-limiting enzyme for the synthesis of polyamines, which in turn suppressed neuroblastoma growth in cell culture (6). It also produced a significant improvement in mice inoculated with neuroblastoma cells when injected intratumorly twice per day for 6 weeks at a dose of 110 mg/kg (Table II). The combination of diaminopropane and bromoacetylcholine was even more instrumental in prolonging the lifespan of neuroblastoma-inoculated mice.

Various routes of administration were used to find an effective alternative to the intratumor route. Bromoacetylcholine and bromoacetate were ineffective with intraperitoneal administration (Table III), mainly because bromoacetylcholine has a permanent positive charge at the

Chemotherapy of Neuroblastoma in Mice with Anticancer Agents

GEORGE C. Y. CHIOU ˣ **and MARILYN K. MARTIN**

Received August 20, 1979, from the *Department of Medical Pharmacology & Toxicology, College of Medicine, Texas A&M University, College Station, TX 77843.* Accepted for publication December 4, 1979.

Abstract □ Neuroblastoma-inoculated A/J mice were treated with various anticancer chemotherapeutic agents, including cyclophosphamide, daunorubicin, vincristine, α-bungarotoxin, dihydroxytryptamine, and diaminopropane. Cyclophosphamide and diaminopropane inhibited neuroblastoma as effectively as bromoacetylcholine and bromoacetate. The effectiveness of these drugs could be related to the inhibition of ornithine decarboxylase, a rate-limiting enzyme for the synthesis of polyamines.

Keyphrases □ Anticancer agents—chemotherapy of neuroblastoma in mice □ Ornithine decarboxylase—inhibition by anticancer agents, chemotherapy of neuroblastoma □ Cyclophosphamide—chemotherapy of neuroblastoma in mice □ Diaminopropane—chemotherapy of neuroblastoma in mice

Despite many efforts, the prognosis of the clinical treatment of neuroblastoma in patients over the age of 1 year is very poor (1). Since the A/J mouse inoculated with C-1300 neuroblastoma cells is considered to be a model of the neuroblastoma disease of humans (2), various anticancer drugs were tested on this animal model to determine an effective way to treat the neuroblastoma disease. Bromoacetylcholine and bromoacetate recently were reported to be effective in inhibiting the neuroblastoma growth *in vivo* (3–6). Therefore, a combination of bromoacetylcholine and other anticancer drugs also was tested in this neuroblastoma mouse model.

METHODS

Adult male A/J mice[1] were inoculated subcutaneously in the interscapular area with 1×10^6 cells of murine C-1300 neuroblastoma cells. Ten days was allowed for a measurable tumor to develop. Drug injections began on the 10th day after neuroblastoma inoculation, and this time was designated as Day 0 of drug treatment. Identical conditions were maintained for the control groups, except that saline was injected instead of drug solutions. Drug treatment was continued for 6 weeks unless otherwise specified. For all injections, the volume of the drug solutions was <50 μl.

Bromoacetylcholine percholate was synthesized by a previously described method (7). Sodium bromoacetate, cyclophosphamide, 1,3-diaminopropane, 5,6-dihydroxytryptamine, α-bungarotoxin, and vincristine were purchased commercially. All drug solutions were freshly prepared at the time of injection.

[1] Jackson Laboratory, Bar Harbor, Me.

RESULTS

It has been established that bromoacetylcholine (30 mg/kg) injected intratumorly one to three times per day and bromoacetate (12 mg/kg) injected intratumorly twice per day inhibit neuroblastoma growth in A/J mice efficiently and prolong the lifespan of these animals by >200% (4, 5). The only anticancer agent that was able to produce an effectiveness equivalent to bromoacetylcholine and bromoacetate was cyclophosphamide (100 mg/kg) injected only once intraperitoneally (Table I). A higher dose (200 mg/kg) of cyclophosphamide reduced its effectiveness due to toxicity. Combination of cyclophosphamide with bromoacetylcholine or bromoacetate did not additionally prolong the lifespan. On the contrary, the lifespan was shortened somewhat as compared to the lifespan of mice receiving the optimal doses of bromoacetylcholine, bromoacetate, and cyclophosphamide administered individually (Table I).

Daunorubicin[2] at a dose of 2 mg/kg injected intravenously twice per week worsened the disease as compared to the control. Combined use of daunorubicin and bromoacetylcholine prolonged the lifespan by only 33%, which was much shorter than the result with bromoacetylcholine alone (Table I).

Vincristine (1 mg/kg) injected intraperitoneally three times daily did not improve the neuroblastoma disease and did not potentiate the effect of bromoacetylcholine (Table I). On the contrary, it shortened the mean lifespan of bromoacetylcholine-treated animals from 73.4 (207% change of lifespan) (5) to 52.1 (129% change of lifespan) days (Table I).

Table II shows the effects of various agents known to inhibit neuroblastoma growth in cell culture on the neuroblastoma growth in A/J mice. α-Bungarotoxin is an inhibitor of neuroblastoma in cell culture (8) but is too toxic to be used *in vivo*. The mice survival rate was shorter than that of the untreated controls (Table II).

5,6-Dihydroxytryptamine has degenerated serotonergic neurons (9, 10) and inhibited gliomas in cell culture (11). However, it did not prolong the lifespan of neuroblastoma-inoculated A/J mice and did not enhance the inhibition of neuroblastoma growth when used in combination with bromoacetylcholine (Table II).

1,3-Diaminopropane was shown to inhibit ornithine decarboxylase, a rate-limiting enzyme for the synthesis of polyamines, which in turn suppressed neuroblastoma growth in cell culture (6). It also produced a significant improvement in mice inoculated with neuroblastoma cells when injected intratumorly twice per day for 6 weeks at a dose of 110 mg/kg (Table II). The combination of diaminopropane and bromoacetylcholine was even more instrumental in prolonging the lifespan of neuroblastoma-inoculated mice.

Various routes of administration were used to find an effective alternative to the intratumor route. Bromoacetylcholine and bromoacetate were ineffective with intraperitoneal administration (Table III), mainly because bromoacetylcholine has a permanent positive charge at the

Bromoacetate	24 sc	10	4–37	18.3 ± 3.3	−36	18

[a] The drug was administered three times daily. [b] See footnote[a], Table I.

quaternary nitrogen group of the molecule and bromoacetate has a negative charge in the molecule, which hinders absorption from the GI system. Intramuscular and subcutaneous injections of bromoacetate also were ineffective in suppressing neuroblastoma growth (Table III). Intratumor injection is the only viable route at this time. Intravenous administration was not tried because the mouse tail vein cannot withstand multiple daily injections for 6 weeks. Larger animal models are sought for experimentation to solve this problem.

DISCUSSION

Neuroblastoma is a cancer that cannot be treated well with current medical knowledge and methodology (1). After unsuccessful attempts to treat neuroblastoma surgically, with immunotherapy, and by radiation therapy, partial success was achieved with chemotherapy (1). Chemotherapy should be explored further.

Among the drugs tested, bromoacetylcholine, bromoacetate, cyclophosphamide, and 1,3-diaminopropane effectively inhibited neuroblastoma growth and prolonged the lifespan of A/J mice inoculated with neuroblastoma cells. Bromoacetylcholine, bromoacetate, and 1,3-diaminopropane are potent inhibitors of ornithine decarboxylase, a rate-limiting enzyme for the synthesis of polyamines. Since cellular levels of polyamines are closely related to cell proliferation and growth (12–17), it is highly possible that neuroblastoma growth is suppressed *via* the inhibition of ornithine decarboxylase (6). The only agent that is not clearly known to inhibit ornithine decarboxylase is cyclophosphamide, because cyclophosphamide must be activated *in vivo* while ornithine decarboxylase activity can only be determined *in vitro* with tissue culture experiments. The effect of cyclophosphamide also may possibly be manifested through the ornithine decarboxylase inhibition *in vivo*. Daunorubicin is an antibiotic that binds tightly with DNA (18) but has no inhibiting action on neuroblastoma growth.

Vincristine inhibits cell mitosis at the metaphase and dissolves the microtubule structures (18). However, it has little effect on ornithine decarboxylase activity, and this fact could be why it is ineffective in the inhibition of neuroblastoma growth.

Although bromoacetylcholine binds to the nicotinic receptor at the neuromuscular junction irreversibly (19), as does α-bungarotoxin (20), the latter compound produced little effect on neuroblastoma growth, indicating that bromoacetylcholine inhibits neuroblastoma growth through an action mechanism that differs from α-bungarotoxin, similar to action at cholinergic receptors. Neuroblastoma cells possess adrenergic, cholinergic, and nonspecific receptors but very few serotonergic receptors. It thus is understandable that neuroblastoma cell growth was not inhibited by a serotonergic neuron degenerator, 5,6-dihydroxytryptamine.

Among the routes of administration studied, intratumor administration for bromoacetylcholine, bromoacetate, and 1,3-diaminopropane and intraperitoneal administration for cyclophosphamide were the best.

In summary, it seems that drugs capable of inhibiting ornithine decarboxylase can suppress the cell growth of neuroblastoma. A more potent ornithine decarboxylase inhibitor that produces few side effects may be developed as an effective weapon to treat neuroblastoma.

Effect of pH, Chlorobutanol, Cysteine Hydrochloride, Ethylenediaminetetraacetic Acid, Propylene Glycol, Sodium Metabisulfite, and Sodium Sulfite on Furosemide Stability in Aqueous Solutions

KIRIT A. SHAH *, V. DAS GUPTA ˣ, and KENNETH R. STEWART ‡

Received November 2, 1979, from the *College of Pharmacy, University of Houston, Houston, TX 77004.* Accepted for publication December 20, 1979.

*Present address: College of Pharmacy, Texas Southern University, Houston, TX 77004. ‡Ben Taub Hospital Pharmacy, Houston, TX 77030.

Abstract □ A study was conducted to determine the effects of pH, two antioxidants, a chelating agent, a preservative, and propylene glycol on furosemide stability. Aqueous solutions of furosemide containing 10% alcohol (v/v) were prepared in phosphate buffers with various pH values (5, 6, and 9) whose ionic strength was adjusted to 0.1 *M* with potassium chloride. Some solutions contained chlorobutanol, ethylenediaminetetraacetic acid, or sodium metabisulfite. Another set of aqueous solutions contained phosphate buffer (0.1 *M*), alcohol (10% v/v), and propylene glycol (40% v/v) with or without cysteine hydrochloride, ethylenediaminetetraacetic acid, and sodium sulfite. The solutions were divided into two parts, stored at 24 and 50°, and assayed frequently using a previously developed high-pressure liquid chromatographic procedure. At the lowest pH value (pH 5), furosemide appeared to be very unstable. Cysteine hydrochloride, ethylenediaminetetraacetic acid, and sodium sulfite failed to improve the stability of furosemide. Chlorobutanol and sodium metabisulfite had an adverse effect on the stability, probably due to the fact that they decreased the pH of the solution. The pH value appears to be the only critical factor for the stability of furosemide. Buffered solutions containing propylene glycol were very stable at both temperatures for 170 days, and they tasted good.

Keyphrases □ Furosemide—stability in aqueous solutions, effect of formulation factors □ Diuretics—furosemide, stability in aqueous solutions, effect of formulation factors □ Stability—furosemide in aqueous solutions, effect of formulation factors

Furosemide (I) is a widely used diuretic, but little information is available concerning the stability of this drug in dosage forms. Rowbotham *et al.* (1) reported that aqueous furosemide solutions undergo hydrolysis and photochemical degradation. Quantification of photochemical degradation products of furosemide by the USP XIX (2) UV assay procedures was not successful. A stability-indicating assay for furosemide using high-pressure liquid chromatography (HPLC) was developed by Ghanekar *et al.* (3). It also was reported that an aqueous furosemide solution containing sorbitol and 10% alcohol (v/v) had limited stability. The pH of the solution was adjusted to ~8.5. However, it was difficult to maintain the pH value of the solution, which caused rapid decomposition.

The objectives of the present investigation were to study

the effect of pH, chlorobutanol, cysteine hydrochloride monohydrate (II), ethylenediaminetetraacetic acid (III), sodium sulfite (IV), and sodium metabisulfite (V) on the stability of furosemide in aqueous solutions and to develop an appropriate buffering system to maintain the adjusted pH value.

EXPERIMENTAL

Chemicals and Reagents—All chemicals and reagents were USP, NF, or ACS grade and were used without further purification. Furosemide[1] powder was used as received.

Apparatus—The apparatus was the same as that reported previously (3), except that a variable-wavelength detector[2] set at 254 nm was used. The column also was the same as that reported previously (3).

Preparation of Solutions—A stock solution of furosemide was prepared by dissolving 1.25 g of furosemide in enough alcohol to make 250 ml. The solutions for stability studies were prepared by diluting an appropriate quantity of the stock solution with a buffer of an appropriate pH value (0.05 *M* phosphate buffers of pH 5, 6, and 9 whose ionic strength was adjusted to 0.1 *M* with potassium chloride). The phosphate buffers were prepared according to the USP procedure (4). Before the solutions were diluted to volume, additional ingredients, if any, were added.

Another set of solutions was prepared by dissolving an appropriate quantity of furosemide in 50.0 ml of 0.2 *M* aqueous dibasic potassium phosphate solution and then adding 10 ml of ethanol and bringing the solution to volume (100.0 ml) with propylene glycol. Additional ingredients, if any, were dissolved before bringing the solution to volume. The pH values of these solutions were determined after diluting 5.0 ml to 50.0 ml with water and are reported in Table I. All of the solutions prepared are listed in Table I.

The solutions were divided into two portions, stored at 24 and 50°, and assayed frequently using the HPLC method reported previously (3), except that the absorbance unit for full-scale deflection was 0.1 instead of 0.16 and the injection volume was 20.0 instead of 40.0 μl. The results, which were calculated as previously reported (3), are presented in Tables II and III. Sample chromatograms are presented in Figs. 1 and 2.

17	—	101.1	100.5	—	8.0

[a] Crystals were found in the solution, so it was not reassayed. [b] Not studied at 50° since they were not stable even at room temperature. [c] Color had changed to light yellow.

RESULTS AND DISCUSSION

For convenience, the results from Solutions 1–12 (Table I), which did not contain any propylene glycol, will be discussed first, followed by the results from Solutions 13–17 (Table I), which contained 40% (v/v) propylene glycol.

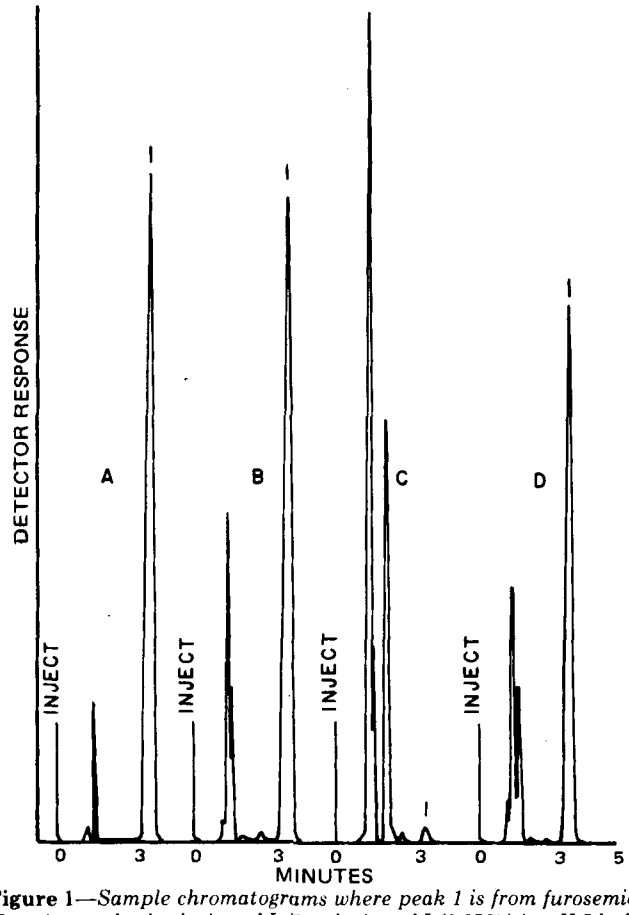

Figure 1—*Sample chromatograms where peak 1 is from furosemide. Key: A, standard solution of I; B, solution of I (0.05%) in pH 5 buffer after 240 days of storage at 50°; C, same as B except that it also contained 0.2% chlorobutanol; and D, same as B except that it also contained 0.05% III.*

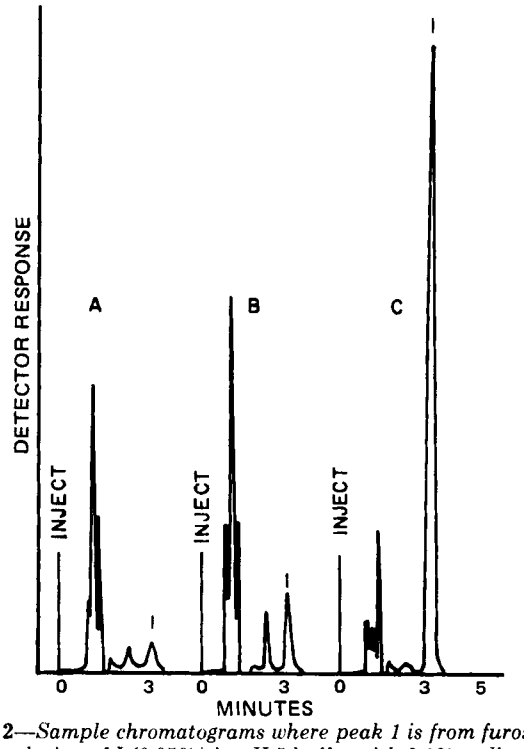

Figure 2—*Sample chromatograms where peak 1 is from furosemide. Key: A, solution of I (0.05%) in pH 5 buffer with 0.1% sodium metabisulfite after 170 days of storage at room temperature; B, same as A except that pH 6 buffer was used; and C, same as A except that pH 9 buffer was used.*

Solutions 1–12 (without Propylene Glycol)—The results indicate that Solutions 1–12 were not very stable for 170 days either at room temperature or at 50° (Tables II and III). Furthermore, the additional ingredients, ethylenediaminetetraacetic acid, chlorobutanol, or sodium metabisulfite, did not improve furosemide stability. In fact, chlorobutanol and sodium metabisulfite had an adverse effect on its stability, especially when added with pH 5 buffers. This effect may be due to a decrease in the pH of the solutions (Table III). Furosemide is known to be unstable at lower pH values (3). The pH values of most solutions changed after storage (Tables II and III).

The effect of sodium metabisulfite (as the concentration was raised from 0.1 to 0.4%) on furosemide stability is interesting. In Solutions 4–6 and 7–9 (Table II), the stability of furosemide improved as the concentration of sodium metabisulfite was increased, perhaps due to initial oxidation of metabisulfite to sulfate by the oxygen present. The sulfate ion increased the rate of decomposition (oxidation) of furosemide. A similar scheme using epinephrine has been reported (5).

Furthermore, the additional amount of sodium metabisulfite, after all of the oxygen was consumed, protected furosemide from the oxidation effect of the sulfate ion. This effect also has been reported (5).

The described effects were not found in Solutions 10–12, probably due to their high pH values (Table II). In these solutions, the effect of pH appears to be more prominent. Moreover, in solutions with basic pH values, furosemide does not appear to be susceptible to oxidation. The same may be true of solutions with pH values above 5.5.

Crystals of furosemide were found in several solutions after 35 days, especially in those kept at room temperature (Table II, Solutions 4–6). Furosemide is known to be poorly soluble in aqueous systems, especially acidic ones.

Several other solutions (Solutions 7, 9, 11, and 12) became discolored after 152 days (Table II). The cause of this discoloration was not determined.

It was not possible to treat the data mathematically because of very little decomposition (Solutions 1–3) or changes in pH values (Solutions 4–12).

Solutions 13–17 (with Propylene Glycol)—Solutions 13–17 proved to be very stable at both 24 and 50°. Considering experimental errors, the results of both temperatures were almost 100% for all solutions at 170 days (Tables II and III). Furthermore, the pH values of the solutions did not change (Tables II and III). However, the addition of cysteine hydrochloride monohydrate (II), ethylenediaminetetraacetic acid, sodium sulfite, or their combinations did not improve furosemide stability. Although the solution containing II became discolored, the loss in furosemide potency was negligible. Compound II apparently was oxidized in this solution. This discoloration did not occur when II was present in combination with sodium sulfite due to the protection provided by the sodium sulfite. Nevertheless, the addition of these ingredients is not desirable. In weakly basic solutions, furosemide does not appear to be susceptible to oxidation.

The only critical factor in furosemide stability is the pH of the solution, which must be slightly basic and not change on storage. A stable liquid dosage form of furosemide can be prepared by dissolving an appropriate quantity of furosemide powder in 0.2 *M* aqueous dibasic potassium phosphate solution (50% of the total volume), adding alcohol (10% v/v), and bringing the solution to volume with propylene glycol. Since the solution did not lose potency at 50° for ~6 months, it should be stable for at least 2 years at room temperature. A panel of three persons approved the taste of the product.

Colorimetric and Spectrophotometric Determinations of Hydrastis Alkaloids in Pharmaceutical Preparations

SAWSAN EL-MASRY ˣ, M. A. KORANY, and A. H. A. ABOU-DONIA

Received October 9, 1979, from the *Faculty of Pharmacy, University of Alexandria, Alexandria, Egypt.* Accepted for publication December 19, 1979.

Abstract □ Hydrastine, canadine, and berberine were determined by the acid-dye technique. At pH 5.6, both the tertiary and the quaternary hydrastis alkaloids formed ion-pairs with bromcresol purple. The liberated hydrastine and canadine from the alkaloid–dye complexes were determined spectrophotometrically in the presence of berberine by the three-wavelength method of analysis. However, berberine could not be assayed successfully by this method due to significant partitioning in the aqueous phase during extraction. At pH 7.2, only berberine could ion-pair with bromcresol purple to form a chloroform-extractable complex. Consequently, the berberine content was analyzed selectively through the colorimetric determination of the combined dye at 580 nm. The suitability of the proposed methods was examined through the analyses of synthetic mixtures of hydrastis alkaloids and samples of hydrastis tincture and liquid extract. Percentage recoveries were 98.2–101.4 for the synthetic mixtures and 98.4–101.7 for the tincture and liquid extract spiked with berberine.

Keyphrases □ Colorimetry—analysis, berberine in pharmaceutical preparations and synthetic mixtures of hydrastis alkaloids, effect of pH on alkaloid–dye complex formation □ Spectrophotometry—analyses, hydrastine and canadine in pharmaceutical preparations and synthetic mixtures of hydrastis alkaloids, effect of pH on alkaloid–dye complex formation □ Hydrastis alkaloids—spectrophotometric and colorimetric determinations of alkaloid–dye complexes, effect of pH on complex formation □ Berberine—hydrastis alkaloid, colorimetric determination, effect of pH on alkaloid–dye complex formation □ Canadine—hydrastis alkaloid, spectrophotometric determination, effect of pH on alkaloid–dye complex formation □ Hydrastine—hydrastis alkaloid, spectrophotometric determination of alkaloid–dye complex, effect of pH on complex formation

The active ingredients and therapeutic uses of hydrastis were reviewed previously (1). The drug and its preparations are official in several pharmacopeias (2). Pharmacopeial assay methods for hydrastis rhizome or its liquid extract determine the hydrastine content while neglecting other alkaloids (3, 4).

BACKGROUND

The BPC (3) assays for hydrastine involve either a gravimetric step (for the liquids) or a titrimetric end-point (for powdered hydrastis). As with most gravimetric methods, the residue obtained was found to be impure since more than one spot was revealed by TLC. The titrimetric assay suffers from the disadvantage that the end-point is masked by the color of the extract.

The procedure of the French Pharmacopoeia (4) depends on the selective extraction by ether of hydrastine from the powdered drug after alkalinization with ammonia. Stanislas *et al.* (5) suggested a modification of the method in which the extracted hydrastine was determined spectrophotometrically at 295 and 313 nm. However, this modified method is relatively time consuming; it requires at least 7 hr.

Paper chromatography followed by colorimetric or spectrofluorometric determination was suggested (6, 7) for the assay of hydrastis. Direct spectrofluorometric determination of berberine, hydrastine, and canadine in synthetic mixtures was attempted by Gaille *et al.* (8). However, when applied to the hydrastis extract, only berberine and canadine could be determined by this method.

Column chromatography followed by spectrophotometric determination of hydrastine and berberine in liquid extracts of hydrastis also was suggested (9). Berberine and coptisine in coptis rhizome were separated by constant-potential electrophoresis followed by fluorescence densitometry at 550 nm (10). TLC was used to separate berberine prior to its determination as the tetrabromophenolphthalein ethyl ester ion-pair (11). Sakai *et al.* (12) determined berberine in pharmaceutical preparations as an ion-pair using 2,6-dichloroindophenol sodium. The ion-pair complex was stable for only 30 min.

The objective of the present work was to devise a simple and sensitive method for the determination of hydrastis alkaloids without chromatographic separation. Although the UV spectra of berberine, hydrastine, and canadine suggest that they can be determined spectrophotometrically by applying the three-wavelength method, it was possible to estimate only hydrastine and canadine in preparations of hydrastis. Because berberine is water soluble (1 in 4.5), it could not be determined by this method due to its incomplete recovery during extraction. Alternatively, berberine was selectively assayed colorimetrically using the acid-dye technique since, at pH 7.2, neither hydrastine nor canadine formed chloroform-extractable complexes with bromcresol purple.

EXPERIMENTAL

Materials—McIlvain buffers of pH 5.6 and 7.2 were prepared by mixing the required volumes of 0.1 *M* citric acid and 0.2 *M* dibasic sodium phosphate. Hydrastis liquid extract BPC, hydrastis tincture BPC, and analytical reagent grade sodium chloride were used. Hydrastine[1], canadine[2], and berberine acid sulfate[1] were used as received.

Solution Preparation—A berberine stock solution was prepared by dissolving 0.25 g of berberine acid sulfate in 100 ml of water. A berberine reference solution (1.25 mg %) was prepared by diluting 0.5 ml of the stock solution to 100 ml with 1 *N* HCl.

The canadine and hydrastine stock solutions were prepared by dissolving 0.2 g of either alkaloidal base in 100 ml of 1 *N* HCl. The canadine and hydrastine reference solutions were prepared by diluting 2 ml of the respective stock solution to 100 ml with 1 *N* HCl. Each reference solution contained 4 mg % of the alkaloidal base.

The bromcresol purple solution was prepared by dissolving 50 mg of the dye[3] in a few drops of 0.1 *N* NaOH and bringing the solution to 100 ml with water.

Methods—*Berberine Content of Hydrastis Tincture and Liquid Extract*—A 5-ml aliquot of hydrastis tincture (or 0.5 ml of hydrastis liquid extract diluted to 5 ml with 60% ethanol) was diluted to 1 liter with pH 7.2 buffer. A 10-ml aliquot (containing 0.05–0.2 mg of berberine) was transferred to a 50-ml separator containing 10 ml of chloroform and 1 ml of the dye solution. After shaking for 1 min, the layers were allowed to separate completely (15 min).

The chloroform layer was transferred to a second separator, and the aqueous layer was reextracted with another 10 ml of chloroform. The combined chloroform extracts were shaken for 15 sec with 10 ml of 0.1 *N* NaOH to liberate the combined dye. The aqueous layer was transferred to a 25-ml volumetric flask. After adjustment to volume, the intensity of the color of the solution was measured at 590 nm. The berberine content was determined by assaying a standard berberine solution concomitantly.

Hydrastine and Canadine Content of Hydrastis Tincture and Liquid Extract—Five milliliters of the tincture (or 0.5 ml of the liquid extract diluted to 5 ml with 60% ethanol) was diluted to 500 ml with pH 5.6 buffer. A 10-ml aliquot (containing 0.2–0.6 mg of total hydrastis alkaloids) was transferred to a 50-ml separator containing 1 ml of the dye solution and 10 ml of chloroform. After shaking for 1 min, the layers were allowed to separate completely.

The chloroform layer was transferred to a second separator, and the extraction was repeated with 2 × 10 ml of chloroform. The combined chloroform layers were extracted with 10 ml of 0.1 *N* NaOH for 15 sec,

Table I—Results of Replicate Assays of Hydrastine, Canadine, and Berberine in Hydrastis Tincture

Assay	Alkaloid Concentration, g % (w/v)		
	Hydrastine[a]	Canadine	Berberine
1	0.229	0.054	0.265
2	0.227	0.050	0.261
3	0.218	0.077	0.262
4	0.223	0.052	0.266
5	0.218	0.054	0.265
6	0.223	0.052	0.262
Mean	0.223	0.056	0.263

[a] The hydrastine content found by the BPC method was 0.21 g % (w/v).

followed by 5 ml of saturated sodium chloride solution. The chloroform layer was evaporated on a water bath just to dryness. The residue was dissolved in 1 *N* HCl, transferred to a 25-ml volumetric flask, and brought to volume. The absorbances of the final solution together with the canadine, hydrastine, and berberine reference solutions were measured concomitantly in 1-cm cells at 285, 295, and 345 nm with a suitable spectrophotometer[4] using 1 *N* HCl as the blank.

The concentrations of canadine, C_a, and hydrastine, C_b, expressed in gram percent (w/v), were calculated from:

$$C_a = \frac{\left(A_1 - A_3\frac{\gamma_1}{\gamma_3}\right)\beta_2 - \left(A_2 - A_3\frac{\gamma_2}{\gamma_3}\right)\beta_1}{\alpha_1\beta_2 - \alpha_2\beta_1} \times \frac{1}{4} \times \frac{500}{10} \times \frac{100}{5} \quad \text{(Eq. 1)}$$

$$C_b = \frac{\left(A_2 - A_3\frac{\gamma_2}{\gamma_3}\right)\alpha_1 - \left(A_1 - A_3\frac{\gamma_1}{\gamma_3}\right)\alpha_2}{\alpha_1\beta_2 - \alpha_2\beta_1} \times \frac{1}{4} \times \frac{500}{10} \times \frac{100}{5} \quad \text{(Eq. 2)}$$

where:

$$A_1 = C_a\alpha_1 + C_b\beta_1 + C_c\gamma_1$$
$$A_2 = C_a\alpha_2 + C_b\beta_2 + C_c\gamma_2$$
$$A_3 = C_c\gamma_3$$

and where A_1, A_2, and A_3 are the absorbances of the final solution at 285, 295, and 345 nm, respectively, and α, β, and γ are the absorptivities of canadine, hydrastine, and berberine, respectively. The subscripts 1, 2, and 3 refer to the respective wavelengths at 285, 295, and 345 nm.

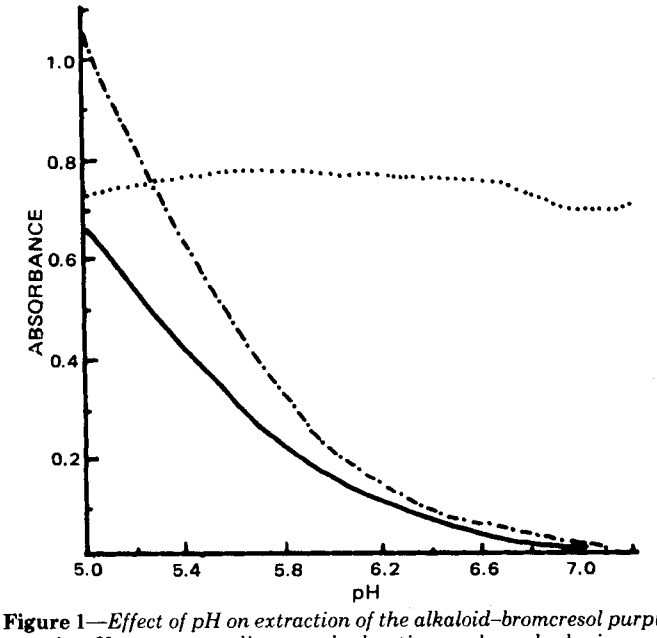

Figure 1—*Effect of pH on extraction of the alkaloid–bromcresol purple complex. Key: —, canadine; -·-, hydrastine; and ·····, berberine.*

[4] Beckman model 24 spectrophotometer.

RESULTS AND DISCUSSION

The λ_{max} values were 230 and 345 (berberine), 285 (canadine), and 295 (hydrastine) nm. Analysis of a synthetic mixture containing 0.2% (w/v) hydrastine, 0.05% (w/v) canadine, and 0.25% (w/v) berberine by the proposed method gave percentage recoveries of 98.2 and 101.4 for canadine and hydrastine, respectively. Direct UV estimation was successful for berberine in synthetic mixtures. However, in preparations where an extraction step was involved, berberine could not be determined successfully (<80% recovery). This result was due mainly to its partitioning between the aqueous and organic phases.

Table I shows the results of replicate assays of hydrastis tincture for hydrastine and canadine by the suggested method. The mean gram percent of hydrastine found (±*SD*) was 0.223 (±0.004). This result compares favorably with the result obtained by the BPC method (0.21% w/v). The slightly lower percentage recovery found by the BPC method might be attributed to incomplete extraction of hydrastine during the assay. For canadine, which oftens represents one-third to one-fourth of the hydrastine content, the results showed more scattering (Table I).

Figure 1 shows the effect of pH on the extractability of alkaloid–bromcresol purple complexes for berberine, canadine, and hydrastine. The formation of the complexes was strongly pH dependent for canadine and hydrastine, with an optimum pH range of 5–5.6. At pH values above 7, any complexes formed between canadine and hydrastine and the dye were not recovered in the chloroform phase. For berberine, the alkaloid–dye complex apparently was formed within the whole pH range studied (5.0–7.2), with the complex extractability being only slightly pH dependent.

The selective formation of the berberine–bromcresol purple complex at pH 7.2 was applied to the assay of this alkaloid in the presence of canadine and hydrastine. Replicate assays for berberine in a synthetic mixture containing the three alkaloids gave a mean percentage recovery (±*SD*) of 100.7 (± 0.31) for six determinations. Results of the berberine assay in the hydrastis tincture are shown in Table I. Recovery experiments made for hydrastis tincture spiked with various berberine concentrations gave a percentage recovery of 98.4–101.7.

The proposed procedures have the advantage of being less time consuming, with the assay requiring an average of 1 hr. The BPC procedure requires >5 hr and 100 ml of the tincture whereas 0.1 ml is required in the proposed method. This paper also presents a sensitive method for the assay of berberine in the presence of other tertiary hydrastis alkaloids.

Effect of Etidronate Disodium on Filterability of Sickle Cell Erythrocytes

B. F. VAN DUZEE ˣ, R. J. SUNBERG, and J. J. BENEDICT

Received October 4, 1979, from the *Miami Valley Laboratories, Procter & Gamble Company, Cincinnati, OH 45247.* Accepted for publication December 19, 1979.

Abstract □ The effect of etidronate disodium on the deformability of human sickle cell erythrocytes was determined. A filtration process that demonstrated changes in trapping of ^{51}Cr-tagged sickle cells in the filtration apparatus was used to evaluate drug effects. Compared to the nontreated control, etidronate disodium [disodium dihydrogen (1-hydroxyethylidene)diphosphonate] reduced the trapping of sickled cells at low concentrations and increased trapping at high concentrations. These results indicate that etidronate disodium alters the deformability of sickled erythrocytes.

Keyphrases □ Etidronate disodium—effect on filterability of sickle cell erythrocytes □ Erythrocytes—sickle cell, effect of etidronate disodium on filterability □ Blood cell membrane—deformability of sickled erythrocytes, effect of etidronate disodium □ Sickle cell anemia—deformability of erythrocytes, effect of etidronate disodium

Sickle cell anemia has been studied intensively for the last decade. It is a unique disease in that its etiology is well known. The link between the genetically determined structural defect in the hemoglobin molecule and the clinical manifestations of the disease make it an excellent system for study by molecular biologists.

BACKGROUND

Despite the well-understood cause of the disease, some details about the sickling process are poorly understood. For example, it was shown only recently that the erythrocyte membrane may play an important role in the sickling process (1). Measurements of the deformability of erythrocytes as a function of time after deoxygenation showed that erythrocytes containing sickle cell hemoglobin became less deformable before any appreciable gelation of the sickle cell hemoglobin occurred. This finding is taken as evidence that the erythrocyte membrane is not only abnormal but that it also contributes significantly to the rigidity of the sickled erythrocyte.

One factor considered to be responsible for the abnormal membrane rigidity of the sickled erythrocyte is the presence of a high level of calcium in the cell (2). This calcium is expected to bind to the erythrocyte membrane, altering its deformability much as it does in normal erythrocytes (3). Another factor involved in the process is hemoglobin binding to the erythrocyte membrane. It was shown that the extent of hemoglobin binding to the membrane influences membrane rigidity and that normal hemoglobin binds to the sickled erythrocyte membrane to a greater extent than to the normal erythrocyte membrane (4).

Knowledge of the role of the erythrocyte membrane in deformability and its association with abnormally high levels of calcium has led to a new approach in the search for agents useful for therapeutic treatment of sickle cell disease. Investigators have begun looking for compounds that alter the calcium content of membranes (1). Anesthetics perform this function, and at least one, procaine hydrochloride, was shown to improve the filterability (deformability) of sickled erythrocytes (5). This approach has the potential of producing new and useful compounds for the treatment of sickle cell disease.

During early clinical trials of a diphosphonate-based bone scanning agent[1], patients with sickle cell disease had a high soft tissue uptake of the scanning agent in their extremities. Since diphosphonates adsorb strongly to calcium salts, it was suggested that this uptake might be due to the adsorption of the scanning agent to calcium in the erythrocytes trapped in the extremities. If this adsorption did occur, the deformability of the erythrocyte might perhaps be altered by etidronate disodium, which was the diphosphonate used in the scanning agent. Consequently, an investigation was initiated to determine if etidronate disodium alters sickle cell erythrocyte deformability.

EXPERIMENTAL

The filterability of erythrocyte suspensions generally is accepted as a measure of the deformability of the erythrocytes (6). Consequently, filterability was chosen as the parameter to determine the effects of etidronate disodium on deformability. The specific technique was adapted from the method of Wagner *et al.* (4).

Approximately 10 ml of blood was obtained from individual patients with sickle cell anemia whose hematology was well characterized. The samples were washed three times in an isotonic buffer solution containing 107 m*M* NaCl, 6 m*M* glucose, 400 mg of albumin/ml, and pH 7.4, 30 m*M* phosphate. The cells were tagged with sodium [^{51}Cr]chromate and treated with either etidronate disodium[2] or potassium cyanate.

The tagging was accomplished by splitting the sample in thirds. One-third of the sample (the negative control) was suspended in the isotonic buffer with 50 μCi of sodium [^{51}Cr]chromate and incubated for 1 hr at 37°. Another third (the positive control) (2) was suspended in a solution containing sodium [^{51}Cr]chromate as described and the same concentrations of glucose, albumin, and phosphate as the standard buffer but also containing potassium cyanate. The potassium cyanate concentration was varied from one experiment to the next, with the isotonicity of the solutions maintained by addition of sodium chloride to the buffer. The remaining one-third of the sample was suspended in buffer and treated in the same manner as the positive control, except that etidronate disodium was substituted for potassium cyanate.

The suspensions then were incubated for 1 hr at 37°. After incubation, the cell suspensions were washed three times with the isotonic buffer and were suspended in a ratio of 1:9 with unlabeled washed cells from a normal healthy donor to a final hematocrit of 1%. At this point, cell suspensions were stored overnight at 4°. The cells were equilibrated the next day to a partial pressure of oxygen of 26 mm Hg at 37° and filtered through 5-μm

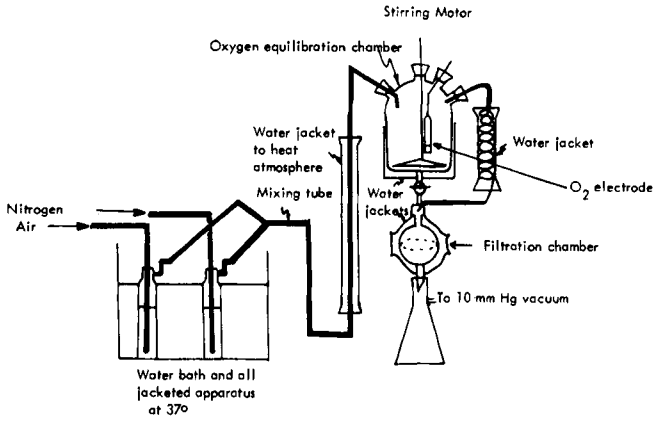

Figure 1—*Schematic diagram of the filtration apparatus. The erythrocyte suspension is introduced into the oxygen equilibration chamber where the partial pressure of oxygen and temperature are monitored. The air–nitrogen mixture is saturated with water and heated to 37° before it is introduced into the equilibration chamber. When the system is equilibrated (partial pressure of oxygen of 26 mm Hg and temperature of 37°), ~5 ml of suspension is transferred directly to the filtration chamber. Then a 10-mm Hg vacuum differential is applied to the filtration system, and the suspension passes through the filter.*

Control		33.6 ± 4.5	
Potassium cyanate	107	5.1 ± 0.5	<0.001
Etidronate disodium	0.001	35.5 ± 11.0	NS

[a] The *p* values were determined using a single-tailed Student *t* test.

polycarbonate filter disks with a 10-mm Hg pressure differential. The filtration apparatus is described in Fig. 1. Following filtration, the filter paper and filtrate were counted in a well-type scintillation counter, and the percentage of cells that were not deformable enough to pass through the 5-μm pores of the filter disk were determined as:

$$\% \text{ trapping} = \frac{\text{number of trapped cells}}{\text{total number of cells}} \times 100 - \frac{\text{cpm from filter disk}}{\text{cpm from filter disk + cpm from filtrate}} \times 100 \quad \text{(Eq. 1)}$$

The percent trapping is taken as a measure of deformability. The larger the trapping, the lower is the deformability.

RESULTS AND DISCUSSION

The results from five filtration experiments are shown in Table I. The values reported are the means (±*SD*) of five filtrations per treatment group. The filtrations for all three treatments in each experiment were completed on the same day.

The average trapping for the controls in each experiment varied from 10.8 to 58.2%. Since the blood samples each came from different donors, this variability was not unexpected. It may have been due to the difference in the sickle cell hemoglobin content or the oxygen affinity of the erythrocytes from individual to individual.

Cyanate is effective in increasing the deformability of sickled erythrocytes and was included in these experiments as a positive control on the procedure (4). The average trapping for the cyanate-treated samples was significantly less than the control trapping in each experiment over the range of 1.0–107 m*M* cyanate. Consequently, it is believed that this apparatus and these procedures were capable of detecting changes in deformability.

In these experiments, etidronate disodium altered the deformability of the sickled erythrocytes. At high concentrations (107 m*M*), the deformability of the erythrocytes was decreased; at lower concentrations

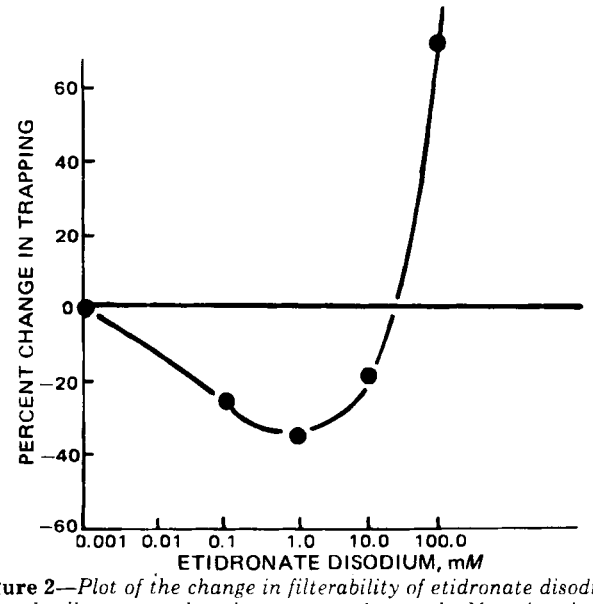

Figure 2—*Plot of the change in filterability of etidronate disodium-treated cells compared to the nontreated controls. Negative changes in trapping indicate increased cell (membrane) deformability, whereas positive changes indicate decreased deformability.*

(0.10–10 m*M*), the deformability of the cells was increased significantly. This biphasic response is quite obvious in Fig. 2, although the position of the minimum is subject to some uncertainty since different blood samples were used at each concentration. This type of biphasic effect is unusual but not unique. For example, isoproterenol and the prostaglandins exhibit a biphasic response on erythrocyte deformability. It is believed that this type of response is produced by the action of the drug on specific membrane receptors (7).

Since filtration experiments generally are considered to be a measure of membrane deformability (6), and since etidronate disodium produces an effect similar to that produced by the membrane actions of prostaglandin and isoproterenol, it is tempting to conclude that the filterability changes seen with etidronate disodium result from an interaction of etidronate disodium and the erythrocyte membrane. However, since sickle cell hemoglobin gelation is known to influence sickle cell erythrocyte filterability, such a conclusion cannot be reached from this work alone.

Radioimmunoassay of Flurazepam in Human Plasma

WILLIAM GLOVER ˣ, JAMES EARLEY, MICHAEL DELANEY, and ROSS DIXON

Received August 22, 1979, from the *Research Division, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication December 12, 1979.

Abstract □ A radioimmunoassay for the determination of the hypnotic flurazepam in plasma was developed. Plasma levels of intact flurazepam were measured following oral administration of therapeutic doses to humans. The procedure employs an antiserum obtained from a rabbit immunized with 3-hemisuccinyloxyflurazepam covalently coupled to bovine serum albumin and tritium-labeled flurazepam as the radioligand. Assay specificity was achieved by chromatographic isolation of flurazepam from plasma extracts on Sephadex LH-20 prior to analysis. The method has a sensitivity limit of 0.1 ng of flurazepam/ml using a 1-ml plasma sample, and the intra- and interassay coefficients of variation did not exceed 9% over a range of 0.1–5 ng/ml. In eight subjects who received a single 30-mg dose of flurazepam, peak plasma concentrations of 0.5–3.0 ng of intact drug/ml were reached after 0.5–1 hr, except in one subject where the peak occurred at 4 hr. The plasma concentrations of flurazepam declined with a harmonic mean apparent half-life of 2.3 hr.

Keyphrases □ Flurazepam—radioimmunoassay, plasma levels in humans □ Radioimmunoassay—flurazepam, plasma levels in humans □ Hypnotic agents—flurazepam, radioimmunoassay, human plasma

Flurazepam hydrochloride[1] (Table I) was synthesized by Sternbach *et al.* (1) and now is the most widely prescribed hypnotic agent for the treatment of insomnia in the United States (2). Studies on the biotransformation of flurazepam in humans and dogs have shown that the drug is metabolized extensively (3). The major metabolite in human plasma is *N*-1-desalkylflurazepam (Table I). Intravenous studies (3) of the elimination of flurazepam in dogs showed that the blood levels of the intact drug disappeared rapidly (half-life of 1.4 hr).

BACKGROUND

Kaplan *et al.* (4) used a fluorometric assay to study the blood level profile of the major flurazepam metabolites in humans following chronic dosage. This procedure requires a two-stage derivatization process involving acid hydrolysis of flurazepam and its metabolites to their respective benzophenones followed by cyclization to the 9-acridinone derivatives. The derivatives then are separated by TLC and are analyzed by a spectrofluorometric procedure. However, the levels of the intact drug were below the assay sensitivity and could not be measured.

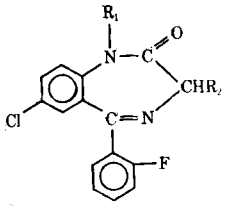
More recently, an electron-capture GLC assay was developed by de Silva *et al.* (5) with sufficient sensitivity to measure the intact *N*-1-desalkyl metabolite. While this method is useful for toxicological work and measurement of the major metabolite present in plasma, it lacks sufficient sensitivity to measure the intact drug after administration of therapeutic doses. Thus, the plasma level profile and the apparent half-life of flurazepam in humans have not been established.

The present report describes the development of a radioimmunoassay to determine the plasma levels of intact flurazepam in humans following a single 30-mg oral dose.

EXPERIMENTAL

Preparation of Immunogen—3-Hydroxyflurazepam (Table I) was refluxed with succinic anhydride in dichloromethane containing triethylamine to yield the desired hapten, 3-hemisuccinyloxyflurazepam (Table I), which was coupled covalently to bovine serum albumin by the mixed anhydride procedure of Erlanger *et al.* (6). The resulting conjugate was dialyzed against 0.05 *M* $NaHCO_3$ followed by dialysis against distilled water and isolated by lyophilization. UV analysis of the immunogen (6) indicated that ~18 moles of the hapten was covalently linked to 1 mole of albumin.

Table I—Flurazepam, the Hapten 3-Hemisuccinyloxyflurazepam, and the Cross-Reactivity of Metabolites Present in Plasma



Compound	R_1	R_2	Cross-Reactivity, %
Flurazepam	$(CH_2)_2N(C_2H_5)_2$	H	100
3-Hydroxyflurazepam	$(CH_2)_2N(C_2H_5)_2$	OH	—
3-Hemisuccinyloxyflurazepam	$(CH_2)_2N(C_2H_5)_2$	$OCO(CH_2)_2COOH$	—
Monodesethylflurazepam	$(CH_2)_2NHC_2H_5$	H	17.0
Didesethylflurazepam	$(CH_2)_2NH_2$	H	3.5
N-1-Hydroxyethylflurazepam	$(CH_2)_2OH$	H	<1.0
N-1-Desalkylflurazepam	H	H	<1.0

Immunization and Antibody Production—A female New Zealand White rabbit was immunized intradermally and boosted intravenously as described previously (7). Serum was collected at monthly intervals and stored at −20°. The antiserum obtained following the second booster immunization was used throughout this study. The antiserum was diluted 1:2000 with assay buffer[2] prior to use.

Extraction of Flurazepam from Plasma—Plasma (1 ml) was buffered to pH 9 with 1 ml of 1 *M* borate buffer and extracted twice with 5 ml of hexane[3] on a reciprocating shaker for 15 min. The combined hexane extracts were evaporated to dryness in a 15-ml conical tube at 40° under nitrogen, and the inside wall of each tube was rinsed down with 1 ml of hexane. Duplicate control plasma samples and internal standards containing 0.125, 0.5, and 1 ng of flurazepam/ml were processed along with the unknowns.

Column Chromatography of Plasma Extracts—Prepacked columns containing 1 g of Sephadex LH-20[4] were washed first with methanol and then equilibrated with hexane–benzene–methanol (95:5:4).

Each plasma extract was dissolved in 0.2 ml of the solvent system, applied to the top of column, and allowed to percolate into the bed. The tube was rinsed with another 0.5-ml portion of the solvent and transferred to the column. The column was developed using the solvent system, and the first 3.5 ml of eluate (which previously was shown to be devoid of flurazepam) was discarded. The next 5 ml of eluate containing the flurazepam was collected in a 20-ml glass scintillation vial and evaporated to dryness under nitrogen at 40°. The residue was dissolved in 0.5 ml of the assay buffer, and the vial was capped and incubated for 1 hr at 37° to obtain maximum dissolution of flurazepam prior to radioimmunoassay.

[1] Flurazepam hydrochloride is the active drug substance in Dalmane. Its chemical structure is 7-chloro-1-[2-(diethylamino)ethyl]-5-(*o*-fluorophenyl)-1,3-dihydro-2*H*-1,4-benzodiazepin-2-one dihydrochloride.

[2] Assay buffer is Dulbecco phosphate-buffered saline (GIBCO, Grand Island, NY 14072).

[3] Hexane is UV grade, Burdick & Jackson Laboratories, Muskegan, Mich.

Table II—Plasma Concentrations[a] (Nanograms per Milliliter) of Flurazepam in Eight Human Subjects following a 30-mg Oral Dose

Hour	Subject 1	2	3	4	5	6	7	8
0.0	NM	NM	NM	NM	NM	NM	NM	NM
0.5	1.00	0.30	0.15	1.00	0.14	1.80	0.24	NM
1.0	0.80	1.10	0.80	1.40	0.75	3.00	0.50	NM
							0.30[b]	
2.0	0.70	0.50	0.40	0.75	0.40	0.60	0.24	NM
3.0	0.50	0.40	0.30	0.45	0.30	0.80	0.20	0.35
4.0	0.30	0.25	0.20	0.40	0.20	0.30	0.19	0.61
							0.12[c]	0.27[c]
6.0	0.17	NM	0.10	0.28	0.17	0.20	0.12	0.27
								0.14[d]
8.0	NM	NM	NM	0.16	NM	0.16	NM	NM

[a] The reported concentrations are based on duplicate analyses of each plasma sample. NM = not measurable. [b] At 1.5 hr. [c] At 5 hr. [d] At 7 hr.

Radioimmunoassay—A calibration curve was generated by adding [^{3}H]flurazepam[5] (15,000 dpm) in 0.1 ml of buffer to duplicate 12 × 75-mm disposable glass culture tubes containing 0.03–2 ng of flurazepam in 0.2 ml of buffer. Following preparation of the standards, duplicate 0.2-ml aliquots of the reconstituted unknown flurazepam fractions were added to tubes containing 0.1 ml of the [^{3}H]flurazepam. Then the diluted antiserum (0.2 ml) was added to all tubes, except the nonspecific-binding control specimen to which was added 0.4 ml of buffer.

Each tube was mixed gently on a vortex mixer and allowed to stand at room temperature for 1 hr. Following the incubation, the antibody-bound radioligand was separated from the unbound fraction by precipitation with saturated ammonium sulfate (7). After the pellet was dissolved in 0.4 ml of water and 3 ml of scintillator[6] to give a clear solution, radioactivity in each tube was quantified in a modified liquid scintillation counter as described previously (8).

The calculation of the unknown flurazepam levels was performed by interpolation from a logit–log standard curve.

Determination of Assay Blank—One-milliliter aliquots of pooled normal human control plasma were extracted and chromatographed as described previously on eight separate columns. A separate control column was developed in the absence of any plasma extract. The fraction containing flurazepam eluate from each column was reconstituted with 0.5 ml of buffer and then analyzed by the radioimmunoassay.

Recovery of Flurazepam from Human Plasma—Various concentrations (0.125–5 ng) of unlabeled flurazepam were added to the control human plasma, incubated for 30 min at 37° and then stored at −20° until they were assayed. Then 1 ml of each plasma standard was extracted and chromatographed as described previously and analyzed by the radioimmunoassay.

RESULTS AND DISCUSSION

Radioimmunoassay Characteristics—The antiserum bound 50% of the radioligand at a final dilution of 1:5000 in a 0.5-ml incubation volume. A logit–log plot of B/B_0 (percent) *versus* concentration of unlabeled flurazepam gave a linear response between 0.03 and 2 ng, where B and B_0 are the amounts of antibody-bound radioligand in the presence and absence of the unlabeled drug, respectively, following correction for nonspecific binding. A typical calibration curve had a slope of −0.98 with a correlation coefficient of 0.99. Repeated analyses of the 0.03-ng standard gave a B/B_0 value of 87%; the working sensitivity of the procedure was ~0.1 ng of flurazepam/ml using a 1-ml plasma sample.

Blank values for eight 1-ml aliquots of control plasma following the extraction and chromatographic procedures were well below (mean B/B_0 = 95 ± 2%) the detection limit while the recovery of internal standards over the range of 0.1–5 ng of flurazepam/ml averaged 82.5 ± 3%.

The intra- and interassay coefficients of variation were determined by repeated analysis of six randomly selected plasma samples from subjects who had received a single 30-mg oral dose of flurazepam over a 6-week period. The coefficients of variation did not exceed 9% over a range of 0.1–1.6 ng of flurazepam/ml.

[5] [^{3}H]Flurazepam, with a specific activity of 27 Ci/mmole, was stored as the free base in toluene at −20°.

[6] Aquasol, New England Nuclear, Boston, MA 02118.

Radioimmunoassay Specificity—The specificity of the antiserum initially was evaluated by cross-reactivity studies involving all of the flurazepam metabolites known to be present in plasma (3). The mono- and didesethyl metabolites exhibited a cross-reactivity of 17 and 3.7%, respectively, while the other possible competitors cross-reacted less than 1% (Table I). As the large substituent at the N-1 position of flurazepam was progressively metabolized to the N-desalkyl metabolite, cross-reactivity decreased, indicating that the substituent at N-1 on the hapten is a major antigenic determinant.

In view of the cross-reactivity of both the mono- and didesethyl metabolites, a specific assay for flurazepam in plasma could not be developed without first separating it from its metabolites. Therefore, column chromatography on Sephadex LH-20 was employed. The elution profile of flurazepam was determined as described previously. Under these conditions, the plasma metabolites are not eluted from the column, thus providing a rapid and reproducible procedure for separating flurazepam from its interfering metabolites.

Plasma Flurazepam Levels in Humans—The method was applied to the analysis of plasma samples from eight subjects who received single 30-mg doses of the drug. Peak plasma concentrations of intact flurazepam were reached after 0.5–1 hr in seven subjects and at 4 hr in one subject (Table II). Although the data could not be used for detailed pharmacokinetic analysis, the intact drug had a harmonic mean apparent half-life in plasma of 2.3 hr.

This study demonstrates that, although orally administered flurazepam undergoes extensive first-pass metabolism to yield N-1-desalkylflurazepam as its major metabolite in plasma, some intact flurazepam does reach the peripheral circulation. The extent to which intact flurazepam contributes to the hypnotic activity of the drug is unknown.

Analysis of Mepivacaine, Bupivacaine, Etidocaine, Lidocaine, and Tetracaine

GEORGE B. PARK, PAUL E. ERDTMANSKY, RICHARD R. BROWN, M. PETER KULLBERG, and JEROME EDELSON ˣ

Received August 20, 1979, from the *Department of Drug Metabolism and Disposition, Sterling-Winthrop Research Institute, Rensselaer, NY 12144.* Accepted for publication December 4, 1979.

Abstract □ A GLC method, employing a nitrogen–phosphorus-sensitive detector, is described for the analysis of mepivacaine, bupivacaine, etidocaine, lidocaine, and tetracaine in biological fluids. The method is simple, reliable, and sensitive, with a practical limit of sensitivity of ~2.5 ng/ml, well below therapeutic plasma levels. Extensive start-up procedures and sample preparation are not required.

Keyphrases □ GLC—analysis, mepivacaine, bupivacaine, etidocaine, lidocaine, and tetracaine in biological fluids □ Anesthetics, local—simultaneous GLC analysis of mepivacaine, bupivacaine, etidocaine, lidocaine, and tetracaine in biological fluids □ Mepivacaine—simultaneous GLC analysis with bupivacaine, etidocaine, lidocaine, and tetracaine in biological fluids □ Bupivacaine—simultaneous GLC analysis with mepivacaine, etidocaine, lidocaine, and tetracaine in biological fluids □ Etidocaine—simultaneous GLC analysis with mepivacaine, bupivacaine, lidocaine, and tetracaine in biological fluids □ Lidocaine—simultaneous GLC analysis with mepivacaine, bupivacaine, etidocaine, and tetracaine in biological fluids □ Tetracaine—simultaneous GLC analysis with mepivacaine, bupivacaine, etidocaine, and lidocaine in biological fluids

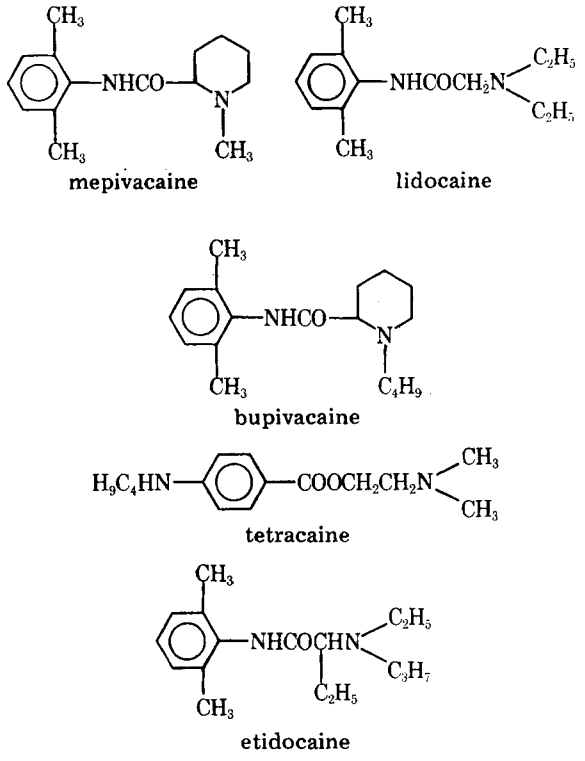
GLC has been the method of choice for the quantitative analysis of basic drugs in biological media for many years. Goehl and Davison (1) reported a method, developed in these laboratories, for the analysis of meperidine by GLC with flame-ionization detection; an improved, general flame-ionization GLC method for basic drugs was described by Mather and Tucker (2). Other methods for basic drugs, based on GLC with various detectors, have been published (3–10). The most sensitive methods utilize GLC–mass spectrometry (11, 12).

This paper describes a GLC method, employing a nitrogen–phosphorus-sensitive detector, that was used to determine mepivacaine, bupivacaine, etidocaine, lidocaine, and tetracaine in various biological fluids including plasma, cerebrospinal fluid, placental blood, and umbilical cord blood. It has proven to be facile, dependable, and equally applicable to a single sample or a large number of samples. Start-up time is minimal, and the sensitivity of the assay is several times greater than that of other reported GLC methods and is comparable to reported GLC–mass spectrometry methods.

EXPERIMENTAL

Reagents—Bupivacaine hydrochloride[1], mepivacaine hydrochloride[2], etidocaine hydrochloride[3], reagent grade ether, methanol, hydrochloric acid, and sodium hydroxide were used as received.

Apparatus—The gas–liquid chromatograph[4] was fitted with a nitrogen–phosphorus detector. Columns (122 and 183 cm) packed with OV-1 or OV-17 on 100–120-mesh Ultrabond[5] or on 100–120-mesh Gas Chrom Q[6] were used, depending on the resolution required. Typical operating parameters were: column temperature, 200 or 250°; injector temperature, 300°; detector temperature, 350°; helium carrier gas flow, 35 ml/min; hydrogen detector gas flow, 5 ml/min; air detector gas flow, 50 ml/min; and detector bead voltage, 20 v.



Procedure—To a 12-ml, round-bottom centrifuge tube fitted with a fluoroplastic-lined screw cap were added 1.0 ml of plasma, 25 μl of the internal standard solution (10 μg/ml in methanol), and 5.0 ml of ether. The tube was shaken on a horizontal shaker for 10 min and centrifuged. After the aqueous layer was frozen in a dry ice–acetone bath, the ether layer was transferred to a clean 12-ml centrifuge tube and treated with 0.2 ml of 1.0 *N* HCl. The tube was shaken, centrifuged, and frozen as before, and the ether phase was discarded.

Following the addition of 0.2 ml of 2.0 *N* NaOH, the aqueous phase was extracted with 5.0 ml of ether and frozen. The ether phase was decanted into a 6-ml, glass-stoppered conical tube and dried at 50° with a gentle stream of dry air. The residue was dissolved in 50 μl of methanol, and 1.0 μl of the solution was analyzed by GLC.

For the analysis of related esters, such as tetracaine, hydrolysis of the ester function must be prevented (13) by: (*a*) utilizing sodium arsenite (50 mg/ml of blood) as an esterase inhibitor, and (*b*) eliminating the back-extraction step.

RESULTS AND DISCUSSION

Figure 1 is a chromatogram, obtained with 3% OV-17 on Ultrabond, of a sample containing equal amounts of etidocaine, bupivacaine, and mepivacaine. Figure 2 shows chromatograms, obtained with 10% OV-1 on Gas Chrom Q, of a blank plasma standard, a 0.2-μg/ml plasma standard, and a clinical plasma sample using bupivacaine as an internal

Chromatographic conditions included a 183-cm × 2-mm (i.d.) column packed with 10% OV-1 on 100–120-mesh Gas Chrom Q, an injector temperature of 300°, a column temperature of 250°, a detector temperature of 350°, a carrier gas (helium) flow rate of 35 ml/min, and detector gases of hydrogen and air at flow rates of 5 and 50 ml/min, respectively.*

standard for etidocaine. The resolution obtained from the different columns is more of a function of the efficiency of the column, the carrier gas flow rate, and the temperature than of the stationary phase used. This effect is an added advantage since a particular column is not required, depending on the resolution requirements.

The plasma sample represented in Fig. 2C was one of 72 samples in a study involving anephric patients. The large peak eluting just after bupivacaine in this chromatogram was seen in the plasma of all of the patients studied but was not observed in the standards. Similar peaks, observed in samples collected in tubes with rubber stoppers, were identified by mass spectral analysis as the plasticizer tributoxyethyl phosphate. This phenomenon was reported by previous investigators (14), and it did not interfere with the analysis. By avoiding this plasticizer, the analysis time can be shortened; if high sensitivity is not required, the back-extraction step in sample preparation can be eliminated.

The analytical method works equally well for mepivacaine, bupivacaine, etidocaine, lidocaine, and tetracaine. However, tetracaine is hydrolyzed rapidly by plasma pseudocholinesterase, making its detection after normal doses extremely difficult (13). The minimum quantifiable level, defined as the concentration whose lower 80% confidence limit just encompasses zero[7], was ~20 ng/ml for each of the five drugs when duplicate standards of 0 and 50–500 ng/ml of the drug were used to produce the calibration curve. The minimum quantifiable level is dependent on the concentrations of the standards used, and lower values can be generated by using lower concentration standards. For example, a minimum quantifiable level of 0.8 ng/ml was calculated using duplicate mepivacaine standards of 0 and 2.5–20 ng/ml in plasma with bupivacaine as an internal standard. The practical limit of sensitivity is 2.5 ng/ml, with the size of the solvent front as the limiting factor. The standard error of the assay, calculated from the pure error term of the least-squares fit of the standards for three assays, using standards of 0 and 50–500 ng/ml was ±2 ng/ml.

The described method has proven to be simple, reliable, and sensitive, giving a linear response in the analysis of mepivacaine, bupivacaine, etidocaine, lidocaine, and tetracaine. Any of these compounds can be used as an internal standard for one or all of the others. Except for tetracaine, the sensitivity of the assay is well below that required to determine therapeutic levels and, for specific applications, can be extended to somewhat lower levels. Previously, this sensitivity was possible only through GLC–mass spectrometry. Since extensive start-up procedures and sample pretreatment are not required, the method is equally applicable to a single sample or numerous samples. It has been used to analyze plasma, cerebrospinal fluid, placental blood, and umbilical cord blood for drug concentrations.

Dependence of Area under the Curve on Proquazone Particle Size and *In Vitro* Dissolution Rate

FRITZ NIMMERFALL and JOACHIM ROSENTHALER ˣ

Received November 14, 1979, from the *Pharmaceutical Department, Sandoz Ltd., Basel, Switzerland.* Accepted for publication January 11, 1980.

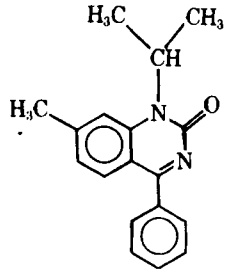
Abstract □ The *in vitro* dissolution and GI absorption of various sieve fractions of proquazone were studied (particle-size ranges of 45–74, 160–300, and 500–1000 μm). The dissolution rates of preparations F45, F160, and F500 were determined *in vitro* in a flow-through assembly in artificial gastric juice at 37°. The time required for 63% of the maximum amount of soluble drug to pass into solution was characterized by the dissolution variable τ_D. The *in vitro* dissolution rates for the preparations differed significantly in the order $\tau_{D,F45} < \tau_{D,F160} < \tau_{D,F500}$. After oral administration of 300 mg of the fractions to each of eight rhesus monkeys, the area under the plasma level–time curve (AUC) differed significantly in the order $AUC_{F45} > AUC_{F160} > AUC_{F500}$. The dissolution rate increased with decreasing particle size. The AUC increased with decreasing particle size and with increasing dissolution rate. These results indicate that the dissolution rate probably determines the extent of absorption when dissolution is rate limiting.

Keyphrases □ Proquazone—effect of particle size on area under the curve □ Dissolution rate, *in vitro*—proquazone, dependence on particle size □ Particle size—proquazone, effect on *in vitro* dissolution rate

After oral administration of solid dosage forms, absorption from the GI tract can be described as a sum of two consecutive transport processes: (*a*) dissolution of the drug from the dosage form (which produces a solution, micelles, or a solubilized entity), characterized by the dissolution rate constant k_1 for dissolution *in vivo;* and (*b*) transport of the drug to and through the intestinal membranes and its penetration into the general circulation, characterized by the total absorption rate constant k_2.

It is possible to distinguish between two fundamentally different cases (1): either the dissolution proceeds more slowly than the absorption ($k_1 < k_2$), or the absorption proceeds more slowly than the dissolution ($k_1 > k_2$). When $k_1 < k_2$, it should be possible to increase the absorption rate by increasing k_1 through a reduction in the particle size (2). When $k_1 > k_2$, a reduction in the particle size cannot affect the absorption rate.

The effect of particle size on relative absorbability has been demonstrated for several drugs, *e.g.*, griseofulvin (3), tetracycline (4), tolbutamide (5), and benoxaprofen (6). There also have been reviews on this subject (7–9). The relationship between particle surface area and GI absorption holds when absorption is dissolution rate limited, *i.e.*, when $k_1 < k_2$. For example, for proquazone, with a saturation solubility of 0.1% in artificial gastric juice, the area under the curve as a function of particle size and as a function of the *in vitro* dissolution rate was investigated. Proquazone[1] (I) is a quinazolidine anti-inflammatory drug.



I

EXPERIMENTAL

The experimental preparation was crystallized from ethyl acetate. A sonic sifter[2] followed by an air-jet sieve[3] was used to fractionate the product into the following ranges: 45–74 μm (F45), 160–300 μm (F160), and 500–1000 μm (F500). Care was taken to ensure that the particle-size ranges did not overlap. The experimental fractions were packed by hand in hard gelatin capsules for oral administration. The packing appeared to be very loose when the content was inspected.

The measurement of the dissolution rate was carried out in a flow-through assembly at a rate of 33 ml/min and at 37° (10). The solvent consisted of 0.082 *N* HCl and 0.034 *M* NaCl at pH 1.2. Samples were drawn after 5, 10, 15, 20, 25, 30, 45, 60, 90, 120, 180, and 240 min. The concentration of free drug was determined spectrophotometrically at 232 nm.

Male rhesus monkeys (*Macaca mulatta*), ~3 years old and 8–10 kg, received no food for a period extending from 20 hr before administration to 4 hr after it, but they had free access to water. A 300-mg proquazone

Table I—*In Vitro* Dissolution Rate (Percent Dissolved) at a Given Time

Minutes	F45 Mean[a]	F45 SD[b]	F160 Mean	F160 SD	F500 Mean	F500 SD
5	8.6	4.4	4.2	1.2	2.5	0.6
10	43.1	2.9	13.1	1.4	6.8	0.7
15	68.6	4.1	21.9	2.0	10.8	0.7
20	81.5	4.0	30.5	2.2	14.9	1.1
25	85.5	3.7	38.3	2.0	18.9	1.3
30	88.6	3.2	45.4	2.5	22.9	1.5
45	93.2	2.4	61.9	2.2	33.0	1.9
60	95.6	2.3	73.9	1.8	46.9	10.2
90	97.6	2.0	88.2	1.3	60.7	8.5
120	97.7	2.7	94.8	1.0	68.5	2.6
180	97.6	2.3	98.7	0.6	83.8	1.8
240	96.7	2.6	99.2	1.0	91.7	2.3
τ_D, min[c]	8.5	1.2	42.8	2.9	93.1	9.8

[a] Three determinations. [b] Standard deviation. [c] Values for the time where 63% of the maximum amount of soluble drug passes into solution were obtained using the Weibull distribution. This distribution is a general linearization function that was described for dissolution rate curves (17). The τ_D values were estimated according to a plot that was obtained using the published empirical function (14) and, therefore, may not necessarily correspond to the experimental timing where 63% of the drug was dissolved.

capsule was administered to each animal orally by provoking a swallowing reflex with the finger. The capsule was rinsed down with 5 ml of tap water. Blood, 2.5 ml, was drawn at 0, 0.33, 0.66, 1, 1.5, 2, 2.5, 3, 4, 6, 8, and 24 hr.

The fluorometric method detected the unchanged compound and the 7-hydroxymethyl metabolite in the plasma. The plasma concentration is expressed in nanogram equivalents of proquazone per milliliter. By the addition of 2 *N* sodium carbonate, the alkaline plasma sample (1 ml) was extracted into *n*-heptane. This sample was reextracted into 5 *N* aqueous HCl. The compound was excited at 326 nm, and its emission was measured at 510 nm.

For the *in vitro* dissolution experiments, the homogeneity of the mean values was tested by simple analysis of variance and the differences between mean values were tested by the Student–Newman–Keuls test (11).

The plan for the experiments in laboratory animals was arranged according to two independent random designs based on 4 × 4 Latin squares. Since another proquazone preparation had to be tested, it was included in the experimental design but was not evaluated further. The homogeneity of the mean values was tested by analysis of variance for repeated Latin squares (12), and the distinction between mean values was verified by Tukey's test (13).

RESULTS AND DISCUSSION

The experiments on the dissolution rate were evaluated by means of the dissolution variable τ_D (14). The τ_D value is the time in minutes during which 63% of the maximum amount of soluble drug passes into solution.

Table II—Mean Plasma Level Data[a] (Nanogram Equivalents per Milliliter) for Proquazone

Hours	F45 Mean	F45 SD[b]	F160 Mean	F160 SD	F500 Mean	F500 SD
0	0		0		0	
0.33	229	266	41	80	11	15
0.66	834	727	84	125	66	60
1	1191	798	106	146	83	61
1.5	1217	820	116	141	76	47
2	830	563	122	127	62	40
2.5	601	297	101	107	57	41
3	509	238	125	109	56	71
4	357	185	159	165	64	87
6	231	118	149	98	61	88
8	152	71	75	36	56	59
24	153	182	105	97	43	24
AUC[c]	6156	3159	1966	674	986	499

[a] Experiments were conducted in eight rhesus monkeys after oral gavage of various sieve fractions of the drug: F45 (45–74 μm), F160 (160–300 μm), and F500 (500–1000 μm). [b] Standard deviation. [c] The area under the plasma level–time curve (*AUC*) (nanogram equivalents per milliliter per hour) was estimated by an approximate integration formula, the trapezoidal rule.

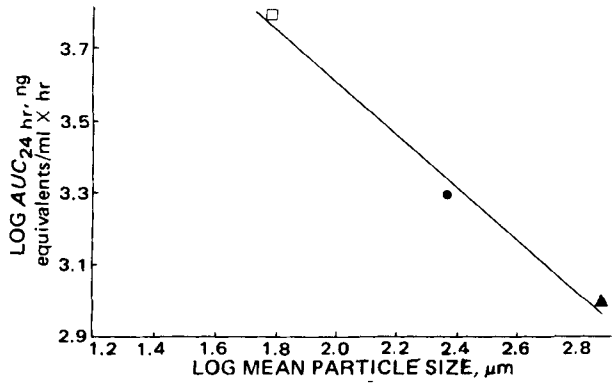

Figure 1—*Linear relationship between the logarithm of the mean value of the area under the plasma level–time curve* (AUC) *and the logarithm of the mean value of the particle size for preparations F45 (45–74 μm, □), F160 (160–300 μm, ●), and F500 (500–1000 μm, ▲).*

In the experiments in rhesus monkeys, three of the animals had to be replaced. The influence of the particular animal was negligible in comparison with the clearly significant effect of the product; *i.e.*, the variance component caused by the animals was about three times less than that caused by the product. Blood samples could only be obtained up to a maximum period of 24 hr because of sampling difficulties. Therefore, the area under the plasma concentration–time curve (*AUC*) was integrated up to 24 hr employing the trapezoidal rule.

The fluorometric analysis was carried out on plasma samples on the assumption that there was a constant distribution of the drug and metabolites between plasma and blood cells. From *in vitro* binding experiments using human blood, the quantity of drug and metabolites bound to blood cells was known to amount to ~20%. To comply with the conditions necessary for the analysis of variance, the figures for the *AUC* were submitted to a logarithmic transformation. Because of the small number of particle-size ranges investigated, no attempt was made to establish quantitative correlative equations. Nalimov's test was applied to the measurements to detect outliers before statistical analysis (15). Significant outliers ($p < 0.01$) were replaced by the next highest or the next lowest value (16).

Table I shows that the *in vitro* dissolution rate increased with decreasing particle size. The statistical analysis of the dissolution variable, τ_D, of preparations F45, F160, and F500 yielded the following significant series ($p = 0.01$): $\tau_{D,F45} < \tau_{D,F160} < \tau_{D,F500}$. By calculation, log τ_D for F45, F160, and F500 for the particle-size ranges investigated was a linear function of the logarithm of the mean particle size.

The mean plasma level–time profile (Table II) shows characteristic differences. Preparation F45 yielded a peak value (1217 ng equivalents/ml) at 1.5 hr, and this value was much higher than those obtained for F160 and F500, which were 159 ng equivalents/ml at 4 hr and 83 ng equivalents/ml at 1 hr, respectively. From this result, it can be concluded that the relationship between the plasma level and particle size is particularly

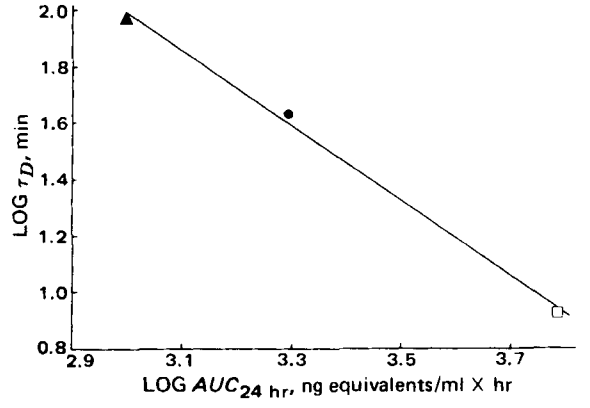

Figure 2—*Linear relationship between the logarithm of the area under the plasma level–time curve* (AUC) *and the logarithm of the mean value of the dissolution variable, τ_D, of proquazone for preparations F45 (45–74 μm, □), F160 (160–300 μm, ●), and F500 (500–1000 μm, ▲).*

critical when it exceeds a certain range, *i.e.*, 45–74 μm. The statistical analysis of the area under the curve (Table II) yielded the following sequence: $AUC_{F45} > AUC_{F160} > AUC_{F500}$. Figure 1 shows that for these preparations, there was a nearly linear relationship between the logarithm of the area under the curve and the logarithm of the mean particle size in the particle-size range investigated. Therefore, the dissolution of the drug in the intestines appears to constitute the rate-limiting step for the whole process of intestinal absorption; *i.e.*, $k_1 < k_2$.

Figure 2 shows a clear linear relationship between the logarithm of the area under the curve and log τ_D. The statistically significant difference between the area under the curve and τ_D for the preparations suggests that there is a genuine correlation between the *AUC* and the *in vitro* dissolution rate.

These results indicate that it may be possible, in principle, to estimate the *AUC* from the *in vitro* dissolution rate. The same correlation probably is obtained for any drug where dissolution is the rate-limiting step in absorption.

Correlation between Porosity and Dissolution Rate Constants for Disintegrating Tablets

Keyphrases □ Correlation coefficients—disintegrating tablets, relationship between porosity and dissolution rate □ Disintegration—tablets, correlation between porosity and dissolution rate □ Dissolution rate—correlation with porosity for disintegrating tablets □ Tablet disintegration—correlation between porosity and dissolution rate

To the Editor:

The importance of tablet porosity from a mechanical point of view has been discussed extensively (1, 2). Porosity also has been linked to the release characteristics of drugs from dosage forms and enters directly into the Higuchi square root law for dissolution (3). In the latter case, both penetration and diffusion characteristics are important.

There are cases in which tablets disintegrate and where the dissolution is relatively rapid so that the dissolution is a function of the disintegration (4, 5). However, there are cases in which tablets disintegrate fairly rapidly and where the dissolution is dictated by the rapid penetration of water into the granule. If the dissolution of the active ingredient and its diffusion out through the granule are rapid in relation to the penetration, then the dissolution is given by the amount of water that penetrates, *i.e.*, by an equation of the type described by Jost (6, 7):

$$\ln (m/m_0) = -k(t - t_i) \qquad \text{(Eq. 1)}$$

where m is the undissolved mass at time t, t_i is the disintegration time, and k is the dissolution constant (in reciprocal time units). Since the penetration rate is expected to be a function of the porosity, ϵ, of the tablet, then k also should be a function of ϵ. This argument assumes that the granules after disintegration have the same porosity as did the tablet before disintegration (8).

In a recent study in these laboratories, tablets were formed from granulations made by several processes: (*a*) fluid bed granulation[1], (*b*) chopper–ribbon blender[2], (*c*) chopper–ribbon blender followed by an oscillating granulator, and (*d*) chopper–ribbon blender followed by a rotating granulator[3]. The formula used was equal parts of dibasic calcium phosphate (anhydrous) and sulfanilamide granulated with 0.7 parts of 5% cornstarch paste. Drying was carried out to 1% loss on drying. Several differences were observed among these processes, and the phenomena related to dissolution and porosity will be discussed.

The granulations were screened and separated into four size fractions (<315, 315–400, 400–630, and >630 μm). Each fraction was compressed at three machine pressures (1200, 2400, and 3600 kg), and the resulting 12 batches of tablets from the four manufacturing procedures were subjected to dissolution tests by the beaker method (9). The porosities were measured using a mercury porosimeter.

The dissolution tests followed the relationship expressed in Eq. 1, and the prepared tablets had dissolution rate constants described by:

$$k = a_i + b_i\epsilon \qquad \text{(Eq. 2)}$$

critical when it exceeds a certain range, *i.e.*, 45–74 μm. The statistical analysis of the area under the curve (Table II) yielded the following sequence: $AUC_{F45} > AUC_{F160} > AUC_{F500}$. Figure 1 shows that for these preparations, there was a nearly linear relationship between the logarithm of the area under the curve and the logarithm of the mean particle size in the particle-size range investigated. Therefore, the dissolution of the drug in the intestines appears to constitute the rate-limiting step for the whole process of intestinal absorption; *i.e.*, $k_1 < k_2$.

Figure 2 shows a clear linear relationship between the logarithm of the area under the curve and log τ_D. The statistically significant difference between the area under the curve and τ_D for the preparations suggests that there is a genuine correlation between the *AUC* and the *in vitro* dissolution rate.

These results indicate that it may be possible, in principle, to estimate the *AUC* from the *in vitro* dissolution rate. The same correlation probably is obtained for any drug where dissolution is the rate-limiting step in absorption.

Correlation between Porosity and Dissolution Rate Constants for Disintegrating Tablets

Keyphrases □ Correlation coefficients—disintegrating tablets, relationship between porosity and dissolution rate □ Disintegration—tablets, correlation between porosity and dissolution rate □ Dissolution rate—correlation with porosity for disintegrating tablets □ Tablet disintegration—correlation between porosity and dissolution rate

To the Editor:

The importance of tablet porosity from a mechanical point of view has been discussed extensively (1, 2). Porosity also has been linked to the release characteristics of drugs from dosage forms and enters directly into the Higuchi square root law for dissolution (3). In the latter case, both penetration and diffusion characteristics are important.

There are cases in which tablets disintegrate and where the dissolution is relatively rapid so that the dissolution is a function of the disintegration (4, 5). However, there are cases in which tablets disintegrate fairly rapidly and where the dissolution is dictated by the rapid penetration of water into the granule. If the dissolution of the active ingredient and its diffusion out through the granule are rapid in relation to the penetration, then the dissolution is given by the amount of water that penetrates, *i.e.*, by an equation of the type described by Jost (6, 7):

$$\ln (m/m_0) = -k(t - t_i) \qquad \text{(Eq. 1)}$$

where m is the undissolved mass at time t, t_i is the disintegration time, and k is the dissolution constant (in reciprocal time units). Since the penetration rate is expected to be a function of the porosity, ϵ, of the tablet, then k also should be a function of ϵ. This argument assumes that the granules after disintegration have the same porosity as did the tablet before disintegration (8).

In a recent study in these laboratories, tablets were formed from granulations made by several processes: (*a*) fluid bed granulation[1], (*b*) chopper–ribbon blender[2], (*c*) chopper–ribbon blender followed by an oscillating granulator, and (*d*) chopper–ribbon blender followed by a rotating granulator[3]. The formula used was equal parts of dibasic calcium phosphate (anhydrous) and sulfanilamide granulated with 0.7 parts of 5% cornstarch paste. Drying was carried out to 1% loss on drying. Several differences were observed among these processes, and the phenomena related to dissolution and porosity will be discussed.

The granulations were screened and separated into four size fractions (<315, 315–400, 400–630, and >630 μm). Each fraction was compressed at three machine pressures (1200, 2400, and 3600 kg), and the resulting 12 batches of tablets from the four manufacturing procedures were subjected to dissolution tests by the beaker method (9). The porosities were measured using a mercury porosimeter.

The dissolution tests followed the relationship expressed in Eq. 1, and the prepared tablets had dissolution rate constants described by:

$$k = a_i + b_i\epsilon \qquad \text{(Eq. 2)}$$

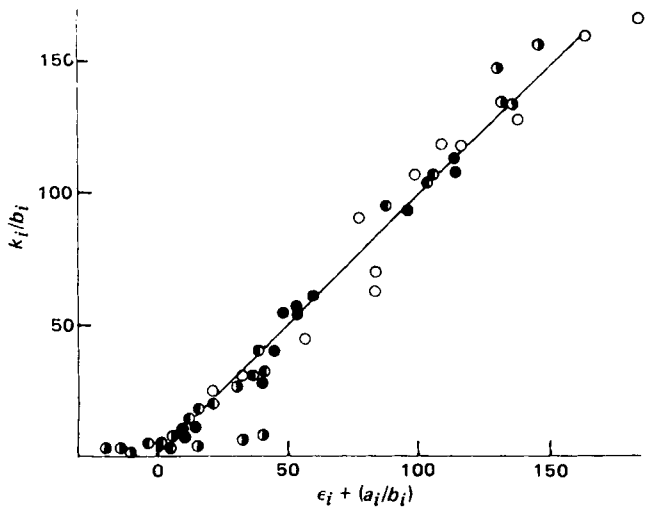

Figure 1—*Plot of* k_i/b_i versus $\epsilon_i + (a_i/b_i)$ *according to Eq. 3. Key:* ○, *chopper–ribbon blender;* ●, *chopper–ribbon blender followed by an oscillating granulator;* ◐, *chopper–ribbon blender followed by a rotating granulator; and* ◑, *fluid bed granulation.*

where a_i and b_i are constants and the subscript i refers to the ith condition (sieve fraction, manufacturing method, or compression pressure). The constants a and b are functions of these variables. Therefore, there are 48 lines corresponding to Eq. 1. The correlation coefficients generally were >0.94, and it is possible to tabulate all 48 values or draw 48 regression lines on one graph. For graphical presentation, a method (10) was used for which the data for each condition were recast in the following form:

$$k/b_i = \epsilon + (a_i/b_i) \qquad \text{(Eq. 3)}$$

where k/b_i and $\epsilon + (a_i/b_i)$ are dimensionless parameters. When one parameter is plotted as a function of the other, a straight line with a unity slope and a zero intercept should result. The 48 data points are plotted in Fig. 1 (the origin is offset), which shows visual agreement with the statements. The treatment is not statistical since the two variables (the left- and right-hand expressions in Eq. 3) are not independent. If a least-squares fit is drawn, the following relationship is obtained:

$$k/b_i = (0.98 \pm 0.05)[\epsilon + (a_i/b_i)] + (0.22 \pm 0.30) \qquad \text{(Eq. 4)}$$

in accordance with a unity slope and a zero intercept.

Equation 3 includes all of the data points, but Fig. 1 shows that the relationship fails at very low porosity values (high compression pressures). The four cases where $-a_i/b_i > \epsilon_i$ [*i.e.*, where values of $\epsilon_i + (a_i/b_i)$ are negative] do not seem to be part of the line. In these four cases, the adherence to Eq. 1 also was marginal (the correlation coefficients for these four points were 0.85–0.91), whereas the agreement was good to excellent in all of the other cases (*i.e.*, correlation coefficients of >0.94).

The data and the treatment show that there is a correlation between the dissolution constants, k, and the porosity, ϵ, in the case where a tablet disintegrates into porous granules and the limiting process is the penetration of water into the dislodged granule.

Identification of Subvisible Barium Sulfate Crystals in Parenteral Solutions

Keyphrases □ Barium sulfate—crystal formation in commercial parenteral solutions, identification by polarizing microscopy, scanning electron microscopy, micro X-ray powder diffraction, and micro Raman spectroscopy □ Parenteral solutions, commercial—barium sulfate crystal formation, identification by polarizing microscopy, scanning electron microscopy, micro X-ray powder diffraction, and micro Raman spectroscopy □ Crystals—barium sulfate formation in commercial parenteral solutions, characterization by polarizing microscopy, scanning electron microscopy, micro X-ray powder diffraction, and micro Raman spectroscopy

To the Editor:

Concern about the presence of particulate matter in parenteral products is increasing, and certain harmful effects when such contamination is introduced into the body during intravenous therapy have been described (1–4). Additionally, studies in our laboratory implicated particulate contamination in infusion fluids as a cause of phlebitis (5–7).

To gain insight into the nature and clinical significance of particulate matter in intravenous solutions, an extensive research program has been undertaken in cooperation with the Food and Drug Administration, which includes the identification of particulate matter in parenteral products. During this investigation, barium sulfate crystals were isolated and identified in six parenteral solutions packaged both in sealed glass ampuls and in glass vials with rubber stoppers. The conclusive identification of barium sulfate crystals was achieved through the correlation of analytical data from polarizing microscopy, scanning electron microscopy with energy-dispersive X-ray analysis capability, micro X-ray powder diffraction, and micro Raman spectroscopy.

With the polarizing microscope, barium sulfate crystals isolated from the parenteral solutions appeared as single or agglomerated, well-formed, birefringent crystals, 8–30

μm in maximum linear dimension with symmetrical edges and smooth surfaces. Under crossed polars, the crystals were birefringent and had symmetrical extinction. The high melting point (>300°) is indicative of the inorganic nature of the particles. Following characterization by polarizing microscopy, the crystals were examined by scanning electron microscopy and analyzed by energy-dispersive X-ray analysis to obtain the elemental composition. Under scanning electron microscopy, the crystals appeared as perfect rhombohedra with smooth surfaces (Fig. 1). The energy-dispersive X-ray analysis spectrum (Fig. 2), monitored for 40 sec, indicated strong signals of sulfur (2.31 kev) and barium (4.47, 4.83, 5.13, and 5.45 kev) (8).

To identify the crystals conclusively, micro X-ray powder diffraction was employed. A 57.3-mm diameter X-ray Phillips camera was used with the diameter reduced to 28.98 mm by means of a brass insert, which shortens the exposure time and reduces the dark film background (9). Eight to 10 crystals were subjected to X-rays under vacuum for 12–16 hr. By adjusting the energy output to 35 kv and 15 mamp and using a CuKα radiation source and a nickel filter, a diffraction pattern was obtained. The *d* spacings calculated from the diffraction pattern using the

Table II—Parenteral Solutions Containing Barium Sulfate Crystals

Product	Type of Glass Container	Source of Sulfate or Bisulfite Ions
Procaine hydrochloride, 2%	30-ml vial	Antioxidant
Kanamycin sulfate, 0.5 g/2 ml	2-ml vial	Drug
Meperidine hydrochloride, 100 mg/ml	1-ml vial	Antioxidant
Magnesium sulfate, 5 g/10 ml	10-ml vial (plunger) and rubber closure	Drug
Atropine sulfate, 0.5 mg/ml	1-ml ampul	Drug
Promethazine hydrochloride, 25 mg/ml	1-ml ampul	Antioxidant

Bragg equation show maximum relative intensities at 3.42, 3.08, and 2.11 Å, which match well with those reported for barium sulfate (10) (Table I).

Barium sulfate crystals in parenteral solutions also were identified by micro Raman spectroscopy[1]. An instrument for this technique became available recently and provides the composition of the particulate sample on the molecular scale. The sample is mounted on an ordinary microscope slide, the laser beam is focused on the crystal to be analyzed, and a Raman spectrum is obtained. The spectrum of particles isolated from a parenteral product (Fig. 3) compares well with the reference spectrum of known barium sulfate crystals (Fig. 4). The spectrum of sample particles exhibited peaks at 455, 988, and 1135 cm^{-1}, and the reference particles exhibited peaks at 450, 988, and 1135 cm^{-1}.

Using the described microanalytical techniques, crystals detected in six commercial parenteral solutions were identified as barium sulfate. The solutions are listed in Table II; on the basis that barium sulfate forms *in situ*[2], the sulfate ions appear to originate from the anion of the drug and/or the bisulfite ion of the antioxidant. The barium ions appear to come from the borosilicate glass, which contains up to 5% BaO (11).

[1] Microprobe MOLE, Instruments SA, Metuchen, NJ 08840.

[2] $BaO + H_2O \rightarrow Ba(OH)_2$.

$Ba^{2+} + SO_4^{2-} \rightarrow BaSO_4 \downarrow$.

$2SO_3^{2-} + O_2 \rightarrow 2SO_4^{2-}$.

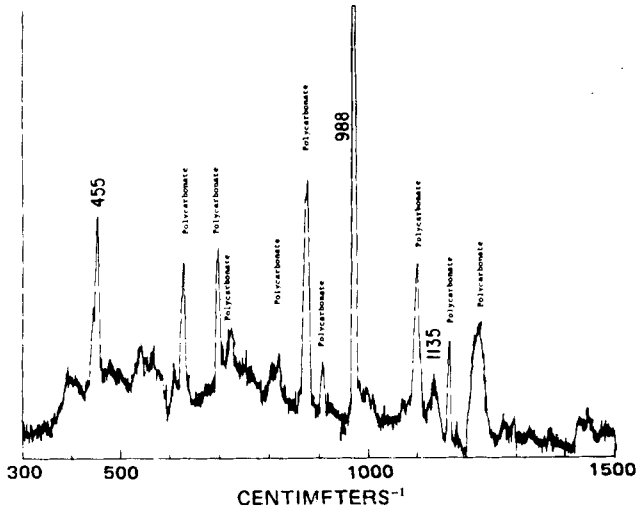

Figure 3—*Raman spectrum of barium sulfate crystal isolated from a parenteral product on a 0.45-μm polycarbonate filter (Nuclepore Corp., Pleasanton, Calif.). Peaks due to the crystal appear at 455, 988, and 1135 cm^{-1}.*

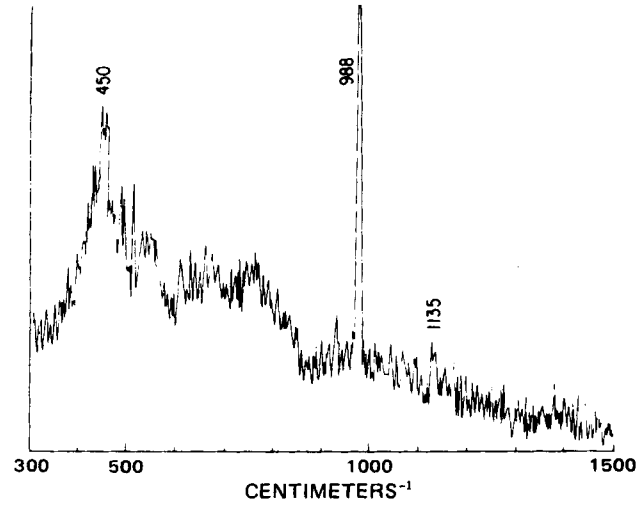

Figure 4—*Raman spectrum of reference barium sulfate crystals on a glass slide showing peaks at 450, 988, and 1135 cm^{-1}.*

In a preliminary experiment, we were able to generate barium sulfate crystals in 10-ml ampuls containing particulate-free solutions of either 0.2% sodium sulfate or 0.2% sodium bisulfite. These ampuls were autoclaved for 2 hr and stored at room temperature for 30 days. Ampuls containing particulate-free water treated identically did not produce any crystals.

Barium sulfate is so insoluble that it can be tolerated orally since it is the barium ion that is highly toxic. However, crystals injected intravenously will lodge in various tissues, depending on their size, and can cause irritation. Therefore, it is important to define the conditions under which barium sulfate crystals form in parenteral products and to devise a means for preventing their formation, such as siliconizing the glass surface or adding either a complexing agent (*i.e.*, ethylenediaminetetraacetic acid) or a nucleation inhibitor (*i.e.*, polyvinylpyrrolidone).

Prediction of Steady-State Behavior of Metabolite from Dosing of Parent Drug

Keyphrases □ Metabolism—prediction of steady-state metabolite concentration, cinromide and carbamazepine, monkeys □ Steady-state concentration—prediction of metabolite and parent drug concentrations, metabolism, cinromide and carbamazepine, monkeys □ Cinromide—prediction of steady-state metabolite concentration, monkeys □ Carbamazepine—prediction of steady-state metabolite concentration, monkeys

To the Editor:

It has become apparent that the metabolites of many drugs contribute to the observed clinical efficacy and/or toxicity (1). In assessing the contribution of a given metabolite during chronic dosing, the relative steady-state concentrations of the metabolite and the parent drug (as well as the relative potencies) must be determined. This steady-state ratio was shown to be dependent only on the formation and elimination clearances of the metabolite (2, 3):

$$\frac{C^*_m}{C^*_p} = \frac{Cl_f}{Cl_m} = \frac{f_m Cl_p}{Cl_m} \qquad \text{(Eq. 1)}$$

where C^*_m and C^*_p represent the steady-state plasma concentrations of the metabolite and the parent drug, respectively; Cl_f and Cl_m represent the formation clearance and intrinsic clearance (4) of the metabolite, respectively; f_m is the fraction of the parent drug metabolized to this metabolite; and Cl_p is the systemic clearance of the parent drug.

From Eq. 1, it appears that knowledge of the metabolite clearance and the fraction metabolized (or formation clearance) is necessary to calculate this ratio. The purpose of the present report is to show that the steady-state metabolite to parent drug ratio, as well as the actual steady-state metabolite concentration, can be determined from administration of a single dose of the parent drug without administration of the metabolite. A change in the admin-

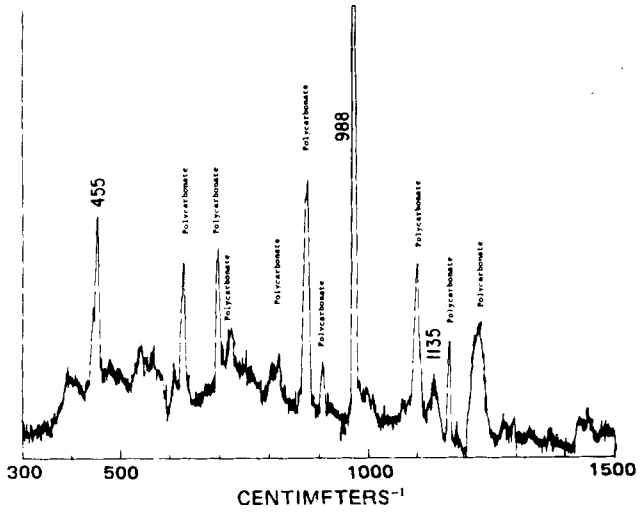

Figure 3—*Raman spectrum of barium sulfate crystal isolated from a parenteral product on a 0.45-μm polycarbonate filter (Nuclepore Corp., Pleasanton, Calif.). Peaks due to the crystal appear at 455, 988, and 1135 cm^{-1}.*

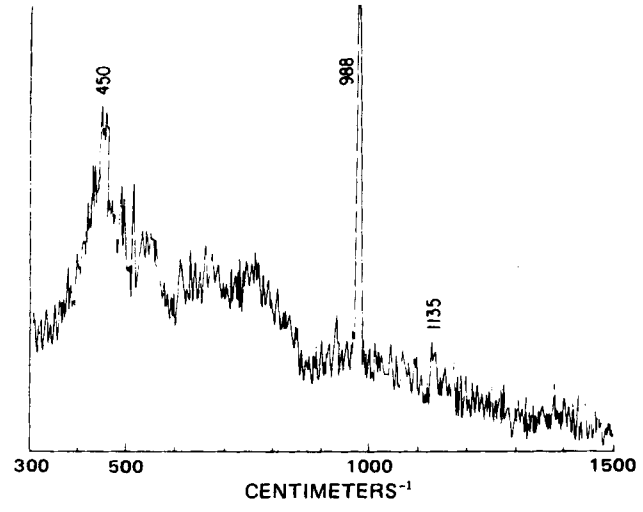

Figure 4—*Raman spectrum of reference barium sulfate crystals on a glass slide showing peaks at 450, 988, and 1135 cm^{-1}.*

In a preliminary experiment, we were able to generate barium sulfate crystals in 10-ml ampuls containing particulate-free solutions of either 0.2% sodium sulfate or 0.2% sodium bisulfite. These ampuls were autoclaved for 2 hr and stored at room temperature for 30 days. Ampuls containing particulate-free water treated identically did not produce any crystals.

Barium sulfate is so insoluble that it can be tolerated orally since it is the barium ion that is highly toxic. However, crystals injected intravenously will lodge in various tissues, depending on their size, and can cause irritation. Therefore, it is important to define the conditions under which barium sulfate crystals form in parenteral products and to devise a means for preventing their formation, such as siliconizing the glass surface or adding either a complexing agent (*i.e.*, ethylenediaminetetraacetic acid) or a nucleation inhibitor (*i.e.*, polyvinylpyrrolidone).

Prediction of Steady-State Behavior of Metabolite from Dosing of Parent Drug

Keyphrases □ Metabolism—prediction of steady-state metabolite concentration, cinromide and carbamazepine, monkeys □ Steady-state concentration—prediction of metabolite and parent drug concentrations, metabolism, cinromide and carbamazepine, monkeys □ Cinromide—prediction of steady-state metabolite concentration, monkeys □ Carbamazepine—prediction of steady-state metabolite concentration, monkeys

To the Editor:

It has become apparent that the metabolites of many drugs contribute to the observed clinical efficacy and/or toxicity (1). In assessing the contribution of a given metabolite during chronic dosing, the relative steady-state concentrations of the metabolite and the parent drug (as well as the relative potencies) must be determined. This steady-state ratio was shown to be dependent only on the formation and elimination clearances of the metabolite (2, 3):

$$\frac{C^*_m}{C^*_p} = \frac{Cl_f}{Cl_m} = \frac{f_m Cl_p}{Cl_m} \qquad \text{(Eq. 1)}$$

where C^*_m and C^*_p represent the steady-state plasma concentrations of the metabolite and the parent drug, respectively; Cl_f and Cl_m represent the formation clearance and intrinsic clearance (4) of the metabolite, respectively; f_m is the fraction of the parent drug metabolized to this metabolite; and Cl_p is the systemic clearance of the parent drug.

From Eq. 1, it appears that knowledge of the metabolite clearance and the fraction metabolized (or formation clearance) is necessary to calculate this ratio. The purpose of the present report is to show that the steady-state metabolite to parent drug ratio, as well as the actual steady-state metabolite concentration, can be determined from administration of a single dose of the parent drug without administration of the metabolite. A change in the admin-

istration route from systemic to oral results in a first-pass effect for drugs with medium or high extraction ratios. Methods for such corrections are provided. Preliminary experimental data with two drugs support the proposed theoretical approaches.

Equation 1 was derived assuming one-compartmental distribution and first-order elimination for the parent drug and the metabolite. It also is valid if either species (or both) exhibits multicompartmental behavior (mamillary model), as long as elimination occurs from the central compartment.

In Eq. 1, Cl_p and f_m can be expressed in a model-independent manner using areas under the curve (5):

$$Cl_p = \frac{D_p}{(AUC_p)_p} \qquad \text{(Eq. 2)}$$

$$f_m = \left(\frac{(AUC_m)_p}{D_p}\right)\left(\frac{D_m}{(AUC_m)_m}\right) = \left(\frac{(AUC_m)_p}{D_p}\right)Cl_m \qquad \text{(Eq. 3)}$$

where AUC is the area under the plasma concentration (molar)–time curve from zero to infinity; $(AUC_c)_b$ represents the AUC of c after a single dose of b; the subscripts m and p refer to the metabolite and the parent drug, respectively; and D refers to the dose in molar units.

The formation clearance, Cl_f, then is given by the product of Eqs. 2 and 3:

$$Cl_f = \left(\frac{(AUC_m)_p}{(AUC_p)_p}\right)Cl_m \qquad \text{(Eq. 4)}$$

Substitution of Eq. 4 into Eq. 1 shows that the steady-state ratio, C^*_m/C^*_p, becomes equal to the ratio of the areas of the metabolite and the parent drug after a single dose:

$$\frac{C^*_m}{C^*_p} = \frac{(AUC_m)_p}{(AUC_p)_p} \qquad \text{(Eq. 5)}$$

Equation 5 shows that the ratio of the steady-state concentrations of the metabolite and the parent drug can be predicted from concentration–time data obtained after a single intravenous dose of the parent drug. This relationship assumes linearity (with respect to dose and time) for the parent drug and the metabolite. This prediction requires the monitoring of metabolite and parent drug levels but does not require administration of the metabolite.

Equation 5 also can be used to calculate the actual steady-state concentration of the metabolite achieved by a given infusion rate, R_0, of the parent drug:

$$C^*_m = \left(\frac{(AUC_m)_p}{(AUC_p)_p}\right)C^*_p \qquad \text{(Eq. 6)}$$

With Eq. 2, C^*_p can be expressed as:

$$C^*_p = \frac{R_0}{Cl_p} = \frac{R_0(AUC_p)_p}{D_p} \qquad \text{(Eq. 7)}$$

Substitution of C^*_p from Eq. 7 into Eq. 6 yields:

$$C^*_m = \frac{R_0}{D_p}(AUC_m)_p \qquad \text{(Eq. 8)}$$

From a practical point of view, Eq. 8 implies that the steady-state metabolite concentration can be calculated by monitoring only metabolite levels without knowledge of parent drug levels (following administration of a single dose of the parent drug).

Equations 5 and 8 are directly applicable to the multiple dosing situation without any modifications as long as the multiple doses are given by the same route as the single dose (*i.e.*, the same dosage form). When there is a change in the administration route, Eqs. 5 and 8 must be modified. For instance, to estimate the C^*_m/C^*_p ratio after multiple oral doses from areas under the curve obtained after a single intravenous dose, a correction for any first-pass effect of the parent drug must be included so that Eq. 5 becomes:

$$\frac{\overline{C}^*_m}{\overline{C}^*_p} = \left[\frac{(AUC_m)_p}{(AUC_p)_p}\right]_{iv}\frac{1}{F_p} \qquad \text{(Eq. 9)}$$

where F_p represents the fraction of the dose of the parent drug systemically available, and $\overline{C}^*_m$ and $\overline{C}^*_p$ refer to the average concentrations during a dosing interval (a fixed-dose, fixed-time schedule).

Similarly, to estimate the average steady-state concentration of the metabolite after multiple oral doses from the area under the curve obtained after a single intravenous dose, Eq. 8 becomes:

$$\overline{C}^*_m = \left[\frac{(AUC_m)_p}{D_p}\right]_{iv} f_a \times \text{dose rate} \qquad \text{(Eq. 10)}$$

where f_a represents the dose fraction absorbed into the portal circulation; no correction for the first-pass effect of the parent drug is necessary. The applicability of Eqs. 5 and 8 was verified using data obtained during the pharmacokinetic characterization of cinromide and carbamazepine in rhesus monkeys.

Cinromide [(*E*)-*m*-bromo-*N*-ethylcinnamamide], a new antiepileptic drug[1], is metabolized by *N*-deethylation to 3-bromocinnamamide (6, 7). Short-term (not to steady state) and long-term (to steady state) infusions of the parent drug were administered to two monkeys. The C^*_m/C^*_p ratios and C^*_m values for the long-term infusions were predicted from the short infusion studies. Table I shows the agreement between the predicted and experimental values.

Carbamazepine is metabolized to a 10,11-epoxide, and the kinetics of the parent drug and the metabolite were elucidated (2). Single-dose intravenous studies with the parent drug in two monkeys enabled a prediction of C^*_m/C^*_p and C^*_m. These values compared favorably with the corresponding values obtained during a zero-order intravenous infusion of carbamazepine to the steady state (Table I).

The proposed theoretical approach has applications in drug development and in therapeutics. In the preclinical evaluation of new drugs, prediction of steady-state metabolite concentrations is useful in planning efficacy and toxicity studies. Furthermore, clinical monitoring of me-

Glass Transition Temperature of Citric Acid

Keyphrases □ Glass transition temperature—citric acid, glass formation, temperature variations due to water loss variations □ Citric acid—glass formation, glass transition temperature, comparison of anhydrous and monohydrate forms of citric acid □ Glass formation—citric acid, glass transition temperature

To the Editor:

A recent publication (1) examined solid dispersion systems using techniques similar to those we described previously (2, 3). Discrepancies between the glass transition temperature observed by the two groups of investigators (33–36°) have been explained as being due to an artifact. We hope the present observations will clarify the matter.

The glass transition temperature cannot be given an absolute value other than that extrapolated to a zero heating rate (4), because it is dependent on the rate of quenching of the glass and the heating rate employed to measure the transition. This was shown clearly by Rötger (5), who characterized the glass transition temperature by two rate indexes applicable to the quenching and heating rates of the sample. One immediate difference between the two reported studies (1, 3) was the heating rate employed during the measurement of the glass transition. Timko and Lordi (1) used 10°/min, whereas we used 2°/min (3). We also quoted the glass transition temperature as the onset of the transition (first deviation from the thermogram[1] baseline) rather than the extrapolated onset of Timko and Lordi (1), because this approach appeared to give better precision with different sample sizes. At 2°/min, the difference between the extrapolated onset and the initial deviation is only ~0.5–1°.

Table I—Effect of Water on Glass Transition Temperature

Water Added to Melt, % (w/w)	Glass Transition Temperature
3	−8–−13°
4	−13–−18°
5	−23–−26°

However, these two differences do not account for the large discrepancy reported in the two studies. For example, with our methods, the glass transition temperature of anhydrous citric acid was 7°, rather than 10° as quoted by Timko and Lordi (1).

The second difference in the two studies was the use of citric acid monohydrate (2, 3) rather than anhydrous citric acid. We believe that the discrepancy in the glass transition temperature of the two materials is due to the water bound in the glass of the monohydrate, which is difficult to remove from the melt at 150° (the temperature used in our method). This concept is in agreement with our previous suggestion (2) that using the monohydrate is advantageous because of the formation of a citric acid solution.

Since the devitrified glasses contain anhydrous citric acid, water probably is lost during crystallization of the melt and should be detectable as a weight loss. We measured the weight loss on devitrification and drying at 60° after heating the monohydrate melt for varying periods at 140–150°. After 4 min of heating, the weight loss was 4.8–5.6% (w/w); after 10 min of heating, it was reduced only to 4.3–5.3% (w/w).

The effect of water on the glass transition temperature can be shown by incorporating water into a melt of anhydrous citric acid produced by the method outlined previously (2) and above and measuring the glass transition temperature as described previously (3). The results are shown in Table I. There is some variation in the glass transition temperature due to variation in water loss on its addition to the melt. However, if the water is added when the melt is relatively cool, it induces crystallization; therefore, the system has to be reheated, resulting again in loss of water. These results are consistent with the reported weight losses and suggest that ~4.5% moisture is in the glass. If 9% (w/w) water (the amount present in the monohydrate) is added to anhydrous citric acid before melting and the glass preparation method is repeated, the glass transition temperature is −23–−24°, which is consistent with our previous results.

The results suggest that when the monohydrate is used, an unavoidable amount of water is present in the glass, which affects the glass transition temperature. This effect is reproducible, suggesting a consistent amount of entrapment in the melt. Furthermore, the properties of the anhydrous and monohydrate glasses are similar because, as a continuation of previous work (6), we found that the effect of phenobarbital on the citric acid (monohydrate) transition temperature was similar to that reported by Timko and Lordi (1).

Charge Transfer Effect through Hydrogen Bonding in Caffeine–*p*-Cresol and Theophylline–*p*-Cresol Complexes

Keyphrases □ Charge transfer effect—hydrogen bonding in caffeine–*p*-cresol and theophylline–*p*-cresol complexes □ Caffeine—hydrogen bonding in complex with *p*-cresol □ Theophylline—hydrogen bonding in complex with *p*-cresol

To the Editor:

Charge transfer transitions were detected in the UV absorption spectra of mixtures containing caffeine–*p*-cresol and theophylline–*p*-cresol in chloroform (1). To gain more information about the bonding mechanism and the various geometries of the complexes that may exist in solution, we conducted an IR study of the two combinations.

Changes can be detected in the IR absorption bands of the compounds mixed in chloroform. [The frequencies, expressed in reciprocal centimeters, were assigned according to Cross (2) and Silverstein and Bassler (3).]

Caffeine–*p*-Cresol (Fig. 1)—p-*Cresol*—The intensity of the free OH stretching vibration of *p*-cresol at 3590 decreased. The intensity of the intermolecular hydrogen-bonded OH stretching vibration increased appreciably, with a slight shift toward a longer wavelength (~5). A measurable increase in the intensity of the in-plane skeletal stretching vibrations was detected at 1615, 1595, and 1502.

Caffeine—The intensity of the CH stretching vibrations of the caffeine methyl groups at 2980 and 2945 decreased slightly. A decrease in the intensity of the carbonyl groups at C_2 (1700) and C_6 (1655) was found, with the stretching vibration at C_6 affected more.

Theophylline–*p*-Cresol (Fig. 2)—p-*Cresol*—The intensity of the free OH stretching vibration at 3590 decreased considerably. An appreciable increase in the intensity of the hydrogen-bonded OH stretching vibration at 3370 of the self-associated species was observed, with a considerable shift toward a longer wavelength (3320). The intensity of the aromatic CH stretching vibration at 2990 decreased noticeably, while a slight decrease was observed in the bands of the CH stretching vibrations of the methyl group at 2920 and 2860. The intensity at 1615 and 1502 of the in-plane skeletal stretching vibrations decreased slightly.

Theophylline—An increase in the free NH stretching vibration at 3425 was observed. The broad band of the hydrogen-bonded NH overlapping the CH stretching vibration at 3300–3000 seemed to be affected to a different extent; the maximum percentage increase was at 3260, while the minimum increase was at 3150. At 3060, a noticeable decrease was found. The intensity of the bands at 2990 and 2952, representing the CH methyl stretching vibrations, was decreased. A considerable decrease was found in the intensity of the C_2=O band at 1700, while a smaller decrease was found for the C_6=O band at 1655. A decrease was observed at 1551 of the C=C and C=N stretching vibrations of the ring.

Based on theory and experimental observations (4–7), changes in the IR spectra may be explained as being due to the formation of heterogeneous complexes or to the formation of self-associated species.

Calculation of dilution effects on *p*-cresol in chloroform

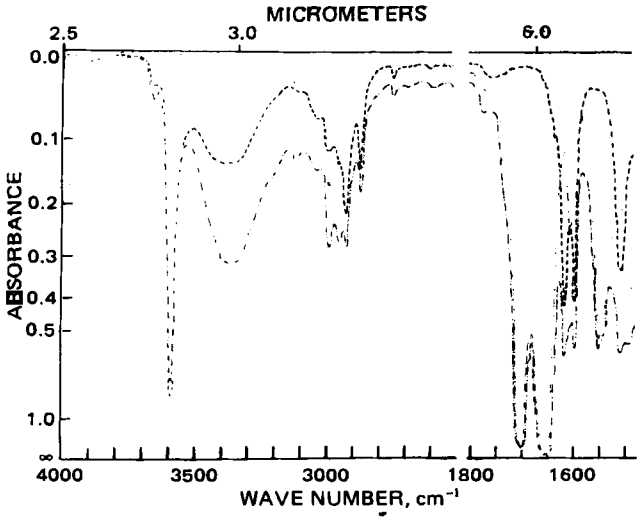

Figure 1—*IR spectra of chloroform solutions containing 4 × 10^{-2} M caffeine (–·–·–), 1.5 × 10^{-1} M p-cresol (- - -), and an equimolar mixture of the pure components (——). The baseline of the solvent is represented by the dotted line. Measurements were taken in the sodium chloride cells with a 0.05-cm path length at ~22°. The materials and methods used were those given by Al-Ani and Borazan (1).*

Caffeine–*p*-Cresol (Fig. 1)—p-*Cresol*—The intensity of the free OH stretching vibration of *p*-cresol at 3590 decreased. The intensity of the intermolecular hydrogen-bonded OH stretching vibration increased appreciably, with a slight shift toward a longer wavelength (~5). A measurable increase in the intensity of the in-plane skeletal stretching vibrations was detected at 1615, 1595, and 1502.

Caffeine—The intensity of the CH stretching vibrations of the caffeine methyl groups at 2980 and 2945 decreased slightly. A decrease in the intensity of the carbonyl groups at C_2 (1700) and C_6 (1655) was found, with the stretching vibration at C_6 affected more.

Theophylline–*p*-Cresol (Fig. 2)—p-*Cresol*—The intensity of the free OH stretching vibration at 3590 decreased considerably. An appreciable increase in the intensity of the hydrogen-bonded OH stretching vibration at 3370 of the self-associated species was observed, with a considerable shift toward a longer wavelength (3320). The intensity of the aromatic CH stretching vibration at 2990 decreased noticeably, while a slight decrease was observed in the bands of the CH stretching vibrations of the methyl group at 2920 and 2860. The intensity at 1615 and 1502 of the in-plane skeletal stretching vibrations decreased slightly.

Theophylline—An increase in the free NH stretching vibration at 3425 was observed. The broad band of the hydrogen-bonded NH overlapping the CH stretching vibration at 3300–3000 seemed to be affected to a different extent; the maximum percentage increase was at 3260, while the minimum increase was at 3150. At 3060, a noticeable decrease was found. The intensity of the bands at 2990 and 2952, representing the CH methyl stretching vibrations, was decreased. A considerable decrease was found in the intensity of the C_2=O band at 1700, while a smaller decrease was found for the C_6=O band at 1655. A decrease was observed at 1551 of the C=C and C=N stretching vibrations of the ring.

Based on theory and experimental observations (4–7), changes in the IR spectra may be explained as being due to the formation of heterogeneous complexes or to the formation of self-associated species.

Calculation of dilution effects on *p*-cresol in chloroform

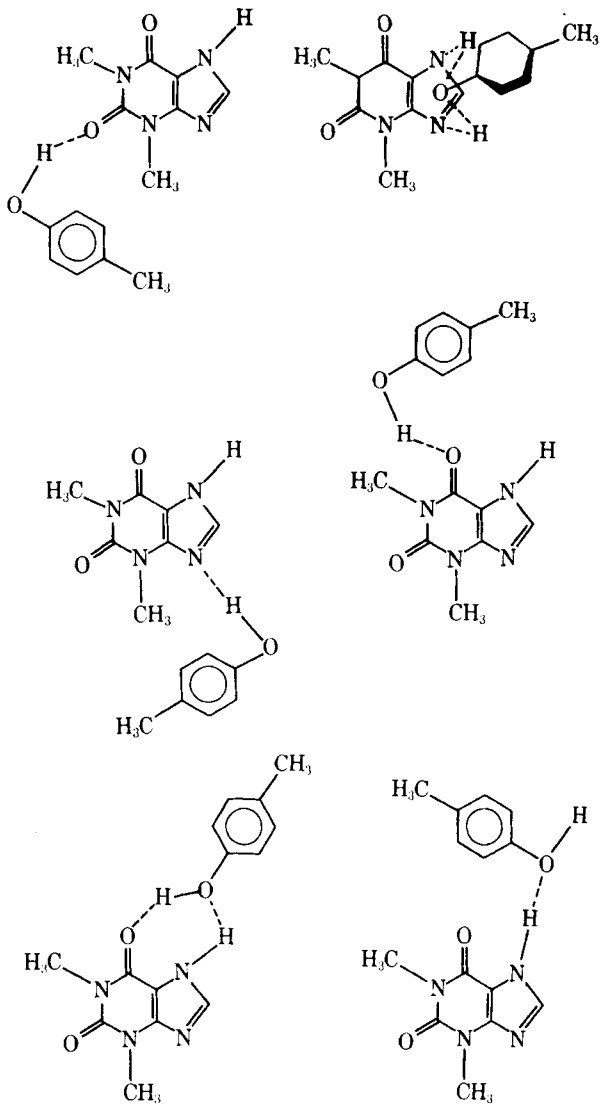
Proposed models for 1:1 caffeine–p-cresol complex in chloroform



Proposed models 1:1 theophylline–p-cresol complex in chloroform

indicated that the band at 3590 increased while the band at 3370 decreased. These results are further evidence that the first band can be attributed to the free OH stretching vibration while the second one can be assigned to the hydrogen-bonded OH of the self-associated species. The band at 2990 of the aromatic CH stretching vibration also increased. However, bands belonging to the CH stretching vibrations of the methyl groups (2920 and 2860) were unaffected; those of the in-plane skeletal stretching vibrations (1615, 1595, and 1502) all increased. The band at 1502 was shifted toward shorter wavelength (1512) with a drastic increase in absorption.

All of these results indicate the presence of self-associated molecules. The groups involved in bonding are the hydroxyl group and the benzene ring. However, it is difficult to propose an exact geometry or a stoichiometry of such self-associated species. Nevertheless, the following geometries of the self-associated aggregates may be proposed: hydrogen-bonded dimers, stacks of hydrogen-bonded dimers with methyl groups projected away from each other, stacked hydrogen-bonded dimers, and spherically oriented polymers with the OH groups projected inward and the nonpolar methyl groups oriented outside.

It is evident from changes in the IR spectrum (Fig. 1) of the solution containing caffeine–*p*-cresol that the areas that contribute most to the formation of the complex are the OH group and the skeletal carbons of *p*-cresol and the $C_2{=}O$, $C_6{=}O$, and CH_3 groups of caffeine. The models proposed for the geometry of a 1:1 complex are presented.

When theophylline is mixed with *p*-cresol, a complex appears to be formed (Fig. 2). The groups predominantly involved in formation of such a complex are the OH group and the aromatic CH group of *p*-cresol and the NH, aromatic CH, methyl CH, $C_2{=}O$, and $C_6{=}O$ groups of theophylline. The formation of a planar complex where hydrogen bonding is the dominant attractive force contributing to its formation may be proposed.

The increase in the intensity of the band corresponding to the free NH stretching vibration at 3425 may be due to overlapping with the hydrogen-bonded hydroxyl group of *p*-cresol or may result because dimers and polymers of theophylline, held together through hydrogen bonds with their NH groups, dissociate to interact with molecules of *p*-cresol and to free some of the bonded NH groups.

The equilibrium constants, calculated at 22°, of both

complexes were 0.22 and 0.16 M^{-1} for caffeine–*p*-cresol and theophylline–*p*-cresol, respectively, at 308 nm (1). On the other hand, the molar absorptivities of these complexes at the intermolecular hydrogen-bonded OH stretching vibration band, 3370 cm^{-1}, were $\sim 3 \times 10^3$ and $\sim 4.3 \times 10^3$ for caffeine–*p*-cresol and theophylline–*p*-cresol, respectively.

The present work supported the theory that hydrogen bonding is a type of charge transfer phenomenon (8–10).

Pilocarpine Ocular Distribution Volume

Keyphrases □ Pilocarpine—ocular volume of distribution □ Volumes of distribution—ocular distribution of pilocarpine □ Ophthalmic drugs—pilocarpine, ocular volume of distribution

To the Editor:

It is well established that drugs introduced into the body by various routes distribute to and equilibrate with the blood as well as numerous body tissues. Thus, the apparent volume of distribution has become a useful parameter in explaining the drug concentrations achieved in the blood after dosing and for determining the extent of absorption of various agents administered in different formulations or dosage forms.

Similarly, apparent distribution volumes also are useful in describing the ocular disposition characteristics of drugs administered topically to the eye. To make meaningful statements regarding the bioavailability of an ophthalmic preparation, it is necessary to know the apparent volume of distribution for that drug in the eye.

As with volumes of distribution obtained for drugs administered by other routes, various factors can affect apparent volumes of distribution of ocular drugs. These factors include protein binding, tissue distribution, pigmentation of the eye, and, of course, any pharmacological action the drug itself might exert. Therefore, the following discussion is limited to pharmacokinetic data obtained in albino rabbits of approximately the same weight.

Conrad and Robinson (1) developed a method of quantitating apparent ocular drug distribution volumes in experimental animals by injecting drug directly into the anterior chamber and monitoring the decline in the aqueous humor concentration as a function of time. The data from the study were used subsequently[1] (2, 3) to quantitate and describe the disposition of drugs in the eye.

Conrad and Robinson (1) determined the apparent volumes of distribution and elimination rate constants for both a therapeutically active substance (pilocarpine) and a nondistributing species (inulin). From the relationship:

$$Cl = V_d K \qquad \text{(Eq. 1)}$$

and the values obtained for inulin, a clearance of 4.59 μl/min from the aqueous humor was obtained. Since inulin neither binds nor distributes into the tissues and exits the anterior chamber solely *via* aqueous humor drainage, this value should represent normal aqueous humor turnover. The calculated value is consistent with values reported by other investigators (4, 5) for aqueous humor turnover in rabbits. Similarly, unless an agent is known to decrease aqueous humor turnover, the value of 4.59 μl/min also should represent the slowest possible clearance of any compound from the aqueous humor.

Following intracameral injection, the aqueous humor concentration of pilocarpine declined monoexponentially with an apparent first-order elimination rate constant of 0.059 min^{-1}. Based on the reported volume of distribution of 575 μl, a clearance value of 33.9 μl/min was obtained for pilocarpine. Since pilocarpine is known to facilitate aqueous humor outflow, it is not surprising that the elimination rate constant for pilocarpine and, in turn, the clearance were greater than those observed for inulin.

In a recent study by Makoid and Robinson (6), the decline of pilocarpine concentration in the aqueous humor following topical dosing was multiexponential when followed for 12 hr. Conrad and Robinson (1) only followed the aqueous humor concentration of pilocarpine for 1 hr after direct intracameral injection. The effect that this apparent discrepancy might have in determining the ocular volume of distribution for pilocarpine led us to examine further the decline in the aqueous humor concentration following direct injection into the aqueous humor.

For this study, the experimental procedure of Conrad and Robinson was repeated with pilocarpine of a higher specific activity (19.7 mCi/mg). In the original study, Conrad and Robinson (1) measured aqueous humor levels of pilocarpine at 5, 10, 15, 20, 30, and 60 min after injection, but they stated that the accuracy of their 60-min time point was in doubt. In our study, the 30-min point was excluded; however, a 25-min point was added, and sampling was extended to include 45-, 60-, 90-, and 120-min points.

Figure 1 shows the results of this study when 10 μl of 1×10^{-4} *M* pilocarpine was injected intracamerally. The

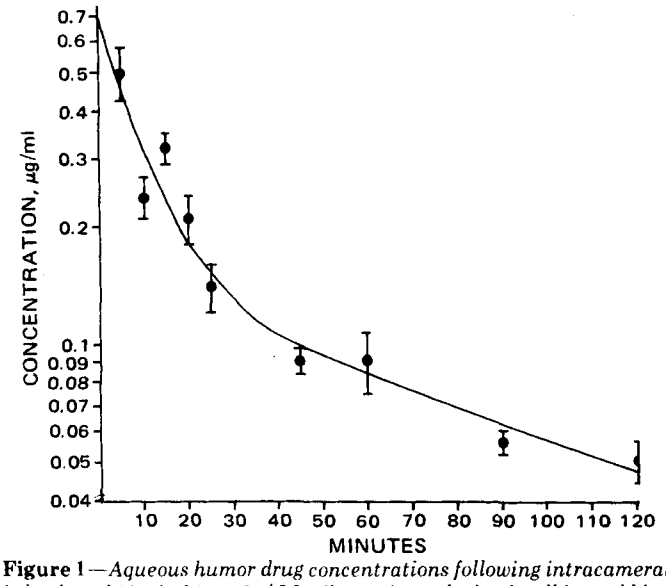

Figure 1—*Aqueous humor drug concentrations following intracameral injection of 10 μl of 1 × 10^{-4} M pilocarpine solution in albino rabbits. Points represent the mean of at least seven determinations. Bars represent the standard error of the mean. The solid line is the nonlinear regression line of the data fitted to a biexponential equation using the NONLIN program.*

absolute pilocarpine levels obtained are in reasonable agreement with those of Conrad and Robinson for the first 25 min. However, when later time points are considered, the curve clearly is not monoexponential. When the data reported here for the first 25 min are fitted to a monoexponential equation, an apparent volume of distribution and an elimination rate similar to those of Conrad and Robinson are obtained. However, due to the curvature noted at later time points, the short sampling period reported by Conrad and Robinson evidently resulted in an underestimation of the apparent ocular distribution volume for pilocarpine and represents a nonequilibrium apparent volume of distribution. This interpretation was mentioned by Conrad and Robinson but was rejected by reference to unpublished data.

The concept of a changing volume of distribution with time is, of course, not new and is expected with tissues that equilibrate slowly (7). Preliminary studies in this laboratory indicate that the partitioning of pilocarpine between aqueous humor and some ocular tissues is, in fact, a slow process. In addition, due to the effect of pilocarpine on aqueous humor turnover, it is to be expected that the slope of the pilocarpine decline from aqueous humor following intracameral injection would not remain constant over time. Ongoing experiments in this laboratory indicate that if pilocarpine levels are followed for times longer than those shown in Fig. 1, the slope becomes even more shallow. Therefore, a combination of factors, slow equilibration along with pilocarpine's pharmacological effect, makes it difficult to assign precise values to the ocular volume of distribution or, in turn, to the clearance of pilocarpine.

From a practical standpoint, apparent volumes of distribution obtained in short-term studies such as those of Conrad and Robinson may suffice for some drugs in describing aqueous humor drug levels in single-dose situations since most of the drug is eliminated quite rapidly. However, such studies usually will not suffice to predict aqueous humor drug levels over a long time or in steady-state situations. Therefore, pharmacokinetic data obtained during ocular multiple dosing or steady-state conditions may require a somewhat different interpretation than those obtained during short duration, single-dose studies.

Applications of TLC and Bioautography to Detect Contaminated Antibiotic Residues: Tetracycline Identification Scheme

Keyphrases □ Cephalosporins—TLC–bioautographic analysis as contaminants in various tetracyclines □ Penicillin—TLC–bioautographic analysis as contaminant in erythromycin □ Tetracyclines, various—TLC–bioautographic analysis of four cephalosporins as contaminants □ Erythromycin—TLC–bioautographic analysis of penicillin and ampicillin as contaminants

To the Editor:

A method to detect penicillin and ampicillin as contaminants in various tetracyclines and penicillamine was reported previously (1). The method utilizes TLC followed by bioautography and has been applied to other contamination situations and antibiotic standard problems. The cephalosporins are related closely to penicillin in chemical structure, antimicrobial activity, and allergenicity. In addition to the occurrence of allergenic cross-reactivity with penicillin, several cases of apparent primary allergy to cephalosporins in patients not known to be hypersensitive have been reported (2). Minor modification of the assay permitted the separation of four cephalosporin contaminants from seven tetracyclines: demeclocycline, methacycline, minocycline, chlortetracycline, oxytetracycline, doxycycline, and tetracycline.

The original method was followed with several excep-

Table I—R_f Values and Detection Limits of Cephalosporins

Antibiotic	R_f	Detection Limit, μg
Cephalothin	0.65	0.01
Cephaloridine	0.41	0.01
Cephalexin	0.59	0.005
Cephaloglycin	0.38	0.01

tions. The standard solutions of the cephalosporins were prepared at concentrations of 1.0, 0.5, 0.25, and 0.125 μg/ml, and the mobile phase composition was adjusted to a barbital acetate buffer (pH 7.4) to acetone ratio of 80:20 (v/v). The tetracyclines remained near the starting point; the cephalosporins migrated with the R_f values indicated in Table I.

Similarly, erythromycin is administered frequently to patients sensitive to penicillin. Thus, any contamination of erythromycin by penicillin is particularly undesirable for such patients. The existing conventional methods to detect penicillin in erythromycin are extraction procedures followed by cylinder–plate assay or direct cylinder–plate assay. These methods are time consuming and require much more sample handling than does this TLC method. Again, the same methodology was followed except that the mobile phase composition ratio was changed to 90:10 (v/v). Erythromycin base, erythromycin stearate, and erythromycin stearate tablets were assayed. The erythromycin remained at the spotting point, whereas the R_f value for penicillin G was 0.24 and that for ampicillin was 0.47.

The original system has been helpful in assessing the purity of some antibiotic standards. UV spectrophotometry is the official identity test for many antibiotics, including penicillin V. When a proposed standard of penicillin V potassium was assayed, the spectrum showed an additional peak. The following solutions were chromatographed in this system: penicillin V potassium, the proposed standard; penicillin V potassium, the working standard; a mixture of penicillin G potassium and penicillin V potassium; penicillin G potassium, the working standard; and *p*-hydroxypenicillin V potassium. The results are shown in Fig. 1. Carbenicillin, amoxicillin, neomycin, and cyclacillin were assayed using this system.

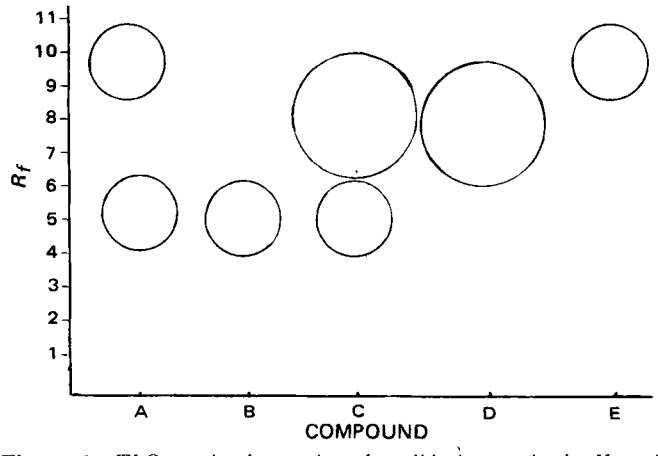

Figure 1—*TLC results for purity of antibiotic standards. Key: A, penicillin V potassium, proposed standard, 0.1 μg; B, penicillin V potassium, working standard, 0.1 μg; C, penicillin G potassium, 0.005 μg, and penicillin V potassium, 0.1 μg; D, penicillin G potassium, working standard, 0.005 μg; and E, p-hydroxypenicillin V potassium, 0.01 μg.*

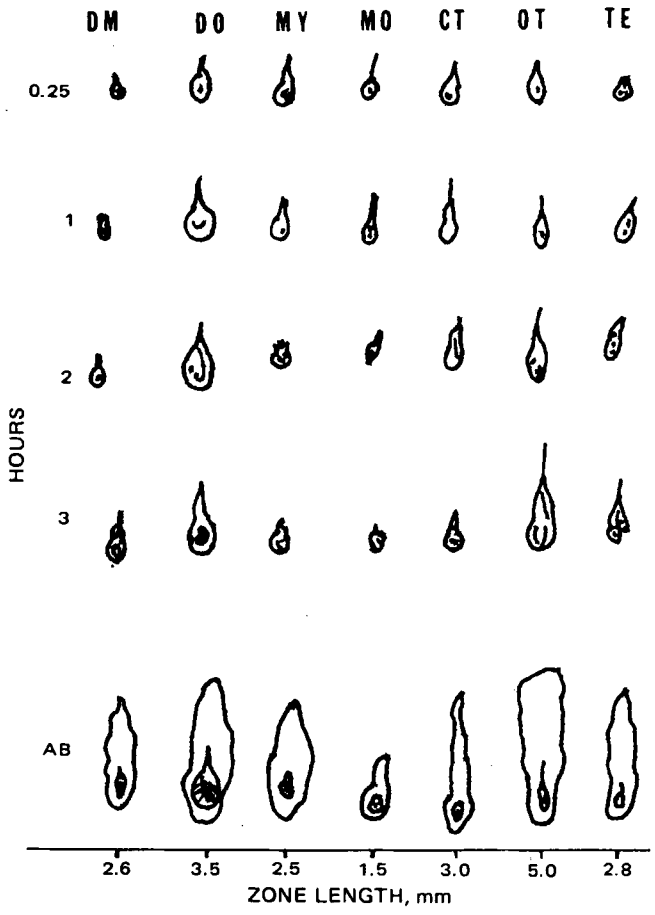

Figure 2—*Bioautography of seven antibiotic standards (left to right): DM, demeclocycline; DO, doxycycline; MY, methacycline; MO, minocycline; CT, chlortetracycline; OT, oxytetracycline; and TE, tetracycline. Top to bottom and left to right: 0.25 hr—yellow, pale yellow with pink tint, pale yellow, yellow, yellow, yellow, and yellow; 1 hr—yellow circle with purple beard, yellow center with pink outline, pale yellow, yellow, yellow, yellow, and yellow with pink beard; 2 hr—yellow center with purple beard, yellow center with rose outline, yellow center with pink outline, yellow, yellow center with gray beard, pale yellow, and orange center with purple beard; 3 hr—light brown, dark brown with yellow center, pale-orange outline with gray beard, bright yellow, bright yellow with tan beard, pale yellow, and gray. The spots obtained after the bioautograph are denoted by AB.*

The method described in the *Code of Federal Regulations* (paragraph 436.308) to identify the tetracyclines is a paper chromatographic technique in which individual tetracyclines are identified presumptively when the R_f value of the unknown matches the R_f value of a known tetracycline. During the development of this thin-layer technique, it was noted that, after the chromatographic procedure, a series of color changes takes place that is unique for each tetracycline spot. Each spot develops in an individual manner with regard to shape and color so that no two give the exact same pictures. After the bioautograph, no two zones have identical configurations. The combination of shape and color at the point of origin and individual shapes of the zones of inhibition can serve as a means of identification. As in the paper chromatographic method, an unknown sample can be run with the seven known standards and readily identified (Fig. 2).

Since this TLC system is quite adaptable and the biological phase is readily adjusted for particular needs, variations of the basic system should be applied success-

fully to other contamination problems and other areas of interest.

BOOKS

REVIEWS

Drug Design, Vol. VIII. Edited by E. J. ARIENS. Academic, 111 Fifth Ave., New York, NY 10003. 1979. 420 pp. 15 × 23 cm. $42.00.

This book is the eighth member of a continuing set, which collectively comprises Volume 11 of the series of monographs entitled "Medicinal Chemistry." Dr. Ariens has produced another valuable book. As stated in the preface of this volume, the term "drug" is to be interpreted in the widest sense. Indeed, this volume includes such diverse agents as synthetic sweeteners, ionophores, and potential environmental pollutants.

In the first chapter, Martin discusses "Advances in the Methodology of Quantitative Drug Design." This chapter is a systematic survey of the approaches available for finding the substituent group giving optimum activity from a lead compound either by batch or stepwise selection of new derivatives. The parameters for describing electronic, steric, and, particularly, lipophilic effects of substituents are considered. Considerable attention is devoted to theoretical models for the distribution of drugs into different compartments depending on their physicochemical properties. Finally, the information that can be obtained by regression and discriminate analyses is discussed. The most valuable aspect of the chapter probably is the many caveats concerning the limitations and pitfalls of quantitative structure–activity relationship methods.

In the second chapter, Kirschner and Kowalski deal with the "Application of Pattern Recognition to Drug Design." The first portion covers the general methodology of pattern recognition, and the second portion covers applications to drugs. Although development of this powerful mathematical tool has been initiated, much more work is needed.

In Chapter 3, the design of drug delivery systems that will release a constant amount of drug over a long period is discussed by Chandrasekaran, Theeuwes, and Yum. This chapter primarily describes the features and theory behind three currently available systems; OROS Theophyllin for oral use, a transdermal scopolamine system, and the Alzet osmotic minipump. Chapter 4 is an excellent discussion of the use of receptor binding data for the design of steroid hormones by Raynaud, Ojasoo, Bouton, and Philibert. The general techniques of receptor isolation and displacement of bound, radiolabeled ligands for various hormonal activities are presented. Then, the specific structure–activity relationships for receptor binding of estrogens, progestins, androgens, and mineralcorticoid and glucocorticoid hormones are considered. The relationship between receptor binding and *in vivo* activity is discussed last.

The fifth chapter, authored by Crosby, DuBois, and Wingard, covers synthetic sweeteners. There is an interesting discussion of the theory of taste and the known structure–activity relationships for sweet substances; however, too much basic material on molecular interactions, Hansch treatment, *etc.*, is included that is covered elsewhere in the series and detracts from this chapter. Chapter 6, "Prospective Assessment of Environmental Effects of Chemicals," by Hueck-van der Plas and Hueck is concerned with the test systems that can be used to predict the environmental impact of chemicals. This chapter probably will be of more interest to researchers dealing with agricultural chemicals rather than to those concerned with drugs for human use.

The final chapter is fascinating; it describes the "Design of Selective Ion Binding Macrocyclic Compounds and Their Biological Applications" and was authored by Izatt, Lamb, Eatough, Christensen, and Rytting. The factors affecting the selective-ion complexation by crown ethers and derivatives are discussed in detail.

This volume generally is well written and free from typographical errors. Every medicinal chemist should find something of interest.

Foreign Compound Metabolism in Mammals, Vol. 5. A Review of the Literature Published During 1976 and 1977. Senior Reporter, D. E. HATHWAY. The Chemical Society, Burlington House, London W1V OBN, England. 1979. 567 pp. 13 × 22 cm. Price $70.00. (Available from the American Chemical Society, 1155 16th St., N.W., Washington, DC 20036.)

This volume is an organized condensation of almost 3000 major metabolism–pharmacokinetics papers published in 1976 and 1977. The first half of the volume consists of five subject-oriented chapters, which are followed by eight product-oriented chapters.

Chapter 1, Drug Kinetics by P. G. Wellington, is the longest chapter (86 pages) and has the highest density of references (758 total references for a mean of 8.6 references/page). This chapter has 20 well-selected sections and deals with prostaglandins, ethanol, inorganic ions, and diagnostic agents in addition to a wide variety of drug classes. Chapter 2, Enzymic Mechanisms of Oxidation, Reduction, and Hydrolysis by P. Bentley and F. Oesch, interestingly covers the assigned terrain. Many readers will appreciate the subsection on epoxide hydratase for its inclusion of topics such as control and induction and occurrence in extrahepatic tissues.

P. C. Hirom and P. Millburn cover Enzymic Mechanisms of Conjugation (Chapter 3) in a fairly lively fashion. They briefly discuss new conjugation reactions and amino acid conjugations, and they animate their treatment of "the usual suspects" by reporting the tissue distribution of the enzymes responsible for conjugations with glucuronic acid, sulfate, and glutathione. In Chapter 4, J. D. Baty deals selectively and well with Species, Strain, and Sex Differences in Metabolism. Beside discussing comparative catabolic and conjugation reactions, Baty focuses on comparative differences in biliary excretion. The final subject-oriented chapter, Mechanisms of Chemical Carcinogenesis by D. E. Hathway, has this reviewer's enthusiastic endorsement for its interesting, valuable, and topical content. Its 54 pages utilize 358 well-chosen references that are integrated superbly.

The first product-oriented chapter has a more pharmacological orientation than do the others. This chapter, the Effect of Drugs on the Central Nervous System by B. E. Leonard, integrates mechanisms of action with biotransformations. C. Rhodes divides his report on Cardiovascular Drugs into sections dealing with thrombosis, hypertension, and cardiac disorders and summarizes some particularly interesting interspecies differences in biotransformation pathways of numerous drugs. L. G. Dring and P. Millburn address the metabolism of Sympathomimetic Amines and Bronchodilators and underscore many differences between *in vivo* and *in vitro* biotransformation routes.

Beside discussing comparative catabolic and conjugation reactions, Baty focuses on comparative differences in biliary excretion. The final subject-oriented chapter, Mechanisms of Chemical Carcinogenesis by D. E. Hathway, has this reviewer's enthusiastic endorsement for its interesting, valuable, and topical content. Its 54 pages utilize 358 well-chosen references that are integrated superbly.

The first product-oriented chapter has a more pharmacological orientation than do the others. This chapter, the Effect of Drugs on the Central Nervous System by B. E. Leonard, integrates mechanisms of action with biotransformations. C. Rhodes divides his report on Cardiovascular Drugs into sections dealing with thrombosis, hypertension, and cardiac disorders and summarizes some particularly interesting interspecies differences in biotransformation pathways of numerous drugs. L. G. Dring and P. Millburn address the metabolism of Sympathomimetic Amines and Bronchodilators and underscore many differences between *in vivo* and *in vitro* biotransformation routes.

The short chapter on Anti-Infective Agents by P. Johnson and J. D. Coombes deals with the biotransformation of some unusual structures while covering antiparasitics, antibiotics, antimycotic agents, antidiarrheals, antitubercular drugs, antivirals, and sulfonamides. Interesting interspecies and *in vivo–in vitro* comparisons pervade the coverage of Prostaglandins and Steroids by G. R. Bourne and D. E. Hathway. In the chapter on Food Constituents, D. E. Hathway objectively evaluates the saccharin and cyclamate problems under the heading of sweetening agents and deals with single-cell proteins, flour, vitamins, urethane and diethyl dicarbonate, food colorants, flavoring principles, and natural constituents.

C. T. Bedford reviews Agricultural Chemicals in sections on animal health products, rodenticides, insecticides, herbicides, and fungicides. This chapter is enlivened by descriptions of an anticoagulant with selective toxicity for vampire bats, an anthelmintic that is degraded to benzene, and an ususual example of *N*-dearylation. C. T. Bedford also contributed the final chapter, Industrial Chemicals and Miscellaneous Organic Compounds, which contains sections on aliphatic compounds, aromatic compounds, heteroaromatic compounds, and organometallic and inorganic compounds. Like the previous chapter, this chapter summarizes the biotransformation of many important environmental contaminants. Some of the more interesting reactions involve the formation of a metabolite of 4-dimethylaminophenol, which contains three glutathione residues attached to a single aromatic ring, and the formation of phosgene and carbon monoxide as metabolites.

The few typographical errors in this book are readily understood, as are the misspellings of the names of some prominent scientists in the author index. The compound index lists only substrates, not metabolites. More unfortunate is the absence of a comprehensive subject index that would enable readers to use the volume cross-sectionally; for example, to collect valuable information on studies performed in the wide variety of species covered in the volume (including humans, subhuman primates, sheep, cattle, lambs, pigs, tree shrews, and insects) or on reaction types or sites of biotransformation.

Overall, this volume is recommended highly as an organized source of metabolism–pharmacokinetics literature on important xenobiotics of many kinds. One of its major achievements is that it demonstrates the richness of opportunities for valuable future investigations.

Quality Control in the Pharmaceutical Industry, Vol. 3. Edited by M. S. COOPER. Academic, 111 Fifth Ave., New York, NY 10003. 1979. 292 pp. 15.5 × 22.5 cm. Price $29.50.

Volume 3 of this series consists of six chapters covering the interpretation of current good manufacturing practice regulations, the auditing function in the total control of quality, filtrative sterilization with porous membranes, bioavailability standards for pharmaceutical products, quality control of poliomyelitis vaccines, and quality control of ophthalmic products.

The chapter by A. S. Arambulo on "Interpretation of Current Good Manufacturing Practice Regulations" exceeds 100 pages and presents an excellent comprehensive review. The concept and parts of the regulations are discussed and illustrated by examples. This chapter should be of special interest to graduate students and recent graduates who are joining the pharmaceutical industry and to management personnel who have not been trained as physical or biological scientists.

The chapter on "Auditing Function in the Total Control of Quality" by A. J. Schmitz, Jr., reviews the quality control of the product and the quality control of operations and control techniques. Auditing includes managerial review of quality assurance to a firm to procure, produce, distribute, and control all phases of the function of a firm including facilities, personnel, standards, and the auditing method.

The chapter on "Filtrative Sterilization with Porous Membranes" by T. H. Meltzer and R. C. Lukaszewicz is concerned with the technology of porous membranes. It does not discuss sterility testing, but it does discuss pore properties, manufacture, filter rating, retentivity, and types of filters used. Prefilters and filter construction, design, preparation for use, and usage are discussed.

The chapter on "Bioavailability Standards for Pharmaceutical Products" by R. V. Smith and G. J. Yakatan is the shortest chapter. It presents elemental remarks on bioequivalency and gives an overview of analytical methods and their selection in bioavailability studies.

The chapter on "Quality Control of Poliomyelitis Vaccines" is by P. B. Stone. A review is given of tissue culture and animal testing of inactivated polio vaccine and the testing of live polio vaccine for adventitious agents, mycoplasma, and identity.

The chapter on "Quality Control of Ophthalmic Products" by J. D. Mullins and T. C. Fleming presents an elemental review of the anatomy of the eye, absorption, ophthalmic dosages, formulation, and processing.

This volume presents useful information for those seeking an overview of quality control in the specific areas covered; however, pharmaceutical scientists currently involved in quality assurance may find the treatment too cursory.

Handbook of Analytical Derivatization Reactions. By DANIEL R. KNAPP. Wiley, One Wiley Drive, Somerset, NJ 08873. 1979. 741 pp. 15 × 23 cm. Price $34.95.

This book presents a collection of analytical derivatization methods for gas chromatographic, liquid chromatographic, and mass spectral analysis. The reactions involve only the covalent derivatives of organic compounds formed prior to analysis. Part I briefly discusses the uses of analytical derivatization, the types of derivatives formed, and a typical apparatus employed in such reactions.

Part II features 15 sections concerning the derivatization of particular compound types. Among the classes considered are steroids, prostaglandins, and drugs. An overview of derivatization for the sample type is given along with specific derivatization methods. For each major compound type, the derivatization reactions are organized further into subsections of the compound type and within each subsection according to the type of derivative formed. Each method description includes structural formulas for the reaction, experimental directions, and references to the original literature. Sections on derivatives for substituent location by mass spectrometry and derivatives for chromatographic separation of optical isomers also are included.

Part III contains author and general subject indexes along with appendixes listing the composition of brand name reagents and U.S. and foreign suppliers of reagents and apparatuses used for analytical derivatization. An index of the derivatives and reagents discussed in Part II also is included.

This book should serve both as a self-contained methodology reference and as an introduction to the literature on analytical derivatization.

Staff Review

Pharmacognosy, 11th ed. By G. E. TREASE and W. C. EVANS. Cassell and Collier Macmillan Publishers Ltd., 35 Red Lion Square, London WC1R 49G, England. 1978. 784 pp. 16 × 23 cm. Price $32.50.

This is the 11th edition of a longstanding series of revisions that trace their origin to the original work in 1934. The latest revision reflects the increasing awareness and knowledge of the active constituents of natural, particularly vegetable, drugs. The book has been partially rearranged from the 10th edition with lengthy revisions in the parts dealing with drug sources, including production and quality control and the consideration of the various classes of drugs of biological origin.

The book is composed of eight parts with a total of 41 chapters, including an index. It is liberally filled with numerous structural formulas, pictures (none in color), tables, and illustrations. Part 1 (Chapters 1–3) deals with drug classification, the literature of pharmacognosy, and plant nomenclature and taxonomy. Part 2 (Chapters 4–7) covers plant morphology, anatomy, histology, and cellular content. Part 3 (Chapters 8–12) discusses the botanical and chemical characteristics of the more important orders and families of both nonflowering and flowering plants with references taken from Volumes 74–84 of *Chemical Abstracts*. Part 4 (Chapters 13–18) includes a discussion of the sources of crude drugs, drug production, quality control, drug deterioration, and plant growth regu-

The short chapter on Anti-Infective Agents by P. Johnson and J. D. This chapter should be of special interest to graduate students and recent graduates who are joining the pharmaceutical industry and to management personnel who have not been trained as physical or biological scientists.

The chapter on "Auditing Function in the Total Control of Quality" by A. J. Schmitz, Jr., reviews the quality control of the product and the quality control of operations and control techniques. Auditing includes managerial review of quality assurance to a firm to procure, produce, distribute, and control all phases of the function of a firm including facilities, personnel, standards, and the auditing method.

The chapter on "Filtrative Sterilization with Porous Membranes" by T. H. Meltzer and R. C. Lukaszewicz is concerned with the technology of porous membranes. It does not discuss sterility testing, but it does discuss pore properties, manufacture, filter rating, retentivity, and types of filters used. Prefilters and filter construction, design, preparation for use, and usage are discussed.

The chapter on "Bioavailability Standards for Pharmaceutical Products" by R. V. Smith and G. J. Yakatan is the shortest chapter. It presents elemental remarks on bioequivalency and gives an overview of analytical methods and their selection in bioavailability studies.

The chapter on "Quality Control of Poliomyelitis Vaccines" is by P. B. Stone. A review is given of tissue culture and animal testing of inactivated polio vaccine and the testing of live polio vaccine for adventitious agents, mycoplasma, and identity.

The chapter on "Quality Control of Ophthalmic Products" by J. D. Mullins and T. C. Fleming presents an elemental review of the anatomy of the eye, absorption, ophthalmic dosages, formulation, and processing.

This volume presents useful information for those seeking an overview of quality control in the specific areas covered; however, pharmaceutical scientists currently involved in quality assurance may find the treatment too cursory.

Handbook of Analytical Derivatization Reactions. By DANIEL R. KNAPP. Wiley, One Wiley Drive, Somerset, NJ 08873. 1979. 741 pp. 15 × 23 cm. Price $34.95.

This book presents a collection of analytical derivatization methods for gas chromatographic, liquid chromatographic, and mass spectral analysis. The reactions involve only the covalent derivatives of organic compounds formed prior to analysis. Part I briefly discusses the uses of analytical derivatization, the types of derivatives formed, and a typical apparatus employed in such reactions.

Part II features 15 sections concerning the derivatization of particular compound types. Among the classes considered are steroids, prostaglandins, and drugs. An overview of derivatization for the sample type is given along with specific derivatization methods. For each major compound type, the derivatization reactions are organized further into subsections of the compound type and within each subsection according to the type of derivative formed. Each method description includes structural formulas for the reaction, experimental directions, and references to the original literature. Sections on derivatives for substituent location by mass spectrometry and derivatives for chromatographic separation of optical isomers also are included.

Part III contains author and general subject indexes along with appendixes listing the composition of brand name reagents and U.S. and foreign suppliers of reagents and apparatuses used for analytical derivatization. An index of the derivatives and reagents discussed in Part II also is included.

This book should serve both as a self-contained methodology reference and as an introduction to the literature on analytical derivatization.

Staff Review

Pharmacognosy, 11th ed. By G. E. TREASE and W. C. EVANS. Cassell and Collier Macmillan Publishers Ltd., 35 Red Lion Square, London WC1R 49G, England. 1978. 784 pp. 16 × 23 cm. Price $32.50.

This is the 11th edition of a longstanding series of revisions that trace their origin to the original work in 1934. The latest revision reflects the increasing awareness and knowledge of the active constituents of natural, particularly vegetable, drugs. The book has been partially rearranged from the 10th edition with lengthy revisions in the parts dealing with drug sources, including production and quality control and the consideration of the various classes of drugs of biological origin.

The book is composed of eight parts with a total of 41 chapters, including an index. It is liberally filled with numerous structural formulas, pictures (none in color), tables, and illustrations. Part 1 (Chapters 1–3) deals with drug classification, the literature of pharmacognosy, and plant nomenclature and taxonomy. Part 2 (Chapters 4–7) covers plant morphology, anatomy, histology, and cellular content. Part 3 (Chapters 8–12) discusses the botanical and chemical characteristics of the more important orders and families of both nonflowering and flowering plants with references taken from Volumes 74–84 of *Chemical Abstracts*. Part 4 (Chapters 13–18) includes a discussion of the sources of crude drugs, drug production, quality control, drug deterioration, and plant growth regu-

The short chapter on Anti-Infective Agents by P. Johnson and J. D. Coombes deals with the biotransformation of some unusual structures while covering antiparasitics, antibiotics, antimycotic agents, antidiarrheals, antitubercular drugs, antivirals, and sulfonamides. Interesting interspecies and *in vivo–in vitro* comparisons pervade the coverage of Prostaglandins and Steroids by G. R. Bourne and D. E. Hathway. In the chapter on Food Constituents, D. E. Hathway objectively evaluates the saccharin and cyclamate problems under the heading of sweetening agents and deals with single-cell proteins, flour, vitamins, urethane and diethyl dicarbonate, food colorants, flavoring principles, and natural constituents.

C. T. Bedford reviews Agricultural Chemicals in sections on animal health products, rodenticides, insecticides, herbicides, and fungicides. This chapter is enlivened by descriptions of an anticoagulant with selective toxicity for vampire bats, an anthelmintic that is degraded to benzene, and an ususual example of *N*-dearylation. C. T. Bedford also contributed the final chapter, Industrial Chemicals and Miscellaneous Organic Compounds, which contains sections on aliphatic compounds, aromatic compounds, heteroaromatic compounds, and organometallic and inorganic compounds. Like the previous chapter, this chapter summarizes the biotransformation of many important environmental contaminants. Some of the more interesting reactions involve the formation of a metabolite of 4-dimethylaminophenol, which contains three glutathione residues attached to a single aromatic ring, and the formation of phosgene and carbon monoxide as metabolites.

The few typographical errors in this book are readily understood, as are the misspellings of the names of some prominent scientists in the author index. The compound index lists only substrates, not metabolites. More unfortunate is the absence of a comprehensive subject index that would enable readers to use the volume cross-sectionally; for example, to collect valuable information on studies performed in the wide variety of species covered in the volume (including humans, subhuman primates, sheep, cattle, lambs, pigs, tree shrews, and insects) or on reaction types or sites of biotransformation.

Overall, this volume is recommended highly as an organized source of metabolism–pharmacokinetics literature on important xenobiotics of many kinds. One of its major achievements is that it demonstrates the richness of opportunities for valuable future investigations.

Quality Control in the Pharmaceutical Industry, Vol. 3. Edited by M. S. COOPER. Academic, 111 Fifth Ave., New York, NY 10003. 1979. 292 pp. 15.5 × 22.5 cm. Price $29.50.

Volume 3 of this series consists of six chapters covering the interpretation of current good manufacturing practice regulations, the auditing function in the total control of quality, filtrative sterilization with porous membranes, bioavailability standards for pharmaceutical products, quality control of poliomyelitis vaccines, and quality control of ophthalmic products.

The chapter by A. S. Arambulo on "Interpretation of Current Good Manufacturing Practice Regulations" exceeds 100 pages and presents an excellent comprehensive review. The concept and parts of the regulations are discussed and illustrated by examples. This chapter should be of special interest to graduate students and recent graduates who are joining the pharmaceutical industry and to management personnel who have not been trained as physical or biological scientists.

Pharmacognosy, 11th ed. By G. E. TREASE and W. C. EVANS. Cassell and Collier Macmillan Publishers Ltd., 35 Red Lion Square, London WC1R 49G, England. 1978. 784 pp. 16 × 23 cm. Price $32.50.

This is the 11th edition of a longstanding series of revisions that trace their origin to the original work in 1934. The latest revision reflects the increasing awareness and knowledge of the active constituents of natural, particularly vegetable, drugs. The book has been partially rearranged from the 10th edition with lengthy revisions in the parts dealing with drug sources, including production and quality control and the consideration of the various classes of drugs of biological origin.

The book is composed of eight parts with a total of 41 chapters, including an index. It is liberally filled with numerous structural formulas, pictures (none in color), tables, and illustrations. Part 1 (Chapters 1–3) deals with drug classification, the literature of pharmacognosy, and plant nomenclature and taxonomy. Part 2 (Chapters 4–7) covers plant morphology, anatomy, histology, and cellular content. Part 3 (Chapters 8–12) discusses the botanical and chemical characteristics of the more important orders and families of both nonflowering and flowering plants with references taken from Volumes 74–84 of *Chemical Abstracts*. Part 4 (Chapters 13–18) includes a discussion of the sources of crude drugs, drug production, quality control, drug deterioration, and plant growth regu-

lators and a summary of the pharmacological actions of plant drugs.

Part 5 (Chapters 19–22) discusses phytochemistry, biogenesis, and basic and secondary phytometabolism with a small section on microbial conversions and aberrant syntheses in higher plants. Part 6 (Chapters 23–35) constitutes the bulk of the book and is a discussion of the drugs of biological origin, organized by chemical class (*e.g.*, carbohydrates and alkaloids) or by biological activity (plant tumor inhibitors, hallucinogens, and pesticides). Part 7 (Chapters 36 and 37) concerns genetics and comparative phytochemistry, while Part 8 (Chapters 38–41) finishes the book with a discussion of microscopy.

One can find some inconsistencies in this book, as in any text. For instance, the stereochemistry of the cardiac steroid glycosides is not illustrated in Chapter 27 (although these features are discussed), while the stereochemistry of the tropane alkaloids hyoscyamine and hyoscine is nicely illustrated in Chapter 30. A somewhat disturbing feature is that the authors chose to discuss the pharmacological activities of plant-derived drugs in one specific chapter instead of with the specific compound in the appropriate chapter. To my knowledge, there is little or no mention of the commonly occurring adverse effects associated with therapy with plant-derived drugs. There is no discussion of immunizing biologicals nor of antibiotics as therapeutic agents. Finally, the chapter on tumor inhibitors from plants seems weak and is particularly lacking in structural illustrations.

The writing of a textbook on pharmacognosy is a labor of love in many ways. It is a particularly broad subject and it is difficult to be "all things to all people." The authors have worked diligently to "marry" biology, biochemistry, chemistry, plant histology/anatomy, and pharmacology into one voluminous work. As the authors state: "The new edition has the same purpose as its predecessors, namely to give a comprehensive presentation of pharmacognosy which complements the very varied treatments which the subject receives in schools of pharmacy throughout the world." Despite some shortcomings, the book adequately fulfills its broad-based mission, and I recommend that anyone involved in the broad discipline of pharmacognosy should obtain a copy. Furthermore, libraries of pharmacy schools and institutions interested in natural products should be interested in this work.

Quality Control in the Pharmaceutical Industry, Vol. 3. Edited by M. S. COOPER. Academic, 111 Fifth Ave., New York, NY 10003. 1979. 292 pp. 15.5 × 22.5 cm. Price $29.50.

Volume 3 of this series consists of six chapters covering the interpretation of current good manufacturing practice regulations, the auditing function in the total control of quality, filtrative sterilization with porous membranes, bioavailability standards for pharmaceutical products, quality control of poliomyelitis vaccines, and quality control of ophthalmic products.

The chapter by A. S. Arambulo on "Interpretation of Current Good Manufacturing Practice Regulations" exceeds 100 pages and presents an excellent comprehensive review. The concept and parts of the regulations are discussed and illustrated by examples. This chapter should be of special interest to graduate students and recent graduates who are joining the pharmaceutical industry and to management personnel who have not been trained as physical or biological scientists.

The chapter on "Auditing Function in the Total Control of Quality" by A. J. Schmitz, Jr., reviews the quality control of the product and the quality control of operations and control techniques. Auditing includes managerial review of quality assurance to a firm to procure, produce, distribute, and control all phases of the function of a firm including facilities, personnel, standards, and the auditing method.

The chapter on "Filtrative Sterilization with Porous Membranes" by T. H. Meltzer and R. C. Lukaszewicz is concerned with the technology of porous membranes. It does not discuss sterility testing, but it does discuss pore properties, manufacture, filter rating, retentivity, and types of filters used. Prefilters and filter construction, design, preparation for use, and usage are discussed.

The chapter on "Bioavailability Standards for Pharmaceutical Products" by R. V. Smith and G. J. Yakatan is the shortest chapter. It presents elemental remarks on bioequivalency and gives an overview of analytical methods and their selection in bioavailability studies.

The chapter on "Quality Control of Poliomyelitis Vaccines" is by P. B. Stone. A review is given of tissue culture and animal testing of inactivated polio vaccine and the testing of live polio vaccine for adventitious agents, mycoplasma, and identity.

The chapter on "Quality Control of Ophthalmic Products" by J. D. Mullins and T. C. Fleming presents an elemental review of the anatomy of the eye, absorption, ophthalmic dosages, formulation, and processing.

This volume presents useful information for those seeking an overview of quality control in the specific areas covered; however, pharmaceutical scientists currently involved in quality assurance may find the treatment too cursory.

Handbook of Analytical Derivatization Reactions. By DANIEL R. KNAPP. Wiley, One Wiley Drive, Somerset, NJ 08873. 1979. 741 pp. 15 × 23 cm. Price $34.95.

This book presents a collection of analytical derivatization methods for gas chromatographic, liquid chromatographic, and mass spectral analysis. The reactions involve only the covalent derivatives of organic compounds formed prior to analysis. Part I briefly discusses the uses of analytical derivatization, the types of derivatives formed, and a typical apparatus employed in such reactions.

Part II features 15 sections concerning the derivatization of particular compound types. Among the classes considered are steroids, prostaglandins, and drugs. An overview of derivatization for the sample type is given along with specific derivatization methods. For each major compound type, the derivatization reactions are organized further into subsections of the compound type and within each subsection according to the type of derivative formed. Each method description includes structural formulas for the reaction, experimental directions, and references to the original literature. Sections on derivatives for substituent location by mass spectrometry and derivatives for chromatographic separation of optical isomers also are included.

Part III contains author and general subject indexes along with appendixes listing the composition of brand name reagents and U.S. and foreign suppliers of reagents and apparatuses used for analytical derivatization. An index of the derivatives and reagents discussed in Part II also is included.

This book should serve both as a self-contained methodology reference and as an introduction to the literature on analytical derivatization.

Staff Review

Pharmacognosy, 11th ed. By G. E. TREASE and W. C. EVANS. Cassell and Collier Macmillan Publishers Ltd., 35 Red Lion Square, London WC1R 49G, England. 1978. 784 pp. 16 × 23 cm. Price $32.50.

This is the 11th edition of a longstanding series of revisions that trace their origin to the original work in 1934. The latest revision reflects the increasing awareness and knowledge of the active constituents of natural, particularly vegetable, drugs. The book has been partially rearranged from the 10th edition with lengthy revisions in the parts dealing with drug sources, including production and quality control and the consideration of the various classes of drugs of biological origin.

The book is composed of eight parts with a total of 41 chapters, including an index. It is liberally filled with numerous structural formulas, pictures (none in color), tables, and illustrations. Part 1 (Chapters 1–3) deals with drug classification, the literature of pharmacognosy, and plant nomenclature and taxonomy. Part 2 (Chapters 4–7) covers plant morphology, anatomy, histology, and cellular content. Part 3 (Chapters 8–12) discusses the botanical and chemical characteristics of the more important orders and families of both nonflowering and flowering plants with references taken from Volumes 74–84 of *Chemical Abstracts*. Part 4 (Chapters 13–18) includes a discussion of the sources of crude drugs, drug production, quality control, drug deterioration, and plant growth regu-

lators and a summary of the pharmacological actions of plant drugs.

Part 5 (Chapters 19–22) discusses phytochemistry, biogenesis, and basic and secondary phytometabolism with a small section on microbial conversions and aberrant syntheses in higher plants. Part 6 (Chapters 23–35) constitutes the bulk of the book and is a discussion of the drugs of biological origin, organized by chemical class (*e.g.*, carbohydrates and alkaloids) or by biological activity (plant tumor inhibitors, hallucinogens, and pesticides). Part 7 (Chapters 36 and 37) concerns genetics and comparative phytochemistry, while Part 8 (Chapters 38–41) finishes the book with a discussion of microscopy.

One can find some inconsistencies in this book, as in any text. For instance, the stereochemistry of the cardiac steroid glycosides is not illustrated in Chapter 27 (although these features are discussed), while the stereochemistry of the tropane alkaloids hyoscyamine and hyoscine is nicely illustrated in Chapter 30. A somewhat disturbing feature is that the authors chose to discuss the pharmacological activities of plant-derived drugs in one specific chapter instead of with the specific compound in the appropriate chapter. To my knowledge, there is little or no mention of the commonly occurring adverse effects associated with therapy with plant-derived drugs. There is no discussion of immunizing biologicals nor of antibiotics as therapeutic agents. Finally, the chapter on tumor inhibitors from plants seems weak and is particularly lacking in structural illustrations.

The writing of a textbook on pharmacognosy is a labor of love in many ways. It is a particularly broad subject and it is difficult to be "all things to all people." The authors have worked diligently to "marry" biology, biochemistry, chemistry, plant histology/anatomy, and pharmacology into one voluminous work. As the authors state: "The new edition has the same purpose as its predecessors, namely to give a comprehensive presentation of pharmacognosy which complements the very varied treatments which the subject receives in schools of pharmacy throughout the world." Despite some shortcomings, the book adequately fulfills its broad-based mission, and I recommend that anyone involved in the broad discipline of pharmacognosy should obtain a copy. Furthermore, libraries of pharmacy schools and institutions interested in natural products should be interested in this work.

WHERE HAVE ALL THE RESEARCHERS GONE?

The "researchers" referred to in the title of this editorial are the clinical research people who conduct the studies concerning safety and effectiveness of new drugs using human volunteers as test subjects.

Twenty-five years ago, it seemed that people conducting clinical trials were the proverbial "a-dime-a-dozen." Today, however, they are few and far between; and their number keeps shrinking at an alarming pace.

What has happened? What has caused this major shift? Is the net effect good or bad? And what impact will this have for the future of new drug development? A brief recapitulation and examination of this general phenomenon would appear to be in order.

Drug testing was an extremely lax business back in the 1950s. Furthermore, not only was it simple and easy for virtually any medical practitioner to begin conducting clinical experiments using human subjects—without their consent or even their knowledge—but it was also glamorous, exciting, and the "in thing" among many physicians. Not surprisingly, abuses were commonplace and the results and findings of these pseudoscientific studies by mostly untrained researchers were frequently of questionable validity and doubtful value.

Reform in the shape of the 1962 amendments to the Federal Food, Drug, and Cosmetic Act, coupled with related FDA regulations, changed this situation very abruptly by the mid-60s. "Experts qualified by scientific training and experience," "submission of preclinical test" protocols, "signed agreements from each such investigator," "the establishment and maintenance of records," "making of reports to the Secretary of HEW," certification of "informed human consent," and granting general authority for FDA inspectors to have "access to, to copy, and to verify all such records," were some of the new provisions of that legislation which directly related to the future operation of clinical investigators and their work.

In retrospect, that new law and its associated regulations had a very salutory effect. Most of the abuses were curbed, the amateur researchers were effectively weeded out, and the remaining people constituted a largely conscientious, qualified, and professional core of medical scientists. Indeed, almost overnight, clinical pharmacology came into its own, and this cadre of clinical investigators became regarded as a highly respectable sort of subdiscipline or specialty group.

But because some abuses continued, and because a few investigators were dishonest and got caught at it, increasingly stringent rules and regulations were subsequently promulgated to govern the operation of clinical investigators. Concurrently, other forces were at play that also impacted on the area of clinical investigations and on those who conduct such studies.

One of these was concern over the use of prisoners in human drug trials and the question of whether prisoners could participate in a truly voluntary fashion. A second development was the surge of malpractice cases and the soaring costs of settling liability claims and judgments. A third development was our growing sophistication as to what is needed to produce a valid drug investigation—including, for example, larger and better selected patient populations, adequate controls, and double-blind study designs.

More recently, there have been some other changes. Institutional review boards, or IRBs, have been established and have become a formal part of the clinical investigation process. They provide a broad perspective in reviewing the drug investigator's study plan, the suitability of its design, and the protection offered the patients participating. All of this is good, but it greatly lessens the feeling of freedom and hence the challenge that once attracted clinical investigators to such work.

The same can be said of FDA inspections which now are both more frequent and more thorough. They, too, give society greater confidence that patients' rights are protected and that society is being properly served; but concurrently, they also add greatly to the annoyance and frustration level of the clinical investigator who is subjected to this often intense scrutiny.

Increasingly, we are hearing reports that good people are dropping out of the pool of clinical researchers and that new people are reluctant to embark on careers in that field. Consequently, the field is giving signs that it is beginning to dry up, at least in this country. Partially, the impact has been dulled because many drug firms are now drawing upon foreign data to support their new drug applications. But that is no real or long-term solution for the problem.

If this country is to continue to benefit from the introduction of important new drugs, we need to find an answer that will somehow rejuvenate clinical testing in the United States, while continuing to afford reasonable protection for those who participate as test subjects in such studies. And the importance of this problem is such that it calls for prompt attention and serious consideration.

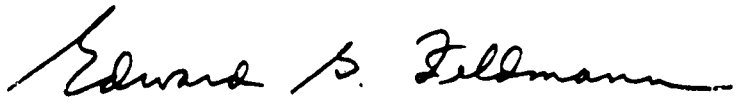
If this country is to continue to benefit from the introduction of important new drugs, we need to find an answer that will somehow rejuvenate clinical testing in the United States, while continuing to afford reasonable protection for those who participate as test subjects in such studies. And the importance of this problem is such that it calls for prompt attention and serious consideration.



Suspension Theory—Psychological/ Physiological States

The tissues composing the body can be viewed as cell suspension systems. The various individual tissues organize and coordinate to function as a whole system.

The cells of each local tissue continuously fluctuate between the coagulated and flocculated aggregation states. In addition, blood cells can exist in the dispersed state as separate entities.

By flocculated is meant an aggregation of cells held together by bridging macromolecules in an open network structure. Entrapped in the openings of the network is polar bulk water.

By coagulated is meant an aggregation held together by films of macromolecules that cover the adhering surfaces of closely adjacent cells. The water in which the cells are suspended is bound and forms part of an interstitial structured matrix, which is nonpolar in its solvent properties[1,2].

It was postulated[1] and then shown[3,4] that a direct correlation exists between psychological states and erythrocyte sedimentation rates and, thereby, between psychological states and the red blood cell aggregation state producing the erythrocyte sedimentation rate[5]. The normal emotional state exists with a dynamic equilibrium among the dispersed, coagulated, and flocculated suspension states. Increasing emotional agitation up to the manic state shifts the aggregation equilibrium to a predominately flocculated state. Conversely, the depressed state (manic-depressive) shifts the suspension states to predominately a coagulated aggregation.

If it is assumed that the normal emotional state is the ground state with respect to free energy content, any increase in stress, psychological or physical, produces an increase in matrix structure breakers (catecholamines, *etc.*), which is accompanied by liberation of metabolic energy, *i.e.*, a decrease in enthalpy. There is a corresponding increase in the entropy as reflected in the shift toward a flocculated and dispersed system. Thus, fuel for responding to the stress is at the expense of the free energy content of the total body as well as the local tissues involved. Countervailing conditions toward normal and depressive states are initiated by removal of the stress or prolonged presence of stress with excessive expenditure of the free energy.

The presence of stress is accompanied by rising levels of macromolecules, chiefly albumin, along with the catecholamines.

Removal of stress lowers catecholamine as well as other energy-stimulating hormone production, thereby permitting excess macromolecules to layer out on cell surfaces. Sufficient film production on cell surfaces results in a shift toward coagulation.

Prolonged presence of stress results in depletion of local tissue free energy. The liberation of chemical energy decreases and then ceases. The entropy of the tissue cellular suspensions then becomes increasingly more negative as the cells begin to pack closely together and to form the more structured coagulated state. The coagulated state permits regeneration of free energy and eventually the metabolic processes that start the cycle toward the flocculated state.

In summary, as the manic stage is approached, the change in entropy of the cell suspensions becomes increasingly positive as the change in enthalpy becomes increasingly negative. As the depressed stage is approached, the entropy becomes increasingly negative. With time, the local tissue enthalpy becomes increasingly positive. The local tissue free energy is increased as the by-product of the metabolic processes occurring in the other tissues.

The coagulated state is the state of energy regeneration, growth, and division. Its organization is controlled by the external environment. The flocculated state is the state of energy expenditure and internal control of tissue organization (contact inhibition)[6]. In the extreme case, depression is an energy-rich state, energy that the body cannot liberate. The energy is expended on the tissues of the internal environment. In the manic state, excessive amounts of energy are being expended on the external environment. The body is continually responding to stress with psychological–physiological buffering processes.

Accordingly, after a period of stress, sleep is a process for regenerating reversible thermodynamic states under optimum conditions. In sleep, there is a minimum of external energy-stimulating signals.

In aging, the reversible coagulation–flocculation process proceeds with a slow loss of entropy regeneration and reversibility and, thereby, a loss of ability to organize cell tissue aggregates. The final result is the loss of internal control of body organization and finally death, although individual cells might still live.

The immortality of cancer cells, an irreversible coagulated state, is obtained at the loss of the ability to go to an organized state, *e.g.*, the flocculated state[6].

Cost Evaluation of Alternative Pharmaceutical Tableting Processes by Simulation

R. M. FRANZ, G. S. BANKER, J. R. BUCK *, and G. E. PECK x

Received August 20, 1979, from the *Department of Industrial and Physical Pharmacy, Purdue University, School of Pharmacy and Pharmacal Sciences, West Lafayette, IN 47907.* Accepted for publication January 18, 1980. *School of Industrial Engineering, Purdue University, West Lafayette, IN 47907.

Abstract □ A simulation model and a subsequent computer program were developed as experimentation methods for evaluating tableting processes with respect to cost. These methods also allow estimation of the various times involved in a tableting operation (*e.g.*, the processing time). The model was programmed in FORTRAN using the GASP IV simulation language. After verification of the program, experiments were run that involved comparing different levels of specific input variables to determine which variable had an effect on the cost–time relationships of a particular processing method. Among the possible input variables chosen for evaluation were the drying method, the type of tableting machine, the batch size, the labor rate, and the operation of the equipment in the process. An analysis of variance was made, and three separate regression equations were developed that described the relationship between the input variables and the dependent variables of processing cost and time. Graphs were developed from the regression equations by manipulating them through series of different independent variables. These graphs then were used in determining minimum costs and times, breakeven points, and rates of change, as well as in simple evaluation of processes through graphic representation. By using the simulation program to run experiments and then by analyzing them, results can be obtained to help in making intelligent decisions about the cost–time relationships of a particular tableting procedure before it is implemented.

Keyphrases □ Tableting processes—cost evaluation, simulation model □ Models, simulation—cost evaluation of tableting processes □ Cost evaluation—tableting processes, simulation model □ Processing formulations—tableting procedures, cost evaluation, simulation model

The effects of alternative processing methods and formulations on the physical, chemical, and biological characteristics of tablet dosage forms (1, 2) have been discussed extensively. Although these alternative processes and formulations can affect the time and cost for tablet production, little information has been published on these time–cost effects. This paper describes a method for assessing various processing time and cost effects with specific alternative formulations and processing techniques. The general implications of these effects also are shown.

The basic element of this method is a computer simulation encompassing the various tablet-processing techniques. Although simulation has been used in the pharmaceutical industry for the development of a completely computerized tableting plant (3) and for various chemical and business operations, these simulations are specific for a particular company and application. Also, these simulations have been employed to answer specific questions.

The approach illustrated here is generalized to simulate virtually any tableting operation, and it is coupled with an example of an experimental design so that inferences can be made over numerous factors that change from one tableting operation to another. In this way, the individual simulation serves as a basic experimental unit, much as would an individual laboratory experiment. Results from such simulations thus can be used in process analysis, design, and performance evaluation with respect to cost–time information.

MODEL

Development—A general simulation model for the tableting of pharmaceutical products was developed. The model was constructed so that any of the three basic tableting methods (wet granulation, direct compression, and slugging) as well as variations in these methods could be simulated. The basic unit operations employed by these methods were arranged in linear fashion as shown in Part A of Fig. 1. To simulate a particular tablet processing technique, unit operations that are not part of the technique are excluded by having a zero time interval. In this way, a single model can simulate two or more tableting methods where any differences in the methods are inputted explicitly in the program.

General unit operation input variables are included in every step of the model (Fig. 1, Part B). The times involved in each unit operation are determined by the type of equipment used in that particular step. These times reflect the cost involved per unit operation. Power and depreciation are other cost components. Only linear depreciation is used in the model,

as noted in Table I, which also includes some of the important equations used in the model (4, 5). The utilization factor used here is unity minus the fraction of time the equipment is idle. The utilization factor adjusts the actual batch time to account for a proportional amount of the idle time for the equipment.

Unit operation-specific input variables that are used in only certain operations are given in Part C of Fig. 1. These variables include warehousing costs, but only those incurred during the staging operations before the final product is complete.

Table I—Partial List of Basic Equations Used in the Model [a]

Computed Output	Equations	Variables
Power consumption cost per unit operation (PCC)	PCC = (HP) (UOPT) (ER) (0.012426432)	HP = Horsepower of the equipment in the unit operation UOPT = Unit operation processing time (minutes) ER = Electrical rate (dollars per kilowatt hour) 0.012426432 = Conversion factor
Labor cost per unit operation (LC)	LC = (PT + CT + UOPT + TBUO) (LR)	PT = Unit operation preparation time CT = Unit operation cleaning time UOPT = Unit operation processing time TBUO = Time between unit operations LR = Labor rate (dollars per hour)
Total cost per unit operation (TCUO)	TCUO = PCC + LED + LC + AC	PCC = Power consumption cost per unit operation LED = Linear equipment depreciation per unit operation LC = Labor cost per unit operation AC = Additional costs (*i.e.*, raw materials, bulk packaging costs, and warehouse cost)
Total cost per batch (TCB)	TCB = $\Sigma_{i=1}^{x}$TCUO, where x is the total number of unit operations in the process	TCUO = Total cost per unit operation
Processing cost per batch (PC)	PC = TCB − CRM	TCB = Total cost per batch CRM = Cost of raw materials
Process and formulation controllable cost (FCC)	FCC = (EC − PC)/SY	EC = Excipient cost PC = Processing cost SY = Standard yield per batch
Standard yield cost per tablet (SYCT)	SYCT = TCPT/SY	TCPT = Theoretical cost per tablet SY = Standard yield per batch
Linear equipment depreciation per unit operation (LED)	LED = [(IC − SV)/(SL × 525,960 × UF)] (UOPT + PT + CT)	IC = Initial cost of each piece of equipment in the process SV = Salvage value of each piece of equipment in the process SL = Service life of each piece of equipment in the process UF = Utilization of each piece of equipment in the process 525,960 = Conversion factor UOPT = Unit operation processing time PT = Unit operation preparation time CT = Unit operation cleaning time

[a] All times are in minutes.

simulation are given in Part D of Fig. 1.

The final cost–time output needed for process analysis and evaluation is denoted as Part E in Fig. 1. The *Appendix* gives detailed information regarding this output. In addition, various histograms and tables that show the cost breakdowns for individual unit operations are provided by the basic program to aid in specific process verifications and corrections.

The basic simulation model was kept simple to reduce computer costs and to make it easier for users to adjust to specific operational variations. Adjustments to the input data will be needed when the operation being simulated deviates from the assumptions made in constructing the basic model. These assumptions and some of the required adjustments include the following:

1. The time "between" unit operations is included in the cost of the successive operation.

2. If a unit operation is skipped, then the time between it and the successive unit operation is uniform. The time "between" unit operations is dictated by the unit operation being left, *not* by the next unit operation in the process. This convention allows variations in the sequences of unit operations.

3. Equipment depreciation for each unit operation in a process is based on the unit operation processing time, cleaning time, and preparation time. The batch depreciation is the sum of the individual depreciations of the unit operations.

4. Labor cost for a unit operation includes the time between the current and the previous unit operation, cleaning time, preparation time, and unit operation processing time multiplied by a single labor rate. If multiple labor rates are involved, then a single composite labor rate can be used.

5. The unit operation processing labor time is equal to the unit operation processing time, except in the drying step (tray drying only) and the staging step. In the drying and staging steps, the unit operation processing labor time is much less than the unit operation processing time.

6. Costs are assigned only to the particular batch being processed. Accordingly, the time a laborer works on more than one batch during any particular processing step is not included in the final cost estimates.

7. The laborer can do only one thing at a time. For example, if the mixing unit operation lasted 15 min, the laborer would be at this step for 15 min and would *not* be starting the next unit operation in advance. The only exceptions are the drying and staging unit operations, where the unit operation processing labor time differs from the unit operation processing time.

8. All equipment used is powered by electricity; or if it is powered by some alternative form of energy, it can be converted into equivalent electrical units (kilowatt hours).

Data—Data were collected from various pharmaceutical manufac-

turing firms on specific operations performed, sequences of operations, equipment specifications and layouts, products made, manpower requirements, approximate time requirements, and other relevant features to assure reasonable generality of the model and to provide reasonable values and ranges for various parameters and coefficients.

Time and cost variations occur randomly in the unit operations, and an allowance was made in the basic model to include these uncertainties. Time data were collected in triangular distribution form to provide users with a consistent and highly intuitive method for including these uncertainties (6). With the triangular distribution, users must specify the minimum value, the most likely or modal value, and the maximum value for the random time variable being described. Distributions representative of the data collected were used in the program, but other distributions can be incorporated, if necessary, with a minimum of programming effort. Figure 2 shows the probability density and cumulative probability functions of the triangular distribution.

The probability density function is described by:

$$F(X) = \frac{2(X - A)}{(M - A)(B - A)} \qquad A \le X \le M \qquad \text{(Eq. 1}a\text{)}$$

$$F(X) = \frac{2(B - X)}{(B - M)(B - A)} \qquad M \le X \le B \qquad \text{(Eq. 1}b\text{)}$$

$$F(X) = 0 \qquad \text{otherwise} \qquad \text{(Eq. 1}c\text{)}$$

The cumulative probability function is described by:

$$F^*(X) = \frac{(X - A)^2}{(M - A)(B - A)} \qquad A \le X \le M \qquad \text{(Eq. 2}a\text{)}$$

$$F^*(X) = \frac{(M - A)}{(B - A)} + \frac{(B - M)^2 - (B - X)^2}{(B - M)(B - A)} \qquad M \le X \le B \qquad \text{(Eq. 2}b\text{)}$$

where X is the random time variable, A is the minimum value, B is the maximum value, and M is the modal (most likely) value. This distribution allows for asymmetry in the random variable, which often occurs in processing time requirements. In the computer program, a uniform random deviate is called and converted to a value of X through the cumulative probability function described by Eqs. 2*a* and 2*b*.

Programming—The model was programmed in FORTRAN with the

aid of a computer simulation package called GASP IV (7). GASP IV allows users to build computer simulations with a minimum of effort. The programmer develops subroutines that interact with various GASP IV subroutines. Subroutines in the GASP IV package provide much of the statistical analysis used in the simulation and in creating the cost–time histograms in the program output. Each unit operation in the model was programmed as a separate subroutine so that users could incorporate additional cost–time features into any unit operation with a minimum of difficulty.

By using different initial uniform random deviates, a different stream of random numbers are generated with each simulation run and are converted to random variations in time and cost output through the specific forms of the triangular distributions. These variations take the form of an average and a standard deviation for each cost–time output of the model. This result is indicated in the simplified flow diagram of the computer program shown in Fig. 3.

Table II shows a sample of the output averages and standard deviations to illustrate the management information provided by the basic simulation program.

Verification—The model verification was accomplished in two steps. The first step involved inspection by pharmaceutical processing personnel, including tableting operation supervisors and directors of pharmaceutical manufacturing departments, of the model concept, assumptions, and variable values to assure that they were representative of actual tableting processes.

The second step involved taking various tablet products from different companies, running the simulation on them as specified by their processing sheets, and then comparing the average simulated processing times with the average time reported in the company's records. Table III shows the results of these comparisons and the percentage differences between the simulation and the actual processing times. No relationships between simulation errors and actual processing times were evident from these data when they were plotted on a scattergram. Final cost data comparisons could not be obtained for proprietary reasons.

Model Application—Numerous experiments were run using the simulation, especially those involving interprocess analysis. The experiment illustrated here is an example of an intraprocess analysis. The goal was to determine how different levels of specific processing variables affect the final processing time and processing cost of a particular wet granulation tableting technique.

Numerous variables affect the processing time and cost. The variables chosen for investigation were the type of drying (tray or fluid bed), the type of tableting machine, the batch size, the average utilization of all equipment in the process, and the labor rate.

Except for the variable of the type of drying, there are many options for each variable, so the number of combinations possible is extremely large. Consequently, investigation of even a small fraction of these combinations is economically unfeasible in a search for more economical

tableting methods. An alternative approach is to use an experimental design that analyzes the effect of entire variables and their interactions to identify those that affect the processing time and cost. This approach allows identification of those variables and interactions where processing times and costs do change significantly, thereby reducing the number of variables to be considered.

Once the significant variables and interactions are identified, a formula for describing the processing time and cost can be devised through regression methods to show the magnitude of these time and cost effects. Various decision rules then can be developed with these formulas to aid in the management of the tableting process, the potential purchase of new equipment, or the design of a new tableting process. Some of these features will be demonstrated here. In addition, optimization methods may be employed to find the most economic processing method following the concepts discussed previously (8–10). A variety of experimental designs, regression procedures, and optimization techniques can be employed in this conceptual approach, but the choice among these alternatives is beyond the scope of this investigation.

EXPERIMENTAL

The particular tableting technique being investigated, as well as the fixed unit operation input, is shown in Table IV. The levels of the fixed input remain the same throughout the entire experiment. Salvage values for all equipment were estimated to be zero at the end of the service life of 15 years.

The different levels of the variables of the drying method, tableting machine, utilization factor, batch size, and labor rate used in the experimental design approach are noted in Table V. All of the variables in Table V were assumed to be continuous between the levels tested, except for the drying method, which was considered discrete.

A five-way split–split plot experimental design was employed. This design allows the experimental conditions to be run twice using two separate sets of initial uniform random deviates, which are used to obtain random time variables from the different triangular time distributions. It was assumed that the effect of the two different sets of initial uniform random deviates would be statistically insignificant; consequently, the interactions involving this effect could be pooled together as an error term. This error term then could be used in an analysis of variance. A test was made on this assumption by rerunning the simulation strictly at the model value for all of the triangular time distributions and comparing the average processing time and cost output without variability to that obtained from the results using the different sets of initial uniform random deviates. Since there was an insignificant difference, this assumption was partially verified.

Before running an analysis of variance, the generated processing cost and time outputs were checked to assure homogeneous variances. Since the processing cost means were proportional to the cost variances, a logarithmic transformation of these data was made, and the Burr–Foster Q test (11) assured homogeneity at a 0.01 level of significance. Mean processing time data were separated into tray drying and fluid bed drying categories due to trends in the data within each method. The need for this separation was expected since drying method levels were considered discrete. Logarithmic and fourth-root logarithmic transformations on the tray drying and fluid bed drying processing time data, respectively, gave homogeneous variances at the 0.01 level of significance as confirmed by the Burr–Foster Q test.

An analysis of variance was performed separately on each of three data sets: (*a*) the processing cost with both drying methods, (*b*) the processing time using tray drying, and (*c*) the processing time using fluid bed drying. The results showed that the effects of the two different sets of initial uniform random deviates were insignificant. The main effects and interactions that were statistically significant in the analysis of variance are listed in Table VI.

A second-order stepwise regression analysis was performed on those variables found to be statistically significant in the analysis of variance. The equations developed by this analysis, as well as the squared correlation coefficients, are given in Table VII.

RESULTS AND DISCUSSION

Graphical Development—The regression equations in Table VII were programmed on a digital computer and manipulated through a series of over 100 points between the high and low levels of the factors tested. The graphs shown in Figs. 4–7 were selected for discussion from among the many that were developed using a computer plotting technique and the points generated from the regression equations.

Processing Time Analysis—The processing time increased as a function of increasing batch size (between 0.5×10^6 and 1.5×10^6 tablets/batch), as expected, but the rate of increase always was greater with tablet machine A[1]. The reason for this greater rate of increase was that tablet machine A had a lower speed than tablet machine B[2], so it took longer for tablet machine A to produce a fixed batch size of tablets than tablet machine B. Tray-dried batches made with tablet machine A always had longer processing times than fluid bed-dried and tablet machine B-produced batches. The most interesting feature of this test was that processing times were almost linear functions of the batch size, even though there were interactions and higher order terms in the regression equation.

Another test was made on the processing time as a function of the mean tableting rate for different batch sizes with different drying methods as shown in Fig. 4. The tray-dried processing time for a fixed batch size was offset by a constant processing time of ~27.8 hr more per batch than the fluid bed-dried[3] processing time. Beside the decrease of the batch processing time with increased tableting rates, the processing time effects also were marginally decreased (Fig. 4).

Although the effects of the examples follow the form of intuitive expectations, the magnitude of these effects would be difficult to anticipate without considerable data. However, use of the graph allows easy visual understanding of the trends caused by these effects as well as computation of their magnitude.

Processing Cost Analysis—Figure 5 illustrates how the processing cost decreases with increasing mean tableting rate using different combinations of drying methods and batch sizes. The processing cost change over the limits of the tableting rate (mean tablets per minute) becomes

less as the batch size decreases. Breakeven points normally are observed when only one factor is changing, but the breakeven points shown here are between different batch sizes as well as between different drying methods. For example, at a production rate of ~7207 tablets/min, the processing cost per 1000 tablets is about 24¢ for a 1,500,000-tablet batch that is fluid bed dried compared to 28¢/1000 tablets for a 1,250,000-tablet tray-dried batch. To find a true cost breakeven point between these two curves, the mean tablets per minute *versus* the processing cost per fixed number of tablets (*i.e.*, per thousand) has to be plotted. This can be done easily using Fig. 5.

Figure 6 shows how the processing cost per batch increases with increasing batch size using different combinations of tableting machines, utilization factors, and drying methods. Processing costs with tablet

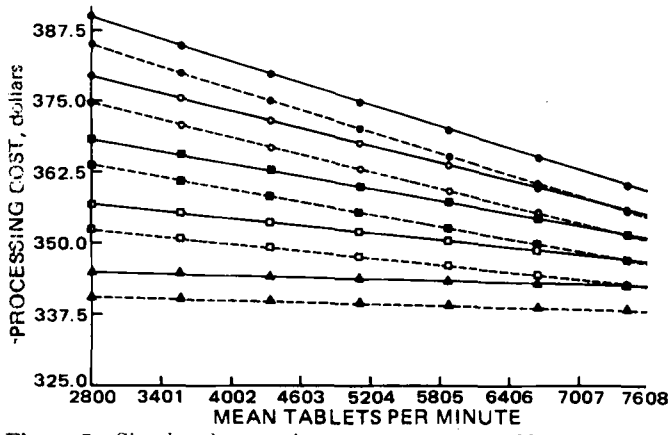

Figure 5—*Simulated processing cost* versus *mean tablets per minute produced curves for different combinations of drying methods and batch sizes at a fixed labor rate of $5.50/hr and utilization factor (UF) of 1.0. Key: -●-, tray dried, 1,500,000 tablets; --●--, fluid bed dried, 1,500,000 tablets; -○-, tray dried, 1,250,000 tablets; --○--, fluid bed dried, 1,250,000 tablets; -■-, tray dried, 1,000,000 tablets; --■--, fluid bed dried, 1,000,000 tablets; -□-, tray dried, 750,000 tablets; --□--, fluid bed dried, 750,000 tablets; -▲-, tray dried, 500,000 tablets; and --▲--, fluid bed dried, 500,000 tablets.*

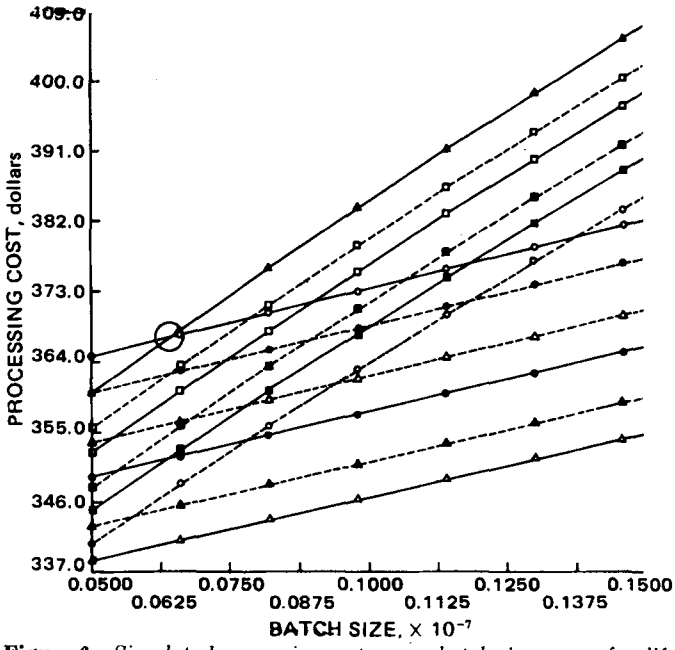

Figure 6—*Simulated processing cost* versus *batch size curves for different combinations of tableting machines, utilization factors (UF), and drying methods at a fixed labor rate of $5.50/hr. Key: -▲-, tablet machine A, UF = 0.5, tray dried; --□--, tablet machine A, UF = 0.5, fluid bed dried; -□-, tablet machine A, UF = 0.75, tray dried; --■--, tablet machine A, UF = 0.75, fluid bed dried; -■-, tablet machine A, UF = 1.0, tray dried; --○--, tablet machine A, UF = 1.0, fluid bed dried; -○-, tablet machine B, UF = 0.5, tray dried; --●--, tablet machine B, UF = 0.5, fluid bed dried; --△--, tablet machine B, UF = 0.75, tray dried; -●-, tablet machine B, UF = 0.75, fluid bed dried; --▲--, tablet machine B, UF = 1.0, tray dried; and -△-, tablet machine B, UF = 1.0, fluid bed dried.*

machine A are lower than tablet machine B with small batch sizes, but these costs increase at a greater rate with increasing batch sizes. As a result, there is a breakeven point with the batch size. For example at ~640,625 tablets/batch, the curves for tray-dried tablets with a utilization factor of 0.5 intersect. This breakeven point can be seen in the encircled area of Fig. 6. The only difference in these two curves is the type of tableting machine used. Tablet machine A is less expensive to operate at small batch sizes due to its smaller power cost and equipment depreciation charged per batch. However, as the batch size increases, tablet machine B becomes less expensive to operate due to its high production output and, thus, minimal tableting unit operation processing labor cost. The cleaning and preparation time for both tablet machines were assumed to be approximately the same. For a constant utilization factor, Fig. 6 shows that the breakeven batch size is the same for tray drying or fluid bed drying. As the utilization factor increases, the breakeven batch sizes decrease. Increases in processing cost with larger batch sizes are approximately linear with tablet machine B, but those with tablet machine A tend to be slightly marginally decreasing.

Figure 7 illustrates how the processing cost changes with increasing labor rate up to $8.25/hr using all combinations of drying methods, tableting machines, and utilization factors at a fixed batch size of 1,000,000 tablets. The processing costs increase with labor rate in a marginally increasing manner up to $8.25/hr. Figure 7 also shows that for a given utilization factor and a given tableting machine, fluid bed drying has a lower processing cost than tray drying. Figure 7 may be useful in evaluating processes as labor rates become inflated.

Processing Time–Processing Cost Interaction—By comparing the graphs where the dependent variable is processing time with graphs where the dependent variable is processing cost, it is evident that the drying method affects the processing time to a greater extent than does the tableting rate while the tableting rate affects the processing cost more than the drying method. This observation indicates that while the cost of either drying method varies little per batch, the time difference between the two is great. The time saved by using fluid bed drying over tray drying could be used for increased production of other product batches. Since the simulation only represents the cost–time variables for a single batch of a single product, multiple-batch and multiple-product considerations should be kept in mind.

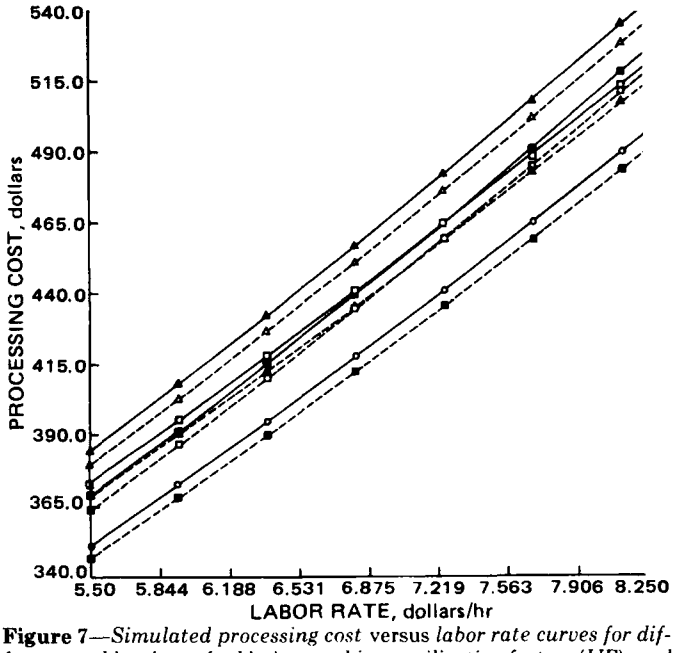

Figure 7—*Simulated processing cost* versus *labor rate curves for different combinations of tableting machines, utilization factors (UF), and drying methods at a fixed batch size of 1,000,000 tablets. Key: –▲–, tablet machine A, UF = 0.5, tray dried; --△--, tablet machine A, UF = 0.5, fluid bed dried; –■–, tablet machine A, UF = 1.0, tray dried; –□–, tablet machine B, UF = 0.5, tray dried; --□--, tablet machine A, UF = 1.0, fluid bed dried; --▲--, tablet machine B, UF = 0.5, fluid bed dried; –○–, tablet machine B, UF = 1.0, tray dried; and --■--, tablet machine B, UF = 1.0, fluid bed dried.*

CONCLUSIONS

1. The model and simulation program shown here can be used in intraprocess as well as interprocess cost and time evaluations.

2. The simulation program itself can be used as an experimentation method, with an almost unlimited number of experiments and manipulations possible at a fraction of the cost and time of the actual processing experiments.

3. Statistical methods as well as optimization techniques can be applied to the experimental simulation output to make optimal decisions about the results.

4. The model and simulation can be a tool in making management and process-engineering decisions concerning tableting cost and time considerations, especially with processes that are new or being updated.

APPENDIX

The following cost–time outputs for each run of the simulation program may be defined:

1. Tablets per batch—the number of tablets produced in a batch. It is the theoretical yield rather than the standard yield of tablets.

2. Cost per batch—the total cost per batch, including raw material cost, labor cost, equipment depreciation, power consumption costs, warehouse costs, and bulk packaging costs.

3. Cost of raw materials—the cost of both active and inactive ingredients in the formulation.

4. Excipient cost—the cost of the raw materials *minus* the cost of the active ingredients in the formulation.

5. Process cost—the total cost minus the cost of the raw materials.

6. Process and formulation controllable cost—the processing cost plus the excipient cost divided by the standard yield per batch. This cost will change if one uses a different process or a different formulation.

7. Cost per tablet—the total cost divided by the theoretical number of tablets.

8. Standard yield cost per tablet—the cost per tablet divided by the standard yield per batch.

9. Process cost per tablet—the process cost divided by the theoretical number of tablets produced.

10. Labor cost per unit operation—the average labor cost per step including the end-of-process step.

11. Labor cost per batch—the total labor cost per batch.

12. Cost per unit operation—the same explanation as in the section on labor cost per step applies here. This cost is the total *average* cost per step. It includes raw material costs.

13. Equipment depreciation—the total equipment depreciation that can be assigned to this particular batch.

14. Power costs—the cost of the energy consumed by the equipment during the process.

15. Warehouse costs—the total cost of using warehouse space to store a batch of unfinished product.

16. Package costs—the cost of bulk packaging the unfinished product to be stored or bulk packaging the final product to be stored. It is a fixed number in that the formulator must know the cost.

17. Yearly production cost—the total cost per batch multiplied by the number of batches produced per year.

18. Yearly process and formulation controllable cost—the per batch formulator controllable cost multiplied by the number of batches per year.

19. Processing time plus time between steps—the total time it takes to process a batch. This time does not include cleaning or preparation time; it only includes the time it takes to produce a batch if everything is prepared and cleaned.

20. Total labor time—the total labor time spent in producing a batch. It is the time that a laborer is paid for that can be assigned to a particular batch.

21. Cleaning and preparation time—the total cleaning and preparation time spent during the production of a batch.

Derivative and Graphical Procedures for Correction of Irrelevant UV Spectrophotometric Absorption in Changeable Matrixes

J. TRAVESET *, V. SUCH *, R. GONZALO *, and E. GELPI ‡x

Received December 10, 1979, from the *Departamento de Análisis y Control, Lácer S.A., Cerdeña 350, Barcelona-25, Spain, and the ‡Instituto de Química Bio-orgánica, CSIC, Jorge Girona Salgado s/n, Barcelona-34, Spain. Accepted for publication January 15, 1980.

Abstract □ The application of direct zero-order UV spectrophotometric and graphical or derivative background correction methods to selected pharmaceutical preparations shows their relative advantages in different situations. The assay of the active components in a changeable matrix is a problem with formulations having a limited shelflife. Although the standard three-point correction procedures can provide accurate data, there are practical problems if the irrelevant absorption band is such that only the derivative approach gives enough resolving power for reliable qualitative and quantitative determinations.

Keyphrases □ Excipients—solutions, suspensions, and suppositories, changeable matrixes and their effect on UV absorbance spectra, comparison of three background correction methods □ Spectroscopy, UV—changeable matrixes of pharmaceutical preparations, comparison of three background correction methods, interference by excipients or degradation products □ Degradation—pharmaceutical preparations, effect on UV absorbance spectra, comparison of three background correction methods, changeable matrixes

The assay of certain drugs or natural products by classical UV spectroscopic techniques usually can be accomplished by simple and direct procedures. These procedures generally involve reading the absorbance of the sample *versus* that of a standard at selected wavelengths, except where the analyte is part of a complex matrix containing other UV-absorbing degradation products and chemicals (1). In such a situation, the spectral overlapping of the irrelevant absorption bands produced by the interfering components can be so strong as to mask completely the band of the compound, making it difficult or impossible to determine not only its concentration but also its presence. Since the irrelevant absorption of multicomponent samples cannot be suppressed efficiently due to the inherent lack of resolution of the classical UV spectroscopic techniques, its effects must be compensated for by often cumbersome sample cleanup and separation procedures. Thus, the convenience of the direct UV readings using a conventional spectrophotometer is lost.

BACKGROUND

The practical limitation derived from variable and nonspecific spectral interferences has been treated by mathematical and graphical methods, ranging from very simple to tedious and lengthy procedures, according to the shape of the irrelevant absorption spectrum (2). The Morton–Stubbs (3) three-point correction method has been used extensively where there is an unknown or variable contribution to the measured absorption. However, the method assumes that the irrelevant absorption is linear over the working wavelength range (4).

Background interferences also have been corrected by the application of absorbance ratios and orthogonal function coefficients (5, 6), which are sensitive to instrumental parameters and difficult to apply if the irrelevant background absorption is similar to the spectral band of the analyte (4). The method of Glenn (5) was applied and evaluated by Wahbi and Abdine (7), who, in spite of considering it useful in many cases, acknowledged that it may give unsatisfactory results if the polynomial, number of points, and wavelength range and intervals are not selected properly. Furthermore, many of these methods require special attention to operational parameters, which detracts from their applicability to many practical problems in pharmaceutical analyses.

On the other hand, the recently introduced commercial systems that can produce a graphic display of the derivative ($dA/d\lambda$ or $d^2A/d\lambda^2$) of the analog signal given by the spectrophotometer provide a different approach to these problems. In many cases, the derivative techniques allow resolution of two spectral bands of very close wavelength so they can be used in the quantitative spectrophotometric assay of complex mixtures of spectrally interfering substances (8).

The derivative spectroscopy technique was introduced (9) as a means of resolving two overlapping spectral bands of almost coincident wavelength. However, the potential of this technique for pharmaceutical analysis has not been studied in detail, although it could be easily inferred from the small, though significant, body of data reported by different laboratories. For instance, derivative recording of UV spectra was applied successfully to steroid structure determination (10) and to the quantitation of mutually interfering rare earth elements and dyes (11) and gases (12, 13). The quantitation of pyrene in the presence of excess anthracene by derivative luminescence also was reported (14), and more recently, the technique was used in biology to determine total urinary porphyrins (15) as well as phenylalanine residues in proteins (16).

A recent communication discussed second derivative UV–visible spectrophotometry for the quantitation of drugs in their dosage forms (17) and reported coefficients of variation of better than 2% for routine quality control. A general review of derivative and wavelength modulation spectroscopy appeared recently, which mentioned other selected applications (18). All of these data support the idea that derivative spectroscopy may have considerable potential in routine quantitative measurements (18, 19).

Thus, considering the present state of the art with regard to UV determinations of a complex matrix in pharmaceutical preparations, comparative assessment was desired for the applicability of simple, direct, graphical–algebraical and derivative UV measurements in cases where: (*a*) the background absorption of excipients or other products may not be constant due to manual batch-to-batch variations, and (*b*) the corresponding excipient absorbance is either strong (samples with large excipient concentrations) or weak compared to that of the substance assayed (samples with few excipients and a large amount of active drug). Four examples representative of the various cases usually encountered in pharmaceutical analysis were considered.

EXPERIMENTAL

Apparatus—A double-beam ratio recording, scanning, grating spectrophotometer[1] with a variable bandpass from 0.2 to 4.0 nm was used. This spectrophotometer was equipped with a derivative spectrum attachment[2] consisting of an analog differentiating circuit that can record optionally the first or second derivative spectrum and the original (zero-order) spectrum.

The spectra were obtained at a bandpass of 1 nm and a scanning speed of 240 nm/min. The recorder response was set at medium, and the scan speed was set to 12 cm/min at a span of 1 or 2 and a mode of 0.5.

Pharmaceutical Preparations—*Suppositories*—The active ingredients in the suppositories were: dipyrone (1 g), anisotropine methylbromide (0.020 g), and phenobarbital (0.015 g). The suppositories also contained 2.204 g of saturated fatty acid glycerides as excipients and had a total weight of 3.24 g.

Solutions—One solution contained 1.58 g of oxyfedrine hydrochloride (a sympathomimetic agent) and 113.2 g of excipients brought to a total volume of 150 ml with distilled water. Estradiol benzoate (10 mg/ml) was

contained in a suspension of lecithin (8 mg/ml) and chlorobutanol (3 mg/ml). An excipient solution (100 ml) contained 0.2 g of progesterone.

All preparations except the progesterone-containing formula were commercial preparations. For the three solutions, the only sample preparation needed prior to the actual determinations was simple dilution to a predetermined volume with a suitable solvent. However, since phenobarbital was present in a ratio of 1 part to 216 parts of excipients, the suppositories first were subjected to a cleanup procedure to remove a significant proportion of the unwanted materials.

Cleanup Procedure for Phenobarbital in Suppositories—The sample to be assayed (three suppositories, equivalent to 45 mg of phenobarbital) was placed in a 250-ml erlenmeyer flask and dissolved in ~200 ml of ether. The solution was filtered[3], and the filtrate was collected in a 500-ml volumetric flask and taken to dryness on a rotary-film evaporator.

The dry residue was extracted with 200 ml of 10% NH_4OH in ethanol at ~50°. The filtrate was cooled in an ice bath under agitation, filtered[3] again under vacuum, and collected in a 250-ml flask. The residue on the filter paper was washed, and the filtrate was brought to volume with the ammonium hydroxide–ethanol solution. A 5-ml aliquot was diluted to 100 ml with ammonium hydroxide in ethanol to obtain a final phenobarbital concentration of 9 μg/ml.

RESULTS AND DISCUSSION

Phenobarbital in Suppositories—Standard solutions of phenobarbital and of the excipient mixture of the commercial preparations were run individually on the UV spectrophotometer and gave the absorption spectra shown in Fig. 1 (peaks a and b). The corresponding absorption spectrum of a commercial product extract (phenobarbital plus excipients) is also illustrated in Fig. 1 (peak c). In this case, the spectral band was displaced upward due to the background interference of the coextracted excipients, which was clearly reflected in the absorbance value (A_1) at 280 nm (Fig. 1, peak c). Quantitatively, this spectral interference significantly affected the direct measurement of the absorbance value at the peak maximum. Consequently, the relative error obtained by direct UV determinations of the known phenobarbital amounts added to the residual excipient matrix remaining after extraction of the suppositories was +14.3% (Table I).

In contrast, the peak-to-peak (ΔI) measurement of the second derivative spectra of the same samples (Fig. 1, peak d) reduced the relative error to −4.2%. Accordingly, the dispersion of these comparative data indicates that the applicability of the procedure is neither dependent on nor limited by the extraction efficiency of the active drug but instead by the method used to quantitate the UV absorbance curves. As will be demonstrated with other examples, this case is often true in the application of UV spectrophotometric techniques for the quantitation of pharmaceutical preparations.

Average, %[b]	114.3	95.8
Relative error,	+14.3	−4.2
SD, %	4.0	0.6

[a] Heavy spectral interferences, due to relatively large quantities of excipients, were removed partially by preextraction of reconstituted samples (n = 5) lacking phenobarbital but prepared according to the manufacturing process. These excipient samples were extracted according to the procedure outlined in the text. A known amount of phenobarbital (equivalent to that contained in the commercial formulas) was next added to the extracts, which thus were certified to contain the specified amount of active drug. [b] n = 5.

[a] Recently prepared commercial suppositories with a declared value of 15 mg/suppository.

The experimental data proved that phenobarbital was extracted efficiently from the suppositories in a 97% yield (average of five derivative determinations, *SD* 1.6%). Nevertheless, to discard the possibility of a loss due to faulty extraction or to any other unexplained causes, the active drug was added to the final ethanol solution of the extract, thus ensuring that each test sample contained exactly the specified amount of phenobarbital. By removing this possible sampling error, it was expected that the values obtained from the different spectroscopic measurements would allow for a true and representative assessment of the UV background correction methods.

An application of the direct UV reading and second derivative procedures (Fig. 1, peak d) to the control assay of suppositories randomly selected from a single recent batch gave the results shown in Table II. The relative errors from both methods represent the kind of data consistently obtained in this laboratory since the introduction of second derivative UV spectroscopic methods for routine control work on complex changeable matrixes. Moreover, the −3–−4% error of these second derivative determinations could be a consequence of the second derivative UV absorption band of the blank sample (no phenobarbital added) (Fig. 1, peak e).

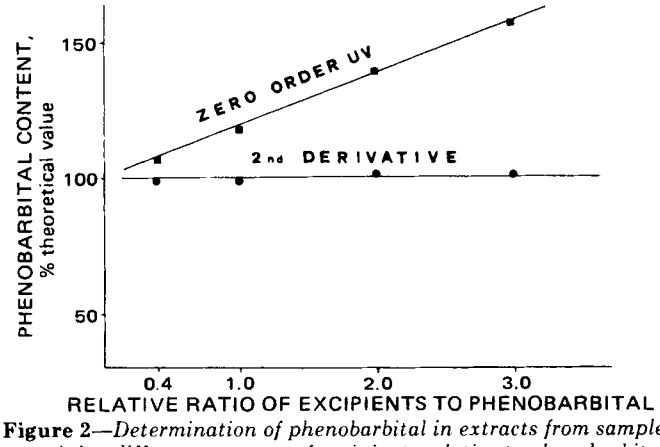

Figure 2—*Determination of phenobarbital in extracts from samples containing different amounts of excipients relative to phenobarbital.*

Table III—Comparison of Phenobarbital Content (Percent) in Aged Commercial Preparations by Different Methods

Sample	HPTLC	Direct UV[a]	Second Derivative UV	UV with Morton–Stubbs Three-Point Correction[a]
D-1 (1969)	79	108.0 (29)	79.3 (0.3)	82.5 (3.5)
D-2 (1969)	91.1	127.7 (36.6)	88.3 (−1.8)	90.7 (−0.4)
F-1 (1971)	94.7	115.9 (21.2)	94.8 (0.1)	—
F-2 (1971)	84.2	106.8 (22.6)	79.7 (−4.5)	82.3 (−1.9)

[a] The differences relative to the HPTLC determinations are given in parentheses (8).

The small positive signal at 242 nm (indicated by the arrow) has a subtracting effect on the total amplitude of the ΔI measured. These results are in agreement with the errors calculated theoretically for a similar case. According to the data reported previously (20) using the same peak-to-peak (ΔI) measurement of the second derivative band, theoretical systematic errors of −2–−4.3% and a random error of 1.8% were found, which compare favorably with the data in this report.

The potential of the derivative data for quantitation is demonstrated in Fig. 2, which shows that the increase in the excipient concentration relative to that of phenobarbital affected the zero-order UV determinations of this active drug with relative errors of up to 58%, without much effect on the derivative measurements.

Although the example given proves in principle the higher reliability of the derivative UV data, it also could be argued that a three-point Morton–Stubbs (3) background correction often still could compete favorably with the derivative procedures. In pharmaceutical product analysis, the procedure is applicable, providing that the excipients give a uniform background and can be used as a kind of "blank" (1). However, even in such a case, the irrelevant background absorption should be constant in each sample, which may be difficult to achieve due to the usual variations between excipient batches. This factor is especially important in aged commercial preparations that also contain undefined amounts of unknown degradation products. Furthermore, the operating conditions must remain perfectly reproducible. And the corresponding absorbance must be weak in comparison to that of the active drug (1), a condition that often cannot be met without lengthy concentration or cleanup procedures (4), as was done in this study to increase the ratio of phenobarbital to excipients (initially, 1:216).

For these reasons, the results of the direct, derivative, and three-point UV methods were compared for the quantitative determination of phenobarbital in aged commercial preparations. These samples were considered to be representative of cases in which the background absorption changes with time due to the formation of unknown degradation products (*i.e.*, no reference samples available as "blanks"). The results (Table III) demonstrate that when a derivative UV spectrophotometer is unavailable, the Morton–Stubbs correction provides comparable data; in this case, the amount of phenobarbital remaining undegraded in the four samples was determined by separating it from the excipients and degradation products using high-performance TLC (HPTLC). These samples then were quantitated spectrophotometrically (8).

Oxyfedrine Hydrochloride Solution—The UV absorption spectrum of a standard oxyfedrine solution as the hydrochloride (Fig. 3a) showed two maxima in the 350–220 range, one centered at 310 nm and the other at 252 nm. The absorption spectrum of the excipient mixture was characterized by a peak at 270 nm with an appreciable shoulder at 310 nm (Fig. 3b). This comparison represents an interesting practical case since the difference in absorption maxima of the active drug and the excipient blank (252 *versus* 270 nm) was such that the inflection point in the composite spectrum (at the position indicated by the arrow in Fig. 3c) in many cases was obliterated completely. The result was a continuous straight slope that precluded any meaningful qualitative or quantitative work without isolation of the active product from the excipient mixture or the application of background correction methods.

Furthermore, the inapplicability of the uncorrected measurements for quantitative purposes is demonstrated in the plot of Fig. 4, where even at a low ratio of excipients to oxyfedrine (0.5), the zero-order data included a 20% error. This situation deteriorated further as the matrix changed due to increased concentrations of those excipients responsible for the irrelevant background absorption relative to the concentration of the active drug. As shown, at a relative ratio of two, the uncorrected error was 70% relative to the true 100% value. The corresponding values obtained with UV derivative techniques or the Morton–Stubbs three-point correction (Fig. 4) stayed within a 12% margin of error. A good

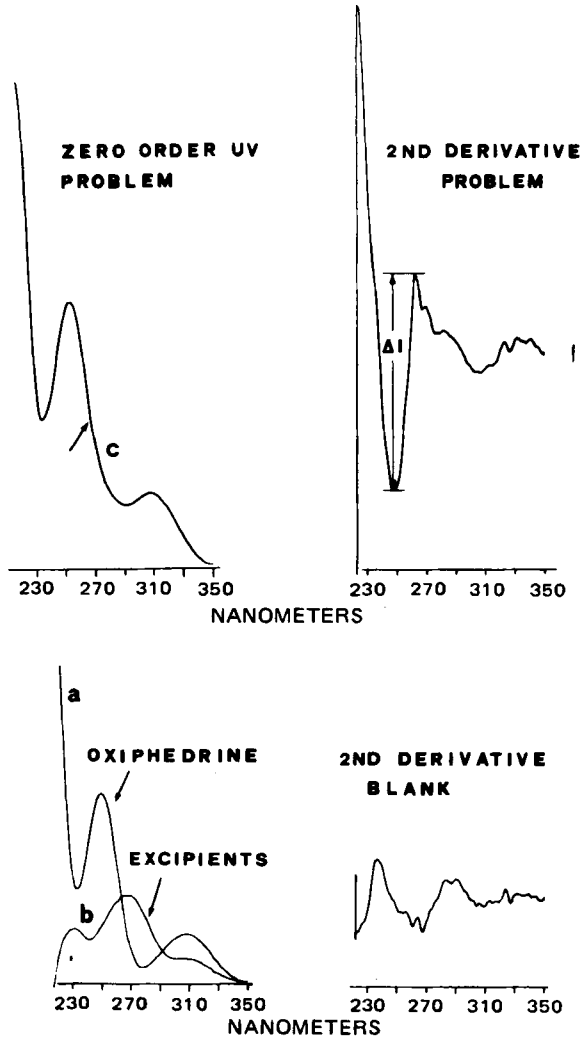

Figure 3—*Zero-order and second derivative UV spectra of oxyfedrine-containing formulation. Key: a, UV spectrum of oxyfedrine alone; b, UV spectrum of the excipients; and c, UV spectrum of the mixture.*

correlation between both correction methods thus is illustrated by this practical application. However, as the next two examples indicate, this case is not always true.

Progesterone in Solution—Figure 5 shows the results obtained with a noncommercial progesterone-containing product according to the zero-order and second derivative UV spectroscopic methods. The UV determination of progesterone alone does not pose any special difficulties. However, in these mixtures, it gave a spectrum in which the absorbance

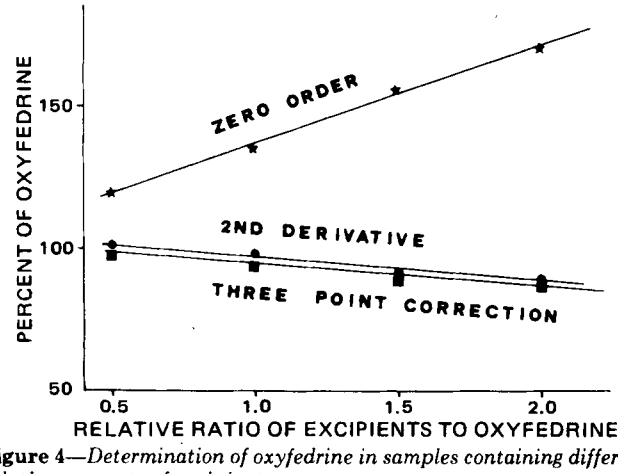

Figure 4—*Determination of oxyfedrine in samples containing different relative amounts of excipients.*

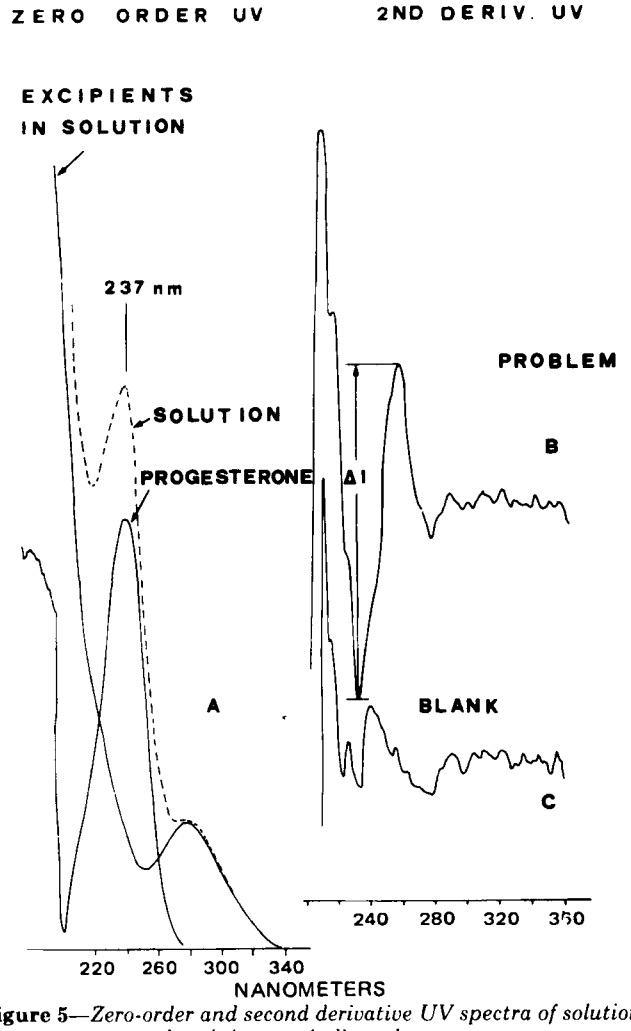

Figure 5—*Zero-order and second derivative UV spectra of solutions of progesterone and excipients as indicated.*

band with its characteristic 237-nm maximum became a shoulder. On the first determinations carried out on this preparation, it was observed that at a progesterone concentration of 10 μg/ml, corresponding to a progesterone to excipients ratio of one, the direct zero-order UV measurements produced relative errors of +37 and 45% for replicate sample determinations while the second derivative and three-point correction methods gave errors of −5.4 and +11.9%, respectively. In contrast with the previous two cases, the relative error calculated by the three-point method was significantly higher than the value computed from the second derivative (ΔI in Fig. 5). Therefore, it was necessary to analyze different solutions characterized by values of the progesterone to excipients below or above the usual ratio of one. The results obtained are plotted in Fig. 6. In this case, since the level of the irrelevant background absorption was kept constant while the amount of the active drug was increased, the points on the graph were distributed, as expected, along curves asymptotically approaching the theoretical value.

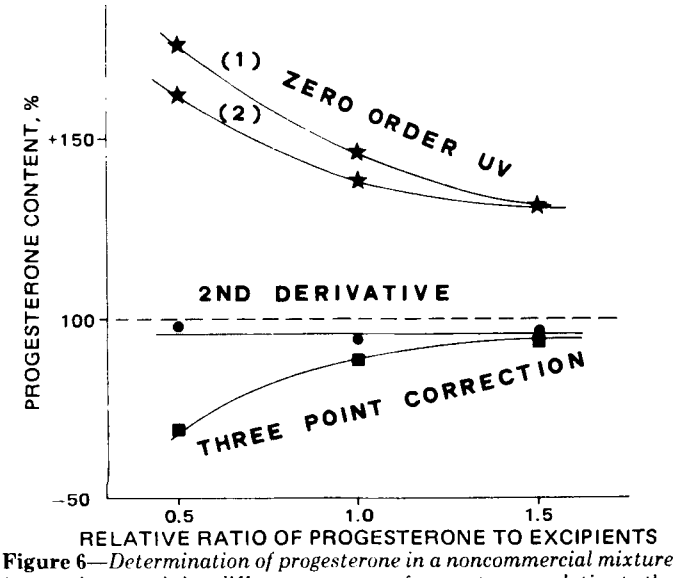

Figure 6—*Determination of progesterone in a noncommercial mixture in samples containing different amounts of progesterone relative to the excipients. The two zero-order UV curve determinations were carried out on different samples. As indicated in Table IV, the points of curve 2 are the average values obtained from the UV readings of two solutions from the same sample.*

Table IV—Replicate Determination of Progesterone in Samples with a Progesterone to Excipient Ratio of 1:2

Method	Solution A, %	Solution B, %
Direct UV	162.8	160.8
Derivative UV	99.0	98.2
Three-point correction	71.4 68.4	63.9
$\frac{A_{\lambda_{max}}}{A_{\lambda_1}} = \frac{A_{\lambda_{max}}}{A_{\lambda_2}}$	1.174 1.076	1.130

The results demonstrate that the only points not seriously affected by the changing interference due to the background absorption were those of the derivative determinations. Also, as expected, when the relative amount of the active drug in the preparation increased, the relative error given by the three-point correction approached the value obtained by derivative analysis, fulfilling the requirement that the background absorbance must be weak relative to that of the substance being determined (1). The points represented for the three-point correction curve in Fig. 6 are the average values of two determinations on the same solution carried out at different absorbance ratios, as indicated in Table IV (Solution A). Solution B (Table IV), determined at a different $A_{\lambda_{max}}/A_{\lambda_1}$ ratio, gave a similar value. From a consideration of the absorption spectrum, slightly different wavelengths were selected on each side of the peak maximum at 241 nm to give different absorbance ratios (Table IV). Nevertheless, the results were comparable.

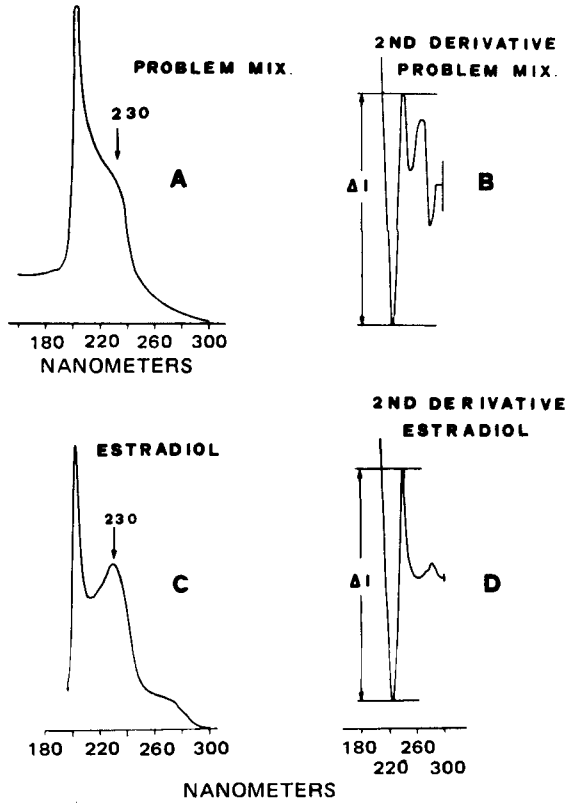

Figure 7—*Curve A, zero-order UV spectrum of an estradiol benzoate suspension in lecithin; curve B, second derivative UV spectrum of the same; curve C, UV spectrum of estradiol benzoate; and curve D, second derivative UV spectrum of estradiol benzoate.*

Table V—Estradiol Benzoate Determination in the Presence of Lecithin in Different Proportions

Method	Estradiol Benzoate–Lecithin Ratio		
	1:0.8	1:5	1:10
Direct UV reading	103	121.8	143.6
Derivative UV	101.2	105	108.8
Three-point correction[a]	96.8	111.3	115.0

[a] $A_{\lambda_{max}}/A_{\lambda_1}$ = 1152. Absorbances were read at 221.6, 231, and 237.6 nm for the three-point correction.

Estradiol Benzoate in Suspension—A final representative case where the derivative techniques demonstrated their superiority over other background-correction methods is illustrated by the assay of estradiol in a pharmaceutical suspension with lecithin. At the usual concentrations in the pharmaceutical preparation analyzed (1:0.8), the characteristic 230-nm spectrum of estradiol benzoate (Fig. 7C) was masked by the spectrum of the problem mixture (Fig. 7A). Under these conditions (*e.g.*, relatively high active drug to lecithin ratio), the three methods gave values that fit within a 3.5% margin of error, with the second derivative determination being the most accurate (Table V). However, when this ratio was diminished, the relative error increased proportionally, representing a case where the three-point correction cannot cope with the level of irrelevant background interference. Evidently, this method requires a cleanup procedure to remove as much of the interfering compound as possible, thus increasing the relative concentration ratio to more amenable values. The more simple approach is to cancel as much of this background effect as possible by the application of second derivative UV spectroscopic techniques.

Conclusions—An appraisal of the UV assay of active drugs in pharmaceutical preparations illustrates the kind of results that can be expected by application of graphical and derivative background correction procedures to samples whose background absorption characteristics preclude a direct reading of the UV spectra.

Depending on the ratio of the active drug to the rest of the components in a given formulation (excipients and degradation products), the direct quantitation of the uncorrected UV absorption spectra may lead to significant errors relative to the formulated values. These values, allowing for factors such as extraction efficiency whenever applicable, are well established by the formulation of the commercial product, except products with a limited shelflife.

By working with changeable matrixes (varying the active drug to excipient ratio), it also was shown that the derivative and three-point correction techniques provide comparable results in some cases. In general, both can compensate for the irrelevant UV absorption from the secondary sample ingredients, as long as it is within reasonable limits. However, the graphical Morton–Stubbs three-point correction procedure sometimes cannot cope with the level of interference, leaving the derivative spectroscopic procedure as the only method giving reliable results over a relatively wide span of drug to excipient ratios.

Likewise, the three-point or other related correction methods (3–7) are applicable qualitatively as long as there is an identifiable, though distorted, UV profile characteristic of the product assayed. On the other hand, there are situations where it becomes difficult, if not impossible, to infer the presence of the active product, because its characteristic UV pattern may be masked totally by the background. One such situation is the assay of estradiol.

Comparative Pharmacokinetics of Coumarin Anticoagulants XLVI: Effect of Treatment with Phenobarbital on Pharmacokinetics of (S)-(−)-Warfarin in Rats

AVRAHAM YACOBI, JOHN T. SLATTERY, and GERHARD LEVY ˣ

Received December 17, 1979, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication January 22, 1980.

Abstract □ This investigation was carried out (*a*) to determine if the enzyme inductive effect produced by phenobarbital reduces the interindividual variability in the biotransformation of a drug, as suggested in the literature; (*b*) to test whether the intrinsic clearance of free drug, for drugs exhibiting restrictive clearance, reflects the activity of drug-metabolizing enzyme systems; and (*c*) to determine if enzyme induction affects the apparent volume of distribution of a drug that tends to concentrate in the liver. Twelve pairs of adult male rats, matched with respect to their serum warfarin free fraction, received an intravenous injection of (*S*)-(−)-warfarin, 0.6 mg/kg, after four daily injections of either saline solution or phenobarbital (75 mg/kg). Phenobarbital treatment increased both the total and intrinsic clearance of (*S*)-(−)-warfarin almost threefold but did not reduce the coefficient of variation of the intrinsic clearance. Serum protein binding of (*S*)-(−)-warfarin was not affected by phenobarbital treatment. The biological half-life of warfarin and the duration of its anticoagulant effect were reduced substantially by treatment with phenobarbital. Consistent with pharmacokinetic theory, the relationship between total clearance and the free fraction of warfarin in serum remained approximately linear, but the slope of the regression line was increased for the animals treated with phenobarbital.

Keyphrases □ Warfarin—pharmacokinetics, effect of phenobarbital on drug biotransformation and enzyme induction, rats □ Pharmacokinetics—warfarin biotransformation, inductive enzyme effect of phenobarbital, rats □ Phenobarbital—effect on enzyme induction, effect on warfarin biotransformation, pharmacokinetics, intersubject variability determination, rats □ Anticoagulants—warfarin, effect of phenobarbital on warfarin biotransformation, rats

It is well known that treatment with phenobarbital enhances the elimination of warfarin in both humans and rats (1–7). *In vitro* studies indicated that phenobarbital causes induction of the enzyme system(s) responsible for the biotransformation of warfarin (6), but these studies failed to test for variability in the degree of induction (as measured by the enhancement of warfarin elimination) as a function of the elimination kinetics of warfarin prior to enzyme induction. This question is important because there are pronounced interindividual differences in the elimination kinetics of warfarin in humans as well as in animals (8, 9).

BACKGROUND

Intersubject variability in antipyrine half-life decreased when subjects were treated with phenobarbital, and it was suggested that treatment with phenobarbital (or another enzyme inducer) might have a similar effect on the variability in the elimination kinetics of other drugs (10). In the cited study, the relative decrease in the half-life of antipyrine after phenobarbital administration was proportional to the prephenobarbital half-life.

Previous reports in this series showed that the total body clearance of warfarin is highly dependent on the serum protein binding of the drug, specifically on its free fraction in serum (9, 11). Recent studies revealed a 15-fold range in the serum free fraction of warfarin in rats (8, 12) and an approximately fourfold variation in humans (9, 13–15).

The proportionality constant between the total clearance and the free fraction for nonperfusion rate-limited systems is the intrinsic clearance k''. Thus, $k'' = TC/f_p$, where TC is the total body clearance and f_p is the free fraction of drug in serum or plasma (11). An essentially linear relationship between TC and f_p of warfarin has been observed in both humans and rats (9, 11). This relationship permits isolation of the effects of certain treatments or procedures on the protein binding of a drug from the effects on the activity of enzymes responsible for the biotransformation of that drug. This ability should help to determine the reasons for a change in the total clearance of a drug.

If enzyme induction leads to a decrease of the intersubject variability in the biotransformation kinetics of a drug, then a decrease in the coefficient of variation of k'' should be observed. Furthermore, if the relative degree of enhancement of drug elimination caused by induction of an enzyme system is proportional to the preinduction activity of the enzyme system, then the relative increase in intrinsic clearance caused by induction should be proportional to its preinduction (control) value.

Treatment of rats with phenobarbital produces an increase in their relative liver weight (16). Since the liver contains a large fraction of the amount of warfarin in the body of a rat (8, 17), treatment of rats with phenobarbital might increase the apparent volume of distribution of warfarin. This possibility has not been explored to date.

The purposes of this investigation were (*a*) to determine if the enzyme inductive effect produced by phenobarbital reduces the interindividual variability in the biotransformation of (*S*)-(−)-warfarin; (*b*) to test whether the intrinsic clearance of free (*S*)-(−)-warfarin reflects the activity of drug-metabolizing enzyme systems; and (*c*) to determine if enzyme induction affects the apparent volume of distribution of (*S*)-(−)-warfarin. (*S*)-(−)-Warfarin rather than racemic warfarin was used to decrease the complexity of the experiment since the metabolism of the individual enantiomers might be induced to a different extent. Since the (*S*)-(−)-enantiomer of warfarin is a more potent anticoagulant and has a longer biological half-life than the (*R*)-(+)-enantiomer in rats (18), experiments with (*S*)-(−)-warfarin are easier to perform.

EXPERIMENTAL

Seventy-two adult male Sprague–Dawley rats[1], 250–300 g initially and 320–400 g during the study, were screened to obtain two groups of rats matched individually with respect to their free fraction of warfarin in serum.

For screening purposes, 3 ml of blood was taken from the tail artery of the rats and the serum was separated. Approximately 1 μg/ml of racemic [^{14}C]warfarin[2] (specific activity 76 μCi/mg) was added to the serum, and its free fraction was determined by equilibrium dialysis for 20 hr against isotonic pH 7.4 phosphate buffer at 37° (8). Twenty-four rats were paired according to their free fraction of warfarin in serum. One member of each pair was assigned to the group to be treated with phenobarbital, and the other served as a control. The free fraction values ranged from 0.00296 to 0.0158.

Two weeks after the screening experiment, the rats in the group designated for phenobarbital treatment received 75 mg of phenobarbital/kg ip daily for 4 days, while the control group received injections of a comparable volume of normal saline for the same period. The rats had unrestricted access to food[3] and water throughout the study.

On Day 5, the rats in both groups received a single dose of [^{3}H](*S*)-(−)-warfarin[4] (0.578 mg/kg, specific activity 0.943 mCi/mg, in isotonic

Table I—Effect of Phenobarbital on Pharmacokinetics of (*S*)-(−)-Warfarin in Matched Pairs of Rats [a]

Parameter	Control	Phenobarbital	Ratio of Phenobarbital to Control
Serum free fraction × 100	0.266–1.29[b]	0.315–1.42	1.04 ± 0.14[b]
Half-life, hr	10.6–47.2	3.28–30.1	0.409 ± 0.114
Volume of distribution, ml/kg	103–155	112–185	1.13 ± 0.08
Total clearance, ml/(hr kg)	1.56–9.62	2.58–35.5	2.95 ± 0.78
Intrinsic clearance of free drug, [ml/(hr kg)] × 100	7.00 ± 1.65[b]	19.9 ± 5.07[c]	2.85 ± 0.80[b]
Duration of anticoagulant effect[d], hr	62–124	25–75	0.469 ± 0.079

[a] Twelve pairs of rats matched with respect to their serum free fraction of racemic warfarin. Results are shown as ranges of values for those parameters that are not normally distributed due to the intentional selection of animals with a wide range of free fraction values. Ratio and intrinsic clearance data are reported as the mean ± *SD*. [b] Data from 11 animals or animal pairs only due to loss of the blood sample for the serum free fraction determination from one rat. [c] Statistically significantly different from control (*t* test, $p < 0.001$). [d] Time required for prothrombin complex activity to return to 60% of normal after intravenous injection of 0.6 mg/kg.

saline adjusted to pH 7.4) *via* the tail vein. Blood samples (0.27 ml) were obtained at ~2–6-hr intervals from the tail artery (19). The plasma was separated, and the warfarin concentration in 0.1 ml of plasma was determined by TLC and scintillation counting as described previously (8, 20). Tritium exchange has been shown to be negligible under these experimental conditions (21). Prothrombin complex activity in plasma was measured (19) to determine the duration of the anticoagulant effect.

At the completion of the study, the rats were sacrificed by removing as much blood as possible from the abdominal aorta under ether anesthesia. The serum was separated, 0.5 μg/ml of [^{3}H](*S*)-(−)-warfarin (specific activity 3.77 mCi/mg) was added, and the free fraction was determined by equilibrium dialysis as described. The total intrinsic clearances, half-life, and apparent volume of distribution were determined as described previously (18, 20).

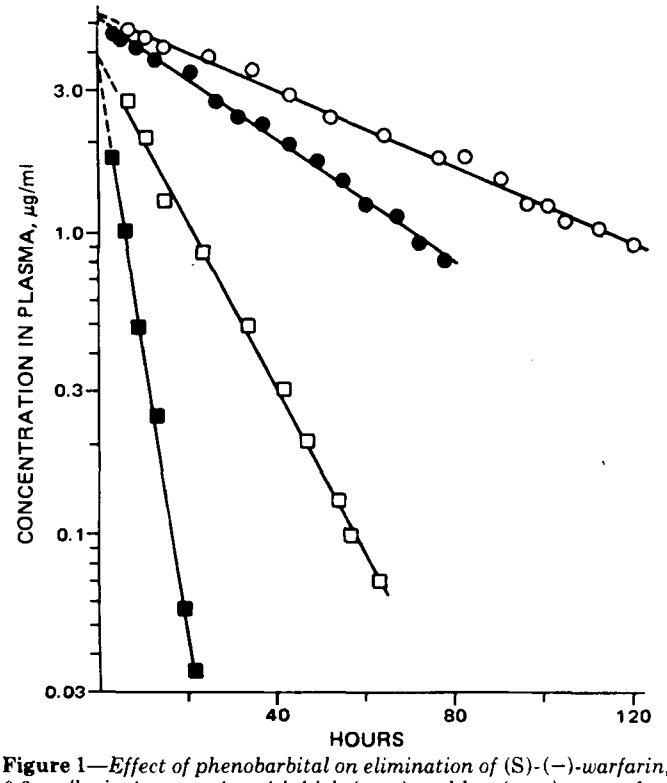

Figure 1—*Effect of phenobarbital on elimination of* (S)-(−)-*warfarin, 0.6 mg/kg iv, in rat pairs with high* (□,■) *and low* (○,●) *serum free fraction values of the drug. Key: solid symbols, phenobarbital-treated animals; and open symbols, control animals.*

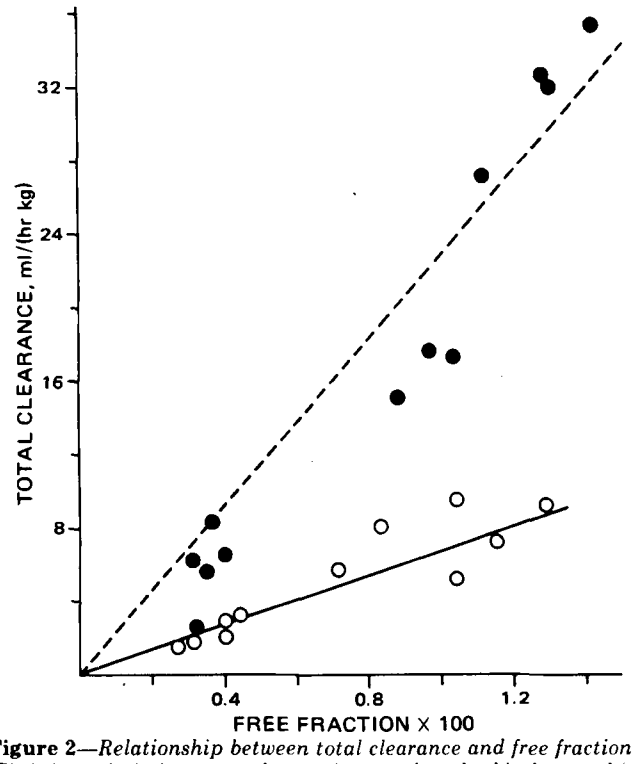

Figure 2—*Relationship between total clearance and free fraction of* (S)-(−)-*warfarin in serum of rats. Key:* ●, *phenobarbital treated* ($r = 0.968$, $p < 0.001$); *and* ○, *control* ($r = 0.902$, $p < 0.001$). *Regression lines were forced through the origin.*

RESULTS

The initial screening study permitted the selection of well-matched pairs of rats over a wide range of serum racemic warfarin free fraction values. The mean ± *SD* of the free fraction ratios of the 12 pairs was 1.00 ± 0.05. The correlation coefficient of the free fraction values for the two members of each pair in the entire group was 0.995 ($p < 0.001$).

In agreement with previous observations (18), the free fraction value of racemic warfarin determined in the screening study correlated strongly with that of the free fraction of (*S*)-(−)-warfarin determined at the end of the experiment ($r = 0.982$, $p < 0.001$), indicating the suitability of the racemic warfarin free fraction for screening purposes. The ratio of racemic to (*S*)-(−)-warfarin free fraction values (mean ± *SD*) was 1.12 ± 0.068 for the control rats and 1.10 ± 0.18 for the phenobarbital-treated rats, showing that phenobarbital treatment had no apparent effect on the free fraction of warfarin in serum. This lack of effect is consistent with previous observations (22).

The similarity of warfarin free fraction values in the rat pairs was maintained throughout the study (Table I). The correlation coefficient of the free fraction value of (*S*)-(−)-warfarin within pairs at the end of the study was 0.984 ($p < 0.001$).

The time course of the (*S*)-(−)-warfarin concentration in serum after intravenous injection in individual members of two pairs of rats (those with the highest and lowest mean free fraction values, respectively) is shown in Fig. 1. A summary of the pharmacokinetic data obtained in the study is presented in Table I. The biological half-life of (*S*)-(−)-warfarin and the duration of the anticoagulant effect in rats treated with phenobarbital were ~ 50–60% shorter on the average than those of the control member of each pair. On the other hand, the apparent volume of distribution showed no statistically significant change by the Wilcoxon test, even though it was larger in 11 of 12 phenobarbital-treated animals than in their controls. A strong correlation was observed in both groups between the first-order elimination rate constant and the free fraction of (*S*)-(−)-warfarin in serum ($r = 0.983$ and $r = 0.938$ for phenobarbital-treated and control groups, respectively; $p < 0.001$ for both groups). As observed previously (8), the apparent volume of distribution also correlated with the free fraction of warfarin in serum based on combined results from both groups ($r = 0.713$, $p < 0.001$).

On the average, the total clearance of (*S*)-(−)-warfarin was almost three times higher in rats treated with phenobarbital than in their respective controls (Table I). The intrinsic clearance in the phenobarbital-treated rats also was approximately three times higher on the average than that

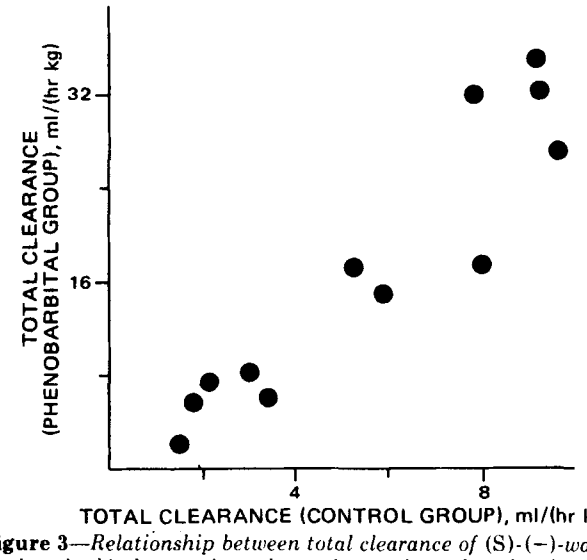

Figure 3—*Relationship between total clearance of* (S)-(−)-*warfarin in phenobarbital-treated member and control member of each matched pair of rats* ($r = 0.931$, $p < 0.001$).

of the control member of each pair. Treatment with phenobarbital did not decrease the coefficient of variation of the intrinsic clearance; it was 24% in the control group and 26% in the phenobarbital group.

The relationship between the free fraction of (*S*)-(−)-warfarin in serum and the total clearance for control and phenobarbital-treated animals is shown in Fig. 2. Essentially linear relationships were obtained in each case. The slope of a plot of the relative increase (expressed in percent) in the intrinsic clearance caused by phenobarbital treatment (comparing members of matched rat pairs) *versus* the control intrinsic clearance was not significantly different from zero. There was a strong and apparently linear relationship between the total clearance of (*S*)-(−)-warfarin in the control member and phenobarbital-treated member of each rat pair (Fig. 3).

DISCUSSION

The dose and the duration of phenobarbital administration used in this study were sufficient to produce a pronounced enzyme inductive effect as reflected by an almost threefold increase in the intrinsic clearance of (*S*)-(−)-warfarin. However, enzyme induction did not decrease the interindividual variability of the intrinsic clearance; there was essentially no difference in the coefficient of variation of the intrinsic clearance between the control and treated animals. Since phenobarbital treatment had no effect on the serum protein binding of (*S*)-(−)-warfarin, and since the relative effect of enzyme induction was independent of the normal intrinsic clearance value, the relationship between the total clearance and the serum free fraction remained essentially linear as predicted by theory (11). Thus, the slope of such a plot, *i.e.*, the intrinsic clearance of free drug, does reflect the effect of enzyme induction.

In a recent study, it was found that the liver contains about 44% of the total amount of warfarin in normal (not phenobarbital-treated) rats (8). The phenobarbital treatment regimen used in this study increased the relative liver weight of rats by ~22% (16). This increase suggests that the apparent volume of distribution of warfarin should increase by ~10% in phenobarbital-treated rats. The results of the present study show that the apparent volume of distribution of (*S*)-(−)-warfarin was increased by 13% on the average, but this increase was not statistically significant. Statistical analysis of the data for the probability of a type II error strongly suggests ($P_B \simeq 0.4$) that a real difference of 10% would not be detected in our study at $\alpha = 0.05$ (23).

Branch and Shand (24) recently reevaluated previously published data on the effect of enzyme induction on antipyrine elimination kinetics in humans. Rather than basing their analysis on the biological half-life as did Vesell and Page (10), they used the clearance value as a more appropriate index of the activity of antipyrine-metabolizing enzyme systems. They found that the intersubject variability of antipyrine clearance by nine normal subjects was as large after phenobarbital treatment as in the noninduced state. The results of the present study with warfarin are consistent with these conclusions and are particularly noteworthy because the degree of enzyme induction was more pronounced than in the antipyrine study.

Stability of Brompton Mixtures: Determination of Heroin (Diacetylmorphine) and Cocaine in Presence of Their Hydrolysis Products

G. K. POOCHIKIAN ˣ and J. C. CRADOCK

Received October 12, 1979, from the *Analytical and Product Development Section, Pharmaceutical Resources Branch, National Cancer Institute, Bethesda, MD 20205.* Accepted for publication January 23, 1980.

Abstract □ The application of a rapid, selective, and sensitive reversed-phase high-performance liquid chromatographic method to the separation of the hydrochloride salts of heroin (diacetylmorphine) and cocaine and their hydrolysis products is described. The method was used to study the stability of heroin and cocaine in Brompton mixtures in pharmaceutically useful pH range and vehicles at different temperatures. The pH range of optimal stability for both heroin and cocaine was 3.0–3.5. The disappearance of heroin and cocaine in Brompton mixtures followed pseudo-first-order kinetics in buffered solutions. Increased alcohol and decreased syrup concentrations diminished heroin hydrolysis but did not influence cocaine stability. Substitution of morphine for heroin in Brompton mixtures markedly increased the rate of cocaine hydrolysis.

Keyphrases □ Cocaine—high-performance liquid chromatographic analysis with heroin and hydrolysis products, Brompton mixtures □ Heroin—high-performance liquid chromatographic analysis with cocaine and hydrolysis products, Brompton mixtures □ High-performance liquid chromatography—analysis, cocaine and heroin with hydrolysis products, Brompton mixtures □ Brompton mixtures—stability, high-performance liquid chromatographic analysis of cocaine and heroin with hydrolysis products □ Diacetylmorphine—high-performance liquid chromatographic analysis with cocaine and hydrolysis products, Brompton mixtures

The treatment of patients with chronic severe pain has triggered interest in the use of morphine and heroin (diacetylmorphine) in popular oral formulations, namely Haustus elixir and diacetylmorphine and cocaine elixir, respectively (1). The latter formulation, referred to as a Brompton mixture, has been in use in Great Britain and Canada. Since heroin is a Schedule I narcotic in the United States, morphine frequently is substituted for this agent. There is no set composition for Brompton mixture. However, most variations contain salts of morphine or heroin combined with cocaine hydrochloride (hereafter referred to as their respective bases), alcohol, and a sweetening agent in an aqueous medium. Varying degrees of effectiveness have been reported for these analgesic mixtures (2–4).

The hydrolysis of diacetylmorphine to morphine *via* 6-monoacetylmorphine has been confirmed qualitatively (5, 6) and quantitatively (7). Furthermore, numerous methods have been published for the stability determination of cocaine (8–10). Several methods include the determination of one or more of its hydrolysis products, mainly benzoylecgonine, ecgonine, and benzoic acid (10–12). However, no single system has been used for both of these substances in the presence of their decomposition products.

Separation and quantitation of these components in such a complex mixture by TLC (12–14) is laborious and quantitatively imprecise. GLC requires extraction and derivatization and suffers from thermal degradation limitations (8, 9, 12). On the other hand, the reversed-phase high-performance liquid chromatographic (HPLC) method described here allows the simultaneous quantitation of heroin and cocaine in the presence of their hydrolytic products, an internal standard, and "inert" components by a simple, direct isocratic elution on a single analytical column. The separation was carried out in aqueous solution at a pH that showed minimal degradation of heroin and cocaine and eliminated preparatory procedures. The HPLC–UV method was applied to evaluate the stability of morphine or heroin plus cocaine at various temperatures and pH levels. The influence of alcohol and sucrose concentrations on heroin and cocaine stability was studied also.

EXPERIMENTAL

Reagents—Hydrochloride salts of heroin, 6-monoacetylmorphine, morphine, cocaine, and benzoylecgonine were used as received[1]. Benzoic acid, 2-chloro-3-nitropyridine, and the internal standard, 4-chloropyridine hydrochloride, were obtained commercially[2]. Acetonitrile[3] (HPLC grade) and distilled water were filtered through 0.45-μm solvent-resistant filters[4]. All other chemicals were reagent grade and were used without further purification.

Equipment—A modular high-pressure liquid chromatograph equipped with a constant-flow pump[5] was used to deliver the eluent to a stainless steel column packed with fully porous 10-μm silica particles bonded with a monomolecular layer of octadecylsilane[6]. Injections were made with a rotary valve injector equipped with a 10-μl injection loop[7]. No attempt was made to control the column temperature. A variable-wavelength UV detector[8] set at 235 nm was operated at an attenuation of 0.02 aufs, and the integrator output to the recorder was attenuated ×4 to detect the eluted compounds. The output signals were recorded with a strip-chart recorder[9].

Peak retention times and peak areas were monitored and quantitated automatically relative to the internal standard by area measurements using a computing integrator[10].

Chromatographic Conditions—The chromatographic mobile phase consisted of one volume of acetonitrile and three volumes of 0.015 *M* monobasic potassium phosphate adjusted to pH 3.0 with 2 *N* phosphoric acid[11]. The apparent pH of the eluent mixture was 3.30. The column pressure at a flow rate of 0.8 ml/min was ~620 psi. Separations were effected isocratically at ambient temperature. The chromatographic parameters, *i.e.*, capacity factors (k'), separation factors (relative retention, α), and resolution (R_s), of various solutes were calculated from the adjusted retention times (15).

Preparation of Solutions—Heroin and cocaine were dissolved in appropriate media (Table I) to yield concentrations of 1 and 0.5 mg/ml, respectively. Morphine–cocaine solutions at respective concentrations of 1 and 0.5 mg/ml were prepared only in the "standard vehicle" (II).

The solutions were filtered[4] through solvent-resistant filters and dispensed promptly (1.0 ml) in 2-ml flint ampuls. These ampuls were sealed

and stored at 5 ± 0.1, 25 ± 0.1, and 50 ± 0.1°. Periodically, 300-μl samples were removed and diluted to 2.0 ml with the mobile phase containing 85 μg/ml of the internal standard, 4-chloropyridine hydrochloride. The stability of heroin, morphine, and cocaine in these mixtures was monitored over a period not exceeding 65 days.

RESULTS AND DISCUSSION

Chromatographic Behavior—The hydrochlorides of morphine, 6-monoacetylmorphine, benzoylecgonine, 4-chloropyridine, heroin, and cocaine were eluted in that order. Figure 1 illustrates the separation of a synthetic mixture of these substances and benzoic acid. The chromatographic retention data for each substance are listed in Table II. At a flow rate of 0.8 ml/min, the analysis time was ~22 min, and baseline resolution was achieved in nearly every case. The retention times (T_R in seconds), k', α, and R_s for all of these substances in hydrolyzed samples were identical to those determined for the synthetic mixture. During the 2-month study, there was no noticeable loss in column performance.

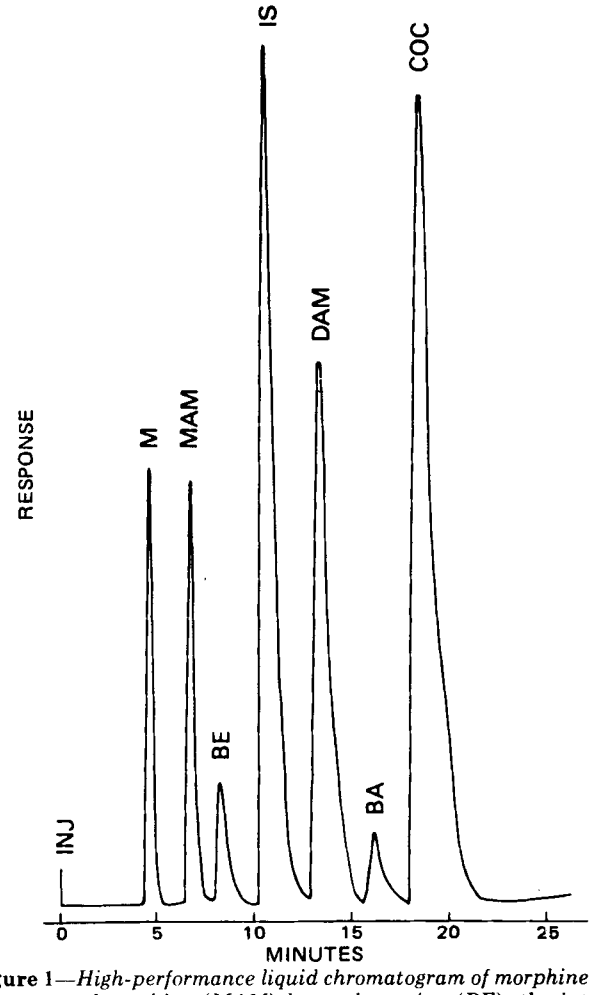

Figure 1—*High-performance liquid chromatogram of morphine (M), 6-monoacetylmorphine (MAM) benzoylecgonine (BE), the internal standard (IS), diacetylmorphine (DAM), benzoic acid (BA), and cocaine (COC).*

12.5 (VI)	4	5
25 (II)	2	5
40 (VII)	1.5	5

The HPLC system may be used to quantitate every component in solution when desired. In this study, only the disappearance of heroin and cocaine was followed. The chromatographic responses for these compounds were linear ($r > 0.999$) in the working concentration range (20–200 μg/ml). The sensitivity limits were 10 ng for heroin and 3 ng for cocaine with a signal-to-noise ratio of better than five. To reduce the duration of each analysis, 4-chloropyridine hydrochloride was selected as the internal standard on the basis of its shorter retention time. However, 2-chloro-3-nitropyridine may be used instead (Table II).

Effects of Alcohol and Syrup Concentrations—The disappearance rates of heroin and cocaine as a function of the alcohol content in the mixture containing a fixed concentration of simple syrup were evaluated at various temperatures (5 ± 0.1, 25 ± 0.1, and 50 ± 0.1°) (Table III). Cocaine was stable at 25 and 5° and did not approach the t_{90} values (time for 10% disappearance of original concentration) during the 2-month observation period. However, heroin was markedly less stable at all temperatures studied. Thus, recommendations are based on the stability of heroin in these mixtures.

Hydrolysis of heroin was diminished with increasing proportions of alcohol, while the disappearance rate of cocaine was unaffected. Under the usual alcohol concentrations found in Brompton mixtures (12.5–25%), these solutions had a useful life of 10–14 days at 25°. However, the stability of diacetylmorphine was markedly enhanced in alcohol. The t_{90} of either heroin or cocaine in ethanol was >45 days at 50°. When stored at 5°, such a mixture may be used as a stock solution to facilitate preparation of Brompton mixtures at the time of dispensing.

Unlike alcohol, decreasing the syrup content at a fixed alcohol concentration in the mixture had a less pronounced effect on diacetylmorphine and no effect on cocaine stability (Table IV).

Effects of pH and Temperature—The influence of the Brompton mixture pH on the stability of heroin and cocaine was of interest since

Table V—Disappearance Rates of Heroin and Cocaine in Various Brompton Mixtures

[a] Period (days) for 10% disappearance of original concentration is given in parentheses.

Table VI—Effects of Morphine and Heroin on Cocaine in Brompton Mixture

Vehicle	t_{90} at 25 ± 0.1°, days		t_{90} at 50 ± 0.1°, days	
	Heroin	Cocaine	Heroin	Cocaine
II	10	>60	2	5
IIa[a]	—	—	1.75	—
IIb[b]	—	10	—	1.5
XII	—	—	2.9	6.5
XIIa[c]	—	>60	—	11

[a] Contains only heroin (1 mg/ml) in standard vehicle II. [b] Contains morphine (1 mg/ml) and cocaine (0.5 mg/ml) in vehicle II. [c] Contains only cocaine (0.5 mg/ml) in vehicle XII.

the optimal pH values for minimal degradation of diacetylmorphine (7) and cocaine (11, 17) were shown separately to be 4.0–4.5 and 2.5–3.0, respectively. Hence, the pH range of 2.30–5.25 was chosen. The results (Table V) indicate that the optimal pH is between 3.0 and 3.5 for the overall minimal hydrolysis of heroin and cocaine in such a mixture.

The available data show the predominant influence of temperature on the rate of diacetylmorphine and, particularly, of cocaine hydrolysis in the Brompton mixture (Tables III and VI). A 10-fold decrease in temperature of the Brompton mixture diminished the rate of hydrolysis of heroin by ~10-fold and that of cocaine by at least 50-fold.

Kinetic Evaluations—Semilog plots of heroin or cocaine concentrations in the Brompton mixture *versus* time exhibited excellent linearity ($r > 0.99$) in 95% ethanol or buffered solutions (V and IX–XIII). Thus, the disappearance of heroin and cocaine followed pseudo-first-order kinetics under the conditions studied. Table V presents the calculated pseudo-first-order rate constants and t_{90} values at 50 ± 0.1° for heroin (2.36×10^{-3} *M*) and cocaine (1.47×10^{-3} *M*) in 0.05 *M* citrate buffers (18) or in 95% ethanol.

However, the disappearance rates of both diacetylmorphine and cocaine in unbuffered solutions (common in Brompton mixtures) at 25 ± 0.1 and 50 ± 0.1° were biphasic. A rapid change was followed by a more gradual one, with the final phase being linear on a semilogarithmic plot ($r > 0.99$). The extent of the initial change and the terminal phase slope of each solution were temperature dependent and were more dominant at high temperature. The t_{90} values of heroin and cocaine in these solutions were determined from the respective plots of concentration *versus* time. At 5 ± 0.1°, the hydrolysis rates of heroin and cocaine in unbuffered Brompton mixtures followed pseudo-first-order kinetics over the period studied (Table V). However, the amount of hydrolysis was minimal and did not approach t_{90} values.

Effects of Heroin, Cocaine, and Morphine—The results (Table VI) indicated that although cocaine had no effect on the heroin decomposition rate in the Brompton mixture (II *versus* IIa), the presence of diacetylmorphine increased the cocaine decomposition rate in the mixture (XII *versus* XIIa).

The frequent substitution of morphine for heroin in the Brompton mixture in the United States warranted a study to determine the effect of this substitution on the stability of cocaine and morphine in 12.5% alcohol and 25% simple syrup USP. Morphine appeared to be stable, but such a replacement adversely affected the cocaine hydrolysis rate at all temperatures studied (II *versus* IIb). In fact, the t_{90} value (10 days) was essentially the same as that observed in the diacetylmorphine–cocaine mixture at 25°. This acceleration of cocaine hydrolysis is of special concern. Cocaine hydrolyzes to pharmacologically inactive substances (19), whereas the diacetylmorphine decomposition products, 6-monoacetylmorphine and morphine, retain analgesic activity. The chemical stability of both cocaine and diacetylmorphine was enhanced by adjustment to pH 3.0–3.5. However, the biological effects of this pH adjustment have not been evaluated.

GLC–Mass Spectrometric Procedure with Selected-Ion Monitoring for Determination of Plasma Concentrations of Unlabeled and Labeled Barbital following Simultaneous Oral and Intravenous Administration

F. VARIN *, C. MARCHAND *†, P. LAROCHELLE *, and K. K. MIDHA ‡§x

Received September 26, 1979, from the **Department of Pharmacology, University of Montreal, Montreal, Quebec H3C 3J7, Canada,* and the ‡*Drug Research Laboratories, Health Protection Branch, Health and Welfare Canada, Ottawa, Ontario K1A 0L2, Canada.* Accepted for publication January 7, 1980. §Present address: College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0, Canada. †Deceased.

Abstract □ A GLC–mass spectrometric method employing specific-ion monitoring was developed for the determination of plasma concentrations of labeled ($^{15}N_{1,3}$, $^{13}C_2$) and unlabeled barbital following simultaneous intravenous and oral administration. This method proved to be more sensitive and precise than the method employing GLC with flame-ionization detection or GLC with alkali flame-ionization detection. After extraction of [$^{15}N_{1,3}$, $^{13}C_2$]barbital, barbital, and the internal standard, butalbital, from plasma with ether, the organic solvent is evaporated, and the labeled and unlabeled drug as well as the internal standard are converted into their *N,N*-dimethyl derivatives by treatment with diazomethane. The excess reagent is evaporated, and the resulting methyl derivatives are analyzed by GLC–mass spectrometry with selected-ion monitoring. The method is sufficiently sensitive to determine 0.5 μg of the labeled and unlabeled drug/ml with a relative standard deviation of <5%. The application of the method to the determination of the plasma concentration of labeled and unlabeled drug over 6 days following simultaneous oral and intravenous administration of a single dose is demonstrated.

Keyphrases □ Barbital—plasma concentrations of unlabeled and labeled drug following simultaneous oral and intravenous administration, GLC–mass spectrometric analysis □ GLC–mass spectrometry—analysis of plasma concentrations of unlabeled and labeled barbital following simultaneous oral and intravenous administration, specific-ion monitoring □ Pharmacokinetics—barbital, plasma concentrations of unlabeled and labeled drug following simultaneous oral and intravenous administration, GLC–mass spectrometric analysis

Barbiturates have been investigated extensively. GLC procedures employing flame-ionization detection have been preferred for the quantitative determination of barbiturates in biological fluids and tissues (1–5). GLC techniques using newer and more sensitive detectors than flame-ionization detectors, such as alkali flame-ionization detectors and electron-capture detectors, also have been explored (6, 7). Analysis of barbiturates by high-pressure liquid chromatography was reported (8). More recently, barbiturates have been analyzed by rapid and specific radioimmunoassay (9, 10) and by GLC–mass spectrometric procedures (11–13).

To study the effect of congestive heart failure on drug disposition, a procedure capable of simultaneously and separately quantitating the amounts of drug in plasma originating from oral as well as intravenous dosing was required. Simultaneous quantitation of the two fractions in the same plasma sample was essential because congestive heart failure is not easily stabilized and pharmacokinetic parameters may differ in successive studies.

Barbital was chosen as the model drug for this study since it is not metabolized; the determination of pharmacokinetic parameters therefore is simplified. Stable isotopically labeled barbital was given intravenously at the same time that unlabeled barbital was administered orally. A GLC–mass spectrometric method employing a specific-ion monitoring technique was developed for the simultaneous quantitation of barbital given by the two routes.

EXPERIMENTAL

Reagents—Barbital sodium[1], ether[2], hydrochloric acid[3], sodium sulfate[4], methanol[5], and butalbital[6] were used. [$^{15}N_{1,3}$, $^{13}C_2$]Barbital sodium[7] was specified to contain at least 90 atom % of carbon 13 and 95 atom % of nitrogen 15. Diazomethane was generated using a commercially available kit[8]. Plasma was obtained from the Red Cross Blood Bank.

Animals—Male Sprague–Dawley rats were assigned randomly to two groups. The first group (276 ± 2 g, n = 5) was administered 25 mg of barbital sodium/kg iv. The second group (271 ± 7 g, n = 5) was treated similarly with [$^{15}N_{1,3}$, $^{13}C_2$]barbital sodium. Two hours after treatment, rats were sacrificed by decapitation; their blood was collected in a heparinized[9] centrifuge tube (50 IU/ml of 0.9% NaCl solution). Plasma obtained after centrifugation for 20 min was frozen until it was assayed.

Standards—Stock solutions equivalent to 1 mg of the acid form/ml were prepared by dissolving the appropriate amounts of the sodium salts of both labeled and unlabeled barbital in methanol. Appropriate dilutions were prepared as required. Aliquots of the stock solution containing 1 mg/ml of butalbital in methanol were diluted before assay with 0.25 *N* HCl to obtain the working internal standard solution (10 μg/ml).

Extraction from Plasma—To 1 ml of a human or rat plasma sample (spiked or from dosed animals) in screw-capped[10] culture tubes was added 1 ml of the internal standard solution. The samples were mixed[11] and then extracted with 10 ml of anhydrous ether by mixing[12] for 10 min. After separation by centrifugation[13] for 10 min, the organic phase was transferred with a pipet and desiccated with anhydrous sodium sulfate. After further centrifugation for 10 min, the organic phase was decanted into an evaporating tube[14] and evaporated[15] to dryness at 50° under a dry nitrogen stream. The samples then were frozen until analysis.

Methylation was carried out immediately before the GLC–mass spectrometric analysis to avoid any breakdown and formation of side products. The dried extract was dissolved in 50 μl of methanol by mixing, and 1 ml of ethereal diazomethane was added. The sample was mixed and allowed to react at room temperature for 5 min. The excess diazomethane

[$^{15}N_{1,3}$, $^{13}C_2$]Barbital		
0.5	0.560	112.08 ± 2.50
2.0	1.90	95.21 ± 6.19
10.0	8.98	89.80 ± 2.74
Mean		99.00 ± 10.56

[a] $n = 4$.

was removed by evaporation at 50°, leaving a methanolic solution that was injected in aliquots of 1–2 μl into the gas–liquid chromatograph.

GLC with Flame-Ionization Detection—The gas–liquid chromatograph[16] was equipped with a flame-ionization detector. The column was coiled glass tubing, 1.83 m long × 2 mm i.d., packed with 3% phenylmethylsilicone[17] on acid-washed, dimethylchlorosilane-treated, flux-calcined diatomite support[18] (80–100 mesh). The operating temperatures were: injection port, 250°; column, 225°; and detector, 275°. The carrier gas was nitrogen at a 35-ml/min flow rate. The hydrogen and compressed air flow rates were adjusted to give the maximum response. Pentobarbital[19] (30 μg/ml of plasma) was the internal standard. Flash-heater methylation was carried out with trimethylanilinium hydroxide in methanol[20].

GLC with Alkali Flame-Ionization Detection—The gas–liquid chromatograph[16] was equipped with an alkali flame-ionization detector. The operating temperatures were: injection port, 275°; column, 170°; and detector, 300°. The internal standard was aminopyrine[21] (10 μg/ml of plasma). The column was the same as that described for the method with flame-ionization detection.

GLC–Mass Spectrometry—The gas–liquid chromatograph–mass spectrometer[22] was operated in the electron-impact mode with 70 ev as the ionization beam energy. The source was maintained at 200°. The chromatographic column was a coiled glass tube, 1.22 m long × 2 mm i.d., packed with 3% cyanopropylmethyl phenylmethylsilicone[23] on acid-washed, dimethylchlorosilane-treated, flux-calcined diatomite support[24] (100–120 mesh). The injection port, the column, and the interface temperatures were 250, 150, and 275°, respectively. The carrier gas was helium at a 35-ml/min flow rate.

Reference Samples for Recovery—The acid form of barbital was obtained by successive extractions of an acidified aqueous solution of barbital sodium with ether. The combined extracts were evaporated and dried at 80° overnight. The reference solution of barbital (1 mg/ml) was prepared by dissolving appropriate amounts of the drug in methanol. Different volumes of this solution were added to each evaporating tube to obtain four solutions at each of three concentrations (Table I). The external standard (10 μg of butalbital) and 10 ml of anhydrous ether then were added. The mixture was evaporated to dryness at 55° under a dry nitrogen stream. Methylation was carried out as described, and aliquots (1–2 μl) were injected into the gas–liquid chromatograph–mass spectrometer. The mean of the peak area ratio thus obtained was designated as the 100% value.

For the recovery experiments for barbital sodium, amounts equivalent to the acid form added to plasma (1.0 ml) were extracted with ether as described. Then 10 μg of butalbital was added to the organic extract and the procedure was followed. The recovery of barbital was calculated from the peak ratio thus obtained (mean ± *SD*) compared to the value designated as 100%. The same procedure was followed for the recovery of [$^{15}N_{1,3}$, $^{13}C_2$]barbital sodium.

Calibration Curve—Calibration curves were assembled from the results of spiked control plasma by plotting the peak area ratios *versus* the concentration of the drug (Tables II and III). Peak area ratios were calculated by dividing the peak area under each ion investigated (*e.g.*, *m/e* 169 for barbital and *m/e* 172 for labeled barbital) by the peak area under the ion (*m/e* 196) monitored for the internal standard.

6.0	6	0.590 ± 0.015	2.57

[a] Mean *CV* was 3.73% for $y = mx$, where $m = 0.099 \pm 0.001$; $r^2 = 0.999$.

RESULTS AND DISCUSSION

Methylation of barbital with diazomethane gave a major peak (99% by the peak area on the total-ion monitor) when it was analyzed under the described conditions. GLC–mass spectrometric analysis of the eluted compound did not show a molecular ion (*m/e* 212); however, other diagnostic ions at *m/e* 184, 183, 169, 126, and 112 supported identification of the compound as N_1,N_3-dimethylbarbital. Similarly, methylation of [$^{15}N_{1,3}$, $^{13}C_2$]barbital gave a peak with the same retention time (1.1 min) with major ions at *m/e* 187, 186, 172, 127, and 113 (Fig. 1). The ions were consistent with the fragmentation pattern reported (14) for N_1,N_3-dimethylbarbital. The isotopic purity of the labeled compound is demonstrated by the absence of an ion at *m/e* 169 (Fig. 1).

Mass spectral analysis of the methylated internal standard, butalbital, suggested that the N_1,N_3-dimethylated derivative was formed (99% by the peak area). The mass spectrum showed no molecular ion; however, characteristic ions at *m/e* 209, 196, 195, 181, and 74 were consistent with identification of the compound as the N_1,N_3-dimethyl derivative.

The use of diazomethane as a suitable methylating agent for barbiturates was reported previously (15). Dried extracts of samples are stable for periods of months when kept at −20°. However, when diazomethane is added to them, analysis must be completed within 12 hr. In preliminary studies, flash-heater methylation with the safer reagent, trimethylanilinium hydroxide, was tried; however, because of the decomposition of the barbital derivative, it was abandoned. Diazomethane methylation of barbital and bultalbital gave the desired N_1,N_3-dimethyl derivative of the compounds with negligible amounts of by-products (methyl enol ethers).

Single-ion chromatograms obtained after methylation of a reference sample containing [$^{15}N_{1,3}$, $^{13}C_2$]barbital and butalbital in methanol are

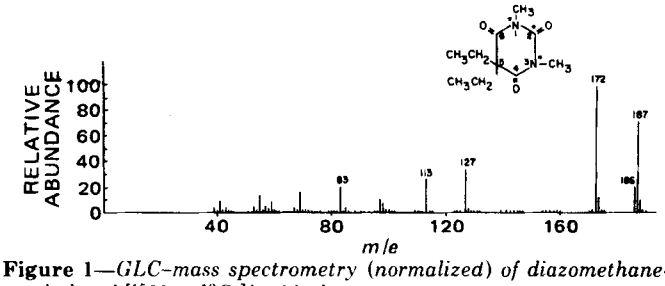

Figure 1—*GLC–mass spectrometry (normalized) of diazomethane-methylated* [$^{15}N_{1,3}$, $^{13}C_2$]*barbital.*

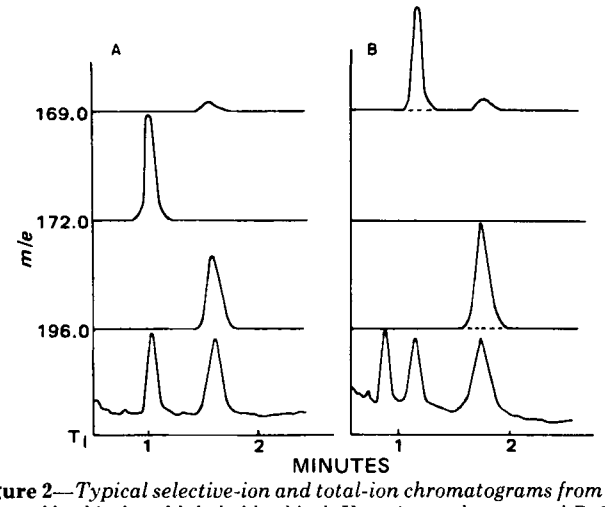

Figure 2—*Typical selective-ion and total-ion chromatograms from the assay of barbital and labeled barbital. Key: A, no plasma; and B, 2-hr plasma sample from a barbital-treated rat. The ions at* m/e *169, 172, and 196 represent barbital, [$^{15}N_{1,3}$, $^{13}C_2$]barbital, and the internal standard, butalbital, respectively.*

shown in Fig. 2*a*. The isotopic purity of the labeled compound is established further by the absence of a signal due to the *m/e* 169 ion (relative abundance <0.2%). Figure 2*b* shows a typical single-ion chromatogram obtained from a 2-hr plasma sample of a barbital-treated rat. The plasma had to be diluted with Red Cross Blood Bank plasma to fit the peak in the linear portion of the detector response curve. To rule out the possibility of any difference between the plasma disposition of barbital and [$^{15}N_{1,3}$, $^{13}C_2$]barbital, two groups of rats were treated with each drug respectively as described under *Experimental*. Comparison of 2-hr plasma concentrations in treated rats is illustrated in Table IV. Results are expressed as the mean for five rats. Results were compared using the Student *t* test, and no statistical difference could be found. Therefore, it was concluded that there was no isotopic effect in the plasma disposition of [$^{15}N_{1,3}$, $^{13}C_2$]barbital sodium in rats.

The overall recoveries of barbital and labeled barbital from plasma are summarized in Table I. Mean percent recoveries of 89 and 99% were considered satisfactory. Recoveries of slightly over 100% sometimes were observed at very low concentrations. This artifact probably is due to background noise.

The accuracy and precision of the GLC–mass spectrometric assay are demonstrated in Tables II and III. Results from at least five determinations of each barbital concentration, ranging from 0.3 to 10 μg/ml of plasma, were obtained as described under *Experimental*. The overall coefficients of variation for barbital and [$^{15}N_{1,3}$, $^{13}C_2$]barbital were 4.36 and 3.73%, respectively. The GLC–mass spectrometric response was linear for both compounds within this concentration range. The detection limit was 1 ng on-column (3× noise). The calibration curves for barbital and labeled barbital were straight lines with an intercept of 0.020 and 0.003, respectively, when they were not forced through the origin. Mean slopes of 0.109 ± 0.002 and 0.099 ± 0.001 for the two compounds were obtained when linear regression without the intercept program was applied.

The sensitivity of the GLC–mass spectrometric detection using single-ion monitoring was compared against GLC with flame-ionization detection and GLC with alkali flame-ionization detection when the same

Barbital[a] Added, μg	*n*	Mean Peak Area Ratio ± *SD*	*CV*, %
5.0	12	0.13 ± 0.015	11.8
8.0	14	0.227 ± 0.031	13.7
15.0	8	0.414 ± 0.012	2.83
30.0	12	0.765 ± 0.016	2.09
50.0	10	1.309 ± 0.036	2.77

[a] Mean *CV* was 6.64% with $y = mx + b$, where $m = 0.025 \pm 0.012$ and $b = 0.027$; $r^2 = 0.995$.

Table VI—Estimation of Barbital Added to Plasma by GLC with Alkali Flame-Ionization Detection

Barbital[a] Added, μg	*n*	Mean Peak Area Ratio ± *SD*	*CV*, %
1.0	6	0.132 ± 0.024	18.41
5.0	8	0.543 ± 0.036	6.78
10.0	8	1.028 ± 0.059	5.71
20.0	6	2.168 ± 0.087	3.87
30.0	8	3.257 ± 0.212	6.53

[a] Mean *CV* was 8.26% with $y = mx + b$, where $m = 0.107 \pm 0.050$ and $b = 0.008$; $r^2 = 0.993$.

extraction procedure was employed (see *Experimental*). As shown in Tables V and VI, both methods are applicable when plasma barbital concentrations of >5 μg/ml are expected. However, the GLC–mass spectrometric method offers the greatest sensitivity and precision and is more suited to quantitation in the therapeutic range, *e.g.*, <5 μg/ml.

Figure 3*a* shows selective-ion and total-ion chromatograms obtained from control plasma processed as described under *Experimental* but with the internal standard omitted. Most of the endogenous plasma constituents were eluted at 0.86 min. No extraneous peaks that interfered with the selected ions for labeled (*m/e* 172) and unlabeled (*m/e* 169) barbital or butalbital (*m/e* 196) were observed over 20 min (2 min shown). Figure 3*b* shows typical selective-ion and total-ion chromatograms from a 2-hr plasma sample collected from a human volunteer treated with [$^{15}N_{1,3}$, $^{13}C_2$]barbital sodium intravenously and barbital sodium orally at the same time. The signals at *m/e* 169 and 172 represent 7.62 μg of unlabeled barbital/ml and 2.51 μg of labeled barbital/ml, respectively.

Application of the GLC–mass spectrometric procedure to the determination of plasma levels of both labeled and unlabeled barbital is shown in Fig. 4. A dose of 1.5 mg of [$^{15}N_{1,3}$, $^{13}C_2$]barbital sodium/kg was injected intravenously (within 20 sec) into a healthy female volunteer (65 kg); at the same time, she swallowed a capsule containing 4.5 mg of barbital

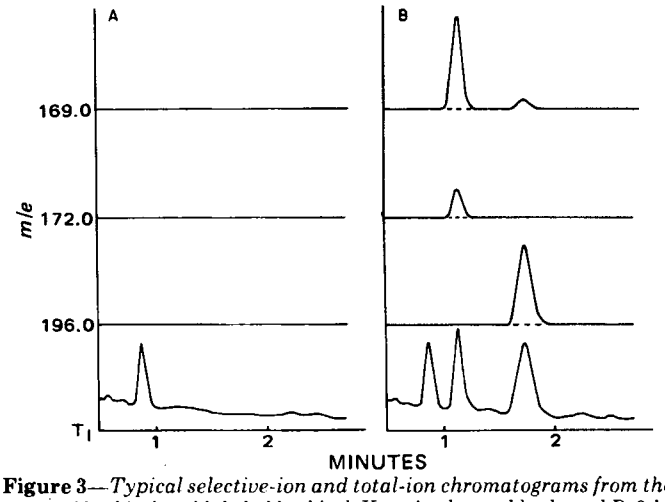

Figure 3—*Typical selective-ion and total-ion chromatograms from the assay of barbital and labeled barbital. The signals at* m/e *169 and 172 represent 7.62 μg of barbital/ml and 2.51 μg of labeled barbital/ml, respectively. The signal at* m/e *196 is that for the internal standard, butalbital.*

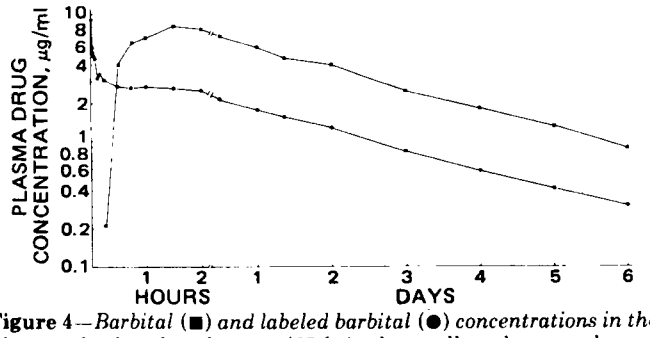

Figure 4—*Barbital (■) and labeled barbital (●) concentrations in the plasma of a female volunteer (65 kg) who swallowed a capsule containing 4.5 mg of barbital sodium/kg and simultaneously received 1.5 mg of [$^{15}N_{1,3}$, $^{13}C_2$]barbital sodium/kg iv (within 20 sec).*

sodium/kg. Blood (7 ml) was withdrawn at intervals over 6 days, and aliquots of plasma (1.0 ml) were assayed for barbital. Concentration–time curves of both isotopes in plasma are illustrated in Fig. 4, and the parallelism observed between their elimination phases strongly supports the evidence that both isotopes behave similarly in the organism.

In conclusion, the described GLC–mass spectrometric procedure is sensitive and specific and should be applicable to studies on the effect of congestive heart failure on barbital disposition.

Permeability of Everted Rat Small Intestine to Lidocaine and Derivatives

PETER J. CASCELLA * and STUART FELDMAN ‡x

Received June 11, 1979, from the **College of Pharmacy, South Dakota State University, Brookings, SD 57006*, and the ‡*Department of Pharmaceutics, University of Houston, Houston, TX 77004.* Accepted for publication January 8, 1980.

Abstract □ The transfer rates of lidocaine and five derivatives were measured across the everted rat intestine. No obvious relationship was observed between the first-order rate constants for transfer and the lipophilicity of the compounds as measured by their apparent partition coefficients. The intestinal mucosal epithelium also did not appear to be the rate-limiting barrier for the passage of these agents across the intestinal membrane regardless of the respective clearance of the compound. It is suggested that the ionized form of these agents may be capable of crossing the intestinal barrier at substantial rates, although it is not known if a similar situation exists *in vivo*. The transfer rate is believed to be due to the passage of intact drug and not the metabolite.

Keyphrases □ Lidocaine—determination of transfer and clearance rates of parent drug and analogs across everted rat intestinal mucosa, mucosal concentrations and pH, *in vitro* absorption □ Absorption—lidocaine and derivatives, determination of transfer rates across everted rat intestinal mucosa, *in vitro* □ Permeability—lidocaine and derivatives across everted rat intestinal mucosa, *in vitro* absorption

The *in vitro* everted rat small intestine is a technique that has been utilized as a biological screen for the assessment of drug permeability and may be indicative of *in vivo* absorption problems. Feldman *et al.* (1) found a rank-order agreement between the *in vitro* transfer of prednisolone across the everted rat small intestine in the presence of various substituted propionamides with that reported for *in situ* experiments in the rat. Kaplan and Cotler (2) used the everted rat intestine as a biological screen to assess permeability characteristics of numerous compounds and concluded that this technique, employed along with a dissolution screen, allows evaluation of potential problems in the initial stages of product development.

The nature of the mechanical separation of the intestine from the intact animal imparts inherent advantages and disadvantages to the technique. Separation enables the investigator to control the physical environment of the intestinal preparation and to study some effects of the physicochemical properties of the drugs on the transfer of these agents across the intestinal preparation. However, separation of the intestinal preparation may alter or obliterate some important influencing factors present in the absorption of a compound *in vivo*. Concern has been expressed over viability (2–5), structural integrity (6), and the presence of unnatural absorption barriers.

This study concerned the transfer rates of lidocaine (I) and five experimental derivatives across the everted rat intestine. These compounds were chosen because they represent minor molecular modifications of the parent

Permeability of Everted Rat Small Intestine to Lidocaine and Derivatives

PETER J. CASCELLA * and STUART FELDMAN ‡x

Received June 11, 1979, from the **College of Pharmacy, South Dakota State University, Brookings, SD 57006*, and the ‡*Department of Pharmaceutics, University of Houston, Houston, TX 77004.* Accepted for publication January 8, 1980.

Abstract □ The transfer rates of lidocaine and five derivatives were measured across the everted rat intestine. No obvious relationship was observed between the first-order rate constants for transfer and the lipophilicity of the compounds as measured by their apparent partition coefficients. The intestinal mucosal epithelium also did not appear to be the rate-limiting barrier for the passage of these agents across the intestinal membrane regardless of the respective clearance of the compound. It is suggested that the ionized form of these agents may be capable of crossing the intestinal barrier at substantial rates, although it is not known if a similar situation exists *in vivo*. The transfer rate is believed to be due to the passage of intact drug and not the metabolite.

Keyphrases □ Lidocaine—determination of transfer and clearance rates of parent drug and analogs across everted rat intestinal mucosa, mucosal concentrations and pH, *in vitro* absorption □ Absorption—lidocaine and derivatives, determination of transfer rates across everted rat intestinal mucosa, *in vitro* □ Permeability—lidocaine and derivatives across everted rat intestinal mucosa, *in vitro* absorption

The *in vitro* everted rat small intestine is a technique that has been utilized as a biological screen for the assessment of drug permeability and may be indicative of *in vivo* absorption problems. Feldman *et al.* (1) found a rank-order agreement between the *in vitro* transfer of prednisolone across the everted rat small intestine in the presence of various substituted propionamides with that reported for *in situ* experiments in the rat. Kaplan and Cotler (2) used the everted rat intestine as a biological screen to assess permeability characteristics of numerous compounds and concluded that this technique, employed along with a dissolution screen, allows evaluation of potential problems in the initial stages of product development.

The nature of the mechanical separation of the intestine from the intact animal imparts inherent advantages and disadvantages to the technique. Separation enables the investigator to control the physical environment of the intestinal preparation and to study some effects of the physicochemical properties of the drugs on the transfer of these agents across the intestinal preparation. However, separation of the intestinal preparation may alter or obliterate some important influencing factors present in the absorption of a compound *in vivo*. Concern has been expressed over viability (2–5), structural integrity (6), and the presence of unnatural absorption barriers.

This study concerned the transfer rates of lidocaine (I) and five experimental derivatives across the everted rat intestine. These compounds were chosen because they represent minor molecular modifications of the parent

0022-3549/80/0600-0643$01.00/0
© 1980, American Pharmaceutical Association

compound lidocaine and have some similar physicochemical properties, such as molecular weight and size, but a relatively wide degree of difference in their lipophilicity. Previous studies (7) in these laboratories showed that the effect of lidocaine and these derivatives on the pharmacological end-points of overturn and death in goldfish was related to the lipophilicity of these compounds and the effect on the absorption rate.

EXPERIMENTAL

Determination of Transfer Rates of Drugs across Everted Rat Intestine—Sprague–Dawley rats[1], 200–300 g, were fasted 24 hr prior to the experiment. Water was allowed *ad libitum*. The animals were anesthetized with ether, a midline abdominal incision was made, and the intestine was cut at the ileo–cecal junction. The intestine also was cut at the pyloric junction and removed from the animal. The first 15 cm proximal to the pyloric junction was discarded, and the remaining intestinal segment was rinsed inside and out with normal saline.

The proximal portion of the intestine was fastened to a glass rod, and the intestine was everted. Two consecutive 10-cm everted intestinal segments were attached to cannulas, placed in 60 ml of mucosal solution in a test tube, suspended in a constant-temperature water bath[2] at 37°, and oxygenated with 95% oxygen–5% carbon dioxide. The mucosal solution was modified Krebs bicarbonate buffer (8) of either pH 6.4 or 7.4 containing various concentrations of lidocaine or its derivatives[3]. Two milliliters of serosal solution consisting of the modified Krebs bicarbonate buffer without any drug present was introduced into the everted segment *via* a syringe and polyethylene tubing. At the end of the predetermined sampling time, the serosal solution was removed and the serosa was rinsed with 2 ml of the modified Krebs bicarbonate buffer. This rinse was combined with the initial sample and was retained for analysis. Two milliliters of fresh serosal solution then was added to the everted segment for the next sampling interval.

Stripping Experiments—The procedure for the preparation of the segments was modified as follows. Either the proximal or distal segment was stripped of its epithelial layer after eversion by running forceps up and down the length of the segment until the epithelial tissue was sloughed off about the tips of the forceps. The experiment then was performed as described previously.

Assay—The samples were alkalinized by the addition of 1 ml of 2 *N* NaOH and extracted into 10 ml of carbon tetrachloride by shaking[4] for 5 min. The aqueous layer was aspirated, and 8 ml of the organic phase was shaken with 10 ml of 0.004% bromthymol blue in pH 6.0, 0.05 *M* phosphate buffer for 5 min. Following centrifugation[5] for 6 min at 4000 rpm, the bromthymol blue layer was removed by aspiration. Five milliliters of the organic layer and 5 ml of 0.1 *N* NaOH solution were shaken for 5 min, and the samples were centrifuged[6] at 2000 rpm for 5 min. The aqueous supernate was read at 615 nm on a double-beam spectrophotometer[7].

The drug concentration in each sample was determined using absorbance *versus* concentration plots obtained in the described manner which were linear over the concentration range studied.

Qualitative Assay for Metabolites—Everted sacs were attached to cannulas and placed in 60 ml of bathing mucosal solutions consisting of pH 7.4 modified Krebs bicarbonate buffer containing 400 μg of lidocaine/ml. Two milliliters of the buffer was placed on the serosal side of the membrane. A 10-cm long segment of intestine was used as a blank and was placed in an erlenmeyer flask containing the pH 7.4 buffer. All solutions were placed in a constant-temperature water bath at 37° and oxygenated with 95% oxygen–5% carbon dioxide.

At the end of 1 hr, the sacs were removed from the bath and serosal samples were placed in glass bottles. Sacs were washed with 2 ml of the pH 7.4 buffer, which was added to serosal samples. Two milliliters of mucosal solution was taken and added to bottles containing 2 ml of the buffer. To the serosal and mucosal samples, 1 ml of 2 *N* NaOH was added. The treated and untreated sacs were rinsed with distilled water and added to bottles containing 4 ml of the buffer and 1 ml of 2 *N* NaOH.

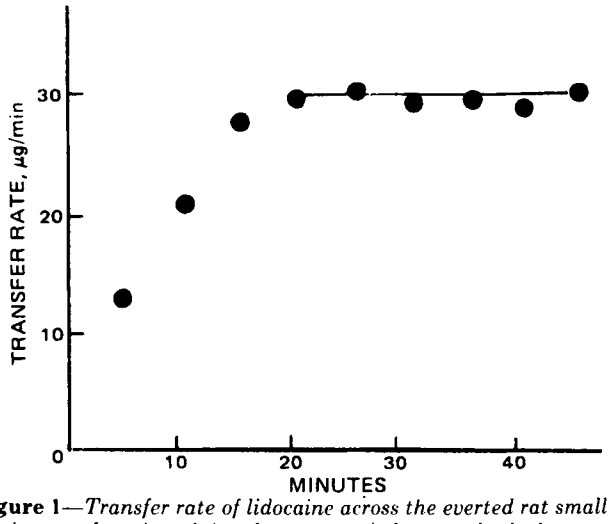

Figure 1—*Transfer rate of lidocaine across the everted rat small intestine as a function of time for a 400-μg/ml mucosal solution.*

Sacs were homogenized[8] and centrifuged[9] at 10,000 rpm for 10 min. The supernate was added to 5 ml of benzene. The serosal and mucosal samples also were added to 5 ml of benzene. All samples then were shaken and centrifuged[6] at 2000 rpm for 5 min. The supernatant benzene then was drawn off and placed in test tubes immersed in a constant-temperature water bath[2], which was maintained at 50° under a continuous-flow air hood until the benzene was evaporated completely.

The evaporated samples were reconstituted with 100 μl of benzene of which 5 μl was injected into a gas–liquid chromatograph[10] equipped with a flame-ionization detector. A 198-cm × 3.2-mm column, packed with 3% OV-17 coated onto 100–120-mesh Gas Chrom Q, was utilized. The

operating temperatures were: injection port, 250°; detector, 260°; and column, 180°. Nitrogen was used as the carrier gas at a flow rate of 42 ml/min.

RESULTS AND DISCUSSION

Drug concentrations in each sample were converted into amounts of the drug, which then were divided by the sampling time to give the average transfer rate (micrograms per minute). The time at which the transfer rate plateaus can be considered as the start of steady-state transfer of drug. A typical plot of the transfer rate as a function of time is illustrated in Fig. 1 for lidocaine. In this example, the time to reach steady state is ~20 min. The cumulative amount of drug transferred as a function of time for each drug was plotted, and a representative plot is illustrated in Fig. 2 for lidocaine. The slope of the line calculated from the values obtained after steady state is achieved represents the transfer rate (micrograms per minute) for the respective compound and was obtained by linear least-squares analysis.

The average transfer rates for lidocaine were determined for 200-, 400-, and 700-μg/ml mucosal concentrations of the drug at pH 7.4. The slopes (transfer rate) of the cumulative amount *versus* time plots as determined by linear least-squares analyses are listed in Table I. The drug clearance is defined as the milliliters of drug solution completely cleared of drug per unit time and can be obtained from:

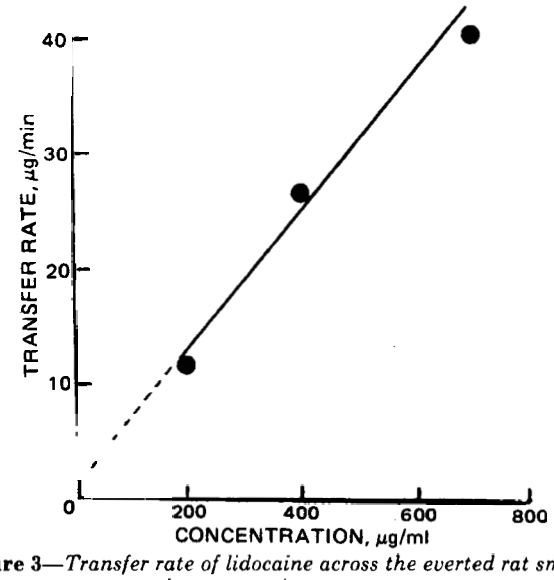

Figure 3—*Transfer rate of lidocaine across the everted rat small intestine* versus *mucosal concentration.*

$$Cl = \frac{\Delta x/\Delta t}{C} \qquad \text{(Eq. 1)}$$

where Cl is the clearance of the respective compound, $\Delta x/\Delta t$ is the rate of drug transferred from the driving-force compartment (mucosal solution), and C is the drug concentration in the driving-force compartment. If one assumes that the transfer of drug occurs *via* a passive first-order process, then the drug clearance would be expected to be identical at the different concentrations since the clearances are reflective of a rate of transfer per unit concentration. Inspection of Table I shows no obvious trend of clearance with respect to drug concentration in the mucosal solution. A linear relationship is observed between the average transfer rates and the drug concentration in the mucosal solution (Fig. 3). The average clearance of lidocaine obtained from the slope of the transfer rate *versus* concentration plot was 0.0571 ml/min.

Since the experiments used two segments from the same intestinal preparation of each rat, a statistical analysis was performed to determine whether selection of one segment over another led to significant differences in the observed rates. In general, the selection of one segment over another probably is of greater concern for a drug transported by an active process due to site specificity of the carrier. However, if the size or composition of the intestinal barrier were to change dramatically from one segment to another, changes in the transfer rates reflecting these alterations might be observed.

A *t* test was utilized to determine if any significant differences existed between the proximal and distal segments of the intestinal preparations in terms of transfer rates for the 200-μg/ml mucosal solution (Table II). No differences were found for transfer rates with regard to the segment of the intestinal preparation used. Therefore, no distinction will be made between the proximal and distal segments employed in this study.

Table III includes the structural formulas for lidocaine and the five derivatives. Molecular modification of the lidocaine molecule involves the substitution of methyl, ethyl, and propyl groups at the R_1, R_2, and R_3 positions of the lidocaine molecule. The pKa values of the compounds ranged from 7.22 for II to 7.98 for V. The partition coefficients between *n*-heptane–pH 7.4 buffer[11] and *n*-octanol–pH 7.4 buffer[12] also are listed in Table III.

The transfer rates and clearances for the lidocaine derivatives also were determined utilizing a 400-μg/ml mucosal concentration (Table IV). The

Table V—Rank-Order Relationship for Lidocaine and Five Derivatives

Rank	Partition Coefficient (*n*-heptane–pH 7.4 buffer)	Partition Coefficient (*n*-octanol–pH 7.4 buffer)	Rate Constant
1[a]	VI	VI	I
2	V	V	IV
3	I	I	V
4	IV	IV	VI
5	III	III	II
6	II	II	III

[a] The largest value.

apparent rates ranged from 15.03 ± 0.70 μg/min for III (clearance of 0.0380 ml/min) to 27.34 ± 2.84 μg/min for lidocaine (I) (clearance of 0.68 ml/min). Dividing the rate (micrograms per minute) by the total amount of drug (micrograms) in the mucosal solution or dividing the clearance by the volume of mucosal solution yields the apparent first-order rate constant (Table IV).

Table V gives the rank ordering of lidocaine and the five derivatives in terms of the apparent rate constant and partition coefficient. No apparent relationship appears to exist between the first-order rate constants for transfer and the partition coefficients. Kakemi *et al.* (9) demonstrated a rather good logarithmic relationship between the gastric absorption rate constants for numerous barbiturate derivatives and their corresponding partition coefficients. Plots of the logarithm of the apparent rate constant as a function of the logarithm of the partition coefficient between *n*-heptane–pH 7.4 buffer and *n*-octanol–pH 7.4 buffer are illustrated in Figs. 4 and 5. No relationship appears to exist between the observed transfer rate constants and the partition coefficient regardless of which partition coefficient is used.

To determine if the ionized form of the drug moiety also is capable of being transferred across the everted rat intestine, experiments were performed using lidocaine at pH 6.4 and a mucosal concentration of 400 μg/ml. Figure 6 is a representative plot of the transfer rate of lidocaine as a function of time. The transfer rates were obtained from the cumulative amount *versus* time plots, and the average transfer rates of lidocaine are listed in Table VI. The average transfer rate at pH 7.4 was ~27 μg/min; at pH 6.4, it was ~22 μg/min. A Student *t* test showed that the difference in rates at the two different pH values was significant ($p < 0.001$). It is possible, by using simultaneous equations, to calculate the approximate transfer rates for the unionized and ionized species. The transfer rate is given by:

$$R_t = f_i R_i + f_u R_u \qquad \text{(Eq. 2)}$$

where R_t is the total transfer rate, f is the fraction of drug that exists as a specific species, and R_i and R_u are the respective transfer rates of the ionized and unionized species. Substituting the average transfer rate and the drug fraction that exists as each respective species yields at pH 7.4:

$$27.34 = 0.68R_i + 0.32R_u \qquad \text{(Eq. 3)}$$

and at pH 6.4:

$$22.16 = 0.95R_i + 0.05R_u \qquad \text{(Eq. 4)}$$

Multiplying Eq. 3 by 1.39706 and subtracting from Eq. 4 yield:

$$-16.036 = -0.397R_u \qquad \text{(Eq. 5)}$$

Multiplying both sides of Eq. 5 by −1 and solving for R_u yield:

$$40.39\ \mu g/min = R_u \qquad \text{(Eq. 6)}$$

Substituting 40.39 back into Eq. 3 and solving for R_i yield:

$$21.20\ \mu g/min = R_i \qquad \text{(Eq. 7)}$$

It appears that the ionized species is capable of crossing the everted rat small intestine at a relatively high rate. Whether the same situation exists *in vivo* is not known. The ability of the ionized species to cross the *in vitro* intestinal preparation may be a manifestation of the mechanical process of everting the intestine as well as a loss of structural integrity with time.

Since the *in vitro* everted rat intestine includes the presence of unnatural absorption barriers, evaluation of whether differences in the transfer rates would occur if the intestinal mucosal epithelium was

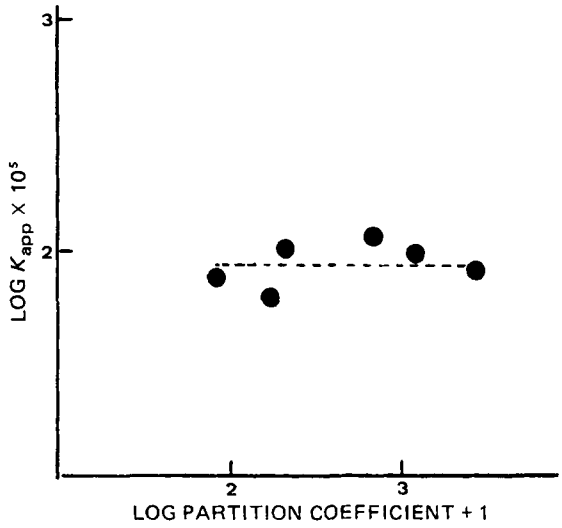

Figure 5—*Log–log plot of apparent transfer rate constants for anesthetic agents across the everted rat small intestine as a function of the partition coefficient* (n-*octanol–pH 7.4 buffer*).

Table VII—Average Transfer Rates for Lidocaine and II across Stripped and Unstripped Intestinal Segments at pH 7.4 and 6.4

Compound	Intestinal Segment[a]	pH	Transfer Rate, μg/min
I	Stripped	7.4	25.70 ± 2.84
I	Unstripped	7.4	26.79 ± 4.22
I	Stripped	6.4	21.27 ± 2.57
I	Unstripped	6.4	22.62 ± 1.36
II	Stripped	7.4	17.64 ± 2.80
II	Unstripped	7.4	16.66 ± 1.72

[a] Three segments were used.

stripped from the intestinal segments was desired. In the *in vitro* model, the intestinal mucosal epithelium represents a distinct barrier that may be rate limiting *in vivo*. Experiments were performed utilizing a 400-μg/ml mucosal concentration of lidocaine at pH 7.4 and 6.4. Stripping was performed alternately on the proximal and distal segments of the intestinal preparations. A representative plot of the cumulative amount transferred as a function of time is illustrated in Fig. 7. The rates for the stripped and unstripped segments at pH 7.4 and 6.4 are listed in Table VII. Statistical analysis using the Student t test showed that the transfer rates of lidocaine were not significantly ($p > 0.05$) different between the stripped and unstripped segments at either pH studied. Since the fraction of unionized and ionized species changed dramatically between the two pH values studied and the rates for the stripped and unstripped were the same, the intestinal mucosal epithelium apparently is not the rate-limiting barrier for either species.

Since previous studies (10, 11) suggested that the intestinal mucosal epithelium may be rate limiting for compounds with low clearances and not for compounds with high clearances, it was decided to evaluate whether the intestinal mucosal epithelium was rate limiting for one compound with a lower clearance than lidocaine. Compound III would have been the ideal selection, but lack of a sufficient quantity prohibited its use. Therefore, II was chosen. It has a clearance of 0.0439 ml/min and was utilized with stripping again performed alternately on the proximal and distal segments. The results are listed in Table VII, with the statistical analysis using the Student t test showing no significant difference ($p > 0.05$) between the transfer rates of the stripped and unstripped intestinal segments. Therefore, II, which has the next to lowest clearance value of the drugs investigated, also does not appear to be rate limited in its transfer by the intestinal mucosal membrane.

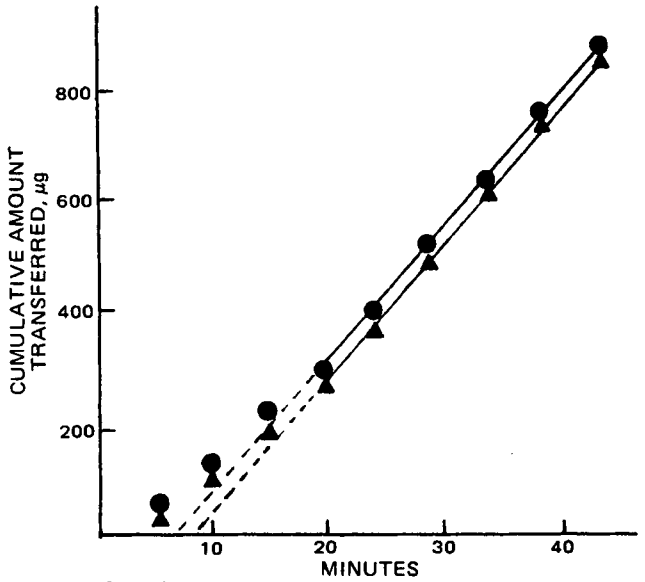

Figure 7—*Cumulative amount of lidocaine transferred across the everted rat small intestine as a function of time from a 400-μg/ml mucosal solution. Key: ●, unstripped intestinal preparation; and ▲, stripped intestinal preparation.*

Since the absorption rate of a drug *in vivo* can be defined as the rate of appearance of free unchanged drug, a qualitative evaluation was performed to determine if the transfer rate of the drug *in vitro* represents the transfer rate of the parent molecule and not the metabolite formed by a first-pass intestinal metabolic phenomenon. Everted sacs were suspended in mucosal solutions containing 400 μg of lidocaine/ml in the pH 7.4 buffer. The inside of the sac (serosa) also was filled with 2 ml of the same solutions. At the end of the predetermined incubation time, the mucosal solution, serosal solution, and tissue homogenates were assayed by GLC.

Only one peak was evident in all of the samples for the mucosal and serosal solutions and for the proximal or distal tissue homogenates. These samples all had the same retention time (10 min) as the control lidocaine samples. No peaks indicative of a lidocaine metabolite were observed[13]. Since amide-linked local anesthetics are metabolized almost completely by the liver in both humans (12) and rats (13), it appears reasonable to conclude that the transfer rates of the compounds across the everted rat small intestine are reflective of the transfer of intact drug.

From these results, it appears that the anesthetic agents are absorbed across the everted rat small intestine by a passive process with no apparent metabolism. The ionized drug molecule also is capable of crossing the membrane at appreciable rates, although it is somewhat lower than the unionized species. No apparent relationship was found between the rate constants and their respective lipophilicity. This result is in contrast to previous studies in goldfish (7). Removal of the epithelial layer by stripping did not appear to affect the transfer rates significantly, regardless of the clearance of the compound or the pH of the bathing solution. Thus, the intestinal mucosal epithelium apparently is not the rate-limiting barrier for the transfer of these compounds across the everted rat small intestine. The relationship between the parameters obtained in the present *in vitro* study and absorption of these agents in an intact animal remains to be evaluated.

Lipophilicity, Molecular Weight, and Drug Action: Reexamination of Parabolic and Bilinear Models

ERIC J. LIEN ˣ **and P. H. WANG**

Received October 4, 1979, from the *Section of Biomedicinal Chemistry, School of Pharmacy, University of Southern California, Los Angeles, CA 90033.* Accepted for publication January 7, 1980.

Abstract □ The effect of molecular weight on drug diffusion and drug action has been described based on the relation $D = (RT/6\pi\eta N)(\sqrt[3]{4\pi N/3M\bar{v}})$, an inverse relation between the clearance of drugs through artificial membranes and molecular weights, and apparent correlations between log (1/dose) and log mol. wt. for various central nervous system-acting drugs, anticancer drugs, and water-soluble vitamins. *In situ* rat jejunum permeability data of various drugs were correlated with log P (octanol–buffer) and log mol. wt. A parabolic equation of log P combined with log mol. wt. proposed previously was shown to give significant correlations for hydrolysis data of amides and antifungal data of amines. This model is mathematically simpler and easier to interpret than the more complex curvilinear and bilinear models.

Keyphrases □ Molecular weight—effect on drug diffusion and activity, parabolic model □ Diffusion—effect of molecular weight, parabolic model □ Structure–activity relationships—effect of molecular weight, parabolic model

While the importance of lipophilicity (partition coefficient) in drug action has been well recognized (1, 2), the effect of molecular weight on the biological activity of drugs has not been appreciated fully. This report discusses the rationale of including a log mol. wt. term in quantitative structure–activity correlations by using specific examples of drug absorption data and *in vitro* biological data. Statistical analysis is employed to assess the significant contribution of the log mol. wt. term above and beyond the contribution from lipophilicity (log P).

MATHEMATICAL MODELS

Few of the various mathematical models developed (3–12) include the effect of the change in molecular weight among homologs, analogs, or congeners (13, 14). Several of these models are discussed here.

Model A—A parabolic model based on a nonsteady-state theory (3–5):

$$\log 1/C = -k(\log P)^2 + k' \log P + k'' \qquad \text{(Eq. 1)}$$

where C is the drug concentration required to produce a standard biological response (*e.g.*, ED_{50} and I_{50}), P is the 1-octanol–water partition coefficient, and k, k', and k'' are derived by the least-squares method.

Model B—The curvilinear model of Franke and Oehme (7):

$$\log 1/C = a \log P + b \qquad \text{for } \log P < \log P_x \qquad \text{(Eq. 2a)}$$

$$\log 1/C = \alpha(\log P)^2 + \beta(\log P) + \gamma \qquad \text{for } \log P > \log P_x \qquad \text{(Eq. 2b)}$$

where α, β, and γ are derived by least-squares fit and P_x is the limit of the straight line.

Model C—A bilinear model (8, 9):

$$\log 1/C = a \log P - b \log(\beta P + 1) + c \qquad \text{(Eq. 3)}$$

where a, b, β, and c are coefficients derived from the regression analysis.

Model D—The Hyde model (10):

$$\log C = \text{constant} + \log(a + 10^{-\pi}) \qquad \text{(Eq. 4)}$$

where π is the Hansch π constant.

Model E—The Higuchi–Davis model (equilibrium model) (11):

$$D = C_w V_w + \sum_{i=1}^{i=t} C_i V_i \qquad \text{(Eq. 5)}$$

$$C_w = \frac{D}{V_{aq} + P_i V_i} \qquad \text{(Eq. 6)}$$

$$C_r = C_w P_r = \frac{DP_r}{V_w + \sum_{i=1}^{i=t} P_i V_i} \qquad \text{(Eq. 7)}$$

where D is the amount of drug, C_w is the concentration in the water phase, C_r is the drug concentration on the receptor, and $P_i = C_i/C_w$.

Model F—The asymptotic model of Ho *et al.* (12):

$$P^*_{app} = \frac{1}{\frac{1}{P^*_{aq}} + \frac{1}{P^*_p + P^*_{e,lipid}}} \qquad \text{(Eq. 8)}$$

where P^*_{app} is the predicted apparent permeability coefficient; P^*_{aq}, P^*_p, and $P^*_{e,lipid}$ are the permeability coefficients of the aqueous diffusion layer, aqueous pores, and lipid membrane diffusion–bioconversion pathway, respectively; and $P^*_{e,lipid} = (10^{n\pi}/X_s)$, where X_s is the fraction of the undissociated form.

Model G—The Lien model (13):

$$\log \%\,\text{Abs. or } \log k = -k_1(\log P)^2 + k_2(\log P) + m[\log(U/D)] + n(\log \text{mol. wt.}) + q(\log \chi) + k_3 \qquad \text{(Eq. 9)}$$

where U/D = (pKa − pH) for acids and χ is a parameter to account for branching or stereochemical factors.

Regardless of the fact that in many instances there is a high degree of covariance between the partition coefficient (log P) and the molecular weight (log mol. wt.) while in other cases there may not be a wide spread in the molecular weight, the molecular weight may affect both *in vitro* drug diffusion and *in vivo* drug action in the following ways:

1. An inverse relationship exists between the diffusion coefficient (D) and the molecular weight [(mol. wt.)$^{1/3}$] according to the Sutherland and Einstein equation:

$$D = \frac{RT}{6\pi\eta r N} = \frac{RT}{6\pi\eta N}\sqrt[3]{\frac{4\pi N}{3M\bar{v}}} \qquad \text{(Eq. 10)}$$

where η is the viscosity of the solution, r is the radius of the spherical particle, N is Avogadro's number, $\bar{v}$ is the partial specific volume in cubic centimeters per gram of the solute, and M is the molecular weight (15, 16).

2. An inverse relationship exists between log clearance and log mol. wt. for clearance through artificial membranes and possibly through biological membranes and the kidneys as well according to (17):

$$\log \text{clearance} = -0.432 \log \text{mol. wt.} + 2.701 \qquad n = 6 \quad r = 0.997 \quad s = 0.016 \qquad \text{(Eq. 11)}$$

for drugs with molecular weights less than 1000.

3. Direct apparent correlations appear to exist between log (1/dose) and log mol. wt. of various central nervous system-acting drugs, anticancer drugs, and water-soluble vitamins (14).

Accumulated data have shown that in many cases where a bilinear model gives a better correlation than a parabolic model, one can obtain equally good correlation simply by including a log mol. wt. term in the equation. Furthermore, when log $1/C$ or log K is corrected for the difference in log mol. wt., a bilinear dependence on log P usually is restored to a parabolic dependence (or only part of a parabola) (Eqs. 12–21 and Figs. 1–3).

RESULTS AND DISCUSSION

The biological data and the physicochemical constants used in the regression analysis are summarized in Tables I–III.

Equations 12–17 were derived from the data of Ho *et al.* (12). Since

0022-3549/80/0600-0648$01.00/0
© 1980, American Pharmaceutical Association

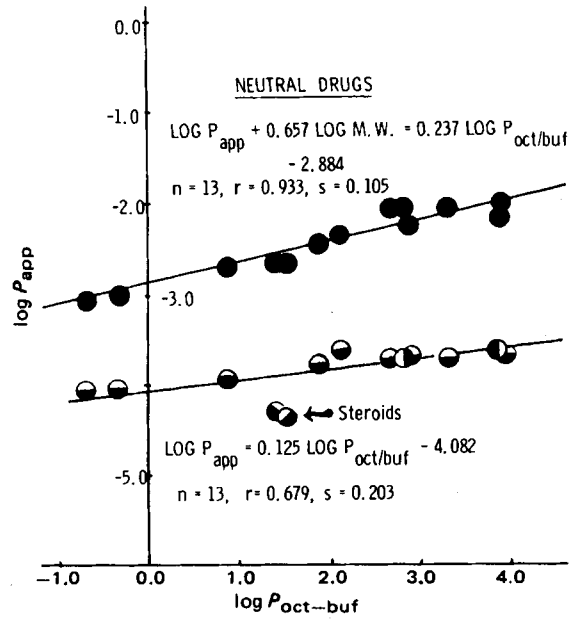

Figure 1—*Linear dependence of the apparent permeability coefficient on the uncorrected octanol–buffer (pH 6.0) partition coefficient for 13 neutral compounds. Lower permeability coefficients (log P_{app}) for the steroids result when the log mol. wt. term is not included.*

the uncorrected octanol–buffer (pH 6.0) partition coefficients were used, no apparent correlation could be obtained when both neutral and acidic drugs were included. When these two groups were separated, statistically highly significant correlations were obtained, as judged from the correlation coefficient r and the standard deviation s of the regression for permeability (log P_{app}) through the rat jejunum with high stirring (12).

For both neutral and acidic drugs, the equations are:

$$\log P_{app} = 0.090 \log P_{(oct\text{-}buf)} - 3.967$$
$$n = 24 \quad r = 0.407 \quad s = 0.258 \qquad \text{(Eq. 12)}$$

$$\log P_{app} = 0.183 \log P_{(oct\text{-}buf)} - 0.689 \log \text{mol. wt.} - 2.627$$
$$n = 24 \quad r = 0.740 \quad s = 0.195 \qquad \text{(Eq. 13)}$$

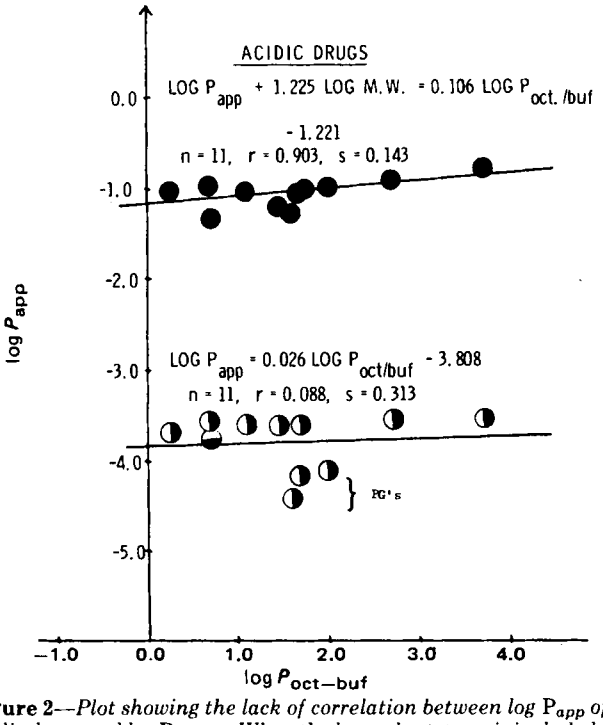

Figure 2—*Plot showing the lack of correlation between log P_{app} of 11 acidic drugs and log $P_{oct\text{-}buf}$. When the log mol. wt. term is included, the correlation becomes statistically significant.*

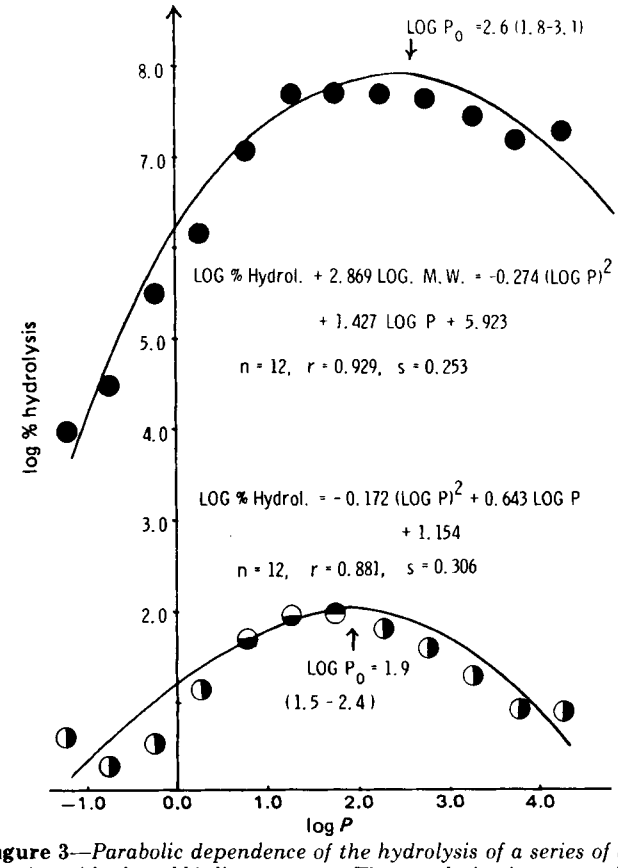

Figure 3—*Parabolic dependence of the hydrolysis of a series of aliphatic amides by rabbit liver extracts. The correlation improves when the log mol. wt. term is included.*

For neutral drugs only, they are:

$$\log P_{app} = 0.125 \log P_{(oct\text{-}buf)} - 4.082$$
$$n = 13 \quad r = 0.679 \quad s = 0.203 \qquad \text{(Eq. 14)}$$

$$\log P_{app} = 0.237 \log P_{(oct\text{-}buf)} - 0.657 \log \text{mol. wt.} - 2.884$$
$$n = 13 \quad r = 0.933 \quad s = 0.105 \qquad \text{(Eq. 15)}$$

For acidic drugs only, they are:

$$\log P_{app} = 0.026 \log P_{(oct\text{-}buf)} - 3.808$$
$$n = 11 \quad r = 0.088 \quad s = 0.313 \qquad \text{(Eq. 16)}$$

$$\log P_{app} = 0.106 \log P_{(oct\text{-}buf)} - 1.225 \log \text{mol. wt.} - 1.221$$
$$n = 11 \quad r = 0.903 \quad s = 0.143 \qquad \text{(Eq. 17)}$$

The log mol. wt. term is significant at the 99.95 percentile level in Eqs. 15 and 17 as indicated by an F test ($F_{1,10} = 31.4$ and $F_{1,8} = 35.1$, respectively).

For the limited data available, addition of the $(\log P)^2$ term did not result in significant improvement in the correlation.

Equations 18 and 19 were derived from the data of Bray *et al.* (18) on the hydrolysis of aliphatic amides by amidase from rabbit liver extract:

$$\log \% \text{ hydrolysis} = -0.172 (\log P)^2 + 0.643 \log P + 1.154$$
$$n = 12 \quad r = 0.881 \quad s = 0.306 \qquad \text{(Eq. 18)}$$

$$\log \% \text{ hydrolysis} = -0.274 (\log P)^2 + 1.427 \log P - 2.869 \log \text{mol. wt.} + 5.923$$
$$n = 12 \quad r = 0.929 \quad s = 0.253 \qquad \text{(Eq. 19)}$$

The addition of the log mol. wt. term to the parabolic equation of log P again significantly improves the correlation at the 90 percentile level ($F_{1,8} = 5.12$).

Equations 20 and 21 were derived from the antifungal data of a series of aliphatic amines against *Rhinocladium beurmanni* (19):

$$\log 1/C = -0.199 (\log P)^2 + 2.119 \log P - 1.382$$
$$n = 15 \quad r = 0.967 \quad s = 0.354 \qquad \text{(Eq. 20)}$$

Table II—Hydrolysis of Aliphatic Amides by Rabbit-Liver Extracts and Physicochemical Parameters Used in the Regression Analysis

Amide	log % Hydrolysis Exp.[a]	log % Hydrolysis Calc.[b]	log mol. wt.	log P (oct–water)[c]
CH_3	0.602	0.418	1.177	−1.21
C_2H_5	0.301	0.574	1.463	−0.71
C_3H_7	0.544	0.617	1.741	−0.21[d]
C_4H_9	1.114	1.273	1.757	0.29
C_5H_{11}	1.748	1.566	1.852	0.79
C_6H_{13}	1.964	1.605	1.988	1.29
C_7H_{15}	1.964	1.873	1.996	1.79
C_8H_{17}	1.806	1.860	2.054	2.29
C_9H_{19}	1.597	1.731	2.105	2.79
$C_{10}H_{21}$	1.255	1.481	2.150	3.29
$C_{11}H_{23}$	0.903	1.106	2.191	3.79
$C_{12}H_{25}$	0.903	0.602	2.229	4.29

[a] Taken from Ref. 18. [b] Calculated from Eq. 19. [c] Calculated from the value of $C_3H_7CONH_2$ by subtracting or adding 0.50 for each CH_2 unit. [d] Experimentally determined value taken from A. Leo, C. Hansch, and D. Elkins, *Chem. Rev.*, **71**, 525 (1971).

$$\log 1/C = -0.499 (\log P)^2 + 8.010 \log P - 42.691 \log \text{mol. wt.} + 74.281$$
$$n = 15 \quad r = 0.994 \quad s = 0.161 \qquad \text{(Eq. 21)}$$

The log mol. wt. term in Eq. 21 is significant at the 99.95 percentile level ($F_{1,11} = 46.7$). The relatively large coefficient associated with the log mol. wt. term and the large constant term in Eq. 21 probably are due to the fact that the log mol. wt. values range only from 1.864 to 2.431. Similarly, high coefficients were obtained for many other sets of antimicrobial data from the same and other sources. In some cases when the parabolic equation of log P gave an almost perfect correlation ($r \geq 0.97$), the addition of the log mol. wt. term did not further improve the correlation. In reality, when one considers the experimental errors involved, a correlation coefficient of ~0.95–0.97 (r^2 of ~0.90–0.94) probably is the maximum limit one should expect.

The data suggest that the semiempirical model of Lien (13) can be used when there is a fairly wide spread in the molecular weights of the drug molecules. The advantages of this model are the simplicity of the mathematical equation (one can use any standard linear or nonlinear regression programs) and the more understandable physical meaning linking diffusion and molecular weight.

Particle-Size Analysis of Pharmaceutical Powders

L. J. BEAUBIEN and A. J. VANDERWIELEN ˣ

Received October 29, 1979, from *Product Control II, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication January 17, 1980.

Abstract □ An automated electrolytic sensing zone (electrozone) method was developed to determine the particle-size distribution of milled and micronized pharmaceutical powders. The powdered drugs obeyed log-normal statistics, and the distributions were well defined by their geometric volume mean diameter and the geometric standard deviation. The results show that accurate data can be obtained between 2 and 80 μm with a precision of ~0.5 μm. Pulse-width analyses were performed to determine the feasibility of using a pulse-width discrimination program. However, in this case, the program discriminates against real particles and, therefore, its usefulness is limited. Milled and micronized materials are described adequately by a spherical diameter, and the automated electrozone system described is an excellent method for quality control purposes.

Keyphrases □ *Particle-size distribution*—milled and micronized pharmaceutical powders, geometric volume mean diameter, electrolytic sensing zone method with and without a pulse-width discriminator □ Distribution, particle size—milled and micronized pharmaceutical powders, geometric volume mean diameter, electrolytic sensing zone method with and without a pulse-width discriminator □ Powders—milled and micronized, particle-size distribution, geometric volume mean diameter, electrolytic sensing zone method with and without a pulse-width discriminator.

The physical properties of pharmaceutical powders are as important to an acceptable drug formulation as are its chemical properties (1). For example, the solubility, dissolution rate, and processing characteristics often depend on the particle size of the powders. Furthermore, the particle size can influence the bioavailability of poorly soluble drugs (2).

The growing need for particulate analyses and determination of particulate-size distributions in the quality control of pharmaceutical products emphasizes the need for efficient and reproducible methods. The popular microscopic method has several disadvantages for use in a quality control laboratory operation. It is time consuming, the counting and sizing results are subject to the judgment and experience of the microscopist, and the analyst cannot readily discern particles that are <5 μm long.

Other methods are available for the particle-size analysis of powdered drugs (1, 3). One method that overcomes the disadvantages of the microscopic determinations utilizes the Coulter or electrozone principle (electrolytic sensing). This electrical sensing zone method is capable of detecting and sizing small particles and counting a statistically significant number of particles.

The present study is part of a continuing project to automate the particle-size analysis of powdered drugs used for formulating suspensions, capsules, and tablets. Milled and micronized materials were studied since these particle reduction methods create particles that are well suited for particle sizing by an electrical sensing zone.

EXPERIMENTAL

Materials—The micronized steroids and spectinomycin hydrochloride were commercially available[1]. Research grade sodium chloride, lithium chloride, and 3A ethanol (contains 5% methanol) were used in the electrolytic solutions. Polysorbate 80 (polyoxyethylene 20 sorbitan monooleate) was used as a wetting agent. Polystyrene spheres of 2.0, 3.5, 5.2, 8.0, 9.8, 10.3, 17.7, 20.0, 32.0, 40.0, and 80.0 μm^2 were used to calibrate the instrument. Neomycin sulfate was selected as a mold inhibitor[1].

Equipment—The particle-size analyses were carried out using a multichannel electrozone particle-size analyzer interfaced to a digital minicomputer[3]. The system is depicted graphically in Fig. 1. Orifice tubes with diameters of 48, 76, 120, and 190 μm were used. The depths of the orifices were between 75 and 100% of the diameter.

Electrolyte—The aqueous electrolyte consisted of 0.9% NaCl, 0.1% polysorbate 80, and neomycin sulfate (4 g/liter) in water saturated with the bulk drug to be analyzed. The solution was prepared by stirring the powdered drug into the aqueous solution for 20 min and filtering once through a 0.22-μm filter. The alcoholic electrolyte was made in a similar manner using lithium chloride and 3A ethanol.

Sample Preparation—About 100 mg of the steroid was placed in ~25 ml of the saturated electrolyte. The vial containing the powdered drug and the electrolyte then was immersed in an ultrasonic bath for a time sufficient to disperse the sample and break up the agglomerated particles. The required time varied from 2 to 10 min, depending on the material. No prior sample preparation was required for spectinomycin hydrochloride.

Particle-Size Determination—For the steriods, a few (1–4) drops of the sonicated suspension were added to the counting cell until the count was between 10 and 100 times greater than the background at the most sensitive current setting. Care also was taken to ensure that the coincident count (*i.e.*, two particles counted as one) was <10%. The background count should be maintained at a level of ~5% of the sample count in the lowest channel. The analysis then was performed under computer control until 2000 counts were accumulated in one of the 128 raw data channels. The particle size in each channel then was calculated by the computer using the calibration tables stored on the flexible disk

system. This operation was repeated at several current settings until a complete distribution was obtained.

The analyses of spectinomycin hydrochloride were performed in a similar manner, except that a small amount of powder (~9 mg) was introduced directly into the saturated 3A ethanolic electrolyte solution that had been normalized previously. This suspension was stirred vigorously for 15–30 sec before proceeding with the particle-size analysis.

RESULTS AND DISCUSSION

Spectinomycin Hydrochloride—During this investigation, the resistivities of several electrolytes were measured using a conductivity bridge (Table I). Resistivity is important because it limits the maximum

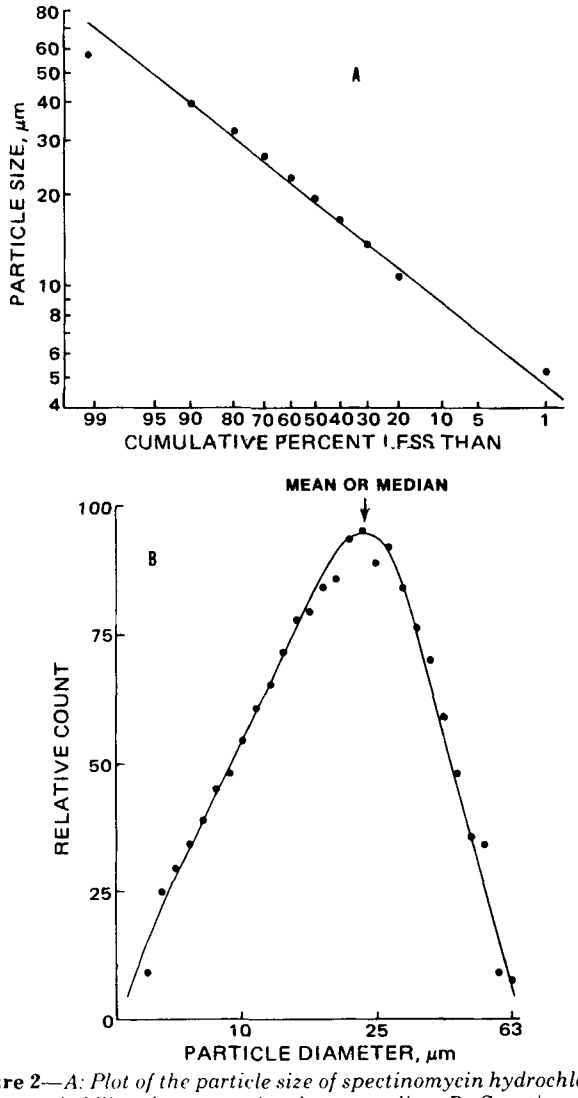

Figure 2—*A: Plot of the particle size of spectinomycin hydrochloride versus probability demonstrating log-normality. B: Spectinomycin hydrochloride particle-size distribution on a volume or mass basis.*

76, 120	31.3, 32.3	32.0
120	40.4	40.0
190	83.0	80.0

[a] The relative standard deviation as listed by Duke Standards was 10%.

usable current through the appearance of thermal noise. Thermal noise occurs due to power dissipation at the orifice (*e.g.*, released bubbles of dissolved gases). This effect is observed as ragged baseline grass on the display scope or is viewed microscopically as a grayish stream line trailing from the orifice.

Power dissipation and hence thermal noise are inversely proportional to the orifice size. Consequently, an electrolyte of low resistivity is required when a small orifice is used. A resistivity in the range of 10–100 ohm-cm is considered optimum, although solutions having a resistivity between 1 and 1000 ohm-cm are usable. Spectinomycin hydrochloride is an electrical nonconductor that is soluble in water and methanol but is only slightly soluble in 3A ethanol. Therefore, even though the lithium chloride–3A solution has a conductivity that is outside the optimum range, it was the electrolyte of choice because of the low solubility of spectinomycin hydrochloride in this solution.

The measured primary spectinomycin particles obeyed log-normal statistics when the data were converted to a volume or mass basis as shown in Fig. 2A (4). A typical volume distribution is depicted in Fig. 2B. For a log-normal distribution, only the geometric mean and the standard deviation are needed to define the whole distribution function. These values can be calculated from a log-normal plot of the cumulative data. A computer program was used to calculate the geometric volume mean (mass median) diameter ($\overline{M}v$) and the geometric standard deviation (σ) defined by:

$$\overline{M}v = \exp\left(\frac{\sum_{i=1}^{n} N_i \ln M_i}{\sum N_i}\right) \qquad \text{(Eq. 1)}$$

and:

$$\sigma = \exp\left(\sqrt{\frac{\sum_{i=1}^{n} N_i(\ln M_i - \ln \overline{M}v)}{\sum_{i=1}^{n} N_i}}\right) \qquad \text{(Eq. 2)}$$

where M is the particle diameter on the volume or mass basis, and N is the number of particles. The geometric count mean diameter, $\overline{M}c$, was derived from the geometric volume mean diameter by the relation:

$$\overline{M}c = \exp\left[\ln \overline{M}v - 3.0\,(\ln \sigma)^2\right] \qquad \text{(Eq. 3)}$$

The orifice tubes were calibrated using polystyrene spheres of known

32-μm Polystyrene	1/2	116	13

[a] Log = 8 and gain = 2⅛ for all analyses. [b] *SD* = 0.425 × (full width at half maximum).

diameter. The data (Table II) show that there was good agreement between the present results and the microscopic results of the manufacturer. A linear regression of the data for the observed size *versus* the microscopic size showed that the method was linear with little or no bias (slope 0.97, intercept 0.3, and correlation coefficient 0.999). The precision (Table III) of the method was excellent for the volume mean diameter (*RSD* 2.3%) and adequate for calculating the count mean diameter (*RSD* 8.0%).

Spectinomycin hydrochloride is formulated as a powder for resuspension. It is injected into muscle tissue as a saturated aqueous suspension, and the particle size must be controlled for patient comfort and good injection properties (*i.e.*, the suspension should not block the injection needle). The results in Table IV show that different size particles were created by different milling speeds. This observation indicates that the method is capable of determining the effectiveness of particle reduction during the milling operation and, therefore, makes an excellent quality control method.

Pulse-Width Analysis—There is a direct relationship between the basic transit time of small spheres flowing through the center of the orifice tube aperture and the width of the electrical pulse produced (5). The pulse-width overlay for the analysis program allows the analyzer to provide data on typical transit times for solid particles. The results of the pulse-width analysis are listed in Table V, and typical distribution curves are illustrated in Figs. 3 and 4. It took a normal particle of spectinomycin hydrochloride 32 μsec to travel through an orifice that was 90–120 μm deep. Prolonged transit times result if the particles are near the aperture wall where the fluid velocity is less or if they are prolate or oblate ellipsoids or flexible structures (5). The results indicate that particle size also has an important effect. This effect is well illustrated by the fact that the apparent transit time was almost twice as long (63 μsec) for the 32-μm

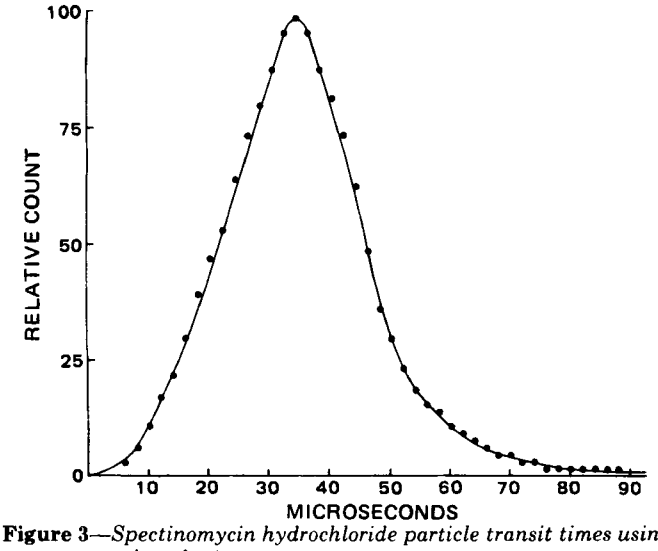

Figure 3—*Spectinomycin hydrochloride particle transit times using a current setting of 1.414 mamp.*

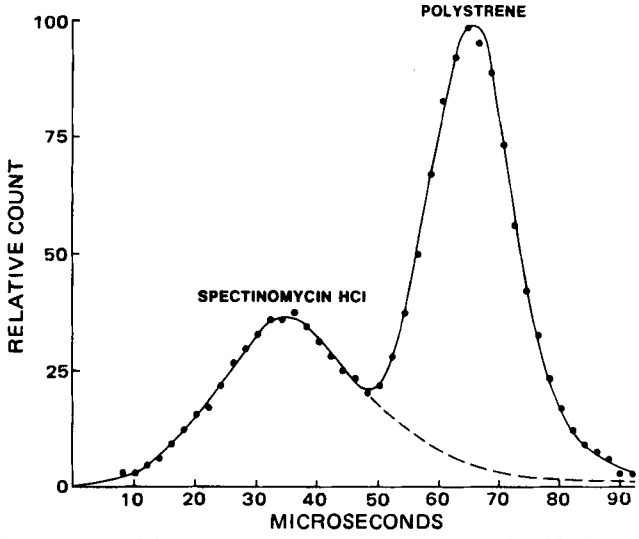

Figure 4—*Particle transit times of spectinomycin hydrochloride and 32-μm polystyrene spheres using a current setting of 0.062 mamp.*

reference than for the spectinomycin whose average particle size was 19 μm (Table III).

It has been suggested that since pulses produced by particles traveling along the orifice walls have correspondingly longer durations than pulses produced by particles passing along the orifice axis, the undesirable pulses may be eliminated by pulse-width discrimination. However, as noted earlier, this effect also would discriminate against the larger particles present. The effect of using a pulse-width discrimination of 79 μsec (pulses greater than 79 μsec are not counted) can be demonstrated by comparing the results listed in Tables III and VI. These data were obtained on the same sample of material. The apparent smaller geometric volume mean diameter (12.8 *versus* 18.8 μm) can only be the result of the computer ignoring the larger particles. It is suggested that pulse-width discrimination is a viable technique only if all of the particles are much smaller (≤10%) than the orifice length and diameter.

Steroids—The aqueous saline solution was chosen as the electrolyte and saturated with bulk drug even though the steroids are rather insoluble in water. This precaution controls the nonproportional dissolution of the smaller particles relative to the larger ones. As a further check on dissolution, the number of particles in 100 μl of prepared sample was counted before and after the determination at a fixed current. Comparison of these counts indicated that sample dissolution (or decomposition) was negligible.

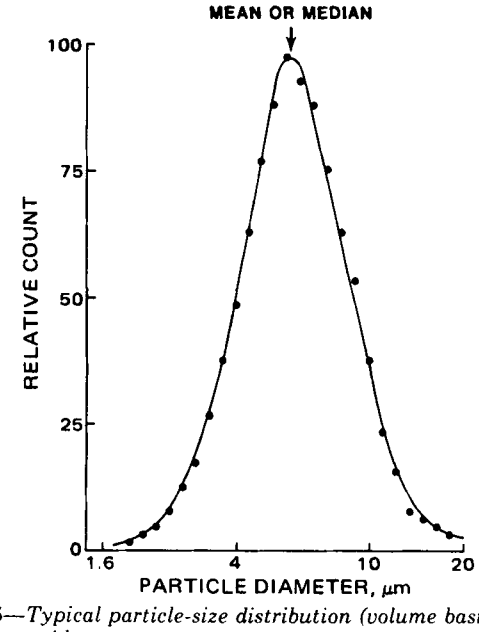

Figure 5—*Typical particle-size distribution (volume basis) of a micronized steroid.*

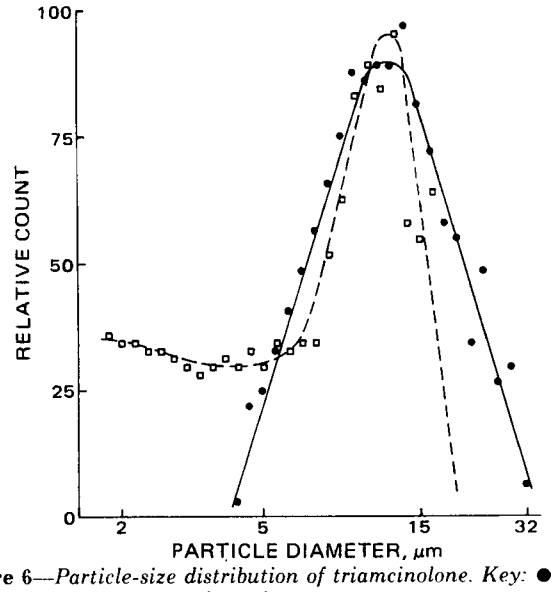

Figure 6—*Particle-size distribution of triamcinolone. Key: ●, nonsonicated; and □, sonicated 10 min.*

One basic objective of particle-size determinations is to measure the size of primary particles rather than the size of agglomerates or fractured primary particles. In general, samples routinely are sonicated to break up agglomerates into primary particles prior to obtaining particle-size distributions. Since extended sonication can reduce the size of polyethylene spheres (6), the effects of sonication on steroid particle size was examined.

The effect of sonication time on the agglomerate and primary particle size indicated that optimum times exist for each of these steroids. Samples were prepared as described under *Experimental*, except that the time of sample sonication was varied. All steroids displayed a rapid initial decrease in their volume mean and in the cumulative percent of observed particles with a diameter greater than 10 or 20 μm. This apparent decrease in size with sonication leveled off within the optimum times listed in Table VII. The appearance of the size distribution remained smooth and log-normal for all of the micronized steroids (Fig. 5). However, for triamcinolone (not micronized), the ratio of small to large particles increased with sonication time (Fig. 6).

The effect of sample dispersion also was studied using microscopic methods. The results (Fig. 7) confirm that sample sonication disperses the agglomerates into single crystals for counting and sizing. This observation was true for all of the steroids except triamcinolone. This steroid exists as individual crystals with very few agglomerates. The deterioration (Fig. 6) of the triamcinolone particle-size distribution upon sonication observed with the celloscope and the fact that sonication is known to fracture particles (6) suggest that sonication results in primary particle breakdown for this steroid.

The case of triamcinolone is important because it points out that, although dispersion of samples by ultrasonication works well, it should not be used without examining the effects on the material to be dispersed. This consideration is important for any analytical measurement made directly on the solid material. The distributions depicted in Fig. 6 show that a significant number of small particles are created by sonication. It is clear that a sample sonicated for 10 min does not represent the actual particle size of triamcinolone. As shown by the unsonicated sample in Fig. 6 and the results listed in Table VIII, it is possible to obtain a rea-

sonable measure of the particle size for triamcinolone by shaking the sample vial gently to disperse the powder. The results presented for triamcinolone indicate that the method of sampling and dispersion is as important to the particle-size measurement as the parameters relating directly to the measurement. In fact, it was found previously that the error in counting particles by the electrozone method is less than the error due to sampling (3).

CONCLUSIONS

Experience has shown that, for pharmaceutical powders, the volume or mass basis (identical to volume if the measured particles have equal densities) is the most useful way of representing particle diameters for milled and micronized powders. These powders usually have log-normal particle distributions (7) that can be described completely by the geometric median or mean diameter and the geometric standard deviation. In addition, milled and micronized materials are described adequately by a spherical diameter; therefore, the automated electrozone system described in this paper is excellent for quality control purposes.

The electrolytic sensing zone method does have some limitations. The particles must be relatively insoluble in a solvent that has a moderate dielectric constant. Unusually shaped particles (*i.e.*, long rods or platelets) are converted to a mean diameter that is considerably less than the longest dimension of the actual particle. For example, a sphere of 4-μm diameter would have approximately the same volume as a cylinder of diameter 2.5 μm and length 7.5 μm. Thus, the method is relatively insensitive to particle shape. However, the advantages clearly outnumber the disadvantages. The method is highly sensitive, fast, and generally applicable. Sample preparation and data reduction are simple. The operator-fatigue factor is much less than for microscopy.

Simultaneous Partitioning and Hydrolysis Kinetics of Amoxicillin and Ampicillin

ERIC TOMLINSON, ROBERT E. NOTARI ˣ, and PETER R. BYRON *

Received June 27, 1979, from the *College of Pharmacy, Ohio State University, Columbus, OH 43210.* Accepted for publication January 16, 1980. *Present address: Department of Pharmacy, University of Aston in Birmingham, Birmingham, B4 7ET, England.

Abstract □ The kinetics of ampicillin and amoxicillin partitioning with simultaneous acid-catalyzed hydrolysis were studied in a stirred transfer cell containing isobutanol as the extract and aqueous hydrochloric acid (0.1–0.5 *N*) as the raffinate at 37°. Biexponential data for the concentration in both the raffinate (C_1) and the extract (C_2) as a function of time were analyzed simultaneously by nonlinear regression to estimate the apparent first-order rate constant for transfer from hydrochloric acid to isobutanol (k'_{12}), the reverse transfer constant (k'_{21}), and the hydrolysis rate constant (k). Agreement between k values determined in the presence of simultaneous partitioning and those determined in the absence of partitioning (k_{app}) verified the nonlinear estimates. Apparent partition coefficients, which represent the values that would be obtained in the absence of hydrolysis ($K'_D = C_1^\infty/C_2^\infty$), were estimated from $K'_D = k'_{12}/k'_{21}$. During terminal monoexponential loss, where $C_1 \simeq Y'e^{-\beta t}$ and $C_2 \simeq Z'e^{-\beta t}$, the kinetically controlled C_2/C_1 ratio (r) is described by $[k'_{12}/(k'_{21} - \beta)]$, which decreases with decreasing k values until r approaches K'_D. The difference between the terminal concentration ratio, r, and its corresponding partition coefficient, K'_D, is a measure of the degree to which kinetic processes control distribution. Both ampicillin and amoxicillin showed kinetic control of the distribution ratios in 0.5 *N* HCl, where the hydrolysis rate constant was significant relative to the distribution rate constants. Ampicillin had $r \simeq 1.74$ and $K'_D \simeq 0.92$; amoxicillin had $r \simeq 0.95$ and $K'_D \simeq 0.65$. As the $(k'_{12} + k'_{21})/k$ ratio increased, the r values approached K'_D so that in 0.1 *N* HCl, $r \approx K'_D = 0.33$ for amoxicillin and $r \approx 0.6$ and $K'_D \approx 0.56$ for ampicillin. In general, amoxicillin distribution rate constants ($k'_{12} + k'_{21}$) were roughly twice those of ampicillin, whereas ampicillin K'_D and r values were nearly double those of amoxicillin. Thus, the kinetic and thermodynamic rank orders are opposite. This result may have implications in drug design *via* molecular modification.

Keyphrases □ Amoxicillin—kinetics of simultaneous partitioning and hydrolysis □ Ampicillin—kinetics of simultaneous partitioning and hydrolysis □ Hydrolysis kinetics—amoxicillin and ampicillin, simultaneous partitioning □ Partitioning kinetics—amoxicillin and ampicillin, simultaneous hydrolysis □ Kinetics—amoxicillin and ampicillin, simultaneous partitioning and hydrolysis

A stirred transfer cell can be used to determine the rate constants for distribution between partially miscible phases with simultaneous degradation in the aqueous phase (1). This technique is potentially useful for comparing the partitioning of closely related drugs under conditions where they are not stable. The method allows calculation of the apparent partition coefficient, K'_D, that would be observed if the drug were stable. It also allows estimation of the concentration ratio, r, of the two phases at a time sufficiently long for r to approach a constant value. Thus, the calculated equilibrium value, K'_D, and the kinetic value, r, can be compared. If these values vary

F	9.3	1.9
G	8.3	1.8
H	8.7	1.8

sonable measure of the particle size for triamcinolone by shaking the sample vial gently to disperse the powder. The results presented for triamcinolone indicate that the method of sampling and dispersion is as important to the particle-size measurement as the parameters relating directly to the measurement. In fact, it was found previously that the error in counting particles by the electrozone method is less than the error due to sampling (3).

CONCLUSIONS

Experience has shown that, for pharmaceutical powders, the volume or mass basis (identical to volume if the measured particles have equal densities) is the most useful way of representing particle diameters for milled and micronized powders. These powders usually have log-normal particle distributions (7) that can be described completely by the geometric median or mean diameter and the geometric standard deviation. In addition, milled and micronized materials are described adequately by a spherical diameter; therefore, the automated electrozone system described in this paper is excellent for quality control purposes.

The electrolytic sensing zone method does have some limitations. The particles must be relatively insoluble in a solvent that has a moderate dielectric constant. Unusually shaped particles (*i.e.*, long rods or platelets) are converted to a mean diameter that is considerably less than the longest dimension of the actual particle. For example, a sphere of 4-μm diameter would have approximately the same volume as a cylinder of diameter 2.5 μm and length 7.5 μm. Thus, the method is relatively insensitive to particle shape. However, the advantages clearly outnumber the disadvantages. The method is highly sensitive, fast, and generally applicable. Sample preparation and data reduction are simple. The operator-fatigue factor is much less than for microscopy.

widely, *e.g.*, $r > K'_D$, then the phase ratio is controlled by the rate constants. This observation may be important for molecular modification.

BACKGROUND

Ampicillin and amoxicillin were studied because of their molecular similarity and the dramatic increase in the oral absorption of amoxicillin compared to ampicillin (2). The kinetics of acid-catalyzed hydrolysis and partitioning into isobutanol are represented in Scheme I:

$$C_{1p} \xleftarrow{k} C_1 \underset{k'_{21}}{\overset{k'_{12}}{\rightleftharpoons}} C_2$$

Scheme I

where k represents the apparent first-order hydrolysis constant; the distribution constants, k'_{12} and k'_{21}, were described previously (1). The penicillin concentration in the raffinate is represented by C_1 and that in the extract is represented by C_2. The hydrolysis product concentration in the raffinate is represented by C_{1p}. According to theory (1), the concentration in the raffinate (aqueous hydrochloric acid) is described by:

$$C_1 = X'e^{-\alpha t} + Y'e^{-\beta t} \qquad \text{(Eq. 1)}$$

where $X' = C_1^0(\alpha - k'_{21})/(\alpha - \beta)$, $Y' = C_1^0(k'_{21} - \beta)/(\alpha - \beta)$, C_1^0 is the initial concentration in the raffinate, and α and β are as defined previously (1). The concentration in the extract (isobutanol) is described by:

$$C_2 = Z'(e^{-\beta t} - e^{-\alpha t}) \qquad \text{(Eq. 2)}$$

where $Z' = C_1^0 k'_{12}/(\alpha - \beta)$. In agreement with theory, both penicillins illustrate kinetic control of the phase ratios when hydrolysis is significant.

EXPERIMENTAL

Analytical Methods—Amoxicillin trihydrate[1] (85.0% amoxicillin) and ampicillin trihydrate[1] (83.7% ampicillin) were 97% pure after accounting for the water of hydration when they were assayed by the acid degradation method. All other materials were analytical grade.

Both penicillins were assayed by a literature method that involves reaction with hydroxylamine and subsequent complexation with a ferric reagent (3). Absorbance was measured at 486 nm against appropriate blanks that were modified to accommodate aqueous acid or isobutanol samples.

Kinetics of Simultaneous Partitioning and Hydrolysis of Ampicillin and Amoxicillin—Aqueous hydrochloric acid (0.1–0.5 N) and isobutanol were equilibrated by shaking at 37°. The phases then were separated and kept at 37°. A stirred transfer cell containing 100 ml of each of the previously equilibrated phases was used to study the kinetics of simultaneous partitioning and hydrolysis at 37°. This system was described previously (1).

Samples of ampicillin or amoxicillin were introduced into the aqueous phase. Aliquots (0.25 or 0.5 ml) were withdrawn simultaneously from both phases as a function of time and assayed. The phase volume ratio thus was kept constant. The number of samples withdrawn was limited to provide a maximum decrease in the total volume of ~5%. Experimental conditions are listed in Tables I and II.

Control Experiments for Kinetics of Degradation in Separated Phases—Experimental controls were designed to take into account both the miscibility of phases and the partitioning of hydrochloric acid into isobutanol during the equilibration step. Aqueous hydrochloric acid (0.1–0.7 N) and isobutanol were equilibrated by shaking at 37°. The phases were separated, and the aqueous acid was kept at 37°. A penicillin sample then was dissolved in the acid to provide an initial concentration of $\sim 4.5 \times 10^{-2}$ M. Aliquots were assayed as a function of time. Experimental conditions are listed in Table III. Apparent first-order rate constants, k_{app}, were obtained from the negative slopes of linear plots of ln [concentration] *versus* time.

Degradation in the isobutanol phase was shown to be insignificant by the following technique. Experiments were initiated as described for the simultaneous partitioning and hydrolysis with the 0.5 N HCl system. After the isobutanol phase had achieved a peak penicillin concentration, the phases were separated; the isobutanol phase was maintained at 37°. Aliquots were assayed as a function of time for 24 hr. The apparent first-order rate constants were negligible relative to those for hydrolysis in the aqueous controls. The rate constant for amoxicillin was 1% of the control, and that for ampicillin was 2% of the control. Therefore, Scheme I is adequate to describe the simultaneous partitioning and hydrolysis experiments.

RESULTS AND DISCUSSION

Kinetics of Hydrolysis of Amoxicillin and Ampicillin—In aqueous solutions, aminopenicillins can undergo hydrolysis with simultaneous polymerization. Bundgaard (4, 5) demonstrated both ampicillin and amoxicillin dimerization *via* nucleophilic attack by the free side-chain amino group in one molecule on the β-lactam of a second molecule. The percentage of total degradation attributed to dimerization ranged from 98% at pH 8.10 (0.673 M) to 13% at pH 9.10 (0.054 M) for ampicillin and from 93% at pH 8.6 (0.477 M) to 9% at pH 10 (0.024 M) for amoxicillin. Under the conditions in Table III, both penicillins are in the cationic form (AH^+) since, in both cases, the pKa (35°) of the carboxylic acid is ~2.6

[1] Beecham Pharmaceuticals, Sussex, England.

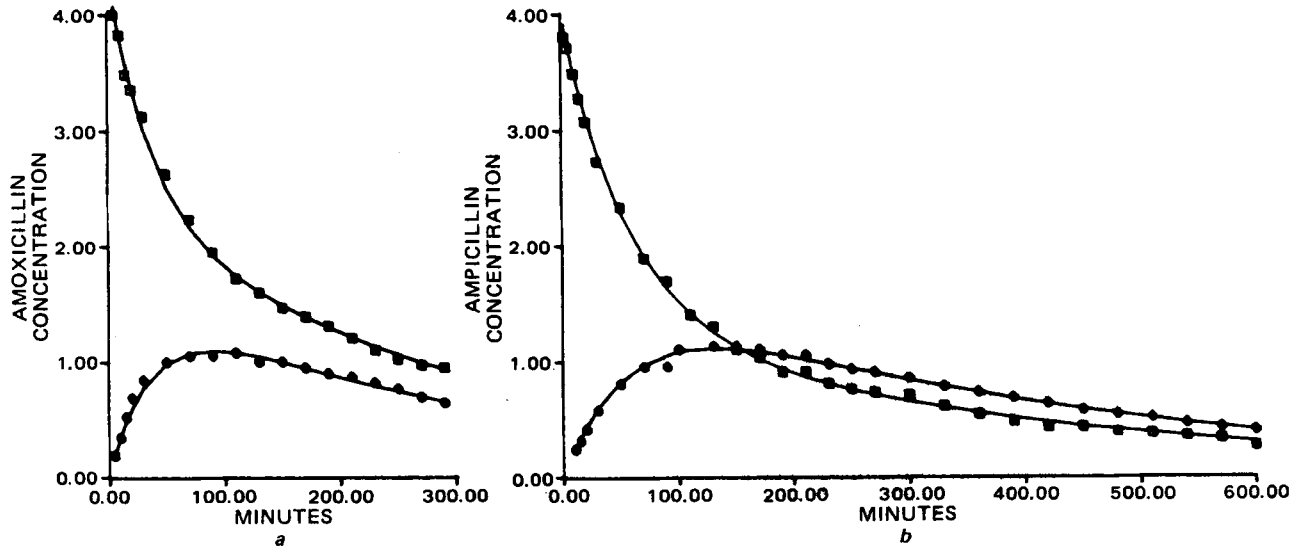

Figure 1—*Data representing the simultaneous determination of* C_1 (□) *and* C_2 (○) *in Scheme I using a stirred transfer cell containing 0.3* N *HCl and isobutanol (preequilibrated) at 37° at 75 rpm. The curves were obtained by simultaneous nonlinear regression based on Eqs. 1 and 2. The resulting estimates for the rate constants are given in Tables I and II.*

and that of the side-chain protonated amine is ~7.2 (4, 5). The lack of unprotonated amine to act as the nucleophile together with the dilute solutions (~0.04 *M*) makes self-association unlikely. Hou and Poole (6) reported simple first-order hydrolysis in the presence of 0.04–0.20 *N* HCl at 35°.

The precise degradation mechanism is not critical to this study since identical conditions were employed for both the simultaneous partitioning and hydrolysis kinetics (Tables I and II) and the controls (Table III). Furthermore, it is not necessary to determine the exact content of the two phases since hydrolysis in the aqueous phase is carried out as a control in which phase separation represents the sole difference between the experiments. At 37°, the solubility of isobutanol in water is ~7.4% (w/w) and that of water in isobutanol is ~18% (w/w) (7). Miscibility of the solvents, while significant, was kept constant throughout all experiments by preequilibration. Therefore, the reported rate constants are associated with water–isobutanol–hydrochloric acid mixtures. This technique provides a simple control experiment without requiring an exact definition of the phases.

Kinetics of Simultaneous Partitioning and Hydrolysis of Ampicillin and Amoxicillin—A previous report (1) demonstrated that the apparent partition coefficient, K'_D, defined by:

$$K'_D = C_2^\infty / C_1^\infty \qquad \text{(Eq. 3)}$$

where, at constant pH, C_2^∞ is the equilibrium concentration in the extract and C_1^∞ is the equilibrium concentration in the raffinate, may be calculated from:

$$K'_D = k'_{12}/k'_{21} \qquad \text{(Eq. 4)}$$

where k'_{12} and k'_{21} are the observed first-order rate constants for transfer from the raffinate to the extract and from the extract to the raffinate, respectively. Data for both phases (such as those shown in Fig. 1) were analyzed simultaneously using nonlinear regression (8) for the best estimates of k'_{12}, k'_{21}, and k based on Eqs. 1 and 2, which are derived from Scheme I.

According to theory, the rate constants for hydrolysis (k in Scheme I) should agree with those determined without partitioning under the same aqueous conditions (1). Thus, a plot of the k values *versus* the k_{app} values (Table II) should be linear with a slope of unity and an intercept of zero. Figure 2 shows good agreement with this prediction. Figure 2*a*, for ampicillin, has a slope of 0.97 and an intercept of 0.6×10^{-3}. Figure 2*b*, for amoxicillin, has a slope of 1.0 and an intercept of -0.05×10^{-3}. In both cases, the correlation coefficient exceeds 0.996. The hydrolysis rate constant also should be independent of the stirring rate. Tables I and II show good agreement between the k values determined with different stirring rates.

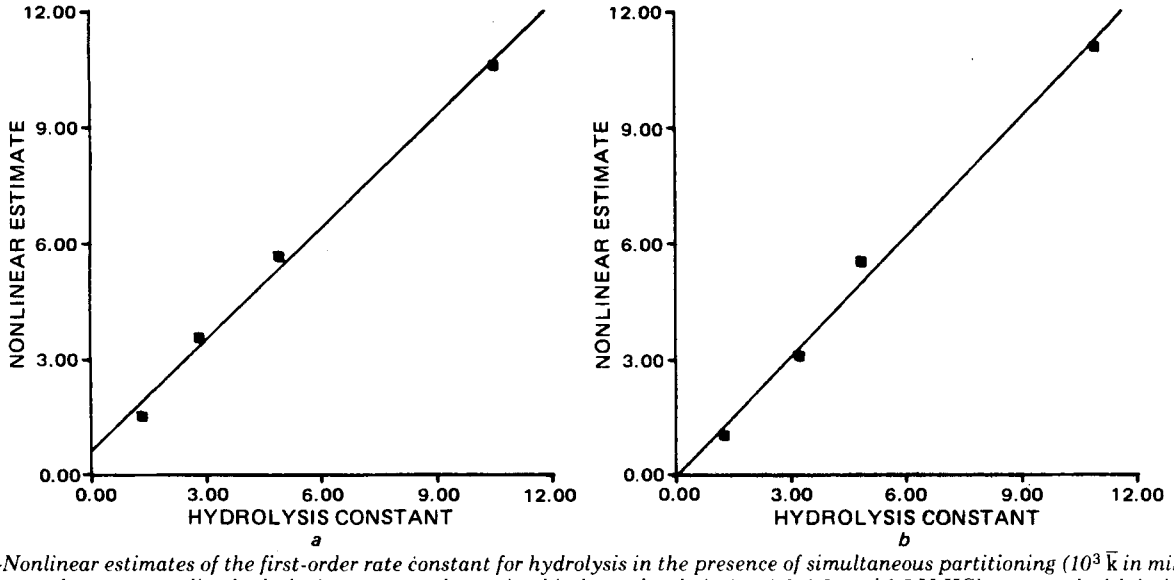

Figure 2—*Nonlinear estimates of the first-order rate constant for hydrolysis in the presence of simultaneous partitioning (10^3 $\bar{k}$ in min^{-1}, Tables I and II)* versus *the corresponding hydrolysis constants determined independently in 0.1, 0.2, 0.3, and 0.5* N *HCl saturated with isobutanol (10^3 k_{app} in min^{-1}; Table III) for ampicillin* (a) *and amoxicillin* (b). *In each case, the correlation coefficient of the regression line exceeds 0.996 and the slope is ~1.*

The apparent partition coefficient that would be obtained for the penicillin if it were stable in aqueous hydrochloric acid may be calculated from Eq. 4. Estimates for k'_{12}, k'_{21}, and K'_D are given in Tables I and II. Contrary to the values for hydrolysis, k, the distribution constants increase with increased stirring rate, as expected. However, the partition coefficient, K'_D, should be independent of the stirring rate. Comparison of the K'_D values at a fixed hydrochloric acid concentration but with different stirring rates shows good agreement between the estimates.

There also is evidence for an increase in K'_D with increasing hydrochloric acid concentration. Since the pKa values are ~2.6 (carboxylic acid) and ~7.2 (protonated amine), both penicillins exist in the cationic form (AH^+) under these conditions. [The pKa of the phenolic hydroxyl group on amoxicillin is 9.5 at 35° (5)]. Therefore, it is not likely that the increase in K'_D is due to any pH effect on the ionic species. Examination of the values for k'_{12} and k'_{21} reveals that k'_{21} is relatively independent of the hydrochloric acid concentration but that k'_{12} increases with increased hydrochloric acid concentration. Therefore, the observed increase is due to an effect in the aqueous phase since the rate constant for transfer from isobutanol to aqueous hydrochloric acid is relatively constant. This should not be due to the increase in ionic strength in going from 0.1 to 0.5 N HCl. Since the aqueous solutes are in the form of cations (AH^+), increased ionic strength would be expected to decrease the activity coefficient, thus decreasing the apparent K'_D value since the latter is based on concentration measurements.

A second and more likely possibility is the increased rate of diffusion of the neutral ion-pair (AH^+, Cl^-), as reported previously for bromide on the dextromethorphanium ion (9). This effect appears to be very likely based on the work of Hurwitz and Carney (10), who enhanced the apparent partition coefficients for ampicillin using several ion-pair or adduct-forming additives. At pH 7, quaternary compounds were the most effective, but the results also were dependent on the anion. For example, the chloroform–water K'_D values using tetraheptylammonium with various anions were: acetate, 4.78; hydroxide, 1.74; chloride, 1.80; bromide, 0.46; and iodide, 0.016. At pH 3, the anions trichloroacetate (added as the carboxylic acid, pKa = 0.70) and picric acid (as the phenol, pKa = 0.38) increased the K'_D value in octanol by ~30 and ~250 times, respectively. Thus, chloride was effective as the counteranion at pH 7. At pH 3, where ampicillin exists in the AH^+ form, K'_D was increased by the addition of anions without the quaternary cations. These observations support the suggestion that the increase in k'_{12} values with increased hydrochloric acid may be due to the formation of the neutral ion-pair (AH^+, Cl^-).

Both penicillins illustrate the difference between the observed phase ratios, r, and the apparent partition coefficients, K'_D. This difference was most pronounced with 0.5 N HCl. When a constant r value was observed, the values agreed with those calculated from Eq. 5 (11):

$$r = k'_{12}/(k'_{21} - \beta) \qquad \text{(Eq. 5)}$$

For example, with 0.5 N HCl, where β is most significant relative to k'_{12} and k'_{21}, the ampicillin r value was 1.78, while K'_D was 0.94. This result illustrates how kinetic control can reverse the expected results based on partition coefficients. Here, the K'_D value predicts that the aqueous concentration should be greater than that in the isobutanol phase. However, the concentration in isobutanol was 1.78 times that of the aqueous phase. As the hydrochloric acid concentration decreased, r approached K'_D. This result is due to the decreasing significance of the competing hydrolysis process.

The observed rate constant for the partitioning between the phases is the sum of the forward and reverse constants, k'_{12} and k'_{21} (1). If this sum becomes large enough relative to the hydrolysis constant, k, then r approaches K'_D. This effect has been referred to as preequilibrium, and a first approximation that $(k'_{12} + k'_{21}) \geq 20k$ will provide $r \approx K'_D$ has been suggested (11). In both cases (Tables I and II), k decreased nearly 10-fold as the hydrochloric acid concentration was decreased from 0.5 to 0.1 N. At the same time, k'_{21} remained nearly constant, while k'_{12} only decreased to about 60% of its value using 0.5 N HCl. Therefore, the $(k'_{12} + k'_{21})/k$ ratio increased 10-fold (75 rpm) and eight-fold (120 rpm) for amoxicillin and six-fold (75 rpm) and 5.6-fold (120 rpm) for ampicillin. The r values for amoxicillin at 0.1 N HCl were the same as its K'_D values since the $(k'_{12} + k'_{21})/k$ ratios were 24 (75 rpm) and 27 (120 rpm).

Although the K'_D and r values were larger for ampicillin than for amoxicillin, the rate constants for distribution $(k'_{12} + k'_{21})$ were nearly twice as large for amoxicillin. Amoxicillin thus distributed more rapidly but showed a lower isobutanol concentration for any given C_1 value. With significant hydrolysis, neither drug distribution ratio (C_2/C_1) was reflected by the K'_D values.

These observations illustrate one potential limitation in the application of partition coefficients to biological systems. The use of partition coefficients to predict the biological activity of structurally nonspecific drugs has received much attention since its inception (Meyer–Overton law). These well-accepted concepts are included in most undergraduate textbooks on medicinal chemistry. Further quantitation of these principles uses linear free energy relationships of the type known to chemists as Hammett $\sigma\rho$ functions. Since K'_D values are thermodynamic parameters, they describe equilibrium ratios rather than distribution rates. For systems that do not achieve equilibrium, such as an intravenous injection of a rapidly metabolized drug, the apparent distribution ratio may be predicted better from kinetic parameters. Comparisons of the type reported here for ampicillin and amoxicillin may be useful in drug design *via* molecular modification.

Conclusion—Ampicillin and amoxicillin both illustrated a difference between the observed isobutanol–aqueous phase concentration ratio, r, and that predicted by the partition coefficient value, K'_D, when 0.5 N HCl was used. This difference diminished as the hydrochloric acid concentration (and, therefore, the hydrolysis rate) was decreased. Both the r and K'_D values were roughly twice as large for ampicillin compared to amoxicillin. However, the sums of the distribution rate constants for amoxicillin were larger than those for ampicillin. There was no significant difference between the hydrolysis rate constants for the compounds. The estimates for the hydrolysis rate constants in the presence of partitioning were in good agreement with those determined independently.

Extended Hildebrand Approach: Solubility of Caffeine in Dioxane–Water Mixtures

A. ADJEI, J. NEWBURGER, and A. MARTIN ˣ

Received November 19, 1979, from the *Drug Dynamics Institute, College of Pharmacy, University of Texas, Austin, TX 78712.* Accepted for publication January 18, 1980.

Abstract □ The solubility of caffeine in various dioxane–water mixtures was analyzed in terms of solute–solvent interactions using a modified version of the Hildebrand treatment for regular solutions. The solubility equation employs a term (W) to replace the geometric mean $(c_1c_2)^{1/2}$, where c_1 and c_2 are the cohesive energy densities for the solvent and solute, respectively. The new equation provides an accurate prediction of solubility once the interaction energy, W, is obtained. In this case, the energy term is regressed against a polynomial in δ_1 of the binary mixture. A quartic expression of W in terms of the solvent solubility parameter was found for predicting the solubility of caffeine in dioxane–water mixtures. The expression yields an error in mole fraction solubility of <3%, a value approximating that of the experimentally determined solubility. The one exception to a good fit is near the maximum solubility, where a depression or valley occurs between the two peaks in solubility data; at this point, the theoretical equation predicts the solubility within ~9%. The new model also may be used to estimate the solubility of drug molecules employing the volume fraction of water in the solvent mixture instead of the composite solubility parameter, δ_1. The method has potential usefulness in preformulation and formulation studies during which solubility determination is important for drug design.

Keyphrases □ Caffeine—solubility in water–dioxane mixtures, extended Hildebrand approach, mathematical prediction of solute–solvent solubilities □ Solubility—caffeine in water–dioxane mixtures, prediction of solubility, extended Hildebrand approach □ Hildebrand solubility equation, modified—caffeine in water–dioxane mixtures, solubility predictions

In previous reports (1, 2), the Hildebrand–Scatchard solubility approach (3) to the prediction of solubility was extended to semipolar crystalline drugs in pure solvents and in polar binary solvent mixtures. The equation for calculating the solubility of drug molecules in polar and nonpolar solvents is (2):

$$-\log X_2 = \frac{\Delta S_m^f}{R}\log\frac{T_m}{T} + \frac{V_2\phi_1^2}{2.303RT}(\delta_1^2 + \delta_2^2 - 2\delta_1\delta_2) + \frac{V_2\phi_1^2}{2.303RT}(2\delta_1\delta_2 - 2W) \quad \text{(Eq. 1}a\text{)}$$

or:

$$-\log X_2 = \frac{\Delta S_m^f}{R}\log\frac{T_m}{T} + \frac{V_2\phi_1^2}{2.303RT}(\delta_1^2 + \delta_2^2 - 2W) \quad \text{(Eq. 1}b\text{)}$$

where X_2 is the mole fraction solubility of the crystalline solute at temperature T on the Kelvin scale; ΔS_m^f is the entropy of fusion of the crystalline drug molecule at its melting point, T_m; R is the molar gas constant; V_2 is the molar volume of the solute, and ϕ_1 is the volume fraction of the pure or mixed solvent. The solubility parameters for the solvent (subscript 1) and the solute (subscript 2) are δ_1 and δ_2, respectively. The W expression is an interaction term which, in regular solution theory, is taken to be equal to a geometric mean, $(c_1c_2)^{1/2}$, where c_1 is the cohesive energy density of the solvent (δ_1^2) and c_2 is the cohesive energy density of the solute (δ_2^2).

The first right-hand term of Eq. 1b is the negative logarithm of the ideal solubility ($-\log X_2^i$), and the second term is the logarithmic solute activity coefficient ($\log \alpha_2$). In Eq. 1a, $\log \alpha_2$ is divided into the regular solution term for van der Waals interaction energies ($\log \alpha_v$) and a final term ($\log \alpha_R$) representing residual solute–solvent interactions (2). The quantities $V_2\phi_1^2/(2.303RT)$ will be represented by A.

In the present approach, W is evaluated from knowledge of the other terms in Eq. 1, obtained experimentally or found in the literature. In polar systems, W equals the geometric mean $(c_1c_2)^{1/2}$ only at points A and B along the solubility profile (Fig. 1) where the real solubility line crosses the regular solution line. This fact emphasizes that the Hildebrand–Scatchard equation (3), written in terms of cohesive energy densities:

$$-\log X_2 = \frac{\Delta S_m^f}{R}\log\frac{T_m}{T} + \frac{V_2\phi_1^2}{2.303RT}\{c_1 + c_2 + 2(c_1c_2)^{1/2}\} \quad \text{(Eq. 2)}$$

correctly calculates the solubility of drugs in mixed polar solvents only at these two points in Fig. 1.

A better approach is not to restrict the interaction term W to a geometric mean but rather to evaluate it experimentally from the solubility of the solute in various solvent concentrations in a binary mixture employing Eq. 1b. An empirical equation for W as a function of solubility parameters of the solvent mixture remains to be discovered. Then, back-calculating W and substituting into Eq. 1 permit the mole fraction solubility of a drug (solute) to be predicted in essentially any solvent mixture.

EXPERIMENTAL

The solubility of crystalline caffeine[1] in dioxane, water, and mixtures of dioxane and water was determined as described for theophylline solutions (2). The other quantities required for predicting drug solubility in mixed solvents also were discussed (2). The solubility parameter, δ_2, for caffeine may be obtained from the peak solubility (Fig. 1), where the solvent δ_1 value should approximate the δ_2 value as required by Eq. 2. A more accurate determination (4) may be obtained by a differential method, plotting $\Delta X_2/\Delta\delta_1$ *versus* δ_1 (Fig. 2) and reading δ_2 as the δ_1 value at the apex of this curve.

RESULTS AND DISCUSSION

To obtain the ideal solubility of caffeine, the procedures described under *Experimental* were employed; the following values were obtained: ΔH_m^f, 5044 cal/mole; T_m, 512°K; and $\Delta S_m^f = \Delta H_m^f/T_m$, 9.85 cal/mole/degree. The ideal mole fraction solubility of caffeine was calculated from these values: $X_2^i = 0.06845$ ($\log X_2^i = -1.1646$). The molar volume of caffeine is 144 cm³/mole, which may be obtained as an average of the apparent molar volume in the mixtures (5). It also may be estimated by the group contribution method of Fedors (6).

The experimental solubility of caffeine at 25 ± 0.1° in dioxane–water mixtures is plotted in Fig. 1 *versus* the solubility parameter, δ_1, of the various mixed solvent systems. Also shown in Fig. 1 are the ideal solubility ($X_2^i = 0.06845$) and the regular solution curve (Eq. 2). The solubility of caffeine ($\delta_2 = 13.8$) in pure dioxane ($\delta_1 = 10.0$), pure water ($\delta_1 = 23.5$), and in the mixture of the two solvents is represented by the solid circles in Fig. 1. The maximum solubility of caffeine in the mixture is X_2 =

0.0282 and occurs at δ_1 = 13.8. This value is well below the ideal solubility, X_2^i = 0.06845, as predicted from regular solution theory. The discrepancy between the results using the original Hildebrand equation and the experimental points demonstrates that Eq. 2 cannot be used to predict drug solubility in polar solvent systems.

Solubility Prediction Using Regression of *W versus* δ_1—Equation 1, differing from Eq. 2 in that the geometric mean is not used, provides an accurate prediction of solubility once W is obtained. Although W presently cannot be estimated based on fundamental physicochemical properties of the solute and solvent, W may be regressed against a polynomial in δ_1 of the solvent mixtures as described previously (1, 2). The following quadratic, cubic, and quartic equations were obtained using the experimental solubility data for caffeine in dioxane–water mixtures:

$$W = 79.4113802 + 1.8685725\delta_1 + 0.4356481\delta_1^2 \quad \text{(Eq. 3)}$$

$$W = 66.3515007 + 4.3901982\delta_1 + 0.2792065\delta_1^2 + 0.0031281\delta_1^3 \quad \text{(Eq. 4)}$$

$$W = 15.0752785 + 17.6279025\delta_1 - 0.9668266\delta_1^2 + 0.0539120\delta_1^3 - 0.0007578\delta_1^4 \quad \text{(Eq. 5)}$$

The W values calculated using these expressions compared favorably

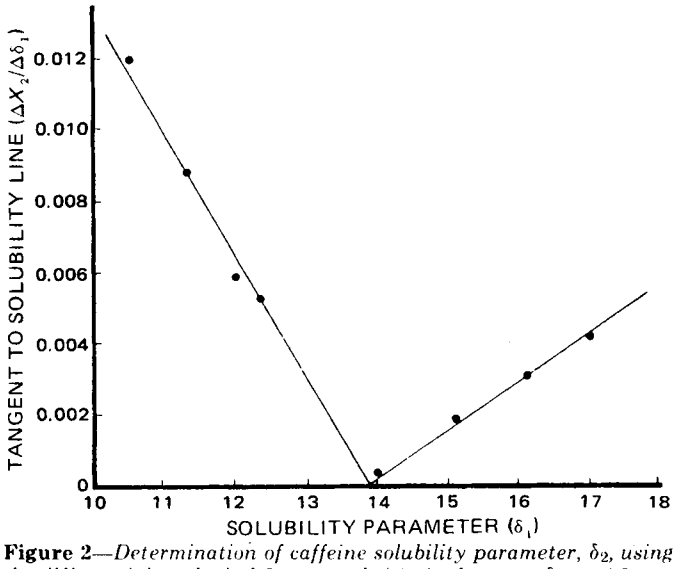

Figure 2—*Determination of caffeine solubility parameter, δ_2, using the differential method of James* et al. *(4). At the apex, δ_2 = 13.8.*

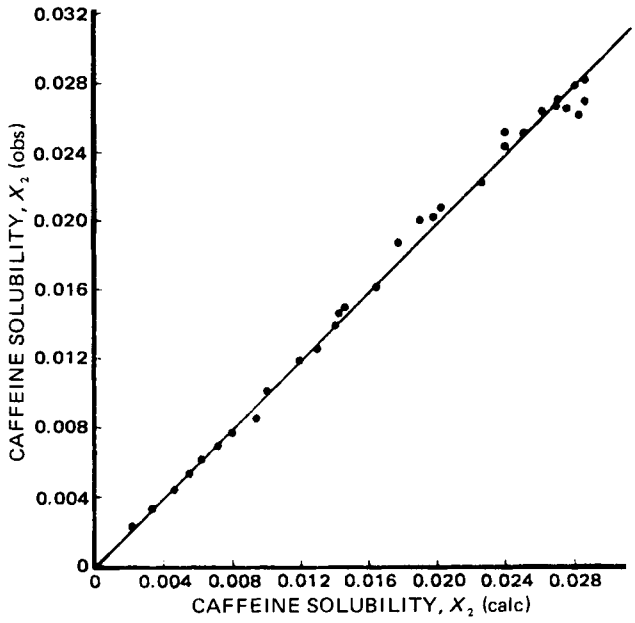

Figure 3—*Comparison of 31 observed caffeine solubilities in dioxane–water systems at 25° with solubilities predicted by the extended Hildebrand approach. The intercept of the line is 0.001, and the slope is 0.999. The correlation coefficient, r^2, is 0.989 for* n = 31.

with the original W values computed using Eq. 1. The solid line plotted in Fig. 1 was obtained employing the quartic expression (Eq. 5). This calculated solubility curve fits the experimental data points quite well (Figs. 1 and 3), predicting the solubility of caffeine in dioxane–water mixtures at most points within an error of ~3%, a value approximating the error in experimentally determined solubility values.

One notable exception to the fit is near the peak solubility where a depression or valley occurs between two peaks in the solubility data. Here the theoretical equation cannot reproduce the exact solubility and results in an error of 8.6%. Paruta *et al.* (7) first reported the peaks and valleys in solubility data and demonstrated essentially the same profile for caffeine as shown in Fig. 1. These workers (7) attributed the decreased solubility of caffeine in the dioxane–water mixture at this solvent composition to solvation or to the possible self-association of caffeine into polymeric forms as reported previously (8).

Equations 3–5 are empirical expressions and cannot be expected to reproduce the acute change in solubility represented by small peaks and

[a] Data selected from the 31 solubility points shown in Fig. 1. Calculated solubilities were obtained with the help of Eq. 8 as described in the text. [b] $A = V_2\phi_1^2/(2.303RT)$ in Eqs. 1 and 2.

valleys in a solubility profile. The calculated solubility line (solid line of Fig. 1), representing the quartic expression (Eq. 5), passes smoothly through the points about the peak solubility, ignoring the slight depression (dotted line at the peak in Fig. 1) at the maximum solubility. This kind of second-order deviation in drug solubility in polar solvents requires additional investigation and a considerably refined model for its characterization.

Predicting Drug Solubility from Solvent Concentration—The solubility parameter, δ_1, against which W is regressed to calculate solubility is calculated for a mixture of two solvents, a and b, using:

$$\delta_1 = \frac{\phi_a\delta_a + \phi_b\delta_b}{\phi_a + \phi_b} \quad \text{(Eq. 6)}$$

where the total volume fraction of the two solvents is given by:

$$\phi_1 = \phi_a + \phi_b \quad \text{(Eq. 7)}$$

Therefore, it is possible to express δ_1 in terms of the volume fraction (or volume percent) of either binary solvent species. The solubility parameter, δ_1, is plotted in Fig. 4 against the volume fraction of water in the mixture. A straight line is obtained, which suggests the possibility of bypassing W and δ_1 and back-calculating $\log \alpha_2/A$ by regressing it directly against the volume fraction of water, ϕ_w, in the solvent mixture. The quartic regression equation becomes:

$$\log \alpha_2/A = 8.409751 - 38.419518\phi_w + 109.607554\phi_w^2 - 114.353521\phi_w^3 + 49.383099\phi_w^4 \quad \text{(Eq. 8)}$$

Equation 8 yields the calculated solubility data found in Table I. For example, at 65% water, a volume fraction, ϕ_w, of 0.65 is substituted in Eq. 8, which yields 7.157 for $\log \alpha_2/A$. This value is multiplied by A to obtain $\log \alpha_2$ or 0.68299. Log α_2 then is added to $-\log X_2^i$, which is 1.1646, to obtain the negative logarithm of the solubility, $-\log X_2$. The sign is changed and the antilog is calculated to obtain X_2 = 0.01420. This result is within 3.1% of X_2 (obs) = 0.01465. The procedure is shown more clearly as:

$$\log \alpha_2 - \log X_2^i = -\log X_2 \quad \text{(Eq. 9a)}$$

$$0.68299 + 1.1646 = 1.84759 = -\log X_2 \quad \text{(Eq. 9b)}$$

$$\text{antilog}\,(-1.84759) = X_2 = 0.01420 \quad \text{(Eq. 9c)}$$

CONCLUSIONS

The extended Hildebrand approach to solubility employs a power series (quartic) equation in δ_1 to back-calculate W, which reproduces the solubility of caffeine in dioxane–water mixtures within the accuracy ordinarily achieved in experimental solubility results.

Hildebrand *et al.* (9) made the following observations: "Plato asserted that heavenly bodies move in circles because a circle is the most perfect geometrical figure. He was wrong: the most perfect geometrical construct is a straight line between two axes; one which expresses theory, the other which states the facts" (9). To test this Hildebrand hypothesis, Fig. 3 was drawn, and an almost straight line of zero intercept was obtained, r^2 = 0.989.

The close correlation of calculated results with experimental solubility is gratifying, although the extended method cannot be called a theory. At best, the method is semiempirical, because one uses solubilities originally to obtain the W values. Then W (or $\log \alpha_2/A$) is regressed in terms of solvent δ values or volume fractions of a solvent in the mixture to back-calculate solubilities. It is surprising that such good fits of the data have been obtained both with theophylline (2) and with caffeine in binary solvent systems. However, dioxane–water mixtures are relatively well behaved, producing fairly uniform bell-shaped solubility profiles; other solvent pairs may not perform as well. Limited experience with the solubility of drugs in pure solvents shows that the extended Hildebrand approach will prove useful for pure solvent systems only if a technique more fundamental than power series regression on δ_1 is found.

Effects of Different Buffer Species on Partition Coefficients of Drugs Used in Quantitative Structure–Activity Relationships

POU-HSIUNG WANG and ERIC J. LIEN ˣ

Received December 10, 1979, from the *Section of Biomedicinal Chemistry, School of Pharmacy, University of Southern California, Los Angeles, CA 90033.* Accepted for publication January 29, 1980.

Abstract □ A study was conducted in which the same organic solvent, 1-octanol, and different buffer systems were used to obtain intercorrelations among log P_{corr} values given by log P (octanol–water) = a log P (octanol–buffer) + b, where a and b are different constants for the different systems used. The range of a was 0.418–1.156 and that of b was −1.962–1.176 for the four buffer systems examined. Only with neutral drugs was the slope (a) close to 1.0 and the intercept (b) close to 0.0 for the three buffer systems studied. For acidic drugs, only 1-octanol–phosphate buffer gave a 1:1 correlation with 1-octanol–water partition coefficients. Acetate and bicarbonate buffer systems gave different correlations. For basic drugs, none of the three systems examined gave a 1:1 correlation with 1-octanol–water partition coefficients.

Keyphrases □ Partition coefficients—acidic, basic, and neutral drugs, effects of various octanol–buffer systems □ Solvents—various octanol–buffer systems, effects on partitioning of acidic, basic, and neutral drugs □ Buffers—various octanol–buffer systems, effects on partitioning of acidic, basic, and neutral drugs

The distribution of a drug or chemical compound between two phases in which it is soluble is an important topic. Nernst (1) emphasized that the partition coefficient is constant only if a single molecular species is distributed between two immiscible phases. Therefore, partitioning can be considered as classical thermodynamics in an equilibrium process. Pharmacologists became interested in the partition coefficient following the work of Meyer (2) and Overton (3), who first showed the parallel relationship between the nonspecific narcotic activity of drugs and their oil–water partition coeffients. In biochemical and pharmacological systems, the partition coefficient is an extrathermodynamic property and is a useful parameter for hydrophobic interactions with macromolecules, membranes, enzymes, and drug receptors.

BACKGROUND

There has been a recent rapid development in correlation studies of molecular structure with biological activity based on a model that utilizes the partition coefficient of the active compound in a reference partition system as a major parameter in the correlation equation. Hansch and coworkers (4–9) successfully used the linear free energy approach to establish quantitative structure–activity relationships for many biological systems. Lien and coworkers (10–18) studied the quantitative structure–activity relationships of various derivatives of drugs having a high correlation of biological activity with lipophilicity. The linear free energy relationship approach still has limitations due to the nonadditivity of the partition coefficients of some organic compounds (19, 20).

Among the many solvent systems studied, 1-octanol–water has been used most for quantitative structure–activity relationship studies (21, 22). The possible intermolecular interactions of solute molecules have not been studied systematically. Purcell *et al.* (23) stated that the behavior of aliphatic acids can be complex but can be controlled by proper buffering. Several investigators (24–26) recently used phosphate buffer systems in which the ionic strength was adjusted by inorganic compounds (*i.e.*, sodium chloride, potassium chloride, *etc.*); the pKa values of the drug were determined using the Debye–Hückel equation. This factor then was used to calculate the degree of ionization (α) in the measurement of the partition coefficient.

Ballard (27), who has done extensive work in this field, recently studied the carbonic acid system. He suggested that the pKa value of carbonic acid is a mixed constant involving the pKa of carbonic acid, the hydration of carbon dioxide in solution to form carbonic acid, and the activity and degree of dissociation of bicarbonate ion. He concluded that the thermodynamic pKa value of carbonic acid probably is not as affected by pH as is pKa′. However, both pKa and pKa′ are affected by temperature.

Other investigators (27–31) used phosphate buffers without adjusting the ionic strength. Rouot *et al.* (32) used a combined buffer system such as 0.067 M KH_2PO_4 mixed with 0.067 M Na_2HPO_4, while Moore and Koreeda (33) used citric acid (pH 1.8) and sodium bicarbonate (pH 9.0) in addition to phosphate buffer (pH 7.00). Marco *et al.* (34) used a pH 7.4 tris(hydroxymethyl)aminomethane hydrochloride buffer system. The pKa′ values were ignored in all of these investigations.

Each buffer species has its optimum pH range. It is questionable whether only one buffer can be utilized for a wide range of pH values. Moser *et al.* (35) suggested that the measurement of the partition coefficient of many weak acids is valid only within a pH range of about three units above the pKa. Above this range, they showed that such effects as ion-pair extraction of some species with buffer counterions can cause extreme deviations from the straight line described by the log P *versus* pH plot.

Dearden and George (36) criticized the assumption that the ionized fractions of an ionizable drug are insoluble in the lipid phases. It generally is assumed that the partition coefficient of the unionized species may be measured from the experimental apparent distribution coefficient at a pH giving a significant degree of ionization and the pKa of the solute. However, when octanol is saturated with water, the small amount of water in the octanol layer may be expected to dissolve some ionized species. It was concluded that differences in log P values between unionized and ionized species decreased steadily as log P was increased due to ion-pair formation with buffer counterions (36). Thus, the extraction of such ion-pairs into the nonaqueous phase should be related directly to the lipophilicity of the drug. The buffer system still retains a certain complexity when it comes to the measurement of the partition coefficient of a drug. There are some advantages in using a particular buffer system since it may increase the solubility of a drug, keep the pH of the medium constant, and/or retain the neutral form of the drug to avoid intermolecular interaction.

In measuring the partition coefficient, the ratio of the concentrations of the solute in two immiscible solvents is determined after equilibrium is reached. Mathematically, it may be defined as $C_{organic}/C_{aqueous}$. The 1-octanol–water system is a system of two immiscible solvents that has been used extensively. In the Pomona College data bank, Hansch and coworkers collected several thousand compounds for which the partition coefficients were measured in 1-octanol–water. Therefore, 1-octanol–water is the most frequently used system for comparative correlation studies. In addition, many diverse immiscible systems have been employed to avoid hydrogen bonding, solubility problems, *etc.* These systems have parallel relationships with the 1-octanol–water system and with each other. Examples of other organic solvents are chloroform, heptane, cyclohexane, butanol, and oil.

In the measurement of the partition coefficient of a drug, one considers the species that distributes to the binary phases, a water-saturated organic solvent phase and an organic solvent-saturated water phase; the partition coefficient should not be mistaken as arising from a system composed of simply one pure solvent phase and one pure water phase. The true (corrected) partition coefficient, P_{corr}, should characterize the transfer of only an undissociated molecular species. It generally is assumed that the true or corrected partition coefficient of a drug is independent of the pH and the buffer species used. In other words, one can use different buffer systems and a given organic solvent (*e.g.*, 1-octanol) in measuring the partition coefficient of an acidic or basic drug as long

0022-3549/80/0600-0662$01.00/0
© 1980, American Pharmaceutical Association

as one considers the degree of ionization. The true partition coefficient of the undissociated form then is obtained from $P_{corr} = P_{app}/(1 - \alpha)$, where α is the degree of ionization. The α value can be readily calculated from $\alpha = 1/[1 + \text{antilog (pKa} - \text{pH)}]$ for acids and $\alpha = 1/[1 + \text{antilog (pH} - \text{pKa)}]$ for bases; these expressions are obtained from buffer equations.

The validity of the assumption that only the pH of the buffer system will affect the apparent partition coefficient, but not the pH of the buffer species, has been questioned but has never been proven or disproven. The major objectives of this study were to explore whether this assumption is valid and to ascertain how the results obtained may affect quantitative structure–activity relationship studies.

EXPERIMENTAL[1]

pKa Values—The pKa values of the drugs studied were obtained from the literature (38, 39). The pKa values of several drugs were estimated from homologs or analogs (Table I).

Purification of 1-Octanol—Recent grade 1-octanol was purified by shaking with 1 *N* NaOH, shaking with 1 *N* H_2SO_4, shaking with 5% $NaHCO_3$, drying with excess anhydrous magnesium sulfate, and fractional distillation with collection of the fraction at the boiling range of 192–194° (23, 40). The purified solvent did not show any UV-absorbing contaminant.

Buffer Preparation—Buffer systems such as acetate, phosphate, tris(hydroxymethyl)aminomethane, and bicarbonate were prepared as stock solutions according to a literature procedure (41) and then were diluted to 0.01 *M*. The pH values were adjusted by adding 0.1 *N* HCl or NaOH and were checked with a digital pH meter[2]. Each buffer was within the appropriate pH range for its own optimum buffer capacity.

The acetate buffer pH was adjusted to 4.00. Both the phosphate buffer and the tris(hydroxymethyl)aminomethane buffer were adjusted to pH 7.40. The pH value of the bicarbonate buffer was 9.20. The pH value of the deionized, distilled water was 6.90 ± 0.05. The pH value always changed when acidic or basic drugs were dissolved in water saturated with 1-octanol, so the final pH value of the water layer was measured after partitioning.

Determination of Apparent and True (or Corrected) Partition Coefficients—The drugs were partitioned between 1-octanol saturated with buffer (or distilled water) and the same aqueous phase saturated with 1-octanol. In most cases, a 1:1 (v/v) ratio (*i.e.*, 25 ml:25 ml) of 1-octanol to buffer (or water) was used. The drug was dissolved first in the aqueous phase and then equilibrated with gentle shaking for 3–4 hr at room temperature (25 ± 1°) followed by centrifugation for 30 min. A standard curve was obtained from six or eight points of the drug solution by the UV or visible spectrophotometric method[3] to give an absorbance of 0.2–0.9 in a 3-ml cell. The concentration of the sample in the aqueous phase after equilibrium and separation was determined from the absorbance and the standard curve. The absorbance of the sample was adjusted to 0.2–0.9 by dilution.

The apparent partition coefficient was calculated from $P_{app} = C_{1\text{-octanol}}/C_{aqueous}$. Each determination was done at least in quadruplicate using different amounts of the sample, and the mean and standard deviation were determined ($SD \leq 0.03$). Values with a deviation of >0.03 were remeasured. The true or corrected partition coefficient (log P_{corr} value) was calculated from $P_{corr} = P_{app}/(1 - \alpha)$, where α is the degree of drug ionization at the given pH. The problem of the low solubility of benzoic acid, hydrocortisone, and 5-methyl-5-phenylhydantoin was circumvented by using <2% absolute methanol.

Regression Analysis—For the regression analysis, a least-squares program was used to derive the equations listed in Table II and run on a computer through a remote terminal[4].

RESULTS AND DISCUSSION

The apparent and corrected partition coefficients of various drugs measured in this study are summarized in Tables I, III, and IV.

Bonner and Woolsey (42) showed that different solutes and temperature may affect the structure of water (*i.e.*, the percentage of unbonded water molecules and the number of water molecules on different solutes), which undoubtedly affects the solubility of a drug in the aqueous phase and the organic–aqueous partition coefficient. The buffer and water may form a complex structure, and since the buffer has a counterion function (ion-pair function), it may affect the physicochemical properties of the drug. The pH value of distilled water changes by ~2.5 when a certain amount of acidic drug is dissolved in the water layer. Therefore, after partitioning, the final pH value of the water layer has to be determined by a pH meter. Equations correlating the log P_{corr} values obtained from different systems with those from 1-octanol–water are summarized in Tables II and V and Figs. 1–3.

In Table II, according to the slopes and intercepts in the equations, acidic, basic, and neutral drugs should not be grouped together in a single equation in most cases. The correlation coefficients and standard deviations of separate equations are much better than those of the composite equation (compare Eqs. 1–3 with Eqs. 5–7, 8–10, and 11–13). Several basic drugs such as propanolol and labetalol were not soluble enough in an alkaline pH (9.2). Hence, the partition coefficients could not be determined by the conventional methodology; consequently, Eq. 7 has only six data points. For a basic drug with Eqs. 5, 6, and 7, the slopes are 0.870, 0.421, and 0.496, respectively; they are all less then one, and the intercepts are −1.253, 1.143, and 1.137, which do not approach zero. If the slope of an equation is approximately one and the intercept approaches zero, it may be interpreted that the ratio of the true partition coefficient of the drug in octanol–water and in octanol–buffer is 1:1. In this case, the true partition coefficient, which was measured in octanol–buffer, is equivalent to that obtained in octanol–water. These values could be utilized in quantitative structure–activity relationship studies without correction.

It may be seen from Eqs. 5–7 that no 1:1 ratio exists between the three systems examined. Equation 5 has a higher slope and a lower intercept compared to Eqs. 6 and 7. It is suggested that the acetate buffer interacts with the protonated form of basic drug molecules and increases their lipophilicity. On the other hand, phosphate buffer and bicarbonate buffer attract basic drug molecules in the aqueous layer. For acidic drugs, according to the slope (0.984) and the intercept (0.081) from Eq. 9, the measured partition coefficients of acidic drugs in phosphate buffer as well as in octanol–water can be combined in the quantitative structure–activity relationship work. The partition coefficient of the acidic drug measured in acetate buffer or in bicarbonate buffer must be corrected with the necessary equations before extrapolation to octanol–water.

For neutral drugs, the slopes of Eqs. 11, 12, and 13 are 0.988, 0.992, and 0.997, respectively, all of which are very close to one, and the intercepts are −0.020, −0.045, and −0.025, respectively, which are nearly zero. The measured partition coefficients of neutral drugs in any of the three buffer systems will give similar results to the octanol–water system. The slope of Eq. 4 is 0.985, which is close to unity, and the intercept is 0.015, which approaches zero. Therefore, the partitioning behavior of the drugs analyzed in octanol–tris(hydroxymethyl)aminomethane is the same as in octanol–phosphate.

The ability of counterions in different buffers to affect the mechanism of intermolecular or intramolecular bonding forces in the partitioning behavior presents a complex problem. In the measurement of the partition coefficients of drugs, many different solvent systems have been used to ensure proper solubility of the drug. Equations for various organic solvent systems were published by Hansch and Leo (21, 22). It is proposed that the equations obtained from this study, as outlined in Table II, be used to correct for different buffer systems. These equations should be important in quantitative structure–activity relationship studies since no previous systematic study with different buffers has been reported.

Salicylic acid may be used to illustrate the complex phenomenon of molecular interaction in partitioning. According to the Debye–Hückel equation (43), the errors in the measurement of the partition coefficient of salicylic acid and phenformin might be attributed to the difference between pKa and pKa′ due to the ionic strength of the electrolytes.

[1] Phenolsulfonphthalein, 1-octanol (reagent grade), and salicylic acid were purchased from Fisher Scientific Co. Atropine sulfate and hydrocortisone were purchased from Sigma Chemical Co. Benzoic acid was purchased from Pfizer, Inc. 3,5-Diamino-1,2,4-triazole was purchased from Aldrich Chemical Co. Thiosemicarbazide was purchased from Eastman Organic Chemicals. Phthalimide potassium was purchased from Matheson, Coleman & Bell. Theobromine and ephedrine hydrochloride were purchased from Merck & Co. Thiourea and sulfanilamide were purchased from Mallinckrodt Chemical Works. Procainamide hydrochloride was purchased from Pfaltz & Bauer. Sulfadiazine sodium was purchased from City Chemical Corp. Diphenhydramine, propranolol, labetalol, atenolol, metoprolol, and methapyrilene hydrochloride were kindly provided by Dr. S. H. Wan, School of Pharmacy, University of Southern California. 5-Methyl-5-phenylhydantoin was kindly provided by Dr. J. Cohen, School of Pharmacy, University of Southern California. Trimethylene thiourea, *N,N′*-diethylethylene thiourea, butylene thiourea, and ethylene thiourea were synthesized by Lien (37).

N,N′-Trimethylene thiourea	—	1.00	−0.68	−0.68 ± 0.02
N,N′-Diethylethylene thiourea	—	1.00	1.13	1.13 ± 0.01

Therefore, pKa′ is introduced to correct for the ionic strength of electrolytes according to:

$$pKa' = pKa + \frac{0.51(2Z-1)\sqrt{\mu}}{1+\sqrt{\mu}}$$

where μ is the ionic strength of the electrolytes. In this study, the concentration of the buffer solution was 0.01 *M*. The second term in the equation contributed to the increase in the pKa′ value by ~0.05. However, the corrected value of α was not altered substantially. The value of pKa′ did not affect log P_{corr} of the drug in this study. The salicylic acid was dissolved in water, which resulted in a pH change of the solution from 6.8 to 4.33. According to $\alpha = 1/[1 + \text{antilog}(pKa - pH)]$, α is 0.9744. Therefore, it may be assumed that most of the drug molecules have ionized and subsequently are concentrated in the aqueous layer. This effect

Table V—Intercorrelation between log P_{corr} in Octanol–Water and log P_{corr} in Octanol–Buffer

			log P (octanol–water) = a log P (octanol–buffer) + b	
			a	b
Drug	Buffer	pH	(slope)	(intercept)
Basic	Acetate	4.0	0.870	−1.253
	Phosphate	7.4	0.421	1.143
	Bicarbonate	9.2	0.496	1.137
Acidic	Acetate	4.0	1.156	−0.217
	Phosphate	7.4	0.984	0.081
	Bicarbonate	9.2	0.895	−0.304
Neutral	Acetate	4.0	0.988	−0.020
	Phosphate	7.4	0.992	−0.045
	Bicarbonate	9.2	0.997	−0.025

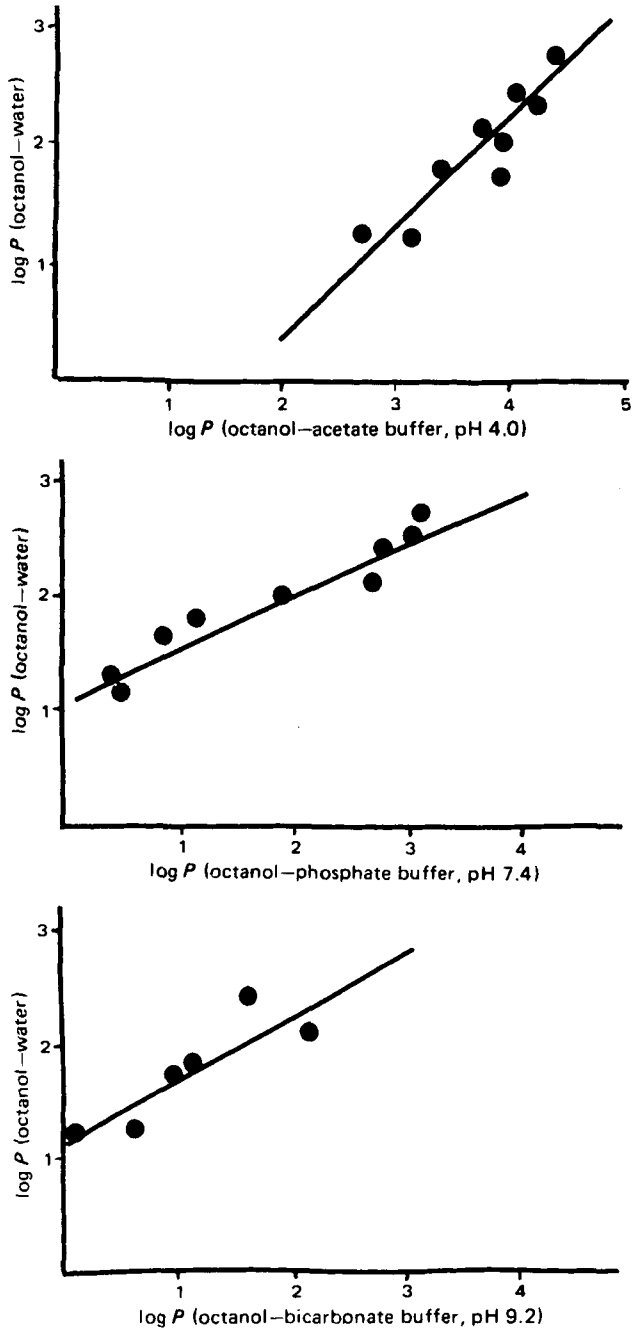

Figure 1—*Linear relationships between the corrected (true) partition coefficient in 1-octanol–water and that in 1-octanol–buffer for basic drugs.*

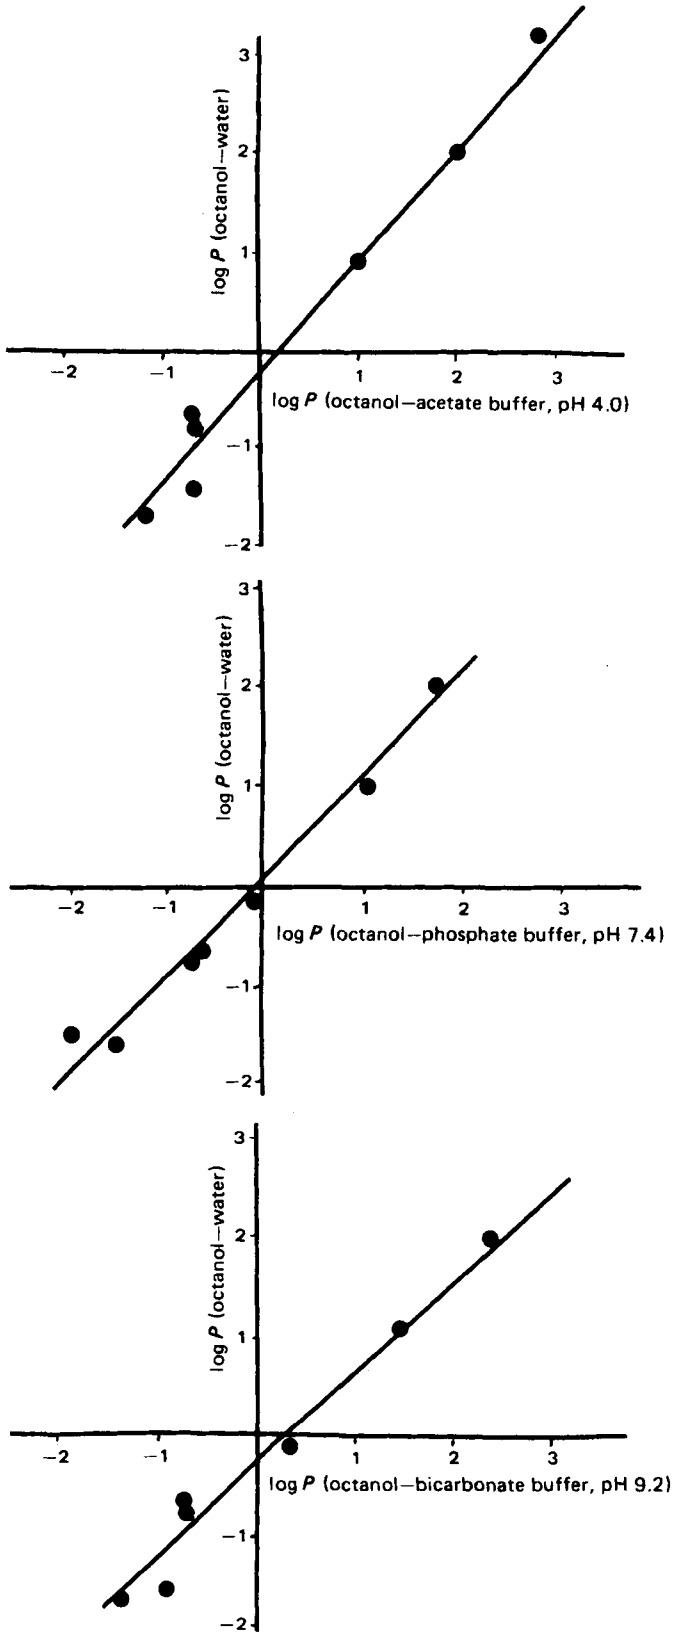

Figure 2—*Linear relationships between the corrected (true) partition coefficient in 1-octanol–water and that in 1-octanol–buffer for acidic drugs.*

would result in a very low value for the apparent partition coefficient. Consequently, the $1 - \alpha$ value is very small. A small error in $1 - \alpha$ will result in a large difference in log P_{corr}. If one utilizes π constants or fragment constants, f (44, 45), to calculate log P_{corr} of salicylic acid, the value appears to be much lower than that obtained in Table I. It appears

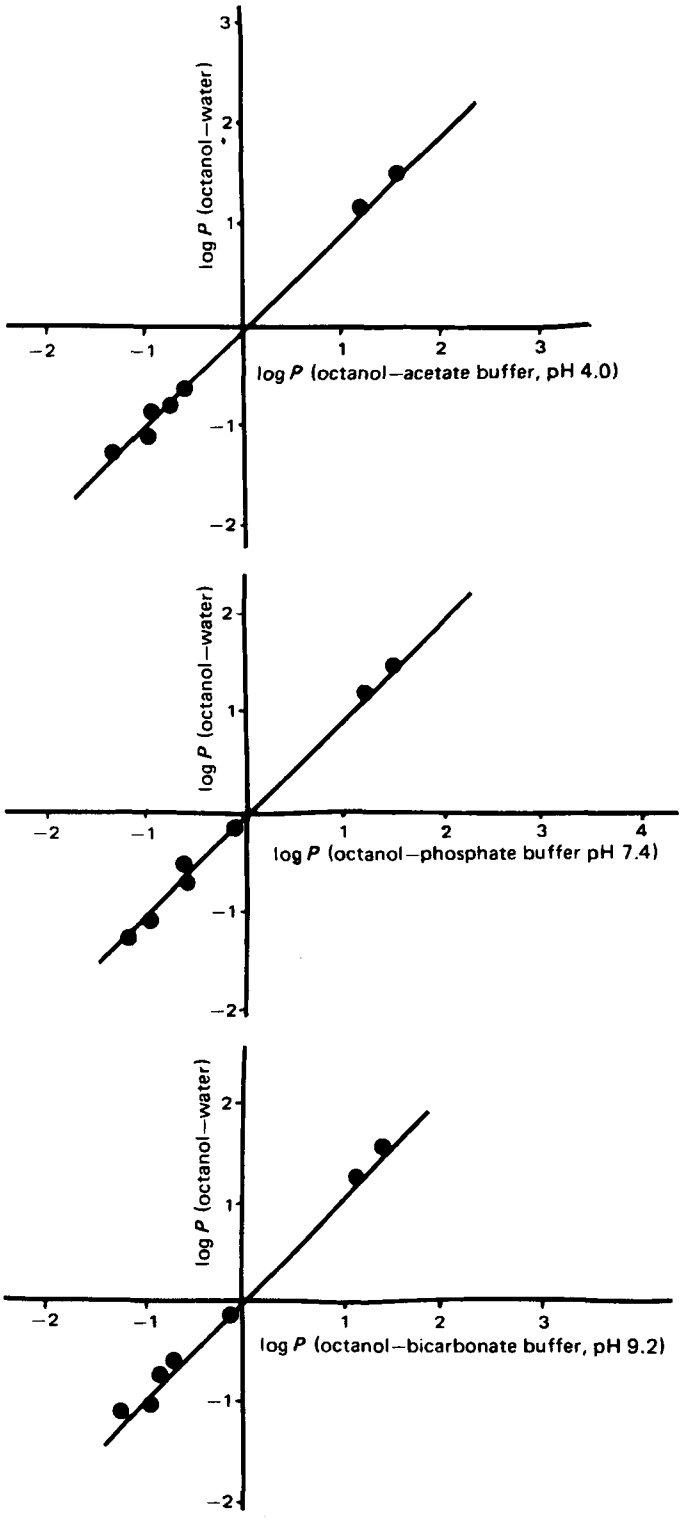

Figure 3—*Linear relationships between the corrected (true) partition coefficient in 1-octanol–water and that in 1-octanol–buffer for neutral drugs.*

to be an outlier on the statistical line. This result may be attributed to entrapment of the ionized species by the small amount of the buffer solution dissolved in the octanol phase. Phenformin, a basic drug highly ionized at low pH, presents the same problem. Consequently, both of these outliers were deleted from the appropriate equations.

Both water and buffer species have their own intrinsic capacity, which may affect the partitioning behavior of the drug. A comparison of acetate buffer, tris(hydroxymethyl)aminomethane buffer, phosphate buffer, and bicarbonate buffer reveals that the phosphate buffer is similar to water, according to Eqs. 6, 9, and 12. All of these equations have high correlation coefficients. It may be concluded that phosphate buffer (pH 7.4) is appropriate to keep the constant pH in the measurement of the partition coefficient of neutral and acidic drugs as long as they are soluble enough in the system.

CONCLUSION

These findings have significant bearing on quantitative structure–activity relationship studies; *i.e.*, the true partition coefficients (log P_{corr}) of acidic and basic drugs obtained from different buffer systems may not be suitable for regression analysis without correction. For acidic and neutral drugs, the phosphate buffer (pH 7.4) appears to give log P_{corr} values closer to those obtained from octanol–water than acetate and bicarbonate buffers. Therefore, the phosphate buffer system probably is the most suitable system for measuring true (or corrected) partition coefficients for quantitative structure–activity relationship work as long as the drug is soluble enough in this system. For basic drugs, any discrepancies must be corrected when different buffer systems are used in the measurement of partition coefficients.

Effect of Polybasic Acids on Structure of Aluminum Hydroxycarbonate Gel

MING K. WANG *, JOE L. WHITE *, and STANLEY L. HEM ‡x

Received September 24, 1979, from the **Department of Agronomy and the* ‡*Department of Industrial and Physical Pharmacy, Purdue University, West Lafayette, IN 47907.* Accepted for publication January 11, 1980.

Abstract □ The effect of oxalic acid, citric acid, and their sodium salts on the structure of aluminum hydroxycarbonate gel was studied to illustrate the various mechanisms by which polybasic acids interact with aluminum hydroxycarbonate gel. Analysis of changes in the pH-stat titrigram, the carbonate to aluminum ratio, the aluminum content of the supernate following centrifugation, and the adsorption of the organic solute indicates that polybasic acids may: (*a*) partially neutralize the aluminum hydroxycarbonate gel by a general acid effect, (*b*) modify the aluminum hydroxycarbonate surface by adsorption of the anionic form of the polybasic acid, (*c*) extract aluminum by the formation of a soluble complex, and (*d*) lead to the precipitation of a new crystalline phase.

Keyphrases □ Polybasic acids—oxalic acid, citric acid, and their sodium salts, effect on aluminum hydroxycarbonate gel structure, complexation of polybasic acids with aluminum, adsorption of polybasic anion, acid neutralization □ Complexation—polybasic acids and their sodium salts with aluminum hydroxycarbonate gel, acid neutralization, structural changes in aluminum hydroxycarbonate gel □ Acid neutralization—complex formation with polybasic acids and aluminum hydroxycarbonate gel □ Aluminum hydroxycarbonate—complexation with polybasic acids and their sodium salts, structural changes, acid neutralization

Citric acid, oxalic acid, and other polybasic acids can inhibit the crystallization of aluminum hydroxide and form complexes with aluminum (1–3). Gibaldi and Mufson (4) found that the neutralization of dried aluminum hydroxide gel was inhibited when sodium citrate or sodium tartrate was added to the 0.1 *N* HCl used as the reaction medium. It was concluded that dried aluminum hydroxide gel reacts with sodium citrate or sodium tartrate to produce a water-soluble complex as well as to reduce surface area by flocculation.

Polybasic acids are important in soil-weathering reactions due to their role in complexing and solubilizing aluminum (5, 6). In addition, it was found that the edge faces of gibbsite (7), as well as synthetic goethite (8), can adsorb oxalate anion.

The nature of the interaction of polybasic acids with the surface of aluminum hydroxycarbonate has not been examined in detail. This study describes the mechanisms by which polybasic acids interact with aluminum hydroxycarbonate and the effect of these interactions on the acid reactivity of aluminum hydroxycarbonate gel.

EXPERIMENTAL

An aluminum hydroxycarbonate gel that exhibited a moderate rate of acid neutralization was selected so that any increase or decrease in the acid neutralization rate would be observed easily. The gel was amorphous to X-rays and had an IR spectrum characteristic of aluminum hydroxycarbonate gel (9).

Mixtures containing 0.2 *M* equivalent aluminum oxide and either 0.1 or 0.2 *M* polybasic acid or salt were prepared by dissolving the polybasic acid or salt in water and adding the solution to an appropriate quantity of aluminum hydroxycarbonate gel with mixing.

The acid neutralization reaction was monitored by an automated pH-stat titration at pH 3.0 and 25° (10).

The carbonate content was determined by gasometric displacement using the Chittick apparatus[1] (11) and is expressed as the molar ratio of carbonate to aluminum.

The aluminum content of the supernate was determined by centrifuging at 15,000 rpm (27,000×*g*) for 30 min and measuring the aluminum content of the supernate by atomic absorption spectroscopy. The result represents the aluminum-ion content as well as the aluminum content of hydroxyaluminum polymers that remain in the supernate after centrifugation. The aluminum content of the supernate depended on the conditions of centrifugation, and all results reported were obtained under carefully standardized conditions.

The distribution of the organic solute was monitored by analyzing both the supernate and the solid phase for organic carbon content by the Walkley–Black method (12). In every case, the sum of the organic carbon in solution and in the solid phase was 82–101% of the theoretical carbon content.

The solid phase that formed when 0.2 *M* citric acid was added to the aluminum hydroxycarbonate gel was analyzed by X-ray diffraction[2] and IR spectroscopy. A sample of the solid phase was vacuum dried over phosphorus pentoxide and ground to a fine powder with an agate mortar

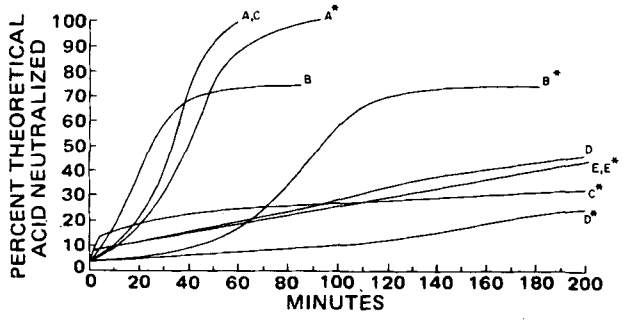

Figure 1—*The pH-stat titrigrams at pH 3.0 and 25° for aluminum hydroxycarbonate gel equivalent to 0.2 M Al_2O_3 with 0.1 M polybasic acids. Key: A, control; B, oxalic acid; C, sodium oxalate; D, citric acid; E, sodium citrate; and *, aged at 40° for 2 weeks.*

and pestle. Powder mounts for X-ray diffraction were prepared using McCreery mounts. The diffraction pattern was recorded from 6 to 55° 2θ under the following conditions: CuK_γ radiation, 40 kv, 20 mamp, 500 cps full scale, and 2°/min scan speed. IR spectra[3] were obtained by pressing a disk containing 0.5 mg of the dried powder with 300 mg of potassium bromide.

RESULTS

Figure 1 shows the pH-stat titrigrams of aluminum hydroxycarbonate gel immediately following the addition of 0.1 *M* oxalic acid, citric acid, sodium oxalate, or sodium citrate and after aging for 2 weeks at 40°. As expected, the acid neutralization rate decreased slightly during aging of the control aluminum hydroxycarbonate gel (Fig. 1A).

Oxalic acid (Fig. 1B) caused an initial decrease in the total amount of neutralized acid that was related directly to the oxalic acid concentration. In addition, a more rapid acid neutralization rate was observed immediately following oxalic acid addition. However, the acid neutralization rate decreased much more rapidly with aging (Fig. 1B*) than did the rate for the control aluminum hydroxycarbonate gel.

Sodium oxalate initially did not affect the pH-stat titrigram (Fig. 1C). However, a totally different acid neutralization profile was observed upon aging; it was characterized by a two-phase titrigram in which ~15% of the acid was neutralized immediately and the major portion followed a slow, zero-order reaction (Fig. 1C*).

The addition of citric acid substantially decreased the acid neutralization rate (Fig. 1D), which decreased further upon aging (Fig. 1D*). However, the pH-stat titrigram still shows evidence of the three-phase titrigram that characterized aluminum hydroxycarbonate gel (9).

The addition of sodium citrate resulted in a slow, two-phase neutralization reaction, which did not change during aging (Fig. 1E).

The polybasic acids caused a decrease in pH accompanied by a decrease in the carbonate to aluminum ratio (Table I). This effect also was observed when 0.1 *M* HCl was added to the aluminum hydroxycarbonate gel. The carbonate to aluminum ratio was not affected by the addition of sodium oxalate or sodium citrate.

Oxalic acid caused an initial increase in the aluminum content of the supernate, which decreased slowly during aging. Citric acid initially produced a high level of aluminum in the supernate, which dropped significantly during aging. The addition of 0.2 *M* citric acid converted the liquid gel into a solid within 30 min of mixing. Hydrochloric acid increased the aluminum content in the supernate, which increased further upon aging.

Sodium oxalate caused a small increase in the aluminum content of the supernate, which did not change during aging. A substantial increase in the aluminum content of the supernate occurred following the addition of sodium citrate, with approximately half of the aluminum in the gel solubilized by the addition of 0.2 *M* sodium citrate.

The adsorption of the polybasic acid or its salt was measured by determining the carbon content of the supernate and the solid phase (Table I). Approximately 40% of the added oxalic acid was in solution immediately following the addition of oxalic acid. The oxalic acid concentration in solution slowly decreased during aging. Sodium oxalate showed the same pattern, except that higher levels of oxalate ion were found in solution.

[a] Sample obtained from Pfaltz and Bauer, Stamford, Conn., was amorphous to X-rays. [b] Data from A.S.T.M. Card 15-985. [c] Data from A.S.T.M. Card 16-1170.

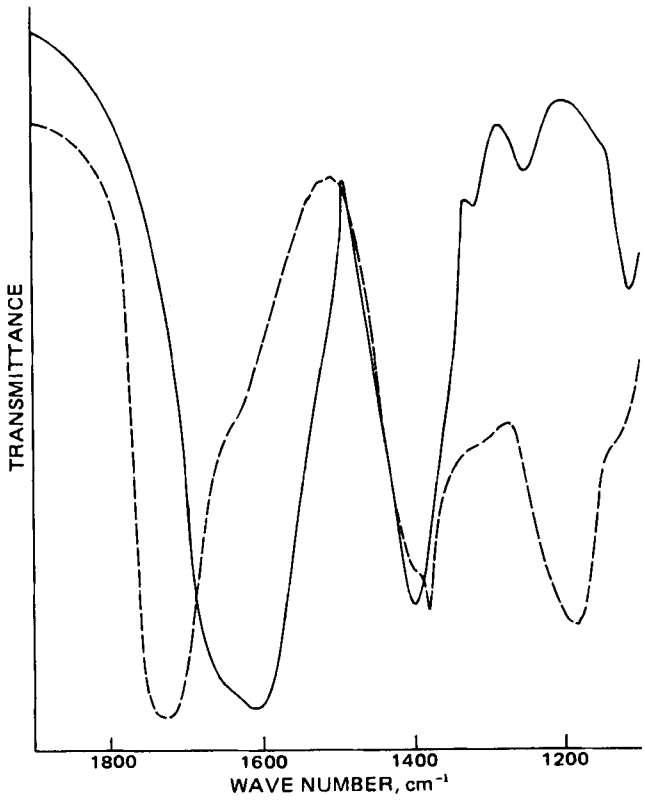

Figure 2—*IR spectra of citric acid (- -) and the solid phase that formed from a mixture of 0.2* M *citric acid and aluminum hydroxycarbonate gel equivalent to 0.2* M Al_2O_3 *(—).*

A high citric acid level was seen in solution initially but dropped sharply during aging. Most of the added sodium citrate was present in solution both initially and during aging.

The X-ray diffractogram and IR spectrum of the solid that formed upon the addition of 0.2 *M* citric acid are shown in Table II and Fig. 2, respectively. The appearance of a new phase is indicated by the peaks in the X-ray diffractogram, which differ from that of citric acid, sodium citrate, or aluminum citrate. The reaction of citric acid with aluminum to form citrate anion in the new phase was confirmed by the shift of the carbonyl stretching band of citric acid at 1730 cm^{-1} to an unresolved doublet with maxima at 1615 and 1640 cm^{-1}.

DISCUSSION

Polybasic acids and their salts cause significant changes in the structure of aluminum hydroxycarbonate gel that affect both acid reactivity and stability, and several mechanisms may be responsible for these changes.

Oxalic acid appears to act by a general acid effect, which causes partial neutralization of the aluminum hydroxycarbonate gel. This effect is suggested by the decrease in the total amount of acid neutralized, the loss of carbonate from the gel structure, and the increased aluminum content of the supernate.

The increased acid neutralization rate following the addition of oxalic acid agrees with the previous observation (13) that the reaction of structural carbonate with acid disrupts the gel structure and increases the porosity. This effect facilitates diffusion of acid into the gel and leads to an accelerated acid neutralization rate. However, the gel is expected to polymerize more rapidly upon aging in the absence of structural carbonate. This behavior was confirmed by the large decrease in the acid neutralization rate upon aging (Fig. 1B*).

Adsorption of the oxalate anion produced in the neutralization reaction of oxalic acid and aluminum hydroxycarbonate gel may occur, as suggested by the decreased concentration of organic carbon in solution. Evidence for the adsorption of oxalate anion also was seen when sodium oxalate was added to the aluminum hydroxycarbonate gel. No immediate effect was observed on the pH-stat titrigram, but the slow, constant rate of acid neutralization observed after aging (Fig. 1C*) suggests that oxalate anion is adsorbed by the aluminum hydroxycarbonate surface and that the acid neutralization rate is controlled by the diffusion of protons through the adsorbed oxalate layer to the aluminum hydroxycarbonate gel surface.

The carbonate to aluminum ratio was not affected by sodium oxalate. However, the amount of oxalate anion in solution decreased during aging, and only a relatively small increase in the aluminum content of the supernate was observed. This behavior supports the proposed surface adsorption mechanism.

The addition of sodium citrate to aluminum hydroxycarbonate gel also produced a pH-stat titrigram consisting primarily of a slow, zero-order acid neutralization reaction, which did not change during aging.

It is hypothesized that citrate anion is adsorbed by the aluminum hydroxycarbonate surface, producing the same type of diffusion-controlled acid neutralization as was seen in the aged sodium oxalate sample.

Adsorption of citrate anion occurs immediately in contrast to oxalate anion. The increase in the aluminum content of the supernate to ~60% following aging of the 0.2 *M* sodium citrate sample and the high levels of citrate anion in solution suggest that, following citrate anion adsorption, aluminum is extracted from the aluminum hydroxycarbonate through the formation of a soluble complex.

Citric acid caused the greatest decrease in the acid neutralization rate. After aging for 2 weeks at 40°, only 30% of the theoretical amount of acid was neutralized in 200 min (Fig. 1D*).

The decrease in the carbonate to aluminum ratio and the high initial aluminum content of the supernate suggest that citric acid acts by a general acid effect to neutralize partially the aluminum hydroxycarbonate gel. However, the mechanism by which citric acid affects the gel structure appears to be more complex than that observed for oxalic acid.

The sharp decrease in both aluminum in the supernate and organic carbon in solution during aging suggests the precipitation of a new phase containing aluminum and citrate. When 0.2 *M* citric acid was added, the aluminum hydroxycarbonate gel turned solid within 30 min. The structure of the solid phase that formed is not known; the new phase contained citrate anion, but the X-ray diffractogram differed from that for sodium or aluminum citrate.

Although the crystalline phase was not identified, its formation rate is dependent on the citric acid concentration. The crystalline phase does not exhibit acid neutralization properties when measured by pH-stat titration at pH 3, and its formation destroys the antacid properties of aluminum hydroxycarbonate gel.

Deiodination Kinetics of Water-Soluble Radiopaques

YU-CHANG JOHN WANG

Received July 29, 1979, from *Pharmaceutical R & D, Squibb Institute for Medical Research, New Brunswick, NJ 08903.* Accepted for publication January 16, 1980.

Abstract □ Deiodination of diatrizoic acid, an anionic radiopaque, was found to be catalyzed by Cu(II). Through a detailed study of *o*-iodobenzoic acid, a model compound, the copper-catalyzed S_N1 mechanism was established based on observations of common ion, salt, and pH effects. *Meta*- and *para*-iodobenzoic acids were unreactive. Deiodination thus was facilitated by a neighboring carboxylate that attracted copper. Iopamidol, a nonionic radiopaque, also underwent deiodination. At pH 7 or above, the hydroxide-ion substitution predominated. At pH below 7, the reaction is in favor of the copper-catalyzed S_N1 mechanism.

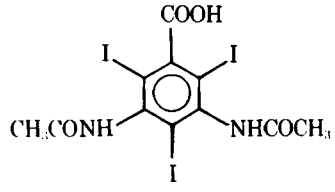
Keyphrases □ Diatrizoic acid—radiopaque, deiodination kinetics □ *o*-Iodobenzoic acid—deiodination, metal-catalyzed S_N1 mechanism □ Iopamidol—radiopaque, deiodination mechanism □ Kinetics—aromatic S_N1 deiodination of radiopaques □ Radiopaques—diatrizoic acid and iopamidol, deiodination kinetics □ Metal catalysis—neighboring carboxylate deiodination

The most important radiopaques are the water-soluble, anionic compounds such as diatrizoic acid (I), iothalamic acid, and iodipamide. These compounds are benzoic acid derivatives with two or three iodines attached to the benzene ring. There appears to be no evidence in the literature that appreciable deiodination occurs in products containing any of these compounds (1). However, experiments in these laboratories showed that significant deiodination took place in the absence of chelating agents.

Since the mechanism of this reaction was not established, this paper will discuss the deiodination kinetics of diatrizoic acid as a representative of anionic radiopaques. A model compound, *o*-iodobenzoic acid, was studied to support the proposed mechanism. A new nonionic radiopaque, iopamidol (II) (2), also was examined, and its deiodination kinetics were compared with those of diatrizoic acid.

EXPERIMENTAL

Materials—Diatrizoic acid[1], iopamidol[2], 8-hydroxyquinoline[3], and



I

m- and *p*-iodobenzoic acids[3] were used without further purification; *o*-iodobenzoic acid[3] was recrystallized twice from ethanol–water. All other chemicals were reagent grade. The water used complied with the USP specifications for purified water.

Deiodination of Diatrizoic Acid—Diatrizoic acid was dissolved in water with a stoichiometric amount of sodium hydroxide. Sørensen phosphate buffer (3) was added to bring the final phosphate concentration to 0.0067 *M*. The chelating agent employed was edetate disodium USP at 0.04% (w/v). The amount of iodide produced after stressed conditions was determined by the USP method (4), which specifies the measurement of the absorbance of iodine in a toluene extract at 495 nm[4] after the iodide has been oxidized to iodine. The concentration was calculated from a standard curve obtained from potassium iodide solutions. Similar to the USP specification, the amount of iodide found was expressed as the percentage of the weight of iodide with respect to the weight of radiopaque in the same solution.

Kinetic Studies for *o*-Iodobenzoic Acid—*o*-Iodobenzoic acid was dissolved in water with a stoichiometric amount of sodium hydroxide. Sørensen phosphate buffer at 0.0067 *M* and cupric sulfate at 0.5 ppm of Cu(II) were used unless stated otherwise. Solutions were immersed in a constant-temperature (±0.1°) oil bath[5], and samples were removed periodically for UV assay. Absorbances of the samples at 295 nm were used

Table I—Production of Iodide from Diatrizoic Acid Solutions [a] at Various pH Values

pH	Iodide Found[b], % [c]
7.8	0.371
7.4	0.388
7.0	0.333
6.6	0.227
6.2	0.150

[a] Solutions contained 20% (w/v) diatrizoic acid and 0.0067 *M* Sørensen phosphate buffer and were assayed after autoclaving at 120° for 30 min. [b] Unautoclaved samples and samples containing 0.04% (w/v) edetate disodium autoclaved at 120° for 30 min showed undetectable amounts of iodide (<0.0001%). [c] The weight percent of iodide with respect to the weight of diatrizoic acid in the same solution.

to calculate the amount of salicylic acid produced in the reaction. The residual amount of *o*-iodobenzoic acid, employed in the semilogarithmic plot, was obtained by subtracting the concentration of salicylic acid produced from the initial concentration of *o*-iodobenzoic acid. The reaction rates were calculated graphically from the initial slopes.

In one experiment, deiodination was followed simultaneously by three assay methods: the iodine assay, which was the same as for diatrizoic acid; the colorimetric assay, which measures the violet color produced by salicylic acid in the presence of ferric chloride; and the UV assay.

In another experiment, samples were analyzed by high-pressure liquid chromatography (HPLC) to identify the degradants produced in the kinetic study. The column was prepacked with reversed-phase Partisil ODS-2[6]. The mobile phase was methanol–water–phosphoric acid (48:52:0.04). The UV detector[7] was operated at 240 nm. The flow rate[8] was 2 ml/min, and the volume of the injector[9] loop was 20 μl.

Deiodination of *o*-, *m*-, and *p*-Iodobenzoic Acids—Solutions of these compounds at 0.5 *M* were prepared by the addition of a stoichiometric amount of sodium hydroxide, 0.0067 *M* phosphate buffer, and 0.04 m*M* of Cu(II). After autoclave sterilization, the iodide content in these solutions was determined by the method described for diatrizoic acid.

Deiodination of Iopamidol—The reaction kinetics were followed by monitoring the iodide content. The solution pH values were maintained by 0.0067 *M* Sørensen phosphate buffer, and the iodide concentration was assayed by the procedure described for diatrizoic acid solutions.

Since the iodide ion produced by deiodination was much less than 1% of the iopamidol, a typical equation for first-order kinetics can be simplified (5) through approximation in an infinite series:

$$k_0 = \frac{1}{t}\log_e \frac{[\text{iopamidol}]}{[\text{iopamidol}] - [I_t]} = \left(\frac{1}{t}\right)\frac{[I_t]}{[\text{iopamidol}]} \qquad \text{(Eq. 1)}$$

RESULTS AND DISCUSSION

Deiodination of Diatrizoic Acid—To examine the effect of chelating agents, 20% diatrizoic acid solutions at various pH values were autoclaved at 120° for 30 min. Table I shows the production of the iodide content in solutions without a chelating agent. The iodide content, although small, exceeded the USP limit of 0.02%. Under the same conditions, preparations containing edetate disodium (0.04%) yielded undetectable amounts of iodide (<0.0001%). Therefore, it was concluded that in solutions without edetate, the trace amounts of heavy metals catalyzed the liberation of iodine from diatrizoic acid.

A spectrochemical analysis of water from the same source revealed a heavy metal content at the parts-per-billion level: Fe, 16; Cu, 9; Pb, 3; Ni, 1.4; and Zn, 37. The 0.0067 *M* phosphate buffer may contribute ~6 ppb or less of heavy metals. Since the USP limit for heavy metals for radiopaque compounds is 20 ppm, the majority of the heavy metal in the diatrizoic acid solution probably comes from the bulk compound; therefore, a heavy metal concentration in the parts-per-million range results.

To identify the metal responsible for catalysis, solutions of low metal content were obtained by extracting the same 20% diatrizoic acid solution at pH 7 with chloroform containing 0.1% 8-hydroxyquinoline. This solution was subdivided and spiked with 1 ppm each of Cu(II), Fe(III), and Fe(II) as the sulfate salt, Co(II), Zn(II), and Ag(I) as the nitrate salt, or Pb(II) as lead acetate. After autoclaving for 30 min, only the solution

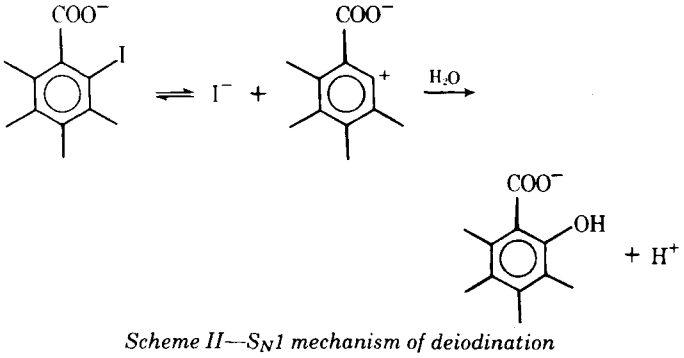
[a] For Cu(II), 1 ppm is equivalent to 0.015 m*M*. [b] All solutions included 0.0067 *M* Sørensen phosphate buffer and a stoichiometric amount of sodium hydroxide. [c] The standard deviation of k_0 for Experiments 1–12 is 0.00577.



Scheme II—S_N1 mechanism of deiodination

spiked with Cu(II) yielded a detectable iodide content. From these results, it is evident that Cu(II) catalyzed the deiodination of diatrizoic acid. By using a chelating agent such as edetate disodium, this reaction can be retarded.

To investigate the Cu(II)-catalyzed deiodination further, production of iodide in a diatrizoic acid solution was monitored as a function of time. Figure 1 shows the increasing iodide content as the solution was heated at 90°. By assuming that each diatrizoic acid molecule produces only one iodide ion, a semilogarithmic first-order plot (not shown) of the diatrizoic acid concentration *versus* time resulted in a significant curvature. To explain this deviation from first-order kinetics, the two possible mechanisms (6) for deiodination were examined.

The S_N2 Mechanism—At constant pH, the S_N2 mechanism (Scheme I) cannot explain the curvature observed in the first-order plot of diatrizoic acid. In addition, the deiodination of diatrizoic acid is independent of the pH between pH 6 and 8 (Table I), and that observation does not support a bimolecular reaction in which the hydroxide ion takes part in the rate-determining step.

The S_N1 Mechanism—The first step in the S_N1 mechanism (Scheme II), the rate-determining step, is the formation of carbonium ion. The iodide produced in the first step can inhibit further deiodination through the reversible reaction and thus accounts for the curvature observed in the semilog plot. In addition, this mechanism requires pH independence, which is consistent with the observed results. The aromatic S_N1 mechanism is well established for the dissociation of diazonium salts. However, for aromatic halides, even active ones, a unimolecular S_N1 mechanism has not been observed with certainty (7).

To obtain further support that an S_N1 mechanism is operative in deiodination, a simple model compound was studied because a diatrizoic acid contains other labile moieties such as anilide linkages that may perturb the reactivity of the molecule and complicate the mechanism. *o*-Iodobenzoic acid was selected for its structural similarity to radiopaque compounds in general. Furthermore, deiodination kinetics can be followed by a simple UV assay of its deiodination product, salicylic acid, rather than by the more time-consuming iodide assay.

Deiodination of *o*-Iodobenzoic Acid—At neutral pH, *o*-iodobenzoic acid hydrolyzes to yield equal moles of salicylic acid, iodide, and the hydronium ion. Typical UV spectral changes are illustrated in Fig. 2. In one experiment, the reaction was followed by UV, colorimetric, and iodine assays, and the consistent results verified that deiodination of *o*-iodobenzoic acid, within experimental errors, produced only salicylic acid and iodide. This fact also was supported by the HPLC evidence shown in Fig. 3, in which only iodide and salicylic acid could be identified on the chromatogram. Figure 3 also shows that salicylic acid was stable under the conditions of the kinetic study, with decarboxylation, in particular, not taking place.

A semilogarithmic plot of the *o*-iodobenzoic acid concentration *versus* time shows that a typical reaction initially is rectilinear and finally exhibits definite exponential decline (Fig. 4). The pseudo-first-order rate constants, k_0, were calculated graphically from the initial slopes from:

$$\log_e \frac{A_0}{A_t} = -k_0 t \qquad \text{(Eq. 2)}$$

where A_0 and A_t are the *o*-iodobenzoic acid concentrations at times zero and t, respectively. The time was measured in hours. Rate constants under various conditions are shown in Table II. In Experiments 1–3 and 5 in Table II, in which the initial concentration of *o*-iodobenzoic acid was varied, consistent rate constants further demonstrated that the reaction is first order with respect to the *o*-iodobenzoic acid concentration.

Since deiodination required Cu(II) as a catalyst, the reaction product, salicylic acid, might chelate copper, affect reaction rates, and thus cause a curvature in the semilog plot. Experiments 4 and 5 (Table II) showed that the reaction rate remained constant with excess salicylic acid. A Cu(II)–salicylate complex probably still is capable of catalyzing deiodination. The fact that deiodination is independent of pH between pH 6 and 8, as demonstrated with diatrizoic acid (Table I), also was shown by Experiments 5–8 (Table II).

The effect of the Cu(II) concentration was illustrated by Experiments 8–11 (Table II), which showed that the reaction seemed to be independent of the Cu(II) concentration between 0.25 and 5.08 ppm. Solutions spiked with Cu(II) in this concentration range resulted in essentially constant reaction rates. Without spiking, the reactions rates often were scattered, perhaps due to various amounts of Cu(II) introduced as impurities in water, buffer, or bulk compounds.

Addition of a small amount of potassium iodide greatly retarded deiodination. For the deiodination of *o*-iodobenzoic acid, iodide is the common ion. The magnitude of the common ion effect (8), α[10], can be

[10] The common ion effect can be used as strong evidence for a carbonium-ion intermediate. In deiodination reactions, the α value measures the relative reactivities of iodide and water to the carbonium ion. Generally, the more stable the intermediate carbonium is, the larger α is.

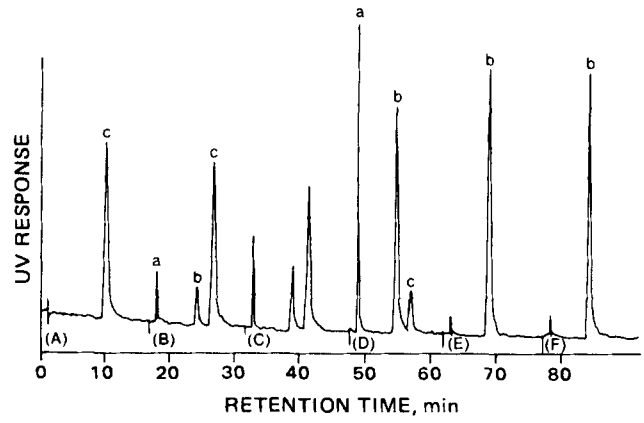


Figure 3—*High-pressure liquid chromatograms from kinetic studies of o-iodobenzoic acid (0.002 M) in pH 7 phosphate buffer and 4 ppm of Cu(II) at 90° for 0 hr (A), 1 hr (B), 2 hr (C), and 24 hr (D) and for salicylic acid under the same conditions for 0 hr (E) and 24 hr (F). Key: a, iodide; b, salicylic acid; and c, o-iodobenzoic acid.*

calculated from:

$$\alpha = \frac{1}{[I^-]}\left(\frac{k_0}{k_1} - 1\right) \qquad \text{(Eq. 3)}$$

where k_1 is the initial rate constant with an added iodide concentration of $[I^-]$ and k_0 is the rate constant at $[I^-] = 0$.

The α values for deiodination were 400 and 517 when the iodide concentrations were 1.2 and 2.4 mM, respectively. These values are on the same order of magnitude as the α values for the S_N1 hydrolysis of triphenylmethyl chloride (9). Such large α values for iodobenzoic acid lend strong support to the proposed S_N1 mechanism.

Addition of other halide ions, such as sodium bromide, did not affect reaction rates (Experiment 16). Increasing the ionic strength by adding large amounts of salt, such as potassium nitrate, enhanced deiodination (Experiment 17). These observations support an S_N1 mechanism. From an Arrhenius plot (Fig. 5) of the rate constants at five temperatures (Experiments 1 and 18–21), the heat of activation was calculated graphically to be 34 kcal/mole, which is comparable to many unimolecular S_N1 reactions (10).

Deiodination of *m*- and *p*-Iodobenzoic Acids—Apart from Cu(II) catalysis, deiodination is clearly of the S_N1 type for o-iodobenzoic acid. This reaction could be a unique instance of unimolecular aromatic substitutions in addition to the decomposition of diazonium ions. In the S_N1 mechanism, the neighboring carboxylate can function in either of two ways to facilitate the reaction. First, through electronic resonance effects, the negative carboxylate moiety could stabilize the formation of positive carbonium intermediates. If this were the case, *p*-iodobenzoic acid should undergo a reaction similar to o-iodobenzoic acid. Second, through a chelation effect, the carboxylate moiety could associate with copper ions, bringing them close to the reaction site and, perhaps, assisting the copper ion in polarizing the carbon–iodine bond. If this were the case, only o-iodobenzoic acid would be reactive and the *m*- and *p*-analogs would not be.

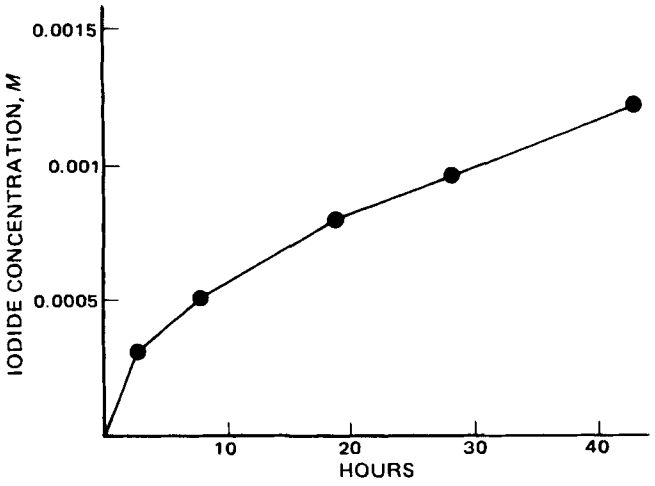

Figure 4—*First-order plot of deiodination of o-iodobenzoic acid.*

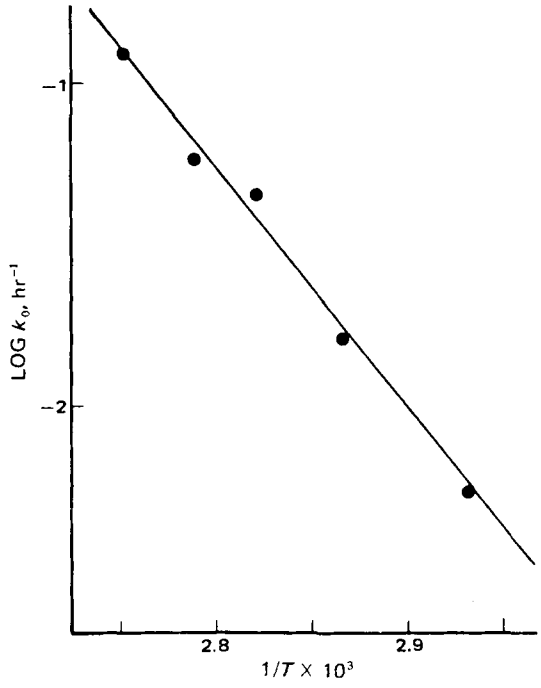

Figure 5—*Arrhenius plot of deiodination of o-iodobenzoic acid at pH 7.0 with Cu(II) catalysis.*

Table III demonstrates that *m*- and *p*-analogs of iodobenzoic acid produced almost negligible amounts of iodide. The reaction rates of *o*-iodobenzoic acid and diatrizoic acid were comparable. These results ruled out any possible effect from electronic resonance and favored the second alternative of copper complexation by the *ortho*-carboxylate. This result also indicated that the two iodines adjacent to carboxylate in diatrizoic acid are most vulnerable to deiodination.

Deiodination of Iopamidol—The anionic radiopaque benzoic acid derivatives were examined in the previous sections. However, the newly developed nonionic radiopaques, due to a lack of negatively charged carboxylate moieties, tend to undergo deiodination *via* other mechanisms.

Table III—Deiodination of Diatrizoic Acid and *o*-, *m*-, and *p*-Iodobenzoic Acids upon Autoclaving [a,b]

Compound	Iodide Produced, *M*
Diatrizoic acid	0.0397
o-Iodobenzoic acid	0.0452
m-Iodobenzoic acid	0.00001
p-Iodobenzoic acid	0.00003

[a] Solutions contained 0.5 *M* compound, 0.04 m*M* $CuSO_4$, and 0.0067 *M* Sørensen phosphate buffer to maintain the pH at 7.6. [b] Samples were subjected to 30 min of autoclave sterilization at 120°.

An understanding of deiodination of this class of compounds is beneficial.

Deiodination of iopamidol was found to be extremely slow. To study the mechanism, samples had to be subjected to more drastic conditions, *i.e.*, 90 min of 120° autoclave treatment. The production of iodide was plotted against the number of 90-min cycles (Fig. 6). In the range of ~0.01% or less, the iodide content could be considered rectilinear with respect to the number of cycles. The reaction rate can be calculated directly from the iodide content and reaction time. Figure 7 shows the semilogarithmic plot of the reaction rate constants at various pH values. In the absence of a chelating agent, thus probably causing the reaction to be catalyzed by copper, a plateau on the rate–pH profile suggests a predominant S_N1 mechanism that would be similar to the S_N1 mechanism already described.

In the presence of a chelating agent, such as edetate disodium, a unit slope on the pH–rate profile indicates that the reaction is dependent on the hydroxide-ion concentration and clearly suggests an S_N2 mechanism. The S_N2 mechanism becomes more important as the pH increases due to the increase of the hydroxide concentration. At pH values above 7.5, the S_N2 mechanism overshadows the S_N1 mechanism. The deiodination is predominantly a substitution of hydroxide ion and occurs regardless of the presence of a chelating agent.

The different behavior of diatrizoic acid and iopamidol can be summarized as follows. In diatrizoic acid, the carboxylate group promoted the S_N1 mechanism by drawing the copper ion closer to the reaction center or by stabilizing the carbonium charge. The S_N2 mechanism was completely inoperative because of the repulsion of hydroxide ion by the same negative charge. In iopamidol, the absence of carboxylate eased the attack by hydroxide ion, and thus the S_N2 mechanism was operable, although only in barely detectable rates. The Cu(II) ions catalyzed the deiodination of iopamidol; however, the S_N1 reaction was much slower than that of diatrizoic acid.

CONCLUSION

This investigation was undertaken to determine the deiodination mechanism of certain water-soluble radiopaques. For the benefit of formulating injectable radiopaques, deiodination was examined only at neutral pH values. Evidence has been presented to show that, in anionic radiopaques, deiodination proceeds by an S_N1 mechanism, which also requires the assistance of neighboring carboxylate groups and Cu(II) ion. By studying a model compound, *o*-iodobenzoic acid, the high magnitude of the common ion effect, salt effect, pH independency, and high activation energy, characteristics of an S_N1 reaction, were observed. In nonionic radiopaques, because of the absence of negatively charged carboxylate, deiodination is facilitated by hydroxide ion. With trace metal, S_N1 deiodination of a nonionic radiopaque remains operative, although at a much slower rate than an anionic radiopaque.

Solubility of Polar Organic Solutes in Nonaqueous Systems: Role of Specific Interactions

BRADLEY D. ANDERSON, J. HOWARD RYTTING ˣ, and TAKERU HIGUCHI

Received February 26, 1979, from the *Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66045.* Accepted for publication January 10, 1980.

Abstract □ The changes in solubility of several polar organic solutes when polar organic solvents are added to a relatively inert solvent such as isooctane were determined. The relative changes in solubility predicted from regular solution theory using solubility parameters often did not agree with the observed results. However, the solubilities could be rationalized mathematically by assuming the formation of specific solute–solvent complexes. Agreement of the thermodynamic data reported here with such models provides further evidence that specific interactions, when they occur, are more important than the bulk properties of the pure components in determining drug solubilities in nonaqueous systems. Specific examples demonstrate the relationship between the solubility and molecular structure of the solute and solvent. For example, solubility can be related to the hydrogen-donating and hydrogen-accepting abilities of the solute and solvent. Steric factors also appear to play a role in solubility, while structural modifications in a solute or solvent molecule far removed from the interactive functional group have little influence on molar solubility changes with the added polar cosolvent.

Keyphrases □ Solubility—polar organic solutes in nonaqueous systems, role of specific interactions □ Solute–solvent interactions—polar organic solutes in nonaqueous systems, role of specific interactions □ Solvents, nonaqueous—solubility of polar organic solutes, role of specific interactions

The solubility of a drug in a given solvent is an important property in pharmaceutical chemistry. Much work in drug design and drug product formulation stems from a need to achieve higher or lower solubilities to promote drug stability and bioavailability, to obtain controlled release rates, to avoid unpleasant side effects, and to optimize drug delivery to a target site. Consequently, the ability to predict drug solubility from molecular structure would be useful.

Current methods of solubility prediction often rely on the premise that the solubility of a solute in a given solvent is related simply to the bulk properties of the pure components. Such expressions as "polar solutes dissolve in polar solvents" or "like dissolves like" are based on this approach. This assumption also is the basis of a popular predictive method derived from regular solution theory, in which solubility is predicted from the solubility parameters of the pure components (1). Although this approach originally was intended strictly for systems involving only London dispersion forces, its use has been extended to include quite polar solution components in some cases (2, 3).

Recent studies indicated that the relative solubilities of polar solutes in both polar and nonpolar organic solvents often may be unrelated to the bulk properties of the pure components but are highly sensitive to the functional groups of the interacting molecules (4–9). One study suggested that specific intermolecular interactions, when they occur, often are the dominant factors in determining solubility, with corrections based on regular solution theory being unnecessary (4).

In the present study, the relative solubilities of several organic substances in various solvents or cosolvent mixtures were compared with predicted solubilities from regular solution theory and from a model assuming the existence of stoichiometric solvate species. The results indicate that the relative solubilities of polar substances in solvents that interact specifically with the solute are determined largely by these specific interactions.

EXPERIMENTAL

Reagents—Isooctane[1], with a stated purity of ≥99 mole %, was used without further purification. *n*-Butyl ether[2] was purified by slow shaking with an alkaline-saturated potassium permanganate solution followed by repeated washing with distilled water, concentrated sulfuric acid, and water. It was dried with calcium chloride overnight. This liquid then was distilled from sodium, and the middle fraction was collected and stored under nitrogen in an amber glass bottle.

n-Butyl ether[3], with a stated purity of 99%, was used without further purification. *n*-Pentyl ether[4] was treated similarly to *n*-butyl ether. *n*-Butyl *n*-butyrate[5] was shaken with 2 *N* NaOH, washed repeatedly with distilled water, dried over anhydrous magnesium sulfate, and then distilled under reduced pressure. The middle fraction was collected for use. Chloroform[6] was purified by washing with water to remove the ethanol preservative, dried over calcium chloride, and distilled. All solvents were stored over 4-Å molecular sieves[7] to remove possible trace amounts of water.

The solutes selected had relatively low isooctane solubilities and a minimum number of hydrogen donor or acceptor functional groups available for interaction with solvent molecules. Anthracene[3] had a claimed purity of 99.7% and was used without further purification. Anthraquinone[2], *p*-iodophenol[3], and *p*-nitrophenol[8] were recrystallized from chloroform–isooctane. Carbazole[3] and *p*-phenylphenol[3], with an indicated purity of 99+ and 97%, respectively, were recrystallized further from acetone–isooctane. 2,4,6-Triiodophenol[3] was recrystallized from methanol.

Solubility Determination—Solubilities of the solutes were determined in a series of solvents or cosolvent mixtures ranging from 100% isooctane to 100% ether, ester, or chloroform. Isooctane–interactive cosolvent mixtures were prepared by weight. Cosolvent molarities were calculated from the densities of the pure components. A series of vials was prepared, each containing an amount of solid well in excess of its estimated saturation solubility and ~5 ml of one of the described solvents or cosolvent mixtures. The vials were sealed[9] and brought to equilibrium by rotating in a constant-temperature bath at 25° for at least 2 days. Random duplicate samples were allowed to equilibrate for longer periods, but no significant differences in saturation solubility were observed.

The molar concentration of solute in solution was determined spectrophotometrically[10] by filtering[11] a portion of the solution and diluting a known aliquot as required. The filter assemblies, pipets, and other materials used in transferring the original sample were maintained at a temperature equal to the sample equilibration temperature prior to sampling. The solvent used as a diluent in the spectrophotometric de-

terminations was methanol or methanol containing 0.1 *N* HCl. While the nonphenolic compounds obeyed Beer's law in methanol, the phenols followed Beer's law more closely at low concentrations when the solvent was acidified.

RESULTS AND DISCUSSION

The molar solubilities determined in this study for various organic substances in several organic solvents are listed in Table I. Compounds expected to be strong hydrogen donors (phenols), weak hydrogen donors (chloroform and carbazole), and hydrogen acceptors (ethers, butyl butyrate, and anthraquinone) are included. Table II lists the molar solubility of carbazole in various interactive and inert solvents.

Comparison of Experimental Data with Regular Solution Theory Predictions—The term regular solution as proposed by Hildebrand in 1929 refers to solutions in which the entropy change is the same as for an ideal solution of the same composition but where the heat content increases with mixing (1). Regular solution theory gave rise to the now familiar solubility equation, expressed here in terms of the activity coefficient of the solute, γ_2:

$$\gamma_2 = \exp \frac{V_2\phi_1^2(\delta_1 - \delta_2)^2}{RT} \qquad \text{(Eq. 1)}$$

where δ_1 and δ_2 are the solubility parameters or cohesive energy densities [$\delta = (\Delta E/V)^{1/2}$] of the solute and solvent, respectively (12). Equation 1 involves an important assumption, the geometric mean rule, that frequently has been incorrectly taken for granted. In using solubility parameters, it is assumed that the energy of interaction of unlike molecules is given by the geometric mean of the interaction of like pairs ($\epsilon_{12} = [\epsilon_{11}\epsilon_{22}]^{1/2}$). This assumption is strictly true only for nonpolar molecules interacting *via* London dispersion forces (13). The geometric mean rule should not be presumed to be valid for either polar solutes or solvents.

The failure of simple one-component solubility parameter theory in systems of polar or interactive components has been recognized (14). However, since this approach still is widely used and recommended, several additional examples may illustrate the inadequacy of regular solution theory for predicting the solubilities of substances considered in this study.

The solubility parameters for various solvents are listed in Table II along with the molar solubility of carbazole in those solvents. The solubility parameter of carbazole is estimated as ~10, and its molar volume is ~150 cm^3. By comparing the solubility parameters of the hydrocarbon solvents in Table II, the solubility of carbazole predicted from regular solution theory should be five times higher in hexadecane and cyclohexane than in isooctane. The actual solubilities are relatively constant in these hydrocarbon solvents, which is intuitively satisfying considering the chemical similarity of these solvent molecules. Also, previous studies showed that the molar solubilities of several other polar solutes are relatively independent of the alkane reference solvent chosen (4, 5). Although molar volume corrections may be a factor, these errors apparently are compensated for by using molarity as the concentration unit. In addition, recent work suggested that even for systems involving components of markedly different molal volumes, the assumption of ideal entropy of mixing gives more satisfactory agreement with observed results than do theories considering molal volume differences (15).

From a comparison of solubility parameters in Table II, the solubility of carbazole in some hydrocarbon solvents should be roughly equal to or higher than its solubility in ethyl ether (δ = 7.4), butyl ether (δ = 7.5), pentyl ether (δ = 7.9), and butyl butyrate (δ = 8.0). However, the observed solubilities are 20–100 times higher in the hydrogen-accepting solvents than in the relatively inert alkane solvents, a result that cannot be accounted for by regular solution theory but is readily explainable from a consideration of the specific interactions occurring.

In general, one would predict from regular solution theory that, for all solutes in this study, the order of solubility should be chloroform > butyl butyrate > ethers ≃ hydrocarbons. These predictions obviously are not confirmed in Table II or by the relevant data for phenylphenol in Table I. Only for anthraquinone (and perhaps anthracene) is the solubility highest in chloroform, which also would be predicted from the knowledge that anthraquinone is a hydrogen acceptor and chloroform is a weak hydrogen donor.

In some instances, it may be possible to rationalize a particular change in solubility between two solvents using solubility parameters, even though the molecules involved would be expected to interact through hydrogen bonding. For example, the ratio of the solubility of anthraquinone in chloroform to its solubility in isooctane is 77 (using mole fractions) and is consistent with a solubility parameter of ~11.8, assuming

Table II—Molar Solubility of Carbazole at 25° in Several Solvents with Various Solubility Parameters (δ)

a molar volume of 150 cm^3 for anthraquinone. A further test of this solubility parameter is to determine whether the theory can reliably predict solubilities between these two solvent extremes, that is, in mixed solvents. From regular solution theory, the solubility parameter of a mixed solvent is the weighted average (based on volume fractions) of the solubility parameters of the pure components (1):

$$\delta = \phi_1\delta_1 + \phi_2\delta_2 \qquad \text{(Eq. 2)}$$

With Eq. 2, the predicted solubility values for anthraquinone in chloroform–isooctane cosolvent mixtures can be represented by the dashed line in Fig. 1. In comparison to the experimental points, the predicted solubilities increase much too gradually at low chloroform concentrations, illustrating the failure of the solubility parameter approach to predict the shape of the solubility profile for this example.

The inadequacy of the simple one-component solubility parameter approach has led to many more or less empirical multicomponent solubility parameters to incorporate the effects of specific interactions (13, 16). Although such attempts generally lack a firm theoretical foundation, they demonstrate that specific interactions are of great importance in many cases.

Specific Interactions and Solubility—Much early criticism of the specific interaction theory was based on the difficulty in proving the existence of "species" from thermodynamic data alone (1). However, a wealth of spectroscopic data now documents the formation of stoichiometric species through hydrogen-bonding interactions. Abundant evidence, based on IR frequency shifts (17), ^{1}H-NMR data (18, 19), and ^{13}C-NMR studies (20), supports the existence of molecular complexes between various hydrogen donors [including phenols (21) and chloroform (22)] and hydrogen acceptors [even for such a weak hydrogen acceptor as benzene (23)].

It would be unreasonable to assume that hydrogen-bonding interactions are not an important contribution to the solubilities of interest in the present study, based on the available spectroscopic data. Additional features supporting the contention that specific interactions such as hydrogen bonding are reflected in the solubility data reported here will be discussed later.

Mathematical Treatment of Solubility Data in Terms of Solute–Solvent Species Formation—Typical diagrams of solubility *versus* molarity of the interactive cosolvent are shown in Figs. 2 and 3 for *p*-phenylphenol and carbazole in the presence of various complexing agents. A plot of the solubility of anthraquinone *versus* chloroform molarity was shown in Fig. 1. The solubility curves generally are parabolic. These curves can be fitted mathematically using a model that assumes solvate species formation.

Solubility in Unassociated Solvents—It is assumed that the following equilibria hold between the solute, S, and the complexing agents or interacting cosolvents, L:

$$S + L \rightleftharpoons SL \overset{+L}{\rightleftharpoons} SL_2 \overset{+L}{\rightleftharpoons} \ldots SL_n$$

Scheme I

Each reaction is defined by an equilibrium constant for formation of the complex:

$$K_{1:1} = \frac{[SL]}{[S_0][L_f]} \qquad \text{(Eq. 3)}$$

$$K_{1:n} = \frac{[SL_n]}{[SL_{n-1}][L_f]} \qquad \text{(Eq. 4)}$$

where the concentrations are expressed as molarities; S_0 is the saturation solubility of solute in isooctane, which is assumed to represent the free solute concentration in the cosolvent mixtures; and L_f is the free (uncomplexed) ligand. It also is assumed that a single solute molecule is present in each complex, but the mathematical form of the resulting equation is not changed by allowing more than one solute per complex. Throughout this discussion, it is assumed that the activity coefficients of all species are one where the standard state in every case is a 1 M solution of solute behaving as if it were completely surrounded by isooctane solvent. The total solubility of solute in any system can be expressed as:

$$S_T = [S_0] + K_{1:1}[S_0][L_f] + K_{1:2}K_{1:1}[S_0][L_f]^2 + \ldots \qquad \text{(Eq. 5)}$$

and L_T, the total complexing agent added, is:

$$L_T = [L_f] + K_{1:1}[S_0][L_f] + 2K_{1:2}K_{1:1}[S_0][L_f]^2 + \ldots \qquad \text{(Eq. 6)}$$

The total concentration of interactive cosolvent, L_T, is equal to L_f in the absence of solute. This relationship is true only when the extent of self-association of cosolvent is negligible, and it cannot be assumed for alcohol cosolvents.

As is evident from Eq. 5, the shape of the plots of solubility *versus* cosolvent added should be concave upward in unassociated solvents, in agreement with the data in Figs. 1–3.

Estimation of Equilibrium Constants—If S_0, the solubility of the solute in isooctane, is very low, the amount of ligand in complexes is small

[a] The $\sigma\%$ value is the square root of the sum of the squares of the percent deviation between the calculated and observed solubilities divided by the degrees of freedom. [b] Fit of data below 0.1 *M*. [c] Fit of data in 1:1 region only.

and $[L_T] \simeq [L_f]$. Also, at low concentrations of L, only 1:1 complexes are important, and a plot of the fractional change in solubility *versus* ligand added gives a straight line at low cosolvent concentrations with a slope of $K_{1:1}$:

$$\text{fractional change in solubility} = \frac{[S_T] - [S_0]}{[S_0]} = K_{1:1}[L_T] \qquad \text{(Eq. 7)}$$

Such plots are shown in Fig. 4 for several substances in butyl ether. At higher cosolvent molarities, two-parameter equations containing terms for 1:1 and 1:2 complexes were needed to describe the data adequately. Only two parameters were necessary to describe completely the entire solubility curve in all solvents except chloroform, where three parameters often were required (Table III).

Graphical methods are quite cumbersome when an appreciable amount of the added cosolvent exists in complexed form, because L_T then does not equal the free ligand concentration. Therefore, a computer program using the simplex method of least squares (24, 25) was written to solve Eqs. 5 and 6 simultaneously, optimizing the variables $K_{1:1}$, $K_{1:2}$, and $K_{1:3}$. The sum of squares of the percent deviation of the experimental solubilities from the calculated solubilities was minimized to give equal weight to each point. The computer-calculated complexation constants for those instances where specific interactions can reasonably be assumed are listed in Table III. Constants determined graphically (Fig. 4) usually were within 10% of the computer-optimized values.

Choices of Most Important Factors in Predicting Solubility—Nonaqueous systems of pharmaceutical interest generally involve polar solutes in polar, interactive solvents. Therefore, predictive relationships between solubility and one or more independent variables that express the interactive tendencies of the molecules involved would be valuable. It was shown in the preceding discussion that solubility parameters, which reflect bulk properties of the pure components, often are not related to the observed relative solubilities. However, specific solvation models can readily account for the solubility behavior.

By first determining the solubilities in an alkane solvent, an estimate of factors that are not related to specific interactions in solution is obtained. Differences in alkane solubilities largely reflect differences in solute crystalline energies, although dispersion interactions between the solute and solvent also may vary with molecular structure. In interactive solvents, the specific interaction component, which is of primary interest here, is reflected by the change in solubility from that in isooctane.

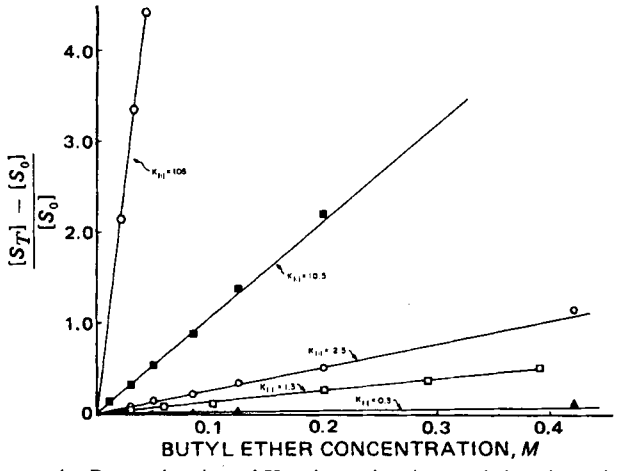

Figure 4—*Determination of* $K_{1:1}$ *from the slopes of the plots of the fractional change in solubility* versus *butyl ether molarity in isooctane at 25° (see Eq. 7). Key:* ○, p-*nitrophenol;* ■, p-*phenylphenol;* ○, *carbazole;* □, *2,4,6-triiodophenol; and* ▲, *anthracene.*

While the fact that these systems can be fit with solvation models does not prove conclusively that the solubility changes are due largely to specific interactions, the $K_{1:1}$ values obtained from the solubility data are consistent with what is expected from a consideration of the relative hydrogen-donating and hydrogen-accepting abilities of the respective molecules (8). A brief comparison of the solubility data in Table I provides a qualitative indication of the importance of hydrogen bonding in determining relative solubilities. The solubility of the strong hydrogen donor *p*-nitrophenol increases by almost 4000-fold in going from isooctane to the hydrogen-acceptor solvent butyl ether. The solubility of the weaker hydrogen donor carbazole increases by ~38 times in going from isooctane to butyl ether; anthracene, which has no donatable hydrogens, differs by a factor of only three in the two solvents.

These large differences cannot be accounted for by solubility parameters since the solubility parameter of butyl ether is quite similar to that of isooctane. However, they are quite consistent with specific interaction theory.

It also is instructive to compare the butyl ether–isooctane solubility ratios for *p*-nitro-, *p*-iodo-, and *p*-phenylphenols, which are 3850, 226, and 169, respectively. These phenols are listed in order of decreasing acidity and also decreasing hydrogen-donating ability based on literature data (8).

Empirical correlations of equilibrium data based on linear free energy relationships were applied previously in hydrogen-bonded systems (8, 26), usually taking the form of the Hammett equation (27, 28), $\log (K/K_0) = \rho\sigma$, where K and K_0 are the equilibrium constants of a substituted and an unsubstituted solute species, respectively; ρ reflects the sensitivity of the reaction to solute substituent changes; and σ represents the Hammett substituent constant. Higuchi *et al.* (8) derived a similar equation, $\log (K/K_0) = h_d h_a$, and calculated h_d and h_a values for donors and acceptors in nonpolar solvents, where h_d is a measure of the effect of change in the hydrogen donor on hydrogen bonding and h_a measures the influence of the acceptor on the interaction.

Figure 5 is a plot of $\log K_{1:1}$ derived from the solubility data of the *para*-substituted phenols in butyl ether *versus* the Hammett σ_p substituent constant obtained from the effect of these *para*-substituents on the ionization of benzoic acids in water[12] (29). Because the ionization

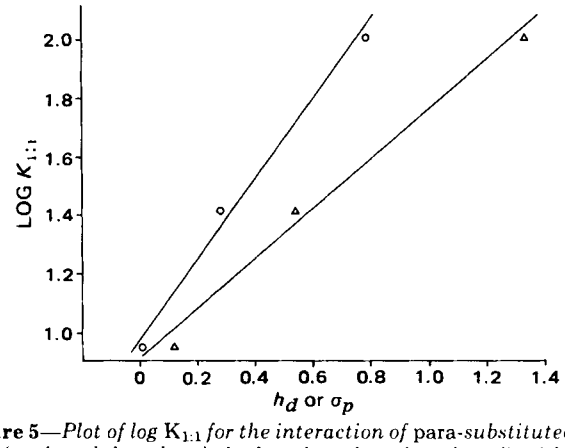

Figure 5—*Plot of log* $K_{1:1}$ *for the interaction of* para-*substituted phenols* (p-*phenylphenol,* p-*iodophenol, and* p-*nitrophenol) with butyl ether in isooctane at 25°* versus *the Hammett* σ_p *substituent* (●) *constant and* versus *Higuchi* h_d *values* (△).

[12] Resonance effects are less important in hydrogen bonding than in Brönsted acidity and basicity, so poor correlations of hydrogen bonding with acidity are obtained with σ^- values, which reflect the substituent effect on phenol ionization (14).

Table IV—Standard Free Energies of Transfer of Solute ($\Delta G°$) from Isooctane to Various Interactive Solvents and the Calculated Hydrogen-Bonding Contribution to the Free Energy from $K_{1:1}$ Values ($\Delta G°_{HB}$)

	$\Delta G°$[a]	$\Delta G°_{HB}$[a]	$\Delta G°$[a]	$\Delta G°_{HB}$[a]	$\Delta G°$[a]	$\Delta G°_{HB}$[a]	$\Delta G°$[a]	$\Delta G°_{HB}$[a]
p-Nitrophenol	−4.90	−3.6	—	—	—	—	—	—
p-Iodophenol	−3.2	−2.5	—	—	—	—	—	—
p-Phenylphenol	−3.0	−2.3	−2.7	−2.2	−3.7	−2.8	−2.6	−1.4
Carbazole	−2.1	−1.6	−1.9	−1.4	−2.9	−2.2	−2.4	−1.3
2,4,6-Triiodophenol	−1.8	−1.2	—	—	—	—	—	—
Anthraquinone	—	—	—	—	—	—	−3.0	−1.5

[a] Units are kilocalories per mole.

constants in nonpolar media have not been determined, a direct correlation with acidity under the same solvent conditions is impossible. Figure 5 also shows the plot of the same values of log $K_{1:1}$ *versus* Higuchi's h_d values (8), which were derived from both thermodynamic and spectroscopic data. This correlation clearly suggests that the $K_{1:1}$ values reflect hydrogen-bonding interactions.

Steric effects also come into play in solubility, as demonstrated by the relatively low $K_{1:1}$ and low solubility for 2,4,6-triiodophenol in butyl ether, a hydrogen-accepting solvent (Table III). This effect presumably is due to the steric hindrance to hydrogen bonding by the *ortho*-iodo groups.

While solubility is quite sensitive to the solute and solvent functional group composition, structural alterations that are not in the vicinity of an interacting functional group and do not alter the acidity or basicity of the functional group have little influence on solubility differences in organic solvents. For example, $K_{1:1}$ values for the interaction of carbazole with ethers varying in alkyl chain length are 3.53 M^{-1} for ethyl ether (5), 2.5 M^{-1} for butyl ether, and 1.9 M^{-1} for pentyl ether. Furthermore, $K_{1:1}$ for the interaction of *p*-phenylphenol with butyl ether is 8.9 M^{-1}; with pentyl ether, it is 8.3 M^{-1}. Solubilities in the pure ethers differ by a much larger amount (Table II), due in part to the greater concentration of ether oxygens in pure ethers of shorter chain length.

The $K_{1:2}$ values listed in Table III are very small and relatively insensitive to the molecular structure of the solute or solvent. These constants cannot justifiably be called specific interaction constants. The much smaller magnitudes of $K_{1:2}$ suggest that the 1:1 solute–solvent interactions are saturable, a characteristic of specific interactions. For instance, for the nitrophenol–butyl ether system, $K_{1:1}$ = 102.5 liters/mole and $K_{1:2}$ = 0.56 liter/mole. The strong hydrogen-bonding tendency between these two species does not carry over into the 1:2 interaction since the hydrogen-donating tendency of *p*-nitrophenol is "saturated" in forming the 1:1 complex.

If it is assumed that the $K_{1:1}$ values obtained in dilute solutions of the interactive cosolvents represent specific interactions, one can calculate the contribution of this specific interaction to the overall transfer free energy from isooctane to pure solvent (Table IV). This comparison ignores the likelihood that complexes larger than 1:1 may exist in the pure interactive solvent. For example, 1:2 complexes are expected to be quite important in chloroform solutions of anthraquinone since anthraquinone has two hydrogen-acceptor sites. Therefore, the specific interaction contributions to solubility expressed in Table IV probably are minimum estimates. However, nonspecific contributions to the $K_{1:1}$ values in dilute solution also may be a factor, particularly when the $K_{1:1}$ values are small.

In most cases, the specific interaction contribution to the overall free energy of transfer is the major factor, as is evident from Table IV. The differences may be composed of higher order molecular complexes or nonspecific effects, but these differences generally are small compared to the overall transfer free energy. Clearly, the specific interaction tendency should receive the greatest emphasis in attempts to predict solubility in similar systems.

CONCLUSION

It was shown that solubilities of polar organic substances in polar organic solvents can be rationalized quantitatively by assuming the formation of stoichiometric solvate species. Additional evidence also supports the contention that specific interactions are more important than bulk properties of the pure components in determining relative solubilities.

GLC Determination of Bretylium in Biological Fluids

CHII-MING LAI, BURDE L. KAMATH, JAMES E. CARTER, PAUL ERHARDT, ZEE M. LOOK, and AVRAHAM YACOBI ×

Received November 16, 1979, from the *Department of Pharmaceutical Development, Research and Development Department, Arnar-Stone Laboratories Inc., McGaw Park, IL 60085.* Accepted for publication January 9, 1980.

Abstract □ Bretylium [(*o*-bromobenzyl)ethyldimethylamine] is a quaternary ammonium compound used as the tosylate salt for treatment of ventricular fibrillation in humans. A sensitive assay was developed for the determination of low bretylium concentrations in plasma and urine. The internal standards were (*p*-bromobenzyl)ethyldimethylammonium *p*-toluenesulfonate and (*o*-methoxybenzyl)ethyldimethylammonium *p*-toluenesulfonate. Samples were deproteinized with acetonitrile and extracted with methylene chloride. After the evaporation of the organic phase, the residue was reacted with sodium 2,4,5,-trichlorothiophenolate in methanol. This procedure yielded volatile compounds with excellent electron-capture capabilities for the GLC analysis. The assay sensitivity is 5 ng/ml. The extraction recovery of bretylium as determined by a direct radioactivity measurement was 90 and 97% for plasma and urine, respectively. The method is highly reproducible with no significant day-to-day variations. Comparisons of 60 standard plasma samples, 25 standard urine samples, and plasma samples from a dog that received [^{14}C]bretylium showed excellent agreement between the GLC method and direct radioactivity measurement of bretylium.

Keyphrases □ Bretylium—determination in biological fluids by GLC and direct radioactivity measurement, humans □ GLC—analysis of bretylium in biological fluids, humans □ Radiochemistry—analysis of bretylium in biological fluids, compared to GLC determination, humans

Bretylium [(*o*-bromobenzyl)ethyldimethylamine] is a quaternary ammonium compound used as the tosylate salt for the treatment of ventricular fibrillation in humans (1, 2). Various methods for its determination have been reported (3–7). The most promising method is a GLC analysis (6) utilizing sodium thiophenolate to react with bretylium to produce *o*-bromobenzyl phenylthio ether. However, it is tedious and lacks sufficient sensitivity.

This paper reports a simplified and sensitive GLC method for the determination of bretylium in small plasma and urine samples. The new extraction procedure minimizes the variability in assay recovery and reproducibility. To validate this method, the results of the GLC method were compared with direct radioactivity measurement of [^{14}C]bretylium in standard samples as well as in samples collected from a dog that received the labeled drug.

EXPERIMENTAL

Materials and Methods—A stock solution of bretylium tosylate[1] (I) (10 mg/ml as a quaternary ammonium compound) was prepared in purified water. This solution was used to prepare standard plasma and urine samples containing 5–250 ng of bretylium/ml. The stock solutions of the internal standards, (*p*-bromobenzyl)ethyldimethylammonium *p*-toluenesulfonate[2] (II) and (*o*-methoxybenzyl)ethyldimethylammonium *p*-toluenesulfonate[2] (III) (each containing 1 μg/ml as the quaternary ammonium compound), were prepared in purified water. The glassware used in solution preparation and in the assay was washed with soap, soaked in 4 *N* HNO_3 for 24 hr, rinsed with purified water, and finally rinsed with methanol.

Sodium 2,4,5-trichlorothiophenolate (IV) was used as a reacting agent. It was synthesized by a method similar to that described previously for the preparation of sodium thiophenolate (6, 8). The reagent was only moderately hygroscopic and, when stored in a drying oven, was stable for at least 6 months.

Table I—Recovery of [^{14}C]Bretylium from Plasma and Urine

[^{14}C]Bretylium Added[a], ng/ml	Percent Recovery from Plasma[a]	Percent Recovery from Urine
4.75	90.8 (3.68)	
9.33	89.2 (1.03)	97.3
24.10	90.2 (1.23)	96.3
49.8	89.3 (1.56)	97.4
73.7	90.3 (1.30)	96.1
98.7	92.7 (1.07)	99.3
Mean	90.4 (1.66)	97.2
CV	1.41 —	1.17

[a] Mean of five determinations. The [^{14}C]bretylium concentration was determined by direct scintillation counting of each sample. The numbers in parentheses are the coefficients of variation in percent.

Assay—*Method I*—To 1 ml of plasma or urine was added 0.1 ml of the internal standard solution containing 100 ng of II and 1 ml of acetonitrile[3]. The sample was vortexed for 10 sec and centrifuged at 4000 rpm for 5 min. The supernate was transferred into a 155 × 13-mm polytef-lined screw-capped culture tube[4], extracted with 5 ml of methylene dichloride[5] by gentle shaking for 30 min, and centrifuged at 4000 rpm for 5 min. Five milliliters of the organic layer was evaporated to dryness in a new culture tube. The residue was dissolved in 3 ml of methanol containing 1.0 μg of IV and allowed to react and evaporate to dryness at 60° with vigorous shaking in a vacuum. The same reaction procedure was repeated twice using 1 ml of the substituted thiophenolate solution. The residue was reconstituted with 200 ml of methanol from which 2 μl was injected into the gas–liquid chromatograph.

Method II—To 0.25 ml of plasma or urine was added 0.1 ml of the internal standard solution containing 100 ng of III, 0.5 ml of 0.1 *N* NaCl solution, and 1 ml of acetonitrile. The sample was vortexed for 10 sec and centrifuged at 4000 rpm for 5 min. The supernate was transferred into a culture tube to which 0.2 ml of 1 *N* NaOH was added. The mixture was extracted with 5 ml of methylene dichloride by gentle shaking for 30 min and was centrifuged at 4000 rpm for 5 min. The samples then were treated as in Method I, except that they were reacted only once with 3 ml of methanolic solution containing 1.0 μg of IV.

GLC Procedure—Analysis was performed on a gas–liquid chromatograph[6] equipped with a 2.08-m × 4-mm i.d. silanized glass column (coiled) packed with 3% OV-225 on 100–120-mesh Supelcoport and a ^{63}Ni-electron-capture detector. The injection port, column, and detector temperatures were maintained isothermally at 270, 250, and 300°, respectively. Argon–methane (95:5 v/v) was used as the carrier gas at a flow rate of 50 ml/min (30 ml/min through the column, 20 ml/min directly to the detector as a scavenger gas).

Data acquisition was performed on a laboratory minicomputer[7]. The peak heights of the derivatized bretylium were divided by the peak heights of the derivatized internal standard, and the ratios were used to construct the standard curve and to determine its linearity.

Animal Study—One male beagle dog[8], 13.1 kg, received [^{14}C]bretylium tosylate[9] ([*benzyl*-7-^{14}C], 0.512 μCi/mg), 10 mg/kg iv. Food was withheld for 4 hr after drug administration. Blood samples (5 ml each) were drawn in heparinized vacutainers through the jugular vein at 4, 6, 8, 12, 16, 20, and 24 hr after dosing. The plasma samples were kept frozen until they

were assayed. Plasma samples were analyzed by direct counting of the radioactivity *via* a scintillation counter[10] and by the GLC method described under *Method II*.

RESULTS AND DISCUSSION

Bretylium, a quaternary ammonium compound, can be extracted from biological samples by an ion-pair extraction procedure, a complicated and tedious method described previously (6). In the present study, the use of acetonitrile as a deproteinization agent served to remove the proteins, to purify the biological sample, and to enhance the partitioning of bretylium into methylene dichloride, which was used as the extraction solvent. Although acetonitrile is fully miscible with the aqueous solution, it was almost completely partitioned in the organic layer. The recovery of [^{14}C]bretylium from plasma and urine was 90.4 and 97.2%, respectively (Table I). The coefficient of variation for five samples at each concentration (range 4.8–98.7 ng/ml) ranged from 1.0 to 3.7%. There was no correlation between the extraction recovery and plasma concentrations. This approach simplified the previous procedures for bretylium extraction from plasma and may be useful for extracting other quaternary amines from biological fluids.

To determine bretylium by GLC, Kuntzman *et al.* (6) used sodium thiophenolate, which reacts with the quaternary ammonium compound and yields a volatile derivative, *o*-bromobenzylphenylthio ether. The use of this reagent resulted in a sensitivity of ~70 ng/ml when a large volume (3 ml) of the sample was used. To improve this sensitivity, sodium

o-bromobenzyl 2,4,5-trichlorothiophenyl ether

Scheme I

thiophenolate was replaced by IV, which also readily reacts with bretylium and its congeners to produce derivatives extremely sensitive to electron-capture detection. Scheme I shows the derivative. Although the thiophenolate anion can attack at any of the four amine substituents by an S_N2 process, attack at the *o*-bromobenzyl group, as depicted, is preferred due to resonance stabilization of the reaction transition state (9).

In this study, two internal standards, II (Method I) and III (Method II), were used. Compound III reacts more readily with sodium thiophenolate and makes the assay less time consuming. Figure 1 shows typical chromatograms from the assay. The retention times of the phenylthio ether derivatives were 6.1, 7.4, and 9.4 min. Bretylium usually is given with other drugs that may interfere with the assay. To minimize such interference, one of the two internal standards may be selected, depending on the desired retention time.

Under the assay conditions, there were observable impurity peaks at retention times of 2.7 and 3.4 min that did not interfere with the drug or internal standard peak. As expected, qualitative and quantitative GLC showed that the corresponding primary, secondary, and tertiary amines of bretylium do not react with the thiophenolate and have very poor intrinsic electron-capturing ability. The GLC chromatograms showed symmetrical peaks for bretylium and the internal standards, and there were no indications of interference from those amines.

Figure 2 and Table II show the linearity, reproducibility, day-to-day variation, and recovery data of the assay. Table III lists the precision data of the GLC method for the determination of bretylium in plasma. The slopes of the plots of the peak height ratio of bretylium to that of the internal standard *versus* bretylium concentrations in the range of 5–250 ng/ml were 0.00409, 0.00476, and 0.00449 as determined on Days 1, 3, and 8, respectively (10). There was no statistically significant difference in the slopes, intercepts, and individual concentrations determined on two or three occasions during an 8-day period.

In this study, plasma and urine concentrations of 5 ng/ml were determined easily using a 0.25-ml sample. However, the sensitivity can be improved by simple modifications. The GLC assay was compared with a direct radioactivity measurement in 60 standard plasma samples and 25 standard urine samples (Table II). The correlation coefficients between the results of the two methods were 0.999 for plasma and 0.998 for urine samples. Similarly, plasma samples from a dog that received an intravenous dose of 10 mg of [^{14}C]bretylium tosylate/kg were assayed by both the GLC and the direct radioactivity measurement methods. Figure 3 shows the plasma bretylium concentration *versus* time profile. There was excellent correlation between the results of the two procedures, and there was no significant difference between the data (paired *t* test).

A series of standard plasma samples with concentrations ranging from 5 to 250 ng/ml was kept at ambient temperature for 4 days. The GLC determinations showed results of 102.2 ± 10.5% of the corresponding concentrations of controls that were kept frozen during the same period. These data indicate that bretylium is stable in plasma. This result also is consistent with data reported previously on bretylium stability (7).

The proposed procedure is sensitive and requires a single extraction step without any back-extraction or cleaning procedure. This method offers the distinct advantage of requiring very small biological samples. The choice of the internal standard depends on the individual case and drugs involved. Although both internal standards give essentially the same results, the use of the *o*-methoxy congener is less time consuming. This GLC method may be used in single-dose pharmacokinetic studies in humans and animals. It also may be applicable to quality control tests and drug compatibility studies. Other quaternary amines may be extracted and derivatized in a similar manner.

GLC–Mass Spectrometric Determination of Maprotiline and Its Major Metabolite Using Stable Isotope-Labeled Analog as Internal Standard

SATYA P. JINDAL ˣ, THERESA LUTZ, and PER VESTERGAARD

Received June 14, 1979, from the *Rockland Research Institute, Orangeburg, NY 10962.* Accepted for publication January 18, 1980.

Abstract □ A quantitative GLC–mass spectrometric assay was developed for the determination of maprotiline and its major metabolite, desmethylmaprotiline, in animal and human plasma. The assay utilizes selective-ion focusing to monitor, in a GLC effluent, the fragment ions and the base peaks of maprotiline and desmethylmaprotiline trifluoroacetamides generated by electron-impact ionization. Maprotiline-d_3 was the internal standard. The assay can measure 2 ng of maprotiline (and the metabolite)/ml of plasma with ~5% precision. The curves relating the amounts of maprotiline and the metabolite added *versus* the amounts experimentally found over a large concentration range were linear with nearly zero intercepts and slopes of 0.99 ± 0.01 and 0.98 ± 0.02, respectively. The method was used to study the pharmacokinetic pattern of the drug in rabbits as well as to analyze intact maprotiline and the metabolite in patients maintained on therapeutic doses of maprotiline. Assay specificity was confirmed by complete consistency of the mass spectra of maprotiline and desmethylmaprotiline with those of the authentic materials.

Keyphrases □ Maprotiline—GLC–mass spectrometric analysis, human and animal plasma □ Desmethylmaprotiline—GLC–mass spectrometric analysis, human and animal plasma □ GLC–mass spectrometry—stable isotope-labeled maprotiline, selected-ion monitoring, pharmacokinetics □ Antidepressants—maprotiline, GLC–mass spectrometric analysis, human and animal plasma

Maprotiline, 1-(3-methylaminopropyl)dibenzo[*b,e*]-bicyclo[2,2,2]octadiene[1,2], is a tetracyclic drug with sedative, antiaggressive, and antidepressant effects. In contrast to the tricyclic antidepressants, it has no influence on the central metabolism of 5-hydroxytryptamine and has weak anticholinergic actions (1). As an antidepressant, it has shown equal therapeutic efficacy but fewer side effects compared to tricyclic antidepressants (2–4); it also is less toxic (5, 6) and has less of an effect on the cardiovascular system (7, 8). Maprotiline has been used in Europe for the treatment of patients who had severe side effects with other antidepressants and for depressed patients with cardiovascular symptomatology. It is under evaluation for clinical use in the United States.

A precise and specific assay for maprotiline and its major metabolites in biological fluids and tissues is needed. Assays based on the double radioisotope derivative technique (9), electron-capture detection (10), and specific nitrogen detection (11) have been reported. This report describes a GLC–mass spectrometric assay for the intact drug and its major metabolite, desmethylmaprotiline, in the plasma of rabbits and humans.

GLC–mass spectrometry in the selected-ion monitoring (12–14) mode was used to quantitate plasma levels of the drug and its major metabolite, *N*-desmethylmaprotiline, in rabbits after maprotiline administration. The methodology also was applied to measure steady-state levels of the free drug and the metabolite in the plasma of patients on therapeutic doses. Stable isotope-labeled maprotiline, maprotiline-d_3 ([*N*-*methyl*-^{3}H]maprotiline), was synthesized and used as an internal standard for the estimation of both maprotiline and desmethylmaprotiline.

EXPERIMENTAL

Materials—Analytical grade maprotiline hydrochloride[1], desmethylmaprotiline methanesulfonate[2], trifluoroacetic anhydride[3], ethyl chloroformate[3], and lithium aluminum deuteride[4] were used without further purification. All solvents were analytical grade[5]. Silanized tubes[6] (10 ml) with screw caps[7] were used for extraction; final solvent evaporation was performed in 5-ml glass-stoppered centrifuge tubes[8]. Pasteur pipets with hand-drawn constricted tips were utilized for all solution transfers. Plasma samples were stored frozen at −10° until they were analyzed.

Maprotiline-d_3—Desmethylmaprotiline, upon treatment with ethyl chlorocarbonate, gave the corresponding carbonate (15) in a 78% yield. The carbonate was reduced with lithium aluminum deuteride in tetrahydrofuran to maprotiline-d_3 (16). The material showed satisfactory mass spectral (electron-impact ionization) characteristics. A selective-ion detection analysis of maprotiline-d_3 showed the presence of an ion equivalent to 99 ± 0.2% (n = 5) maprotiline-d_3.

Extraction from Plasma—To 1 ml of plasma was added an appropriate amount of maprotiline-d_3 (typically 70 ng/ml) as an internal standard. The plasma was diluted to 5 ml with borate buffer and sonicated for 0.5 min while keeping the temperature at ~6°. The homogenized material was adjusted to pH 9.5 with 0.1 *N* NH_4OH and extracted twice with 5 ml of benzene. The organic fractions were combined, 1 ml of 0.1 *N* HCl was added, and the solution was shaken for 15 min and centrifuged.

The organic layer was discarded, and the aqueous phase was adjusted to pH 9.5 with 1 *N* NH_4OH and extracted twice with 3 ml of benzene. The organic fractions were combined and dried, and the solvent was evaporated at 50° under a gentle nitrogen stream. Recovery of maprotiline and desmethylmaprotiline added to control plasma was studied at the 10-ng/ml level.

Formation of Derivatives—The dried extract was taken up in 100 μl of ethyl acetate, and 50 μl of trifluoroacetic anhydride was added. The material then was heated in an oil bath at 80° for 45 min. The solution was cooled to room temperature, and the solvents were evaporated at 40° under a gentle nitrogen stream. The dried extract was reconstituted in 50 μl of chloroform, and ~1 μl was injected into the gas–liquid chromograph–mass spectrometer for mass fragmentographic assay.

Instrumentation—The magnetic sector, single-focusing mass spectrometer[9] was interfaced with a gas chromatograph and equipped with a multiple-ion detector–peak matcher accessory (14, 17). GLC was performed on a 1.8-m × 2-mm i.d. glass column silanized with 5% dimethyldichlorosilane in toluene and packed with 1% OV-17 on 100–200-mesh Gas Chrom Q. The column was conditioned for 24 hr at 280° with a flow rate of 20 ml of helium/min. The column temperature was 225°, the flash heater was at 240°, the separator was at 250°, and the ion source was at 275°.

The accelerating voltage was 3.5 kv in the scan mode and 3.0 kv in the multiple-ion detection mode, the ionization potential was 70 ev, and the trap current was set at 60 μamp. The magnetic field was kept constant

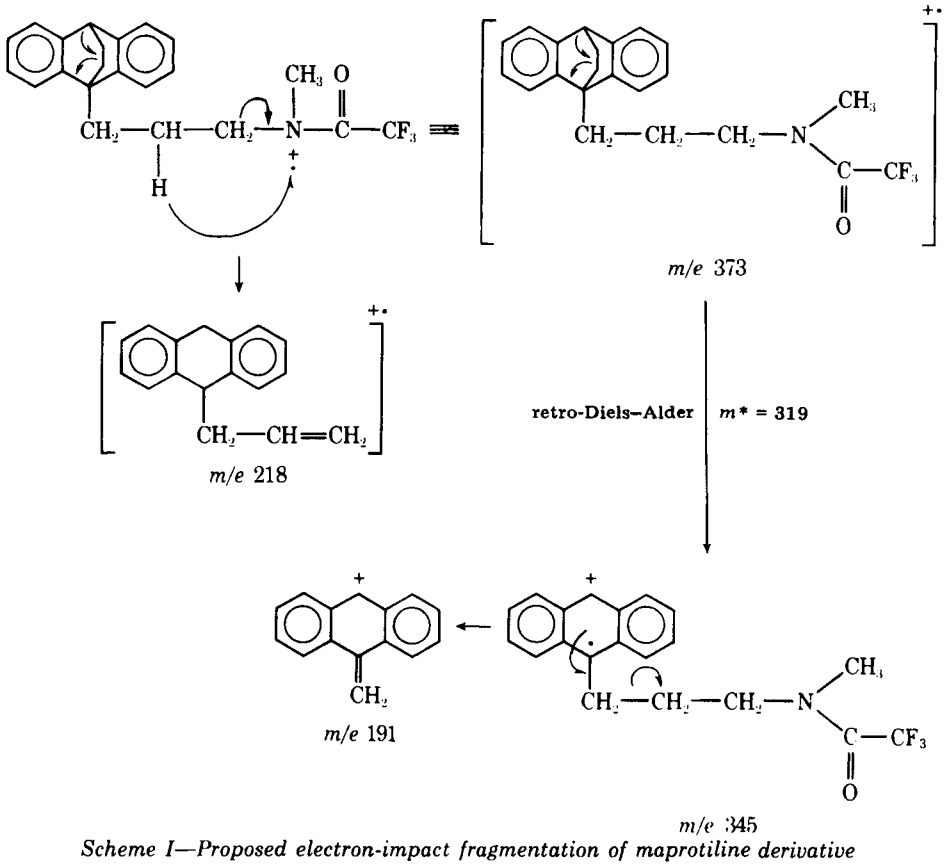

Scheme I—Proposed electron-impact fragmentation of maprotiline derivative

by focusing the background ion (column bleed) at *m/e* 355, and the additional voltages were 752, 600, and 569 v for measuring ion intensities at *m/e* 331, 345, and 348, respectively. The retention times of desmethylmaprotiline and maprotiline trifluoroacetamides were 2.0 and 3.0 min, respectively.

Experiments with Animals—Experiments were performed on rabbits to determine the time course of maprotiline and desmethylmaprotiline in plasma after the intravenous administration of varying drug doses. In a typical experiment, a 6-kg rabbit was given a single intravenous dose of 2.7 mg of maprotiline hydrochloride in water.

Blood samples were drawn and collected in heparinized tubes. The plasma was prepared as usual. An appropriate amount of the internal standard (typically 70 ng) was added to the plasma samples (1.0 ml), and the samples were processed as described. The amounts of endogenous maprotiline and desmethylmaprotiline were calculated from the ratio of ion intensities at *m/e* 345, 331, and 348, respectively.

Human Studies—Plasma of several patients on a normal therapeutic dose of maprotiline was analyzed for maprotiline and the metabolite. An appropriate amount of the internal standard was added to the plasma samples (0.25 ml), and the samples were processed as described. The amounts of endogenous maprotiline and desmethylmaprotiline were calculated from the ratio of ion intensities at *m/e* 345, 331, and 348, respectively.

RESULTS AND DISCUSSION

The mass spectrum of maprotiline trifluoroacetamide (Table I) shows a molecular ion at *m/e* 373, a base peak at *m/e* 345, an intense peak at *m/e* 191, and a peak of modest intensity at *m/e* 218. A reasonable mechanism for the fragmentation is presented in Scheme I. The molecular ion underwent a typical retro-Diels–Alder process (18, 19) to give a radical ion at *m/e* 345, the base peak. The driving force for this reaction must be the expulsion of a stable neutral ethylene molecule and the formation of an unusually stable radical ion at *m/e* 345. Since both the radical site and the cationic site are benzylic in this ion, obviously this very stable ion results in a base peak at *m/e* 345.

This interpretation is substantiated further by the presence of a metastable ion at *m/e* 319. The mass spectrum of maprotiline-d_3 trifluoroacetamide (Table I) confirms this interpretation, since in this case the molecular ion and the base peak, as expected, are shifted to a higher mass by 3 amu. The mass spectrum of desmethylmaprotiline trifluoroacetamide (Table I) shows a molecular ion at *m/e* 359, a base peak at *m/e* 331 as a result of a retro-Diels–Alder process, and a metastable ion at *m/e* 305. The ions at *m/e* 218 and 191 are the common fragment ions appearing in the spectra of maprotiline, maprotiline-d_3, and desmethylmaprotiline trifluoroacetamides.

GLC–Mass Spectrometric Quantitation—The ions at *m/e* 345 and 331 are specific for maprotiline and desmethylmaprotiline (*m/e* 348 for maprotiline-d_3) trifluoroacetamides and are not observed in the electron-impact ionization spectra of other tricyclic antidepressants (20, 21) and known metabolites of maprotiline (22). Consequently, the biological extract along with maprotiline-d_3 was treated with trifluoroacetic anhydride at 80°, the excess reagents were evaporated, and an aliquot of the reconstituted solution was injected into the gas–liquid chromatograph–mass spectrometer; maprotiline was quantitated by measuring the ion intensities at *m/e* 345 and 348 while desmethylmaprotiline was assayed by measuring the ion intensities at *m/e* 331 and 348.

Control plasma samples subjected to the described procedure showed no significant background ions at *m/e* 345, 348, and 331. Known amounts of maprotiline and desmethylmaprotiline and a fixed amount of the isotopic analog (maprotiline-d_3) were added to control plasma and processed as described. Maprotiline and desmethylmaprotiline were quantitated from the ratios of ion intensities at *m/e* 345/348 and 331/348, respectively. Analysis of the data for maprotiline (Fig. 1) gave a slope of 0.99 ± 0.01 and an intercept of 0.15 ± 0.1 ng. Similarly, the data for

[a] Only common major fragments are presented. [b] The values in parentheses represent the percent relative intensity.

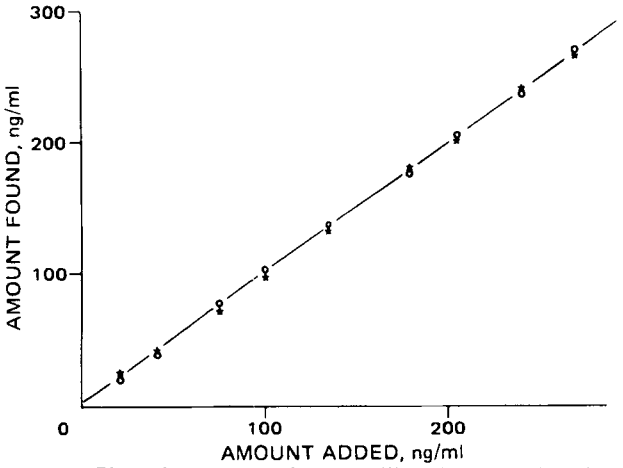

Figure 1—*Plot of amounts of maprotiline (0–285 ng) (O) and desmethylmaprotiline (0–285 ng) (×) added to control plasma versus the amounts found using the described method. Maprotiline-d_3 (70 ng/ml) was added as the internal standard.*

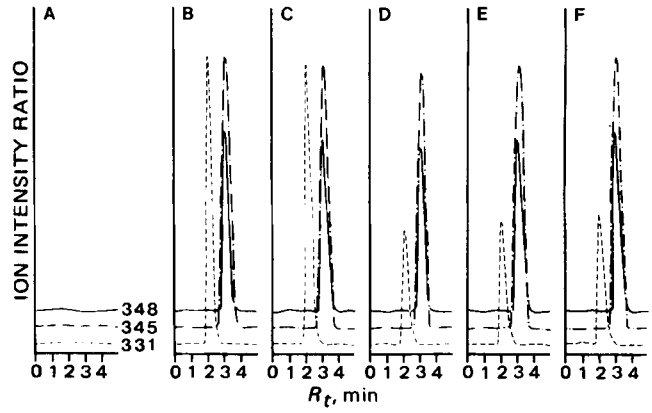

Figure 2—*Selective-ion chromatograms for maprotiline (m/e 345), desmethylmaprotiline (m/e 331), and maprotiline-d_3 (m/e 348). Key: A, control human plasma; B, control human plasma (1 ml) spiked with 10 ng each of maprotiline and desmethylmaprotiline and 7 ng of maprotiline-d_3; C, control rabbit plasma (1 ml) spiked as in B; and D, E, and F, typical rabbit and human plasma.*

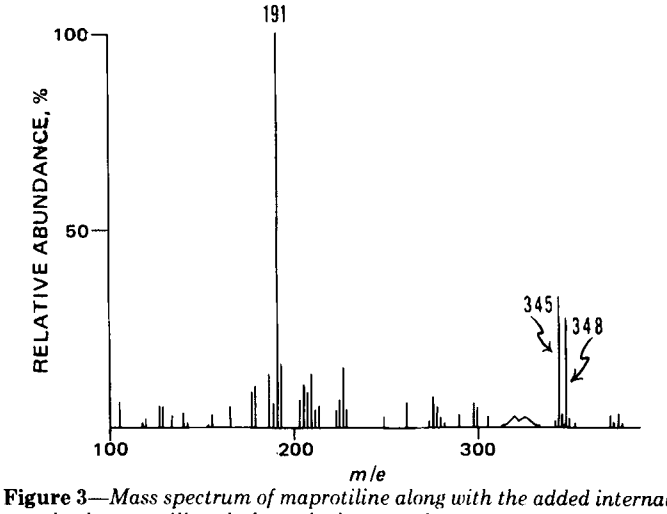

Figure 3—*Mass spectrum of maprotiline along with the added internal standard maprotiline-d_3 from the human plasma extract.*

desmethylmaprotiline (Fig. 1) gave a slope of 0.98 ± 0.01 and an intercept of 0.2 ± 0.11 ng. These data affirm a simple linear relationship between the ion intensity ratios and concentrations of maprotiline and desmethylmaprotiline and exclude any isotopic fractionation in the fragmentation process as well as in the physicochemical steps in the assay.

Six samples containing 10 ng each of maprotiline and desmethylmaprotiline/ml were analyzed using 7.0 ng of maprotiline-d_3/ml as the internal standard. The results were 9.91 ± 0.15 ng/ml for maprotiline and 9.87 ± 0.16 ng/ml for desmethylmaprotiline. These samples were assayed in duplicate; in this set, exactly the same amounts were taken as before, but the internal standard was added after the extraction. The recoveries for these samples, based on comparison of the ion intensity ratios of the two sets, were 82 ± 7% for maprotiline (*m/e* 345/348) and 85 ± 6% for desmethylmaprotiline (*m/e* 331/348). The variability in recoveries is to be expected in trace analysis and is attributed to variable glassware and GLC column adsorption.

Table II shows the concentration of intact drug and its major metabolite in rabbit plasma after a single intravenous dose. The decline of maprotiline concentration in plasma exhibited a typical fast absorption phase (α) followed by a slow disposition phase (β), while desmethylmaprotiline peaked out at ~50 hr after maprotiline administration.

The plasma levels of maprotiline and the metabolite varied considerably in different patients maintained on a normal therapeutic dose. More extensive data are needed for assessment of steady-state concentrations of these materials in human plasma.

Sensitivity and Specificity—The assay for maprotiline and its major metabolite presented here is sensitive, specific, and applicable to other body fluids and tissues. The assay sensitivity is a function of extraction efficiencies, GLC column conditions, and the ion source and cannot be quoted in absolute terms. With good mass spectrometer performance, a clean ion source, a freshly silanized GLC column and glassware, and >50% recoveries, an assay sensitivity of ~2 ng each of maprotiline and desmethylmaprotiline/ml of plasma is possible.

The results from the control plasma and plasma of patients show good specificity of the assay. The mass chromatograms obtained from biological extracts (Fig. 2) show clean and symmetrical peaks. Furthermore, these biological extracts were pure enough so that the entire mass spectra of maprotiline and desmethylmaprotiline trifluoroacetamides could be recorded. The mass spectrum of maprotiline trifluoroacetamide with added maprotiline-d_3 (Fig. 3) shows expected doublets at *m/e* 345–348. Also significant was a singlet of increased relative ion intensity at *m/e* 191, a common fragment ion from the two isotopic species. The mass spectrum of desmethylmaprotiline trifluoroacetamide in the biological extract was identical to that of the authentic material.

Table II—Analyses [a] of Maprotiline and Desmethylmaprotiline in the Plasma of Rabbits and Patients on Maprotiline Therapy

Identification and Analysis of Persistent Contaminants Associated with Gemcadiol

J. PHILIP and D. H. SZULCZEWSKI ˣ

Received August 6, 1979, from *Analytical Research, Warner-Lambert Company, Morris Plains, NJ 07950.* Accepted for publication January 17, 1980.

Abstract □ Application of several analytical probes indicated that certain batches of the investigational new drug gemcadiol (2,2,9,9-tetramethyl-1,10-decanediol) were contaminated with impurities whose nature and source were unknown. Subsequent study showed that these impurities consisted of polymeric material formed by self-condensation of the dialdehyde precursor. Gel permeation chromatographic techniques were found to be useful in the analysis of polymers present in both the aldehyde precursor and the finished drug.

Keyphrases □ Gemcadiol—identification and analysis of persistent contaminants □ Drug impurities—gemcadiol, identification and analysis of persistent contaminants □ Cholesterol-lowering agents, potential—gemcadiol, identification and analysis of persistent contaminants

Gemcadiol (2,2,9,9-tetramethyl-1,10-decanediol, I) is an investigational new drug that is being evaluated as a triglyceride- and cholesterol-lowering agent (1). This drug may be synthesized by a process whose last step involves sodium borohydride reduction of 2,2,9,9-tetramethyl-1,10-decanedial (II) (2).

When various batches of I were analyzed, it became apparent that significant interbatch variation existed for which the cause was not known. This study was conducted to determine the reason for the observed inconsistencies and to provide a more definitive method of analysis.

EXPERIMENTAL

Reagents—The solvents were analytical reagent grade. The sodium borohydride[1] was used as received.

Apparatus—IR spectra were obtained using a grating IR spectrophotometer[2]. GLC was done on a programmable research chromatograph[3] equipped with a flame-ionization detector and an electronic integrator[4]. NMR spectra were obtained on a 90-MHz instrument[5] with deuterochloroform as the solvent and tetramethylsilane as the internal standard.

GLC Studies—GLC studies were performed using 183 × 0.64-cm stainless steel columns packed with 5% silicone gum rubber[6] on silanized diatomaceous earth[7]. Chromatograms were obtained under isothermal conditions (225°) after injection of 2 μl of a 10% solution of the sample in methanol. In certain cases, the solution injected was acidified by adding 1 drop of 3 *N* HCl to 1 ml of the methanolic sample solution.

Liquid Chromatography of I—Liquid chromatographic separation of the components present in impure samples of I was accomplished using modified dextran beads[8] packed in a 40 × 3-cm glass chromatographic column. Methanol (25% v/v) in benzene was the mobile phase. The column was charged with a sample of ~500 mg dissolved in 5 ml of the mobile

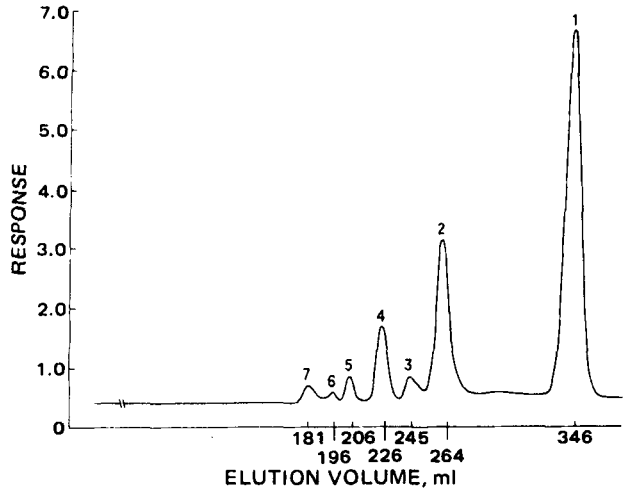

Figure 1—*Liquid chromatogram of polymerized II obtained on a column packed with Bio Beads SX-2 using benzene as the eluent. Elution volumes of each peak are indicated. The indicated molecular weights are: peak 2, 610–690; peak 3, 750–840; peak 4, 940–1060; peak 5, 1200–1400; and peak 6, 1300–1600.*

phase; it was operated at a flow rate of 1 ml/min, and 10-ml fractions were collected. The fractions were transferred to tared aluminum weighing pans[9] (70 mm), the eluent was allowed to evaporate, and the pans were brought to constant weight under a vacuum. The weight of nonvolatile material in each pan then was plotted *versus* the eluent volume to obtain the chromatogram.

Liquid Chromatography of II—The chromatographic system employed for II was essentially the same as that developed by Mulder and Buytenhuys (3). Glass columns (90 × 2.4 cm) packed with porous styrenedivinylbenzene beads[10] were employed with benzene as the mobile phase. The columns were attached to a commercial high-efficiency liquid chromatographic system[11] equipped with a refractive index detector[12]. Five milliliters of a 5% sample solution in benzene was introduced to the column with a sample injection valve[13]. The columns were operated at a flow rate of 20 ml/hr at ambient temperature.

Estimation of Molecular Weights of Components Present in Partially Polymerized II—A mixture containing known compounds of relatively high molecular weights was prepared by dissolving 100 mg of II and 50 mg each of tristearin[14] (mol. wt. 891), trimyristin[14] (mol. wt. 723), and trilaurin[14] (mol. wt. 639) in 5 ml of benzene. A chromatogram was obtained for this mixture using the chromatographic system and conditions described for the liquid chromatography of II. The elution volumes of the known components were noted, and a plot of log mol. wt. *versus* elution volume was constructed.

Although the plot was linear, its slope caused the anticipated molecular weights to be underestimated (specific adsorption effects). Nevertheless, these estimates are the basis for the lower molecular weights of the molecular weight estimate given in Fig. 1. By assuming that the lowest polymeric contaminant of the aldehyde mixture, Component 2, had a molecular weight of 678 and by calibrating the column with this compound and II (mol. wt. 226), the estimates for the upper limit of the range estimate were obtained.

Reduction of Samples of II—In general, 1 g of II was dissolved in 5 ml of 2-propanol and placed in a small beaker containing a magnetic stirring bar. A solution of sodium borohydride (176 mg/g of II) in distilled water was added dropwise with stirring. The resulting mixture was stirred for an additional 30 min.

After the reaction was complete, the mixture was poured into excess water and ice, and this mixture was stirred. The final mixture was extracted with three equal volumes of chloroform, and the chloroform extract was dried over anhydrous magnesium sulfate. After the magnesium sulfate was separated by filtration, the chloroform was evaporated and and the residue was brought to constant weight under vacuum.

Reduction of Components in Impure Samples of II—Each component found in polymerized samples of II was reduced immediately following elution from the chromatographic column by piping the column eluate into separate receivers, each containing 100 mg of sodium borohydride dissolved in water–methanol (10:40). The methanol was evaporated in a rotary evaporator, and excess water was added.

The aqueous mixture was extracted three times with 25-ml portions of chloroform, and the chloroform extracts were pooled. The combined chloroform extracts were back-washed with water until they were neutral to litmus paper and then they were dried over anhydrous magnesium sulfate. After freeing the extract of solid magnesium sulfate, the chloroform was evaporated and the residue was collected.

Preparation and Characterization of 10-Hydroxy-2,2,9,9-tetramethyldecanal (III)—Compound II, 100 g, was dissolved in 128 ml of 2-propanol and was kept stirring in a beaker. A solution of 8.3 g of sodium borohydride in 109 ml of water was added dropwise. At the end of this addition, the reaction mixture was analyzed by GLC and found to be a mixture of 80% I and 20% III. The solvent was evaporated, and the residue was dissolved in warm acetonitrile. Upon cooling, some I crystallized, leaving a supernate containing 32% I and 68% III. Compound III was isolated from the mother liquor as follows.

The solvent was evaporated, and 50 g of the residue was refluxed for 2 hr with 50 g of Girard's Reagent T[15], 50 ml of acetic acid, and 500 ml of 95% ethanol. The alcohol then was evaporated, and the residue was washed three times with 200-ml portions of ether. It then was dissolved in 300 ml of water, and 60 ml of 5 *N* HCl was added. The mixture was heated on the steam bath for 1 hr. The formed oil was separated and dissolved in ether. The ether solution was washed with a dilute potassium bicarbonate solution and then with water. The ether solution was dried over anhydrous magnesium sulfate, and the ether was evaporated.

The residue was free of I and was identified as 10-hydroxy-2,2,9,9-tetramethyldecanal (III). The mass spectrum exhibited a molecular ion

at *m/e* 228. IR analysis gave a strong band at 5.78 μm due to C=O. GLC gave only one peak. The NMR data are given in Table I.

Anal.—Calc. for $C_{14}H_{28}O$: C, 73.68; H, 12.28. Found: C, 73.60; H, 12.20.

Determination of Amount of Polymeric Contaminants in I—Approximately 10 g of Sephadex LH-20 was conditioned by stirring with benzene–methanol (75:25) for several hours. The solvated beads were packed into a 45 × 2-cm glass column. The height of the resin bed was 42 cm. Approximately 200 mg of the sample was weighed accurately and dissolved in 5 ml of the eluent (benzene–methanol). The solution then was introduced into the column, and the column was eluted with benzene–methanol (75:25).

Fractions of 30, 35, and 40 ml were collected and transferred into three tared aluminum pans. The solvent was evaporated, and the pans were dried under vacuum to constant weight. Fractions 2 and 3 contained the total polymeric impurities and the drug, respectively. These fractions were weighed, and the amount of polymeric contaminants in I was calculated from their weights.

RESULTS AND DISCUSSION

Purity estimates of various batches of I, obtained by differential calorimetry[16] (4), are shown in Table II; significant interbatch variation was observed. IR spectra obtained from these batches differed in that the spectrum of the less pure material had extraneous absorption near 9 μm (Fig. 2). The NMR spectra of high and low quality drug were similar (Fig. 3), except for a barely perceptible peak near 4.35 ppm.

Gas–liquid chromatograms obtained from impure batches (Fig. 4, left) were characterized by a large symmetrical peak preceded by a small distorted peak or shoulder. The relative area of the distorted peak or shoulder varied from batch to batch, and its shape suggested it could have arisen from partial thermal decomposition of I itself or associated contaminants. When the methanolic sample solution used for injection was acidified prior to injection, relatively impure samples gave a chromatogram like that shown in Fig. 4 (right). The retention time of two of the observed small peaks corresponded to II and III. The presence of these compounds was confirmed through mass spectrometry and the coincidence of the retention time with authentic samples.

Since the chromatographic behavior of the vapor phase indicated thermal decomposition, other means of separation were investigated. It was determined that extraneous material could be separated from the

drug through gel permeation chromatography using Sephadex LH-20 with methanol–benzene as the eluent[17]. A typical chromatogram obtained on an impure batch of drug is shown in Fig. 5. IR spectra obtained on the material responsible for the various peaks showed strong absorption at ~9 μm for peaks 1–3, whereas the spectrum of peak 4 had no extraneous absorption and was consistent with the pure drug.

More of the major contaminant (peak 3) was obtained[18] for characterization, and the NMR spectrum was informative (Fig. 6). While the spectrum of the contaminant was similar to that of the drug, the details differed. A significant difference was that the signal from the methyl protons occurred at more than one chemical shift, and there was a small but real peak near 4.4 ppm. The complete NMR data obtained on this sample are summarized in Table III.

Structures A and B are consistent with the NMR data and are chemically reasonable (5–8).

Anal.—Calc. for Structure A or B: C, 73.68; H, 12.28. Found: C, 73.70; H, 12.19.

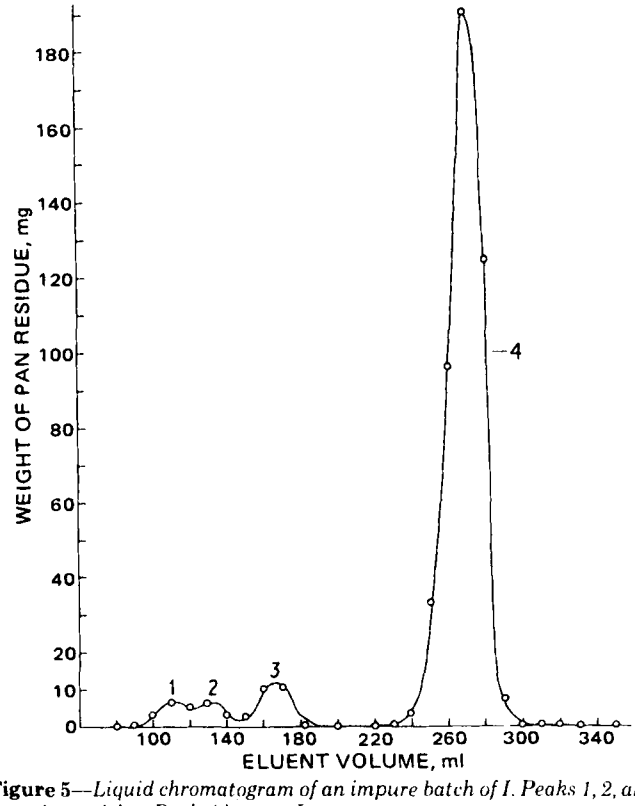

Figure 5—*Liquid chromatogram of an impure batch of I. Peaks 1, 2, and 3 are impurities. Peak 4 is pure I.*

[17] See *Experimental.*

[18] Preparative chromatography using a 45 × 6-cm glass column.

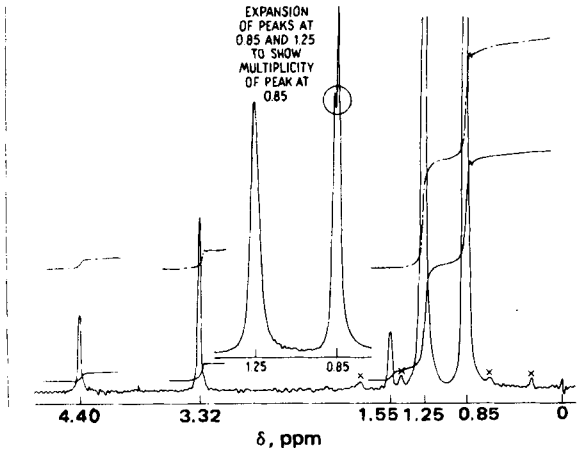

Figure 6—*NMR spectrum of material corresponding to peak 3 in Fig. 5 (2% in deuterochloroform).*

The IR spectrum showed a strong band at 9 μm, suggesting the presence of C—O—C. GLC of an acidified methanolic solution gave only one peak corresponding to 10-hydroxy-2,2,9,9-tetramethyldecanal (III). The molecular weight determined by the Rast procedure (9) was 611 ± 10%. This result and its behavior on the gel permeation column[19] indicate that its molecular weight cannot be 228, so Structure B is favored.

Examination of the IR spectrum of various batches of the dialdehyde precursor (II) revealed that relatively strong absorption near 9 μm existed in some batches but not in others. A sample of dialdehyde giving an IR spectrum that had strong absorption near 9 μm and a sample not having this extraneous absorption were reduced, and the reduction products were chromatographed. The chromatograms obtained showed that impurities were formed only in the case where the dialdehyde gave an IR spectrum with significant absorption near 9 μm.

Since further information regarding the nature of the contaminants in the dialdehyde was desirable, a liquid chromatographic system suitable for their separation was developed and chromatograms were obtained. A chromatogram representative of the dialdehyde with strong 9-μm absorption is shown in Fig. 1. The system employed provided near baseline separation of at least six contaminants.

A range estimate of molecular weights of the various components obtained on the basis of elution volume are included in Fig. 1. Attempts were made to obtain definitive NMR data directly on these contaminants; although peaks were present that could be assigned to ring and aldehyde protons (Table IV), spurious peaks also were observed. These peaks,

B

[19] The elution volume of this material is much less than that of II, whose molecular weight is 228.

Table III—NMR Data Obtained from Material Corresponding to Peak 3 in Fig. 5

Functional Group	Chemical Shift, ppm	Relative Area
CH (a)	4.4	1
CH_3 (b,c)	0.85	12.6
CH_2 (alkyl) (d)	1.25	12.6
OH (e)	1.57	1
CH_2 (CH_2OH) (f)	3.3	2

Table IV—NMR Data Obtained from Material Corresponding to Peak 4 in Fig. 1

Functional Group	Chemical Shift, ppm	Relative Area
CH	4.4	7.5
CH_3	(0.90) −(1.05)	72
CH_2	1.21 1.23 1.29 1.49	122
?	8.04	2
CHO	9.48	3

Table V—NMR Data Obtained from Material Corresponding to Peak 4 in Fig. 1 after Reduction with Sodium Borohydride

Functional Group	Chemical Shift, ppm	Proton Ratio
CH	4.37	1.44
CH_3	0.86	14.2
CH_2 (alkyl)	1.23	14.6
OH	1.67	1.0
CH_2 (CH_2OH)	3.29	1.85

which resulted from oxidation, precluded clear definition of proton ratios.

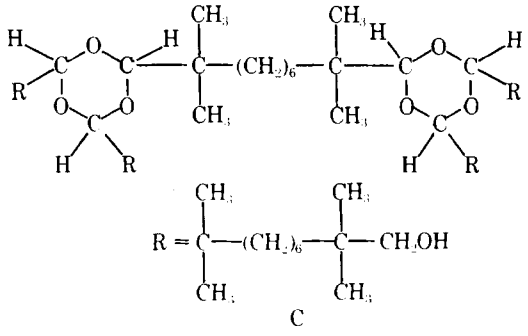
Since the components of the impure dialdehyde were well separated, they were reduced concurrently with elution, and an impure drug sample was spiked with the reduced aldehyde impurities. Liquid chromatograms then were obtained, which indicated that the material responsible for peak 2 (Fig. 1) corresponded to drug contaminant 3 (Fig. 5) and that aldehyde contaminant 4 (Fig. 1) corresponded to drug contaminant 2 (Fig. 5). Since components of the impure dialdehyde were better separated than their reduced counterparts, a sufficient sample of a minor drug contaminant, peak 2 (Fig. 5), was obtained by chromatographing partially polymerized dialdehyde and providing concurrent reduction. This material was a viscous clear liquid.

Anal.—Calc. for $C_{70}H_{138}O_{10}$ (Structure C): C, 73.81; H, 12.13. Found: C, 73.50; H, 12.09.

The molecular weight calculated for Structure C was 1138; the range indicated by gel permeation chromatography was 940–1060.

GLC of the acidic methanolic solution gave both the monoaldehyde monoalcohol (III) and the dialdehyde in a molar ratio of 4:1. The presence of the dialdehyde is significant and indicates that this higher molecular weight impurity contains a dialdehyde bridge incorporated so as to protect both potential aldehyde groups from reduction. The NMR data are presented in Table V.

These properties are consistent with and indicative of Structure C as the structure of the next most abundant drug contaminant.



C

Table VI—Theoretical Proton Ratios for Various Protons Involved in Polymeric Alcohols Containing Various Numbers of Trioxane Rings

Protons	Proton Ratios (Group per OH)			
	1 Ring	2 Rings	3 Rings	4 Rings
Ring CH	1.0	1.5	1.8	2.0
Aliphatic CH_2	12.0	15.0	16.8	18.0
Methyl	12.0	15.0	16.8	18.0

The ratio of various protons having different chemical shifts would be expected to vary as polymerization continued. In particular, the ratio of ring CH, aliphatic CH_2, and methyl protons to hydroxyl protons would increase as the number of bridged trioxane rings increased (Table VI).

While it was important to separate individual components for characterization, this need does not apply for the establishment of drug purity. The gel permeation technique was modified to allow analysis of the total polymeric material in drug samples. To validate this method of analysis, mixtures having known compositions were analyzed. The results (percent impurity added: 0, 5.2, and 9.4; found: 0, 5.1, and 9.4) indicate that the method described under *Experimental* is sufficiently accurate for use.

CONCLUSIONS

Available information indicates that contaminants present in certain batches of I consist of polymeric alcohols characterized by at least one trioxane ring. These contaminants originate in the dialdehyde precursor, which may polymerize to form corresponding compounds. Reduction of polymers present in the dialdehyde yields the alcohol polymers, which may persist throughout purification and contaminate the finished drug. Analysis *via* gel permeation liquid chromatography provides a useful means to analyze the degree of contamination by these polymeric compounds.

Preliminary Model for Streptozocin Metabolism in Mice

JONAS M. WEISSBROD * and RAKESH K. JAIN ‡x

Received June 25, 1979, from the **Department of Chemical Engineering, Columbia University, New York, NY 10027*, and the ‡*Department of Chemical Engineering, Carnegie-Mellon University, Pittsburgh, PA 15213.* Accepted for publication January 18, 1980.

Abstract □ A mathematical model for streptozocin metabolism in mice is presented. By using the available bioassay and chemical assay data for a 300-mg/kg ip injection and the principles of physiologically based pharmacokinetics, a membrane-limited transport model with first-order kinetics was found to simulate the data adequately (average error of <20%). Furthermore, the first-order reaction constant derived in analyzing the bioassay data (0.009 min^{-1}) was in close agreement with the half-life of streptozocin (1 hr) reported previously.

Keyphrases □ Streptozocin—drug metabolism and distribution, mathematical model based on bioassay and chemical assay, mice □ Metabolism—streptozocin distribution and transport, mice, mathematical model □ Diabetes—streptozocin induced, pharmacokinetic model, mice □ Pharmacokinetic models—streptozocin metabolism, bioassay and chemical assay, mice, membrane-limited transport

Streptozocin (NSC-85998), the 2-deoxy-D-glucose derivative of 1-methylnitrosourea (1), has been shown to inhibit primary DNA synthesis in mammalian cells (2, 3). Due to its selective toxicity for pancreatic β-cells, streptozocin has been used to induce diabetes in a variety of animals (4–6). In addition, it has been useful in the treatment of metastatic insulinoma (7, 8).

BACKGROUND

Previous kinetic studies showed that streptozocin degradation obeys first-order reaction kinetics. These studies also indicated the presence of at least two pathways for streptozocin degradation, one involving the *N*-nitroso group and the other involving another portion of the molecule, probably the glucose moiety (9). While chromatography has been used to isolate several streptozocin metabolites (10, 11), their molecular structures have not been identified precisely.

In addition, data for streptozocin concentrations in various tissues of mice as a function of time were obtained previously (10) using three assay methods: bioassay and chemical and radiochemical assays. The bioassay is the closest indicator of the actual streptozocin content, but this method does not preclude the possibility that some drug metabolites also may be bioactive. The chemical assay measures the *N*-nitroso group of streptozocin and its metabolites. The radiochemical assay measures a tritiated hydrogen atom that originally was at the C-6 position of the glucose moiety of streptozocin and must be accounted for either as part of the streptozocin molecule or as part of the several streptozocin metabolites known to exist.

The objective of this study was to utilize these data along with the present knowledge of streptozocin metabolism to develop mathematical models for the distribution, transport, and metabolism of streptozocin in mice.

THEORETICAL

In recent years, physiologically based pharmacokinetic modeling (12, 13) has been applied extensively to predict drug distributions in plasma and various tissues of mammalian systems (14, 15). A pharmacokinetic model is a simplified representation of a real physical system (Scheme I) derived from experimental observations, previous knowledge, and a number of assumptions. It is based on relevant physical and biochemical parameters such as plasma flow rates, tissue volumes, tissue binding constants, mass transfer coefficients, and, when necessary, chemical reaction constants to account for drug metabolism. The validity of the model as a means of predicting tissue drug distributions and excretion rates is tested by comparing model predictions with data. Plasma flow rates and tissue volumes for most species and tissues are readily available in the literature. Mass transfer, binding, and metabolism parameters for a given drug must be estimated from the available data.

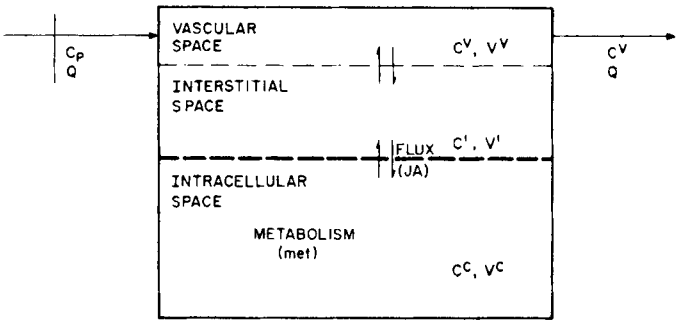

Scheme I—Schematic representation of a typical model compartment where Q is the plasma perfusion rate; C_p is the afferent plasma concentration; V^v, V^i, and V^c are the volumes of the vascular, interstitial, and intracellular spaces, respectively; C^v, C^i, and C^c are the drug concentrations in the vascular, interstitial, and intracellular spaces, respectively; jA is the net flux of drug to the intracellular space; and met is the rate of drug disappearance via metabolism. The vascular and interstitial spaces are combined into a single extracellular subcompartment, and the efferent plasma concentration is assumed to be equal to the extracellular drug concentration.

As shown in Scheme I, a tissue compartment can be divided into three subcompartments: the vascular, interstitial, and intracellular spaces. Drug concentrations in each subcompartment are assumed to be uniform, and the effluent plasma concentration is assumed to be equal to the drug concentration of the vascular subcompartment.

For most drugs and tissues, the vessel wall is more permeable than the cellular membrane, and the vascular and interstitial subcompartments can be combined into a single subcompartment, the extracellular space. Therefore, in the present study, transport in all of the compartments was modeled according to a membrane-limited model, which is similar to models applied previously to methotrexate uptake into the bone marrow, spleen, and intestine of rats (13), dactinomycin (actinomycin D) uptake into the testes of beagle dogs (16), and methotrexate uptake into several types of tumors (17, 18).

With these assumptions and definitions, two nonsteady-state material balance equations for a particular body (or tissue) compartment may be derived:

$$V_i^e \frac{dC_i^e}{dt} = Q_i(C_p - C_i^e) - (jA)_i - q_i C_i^e \qquad \text{(Eq. 1)}$$

$$V_i^c \frac{dC_i^c}{dt} = (jA)_i - (\text{met})_i \qquad \text{(Eq. 2)}$$

where the subscript i refers to the ith body compartment; V_i^e and V_i^c are the volumes of the extracellular and intracellular spaces (milliliters), respectively; C_i^e and C_i^c are the total drug concentrations in the extracellular and intracellular spaces (micrograms per milliliter), respectively; Q_i is the plasma perfusion rate (milliliters per minute); q_i is the drug clearance rate (zero for compartments other than the kidneys and liver) that accounts for drug elimination *via* the urine and bile (milliliters per minute); C_p is the afferent plasma concentration (micrograms per milliliter); $(jA)_i$ is the net flux of drug into the intracellular subcompartment (micrograms per minute); and $(\text{met})_i$ is the rate of drug metabolism in the ith compartment (micrograms per minute).

The net flux $(jA)_i$ between the extracellular and intracellular subcompartments and the relationship between free and bound drug are defined by:

$$(jA)_i = V_i h_i (C_i^e - C_i^c/R_i) \qquad \text{(Eq. 3)}$$

where h_i and R_i are apparent first-order diffusion constants and tissue equilibrium partition coefficients into which the effect of drug binding in the extracellular fluid has been incorporated, respectively. The use of a first-order diffusion constant, h_i, assumes that the transport mechanism across the cell membrane is linear and nonsaturable.

The drug metabolism rate, $(\text{met})_i$, in the intracellular subcompartment is defined by:

$$(\text{met})_i = k_i V_i C_i^c \qquad \text{(Eq. 4)}$$

where k_i is the first-order reaction constant for streptozocin degradation. The use of first-order kinetics to describe streptozocin degradation was verified by previous kinetic studies (9).

Previous pharmacokinetic studies illustrated the applicability of a nonlinear regression analysis to the available plasma data to obtain an exponential equation for plasma concentrations as a function of time (15, 17, 18). This approach was utilized in the present study. Thus, once the parameter values and plasma exponential equations are known, Eqs. 1 and 2 are solved to obtain predictions for streptozocin concentrations in a given tissue as a function of time.

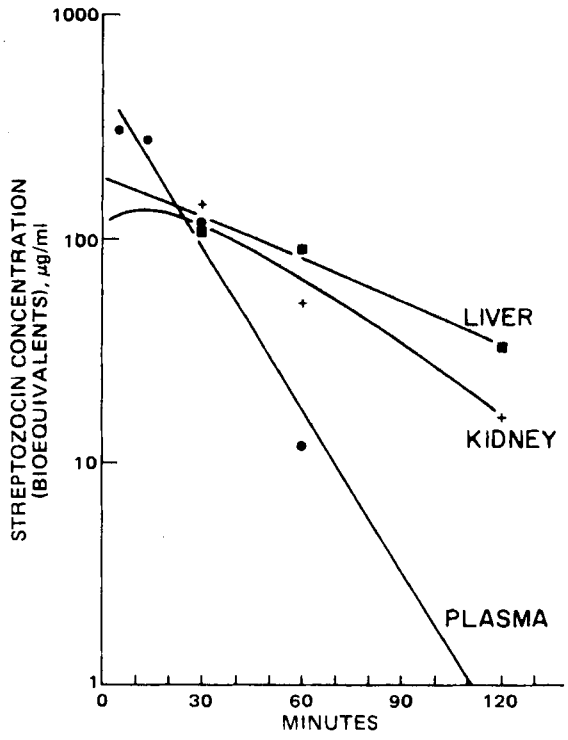

Figure 1—*Streptozocin bioequivalents* versus *time in plasma, liver, and kidneys of mice following an injection of 300 mg/kg ip. Points represent the experimental data of Bhuyan* et al. *(10) for plasma (●), liver (■); and kidneys (+). The curves represent model predictions. The parameters of Table I (bioassay values) and an exponential equation for the plasma concentration ($494.53e^{-0.0549t}$) were used to obtain the simulations.*

To compare model predictions with the data, the average drug concentration in a tissue must be defined as:

$$C_i = (C_i^e V_i^e + C_i^c V_i^c)/V_i \qquad \text{(Eq. 5)}$$

where C_i is the overall drug concentration of the ith compartment (micrograms per milliliter).

EXPERIMENTAL

Data for streptozocin concentrations as a function of time were obtained by Bhuyan *et al.* (10) using three independent assay methods: bioassay, chemical assay, and radiochemical assay. In these experiments, streptozocin (tritiated or unlabeled) was dissolved in phosphate buffer and was administered intraperitoneally to 20-g female BDF_1 (C57BL/6 × DBA/2) mice[1]. At various postinjection times up to 2 hr, groups of mice (four or five per group) were sacrificed; blood samples were collected, tissues were excised, and all were assayed for streptozocin.

The experimental procedures used were those described by Bhuyan *et al.* (10).

RESULTS AND DISCUSSION

Values for the compartmental volumes and tissue flow rates (V_i and Q_i, respectively) for each tissue were obtained from the literature (19). The binding, diffusion, and metabolism constants (R_i, h_i, and k_i) were determined by applying parameter estimation methods (18, 20) to the data of Bhuyan *et al.* (10). With these parameter values (Table I), the chemical and bioassay data for the liver, kidneys, and pancreas were modeled by first obtaining exponential fits for the plasma data and then solving Eqs. 1 and 2 for each tissue. The results are shown in Figs. 1 and

Table I—Model Parameters [a] for Streptozocin Distribution in Mice [b]

Tissue	Tissue Volume (V), ml	Extracellular Volume (V^e), ml[d]	Plasma Flow Rate (Q), ml/min	Partition[c] Coefficient (R) Bio	Partition[c] Coefficient (R) Chem	Diffusion Constant[c] (h), min^{-1} Bio	Diffusion Constant[c] (h), min^{-1} Chem	Reaction Constant[c] (k), min^{-1} Bio	Reaction Constant[c] (k), min^{-1} Chem
Liver[e]	1.30[f]	0.5	1.1[f]	23.6	19.7	0.0164	0.1392	0.0086	0.0041
Kidneys[g]	0.34	0.13	0.8[f]	5.6	7.7	0.0305	0.1625	0.0096	0.0041[h]
Pancreas	0.09[b]	0.04	0.048[b]	—	15.8	—	0.0063	—	0.0041[h]

[a] Data were obtained by bioassay and chemical assay methods. [b] Mice weighed 20 g. [c] Obtained by parameter estimation using the bioassay and chemical assay data of Bhuyan *et al.* (10) for an injection of 300 mg/kg ip. [d] Estimated. [e] Bile clearance, q_1, is negligible (10). [f] Taken from Ref. 19. [g] Kidney clearance, q_k, was estimated from the data of Bhuyan *et al.* (10) to be 0.42 ml/min. [h] Assumed.

2. The average error between the data and the model predictions was 18.3% for the bioassay data (Fig. 1) and 15.1% for the chemical assay data (Fig. 2). The model also was applied to obtain fits for the radiochemical assay data (20). Since the parameter values obtained from the radioassay data are of limited value because of the rapid metabolism of streptozocin, these results are not given here.

The models presented in this report utilize data for an intraperitoneal injection of 300 mg/kg. They also provide a quantitative basis for the prediction of drug distributions at other doses and for other modes of injection. Such extensions were discussed previously for other drugs (16–18). In addition, the development of membrane-limited models for drug transport and the inclusion of terms to account for tissue binding and drug metabolism are emphasized here.

The bioassay is the best available measure of the whole streptozocin molecule. In modeling the bioassay data, a reaction constant of ~0.009 min^{-1} was determined for both the kidneys and the liver. This value is in good agreement with a half-life of ~1 hr, which was reported previously (9).

As stated previously, the chemical assay is a measure of the *N*-nitroso group of streptozocin and its metabolites. Previous investigators related the mode of action of streptozocin and other nitrosoureas to the alkylation of various cell components (*i.e.*, DNA, RNA, nucleic acid precursors, and proteins) and the subsequent inhibition of cell division and other critical biochemical processes (21, 22). The observed suppression of NAD^+ and inhibition of pyridine synthesis (23–27) also may be explained within the context of this mode of action.

The degradation pattern of streptozocin to yield a methyl carbonium ion capable of alkylating various cell constituents can be envisioned as a two-step process with methyldiazonium ion as an intermediate. This process is consistent with the known biological degradation patterns for *N*-nitrosoureido compounds (28) and illustrates the importance of the chemical assay in measuring drug activity relative to the proposed mode of drug action.

While the present analysis describes the available data in mice adequately, more data are needed to characterize the transport and metabolism more precisely. Chromatography has isolated several streptozocin metabolites (10, 11), but further work is needed for their identification. As those findings become available, they can be incorporated into a more complex pharmacokinetic model to describe the drug metabolism. In addition, detailed drug distribution data at different dose levels and for different species should be collected and compared with the present pharmacokinetic model as has been done for other drugs (14). Finally, pharmacokinetic studies on other nitrosoureas and glucose-like drugs would provide quantitative information about their transport, mode of action, and metabolism and additional insights into streptozocin pharmacokinetics.

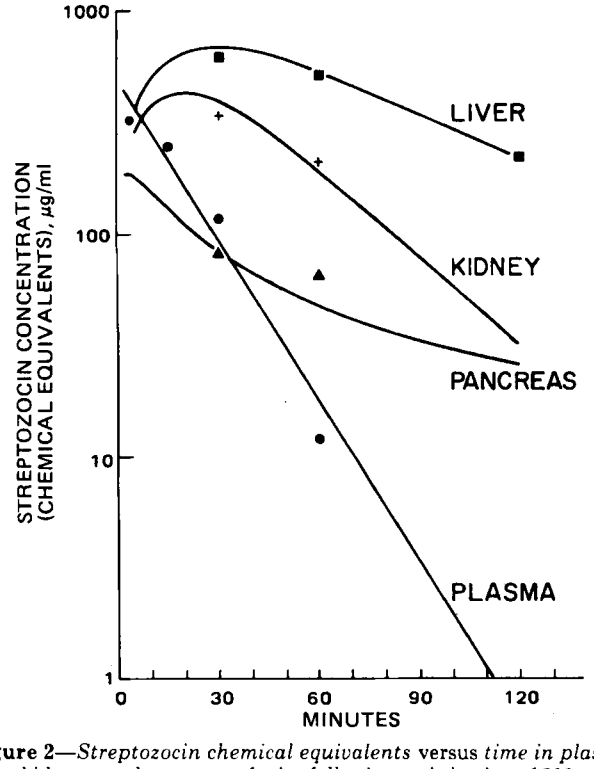

Figure 2—*Streptozocin chemical equivalents* versus *time in plasma, liver, kidneys, and pancreas of mice following an injection of 300 mg/kg ip. Points represent the experimental data of Bhuyan* et al. *(10) for plasma (●), liver (■), kidneys (+), and pancreas (▲). The curves represent model predictions. The parameters from Table I (chemical assay values) and an exponential equation for the plasma concentration ($494.53e^{-0.0549t}$) were used to obtain the simulations.*

Antihyperlipidemic Activity of Sesquiterpene Lactones and Related Compounds

I. H. HALL *x, K. H. LEE *, C. O. STARNES *, O. MURAOKA *, Y. SUMIDA *, and T. G. WADDELL ‡

Received September 28, 1979, from the **Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514*, and the ‡*Department of Chemistry, University of Tennessee at Chattanooga, Chattanooga, TN 37401.* Accepted for publication January 23, 1980.

Abstract □ Some naturally occurring pseudoguaianolides and germacranolides as well as synthetic related compounds were observed to be antihyperlipidemic agents in mice. Several of these compounds at a dose of 20 mg/kg/day resulted in lowering of serum cholesterol by ~30% and of serum triglycerides by ~25%. Thiol-bearing enzymes of lipid synthesis, *i.e.*, acetyl-CoA, citrate-lyase, acetyl-CoA synthetase, and β-hydroxy-β-methylglutaryl-CoA reductase, were inhibited by these agents *in vitro*, supporting the premise that these agents alkylate thiol nucleophiles by a Michael-type addition. The α-methylene-γ-lactone moiety, the β-unsubstituted cyclopentenone ring, and the α-epoxycyclopentanone system of these compounds appeared to be responsible for the lowering of serum lipids.

Keyphrases □ Lactones, sesquiterpene—antihyperlipidemic activity, structure–activity relationships, serum levels of cholesterol and triglycerides, mice □ Structure–activity relationships—sesquiterpene lactones, antihyperlipidemic activity, effect on serum levels of cholesterol and triglycerides, mice □ Antihyperlipidemic activity—sesquiterpene lactones, structure–activity relationships, serum levels of cholesterol and triglycerides, mice

Pseudoguaianolide (I, III, IV, V, X, and XI) and germacranolide (XII and XIII) sesquiterpene lactones and related compounds (XIV and XV) are potent antineoplastic agents, effective against Walker 256 carcinosarcoma, Lewis lung carcinoma, P-388 lymphocytic leukemia, and Ehrlich ascites carcinoma in rodents (1). Furthermore, these agents significantly inhibited induced inflammation and arthritic states in rats (2).

In a study of the effects of sesquiterpene lactones on cellular metabolism as antineoplastics, these agents inhibited β-hydroxy-β-methylglutaryl-CoA reductase activity of 10-day-old Ehrlich ascites tumor cells. For example, helenalin (I) at 7 μmoles caused 67% inhibition. Compound I also lowered the elevated serum cholesterol level of tumor-bearing mice by 39% (3). These observations suggested that the sesquiterpene lactones should be tested as antihyperlipidemic agents.

EXPERIMENTAL

Source of Test Compounds—Some of the test compounds are natural products and were isolated from plant species by literature techniques (4). Helenalin (I) was isolated from *Balduina angustifolia*[1] (5); tenulin (V) (6) and aromaticin (XI) (6, 7) were isolated from *Helenium amarum*[2]; deoxyelephantopin (XII) was obtained from *Elephantopus carolinianus*[3] (8); and eupahyssopin (XIII) was isolated from *Eupatorium hyssopifolium*[4] (9).

Plenolin (III) was obtained by hydrogenation of helenalin to give the identical compound as the naturally occurring product (10). 2,3-Dihydrohelenalin (II) and 2,3-epoxyhelenalin (IV) were chemically modified from helenalin (11). Dihydrotenulin (VI), 2,3-epoxytenulin (VII), isotenulin (VIII), 2,3-epoxyisotenulin (X), and dihydroisotenulin (IX) were prepared by the methods of Waddell *et al.* (11). Thymine α-methylene-γ-lactone (XIV) (12), α-methylene-γ-lactone (XVIII) (13), and 2,3-epoxycyclopentan-1-one (XVI) (14) were prepared by literature methods. 2-Cyclopentenone[5] (XV), maleic anhydride[5] (XVII), clofibrate[6] (XIX), and acetazolamide[7] (XX) were obtained commercially.

Serum Hypolipidemic Activity—CF_1 male mice (~30 g) were fed food[8] with water *ad libitum* for the duration of the experiment. The drugs were suspended in 1% carboxymethylcellulose–water and homogenized. The doses were based on the weekly weights of the mice (15). The compounds were tested at 20 mg/kg/day ip.

On Days 9 and 16, blood was collected by tail vein bleeding in alkali-free nonheparinized microcapillary tubes, which then were centrifuged 3 min to obtain the serum. Duplicate 30-μl samples of nonhemolyzed serum were used to determine the serum cholesterol levels in milligram percent by a modification of the Liebermann–Burchard reaction (16). A separate group of mice were bled on Day 14, and their serum triglyceride levels (milligram percent) were determined using duplicate 25-μl samples (17).

Enzymatic Assays—Compounds were tested *in vitro* at 1 μmole for their effects on the enzymatic activity of a 10% liver homogenate prepared in 0.25 *M* sucrose and 0.001 *M* ethylenediaminetetraacetic acid at pH 7.2. Adenosine triphosphate citrate-lyase activity was measured by the method of Hoffmann *et al.* (18). Acetyl-CoA synthetase activity was determined by the method of Goodridge (19). The acetyl-CoA formed

from both enzymatic assays was coupled with hydroxylamine to produce acetyl hydroxylmate, which was measured at 540 nm.

Acetyl-CoA carboxylase activity was measured by a method (20) utilizing sodium [^{3}H]bicarbonate (6.2 mCi/mmole) after 30 min of incubation at 37° for enzyme polymerization (21). Fatty acid synthetase was determined by the method of Brady *et al.* (22) utilizing incorporation of [2′-^{14}C]malonyl-CoA (37.5 mCi/mmole) into fatty acids. [^{14}C]Acetate (57.8 mCi/mmole) incorporated into cholesterol (β-hydroxy-β-methylglutaryl-CoA reductase activity) was extracted by the method of Wada *et al.* (23) and measured as described by Haven *et al.* (24).

RESULTS

The sesquiterpene lactones and germacranolides significantly lowered serum cholesterol levels in mice (Table I). Helenalin (I), tenulin (V), 2,3-epoxytenulin (VII), isotenulin (VIII), 2,3-epoxyisotenulin (X), deoxyelephantopin (XII), eupahyssopin (XIII), and thymine lactone (XIV) treatment *in vivo* resulted in >30% reduction in the serum cholesterol levels of mice after 16 days.

Helenalin at 6 mg/kg/day and tenulin at 20 mg/kg/day reduced serum triglyceride levels by 24 and 28%, respectively, after 2 weeks of dosing. 2-Cyclopentenone (XV) and eupahyssopin were essentially inactive, causing 2 and 6% reduction of serum triglyceride levels, respectively. Helenalin, tenulin, deoxyelephantopin, eupahyssopin, and 2-cyclopentenone *in vitro* at 1 μmole suppressed the enzymes that regulate acetyl-CoA availability for triglyceride and cholesterol synthesis, *i.e.*, acetyl-CoA synthetase and citrate-lyase activity. The sesquiterpene lactones tested suppressed acetyl-CoA synthetase activity by 41–49% and citrate-lyase activity by 25–39%. The regulatory enzyme of fatty acid synthesis, acetyl-CoA carboxylase, was inhibited 66–84% in the presence of sesquiterpene lactones. Fatty acid synthetase activity also was inhibited 40–52% by these agents. β-Hydroxy-β-methylglutaryl-CoA reductase activity of the liver was inhibited 21–28% by the sesquiterpene lactones tested.

Table I—Serum Cholesterol Levels in CF$_1$ Male Mice after Intraperitoneal Dosing at 20 mg/kg/day

Compound	Percent of Control Day 9	Percent of Control Day 16
I Helenalin (6 mg/kg/day)	60 ± 3[a]	63 ± 4[a]
II 2,3-Dihydrohelenalin	99 ± 5	77 ± 7[a]

DISCUSSION

The sesquiterpene lactones were effective antihyperlipidemic agents in rodents. The α-methylene-γ-lactone moiety, the β-unsubstituted cyclopentenone ring, and the α-epoxycyclopentanone system contributed to the antihyperlipidemic activity of the sesquiterpene lactones and related compounds. Saturation of the 2,3-double bond of the cyclopentenone ring led to a loss of antihyperlipidemic activity, as was seen with II, VI, and IX. The α-epoxycyclopentanone ring system retained the antihyperlipidemic activity regardless of whether the α-methylene group of the γ-lactone ring (11,13-double bond) was reduced (*i.e.*, IV, VII, and X). Compounds containing the α-methyl-γ-lactone group (V and VIII) as opposed to the α-methylene-γ-lactone moiety (I) were equally active, because in both cases the essential cyclopentenone ring was retained (with the exception of III, in which case the 11-methyl group was β-oriented). The configuration of the γ-lactone ring did not appear to play an important role in the ability of the pseudoguaianolides to lower serum cholesterol levels, because the *cis*-fused lactones I and IV were approximately as potent as the *trans*-fused V, VII, VIII, and XI.

Germacranolides that contain the α-methylene-γ-lactone moiety had significant antihypercholesterolemic activity, *e.g.*, deoxyelephantopin (XII) and eupahyssopin (XIII). In addition to the essential α-methylene-γ-lactone moiety, XIII contains an ester side chain, a primary hydroxyl group, and an epoxy ring, which may contribute to the pharmacological activity. Compound XII, in addition to the α-methylene-γ-lactone, contains an α,β-unsaturated-γ-lactone ring and an ester side chain. The simple 2-cyclopentenone (XV), 2,3-epoxycyclopentan-1-one (XVI), maleic anhydride (XVII), and α-methylene-γ-lactone (XVIII) were not as active in lowering serum cholesterol, indicating that some other steric, configurational, or conformational arrangement was required for potent activity. The sesquiterpene lactones also were observed to lower serum triglycerides.

The proposed mechanism of action of the sesquiterpene lactones is the formation of adducts with the thiol groups of enzymes by a rapid Michael-type addition of the α-methylene-γ-lactone moiety or cyclopentenone ring system to the thiol nucleophile, thereby inactivating the enzyme (25, 26). Helenalin and tenulin block cellular metabolism by inhibiting key regulatory thiol-bearing enzymes, *e.g.*, DNA polymerase (6, 27) and phosphofructokinase (25). The β-hydroxy-β-methylglutaryl-CoA reductase, acetyl-CoA carboxylase, and fatty acid synthetase reportedly contain exposed thiol groups (28, 29). Further elevated cyclic adenosine monophosphate levels, which helenalin elevated by 194% (30), were related to the reduction of β-hydroxy-β-methylglutaryl-CoA reductase activity (31) and fatty acid synthesis by modulating acetyl-CoA carboxylase, fatty acid synthetase, and cytosol pyruvate levels for acetyl-CoA generation (32). For these reasons, several key regulatory enzymes in the genesis of fatty acid and cholesterol synthesis were measured to evaluate the effects of sesquiterpene lactones *in vivo*.

Studies on the generation of acetyl-CoA for fatty acid and cholesterol synthesis from cytosol acetate and citrate showed that the pseudoguaianolides (helenalin and tenulin) and the germacranolides (deoxyelephantopin and eupahyssopin) equally suppressed the activities of these two enzymes. Acetyl-CoA carboxylase activity, the regulatory enzyme of fatty acid synthesis, was reduced drastically in the presence of the sesquiterpene lactones, with helenalin being the most potent agent. Fatty acid synthetase activity also was reduced in the presence of the sesquiterpene lactones by ~50%. β-Hydroxy-β-methylglutaryl-CoA reductase activity was inhibited equally by the sesquiterpene lactones. The commercially available clofibrate, present at 41 μmoles, resulted in 23% inhibition, indicating that the sesquiterpene lactones were far more potent in inhibiting this enzyme that regulates cholesterol synthesis. Clofibrate required a dose of 300 mg/kg/day in rodents to reduce serum cholesterol levels and had no effect at 20 mg/kg/day. Thus, it can be concluded that the sesquiterpene lactones possess sufficient ability to block lipogenesis to warrant further investigation as antihyperlipidemic agents.

Evaluation of Nystatin Stability Using Tristimulus Colorimetry

JOHN E. FAIRBROTHER *, WILLIAM F. HEYES ˣ, GEOFFREY CLARKE, and PETER R. WOOD ‡

Received May 7, 1979, from the *Squibb Institute for Medical Research, International Development Laboratory, Moreton, Merseyside L46 1QW, United Kingdom.* Accepted for publication January 22, 1980. *Present address: School of Pharmacy, Nottingham University, United Kingdom. ‡Present address: Syntex Research Centre, Heriot Watt University, Edinburgh, United Kingdom.

Abstract □ A tristimulus reflectance spectrophotometer was used to examine the color changes of nystatin during accelerated stability studies, and a relationship was observed between the loss of microbiological potency and the change in color during thermal degradation. By substitution of the measured tristimulus values in the Kubelka–Munk equation, the remission function was calculated and resulted in a linear response with time. Application of the technique to bulk raw materials and formulated products is demonstrated, and uses of the technique are discussed.

Keyphrases □ Colorimetry—nystatin, thermal degradation, relationship between loss of microbiological potency and color change □ Degradation, thermal—nystatin, colorimetry, relationship between loss of microbiological potency, and color change □ Nystatin—thermal degradation, colorimetry, relationship between loss of microbiological potency and color change □ Antifungal agents—nystatin, thermal degradation colorimetry, relationship between loss of microbiological potency and color change

The most frequent use of surface color measurements in the pharmaceutical industry has been the monitoring of color stability of coated tablets (1). Alternative uses of the procedure have been described, particularly in preformulation and stability studies. These applications generally involve the determination of the discoloration exhibited by a particular drug–excipient mixture or formulation. By this means, the incompatibility of various mixtures was reported (2–6), and the stability of active ingredients in formulated products was determined (7). Prediction of the shelflife of tablets also may be assessed by this technique (8, 9). A comprehensive review of the pharmaceutical applications of tristimulus colorimetry and diffuse reflectance spectroscopy was published recently (10). The stability of the polyene antibiotic nystatin was evaluated in these laboratories by monitoring the color change at elevated temperatures. The color change at a solid surface is measured quantitatively by diffuse reflectance spectrometry, and monochromatic light generally is used to illuminate the sample. Alternatively, illumination may be by a white light source, and the values of each of the three primary color components (the tristimulus values) of the reflected light are determined. This technique usually is referred to as tristimulus colorimetry.

For nystatin, a visual relationship between the degree of browning observed and the loss of microbiological potency was demonstrated previously[1]. Therefore, tristimulus colorimetry was used to quantitate the observed color changes since the measurement of the tristimulus values closely parallels the color discrimination obtained with the human eye.

THEORY

To quantitate the observed degradation of nystatin, it was necessary to derive a suitable equation so that a relationship between the color and intensity of the reflected light, as described by the tristimulus values, and the concentration of colored material in the reflecting surface was defined. Kubelka and Munk (11, 12) derived an equation to describe the phenomenon of diffuse reflectance. For the special case of an infinitely thick opaque layer, it is:

$$f(R_\infty) = \frac{(1 - R_\infty)^2}{2R_\infty} = \frac{k}{s} \qquad \text{(Eq. 1)}$$

where R_∞ is the diffuse reflectance of the layer relative to a nonabsorbing standard, k is the molar absorption coefficient, s is the scattering coefficient, and $f(R_\infty)$ is the remission function. In practice, this requirement will be satisfied by a layer of material several millimeters deep.

The color of light reflected from the sample surface is described by the measured tristimulus values X, Y, and Z. The Y value corresponds to the Munsell value, which measures the degree of sample darkening, without regard to hue or chroma. The tristimulus values are used to calculate the chromaticity coordinates x, y, and z according to $x = X/(X + Y + Z)$, $y = Y/(X + Y + Z)$, and $z = Z/(X + Y + Z)$.

Tristimulus values are measured relative to a nonabsorbing standard, usually a white ceramic tile. For this study, the color of a sample before and after degradation was compared. This comparison may be achieved if the color of the degraded material is determined using the material prior to degradation as the standard. However, this procedure introduces practical difficulties and necessitates a large supply of original material. To overcome these difficulties, all materials were measured against a white tile as the standard, and the relative color change was calculated from the expression x_0/x_t, where x_0 is the initial chromaticity coordinate of the sample and x_t is the chromaticity coordinate at time t.

Substitution of these values into the Kubelka–Munk equation gives:

$$f(R_\infty) = \frac{(1 - x_0/x_t)^2}{2x_0/x_t} \qquad \text{(Eq. 2)}$$

The most frequent use of surface color measurements in the pharmaceutical industry has been the monitoring of color stability of coated tablets (1). Alternative uses of the procedure have been described, particularly in preformulation and stability studies. These applications generally involve the determination of the discoloration exhibited by a particular drug–excipient mixture or formulation. By this means, the incompatibility of various mixtures was reported (2–6), and the stability of active ingredients in formulated products was determined (7). Prediction of the shelflife of tablets also may be assessed by this technique (8, 9). A comprehensive review of the pharmaceutical applications of tristimulus colorimetry and diffuse reflectance spectroscopy was published recently (10). The stability of the polyene antibiotic nystatin was evaluated in these laboratories by monitoring the color change at elevated temperatures. The color change at a solid surface is measured quantitatively by diffuse reflectance spectrometry, and monochromatic light generally is used to illuminate the sample. Alternatively, illumination may be by a white light source, and the values of each of the three primary color components (the tristimulus values) of the reflected light are determined. This technique usually is referred to as tristimulus colorimetry.

For nystatin, a visual relationship between the degree of browning observed and the loss of microbiological potency was demonstrated previously[1]. Therefore, tristimulus colorimetry was used to quantitate the observed color changes since the measurement of the tristimulus values closely parallels the color discrimination obtained with the human eye.

THEORY

To quantitate the observed degradation of nystatin, it was necessary to derive a suitable equation so that a relationship between the color and intensity of the reflected light, as described by the tristimulus values, and the concentration of colored material in the reflecting surface was defined. Kubelka and Munk (11, 12) derived an equation to describe the phenomenon of diffuse reflectance. For the special case of an infinitely thick opaque layer, it is:

$$f(R_\infty) = \frac{(1 - R_\infty)^2}{2R_\infty} = \frac{k}{s} \qquad \text{(Eq. 1)}$$

where R_∞ is the diffuse reflectance of the layer relative to a nonabsorbing standard, k is the molar absorption coefficient, s is the scattering coefficient, and $f(R_\infty)$ is the remission function. In practice, this requirement will be satisfied by a layer of material several millimeters deep.

The color of light reflected from the sample surface is described by the measured tristimulus values X, Y, and Z. The Y value corresponds to the Munsell value, which measures the degree of sample darkening, without regard to hue or chroma. The tristimulus values are used to calculate the chromaticity coordinates x, y, and z according to $x = X/(X + Y + Z)$, $y = Y/(X + Y + Z)$, and $z = Z/(X + Y + Z)$.

Tristimulus values are measured relative to a nonabsorbing standard, usually a white ceramic tile. For this study, the color of a sample before and after degradation was compared. This comparison may be achieved if the color of the degraded material is determined using the material prior to degradation as the standard. However, this procedure introduces practical difficulties and necessitates a large supply of original material. To overcome these difficulties, all materials were measured against a white tile as the standard, and the relative color change was calculated from the expression x_0/x_t, where x_0 is the initial chromaticity coordinate of the sample and x_t is the chromaticity coordinate at time t.

Substitution of these values into the Kubelka–Munk equation gives:

$$f(R_\infty) = \frac{(1 - x_0/x_t)^2}{2x_0/x_t} \qquad \text{(Eq. 2)}$$

Similar equations may be written involving the *y* and *z* chromaticity coordinates.

EXPERIMENTAL

Tristimulus Value Measurements—*Powders*—To determine the tristimulus values of degraded nystatin powder, it was necessary to devise a sample holder. A nickel crucible cover[2] proved to be suitable. The recess in the cover was filled loosely with powder and leveled off with a spatula. The powder then was compressed into the recess by pressing a similar cover on top, resulting in a powder bed that was ~2 mm thick. The underside of this second cover was highly polished so that a smooth powder surface remained after compression.

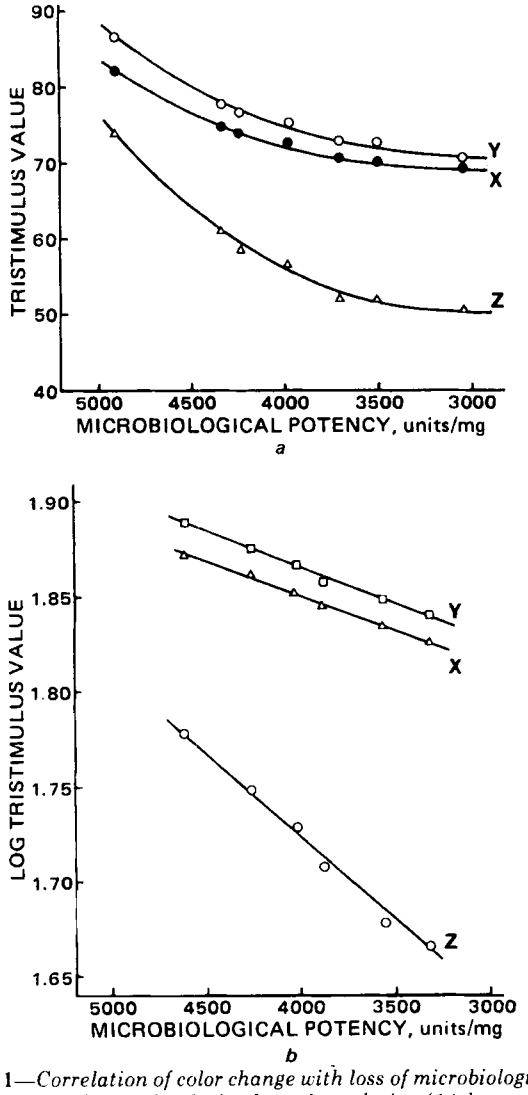

Figure 1—*Correlation of color change with loss of microbiological potency for nystatin powder during heat degradation (14 days at 75°).*

[2] Catalog item 3328-M10, A. H. Thomas, Philadelphia, Pa.

Ointments and Creams—For these formulations, a suitable sample holder consisted of a 3-mm thick polytef spacer, with a hole 30 mm in diameter, sandwiched between two clear glass microscope slides. To prepare a sample for color measurement, one microscope slide was placed beneath the spacer, and the 30-mm orifice was overfilled slightly with the ointment or cream to be tested. The second microscope slide then was placed on top, and the sandwich was gently squeezed together. By this means, all air bubbles were eliminated from the sample surface.

Measurement of the tristimulus values was accomplished by clipping either sample holder over the sample port of the colorimeter[3]. All measurements were made against a standard white tile[4] as the reference and with the nonspecular insert fitted.

Correlation of Potency with Color Change—Nystatin powder was heated at 75 and 85° in open dishes and in sealed screw-top bottles. Stored material was sampled at 24-hr intervals for 14 days. The color of the samples was determined as already described. The microbiological potencies of the same samples were determined by the agar-plate procedure using *Saccharomyces cereviseae*[5] (SQ 1600) and referenced against the current nystatin reference standard.

Degradation of Nystatin Powder and Formulations—Ointment and cream formulations were filled into Araldite-lined aluminum tubes and stored in thermostatically controlled environments at 20, 32, and 40°. The color of samples was assessed after 3, 6, and 12 months of storage. Additional examination of the samples at 40° was undertaken after 1 and 2 months of storage.

Powders were stored in humidity ovens[6] under ambient and 75% relative humidity (RH); 75% RH was achieved with a saturated aqueous solution of sodium chloride in contact with excess solid phase. Degradation was studied at 75, 85, and 100° by withdrawal of samples at 24-hr intervals for color determination.

RESULTS AND DISCUSSION

Before proceeding with the experimental work, the reproducibility of the proposed methods for tristimulus value determination was appraised. Tristimulus value measurements on representative fractions from the same batch of ointment or raw material (Table I) demonstrated good reproducibility for both sample types. A direct comparison of the tristimulus values with microbiological potency (Fig. 1*a*) demonstrated that an unprecedented quantitative relationship existed between the two parameters during the heat degradation of nystatin. The results represent the observed degradation over 14 days at 75°. Similar curves were obtained at higher temperatures. Furthermore, a linear correlation was obtained when the tristimulus values were plotted as logarithmic functions (Fig. 1*b*). Therefore, quantitation of the color change of the antibiotic is an alternative method of assessing the microbiological stability of nystatin.

Further examination of the heat-degraded nystatin by reversed-phase

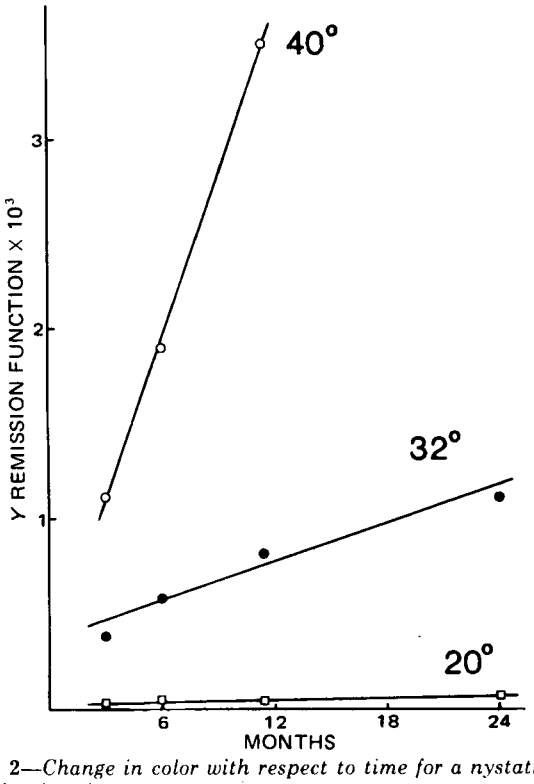

Figure 2—*Change in color with respect to time for a nystatin–steroid–lidocaine ointment.*

high-performance liquid chromatography[7] indicated that the observed color change also was related to the chemical decomposition of nystatin. A chemical decomposition of 13% was observed during the 14-day degradation period.

Ointments and Creams—To determine the applicability of the method to ointment and cream formulations, nystatin–steroid preparations were examined at intervals throughout the normal stability program, and the Kubelka–Munk functions were calculated from the tristimulus values obtained. A plot of the Kubelka–Munk remission function *versus* time (Fig. 2) for a nystatin–steroid–lidocaine ointment demonstrates a linear response over the time period considered. Either the X or Y function may be used with essentially similar results. The slope of the remission function *versus* time graph represents the degradation rate constant k. The k values obtained for the degradation of the ointment at 20, 32, and 40° were evaluated in accordance with the Arrhenius equation. A plot of log k *versus* $1/T$ resulted in a linear graph, thus suggesting that accelerated stability evaluations at 40° are valid for the prediction of room temperature stability (Fig. 3).

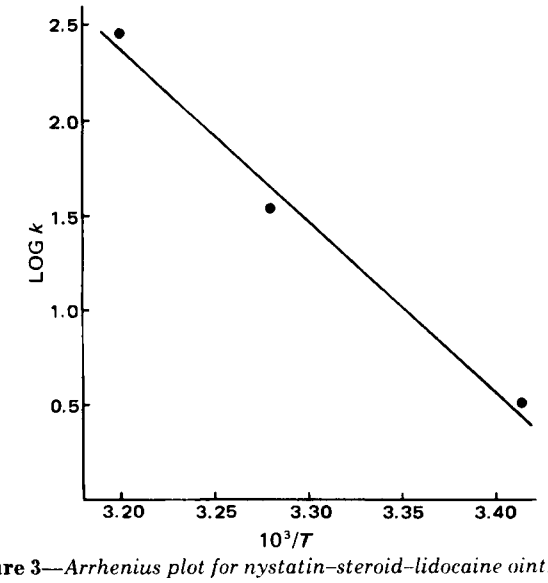

Figure 3—*Arrhenius plot for nystatin–steroid–lidocaine ointment.*

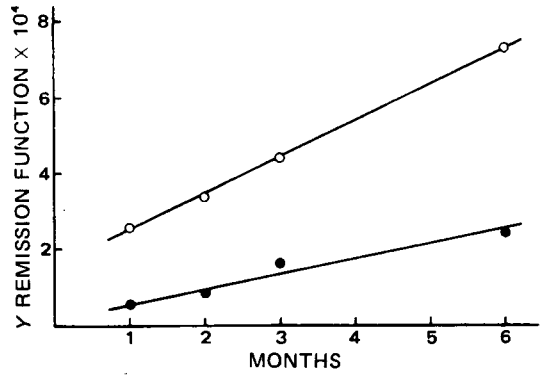

Figure 4—*Comparison of the color change of two nystatin creams. Key:* ●, *with added antioxidant; and* ○, *without antioxidant.*

Discoloration of the antibiotic in two cream formulations is shown in Fig. 4, and a linear response with time again is apparent. The difference in the slope values indicates the difference in stability of the two formulations (one contained an antioxidant) and confirmed data previously obtained in these laboratories using microbiological assays.

Accelerated stability testing of creams and ointments at temperatures higher than 40° has not been attempted.

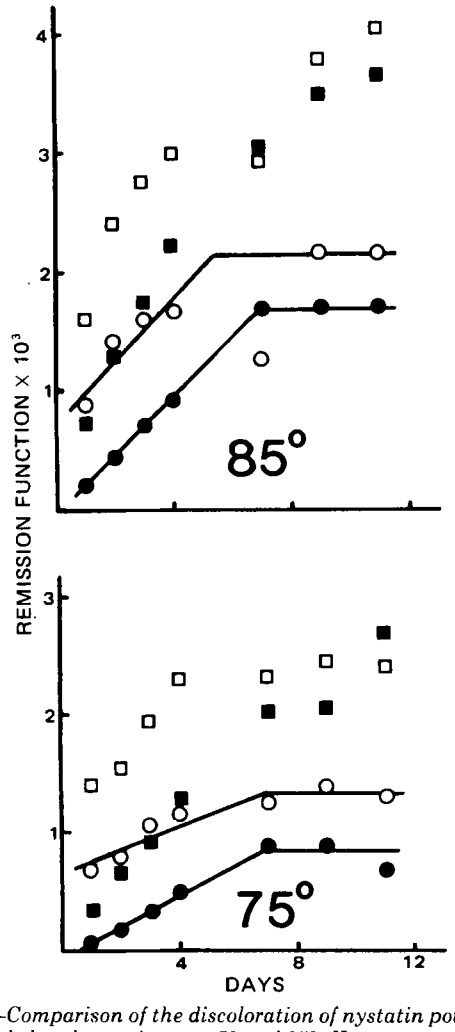

Figure 5—*Comparison of the discoloration of nystatin powder stored in open and closed containers at 75 and 85°. Key:* □, *open dish,* X *remission function;* ■, *closed container,* X *remission function;* ○, *open dish,* Y *remission function; and* ●, *closed container,* Y *remission function.*

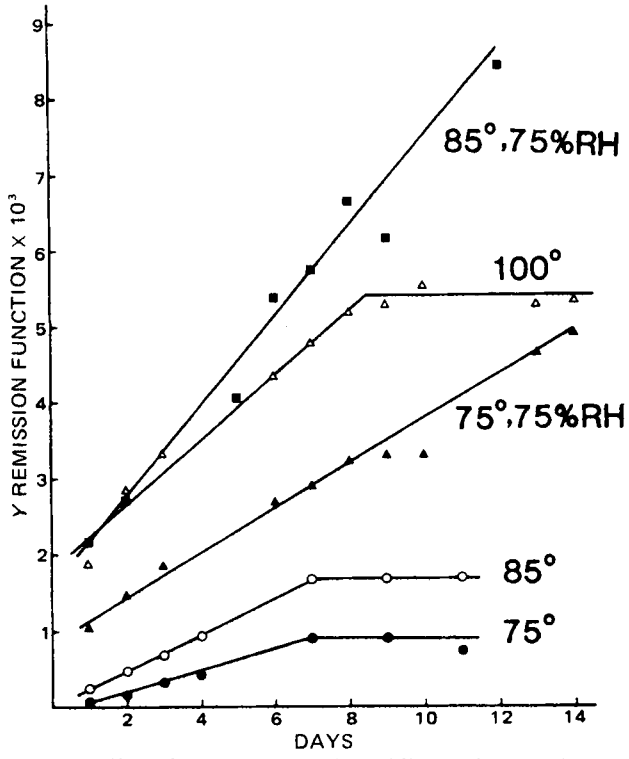

Figure 6—*Effect of temperature and humidity on the rate of nystatin powder discoloration.*

Bulk Raw Material—With the ointment and cream formulations, which are stored in sealed containers during stability monitoring, only one variable (temperature) is possible. However, with solids, the material may be stored in open or closed systems; with open containers, humidity may be included as another variable parameter. Bashkovich *et al.* (13) reported an increase in the rate of nystatin inactivation in a humid atmosphere.

To assess the effect of these variables on the discoloration of nystatin, the antibiotic was stored in open dishes and in sealed screw-top vials at

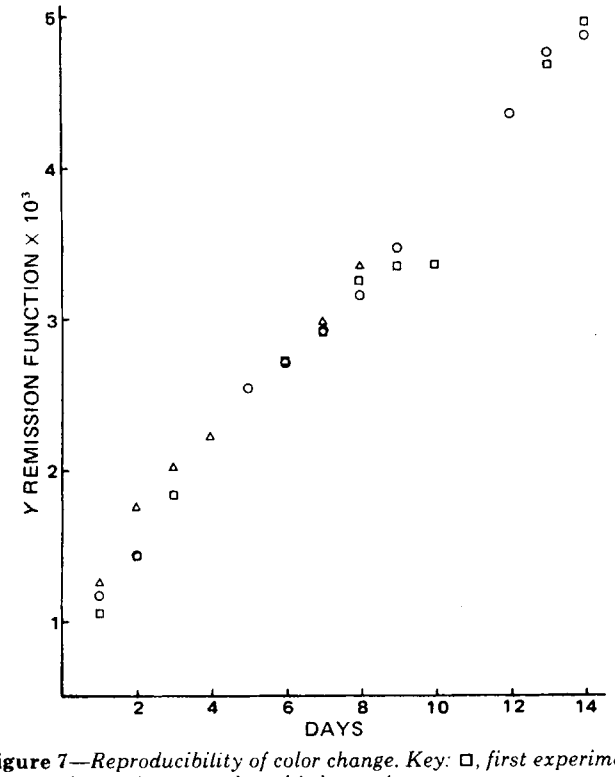

Figure 7—*Reproducibility of color change. Key:* □, *first experiment;* ○, *second experiment; and* ●, *third experiment.*

Table II—Reproducibility of Technique

1	4.57	0.9935
2	4.79	0.9964
3	5.23	0.9928

a series of temperatures. In additional experiments, the powder was stored in an atmosphere of 75% RH in open dishes at elevated temperatures. The color change was determined daily, and the Kubelka–Munk remission functions were calculated from the results.

The use of open and closed containers is compared in Fig. 5, which shows the change in remission function with time. The plots for each type of container demonstrate that essentially similar results were obtained regardless of the temperature. Comparison of the tristimulus values of the degraded nystatin samples, determined before and after thorough mixing of the material, showed little difference, indicating that the color change was not a surface phenomenon but instead took place throughout the entire material.

The effect of moisture on nystatin degradation is demonstrated in Fig. 6. Not only was the degradation rate increased, but the plateau effect, noted with samples stored at ambient relative humidity, was eliminated under humid conditions. The nature of the plateau effect is not understood fully, but it is thought to be due in part to a loss of moisture from the nystatin samples, all of which contained about 5% moisture prior to degradation. This moisture level is normal in the manufactured product.

Only samples stored under humid conditions resulted in a linear change of the Kubelka–Munk remission function throughout the 14-day period. The most satisfactory correlation coefficient was obtained for the nystatin degraded at 75° and 75% RH. To assess the reproducibility of the degradation rate under these conditions, one batch of nystatin was degraded on three separate occasions during 3 months. The results (Fig. 7) show little scatter and indicate the robustness of the procedure. Calculation of the respective slopes and correlation coefficients for each set of points (Table II) demonstrated the reproducibility of the technique.

The linear response thus allows calculation of an actual degradation rate, which is advantageous when comparing factors affecting nystatin stability, as in preformulation studies, or when comparing the stability of bulk nystatin from different sources. Previous investigations were accomplished microbiologically (13–15). However, the decrease in potency observed during the degradation period was nonlinear and allowed only qualitative comparisons. With the alternative procedure described in this paper, it is possible to compare materials and formulations quantitatively, an objective previously unattainable.

If the application of this novel technique to other antibiotics proves successful, the tristimulus colorimetric technique should be established firmly in pharmaceutical analysis.

High-Pressure Liquid Chromatographic Determination of Sulfamethazine Residues in Beef Tissues

DAVID SEYMOUR ˣ **and B. DEAN RUPE**

Received November 8, 1979, from *Jensen-Salsbery Laboratories, Division of Burroughs Wellcome Co., Kansas City, MO 64108.* Accepted for publication January 24, 1980.

Abstract □ A high-pressure liquid chromatographic procedure for the determination of sulfamethazine residues in beef tissues is presented. Tissue samples are extracted and analyzed utilizing normal-phase chromatography and a UV detector at 254 nm. Primary and confirmatory identification and quantitative determination are provided at the tolerance limit of 0.1 ppm of sulfamethazine in tissues. Recoveries obtained from liver, fat, kidney, and muscle tissues were 69, 82, 77, and 76%, respectively, when spiked at the tolerance limit.

Keyphrases □ Sulfamethazine—high-pressure liquid chromatographic determination, beef tissues □ High-pressure liquid chromatography—analysis, sulfamethazine, beef tissues □ Chemotherapeutic agents—sulfamethazine, high-pressure liquid chromatographic determination, beef tissues

Sulfamethazine (I), a chemotherapeutic agent, has been used successfully for more than 30 years in the treatment of infectious diseases in cattle. A tolerance limit of 0.1 ppm has been established for the drug residues in uncooked edible tissues of cattle[1]. The Bratton–Marshall (1) procedure and subsequent modifications (2, 3) were used to indicate the residue levels of I but, due to nonspecificity (4), these procedures no longer meet the rigorous requirements recently established by the regulatory agencies for residue assay procedures.

Several procedures that provide improved specificity for sulfamethazine residues in tissues using TLC (4), GLC (5), and high-pressure liquid chromatography (HPLC) (6) were reported recently. However, no procedure has been approved by the regulatory agencies for use in a tissue residue study. A study was conducted in this laboratory to develop a procedure that could be approved for the determination of sulfamethazine residues in beef tissues. The method employs HPLC to provide a qualitative (both primary and confirmatory) and quantitative assay of I in tissues at the tolerance limit.

EXPERIMENTAL

Materials—Methylene chloride[2], chloroform[2], methanol[3], isooctane[3], and acetic acid[3] were analytical reagent grade and were used as received. Sulfamethazine[4] (I), sulfadimethoxine[5] (III), sulfadiazine[6] (VI), and sulfachlorpyridazine[2] (V) were used as received. Sulfabromomethazine[7] (II) was dissolved in water, buffered to pH 5–6, and extracted into methylene chloride prior to chromatography. Sulfaethoxypyridazine[4] (IV) was obtained by direct dissolution of an equivalent amount of a bolus[8] into methylene chloride.

Apparatus and Chromatographic Parameters—A high-pressure liquid chromatograph[9] was equipped with a septumless injector, a normal-phase 25-cm column[10], a UV detector set at 254 nm, and a strip-chart recorder. Unless otherwise noted, a mobile phase of 65% chloroform, 30.5% isooctane, 4.0% methanol, and 0.5% acetic acid was used. The flow rate was 20 ml/hr, and the UV detector was operated at 0.002 aufs.

Working Standards—Solutions of each sulfonamide were prepared at 8 μg/ml in methylene chloride.

Analytical Standards—Standards equivalent to 0.1, 0.2, and 0.4 ppm of I in tissues were prepared by pipetting 0.5, 1.0, and 2.0 ml, respectively, of a 4-ppm solution of I in methylene chloride into tared 30-ml beakers. The weight of each solution was adjusted to 1 ± 0.02 g by evaporation or addition of methylene chloride immediately prior to injection of a 10-μl aliquot into the liquid chromatograph. *Standards were not allowed to evaporate to dryness.*

Acetylation Technique—One milliliter of methanol and 2 drops of acetic anhydride were added to each sample to be acetylated. The samples then were heated on a hot plate at 80–90° until acetic acid fumes could not be detected. The residue was dissolved in 1 g of methylene chloride, and 10-μl aliquots were injected.

Residue Assay Procedure—The tissues were cut into small pieces (200–300 mg), and 20 ± 0.1 g was weighed into 100-ml beakers. Following the addition of 25 ml of methylene chloride, the samples were mixed with a glass stirring rod and allowed to stand for 20–30 min with frequent stirring. The methylene chloride was decanted into 125-ml separators through a funnel plugged with glass wool. The tissues were extracted with two additional 25-ml portions of methylene chloride, and the aliquots were pooled in their respective separators.

After the addition of 10 ml of 3 *N* H_2SO_4, the samples were extracted for 15 min, and the lower phase was discarded completely. The remaining aqueous phase was washed twice by adding 10 ml of methylene chloride, shaking for 10 min, and discarding the lower phase.

One milliliter of 10% K_2HPO_4 and 3 ml of 40% NaOH were added to each separator. The samples were mixed well and allowed to cool, and the pH was measured with pH paper. A pH of 5–6 was obtained by dropwise addition of 3 *N* H_2SO_4 or 40% NaOH. The final pH was measured potentiometrically.

After the addition of 5 ml of methylene chloride, the samples were extracted for 15 min. The lower phase was dried by draining through a bed of anhydrous sodium sulfate and collected in previously weighed 50-ml beakers. The extraction was repeated, and the extracts were collected in their respective beakers.

The samples were placed on a hot plate at 60–70°, and the weight of the solution was adjusted to 1 ± 0.02 g by evaporation immediately prior to injecting 10 μl into the liquid chromatograph.

Evaporation to dryness of either samples or standards was avoided because of resulting sulfamethazine losses.

After the samples were chromatographed satisfactorily, the samples were acetylated and reinjected.

RESULTS AND DISCUSSION

Qualitative Assay—Ten-microliter samples of each working standard were injected into the liquid chromatograph stabilized at the specified parameters. Retention times of each sample are given in Table I. Primary identification of an unknown sulfonamide can be made by comparison of retention times for the sample to those of authentic standards.

Table I—Sulfonamide Retention Times

Sulfonamide	Retention Time, min
Sulfabromomethazine	3.56
Sulfadimethoxine	3.99
Sulfamethazine	4.34
Sulfaethoxypyridazine	4.60
Sulfachlorpyridazine	5.60
Sulfadiazine	5.55

Table II—Acetylated Sulfonamide Retention Times

Acetylated Sulfonamide	Retention Time, min
Acetylsulfabromomethazine	4.16
Acetylsulfadimethoxine	4.70
Acetylsulfamethazine	5.34
Acetylsulfaethoxypyridazine	5.23
Acetylsulfachlorpyridazine	6.68
Acetylsulfadiazine	6.78

Table III—Retention Times of Sulfadimethoxine, Sulfamethazine, Sulfaethoxypyridazine, and Their Acetylated Derivatives Using the Alternative Solvent System of 97% Chloroform, 2% Acetic Acid, and 1% Ethanol

Sulfonamide	Retention Time, min
Sulfadimethoxine	3.5
Sulfamethazine	4.4
Sulfaethoxypyridazine	5.3
Acetylsulfadimethoxine	8.0
Acetylsulfamethazine	10.2
Acetylsulfaethoxypyridazine	13.5

One-milliliter portions of each working standard were acetylated, and 10-μl aliquots were injected as described. Retention times of each acetylated sulfonamide are given in Table II. Confirmatory identification of an unknown sulfonamide can be made by comparison of its retention time after acetylation to that of acetylated authentic standards.

Improved resolution of I, III, and IV was obtained using an alternative solvent system of 97% chloroform, 2% acetic acid, and 1% ethanol (Fig. 1). Retention times of these three sulfonamides and their acetylated derivatives are given in Table III.

Solutions containing mixtures of sulfamethazine and any of the other sulfonamides examined could be resolved completely with the two solvent systems. Due to column variation, slight adjustment of the mobile phases may be necessary for adequate resolution.

The specificity of the technique, primarily due to the retention times of sulfamethazine and its acetylated derivative, is increased by the tissue extraction procedure. Only compounds possessing amphoteric properties very similar to I are recovered to any significant degree. Many potentially interfering, naturally occurring components of tissue and nearly all drugs other than sulfonamides currently being used in cattle are eliminated prior to chromatography. Although recoveries of sulfonamides other than I have not been confirmed, the potential interference of many compounds (II–VI) is eliminated by the resolutions obtained with the technique. Sulfonamides other than the ones mentioned previously that have been examined and found not to interfere include sulfamerazine, sulfathiazole, sulfanilamide, sulfapyridine, and sulfaquinoline. No compound has been found to date that interferes with the identification of residues of I in tissues using this method.

Quantitative Assay—Analytical standards containing amounts of I equivalent to 0.1, 0.2, and 0.4 ppm in tissues were prepared. Ten-microliter injections of these standards after weight adjustment of the solution to 1 ± 0.02 g gave peak heights proportional to the amounts of I injected. Reproducibility and linearity of the technique are shown by replicate injections of standards at the various concentrations (Table IV). Unknown amounts of I in solution are determined by comparison of sample and standard peak heights obtained from 10-μl injections after weight adjustment to 1 ± 0.02 g.

Residues of I in tissues are calculated from:

$$\frac{\text{sample peak height}}{\text{standard peak height}} \times \frac{\text{micrograms of I in standard}}{\text{weight of sample, g}} = \text{ppm of I} \quad \text{(Eq. 1)}$$

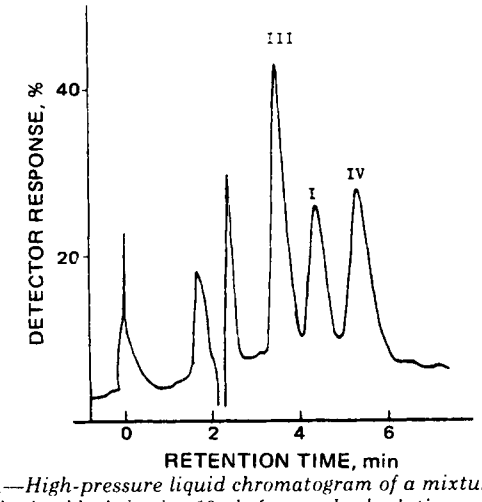

Figure 1—*High-pressure liquid chromatogram of a mixture of I, III, and IV obtained by injecting 10 µl of a standard solution equivalent to 0.1 ppm of each in tissue. The solvent system was 97% chloroform, 2% acetic acid, and 1% ethanol.*

[a] Duplicate samples. [b] Sample lost.

Recovery of I from Tissues—Percent recovery data (Table V) were obtained by taking beef tissues spiked at 0.1, 0.2, and 0.4 ppm of I through the tissue assay procedure and comparing the peak heights obtained to those of the appropriate analytical standards. These data were obtained from five samples of each tissue, in duplicate, at each concentration. Analyses of the data showed >70% average recovery in every tissue at the

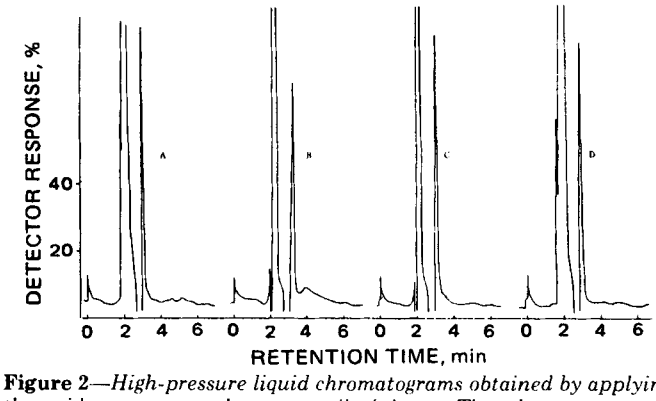

Figure 2—*High-pressure liquid chromatograms obtained by applying the residue assay procedure to unspiked tissues. The solvent system was 65% chloroform, 30.5% isooctane, 4.0% methanol, and 0.5% acetic acid. Key: A, liver; B, kidneys; C, muscle; and D, fat.*

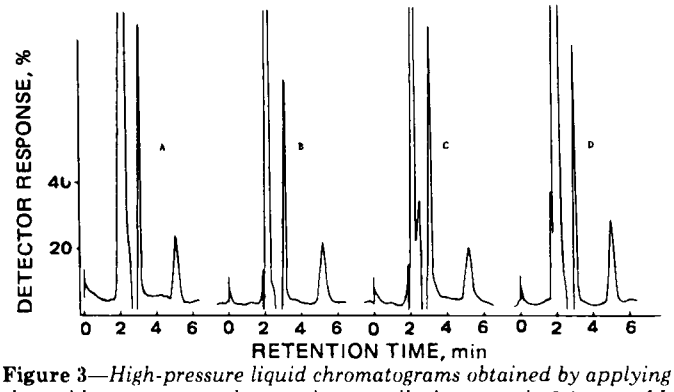

Figure 3—*High-pressure liquid chromatograms obtained by applying the residue assay procedure to tissues spiked to contain 0.1 ppm of I. The solvent system was 65% chloroform, 30.5% isooctane, 4.0% methanol, and 0.5% acetic acid. Key: A, liver; B, kidneys; C, muscle; and D, fat.*

tolerance level except liver, which had a recovery of 69% and a relative standard deviation of ~10% (Table V).

Unspiked tissues typically showed no peak other than random baseline noise in the region where I eluted (Fig. 2). The magnitude of the sulfamethazine signal obtained from tissues spiked at the tolerance limit was ~20% of full scale (Fig. 3). A favorable signal-to-blank ratio at the tolerance limit was obtained with this procedure, allowing low detection limits. The tolerance limit of 0.1 ppm of I in tissues was approximately five times the detection limit of the method.

With slight modifications, the method should be applicable to several sulfonamides currently used in veterinary medicine. Recoveries of sulfamethazine only have been demonstrated to date.

Teratogenic Potential of Cocaine Hydrochloride in CF-1 Mice

MICHAEL P. MAHALIK, RONALD F. GAUTIERI ˣ, and DAVID E. MANN, Jr.

Received December 20, 1979, from the *Department of Pharmacology, School of Pharmacy, Temple University, Philadelphia, PA 19140.* Accepted for publication January 30, 1980.

Abstract □ This investigation revealed that cocaine hydrochloride was teratogenic when administered in nontoxic doses to gravid CF-1 mice on Days 7–12 of gestation. The teratogenic susceptibility of the CF-1 mouse fetus to cocaine hydrochloride was evident throughout this portion of the gestation period. The early appearance of eye defects and the occurrence of skeletal defects later in gestation after cocaine hydrochloride challenge paralleled the sequence of ontogenesis.

Keyphrases □ Cocaine hydrochloride—evaluation as potential teratogen, effect on catecholamine levels in placenta, skeletal and soft tissue malformations in fetal mice □ Teratogenic drugs—cocaine hydrochloride, effect on fetal mice □ Inhibition, competitive—cocaine hydrochloride and norepinephrine, effect on fetal mice

Cocaine (benzoylmethylecgonine), the first local anesthetic discovered, not only inhibits nerve conduction but also prevents norepinephrine reuptake at nerve terminals (1). Because of the latter action, norepinephrine levels are augmented and vasoconstriction occurs (1).

BACKGROUND

Previous studies detected catecholamines in human amniotic fluid (2) and placenta (3). If the mechanisms for storage and release of norepinephrine in the placenta are comparable to those at nerve terminals, increased catecholamine levels induced by cocaine could cause placental vasoconstriction.

A relationship between placental vasoconstriction and fetal anomalies was demonstrated in studies involving mechanical obstruction of uterine and placental vascular flow by clamping, which probably causes fetal malformations through decreased oxygen availability (4–7), and by drugs such as serotonin (8) and morphine (9), which accomplish similar effects pharmacodynamically.

With respect to the autonomic neural involvement of cocaine as a potential teratogen, Furchgott *et al.* (10) detected a specific transfer site with which norepinephrine molecules combine before being transferred to storage or enzymatic inactivation loci. According to Johnson and Kahn (11), the potentiation of norepinephrine responses by cocaine results from competitive inhibition between the local anesthetic and norepinephrine molecules at these transfer sites. Thus, in pregnant mice, cocaine conceivably could induce fetal malformations by raising catecholamine levels which, in turn, cause placental vasoconstriction *via* competitive inhibition.

The purpose of this study was twofold: (*a*) to test the hypothesis that cocaine is a potential teratogen in mice, and (*b*) if the results were affirmative, to ascertain the precise days of gestation when fetal susceptibility to the teratogen is evident.

EXPERIMENTAL

Animals—The test animals were CF-1 mice[1], 25–30 g. Females were placed in aggregate cages, each holding 10 animals. Two weeks after their arrival, the mice were bred if they weighed at least 25 g. Males were placed individually in metal cages (12.5 × 15 × 10 cm) with a wire-mesh front and floor[2]. All animals were maintained on laboratory food[3] and tap water *ad libitum*.

The room housing the animals was protected from exposure to natural sunlight and was equipped with an electrical lighting system[4], which al-

The early appearance of eye defects and the occurrence of skeletal defects later in gestation after cocaine hydrochloride challenge paralleled the sequence of ontogenesis.

Keyphrases □ Cocaine hydrochloride—evaluation as potential teratogen, effect on catecholamine levels in placenta, skeletal and soft tissue malformations in fetal mice □ Teratogenic drugs—cocaine hydrochloride, effect on fetal mice □ Inhibition, competitive—cocaine hydrochloride and norepinephrine, effect on fetal mice

Cocaine (benzoylmethylecgonine), the first local anesthetic discovered, not only inhibits nerve conduction but also prevents norepinephrine reuptake at nerve terminals (1). Because of the latter action, norepinephrine levels are augmented and vasoconstriction occurs (1).

BACKGROUND

Previous studies detected catecholamines in human amniotic fluid (2) and placenta (3). If the mechanisms for storage and release of norepinephrine in the placenta are comparable to those at nerve terminals, increased catecholamine levels induced by cocaine could cause placental vasoconstriction.

A relationship between placental vasoconstriction and fetal anomalies was demonstrated in studies involving mechanical obstruction of uterine and placental vascular flow by clamping, which probably causes fetal malformations through decreased oxygen availability (4–7), and by drugs such as serotonin (8) and morphine (9), which accomplish similar effects pharmacodynamically.

With respect to the autonomic neural involvement of cocaine as a potential teratogen, Furchgott *et al.* (10) detected a specific transfer site with which norepinephrine molecules combine before being transferred to storage or enzymatic inactivation loci. According to Johnson and Kahn (11), the potentiation of norepinephrine responses by cocaine results from competitive inhibition between the local anesthetic and norepinephrine molecules at these transfer sites. Thus, in pregnant mice, cocaine conceivably could induce fetal malformations by raising catecholamine levels which, in turn, cause placental vasoconstriction *via* competitive inhibition.

The purpose of this study was twofold: (*a*) to test the hypothesis that cocaine is a potential teratogen in mice, and (*b*) if the results were affirmative, to ascertain the precise days of gestation when fetal susceptibility to the teratogen is evident.

EXPERIMENTAL

Animals—The test animals were CF-1 mice[1], 25–30 g. Females were placed in aggregate cages, each holding 10 animals. Two weeks after their arrival, the mice were bred if they weighed at least 25 g. Males were placed individually in metal cages (12.5 × 15 × 10 cm) with a wire-mesh front and floor[2]. All animals were maintained on laboratory food[3] and tap water *ad libitum*.

The room housing the animals was protected from exposure to natural sunlight and was equipped with an electrical lighting system[4], which al-

lowed 12 hr of light (7:00 am–7:00 pm) and 12 hr of darkness. The temperature was maintained at 22–26°.

Determination of Teratogenic Dose—The teratogenic dose of a suspected teratogen is based on its relationship to its toxic dose (LD_{50}). To ascertain the LD_{50} of cocaine hydrochloride, 40 female nongravid mice were selected randomly and assigned to one of five groups of eight animals each. Dosage levels for the five groups were 75, 100, 125, 150, and 175 mg/kg, respectively. Each mouse was weighed to the nearest 0.1 g, caged individually, and injected subcutaneously with a freshly prepared cocaine hydrochloride solution into the right side of the abdomen. After each injection, the mice were observed for behavioral changes and fatalities.

The estimated LD_{50} of cocaine hydrochloride in nongravid mice was 113 mg/kg (12). Nongravid animals are acceptable substitutes for gravid animals because the LD_{50} of a drug in gravid mice generally is equivalent to that in nongravid mice (13). Because a dose that produces severe toxicity and behavioral changes in female mice also will exert devastating effects on developing fetuses, the teratogenic dose should be nonlethal and elicit only minimal pharmacological responses.

Stimulation followed by depression and eventual recovery occurred in most animals receiving doses of 100 mg/kg or higher, but deaths also were noted at these levels. At the lowest dose (75 mg/kg), four animals showed no apparent effects; four became excited, developed a Straub tail, and bit the cage, and one convulsed. Although this dosage produced no deaths, it was not regarded as optimal because of excessive stimulation of the central nervous system. Therefore, another randomly selected group of animals was given a 70-mg/kg dose by the same route and procedure. At this level (below the LD_1), no deaths were noted, although convulsions still persisted. A 60-mg/kg dose was given to another group, which showed mild excitatory responses and a Straub tail in the absence of convulsions. Therefore, this dose (60 mg/kg) was selected as the teratogenic dose for this study.

Breeding Procedure and Treatment Regimen—Timed pregnancies were accomplished by placing two females in a cage with a male from 3:00 pm until 7:00 am, whereupon they were removed and examined for vaginal plugs. Animals with plugs were termed gravid, and the day of gestation coincident with their appearance was designated as Day 0. The pregnant mice then were weighed to the nearest 0.1 g[5], and each weight was recorded as the maternal starting weight.

Gravid animals were placed in individual cages identical to those of the males, where they remained undisturbed until the morning of Day 7 of gestation when they were reweighed. A weight gain of 2 g or more confirmed pregnancy. These animals then were assigned randomly to one of 13 groups of eight mice each. Six groups received single injections of cocaine hydrochloride (60 mg/kg) on Day 7, 8, 9, 10, 11, or 12, respectively; six groups received 0.3 ml of normal saline as a single injection on Days 7–12 of gestation (trauma controls). The final group represented untreated controls.

Preparation of Cocaine Hydrochloride Solution—Cocaine hydrochloride solution[6] (2%) was prepared by dissolving the drug in double-distilled water. The sodium chloride solution[7] was prepared commercially. All injections were made subcutaneously with a glass syringe[8].

Examination of Fetuses—Following treatment, each mouse was permitted to proceed to Day 18, the day prior to the termination of gestation, whereupon the terminal maternal weight was recorded. The animal then was sacrificed by cervical dislocation, and its abdomen was opened to expose the peritoneal cavity. The uterine horns were examined grossly for fetal swellings and resorption sites, appearing as small dark nodules, which were counted and recorded.

Following incision of the uterine horns, the exposed fetuses were removed, blotted dry, and weighed to the nearest 0.01 g on a torsion balance[9]. Each fetus was examined grossly for external soft tissue defects and sexed. Viability was determined by reflex movement of the limbs in response to mechanical stimulation with a blunt probe. Every other fetus

was immersed in either a bone-staining solution or Bouin's fixative and processed for skeletal or soft tissue examination, respectively.

Fetuses destined for soft tissue examination were fixed and decalcified in Bouin's fixative for at least 2 weeks, whereupon they were reexamined for external anomalies with a low power binocular dissecting microscope[10] and sectioned according to a literature method (14). Fetuses designated for skeletal examination were processed according to the technique of Staples and Schnell (15). The significance of observed variations among the experimental groups was determined by the Student t test and the uncorrected χ^2 test for binomial populations (16).

RESULTS AND DISCUSSION

The results of this study support the hypothesis that cocaine possesses teratogenic potential. Significant occurrences of soft tissue abnormalities, as compared with those of the controls, were observed on each day of cocaine treatment. Significant skeletal anomalies were observed on Days 7–9 of cocaine treatment as compared with the controls (Table I). Following the subcutaneous administration of cocaine hydrochloride (2%) at 60 mg/kg, a significant incidence of fetuses with exencephaly, cryptorchidism, hydronephrosis, anophthalmia, malformed or missing lenses, delayed ossification of the skull, paws (17), or centrum, extra ribs, malformed or crankshaft sternebrae (18), and split or butterfly xiphoid processes occurred when compared with those observed in the respective control groups (Tables II–VI).

Significant differences also were noted in the resorption (Day 10) and sex ratio (Day 9) when compared with those of the controls (Table I). Data in Table I indicate that cocaine did not alter the maternal mean terminal weights when compared to those of the controls, nor did the maternal weight gain during gestation appear to indicate fetal size or development. Furthermore, the initial starting weight of gravid mice was not responsible for any changes in the mean fetal weight (*i.e.*, there was no apparent

correlation between fetal growth retardation and increased susceptibility to teratogenesis).

The central stimulatory effects of cocaine hydrochloride observed in the dams were minimal, and no fatalities occurred in the treated groups. These results agree with those of previous studies in which other teratogenic drugs also were nonlethal (19). Because of the mild excitability and nonlethality observed with the dose of cocaine hydrochloride employed in this study, there appears to be no correlation between the production of fetal malformations and increased maternal toxicity.

A critical period exists when a maximum frequency of teratogenic insults occurs. Although these periods overlap for different organs and structures, there is a definite time of susceptibility to teratogens, as was confirmed by this investigation. Interference with developmental or biochemical processes at a specific time during ontogenesis by either drug treatment or hypoxia causes defects that parallel the development period of the affected organ or structure. For example, the days of gestation during which the most prominent occurrence of defects was noted in this study corresponded to those reported previously (6, 8, 9, 19).

In addition, there was a correlation between cocaine hydrochloride and other specific treatments and conditions with respect to the production of comparable anomalies on similar days of gestation. For example, the most prominent day for the occurrence of exencephaly and sternebrae defects in this study was Day 9. Previous studies with different agents (8, 19) and hypoxic conditions (6, 20) also found maximum responses for exencephaly and vertebral defects on Day 9 of gestation. It appears that cocaine may decrease placental transfer of oxygen as a contributing factor to its teratogenicity, because hypoxic conditions elicit similar anomalies (*i.e.*, exencephaly) at similar times of the gestation period (6, 8, 19, 20).

A significant incidence of skeletal abnormalities appeared late in gestation whereas eye defects occurred early, paralleling closely the period of ontogenesis for these structures (21, 22) (Tables III and IV). The period of susceptibility of the CF-1 mouse fetus to the teratogenic effects of cocaine hydrochloride was evident throughout the range of drug administration in this study (Days 7–12) and was not confined to any particular day.

Sensitive GLC–Mass Spectrometric Determination of Chlorpheniramine in Serum

JOHN A. THOMPSON *x and FRED H. LEFFERT ‡

Received December 24, 1979, from the *School of Pharmacy, University of Colorado, Boulder, CO 80309, and the ‡National Jewish Hospital, Denver, CO 80206. Accepted for publication January 30, 1980.

Abstract □ A new method was developed for the quantitative analysis of chlorpheniramine in serum using the high sensitivity and selectivity of GLC–mass spectrometry with selected-ion monitoring. Intense fragment ions at *m/e* 203 and 207 from the drug and a tetradeuterated analog, respectively, are monitored continuously. The deuterated quantitation standard can be prepared by a simple exchange reaction. A linear calibration curve was obtained over the range of 0–160 ng/ml of serum using 85 ng of the standard/ml. The sensitivity limit is 1–2 ng/ml, and each serum extract can be analyzed in <2 min. The method was applied to a clinical pharmacokinetic investigation and was sufficiently sensitive to measure chlorpheniramine concentrations through at least 1.5 biological half-lives.

Keyphrases □ Chlorpheniramine—GLC–mass spectrometric analysis, pharmacokinetics, human serum □ GLC–mass spectrometry—analysis, chlorpheniramine, pharmacokinetics, human serum □ Pharmacokinetics—chlorpheniramine, GLC–mass spectrometric analysis, human serum □ Antihistaminics—chlorpheniramine, GLC–mass spectrometric analysis, human serum

Chlorpheniramine is an alkylamine antihistamine widely used to alleviate symptoms of the common cold and of allergic reactions. Despite the importance of this drug, little pharmacokinetic data have been published. In three studies using oral dosing with four to six adult subjects, biological half-lives of 12–15 hr (1), 24.5–36.3 hr (2), and 20.6–42.5 hr (3) were reported. The inconsistencies in the available pharmacokinetic data and the unavailability of data in subjects from different age groups with intravenous dosing established the need for further investigation in this area.

BACKGROUND

Chlorpheniramine is a potent antihistamine recommended for use in relatively small doses (4). Previous studies established the need for assay methods that are sufficiently sensitive to measure ~2 ng of drug/ml of serum (1, 2), a fact that contributed to the paucity of pharmacokinetic data. Although several analytical procedures are available to measure chlorpheniramine (1, 2, 5–10), most of the methods were developed to assay the drug in dosage forms or in urine; only a few of these methods have the necessary sensitivity to measure normal serum levels throughout a kinetic investigation.

TLC with liquid scintillation counting (1) cannot be used routinely because it requires administration of radiolabeled drug to human subjects. TLC followed by chemical conversion to an azo dye and subsequent colorimetric analysis (2) is a laborious procedure. The GLC procedure using electron-capture detection is also complicated (9). This method requires the liquid chromatographic separation of the drug from its metabolites and an oxidation reaction as preliminary steps.

Perhaps the best assay available with regard to sensitivity and analysis time involves GLC–mass spectrometry in the selected-ion mode (10). Disadvantages of this procedure for general application include the necessity to synthesize a deuterium-labeled analog of chlorpheniramine for use as the internal standard and the use of chemical-ionization techniques with trimethylamine as the reagent gas. Many analytical facilities are not equipped for chemical-ionization mass spectrometry.

The assay described in this report utilizes the high sensitivity and selectivity of GLC–mass spectrometry operated in the selected-ion mode with electron-impact ionization. A deuterium-labeled internal standard was prepared by a simple exchange reaction. Serum extracts can be analyzed in <2 min to a level of <2 ng of chlorpheniramine/ml. This method was applied to a clinical pharmacokinetic investigation.

EXPERIMENTAL

Materials—Chlorpheniramine[1], monodemethylchlorpheniramine[2], and didemethylchlorpheniramine[2] were obtained as maleate salts. The tetradeuterated analog of chlorpheniramine was prepared by dissolving 50 mg of the free base in 0.5 ml of 98% deuterosulfuric acid in deuterium oxide[3] (99.5 atom % deuterium) and heating the solution in a sealed glass tube at 120° for 6 hr. The contents were cooled and added slowly to 0.5 ml of deuterium oxide[4] (99.8 atom % deuterium).

Exchanged chlorpheniramine was isolated by adding the acidic solution dropwise to 4.2 ml of 5 *N* NaOH with ice bath cooling followed by extraction with ethyl acetate. The extract was washed with water and dried over anhydrous magnesium sulfate, and the solvent was evaporated. The resulting product was analyzed by TLC[5], GLC[6], high-performance liquid chromatography[7], PMR[8], and mass spectrometry[9] and was found to be chemically homogeneous. Deuterium was incorporated specifically in the *p*-chlorophenyl ring to >98% of the theoretical amount. Overall yields of tetradeuterated chlorpheniramine (chlorpheniramine-d_4) averaged 50%.

Instrumentation—A gas–liquid chromatograph–quadrupole mass spectrometer–computer system[9] was used. The gas–liquid chromatograph was equipped with a glass column (2 mm × 1.8 m) packed with 3% OV-22 on 80–100-mesh Supelcoport[10] and operated at a helium carrier gas flow rate of 30 ml/min. The injection port was maintained at 250°, the column oven was at 270°, the jet separator interface was at 270°, and the ion source was at 180°. The mass spectrometer was operated in the electron-impact mode with an electron energy of 70 ev.

Analytical Procedure—Serum samples, 1 or 2 ml, were placed in 16 × 125-mm disposable glass culture tubes, and 85 ng of chlorpheniramine-d_4 dissolved in 20 μl of methanol was added with vortex mixing. A 1-ml volume of saturated sodium borate solution and 8 ml of hexane[11] were added to each tube. The serum was extracted on a mechanical mixer[12] for 20 min and centrifuged at 2000 rpm for 3 min. The hexane layer was transferred to another tube and concentrated under a nitrogen stream at 40° to ~1 ml. To this solution was added 0.5 ml of 0.1 *N* HCl, the tubes were vortexed for 2 min and centrifuged, and the hexane layer was discarded.

The aqueous solution was brought to pH >9 with a saturated sodium borate solution and was extracted with 1 ml of ethyl acetate[13] by vortex mixing for 2 min. The mixture was centrifuged, and the ethyl acetate layer was transferred to a 1-ml vial[14]. The solvent was evaporated under a nitrogen stream with warming at 40°. The inner surface of the vial was rinsed with 100 μl of methanol[11] and evaporated to concentrate chlorpheniramine at the bottom. The residue was redissolved in 50 μl of acetonitrile[11], and the volume was reduced again under nitrogen to <5 μl.

Analyses were performed by injecting the entire sample (volumes of

2–4 μl) into the gas–liquid chromatograph. After a 30-sec delay, the column effluent was directed into the mass spectrometer, which was operated under computer control in the selected-ion mode. Ions at *m/e* 203 and 207 were monitored continuously with 100-msec dwell times. The chlorpheniramine retention time was 50–60 sec under the conditions employed. Peak areas were determined with the standard system software[9]. Recoveries of chlorpheniramine consistently were in the range from 55 to 70%.

Standard Calibration Curve—Chlorpheniramine maleate was converted to the free base and purified by distillation under reduced pressure. A standard solution was prepared in methanol at a concentration of 1.0 mg/ml. Solutions in methanol were stable for at least 3 months when stored at −20°. Dilutions of the standard solution were prepared at 10, 1.0, and 0.10 μg/ml. Serum samples obtained from a drug-free volunteer were spiked with volumes of the appropriate solution so that no more than 20 μl was added to each milliliter of serum. Chlorpheniramine concentrations were 0, 3, 6, 10, 15, 20, 40, 60, 90, 120, and 160 ng/ml, and each sample contained 85 ng of chlorpheniramine-d_4. Extractions and analyses were performed as described using three or four samples at each concentration. Ratios of *m/e* 203 to 207 peak areas were plotted against known chlorpheniramine concentrations.

Pharmacokinetic Study—A 12-year-old male subject[15] with a history of allergic rhinitis was administered intravenously a 0.01-mg/kg dose of chlorpheniramine maleate over 5 min after removal of a control blood

sample. Blood samples (5–8 ml) were drawn periodically, and the serum was prepared immediately and stored at −70° until it was analyzed. It was established that chlorpheniramine is stable under these conditions for at least 1 year. Analyses were performed as described, and peak ratios were converted to chlorpheniramine concentrations with reference to the standard curve. The plasma concentration *versus* time data were computer fitted (11) to a biexponential equation. After correction for the 5-min infusion period, pharmacokinetic parameters were calculated using standard methods (12).

RESULTS

The electron-impact mass spectrum of chlorpheniramine (Fig. 1) reveals an intense ion at *m/e* 203, which probably is formed by fragmentation of the molecular ion (Scheme I). A complementary ion containing chlorine 37 occurs at *m/e* 205. The relatively high mass and intensity of the *m/e* 203 ion provide an excellent opportunity for quantitation by GLC–mass spectrometry with selected-ion monitoring. The preferred internal standards for this technique are isotopic variants of the compounds to be measured (13). Inspection of the chlorpheniramine spectrum reveals no ions with *m/e* values higher than 206 (except for a small *m/e* 216 ion). Therefore, a deuterated analog should contain at least four deuterium atoms in the part of the molecule that is retained in the fragment ion.

Conditions have been developed for the efficient exchange of the four *p*-chlorophenyl hydrogens for deuterium atoms. The progress of this exchange reaction is shown in Table I. Two hydrogens are exchanged in less than 1 hr at 100°, and the reaction is >98% complete after 48 hr. At 120°, exchange is virtually complete after only 6 hr. A mass spectrum of the tetradeuterated analog of chlorpheniramine (chlorpheniramine-d_4) is shown in Fig. 1. The base peak is shifted to *m/e* 207, and no peak occurs at *m/e* 203 that would interfere with chlorpheniramine quantitation.

The brominated analog of chlorpheniramine is another useful antihistamine that can be quantitated by a similar procedure involving preparation of a tetradeuterated internal standard. Fragmentation of brompheniramine produces a mass spectrum with intense ions at *m/e* 247 and 249 (containing bromine 79 and bromine 81, respectively) with no ions of *m/e* higher than 250. The exchange reaction proceeds in a similar manner to yield brompheniramine-d_4 with intense ions at *m/e* 251 and 253.

A standard calibration curve was developed by adding chlorpheniramine in amounts from 0 to 160 ng together with 85 ng of chlorpheniramine-d_4 to 1.0-ml serum samples and extracting these samples as described under *Experimental*. Extracts were analyzed by monitoring the ion currents for ions at *m/e* 203 and 207. A background signal normally is observed at *m/e* 207 due to bleeding of the silicone rubber septum and of the GLC stationary liquid phase. This relatively small and constant signal easily can be subtracted from the signal of chlorpheniramine-d_4.

With the chromatographic conditions used, the retention time of the drug is 50–60 sec. Typical ion-current profiles obtained with a serum extract containing only the internal standard and with an extract containing both the drug and the internal standard are shown in Fig. 2. Analyses of serum samples yielded data for calculation of a regression line with a correlation coefficient of 0.998. Chlorpheniramine was added to four serum samples (2.0 ml each) at 4.0 ng/ml together with the internal standard. These samples were determined to contain 4.2 ± 0.2 ng of drug/ml (mean ± *SD*). The maximum sensitivity of the method is 1–2 ng/ml using 2 ml of serum.

The principal metabolites of chlorpheniramine that could interfere with the analysis are the products of mono- and di-*N*-demethylation (14,

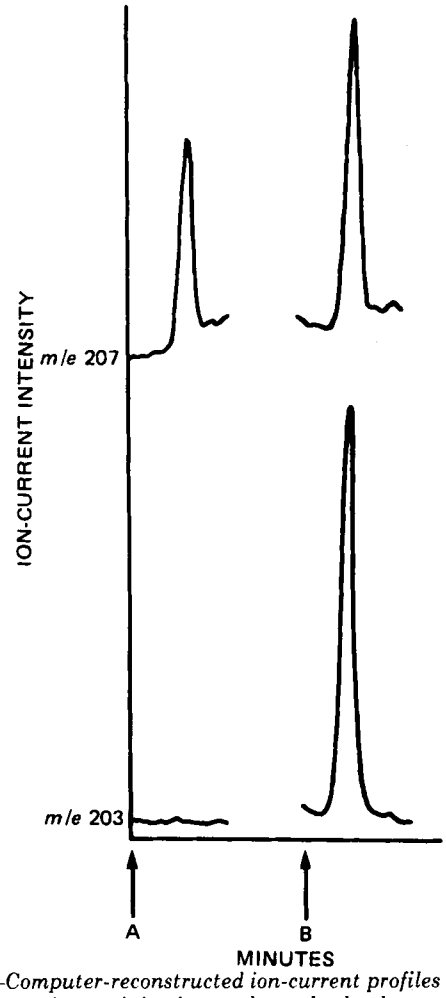

Figure 2—*Computer-reconstructed ion-current profiles of serum extracts. Extract A containing internal standard only was injected at* t = 0. *Extract B containing the internal standard and 10 ng of chlorpheniramine was injected at* t = 2 *min.*

15). The *m/e* 203 ion formed by fragmentation and loss of the amino group appears in the mass spectra of both metabolites. However, with the GLC conditions used in this work, the drug is well separated from its metabolites. The ion-current profiles of chlorpheniramine and monodemethylchlorpheniramine are shown in Fig. 3. The retention time of didemethylchlorpheniramine is greater than that of the metabolite shown, eliminating the possibility of interference with the drug.

The quantitative procedure described here was applied to a pharmacokinetic study of chlorpheniramine in a 12-year-old male subject. The plasma concentration *versus* time curve is shown in Fig. 4, and the selected pharmacokinetic parameters calculated from these data are summarized in Table II.

DISCUSSION

Pharmacokinetic studies of chlorpheniramine require methods capable of producing reliable quantitative data over the range of 2–100 ng/ml of serum. The high sensitivity of the technique involving GLC–mass spectrometry with selected-ion monitoring is particularly well suited to this analysis because of the favorable fragmentation pattern of chlorpheniramine. A high percentage of the total ion current of the compound is due to the *m/e* 203 ion. The selective nature of this analytical technique allows the use of chromatographic conditions with which analyses can be completed rapidly and without interferences from other compounds.

Table II—Pharmacokinetic Parameters for Chlorpheniramine Administered Intravenously to a 12-Year-Old Male Subject

Parameter	Value
Initial dilution volume (V_c)	298.2 ml/kg
Volume of distribution during postdistribution phase (V_β)	562.8 ml/kg
Total body clearance	0.415 ml/min/kg
$t_{1/2}, \alpha$	0.53 hr
$t_{1/2}, \beta$	15.6 hr

The assay reported here is sufficiently sensitive to measure serum levels 24 hr after a single intravenous dose of 0.01 mg/kg. Each extract can be analyzed in <2 min. The chlorpheniramine assay using GLC–mass spectrometry that was published previously (10) involved the use of chemical-ionization conditions. However, the present results show that

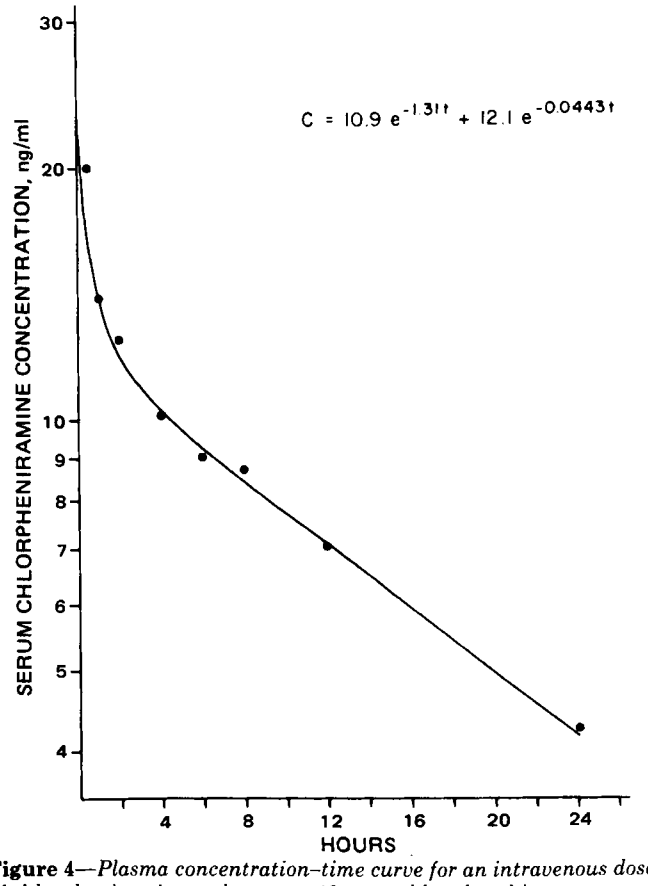

Figure 4—*Plasma concentration–time curve for an intravenous dose of chlorpheniramine maleate to a 12-year-old male subject.*

the more common method of electron-impact ionization is suitable. In addition, the previous investigators used a deuterated analog of chlorpheniramine that must be synthesized. The standard used in the present work can be prepared by a simple exchange reaction and without purification of the deuterated product.

The pharmacokinetic study conducted with one patient demonstrates the utility of the assay. Drug levels during the elimination (β) phase were in the range of 4–10 ng/ml of serum through 24 hr after dosing. These data demonstrate sufficient sensitivity to measure serum levels for a period in excess of 1.5 half-lives of the drug. Biological half-lives reported recently for adults after oral dosing are somewhat higher (2, 3) than the half-life determined in the present study. The young age of the patient and the drug administration route could explain the difference. Work is in progress using the assay described here to obtain pharmacokinetic data for a large group of subjects.

Determination of Chlorambucil in Plasma by GLC with Selected-Ion Monitoring

HANS EHRSSON *x, STAFFAN EKSBORG *, INGER WALLIN *, YVONNE MÅRDE ‡, and BO JOANSSON §

Received September 5, 1979, from the **Karolinska Pharmacy, the* ‡*Laboratory for Mass Spectrometry, Karolinska Institut, and the* §*Department of Oncology, Karolinska Hospital, Box 60024, S-104 01 Stockholm, Sweden.* Accepted for publication January 25, 1980.

Abstract □ A GLC technique with selected-ion monitoring is described for chlorambucil determination in plasma using [^{2}H]chlorambucil as the internal standard. Chlorambucil is extracted from plasma with methylene chloride at pH 3 and converted to a thiazane derivative by reaction with 0.1 *M* sodium sulfide at 80°. The carboxylic group of the chlorambucil derivative is derivatized with allyl bromide using extractive alkylation. Analysis by selected-ion monitoring was performed by focusing at *m/e* 305 (M) and 313. The relative standard deviation was ±5% (n = 5) at the 10-ng/ml level.

Keyphrases □ Chlorambucil—GLC determination with selected-ion monitoring, plasma □ GLC—analysis, chlorambucil, selected-ion monitoring, plasma □ Antineoplastics—chlorambucil, GLC determination with selected-ion monitoring, plasma

Chlorambucil, a nitrogen mustard drug, is used for the treatment of neoplastic diseases. The fate of the drug in humans is partially unknown since analytical methods with sufficient sensitivity and selectivity have not been available. A mass fragmentographic method involving derivatization of the carboxylic group of chlorambucil by methylation was published recently (1). However, large variations in the GLC yield were observed in these laboratories after a derivatization involving alkylation, probably as a result of degradation of the nitrogen mustard group in the GLC system.

This paper presents a GLC technique using selected-ion monitoring for the determination of chlorambucil in plasma. The nitrogen mustard group is converted to a thiazane by reaction with sodium sulfide, followed by extractive alkylation of the carboxylic group.

EXPERIMENTAL

Synthesis of 4-[4-(Thiazane-4-yl)phenyl]butyric Acid (I)—Chlorambucil (25 mg) was dissolved in 10 ml of 0.1 *M* sodium sulfide and heated for 1 hr at 80°. The solution was cooled, acidified (pH ~3) with phosphoric acid, and extracted with methylene chloride (10 ml). The organic phase was separated and evaporated to dryness. The residue was recrystallized from methylene chloride–*n*-hexane (mp 81–82°). The purity (~97%) was established by TLC[1] and potentiometric titration with sodium hydroxide.

The mass spectrum[2] was consistent with the expected structure. There were prominent peaks at *m/e* 266 (20%), 265 (100), 218 (13), 193 (14), 192 (77), 191 (59), 132 (24), 131 (52), 130 (14), 118 (52), 117 (13), and 91 (11). No peak was observed at *m/e* 297, thus establishing that no dithiazane was formed (*cf.*, Ref. 2).

Reaction of Chlorambucil with Sodium Sulfide—Chlorambucil in methanol (0.5 ml) was mixed with an aqueous sodium sulfide solution (10 ml), giving a final chlorambucil concentration of 4 μg/ml. The yield of I was established by liquid chromatography[3] after acidifying part of the solution. The derivatization yields were calculated using the synthetically prepared I as a reference compound.

[a] For definition, see Ref. 3. [b] Microscopic constants from Ref. 3.

Alkylation of I—A solution of the alkylating reagent (I) and the internal standard (decachlorobiphenyl) in methylene chloride (2 ml) was mixed with a solution (2 ml) of 0.1 *M* tetrabutylammonium in 0.1 *M* NaOH. The mixture was shaken at 25°. Part of the organic phase (0.1 ml) was separated and mixed with pH 4 phosphate buffer. The organic phase was analyzed by GLC with flame-ionization detection[4].

Extraction of Chlorambucil from Plasma—Plasma (2.00 ml) containing 8 μg of chlorambucil/ml was mixed with hydrochloric acid, phosphoric acid, or phosphate buffer (0.2 ml). The mixture was extracted with methylene chloride (2.00 ml) for 30 min. An aliquot of the organic phase was separated and evaporated to dryness with nitrogen gas. The residue was dissolved in methanol–water–acetic acid (0.1 *M*) (75:15:10) and analyzed by liquid chromatography[5].

Determination of Chlorambucil in Plasma—Plasma (2.00 ml) was mixed with 0.100 ml of [^{2}H]chlorambucil[6] in ethanol (2.00 μg/ml)[7] and 0.2 ml of 1 *M* phosphoric acid (final pH of ~3) and extracted with 5.00 ml of methylene chloride for 30 min. The organic phase was separated and extracted with 0.5 ml of 0.1 *M* sodium sulfide for 5 min. The aqueous phase was separated and heated for 15 min at 80°. Concentrated phosphoric acid (0.01 ml) was added, and hydrogen sulfide was removed with nitrogen for 5 min. Sodium hydroxide (12 *M*, 0.05 ml), 0.5 *M* tetrabutylammonium (0.2 ml), methylene chloride (0.2 ml), and allyl bromide (0.05 ml) were added, and then the mixture was shaken for 30 min at 25°. The organic phase (1–2 μl) was analyzed by GLC–mass spectrometry[8].

Handling of Blood Samples—Blood samples were obtained by venous puncture using 10-ml glass tubes containing 250 IU of lyophilized heparin. The plasma fraction was separated immediately, and an aliquot was mixed with the internal standard and frozen until it was assayed. Chlorambucil was stable for at least 2 weeks at −20°.

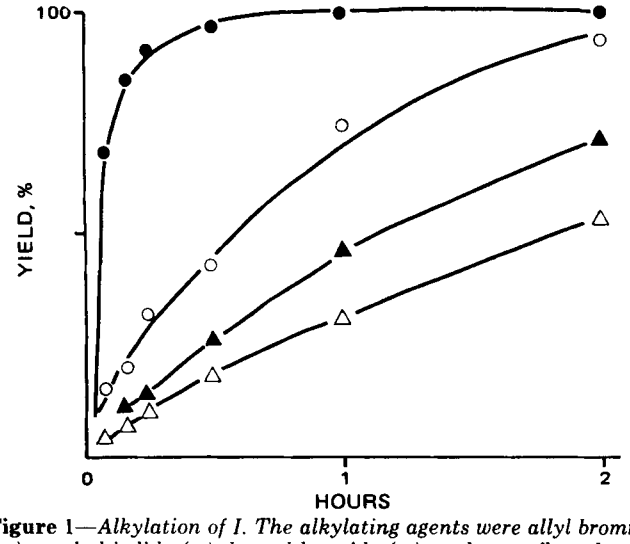

Figure 1—*Alkylation of I. The alkylating agents were allyl bromide (△), methyl iodide (▲), benzyl bromide (○), and pentafluorobenzyl bromide (●); the organic phase was 0.05* M *alkylating agent in methylene chloride; the aqueous phase was 0.100* M *tetrabutylammonium in 0.100* M *NaOH (equal phase volumes); and the temperature was 25.0°.*

Table II—Extraction of Chlorambucil from Human Plasma

pH	log Distribution Ratio (Yield, %)	
	Calculated	Found
1	2.94 (99.9)	0.18 (60 ± 4)
3.2	4.35 (100.0)	>2 (102 ± 4)
7.0	1.91 (98.8)	0.10 (56 ± 2)

RESULTS AND DISCUSSION

Extraction from Plasma—A quantitative extraction of chlorambucil (log $D \sim 2$) theoretically should be obtained within the pH range of 1–7, as revealed by calculations based on the partition coefficient and the acid dissociation constants (Table I). However, the extraction of chlorambucil from plasma was quantitative only at pH ~3, while the yields at pH 1 and 7 were considerably lower (Table II). The extraction yields were unaffected by extraction times of 10–60 min. Obviously, a considerably higher extraction capacity is needed to obtain a quantitative recovery from plasma as compared to pure aqueous solutions. This effect might be due to the fact that chlorambucil is bound extensively to plasma albumin (4), giving a concomitant reduction in the partitioning to the organic phase.

Thiazane Formation—Nitrogen mustards previously were converted to thiazanes by reaction with sodium [^{35}S]sulfide for qualitative metabolic studies (2), but so far the reaction has not been studied quantitatively. The influence of the sodium sulfide concentration on the yield of thiazane was studied by liquid chromatography (Table III). The reaction was complete within 15 min at 80°. Hydrolysis of chlorambucil to 4-[*p*-[di(2-hydroxyethyl)amino]phenyl]butyric acid [*cf.*, Ref. 3] was insignificant, at least in 0.1 or 1 *M* sodium sulfide, reflecting the high nucleophilicity of the sulfide ion. The thiazane yield was only ~25% with a reaction time of 1 hr at 25° (0.10 *M* sodium sulfide).

Protolytic and Partition Properties of I—The protolytic properties of I were evaluated by a photometric technique described previously (3). The base strength of the amino group was considerably higher for I compared to chlorambucil (pK_2 = 4.12 and 2.49, respectively, Table I).

The lipophilic character of chlorambucil was decreased by the thiazane formation, as revealed by a decrease in the partition coefficient to methylene chloride by ~1 log unit (Table I).

Extractive Alkylation of I—The extractive alkylation of I was performed using methylene chloride as the organic phase and 0.1 *M* tetrabutylammonium in 0.1 *M* NaOH as the aqueous phase. More than 90% of I was extracted as an ion-pair into the organic phase, as calculated from the extraction constant ($\log E = 2.17 \pm 0.02$ and $-\log k_{diss} = 4.19 \pm 0.04$, determined according to Ref. 5). Therefore, an increase in the lipophilic character or concentration of the counterion should only slightly affect the reaction rate (6).

The alkylation rates using different alkylating agents are given in Fig. 1. Pentafluorobenzyl bromide showed the highest reactivity, while the lowest one was obtained with allyl bromide. By increasing the concen-

Table III—Influence of Sodium Sulfide Concentration on Yield of I[a]

Minutes	Sodium Sulfide Concentration, *M*		
	0.01	0.10	1.00
	Yield of I, %		
1	46	44	60
5	82	90	94
15	84	92	97
30	87	99	93
60	87	95	97

[a] The temperature was 80°.

Table IV—Relative Retention of Alkyl Derivatives of I [a]

Derivative	Relative Retention
Methyl	1.00
Allyl	1.46
Pentafluorobenzyl	3.50
Benzyl	7.25

[a] The column was packed with 3% OV-17 and was operated at 275°.

tration of allyl bromide to 1 *M*, a quantitative reaction was obtained within 30 min.

GLC Properties of Alkyl Derivatives of I—All of the alkyl derivatives chromatographed with excellent peak symmetry on an OV-17 column. The relative retentions of the derivatives are given in Table IV. The retention increased in the order methyl, allyl, pentafluorobenzyl, and benzyl. Due to their higher volatility, the methyl and allyl derivatives were selected for further studies regarding their selected-ion monitoring properties.

Selected-Ion Monitoring Properties of Methyl and Allyl Derivatives of I—The mass spectra of the allyl and methyl derivatives of I are given in Fig. 2. By focusing the mass spectrometer at the molecular ions of the compounds, a higher selectivity was obtained with respect to the metabolites formed by enzymatic transformation of the butyric acid side chain of chlorambucil as compared to focusing at *m/e* 192 [4-(thiazane-4-yl)benzyl fragment]. Derivatization with allyl bromide and focusing at *m/e* 305 were used in the analytical method since derivatization of plasma blanks with methyl iodide and detection at *m/e* 279 gave an interfering peak with a retention time close to that of the methyl derivative of I.

Internal Standard—Chlorambucil labeled with eight deuterium atoms in the nitrogen mustard moiety was used as the internal standard. It contained <1% of the unlabeled compound. The degradation rate of the internal standard did not differ significantly from that of chlorambucil.

Selectivity—No peaks interfering with the determination of chlorambucil or the internal standard were observed with blank plasma. The thiazane derivative of chlorambucil theoretically could be formed by the reaction of chlorambucil with endogenous sulfur-containing compounds and, if present, be codetermined with chlorambucil. Plasma samples (1, 2, 5, and 6 hr after an oral dose of 10 mg of chlorambucil) were analyzed according to the described procedure, except that the sodium sulfide extraction step was substituted with extraction with 0.1 *M* NaOH. In all cases, the thiazane concentration was below the detection limit (<1 ng/ml of plasma).

Precision—The standard curve obtained from plasma samples was linear in the range studied (10–640 ng/ml). A least-squares analysis gave a correlation coefficient of 0.9999, a slope of $7.96 \times 10^{-3} \pm 2.19 \times 10^{-5}$, and an intercept of $6.00 \times 10^{-2} \pm 7.36 \times 10^{-3}$. The relative standard deviation was ±5% ($n = 5$) at the 10-ng/ml level. A chromatogram obtained from the analysis of a sample containing 30 ng/ml is shown in Fig. 3.

Video Characterization of Flume Patterns of Inhalation Aerosols

S. MISZUK *x, B. M. GUPTA ‡, F. C. CHEN *, C. CLAWANS ‡, and J. Z. KNAPP *

Received October 4, 1979, from **R&D Engineering Department and ‡Pharmaceutical Research and Development, Schering-Plough Corporation, Bloomfield, NJ 07003.* Accepted for publication January 30, 1980.

Abstract □ An *in vitro* technique was developed to characterize the intermittent flume patterns associated with the short bursts of metered-dose aerosols. Two orthogonal video images are utilized to describe the complex shape and direction of the flume pattern. This technique facilitates the evaluation of components manufactured by different suppliers.

Keyphrases □ Aerosols, inhalation—characterization of flume pattern, video technique compared with chemical analysis, delivery systems analyzed □ Delivery systems—inhalation aerosols, flume pattern characterized by video technique □ Distribution—of drug in lung alveoli, analysis of delivery systems, inhalation aerosols, flume patterns characterized by video technique

Various test procedures have been developed to evaluate aerosol products (1). The test methods for delivery rate, pressure measurement, unit spray sampling, container sampling, and propellents analysis are included in NF XIV (2). Particle-size analysis and spray patterns are among several tests that should be performed on inhalation aerosols to ensure their therapeutic effectiveness.

BACKGROUND

Extensive research (3) has been conducted on the relationship of the particle size of an active drug to its distribution and retention in the lungs. The conflict of theories and experimental results has been attributed to such variables as the species of animal used, nonuniform breathing rates, methods of measuring the particle-size distribution, methods of administering the agents used, and the effects of lung moisture content on the size of the inhaled particles (4–6). However, it generally is agreed that the depth of penetration increases with decreasing particle size while the whole lung retention increases with increasing particle size (7, 8). The optimum particle-size range for inhalation of medicinals into the lungs currently is accepted as 0.5–5 μm (9, 10).

While the importance of particle size in inhalation therapy has been well documented, other parameters affecting deposition and retention of inhaled matter have received less attention. Hayton (11) pointed out that, in many instances, a fairly high percentage of the formulation dispensed is retained in the oral adapter, the mouth, and the back of the throat instead of obtaining the desired deep penetration into the bronchi. Various methods have been useful for determining the aerosol dose delivered through an oral adapter to the desired portions of the lungs. Karig *et al.* (12) developed a compartmentalized lung chamber for the evaluation of oral inhalation aerosols. An *in vitro* method was established for evaluating the penetration of solid particles in the lungs using several aerosol generators. Sciarra and Cutie (13) developed a simulated respiratory system for the *in vitro* evaluation of two differently designed oral inhalation delivery systems and demonstrated that the deposition properties of the dose may be a function of the oral inhalation adapter.

The interest in therapeutic and diagnostic uses of inhalation aerosols can be directed at particles within the aerodynamic size range of 1–10 μm in diameter. When the alveolated regions of the lungs are the desired site of therapeutic action, the size is limited to 1–5 μm in diameter. The deposition of particles in the 1–10-μm aerodynamic diameter range is governed by inertial impaction and gravitational settling (14).

With the foregoing discussion, it can be concluded that the particle size and particle distribution within the aerosol cloud are the major factors affecting the site and mass of drug deposition in the airways. Other factors influencing aerosol penetration and deposition in the airways include the synchronization of the aerosol administration with inhalation and the aerosol mist characteristics. The spray pattern at different distances from the mouthpiece of the inhalation adapter can influence the penetration and deposition of particles in the desired portions of the lung. The nature of the flume pattern from an inhalation aerosol will be indicative of spray patterns at different distances.

The purpose of this study was to develop an *in vitro* technique to characterize the flume patterns to demonstrate physical equivalence of valve and actuator performance. With the same inhalation product, the technique also was used to screen actuators by studying their flume patterns. Manufacturers of inhalation aerosols must have alternative suppliers of package components, and this technique can be used as one criterion to demonstrate the equivalent performance of these alternative package components.

EXPERIMENTAL

Materials—The inhalation aerosol contained a suspension of a micronized corticosteroid in a fluorochlorocarbon propellent. The contents were packaged in a 16-ml aluminum can. Sixty-three-microliter valves and inhalation adapters from two suppliers (A and B) were used.

Video Systems—A high-resolution video camera[1] coupled with a macro lens[2] was used to capture the flume patterns of emitted sprays. These patterns were recorded on a 2.54-cm video tape recorder[3] (Fig. 1). This 2.5-cm broadcast quality video tape system provided a higher resolution of the flume patterns that the 1.3-cm video tape system in usual hobby use.

During playback, these flume patterns were displayed on a television monitor[4] from which the desired individual frames of flume pattern were photographed using a view camera[5]. Since video tape resolution is degraded by 50% whenever an individual frame is viewed, an accessory digital image enhancer[6] was employed to improve image contrast by gray-scale adjustment. The benefit of this adjustment was most visible along the fringe area of the aerosol flume. Image enhancement was applied only to the flume display on the video monitor. All of the original video data on the tape remained unchanged.

Imaging Requirements—Since the flume pattern is three dimensional, a single two-dimensional image cannot completely characterize

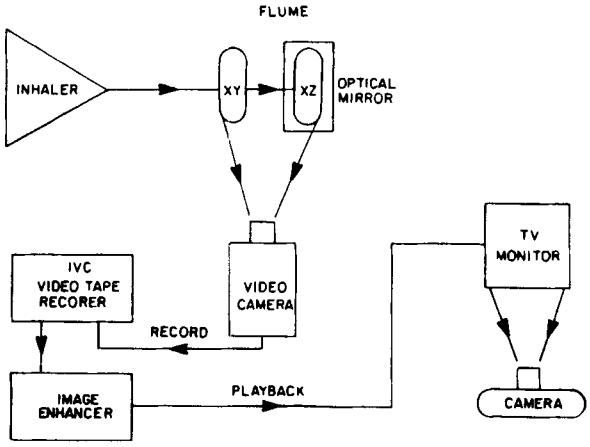

Figure 2—*Apparatus block diagram of flume analysis for orthogonal views.*

its complex shape and direction unless the pattern is symmetrical. When the flume pattern is asymmetric, a combination of two simultaneous orthogonal views is required to describe the character and direction of the flume pattern adequately.

In metered-dose aerosols, the total duration of the burst can be as short as 50 msec, so image delays between the two orthogonal views should be minimized. To achieve minimum delay, the same scan line was utilized for the corresponding image positions. This objective was accomplished by rotating the camera 90° from its usual viewing position. This action reduced the delay from milliseconds to microseconds for equivalent image portions, which was a prerequisite for accurate three-dimensional analysis.

For adequate visualization of the micrometer-sized aerosol droplets, a high-intensity light source was adjusted to deliver the scattered light from the flume droplets forward to the viewing lens (Fig. 2). For optimum contrast in orthogonal views, two flexible fiber optic bundles were used to ensure uniformity of the scattered light intensity in both views. A high quality optical front surface mirror, having a flatness of 0.5 λ, was positioned at a 45° angle to provide simultaneous images in the two orthogonal views of the video camera.

System Operation—Video and optical systems were assembled and arranged as shown in Figs. 2, 3, and 4 for orthogonal, side, and top views, respectively. A black screen was placed parallel to the flume as a background to achieve proper contrast.

The product to be tested, *i.e.*, an inhaler in its respective actuator, was placed in a fixed position (Fig. 4). An operator placed the recording system into the recording mode and subsequently actuated the product to emit a spray. After a single trial spray was emitted, flume patterns of the subsequent two sprays from that product were recorded by the video system. These series of sprays were identified on the video tape by an alphanumeric light-emitting diode configuration, which was recorded simultaneously during each spray burst. In the playback mode, the

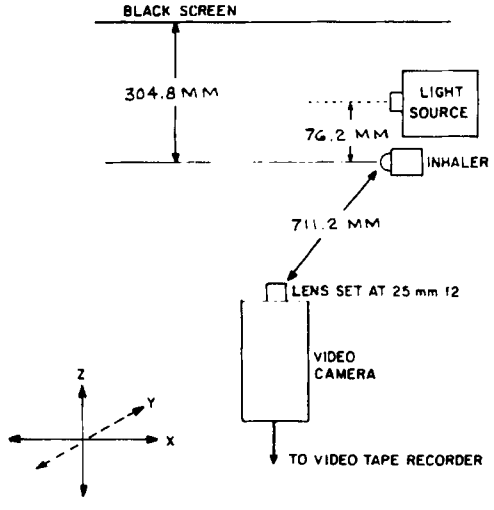

Figure 3—*Apparatus block diagram of flume analysis for side view.*

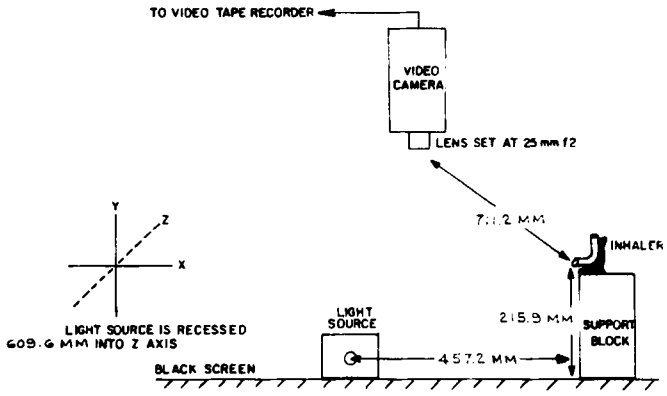

Figure 4—*Apparatus block diagram of flume analysis for top view.*

light-emitting diodes clearly identified the particular spray pattern being tested.

System Output—The output is a video image of the aerosol flume pattern that can be viewed on a video field basis (each field is spaced 16.7 msec apart). The total life of the flume pattern is available from the time it passes from the actuator until it is dissipated in the atmosphere. When flume patterns were observed on a frame-to-frame basis, flume size increased progressively up to the fourth frame (66.7 msec after flume commencement) and thereafter started dissipating. Therefore, the flume pattern in the fourth frame was selected to be photographed for comparison.

RESULTS AND DISCUSSION

Videotapes of flume patterns of the corticosteroid oral inhalers A and B were played and examined. Flume patterns were observed individually on a frame-to-frame basis; flume size increased progressively up to the fourth frame and thereafter started dissipating. For package components A and B, no significant difference was noticed in flume patterns of Sprays 1 and 2. Photographs of these flume patterns in the fourth frame for the top and side view are shown in Figs. 5 and 6, respectively. The similar shape and size of flume patterns for package components A and B indicate equivalent physical performance. This result suggests that the spray emitted from package components A and B will have a similar projectile and force to enter the throat and lung, suggesting equivalent dispensing of the drug by two different actuators to different parts of the respiratory system.

Application of this video system for screening actuators was extended to a nasal inhaler. Figures 7–9 are flume patterns of the orthogonal view of a nasal inhaler obtained using three actuators from the same lot. Each photograph also was taken during the fourth frame of a video field to establish a common basis for analysis.

A typical example for a good flume pattern is shown in Fig. 7. The aerosol spray patterns are symmetrical; if a line were drawn through the center of each flume, each half would be equal and that line would intersect the center of the actuator nozzle. This result indicates that the center of the aerosol spray pattern is at the center of the actuator. Moreover, the exit angles of the spray pattern in both views are parallel to the axis of the actuator nozzle in their respective views.

Marginal actuators yield poor flume patterns with one or more discrepancies with the described criteria for a good flume pattern as illustrated in Fig. 8. The flume patterns in both views exhibit a large displacement from the center of the actuator nozzle. This condition generally yields a poor or marginal delivery of product since a portion of the product is trapped on the inner wall of the nozzle and remains as a residue. In fact, with some actuators, the second burst showed streaking lines in the flume patterns. These lines were the corticosteroid, which was left as a residue in the nozzle and was evacuated with the second burst of propellent. Erratic delivery can be attributed to this actuator, *e.g.*, the first burst is low on product, and the second burst is much higher.

Figure 9 shows the flume pattern from an actuator with a defective nozzle; there is a slight burr around the exit jet of the nozzle. The right portion of the figure (the side view of the actuator) exhibits a very poor flume pattern with heavy streaking lines about the nozzle. These lines indicate a misdirection of the spray inside the nozzle piece. The other orthogonal view lacks these lines, which strongly suggests that two views are necessary for a proper flume definition.

Since the three actuators had a common canister of propellent and were evaluated at a similar video field, one actuator can be accepted as good,

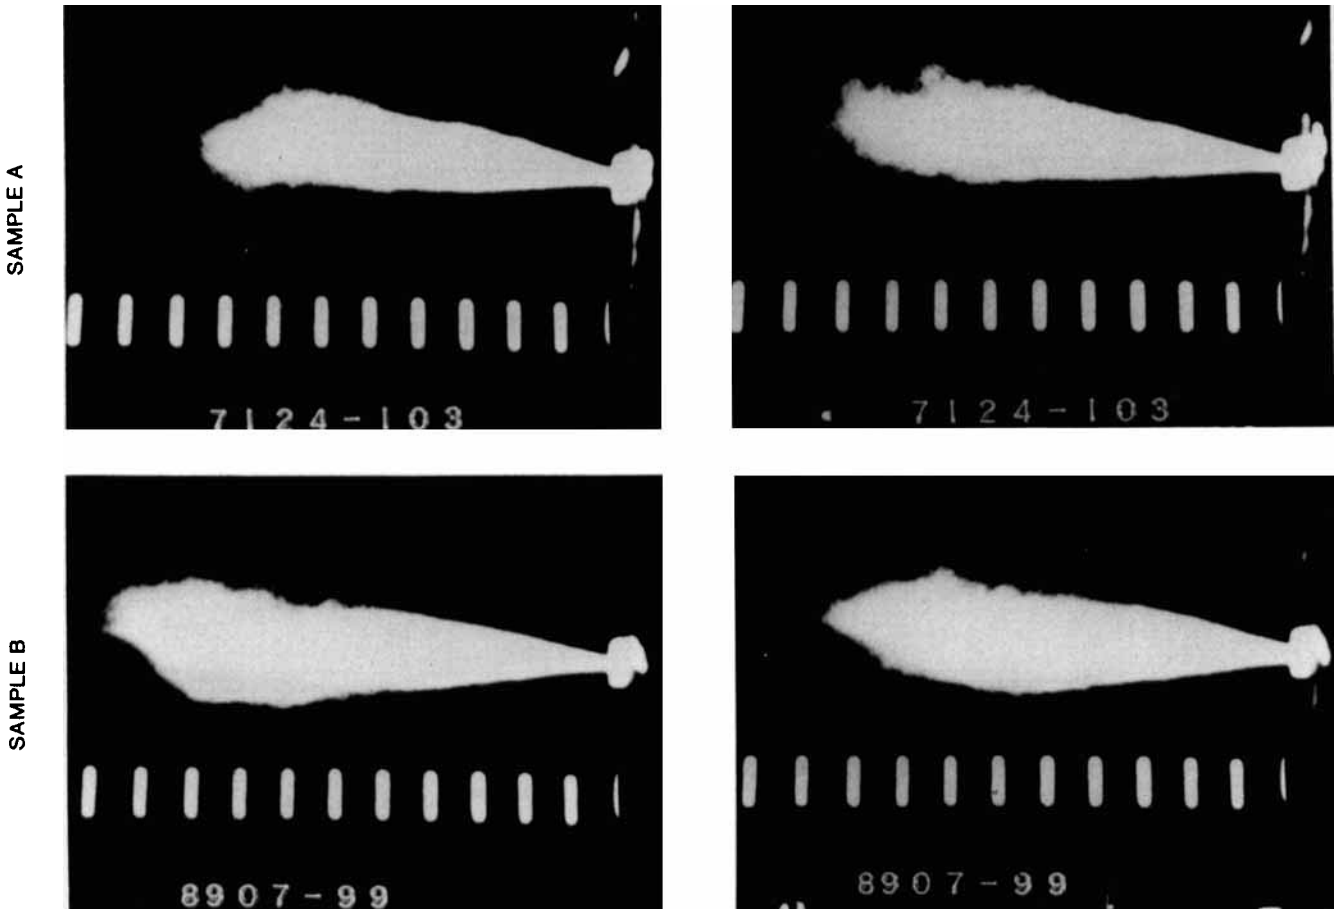

Figure 5—*Series of typical flume patterns that are shown in the top view.*

one as marginal, and one as bad. This video technique can be used to screen potentially bad actuators. To establish a comparison between the video technique and chemical analysis, 20 actuators were studied by both techniques. In the video technique, based on the described criteria, the quality of actuators was rated good (G), fair (F), and poor (P) (Table I).

The total amount of drug delivered from an actuator and the amount retained on the actuator were determined for 20 actuators by liquid chromatography. The ratio of B to A was calculated for each actuator, where A is the total amount of drug delivered through the actuator and B is the total amount of drug retained on the actuator. The smaller the ratio, the better is the rating. Actuators were rated from one to 20 based on the ratio. A rating of one was given to the actuator with the lowest ratio. Table I lists the ratings obtained by chemical analysis and the video technique. On the basis of these chemical analysis data, five actuators were rated as good, 10 as fair, and five as poor. These results compared very well with the results obtained by the video technique (Table II).

To increase the average amount of drug delivered through an actuator, the following two steps are necessary. First, the use of defective actuators should be eliminated by improving the incoming inspection of these units. Second, the design of the actuators should be modified to improve drug delivery.

The five actuators rated as good by the chemical test had an average delivery of 82%. However, the average yield of the five actuators rated as poor by the chemical test was 69%. To locate the defective parts of the actuators, the following experiments were performed.

The plastic inserts were replaced with machined-steel inserts, and the flume patterns were studied before and after the replacements. The replaced plastic inserts were inspected visually. These steel inserts gave an improved flume pattern after replacing plastic inserts with burrs inside

Table I—Comparison of Results Obtained by Chemical Analysis and the Video Technique

Table II—Number of Actuators within Ratings According to Chemical Analysis and Video Technique

Rating Chemical Number	Number of Actuators within Rating Range	Video Ratings and Number of Actuators within Range		
		G[a]	F[a]	P[a]
1–5	5[b]	4	0	0
6–15	10[b]	1	4	4
16–20	5[b]	0	0	4

[a] G = good, F = fair, and P = poor. [b] One actuator not available for video test.

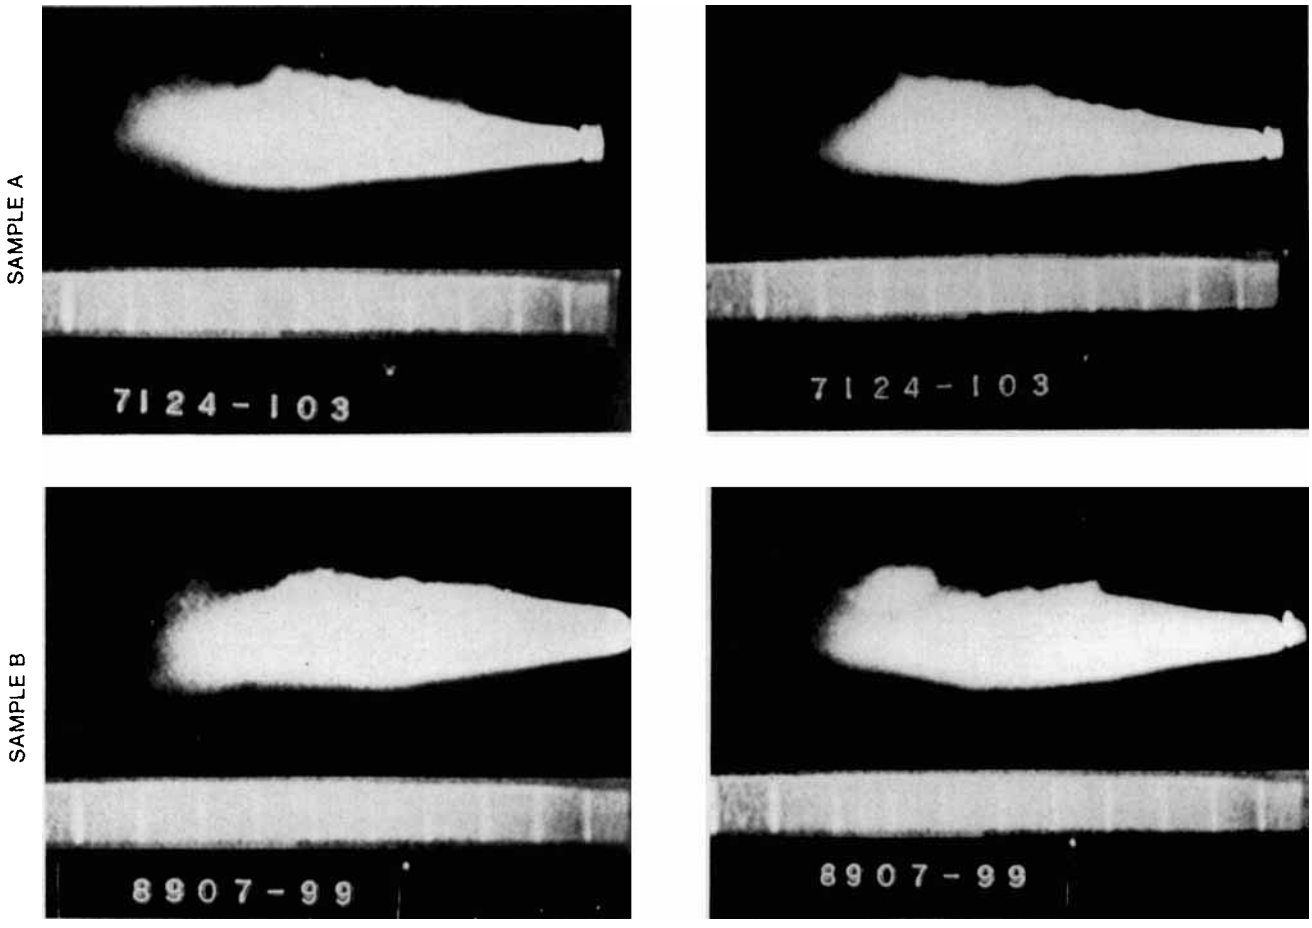

Figure 6—*Flume patterns in the side view of the same samples used in Fig. 5.*

the orifice or with irregular orifice shape. Otherwise, the flume patterns remained unchanged. This result shows that the aerosol ejected through the orifice with a nonzero exit angle with respect to the axis of the delivery tube was caused by skewed seating of the plastic insert. If the plastic inserts are inspected carefully before mounting in the actuators to eliminate those units showing burrs or other nonuniformity in either the rear or the insert tip, the yield of acceptable actuators can be improved.

The flume pattern of the vaporized liquid propellent shows that its spread was wider along the y axis than along the z axis because the propellent was accelerated first in the x–y plane and then along the x axis

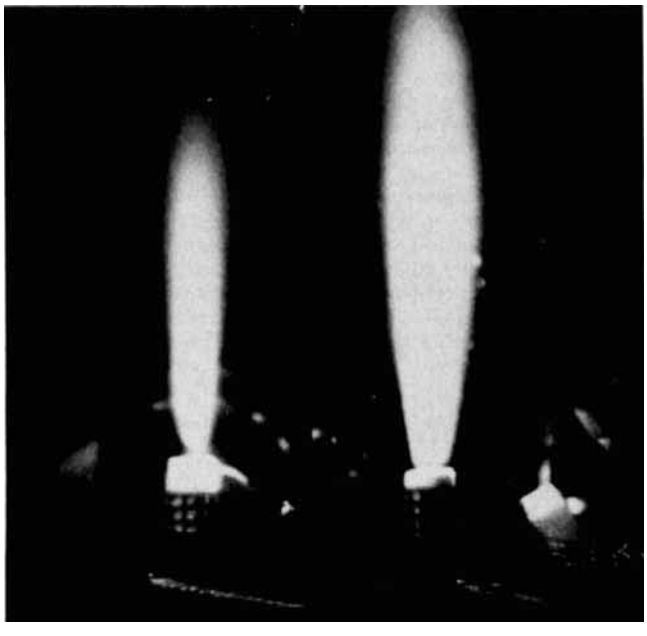

Figure 7—*Typical example of a good flume pattern in the orthogonal view.*

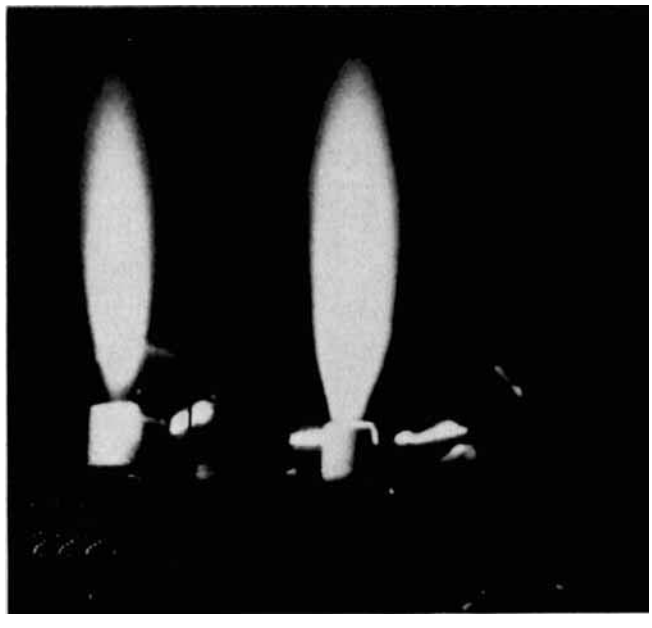

Figure 8—*Typical example of a marginal flume pattern in the orthogonal view.*

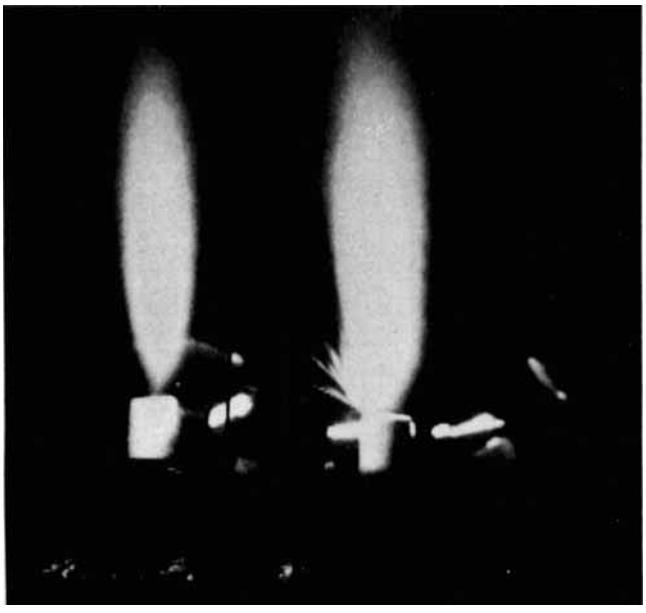

Figure 9—*Flume pattern from an actuator with a defect on its nozzle.*

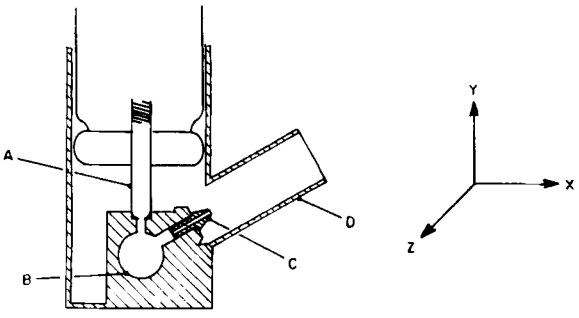

Figure 10—*Cross-sectional view of an actuator and product delivery system.*

(Fig. 10). Since the flume pattern was not cylindrically symmetrical, changing the cross section of the delivery tube from a circular to an elliptical shape with the major axis along the y axis can reduce the amount of drug trapped on the inner surface wall. The video technique also was used to study the flume patterns of an aerosol spray by varying the length of the discharging tip; as expected, the longer the tip, the narrower was the spread of the flume pattern. If the amount of drug retained inside the plastic insert is small compared with that retained on the inner wall of the delivery tube, the path length of the plastic insert could be increased.

After the propellent has been discharged and before it reaches Chamber B, the direction of acceleration has a negative component along the x axis. Thus, if one increases the angle between the axis of the plunger and the axis of the delivery tube, one can increase the drug delivery yield through the actuators.

Microcolumn Chromatographic Cleanup and GLC Determination of 11-Methyl-16,16-dimethylprostaglandin E_2 in Polyethylene Glycol 400 Solutions

RONALD F. QUADREL ˣ, SOOHEE LEE, and FRANCES M. BOGDANSKY

Received December 20, 1979, from the *Quality Control Department, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication January 31, 1980.

Abstract □ An analytical procedure is described for the GLC determination of 11-methyl-16,16-dimethylprostaglandin E_2 in aqueous polyethylene glycol 400 solutions. Because of the nature of the carrier matrix, sample cleanup was required prior to GLC separation. Separation was achieved using a diethylaminoethylcellulose microcolumn. This procedure has proven to be amenable to routine analysis.

Keyphrases □ Prostaglandin analogs—GLC analysis, pre-GLC sample cleanup procedure, polyethylene glycol carrier matrix □ GLC—prostaglandin analog determination, sample cleanup prior to GLC, polyethylene glycol carrier matrix □ Polyethylene glycol—carrier matrix in aqueous prostaglandin analog solutions, GLC analysis, pre-GLC sample cleanup procedure

Research into the synthesis of prostaglandin analogs that provide increased metabolic and chemical stability over naturally occurring prostaglandins has focused on the prostanoid 11-methyl-16,16-dimethylprostaglandin E_2[1] (I), the structure of which differs only slightly from that of natural prostaglandin E_2 (II). Previous studies (1, 2) showed that I is a potent inhibitor of gastric acid secretion in humans and dogs with no appreciable side effects.

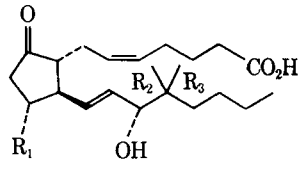
In compliance with the Good Laboratory Practices (GLP) regulations, aqueous solutions of I were analyzed as part of an analytical monitoring program for rat and dog toxicity studies. Many GLC and high-performance liquid chromatographic procedures have been published for the analysis of prostaglandin E_2 (3–13), but none was suitable for the present application because of interferences from excipients in the sample solutions.

This paper describes a sensitive and specific procedure for the analysis of I in aqueous media containing polyethylene glycol 400, butylated hydroxyanisole, and ascorbyl palmitate (III). The procedure involves the elimination of water and polyethylene glycol 400 by utilizing a diethylaminoethylcellulose microcolumn, conversion of I to the trimethylsilyl derivative, and GLC determination.

EXPERIMENTAL

Reagents—All solvents and chemicals were reagent grade unless otherwise specified.

Instrumentation—The gas chromatograph[2] was equipped with a hydrogen flame-ionization detector connected to an electronic chromatographic automation system[3] for peak area integration. The stainless steel column, 2.5 m × 2 mm i.d., was packed with 3% OV-1 on Chromosorb W-HP[4] (80–100 mesh) and conditioned at 320° for 24 hr under nitrogen at a flow rate of 30 ml/min. The instrument parameters were: injector temperature, 280°; detector temperature, 300°; carrier gas (nitrogen) flow rate, 30 ml/min; hydrogen flow rate, 30 ml/min; and air flow rate, 300 ml/min.



I: $R_1 = R_2 = R_3 = CH_3$
II: $R_1 = OH$, $R_2 = R_3 = H$

The column temperature was programmed stepwise isothermally from 0 to 12.5 min at 290°, followed by flash heating to 310° to elute III. Electrometer sensitivity was adjusted to give ~60% full-scale deflection for 8 μl of injected standard solution.

Sample Preparation—Aliquots of the sample solution (2.0 ml for I concentrations of >0.005% and 5.0 ml for those having <0.005%) were diluted to 50 ml with methanol.

Standard Preparation—Standard solutions were prepared by diluting I in methanol to give a final concentration of 8×10^{-3} mg/ml.

Internal Standard Preparation—Stock solutions of *n*-triacontane (IV), the internal standard, were prepared by dissolving 6 mg of IV in 50 ml of hexane. A 1.0-ml aliquot of this solution was added to a 12-ml conical flask and evaporated to dryness under a dry nitrogen stream. The residue was dissolved in 10 ml of trimethylsilylating reagent, which was a mixture of 60% hexamethyldisilazane[5] and 10% trimethylchlorosilane[5] in acetonitrile.

Microcolumn Cleanup Procedure—A diethylaminoethylcellulose[6] slurry was prepared by adding 300 ml of methanol to ~6.0 g of the ion-exchange medium. The slurry was degassed under vacuum for 30 min and transferred to a glass-stoppered solution bottle.

A glass column (15 cm × 6 mm i.d.) was used for the pre-GLC cleanup. The column, fitted with a hydrophilic polyethylene disk tapered to 1.65 mm i.d., was filled with the cellulose slurry to a gel height of 8 ± 1 mm (Fig. 1).

The column bed was washed with 2 ml of methanol, and the effluent was discarded. Based on the concentration of I, various volumes of the sample or standard solution (standard solution, 2.0 ml; samples with I concentrations of >0.02%, 2.0 ml; samples with I concentrations of <0.005%, 4.0 ml; and placebo, 4.0 ml) were applied to the top of the gel and allowed to absorb into the bed; the resulting effluent was discarded.

Interfering excipient substances were washed from the column with 4.0 ml of distilled water applied to the top of the gel bed, and the effluent was discarded. Residual water was removed from the gel by applying a

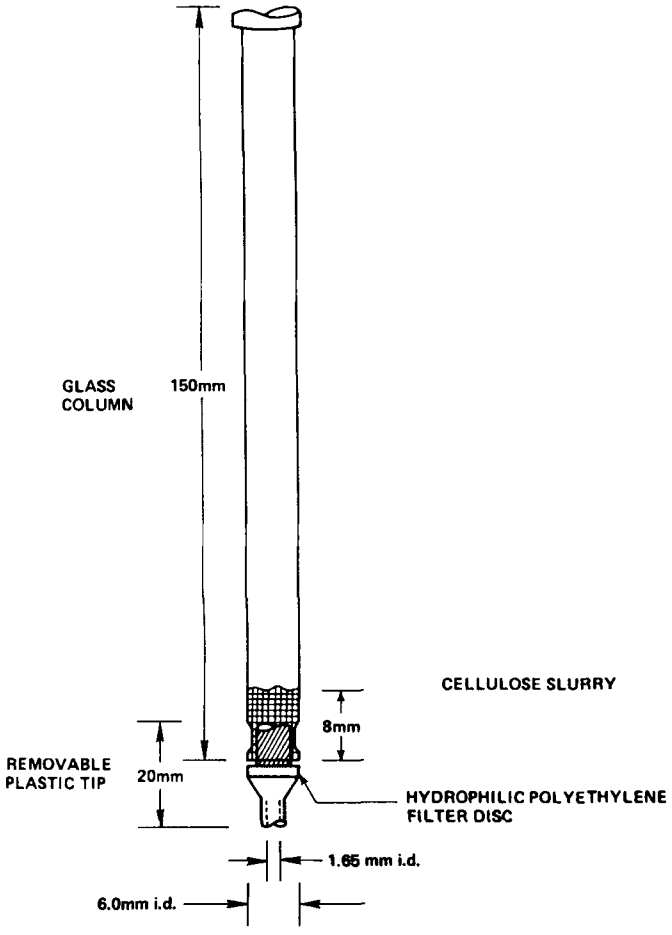

Figure 1—*Diethylaminoethylcellulose microcolumn utilized in pre-GLC sample cleanup procedure.*

gentle nitrogen stream to the top of the column for ~1 min. Compound I was eluted from the column with 7.0 ml of anhydrous ether, and the eluate was evaporated to dryness at room temperature under a nitrogen stream.

Preparation of Trimethylsilyl Derivatives—After the eluate was evaporated carefully to dryness, 400 μl of the trimethylsilylating reagent containing the internal standard (IV) was added, and the solution was left for 30 min at room temperature. This solution was injected onto the GLC column.

Calculations—The concentration of I in 40% polyethylene glycol 400 solutions was determined from:

$$\frac{\text{milligrams of I}}{\text{milliliters of solution}} = \left(\frac{X_{spl}}{Y_{spl}}\right)\left(\frac{Y_{std}}{X_{std}}\right)(C_{std})\left(\frac{DF}{V_I}\right) \qquad \text{(Eq. 1)}$$

where X_{spl} and X_{std} are the peak areas of I in the sample and standard preparations, respectively; Y_{spl} and Y_{std} are the peak areas of IV for the sample and standard, respectively; V_I is the volume of the initial sample aliquot (milliliters); DF is the sample dilution factor; and C_{std} is the concentration of I in the standard solution (milligrams per milliliter).

RESULTS AND DISCUSSION

The samples studied were aqueous solutions containing 40% polyethylene glycol 400, 0.05% ascorbyl palmitate, 0.02% butylated hydroxyanisole, and 0.001–0.02% (0.01–0.2 mg/ml) of I. In all cases, pre-GLC sample cleanup was necessary to eliminate sample matrix interferences.

Column chromatographic techniques have been used widely for sample preparation and cleanup procedures, but few applications employing ion-exchange resins have been reported where the adsorptive properties of the resin matrix were a factor in the separation. By utilizing ion-exchange resins and either nonpolar solvents or electrolyte-free water–alcohol mixtures as eluents, separations have been achieved for sugars (14), alcohols (15), organic acids (16), analgesics (17), and benzene derivatives (18, 19). In each of these applications, the dominant mechanism was adsorption onto the resin matrix with little or no ion exchange occurring.

With this technique, a microcolumn sample cleanup procedure was developed that eliminated matrix interferences in aqueous solutions of I. It was found that I could be separated selectively from polyethylene glycol 400 and isolated from water (water had to be eliminated before silylation reagents could be used) using a microcolumn containing diethylaminoethylcellulose (free base form). Columns were prepared by adding a degassed methanolic slurry of diethylaminoethylcellulose to a gel height of 8 ± 1 mm to a 15-cm × 6-mm i.d. glass column outfitted with a fritted disk. The small void volume of this column, a departure from most conventional procedures, was especially advantageous since only a small volume of solvent was needed for complete elution of I.

Aliquots of sample solutions of I were diluted with methanol and applied onto the microcolumns. Polyethylene glycol 400, I, and III were retained on the diethylaminoethylcellulose due to a combination of adsorption onto the cellulose matrix backbone and ion exchange with the diethylaminoethyl functional groups bound to the cellulose. The ion-exchange interaction was confirmed by attempting the same separation using cellulose without the diethylaminoethyl functional groups. With this medium, definitive separation of polyethylene glycol 400 and I was not accomplished, and the results were not reproducible.

With diethylaminoethylcellulose, solvent systems were investigated

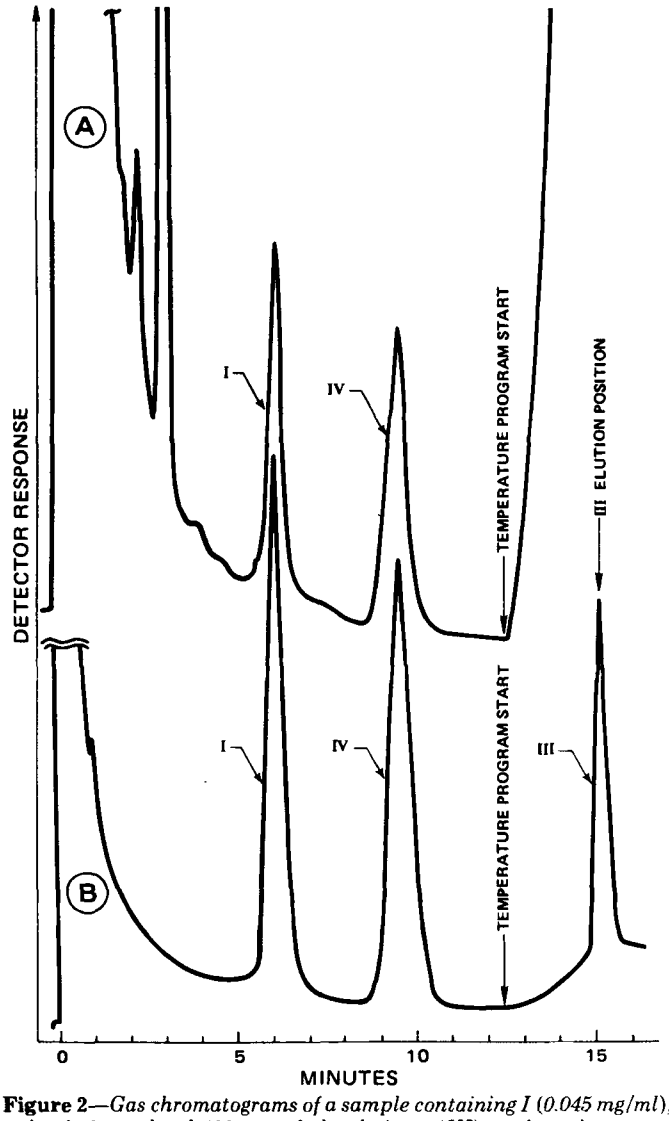

Figure 2—*Gas chromatograms of a sample containing I (0.045 mg/ml), polyethylene glycol 400, ascorbyl palmitate (III), and n-triacontane (IV) as the internal standard after pre-GLC sample cleanup for which detector response was 2 × 10^{-11} amp/sec full scale (A); and a standard stock solution containing I, ascorbyl palmitate (III), and n-triacontane (IV) for which the detector response was 16 × 10^{-11} amp/sec full scale (B).*

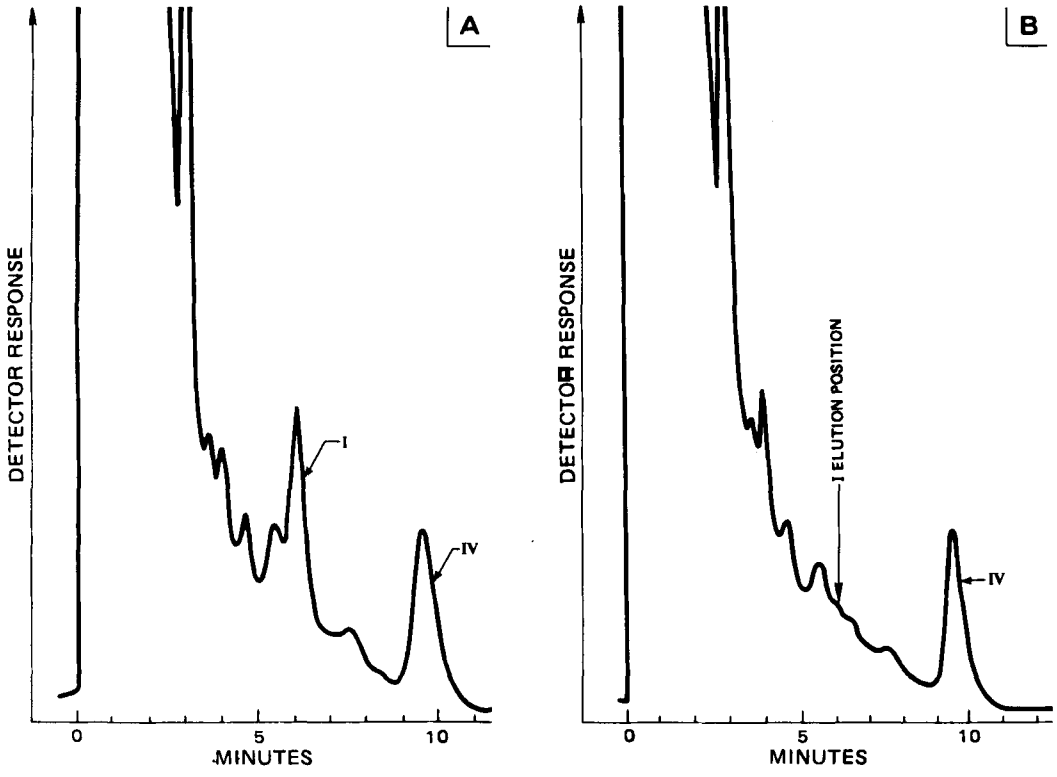

Figure 3—*Gas chromatograms of a sample containing I (0.01 mg/ml), polyethylene glycol 400, and* n*-triacontane (IV) as the internal standard after pre-GLC sample cleanup (A); and a placebo containing* n*-triacontane (IV) as the internal standard, after pre-GLC sample cleanup, prepared at the same excipient concentration level as Sample A (B). The detector response was 2 × 10^{-11} amp/sec full scale.*

Table I—Assay Results for Samples Containing I, Polyethylene Glycol 400, Ascorbyl Palmitate, and Butylated Hydroxyanisole

Sample Claim of I, mg/ml	*n*	Average Result ± *SD*, mg/ml	Percent of Claim	*RSD*, %
0.200	6	0.207 ± 0.00115	103	5.6
0.044	5	0.0469 ± 0.00530	106	11.3
0.010	3	0.00974 ± 0.00042	97.4	4.3

in which I would be retained on the column while polyethylene glycol 400 and III would be eluted; however, no system could be found with these properties that also would provide 100% recovery of I. For this reason, efforts were directed to the development of a system to remove polyethylene glycol 400 and water, leaving the separation of I and III by GLC as the next step.

Polyethylene glycol 400 was removed during the wash step by partitioning with water; I and III, having little affinity for water, remained bound to the column. The latter compounds then were eluted with anhydrous ether. The resulting eluate was evaporated to dryness under a nitrogen stream, and the residue was reacted with silylating reagent.

Baseline separation of I and III was achieved in 16 min by GLC using a 2.5-m × 2-mm i.d., 3% OV-1 on Chromosorb W-HP column for samples containing >0.045 mg of I/ml (Fig. 2). However, artifacts of polyethylene glycol 400 were found in those samples having <0.045 mg of I/ml because of the need to apply significantly more sample to the microcolumn for quantitative detection. Even at low levels, quantitation of I was not affected (Fig. 3).

The trimethylsilyl derivative of I was formed by reaction with a hexamethyldisilazane–trimethylchlorosilane mixture in acetonitrile, with no loss in potency of I detected after 24 hr. In earlier studies with stronger silylating reagents, I degradation was observed by GLC as a peak eluting prior to I.

Results of validation studies have shown that the procedure is accurate, precise, and suitable for routine analysis. The loading capacity of the microcolumns was linear over a range of 7.50–22.5 μg of I, with a least-squares correlation coefficient of 0.997. Results of a recovery study using the standard addition method yielded a mean value of 101%. A method precision study, conducted with 15 replicate samples, yielded a coefficient of variation of 7.3%. The analysis of actual samples over a concentration range of 0.01–0.2 mg of I/ml yielded results with acceptable variation (Table I).

Production and Characterization of Specific Antibody for Radioimmunoassay of Procainamide

P. MOJAVERIAN ˣ **and G. D. CHASE**

Received June 21, 1979, from the *Department of Chemistry, Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104.*
Accepted for publication February 1, 1980.

Abstract □ The production and characterization of a specific antibody for use in the radioimmunoassay of procainamide are described. Cross-reactivity was measured by a nonequilibrium competitive procedure. Procainamide analog concentrations resulting in 50% inhibition were: procainamide, 1.59 nmoles/ml; *N*-acetylprocainamide, 3.55 nmoles/ml; a propyl analog of procainamide, 398 nmoles/ml; procaine, 316 nmoles/ml; lidocaine, >8000 nmoles/ml; and practolol, >16,000 nmoles/ml. Variations in the ability to inhibit binding of labeled procainamide were related to structural similarities and differences. The affinity constant of the antibody for procainamide was 2.9×10^8 liters/mole as measured from a Scatchard plot. The assay allows the direct measurement of procainamide in a 0.1-ml aliquot of diluted serum. The advantages of this method over currently available techniques are its sensitivity, specificity, and simplicity. Furthermore, prior extraction of serum samples is not required. As little as 1 ng of drug/ml of serum can be detected by this method. The accuracy and precision were determined by adding known amounts of procainamide to human serum and then assaying five replicates of each concentration. The within-day and between-day coefficients of variation were 2 and 5%, respectively. The proposed method was used to determine the serum concentration after an intravenous dose of procainamide. A comparison of the radioimmunoassay results with values obtained by a GLC procedure showed excellent agreement.

Keyphrases □ Procainamide—radioimmunoassay in human serum □ Radioimmunoassay—procainamide in human serum □ Antiarrhythmic activity—procainamide, specific antibody production and characterization

Procainamide (I) is a widely used antiarrhythmic with a narrow therapeutic range (1). Since procainamide is very potent, the choice of the proper dosage is critical. Variation in the dose requirement of patients appears to be due mainly to individual differences in procainamide absorption, distribution, and elimination (2, 3).

Determination of plasma concentrations of I has been studied using spectrometric (4), GLC (5), and high-pressure liquid chromatographic (6) procedures. However, various shortcomings exist. A radioimmunoassay for I could provide more than a 1000-fold increase in sensitivity as well as much greater specificity over those levels offered by existing procedures. Radioimmunoassay is based on competition between antigenic determinants of the labeled and unlabeled antigens for a limited number of specific antibody binding sites. Anything that competes for such sites, or in any other way affects the binding of labeled antigen, will influence the results.

The establishment of a practical radioimmunoassay procedure for a particular compound of clinical significance depends, among other factors, on the production of a high affinity antiserum with little cross-reactivity with compounds of similar structure. An ideal antibody is one that reacts with only one species of the molecule (*i.e.*, the antigen). However, antibodies tend to cross-react with compounds other than the specific antigen if there are certain structural similarities. The greater the ability of an antibody to distinguish between minute structural differences, the less is the tendency to cross-react and the greater is the specificity of the antibody. A radioimmunoassay for I is described, with particular emphasis on antibody specificity.

EXPERIMENTAL

Hapten–Protein Condensation—Three drug–protein derivatives were prepared by coupling I[1] to bovine serum albumin[2], egg albumin[3], and rabbit serum albumin[2], respectively. Procainamide was conjugated mainly through the tyrosyl residues of bovine serum albumin *via* a diazotization and condensation procedure (7, 8). Compound I (150 mg) was dissolved in 2 ml of distilled water at 2°, and the pH was adjusted to 9 with 1 *N* NaOH.

Nitrous acid was prepared by mixing 40 mg of sodium nitrite, in 5 ml of ice-cold distilled water, with 1 ml of 1 *N* HCl. This solution was added immediately to the solution of I, and diazotization was allowed to proceed for 15 min with occasional stirring. The diazotized drug solution was added in 1-ml increments to the protein solution (1 g of protein in 50 ml of ice-cold 0.04 *N* NaOH), and the pH was adjusted to 8.5. The mixture was stirred to eliminate any local excess of acid. The pH of this mixture was checked at 15-min intervals for 2 hr and was finally adjusted to 8.5 with 0.1 *N* NaOH. The solution was incubated overnight at 5° to allow completion of the coupling reaction.

The conjugation mixture was dialyzed against distilled water over 2–3 days, thus allowing for the removal of unreacted low molecular weight materials. The purified drug–protein solution was lyophilized and stored frozen in small quantities. The spectrometric analysis of the conjugate (I–bovine serum albumin) indicated that the molar ratio of procainamide to bovine serum albumin was between 20 and 22.

Radioiodination—Radioiodinated antigen was prepared by conjugation of I to rabbit serum albumin with subsequent iodination of the complex by the chloramine-T procedure (9) using 2 mCi of carrier-free sodium [^{125}I]iodide[4]. The I–rabbit serum albumin (2 mg in 0.5 ml of phosphate buffer, pH 7.5) was added to 2 mCi of sodium [^{125}I]iodide (in 0.5 ml of phosphate buffer) and mixed with 2 mg of chloramine-T[5] in 0.5 ml of iodination buffer. After 2 min of incubation, 4 mg of sodium metabisulfite in 0.5 ml of phosphate buffer was added to reduce both chloramine-T and any unreacted iodine. Carrier potassium iodide (5 mg in 0.5 ml of buffer) then was added.

This mixture was incubated at room temperature for 2 min and then was purified by gel filtration in a 0.9 × 15-cm G-25 Sephadex column[6] equilibrated with the iodination buffer. The total iodination mixture (2.5 ml) was added to the column with a plastic disposable syringe, and the column eluate was collected in 0.5-ml fractions, which were counted to determine the radioactivity profile. The radiochemical purity and percent labeling yield were measured, and the specific activity of ^{125}I-labeled I–rabbit serum albumin was calculated (1.90 Ci/mmole of I).

Preparation of Anti-I Serum—The drug–protein conjugate (I–bovine serum albumin) was antigenic when female albino rabbits were given several injections of 0.5–2 mg of complex dissolved in phosphate-buffered saline (pH 7.5) emulsified in a 1:2 ratio of Freund's complete adjuvant[7].

Booster shots were given at 4–5 week intervals, and blood samples were collected 10 days after each booster *via* the marginal ear vein. Development of the drug-specific antibody was followed qualitatively and quantitatively by use of a microgel immunodiffusion technique (10, 11). After 5–6 months, antiserum dilutions of 1:500 and 1:1000 yielded 50% binding of 4 ng of I.

Specificity Analysis—Several antiarrhythmic and cardiac depressants were selected as potential cross-reacting compounds on the basis of their structural similarity with I or because they are coprescribed with I. The compounds selected (shown as their hydrochlorides for I–V) were: *N*-acetylprocainamide[8] (II), a propyl analog of procainamide[1] (III), procaine[2] (IV), lidocaine[9] (V), and practolol[10] (VI).

Cross-reactivity of the antibody was measured by a nonequilibrium competitive procedure: 100 μl of the cross-reacting antigen in the range of 10^{-8}–10^{-3} *M* was mixed with 50 μl of the properly diluted antiserum in a 0.5-ml disposable polypropylene test tube[11] and incubated for 0.5 hr at 5°. Then 10 μl of the radioiodinated antigen (equivalent to 4 ng of the tracer) was added, and the mixture was incubated for 1 hr at 5°. Finally, 100 μl of the second antibody[12] (goat anti-rabbit immunoglobulin G) was added and the tubes were incubated for an additional hour at 5°.

The tubes then were centrifuged for 15 min at 3000 rpm, and the free (supernatant) and bound (precipitated) fractions were separated. The percentage of the iodinated antigen bound to the antibody was calculated in the presence (% B_p) and absence (% B_0) of the unlabeled cross-reacting molecules (12). The percentage of inhibition was calculated from:

$$\text{percentage of inhibition} = \left(\frac{\%\ B_0 - \%\ B_p}{\%\ B_0}\right) \times 100 \qquad \text{(Eq. 1)}$$

The percentage of inhibition was plotted as a function of the logarithm of the cross-reactant concentration (Figs. 1 and 2). The concentration resulting in 50% inhibition of binding with 4 ng of the radiolabeled antigen in a total volume of 260 μl was measured from the graph.

Radioimmunoassay—Procainamide standards were prepared by dilution of a 0.2-mg/ml stock solution in 0.05 *M* phosphate-buffered saline, pH 7.5. Duplicate standards, 0–200 ng, were prepared in the phosphate-buffered saline.

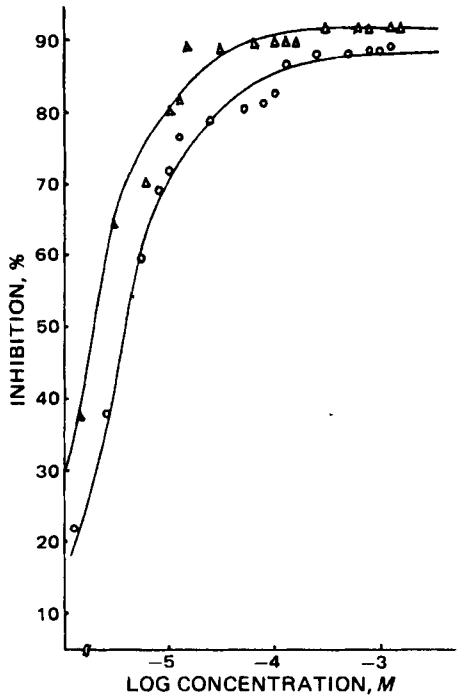

Figure 1—*Competitive inhibition of binding of 4 ng of radioiodinated procainamide by the prior addition of an increasing concentration of unlabeled I (△) or II (○).*

Antiserum was diluted (1:500–1:1000) with the assay buffer to yield 40–60% binding with labeled hapten. Then a 0.1-ml aliquot of diluted antibody was used per tube for the assay. The radioiodinated antigen also was diluted in 0.05 *M* phosphate-buffered saline so that a 0.05-ml aliquot had an activity of 35,000–40,000 cpm. Radioisotopic purity was checked periodically by paper chromatography, using 75% methanol for development. An appropriate dilution of goat anti-rabbit immunoglobulin G was used as the precipitating antibody (0.15 ml/tube). An equilibrium assay procedure was used.

Table I is an outline of the radioimmunoassay protocol. The procedure was as follows. The standards and unknowns were mixed with the radioiodinated antigen, buffer, and the antiserum in 6 × 50-mm disposable culture tubes[13], which were placed inside regular 12 × 75-mm disposable

culture tubes for convenience in handling and centrifugation. All tubes were vortexed for 2–3 sec and then incubated for 3 hr at 25°. Then 0.15 ml of the second antibody was added to all tubes, which were vortexed again for 3 sec.

After centrifugation of the tubes at 3000 rpm for 20 min, the supernate (free fraction) was separated from the precipitate (bound fraction) using a disposable pasteur pipet[14]. The activity of the free and bound fractions was counted using a γ-scintillation spectrometer[15]. The procainamide concentration was plotted as a function of the total-to-bound radioactivity ratio. However, the data also can be processed by use of a computer program (13). The unknown concentrations were measured by interpolation.

Sensitivity and Detectability—Sensitivity was defined by Horwitz (14) as the amount of measured response per unit of stimulus (*i.e.*, the slope of the response curve). Sensitivity should be evaluated from a linear response plot, because a linear dose–response curve gives a constant value for sensitivity. Sensitivity of the procainamide radioimmunoassay system was calculated as the reciprocal of the slope of the dose–response plot (Fig. 3). The detectability or detection limit of a radioimmunoassay procedure is defined as the minimum concentration of the unlabeled antigen that provides a measurable response under defined conditions (14). The detection limit of the system, estimated as the reciprocal of the affinity constant, was 4.8×10^{-9} *M*.

Precision—The precision of the system was determined by addition of known amounts of I to procainamide-free human serum and then assay of five replicates of each concentration (Table II).

Human Study—A healthy, 26-year-old male subject was given an intravenous dose of I (461 mg/30 ml) over 10 min by use of an infusion pump[16]. Blood samples were collected at several postinfusion intervals (Table III). The serum was separated and kept frozen until it was analyzed.

GLC Assay—Procainamide was extracted from the serum with methylene chloride as described by Elson *et al.* (15) and was analyzed by the GLC[17] method of Simons and Levy (16). Each serum sample then was analyzed for procainamide concentration by the radioimmunoassay. The results were compared with values obtained from the GLC procedure (Table III).

RESULTS AND DISCUSSION

The results of the cross-reactivity analysis of the procainamide antibody are summarized in Table IV. Inhibition plots of the cross-reacting analogs are shown in Figs. 1 and 2.

Since procainamide is a low molecular weight drug, *i.e.*, <500, the antiserum usually recognizes the whole structure rather than parts of it. Therefore, the antibody can detect slight changes in molecular structure from that of the immunizing antigen (I). This characteristic of the antibody is more pronounced in the nonequilibrium competitive procedure (Table IV). The results of the cross-reactivity experiments indicate that any modifications in the basic benzamide structure of I (*i.e.*, procaine and lidocaine) diminish the antibody binding stimulated by the I–bovine serum albumin complex. Also, the presence of the tertiary nitrogen and the carbon chain length on this nitrogen influence the immunoreactivity of the molecule.

[17] Series 2400, Varian Aerograph, Palo Alto, Calif. The gas chromatograph was equipped with a flame-ionization detector and had a 0.914-m glass column packed with 10% OV-7 on 100–120-mesh WH-P. The temperatures of the injector, column, and detector were 260, 245, and 280°, respectively.

Table III—Comparison of Procainamide Levels as Measured by Radioimmunoassay and GLC

Postinfusion Time, min	Serum Procainamide Levels, μg/ml	
	Radioimmunoassay	GLC
3	6.95	6.9

Table IV—Summary of Nonequilibrium Competitive Cross-Reactivity of Procainamide Antibody [a] with Structurally Related Compounds

Compound	Concentration for 50% Inhibition of Binding, $M \times 10^{-5}$	Concentration Ratio[b]	Molecular Weight
I	0.159	1.00	272.0
II	0.355	2.30	313.5
III	39.8	250	300.0
IV	316	1987	273.0
V	>800	>5000	272.0
VI	>1600	>10000	266.0

[a] Antibody raised against I-bovine serum albumin. [b] Compared to I.

Differences in 50% inhibition values for the cross-reacting compounds were indicated by inhibition curves with differing slopes. The antibody developed against the hapten differentiates between the antigen and its *N*-acetyl metabolite (II). Although the values of 50% inhibition for these two compounds differ only slightly, twice the concentration of II is required to compete equally with I for the antibody binding sites. In addition, the antibody recognizes the molecular differences between the immunizing antigen and its propyl analog. This analog concentration must be 250 times that of I to inhibit binding by 50%. In the case of procaine, this value is ~2000. The antibody appears to be very sensitive to changes in molecular structure.

The increasing value of 50% inhibition of II–VI parallels the degree of difference between the molecular structure of these compounds and I. Furthermore, the antibody was characterized with respect to its affinity constant by a Scatchard analysis. The calculated value was 2.9×10^8 liters/mole. The radioimmunoassay parameters were adjusted to optimum values. The standard curve showed excellent linearity over the range of 0–100 ng of I/ml. Therefore, patient samples should be diluted properly (about 100-fold) to fall within this concentration range. Dilution also reduces the degree of nonspecific binding. Correction for nonspecific binding was made by subtracting the activity of a nonspecific binding blank from both standards and unknowns.

The proposed method was characterized by evaluation of the sensitivity and detectability of the system, which were 0.04 division/ng of I and 1.3 ng of I/ml, respectively. The precision of the assay is good since the standard error of replicates was ≤1% of the mean value for each concentration measured (Table II). The ratios of the assayed procainamide to that added indicate an acceptable recovery.

The within-day and between-day precision were evaluated by duplicate measurements of identical samples on the same day and on consecutive days. The coefficient of variation, *CV*, was estimated from (17):

$$CV = \sqrt{\frac{\sum d^2}{2n}} \qquad \text{(Eq. 2)}$$

where:

$$d = \left[\frac{\text{highest value of each duplicate}}{\text{lowest value of each duplicate}} - 1\right] \times 100 \qquad \text{(Eq. 3)}$$

and n is the number of duplicate determinations. For the procainamide antibody, the within-day coefficient of variation ranged from 1.4 to 4.2% with a mean of 2.2%. The between-day coefficient of variation ranged from 2.9 to 9.1% with a mean of 5.6%. The coefficient of variation was measured over the concentration range of 0–200 ng/ml.

The validity of the assay was established further by comparing the values obtained by radioimmunoassay to values obtained from a GLC assay. The results (Table III) showed excellent agreement.

In summary, the described method is a sensitive and relatively simple microanalytical procedure, which can be performed directly on an aliquot of serum without prior extraction or purification. This radioimmunoassay procedure permits the simultaneous analysis of a large number of samples.

Hydrolysis of Tetrakis-μ-acetylsalicylato-dicopper(II)

A. A. ALICH *x **and L. E. WITTMERS** ‡

Received October 22, 1979, from the *Department of Chemistry, College of St. Scholastica, Duluth, MN 55811, and the ‡Department of Physiology, School of Medicine, University of Minnesota-Duluth, Duluth, MN 55812. Accepted for publication February 4, 1980.

Abstract □ Hydrolysis rates of acetylsalicylate in the free acid and anion forms and in the dilute solution of the copper complex, tetrakis-μ-acetylsalicylato-dicopper(II), were compared. The hydrolysis rate was unaffected by the presence of copper(II). The pH-dependent rate was 3.64×10^{-4} mmole/liter/min per pH unit at 37° in Ringer's solution. The synthetic procedures commonly used for the preparation of this compound yield a product contaminated with salicylate. This contamination is avoided by synthesis of the compound in methanol, which yields a complex containing no measurable salicylate.

Keyphrases □ Anti-inflammatory agents—aspirin, comparison of hydrolysis rate with that of tetrakis-μ-acetylsalicylato-dicopper(II), pH dependency □ Aspirin—comparison of hydrolysis rate with that of tetrakis-μ-acetylsalicylato-dicopper(II), pH dependency □ Hydrolysis rates—aspirin and tetrakis-μ-acetylsalicylato-dicopper(II), pH dependency

The use of a mixture of copper and salicylate in the treatment of arthritis has been discussed (1–3). Sorenson (4) recently reported that tetrakis-μ-acetylsalicylato-dicopper(II) has greater anti-inflammatory properties than does aspirin (acetylsalicylic acid) alone and suggested that this complex might be the pharmacologically active form of aspirin. This hypothesis generated considerable testing and discussion of the copper complex (5–15), a review of which was given by Sorenson (16, 17).

The evidence presented in the literature concerning Sorenson's hypothesis that the copper complex is the pharmacologically active form of aspirin is limited to observations of the effect of the complex on induced inflammations in laboratory animals (*i.e.*, measurements of paw thickness and volume). It seemed important to assess the relationship between the chemistry of the copper complex and the pharmacological activity of aspirin. The first experiments undertaken involved the hydrolysis of the copper complex to salicylic acid and acetic acid.

The complex was first prepared in 1962 (18), and the X-ray structure was published in 1966 (19). The method used by Manojlovic-Muir (19) yielded a product containing a significant amount of salicylate, so other preparations were sought. This report compares the hydrolysis rates for the complex prepared by three published methods to that for aspirin alone.

EXPERIMENTAL

Materials—The chemicals were reagent grade and were used as obtained with several exceptions. Butyl ether (practical grade) was purified by a literature method (20) and refrigerated in brown glass. Tetrakis-μ-acetylsalicylato-dicopper(II) was prepared by three methods.

Sample B was prepared based on a statement that the complex can be formed in methanol (21). A solution of 25.0 g (0.129 mole) of aspirin in 200 ml of methanol was added to a solution of 13.85 g (0.0694 mole of copper) of copper(II) acetate in 1 liter of methanol. Crystallization of the complex occurred very slowly, and three successive crops of crystals were separated out (53% yield).

Anal.—Calc.: C, 51.25; H, 3.34; Cu, 15.07; O, 30.34. Found[1]: C, 51.04; H, 3.53; Cu, 14.95; O, 30.33.

Sample C was prepared by the method of Sorenson (4), which involves the addition of an aqueous solution of aspirin (pH adjusted to ~11 with 50% NaOH) to an aqueous solution of copper(II) chloride (68% yield).

Found: C, 50.94; H, 3.43; Cu, 14.94; O, 29.96.

Sample D was prepared by the method of Manojlovic-Muir (19) in which stoichiometric amounts of aspirin and copper(II) salicylate are heated in 50% aqueous ethanol to 50° (45% yield).

Found: C, 51.11; H, 3.50; Cu, 15.02; O, 29.90.

Mammalian Ringer's solutions were buffered with acetate to produce solutions of pH 5.8 and with tris(hydroxymethyl)aminomethane to produce solutions of pH 7.5 and 8.8. All solutions were prepared with deionized, glass-distilled water.

Procedures—Hydrolysis was carried out with 2.775 m*M* solutions of aspirin or 0.6953 m*M* solutions of tetrakis-μ-acetylsalicylato-dicopper(II) in the appropriately buffered Ringer's solution at 37° (each mole of complex has 4 moles of acetylsalicylate). Both aspirin and the complex dissolved very slowly. Time zero was taken as the time at which the solid compound was added to the Ringer's solution.

Analysis of salicylic acid (due to hydrolysis) was carried out with the following modifications of a published procedure (20). A 300-μl aliquot of the reaction mixture was extracted into 3.00 ml of butyl ether with shaking at 250 rpm for 10 min. The butyl ether contained 4.0 g of malonic acid/liter to facilitate separation and to prevent further hydrolysis. The two-phase mixture was centrifuged at 2500 rpm for 5 min, the ether layer was drawn off, and the UV spectrum was scanned between 330 and 275 nm[2]. The salicylic acid concentration was determined from a standard curve calculated from absorbances at 307 nm by linear regression analysis. The coefficient of determination (22) for standard curves was ≥0.99. Hydrolysis rates were determined by plotting the appearance of salicylic acid with respect to time over at least 4 hr. Slopes were calculated by linear regression analysis.

Samples for thermal analysis were placed in quartz or platinum crucibles and heated from 0 to 1000° over 20 hr in nitrogen or air at a flow rate of ~1 ml/min[3].

RESULTS

The hydrolyses of acetylsalicylate in aspirin and in the three preparations of tetrakis-μ-acetylsalicylato-dicopper(II) in dilute solution at an acidic pH appear in Fig. 1 as a series of nearly parallel lines. The hydrolysis rates were similar at a given pH (Table I), although the *y* intercepts differ. Table I also gives comparable data for the other pH values at which the experiment was performed.

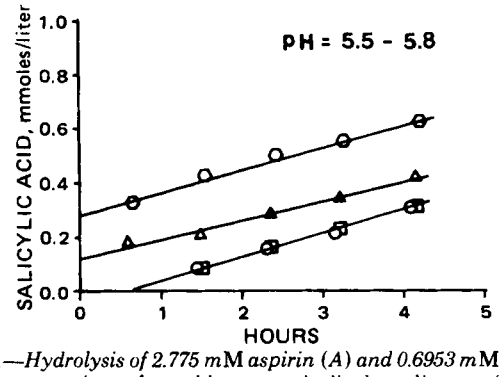

Figure 1—*Hydrolysis of 2.775 m*M *aspirin (A) and 0.6953 m*M *solutions of three preparations of tetrakis-μ-acetylsalicylato-dicopper(II) (B–D) at 37°. Key: ○, Sample A; □, Sample B; △, Sample C; and ○, Sample D.*

Table I—Hydrolysis Rates of 2.775 m*M* Aspirin (A) and 0.6953 m*M* Solutions of Three Preparations of Tetrakis-μ-acetylsalicylato-dicopper(II) (B–D) at 37° and Three pH Values

Sample	pH Range	pH Mean ± *SD*	Hydrolysis Rate, mmoles/liter/min × 10^3	r^2 [a]	Buffer
A	5.50–5.60	5.56 ± 0.055	1.394	0.9993	Acetate
B	5.75–5.80	5.78 ± 0.027	1.425	0.9956	Acetate
C	5.75–5.85	5.81 ± 0.042	1.155	0.9752	Acetate
D	5.65–5.75	5.71 ± 0.042	1.322	0.9904	Acetate
A	6.95–7.10	7.01 ± 0.065	1.580	0.9967	I[b]
B	6.78–6.90	6.83 ± 0.052	1.963	0.9989	I
C	6.80–6.95	6.83 ± 0.067	1.803	0.9983	I
D	6.75–6.95	6.82 ± 0.076	1.849	0.9906	I
A	8.65–8.80	8.69 ± 0.065	2.528	0.9933	I
B	8.62–8.70	8.65 ± 0.029	2.583	0.9948	I
C	8.55–8.70	8.61 ± 0.055	2.373	0.9868	I
D	8.55–8.70	8.61 ± 0.065	2.111	0.9448	I

[a] Coefficient of determination = $r^2 = \left[\Sigma x_i y_i - \frac{\Sigma x_i \Sigma y_i}{n}\right]^2 \Big/ \left[\Sigma x_i^2 - \frac{(\Sigma x_i)^2}{n}\right]\left[\Sigma y_i^2 - \frac{(\Sigma y_i)^2}{n}\right]$. [b] I = Tris(hydroxymethyl)aminomethane.

If the hydrolysis rates from Table I are plotted *versus* pH (nullifying the effect of any initial salicylate present), they fall on a single line, indicating that aspirin in the free form and in the copper complex hydrolyze at a rate of 3.64×10^{-4} mmole/liter/min per unit of pH increase at 37° (Fig. 2). The coefficient of determination (22) for all of these points was 0.878.

Purity assessment of synthesized compounds usually includes melting-point data. All samples of tetrakis-μ-acetylsalicylato-dicopper(II) decomposed without melting. Samples B and C turned from the original blue to green to brown between 220 and 235°. Sample D began to turn green at 180°. Thermal analysis in either air or nitrogen indicated an endothermic reaction at ~240° for all of the samples, which did not correspond to any weight loss. When heated in air, all samples decomposed in three exothermic steps between 250 and 370° to a weight corresponding to copper(II) oxide. Sample D slowly lost ~5% of its weight prior to the onset of the described reactions.

DISCUSSION

Hydrolysis rates of free and bound acetylsalicylate are nearly identical at a given pH, but the curves in Fig. 1 are not superimposable. Extrapolation of hydrolysis curves to zero time in Fig. 1 indicates the initial presence of salicylic acid in Samples C and D. Melting-point and thermal analysis data indicate an impurity in Sample D but not in Sample C. The *y* intercepts in Fig. 1 indicate approximately twice as much salicylate in Sample D as in Sample C. The contamination of Samples C and D with salicylic acid undoubtedly is due to the preparation methods. At the high pH used in the preparation of Sample C (4), hydrolysis occurs rapidly, causing the product to be contaminated with salicylate. Copper(II) salicylate was used in the reaction mixture for the preparation of Sample D (19) and probably contaminated the product. Recrystallization was not mentioned in the original literature for either procedure and was not used in the preparations made in this study.

The solubility of the complex is very slight in any common solvents (23). Thus, contamination by salicylate in the methods used for Samples C and D would be difficult if not impossible to avoid. Furthermore, contamination was not apparent from IR spectra or elemental analysis (nor was such a problem mentioned in the original literature). The *y* intercept for Sample B in Fig. 1 coincides with that of aspirin, indicating that Sample B does not contain salicylate. The data presented here appear to indicate that tetrakis-μ-acetylsalicylato-dicopper(II) should not be prepared in a solution of basic pH and perhaps should be prepared in a nonaqueous solvent such as methanol to prevent contamination with salicylate. This precaution is especially important in experiments concerning the pharmacological activity of the copper complex since salicylate also is pharmacologically active.

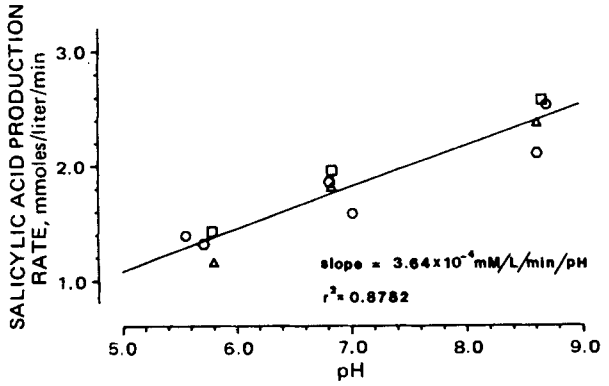

Figure 2—*Hydrolysis rate of aspirin in the free form (A) and in three preparations of tetrakis-μ-acetylsalicylato-dicopper(II) (B–D) as a function of pH. Key: ○, Sample A; □, Sample B; △, Sample C; and ○, Sample D.*

For aspirin alone as well as for Sample B of tetrakis-μ-acetylsalicylato-dicopper(II), Fig. 1 shows an induction period before the appearance of the hydrolysis product, salicylic acid. This induction period would not be present if zero time had been set when all compounds had dissolved (*i.e.*, the vertical axis would be moved to the right by ~30 min). However, the resulting plots would show some salicylic acid in all of the complex preparations and in the aspirin itself (as was the case in preliminary experiments), because hydrolysis begins as soon as any compound is present in solution. To show unambiguously that some salicylate contaminates two of the complex preparations, zero time was taken as described. Use of a sonicator to speed dissolution decreased the length of this period, so it was assumed that the time lag before the appearance of salicylate represents the time required to dissolve the compound.

As observed from Fig. 2, the hydrolysis rate of aspirin, measured by the appearance of salicylic acid, increases with increasing pH and is the same in the complex solutions as in the free form under the experimental conditions. Some inferences concerning the structure in solution may be drawn from this and other information. The crystal structure of the complex has binuclear units of tetrakis-μ-acetylsalicylato-dicopper(II) in which each of the four carboxyl groups is attached to both copper ions. The binuclear units are interconnected into a polymeric structure by a fifth copper–oxygen bond from the acetyl group of a neighboring residue. This bond is nearly 0.3 Å longer than the carboxyl copper–oxygen bonds (19).

Bose and Patel (21) modified this complex, substituting dimethylformamide or dimethyl sulfoxide in the terminal positions for the bond from the acetyl group. They reported that the copper–ligand (dimethylformamide or dimethyl sulfoxide ligand) bond was unusually weak for copper(II) complexes of these ligands. Kato *et al.* (24) reported evidence indicating that the copper(II) complexes of several carboxylic acids that are dimeric in crystalline form are monomeric in aqueous solution. If, in dilute solution, a monomer exists rather than a polymerized dimer, then solvent molecules will occupy the terminal positions and the acetyl group will not be bonded to copper. Thus, hydrolysis would occur at a rate similar to that in free aspirin.

There also is the possibility that the complex is completely dissociated. Sorenson was critical of several experiments on the pharmacological effectiveness of tetrakis-μ-acetylsalicylato-dicopper(II), in which the complex was administered orally in water solution, and suggested that in water the complex probably was dissociated (6, 17), especially at the stomach pH. It has not been possible to determine the extent of complexation under the conditions of this experiment due to the complexity of the solutions.

The stability constant of a 1:1 complex of copper and acetylsalicylate determined polarographically in phosphate buffer at pH 7.4 was 1000

(25). Gaur and Palrecha (26) also determined the stability constants polarographically with a sodium perchlorate supporting electrolyte (no buffer given) and found that 1:1, 1:2, and 1:3 species were formed, having stability constants of 80, 540, and 1610, respectively. Williams *et al.* (10) attempted to determine a stability constant potentiometrically but were unable to do so due to the rapid hydrolysis of acetylsalicylate. It is possible that at the concentrations employed and in the absence of excess acetylsalicylate ion, little complexed species exists. In this case, hydrolysis rates should not be different for solutions made from the copper complex than for those of aspirin.

In summary, the pH-dependent hydrolysis of aspirin was found to occur at the same rate in the free form as in a dilute solution of the tetrakis-μ-acetylsalicylato-dicopper(II) complex. Preparation of this complex in aqueous solution, especially a basic solution, yielded a compound contaminated with significant amounts of salicylic acid.

NOTES

Quantitation of the Antineoplastic Agent Indicine-*N*-oxide in Human Plasma by Differential Pulse Polarography

MADELINE McCOMISH, ITAMAR BODEK, and ALAN R. BRANFMAN ˣ

Received September 27, 1979, from *Arthur D. Little, Inc., Acorn Park, Cambridge, MA 02140.* Accepted for publication January 14, 1980.

Abstract □ A sensitive and reproducible differential pulse polarographic method of analysis was developed for indicine-*N*-oxide (NSC 132319) in human plasma. Lyophilized plasma is extracted with methanol, and the extract is chromatographed over partially deactivated aluminum oxide and reversed-phase silica gel columns. Indicine-*N*-oxide is eluted from the silica gel column with 25% aqueous methanol and quantitated by differential pulse polarography by measurement of the peak current at -0.72 ± 0.03 v (*versus* the saturated calomel electrode). Recovery of indicine-*N*-oxide from plasma was $88 \pm 7\%$ (*SD*) in the 1–20-μg/ml range. The method was linear over the range of 0.5–10 μg/ml of pH 4.6 buffer.

Keyphrases □ Indicine-*N*-oxide—quantitation by differential pulse polarography, human plasma □ Antineoplastics—indicine-*N*-oxide, quantitation by differential pulse polarography, human plasma □ Polarography, differential pulse—indicine-*N*-oxide, quantitation in human plasma

Indicine-*N*-oxide (I) (NSC 132319) is an antineoplastic agent (1) that recently entered clinical trials. The purpose of this investigation was to develop a polarographic method of analysis for use in clinical studies on the physiological disposition of the drug. Assays based on GLC (2) and GLC–mass spectrometry (3–5) have been reported. These assays required derivatization of either indicine-*N*-oxide or its reduced form to a volatile species prior to analysis. The method reported here for the analysis of the drug in biological samples does not require derivatization and is not subject to interference from the reduced form.

With recent advances in instrumentation (6), differential pulse polarography has become a rapid and inexpensive technique. A quantitative polarographic assay was developed in these laboratories for indicine-*N*-oxide in human plasma that combines sufficient sensitivity, reproducibility, and ease of operation for the potential routine analysis of suitable clinical samples (7).

(25). Gaur and Palrecha (26) also determined the stability constants polarographically with a sodium perchlorate supporting electrolyte (no buffer given) and found that 1:1, 1:2, and 1:3 species were formed, having stability constants of 80, 540, and 1610, respectively. Williams *et al.* (10) attempted to determine a stability constant potentiometrically but were unable to do so due to the rapid hydrolysis of acetylsalicylate. It is possible that at the concentrations employed and in the absence of excess acetylsalicylate ion, little complexed species exists. In this case, hydrolysis rates should not be different for solutions made from the copper complex than for those of aspirin.

In summary, the pH-dependent hydrolysis of aspirin was found to occur at the same rate in the free form as in a dilute solution of the tetrakis-μ-acetylsalicylato-dicopper(II) complex. Preparation of this complex in aqueous solution, especially a basic solution, yielded a compound contaminated with significant amounts of salicylic acid.

NOTES

Quantitation of the Antineoplastic Agent Indicine-*N*-oxide in Human Plasma by Differential Pulse Polarography

MADELINE McCOMISH, ITAMAR BODEK, and ALAN R. BRANFMAN ˣ

Received September 27, 1979, from *Arthur D. Little, Inc., Acorn Park, Cambridge, MA 02140.* Accepted for publication January 14, 1980.

Abstract □ A sensitive and reproducible differential pulse polarographic method of analysis was developed for indicine-*N*-oxide (NSC 132319) in human plasma. Lyophilized plasma is extracted with methanol, and the extract is chromatographed over partially deactivated aluminum oxide and reversed-phase silica gel columns. Indicine-*N*-oxide is eluted from the silica gel column with 25% aqueous methanol and quantitated by differential pulse polarography by measurement of the peak current at -0.72 ± 0.03 v (*versus* the saturated calomel electrode). Recovery of indicine-*N*-oxide from plasma was $88 \pm 7\%$ (*SD*) in the 1–20-μg/ml range. The method was linear over the range of 0.5–10 μg/ml of pH 4.6 buffer.

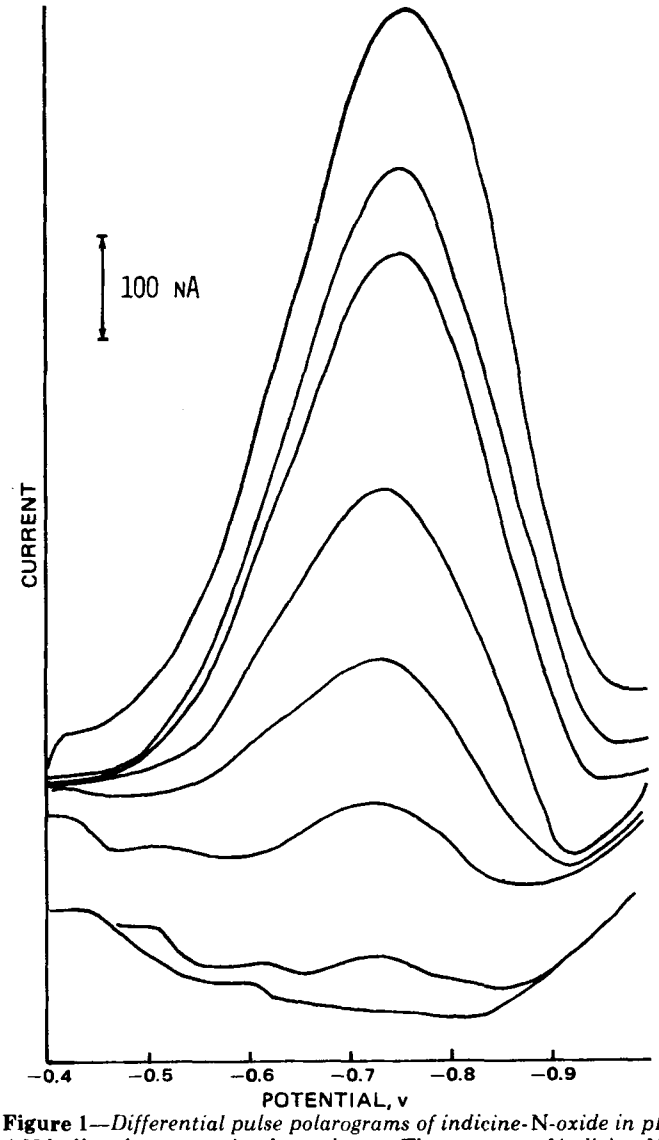

Figure 1—*Differential pulse polarograms of indicine-N-oxide in pH 4.63 buffer after extraction from plasma. The amounts of indicine-N-oxide added to 1 ml of plasma were 0 (plasma blank), 1, 3, 6, 9, 13, 15, 17, and 20 μg. A scale change to 2 μamp was necessary to record the 20-μg samples.*

EXPERIMENTAL

Conditions for Polarographic Analysis—Differential pulse polarograms were run on a polarographic analyzer[1] equipped with a drop timer and used in conjunction with a three-electrode polarographic cell comprised of a dropping mercury electrode, a saturated calomel electrode, and a platinum wire as the auxiliary electrode. The mercury drop time was 0.5 sec using a mercury column 70 cm in height. The current range typically was 1–2 μamp for a peak response of full-scale deflection, and the scan rate was 5 mv/sec.

Argon, cleansed of oxygen by passage through an acidic chromium(II) chloride solution, was used to deoxygenate the sample solutions. While polarograms were recorded, argon was passed continually over the surface of the solution. Samples were scanned from −0.4 to −1.3 v *versus* the saturated calomel electrode, and the differential pulse polarograms were recorded on an *x*–*y* recorder[2].

Reagents and Other Equipment—Indicine-*N*-oxide[3] and indicine[3] were used without further purification. The human plasma used contained the anticoagulant citrate dextrose. All other reagents were analytical grade and were used without further purification. Glass-distilled methanol[4] and deionized water[5] were used in the extraction. Standard buffer solutions[6] (pH 4.63, 5, 6, 7, and 8) were made with distilled water.

Table I—Effect of pH on the Position and Intensity of the Differential Pulse Polarographic Maxima of Indicine-*N*-oxide

pH	E_p[a], v	Intensity at E_p, μamp/μg/ml
1.65[b]	−0.70	0.133
4.63[c]	−0.735	0.141
5.00[d]	−0.775	0.141
5.60[d]	−0.830	0.097
6.00[d]	−0.860	0.091
7.00[e]	−1.08	0.050
8.00[e]	—[f]	~0

[a] Reduction peak potential. [b] 0.05 *M* HCl. [c] 0.05 *M* Sodium acetate–acetic acid. [d] 0.05 *M* Potassium biphthalate. [e] 0.05 *M* Monobasic potassium phosphate–dibasic potassium phosphate. [f] No wave detected.

Standard Solutions—Stock solutions for the preliminary work and standard curves were prepared containing indicine-*N*-oxide in water at 15.8 (5×10^{-2} *M*) and 0.15 (4.8×10^{-4} *M*) mg/ml. Aliquots of the stock solutions (10–200 μl) were added to 15 ml of the appropriate buffers. Most quantitative work was done in the pH 4.63 buffer and with a 2-ml cell. Biological samples were prepared by the addition of suitable aliquots of drug from an aqueous stock solution containing 0.5 mg/ml. Standard curves were prepared by plotting the peak current, corrected for the blank, at −0.72 ± 0.03 v (saturated calomel electrode) *versus* concentration.

Procedure for Analysis in Human Plasma—A known concentration of indicine-*N*-oxide was added to 1 ml of human plasma contained in a 15-ml glass-stoppered centrifuge tube, and the mixture was vortexed for 30 sec. The glass stopper was removed, the tube was covered with a thin film of silanized glass wool, and the mixture was lyophilized[7] overnight. After lyophilization, 3 ml of methanol was passed through the glass wool cover. The glass wool cover then was discarded, the glass stopper was replaced, and the mixture was vortexed for 30 sec. After centrifugation at 700×*g* for 10 min, the supernate was drawn off and set aside.

Methanol (3 ml) was added to the residue, and the mixture again was vortexed and centrifuged as described. The resulting supernate was combined with that from the previous extraction and evaporated under a nitrogen stream to ~1 ml. This 1-ml volume was loaded onto a 3.5-cm column of partially deactivated aluminum oxide[8] (94.5% aluminum oxide–5.5% water, w/w) packed in methanol in a disposable Pasteur pipet. The column was eluted with an additional 10 ml of methanol, and the eluate was evaporated to dryness under a nitrogen stream. This residue was dissolved in 1 ml of water, and the container was washed with an additional 1 ml of water.

Both samples were loaded onto a C_{18} bonded silica gel column[9]. The water effluent was discarded, and 10 ml of 25% aqueous methanol was used to elute the indicine-*N*-oxide from this column. The aqueous methanol eluate was collected and concentrated to 3 ml under a nitrogen stream, and the concentrate was lyophilized overnight. The residue from lyophilization was dissolved in 2 ml of pH 4.6 buffer containing 0.01 *M* KCl. The sample was deoxygenated for 5–10 min and analyzed by differential pulse polarography using the previously described conditions. The final concentrations of indicine-*N*-oxide in the plasma samples used to determine drug recovery were 0, 1, 3, 6, 9, 13, 15, 17, and 20 μg/ml of plasma.

pKa Determinations—The pKa of indicine-*N*-oxide was determined (in duplicate) by titration with 1 *N* HCl at 23°. The *N*-oxide (120 mg) was dissolved in 10 ml of 0.05 *M* KCl (freed of carbon dioxide by bubbling argon through the reagent for 15 min). Hydrochloric acid (1 *N*) was added in 25-μl increments, and the pH was recorded with each increment. The pKa was determined at the point where half-neutralization occurred. The method was checked by determining the pKa of tris(hydroxymethyl)-aminomethane, which has a value of 8.07 at 25° (8) (found 8.04 at 25°).

TLC—TLC was carried out on precoated silica gel plates[10] (20 cm × 20 cm × 0.25 mm) with chloroform–methanol–ammonium hydroxide

RESULTS AND DISCUSSION

Solutions of indicine-*N*-oxide in pH 4.6 buffer exhibited a differential pulse polarographic maximum at −0.72 ± 0.03 v (saturated calomel electrode) (Fig. 1). The potential for this maximum was pH dependent, becoming more negative at higher pH values (Table I). Since similar reduction peak potentials and pH dependencies have been observed for other *N*-oxides (10–12), these data are consistent with reduction of an *N*-oxide moiety. In support of this reduction, no wave was detected for indicine (NSC 136052), the reduced form of indicine-*N*-oxide, under similar polarographic conditions. The pKa of indicine-*N*-oxide was 4.25 ± 0.02 at 23°. This value is consistent with values of other *N*-oxides, which are typically in the 4.3–5.4 range (10–12). The average purity of the drug was 95.9 ± 3% based on the number of millimoles of hydrogen ion added at the equivalence point to the millimoles of *N*-oxide added (based on the weight).

A pH of 4.63 was chosen for the analysis medium because the effect of pH on the peak potential in this region was minimal and the intensity of response was the greatest (Table I). A linear polarographic response was observed over a range of 0.5–10 μg/ml of pH 4.6 buffer. The standard curve parameters determined by a least-squares fit of the data indicated a response of 0.122 ± 0.002 μamp/μg/ml and a correlation coefficient of 0.9997.

Extraction of indicine-*N*-oxide from plasma samples was possible only after lyophilization. Both normal aluminum oxide and reversed-phase (C_{18} bonded silica gel) chromatographic columns were needed to remove other chemical species that gave polarographic responses in the same region as the drug. Qualitative confirmation of the drug in the methanolic extract of the lyophilized residue, the methanolic eluate from the aluminum oxide column, and the methanol–water eluate from the reversed-phase silica gel column was determined by TLC (R_f 0.41). Indicine-*N*-oxide was not retained to any significant extent by either column, as indicated by the recovery data.

Analysis of plasma spiked with known concentrations of indicine-*N*-oxide gave an overall recovery of 88 ± 7% (*SD*) (Table II) over a concentration range of 1–20 μg/ml of plasma. The plasma assay presented here is a reliable, sensitive method that is applicable for clinical use. The method is suitable for the analysis of the parent *N*-oxide in the presence of the known metabolic reduction product, indicine (2).

Synthesis of Phenylurethans of 1,2-Dialkyl-4-pyrazolidinols as Anticonvulsant Agents

MILTON J. KORNET

Received December 10, 1979, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication January 18, 1980.

Abstract □ Twelve phenylurethans of 1,2-dialkyl-4-pyrazolidinols were synthesized and tested for anticonvulsant activity. Several compounds exhibited activity.

Keyphrases □ Phenylurethans—synthesized from 1,2-dialkyl-4-pyrazolidinols, evaluation as anticonvulsant agents □ Anticonvulsant activity—phenylurethans of 1,2-dialkyl-4-pyrazolidinols, synthesis and evaluation for activity □ 1,2-Dialkyl-4-pyrazolidinols—phenylurethan derivatives, synthesis and testing for anticonvulsant activity

4-Pyrazolidinyl benzoates, ester derivatives of 1,2-dialkyl-4-pyrazolidinols (I), reportedly possess local anesthetic activity (1). Since lidocaine (2) and many urethans (3) show anticonvulsant properties, synthesis and testing of a series of phenylurethans (III*a*–III*l*) of 1,2-dialkyl-4-pyrazolidinols as potential anticonvulsant agents were desired.

DISCUSSION

The necessary 1,2-dialkyl-4-pyrazolidinols (I) were obtained from the reaction of epichlorohydrin and 1,2-dialkylhydrazines according to a reported procedure (4). Hydrazinoalcohols possessing methyl (I*a*), ethyl (I*b*), and *n*-propyl (I*c*) substituents were prepared. The 1,2-dialkyl-4-

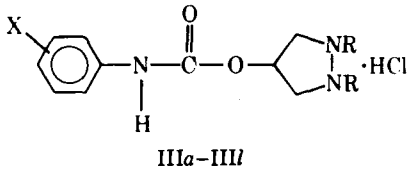
Ib: R = CH_3CH_2
Ic: R = $CH_3(CH_2)_2$



IIIa–IIIl

Scheme I

pyrazolidinols added readily to aryl substituted isocyanates (II) to give the adducts IIIa–IIIl (Scheme I). The latter compounds were isolated uniformly as their hydrochloride salts, and their physical properties are given in Table I.

Compounds IIIa–IIIl were examined in the maximal electroshock seizure (MES) and subcutaneous pentylenetetrazol seizure threshold (sc Met) tests for anticonvulsant activity and neurotoxicity in male mice[1] by reported procedures (5). Seven of the 12 compounds tested showed some degree of anticonvulsant activity (Table II). The most promising compound, IIIh, was evaluated further. The values for MES ED_{50}, sc Met ED_{50}, and TD_{50} (median toxic dose in the rotorod test) for IIIh were 193 (163–218), 336 (234–495), and 414 (353–499) mg/kg, respectively. Because of the moderate activity in this series of compounds, further work appears to be unwarranted.

EXPERIMENTAL[2]

A typical reaction for preparing the hydrochlorides of phenylurethans of 1,2-dialkyl-4-pyrazolidinols (IIIa–IIIl) is described using IIIk as the example. A mixture of 3.48 g (0.03 mole) of Ic (4), 3.99 g (0.03 mole) of p-tolyl isocyanate, and 45 ml of dry toluene was refluxed for 22 hr. The mixture was cooled and extracted twice with 50-ml portions of 2 *N* HCl. The combined acidic extract was washed with 50 ml of benzene, filtered through a sintered-glass funnel, and made basic with solid sodium carbonate. The separated oil was extracted into methylene chloride and dried over magnesium sulfate. Evaporation of the solution under reduced pressure gave an oily residue.

The oily free base was dissolved in absolute ethanol and acidified to pH ~2–3 by dropwise addition of concentrated hydrochloric acid. Upon cooling, a white solid precipitated, which was filtered and washed with cold absolute ethanol. Drying afforded 7.59 g (74% yield) of the hydrochloride salt, mp 156–159°. Recrystallization from absolute ethanol–ether gave analytically pure material, mp 157.5–160°; IR (KBr): 1720 (C=O) cm^{-1}.

[1] No. 1, Carworth Farms.

[2] Melting points were determined on a Thomas-Hoover apparatus and are uncorrected. IR spectra were taken on a Perkin-Elmer 700 spectrophotometer as either liquid films or as potassium bromide pellets. Elemental analyses were performed by Dr. Kurt Eder, Geneva, Switzerland.

Evaluation of ^{99m}Tc-Labeled Iminodiacetic Acid Derivatives of Substituted 2-Aminopyrroles as Hepatobiliary Imaging Agents I

CARL M. DeJULIIS, BERNARD W. GRAHAM ˣ, RONALD J. MATTSON, and J. WALTER SOWELL, Sr.

Received November 5, 1979, from the *College of Pharmacy, University of South Carolina, Columbia, SC 29208.* Accepted for publication January 14, 1980.

Abstract □ *N*-(3-Cyano-4,5-dimethyl-2-pyrrylcarbamoylmethyl)iminodiacetic acid (II*a*) and *N*-(3-cyano-4-methyl-5-benzyl-2-pyrrylcarbamoylmethyl)iminodiacetic acid (II*b*) were synthesized, labeled with technetium 99*m*, and compared with ^{99m}Tc-labeled *p*-isopropylacetanilidoiminodiacetic acid (I) for hepatobiliary activity in rats. All three compounds showed similar clearance of radioactivity from the blood. Comparison of the amount of radioactivity in various organs 1 hr after injection showed no significant difference between I and II*b*. Compound II*a* showed significantly less radioactivity in the GI tract and a higher amount in the kidneys and bladder.

Keyphrases □ Iminodiacetic acid—^{99m}Tc-labeled, derivatives of 2-aminopyrroles, evaluation as hepatobiliary imaging agents, rats □ Lidocaine, 2-aminopyrrole analogs—^{99m}Tc-labeled iminodiacetic acid derivatives, evaluation as hepatobiliary imaging agents, rats □ Radiopharmaceuticals—^{99m}Tc-labeled iminodiacetic acid derivatives of 2-aminopyrroles, evaluation as hepatobiliary imaging agents, rats

Efforts have been made in recent years to formulate ^{99m}Tc-labeled radiopharmaceuticals for use in hepatobiliary scintigraphic imaging. Many lidocaine analogs with an iminodiacetic acid functional group capable of forming a stable complex with technetium 99*m* have been evaluated (1). Most lidocaine derivatives were synthesized by altering the lipophilic substituents on the benzene ring. One compound, *p*-isopropylacetanilidoiminodiacetic acid (I), has shown desirable characteristics and now is available commercially.

Johnson *et al.* (2) recently synthesized a series of 2-diethylaminoacetamido-3-cyano-4-methyl-5-substituted pyrrole analogs of lidocaine. These compounds compared favorably with lidocaine in local anesthetic and antiarrhythmic activities. The iminodiacetic acid derivatives of the methyl- (II*a*) and benzyl- (II*b*) substituted compounds were prepared. These two compounds were labeled with technetium 99*m* and compared with ^{99m}Tc-labeled I for hepatobiliary activity in rats.

EXPERIMENTAL

Chemistry[1]—*N-(3-Cyano-4,5-dimethyl-2-pyrrylcarbamoylmethyl)-iminodiacetic Acid (II*a*)*—A modified procedure of Callery *et al.* (3) was used. A mixture of 2-chloroacetamido-3-cyano-4,5-dimethylpyrrole (5.72 g, 0.027 mole) (2), disodium iminodiacetic acid monohydrate (5.44 g, 0.027 mole), and sodium hydroxide (1.10 g, 0.027 mole) in 100 ml of methanol–water (3:1) was refluxed for 24 hr. The methanol was removed *in vacuo*, 100 ml of water was added to the residue, the suspension was filtered, and the pH of the filtrate was adjusted to 3 by the dropwise addition of concentrated hydrochloric acid. The precipitate was collected and air dried.

The crude product (6.2 g, 76.8% yield) was washed several times with boiling water to yield a brown powder (homogeneous on TLC in methanol, R_f 0.55), mp 203–204.5° dec.; IR (KBr): 3610, 3330, 2210, 1675, 1640, 1430, 1400, 1220, and 725 cm^{-1}; NMR (dimethyl sulfoxide-d_6): δ 1.92 (s, 3H, CH_3 at C-4), 2.03 (s, 3H, CH_3 at C-5), 3.47 (s, 6H, CH_2), 10.75 (s, 1H, N_1H), and 10.3–12.8 (broad s, 3H, NHCO, COOH, and $^+$NH) ppm.

Anal.—Calc. for $C_{13}H_{16}N_4O_5$: C, 50.64; H, 5.23; N, 18.17. Found: C, 50.53; H, 5.23; N, 18.16.

*N-(3-Cyano-4-methyl-5-benzyl -2- pyrrylcarbamoylmethyl)iminodiacetic Acid (II*b*)*—A mixture of 2-chloroacetamido-3-cyano-4-methyl-5-benzylpyrrole (7.77 g, 0.027 mole) (2), disodium iminodiacetic acid monohydrate (5.44 g, 0.027 mole), and sodium hydroxide (1.10 g, 0.027 mole) was condensed according to the procedure described for II*a*. A brown powder was obtained (6.5 g, 62.6% yield) (homogeneous on TLC in methanol, R_f 0.51), mp 190–192° dec.; IR (KBr): 3400, 3330, 2210, 1675, 1620, 1250, 1215, 950, and 710 cm^{-1}; NMR (dimethyl sulfoxide-d_6): δ 1.96 (s, 3H, CH_3 at C-4), 3.79 (s, 2H, CH_2 at C-5), 4.2 (broad s, 6H, CH_2), 7.07 (s, 5H, C_6H_5), 11.25 (broad s, 3H, NHCO, COOH, and $^+$NH), and 11.5 (broad s, 1H, N_1H) ppm.

Anal.—Calc. for $C_{19}H_{20}N_4O_5$: C, 59.37; H, 5.24; N, 14.58. Found: C, 59.23; H, 5.26; N, 14.53.

[1] IR spectra were determined on a Beckman Acculab 4 spectrophotometer using the potassium bromide technique. NMR spectra were determined on a Hitachi Perkin-Elmer R24 high-resolution spectrometer with tetramethylsilane as the internal reference. Melting points were obtained using a Thomas-Hoover capillary apparatus and are uncorrected. TLC was performed using Eastman type 6060 chromatogram sheets (silica gel), and the sheets were developed in an iodine chamber. Carbon, hydrogen, and nitrogen values were obtained from analyses performed by Atlantic Microlabs., Atlanta, Ga.

Table I—Parameters for the Blood Elimination Equation of Technetium 99*m* in Rats following Intravenous Injection of ^{99m}Tc-Labeled I, II*a*, and II*b*[a]

Parameter	I	II*a*	II*b*
A	0.76 (0.05)	0.73 (0.04)	0.81 (0.03)
α	0.40 (0.06)	0.52 (0.04)	0.69 (0.05)
B	0.24 (0.03)	0.27 (0.02)	0.19 (0.01)
β	0.030 (0.005)	0.023 (0.003)	0.027 (0.002)
R_2	91.8	98.2	97.8

[a] Standard errors are given in parentheses.

Labeling with Technetium 99*m*—Technetium 99*m* labeling of I was achieved by adding 7 mCi (1.0 ml) of sodium [^{99m}Tc]pertechnetate (III) eluate from a molybdenum 99–technetium 99*m* generator[2] to a vial containing a lyophilized preparation of 20 mg of I and 0.2 mg of stannous chloride[3].

Preparation of ^{99m}Tc-labeled II*a* and II*b* was accomplished by stannous chloride reduction of III in aqueous solution. Ten milligrams of pure compound was dissolved in 0.3 ml of 0.1 *N* NaOH. This solution was back-titrated with 0.05 *N* HCl to pH 7. Seven millicuries of III in 0.2 ml was added, and the resulting solution was purged with nitrogen for 5 min. After purging, 0.1 ml of freshly prepared stannous chloride (1 mg/ml in 0.05 *N* HCl) was added, and the mixture was kept at room temperature for 20 min. The final solution then was passed through a Millipore filter into a sterile evacuated vial.

The radiochemical purity of the ^{99m}Tc-labeled I was determined using instant TLC[4] with a chloroform–acetone (70:30) solvent system. The radiochemical purity of ^{99m}Tc-labeled II*a* and II*b* was determined using instant TLC with a methyl ethyl ketone solvent system. Examination of the chromatographic strips revealed the bound fraction to be 93% or greater for all of the radiopharmaceuticals.

***In Vivo* Studies**—Fasting, nonhydrated, male Sprague–Dawley[5] rats, 175–240 g, were used. The left jugular vein was exposed and cannulated for each animal after anesthesia was achieved with pentobarbital sodium (30 mg/kg). The animal then was positioned over a rectilinear scanner[6] modified to record the counts arising from the cardiac pool. Following the injection of 0.25 mCi of the ^{99m}Tc-labeled compound into the cannula, sequential counts were obtained for the duration of the study. These counts were used to model the disappearance of the radioactivity from the blood.

Each animal was killed 1 hr after injection of the radiopharmaceutical by overanesthesia with ether. Selected organs were removed from the animal and assayed for radioactivity. The results are reported as the percentage of the total injected radioactivity.

RESULTS

The disappearance of the radioactivity from the blood is described by a two-compartment open model. The computer-fitted equation[7] used to describe the data is:

$$C_B = A \exp(-\alpha t) + B \exp(-\beta t) \qquad \text{(Eq. 1)}$$

where C_B refers to the fraction of the dose retained in the blood (biological) and t is time (minutes). The parameters for Eq. 1 and the correlation coefficient (R^2) for each parameter are listed in Table I. Examination of these data reveals that there was no significant difference among the drugs for the β-phase of the elimination equation; the half-life for the β-phase ranged from 20 to 30 min.

Table II—Percent of Administered Radioactivity at 1 hr after Intravenous Injection of ^{99m}Tc-Labeled I, II*a*, and II*b* in Rat Organs[a]

Rat Organ	I	II*a*	II*b*
GI tract	78.7 (3.3)	38.0 (2.4)	81.5 (2.4)
Liver	2.6 (0.4)	8.0 (0.2)	6.7 (0.9)
Spleen	0.09 (0.03)	0.07 (0.05)	0.15 (0.08)
Kidneys	2.5 (0.2)	11.1 (3.4)	2.3 (0.3)
Lungs	0.17 (0.05)	0.30 (0.18)	0.20 (0.03)
Heart	0.02 (0.01)	0.02 (0.01)	0.07 (0.02)
Carcass	16.2 (3.0)	44.0 (2.8)	9.9 (0.9)

[a] Standard errors are given in parentheses.

Table II shows the distribution of technetium 99*m* in selected organs and tissues of the rat 1 hr after intravenous injection. The data are expressed as the percent of the injected dose and represent the average of three rats for each compound. The carcass values represent the remainder after the removal of the other organs and include the bladder, which accounted for much of the activity.

The organ data following injection of I or II*b* are indistinguishable except for the liver. Excretion into the GI tract accounted for almost 80% of the activity for both compounds. The kidneys retained about 2% of the injected dose, and the carcass contained about 10%. The content of technetium 99*m* in the liver at necropsy was significantly higher for the benzyl compound as compared to I.

The methyl derivative (II*a*) showed significantly less activity in the GI tract than either of the other compounds. Higher amounts of the injected activity were noted in the kidneys and remaining carcass.

Antiproliferative Effects of Inhibitors of Polyamine Synthesis in Tumors of Neural Origin

SHARON K. CHAPMAN ˣ and SUSAN K. GLANT

Received October 22, 1979, from the *Department of Pharmacology and Therapeutics, College of Medicine, University of Florida, Gainesville, FL 32610.* Accepted for publication January 30, 1980.

Abstract □ The antiproliferative properties of inhibitors of polyamine synthesis were evaluated in cultured neuroblastoma and glioma cells. The diamines (1,3-propanediamine, 1,5-pentanediamine, and 1,6-hexanediamine) dramatically decreased neuroblastoma replication and inhibited the rate-limiting enzyme, ornithine decarboxylase. Glioma cells were less sensitive to the diamines in spite of significant drug-induced decreases in enzyme activity. The fact that ornithine decarboxylase was inhibited in both cell lines with different effects on proliferation suggests that the activity of other enzymes in polyamine biosynthesis may be altered selectively by these inhibitors.

Keyphrases □ Polyamines—inhibition of synthesis, effects of inhibitors on tumor cell growth, *in vitro* testing □ Ornithine carboxylase activity—inhibition of polyamine synthesis, effects of inhibitors on tumor cell growth, *in vitro* testing □ Antitumor activity—inhibition of polyamine synthesis, *in vitro* testing of ornithine carboxylase activity

Many chemotherapeutic agents that are effective in tumor treatment have had limited success in the treatment of malignant gliomas and neuroblastomas (1–4). Results have not been satisfactory due to drug toxicity, low tumor remission rates, and short durations of drug effectiveness.

Data have been obtained showing the presence of high levels of ornithine decarboxylase activity in tumor cells of neural origin (5–8). This enzyme catalyzes the rate-limiting reaction in the synthesis of putrescine, spermidine, and spermine (9); its basal activity is the lowest of the enzymes engaged in the synthesis of these polyamines (9, 10).

BACKGROUND

Several studies suggested that polyamine synthesis may be obligatory for tumor proliferation. Heby *et al.* (8) found a positive correlation between the growth rate of a rat brain tumor cell line and ornithine decarboxylase activity; the pattern of fluctuation in spermidine content correlated in a likewise manner (11). In cell-free systems, polyamines influence nearly every aspect of the formation and turnover of DNA, RNA, and protein (12–14). The relationship of polyamine synthesis to rapid growth has been reviewed extensively (10, 15–18).

Since ornithine decarboxylase activity is associated with rapid growth (16), ornithine decarboxylase inhibitors may find application as antiproliferative agents. Results obtained in these laboratories show that the cytolytic effects of bromoacetylcholine and bromoacetate in neuroblastoma are associated with decreased ornithine decarboxylase activity (5). However, recent studies suggested that a similar relationship may not be true in gliomas (20). Bromoacetylcholine and bromoacetate are potent antiproliferative agents in cultured cells of both experimental tumors (19), but ornithine decarboxylase is not inhibited in glioma cells by these agents (20). Although neuroblastoma and glioma have a common embryonic origin, these results suggest that differences may exist in the control mechanisms of polyamine synthesis.

Neuroblastoma cells are sensitive to numerous analogs of the substrate, ornithine, and of the product, putrescine (20). In this cell line, a correlation exists between the antiproliferative effects of these agents and their ability to decrease the activity of ornithine decarboxylase (20). To define further the relationship between polyamine deficiency and decreases in neuronal tumor growth rates, the effects of selective inhibitors of ornithine decarboxylase in cultured neuroblastoma and glioma cells were compared.

EXPERIMENTAL

Tumor Maintenance—Mouse neuroblastoma cells[1] were grown as described previously (5). Rat glioma cells[2] were cultivated in Ham's F-10 nutrient medium[3] supplemented with 50 units of penicillin/ml, 50 mEq of streptomycin/ml, 0.125 μg of amphotericin B/ml, 2% fetal calf serum, and 18% horse serum. Incubation was maintained at 37° with 10% CO_2–90% air and 100% humidity.

Drug Treatment—1,3-Propanediamine dihydrochloride[4], 1,6-hexanediamine[4], 1,5-pentanediamine[4], and α-methylornithine[5] were dissolved in glass-distilled water, neutralized, filter sterilized, and added in 50-μl quantities to 10 ml of the medium at time zero. For assays of ornithine decarboxylase activity, 1×10^6 cells were seeded in 100-mm tissue culture dishes; for cell counting experiments, 5×10^4 cells were seeded in 35-mm tissue culture dishes. Cells were grown for 24 hr after seeding, at which time drugs and fresh medium were added (time zero). Tumor growth was measured by counting the cells in a hemocytometer; viability was determined by trypan blue exclusion.

Ornithine Decarboxylase Assay—Enzyme assays were performed as described previously (5). After the growth medium was removed from the cells, the cells were washed with ice-cold phosphate–saline buffer (0.8% NaCl, 0.02% KCl, 0.115% Na_2HPO_4, and 0.05% KH_2PO_4 at pH 7.2) and suspended in 1.0 ml of assay buffer (0.05 *M* sodium phosphate–potassium phosphate at pH 7.2 containing 1 m*M* 1,4-dithiothreitol, 0.25 m*M* ethylenediaminetetraacetic acid, and 3 μ*M* pyridoxal 5-phosphate). Cells then were scraped off the plate with a rubber policeman and homogenized (20 strokes) with a glass homogenizer. After centrifugation at 4500×*g*, 0.2-ml portions of the supernatant fractions were incubated for 15 min in 15 × 85-mm centrifuge tubes equipped with rubber stoppers that supported polyethylene center wells[6]. Supernatant fractions that were heated at 65° for 10 min before incubation served as controls.

The reaction was initiated when 0.05 ml of 9.5 m*M* [1-^{14}C]L-ornithine[7] (10 Ci/mole) was added. After incubation at 37° for 30 min, 0.2 ml of benzetronium[8] hydroxide was injected into each center well and the reaction was continued for 30 min. To stop the reaction, 1 *M* citric acid (0.3 ml) was injected into the incubation mixture. To release the dissolved carbon dioxide, the tubes were agitated for another 30 min. The center wells then were removed from the tubes and placed into scintillation vials, and the radioactivity was determined with a scintillation counter. Protein was determined with an assay kit[9].

RESULTS

The antiproliferative effects of the ornithine decarboxylase inhibitors are shown in Fig. 1. Neuroblastoma cell growth appeared to be more sensitive than glioma cell growth to all of the agents over the period studied. The diamine inhibitors (1,3-propanediamine, 1,5-pentanediamine, and 1,6-hexanediamine) markedly inhibited neuroblastoma replication; 1,5-pentanediamine and 1,3-propanediamine were effective as early as 24 hr after their addition. These cells were less sensitive to the competitive inhibitor α-methylornithine; a delay of one generation was required before a decrease in cell proliferation was observed using this agent.

In contrast to the neuroblastoma results, normal growth was observed in cultured glioma cells over a 48-hr period in the presence of the inhibitors. After a lag of at least two generations, a notable decrease in tumor

growth was apparent. At this time, α-methylornithine appeared to be slightly more effective than the diamines.

In experiments in which ornithine decarboxylase activity was measured, the antiproliferative effects of the diamines in neuroblastoma correlated with the decrease in enzyme activity (Fig. 2). Similarly, 1,3-propanediamine had no effect on glioma cell proliferation or on inhibition of ornithine decarboxylase activity. There were two exceptions to these parallel relationships:

1. Tumor growth was inhibited by α-methylornithine, but increases in enzyme activity were observed in both cell lines.
2. 1,5-Pentanediamine and 1,6-hexanediamine notably inhibited ornithine decarboxylase activity in glioma cells at a time when normal cell growth was observed.

DISCUSSION

An extensive amount of evidence has led to the concept that continuous polyamine synthesis is required to maintain maximum cell proliferation rates. An increase in ornithine decarboxylase activity is one of the earliest events to occur when cells are transformed from the resting to the growing state (5–7). It still is uncertain whether increases in polyamine synthesis are the cause or the consequence of rapid growth. However, a causal relationship between polyamine depletion and the inhibition of DNA synthesis has been suggested by results showing that exogenous ornithine or polyamines reversed the inhibition of DNA synthesis in tumor cells (21–24).

Most experimental efforts to deplete cellular polyamines have focused on the development of inhibitors of the rate-limiting enzyme, ornithine decarboxylase. Among these are competitive inhibitors such as α-methylornithine (22, 25, 26) and diamines such as 1,3-propanediamine, 1,5-pentanediamine, and 1,6-hexanediamine. The diamines have been shown to act by inducing the formation of macromolecular inhibitors of ornithine decarboxylase (27, 28) and by repressing the induction of the enzyme (28–32). The repression of enzyme synthesis has a relatively selective effect on ornithine decarboxylase; however, *S*-adenosylmethionine decarboxylase activity is inhibited slightly (33). A nonspecific inhibition of protein synthesis or a repression of other enzymes with short half-lives (*e.g.*, tyrosine aminotransferase) has not been demonstrated (33). The diamines are not inhibitory when added to cell-free assays (27–33).

In neuroblastoma, the diamines produced a dramatic decrease in both tumor growth and ornithine decarboxylase activity. In contrast, glioma cells continued to proliferate in the presence of the diamines. Differences in sensitivity probably are not due to drug accessibility since the enzyme was inhibited in both cell lines. These results may be explained by the interactions of the diamines with other enzymes in the polyamine biosynthetic pathway. Recent work with rat ventral prostate extracts (34) and Ehrlich ascites carcinoma cells (29) showed that diamines exert different inhibitory effects on the spermidine and spermine synthetases, regardless of their action on ornithine decarboxylase. Since a functional relationship between spermidine levels and growth rates has been confirmed in some cell lines (8, 11), these higher polyamines may be required for the expression of ornithine decarboxylase activity in proliferation (35).

In glioma cells, spermidine and spermine synthetases may be less sensitive to the diamine inhibitors and/or the half-life of endogenous spermidine may be quite long. In the latter case, the delay before the antiproliferative effects may correspond to the greater time required for spermidine depletion in this cell line. It also is possible that in glioma cells, these nonphysiological amines may be utilized to take over many of the metabolic functions of spermidine or spermine. The requirements for specific polyamines during rapid growth are being investigated.

In the present work, ornithine decarboxylase activity was increased in both neuroblastoma and glioma after treatment with α-methylornithine; competitive inhibition was observed only when the drug was added to cell-free assays (results not shown). This rise in the activity of the target enzyme in intact cells was reported for other cell lines (35) and may result either from a drug-induced increase in the apparent half-life of the enzyme (26, 36) or from a reversal of end-product inhibition of ornithine decarboxylase (24). Theoretically, an increased half-life could result from the ability of α-methylornithine to bind to the enzyme and protect it from degradation (37). However, in rat hepatoma cells, α-methylornithine increased the activities of ornithine decarboxylase as well as *S*-adenosylmethionine decarboxylase (24). This increase in an enzyme for which α-methylornithine is not a substrate is of concern. Reports that competitive ornithine decarboxylase inhibitors cause decreases in putrescine and spermidine levels (22) and that polyamines exert multiple negative feedback controls over both ornithine decarboxylase and *S*-adenosylmethionine decarboxylase (35) collectively favor the interpretation that increases in enzyme activity observed *in vivo* result from a reversal of end-product inhibition.

In summary, antiproliferative effects are achievable in tumors of neural origin using ornithine decarboxylase inhibitors. Some problems with this approach may be overcome by the design of more specific inhibitors of spermidine and spermine synthetases. The fact that ornithine decarboxylase was inhibited in both cell lines with vastly different effects on proliferation suggests that neuroblastoma and glioma cells may provide interesting model systems for drug development.

Antineoplastic Evaluation of Pacific Basin Marine Algae

M. KASHIWAGI *x, J. S. MYNDERSE ‡, R. E. MOORE ‡, and T. R. NORTON *

Received October 18, 1979, from the **Department of Pharmacology, University of Hawaii, Leahi Hospital, Honolulu, HI 96816*, and the ‡*Department of Chemistry, University of Hawaii, Honolulu, HI 96822.* Accepted for publication January 24, 1980.

Abstract □ Extracts of 107 marine alga specimens from Pacific islands were tested for P-388 lymphocytic leukemia and Ehrlich ascites tumor in mice. Several specimens showed high antitumor activity in both systems, with some featuring a notable lack of toxicity.

Keyphrases □ Antineoplastic activity—marine algae from Pacific islands, testing against P-388 lymphocytic leukemia and Ehrlich ascites tumor □ Marine algae—antineoplastic evaluation against P-388 lymphocytic leukemia and Ehrlich ascites tumor □ Antitumor activity—marine algae from Pacific islands, testing against P-388 lymphocytic leukemia and Ehrlich ascites tumor

There have been numerous reports of antitumor substances obtained from terrestrial plants, but no information on antitumor agents from marine plants was published prior to 1977 when Mynderse *et al.* (1) reported that chloroform extracts of some marine blue-green algae showed activity against P-388 lymphocytic leukemia in mice. A P-388 active compound was isolated from one alga, *Lyngbya majuscula* Gomont, and shown to be debromoaplysiatoxin. This finding prompted screening of other marine algae from the Pacific basin for activity against P-388 lymphocytic leukemia and Ehrlich ascites tumor in mice.

The 107 alga specimens were collected from Palau (Western Caroline Islands), Fanning Island (Line Islands), Enewetak Atoll (Marshall Islands), Johnston Island, and the Hawaiian Islands. Voucher samples were retained for most specimens, and the collection site of each sample was recorded carefully.

This paper is a preliminary report of the antitumor activity of crude extracts and some partially purified fractions from these algae.

EXPERIMENTAL

Most algal samples were refrigerated or frozen soon after collection. When refrigerator or freezer facilities were not available, the samples were air dried. The frozen samples were freed from extraneous matter and freeze dried before extraction. The dried samples were powdered in a mortar or blender[1].

There were two general extraction procedures. In Method I, the dried alga was extracted initially with a succession of organic solvents of increasing polarity followed by a final extraction with water. In Method II, the sample was subjected to extraction with 30% ethanol followed by extractions (liquid–liquid) with a succession of organic solvents of the aqueous concentrate.

In Method I, the sample was homogenized in a blender[1] for 5 min with a volume of organic solvent weighing five to 10 times the sample weight. The mixture then was allowed to stand for 24 hr or was stirred for 4–5 hr. The resultant homogenate was centrifuged, and the supernate was

Abstract □ Extracts of 107 marine alga specimens from Pacific islands were tested for P-388 lymphocytic leukemia and Ehrlich ascites tumor in mice. Several specimens showed high antitumor activity in both systems, with some featuring a notable lack of toxicity.

Keyphrases □ Antineoplastic activity—marine algae from Pacific islands, testing against P-388 lymphocytic leukemia and Ehrlich ascites tumor □ Marine algae—antineoplastic evaluation against P-388 lymphocytic leukemia and Ehrlich ascites tumor □ Antitumor activity—marine algae from Pacific islands, testing against P-388 lymphocytic leukemia and Ehrlich ascites tumor

There have been numerous reports of antitumor substances obtained from terrestrial plants, but no information on antitumor agents from marine plants was published prior to 1977 when Mynderse *et al.* (1) reported that chloroform extracts of some marine blue-green algae showed activity against P-388 lymphocytic leukemia in mice. A P-388 active compound was isolated from one alga, *Lyngbya majuscula* Gomont, and shown to be debromoaplysiatoxin. This finding prompted screening of other marine algae from the Pacific basin for activity against P-388 lymphocytic leukemia and Ehrlich ascites tumor in mice.

The 107 alga specimens were collected from Palau (Western Caroline Islands), Fanning Island (Line Islands), Enewetak Atoll (Marshall Islands), Johnston Island, and the Hawaiian Islands. Voucher samples were retained for most specimens, and the collection site of each sample was recorded carefully.

This paper is a preliminary report of the antitumor activity of crude extracts and some partially purified fractions from these algae.

EXPERIMENTAL

Most algal samples were refrigerated or frozen soon after collection. When refrigerator or freezer facilities were not available, the samples were air dried. The frozen samples were freed from extraneous matter and freeze dried before extraction. The dried samples were powdered in a mortar or blender[1].

There were two general extraction procedures. In Method I, the dried alga was extracted initially with a succession of organic solvents of increasing polarity followed by a final extraction with water. In Method II, the sample was subjected to extraction with 30% ethanol followed by extractions (liquid–liquid) with a succession of organic solvents of the aqueous concentrate.

In Method I, the sample was homogenized in a blender[1] for 5 min with a volume of organic solvent weighing five to 10 times the sample weight. The mixture then was allowed to stand for 24 hr or was stirred for 4–5 hr. The resultant homogenate was centrifuged, and the supernate was

evaporated *in vacuo* to yield the crude lipophilic extract. The marc was dried and then soaked in a volume of water weighing five to 10 times the marc weight for 4–5 hr with stirring and for an additional 24 hr or more without stirring. After centrifugation, the supernate was freeze dried to give the water-soluble extract. For initial fractionation, the water-soluble extract was subjected to gel filtration[2] with 0.1 *M* ammonium bicarbonate as the eluent. This procedure was followed by cation-exchange chromatography[3] with a gradient elution of the active compound with 0.03–3.0 *M* ammonium acetate. All column separations were monitored by UV spectroscopy at 280 nm[4].

In Method II, a sample was extracted initially with 30% ethanol in the same manner as described for Method I for the extraction of water-soluble constituents from the marc. After the ethanol was eliminated from the supernate by flash evaporation, this crude extract was extracted further with either *n*-butanol or chloroform to remove lipophilic constituents. The water-soluble fraction then was purified by procedures similar to those described for Method I for the water-soluble crude extract.

The isolation of the purified lipophilic antitumor agents will be reported later.

RESULTS AND DISCUSSION

The results of the screening tests are listed in Tables I and II. Table I shows that eight marine algal extracts had T/C (test/control) values of ≥170% in the P-388 lymphocytic leukemia test. Of these extracts, six species showed T/C activity of >200%. In the Ehrlich ascites tumor system, nine species of algae showed a 100% survival rate at 30 days with no ascitic condition. Several of the groups of mice that survived for 30 days with a nonascitic condition were kept alive for an additional 30 days with no tumor recurrence at the end of the 60-day period.

[2] Sephadex G-25, Pharmacia Fine Chemicals, Piscataway, NJ 08854.
[3] CM Sephadex C-25, Pharmacia Fine Chemicals, Piscataway, NJ 08854.
[4] Model UA-5 absorbance monitor, Instrument Specialties Co., Lincoln, NE 68505.

Some of the algal extracts active against both P-388 leukemia and Ehrlich ascites tumor were subjected to preliminary isolation work (Table I). The finding that some of these crude extracts as well as partially purified fractions showed excellent activity at relatively low dosages with no evidence of toxicity is most encouraging.

Table II lists the marine algae that showed a T/C activity of <125% against P-388 lymphocytic leukemia and <20% survivors at 30 days in the Ehrlich ascites tumor system.

Ocular Absorption of Propranolol in Rabbits

Keyphrases □ Propranolol—ocular absorption in rabbits □ β-Adrenergic blocking agents—propranolol, ocular absorption in rabbits □ Absorption, ocular—propranolol in rabbits

To the Editor:

The topical application of β-adrenergic blocking agents to the eye has been found to be effective in the control of glaucoma (1). However, the precise rate and extent of disposition of these compounds in the various ocular tissues have not been fully established. The purpose of this report is to compare and contrast the ocular absorption of a model β-blocking agent, propranolol, to what is known about the widely used miotic pilocarpine.

Male New Zealand albino rabbits, 3.0–3.6 kg, were minimally restrained in wooden boxes; topical and local anesthetics were not used. A 50-μl dose of 0.5% propranolol hydrochloride in isotonic buffer (pH 7.4) was instilled onto the cornea and allowed to distribute normally within the cul-de-sac. All tissue sampling procedures were performed as outlined previously (2, 3). The tissue samples collected were the whole intact cornea, aqueous humor, iris, and lens. The amount and concentration of propranolol in these tissues were determined spectrophotofluorometrically (4). The minimum detection limit for the drug was ~5 ng.

Figure 1 shows the propranolol concentration in ocular tissues as a function of time. The data indicate that propranolol reached a peak concentration in the aqueous humor at ~30 min. This result corresponds well with previous data for pilocarpine, which has a peak time of 20–30 min. This peak time was anticipated in the current studies since it was shown previously that the apparent ocular pharmacokinetic parameters are largely determined by the parallel first-order loss process in the precorneal area, so that most drugs show similar peak times in the aqueous humor (2, 5). The elimination characteristics of propranolol also are very similar to pilocarpine and suggest that both drugs are lost from the eye *via* the same mechanism, namely, aqueous humor turnover. The rate constant associated with this process for pilocarpine in rabbits is 0.017 min^{-1} (2), and this value is nearly identical to the elimination rate of propranolol from the aqueous humor in the present studies (0.019 min^{-1}).

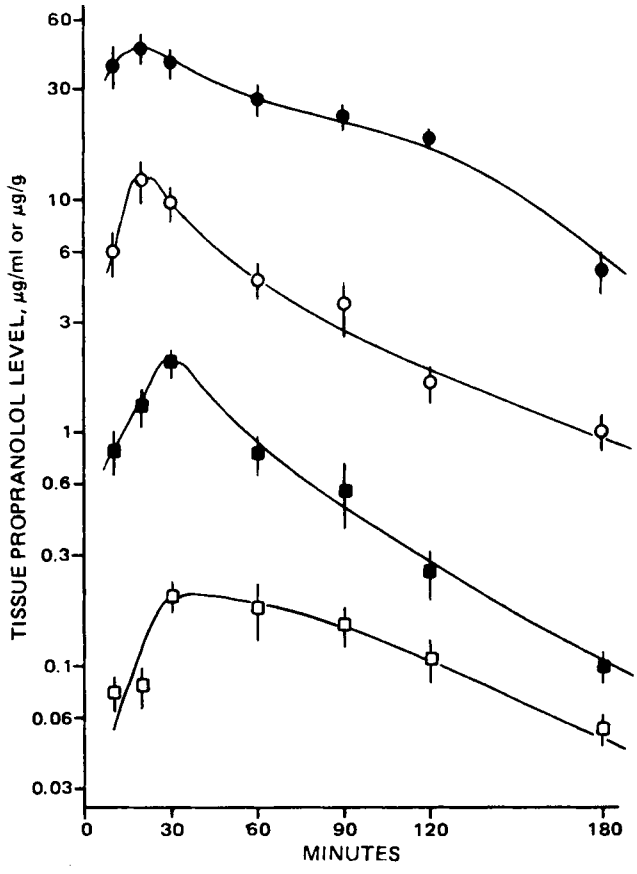

Figure 1—*Concentration of propranolol in various ocular tissues after topical application of propranolol solution. Key:* ●, *cornea;* ○, *iris;* ■, *aqueous humor; and* □, *lens.*

Concentration–time profiles such as those depicted in Fig. 1 can be somewhat misleading in ocular studies of this type which deal with tissues of greatly different distribution volumes. For this reason, it often is useful to consider the amount of drug represented by the peak drug concentration for each tissue. These data are presented in Table I. The rank order for tissue concentration was cornea > iris > aqueous humor > lens, whereas the rank order for tissue amounts was cornea > aqueous humor > iris > lens. The change in rank order for the iris and aqueous humor was due to the 12-fold difference in the wet weights of these

Table I—Amount of Propranolol Represented by the Peak Concentration in Various Ocular Tissues [a]

Tissue	Peak Concentration, μg/g or μg/ml	Amount of Drug Present in Tissue, μg
Cornea	45.90	3.21
Aqueous humor	2.02	0.61
Iris	12.32	0.31
Lens	0.21	0.06

[a] The weights of the tissues are given in the text.

tissues. The approximate wet weight averages for the cornea, iris, aqueous humor, and lens in the current studies were 70, 25, 300, and 300 mg, respectively.

The relative disposition of propranolol in the various ocular tissues also was different than that of pilocarpine. There was a sixfold difference in peak concentration between the iris and the aqueous humor for propranolol, whereas the two tissues were virtually identical with pilocarpine (3). Furthermore, the penetration into the lens relative to other ocular tissues was greater for propranolol than for pilocarpine. Propranolol is known to act as a local anesthetic and as such may influence membrane permeability. It is unclear whether the differences in tissue distribution for propranolol and pilocarpine can be ascribed wholly, or in part, to this effect.

Comparative *In Vitro* and *In Vivo* Antifungal Activity of Tolnaftate and Various Undecylenates

Keyphrases □ Antifungal activity—tolnaftate and various undecylenates, comparison *in vitro* and *in vivo* □ Tolnaftate—antifungal activity *in vitro* and *in vivo*, comparison with various undecylenates □ Undecylenates—antifungal activity *in vitro* and *in vivo*, comparison with tolnaftate

To the Editor:

Amsel *et al.* (1) compared the *in vitro* antifungal activity of undecylenic acid and tolnaftate and drew several conclusions. Among these conclusions were: (*a*) the undecylenate product killed the test organisms more rapidly than the tolnaftate-containing product; (*b*) undecylenates possibly are more effective in *in vitro* killing time than tolnaftate alone, and this finding probably applies to the commercial powders; and (*c*) although the concentrations of active ingredients varied in the commercial products tested, the undecylenates probably are more effective (as determined by killing time) than tolnaftate.

	3 hr	39	23	17
	6 hr	39	25	20

[a] Using 6-mm disk. [b] Values between tolnaftate and undecylenates were statistically significant ($p < 0.0001$) at each time point. [c] Average of two disks. [d] These areas showed decreased mycelial growth but were not completely free of growth. [e] Too near edge of plate.

These conclusions were based on the methods, materials, and results of experiments presented in their paper. We have several concerns regarding their unusual methodology, and we therefore question their results and conclusions. We also wish to present *in vitro* and *in vivo* data using standard methods, which show, in contrast to the Amsel *et al.* (1) report, that tolnaftate is superior to the undecylenates. All data were submitted for statistical analysis using an appropriate analysis of variance, Duncan's multiple statistic test, and Fisher's exact test (2).

Our criticisms of the Amsel *et al.* (1) report are as follows:

Table I—Amount of Propranolol Represented by the Peak Concentration in Various Ocular Tissues [a]

Tissue	Peak Concentration, μg/g or μg/ml	Amount of Drug Present in Tissue, μg
Cornea	45.90	3.21
Aqueous humor	2.02	0.61
Iris	12.32	0.31
Lens	0.21	0.06

[a] The weights of the tissues are given in the text.

tissues. The approximate wet weight averages for the cornea, iris, aqueous humor, and lens in the current studies were 70, 25, 300, and 300 mg, respectively.

The relative disposition of propranolol in the various ocular tissues also was different than that of pilocarpine. There was a sixfold difference in peak concentration between the iris and the aqueous humor for propranolol, whereas the two tissues were virtually identical with pilocarpine (3). Furthermore, the penetration into the lens relative to other ocular tissues was greater for propranolol than for pilocarpine. Propranolol is known to act as a local anesthetic and as such may influence membrane permeability. It is unclear whether the differences in tissue distribution for propranolol and pilocarpine can be ascribed wholly, or in part, to this effect.

Comparative *In Vitro* and *In Vivo* Antifungal Activity of Tolnaftate and Various Undecylenates

Keyphrases □ Antifungal activity—tolnaftate and various undecylenates, comparison *in vitro* and *in vivo* □ Tolnaftate—antifungal activity *in vitro* and *in vivo*, comparison with various undecylenates □ Undecylenates—antifungal activity *in vitro* and *in vivo*, comparison with tolnaftate

To the Editor:

Amsel *et al.* (1) compared the *in vitro* antifungal activity of undecylenic acid and tolnaftate and drew several conclusions. Among these conclusions were: (*a*) the undecylenate product killed the test organisms more rapidly than the tolnaftate-containing product; (*b*) undecylenates possibly are more effective in *in vitro* killing time than tolnaftate alone, and this finding probably applies to the commercial powders; and (*c*) although the concentrations of active ingredients varied in the commercial products tested, the undecylenates probably are more effective (as determined by killing time) than tolnaftate.

Commercial talc	7	0	29	19.1	7.9	4	16
						3	>17
Untreated	5	0	7	18.1	7.0	1	17
						4	>17

[a] Commercial powder A contains 1% tolnaftate; commercial powder C contains 10% calcium undecylenate. [b] Treatment twice daily for 10 days. [c] First day of culture was Day 2. [d] Statistically significant ($p < 0.002$). [e] Statistically significant until Day 15 ($p < 0.05$). [f] Not statistically different. [g] Statistically significant ($p < 0.05$). [h] Statistically significant ($p < 0.002$).

1. Standard procedures for determination of the minimum fungicidal concentration in broth or agar were not used. In addition, the minimum inhibitory concentration for the various preparations used was not given for the test organisms, and the killing time results showed tremendous variation (up to 50%). If this new method is more reproducible than standard ones, all replicates should be the same since death was used as the end-point.

2. Tolnaftate was used as a suspension even though it is readily soluble (polyethylene glycol 400 or acetone) and solutions give more reproducible results than suspensions. In addition, the use of commercial powder A[1] as an aqueous suspension clearly is a weakly active mode of application that was never intended.

3. Polysorbate 20 is a surfactant used for emulsification, dispersion, and solubilization of lipids. Therefore, use of this substance makes the undecylenates more bioavailable since they are fatty acids, but it certainly is not useful for tolnaftate.

4. No evidence is presented that the complex rinsing solution and the washing procedure (only three washes) used for 2% undecylenic acid and 1% tolnaftate (where no differences were seen between the two drugs) were sufficient to wash out both the 20% zinc undecylenate and 2% undecylenic acid in commercial powder D[2] (in contrast to the 1% tolnaftate in commercial powder A) to bring the concentration below the minimum inhibitory concentration.

5. The mycelium remained in the first wash for 1 hr, thereby increasing contact time with the drugs. This situation gives an advantage to the less potent drug.

6. In their Table IV, where clinical isolates were used, differences were significant only one of 15 times. In Table II, seven of 15 contacts were significant. Nevertheless, the authors claimed that the results again were essentially equivalent. Furthermore, Amsel *et al.* made their conclusion on a "global basis" based on six organisms tested *in vitro*.

We compared commercial solution D (Lot 18048, May 1980) with commercial solution T[3] (Lot 7AKU2, April 1982) in a conventional agar diffusion study (3). In our studies, 5 μl of each solution was pipetted onto disks that had been placed on 23 × 23-cm plastic plates containing Sabouraud dextrose agar seeded with *Trichophyton rubrum, T. mentagrophytes,* and *Epidermophyton floccosum* (clinical isolates). Fungi were grown in Sabouraud dextrose broth on a rotary shaker at 28°. After 72 hr, the mycelia were ground into a homogeneous suspension[4]. Four milliliters of the suspension was added to 200 ml of agar and shaken, and the agar was poured and allowed to harden. Disks were removed after 1, 5, 15, and 30 min and 1 and 4 hr, and the plates were incubated at 28°. Activity (measured as zone sizes of inhibition in millimeters) against *T. mentagrophytes* was measured after 72 hr; against *T. rubrum* and *E. floccosum,* it was measured after 6 days. With all three organisms and at all times, the T solution gave much larger zones of inhibition than the D solution, even after only 1 min of contact (Table I). These differences all were highly significant.

We also compared tolnaftate (USP M.I. No. P-03411) to undecylenic acid (M.I. No. P-07413) and zinc undecylenate[5] (Lot 47E343) in minimum inhibitory concentration and agar diffusion test systems against *Microsporum canis, M. gypseum, T. rubrum, T. mentagrophytes, E. floccosum,* and *Aspergillus niger* (clinical isolates). Methods for the agar diffusion tests were as already

[1] Aftate (contains 1% tolnaftate), Plough Corp., Memphis, Tenn.
[2] Desenex (contains 10% undecylenic acid), Pharmacraft, Pennwalt Corp., Rochester, N.Y.
[3] Tinactin (contains 1% tolnaftate), Schering Corp., Kenilworth, N.J.
[4] A Brinkmann Polytron was used.
[5] City Chemical Corp., New York, N.Y.

described with several exceptions. The compounds were solubilized or suspended in acetone (0.1%). Paper disks were dipped into the acetone solution or suspensions, allowed to dry, and then placed on the agar. Disks were removed after 1, 5, and 30 min and 1, 3, and 6 hr, and zone sizes were measured after incubation for 96 hr. As in the previous experiment, tolnaftate gave larger zones of inhibition than undecylenic acid and zinc undecylenate, even after only 1 min of contact (Table II). These differences again were highly significant, with the greatest differences occurring at the early time points.

The minimum inhibitory concentration was obtained in the conventional manner (2) using Sabouraud dextrose broth (Table III). Tolnaftate again was far more active than the two undecylenates in this second model of *in vitro* testing. The minimum inhibitory concentration values for tolnaftate all were <1.0 μg/ml, while the values for the undecylenates ranged from 7.5 to >10 μg/ml after 72 hr of incubation. These differences again were highly significant.

Since our data indicated *in vitro* superiority for tolnaftate over undecylenates and since efficacy *in vivo* certainly is more meaningful, it was of interest to determine if this superiority would be seen with formulated material. Results of a double-blind study comparing commercial powder A (Lot 7A503), commercial powder C[6] (Lot 14765), and commercial talc (USP M.I. No. N-03294) against a topical *T. mentagrophytes* infection in guinea pigs are shown in Table IV. Treatment was topical (powder liberally sprinkled on infected area) twice daily for 10 days. Hair and scales were removed from the infection site and plated onto Mycosel agar every other day. In addition, animals were scored for lesion appearance every day.

Procedures for establishing, culturing, and scoring the infection were described previously (4). All animals treated with commercial powder A were negative (as measured by lack of growth of the infecting organisms) throughout the treatment period (first culture taken after 2 days of treatment), and all remained negative up to 7 days posttreatment, at which time the experiment was terminated. These results were highly significant when compared with commercial powder C. Culture results seen with commercial powder C were similar to those seen with the talc controls. During treatment, all animals treated with commercial powder C remained positive; after treatment, 33% of the cultures obtained from animals treated with commercial powder C and 29% from animals treated with talc were negative. In both groups, no negative cultures were obtained until 15 days after treatment began. In addition, the average lesion scores both during and after treatment were lower with commercial powder A than with commercial powder C, and there was no statistical difference between commercial powder C and untreated controls.

Our results with this guinea pig model are similar to those reported by other investigators using similar procedures (5). In those experiments, 1% tolnaftate powder was compared to commercial powder D to determine the activity of both substances as prophylactic agents. The results showed that 1% tolnaftate powder was far more effective than commercial powder D.

[6] Cruex (contains 10% calcium undecylenate), Pharmacraft, Pennwalt Corp., Rochester, N.Y.

In the 15 years since the guinea pig model was described, the relationship between this model and clinical effectiveness has been demonstrated for many antifungal agents. Tolnaftate (4), clotrimazole (6), and miconazole (7) all were very active in the guinea pig model, and all are presently recommended for clinical use against dermatophytes (8).

Our *in vitro* and *in vivo* data obtained following conventional testing methodology clearly indicate that tolnaftate, commercial solution T, and commercial powder A are far more active than undecylenic acid, zinc undecylenate, commercial powder C, and commercial solution D.

Comparative *In Vitro* and *In Vivo* Antifungal Activity of Tolnaftate and Various Undecylenates: A Rebuttal

Keyphrases □ Antifungal activity—tolnaftate and various undecylenates, comparison *in vitro* and *in vivo* □ Tolnaftate—antifungal activity *in vitro* and *in vivo*, comparison with various undecylenates □ Undecylenates—antifungal activity *in vitro* and *in vivo*, comparison with tolnaftate

To the Editor:

When different groups of scientists perform studies using differing techniques, one may expect somewhat different results, as evidenced by the work of Amsel *et al.* (1) and Loebenberg *et al.* (2). A rebuttal to the Loebenberg *et al.* communication (2) is clearly in order. The stress of Loebenberg *et al.* on our "unusual" methodology seems to hint that the use of a new or nonstandard method may be unacceptable. Our method (1) was reproducible by different investigators, rapid, and equivalent to older "standard" methods.

The following comments are presented in reply to the criticisms of Loebenberg *et al.* (2).

1. Their comment that minimum fungicidal concen-

Comparative *In Vitro* and *In Vivo* Antifungal Activity of Tolnaftate and Various Undecylenates: A Rebuttal

Keyphrases □ Antifungal activity—tolnaftate and various undecylenates, comparison *in vitro* and *in vivo* □ Tolnaftate—antifungal activity *in vitro* and *in vivo*, comparison with various undecylenates □ Undecylenates—antifungal activity *in vitro* and *in vivo*, comparison with tolnaftate

To the Editor:

When different groups of scientists perform studies using differing techniques, one may expect somewhat different results, as evidenced by the work of Amsel *et al.* (1) and Loebenberg *et al.* (2). A rebuttal to the Loebenberg *et al.* communication (2) is clearly in order. The stress of Loebenberg *et al.* on our "unusual" methodology seems to hint that the use of a new or nonstandard method may be unacceptable. Our method (1) was reproducible by different investigators, rapid, and equivalent to older "standard" methods.

The following comments are presented in reply to the criticisms of Loebenberg *et al.* (2).

1. Their comment that minimum fungicidal concen-

0022-3549/80/0600-0741$01.00/0
© 1980, American Pharmaceutical Association

trations as well as minimum inhibitory concentrations for products used were not presented is irrelevant. Our purpose was not to compare the potency of undecylenic acid and tolnaftate (studied at 20–21°) but rather to show differences in their activity (*i.e.*, killing time).

2. Loebenberg *et al.* (2) questioned the use of suspensions *versus* solutions. Suspensions of active ingredients as well as finished products were used to eliminate, as much as possible, problems that frequently occur in *in vitro* testing (*e.g.*, differences in diffusion due to different vehicles). Thus, the use of polyethylene glycol 400 as a solvent for tolnaftate and of ethanol for undecylenic acid (both would be in solution) was, in our opinion, less justified and might have introduced more error into the results than the use of an aqueous suspension for both. Diffusional differences due to the solvent could well overshadow any antifungal action. Also, an "in-use" condition would be mimicked most closely by having the products in aqueous suspension (as might be expected in the humid cutaneous environment).

3. Certainly no claim for "more bioavailability" of undecylenic acid over tolnaftate was made based on an *in vitro* study (1), as suggested by Loebenberg *et al.* (2). We are unaware of any selectivity of polysorbate in aiding dispersion or wetting of any particular product.

4. Preliminary experimentation indicated that rinsing in simple peptone solution did not remove all active drug from the cultures. To ensure complete removal of the active ingredients, the rinsing solutions and procedures described (1) were utilized.

5. It appears to us that if the contact time between the drug and organism were increased, any benefit would be reaped by both compounds and not by one exclusively. The longest contact time was 240 min.

6. Loebenberg *et al.* (2) noted wide variation in our results (1). Although the differences in Table IV are less often significant, the trend is in the same direction as in Table II. Statistical procedures were employed and presented to substantiate the conclusions.

While Loebenberg *et al.* (2) criticized our use of suspensions of commercial powders[1,2], they did not present data on these commercial powders to refute our *in vitro* results. Instead, they compared solutions[1,3] *in vitro*. The vehicles of these products differ markedly (propanol and polyethylene glycol 400, respectively). Therefore, we used an aqueous powder suspension to eliminate vehicle differences and, hence, possible differences in diffusion. Even though lower minimum inhibitory concentrations were noted for tolnaftate, concentration obviously is not the sole criterion of an effective drug.

The introduction by Loebenberg *et al.* (2) of a guinea pig study into a discussion of *in vitro* results is perplexing; here, also, different commercial products were compared[2,4]. Loebenberg *et al.* (2) noted that the average lesion score for one product[2] (16.4) was lower than that for the other[4] (18.2). Whether a difference in scores of 1.8 is significant or of clinical importance is doubtful. Moreover, the guinea pig test system referred to (3) is of limited use. Weinstein *et al.* (3) noted that the system "can have suggestive value only" and that: "The absolute relationship between guinea pig efficacy and clinical utility in acute and particularly chronic human infections has not been established." These investigators (3) also noted that the *in vivo* test can act only as a guide to suggest possible clinical usefulness.

Hygroscopicity of Poorly Soluble Porous Substances

Keyphrases □ Hygroscopicity—poorly soluble and insoluble substances, correlation between pore structure and equilibrium moisture content □ Pore-size distribution—overall porosity of poorly soluble substances, effect on hygroscopicity, equilibrium moisture content □ Equilibrium moisture content—poorly soluble substances, effect of overall porosity on hygroscopicity

To the Editor:

The general problem of hygroscopicity of soluble compounds has been defined (1, 2) and was reviewed recently (3). However, the hygroscopicity of poorly soluble compounds has attracted little attention. El-Sabaawi and Pei (4) showed that a correlation exists between pore structure and equilibrium moisture content for insoluble substances. This report extends this principle to insoluble substances with log-normally distributed pore spaces and shows that the equilibrium moisture curves obtained are of a traditional contour. It is presumed that this principle also extends to poorly soluble substances, as defined in the USP.

A liquid with zero contact angle exerts a vapor pressure when confined in a capillary pore of diameter d which is given by the modified Kelvin equation (5):

$$\ln(P/P^*) = -4\gamma V/[RT(d-t)] \qquad \text{(Eq. 1)}$$

where P is the vapor pressure over the liquid in the pore, P^* is the vapor pressure of pure water at the given temperature T, γ is the interfacial tension between the solid and liquid (water), V is the molar volume of the liquid (water), R is the gas constant, and t is the correction factor for the sorbed layer *in* the pore.

For the purpose of the example and for simplicity, t is neglected in the following equation, so Eq. 1 becomes:

$$\ln(P/P^*) = -4\gamma V/RTd \qquad \text{(Eq. 2)}$$

The hygroscopicity of a compound or powder mixture often is studied by means of equilibrium moisture curves. To obtain these curves, a given amount (W_0, expressed in

trations as well as minimum inhibitory concentrations for products used were not presented is irrelevant. Our purpose was not to compare the potency of undecylenic acid and tolnaftate (studied at 20–21°) but rather to show differences in their activity (*i.e.*, killing time).

2. Loebenberg *et al.* (2) questioned the use of suspensions *versus* solutions. Suspensions of active ingredients as well as finished products were used to eliminate, as much as possible, problems that frequently occur in *in vitro* testing (*e.g.*, differences in diffusion due to different vehicles). Thus, the use of polyethylene glycol 400 as a solvent for tolnaftate and of ethanol for undecylenic acid (both would be in solution) was, in our opinion, less justified and might have introduced more error into the results than the use of an aqueous suspension for both. Diffusional differences due to the solvent could well overshadow any antifungal action. Also, an "in-use" condition would be mimicked most closely by having the products in aqueous suspension (as might be expected in the humid cutaneous environment).

3. Certainly no claim for "more bioavailability" of undecylenic acid over tolnaftate was made based on an *in vitro* study (1), as suggested by Loebenberg *et al.* (2). We are unaware of any selectivity of polysorbate in aiding dispersion or wetting of any particular product.

4. Preliminary experimentation indicated that rinsing in simple peptone solution did not remove all active drug from the cultures. To ensure complete removal of the active ingredients, the rinsing solutions and procedures described (1) were utilized.

5. It appears to us that if the contact time between the drug and organism were increased, any benefit would be reaped by both compounds and not by one exclusively. The longest contact time was 240 min.

6. Loebenberg *et al.* (2) noted wide variation in our results (1). Although the differences in Table IV are less often significant, the trend is in the same direction as in Table II. Statistical procedures were employed and presented to substantiate the conclusions.

While Loebenberg *et al.* (2) criticized our use of suspensions of commercial powders[1,2], they did not present data on these commercial powders to refute our *in vitro* results. Instead, they compared solutions[1,3] *in vitro*. The vehicles of these products differ markedly (propanol and polyethylene glycol 400, respectively). Therefore, we used an aqueous powder suspension to eliminate vehicle differences and, hence, possible differences in diffusion. Even though lower minimum inhibitory concentrations were noted for tolnaftate, concentration obviously is not the sole criterion of an effective drug.

The introduction by Loebenberg *et al.* (2) of a guinea pig study into a discussion of *in vitro* results is perplexing; here, also, different commercial products were compared[2,4]. Loebenberg *et al.* (2) noted that the average lesion score for one product[2] (16.4) was lower than that for the other[4] (18.2). Whether a difference in scores of 1.8 is significant or of clinical importance is doubtful. Moreover, the guinea pig test system referred to (3) is of limited use. Weinstein *et al.* (3) noted that the system "can have suggestive value only" and that: "The absolute relationship between guinea pig efficacy and clinical utility in acute and particularly chronic human infections has not been established." These investigators (3) also noted that the *in vivo* test can act only as a guide to suggest possible clinical usefulness.

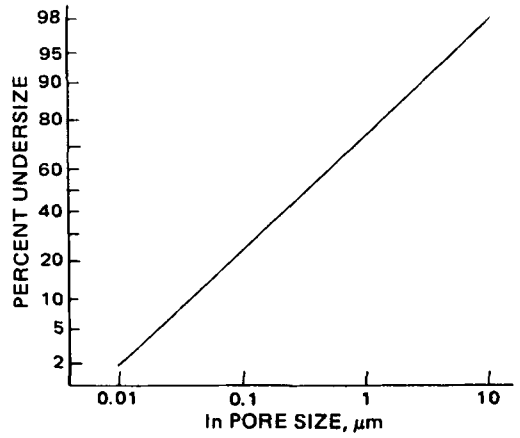

Figure 1—*Example of a log-normal pore-size distribution as used in Table I.*

grams) of a solid substance is exposed in a desiccator to the atmosphere of a saturated salt solution. The relative humidity of the atmosphere is a function of the particular salt used. The experiment is carried out until no more moisture is taken up by the solid, *i.e.*, until its weight, W_f, is constant. The amount $x = (W_f - W_0)100/W_f$ is the moisture content of the solid corresponding to the relative humidity, H, in question. The plot of x *versus* H or of H *versus* x is denoted as the equilibrium moisture curve. An excellent example of this type of experiment that allows interpretation is the work of Sangekar *et al.* (6). However, usually only the apparent kinetics of moisture adsorption are studied and only at one relative humidity (RH).

For an insoluble substance with known pore-size distribution, the equilibrium moisture curve can be deduced from this distribution. This distribution gives the volume fraction of pores with diameters below a certain size. These pores will not allow evaporation of water at pressures above a P value given by Eq. 2. The volume percent of pores (based on the pore volume) can be converted to the volume percent of solids since the total pore volume is known. The pressure, P, can be converted to relative humidity by multiplication by $100/P^*$.

This determination is best illustrated by example. Figure 1 gives an example of a log-normal pore-size distribution with 2% of the pore volume being of diameters below 0.01 μm and 98% being below 10 μm. If the vapor pressure

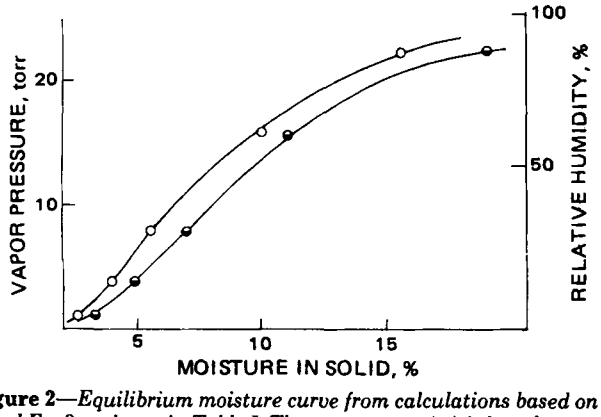

Figure 2—*Equilibrium moisture curve from calculations based on Fig. 1 and Eq. 3 as shown in Table I. The upper curve (○) is based on a solids density of 1.0 g/cm³, and the lower curve (◒) is based on a solids density of 1.25 g/cm³.*

Table I—Calculation of Critical Vapor Pressures from Pore-Size Distribution [a]

Volume Percent of Pores	Pore Diameter, μm	P, torr	Pore Volume[b], %	Moisture Content[c], %
2	<0.01	0.0002	0.4	0.62
11	<0.04	1.24	2.2	3.32
16.5	<0.063	3.78	3.3	4.90
24	<0.1	7.62	4.8	6.98
45	<0.25	15.6	9	12.3
75	<1.0	22.4	15	19.0

[a] Calculated from Fig. 1 and Eq. 3. [b] Assuming 1 cm³ of pores/5 cm³ of solid. [c] Using a true solids density of 1.25 g/cm³ and unit density for water.

above a pore of diameter 10 μm is 25 torr and the vapor pressure of water at the temperature in question is 25.3 torr, then it follows from Eq. 2 that:

$$\ln(P/25.3) = -0.12/d \qquad \text{(Eq. 3)}$$

where P is expressed in torr and d is expressed in micrometers.

A selected number of diameters calculated according to Eq. 3 are shown in Table I. The first column gives the volume percent of pores below the diameter shown in the second column. The vapor pressure corresponding to this diameter is calculated according to Eq. 3 and is shown in the third column. If the overall porosity is 20%, *i.e.*, if there is 1 cm³ of pore space in 5 cm³ of solid volume (*i.e.*, 4 cm³ of actual solid), then the percent of pore volume is as shown in the fourth column. This value is converted to percent moisture content as follows. If, as shown in line 2 of Table I, there is 2.2% of pore volume below 1.24 torr and if the solid has a true density of ρ, then the amount of solid (4 cm³) is $(4/\rho)$ g and the amount of water is 11% of 1 cm³ (1 g), *i.e.*, 0.11 g. Hence, the percent of moisture is $11/[(4/\rho) + 0.11]$.

Figures calculated for a value of $\rho = 1.25$ g/cm³ are shown in the fifth column of Table I and in Fig. 2. Figure 3 is an example taken from the literature (6). The slightly sigmoid nature of the curve in Fig. 2 may not be present in data reported in the literature since, in most cases, the equilibrium moisture curves are not precise below ~35% RH. Furthermore, for the example in Fig. 2, if the solid in a somewhat moist state was prepared for the experiment

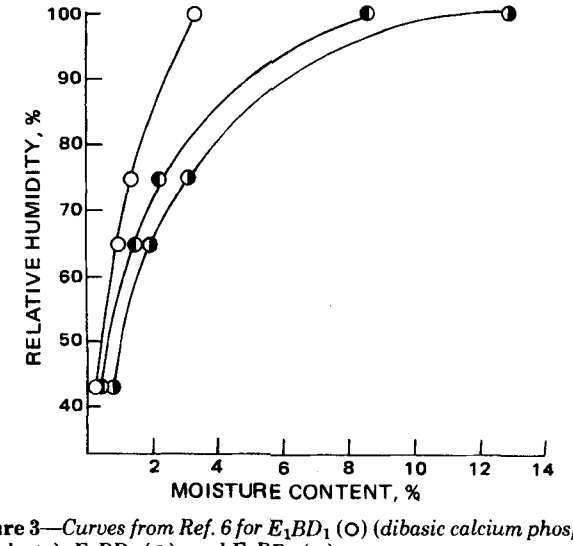

Figure 3—*Curves from Ref. 6 for E_1BD_1 (○) (dibasic calcium phosphate dihydrate), E_6BD_3 (◐), and E_8BD_2 (◑).*

by drying at 26° at a pressure of >3 torr (13% RH) or the equivalent at a higher temperature, then only the last five points would be involved and the shape would lose the initial sigmoid nature.

These comments are confined to situations where no gross swelling or pore-size distortion occurs during moisture uptake (7, 8). Furthermore, the solubility must be sufficiently low so that no significant volume changes or vapor pressure changes can result from dissolution.

Enhancement of Rectal Absorption of Drugs by Adjuvants

Keyphrases □ Absorption, rectal—enhancement by certain adjuvants □ Salicylate—enhancement of rectal absorption of theophylline and lidocaine □ Theophylline—enhancement of rectal absorption by salicylate □ Lidocaine—enhancement of rectal absorption by salicylate

To the Editor:

Rectal drug administration has the potential of overcoming some limitations encountered with other dosage forms. In this communication, we report that the rectal absorption of many drugs is facilitated markedly in the presence of certain adjuvants.

Although specific surfactants were shown to promote drug absorption from the rectum (1), their use seems to damage the rectal mucosa, reducing their suitability as absorption promoters. The adjuvants described in this report appear to function differently.

These observations were made using an *in situ* perfusion method of the rectum similar to that reported by Crommelin *et al.* (2). Six milliliters of drug solution was circulated at a rate of 2 ml/min at 38° through an ~2-cm section of the rectum of male Sprague–Dawley rats weighing 275–300 g. The amount of drug remaining in the perfusate was analyzed by high-pressure liquid chromatography as a function of time. Blood levels also were measured in blood samples taken from a vein in the leg of a rat.

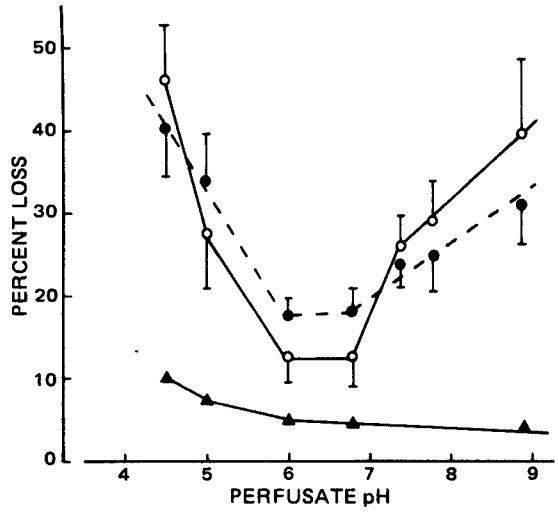

Figure 1—*Percent loss of salicylate or its acidic form (--●--) and theophylline (—○— and —▲—) after 1 hr from the perfusate in the rat rectum. Initial concentrations were 0.5% sodium salicylate (--●--), 0.5% sodium salicylate and 200 μg of theophylline/ml (—○—), and 200 μg of theophylline/ml (—▲—).*

Figure 1 shows the effect of salicylate at various pH values on the disappearance of theophylline from the perfusate in the rat rectum after 60 min of perfusion. The loss of theophylline from the perfusate in the absence of salicylic acid or salicylate was small at all pH values. However, in the presence of 0.5% salicylate at various pH values, the disappearance of theophylline was enhanced greatly, especially below pH 5 and above pH 7.4.

As shown in Fig. 1, the loss of theophylline paralleled the loss of salicylate from the perfusing solution; the greater the disappearance of salicylate from the perfusate, the greater was the loss of theophylline. Furthermore, contrary to the situation with some surfactants, the promotive effect of salicylate did not reflect a permanent change in the rectal membrane, because the effect of salicylate was eliminated by washing the rectum with buffer for 5 min at

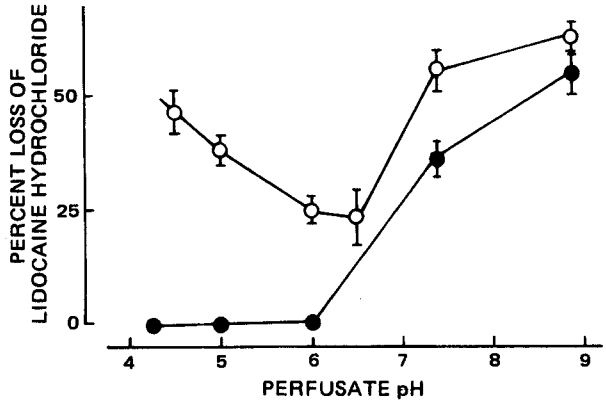

Figure 2—*Effect of pH and salicylate on the disappearance of lidocaine hydrochloride from a perfusate in the rat rectum after 1 hr. The initial lidocaine hydrochloride concentration was 500 μg/ml (○ and ●), and the sodium salicylate concentration was 0.5% (○).*

a rate of 2 ml/min after pretreatment with salicylate; the effect of pretreatment with sodium lauryl sulfate was not eliminated by washing.

After rectal administration of 0.3 ml of theophylline solution (pH 7.4, 15 mg/ml) in the presence of salicylate (15 mg/ml), the blood levels of theophylline and salicylate increased rapidly and simultaneously, reaching maximum levels (41.2 ± 15.9 μg/ml for theophylline and 41.1 ± 14.3 μg/ml for salicylate; $n = 6$) 30 min after administration. The amounts of theophylline and salicylate remaining in the solution were 25.6 ± 4.7 and 30.3 ± 7.2%, respectively. Without salicylate, maximum blood levels of theophylline were <5 μg/ml ($n = 6$).

The presence of salicylate in the perfusate (pH 4.5 or 5.0) also enhanced the disappearance of lidocaine, which is a basic drug and is not absorbed below pH 6.0, from the perfusate in the rat rectum. The effects of salicylate on the disappearance of lidocaine at various pH values are presented in Fig. 2. Thirty minutes after rectal administration of 0.3 ml of lidocaine solution (pH 4.5, 15 mg/ml) in the presence of salicylate (15 mg/ml), lidocaine and salicylate reached maximum levels in the blood (43.3 ± 4.7 μg/ml for lidocaine and 48.5 ± 6.9 μg/ml for salicylate; $n = 6$).

These results indicate that salicylate and/or its acidic form markedly enhance the absorption of various compounds from the rectum. This effect appears to be general for other drugs including cefmetazole and levodopa. Furthermore, three isomers of sodium dihydroxybenzoate (3,4-, 2,5-, and 3,5-dihydroxybenzoates) and homovanillic acid were studied as adjuvants and found to enhance the rectal absorption of both theophylline and lidocaine. These and similar compounds have significant potential as adjuvants for enhancing rectal drug absorption. Studies are continuing on the mechanism of their action.

Kinetic Characterization of Liposomes

Keyphrases □ Liposomes—base-catalyzed hydrolysis of *p*-nitrophenyl acetate in liposomal suspensions □ *p*-Nitrophenyl acetate—base-catalyzed hydrolysis in liposomal suspensions □ Hydrolysis—base-catalyzed degradation of *p*-nitrophenyl acetate in liposomal suspensions

To the Editor:

Liposomes have been investigated extensively for possible use as novel drug carriers for therapeutic purposes (1, 2). From a drug stability viewpoint, we studied the hydrolysis of procaine and 2-diethylaminoethyl *p*-nitrobenzoate in liposomal suspensions and compared it with spontaneous hydrolysis in aqueous bulk solutions (3, 4). The base-catalyzed hydrolysis of procaine was retarded by liposomes; with 2-diethylaminoethyl *p*-nitrobenzoate, both retardation and enhancement were observed, depending on the pH of the dispersed medium.

These ester degradations followed first-order kinetics in the liposomal suspension as well as in the corresponding aqueous bulk solution, regardless of whether retardation or enhancement was observed. This finding indicates that the substrates added in the liposomal medium partitioned into the lipid phase at so fast a rate that it was undetectable, and this partitioning was followed by quasi-first-order degradation, which can be represented by the first-order rate constants defined in the aqueous bulk and lipid phases. Consequently, the partition model was applicable for degradation of these esters.

This communication discusses the base-catalyzed hydrolysis of *p*-nitrophenyl acetate in liposomal suspensions. This compound frequently is used as a substrate in studies of micellar catalysis (5, 6) and of esterase activity of bovine serum albumin and human serum albumin (7, 8).

Figure 1 indicates that the reaction followed first-order kinetics with the ester remaining in the aqueous solution. The reaction clearly was not a continuous process in liposomal suspensions. It was enhanced in the early stage and proceeded in a manner parallel to the spontaneous degradation. The degradation rate was dependent on the lecithin concentration; the more lecithin that was present, the faster was the hydrolysis. Furthermore, enhancement was accelerated more in the unilamellar dispersion system than in the multilamellar one when the lecithin content in

Kinetic Characterization of Liposomes

Keyphrases □ Liposomes—base-catalyzed hydrolysis of *p*-nitrophenyl acetate in liposomal suspensions □ *p*-Nitrophenyl acetate—base-catalyzed hydrolysis in liposomal suspensions □ Hydrolysis—base-catalyzed degradation of *p*-nitrophenyl acetate in liposomal suspensions

To the Editor:

Liposomes have been investigated extensively for possible use as novel drug carriers for therapeutic purposes (1, 2). From a drug stability viewpoint, we studied the hydrolysis of procaine and 2-diethylaminoethyl *p*-nitrobenzoate in liposomal suspensions and compared it with spontaneous hydrolysis in aqueous bulk solutions (3, 4). The base-catalyzed hydrolysis of procaine was retarded by liposomes; with 2-diethylaminoethyl *p*-nitrobenzoate, both retardation and enhancement were observed, depending on the pH of the dispersed medium.

These ester degradations followed first-order kinetics in the liposomal suspension as well as in the corresponding aqueous bulk solution, regardless of whether retardation or enhancement was observed. This finding indicates that the substrates added in the liposomal medium partitioned into the lipid phase at so fast a rate that it was undetectable, and this partitioning was followed by quasi-first-order degradation, which can be represented by the first-order rate constants defined in the aqueous bulk and lipid phases. Consequently, the partition model was applicable for degradation of these esters.

This communication discusses the base-catalyzed hydrolysis of *p*-nitrophenyl acetate in liposomal suspensions. This compound frequently is used as a substrate in studies of micellar catalysis (5, 6) and of esterase activity of bovine serum albumin and human serum albumin (7, 8).

Figure 1 indicates that the reaction followed first-order kinetics with the ester remaining in the aqueous solution. The reaction clearly was not a continuous process in liposomal suspensions. It was enhanced in the early stage and proceeded in a manner parallel to the spontaneous degradation. The degradation rate was dependent on the lecithin concentration; the more lecithin that was present, the faster was the hydrolysis. Furthermore, enhancement was accelerated more in the unilamellar dispersion system than in the multilamellar one when the lecithin content in

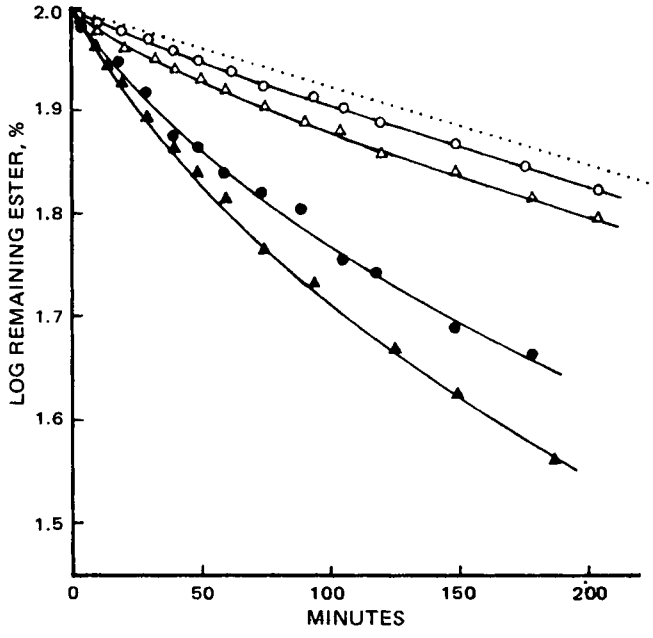

Figure 1—*First-order plots for hydrolysis of* p*-nitrophenyl acetate in aqueous solution and in liposomal suspensions. Tris(hydroxymethyl)-aminomethane buffer at pH 8.0 was used (μ = 0.3, 25°). The initial* p*-nitrophenyl acetate concentration was 5.92 × 10⁻⁴ M. The lecithin concentrations were 2.40 × 10⁻³ M (○ and △) and 8.67 × 10⁻³ M (● and ▲). Key: . . . , spontaneous degradation in water; ○ and ●, multilamellar liposome system; and △ and ▲, unilamellar liposome system. Liposomes were prepared from egg yolk lecithin as described previously (3).*

0022-3549/80/0600-0745$01.00/0

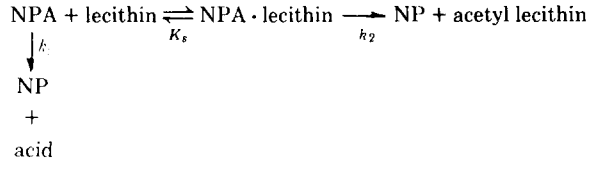
the medium was equal in both cases.

These results suggest that partition theory, which was applied to procaine and 2-diethylaminoethyl *p*-nitrobenzoate and for the evaluation of drug entrapment in liposomes, may not apply to the present case because the liposomes appear to be exhausted by the degradation of *p*-nitrophenyl acetate. The exhaustion may be due to acetylation of the phosphate group of the lecithin molecule, which prevents further orientation of the substrate on the surface of the vesicles from being favorable for the hydroxide-ion attack. Furthermore, as seen in the difference between the rates for unilamellar and multilamellar liposomes, the effective surface area of the vesicles plays a key role, and the reaction occurring on the surface is much more predominant than that in the interior lipid phase.

Binding of *p*-nitrophenyl acetate by liposomes appears to be important at the first stage of the reaction to facilitate hydrolysis. The whole reaction can be treated in a manner analogous to that used for enzymatic catalysis:



Scheme I

where NPA and NP are *p*-nitrophenyl acetate and the product, *p*-nitrophenol, respectively; NPA · lecithin is the substrate–lecithin complex; k_1 and k_2 are the rate constants for the spontaneous and facilitated reactions, respectively; and K_s is the dissociation constant of the complex.

According to Scheme I, the apparent first-order rate constant, k_{obs}, for the appearance of NP can be expressed under the condition of an excess lecithin concentration:

$$k_{obs} = \frac{k_1 K_s + k_2 [\text{lecithin}]}{K_s + [\text{lecithin}]} \qquad \text{(Eq. 1)}$$

By converting Eq. 1 to the double-reciprocal form, a Lineweaver–Burk plot makes it possible to determine K_s and k_2 values. However, since lecithin does not exist as a molecular form in water, k_{obs} does not depend on the practical lecithin concentration but instead on the effective surface area of the vesicles formed, which could be converted to the effective concentration of the lipid based on the ratio of the k_{obs} values of unilamellar and multilamellar liposomes prepared under various conditions with an equal lecithin content.

When the lecithin concentration is moderate, k_{obs} is no longer a constant but becomes a function of the effective concentration of the lipid changing with time. Therefore, the effective concentration is an adjustable parameter that is fitted best by a nonlinear optimization procedure in addition to the k_2 value.

Thus, the surface properties of liposomes, if they are prepared under the same conditions except for size reduction procedures, may greatly affect the stability of a drug, especially when the enhancement of degradation is involved.

Quantitative Change in Metabolic Fate of Drug Related to Serum Protein Binding

Keyphrases □ Protein binding, serum—effect on drug metabolism □ Drug metabolism—effect of serum protein binding □ Biotransformation—effect of serum protein binding on drug metabolism

To the Editor:

If a drug is eliminated by renal excretion and by biotransformation, then the fraction of the dose that is metabolized, F_m, is equal to the ratio of the metabolic formation clearance to the total clearance. Thus:

$$F_m = Cl_m/Cl_T \qquad \text{(Eq. 1)}$$

If clearance is not limited or affected by the organ blood perfusion rate and the rates of the clearance processes are proportional to the concentration of free (unbound) drug in serum:

$$F_m = \frac{fCl_{m\ \text{intrinsic}}}{fCl_{T\ \text{intrinsic}}} \qquad \text{(Eq. 2)}$$

where f is the free fraction of drug in serum and the clearance terms represent intrinsic clearances of free drug (1–3). Since f cancels out, F_m is independent of serum protein binding under the stated conditions.

If the renal clearance of a drug involves glomerular filtration (the rate of which usually is proportional to the concentration of free drug in serum) as well as renal tubular secretion and if the rate of tubular secretion is proportional to the concentration of total (free plus bound) drug in serum (3), then F_m is affected by f. Specifically:

$$\text{renal clearance} = fk_g(1 - F) + k_s^*(1 - F) \qquad \text{(Eq. 3)}$$

where k_g is the glomerular filtration clearance referenced to the free drug concentration, k_s^* is the apparent renal secretion clearance referenced to the total drug concentration, and F is a dimensionless constant representing the fraction of filtered and secreted drug that is reabsorbed (3). Proportionality between the renal tubular secretion rate and the total rather than free drug concentration in plasma or serum may occur if the true renal secretion clearance is much higher than the effective renal blood flow (4).

Since total clearance is the sum of the renal and metabolic clearances for drugs eliminated entirely by those two

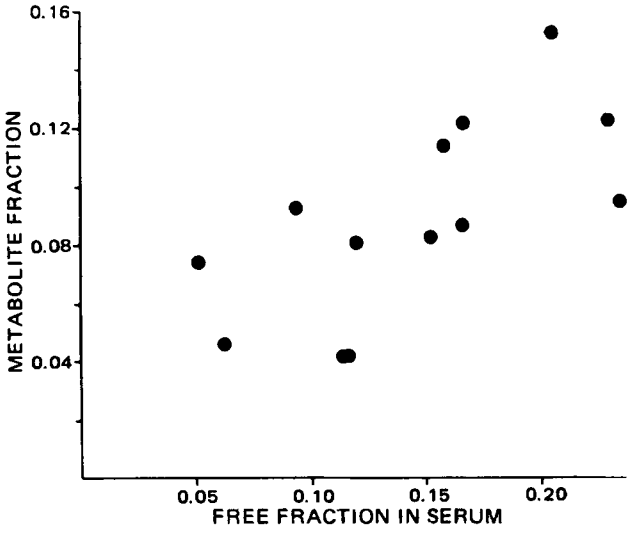

Figure 1—*Relationship between the fraction of a 20-mg/kg iv dose of sulfisoxazole excreted in the urine as metabolites and the free fraction of sulfisoxazole in serum. Data were obtained from 13 rats (6). The correlation coefficient is 0.68;* $p < 0.02$.

types of processes:

$$Cl_T = fk_g(1 - F) + k_s^*(1 - F) + fCl_{m\ \text{intrinsic}} \qquad \text{(Eq. 4)}$$

and the fraction of a dose metabolized is equal to $fCl_{m\ \text{intrinsic}}$ divided by all of the terms on the right side of Eq. 4. Dividing the numerator and denominator of that ratio by f yields:

$$F_m = \frac{Cl_{m\ \text{intrinsic}}}{k_g(1 - F) + Cl_{m\ \text{intrinsic}} + \frac{k_s^*(1 - F)}{f}} \qquad \text{(Eq. 5)}$$

Examination of Eq. 5 reveals that as f increases, F_m also increases. Thus, the fraction of a dose of drug converted to metabolite(s) increases if the serum protein binding of that drug is decreased in blood flowing through the eliminating organs (5)[1]. This conclusion applies only to drugs that are excreted in part by a process whose rate is proportional to the total rather than the free drug concentration in plasma or serum while the rates of other, parallel elimination processes are proportional to the free drug concentration. Sulfisoxazole appears to exhibit such characteristics in rats (6).

In 13 male Sprague–Dawley rats receiving a single intravenous injection of 20 mg of sulfisoxazole/kg, the fraction of the dose recovered in the urine as metabolites ranged from 0.042 to 0.152 and f ranged from 0.0518 to 0.235 (6). Drug concentrations in serum declined biexponentially with no downward curvature, which would occur if renal excretion, the major pathway of elimination, were saturable in the concentration range studied. Reexamination of the experimental data revealed a significant positive correlation between F_m and f (Fig. 1), as predicted by Eq. 5.

One important implication of these findings relates to the mechanism of certain drug interactions. Increased conversion of a drug (A) to its metabolite(s) caused by prior or concomitant administration of another drug (B) usually will be interpreted as resulting from either induction of biotransformation or inhibition of the renal clearance of A. However, if Drug B displaces Drug A from plasma protein binding sites, then the increased biotransformation of Drug A also could occur by the mechanism described in this communication. Another implication concerns the effect of the dose or dosing rate on the metabolic fate of a drug. For drugs that exhibit significant concentration dependence of plasma protein binding (f increases with increasing drug concentration), F_m may increase with increasing dose or dosing rate due to decreased protein binding.

Polyethylene Glycols as Solvents in Implantable Osmotic Pumps

Keyphrases □ Polyethylene glycols—use as solvents in implantable osmotic pumps □ Solvents—polyethylene glycols, use in implantable osmotic pumps □ Drug delivery systems—implantable osmotic pumps, use of polyethylene glycols as solvents

To the Editor:

Implantable osmotic pumps[1] are useful for short-term delivery of water-soluble drugs and hormones (1–4). However, many compounds such as steroids are too insoluble in water to be administered as aqueous solutions (5). Although 5% ethanol and 5% dimethyl sulfoxide increase the concentration range over which lipophilic molecules can be delivered (6), the maximum dose still is quite low. Polyethylene glycols 400 and 600 are excellent solvents for many steroids (Table I) (1,5) and also are useful *in vivo* since they have very low toxicities (7). The objective of these experiments was to evaluate the suitability of polyethylene glycols as solvents with implantable pumps *in vivo*. Since the polyethylene glycols are known to influence fluid balance *in vivo*, the potential effects of the solvents and the pumps also were examined.

The ability of the pumps to function *in vivo* with polyethylene glycols as solvents was evaluated in two ways. Mineralocorticoids are known to induce the amiloride-

[a] The steroids and the polyethylene glycol solvents were obtained from Sigma Chemical Co., St. Louis, MO 63178. The steroids were suspended in the solvent, warmed to ~80°, and sonicated for dissolution. After storage in sealed vials at 37° for >72 hr, samples were centrifuged at 12,000×*g* for 20 min to pellet any insoluble drug. If insoluble drug was detected, additional solvent was added and the process of warming the solution, sonication, and prolonged storage was repeated until solubility was obtained. Since most values were determined only by approaching apparent equilibrium from a supersaturated solution rather than from both sides, the solubilities cannot be considered as rigorously established equilibrium values. Data with soybean oil (Wesson Oil, Hunt Wesson Foods Inc., Fullerton, CA 92634) are shown for comparison only. Results are given as the mean ± *SEM*; the number in parentheses is the number of independent determinations. [b] ND = not determined.

[a] Male Sprague–Dawley rats with intact adrenal glands (controls) and male bilaterally adrenalectomized rats were maintained on Purina Formulab Chow 5008 (Ralston Purina Co., Richmond, IN 47374) *ad libitum*. The control rats were given 150 m*M* NaCl and 29 m*M* sucrose to drink *ad libitum*. The adrenalectomized animals were given the same solution with 5 m*M* KCl. Drugs were dissolved in polyethylene glycol (Table I) and loaded into osmotic pumps (6). The pumps were placed in the peritoneal cavity of ~150-g rats under ether anesthesia. Glass rods used as sham pumps were 5 × 24-mm pieces of fire-polished soft glass. The descending colon was removed under pentobarbital anesthesia (~75 mg/kg ip) and mounted in a 0.28-cm² Schultz chamber perfused with Krebs–Henseleit balanced salt solution containing 5 m*M* D-glucose (Sigma Chemical Co., St. Louis, MO 63178). The short-circuit current was measured with a conventional circuit using calomel electrodes (catalog No. 13-639-79, Fisher Scientific Co., Pittsburgh, PA 15219) (10) and was displayed on a strip-chart recorder (Brush model 110, Instrument Division, Gould Inc., Cleveland, OH 44114). The amiloride sensitivity of the short-circuit current was the portion of the short-circuit current that was sensitive to 25 μ*M* amiloride added to the mucosal surface of the tissue. Results are shown as the mean ± *SEM*; the number in parentheses is the number of animals.

sensitive sodium transport system in the luminal membrane of the rat colon (8–10). The ability of aldosterone administered by the osmotic pumps to induce the amiloride-sensitive sodium transport system was examined initially. Sodium transport was estimated *in vitro* as the short-circuit current, and amiloride sensitivity was judged by the ability of 25 μ*M* amiloride[2] to inhibit the observed short-circuit current when added to the mucosal side of the tissue (10).

After 3–7 days of aldosterone[3] infusion (Table II), 77% of the short-circuit current was inhibited by amiloride while only 7% of the short-circuit current was sensitive to amiloride in the untreated animals. This effect was due to aldosterone since it could be suppressed by the aldosterone antagonist spironolactone. Since the half-time of the amiloride-sensitive sodium transport system in the absence of aldosterone is ~12 hr (10), aldosterone must have been released from the pumps for the entire infusion period (up to 7 days).

The effectiveness of the pumps also was tested by measuring the weight change of male rats during the administration of 17β-estradiol[3]. Estrogens are known to cause a weight reduction in male rats (11–13). Adrenalectomized (ADX) rats[4] treated for 6 days with pumps containing only polyethylene glycol gained 32.2 ± 6.6 g (mean ± *SEM*, $n = 3$); the adrenalectomized rats treated with 145 μg of 17β-estradiol/kg/hr lost 22.3 ± 5.8 g ($n = 3$).

These results indicate that polyethylene glycols are effective solvents for use with osmotic pumps *in vivo*.

Although relatively large volumes of polyethylene glycol (~3 ml/kg) may perturb the fluid balance when injected into the peritoneal cavity (14, 15), the quantity of polyethylene glycol delivered by the pumps (5–10 μl/kg/hr) (1) probably is too low for this problem to be significant. The slight elevation of amiloride-sensitive sodium transport observed with control animals[4] with intact adrenal glands when compared to control animals with sham pumps (glass rods) (Table II) is due to effects of the pumps. The pumps probably act as fluid sinks, reducing the extracellular volume, stimulating the renin–angiotensin system, and causing a slight elevation of the endogenous aldosterone levels. This increase in the circulating aldosterone concentration causes the amiloride sensitivity of the colon to be elevated over that of the sham pump-treated controls (23 *versus* 7%). The renin–angiotensin–aldosterone system probably is responsible for this effect since it was reduced by treatment with spironolactone (Table II) and was abolished in the adrenalectomized animals. Although the pump-mediated increase in the activity of the renin–angiotensin–aldosterone system is small, these results serve to advise potential users of osmotic pumps that sufficient controls are important.

Osmotic pumps are useful for studies of drug efficacy *in vivo* where the actual rate of drug treatment must be maintained over a relatively long period to compare the potency of different compounds adequately. When utilized with appropriate controls, polyethylene glycols greatly expand the usefulness of these pumps to otherwise insoluble lipophilic compounds.

Disintegration Test for Hard Gelatin Capsules

Keyphrases □ Disintegration—hard gelatin capsules, modification of USP and NF tests for tablet disintegration □ Dosage forms—hard gelatin capsules, disintegration test, modification of USP and NF tests for tablet disintegration

To the Editor:

A proposed disintegration test procedure for capsules was published in the USP XX Comment Proof (Vol. 3, No. 56) dated August 14, 1978. This procedure was based on a series of collaborative studies conducted by the Disintegration Test Review Committee of the Pharmaceutical Manufacturers Association (PMA) Quality Control Section. Highlights of these studies are presented in this communication.

The USP and NF describe disintegration tests for five tablet categories. The PMA project was aimed at developing a similar test for hard gelatin capsule products using the apparatus and methodology for tablet disintegration with as few changes as necessary. Three test samples (No. 2 hard gelatin capsules containing 0.5, 1.0, and 1.5% magnesium stearate in lactose) were used in the studies to evaluate procedure variables. Comments on each variable follow.

A cross section of disintegration baskets used in industry was examined. The baskets generally fell into two categories: those with notched shafts and those having shafts equipped with hooks. The former type provides a rigid mounting to the motorized device, and the motion is primarily vertical; the latter basket type provides a nonrigid attachment where the motion is both vertical and rotational. Studies showed that the mounting mode had no influence on the test results. Disintegration times were identical, within normal variation, regardless of the type of mounting used.

The disintegration time of the three test samples could not be differentiated when the plastic disks described in the USP and NF were placed into the basket-rack assembly. The disintegration time for each sample was ~3 min. By eliminating the disks and placing a 10-mesh wire screen on top of the baskets to retain the capsules within the tubes, the disintegration times for the 0.5, 1.0, and 1.5% samples were 12, 25, and 39 min, respectively.

The compendia are not specific about the disintegration test vessel. Committee members reported that both the size of the vessel and the volume of the test vehicle affected the hydrodynamics of the system, thereby influencing the disintegration rate. A 1000-ml, low-form beaker containing ~900 ml of medium was the most convenient and compatible with the dimensions of the basket-rack assembly.

Purified water was a satisfactory test vehicle for the three samples. Reproducibility in disintegration time was improved by the addition of 0.1% benzalkonium chloride. The use of simulated gastric fluid was investigated, but it was reported that hydrogen chloride vapors emanating from the fluid slowly corrode the equipment. Because of variation in the composition of compendial capsule products, collaborators recommended that both the test medium and the disintegration time limit be specified in the individual monographs.

The Committee observed that the longer the path through which the basket travels in its vertical motion, the more rapid is the disintegration time. The USP and NF specify a stroke length of 5–6 cm. In a study involving one test specimen (1.0% magnesium stearate in lactose with an average disintegration time of 25 min), the disintegration time decreased by almost 6 min when the stroke was adjusted from the lower limit, 5 cm, to the upper limit, 6 cm. Therefore, a stroke length of 5.3–5.7 cm was recommended.

The final procedure was submitted to the USP after it was found to be workable in the laboratories of 13 PMA-member companies.

Effect of Smoking on Binding of Lidocaine to Human Serum Proteins

Keyphrases □ Lidocaine—effect of smoking on binding to human serum proteins □ Protein binding—lidocaine, effect of smoking, human serum □ Smoking—effect on binding of lidocaine to human serum proteins

To the Editor:

Cigarette smoking can have striking effects on the disposition of theophylline (1, 2), propranolol (3), and other drugs (4, 5). These changes generally have been ascribed to increased intrinsic hepatic clearance secondary to enzyme induction. However, other mechanisms may be operative. This communication describes the apparent effect

of tobacco smoking on the binding of lidocaine to human serum proteins. Furthermore, we report a significant increase in the lidocaine free fraction as the concentration was increased through the range usually observed in the treatment of ventricular arrhythmias. This observation is consistent with the data reported by Tucker *et al.* (6) and is inconsistent with other reports (7, 8).

Serum samples were obtained from 16 volunteers, eight smokers and eight nonsmokers. Seven of the eight smokers stated that they smoked between 0.88 and 1.25 packs/day, while the other subject smoked either one cigar or one pipeful of tobacco/day (the data from this individual are specifically identified in Fig. 1). The nonsmoking and smoking groups were well matched with respect to sex (six males and two females in each group), age (45 ± 20 *versus* 42 ± 12 years, mean ± *SD*), concurrent medication (none except diuretic therapy for hypertension), serum albumin concentration (4.9 ± 0.5 *versus* 4.7 ± 0.3 g/100 ml), and total serum protein concentration (7.5 ± 0.3 *versus* 7.2 ± 0.4 g/100 ml). All subjects had normal renal and liver function as assessed by an automatic analyzer[1], and all were apparently free of malignant or inflammatory disease.

Venous blood collected into glass syringes after an overnight fast was allowed to clot at room temperature for ~2 hr and then was centrifuged for ~20 min at 1000×*g*. The serum was removed and stored at −20°. The protein binding of lidocaine was determined by equilibrium dialysis using a dialysis membrane[2] in Plexiglas cells. Lidocaine was added to the buffer solution (0.134 *M* phosphate buffer at pH 7.4) to achieve concentrations of 2.0 and 14.0 μg/ml. A trace amount of radiolabeled drug (30 mCi of [*carbonyl*-^{14}C]lidocaine[3] hydrochloride/mmole obtained commercially with >98% radiochemical purity) also was added to the buffer. Serum aliquots were dialyzed in duplicate against an equal volume of buffer for 5 hr at 37°. Final (postdialysis) lidocaine concentrations in all samples were quantitated by liquid scintillation counting.

Substantial intersubject variability of lidocaine free fraction values was observed; at a final concentration of 1.4 μg/ml, the free fraction ranged from 0.208 to 0.342 (mean of 0.280). Little of the variability can be explained by the reproducibility of the method since the relative standard deviation of the determination of the free fraction was 5.6% (n = 22). However, part of this variability appeared to be related to the smoking status of the subjects. The data in Fig. 1 show that at a final lidocaine concentration of 1.4 μg/ml (left panel), smokers had a significantly lower free fraction than nonsmokers (0.258 ± 0.039 *versus* 0.307 ± 0.030; $p < 0.02$). Although there was a trend toward a lower free fraction at a final concentration of 9.0 μg/ml (right panel), the difference between serum binding in smokers and nonsmokers was not statistically significant ($p > 0.15$).

There are several possible explanations for the increased protein binding of lidocaine in the serum of smokers. An exogenous substance contained in tobacco smoke could cause a cooperative interaction between lidocaine and at least one of the binding proteins. However, a more plausible explanation is that the concentration of at least one

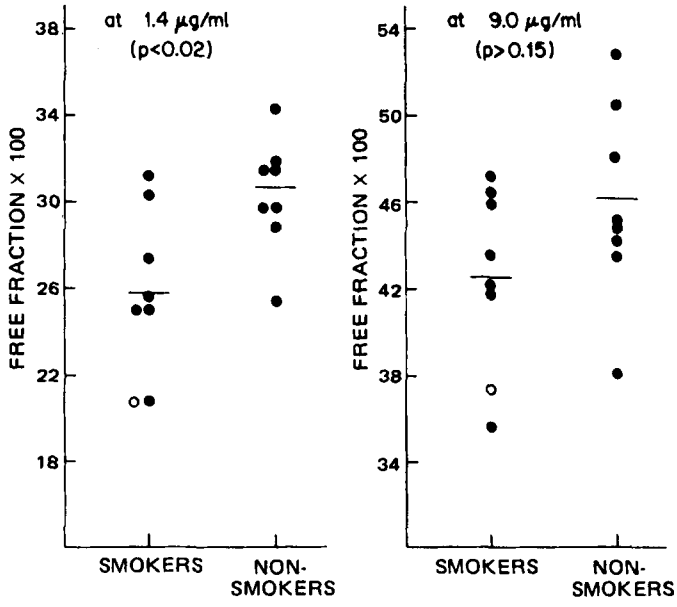

Figure 1—*Effect of smoking on the lidocaine free fraction in volunteers. Serum binding results at final lidocaine concentrations of 1.4 (left) and 9.0 (right) μg/ml are shown. The horizontal bar equals the mean free fraction value. The open symbol represents the data from the one smoker who did not smoke cigarettes.*

protein to which lidocaine binds is elevated in the serum of smokers. Some evidence suggests that the serum concentration of α_1-acid glycoprotein is elevated in smokers (9), and it is known that lidocaine binds to this acute phase reactant protein (10). Thus, the increased binding of lidocaine to the serum proteins of smokers at 1.4 μg/ml could be the result of elevated concentrations of α_1-acid glycoprotein. The failure to achieve statistical significance at a final lidocaine concentration of 9.0 μg/ml probably is related to the facts that, at this concentration, binding to albumin has greater importance (11, 12) than does binding to the glycoprotein (the 50% increase in the free fraction at 9.0 μg/ml suggests saturation of at least one class of binding sites) and, as stated earlier, albumin concentrations were nearly identical in our two populations.

Since increased binding of drugs to serum proteins is known to influence drug disposition and since increased binding of drugs to serum proteins of smokers has not been reported previously, our data may represent a significant new observation for an understanding of the effects of environmental factors on drug disposition. Furthermore, our data support the findings of Tucker *et al.* (6), who reported a lidocaine free fraction of ~0.30 at a serum drug concentration of 2 μg/ml. Finally, we confirmed the striking concentration dependence of lidocaine binding reported by Tucker *et al.* (6).

Effect of Changes in Plasma Protein Binding on Half-Life of Drugs

Keyphrases □ Pharmacokinetics—effect of changes in plasma protein binding on biological half-life of drugs □ Protein binding—effect of changes in plasma protein binding on biological half-life of drugs □ Half-life—effect of changes in plasma protein binding on biological half-life of drugs

To the Editor:

The binding of drugs to plasma proteins and extravascular tissues affects their distribution, elimination, and overall pharmacological activity. If the extent of such binding is altered by the presence of other drugs or the accumulation of certain endogenous compounds in various disease states, subsequent changes in the pharmacokinetic characteristics of the drug may be anticipated. Gibaldi *et al.* (1) suggested that the biological half-life of a drug bound to plasma proteins and tissues in a drug concentration-independent manner is a function largely of tissue binding but is independent of changes in binding to plasma proteins. However, they pointed out that this phenomenon generally is true only for drugs with apparent distribution volumes substantially larger than the plasma space. These drugs include those that distribute throughout the total body water and, more commonly, those that demonstrate extensive tissue binding as well.

The present discussion focuses on situations where the drug is bound to plasma proteins and the unbound drug is excluded from intracellular fluids. While these conditions may apply to only a few drugs, they can be important. A good example is the antibacterial agent sulfisoxazole. This compound is ~86% bound to plasma proteins after therapeutic doses (2) and is distributed only in extracellular fluids (3, 4). Since the drug does not enter the cells, it exhibits a slightly diminished toxicity while producing higher blood levels at lower doses as compared with sulfanilamide and sulfadiazine, both of which distribute throughout body water. Another example is streptomycin, which is distributed in the extracellular fluids and also is bound to plasma proteins, although to a lesser extent than sulfisoxazole (5).

Based on the physiological approach to drug distribution originally developed by Gillette (6), Øie and Tozer (7) recently proposed the following expression for the apparent volume of distribution, V:

$$V = V_P(1 + R_{E/I}) + f_P V_P(V_E/V_P - R_{E/I}) + \frac{V_T f_P}{f_T} \quad \text{(Eq. 1)}$$

where V_P is the plasma volume; V_E is the extracellular space minus the plasma volume; V_T is the physical volume into which the drug distributes minus the extracellular space; $R_{E/I}$ is the ratio of the amount of protein to which the drug binds in extracellular fluids outside the plasma to that in the plasma; and f_P and f_T are the drug fractions unbound in the spaces V_P and V_T, respectively. Furthermore, by assuming the extracellular fluid volume outside the plasma to be 12 liters and the plasma volume to be 3 liters and by assuming that the total extracellular drug-binding protein is distributed so that $R_{E/I}$ is ~1.4, Eq. 1 can be approximated as:

$$V = 7 + 8f_P + V_T\left(\frac{f_P}{f_T}\right) \quad \text{(Eq. 2)}$$

It then was pointed out (7) that if the distribution of a drug is restricted to the extracellular fluid, its apparent volume of distribution becomes:

$$V = 7 + 8f_P \quad \text{(Eq. 3)}$$

It has been shown (8) that the total clearance, Cl, of a drug whose elimination is linear and not perfusion rate limited in the organ of elimination is directly proportional to its free fraction in plasma, *i.e.*:

$$Cl = f_P Cl^* \quad \text{(Eq. 4)}$$

where Cl^* represents the intrinsic clearance. Moreover, since:

$$Cl = V\beta \quad \text{(Eq. 5)}$$

it follows that:

$$\beta = \frac{f_P Cl^*}{V} \quad \text{(Eq. 6)}$$

where, for a drug obeying two-compartment model kinetics, V is V_{area} and β equals ln 2 divided by the terminal half-life, $t_{1/2}$. Substituting Eq. 3 into Eq. 6 gives:

$$\beta = \frac{f_P Cl^*}{7 + 8f_P} \quad \text{(Eq. 7a)}$$

or:

$$t_{1/2} = \frac{\ln 2(7 + 8f_P)}{f_P Cl^*} \quad \text{(Eq. 7b)}$$

Equation 7*b* describes the effect of plasma protein binding on drug biological half-lives. When the fraction of drug unbound in plasma is changed to f'_P and the new β and $t_{1/2}$ are designated as β' and $t'_{1/2}$, respectively, then:

$$\frac{\beta'}{\beta} = \frac{t_{1/2}}{t'_{1/2}} = \frac{f'_P(7 + 8f_P)}{f_P(7 + 8f'_P)} \quad \text{(Eq. 8)}$$

or:

$$\frac{\beta'}{\beta} = \frac{7f'_P + 8f_P f'_P}{7f_P + 8f_P f'_P} \quad \text{(Eq. 9)}$$

Effect of Changes in Plasma Protein Binding on Half-Life of Drugs

Keyphrases □ Pharmacokinetics—effect of changes in plasma protein binding on biological half-life of drugs □ Protein binding—effect of changes in plasma protein binding on biological half-life of drugs □ Half-life—effect of changes in plasma protein binding on biological half-life of drugs

To the Editor:

The binding of drugs to plasma proteins and extravascular tissues affects their distribution, elimination, and overall pharmacological activity. If the extent of such binding is altered by the presence of other drugs or the accumulation of certain endogenous compounds in various disease states, subsequent changes in the pharmacokinetic characteristics of the drug may be anticipated. Gibaldi *et al.* (1) suggested that the biological half-life of a drug bound to plasma proteins and tissues in a drug concentration-independent manner is a function largely of tissue binding but is independent of changes in binding to plasma proteins. However, they pointed out that this phenomenon generally is true only for drugs with apparent distribution volumes substantially larger than the plasma space. These drugs include those that distribute throughout the total body water and, more commonly, those that demonstrate extensive tissue binding as well.

The present discussion focuses on situations where the drug is bound to plasma proteins and the unbound drug is excluded from intracellular fluids. While these conditions may apply to only a few drugs, they can be important. A good example is the antibacterial agent sulfisoxazole. This compound is ~86% bound to plasma proteins after therapeutic doses (2) and is distributed only in extracellular fluids (3, 4). Since the drug does not enter the cells, it exhibits a slightly diminished toxicity while producing higher blood levels at lower doses as compared with sulfanilamide and sulfadiazine, both of which distribute throughout body water. Another example is streptomycin, which is distributed in the extracellular fluids and also is bound to plasma proteins, although to a lesser extent than sulfisoxazole (5).

Based on the physiological approach to drug distribution originally developed by Gillette (6), Øie and Tozer (7) recently proposed the following expression for the apparent volume of distribution, V:

$$V = V_P(1 + R_{E/I}) + f_P V_P(V_E/V_P - R_{E/I}) + \frac{V_T f_P}{f_T} \quad \text{(Eq. 1)}$$

where V_P is the plasma volume; V_E is the extracellular space minus the plasma volume; V_T is the physical volume into which the drug distributes minus the extracellular space; $R_{E/I}$ is the ratio of the amount of protein to which the drug binds in extracellular fluids outside the plasma to that in the plasma; and f_P and f_T are the drug fractions unbound in the spaces V_P and V_T, respectively. Furthermore, by assuming the extracellular fluid volume outside the plasma to be 12 liters and the plasma volume to be 3 liters and by assuming that the total extracellular drug-binding protein is distributed so that $R_{E/I}$ is ~1.4, Eq. 1 can be approximated as:

$$V = 7 + 8f_P + V_T\left(\frac{f_P}{f_T}\right) \quad \text{(Eq. 2)}$$

It then was pointed out (7) that if the distribution of a drug is restricted to the extracellular fluid, its apparent volume of distribution becomes:

$$V = 7 + 8f_P \quad \text{(Eq. 3)}$$

It has been shown (8) that the total clearance, Cl, of a drug whose elimination is linear and not perfusion rate limited in the organ of elimination is directly proportional to its free fraction in plasma, *i.e.*:

$$Cl = f_P Cl^* \quad \text{(Eq. 4)}$$

where Cl^* represents the intrinsic clearance. Moreover, since:

$$Cl = V\beta \quad \text{(Eq. 5)}$$

it follows that:

$$\beta = \frac{f_P Cl^*}{V} \quad \text{(Eq. 6)}$$

where, for a drug obeying two-compartment model kinetics, V is V_{area} and β equals ln 2 divided by the terminal half-life, $t_{1/2}$. Substituting Eq. 3 into Eq. 6 gives:

$$\beta = \frac{f_P Cl^*}{7 + 8f_P} \quad \text{(Eq. 7a)}$$

or:

$$t_{1/2} = \frac{\ln 2(7 + 8f_P)}{f_P Cl^*} \quad \text{(Eq. 7b)}$$

Equation 7*b* describes the effect of plasma protein binding on drug biological half-lives. When the fraction of drug unbound in plasma is changed to f'_P and the new β and $t_{1/2}$ are designated as β' and $t'_{1/2}$, respectively, then:

$$\frac{\beta'}{\beta} = \frac{t_{1/2}}{t'_{1/2}} = \frac{f'_P(7 + 8f_P)}{f_P(7 + 8f'_P)} \quad \text{(Eq. 8)}$$

or:

$$\frac{\beta'}{\beta} = \frac{7f'_P + 8f_P f'_P}{7f_P + 8f_P f'_P} \quad \text{(Eq. 9)}$$

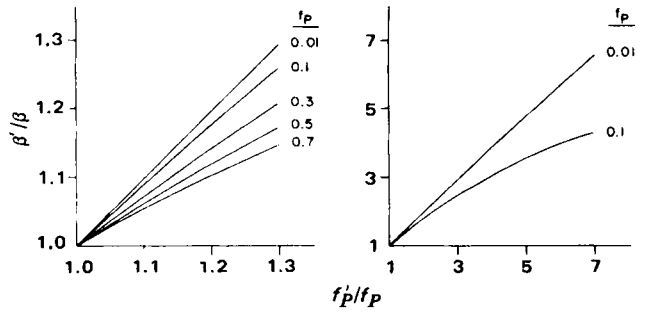

Figure 1—*Relationship between β'/β and f'_P/f_P for drugs with varying degrees of plasma protein binding.*

For the case where the binding of a drug is decreased (*i.e.*, $f'_P > f_P$), it is clear from Eq. 9 that β'/β (or $t_{1/2}/t'_{1/2}$) is smaller than f'_P/f_P but approaches f'_P/f_P as f_P approaches zero or as f'_P approaches f_P. These latter conditions apply to drugs that normally are bound to a large extent or to situations where the decrease in binding is slight.

To illustrate the relationship between relative changes in the drug half-life and plasma protein binding, Fig. 1 was constructed based on Eq. 9 using different f_P values.

From Fig. 1, it is obvious that the relationship between β'/β and f'_P/f_P is almost linear, especially when the change in f_P is relatively small. For drugs that are predominantly plasma protein bound (*e.g.*, $f_P = 0.01$), the slope of the plot is approximately one, indicating that $t_{1/2}$ is inversely proportional to f_P. Although this simple, inverse proportionality vanishes with less extensively bound drugs, the almost linear relationship between β'/β and f'_P/f_P offers a means of rapid estimation of half-life changes as a result of altered plasma protein binding.

When the percentage change in f_P is relatively large, a more rapid loss of linearity in the curves is observed with increasing f_P. Fortunately, for drugs that initially are predominantly unbound, such large percentage increases in f_P are not possible. Furthermore, the β or half-life values of these drugs are relatively insensitive to changes in binding (Fig. 1), and adjustments in the dosage regimen to correct for binding changes may not be necessary.

BOOKS

REVIEWS

Foundations of Molecular Pharmacology, Vol. 1: Medicinal and Pharmaceutical Chemistry. By J. B. STENLAKE. The Athlone Press, University of London, Four Gower St., London WC1, England. 1979. 936 pp. 15 × 23 cm. Price $90.00.

It is easy to be enthusiastic about this well-crafted and scholarly book. The author skillfully leads us through a treatment of principles of organic chemistry applied to pharmaceutical agents. The organizational approach and its careful implementation consistently afford interesting reading.

The book is organized similar to an organic chemistry text. The medicinal agents are organized into 23 chapters by their organic chemical class; such groups as the alkanes, alkenes, benzenoid aromatic hydrocarbons, alkynes, and monohydric alcohols are included. Each chapter discusses the organic chemistry of the particular chemical class. The discussions generally are clear and succinct. The immediate pharmaceutical significance of the particular chemical property is illustrated by one or more examples from the pharmaceutical sciences. For example, following an explanation for the acidic nature of the acetylenic hydrogen atom, it is noted that the formation of a silver acetylide by the addition of silver nitrate is used as a test for identity and is the basis for the assay of some acetylenic pharmaceutical products such as ethclorvynol. Also, after a discussion of hydride reduction of aldehydes and ketones by lithium aluminum hydride and sodium borohydride, there ensues an account of the enzymatic reduction of these functional groups involving hydride donation from NADPH.

Almost all of the transitions from the general organic chemical discussion to the pharmaceutical application are made easily. Additionally, the particular pharmaceutical example usually is appropriate. One effect of this approach is to make the point repeatedly, without ever explicitly stating so, that knowledge of fundamental chemical properties is mandatory for an understanding of pharmaceutical procedures and pharmacological activities.

This reviewer has two minor criticisms relative to the author's pharmaceutical examples. There are several occasions when more appropriate pharmaceutical examples could have been presented. Also, the examples chosen could have been treated more in proportion to their importance. The following are instances in which these criticisms apply.

1. The decarboxylation of salicylic acid on bromination is discussed, but the decarboxylation of *p*-aminosalicylic acid in an acidic aqueous medium is not mentioned.
2. The structures of the amino acids GABA and taurine are given, but only GABA is cited as being an important transmitter.
3. Carbonic anhydrase-inhibiting sulfonamides are treated in detail, but benzothiazides are treated briefly.
4. The importance of ylids in synthesis is not developed.

However, these criticisms are minor, especially considering the great range of the book and the usually impressive appropriateness of the examples.

Medicinal and pharmaceutical chemists and many others in the pharmaceutical sciences should find this book to be an interesting and thought-provoking source of information. Additionally, teachers of medicinal and pharmaceutical chemistry may find that the volume is useful as a supplemental reference for both graduate and undergraduate students. Where the curriculum allows room for a course based on a format similar to that of the book (chemical class → chemical properties → pharmaceutical application), the book can serve as a textbook, although the cost is high.

Chlorophyll Organization and Energy Transfer in Photosynthesis. (Ciba Foundation Symposium 61.) Elsevier/North-Holland Inc., 52 Vanderbilt Ave., New York, NY 10017. 1979. 374 pp. 16 × 24 cm.

This symposium on chlorophyll organization and energy transfer in photosynthesis is a timely update of the basic processes through which plants and microorganisms contribute to the supply of nutritious food, high-quality feed, and fiber. This subject is especially important when one considers that the world population in 1930 reached 3 billion people and that by the year 2000, there will be about 7 billion people in the world. The projected increase underscores the need for a detailed understanding of the conversion of sun energy for sustaining the population growth.

On a more basic level, this symposium covers an important developing area of multidisciplinary science, yielding an updated concept of photosynthetic chemistry and mechanisms. Although many gaps remain in the isolation and characterization of chlorophyll–protein complexes, the symposium addresses itself to the more recent advances in this field.

The topics of the symposium include structure and function in photoreaction-center chlorophyll, properties of chlorophyll on plasticized polyethylene particles, the preparation and characterization of different types of light-harvesting pigment–protein complexes from certain purple bacteria, chlorophyll–protein complexes of brown algae, P700 reaction center and light-harvesting complexes, resonance Raman spectroscopy of chlorophyll–protein complexes, possible structures for chlorophyll, a diamer in Photosystem I of green plants delineated by polarized photochemistry, effects of ions and gravitational forces on the supramolecular organization and excitation energy distribution in chloroplast membranes, fluorescence of light-harvesting chlorophyll a/b–protein complexes, implications for the photosynthetic unit, energy transfer in a model of the photosynthetic unit, dynamics of excitons created by a single picosecond pulse, chlorophyll orientation and exciton migration in the photosynthetic membrane, tripartite and bipartite models of the photochemical apparatus of photosynthesis, picosecond fluorescence from photosynthetic systems *in vivo*, energy transfer and its dependence on membrane properties, quenching of chlorophyll fluorescence and photochemical activity of chloroplasts at low temperature, and transfer and trapping of excitation energy in Photosystem II.

Each topic is followed by an in-depth discussion by the participants, and the symposium is concluded with a general discussion which includes manganese and the evolution of oxygen; the state of chlorophyll in Photosystem I, Photosystem II, and the light-harvesting unit; the Grosser structure of chlorophyll–protein complexes; and comparison of the Paillotin–Swenberg kinetic theory and the Searle–Treswell empirical treatment.

For the most part, the chapters are well balanced and contain a wealth of information. I recommend this book for serious professionals concerned with basic aspects of chlorophyll organization and energy transfer in photosynthesis.

Drug Toxicity. Edited by J. W. GORROD. Taylor and Francis Ltd., 10–14 Macklin St., London WC2B 5WF, England. 1979. 326 pp. 15 × 23 cm.

This volume was compiled from lectures presented at the Aspects of Drug Toxicity Session of the Pharmaceutical Society of Great Britain's Easter School in April 1978. The book is a broad-based basic text in toxicology and is a companion volume to another text, Drug Metabolism in Man.

The opening chapter covers the production of toxic substances from the metabolic conversion of drugs and other foreign substances. This discussion is followed by three chapters indicating how these metabolic processes can be modified by physiological and pharmacological factors. Among the topics discussed are age- and species-specific developmental factors, genetics, and dietary factors, with emphasis placed on pharmacokinetic and metabolic considerations.

The theme of proprietary drug toxicity is introduced with a chapter on the influence of formulations on drug-induced side effects and potential toxic manifestations. This discussion is followed by a consideration of generalized toxicological consequences resulting from drug-induced enzyme induction and enzyme inhibition. Another generalized topic is found in a survey of possible neoplasia induction occurring as a consequence of drug therapy.

These organism-directed discussions are complemented by a series of papers dealing with the effects of drugs and other biologically active substances on specific organs and organ systems. The systems covered include the liver, the lungs, blood and blood-forming organs, the nervous system, the fetus, the optic system, and the skin. Two final chapters cover the development of potentially useful drugs from chemicals toxic to connective tissue and the development of untoward effects during treatment with radiopharmaceuticals.

This text is a balanced blend of the theoretical and practical aspects of drug toxicity. Each chapter is adequately referenced to provide interested individuals with sources of more detailed information. This book provides a well-organized introductory approach for newcomers to the field of toxicology and points them in the direction in which this field is moving.

Comprehensive Organic Chemistry. (A series of six volumes.) Edited by Sir D. BARTON and W. D. OLLIS. Pergamon, Oxford, England. 1979. 18.5 × 27.5 cm. Price $1250. Vol. 1: edited by J. F. STODDART, xiii + 1227 pp. Vol. 2: edited by I. O. SUTHERLAND, xiii + 1329 pp. Vol. 3: edited by D. N. JONES, xv + 1323 pp. Vol. 4: edited by P. G. SAMMES, xiii + 1228 pp. Vol. 5: edited by E. HASLAM, xv + 1205 pp. Vol 6: edited by C. J. DRAYTON, xv + 1628 pp.

The intent for publishing a work of this magnitude, encompassing over 8000 pages, was to provide a comprehensive and readable "work reflecting the current rapid development of modern organic chemistry." The result was perhaps not so much a comprehensive treatment of organic chemistry, as one would find in an encyclopedic series, as it is a comprehensible one, as hopefully stated by the volume editors. In addition to the anticipated treatment of the synthesis and reactions of organic compounds, the series attempts to relate the present development of organic chemistry to such developing subjects as biochemistry, inorganic chemistry, molecular biology, medicinal chemistry, and pharmacology. In this regard, the series was intended to be useful to those who employ the methods of organic chemistry in the study of both natural and synthetic compounds and their function in biological reactions. However, the presentation of organic chemistry as an intrinsic science also has been accomplished, and those facets of the subject that are essential to its present level of development are emphasized and adequately covered. E. Haslam states that the strength of organic chemistry does not lie in its naivete but in its rich diversity; this aspect of the science certainly is evident from the scope of topics selected for treatment.

An enumeration of the contents of the series should be of value to specialists and generalists alike. The treatment is based primarily on functional group chemistry but is presented throughout with the underlying mechanistic considerations. No separate section is devoted to theory, which the editors feel will "age" perhaps more quickly than the facts. The topics covered are arranged in 30 parts. Volume 1 includes a brief treatment of nomenclature and stereochemistry, followed by detailed discussions of hydrocarbons, halogen compounds, alcohols, phenols, ethers and related compounds, and aldehydes and ketones. The second volume is concerned with nitrogen-containing compounds, carboxylic acids and derivatives, and phosphorus compounds. Volume 3 treats organic compounds of sulfur, selenium, tellurium, silicon, and boron and organometallics.

Volume 4 involves heterocyclic compounds and gives a well-selected coverage of both common and uncommon heterocycles. Volume 5 is concerned mainly with compounds of biological importance: nucleic acids, amino acids, proteins, β-lactam antibiotics, enzyme catalysis, lipids, carbohydrates, synthesis of macromolecules, bioorganic chemistry including photosynthesis, and biosynthetic pathways. Volume 6 consists of formula, subject, author, reaction, and reagent indexes. This volume includes additional references, not specified in the text, for some of the subjects. About 20,000 references are cited in Volumes 1–5, and the literature up to mid 1978 generally is covered.

For a contemporary coverage of the entire subject of organic chemistry

Chlorophyll Organization and Energy Transfer in Photosynthesis. (Ciba Foundation Symposium 61.) Elsevier/North-Holland Inc., 52 Vanderbilt Ave., New York, NY 10017. 1979. 374 pp. 16 × 24 cm.

Another generalized topic is found in a survey of possible neoplasia induction occurring as a consequence of drug therapy.

These organism-directed discussions are complemented by a series of papers dealing with the effects of drugs and other biologically active substances on specific organs and organ systems. The systems covered include the liver, the lungs, blood and blood-forming organs, the nervous system, the fetus, the optic system, and the skin. Two final chapters cover the development of potentially useful drugs from chemicals toxic to connective tissue and the development of untoward effects during treatment with radiopharmaceuticals.

This text is a balanced blend of the theoretical and practical aspects of drug toxicity. Each chapter is adequately referenced to provide interested individuals with sources of more detailed information. This book provides a well-organized introductory approach for newcomers to the field of toxicology and points them in the direction in which this field is moving.

Comprehensive Organic Chemistry. (A series of six volumes.) Edited by Sir D. BARTON and W. D. OLLIS. Pergamon, Oxford, England. 1979. 18.5 × 27.5 cm. Price $1250. Vol. 1: edited by J. F. STODDART, xiii + 1227 pp. Vol. 2: edited by I. O. SUTHERLAND, xiii + 1329 pp. Vol. 3: edited by D. N. JONES, xv + 1323 pp. Vol. 4: edited by P. G. SAMMES, xiii + 1228 pp. Vol. 5: edited by E. HASLAM, xv + 1205 pp. Vol 6: edited by C. J. DRAYTON, xv + 1628 pp.

The intent for publishing a work of this magnitude, encompassing over 8000 pages, was to provide a comprehensive and readable "work reflecting the current rapid development of modern organic chemistry." The result was perhaps not so much a comprehensive treatment of organic chemistry, as one would find in an encyclopedic series, as it is a comprehensible one, as hopefully stated by the volume editors. In addition to the anticipated treatment of the synthesis and reactions of organic compounds, the series attempts to relate the present development of organic chemistry to such developing subjects as biochemistry, inorganic chemistry, molecular biology, medicinal chemistry, and pharmacology. In this regard, the series was intended to be useful to those who employ the methods of organic chemistry in the study of both natural and synthetic compounds and their function in biological reactions. However, the presentation of organic chemistry as an intrinsic science also has been accomplished, and those facets of the subject that are essential to its present level of development are emphasized and adequately covered. E. Haslam states that the strength of organic chemistry does not lie in its naivete but in its rich diversity; this aspect of the science certainly is evident from the scope of topics selected for treatment.

An enumeration of the contents of the series should be of value to specialists and generalists alike. The treatment is based primarily on functional group chemistry but is presented throughout with the underlying mechanistic considerations. No separate section is devoted to theory, which the editors feel will "age" perhaps more quickly than the facts. The topics covered are arranged in 30 parts. Volume 1 includes a brief treatment of nomenclature and stereochemistry, followed by detailed discussions of hydrocarbons, halogen compounds, alcohols, phenols, ethers and related compounds, and aldehydes and ketones. The second volume is concerned with nitrogen-containing compounds, carboxylic acids and derivatives, and phosphorus compounds. Volume 3 treats organic compounds of sulfur, selenium, tellurium, silicon, and boron and organometallics.

Volume 4 involves heterocyclic compounds and gives a well-selected coverage of both common and uncommon heterocycles. Volume 5 is concerned mainly with compounds of biological importance: nucleic acids, amino acids, proteins, β-lactam antibiotics, enzyme catalysis, lipids, carbohydrates, synthesis of macromolecules, bioorganic chemistry including photosynthesis, and biosynthetic pathways. Volume 6 consists of formula, subject, author, reaction, and reagent indexes. This volume includes additional references, not specified in the text, for some of the subjects. About 20,000 references are cited in Volumes 1–5, and the literature up to mid 1978 generally is covered.

For a contemporary coverage of the entire subject of organic chemistry

Chlorophyll Organization and Energy Transfer in Photosynthesis. (Ciba Foundation Symposium 61.) Elsevier/North-Holland Inc., 52 Vanderbilt Ave., New York, NY 10017. 1979. 374 pp. 16 × 24 cm.

This symposium on chlorophyll organization and energy transfer in photosynthesis is a timely update of the basic processes through which plants and microorganisms contribute to the supply of nutritious food, high-quality feed, and fiber. This subject is especially important when one considers that the world population in 1930 reached 3 billion people and that by the year 2000, there will be about 7 billion people in the world. The projected increase underscores the need for a detailed understanding of the conversion of sun energy for sustaining the population growth.

On a more basic level, this symposium covers an important developing area of multidisciplinary science, yielding an updated concept of photosynthetic chemistry and mechanisms. Although many gaps remain in the isolation and characterization of chlorophyll–protein complexes, the symposium addresses itself to the more recent advances in this field.

The topics of the symposium include structure and function in photoreaction-center chlorophyll, properties of chlorophyll on plasticized polyethylene particles, the preparation and characterization of different types of light-harvesting pigment–protein complexes from certain purple bacteria, chlorophyll–protein complexes of brown algae, P700 reaction center and light-harvesting complexes, resonance Raman spectroscopy of chlorophyll–protein complexes, possible structures for chlorophyll, a diamer in Photosystem I of green plants delineated by polarized photochemistry, effects of ions and gravitational forces on the supramolecular organization and excitation energy distribution in chloroplast membranes, fluorescence of light-harvesting chlorophyll a/b–protein complexes, implications for the photosynthetic unit, energy transfer in a model of the photosynthetic unit, dynamics of excitons created by a single picosecond pulse, chlorophyll orientation and exciton migration in the photosynthetic membrane, tripartite and bipartite models of the photochemical apparatus of photosynthesis, picosecond fluorescence from photosynthetic systems *in vivo*, energy transfer and its dependence on membrane properties, quenching of chlorophyll fluorescence and photochemical activity of chloroplasts at low temperature, and transfer and trapping of excitation energy in Photosystem II.

Each topic is followed by an in-depth discussion by the participants, and the symposium is concluded with a general discussion which includes manganese and the evolution of oxygen; the state of chlorophyll in Photosystem I, Photosystem II, and the light-harvesting unit; the Grosser structure of chlorophyll–protein complexes; and comparison of the Paillotin–Swenberg kinetic theory and the Searle–Treswell empirical treatment.

For the most part, the chapters are well balanced and contain a wealth of information. I recommend this book for serious professionals concerned with basic aspects of chlorophyll organization and energy transfer in photosynthesis.

Drug Toxicity. Edited by J. W. GORROD. Taylor and Francis Ltd., 10–14 Macklin St., London WC2B 5WF, England. 1979. 326 pp. 15 × 23 cm.

This volume was compiled from lectures presented at the Aspects of Drug Toxicity Session of the Pharmaceutical Society of Great Britain's Easter School in April 1978. The book is a broad-based basic text in toxicology and is a companion volume to another text, Drug Metabolism in Man.

The opening chapter covers the production of toxic substances from the metabolic conversion of drugs and other foreign substances. This discussion is followed by three chapters indicating how these metabolic processes can be modified by physiological and pharmacological factors. Among the topics discussed are age- and species-specific developmental factors, genetics, and dietary factors, with emphasis placed on pharmacokinetic and metabolic considerations.

The theme of proprietary drug toxicity is introduced with a chapter on the influence of formulations on drug-induced side effects and potential toxic manifestations. This discussion is followed by a consideration of generalized toxicological consequences resulting from drug-induced enzyme induction and enzyme inhibition. Another generalized topic is found in a survey of possible neoplasia induction occurring as a consequence of drug therapy.

These organism-directed discussions are complemented by a series of papers dealing with the effects of drugs and other biologically active substances on specific organs and organ systems. The systems covered include the liver, the lungs, blood and blood-forming organs, the nervous system, the fetus, the optic system, and the skin. Two final chapters cover the development of potentially useful drugs from chemicals toxic to connective tissue and the development of untoward effects during treatment with radiopharmaceuticals.

For a contemporary coverage of the entire subject of organic chemistry

and its interrelations with biochemistry, this series perhaps should be the first source consulted. Further detail may be located in monographs on specific topics; but for a comprehensive view of any general topic in organic chemistry, this series should be quite useful. Although the authors were faced with a formidable problem of selecting the most important topics, the series overall has a sufficient balance of new and old information to be of value for some time. For a relatively complete treatment of developments during the past two decades, this series probably is unchallenged by any single work; it represents a reasonable compromise between specialization and encyclopedism.

To the medicinal chemist, the extensive treatment of the newer methods of organic synthesis will be of great interest. Volume 5, which comprises naturally occurring compounds, enzyme catalysis, and biosynthetic pathways, should be of interest to all pharmaceutical scientists. Although relatively few examples of detailed mechanisms of enzyme catalysis are included, or known, the present understanding of the underlying factors is discussed well. The coverage of sulfur chemistry (vol. 3), usually deficient in most general texts on organic chemistry, is remarkably complete. The nitrogen heterocycles (vol. 4) also are given a more extensive treatment than some topics.

This series can be recommended for libraries in pharmacy colleges and in the pharmaceutical industry; the cost of the volumes, of course, would deter the individual purchaser. It is hoped that revisions of this series will be made, retaining the stated goal of keeping the science of organic chemistry comprehensible to those who use it.

Computer Assisted Studies of Chemical Structure and Biological Function. By A. J. STUPER, W. E. BRÜGGER, and P. C. JURS. Wiley, One Wiley Drive, Somerset, NJ 08873. 1979. xi + 220 pp. 16 × 23 cm. Price $23.50.

This book provides a convenient introduction to pattern recognition techniques. It is very well written and sufficiently referenced to allow interested persons access to pertinent literature for more in-depth studies. Preprocessing and classification methods are summarized. Various means of generating molecular descriptions also are described. The methods are applied to tranquilizers and sedatives and to musk and trigeminally active odorants.

This book describes some of the methods used in pattern recognition studies. However, it is inappropriate to view the book as a "how-to-do-it" introduction to pattern recognition. While the algorithms are available, the most appropriate application of these algorithms to biological data still is a developing area. This book should stimulate additional research in this regard.

Antibiotics: Isolation, Separation, and Purification. Edited by MARVIN J. WEINSTEIN and GERALD H. WAGMAN. (Journal of Chromatography Library, Vol. 15.) Elsevier/North-Holland Inc., 52 Vanderbilt Ave., New York, NY 10017. 1978. 769 pp. 16 × 24 cm. Price $84.75.

At first glance, this 15th volume of the Journal of Chromatography Library appears to be an ambitious attempt to describe the isolation, separation, and purification of most of the known antibiotics. The publication contains 17 chapters, each of which is devoted to a group of chemically related antibiotics. Each chapter was written by a different contributor. The editors selected the authors for their competence and knowledge in their respective areas.

The book covers therapeutically useful drugs such as the penicillins, cephalosporins, griseofulvins, lincomycins, macrolide antibiotics, peptide antibiotics, tetracyclines, 2-deoxystreptamine-containing antibiotics, and actinomycins, as well as groups of less well-known antibiotics such as the ansamycins, siderchromes, streptothricins, polyethers, and marine and plant-derived antibiotics.

The contribution by scientists who are knowledgeable in their respective fields is the strength of this publication. However, multiple authorship often leads to variations in the format of the chapters and to unevenness in the depth of the discussions of the antibiotic groups. All of the authors cover in one form or another the subject matter of this volume; in many cases, useful additional information concerning the chemistry, physical characteristics, and therapeutic uses of the antibiotics is included.

The book is not encyclopedic in its coverage; although the naturally occurring penicillins are described, the semisynthetic penicillins are not included. The antitumor drugs, which are considered to be antibiotics in this country, also are not included. Discussions of polymyxin and bacitracin are not among the polypeptide antibiotics. Coverage in some areas appears to be sparse. The contributor for the tetracycline antibiotics included only 52 references for this important class of antibiotics, whereas the author of the streptothricins chapter made reference to 225 publications.

Overall, the publication brings together a lot of useful information, especially in the areas of the less well-known antibiotic groups.

AN EFFORT TO CREATE NEW UNDERSTANDINGS

This month, from July 20–24, many of our pharmacy school educators will be gathering in Boston, Massachusetts, to attend and to participate in the annual meeting of the American Association of Colleges of Pharmacy.

What makes this meeting noteworthy, in our opinion, is the theme topic that will be featured at this year's conference. The AACP utilizes a three-year sequence in issues for policy consideration. This process entails, in turn, (*a*) introducing for review, (*b*) subjecting to study, and (*c*) adopting a position or making a decision regarding each particular issue.

The theme topic for intensive consideration at this 1980 session is entitled "Bridging the Gap Between the Basic Sciences and Clinical Practice: Teaching, Research, and Service." Because of the interest of our readership—as well as our own personal interest—in the basic sciences, we are gratified that the AACP has chosen this theme for current intensive review and study.

Over the years, the respective educational elements of teaching, research, and service have been accorded varying degrees of emphasis in pharmacy academic circles. Indeed, this has happened to the extent that one or the other of the three elements has been given short-shrift in the process, while one of the other two elements has been lavished with attention, funds, and other scarce resources.

Such imbalance has prompted the more observant and concerned pharmacy leaders to voice some alarm and to suggest that, as in the case of a tripod or a three-legged stool, it is critical that all three supporting legs are of relatively equivalent strength if the load is to be properly held in place.

But despite recognizing this need, and despite apparent attempts to provide the desired equilibrium of support, a decided gap has developed between the basic sciences educators and clinical practice educators. The gap seems to have begun to form many years ago when some pharmacy schools began offering advanced degrees; in the process, at least a number of them began to neglect their first mission of undergraduate education. An attitude of disdain even became evident on the part of some faculty members—they wished to have as little as possible to do with the teaching of undergraduate students. In turn, this attitude seemed to evolve into a somewhat comparable but broader disdain for pharmacy practitioners and pharmacy practice, because these were equated with undergraduate—rather than graduate—training and education.

However, about 15 years ago, the pendulum began to swing back as clinical pharmacy first made its appearance in our pharmacy schools and as it subsequently proceeded to spread nationally within just a few short years.

Depending upon the particular pharmacy school, and depending upon the views of the particular people involved, one now hears that in many cases the basic sciences have been drastically downgraded to the point that students at those schools are receiving very inferior training in the sciences. And conversely, others will describe the reverse situation, claiming that too much emphasis is still being accorded the basic sciences and not sufficient attention is devoted to the clinical aspects.

In the competition for resources and the jockeying for position that have ensued, a very unfortunate further development has occurred within many pharmacy school faculties. Basically, a virtual schism has been created between the respective groups of faculty personnel. This split goes beyond the traditional fierce but good-natured rivalry. It appears to be a growing and deeply felt resentment of each group for the other. Moreover, it shows signs of increasing rather than diminishing in its intensity.

Perhaps for this reason, the fact that the AACP meeting in Boston will focus on bridging the science–practice gap becomes all the more important. If open study, debate, and discussion can be successful in bridging this professional strife among our faculty people, such will be a most significant accomplishment. Otherwise, if this schism—with its associated jealousy, back-biting, and squabbling—continues and escalates, we are faced with the eventual prospect that our educational system will literally tear itself apart. Needless to say, that would be tragic for the future of pharmacy in America.

AN EFFORT TO CREATE NEW UNDERSTANDINGS

This month, from July 20–24, many of our pharmacy school educators will be gathering in Boston, Massachusetts, to attend and to participate in the annual meeting of the American Association of Colleges of Pharmacy.

What makes this meeting noteworthy, in our opinion, is the theme topic that will be featured at this year's conference. The AACP utilizes a three-year sequence in issues for policy consideration. This process entails, in turn, (*a*) introducing for review, (*b*) subjecting to study, and (*c*) adopting a position or making a decision regarding each particular issue.

The theme topic for intensive consideration at this 1980 session is entitled "Bridging the Gap Between the Basic Sciences and Clinical Practice: Teaching, Research, and Service." Because of the interest of our readership—as well as our own personal interest—in the basic sciences, we are gratified that the AACP has chosen this theme for current intensive review and study.

Over the years, the respective educational elements of teaching, research, and service have been accorded varying degrees of emphasis in pharmacy academic circles. Indeed, this has happened to the extent that one or the other of the three elements has been given short-shrift in the process, while one of the other two elements has been lavished with attention, funds, and other scarce resources.

Such imbalance has prompted the more observant and concerned pharmacy leaders to voice some alarm and to suggest that, as in the case of a tripod or a three-legged stool, it is critical that all three supporting legs are of relatively equivalent strength if the load is to be properly held in place.

But despite recognizing this need, and despite apparent attempts to provide the desired equilibrium of support, a decided gap has developed between the basic sciences educators and clinical practice educators. The gap seems to have begun to form many years ago when some pharmacy schools began offering advanced degrees; in the process, at least a number of them began to neglect their first mission of undergraduate education. An attitude of disdain even became evident on the part of some faculty members—they wished to have as little as possible to do with the teaching of undergraduate students. In turn, this attitude seemed to evolve into a somewhat comparable but broader disdain for pharmacy practitioners and pharmacy practice, because these were equated with undergraduate—rather than graduate—training and education.

However, about 15 years ago, the pendulum began to swing back as clinical pharmacy first made its appearance in our pharmacy schools and as it subsequently proceeded to spread nationally within just a few short years.

Depending upon the particular pharmacy school, and depending upon the views of the particular people involved, one now hears that in many cases the basic sciences have been drastically downgraded to the point that students at those schools are receiving very inferior training in the sciences. And conversely, others will describe the reverse situation, claiming that too much emphasis is still being accorded the basic sciences and not sufficient attention is devoted to the clinical aspects.

In the competition for resources and the jockeying for position that have ensued, a very unfortunate further development has occurred within many pharmacy school faculties. Basically, a virtual schism has been created between the respective groups of faculty personnel. This split goes beyond the traditional fierce but good-natured rivalry. It appears to be a growing and deeply felt resentment of each group for the other. Moreover, it shows signs of increasing rather than diminishing in its intensity.

Perhaps for this reason, the fact that the AACP meeting in Boston will focus on bridging the science–practice gap becomes all the more important. If open study, debate, and discussion can be successful in bridging this professional strife among our faculty people, such will be a most significant accomplishment. Otherwise, if this schism—with its associated jealousy, back-biting, and squabbling—continues and escalates, we are faced with the eventual prospect that our educational system will literally tear itself apart. Needless to say, that would be tragic for the future of pharmacy in America.

RESEARCH ARTICLES

Clearance of ^{141}Ce-Labeled Microspheres from Blood and Distribution in Specific Organs following Intravenous and Intraarterial Administration in Beagle Dogs

MOTOKO KANKE *, GUY H. SIMMONS, DANIEL L. WEISS ‡, BRACK A. BIVINS, and PATRICK P. DeLUCA ˣ

Received July 26, 1979, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication March 3, 1980. *Present address: Kitasato University, Yokahama, Japan. ‡National Research Council, National Academy of Sciences, Washington, DC 20418.

Abstract □ The clearance of ^{141}Ce-labeled polystyrene divinylbenzene microspheres in the 3–12-μm diameter size range following intravascular administration was found to be size dependent, with the larger spheres clearing the circulation most rapidly. With spheres of high specific activity, dynamic distribution in various organs was determined by continuous whole-body scanning for the 1st hr after administration and by static imaging at selected times thereafter up to 4 weeks. The 7- and 12-μm spheres were filtered mechanically and retained for prolonged periods in the lungs, while the 3- and 5-μm spheres localized and were retained in the liver and spleen. Localization of these smaller spheres appeared to be due to phagocytosis by cells of the reticuloendothelial system; with the 12-μm spheres, there was no evidence of phagocytosis by the pulmonary macrophages of the reticuloendothelial system within 4 weeks postadministration. Intraarterially administered larger microspheres did not show any significantly different distribution patterns from those administered intravenously. Histological examination revealed occasional vascular engorgement about the site of multiple-sphere lodgment, but no destructive tissue phenomenon was apparent in relation to the lodgment of the microspheres.

Keyphrases □ Microspheres—cerium 141 labeled, clearance from blood and distribution in specific organs following intravenous and intraarterial administration, dogs □ Clearance—^{141}Ce-labeled microspheres, clearance from blood following intravenous and intraarterial administration, dogs □ Distribution—^{141}Ce-labeled microspheres, distribution in specific organs following intravenous and intraarterial administration, dogs

Particulate matter found in injectable fluids and drugs has been a cause of concern to both the pharmaceutical industry and the medical practitioner (1–9). Until recently, most research efforts were directed at the amounts, origins, and physical properties of the particulates in parenteral drugs (10–15). Removal of these contaminants with final filters significantly reduces the incidence of infusion phlebitis, a local inflammatory process associated with intravenous fluid administration (16–20). Although some reports suggested that foreign particulates in parenteral fluids may be hazardous, relatively little is known about distribution, relocation, and tissue effects of particulates entering the vascular system.

The possible effects and fate of injected model particulate matter recently were evaluated methodically as a function of the size and number administered intravenously to beagle dogs (21, 22). Of the size ranges chosen for these studies (microspheres of 3, 8, 15, and 25 μm in diameter), only the 3-μm model particles appeared to clear the lung capillary bed after an initial retention period and eventually relocated in the liver and spleen where they remained indefinitely. Although the studies yielded useful information about the ultimate fate of the microspheres, no definitive information concerning the dynamics of this relocation was obtained.

Since the previous study showed that relocation was limited to the smaller spheres, the purpose of this investigation was to obtain a clearer understanding of the time dependency of the observed relocation of a narrower range of microspheres injected intravenously and intraarterially. Four microsphere sizes in the 3–12-μm range were selected and were of higher specific activity than the ones used previously. Additionally, a more intensive histological examination was conducted on specific tissues at various intervals to assess the location of spheres, tissue loads, and possible tissue damage.

EXPERIMENTAL

Microspheres—Polystyrene divinylbenzene microspheres[1] labeled with cerium 141 were obtained as suspensions in normal saline. These

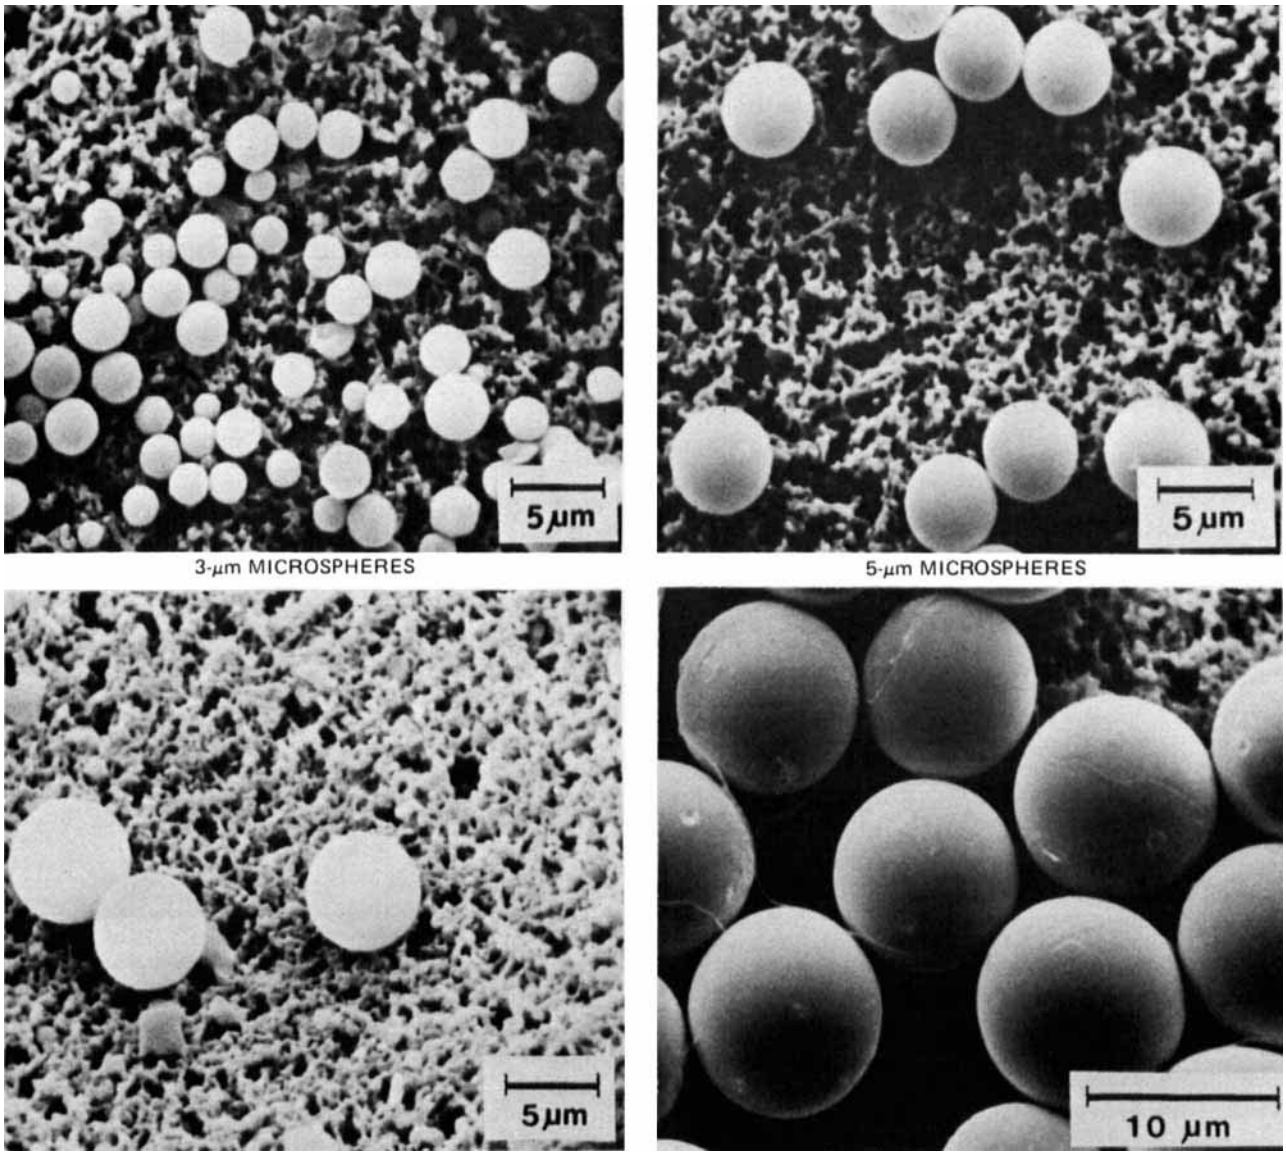

Figure 1—*Scanning electron micrographs of polystyrene divinylbenzene microspheres labeled with cerium 141 at 20 kv (2400× magnification).*

microspheres are shown in the scanning electron microscope photomicrographs in Fig. 1. The specific activity was ~50 mCi/g, five times higher than that used previously (21) to allow for more frequent scanning as well as blood level determinations using small blood samples. The size and number of spheres were controlled using an electronic particle counter[2] and microscopic[3] monitoring.

The permanency of the radioactive tag was checked by filtration of a sample using a 0.45-μm filter and monitoring of the filtrate for activity. Additionally, urine and feces excreted from the first dog of each sphere-size group were collected during the 1st day and analyzed for radioactivity. Analysis of the filtrate and excreta confirmed the permanency of the radioactive tag.

Dose Preparation—Following ultrasonic treatment of the spheres for at least 5 min as well as occasional agitation by hand, doses were drawn into a syringe; the radioactivity was checked with a radioisotope calibrator[4] prior to administration.

Preparation of Experimental Animals—The beagle dogs were 2–3-year-old purebred females weighing 8.1–12.5 kg. The dogs were anesthetized with pentobarbital sodium at a dose of 30 mg/kg iv, and a 20-gauge needle equipped with a three-way stopcock was inserted into the radial veins of the left and right forelegs for intravenous dosing and blood sampling, respectively. For intraarterial administration, a cannula was threaded from the common carotid artery into the left ventricle. The placement of the cannula was verified by demonstration of a left ventricular pressure curve *via* a transducer–recorder hookup.

Each dog was restrained in a supine position on a hard board, placed under a scintillation camera[5], and positioned to align the chest and abdomen for imaging. After completion of imaging, the dogs that had a cannula inserted were given antibiotic prophylaxis with penicillin G procaine at 400,000–1,000,000 units/day im for 1–3 days.

Dose Administration—The size and number of microspheres administered to the beagle dogs are listed in Table I. The prepared dose of microspheres was administered directly from the syringe through the stopcock over 2 min. The syringe and cannula were flushed with 20 ml of sterile water for injection through the stopcock, completing the injection.

Animals were sacrificed at 20 min, 1 hr, 24 hr, or 4 weeks after administration.

Mode of Imaging—For whole-body scanning, the scintillation camera was interfaced to a digital computer[6]. Immediately following dosing, serial images of the chest and abdomen were recorded at the rate of 12 frames/min for the first 2 min followed by 2 frames/min for the next 58 min. Delayed static images were recorded at 2 and 24 hr and 1, 2, and 4

weeks following microsphere administration. All data were stored on magnetic tapes for review and analysis.

Determination of Distribution—Microsphere distributions were determined externally by flagging individual organs using computer-generated images and integrating the counts within each flagged area.

Specific intact organs, including the lungs, liver, spleen, heart, kidneys, brain, and tongue, were removed following sacrifice and scanned individually with the scintillation camera to quantitate the distribution at specific times. Efficiency values with units of counts per minute per microcurie were determined for each organ by adding a known amount of radioactivity to a plastic bag filled with an amount of water equivalent to the mass of the organ. The bag was shaped to simulate the shape of the organ and scanned in the same geometry as the excised organ.

Following the intact organ scanning, small specimens were removed from each organ for histological examination, and the remainder of the organ then was homogenized with a known amount of distilled water in a blender[7]. A 5-ml rubber-top container[8] was 70% filled with an aliquot of the homogenized sample and weighed. One to five samples were prepared for each organ and analyzed using a well-type γ-counter[9]. The counter efficiency was determined beforehand utilizing a known amount of radioactivity.

Blood Level Determination—Approximately 1–2 ml of venous blood was removed immediately after dose administration and at frequent intervals during the initial stage of each run. Total emissions of a weighed

blood sample were counted by a well-type γ-counter for 10 min.

Histological Evaluation—Specific tissue specimens, ~10 × 20 × 3 mm, were cut from the organs listed in Table II. The tissues were processed through formaldehyde fixation, paraffin embedding, and staining with hematoxylin and eosin. Slide preparations 5–14 μm thick were prepared, depending on the size of the microspheres. Direct blood smears and buffy coat smears were prepared with blood samples obtained immediately after dose administration and immediately before sacrifice.

RESULTS

Distribution Patterns—Whole-body scanning showed that almost all of the radioactivity was localized in the central region, with especially high concentrations in the lungs, liver, and spleen. A set of typical temporal distribution curves for these three organs obtained from rapid frame sequential scanning for the first 60 min is shown in Fig. 2. Although the curves were corrected for differences in administered activity, due to the

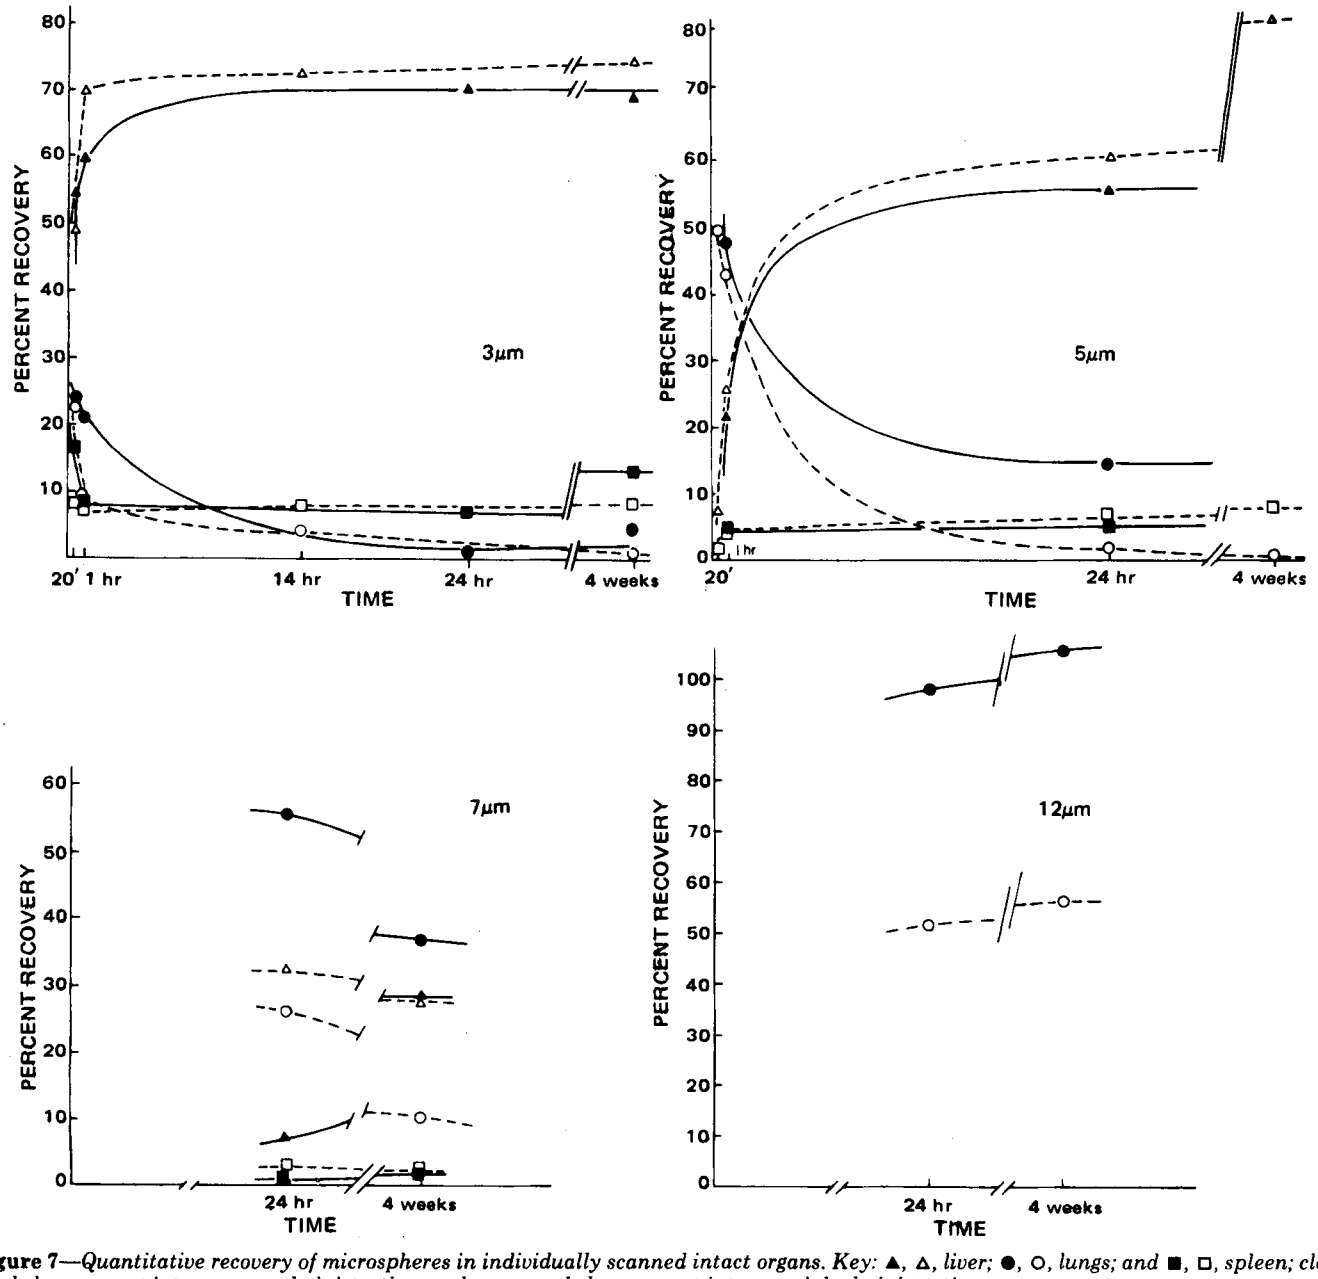

Figure 7—*Quantitative recovery of microspheres in individually scanned intact organs. Key: ▲, △, liver; ●, ○, lungs; and ■, □, spleen; closed symbols represent intravenous administration, and open symbols represent intraarterial administration.*

difficulty in isolating entire organ profiles resulting from organ overlap, only relative counts and not absolute uptake values are shown. However, the curves demonstrate the general distribution over the first 60 min.

No clearcut difference in distribution patterns was observed between intravenous and intraarterial administration of microspheres. With the 3-μm microspheres injected in nine dogs, there was an initial distribution to the lungs followed by rapid clearance from the lungs and localization in the liver and spleen. Six of eight dogs injected with 5-μm spheres exhibited similar lung patterns. With the 7-μm microspheres, retention in the lungs was greater and clearance was more gradual in all five dogs injected. On the other hand, all of the 12-μm microspheres were retained in the lungs.

Following the dynamic imaging for the initial 60 min, static images were recorded from the live animal at 2 and 24 hr and 1, 2, and 4 weeks after dose administration. The relative retention curves for the lungs and liver following either intravenous or intraarterial administration obtained by such external imaging are shown in Figs. 3–6. The 12-μm microspheres distributed only to the lungs regardless of the administration route and were retained in the lung area even at 4 weeks after administration.

Quantitative Determination of Distribution—Following sacrifice, specific organs including the lungs, liver, spleen, heart, kidneys, brain, and tongue were removed and scanned by the scintillation camera. The results are listed in Table III and plotted in Fig. 7. The analyzed data of uniformly homogenized organs are listed in Table IV.

The 3-μm spheres were cleared from the lungs and localized in the liver much more readily than the 5-μm spheres. Within 24 hr, >95% of the 3- and 5-μm spheres appeared to have passed from the lungs of all dogs except one of the 5-μm group, where 12–14% of the microsphere dose was retained in the lungs. Clearance of the 7-μm spheres from the lungs following intravenous administration was much slower than that with the smaller sizes. After 24 hr, over 43% of the dose was still in the lungs and only 7% had localized in the liver. However, after 4 weeks, only 26–37% of the microspheres administered intravenously remained in the lungs, and the level in the liver increased to 20–28%. The 12-μm spheres were not detected outside of the lungs after 24 hr following intravenous administration in dogs that were followed for up to 4 weeks.

There were no significant differences in distribution of the 3- and 5-μm spheres between intravenous and intraarterial administration, but some differences were observed with larger spheres. The 12-μm spheres administered intraarterially were retained in the lungs for at least 4 weeks. A major difference between the intravenous and intraarterial administration with the 12-μm size was that some spheres were detected in the brain and tongue after intraarterial administration.

The results obtained from the two quantitative recovery methods were reasonably close to each other. Therefore, the quantitative determination by imaging the intact organs was chosen as being easier and quicker than the homogenized method.

Blood Levels—Figure 8 shows the typical blood levels of the microspheres over a 2-hr period following intravenous or intraarterial administration. Elimination of spheres from the circulating blood pool appeared to be size dependent and more rapid with larger sizes. The blood levels of 12-μm spheres were essentially the same as background levels within 2 hr after administration, while the 3-μm spheres recirculated longer and maintained higher blood levels than did the larger sizes. The number of spheres administered within the size and volume ranges tested appeared to have no effect on the elimination rate from the blood.

Most curves in Fig. 8 show an increase in blood activity between 10 and 30 min after administration. This phenomenon is not explained easily, and more frequent blood sampling is required to define this portion of the curves.

Histology Data—A histological study of representative tissue samples from multiple organs was undertaken (Table II). Identification of microspheres was facilitated by examination under green and red filtered light. Under these conditions (Fig. 9), the microspheres appear as dense black spheres of smooth regular outline. Therefore, the spheres may be distinguished from cell nuclei, even when samples containing smaller spheres of approximately the same diameter as cell nuclei are evaluated.

Individual 3- and 5-μm microspheres were found consistently in vascular channels, Kupffer cells, and the sinusoids of the liver, spleen, and bone marrow within phagocytizing cells. The cells were vascular endothelium, monocytoid phagocytes, or cells of the reticuloendothelial system. There was moderate engorgement of the sinusoids, which were slightly distended and congested. No multinucleated giant cells appeared to participate in the phagocytic activity.

Larger microspheres and clusters of smaller spheres generally lay free in vascular and sinusoidal channels. A few 7-μm microspheres were phagocytized, but these microspheres represented <10% of the total tissue loads. Figure 9*c* shows three single spheres within slightly distended Kupffer cells. The histology of the liver is inconspicuous except for mild congestion. Figure 9*d* shows a single 12-μm sphere lodged in the pulmonary capillary, and slight engorgement of pulmonary vasculature is evident. The buffy coat smears were all negative, with two exceptions: one dog administered 3-μm spheres and one administered 5-μm spheres showed one and two spheres, respectively, in their buffy coats obtained immediately after injection. While this finding attests to the validity of the procedure, it does not provide information on the subsequent distribution characteristics.

Although occasional vascular engorgement was present around the site of multiple-sphere lodgment and may represent a local hemodynamic response to partial blockage of the vascular channels, destructive tissue phenomena were not seen in relation to the lodgment of the microspheres.

DISCUSSION

These studies confirm that clearance of microspheres from the blood following intravascular injection is size dependent, with the larger diameter spheres clearing most rapidly (Fig. 8). The initial clearance appears to be due to a simple filter effect of the pulmonary capillary beds, although vascular constriction and venous sphincters may play some role in the trapping process. Spheres of 7-μm diameter and larger initially were retained in the lungs, while large numbers of the 3- and 5-μm spheres

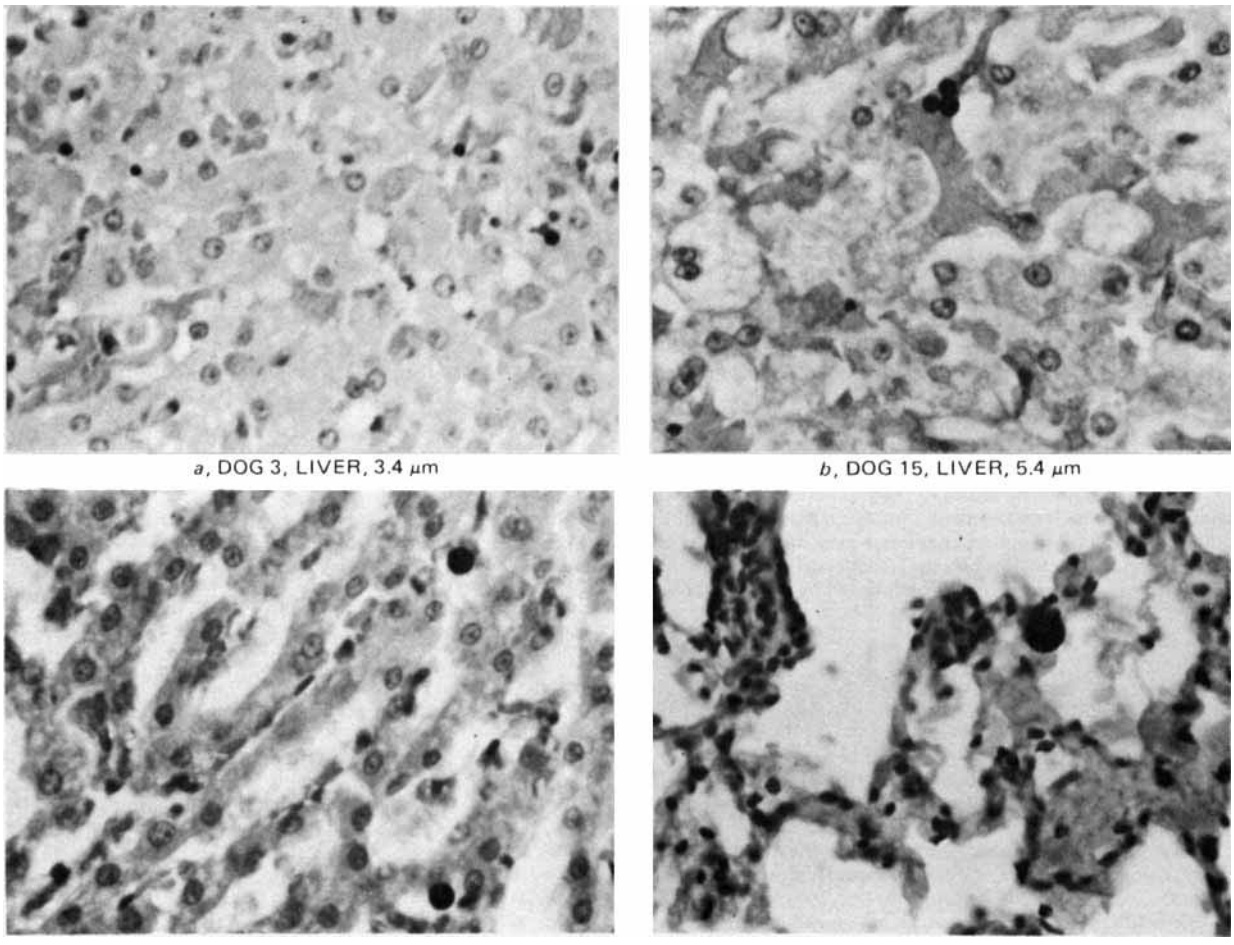

Figure 9—*Photomicrographs of tissue samples. Key:* a, *3-μm spheres in liver;* b, *5-μm spheres in liver;* c, *7-μm spheres in liver; and* d, *12-μm spheres in lungs. Obtained with hematoxylin and eosin stain (160×).*

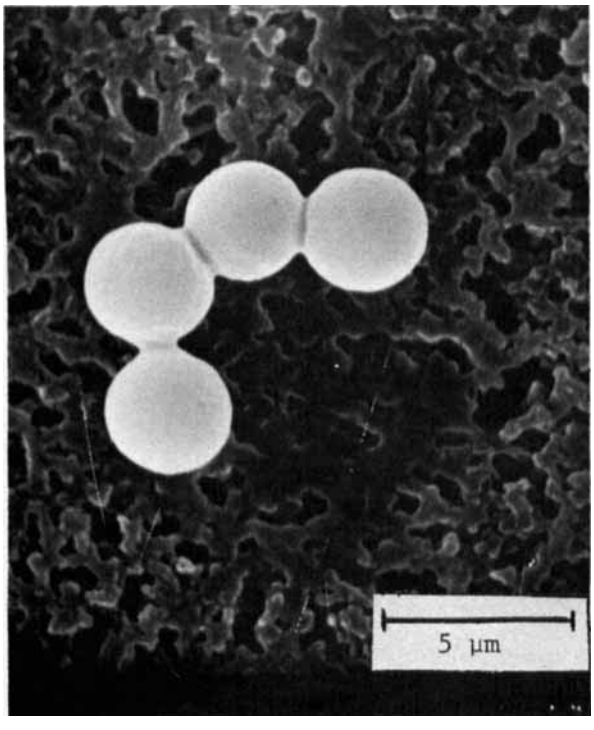

Figure 10—*Scanning electron photomicrograph of 3-μm microspheres from a venous blood sample 1 hr following administration at 20 kv (5000× magnification).*

passed through, implying a critical circulation diameter for nondeformable particles reaching the pulmonary vascular bed.

The increase in blood activity seen between 10 and 30 min following administration of the spheres may be due to washout within the lungs so that spheres initially trapped are washed through opening arteriovenous shunts to recirculate in the bloodstream (Fig. 8). Although 98–99% of the spheres were cleared from the circulation in 10–30 min, blood sampling over the first 2 hr following administration revealed concentrations of 10^4 3-μm spheres, 100–1000 5-μm spheres, 10–100 7-μm spheres, and less than one 12-μm sphere/g of blood. The possible association of the spheres with circulating blood cells warrants further attention and will be undertaken with more sophisticated scanning electron microscopic procedures.

Distribution patterns varied with the sphere size studied and became complex over time. With the 3-μm spheres and in six of eight dogs with the 5-μm spheres, there was initial distribution to the lungs followed by rapid clearance, with localization and retention in the liver and spleen peaking within 20 min of administration for the 3-μm spheres and within 24 hr for the 5-μm spheres (Tables III and IV). This retention is explained by the histological observation of phagocytosis of the 3- and 5-μm spheres by the Kupffer cells of the liver and the sinusoidal lining of the spleen (23, 24).

Clearance of the 7-μm spheres from the lungs to the liver and spleen occurred much more slowly, with 26–37% remaining in the lungs at 4 weeks. This slow migration may be due to retention in the lungs with phagocytosis by pulmonary macrophages and subsequent migration to the reticuloendothelial system. The 12-μm spheres were retained in the lungs from the initial injection throughout the study. Failure of the 12-μm spheres to undergo phagocytosis and relocation may indicate a size limit for phagocytosis of inert particles (25).

No clearcut differences in the clearance or distribution of the 3- and 5-μm spheres were observed between intraarterial and intravenous administration (Fig. 8 and Tables III and IV). For reasons that are not clear, these spheres either passed through or did not enter muscular or visceral

beds following intraarterial administration and recirculated as if they had been injected into the venous system. Minimal differences were seen between intravenous and intraarterial administration of the larger spheres, but 12-μm spheres were detected in the brain and tongue following intraarterial administration. These observations were contrary to expectations and suggest that the flow characteristics of the spheres are such that distribution to peripheral and visceral capillary beds is limited.

In many cases, the 3-μm spheres were seen microscopically to lodge in the studied tissues as agglomerated masses of three to 10 spheres. This property was observed less frequently with the 5-μm spheres and not at all with the 7- and 12-μm spheres. The light microscopy observations did not indicate any significant damage of cells containing the spheres at the substructural or functional levels. Progress in answering these questions will depend on enzyme biochemistry and electron microscopy studies.

Figure 10 shows a cluster of 3-μm microspheres from a venous blood sample obtained 1 hr after administration. Although further investigation is required to clarify this clustering phenomenon, the microspheres may become coated with blood proteins with sticky characteristics and may adsorb platelets on their surface (26–28)[10]. Clustering by surface to surface protein adhesion would be facilitated by slow flow through the capillary and sinusoidal beds and by the high surface to mass ratio of the smaller spheres. Contact among larger spheres may be limited by the diameter of the vascular channels, while the smaller surface to mass ratio may limit the mutual adherence potential exhibited by the 3- and 5-μm spheres.

CONCLUSIONS

1. Elimination of microspheres from the circulation following intravascular administration is size dependent, with the larger diameter spheres clearing most rapidly.

2. Mechanical filtration and prolonged retention of 7-μm and larger spheres in the lungs imply a critical size for passage through the pulmonary vascular bed.

3. Retention of small microspheres (3 and 5 μm) in the liver and spleen for prolonged periods appears to be due to phagocytosis of the spheres by cells of the reticuloendothelial system.

4. Small microspheres (3 μm) tend to agglomerate when administered intravascularly, presumably due to protein adherence and a large surface to mass ratio.

5. Intraarterially administered larger microspheres do not distribute to peripheral and visceral beds differently from the intravenous administration, presumably because of flow characteristics inhibiting peripheral distribution.

6. Large microspheres (12 μm) are not phagocytized by pulmonary macrophages or the reticuloendothelial system within 4 weeks of intravascular administration as are smaller sphere sizes, implying a size limit for phagocytosis of inert particles.

Determination of Ketoprofen in Biological Fluids by Reversed-Phase Chromatography

A. BANNIER ˣ, J. L. BRAZIER, B. RIBON, and C. QUINCY

Received November 27, 1978, from the *Département de Chimie Analytique, Faculté de Pharmacie, 8, Avenue Rockefeller, 69373 Lyon Cedex 2, France.* Accepted for publication February 1, 1980.

Abstract □ A sensitive and specific high-performance liquid chromatographic method was developed for the determination of ketoprofen [2-(3-benzoylphenyl)propionic acid] in plasma and urine. The method includes an extraction of the drug and the internal standard [2-(4-benzoylphenyl)butyric acid] into ether from acidified plasma. The organic phase is evaporated, and the residue is dissolved in the mobile phase (acetonitrile–0.02 *M* phosphate buffer, pH 3) (45:55). A 20-μl aliquot is analyzed on a reversed-phase column. The accuracy is within 1.5% for therapeutic concentrations, and the coefficients of variation are 5.5 and 3.4% for 2 and 10 μg/ml, respectively. For the urine assay, the accuracy is within 3%, and the coefficients of variation are 1.9 and 1.7% for 3 and 50 μg/ml, respectively. This method was applied successfully to the determination of ketoprofen in humans for pharmacokinetic studies.

Keyphrases □ Ketoprofen—high-performance liquid chromatographic analysis, human plasma and urine □ Anti-inflammatory agents—ketoprofen, high-performance liquid chromatographic analysis, human plasma and urine □ High-performance liquid chromatography—analysis, ketoprofen, human plasma and urine

Ketoprofen [2-(3-benzoylphenyl)propionic acid, I] is a benzophenone derivative with anti-inflammatory activity (1). Clinical proof of its therapeutic efficacy (2) has resulted in its wide use in rheumatology, leading to numerous clinical (3–5) and pharmacokinetic (6–9) studies.

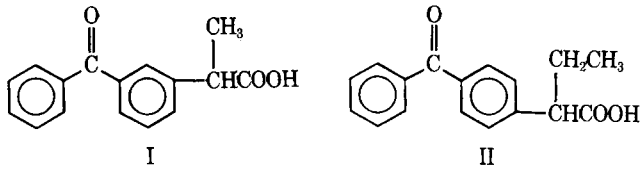
Several methods for the determination of ketoprofen in biological fluids have been reported. Colorimetry and polarography (10) are simple but cannot be applied easily to plasma or serum. TLC (11) is rapid but lacks sensitivity. Methyl (10) and trimethylsilyl esters of ketoprofen (12) can be separated using GLC, and this method can be considered as a reference due to its sensitivity. However, the technique is relatively complex and time consuming, and the resulting precision is only ~10%.

A new rapid and accurate analytical method for ketoprofen was described recently, which involves the determination of its methyl ester by high-performance liquid chromatography (HPLC) (13). This report describes the development of a precise and rapid HPLC assay for determining ketoprofen in biological fluids without derivatization.

EXPERIMENTAL

Reagents and Solvents—Acetonitrile[1], phosphoric acid[1], monobasic potassium phosphate[2], sodium hydroxide[2], acetone[2], sodium sulfate[2] (anhydrous), hydrochloric acid[2], sodium nitrate[1], and ether[2] were analytical grade and were used without further purification. Water was deionized. Ketoprofen and the internal standard [2-(4-benzoylphenyl)-butyric acid, II] were synthesized[3].

HPLC mobile phases of pH 3, 4, 5, 6, and 7 were made from phosphoric acid–monobasic potassium phosphate or monobasic potassium phosphate–dibasic sodium phosphate aqueous buffer solutions diluted with various volumes of acetonitrile (30–70%). The pH of the resulting solutions was adjusted with either 10% NaOH or 10% phosphoric acid. The final phosphate-ion concentration was 0.02 *M*.



I II

Apparatus—The liquid chromatograph[4], equipped with a 254-nm UV detector[5], was operated at ambient temperature. The output of the detector was displayed on a recorder[6] having 10-mv full-scale deflection. The output signal also was fed to an electronic integrator[7] for quantification.

The 10-cm × 4.6-mm i.d. stainless steel columns were packed with Lichrosorb RP 18[2] (5 μm) or RP 8[2] (5 μm) by a balanced-density slurry technique (14). A 20-μl loop injection valve[8] was used to introduce samples into the chromatographic system. The efficiency of newly made columns was tested with a standard mixture using sodium nitrate as an unretained marker. The solvent system was methanol–water (80:20). Under these conditions, the column efficiency was 24,000 theoretical plates for benzene and 21,000 for anthracene.

Stock Solutions—The ketoprofen stock solution (10 mg/100 ml) was prepared by dissolving I in acetone. The internal standard stock solution (10 mg/100 ml) was prepared by dissolving II in acetone. A 10-fold dilution of these two solutions was made before use.

Calculations—The plasma and urine concentrations were calculated using the internal standard method.

Chromatographic Conditions—Columns were preconditioned with the mobile phase until a stable recorder baseline was obtained. The flow rate then was adjusted to 1 ml/min, generating a pressure of nearly 1000

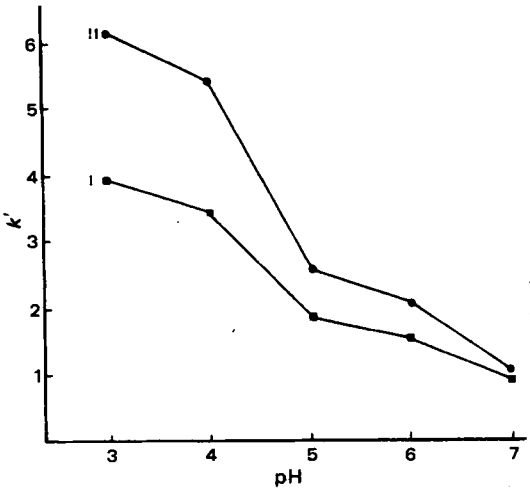


Figure 1—*Effect of variation of the solvent pH on the capacity factors, k', of ketoprofen (I) and the internal standard (II) on a Lichrosorb RP 18 column; the mobile phase was acetonitrile–0.020 M phosphate buffer (40:60).*

psi. The mobile phase solutions were prepared daily and degassed by sonification.

Plasma Extraction—One milliliter of plasma, 1 ml of diluted internal standard, and 1 ml of 1 N HCl were transferred to a 35-ml screw-capped centrifuge tube and extracted by shaking with 25 ml of ether for 5 min.

The organic and aqueous phases were separated by centrifugation for 3 min at 2000 rpm. The ether layer was then pipetted carefully into a 35-ml conical centrifuge tube, dried over anhydrous sodium sulfate, and evaporated to dryness under a nitrogen stream at 40°. The sample residue was reconstituted with various volumes of the mobile phase (200–500 μl), depending on the drug concentration. Aliquots of 20 μl then were injected onto the column.

Urine Extraction—To determine the total ketoprofen excreted in urine, any conjugated drug first was hydrolyzed in an alkaline medium (12). Then, 0.1–0.5 ml of urine, 1 ml of 1 N NaOH, 1 ml of the internal standard stock solution (10 mg/100 ml), and 25 ml of ether were transferred to a 35-ml screw-capped centrifuge tube. The sample was agitated for 5 min, and the organic phase was discarded. The aqueous phase, after acidification with 2 ml of 1 N HCl, was treated similarly to the plasma. The sample residue then was reconstituted with 1–2 ml of the mobile phase, and 20-μl aliquots were injected into the chromatograph.

RESULTS AND DISCUSSION

Reversed-phase chromatography on modified silica (C_{18} or C_8) has replaced ion-exchange chromatography for the separation of many polar ionogenic compounds. The technique, called solvophobic chromatography, was developed by Horváth *et al.* (15, 16). Ketoprofen, a drug with a polar carboxylic functional group, can be determined by such a method.

The internal standard for this determination was proposed by Populaire *et al.* (10). Its structure is very close to that of I, and its physicochemical properties also are similar. Preliminary studies showed that separation of I and II in biological fluids was possible with a mixture of methanol–acetonitrile–0.025 M phosphate buffer (30:15:45) at pH 3 on a 5-μm Lichrosorb RP 18 column. However, under such conditions, retention times were long (8 and 12.8 min, respectively), and the peaks were unacceptably broad.

To determine the optimum chromatographic conditions, variation of the capacity factor, k', with pH was measured on 5-μm Lichrosorb RP

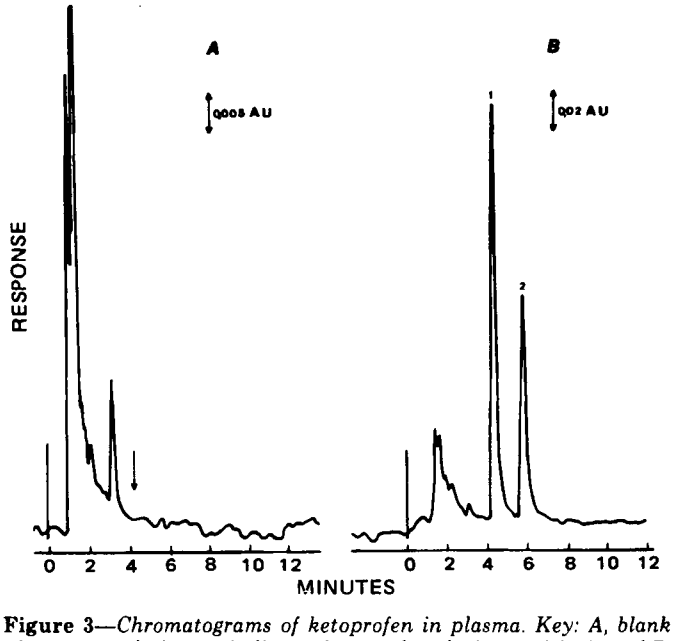

Figure 3—*Chromatograms of ketoprofen in plasma. Key: A, blank plasma sample (arrow indicates ketoprofen elution position); and B, plasma sample with 8.53 μg of ketoprofen/ml (peak 1) and 5 μg of the internal standard/ml (peak 2).*

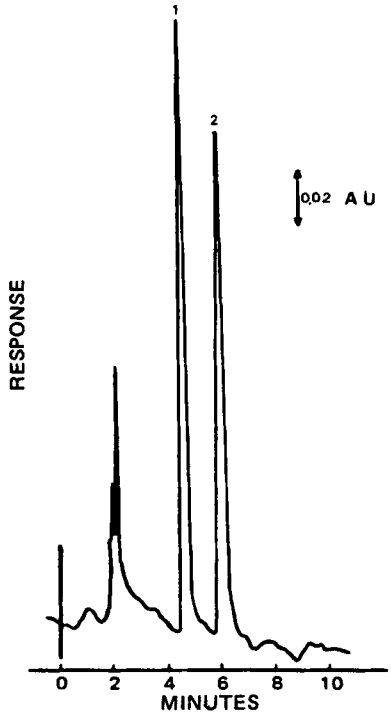

Figure 4—*Chromatogram of ketoprofen in urine for the 0–6-hr collection. The ketoprofen (peak 1) concentration was 189 μg/ml, and the internal standard (peak 2) concentration was 250 μg/ml.*

18 columns with an acetonitrile–phosphate buffer mobile phase. Figure 1 shows that the best separation was obtained at pH 3 ($k_I' = 3.89$, $k_{II}' = 6.10$, $R_S = 3.03$, and $\alpha = 1.57$). At pH 3, I and II were not ionized and thus showed a maximum affinity for the stationary phase. Moreover, Twitchett and Moffat (17) demonstrated that k' is influenced strongly by liposolubility. Figure 2 shows that an increase in the proportion of acetonitrile in the mobile phase decreases k'.

Results for the determination of I on Lichrosorb RP 18 under these conditions are summarized in Table I. Optimization of pH and liposolubility led to a shorter analysis time and better resolution. However, the efficiency of this column still was not sufficient and the peaks remained rather broad. A better separation subsequently was obtained using a 5-μm Lichrosorb RP 8 column. The right side of Table I shows that the chromatographic parameters for I and II were nearly the same for the two stationary phases, but resolution and efficiency were increased because of peak sharpness. Consequently, 5-μm Lichrosorb RP 8 was chosen as the stationary phase for the final determination.

Ether extracts of control plasma were free of endogenous UV (254-nm) absorbing peaks liable to interfere with the assay (Fig. 3). Figure 4, representing the chromatogram of a urine extract under these conditions, shows that ketoprofen and the internal standard were well resolved.

To verify the linearity of the chromatographic response, a plasma calibration curve was run in which the concentration of II was maintained at 5 μg/ml while that of I was varied from 1 to 10 μg/ml. A linear regression analysis of the data resulted in a good linear fit ($r^2 = 0.998$, intercept = 0.027, and slope = 0.200). For the calibration for urine, the concentration of I was varied from 10 to 150 μg/ml. Good linearity was observed ($r^2 = 0.999$, intercept = 0.04, and slope = 0.097).

Reproducibility and Accuracy—Reproducibility and accuracy of the HPLC method were studied by measuring the concentration of I in plasma samples spiked at 2, 5, and 10 μg/ml. The results (Table II) show that accuracy was within 4%. The assay precision for urine was determined for various ketoprofen concentrations (Table III). The lower limit of sensitivity was 0.04 μg/ml for plasma samples and 0.05 μg/ml for urine samples, both measured at a signal-to-noise ratio of 3:1.

Potential Interfering Substances—Retention times for several compounds that might potentially interfere with ketoprofen are shown in Table IV. The chromatographic system provided good specificity, and the column efficiency for these compounds was good. Moreover, no interference was found between ketoprofen and its hydroxylated metabolites since they were not extracted in the acidic medium.

Clinical Study—Figure 5 shows the plasma level in a human subject

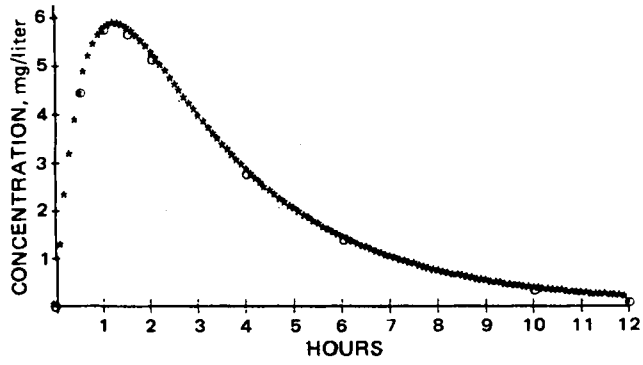

Figure 5—*Plasma decay for ketoprofen after a single oral dose of 100 mg ($K_e = 0.354\ hr^{-1}$ and $K_a = 1.54\ hr^{-1}$).*

following a single oral dose of 100 mg of I in tablet form. Blood samples were collected before medication and after 30 min and 1, 1.5, 2, 4, 6, 10, and 12 hr. The plasma levels of I were measured as described.

In this subject, a peak plasma level of 5.8 μg/ml was reached at 1 hr. The decrease in the plasma level followed a monoexponential decline with an elimination rate constant of 0.354 hr^{-1} and a half-life of 1.97 hr.

The urinary excretion levels of ketoprofen also were determined for the same subject. Urine was collected at intervals of 0–6, 6–12, and 12–24 hr during the first 24 hr following oral administration. A total of 61.2 ± 5.8% of the dose was excreted in 24 hr. These results agree closely with the data reported previously (5, 6, 18) and indicate that the method is well suited for the determination of plasma and urine levels of I in bioavailability and pharmacokinetic studies.

High-Performance Liquid Chromatographic Determination of Epimers, Impurities, and Content of the Glucocorticoid Budesonide and Preparation of Primary Standard

G. ROTH ˣ, A. WIKBY, L. NILSSON, and A. THALÉN

Received October 19, 1979, from the *Research and Development Laboratories, AB Draco (Subsidiary to AB Astra), Box 1707, S-221 01 Lund, Sweden.* Accepted for publication February 1, 1980.

Abstract □ The new glucocorticoid budesonide, a 1:1 mixture of two epimers, was evaluated analytically with respect to drug content, impurities, and epimer distribution in the drug substance. Reversed-phase high-performance liquid chromatographic (HPLC) systems using octadecylsilane columns with different ethanol–water mixtures as eluents were used. Budesonide and its epimers were determined with recoveries of 100.3% (±0.16 *SD*) and 99.7% (±0.27 *SD*), respectively. Individual foreign steroids in the ranges of 0.05–0.2 and 0.2–2% were determined with mean recoveries of 93% (±7.6 *SD*) and 97% (±2.5 *SD*), respectively. Analysis of eight small-scale production batches of budesonide gave a recovery of 99.9% (±0.39 *SD*) for the sum of budesonide and impurities. Analytical data and the procedure for preparation of a budesonide primary standard are given. The proposed HPLC procedure is faster, more accurate, more precise, and more selective than the usual pharmacopeial methods for corticosteroids.

Keyphrases □ Budesonide—high-performance liquid chromatographic analysis of drug content, impurities, and epimer distribution, preparation of primary standard □ Anti-inflammatory agents—budesonide, high-performance liquid chromatographic analysis of drug content, impurities, and epimer distribution, preparation of primary standard □ High-performance liquid chromatography—analysis, budesonide, determination of drug content, impurities, and epimer distribution

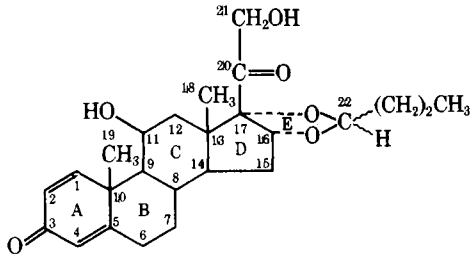
The new nonhalogenated glucocorticoid budesonide with high anti-inflammatory activity was synthesized by Thalén and coworkers (1–3). Evidence was given for the formation of two epimers in a 50:50 ratio. The epimers were isolated by chromatography on Sephadex LH-20 and studied by NMR spectroscopy and mass spectrometry (2, 3). An X-ray study of the molecular structures of the two epimers also was reported (4, 5).

The high-performance liquid chromatographic (HPLC) properties of budesonide and homologous corticosteroids were studied using both normal-phase (6) and reversed-phase (6, 7) systems. Optimal resolution of the budesonide epimers was obtained with octadecylsilane as the support and ethanol in the aqueous mobile phase.

For the assay of several steroid drugs, the USP proposes the separation of the drug substance from impurities by TLC and the final determination of the drug content by the blue tetrazolium method (8). Preliminary work indicated that this procedure was too laborious, time consuming, and not selective enough for accurate evaluation of budesonide batches with respect to drug content and impurities. Furthermore, the epimer distribution could not be determined by this method. The purpose of the present work was to develop HPLC methods for the quantitative evaluation of all of these parameters. This report also deals with the problem of preparing a reliable primary standard substance since an absolute assay for steroids is not available.

EXPERIMENTAL

Chemicals and Solvents—*Budesonide Drug Substance*—Budesonide (I) is a mixture of two epimers, 16α,17α-(22*S*)- and 16α,17α-(22*R*)-propylmethylenedioxypregna-1,4-diene-11β,21-diol-3,20-dione (A and B, respectively). The different solubilities of the epimers result in more Epimer B during purification of the crude substance, which is considered by specifying the limits for the epimer ratio of the drug substance.



I

Flucloronide[1]—Flucloronide was used as the internal standard in the assay of budesonide. The HPLC purity was >99.8%.

Impurity 1—Impurity 1 was 16α-hydroxyprednisolone, the starting material in the synthesis of budesonide. The HPLC purity (254 nm) of the substance[2] was >98%. 16α-Hydroxyprednisolone appeared only in a few budesonide batches.

Impurity 2—Impurity 2 was a 1:1 mixture of two epimers, 16α,17α-(22*S*)- and 16α,17α-(22*R*)-methylmethylenedioxypregna-1,4-diene-11β,21-diol-3,20-dione (the propyl group of budesonide is replaced by a methyl group). The epimers were isolated by column chromatography and identified by NMR spectroscopy and mass spectrometry. Their HPLC purity was >99%.

Impurities 3 and 4—Impurities 3 and 4 were isolated by column chromatography. Work is now in progress[3] to identify them. Their HPLC purity was >99%.

Epimers A and B of Budesonide—Epimers A and B were isolated by column chromatography (2, 3), and the HPLC purity was >99.8%.

Solvents—Analytical or spectroscopic (for ethanol) grade solvents were used.

Apparatus—The liquid chromatograph was equipped with a pump[4], a high-pressure injector[5], and a 254-nm detector[6]. Peak areas were determined with an electronic digital integrator[7].

The columns (3.9 mm i.d. and 300 mm long) were prepacked with porous siliceous microbeads to which stationary phases of octadecylsilane or aminopropylsilane were chemically bonded[8].

Preparation of Budesonide Primary Standard—Budesonide was synthesized according to the method described previously (1, 3). Its purification was divided into seven steps.

The crude product was recrystallized three times from methanol–water (Steps 1–3). Since the repeated recrystallizations led to a significant change in the epimeric distribution, the product was partially resolved by chromatography on Sephadex LH-20, using chloroform as the eluent. Two fractions with different epimeric ratios were collected and evaporated to dryness, dissolved in methylene chloride, and precipitated with petroleum ether. Calculated amounts of the two precipitates were mixed to give budesonide with an epimeric ratio near 50:50 (Step 4). This

Table I—Analytical Data of the Budesonide Primary Standard

Test for	Analytical Method	Content, %
Epimer A of budesonide	HPLC (reversed phase)	46.8
Epimer B of budesonide	HPLC (reversed phase)	53.0
Impurities	HPLC (reversed phase)	0.1
Impurities[a]	HPLC (normal phase)	0.1
Methylene chloride	GLC	<0.05
Petroleum ether	GLC	<0.02
Methanol	GLC	0.01
Water	Coulometric Karl Fischer titration	0.05

[a] The impurities obtained by normal-phase HPLC were identical to those detected by reversed-phase HPLC.

product was purified further by repeated recrystallizations from methanol–water (Step 5), ethanol–water (Step 6), and methanol–water (Step 7). A portion of the substance was dried *in vacuo* to constant weight and then was used for an assay of budesonide. The product was analyzed for foreign steroids and epimeric distribution by HPLC (System 2).

Analytical Procedures—*HPLC Conditions*—The mobile phase for reversed-phase chromatography (on μBondapak C_{18}) was ethanol–water in a 48:52 ratio (v/v) in the assay of budesonide (System 1) or in a 43:57 ratio (v/v) for determination of the epimer ratio and foreign steroids (System 2). Five microliters of the sample or of the standards was injected.

The mobile phase for normal-phase chromatography (on μBondapak NH_2) was heptane–ethanol (91:9 v/v). Five microliters of the samples dissolved in ethanol was injected.

HPLC Assay of Budesonide—For the assay of budesonide drug substance, samples of 14.00–16.00 mg were weighed into 25-ml volumetric flasks. The samples were dissolved and diluted to volume with a flucloronide internal standard solution. The latter was prepared by dissolving 35 mg of flucloronide in 100 ml of ethanol.

The samples were compared with a budesonide primary standard, from which solutions were prepared as for the samples.

Standard Addition Experiments—About 0.2 mg of each of the four impurities was weighed with a precision of 0.2% and dissolved together in 25.00 ml of ethanol. A second stock solution was prepared in the same way with 2 mg of the impurities. Aliquots of these solutions were transferred into flasks containing 14.00–16.00 mg of the budesonide primary standard substance. In this way, seven samples with known contents were prepared. They contained impurities in the range of 0.2–7.5%; *i.e.*, the budesonide content was 92.5–99.8%.

The samples were analyzed for their content of budesonide and impurities by reversed-phase HPLC.

Table II—Molar Absorptivities (254 nm), Absorbance (*A*) (1%, 1 cm) Values (254 nm), and Detector Response Factors for Epimers and Impurities of Budesonide

Compound	Molar Absorptivity	*A*	*A* (Relative)[a]	Response Factor (*R*)[b] Determined by HPLC
Budesonide primary standard	1.26×10^4	292	1.00	1.00
Epimer A of budesonide	1.26×10^4	292	1.00	0.99
Epimer B of budesonide	1.26×10^4	292	1.00	0.99
Impurity 1	1.26×10^4	334	1.14	1.14
Impurity 2	1.22×10^4	303	1.04	1.07
Impurity 3	1.21×10^4	282	0.97	—
Impurity 4	1.18×10^4	275	0.94	0.92

[a] Ratio of *A* (compound) to *A* (budesonide). [b] See text for definition.

Ethanolic solutions of Epimer A (0.103 mg/ml) and Epimer B (0.104 mg/ml) also were prepared. Aliquots of the two solutions were mixed to obtain samples with known epimeric distributions. These samples were used to evaluate the accuracy of the HPLC determination of the epimer distribution.

Detector Response Experiments—Four ethanolic solutions of budesonide were prepared. Each solution contained a known content of Impurity 1, 2, 3, or 4. Five microliters was injected in reversed-phase HPLC System 2. The peak areas of the impurity and of budesonide were determined for each sample. The relative detector response, *R*, was calculated according to:

$$R = \frac{\text{peak area of impurity}}{\text{concentration of impurity}} \times \frac{\text{concentration of budesonide}}{\text{peak area of budesonide}} \quad \text{(Eq. 1)}$$

From spectrophotometric measurements, absorbance (*A*) (1%, 1 cm) values and molar absorptivities were calculated for budesonide, Epimers A and B, and the four impurities.

Analysis of Solvent Residues—The water content of budesonide was analyzed by the coulometric Karl Fischer titration method (9). Organic solvent residues in budesonide originating from the synthesis were analyzed by GLC. The gas–liquid chromatograph[9] was equipped with a flame-ionization detector and a 1.5-m × 1.3-mm Porapak Q glass column. Nitrogen was the carrier gas at a flow rate of 20 ml/min. The injector temperature was 220°, and the oven temperature was 150°.

Two samples were prepared by dissolving 20.0–30.0 mg of budesonide bulk substance in 1.0 ml of absolute methanol and 1.0 ml of ethanol, respectively; 0.02% methanolic solutions of methylene chloride and petroleum ether and 0.02% ethanolic solutions of methanol were prepared and used as standards. One microliter of the samples and standards was injected. Solvent residues of >0.01% could be detected. Corrections for trace impurities in methanol and ethanol were made.

RESULTS AND DISCUSSION

Like other diastereoisomers, Epimers A and B of budesonide differ in solubility. This fact had to be considered in the preparation of the primary standard. During the recrystallizations (Steps 1–3), the ratio of Epimer A to B changed from about 50:50 to about 40:60. In purification Step 4, the epimeric distribution was adjusted back to 49.9:50.1. The final recrystallizations (Steps 5–7) resulted in 46.9% Epimer A and 53.1% Epimer B. The changes in epimeric distribution with the number of recrystallizations limit the purification procedure if the requirements for the epimer ratio in the drug substance specifications are to be fulfilled.
